puberty is usually marked by *thelarche*, or breast development, which normally begins by age 13. Delayed puberty is diagnosed if there is no breast development by age 13, which is 2 to 2.5 standard deviations greater than the mean age of pubertal onset. Pubic hair may be present, because that is largely dependent on adrenal rather than gonadal function. Clinical diagnosis can be made in the absence of menarche by age 15 or 16.¹⁴ Although delayed, puberty may have significant psychosocial implications and carries a risk of inadequate skeletal development and mineralization. Puberty is a time of rapid skeletal growth, with the majority of bone development and mineralization achieved during adolescence. Estrogen plays a major role in this process, and a lack of circulating estrogen puts individuals at risk for inadequate bone density in adulthood.¹⁵

In most cases, delayed puberty is a physiologic (constitutional) delay in which hormonal levels are normal and the hypothalamic-pituitary-gonadal (HPG) axis is intact, but maturation is happening slowly. This physiologic delay tends to be familial, less common in girls than boys, and is frequently diagnosed retrospectively once pubertal progression is complete. Although the exact incidence of this constitutional delay in growth and puberty (CDGP) is unknown, the sentinel and leading study on the issue reported that approximately 30% of girls with delayed puberty ultimately progressed through normal and spontaneous puberty. An additional 19% of girls had functional hypogonadotropic hypogonadism (FHH), essentially an underlying condition or illness (unrelated to gonadal function) responsible for the delayed development (e.g., anorexia nervosa)¹⁶ (Table 25.1). Treatment of FHH includes a correction of the underlying condition, with a possible initiation of hormone therapy if a prolonged recovery is projected. Treatment for CDGP includes expectant management or initiation of hormone therapy in small doses to promote pubertal development and diminish the risk of poor skeletal growth and mineralization.

TABLE 25.1

FREQUENCY AND COMMON CAUSES OF DELAYED PUBERTY OTHER THAN

CONSTITUTIONAL DELAY OF GROWTH AND PUBERTY

DELAYED PUBERTY	HYPERGONADOTROPIC HYPOGONADISM	PERMANENT HYPOGONADOTROPIC HYPOGONADISM	FUNCTIONAL HYPOGONADOTROPIC HYPOGONADISM
Frequency (%)			
Boys	5–10	10	20
Girls	25	20	20
Common causes	Turner syndrome, gonadal dysgenesis, chemotherapy, radiation therapy	Tumors or infiltrative diseases of the central nervous system, GnRH deficiency (isolated hypogonadotropic hypogonadism, Kallmann syndrome), combined pituitary-hormone deficiency, chemotherapy, or radiation therapy	Systemic illness (inflammatory bowel disease, celiac disease, anorexia nervosa, or bulimia), hypothyroid excessive exercise

GnRH, Gonadotropin-releasing hormone.

From Palmert MR, Dunkel L: *N Engl J Med* 366(5):443–453, 2012.

In other cases, a disruption in the HPG axis is the primary cause of delayed puberty. Human gonadal function is partially controlled by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), the release of which is regulated by the pulsatile secretion of hypothalamic gonadotropin-releasing hormone (GnRH).¹⁷ The G-protein–coupled receptor 54 (*GPR54*) has been identified as the gatekeeper gene for activation of the GnRH axis. *GPR54* is required for the normal function of this axis, and data suggest that the ligand kisspeptin-1 may act as a neurohormonal regulator of the GnRH axis.¹⁷

The mechanisms of childhood inhibition of GnRH release and activation are poorly understood but appear to involve feedback inhibition by sex steroids and presumably other central nervous system (CNS) pathways.¹⁴ Given the numerous etiologies contributing to the occurrence of delayed puberty, a thorough evaluation should be conducted that includes physical examination and medical and family history that specifically targets known contributors to delayed

puberty. Laboratory workup may consist of x-ray studies for bone age, measurement of thyroid function, determination of serum levels of prolactin and adrenal and gonadal steroids, radioimmunoassay of plasma gonadotropins, and screening for systemic disorders. Adolescents with high gonadotropin levels require a karyotype to rule out genetic causes, and those with low levels need skull imaging (lateral skull film, computed tomography [CT], or MRI) to rule out pituitary or other CNS infiltrate or tumor. Treatment of delayed puberty depends on the cause; the goal of treatment is the development of secondary sex characteristics and fertility, and the promotion of bone growth and mineralization.¹³ Insufficient sex hormone secretion can be corrected by hormone replacement therapy, such as estrogen. Idiopathic hypogonadotropic hypogonadism is treated with synthetic GnRH or sex hormone administration, or both, and may be lifelong.¹⁴

Precocious Puberty

Precocious puberty is a rare event, affecting about 29 in 100,000 girls.¹⁸ Precocious puberty is defined as the onset of clinical signs of puberty (breast or pubic hair development) before age 8. However, some endocrinologists have recommended that the criteria be changed to reflect the trend toward an earlier onset of puberty, suggesting that pubertal changes before age 6 in black girls or age 7 in white girls are more reflective of abnormal development.¹⁹ Others are concerned that lowering the age of precocious puberty will miss those individuals who present after the age cut-off with a pathologic underlying condition causing early puberty. There have been many postulated causes of precocious puberty (**Box 25.1**), including alterations in genetic factors, an increase in obesity, an increase in protein consumption,^{20,21} and the growing prevalence of molecular compounds known as *endocrine disruptors* in common household products²² (see [What's New? Precocious Puberty](#)). Besides the premature development of secondary sex characteristics, precocity causes premature closure of the epiphysis of long bones, which results in lifelong short stature,²³ and often carries profound psychosocial

consequences.²⁴ Because precocious puberty can be a sign of pathologic conditions, all cases of precocious puberty require thorough evaluation.

Box 25.1

Causes of Precocious Puberty

Central (Gonadotropin-Releasing Hormone [GnRH] Dependent)

Idiopathic

Central nervous system (CNS) disorders

 Congenital anomalies (hydrocephalus)

 Hypothalamic hamartoma

 Postinflammatory/infectious condition

 Trauma

 Tumors (hypothalamic, pineal, other)

 Imprinted gene (*MKRN3*)

Peripheral Puberty (GnRH Independent)

Adrenal hyperplasia or tumor

Environmental endocrine disruptors

Exogenous sex steroid exposure

Exogenous anabolic steroids

Familial Leydig cell hyperplasia

Gonadal tumors or cysts

Human chorionic gonadotropin (hCG)–secreting tumors

 (hepatoblastomas, intracranial lesions)

Hypothyroidism (severe)

McCune-Albright syndrome

Testotoxicosis

Data from Fuqua JS: *J Clin Endocrinol Metab* 98(6):2198–2207, 2013; Rosenfield RL et al: Puberty and its disorders in the female. In Sperling MA, editor: *Pediatric endocrinology*, Philadelphia, PA, 2014, Elsevier Health Sciences; Schoelwer M, Eugster EA: *Endocr Dev* 29:230–239, 2016.

What's New?

Precocious Puberty

Studies implicate obesity, leptin, ghrelin, and environmental endocrine disruptor chemicals (EDCs) as possible contributors to precocious puberty in girls. Obesity may affect the production and secretion of leptin and ghrelin, powerful communicators of satiety, hunger, metabolic rate, and in timing of puberty. EDCs may mimic, block, or alter the normal signaling systems involved in sex hormone secretion, uptake, and use. EDCs include agrochemicals, widespread industrial compounds, and persistent pollutants.

Data from Buluş AD et al: *Toxicol Mech Methods* 26(7):493–500, 2016; Rosenfield RL, Cooke DW, Radovick S: Puberty and its disorders in the female. In Sperling Mark A, editor: *Pediatric endocrinology*, pp 569–663, Philadelphia, PA, 2014, Elsevier Health Sciences; Sørensen K et al: *Horm Res Paediatr* 77(3):137–145, 2012; Trotman GEL: *Curr Opin Obstet Gynecol* 28(5):366–372, 2016; Willemsen RH, Dunger DB: *Endocr Dev* 29:17–35, 2016.

Precocious puberty may be partial, complete, or mixed types ([Box 25.2](#)) and can be further categorized into central (GnRH dependent) and peripheral (GnRH independent) (see [Box 25.1](#)). **Central precocious puberty** is GnRH dependent and occurs when the HPG axis is working normally but prematurely.²³ Central precocious puberty results from failure of central inhibition of the GnRH pulse generator (the gonadostat), often because of CNS abnormality. Although most cases are idiopathic, mutations in the imprinted gene *MKRN3* were recently reported as a cause of central precocious puberty.²⁵

Box 25.2

Primary Forms of Precocious Puberty

Complete Precocious Puberty

Premature development of appropriate characteristics for the child's sex

Hypothalamic-pituitary-ovarian axis working normally but prematurely

In about 10% of cases, lethal central nervous system tumor may be the cause

Partial Precocious Puberty

Partial development of appropriate secondary sex characteristics

Premature thelarche (breast budding) seen in girls between 6 months and 2 years of age

Does not progress to complete puberty (ovulation and menstruation)

Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age

Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

Mixed Precocious Puberty

Causes the child to develop some secondary sex characteristics of the opposite sex

Common causes: adrenal hyperplasia or androgen-secreting tumors

Data from Burchett MLR et al: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Rosenfield RL et al: Puberty and its disorders in the female. In Sperling MA, editor: *Pediatric endocrinology*, Philadelphia, PA, 2014, Elsevier Health Sciences.

The diagnosis of central precocious puberty is one of exclusion.¹⁹ Because a CNS lesion may be missed, children with presumed central precocious puberty require long-term surveillance. Peripheral puberty is GnRH independent and develops when sex hormones are produced by some mechanism other than stimulation by the gonadotropins and is either genetic or exogenous.²⁶ Sex steroid-producing tumors (i.e., gonadal tumors), testotoxicosis, and exposure to exogenous sex steroids (i.e., hormonal contraceptives and environmental endocrine disruptors) are some of the causes (see [Box 25.1](#)).

Partial precocious puberty is the partial early development of appropriate secondary sex characteristics alone or in combination. A girl with incomplete precocious puberty might undergo thelarche or pubarche and, rarely, premature menarche. Premature thelarche can be seen as early as 2 to 24 months of age, and in very small children breast development often reverses. Thelarche is considered premature if it occurs before age 8 years, but is usually a variation of normal and represents the higher end of prepubertal hormone release. Skeletal growth and menarche in these girls occur during the normal timeframe.²⁷ Premature pubarche tends to occur between ages 5 and 8 years. Premature pubarche is usually the consequence of an early increase in the adrenal androgens that leads to early growth of pubic hair and possibly a transient acceleration in growth and bone maturation that has no significant effect on timing of puberty or final height. Sparse hair growth on the genitalia, in the absence of thelarche or menarche, does not represent precocious puberty.²⁷ Girls with premature pubarche and thelarche should be followed through puberty to ensure normal progression; occasionally pathologic conditions may contribute to premature development.

Complete precocious puberty refers to the onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche). **Mixed**

precocious puberty (virilization of a girl or feminization of a boy) causes the child to develop some secondary sex characteristics of the opposite sex. This condition is usually evident at birth and is rare in older children (Box 25.3).

Box 25.3

Causes of Mixed Precocious Puberty

Female (Virilization)

- Congenital adrenal hyperplasia
- Androgen-secreting tumors
 - Adrenal
 - Ovarian
 - Teratoma
- Exogenous androgens

Male (Feminization)

- Estrogen-producing tumors
 - Adrenal
 - Teratoma
 - Hepatoma
 - Testicular
- Exogenous estrogens
- Increased peripheral conversion of androgens to estrogens

Data from Rosenfield RL et al: Puberty and its disorders in the female. In Sperling MA, editor: *Pediatric endocrinology*, Philadelphia, PA, 2014, Elsevier Health Sciences.

The diagnosis and cause of premature development are often straightforward.¹⁸ A thorough history and physical examination are done to determine the velocity of the process and to rule out life-

threatening CNS, ovarian, or adrenal neoplasms. A history of family occurrence helps exclude tumors. Children with precocious puberty also have a tendency toward obesity.²¹

Treatment for all forms of precocious puberty includes identifying and removing the underlying cause or administering appropriate hormones (see [Boxes 25.1](#) and [25.2](#)). If needed, precocious puberty can be reversed. Management goals include diagnosing and treating intracranial disease, arresting maturation until developmentally appropriate, maximizing eventual adult height, and reducing emotional problems. The most common form, central precocious puberty, is usually treated with potent GnRH agonist analogs, which induce reversible, selective suppression of the HPG axis.¹⁸ Because many of these children are obese and childhood obesity is predictive of morbidity in adolescence and adulthood, it is important for clinicians to include assessment and management of obesity as a component of the treatment for central precocious puberty.

Disorders of the Female Reproductive System

Hormonal and Menstrual Alterations

Primary Dysmenorrhea

Primary dysmenorrhea is painful menstruation associated with the release of prostaglandins in ovulatory cycles, but not with pelvic disease. Approximately 90% of all women experience dysmenorrhea, 15% of whom are incapacitated for 1 to 3 days because of pain severity. Primary dysmenorrhea usually begins with the onset of ovulatory cycles with prevalence highest during adolescence.²⁸ In contrast, **secondary dysmenorrhea** is related to pelvic pathologic disorders (i.e., ovarian cysts, adenomyosis, endometriosis) that manifest in later reproductive years and may occur any time in the menstrual cycle.²⁹

◆Pathophysiology.

Primary dysmenorrhea is attributed to excessive endometrial prostaglandin production, primarily released during the first 48 hours of menstruation, when symptoms are the most intense.²⁸ Women with painful periods produce 10 times as much prostaglandin F (PGF₂α), a potent myometrial stimulant and vasoconstrictor, as asymptomatic women. Elevated levels of prostaglandins (especially PGF₂α and PGE₂α) cause uterine hypercontractility, decreased blood flow to the uterus, and increased nerve hypersensitivity, resulting in pain.²⁹ Women with dysmenorrhea may have up-regulated cyclooxygenase (COX) enzyme activity, which contributes to increased synthesis of prostaglandins. Furthermore, leukotriene production is elevated, further contributing to increased levels of pain.²⁹ Women are more likely to report primary dysmenorrhea if they are younger than 30; have not given birth; have a history of pelvic inflammatory disease, sexual assault, premenstrual syndrome, or sterilization; are heavy tobacco or alcohol users; have a family history of dysmenorrhea; or have a body mass index (BMI) less than 20.²⁹ Women who experience severe primary dysmenorrhea appear to have a heightened pain sensitivity; emerging research suggests an alteration in their pain modulating system, putting them at higher risk for functional pain disorders (e.g., fibromyalgia) in later life.³⁰ Women who are anovulatory because they use oral contraceptives rarely have primary dysmenorrhea.²⁹

Secondary dysmenorrhea results from disorders such as endometriosis (the most common cause), endometritis (infection), adenomyosis, pelvic inflammatory disease, obstructive uterine or vaginal anomalies, uterine fibroids, polyps, tumors, ovarian cysts, pelvic congestion syndrome, or nonhormonal intrauterine devices (IUDs).²⁸

◆Clinical Manifestations.

The chief symptom of dysmenorrhea is pelvic pain associated with the onset of menses. The pain often radiates into the groin and may be accompanied by backache, anorexia, vomiting, diarrhea, syncope,

insomnia, and headache. The latter symptoms are caused by entry of prostaglandins and prostaglandin metabolites into the systemic circulation. Usually the discomfort associated with primary dysmenorrhea begins shortly before the onset of menstruation and persists for the first 1 to 3 days of menstrual flow.²⁸

◆Evaluation and Treatment.

Primary dysmenorrhea can be differentiated from secondary dysmenorrhea by a thorough history and pelvic examination. Administration of nonsteroidal antiinflammatory drugs (NSAIDs, e.g., ibuprofen) is the treatment of choice because these medications reduce COX enzyme activity, and thus prostaglandin production. NSAIDs work in the majority of women with primary dysmenorrhea and are most effective if started at the first sign of bleeding or cramping.³¹ In women who desire contraception or do not respond to NSAIDs, dysmenorrhea may be relieved with hormonal contraceptives, such as combined estrogen-progestin pills or the progestin-only intrauterine device (IUD).³² Hormonal contraception stops ovulation and creates an atrophic endometrium, thereby decreasing prostaglandin synthesis and myometrial contractility. Other treatment approaches with some evidence of effectiveness in pain relief include transdermal nitroglycerin patches to diminish uterine contractility, local application of heat, acupuncture, transcutaneous electrical nerve stimulation (TENS), increased physical activity, stress reduction through meditation, additional sleep, and supplements such as thiamine, vitamin E, and herbal treatments.²⁹

Amenorrhea

Amenorrhea means lack of menstruation, and the most common causes (aside from pregnancy) are chromosomal abnormalities, hypothalamic dysfunction, polycystic ovarian syndrome, hyperprolactinemia, hypothyroidism, malnutrition, and ovarian failure.³³ **Primary amenorrhea** is the failure of menarche and the absence of menstruation by age 13 years, without the development of secondary sex characteristics, or by age 15 regardless of the presence

of secondary sex characteristics (see the Alterations of Sexual Maturation section for a discussion of delayed puberty).³⁴ Primary amenorrhea differs from delayed puberty in that most cases of delayed puberty require only reassurance, but when the diagnosis of primary amenorrhea is reached, a thorough evaluation is needed. **Secondary amenorrhea** is the absence of regular menses for 3 months or irregular menses for 6 months in women who have previously menstruated. Pregnancy is the most common condition to exclude before further evaluation.

◆Pathophysiology.

There are numerous classifications of the etiologies of primary amenorrhea. One approach to understanding the pathophysiology is through compartmentalization. *Compartment IV disorders* include CNS disorders, in particular hypothalamic disorders. In some of the congenital syndromes that cause primary amenorrhea, the hypothalamic-pituitary-ovarian (HPO) axis is dysfunctional. The hypothalamus is unable to synthesize GnRH, so the pituitary fails to secrete LH and FSH. Therefore the ovary does not receive the hormonal signals required to stimulate estrogen production, and ovulation and menstruation do not occur. Because the ovarian hormones are absent, estrogen-dependent sex characteristics do not develop. CNS tumors can cause these disruptions in the hypothalamic-pituitary-ovarian axis. Other etiologies of amenorrhea caused by a dysfunction in the hypothalamus can include malnutrition (e.g., anorexia nervosa), stress, infection (e.g., meningitis, syphilis), or traumatic brain injury.³³

Compartment III disorders are disorders of the anterior pituitary gland including tumors. Some anatomic defects of the CNS, whether congenital or acquired, impinge on the hypothalamic-pituitary unit so as to interfere with, or interrupt, the secretion of GnRH or FSH and LH. Examples of such defects include hydrocephalus, craniopharyngiomas, and other space-occupying lesions of the CNS. Again the target organ, the ovary, does not receive the necessary signals and ovulation and menstruation do not occur. In some cases,

these lesions develop between the onset and conclusion of puberty. Therefore skeletal growth may occur and secondary sex characteristics may develop, but sexual maturation is interrupted before menarche. Autoimmune disease, hyperprolactinemia, and some medications also can affect the pituitary and disrupt normal menstruation.

Compartment II disorders involve the ovary and are often linked with genetic abnormalities. These include gonadal dysgenesis (Turner syndrome) or androgen insensitivity syndrome (AIS). Turner syndrome involves the lack of two functional and complete X chromosomes in at least some body tissues (45,X/46,XX; structural X or Y abnormalities; mosaicism),³³ which results in the ovaries lacking gametes and ovarian failure. Without primitive gametes and follicles, follicular development and estrogen secretion cannot occur. Lack of estrogen accounts for failure of secondary sex characteristic development and amenorrhea, although there are high levels of circulating FSH and LH.³³

As mentioned previously, an individual with AIS is male genetically and their body produces testosterone. However, their cells do not have a receptor for testosterone, which is needed to activate the development of male genitalia.³⁴ Because target tissues have estrogen receptors, most individuals with AIS have female external genitalia and female secondary sex characteristics. With the exception of a small vagina, internal female genitalia are absent, accounting for amenorrhea and infertility.³⁴

Compartment I disorders are anatomic defects of the outflow tract associated with primary amenorrhea. They include congenital absence of the vagina and uterus and congenital uterine hypoplasia. Genetically normal females without a uterus or vagina usually have normal ovarian function. Therefore skeletal growth occurs and secondary sex characteristics develop in the proper sequence, but menstruation does not occur because the uterus is too small or malformed to produce substantial endometrium.

◆Clinical Manifestations.

The major clinical manifestation of primary amenorrhea is the absence

of the first menstrual period. The cause of the amenorrhea determines whether secondary sex characteristics and height are affected.

◆Evaluation and Treatment.

Diagnosis of primary amenorrhea is based on history and physical examination and determination of whether secondary sexual characteristics are present or absent. Absence of these sexual characteristics indicates that a female has never been exposed to estrogen. If ovarian steroid hormone levels are low, the individual has the appearance of an immature female. Physical examination may show structural or physiologic alterations of the reproductive tract as outlined at the beginning of the chapter. Laboratory studies may be required to document karyotype, abnormal levels of gonadotropins, thyroid and prolactin levels, and ovarian hormones. Diagnostic imaging is used to document structural abnormalities³⁵ (see [Fig. 25.1](#)).

Treatment involves correction of any underlying disorders and use of hormone replacement therapy to induce the development of secondary sex characteristics as necessary (see the section on Alterations of Sexual Maturation for a discussion of delayed puberty). Although surgical alteration of the genitalia may be undertaken to correct structural abnormalities, surgery should be delayed until the individual can make a truly informed decision. Hormonal manipulation or embryo transplantation may make pregnancy possible for women with primary amenorrhea who have a normal uterus.

Secondary Amenorrhea

A wide variety of disorders and physiologic conditions are associated with secondary amenorrhea. Besides disease, secondary amenorrhea can be triggered by dramatic weight loss, whether the loss results from malnutrition or excessive exercise. Secondary amenorrhea is common during early adolescence and the perimenopausal period, pregnancy, and lactation. The most common causes (after pregnancy) are thyroid disorders (e.g., hypothyroidism), hyperprolactinemia, HPO interruption secondary to excessive exercise, stress, weight loss,

and polycystic ovary syndrome (PCOS). The factors leading to secondary amenorrhea also may cause primary amenorrhea in a young woman who has not begun to menstruate.

◆Pathophysiology.

The causes of secondary amenorrhea are summarized in [Fig. 25.2](#). In women with normal ovarian steroid hormone levels, secondary amenorrhea may be caused by structural abnormalities (müllerian anomalies), Asherman syndrome (removal of the endometrial decidua basalis), or removal of the uterus. In women with elevated ovarian steroid hormone levels, inhibited ovulation leads to amenorrhea. An excess of ovarian hormones disrupts feedback relationships within the HPO axis, preventing ovulation. Depressed ovarian hormone levels, which are associated with a variety of clinical disorders, also cause amenorrhea by preventing ovulation. Lack of ovulation, termed **anovulation**, may result from increased levels of prolactin, decreased levels of gonadotropins, irregular secretion of gonadotropins, or abnormally low levels of CNS neurotransmitters (i.e., dopamine and GnRH). Any of these variables alters the feedback effects that the ovarian hormones have on the hypothalamus and pituitary.

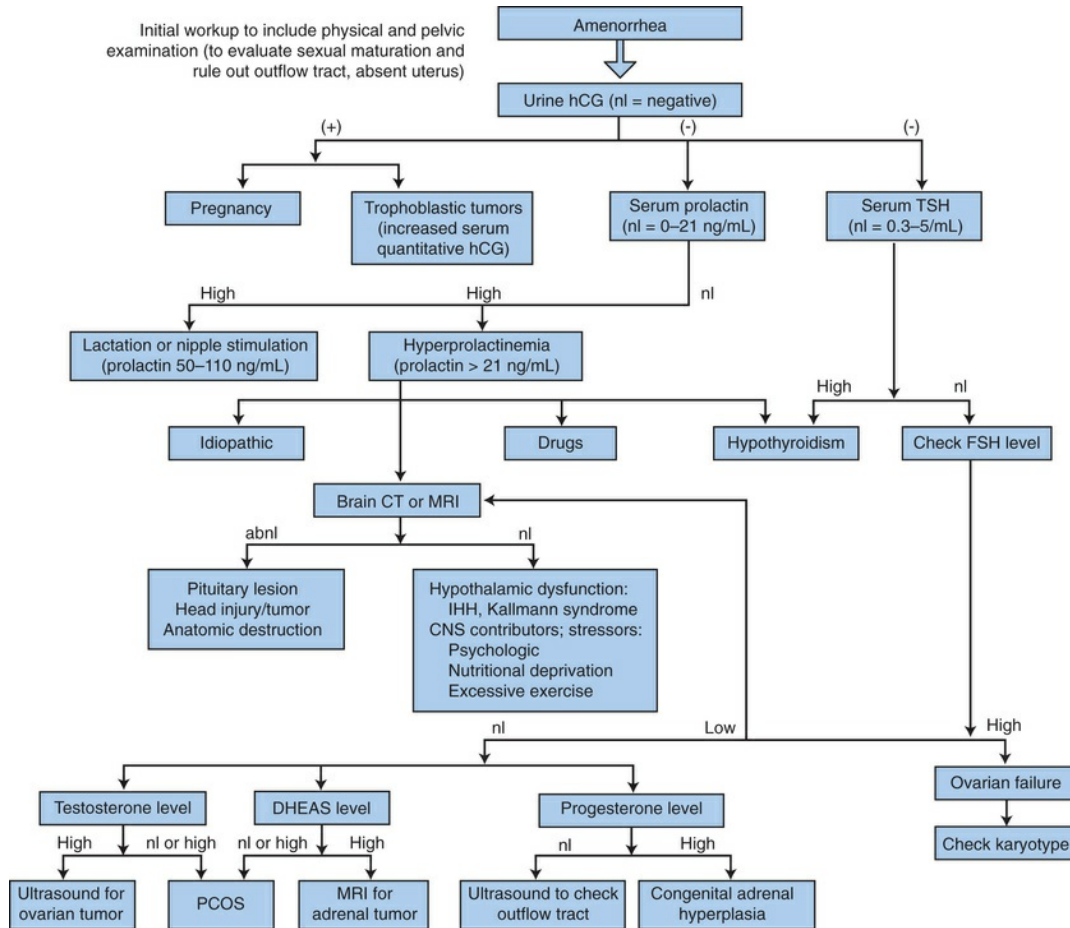

FIGURE 25.2 Diagnosis of Amenorrhea. Pregnancy is the most common cause of amenorrhea. CNS, Central nervous system; CT, computed tomography; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; IHH, idiopathic hypogonadotropic hypogonadism; MRI, magnetic resonance imaging; nl, normal; PCOS, polycystic ovary syndrome; TSH, thyroid-stimulating hormone. (Adapted from Hoffman BL et al, editors: *Williams gynecology*, ed 3, New York, 2016, McGraw-Hill.)

High levels of prolactin are physiologic during lactation because it increases milk production and suppresses ovulation, preventing closely spaced pregnancies. However, high levels of prolactin not related to lactation are abnormal and will disrupt the menstrual cycle. **Hyperprolactinemia** (overproduction of prolactin by the pituitary) may have indirect effects that lead to decreased secretion of GnRH by the hypothalamus. The result is a reduction in FSH and LH secretion followed by anovulation and secondary amenorrhea. Hyperprolactinemia should be diagnosed through blood testing for both normal-size and large molecular prolactin (macroprolactin).

Hyperprolactinemia can have many causes including medication side effects, hypothyroidism, excessive nipple stimulation, and pituitary tumors.³⁶

◆Clinical Manifestations.

The major manifestation of secondary amenorrhea is the absence of menses after previous menstrual periods. Infertility, vasomotor flushes, vaginal atrophy, acne, osteopenia, and **hirsutism** (abnormal hairiness) also may be present, depending on the underlying cause of the amenorrhea.

◆Evaluation and Treatment.

Pregnancy is the most common cause of amenorrhea and must be ruled out before other evaluations. The menstrual cycle also may stop or become irregular in response to stress, extreme exercise, large dietary changes, eating disorders, or sleep abnormalities. A thorough history of the woman's life and stressors is important in assessing amenorrhea. Diagnosis of the organic cause of secondary amenorrhea involves the identification of underlying hormonal or anatomic alterations. A woman with secondary amenorrhea and normal secondary sex characteristics should have a complete history and physical examination. After ruling out pregnancy and performing an in-depth history, initial laboratory evaluation includes measurement of thyroid-stimulating hormone (TSH) and prolactin levels (Fig. 25.3). Elevated prolactin levels warrant further investigation, including a complete medication history, TSH level measurement, and brain CT or MRI if warranted.³³ If these initial tests are normal, further testing would include measurement of gonadotropins (FSH), estrogen and testosterone, ultrasonography of the outflow tract and ovaries or adrenal MRI, or both.

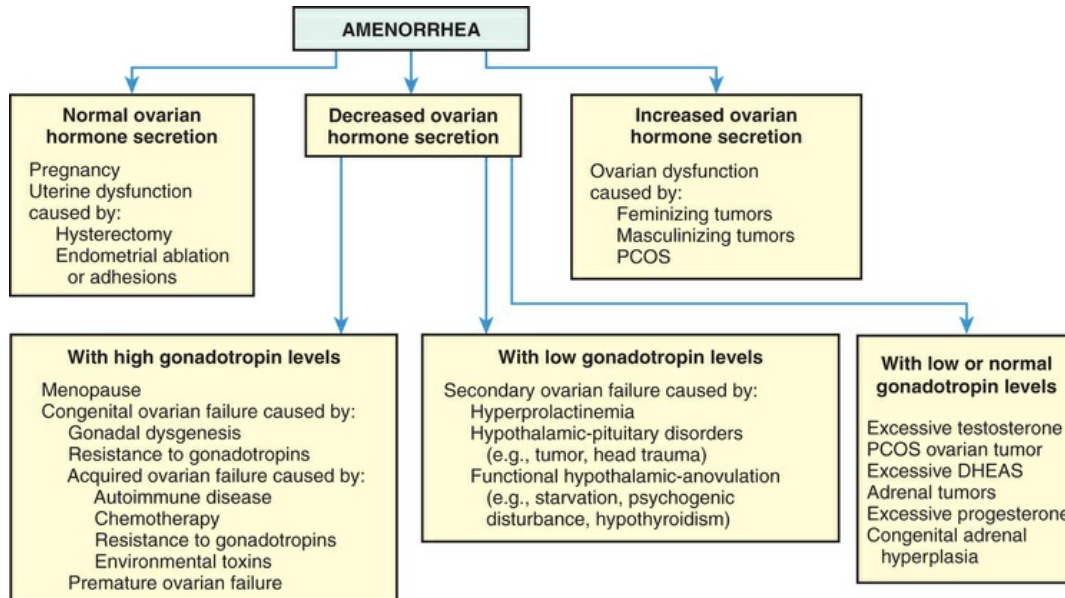

FIGURE 25.3 Causes of Secondary Amenorrhea. Of note, hypothyroidism is a relatively common condition and should be ruled out as the cause of hyperprolactinemia before more extensive evaluation (i.e., computed tomography or magnetic resonance imaging) occurs. *DHEAS*, Dehydroepiandrosterone sulfate; *PCOS*, polycystic ovary syndrome.

Treatment of amenorrhea depends on the cause and the woman's psychologic need for cycle stability. Treatments may include replacing deficient hormones (e.g., estrogens, thyroid hormone, glucocorticoids, gonadotropins) or correcting underlying pathologic conditions (e.g., tumor removal).³⁴ A diagnosis of PCOS might be treated with an insulin-sensitizing agent, such as metformin, as well as ovulation-inducing drugs if fertility is desired (a discussion of PCOS is in the section on Disorders of the Female Reproductive System).

Some treatments for amenorrhea prevent pregnancy, whereas others may restore fertility. The choice of treatment may be influenced by the woman's childbearing plans. After pathologic conditions have been corrected and the menstrual cycle stabilized, fertility may return. Occasionally, women with secondary amenorrhea may need additional ovulation-inducing drugs to assist conception, whereas others are able to conceive naturally.³⁴

Abnormal Uterine Bleeding

Menstrual irregularity or abnormal bleeding patterns (Table 25.2)

account for approximately 33% of all gynecologic visits. For many years, these abnormal patterns were poorly and inconsistently defined, and in 2010 the International Federation of Gynecology and Obstetrics (FIGO) developed a new system of definition and classification that has been adopted in the United States. The outdated definitions remain commonly used and are included in [Table 25.2](#). **Abnormal uterine bleeding (AUB)** is bleeding that is abnormal in duration, volume, frequency, or regularity; and has been present for the majority of the previous 6 months.³⁷ AUB may be acute or chronic and is classified by the cause of bleeding using an internationally recognized PALM-COEIN system. PALM-COEIN stands for **p**olyp, **a**denomyosis, **l**eiomyoma, and **m**alignancy and hyperplasia; and **c**oagulopathy, **o**vulatory dysfunction, **e**ndometrial, **i**atrogenic, and **n**ot-yet classified ([Fig. 25.4](#)). The first group, PALM, consists of disorders of tissue or structure that are diagnosed through imaging or biopsy. The second group, COEIN, consists of nonstructural causes of AUB. More than one etiology may contribute to a woman's AUB.³⁸

TABLE 25.2

ABNORMAL UTERINE BLEEDING

CURRENT TERMINOLOGY	OUTDATED TERMINOLOGY	DEFINITION
Chronic AUB	Menometrorrhagia Menorrhagia Menorrhea Polymenorrhea	Abnormal uterine bleeding for at least 4 out of 6 months; abnormal bleeding is characterized by increased amount, regularity, and/or timing
Acute AUB		Single episode of severe uterine bleeding that is sufficient to require immediate intervention to prevent further blood loss
Intermenstrual bleeding (AUB/IMB)	Metrorrhagia	Uterine bleeding that occurs between regular menstrual cycles; intermenstrual bleeding can be random or predictable.
Heavy menstrual bleeding (HMB/AUB)	Hypermenorrhea	Increased menstrual volume that interferes with a woman's physical, emotional, and social quality of life

AUB, Abnormal uterine bleeding.

Data from Fraser IS et al: *Semin Reprod Med* 29(5):383–390, 2011; Munro MG et al: *Int J Gynecol Obstet* 113(1):3–13, 2011.

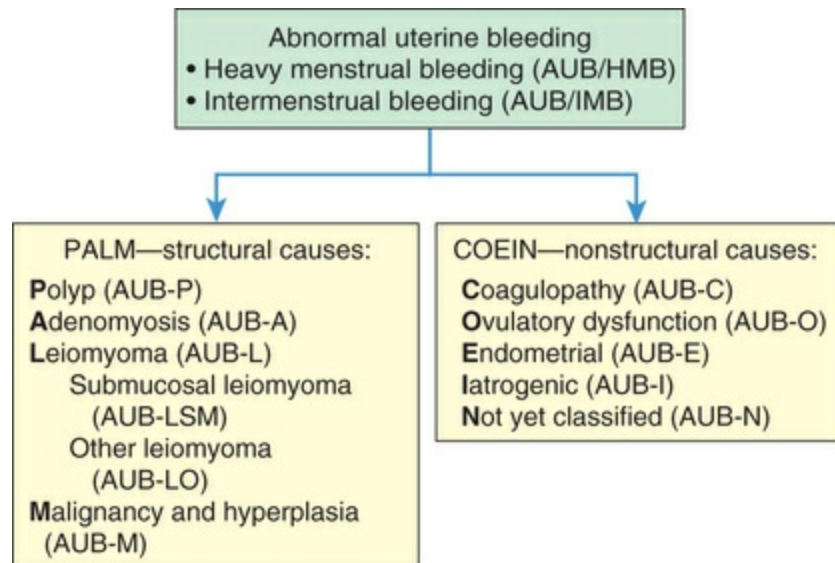

FIGURE 25.4 PALM-COEIN System for Classification of Abnormal Uterine Bleeding. *AUB*, Abnormal uterine bleeding. (From Committee Opinion No. 557, American College of Obstetricians and Gynecologists: *Obstet Gynecol* 121:891–896, 2013.)

In premenstrual or menopausal women, any bleeding is considered abnormal. For reproductive-aged women, normal uterine bleeding is every 28 days with variation up to 7 days. Therefore bleeding more frequently than every 21 days, or less frequently than every 35 days, is considered abnormal. Menstrual bleeding for longer than 7 days also is considered abnormal.³⁹ Studies show that 10% to 30% of women will experience AUB in their lifetime.⁴⁰ Approximately one-third of all gynecologic visits for premenopausal women and three-quarters of all visits for perimenopausal and menopausal women are because of AUB.⁴¹ AUB (all etiologies) is the leading reason for hysterectomy in the United States.⁴² Perimenopausal women are most commonly affected by AUB.

◆Pathophysiology.

The majority of abnormal uterine bleeding is due to lack of ovulation.⁴¹ Normal, regular periods are the result of a complex

interplay between the hypothalamus, pituitary, ovary, and the uterine endometrium (see [Chapter 24](#)). Disruptions in this system can affect the amount and structure of the uterine endometrium, causing it to shed irregularly or heavily. Although anovulatory AUB may occur at any time during the reproductive years, it tends to occur in adolescents and perimenopausal women more frequently, because women at the edges of the reproductive years are more likely to ovulate irregularly. The formation of a follicle and its rupture to release an ovum are important components of the menstrual cycle. As the follicle forms, it produces estrogen, which causes proliferation of the endometrium. Following ovulation, the remaining portions of the follicle, known as the *corpus luteum*, release progesterone. The progesterone acts on the proliferating endometrium to limit growth and cause changes in the vasculature of the endometrium, which limits bleeding during endometrial shedding.

If a follicle forms but never releases the ovum, the follicle may continue to produce estrogen (estradiol [E₂]), encouraging endometrial proliferation beyond the normal 14-day time window. In addition, the lack of progesterone causes the thickened endometrium to be unable to shed in a predictable fashion without excessive blood loss. Women who fail to ovulate experience irregularities in their menstrual bleeding related to the lack of progesterone and, in some cases, an excess of estrogen.

Many conditions are associated with irregular ovulation, including physiologic changes of aging (e.g., adolescent and perimenopausal women); PCOS, in which follicles begin to form but never reach maturation and rupture; obesity because adipose tissue excretes estrogen, which can suppress the HPG axis; hyperthyroidism and hypothyroidism; and estrogen-secreting ovarian neoplasms.

Without ovulation, menstrual flow may become irregular, excessive, or both, resulting from the large quantity of tissue available for bleeding and the random breakdown of tissue that results in exposure of vascular channels. In the absence of adequate progesterone levels, usual endometrial control mechanisms are missing, such as vasoconstrictive rhythmicity, tight coiling of spiral

vessels, and orderly collapse, and stasis does not occur. Unopposed estrogen induces a progression of endometrial responses beginning with proliferation, hyperplasia, and adenomatous hyperplasia. Over a course of many years, unopposed estrogen may end with atypia and carcinoma.

Abnormal menstrual bleeding also can result from defects of the corpus luteum, resulting in progesterone deficiencies, or from abnormalities of the uterus or cervix, such as endometrial polyps, uterine fibroids, or even uterine or cervical cancers. (These conditions are covered in more detail later in the chapter.) Coagulation defects also can cause heavy and abnormal uterine bleeding and should be suspected in younger women with a history of extensive bruising or bleeding during dental procedures. Iatrogenic AUB can be caused by intrauterine devices or long-acting contraceptive implants or medications, such as anticoagulants, steroids, digitalis, phenytoin, or hypothalamic depressants.

◆Clinical Manifestations.

Abnormal uterine bleeding is characterized by unpredictable and variable bleeding. Especially during perimenopause, abnormal bleeding also may involve increased menstrual flow and the passage of large clots, leading to excessive blood loss. Excessive bleeding can lead to iron deficiency anemia and associated symptoms (fatigue, shortness of breath). AUB also may cause pain, decreased productivity, and sexual dysfunction.

◆Evaluation and Treatment.

The first step in assessing abnormal bleeding is to determine the cause of bleeding. If an organic cause can be found, the focus is on eliminating the pathologic disorder or mitigating its effects. To determine the cause of the bleeding, a complete and thorough history and physical examination, including transvaginal ultrasound, is needed. The woman's age and risk factors for other abnormal conditions are important in assessing the likely cause of the bleeding. Initial laboratory evaluation includes a complete blood count,

measurement of thyroid-stimulating hormone levels, and coagulation studies if indicated. If no cause can be found, it is usually assumed that the bleeding is caused by lack of regular ovulation. Treatment goals include preventing or controlling abnormal bleeding, identifying underlying disease, and inducing regular menstrual cycles. Treatment varies greatly by the age of the woman and her desire for current and future fertility.

NSAIDs, such as ibuprofen and naproxen, are often first-line treatments for excessive menstrual bleeding because they reduce prostaglandin synthesis within the endometrial tissues, which causes vasoconstriction and decreased menstrual blood loss. NSAIDs can reduce menstrual bleeding significantly with minimal side effects.⁴³ For best effect, they should be taken in the few days preceding the beginning of the menstrual period and be continued through the days of heaviest bleeding. NSAIDs are not as effective in controlling menstrual blood loss as hormonal therapies, but they are readily available without a prescription.

Young women and those of childbearing age with abnormal bleeding are often treated with hormonal therapies to override the HPG axis and mimic normal menstrual bleeding or suppress it entirely. Common treatments include oral contraceptive pills that contain both estrogen and progesterone, long-term treatment with medroxyprogesterone (Depo-Provera) (although the U.S. Food and Drug Administration [FDA] black box warning about potential bone loss has drastically curtailed the use of this therapy), and the levonorgestrel intrauterine device (LNG-IUD). The LNG-IUD has a dual indication from the FDA for both birth control and suppression of abnormal menstrual bleeding. The device releases a steady amount of progesterone into the uterus to stabilize and suppress the uterine lining. In addition, the progesterone suppresses the HPG axis, preventing ovulation. There is no strong evidence to differentiate whether estrogen and progesterone or progesterone alone is superior in the treatment of abnormal uterine bleeding; the woman should be allowed to select a treatment regimen that is compatible with lifestyle and needs.⁴³

Women who are greater than 35 years old and smoke cigarettes may not be candidates for oral contraceptive pills because the estrogen increases their risk of cardiovascular incidents, such as myocardial infarction. However, the LNG-IUD can still be used because it contains only progesterone. The LNG-IUD is widely used as a first step in controlling perimenopausal bleeding because it can be inserted in a clinic office and is easily removed. The LNG-IUD decreases blood loss by 86% to 97% by decreasing endometrial proliferation and has similar success rates as more invasive procedures, such as ablation or hysterectomy.⁴⁴ Women who do not wish to have future pregnancies also can opt for treatments that permanently suppress their uterine lining. These treatments include ablation, where the lining is burned to prevent future proliferation of the endometrial cells, and complete removal of the uterus in hysterectomy.³⁹

If a woman is menopausal, and has not had a menstrual period for more than 1 year, all vaginal bleeding should be investigated to rule out uterine and other cancers. Appropriate initial evaluation includes ultrasound and endometrial biopsy to exclude uterine cancer.³⁹

Women with coagulation disorders may have excessive menstrual bleeding because they have a predisposition to bleeding or because they are taking anticoagulant medications to overcome a genetic predisposition to excessive clotting.³⁸ To control their menstrual bleeding, these women can opt for cycle suppression. Provision of birth control for these women is important because pregnancy may be a risk to their health.⁴⁴

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is the most common cause of anovulation and ovulatory dysfunction in women. Although PCOS presents in a variety of ways, it is defined as having at least two of the following three features: irregular ovulation, elevated levels of androgens (e.g., testosterone), and the appearance of polycystic ovaries on ultrasound.⁴⁵ Polycystic ovaries do not have to be present to diagnose PCOS, and conversely their presence alone does not

establish the diagnosis. The diagnosis is one of exclusion, and all other disorders potentially responsible for the clinical findings also must be ruled out, including thyroid dysfunction, hyperprolactinemia, and congenital adrenal hyperplasia.⁴⁶ PCOS is associated with metabolic dysfunction, including dyslipidemia, insulin resistance, and obesity. PCOS remains one of the most common endocrine disturbances affecting women, especially young women, and is a leading cause of infertility in the United States, where prevalence rates are estimated at between 5% and 15% of women.⁴⁷

There is a strong genetic component to PCOS, and various features of the syndrome may be differentially inherited.⁴⁸ Confusing the issue is the frequency, expression, and timing of PCOS symptoms and diagnosis. From 22% to 30% of women have polycystic ovaries on ultrasound, with 80% having one or more symptoms of the syndrome; 80% of women with normal ovaries also experience one or more PCOS symptoms. Signs and symptoms of women with PCOS may change over time, with metabolic syndrome becoming more prominent with age. In addition, polycystic ovaries may be associated with Cushing syndrome, acromegaly, premature ovarian failure, simple obesity, congenital adrenal hyperplasia, thyroid disease, androgen-producing adrenal tumors or ovarian tumors (Fig. 25.5), and syndromes with hyperprolactinemia.⁴⁶

FIGURE 25.5 Polycystic Ovary. A, Surgical view of polycystic ovaries. B, Ultrasound of polycystic ovary. (A From Symonds EM, Macpherson MBA: *Diagnosis in color: obstetrics and gynecology*, London, 1997, Mosby-Wolfe. B From King J: *J Midwifery Womens Health* 51[6]:415–422, 2006. Reprinted with permission.)

◆Pathophysiology.

Although the underlying cause of PCOS is unknown, a genetic basis is suspected. Initial identification of genes involved in steroid biosynthesis, androgen biosynthesis, and insulin receptors within the

ovary indicates genetic involvement. No single factor fully accounts for the abnormalities of PCOS.⁴⁸ A hyperandrogenic state is a cardinal feature in the pathogenesis of PCOS. However, glucose intolerance/insulin resistance (IR) and hyperinsulinemia often run parallel to and markedly aggravate the hyperandrogenic state, thus contributing to the severity of signs and symptoms of PCOS.⁴⁷ Women with PCOS are three times as likely to have insulin resistance. This number is even higher among obese women, who account for approximately 60% of women with PCOS.⁴⁹

Insulin stimulates androgen secretion by the ovarian stroma and reduces serum sex hormone-binding globulin (SHBG) directly and independently. The net effect is an increase in free testosterone levels. Excessive androgens affect follicular growth, and insulin affects follicular decline by suppressing apoptosis and enabling follicles to persist⁴⁹ (Fig. 25.6). Further, there appears to be a genetic ovarian defect in PCOS, which makes the ovary either more susceptible to or sensitive to insulin's stimulation of androgen production. Recent research suggests that decreased intraovarian receptors for estrogen receptor- α or insulin-like growth factor 1 (IGF-1), increased leptin levels, or direct infrared radiation within selective ovarian cells (fibroblasts) may contribute to this phenomenon.⁴⁹ Intrauterine and early childhood environments may also contribute to the development of PCOS (see [What's New? Early Programming for PCOS?](#)).

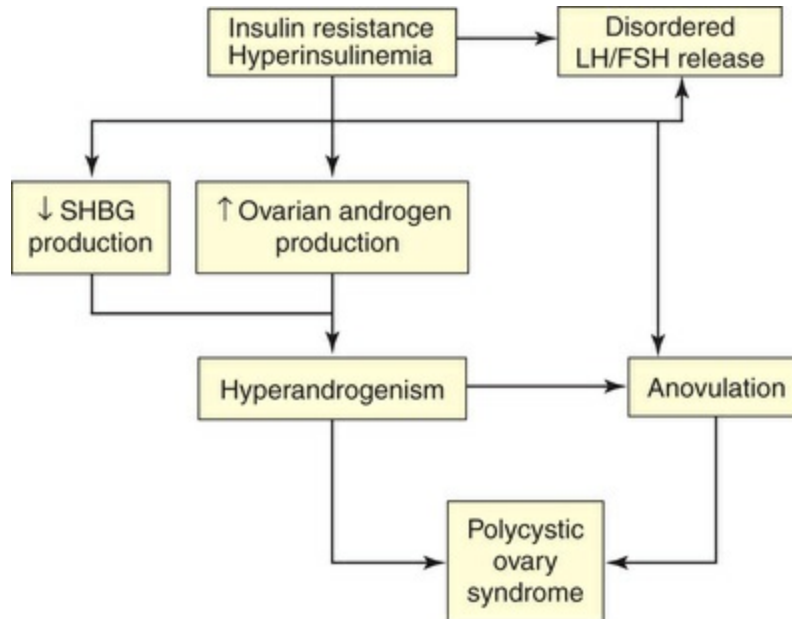

FIGURE 25.6 Insulin Resistance and Hyperinsulinemia in Polycystic Ovary Syndrome (PCOS). See text. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone; *SHBG*, sex hormone-binding globulin. (From Franks S, Berga SL: *Fertil Steril* 97[1]:2–6, 2012.)

What's New?

Early Programming for PCOS?

A fetal environment containing abnormal levels of pollutants, hormones, and other factors yet undefined can induce epigenetic modifications of the DNA and increased risk for adult disease. Female fetuses exposed to testosterone at levels normally found with male fetuses appear programmed to develop altered TGF- β signaling and increased risk of hyperinsulinemia and hyperandrogenism related to PCOS.

Data from Diamanti-Kandarakis E, Dunaif A: *Endocr Rev* 33(6):981–1030, 2012.

Weight gain tends to aggravate symptoms, whereas weight loss may ameliorate some of the endocrine and metabolic events and thus decrease symptoms. Women with PCOS tend to have increased leptin

levels (leptin levels are increased in thin as well as overweight women with PCOS).⁴⁸ Leptin influences the hypothalamic pulsatility of GnRH and consequent interaction along the entire HPO axis. Feedback from the polycystic ovary is disturbed because of changes in ovarian steroid and nonsteroidal (inhibins and related proteins) hormones.

In PCOS there is dysfunction in ovarian follicle development.⁵⁰ Inappropriate gonadotropin secretion triggers the beginning of a vicious cycle that perpetuates anovulation. Typically, levels of FSH are low or below normal and LH levels and LH bioactivity are elevated. An increased frequency of GnRH pulses appears to cause increased frequency of LH pulses.^{48,50} Persistent LH elevation causes an increase in the levels of androgens (dehydroepiandrosterone sulfate [DHEAS] from the adrenal glands and testosterone, androstenedione, and DHEAS from the ovary). Androgens are converted to estrogen in peripheral tissues, and increased testosterone levels cause a significant reduction (approximately 50%) in SHBG, which in turn causes increased levels of free estradiol. Elevated estrogen levels trigger a positive-feedback response in LH and a negative-feedback response in FSH. Because FSH levels are not totally depressed, new follicular growth is continuously stimulated, but not to full maturation and ovulation. The accumulation of follicular tissue in various stages of development allows an increased and relatively constant production of steroids in response to gonadotropin stimulation. Thus PCOS is characterized by excessive production of both androgen and estrogen.

Increased androgen secretion by the ovaries contributes to premature follicular failure (atresia) and persistent anovulation. In turn, persistent anovulation causes enlarged polycystic ovaries characterized by a smooth, pearly white capsule. This characteristic appearance is caused by an increase of surface area and increased volume of up to 2.8 times, doubling of growing and atretic follicles, thickening of the tunica (outermost area) by 50%, increasing cortical stromal thickening by one-third and a fivefold increase in subcortical stroma, and escalating hyperplasia. With advancing age, menstrual irregularities may improve while the incidence of metabolic syndrome

and type 2 diabetes mellitus increases. Women with PCOS have a three times greater incidence of uterine cancer in later life than normally cycling women related to the anovulatory lack of progesterone in PCOS. Without treatment for anovulation, women with PCOS have a 9% lifetime risk for endometrial cancers related to the effects of unopposed estrogen.⁴⁷

◆Clinical Manifestations.

Clinical manifestations of PCOS usually appear within 2 years of puberty but may present after a variable period of normal menstrual function and, possibly, pregnancy. The symptoms are related to anovulation, hyperandrogenism, and insulin resistance and include dysfunctional bleeding or amenorrhea, hirsutism, acne, acanthosis nigricans, and infertility. Approximately 60% of women with PCOS are obese.⁵¹ Box 25.4 contains a list of signs and symptoms, summary of hormonal disturbances, and complications of PCOS. In addition, women with PCOS are more likely to experience sleep apnea than unaffected women, which results in impaired sleep and may reduce their overall quality of life.⁵²

Box 25.4

Clinical Manifestations of Polycystic Ovary Syndrome

Presenting Signs and Symptoms (% of Women Affected)

- Obesity (41%)
- Menstrual disturbance (70% [i.e., dysfunctional uterine bleeding])
- Oligomenorrhea (47%)
- Amenorrhea (19%)
- Regular menstruation (48%)

Hyperandrogenism (69% to 74%)
Infertility (73% of anovulatory infertility)
Asymptomatic (20% of those with PCOS)

Hormonal Disturbances

Increased insulin (independent of obesity)
Decreased SHBG
Increased androgens (testosterone, androstenedione)
Increased DHEA (occurs in 50% of women)
Increased LH (genetic variant LH- β subunit)
Increased prolactin
Increased leptin, especially in obesity (independent of insulin)
Suggested decreased insulin-like growth factor (IGF-1) receptors on theca cells
Possible decreased estrogen receptors (intraovarian and along hypothalamic-pituitary axis)

Possible Late Sequelae

Dyslipidemia: increased low-density lipoproteins, decreased high-density lipoproteins, increased triglycerides
Diabetes mellitus (30% of women with or without obesity develop type 2 diabetes mellitus by age 30)
Cardiovascular disease; hypertension
Endometrial hyperplasia and carcinoma (anovulatory women are hyperestrogenic)

Other

Women with PCOS are at increased risk of gestational diabetes mellitus, pregnancy-induced hypertension, preterm birth, and perinatal mortality

DHEA, Dehydroepiandrosterone; *LH*, luteinizing hormone; *PCOS*, polycystic ovary syndrome; *SHBG*, sex hormone-binding globulin.

◆ Evaluation and Treatment.

Diagnosis of PCOS is based on evidence of androgen excess, chronic anovulation, and sonographic evidence of polycystic ovaries with at least two of the three criteria present. Tests for impaired glucose tolerance are recommended. As stated, polycystic ovaries do not have to be present and, conversely, their presence alone does not establish the diagnosis. Because of the normalcy of anovulatory cycles in adolescence, evidence of hyperandrogenism (in the setting of irregular menses) must be present before PCOS is diagnosed in an adolescent female.⁴⁶ Goals of treatment include reversing signs and symptoms of androgen excess, instituting cyclic menstruation, restoring fertility, and ameliorating any associated metabolic or endocrine, or both, disturbances.⁴⁷ First-line treatment of PCOS includes combined oral contraceptives (COCs) for management of symptoms (e.g., hirsutism, acne) and to establish regular menses. For those women with PCOS who are overweight or obese, lifestyle modifications, including regular exercise and weight loss, also are considered first-line treatments. Women with insulin resistance, or those women who do not respond to contraceptive therapy, may benefit from the insulin sensitizer metformin.^{46,47} If COCs are not used and pregnancy is not desired, progesterone therapy is recommended to oppose estrogen's effects on the endometrium and as a means to initiate monthly withdrawal bleeding (at the expense of continued hirsutism).

For overweight or obese infertile women desiring pregnancy, lifestyle modifications are first-line therapy. Even a small reduction of weight restores ovulation and increases insulin sensitivity by 71% in obese women with PCOS. Reduction of insulin by loss of abdominal

fat appears crucial in restoring ovulation.⁵³

Clomiphene citrate, an antiestrogen, can be used to facilitate ovulation⁴⁶ and can be combined with metformin for improved outcomes.⁴⁶ Management of PCOS is a nearly lifelong process because the effects of the syndrome persist past childbearing years. Appropriate primary care is needed to control the systemic features of PCOS so that it has minimal impact on a woman's life and health outcomes.

Premenstrual Disorders

Premenstrual syndrome (PMS) and **premenstrual dysphoric disorder (PMDD)** are the cyclic recurrence (in the luteal phase of the menstrual cycle) of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities and resolve after menstruation. The prevalence of PMS and PMDD is difficult to determine, in part because of the wide-ranging nature of accepted symptoms, but it is estimated that 12% of menstruating women are significantly affected by these disorders, with 3% to 8% meeting criteria for PMDD.^{54,55} Symptoms of PMS and PMDD begin after ovulation during the luteal phase and persist up to 4 days into the menstrual cycle.⁵⁵

◆Pathophysiology.

The psychologic and physiologic changes of PMS/PMDD occur in the luteal phase of ovulatory cycles and are linked with the complex hormonal changes of the menstrual cycle. There are many theories on the cause(s) of the disorder, including that the drop in estrogen level following ovulation and the immediate rise in progesterone level interact with hormones and neurotransmitters to cause symptoms.⁵⁶ However, the mechanisms involved are not known and may include an individual sensitivity to hormone levels. Furthermore, the neurotransmitters serotonin, gamma-aminobutyric acid (GABA), and noradrenaline may have mediating or moderating roles on symptom manifestation. These neurotransmitters have demonstrated interactions with estrogen and progesterone and *all* of these are

neuroactive with known mood and behavior effects, including negative mood, irritability, aggression, and impulse control.⁵⁶ Sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS), which explains some PMS/PMDD signs and symptoms (e.g., water retention, bloating, weight gain). There is a predisposition of PMS to occur in families, perhaps because of genetics or shared environment; however, no genes have been identified.

◆Clinical Manifestations.

The pattern of symptom frequency and severity is more important than specific complaints. Nearly 300 physical, emotional, and behavioral symptoms have been attributed to PMS/PMDD. Emotional symptoms, particularly depression, anger, irritability, and fatigue, have been reported as the most prominent and the most distressing, whereas physical symptoms seem to be the least prevalent and problematic. Physical symptoms include breast tenderness, abdominal bloating, headache, and swelling of extremities. In addition, underlying physical or psychologic disease may be aggravated premenstrually and must be diagnosed and treated independently from PMS/PMDD.

◆Evaluation and Treatment.

Diagnosis of PMS/PMDD is based on prospective health history and symptoms, with completion of a 2-month prospective symptom questionnaire, which is considered the gold standard. Diagnostic criteria for PMDD are presented in [Box 25.5](#). Because the cause of PMS is not known and cannot be reduced to a single biologic explanation, and because the occurrence and severity of PMS are mediated by lifestyle and social and psychologic factors, treatment for PMS is symptomatic. Initial treatment focuses on validating the premenstrual experience, relieving the physical and psychologic symptoms, and eliminating contributing factors, as well as treatment of coexisting or underlying disorders.

Box 25.5

Diagnostic Criteria for Premenstrual Dysphoric Disorder

- A. ≥ 5 symptoms below: occur in most cycles during the week before menses onset, improve within a few days after menses onset, and diminish in the week postmenses
- B. One (or more) of the following symptoms must be present:
 - a. Marked affective lability
 - b. Marked irritability or anger or increased interpersonal conflicts
 - c. Marked anxiety, tension
- C. One (or more) of the following symptoms must also be present:
 - a. Decreased interest
 - b. Difficulty concentrating
 - c. Easy fatigability, low energy
 - d. Increase or decrease in sleep
 - e. Feelings of being overwhelmed
 - f. Physical symptoms such as breast tenderness, muscle or joint aches, “bloating” or weight gain

NOTE: Criteria A–C must be present for most menstrual cycles in the preceding year

- D. Symptoms are associated with significant distress or interferences with work, school, relationships
- E. The disturbance is not merely an exacerbation of another disorder such as major depression, panic disorder, persistent depressive disorder, or a personality disorder
- F. Criterion A should be confirmed by prospective daily ratings in at least two symptomatic cycles
- G. The symptoms are not due to physiological effects of a

substance or another medical condition

Data from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders*, ed 5, Washington, 2013, Author.

Nonpharmacologic methods are first-line treatments for women who have mild symptoms or do not desire medication. These include acupuncture, herbal or mineral supplements, and lifestyle modifications. Lifestyle changes include regular exercise, appropriate sleep, and stress reduction during the premenstrual period. Calcium supplementation has been shown to decrease symptoms, although it is not as effective as pharmacologic treatment.⁵⁷ Vitamin B₆, vitamin D, and vitamin E also have been studied, but sample sizes are small and no clear evidence exists regarding their efficacy. Several studies of the herbal preparations vitex agnus-castus and ginkgo biloba have shown a reduction in symptoms as compared with a placebo.⁵⁸ Finally, cognitive-behavioral therapy, which assists individuals in identifying and restructuring thought or behavior patterns, has been effective in improving coping in the context of other chronic pain conditions; several small trials have shown positive effects in individuals with PMS/PMDD.⁵⁹

If nonpharmacologic methods fail or symptoms are severe, medical therapy is indicated. Two major forms of pharmacologic treatment include the use of hormonal cycle regulation and use of selective serotonin reuptake inhibitor (SSRI) antidepressants. If a woman does not desire immediate fertility, COCs may regulate her menstrual cycle and decrease levels of circulating steroidal hormones. The oral contraceptive pill containing estrogen and progesterone has shown benefits in decreasing PMS/PMDD, in particular bloating, breast tenderness, and headache.^{58,60} Oral contraceptive pills also can be used continuously for up to 3 months to decrease the frequency of menstrual periods and PMS/PMDD.⁵⁵

SSRIs have been well studied for use in prevention and treatment of PMS/PMDD and are first-line therapy for severe symptomatology.⁵⁸ They are used to treat psychological symptoms and also have a

beneficial effect on physical symptoms.³¹ These medications are effective when taken either continuously or limited to the luteal phase of the menstrual cycle. They may have undesired side effects, such as nausea, fatigue, or decreased libido, but these are largely dose-dependent.³¹ Serotonin-norepinephrine reuptake inhibitors (SNRIs) and the antipsychotic medication Seroquel (quetiapine fumarate) also have been shown to improve symptomatology; however, more research is needed.⁵⁵

Infection and Inflammation

Infections of the genital tract may result from exogenous or endogenous microorganisms. Exogenous pathogens are most often sexually transmitted (see [Chapter 27](#)). Endogenous causes of infection include microorganisms that are normally present in the vagina, bowel, or vulva. Infection occurs if these microorganisms overproliferate or migrate to a new location or if the immune system and other defense mechanisms are impaired.

A number of skin disorders also can affect the vulva. They include reactive dermatitis, contact dermatitis, psoriasis, and impetigo. (See [Chapter 47](#) for a discussion of skin disorders.) Many infectious disorders that affect the vulva and vagina are sexually transmitted; these disorders are described in [Chapter 27](#).

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection and affects an estimated 800,000 to 1,000,000 women per year.^{61,62} PID may involve any or all organs in the upper genital tract—the uterus, fallopian tubes, or ovaries—and, in its most severe form, the entire peritoneal cavity. Inflammation of the fallopian tubes is termed **salpingitis** ([Fig. 25.7](#)); inflammation of the ovaries is called **oophoritis**. Most cases of PID are caused by sexually transmitted microorganisms, such as chlamydia and gonorrhea, that migrate from the vagina to the uterus, fallopian tubes, and ovaries. The ascension of these microorganisms into the upper genital tract

may be facilitated by disruptions in the normal vaginal flora.^{63,64}

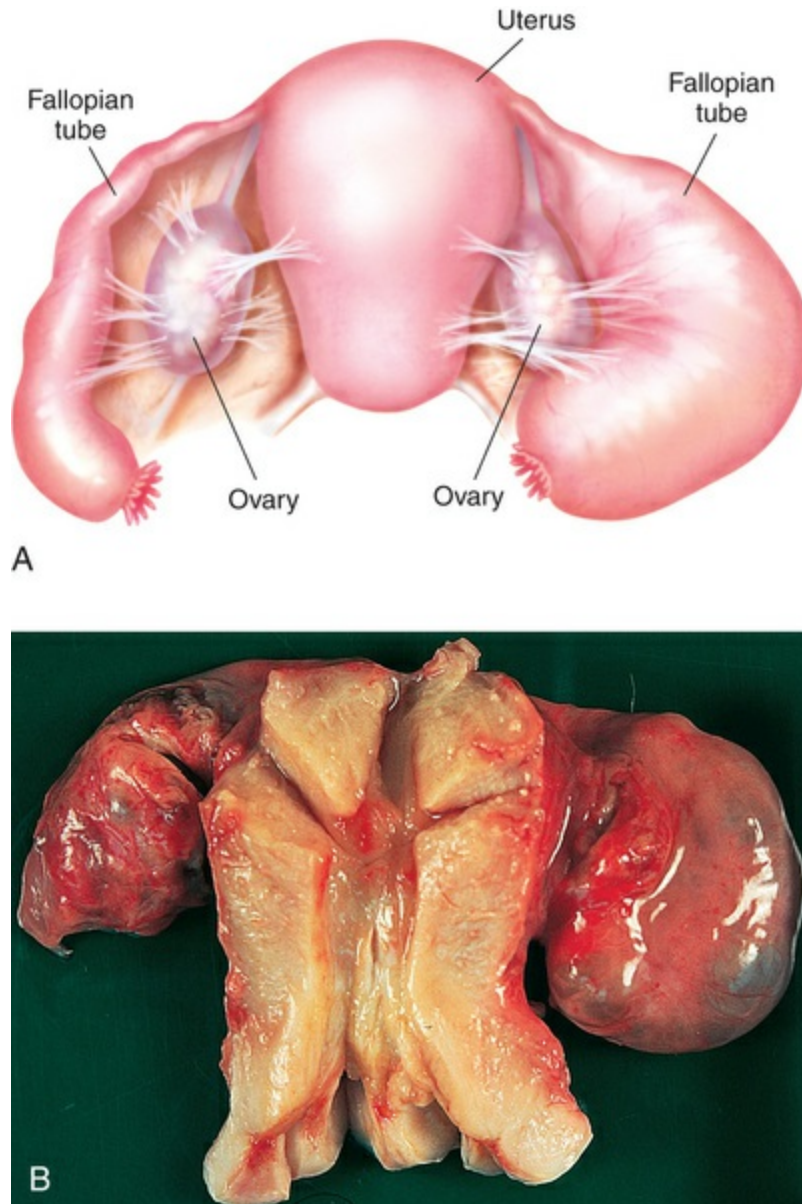

FIGURE 25.7 Salpingitis. A, Advanced pyosalpinx. Note the swollen fallopian tubes. B, Bilateral, retort-shaped, swollen, sealed tubes and adhesions of ovaries are typical of salpingitis. (A From Seidel HM et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby. B From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Pelvic inflammatory disease is very common in the United States and around the world and has both immediate and long-term health

implications for women. Infections of the upper reproductive tract cause changes to the delicate cells of the fallopian/uterine tubes, which can affect fertility and increase the risk of ectopic pregnancy.⁶⁵

◆Pathophysiology.

The development of upper genital tract infections is mediated by the failure of a number of defense mechanisms that usually are effective in preventing PID. Virulence of the organism, size of the inoculum, and defense status of the individual determine whether an infectious process results. Gonorrhea and chlamydia are the main infectious causes of PID.⁶⁶ These microorganisms can infect the vagina and cervix but do not usually ascend into the upper genital tract and cause PID (Fig. 25.8). However, when the normal vaginal microbial flora is disrupted, the pathogens can more easily ascend through the cervix.

FIGURE 25.8 Ascension of Pelvic Inflammatory Disease (PID). Microorganisms from the lower genital tract ascend into the endometrium, fallopian tubes, and peritoneum to cause endometritis-salpingitis-peritonitis (pelvic inflammatory disease). The *arrows* indicate the “flow” of microorganisms from the lower genital tract to the upper genital tract. This is noted as an ascending infection in the text. (Adapted from Brooks ML: *Exploring medical language*, ed 8, St Louis, 2012, Mosby.)

Many anaerobic bacteria have been implicated in increasing the risk of PID because they alter the pH of the vaginal environment and may decrease the integrity of the mucus blocking the cervical canal.⁶³

Bacterial vaginosis (BV) is present in up to 66% of women with PID; and other anaerobes, such as *Bacteroides*, *Gardnerella vaginalis*, and *Haemophilus influenzae*, and genital tract mycoplasmas (*Mycoplasma hominis*, *Mycoplasma genitalis*, and *Ureaplasma urealyticum*) are frequently isolated from women with PID (see [Chapter 27](#) for further discussion of BV). *Escherichia coli* may contribute to pelvic infections in older women. Therefore although gonorrhea and chlamydia are the main pathogens in PID, the disease is really polymicrobial and is treated with a broad spectrum of antibiotics to ensure that all the causative agents are eliminated.^{63,66}

Once the infection is established within the uterus and fallopian/uterine tubes, the infection may induce changes in the columnar epithelium lining the upper reproductive tract, causing permanent damage. The resultant inflammatory response causes localized edema and, occasionally, obstruction or necrosis of the area. Gonorrhea gonococci attach to the fallopian tubes and excrete a substance toxic to the tubal mucosa, causing further inflammation and damage. Chlamydia enters the tubal cells and replicates, bursting the cell membrane as it reproduces, causing permanent scarring. Gonorrhea and chlamydia can spread to the abdominal cavity through the openings of the fallopian/uterine tubes. Other mechanisms that may contribute to PID include lymphatic drainage with parametrial spread of the infection, sexual intercourse, and retrograde menstruation.⁶⁷

The rate of mortality from PID in the United States is fairly low. However, PID infection results in permanent changes to the ciliated epithelium of the fallopian or uterine tubes. Studies suggest that approximately 20% to 50% of women with PID subsequently struggle with infertility.⁶⁵ A recent study found that one episode of mild, subclinical PID resulted in a 40% decrease in later pregnancy rates, and multiple episodes of PID further increase the risk of infertility.⁶⁸ Scarring caused by PID greatly increases the risk of later ectopic pregnancy by up to 10-fold because the mobility of an egg through the fallopian tubes is slowed by damaged cilia.⁶⁷ Scarring and adhesions also can result in chronic pelvic pain and, potentially, an increased

risk of later uterine cancer.⁶⁷

◆Clinical Manifestations.

The clinical manifestations of PID vary from sudden, severe abdominal pain with fever to no symptoms at all. An asymptomatic cervicitis with or without discharge may be present for some time before PID develops. The first sign of the ascending infection may be the onset of low bilateral abdominal pain, most often characterized as dull and steady with a gradual onset.⁶⁶ Symptoms are more likely to develop during or immediately after menstruation. The pain of PID may worsen with walking, intercourse, or other activities involving movement. Other manifestations of PID include dysuria (difficult or painful urination), dyspareunia (pain with sexual intercourse), and irregular bleeding.⁶⁷

◆Evaluation and Treatment.

PID often has limited or vague clinical symptoms, leading to undertreatment and subsequent long-term health effects.⁶² Because PID is a substantial health risk to a woman, the Centers for Disease Control and Prevention (CDC) encourage clinicians to consider PID as a likely diagnosis when a sexually-active woman has abdominal or pelvic tenderness and *one* of the following: cervical motion tenderness, uterine tenderness, or adnexal tenderness.⁶⁶ [Box 25.6](#) lists the diagnostic criteria for PID. No laboratory tests or studies are needed to begin treatment; however, additional information can improve the specificity of diagnosis.⁶⁶ Abdominal pain in women can have many causes, and it is important to rule out other diagnoses ([Fig. 25.9](#)); however, further studies to rule out other diagnoses can be done while treating for PID.⁶⁶

Box 25.6

Diagnostic Criteria for Pelvic Inflammatory Disease (PID)

Minimum Criteria (One or More Needed for Diagnosis)

Cervical motion tenderness, *or*
Uterine tenderness, *or*
Adnexal tenderness

Additional Criteria That Increase Specificity of Diagnosis

Fever >38.3°C (>101°F)
Mucopurulent cervical or vaginal discharge, or cervical friability
Numerous white blood cells on saline wet prep
Elevated C-reactive protein
Elevated erythrocyte sedimentation rate
Documented infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*

Definitive Criteria (*Not* Needed for Treatment)

Transvaginal ultrasound, magnetic resonance imaging, *or* Doppler studies showing thickened and fluid-filled tubes
Laparoscopic visualization of PID-related abnormalities
Endometrial biopsy with evidence of endometritis

From Centers for Disease Control and Prevention (CDC): *Pelvic inflammatory disease (PID) treatment and care*, Atlanta, GA, 2015, U.S. Department of Health and Human Services.

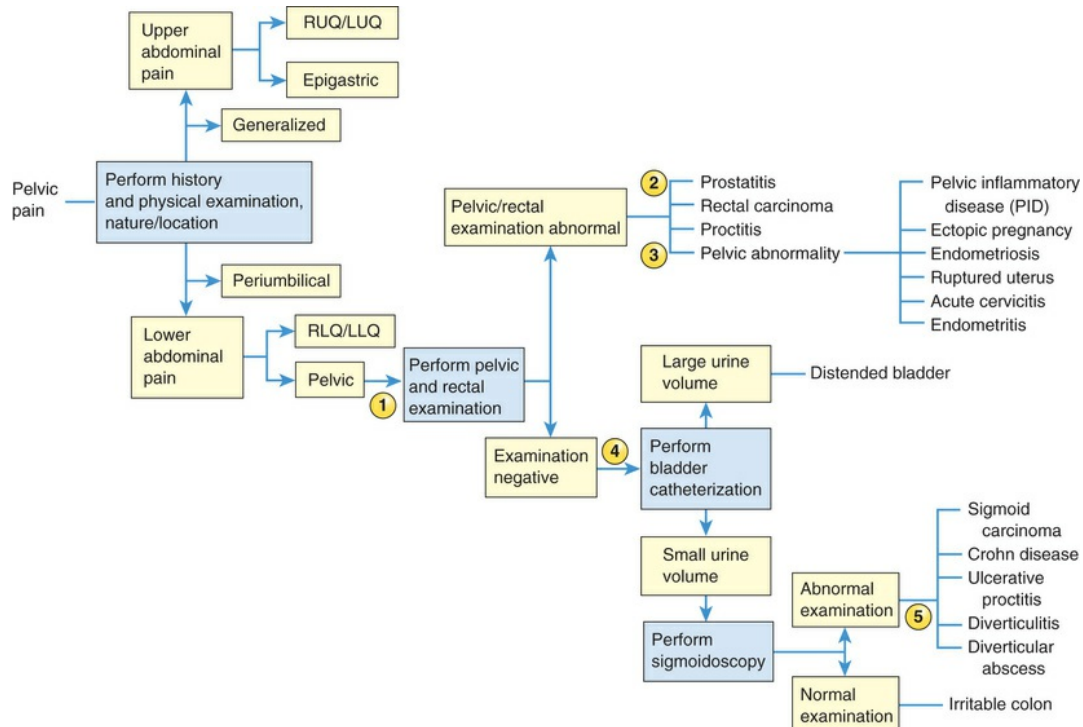

FIGURE 25.9 Diagnostic Algorithm for Pelvic Pain. LLQ, Left lower quadrant; LUQ, left upper quadrant; RLQ, right lower quadrant; RUQ, right upper quadrant.

Because of the significance of the complications of PID, rapid treatment is recommended even before the causative pathogen can be identified. Because treatment is empiric, it needs to be effective against a broad range of pathogens, especially chlamydia, gonorrhea, and anaerobic bacteria.⁶⁶ Treatment is usually conducted in an outpatient setting unless the woman has symptoms of advanced infection, cannot take oral medications, or is pregnant; or if other pathologic conditions cannot be excluded. The CDC-recommended outpatient regimen is shown in [Box 25.7](#).⁶⁶ Although alternative treatment regimens are available, the growing antibiotic resistance of gonorrhea limits antibiotic choices. The CDC is closely monitoring gonorrhea's antibiotic sensitivity and updates treatment guidelines periodically to reflect new information.⁶⁶ The most up-to-date treatment guidelines can be found on the CDC website.

Box 25.7

CDC Recommended Oral Treatment for Pelvic Inflammatory Disease

Ceftriaxone: 250 mg IM in a single dose

Doxycycline: 100 mg orally twice a day for 14 days

WITH or WITHOUT

Metronidazole: 500 mg orally twice a day for 14 days

Data from Centers for Disease Control and Prevention (CDC): *Pelvic inflammatory disease (PID) treatment and care*, Atlanta, GA, 2015, U.S. Department of Health and Human Services.

Sexual partners of women with PID also should also receive treatment, even if they are asymptomatic. Women receiving treatment should be reevaluated by their care provider in 3 days to ensure antibiotic treatment is effective.⁶⁶ Because women with a history of PID are at increased risk for ectopic pregnancy, they should seek care as soon as they know they are pregnant because ectopic pregnancy is a major cause of maternal mortality.⁶² Additionally, all sexually-active women younger than age 25 should receive minimal annual screening for chlamydia and gonorrhea, as well as women older than age 25 with a new sexual partner, more than one sexual partner, a partner who has been diagnosed with a sexually transmitted infection (STI), or a partner with more than one sexual partner.

Vaginitis

Vaginitis is irritation of the vagina that can be caused by a variety of microorganisms, irritants, or pathologies, or by a disruption of the normal flora of the vagina. Vaginitis is characterized by complaints of vaginal irritation, itching, burning, odor, or abnormal discharge. Clinically, an increase in the number of white blood cells or abnormal or foreign cells, or both, is observed on saline wet prep examination. The major causes of vaginitis are overgrowth of normal flora, sexually transmitted diseases, and vaginal irritation related to low estrogen

levels during menopause (a condition known as *atrophic vaginitis*). The primary forms of vaginitis are vulvovaginal candidiasis or yeast vaginitis, bacterial vaginosis, or trichomoniasis.^{69,70}

The irritation of vaginitis is related to an alteration in the vaginal environment, including changes in skin integrity, immune reaction, and particularly vaginal pH. The pH of the vagina depends on cervical secretions and the presence of normal flora that help maintain an acidic environment. A neutral or alkaline pH normally occurs before puberty, after menopause, and during pregnancy. The acidic nature of vaginal secretions during the reproductive years provides protection against a variety of sexually transmitted pathogens and establishes a healthy microflora in the vagina (see [Chapter 27](#)). Changes in the vaginal pH may predispose a woman to infection. Many substances and conditions can alter vaginal pH including exposure to soaps, spermicides, douches, feminine hygiene sprays, semen, or deodorant menstrual pads or tampons; and conditions associated with increased glycogen content of vaginal secretions, such as pregnancy or diabetes. Antibiotics can destroy normal vaginal flora, facilitating overgrowth of *Candida albicans*, causing a yeast vaginitis.

Normally vaginal discharge is a clear, milky, or cloudy secretion with a slippery or clumpy texture. It is nonirritating, has a mild smell, and may yellow after drying. Throughout the menstrual cycle the amount and texture of a woman's discharge change in response to hormonal fluctuation. Vaginal secretions increase at the time of ovulation, during pregnancy (because of increased estrogen levels), and with sexual arousal; just before menstruation, vaginal discharge becomes thick and sticky. Unusual changes in the amount, color, or texture of vaginal discharge may signal an infection, especially if the discharge is copious, malodorous, or irritating. Irritation of the vaginal area may be the result of many factors.

Diagnosis of the cause of vaginitis is based on history, physical examination, and examination of the discharge by wet mount; treatment by physical symptoms alone is inadequate.⁷⁰ Treatment involves developing and maintaining an acidic environment, relieving

symptoms (usually pruritus), and administering antimicrobial or antifungal medications to eradicate the infectious organism. If the infection can be sexually transmitted, a woman's partner also will be treated. Research suggests that probiotics, especially *Lactobacillus rhamnosus*, can encourage normal vaginal flora and decrease the incidence of vaginitis in women at risk for vaginitis.^{71,72}

Cervicitis

Cervicitis is a nonspecific term used to describe inflammation of the cervix. The CDC defines cervicitis as having two diagnostic signs: a purulent or mucopurulent discharge from the cervical os or endocervical bleeding, or both, induced by gently introducing a cotton swab into the cervix.⁷³ Cervicitis can have infectious or noninfectious causes, with approximately half of all cases caused by sexually transmitted pathogens.^{74,75} Chemicals and substances introduced into the vagina can cause cervicitis in addition to disrupting the normal vaginal flora. Age and risk factors are important in assessing a woman with cervicitis. Younger women are at risk for sexually transmitted infections (STIs) and should be tested for chlamydia, gonorrhea, and *Trichomonas*. Older women with cervicitis may have STIs but are more likely to have irritation from abnormal vaginal flora related to low vaginal estrogen levels. In cases where no infectious agent is found, pharmacologic therapy may still be effective. Surgery may be an option or necessary for unresponsive and chronic cases.⁷⁴

Mucopurulent cervicitis (MPC) usually is caused by one or more sexually transmitted pathogens, such as *Trichomonas*, *Gonorrhea*, *Chlamydia*, *Mycoplasma*, or *Ureaplasma*. Infection causes the cervix to become red and edematous. A mucopurulent (mucus- and pus-containing) exudate drains from the external cervical os, and the individual may report pelvic pain, bleeding, or dysuria. The cervix often becomes friable, bleeding easily during sexual intercourse or with pelvic examinations and Papanicolaou (Pap) smears. Because mucopurulent cervicitis is a symptom of PID, women at risk for STIs, especially those less than 25 years old, should receive treatment for PID while awaiting results of microbial testing.⁷³ If the woman is not

at risk for STIs, a thorough evaluation often reveals another cause for the inflammation.

Vulvodynia

Vulvodynia (also referred to as *vulvitis*, *vestibulitis*, or *vulvovestibulitis*) is chronic pain and inflammation of the vulva or vestibule, or both. In many cases it may represent several disorders without an identifiable cause. Vulvodynia is fairly common, affecting up to 16% of women at some point in life.⁷⁶ Whereas the inflammation of vulvodynia may be caused by contact dermatitis (i.e., exposure to soaps, detergents, lotions, sprays, shaving, menstrual pads/tampons, perfumed toilet paper, tight-fitting clothes), the condition may be more complex and represent abnormalities in multiple systems, including vestibular mucosa, pelvic floor musculature, and CNS pain regulatory pathways.⁷⁶ The condition may also represent an autoimmune reaction, similar to fibromyalgia. Genetic and psychologic links have also been proposed and studied.⁷⁷ The mechanisms are poorly understood; thus vulvodynia is difficult to evaluate and treat. Vulvodynia can be classified as generalized or localized and as provoked and unprovoked.⁷⁷ Vulvodynia may increase susceptibility to vaginal infection; likewise, it may be caused by vaginal infections (e.g., candidiasis, trichomoniasis) that spread to the labia, where they cause inflammation and edema. Other skin diseases, such as tinea cruris, psoriasis, lichen sclerosus, and inflammation of the apocrine (sweat) glands, can involve the vulva (see [Chapter 47](#)). Assessment includes excluding and treating conditions that may contribute to or cause vulvar inflammation (e.g., *Candida*, STI, seborrhea, psoriasis, lichen sclerosus, and contact dermatitis), and gently probing the vagina (e.g., labia majora and minora, vestibule, interlabial sulcus, clitoris) with a cotton-tipped swab to assess whether the pain is generalized or local to one region and how the pain is perceived in terms of quality (e.g., sharp, burning) and severity.

Treatment is focused on identifying and treating any infectious cause or comorbid contributor and using a multidisciplinary approach to address both the physical and the emotional aspects of the disorder.

Women are advised to avoid potential irritants and to wear loose cotton clothing, use mild soaps, and apply a vaginal emollient (e.g., coconut or vegetable oil) after bathing. Studies on treatments are limited but suggest that women may benefit from topical lidocaine (Xylocaine) or estrogen cream; topical or systemic antidepressants or anxiolytics; Botox injections into the affected nerve; dietary modifications; physical therapy; behavioral or sexual counseling, or both; acupuncture; nerve blocks; or vestibulectomy.⁷⁶

Bartholinitis

Bartholinitis, or **Bartholin cyst**, is an inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands ([Fig. 25.10](#)). The usual causes of bartholinitis are microorganisms that infect the lower female reproductive tract, such as streptococci, staphylococci, and sexually transmitted pathogens.

FIGURE 25.10 Inflammation of Bartholin Gland. (Modified from Gershenson DM et al: *Operative gynecology*, ed 2, Philadelphia, 2001, W.B. Saunders. In Fuller JK: *Surgical technology*, ed 6, Philadelphia, 2013, Saunders.)

Infection or trauma causes inflammatory changes that narrow the distal portion of the duct, leading to obstruction and stasis of glandular secretions. The obstruction, or cyst, varies from 1 to 8 cm in diameter and is located in the posterolateral portion of the vulva. The cyst may be reddened and painful, and pus may be visible at the opening of the duct. Any exudate should be tested for gonorrhea and chlamydia. The individual may have symptoms of the initiating infection, fever, and malaise. Diagnosis of a Bartholin cyst is based on the clinical manifestations and the identification of infectious microorganisms.

Most Bartholin cysts are asymptomatic and require no treatment in women younger than age 40.⁷⁸ However, if they are uncomfortable or show signs of infection, treatment is advised to prevent abscess formation. Treatment is controversial but involves broad-spectrum antibiotics for suspected infection.⁷⁸ Some clinicians also attempt to drain the cyst using hot soaks, needle aspiration, insertion of a catheter, or marsupialization of the infected gland. No one treatment has proved to be superior in symptom relief and prevention of recurrence. In women older than 40, drainage and biopsy are advised to rule out carcinoma.⁷⁸

Pelvic Organ Prolapse

The bladder, urethra, and rectum are supported by the endopelvic fascia and the perineal muscles, particularly the levator ani group. This muscular and fascial tissue loses tone and strength with aging and may not maintain the pelvic organs in the proper position. The pelvic area contains many organs and has the force of gravity and the abdominal contents pushing down on it. If the pelvic fascia and musculature are not firm, the pelvic organs may move to fill any space voids. With weak support, the bladder and rectum tend to push into the vagina and vaginal wall. The vagina is an opening in the pelvic musculature for intercourse and childbirth. (Chapter 24 contains a discussion of pelvic support structures.) However, as gravity acts on the pelvis, this opening becomes a weakness in the musculature support of the entire pelvic cavity. Without proper support from the

vaginal muscles and fascia, the uterus and bulging vaginal walls can begin to herniate through the vaginal opening.

Pelvic organ prolapse (POP) is the descent of one or more of the following into the vaginal space: the vaginal wall, the uterus, or the apex of the vagina (after a hysterectomy).⁷⁹ Up to 50% of women have some version of POP on physical examination. However, most women have no symptoms, and there is no need for intervention. As the degree of prolapse increases, women feel more vaginal pressure. Bulging of the organs beyond the hymenal ring or vaginal entrance is commonly used as the clinical indicator for significant prolapse.⁷⁹ When prolapse becomes severe, the function of the surrounding organs can be altered. For instance, as the bladder is pulled posteriorly, incontinence and incomplete voiding become more common. As the bowel bulges into the vaginal space, defecation becomes more difficult. The severity of POP and its symptoms increase with age, and half of women older than age 50 have symptoms of POP.⁷⁹

POP is multifactorial, but several factors contribute to the weakening the pelvic fascia that support the female reproductive tract. Trauma is the most common risk factor, including vaginal birth (especially with a large baby or forceps) and hysterectomy.⁷⁹ Both of these events can cause disruption or tearing of the pelvic fascia. Chronic stress on the pelvic fascia also contributes to risk. Pregnancy, obesity, prolonged standing, and chronic constipation are associated with stretching of the fascia and prolapse over time. Women with connective tissue disorders are also at risk, so there is a strong genetic/familial component. In addition, risk of prolapse increases with age because of cumulative effects of stress on the pelvic floor. Because estrogen improves vascularity of the pelvic area, postmenopausal women are at risk since their fascia and pelvis musculature lose resilience with diminished estrogen levels.⁷⁹ A list of risk factors is contained in [Box 25.8](#).

Box 25.8

Risk Factors Associated With Pelvic Organ Prolapse

- Menopause
 - Aging
 - Hypoestrogenism
- Chronically increased
 - Intraabdominal pressure
 - Pregnancy
 - Coughing (lung disease)
 - Constipation
 - Obesity
 - Prolonged standing or lifting
- Pelvic floor trauma
 - Vaginal childbirth
 - Hysterectomy
- Genetic factors
 - Connective tissue disorders
 - Spina bifida

From Barber MD: *Br Med J* 354:i3853, 2016; Schaefer JI: Pelvic organ prolapse. In Hoffman BL et al, editors: *Williams gynecology*, ed 3, pp 538–561, New York, 2016, McGraw-Hill.

The trend is to use terminology that describes physical examination findings, thus avoiding assumptions about structural involvement (Box 25.9). The terms *cystocele* and *rectocele* may be used when the structures involved (bladder and rectum, respectively) have been definitively identified (i.e., an anterior vaginal wall prolapse may or may not be a cystocele involving the urinary bladder) (see Fig. 25.12). Examining the woman in multiple positions and while straining maximally provides the best information about the degree of pelvic organ relaxation.⁷⁹ Physical examination may be augmented with imaging by ultrasound, or magnetic resonance. Several systems are used to describe prolapse. One in widespread clinical use is based on

physical examination findings (see [Box 25.9](#)) and uses a grading system to describe the extent of the prolapse ([Box 25.10](#)). Subjective reports regarding the symptoms and effects of POP can be assessed through direct questioning or by using questionnaires such as the Pelvic Floor Impact Questionnaire or the Pelvic Floor Distress Inventory.

Box 25.10

Evaluation of Pelvic Organ Prolapse (Baden-Walker Halfway Scoring System)

Grade 0: Normal position, no prolapse
Grade 1: Descent halfway to the hymen
Grade 2: Descent reaches the hymen
Grade 3: Descent halfway past hymen
Grade 4: Maximum possible descent for each site
NOTE: Any type of prolapse (posterior, apical, anterior vaginal,

uterine, etc.) can be graded using this system.

From Baden WF, Walker TA: *Clin Obstet Gynecol* 15:1070–1072, 1972.

Uterine prolapse is descent of the cervix or entire uterus into the vaginal canal (Fig. 25.11). In severe cases the uterus falls completely through the vagina and protrudes from the introitus. Symptoms of other pelvic floor disorders also may be present.

FIGURE 25.11 Degrees of Uterine Prolapse. Grade 1 is minimal and rarely requires correction; Grade 2 prolapse has moderate symptoms, and Grade 3 prolapse is severe. The uterus is so low that the cervix protrudes from the vagina. (From Phillips N: *Berry & Kohn's operating room technique*, ed 12, Philadelphia, 2013, Mosby.)

Fig. 25.12 shows vaginal prolapse caused by cystocele and rectocele. **Cystocele** is descent of a portion of the posterior bladder wall and trigone into the vaginal canal. In severe cases, the bladder and anterior vaginal wall bulge outside the introitus. Occasionally a cystocele causes significant residual urine and an increased rate of bladder infections.

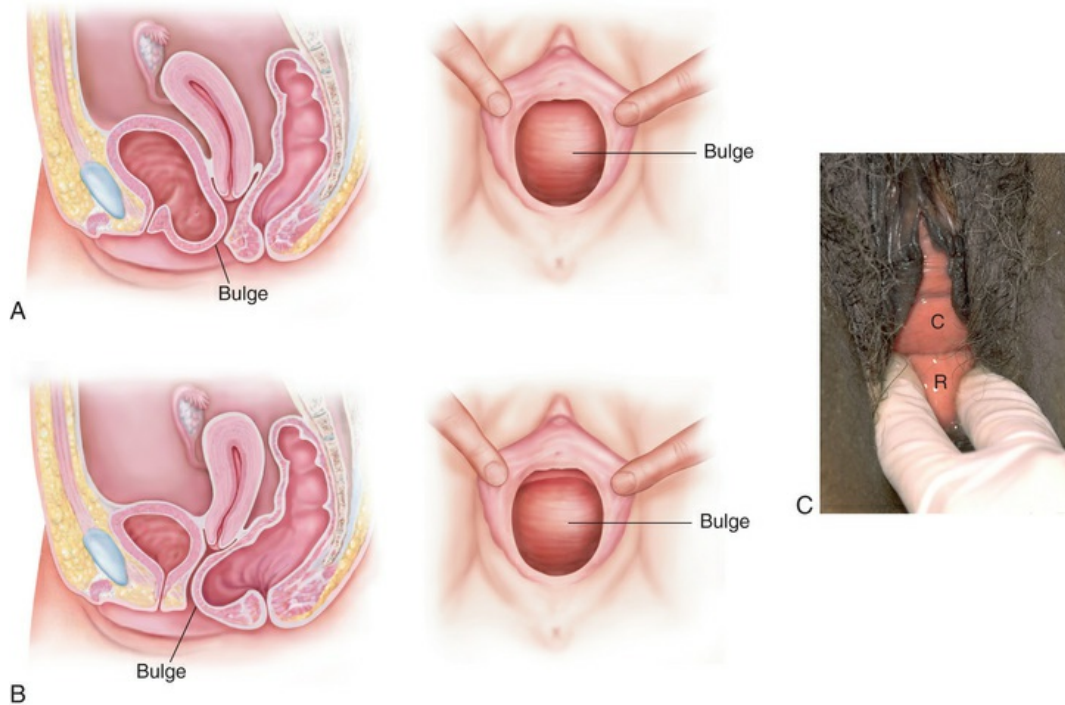

FIGURE 25.12 Cystocele and Rectocele. A, Grade 2: anterior vaginal wall prolapse. B, Grade 2: posterior wall prolapse. C, Photo showing cystocele (C) and rectocele (R). (A and B From Seidel H et al: *Mosby's guide to physical examination*, ed 4, St Louis, 1999, Mosby. C From Seidel HM et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.)

A **rectocele** is the bulging of the rectum and posterior vaginal wall into the vaginal canal. Although most rectoceles are asymptomatic, larger ones cause vaginal pressure, rectal fullness, and incomplete bowel evacuation. If rectoceles are severe, defecation is difficult and can be facilitated by applying manual pressure to the posterior vaginal wall.

An **enterocele** is herniation of the rectouterine pouch into the rectovaginal septum (between the rectum and posterior vaginal wall). It can be congenital or acquired. Congenital enteroceles rarely cause symptoms or progress in size. Enteroceles also can result from a muscular weakness caused by previous surgery, especially surgeries through the vagina, or by pelvic relaxation disorders, such as uterine prolapse, cystocele, and rectocele. Most large enteroceles are found in grossly obese and older adults and can be complicated by rupture or complete eversion of the vagina with trophic ulceration, edema, and fibrosis. Treatment is surgical. [Box 25.11](#) summarizes the symptoms

and treatments of POP.

Box 25.11

Pelvic Organ Prolapse: Symptoms and Treatments

SYMPTOMS	TREATMENT
<p>Urinary Sensation of incomplete emptying of bladder Urinary incontinence Urinary frequency/urgency Bladder “splinting” to accomplish voiding</p> <p>Bowel Constipation or feeling of rectal fullness or blockage Difficult defecation Stool or flatus incontinence</p> <p>Urgency Manual “splinting” of posterior vaginal wall to accomplish defecation</p> <p>Pain and Bulging Vaginal, bladder, rectum Pelvic pressure, bulging, pain Lower back pain</p> <p>Sexual Dyspareunia Decreased sensation, lubrication, arousal</p>	<p>Depending on age of woman and cause and severity of the condition: Isometric exercise to strengthen the pubococcygeal muscle (Kegels) Estrogen to improve tone and vascularity of fascial support (postmenopausal) Pessary (a removable device) to hold pelvic organs in place Weight loss Avoidance of constipation Treatment of cough/lung conditions</p> <p>Surgical Reconstructive: autologous grafts; synthetic mesh/sling Obliterative (most extreme)</p>

Treatment of POP depends on the severity of symptoms and the physical condition of the woman. Treatment is often progressive with less aggressive treatments tried first. The pelvic fascia may be strengthened through Kegel exercises (repetitive isometric tightening and relaxing of the pubococcygeal muscles) or by estrogen therapy in menopausal women. Maintaining a healthy body mass index (BMI), preventing constipation, and treating chronic cough or constipation may help as well. A common treatment is a **pessary**, which is a removable device that, when placed in the vagina, holds the uterus in

position.⁸⁰ Surgical repair with or without hysterectomy is the treatment of last resort. Women should be active participants in the decision-making surrounding treatment because they need to balance expectations for improvement with potential side effects⁷⁹ (see [What's New? Vaginal Mesh](#)).

What's New?

Vaginal Mesh

Because pelvic organ prolapse is often a result of weakened pelvic fascia and musculature, a surgical mesh was developed to improve pelvic support. This mesh was designed to be placed surgically along the area needing support. The goal was to have the woman's tissues grow through the mesh and provide consistent, long-term support. However, women who received the surgical mesh had a high rate of complications, including infection and persistent postoperative pain. In many cases the mesh eroded through the tissue, protruding into the vagina and perforating other organs. In addition, the mesh may shrink over time, causing vaginal shortening, tightening, and pain. The U.S. Food and Drug Administration (FDA) has issued several warnings about the mesh to caution women and practitioners and encourage fully informed consent about the risks and benefits of mesh placement, and the FDA has reclassified the surgical mesh based on the lack of data about the safety of implanted mesh.

Data from U.S. Food and Drug Administration: Reclassification of surgical mesh for transvaginal pelvic organ prolapse repair and surgical instrumentation for urogynecologic surgical mesh procedures: designation of special controls for urogynecologic surgical mesh instrumentation 2014, 2015. Available at:

<https://www.federalregister.gov/documents/2014/05/01/2014-09907/reclassification-of-surgical-mesh-for-transvaginal-pelvic-organ-prolapse-repair-and-surgical>. Accessed Sept 19, 2016.

Benign Growths and Proliferative Conditions

Benign Ovarian Cysts

Benign cysts of the ovary may occur at any time during the life span, but are most common during the reproductive years and, in particular, at the extremes of those years (Fig. 25.13). An increase in benign ovarian cysts occurs when hormonal imbalances are more likely (e.g., during puberty and menopause).⁸¹ However, ovarian masses can occur during fetal development and throughout childhood as well.⁸²

FIGURE 25.13 Ovarian Cyst.

Benign ovarian cysts are quite common and are the fourth leading diagnosis for gynecologic hospital admissions.⁸³ Two common causes of benign ovarian enlargement in ovulating women are follicular cysts and corpus luteum cysts. These cysts are called **functional cysts** because they are caused by variations of normal physiologic events. Follicular and corpus luteum cysts are usually unilateral. They are typically 5 to 6 cm in diameter but can grow as large as 8 to 10 cm. Most women are asymptomatic. Any ovarian mass greater than 6 cm or noted for a period longer than 12 weeks should be referred to a gynecologist.⁸⁴

Benign cysts of the ovary are produced when a follicle or a number of follicles are stimulated but no dominant follicle develops and completes the maturity process. Every month about 120 follicles are

stimulated, but in most cycles only 1 follicle succeeds in ovulating a mature ovum. Normally, during the early follicular phase of the menstrual cycle, follicles of the ovary respond to hormonal signals from the pituitary gland. The pituitary produces FSH to mature follicles in the ovary. As the follicles enlarge, granulosa cells in the follicle multiply and secrete estradiol (a form of estrogen). As a dominant follicle develops, it secretes higher levels of estradiol, which stimulates the LH surge that comes from the pituitary. A small cyst on the ovary during the follicular phase is normal. The LH surge stimulates the follicle to rupture, releasing the ovum and transforming the granulosa cells of the dominant follicle into the corpus luteum. If the dominant follicle develops properly before ovulation, the corpus luteum becomes vascularized and secretes progesterone. Progesterone arrests development of other follicles in both ovaries in that cycle. LH, proteolytic enzymes, and prostaglandins trigger follicular rupture and release of the ovum.

Follicular cysts can be caused by a transient condition in which the dominant follicle fails to rupture or one or more of the nondominant follicles fail to regress. This disturbance is not well understood. It may be that the hypothalamus does not receive or send a message strong enough to increase FSH levels needed to develop or mature a dominant follicle. The hypothalamus monitors blood levels of estradiol and progesterone; when FSH level is low, estradiol does not increase enough to stimulate LH. Evidence indicates that when progesterone is not being produced, the hypothalamus releases GnRH to increase the FSH level.⁸⁵ FSH continues to stimulate follicles to mature, and the granulosa cells grow and, presumably, estradiol increases. This abnormal cycle continues to stimulate follicular size and causes follicular cysts to develop. Clinical symptoms of follicular cysts or even a single cyst are bloating, swollen and tender breasts, and heavy or irregular menses. After several subsequent cycles in which hormone levels once again follow a regular cycle and progesterone levels are restored, cysts usually are absorbed or regress.

Follicular cysts can vary in size and symptoms from one episode to the next and often can recur. Most are fluid filled; the more solid an

ovarian cyst, the greater the chance of malignancy. Follicular cysts can be treated with combined estrogen-progestin oral contraceptives because they block the HPG axis, effectively quieting the ovary. Progestin-only contraceptives, however, increase the likelihood of developing follicular cysts because ovarian function is diminished, but not suppressed, leading to an increased number of immature follicles.⁸¹

A **corpus luteum cyst** is normally formed by the granulosa cells left behind after ovulation. This cyst is highly vascularized but limited in size and spontaneously regresses as part of the normal menstrual cycle. However, an abnormal or hemorrhagic cyst may develop because of a hormonal imbalance in low LH and progesterone levels causing an inadequate development of the corpus luteum. In some cases, large cysts can rupture, causing hemorrhage.⁸²

Corpus luteum cysts are less common than follicular cysts, but luteal cysts typically cause more symptoms, particularly if they rupture. Manifestations include dull, unilateral pelvic pain and amenorrhea or delayed menstruation, followed by irregular or heavier than usual bleeding. Rupture occasionally occurs and can cause massive bleeding with excruciating pain; immediate surgery may be required. Corpus luteum cysts usually regress spontaneously in nonpregnant women. A persistent corpus luteum cyst is a normal finding within the first trimester of pregnancy since the corpus luteum produces progesterone to support the pregnancy until the placenta is established.⁸¹ Following the development of a large, painful, or hemorrhagic cyst, oral contraceptives can be used to suppress ovarian function and prevent future cysts.

Dermoid cysts are ovarian teratomas that contain elements of all three germ layers; they are common ovarian neoplasms. These growths may contain mature tissue including skin, hair, sebaceous and sweat glands, muscle fibers, cartilage, teeth, and bone. Dermoid cysts are usually asymptomatic and are found incidentally on pelvic examination. However, these cysts should be carefully evaluated for removal because they have malignant potential.⁸¹

Torsion of the ovary is a rare complication of ovarian cysts or tumors

or enlargement of the ovary and can occur in girls or women. If a cyst is large enough it can cause the ovary to twist on its ligaments, pinching off blood supply to the ovary and causing extreme pain. Ovarian torsion is rare but is a gynecologic emergency. Individuals present with acute, severe unilateral abdominal or pelvic pain. Ovarian torsion is treated surgically.⁸⁶

Endometrial Polyps

An **endometrial polyp** is a benign mass of endometrial tissue, covered by a surface epithelium, and contains a variable amount of glands, stroma, and blood vessels. Endometrial polyps can occur anywhere within the uterus. Polyps are morphologically diverse and usually classified as hyperplastic, atrophic (or inactive), or functional. In the last case, the surface epithelium may be “out of phase” with other endometrial tissue. Hyperplastic polyps are often pedunculated and may be mistaken for endometrial hyperplasia or, if large, adenocarcinoma (Fig. 25.14). Although polyps most often develop in women between ages 40 and 50, they can occur at all ages. These are often related to estrogen stimulation. An estimated 20% to 25% of women have uterine polyps, including as many as 35% of women with abnormal uterine bleeding.⁸²

FIGURE 25.14 Uterine Polyps Visible Through Hysteroscopy. (From Cheng C et al: *J Minim Invasive Gynecol* 16[6]:739–742, 2009.)

Endometrial polyps are a common cause of intermenstrual or excessive menstrual bleeding. Diagnosis is made by transvaginal sonography or hysteroscopy. Risk factors include advanced age; obesity; nulliparity; early menarche or late menopause, or both; diabetes; tamoxifen use; hypertension; and estrogenic states (i.e., anovulatory cycles and unopposed estrogen). Malignancy is rare (up to 4.8% of polyps have evidence of malignancy); however, polyps that cause abnormal bleeding have twice the rate of malignancy of asymptomatic polyps.⁸⁷ Coexistence of a separate endometrial atypical hyperplasia or adenocarcinoma is common. Uterine polyps have a high rate of spontaneous resolution but have been associated with suboptimal fertility.^{82,88} Polypectomy can be performed through hysteroscopy for symptomatic women, for those at risk for malignancy, or for women who are struggling to conceive.⁸⁹

Leiomyomas

Leiomyomas, commonly called **myomas** or **uterine fibroids**, are benign smooth muscle tumors in the myometrium (Fig. 25.15). Leiomyomas are the most common benign tumors of the uterus, affecting as many as 70% to 80% of all women, and most remain small, asymptomatic, and clinically insignificant.⁹⁰ Prevalence increases in women ages 30 to 50 but decreases with menopause. The incidence of leiomyomas in black and Asian women is two to five times higher than that in white women, and the age of onset for black women is, on average, 10 years earlier than that for white women.⁹¹ Complications related to leiomyomas are the primary reason for gynecologic hospitalizations and account for 30% of all hysterectomies in women less than 40 years of age.^{83,91}

FIGURE 25.15 Leiomyoma (Fibroid) Classification System. (From Munro M et al: *Int Gynaecol Obstet* 113[1]:3–13, 2011.)

The cause of uterine leiomyomas is unknown, although their size appears to be related to estrogen, progesterone, growth factors, angiogenesis, and apoptosis. There is a genetic component to fibroids, and the leiomyomas exhibit chromosomal changes within their tissues.⁹² Leiomyomas are estrogen- and progesterone-sensitive and are found to have increased numbers of estrogen receptors.⁸² Uterine leiomyomas are not seen before menarche, and those that develop during the reproductive years generally decrease in size after menopause. Occurrence is multifactorial but often linked with estrogen exposure. Tumors in pregnant women may enlarge rapidly

but often decrease in size after the end of the pregnancy. Risk factors for fibroids include nulliparity, obesity, PCOS, black race, postmenopausal hormone use, and hypertension.⁹²

◆Pathophysiology.

Most leiomyomas occur in multiples in the fundus of the uterus, although they may occur singly and throughout the uterus. Leiomyomas are classified as subserous, submucous, or intramural according to their location within the various layers of the uterine wall (Fig. 25.16). Uterine leiomyomas are usually firm and surrounded by a connective tissue layer. Unlike cancer, leiomyomas are unable to cause blood vessel proliferation to support their growth. Degeneration and necrosis may occur when a large leiomyoma outgrows its blood supply; the ensuing tissue necrosis causes pain.

FIGURE 25.16 Leiomyomas. A, Uterine section showing whorl-like appearance and locations of leiomyomas, which are also called *uterine fibroids*. B, Multiple leiomyomas in sagittal section. Typical, well-circumscribed, solid, light gray nodules distort uterus. (B From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

◀Clinical Manifestations.

The major clinical manifestations of leiomyomas are abnormal uterine bleeding, pain, and symptoms related to pressure on nearby structures. The leiomyoma may distort the uterine cavity and increase the endometrial surface area. This increase may account for the increased menstrual bleeding that is associated with leiomyomas. Pain is not an early symptom but tends to occur with the devascularization of larger leiomyomas. It is also associated with blood vessel compression that limits blood supply to adjacent structures. Symptoms of abdominal pressure are slow to develop, apparently because the tumor is relatively slow growing, enabling adjacent structures to adapt to pressure. Pressure on the bladder may contribute to urinary frequency, urgency, and dysuria. Pressure on the ureter may cause it to become distended “upstream” from the pressure point; rectosigmoid pressure may lead to constipation. A sensation of abdominal or genital heaviness may be felt with larger tumors. Fibroids also may contribute to infertility and subfertility.

◆ Evaluation and Treatment.

Uterine leiomyomas are suspected when the bimanual examination discloses uterine enlargement and irregular, nontender nodularity of the uterus. Pelvic sonography or MRI confirms diagnosis.⁸² Treatment depends on the symptoms, tumor size, age, reproductive status, overall health of the individual, and the woman's preference.⁹³ Most myomas are asymptomatic and can be managed by observation only. Medical treatment for symptomatic women not desiring pregnancy is aimed at shrinking the myoma, or reducing symptoms, or both. Some leiomyomas shrink in response to oral contraceptives; however, oral contraceptive pills (OCPs) may enhance growth, so they should be monitored carefully. An LNG-IUD (progestin-only) may be helpful for women who wish to reduce their bleeding and decrease the size of the tumors, if their uterine cavity is not completely blocked by large fibroids. GnRH agonists are usually a temporary management for those close to menopause or as a presurgical treatment. GnRH side effects related to decreased levels of estrogen, including hot flashes and osteoporosis, limit its usefulness. Various selective estrogen

receptor modulators have been studied alone and in conjunction with GnRH agonists and appear effective, although more research is needed, especially because these agents may decrease bone density.⁹³ GnRH antagonists also have been shown to reduce fibroid volume. Progesterone receptor agonists, such as mifepristone (RU486) and ulipristal acetate, also have shown some effectiveness in shrinking leiomyomas; these have been approved for use in Europe for the purpose of shrinking fibroids before surgery. Promising nonpharmacologic therapies include green tea extract, curcumin (the active ingredient in turmeric), vitamin D, and herbal preparations used in Chinese medicine specifically to treat fibroids.⁹³

Surgical treatments are commonly used but may be decreasing in frequency. Hysterectomy is commonly performed for bleeding and pain related to fibroids. Myomectomy, or removal of the fibroid from the muscle of the uterus, may be less invasive than a full hysterectomy and remains the standard of treatment for women wishing to preserve their fertility. Newer less-invasive treatments that show promise include uterine artery embolization, and MRI-guided ultrasonography to coagulate areas of the fibroid, causing tissue destruction and involution. The benefits and risks of each therapy should be carefully explored with women who experience severe symptoms.⁹³

Adenomyosis

Adenomyosis is the presence of endometrial tissue within the uterine myometrium. Endometrial cells migrate into the myometrial layer through an unknown mechanism. Estrogen and progesterone likely play a role and, perhaps, metaplasia of müllerian tissue. Unlike endometriosis, this tissue does not respond to cyclic hormone changes. It is more commonly found during the late reproductive years; however, because adenomyosis is generally diagnosed after hysterectomy, time of diagnosis may not correspond with incidence. Adenomyosis has been found in up to 30% to 60% of hysterectomy specimens from otherwise normal women; rates are higher for women taking tamoxifen.⁸² Parity also increases the risk for adenomyosis, as does any history of uterine surgery. While women diagnosed with

adenomyosis are often out of their childbearing years, those with adenomyosis who become pregnant are at risk for poor outcomes, including preterm labor, preterm premature rupture of membranes, and low birth weight.⁸²

Adenomyosis may be asymptomatic or may be associated with abnormal menstrual bleeding, dysmenorrhea, dyspareunia, uterine enlargement, uterine tenderness during menstruation, chronic pelvic pain, and infertility.⁹⁴ Secondary dysmenorrhea becomes increasingly severe as disease progresses. On bimanual examination the uterus is diffusely enlarged (two to three times the expected size), globular, and most tender just before or after menstruation. Diagnosis is confirmed with ultrasound or MRI.⁹⁴ Treatment is symptomatic and first-line therapies include NSAIDs, combined oral contraceptives, and the LNG-IUD. Other promising medical treatments include selective estrogen receptor modulators, high-dose progestins, selective progesterone receptor modulators, aromatase inhibitors, and GnRH agonists.⁹⁵ Surgical treatment includes resection of localized areas of adenomyosis (though this is difficult) or, if severe, hysterectomy. Uterine artery embolization and uterine ablation have shown good initial results but need further testing. In addition, there is an emerging body of research looking at the use of high-intensity ultrasound and other interventional radiology treatments.⁹⁵ Decisions are based on managing symptoms and whether future fertility is desired.

Endometriosis

Endometriosis is the presence of functioning endometrial tissue or implants outside the uterus. Like normal endometrial tissue, the ectopic (out of place) endometrium responds to the hormonal fluctuations of the menstrual cycle. Common sites of implantation include the pelvic peritoneum, ovaries, and uterosacral ligaments. Endometriosis primarily affects younger (premenopausal) women, with peak incidence in the third decade. However, the overall incidence of endometriosis is difficult to determine, particularly in asymptomatic adolescent and fertile women. It is estimated that 11%

of asymptomatic women have endometriosis; however, as many as 50% of women evaluated for pelvic pain, infertility, or a pelvic mass are diagnosed as having endometriosis.⁹⁶ It is the third most common reason for hysterectomy.⁹⁷ In addition, women with endometriosis are at greater risk for cancers, especially ovarian cancer.⁹⁸

The cause of endometriosis is not known, but multiple theories have been proposed. One commonly accepted theory was proposed in 1927,⁹⁹ and suggested that endometriosis is caused by the implantation of endometrial cells during **retrograde menstruation**, in which menstrual fluids move through the fallopian tubes and into the pelvic cavity. Indeed, there is a higher incidence of endometriosis in women who have an obstructed menstrual flow.⁹⁷ However, it is now known that although retrograde menstruation occurs in almost all women, not all women develop endometriosis.

Another theory is that women with endometriosis have impaired cellular and humoral immunity. Alterations in cytokine and growth factor signaling have been identified. Cytotoxic T-cell and natural killer (NK) cell activity has been found to be depressed. At the same time, increased numbers of macrophages appear to be stimulating endometrial cell proliferation outside the uterus. An autoimmune response is also suspected.¹⁰⁰ Such alterations may cause the body to tolerate ectopic implantation of endometrial cells. Researchers also have proposed that endometrial cells spread through the lymphatic or vascular systems or that multipotential cells in the epithelial coverings of reproductive organs are somehow stimulated to develop into endometrial and metaplastic cells. Another theory, supported by recent findings of endometriosis found in female fetuses,¹⁰¹ is that endometrial cells may spread outside the uterus during fetal organogenesis. A genetic predisposition to endometriosis has been documented, and genetic polymorphisms have been identified; emerging research also suggests that there may be a disruption in gene expression during embryogenesis that is responsible for the generation of endometriosis.¹⁰²

◆Pathophysiology.

Endometrial implants can occur throughout the body but generally occur in the pelvic and abdominal cavities. The most common sites of implantation are the ovaries, uterine ligaments, rectovaginal septum, and pelvic peritoneum (Fig. 25.17). Other sites of implantation are the sigmoid colon, small intestine, rectum, appendix, bladder, uterus, vulva, vagina, cervix, lymph nodes, extremities, pleural cavity, lungs, laparotomy scars, and hernial sacs. Indeed, pathologic studies have found endometriosis on all organs of the body except the spleen.¹⁰³

FIGURE 25.17 Pelvic Sites of Endometrial Implantation. Endometrial cells may enter the pelvic cavity during retrograde menstruation.

The growth of endometrial lesions depends on estrogen exposure. Endometriosis lesions are affected by ovarian hormones in the same manner as endometrial tissue within the uterus, with the exception of marked progesterone resistance of the endometriosis cells. Cyclic changes depend on the vascularity and blood supply of the lesion and the presence of glandular and stromal cells. Given that blood supply is sufficient, the ectopic endometrium proliferates, breaks down, and bleeds with the normal menstrual cycle. The bleeding causes inflammation, triggering a cascade of cellular inflammatory

mediators, including cytokines, chemokines, growth factors, and protective factors such as secretory leukocyte protease inhibitor and superoxide dismutase.¹⁰⁰ The inflammation may lead to fibrosis, scarring, adhesions, and pain.

◆Clinical Manifestations.

The clinical manifestations of endometriosis can mimic other disease processes (i.e., PID, irritable bowel syndrome, ovarian cysts). Symptoms are variable in frequency and severity and most commonly include pain and infertility. Women with endometriosis report progressive dysmenorrhea, dysuria, dyschezia (pain on defecation), and dyspareunia (pain on intercourse); they may also report constipation and abnormal vaginal bleeding. If implants are located within the pelvis they can cause an asymptomatic pelvic mass having irregular, movable nodules and a fixed, retroverted uterus. Most symptoms of endometriosis can be explained by the proliferation, breakdown, and bleeding of the ectopic endometrial tissue with subsequent formation of adhesions. In most instances, however, the degree of endometriosis is not related to the frequency or severity of symptoms.⁹⁷ Dysmenorrhea, for example, does not appear to be related to the degree of endometriosis. With involvement of the rectovaginal septum or the uterosacral ligaments, dyspareunia develops. Dyschezia occurs with bleeding of ectopic endometrium in the rectosigmoid musculature and subsequent fibrosis.

Approximately 25% to 40% of women with infertility have endometriosis. The link between endometriosis and infertility is strong, yet the degree of disease and infertility is not as closely associated. That is, women with untreated minimal to mild disease may have high pregnancy rates or may experience infertility.¹⁰⁰ The exact mechanism for infertility in women with endometriosis is unknown. Infertility may result from mechanical interference with ovulation or ovum transport through the fallopian tube because of adhesions and the effects of inflammation and cytokine activity. However, the infertility also could be a result of the underlying autoimmune disorder that caused the endometriosis.⁹⁶ There are

conflicting reports regarding the effect of endometriosis on sperm activity. An increased phagocytosis of spermatozoa by macrophages has been observed. The uterine endometrium in women with endometriosis appears to have an overactive response to estrogen and an underactive response to progesterone, impairing the endometrial receptivity to blastocyst implantation, decreasing the chance of successful pregnancy.¹⁰⁴ Women with endometriosis who achieve pregnancy naturally or through in vitro fertilization (IVF) also seem to be at higher risk for poor obstetric outcomes, including preterm birth, small-for-gestational-age babies, and placental complications.¹⁰⁵

◆Evaluation and Treatment.

A presumptive diagnosis can be made based on clinical manifestations, but laparoscopy is required for definitive diagnosis of endometriosis. A uniform classification system that includes both extent and severity has been developed but still does not correlate well with a woman's symptoms. Treatment is aimed at preventing or decreasing progression and spread, alleviating pain, and restoring fertility. Current therapies include suppression of ovulation with continuous estrogen-progestin COCs, danazol (which diminishes the midcycle LH surge), GnRH agonists/analogs in oral or depot formulations (to suppress ovarian hormones), and the antiprogestins gestrinone, mifepristone (RU486), and dienogest (inhibit ovulation and disrupt endometrial integrity); and atrophy of the endometrium with progestins, including medroxyprogesterone acetate (DMPA), oral progestins, the etonogestrel rod, or an LNG-IUD.^{106,107} Conservative surgical treatment includes laparoscopic removal of ectopic endometrium with conventional or laser techniques. Effectiveness may be increased when medical regimens are combined with surgical techniques. All treatments have risks or side effects, and recurrent symptoms develop in the majority of women within a few years, even with surgical treatments. Women should be fully informed about all options and carefully weigh the risk-to-benefit ratio of nonreversible treatments.¹⁰⁸

Cancer

Malignant tumors of the female reproductive system are common. Cancers of the female reproductive tract can often grow large before causing pain because the pelvis and abdomen are poorly innervated and designed to accommodate a growing fetus. Reproductive tract cancers are more likely to be diagnosed early if there are symptoms. Uterine cancer is the third leading cancer diagnosis in women (behind breast and lung cancers) but is only the seventh leading cause of death, in part because symptoms of vaginal bleeding prompt women to seek treatment. Ovarian cancer, on the other hand, occurs less frequently, at 2.6% of new cancer diagnoses in women, but is the sixth leading cause of death from cancer related to its lack of symptoms and lack of clear screening or diagnostic testing.¹ Cervical cancer is also generally asymptomatic until the cancer has progressed, but early detection is possible with routine screening. Two percent of cancers in women begin in the cervix, but the death rate from cervical cancer has declined by half since the advent of screening techniques.¹

Cervical Cancer

Cancer of the cervix is the leading cancer-related death in most of Africa, Central America, and South-Central Asia; however, it has a lower prevalence in the United States.^{1,109} In the United States, rates of cervical cancer incidence and mortality have declined by half since 1975, largely because of the increased prevalence and frequency of cervical cancer screening with the Papanicolaou (Pap) test. In 2016, the American Cancer Society estimated 12,990 new cases of invasive cervical cancer and 4120 cervical cancer deaths.¹

◆Pathophysiology.

It is established that cervical cancer is almost exclusively caused by cervical human papillomavirus (HPV) infection. Infection with “high-risk” (oncogenic) types of HPV is a necessary precursor to development of cervical dysplasia, otherwise known as the *precancerous cell changes that lead to invasive cancer* (also see [Chapter 12](#)).

Precancerous dysplasia, also called *cervical intraepithelial carcinoma (CIN)* and *cervical carcinoma in situ (CIS)*, is a more advanced form of these cell changes. Importantly, cervical dysplasia can be detected noninvasively through examination of the cervical cells. If dysplasia is detected early, treatment is available to prevent invasive cancer.

Most sexually active women will contract HPV at some point in their lifetime; most of these infections are asymptomatic and resolve spontaneously. However, high-risk HPV may persist and cause abnormal cellular changes that can become cancerous¹¹⁰ (also see [Chapter 27](#)). HPV strains 16 and 18 are most often implicated as causing 70% of all cervical cancers and also contribute to many vaginal, vulvar, penile, anal, and oropharyngeal cancers.¹¹¹ Most HPV infections are cleared by the immune system; the vast majority of infections do not cause cervical cancer. For this reason, screening for cervical cancer before age 21 is not recommended. Previous efforts at early screening resulted in many young women receiving treatments on their cervix that may have been unnecessary. These treatments destroyed or removed cervical cells and in many cases altered the structural integrity of the cervix, resulting in an increase in preterm births in women treated without substantially decreasing the later rates of cervical cancer.¹¹²

It is unknown why some women are able to clear HPV infection and others cannot. Women with multiple sexual partners are more likely to be exposed to high-risk HPV, but women with only one lifetime sexual partner also can become infected. Smoking has been shown to increase the risks of persistent infection and later development of cervical cancer; in addition, women who have had many children, have a long history of oral contraceptive use, and are immunocompromised also are at higher risk of cervical cancer.¹ Women who use vaginal douches also seem to be at increased risk of HPV infection, likely caused by the alteration in the cervico-vaginal microbiome;¹¹³ on the contrary, women with healthy vaginal microbiomes, marked by adequate quantities of lactobacilli, seem to have a decreased prevalence and increased clearance of HPV.¹¹⁴ Anything that affects the integrity of the immune system may affect

the later risk of cervical cancer, including tobacco use, poor nutrition, chronic stress, and immunosuppressant medications.^{115,116} HIV infection greatly increases the risk that women infected with HPV will develop cervical cancer, and women with HIV should be screened for cervical cancer more frequently than women without HIV.¹¹⁷ In addition, high-risk HPV is found more frequently in women who are coinfecting with chlamydia or gonorrhea, suggesting that those infectious processes may support the persistence of HPV in those women.^{118,119} It is hoped that the widespread use of the HPV vaccine in boys and girls will decrease rates of invasive cervical, genital, and anal cancers over the next several decades.¹

There are two main cell types of the cervix: squamous epithelium cells and columnar epithelial cells. The line where the two cells types meet, known as the **transformation zone**, is very vulnerable to the oncogenic effects of HPV, and this is where carcinoma in situ is most likely to develop (Fig. 25.18). In this zone, columnar epithelium is constantly being replaced by squamous epithelium in a process known as *metaplasia*. Metaplasia is thought to be affected by hormonal levels; change in cervical epithelium is not understood as well as endometrial tissue change in response to fluctuating hormones. Because metaplastic cells are at increased risk of incorporating foreign or abnormal genetic material, neoplastic changes are most common in the transformation zone.

FIGURE 25.18 Cervical Carcinoma in Situ. Typical transformation zone, where the columnar (grapelike) epithelium is replaced by metaplastic epithelium. At its outer edge the metaplastic epithelium adjoins the squamous epithelium, which extends into the vagina. (From Coppleson M, Pixley E, Reid B: *Colposcopy: a scientific approach to the cervix in health and disease*, Springfield, IL, 1971, Charles C Thomas.)

Young women are especially vulnerable to HPV because of their cervical anatomy. Squamous epithelial cells in older women cover the portions of the cervix that protrude into the vagina, and columnar epithelial cells line the inner portions of the cervical canal. The location of the transformation zone changes as girls and women age and in response to estrogen and vaginal pH changes. In girls and young women, a large portion of their cervix is covered with columnar epithelium, a condition known as *squamous metaplasia*.¹¹¹ As women age, the transformation zone moves as the squamous epithelium covers the surface of the cervix. Therefore the younger a

woman is when she contacts HPV, the more sensitive cervical cells are exposed. This is one reason vaccinations against HPV are aimed at women before the initiation of sexual activity.¹¹¹ Many chromosomes may contain genes that relate to HPV-linked cervical cancer.¹²⁰ Like other cancers, cervical cancer requires the accumulation of genetic alterations for carcinogenesis to occur. Several genetic mutations have been identified, including some that have not been seen in other cancers.¹²⁰ Several chromosome regions with recurrent loss of heterozygosity (LOH) have been identified (also see [Chapter 12](#)). In addition, other genes may influence a woman's receptivity to HPV.¹²¹ For instance, HPV may up-regulate the E6 oncoprotein in certain gene sequences, causing a greater production of vascular epidermal growth factor, which allows the tumor to promote blood vessel growth toward the proliferating cells, fueling growth.^{120,121} Moreover, mutations in genes regulating the immune response have also been identified as playing a role in the development of cervical cancer.¹²⁰

◆Clinical Manifestations.

Cervical neoplasms are predominantly asymptomatic; therefore regular Pap test or HPV screening is necessary for early detection (see [Chapter 27](#) for screening frequency guidelines). About 90% of cervical cancer cases can be detected through early use of regular screening tests (see [What's New? Cervical Cancer Screening in the Developing World](#)). If symptoms exist, they may include vaginal bleeding or abnormal discharge. Bleeding is variable and may occur after intercourse or between menstrual periods. Vaginal discharge is a less common presenting symptom and may be serosanguineous or yellowish with a foul odor. Bleeding and discharge are subtle and are likely to be disregarded by premenopausal women. Postmenopausal women are more likely to seek medical attention if these signs appear. Advanced disease may cause urinary or rectal symptoms and pelvic or back pain along with anemia.

What's New?

Cervical Cancer Screening in the Developing World

The problem with the use of the conventional Papanicolaou (Pap) test in screening for cervical cancer is the low sensitivity of the test, which ranges between 44% and 77%. This means that a large number of cervical abnormalities (23% to 56%) can be missed with a single test! Thus the success of Pap test screening in reducing cervical cancer in the United States lies in the frequency of screenings and that cervical cancer is a slowly progressive condition. However, a high frequency of Pap test screenings is often not feasible, either economically, socially, culturally, or logistically, in many countries and in some regions leads to much higher rates of invasive cervical cancer for women in such populations or locales. Multiple, large, well-conducted studies have demonstrated that human papillomavirus (HPV) testing is considerably more sensitive (between 97% and 98%) than either conventional or liquid-based Pap testing. HPV infection is known to be the required precursor to cervical cancer. With sensitive HPV tests now widely available, requiring less frequent screening (every 3 to 5 years), the future of cervical cancer screening may rely on HPV screening, not on conventional cervical cytology testing.

In settings where there is not even adequate infrastructure for HPV testing, several studies have shown that simple visualization with acetic acid (VIA) can be used to diagnosis women with HPV infection and then immediately provide onsite cryotherapy to reduce rates of later cervical cancer. Although not ideal, this approach shows promise in low-resources settings, especially when the baseline rate of HIV infection is high, because it allows women to be screened and treated on the same visit.

Data from Campos NG et al: *Int J Cancer* 2015 137(9):2208–2219, 2015.

◆ Evaluation and Treatment.

Women should be screened for cervical cancer and risk for future cervical cancer through Pap and HPV testing.¹²² For women aged 30 to 65 years, HPV testing is now recommended at the same time as the Pap test because it is noninvasive and identifies women at later risk for cellular abnormalities leading to cancer; indeed, HPV is often detectable for more than a decade before any noticed cellular changes. For women aged 21 to 29, HPV testing is only indicated if the Pap test is abnormal, which is known as *reflex HPV testing*.¹²² Recent studies suggest that HPV testing alone may be as effective but less expensive than co-testing or reflex testing. The WHO recommends HPV testing in settings where HPV tests are available but Pap tests are not.

A Pap test involves the noninvasive collection of cellular samples from the surface of the cervix during a pelvic examination, using a speculum to allow for visualization of the cervix. Cervical cytologic examination is most accurate if cells are obtained from both the endocervix and the ectocervix, which involves placing the collection device (a small brush or broom) into the cervical os. These cells are then sent to a laboratory for analysis. When dysplasia is detected, further testing is indicated for diagnosis. Colposcopy involves examining the cervix visually and taking needed biopsies. An acetic acid (vinegar) solution is applied to the cervix, making areas of HPV infection stand out in a white color, known as *aceto-white*. The cervix is then viewed under magnification for aceto-white areas, changes in the epithelium, and the presence of abnormal vascular patterns.¹²³ Abnormal areas of the cervix are biopsied. Because the vulnerable transformation zones move into the cervical canal as a woman ages, the endocervix is sampled using curettage for diagnosis (Table 25.3).

TABLE 25.3

CERVICAL EPITHELIAL CELL ABNORMALITIES (PRECANCEROUS CERVICAL NEOPLASIAS)

CYTOLOGY REPORT	TYPE OF INTRAEPITHELIAL LESION
Atypical squamous cells of undetermined significance (ASC-US)	Suggestive of but do not meet criteria for LSIL (mild dysplasia)

Atypical squamous cells—cannot exclude HSIL (ASC-H)	Do not meet criteria for HSIL but do not preclude HSIL (potentially CIN I/II; moderate to severe dysplasia)
LSIL	CIN 1 (mild dysplasia)
HSIL	CIN 2 and 3 (moderate to severe dysplasia and CIS)

CIN, Cervical intraepithelial neoplasia; *CIS*, carcinoma in situ; *HSIL*, high-grade squamous intraepithelial lesion; *LSIL*, low-grade squamous intraepithelial lesion.

The progressive neoplastic changes of cervical cells are classified on a continuum from cervical intraepithelial neoplasia (dysplasia), to cervical carcinoma in situ (full epithelial thickness of the cervix is involved), to invasive carcinoma (see [Tables 25.3](#) and [25.4](#)). Various terms are used to describe the cellular changes in the cervix based on how the cells were obtained. Screening for cervical cancer is done with a Pap test, and the cytology report describes test findings; these terms are outlined on the left side of [Table 25.3](#). If a Pap test has abnormal findings, a biopsy of the affected tissue is taken during a colposcopy. The biopsy reveals the actual extent of the lesion within the cervix. Terminology used in pathology reports is listed on the right side of [Table 25.3](#). Pathology reports that involve cancerous changes begin with the abbreviation *CIN* or *CIS*; cervical intraepithelial neoplasia and carcinoma in situ, respectively.

TABLE 25.4

CLINICAL STAGING FOR CANCER OF THE CERVIX

STAGE	CHARACTERISTICS
0	Cancer in situ, intraepithelial carcinoma; earliest stage of cancer; cancer confined to its original site
I	Carcinoma confined to cervix (extension to corpus disregarded)
IA	Earliest form of stage I; there is very small amount of cancer, which is visible only under a microscope
IA1	Area of invasion is <3 mm (about $\frac{1}{8}$ inch) deep and <7 mm (about $\frac{1}{3}$ inch) wide
IA2	Area of invasion is between 3 and 5 mm (about $\frac{1}{5}$ inch) deep, and <7 mm (about $\frac{1}{3}$ inch) wide
IB	Includes cancers that can be seen without a microscope; also includes cancers seen only with a microscope that have spread deeper than 5 mm (about $\frac{1}{5}$ inch) into connective tissue of the

	cervix or are wider than 7 mm
IB1	IB cancer that is no larger than 4 cm (about 1½ inches)
IB2	IB cancer that is >4 cm
II	Cancer has spread beyond the cervix to the upper part of the vagina; cancer does not involve the lower third of the vagina
IIA	Cancer has spread beyond the cervix to the upper part of the vagina; cancer does not involve the lower third of the vagina
IIB	Cancer has spread to the tissue next to the cervix, called the <i>parametrial tissue</i>
III	Cancer has spread to the lower part of the vagina or the pelvic wall; cancer may be blocking the ureters (tubes that carry urine from the kidneys to the bladder)
IIIA	Cancer has spread to the lower third of the vagina but not to the pelvic wall
IIIB	Cancer extends to the pelvic wall, blocks urine flow to the bladder, or both
IV	Most advanced stage of cervical cancer; cancer has spread to other parts of the body
IVA	Cancer has spread to the bladder or rectum, which are organs close to the cervix
IVB	Cancer has spread to distant organs beyond the pelvic area, such as the lungs

Reprinted from the American Cancer Society's Cancer Information Database with permission.

Cervical dysplasia is replacement of some epithelial cells by atypical neoplastic cells, and is “staged” depending on the depth of epithelial involvement (Fig. 25.19). Risk of progression to invasive carcinoma rises steadily with the severity of dysplasia; however, women with intact immune systems are likely to resolve dysplasia on their own. At least a third or more of all cervical intraepithelial lesions persist without progression or regression. Women with CIN 1 (low-grade squamous intraepithelial lesion [LSIL] or mild dysplasia) have an 11% chance of progression to CIS and a 1% chance of progression to cervical invasion. Women with CIN 2 have a 22% chance of progression to CIS and a 5% chance of invasive lesions. In cervical CIN 3 or HSIL (high-grade squamous intraepithelial lesion), all or most of the cervical epithelium shows cellular features of carcinoma; however, underlying tissue is not affected. At least 12% of women with CIN 3 (CIS) progress to cervical invasion.

FIGURE 25.19 Cervical Intraepithelial Neoplasia (CIN). A, Diagram of cervical endothelium showing progressive degrees of CIN. B, Normal multiparous cervix. C, CIN stage 1. Note the white appearance of part of the anterior lip of the cervix associated with neoplastic changes. D, CIN stage 2. Lesions reflected in distant capillaries. E, CIN stage 3. Lesion predominantly around the external os. (A From Herbst AL et al: *Comprehensive gynecology*, ed 2, St Louis, 1992, Mosby. B–E From Symonds EM, Macpherson MBA: *Color atlas of obstetrics and gynecology*, London, 1994, Mosby-Wolfe.)

CIS is generally a precursor of invasive carcinoma of the cervix. A number of factors, including tumor type, contribute to the rate at

which CIS becomes invasive. Because of the ease of Pap test screening, invasive cervical cancer is rare within the United States but much more common in the developing world, where screening is not available. **Invasive carcinoma of the cervix** consists of cancer invasion into adjacent tissues and metastasis. Adjacent tissues most often involved are the ureters and structures of the lateral pelvic wall, the vaginal stroma and epithelium, and the lower uterine segment and myometrium. The internal, external, and common iliac lymph nodes and the obturator nodes are common sites of lymphatic involvement. Invasive cervical cancer is most often discovered through Pap tests, tentatively diagnosed with a biopsy during a colposcopy, and then further diagnosed using surgery and lymphangiography, CT scan, MRI, ultrasonography, or radioimmunodetection methods. The staging system for carcinoma of the cervix is shown in [Table 25.4](#).

Treatment depends on the degree of neoplastic change, the size and location of the lesion, and the extent of metastatic spread. For premalignant cellular changes and CIS, the goal is to kill or remove abnormal cells; these procedures can be done in a clinic with the administration of a local anesthetic. Invasive carcinoma requires surgery, including removal of the cervix and other affected tissues.

Common treatments can be classified as ablative, when the cells are killed without being removed, or excisional, in which the abnormal cells are physically removed from the cervix. Ablative therapies are appropriate for lower levels of cervical dysplasia because they leave the cervix intact, which may be beneficial for later childbearing. However, they do not provide a tissue sample for testing. Ablative surgeries include cryotherapy and cold coagulation in which extreme cold is applied to the surface of the cervix. Carbon dioxide laser and electrocoagulation also are used to kill abnormal cells and coagulate vessels supporting their growth. Excisional therapies are appropriate if a more advanced lesion is suspected because they produce tissue for analysis. Excisional therapies include conization, in which a cone-shaped portion of the cervix is removed, and the loop electrosurgical excision procedure (LEEP), in which a small looped wire with electric current generates heat and destroys cancer cells. Heat, cold, or lasers

are used in excisional procedures to simultaneously excise the tissue and obliterate abnormal blood vessels.

For invasive cervical carcinoma, treatment depends on the stage of the tumor. Surgical intervention may include a hysterectomy, pelvic lymphadenectomy, or pelvic exenteration (radical removal of the contents of the body cavity). Multidrug chemotherapy regimens also have been used alone or in combination with radiation, and emerging treatments targeting specific cancer genes show promise.¹²⁴ Smokers tend to have a higher stage of disease at diagnosis, and their cancer is more resistant to radiation treatment.

With early detection and treatment, prognosis is excellent. Overall, the 5-year survival rate is 92% for stage IA or lower (e.g., early detection). For women diagnosed with cervical carcinoma, the 5-year survival rate is 68%.¹ The prevention of HPV infection may be the key to substantially reducing the risk of cervical cancer. There are currently three licensed HPV vaccines available in the United States: one that protects against two strains of HPV (16 and 18), four strains of HPV (6, 11, 16, and 18), and nine strains of HPV (6, 11, 16, 18, 31, 33, 45, 52, and 58).¹¹⁰ It is recommended that all young men and women be vaccinated¹²⁵ (Table 25.5). More recent studies indicate that 63% of girls have received at least one dose of the vaccine¹¹⁰ and 42% are fully vaccinated; and that rates of HPV infection in young women have been cut in half.¹²⁶ As vaccine uptake increases and longitudinal studies persist, further reductions are likely to be seen in cervical cancer-related mortality and morbidity over the next 20 years.

TABLE 25.5

HUMAN PAPILLOMAVIRUS VACCINE RECOMMENDATIONS

Eligible individuals: 11- or 12-year old girls and boys; females aged 13–26 who have not already been vaccinated; males aged 13–21 who have not been vaccinated; males aged 21–26 who have not been vaccinated and are immunocompromised or who have sex with men.	
VACCINE TYPE	RECOMMENDED FOR
Cervarix	Females ages 11–12
(HPV #16, 18)	Females ages 13–26 who have not been previously vaccinated
Gardasil	Females and males ages 11–12

(HPV #6, 11, 16, 18)	Females ages 13–26 and males ages 13–21 who have not been previously vaccinated Unvaccinated males ages 22–26 who have sex with men or who are immunocompromised
Gardasil 9	Females and males ages 11–12
(HPV #6, 11, 16, 18, 31, 33, 45, 52, 58)	Females ages 13–26 and males ages 13–21 who have not been previously vaccinated Unvaccinated males ages 22–26 who have sex with men or who are immunocompromised

Data adapted from Centers for Disease Control and Prevention: *HPV vaccine information for clinicians*. Available at <https://www.cdc.gov/hpv/hcp/need-to-know.pdf>.

Vaginal Cancer

Cancer of the vagina is the rarest of the female genital cancers and accounts for less than 2% of gynecologic cancers.¹²⁷ In 2016, there were an estimated 4620 diagnoses of vaginal cancer, and 950 deaths.¹²⁷ Vaginal and cervical cancers are thought to have similar epidemiology. Both start as intraepithelial lesions, occur in women who have been sexually active, and are associated with HPV infection. Prior carcinoma of the cervix or uterus places a woman at higher risk for developing vaginal cancer.¹²⁸ In utero exposure to nonsteroidal estrogens is a risk factor: It has been estimated that 100,000 to 160,000 women were exposed in utero to such nonsteroidal estrogens as DES, dienestrol, or hexestrol from 1960 to 1971.¹²⁹ Exposure to such hormones during the first 3 months of gestation inhibits the normal replacement of columnar epithelium by squamous epithelium in the vagina of the fetus. The columnar epithelium, which is not normally found in the vagina, may then undergo malignant transformation. Not all women exposed to DES in utero develop neoplastic changes in the vagina, however.¹²⁹

Vaginal cancer is usually diagnosed in women in their 60s and 70s, but the cellular changes begin many years before the appearance of clinically apparent disease.¹²⁷ The most common type of vaginal cancer is squamous cell carcinoma. About 90% of tumors are squamous cell-type cancers; the remaining 10% are adenocarcinomas,

sarcomas (rare), and melanomas (rare). Nonsquamous types of cancer are more common in younger women. Vaginal sarcomas can develop in children younger than 5 years, and adenocarcinomas are the most common in women less than 30 years old.¹²⁷

Vaginal cancer is generally asymptomatic until fairly late in the disease process. The major symptom of invasive cancer is vaginal bleeding or bloody discharge. Other symptoms can include vaginal discharge, vulvar pruritus, rectal or bladder symptoms, pain, or leg edema.

Several mechanisms can be used to diagnose vaginal cancer including Pap testing of abnormal vaginal skin, colposcopy, and biopsy. Once a diagnosis of cancer is established, the size and extent of the lesion are determined using MRI, before surgery.¹³⁰ Like cervical neoplasms, vaginal cancers are classified as intraepithelial neoplasia (dysplasia), CIS, or invasive carcinoma and are staged based on extension into local tissues and metastasis to distant organs. Treatment depends on the type and extent of the cancer and the overall health and expectations of the woman.¹³⁰ Potential treatment modalities include laser therapy or removal, or both, of the affected tissues (vagina, uterus, bladder, and rectum); excision of lymph nodes; radiation; and chemotherapy. Many women with invasive vaginal cancer develop recurrent pelvic cancer and need intensive monitoring for recurrence. Recurrence and survival rates vary greatly by the type and extent of cancer and the aggressiveness of the treatment regimen.¹³⁰ HPV vaccination is the primary form of prevention.¹²⁸

Vulvar Cancer

Cancer of the vulva is responsible for about 3% to 5% of all gynecologic cancers; however, there has been a steady increase in the incidence of vulvar cancers over the last 30 years. There were an estimated 5950 new diagnoses and 1110 deaths in 2016. The majority (90%) are squamous cell carcinomas, although melanoma (5%), Bartholin gland carcinoma (2%), sarcoma (2%), and adenosquamous carcinoma (1%) may occur. A history of HPV infection related to 20%

to 80% of vulvar cancers, depending on type; interestingly, HPV-related lesions have a better prognosis than those that are not positive for HPV.¹³¹ Previous squamous dysplasia of the vagina or cervix also is a major risk factor, as are smoking and HIV infections.¹³² Although it usually affects postmenopausal women (median age of presentation is women in their 60s), vulvar cancer has been diagnosed in women between ages 30 and 90.¹³² Usually women have a history of vulvar irritation and pruritus (70%); urinary symptoms and discharge are less common. In addition, there may be a hard ulcerated area of the vulva, large cauliflower lesions, or lesions similar to those of chronic dermatitis. Biopsy confirms the diagnosis. Treatment options include primarily ablative or excisional surgery, and sometimes radiation with or without chemotherapy. Less extensive removal of vulvar tissue is being studied to decrease postsurgical morbidity and maintain function.¹³³ Prognosis depends on lesion size and location, histology, and lymph involvement; risk of metastasis increases with tumor size. The 5-year survival rate depends on the extent of the lesion, the treatment, and the overall health of the woman. Cancer caught in the early stages has a greater than 90% 5-year survival rate with progressively poorer prognosis with advancing stages.^{133,134}

Endometrial Cancer and Uterine Sarcoma

Endometrial carcinomas arise within the glandular epithelium of the uterine lining. Estimates include 60,050 new cases in 2016, with approximately 10,470 deaths.¹ Most cases occur in postmenopausal women (Fig. 25.20), with peak incidence occurring in the late 50s to early 60s.¹³⁵ Women have a 3% lifetime risk of developing uterine cancer. Although incidence rates are higher in white than in black women, mortality rates in black women are nearly twice as high, primarily because cancers are more likely to be diagnosed in advanced stages.¹ The primary risk factor is prolonged exposure to estrogen without the presence of progesterone. Estrogen causes endometrial proliferation, whereas progesterone changes the uterine lining to limit proliferation and encourage normal shedding. Estrogen without the presence of progesterone is known as *unopposed estrogen*

because its proliferating effects are not restrained. Exposure to unopposed estrogen includes estrogen-only hormone replacement therapy, tamoxifen use, early menarche, late menopause, never having children, and a failure to ovulate (i.e., PCOS and anovulatory cycles typical of the late reproductive years). Obesity also is a known source of endogenous estrogen and is a risk factor for endometrial cancer (see Fig. 25.20).¹³⁶ Other risk factors not directly related to estrogen include diabetes, gallbladder disease, and hypertension, though obesity may be a mediating factor for these risks. A family history of colon, endometrial, or ovarian cancer could signal hereditary nonpolyposis colorectal cancer (HNPCC); women with this family history may wish to explore genetic testing and more aggressive screening.¹³⁷

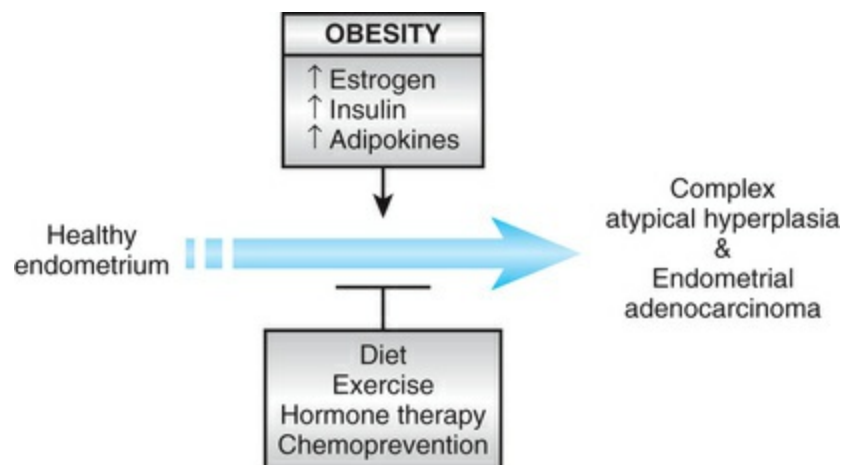

FIGURE 25.20 Endometrial Cancer. Overview of the contribution of obesity to endometrial cancer progression and preventive strategies. (From Schmandt RE et al: *Am J Obstet Gynecol* 205[6]:518–525, 2011.)

Although estrogen and obesity increase the risk of endometrial cancer, several interventions have been shown to decrease the risk of cancer. A review of modifiable risk factors and prevention for endometrial hyperplasia and cancer indicates that controlling obesity, hypertension, and diabetes may reduce an individual's risk of endometrial cancer.^{138,139} Exposure to progesterone also decreases the risk of endometrial cancer both immediately and long term. Large amounts of progesterone are released during pregnancy. Smaller, but

still effective, amounts of progesterone are in OCPs and the progestin-containing IUD. The use of birth control pills can decrease the risk of endometrial cancer by 80%, even more than a decade after use.¹³⁵ The progestin-containing IUD is used to prevent endometrial abnormalities in women who need to take tamoxifen as part of breast cancer prevention¹⁴⁰ and has shown promise in protecting the endometria of obese women¹⁴¹ with an estimated 50% reduction in endometrial cancer incidence among obese women using a LNG-IUD.

About 75% of endometrial cancers are adenocarcinomas. Abnormal vaginal bleeding caused by disruption of the endometrial surface by neoplastic processes is the most common clinical manifestation of endometrial cancer. Pain and weight loss are symptoms of late disease.

Screening methods for early detection of endometrial cancer are as effective as those for cervical cancer. Pap tests, highly effective in detecting cervical dysplasia, are ineffective in detecting early endometrial cancer. Transvaginal ultrasound (TVUS) may be used to measure endometrial thickness and screen postmenopausal and high-risk premenopausal women. If the endometrium is abnormally thick (defined as >5 mm), then further testing, such as endometrial biopsy, is warranted to rule out cancer, especially in high-risk women.¹⁴² Endometrial biopsies can be performed in a normal clinic with minimal additional equipment. The biopsy involves placement of a small thin tube through the cervix to collect a specimen of the endometrium for analysis.¹⁴² Once cancer is confirmed by biopsy, a laparoscopy and MRI may be performed to determine stage of disease.

Uterine cancers can be divided into two types by histology. Type I tumors are by far the most common and result from estrogen exposure leading to endometrial hyperplasia. Type II cancers make up 10% of endometrial cancers but are more likely to be invasive into the uterine muscle and metastasize beyond their original location, resulting in a much greater risk for death.¹⁴² Treatment is based on the cancer type and the extent of the disease. For women with simple hyperplasia, progestin therapy (orally or through LNG-IUD) may

often suffice. However, treatment for atypical hyperplasia or invasive disease usually includes surgical intervention, such as curettage for carcinoma in situ, total abdominal hysterectomy with bilateral salpingo-oophorectomy, and lymphadenectomy.¹⁴³ Chemotherapy and radiation also may be used. The 5-year relative survival rate is 82%. There are health disparities in survival rates; the 5-year survival rate for white women is 84% compared to 62% in black women, partly because white women are likely to be diagnosed at earlier stages of the disease.¹

Uterine sarcomas are rare neoplasms that arise from mesenchymal tissues of and near the uterus, including myometrial smooth muscle, endometrial stroma, or adjacent connective tissues. Uterine sarcomas are rare, constituting up to 3% of all genital tract cancers and 3% to 5% of all uterine malignancies. The average age at diagnosis is the early 50s, though some sarcomas can form in childhood. Uterine sarcomas can be divided into endometrial stromal sarcoma, leiomyosarcoma, and adenosarcoma based on the involved tissue types. The very low occurrence and diversity of cellular composition of these tumors explain the lack of epidemiologic and treatment data.¹⁴⁴ Thus relatively few risk factors have been identified. However, prior pelvic radiation therapy, chronic excess estrogen exposure, use of tamoxifen, and black race have been cited as risks. Symptoms include abnormal uterine bleeding, awareness of a mass, and pelvic pressure or pain. Vaginal discharge may be profuse and foul. Gastrointestinal and genitourinary complaints are common. Treatment consists of total hysterectomy, which may include bilateral salpingo-oophorectomy and selective lymphadenectomy followed by radiation therapy or chemotherapy, or both. Molecularly targeted therapies are also under investigation.^{145,146} Five-year survival rates range from 50% in early disease to 5% in advanced disease. Like most cancers, stage and histopathologic analyses are the most important determinants of prognosis. The survival rate at 5 years for stage I disease is 50%. Few women survive advanced-stage disease.¹⁴⁵

Ovarian Cancer

The incidence of ovarian cancer is estimated at 22,280 women in the United States in 2016. In 2013 ovarian cancer accounted for 3% of all cancers among women and 21% of gynecologic cancers; it caused more deaths (14,240) than any other female reproductive cancer. From 2003 to 2012, the incidence declined at a rate of 0.9% per year.¹ Ovarian cancer in women older than 40 years is associated with conditions associated with increased ovulation over the lifetime, such as early menarche, late menopause, and nulliparity.¹⁴⁷⁻¹⁴⁹ A history of endometriosis also increases risk.¹⁵⁰ There is a genetic component to ovarian cancer and women with a *BRCA1* or *BRCA2* mutation have a 40% to 60% lifetime risk of ovarian cancer. Women who have this gene tend to be diagnosed approximately 10 years before women without the genetic predisposition.¹⁴⁷ Factors that suppress ovulation decrease the risk of ovarian cancer and include pregnancies, prolonged lactation, and the use of hormonal contraceptives that limit ovulation, including the birth control pill.¹⁴⁹ Tubal ligation and hysterectomy, and specifically the prevention of retrograde menses around the ovary, also have been shown to decrease risk.¹⁵¹

◆Pathophysiology.

There is controversy about the pathogenesis of ovarian cancer. The great majority of ovarian cancers are sporadic and not associated with a known pattern of inheritance.¹⁵² Of the approximately 20% of cancers that are familial, the majority are associated with the breast cancer susceptibility gene 1 (*BRCA1*) and a smaller number with mutations of *BRCA2* or mismatched repair genes (HNPCC syndrome). Various pathways have been proposed. Women and families who are more susceptible to cancer may have errors in the ability to repair cellular DNA, related to abnormalities in several genes responsible for repair of damaged DNA.¹⁵³ In sporadic ovarian cancer, *BRCA1* and *BRCA2* are rarely mutated. A newer theory proposes that many spontaneous, nonhereditary ovarian tumors arise from the migration of cells from tissues of mesoderm origin to the surface of the ovary.^{147,154} Cells from a variety of intraabdominal locations, including endometrial tissue and epithelium of the fallopian/uterine tubes, can

attach to the ovary (Fig. 25.21). The local ovarian environment, including the ovarian stroma, may then interact with the transplanted cells to enhance cellular growth and encourage metastasis^{147,154} (Fig. 25.22).

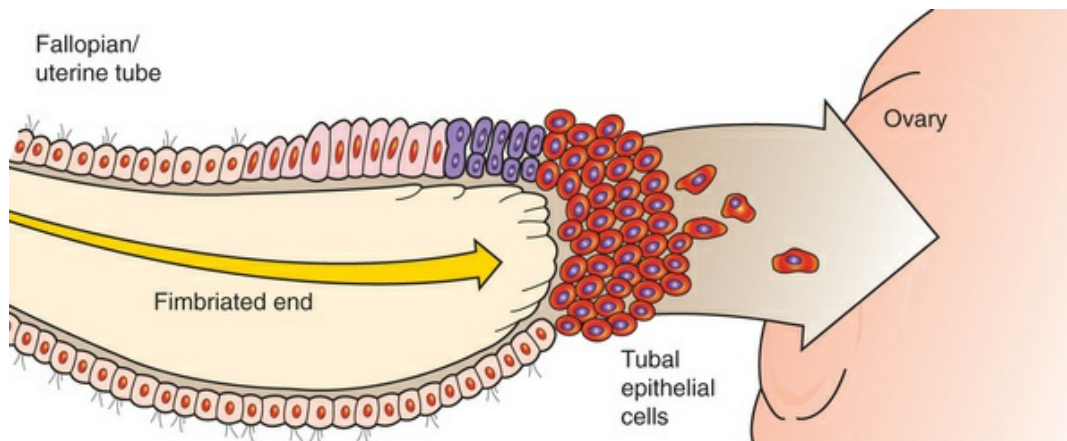

FIGURE 25.21 Migration of Epithelial Cells from the Fallopian/Uterine Tubes to the Ovary. (Adapted from Kurman RJ, Shih IM: *Am J Surg Pathol* 34[3]:433, 2010.)

FIGURE 25.22 Ovarian Stroma. The ovarian stroma interacts with precancerous and cancerous cells within the ovary. (From Schauer IG et al:

The two major types of ovarian cancer are epithelial ovarian neoplasms and germ-cell neoplasms. Most ovarian malignancies are epithelial ovarian neoplasms that usually develop from the surface epithelium of the ovary or the epithelium that lines cysts immediately beneath the ovarian surface, or may be cells that have migrated from precursor lesions in the fallopian/uterine tubes.^{147,154} Most epithelial cancers seem to arise from a single cell (i.e., clonal) because of a loss of tumor-suppressor genes and activation of oncogenes (see [Chapter 12](#)). Epithelial ovarian tumors may have cellular similarities to other tissues within the abdomen, including the lining of the fallopian/uterine tubes, or the endometrium, or be undifferentiated. Tumors are often classified as type I (low grade) and type II (high grade) based on their cellular type. Type I tumors grow more slowly and are genetically stable. Type II tumors often grow rapidly and aggressively and often have genetic mutations; type II tumors have a poorer prognosis¹⁵⁵ ([Fig. 25.23](#)). The 5-year survival rate is 92% if treated in stage I; however, only 15% of ovarian cancers are diagnosed this early. The 5-year survival rate varies by age at diagnosis, with women younger than 65 having a 58% rate compared to 28% survival in women older than 65.¹

FIGURE 25.23 Ovarian Tumors. Bilateral multicystic ovarian tumors. (From Symonds EM, Macpherson MBA: *Color atlas of obstetrics and gynecology*, London, 1994, Mosby-Wolfe.)

Germ-cell tumors are derived from the primitive germ cells (gametes) of the embryonic gonad and may be malignant or benign. The benign cystic teratoma accounts for approximately 10% of all ovarian tumors. These tumors represent an error in meiosis that results in the formation of ectoderm, endoderm, and mesoderm cell lines. Hair, teeth, and skin can be visualized within cystic teratomas. If the germ-cell tumor is malignant, it tends to be highly aggressive and rapidly growing with a poor prognosis. Cystic hygromas and other germ-cell tumors can occur on the ovaries of girls and women. Germ-cell tumors in children can be particularly aggressive.

◆Clinical Manifestations.

Ovarian cancer is commonly asymptomatic until the tumors have grown very large. Given the location of the ovaries, assessing abnormalities on routine gynecologic examination poses difficulty, especially in obese women. There is no sensitive and specific test for ovarian cancer for screening low-risk women, and routine screening of women without risk factors has not been shown to be beneficial and may cause harm because more women have unnecessary surgical procedures.¹⁴⁸

Common first symptoms of ovarian cancer are vague and include persistent abdominal distention, loss of appetite due to early satiety, and pelvic pain. Screening is warranted if women have a new onset of these symptoms that persist for more than 12 days each month. However, many women fail to notice the very first signs of ovarian cancer because they are vague and fairly common in older women. The disease is most commonly diagnosed after metastasis has occurred. Consequently, ovarian cancer is often termed the *silent killer*. Symptoms of advanced disease include pain and abdominal swelling from the primary ovarian mass or ascites and abdominal distention (Fig. 25.24). Gastrointestinal manifestations may include dyspepsia, vomiting, and alterations in bowel habits caused by mechanical obstruction. Abnormal vaginal bleeding may occur if the postmenopausal endometrium is stimulated by a hormone-secreting tumor. The tumor also may cause ulcerations through the vaginal wall

that result in bleeding. There also can be a feeling of pressure in the pelvis and leg pain.

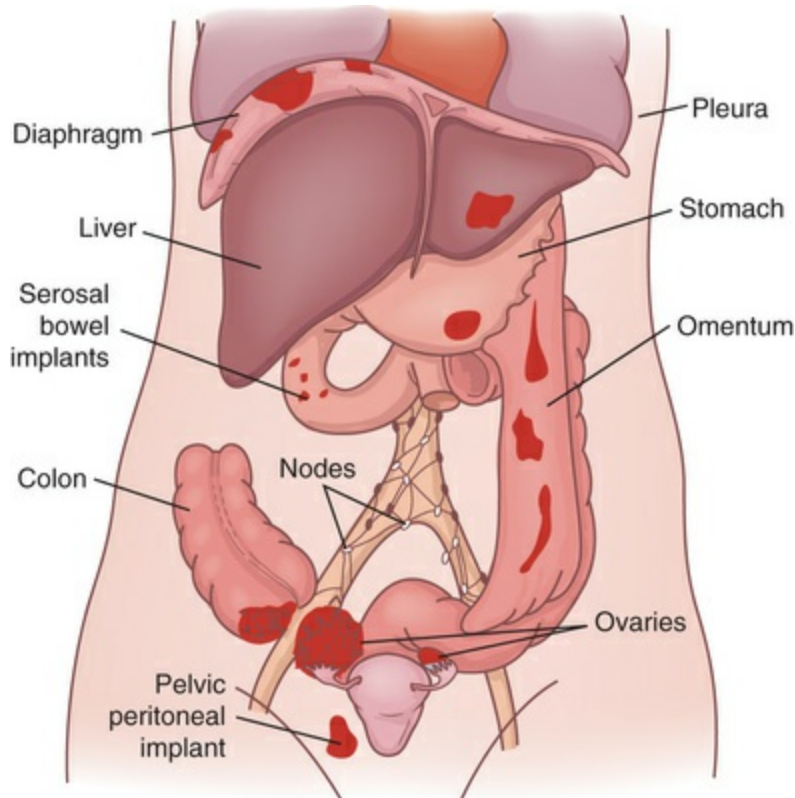

FIGURE 25.24 Large Malignant Ovarian Tumor and Metastasis of Ovarian Cancer. Pattern of spread for epithelial cancer of the ovary.

Tumor obstruction of vascular channels can cause venous and, occasionally, arterial thrombosis. Alterations in coagulability also occur, contributing to clot formation. Metastasis often causes pleural effusion.

◆Evaluation and Treatment.

Because ovarian cancer has no early symptoms and there is no cost-effective screening technique for early detection, disease usually is advanced by the time treatment is sought. Screening procedures including gynecologic assessment, vaginal ultrasound, and CA-125 assay have low predictive value in women without special risk factors.¹⁵⁶ Women with symptoms of disease, as outlined earlier,

should be assessed with minimally-invasive tests first. Screening commonly begins with a CA-125 blood test looking for specific cancer markers and a transvaginal ultrasound.¹⁴⁷ Increased CA-125 levels are found in about 78% to 80% of nonmucinous ovarian cancers; however, elevated levels are produced in 29% of nongynecologic tumors and in a variety of noncancerous conditions, for example, endometriosis, PID, benign ovarian cysts, myomas, and pregnancy.

Women less than 40 years of age are more likely to have nonepithelial cell tumors and should be assessed with blood tests to look for the CA-125 marker α -fetoprotein (AFP), and for β -human chorionic growth hormone to screen for tumors of nonepithelial cell origin.¹⁵⁷ Some types of germ cells and, rarely, adenocarcinoma may be associated with increased levels of AFP, hCG, or CA-125.

If initial tests are suspicious for a cancerous mass, diagnosis is confirmed by biopsy and extent of the disease is determined by ultrasound, CT, MRI, or other imaging techniques. Women undergoing surgery for ovarian cancer staging receive a thorough assessment for metastasis. The International Federation of Gynecologists and Obstetricians (FIGO) staging system is described in [Table 25.6](#). Other studies may be used to determine the extent of metastasis. These include an upper gastrointestinal series, barium enema, intravenous pyelogram (IVP), mammography, and lymphography.

TABLE 25.6

FIGO STAGING OF CARCINOMA OF THE OVARY

STAGE	CHARACTERISTICS
I	Growth limited to the ovaries
IA	Growth limited to one ovary
IB	Growth limited to both ovaries; no ascites
IC	Tumor either stage IA or stage IB, with ruptured capsule, ascites present, or with positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes

IIB	Extension to other pelvic tissues
IIC	Tumor either stage IIA or stage IIB but with ruptured capsule, with ascites present, or with positive peritoneal washings
III	Growth involving one or both ovaries, with metastasis into the abdomen, and/or to the lymph nodes
IIIA	Microscopic involvement of abdominal peritoneal surfaces
IIIB	Disease up to 2-cm diameter
IIIC	Disease greater than 2-cm diameter, with or without regional lymph nodes
IV	Distant metastasis excluding peritoneal metastases
IVA	Pleural effusion with positive cytology; parenchymal metastases and metastases to extraabdominal organs

FIGO, International Federation of Gynecologists and Obstetricians.

Data from Prat J: *Int J Gynaecol Obstet* 124(1):1–5, 2014.

The initial approach to treatment is surgery, which is performed to determine the stage of disease and to remove as much of the tumor as possible. Future treatment is then customized based on the clinical stage of the cancer, the woman's desires, and the cell type and sensitivity of the cancer cells. Ideally, treatment plans are developed and implemented by a multidisciplinary team from a variety of disciplines including surgeons, pathologists, and oncologists.¹⁵⁷

Radiation therapy and chemotherapy with an agent containing platinum are common treatments.¹⁴⁷ Even after initially effective treatment, 55% to 75% of women relapse, and less than 20% survive long-term with stage III or IV disease. New therapies under investigation include small-molecular-weight inhibitors, monoclonal antibodies, epidermal growth factor receptors, and gene therapy.¹⁴⁷ Survivors of ovarian cancer should be monitored with serial CA-125 testing. Prophylactic removal of the ovaries and fallopian tubes is associated with increased survival rates among those carrying a *BRCA* mutation, and is considered for those women who do not desire fertility.¹⁵⁸

Sexual Dysfunction

Sexual dysfunction is the lack of satisfaction with sexual function resulting from pain or a deficiency in sexual desire, arousal, or

orgasm/climax.^{159,160} Moreover, in order to meet diagnostic criteria, these symptoms should cause distress and persist for at least 3 months. Sexual function and dysfunction result from a complex interplay of the individual, culture, and physiology.¹⁶⁰ Sexual problems are multifaceted and often difficult to diagnose; adequate research is still needed. Sexual dysfunction can have organic or psychogenic causes or, more commonly, be a combination of both.¹⁶⁰ Studies show that at any given time up to 40% to 50% of adult women have some form of sexual dysfunction.¹⁶¹

The sexual response cycle is complex, involving the brain/mind, sympathetic and parasympathetic nervous systems, the systemic and local vasculature, and local innervation. Any disruption in these systems can affect sexual response. Chronic medical conditions can greatly affect both sexual desire and sexual function (Table 25.7). Acute illness and infections also can affect the woman's desire and ability to engage in fulfilling sexual activity. Vaginal infections are especially problematic because they can lead to vaginal irritation and pain with friction. Medications also can disrupt the sexual response cycle. Antihypertensives and antidepressants are commonly associated with sexual problems.¹⁶² Surgeries on the genital area can disrupt nerve pathways and hysterectomy may affect sexual function because the uterus, cervix, and vagina are involved in sexual response and orgasm. The mind is a large component of sexual response, and any stressor that affects the woman can affect her sexual response, including her feelings about her sexuality and relationship, as well as past sexual abuse.¹⁶³ A thorough history is needed to assess for sexual dysfunction, and testing is appropriate to assess for organic dysfunction (Fig. 25.25). The American College of Obstetricians and Gynecologists divides sexual dysfunction into four categories: disorders of desire, arousal, orgasm, and sexual pain.¹⁵⁹

TABLE 25.7

POSSIBLE EFFECTS OF CHRONIC DISEASE ON SEXUAL FUNCTIONING IN WOMEN

DISEASE	SEXUAL FUNCTION

Cerebral palsy	Intact genital sensations, decreased lubrication; difficulty with sexual activity/positioning because of muscle spasticity, rigidity, and/or weakness; pain with positioning caused by contracture of knees and hips or because of increased spasms with arousal
Cerebrovascular accident (CVA)	Difficulties in sexual positioning and sensitivity because of impaired motor strength, coordination, or paralysis; decreased sex drive with stroke on the dominant side of the brain
Diabetes	Diminished intensity of orgasm and gradual decline in ability to achieve orgasm; decreased lubrication and/or recurrent vaginal infections with resultant dyspareunia
Chronic renal failure	Decreased arousal; increasingly rare and less intense orgasms; decreased lubrication
Rheumatoid arthritis (RA)	Painful sexual activity/positions because of swollen, painful joints, muscular atrophy and joint contracture; decreased sex drive because of pain, fatigue, and/or medication; genital sensations remain intact
Systemic lupus erythematosus (SLE)	Similar to RA; decreased lubrication and vaginal lesions result in painful penetration
Myocardial infarction (MI)	Most literature male oriented; problems related to medications
Multiple sclerosis (MS)	Diminished genital sensitivity; decreased lubrication; declining orgasmic ability; difficulty with sexual activity because of muscle weakness, pain, or incontinence
Spinal cord injury	Reflex sexual response with injury above sacral area; disrupted response with lesion at or below sacrum; loss of sensation, decreased lubrication; spasticity, incontinence, or pain with arousal; continued orgasmic sensations or sensations diffused in general or to specific body parts, such as breast or lips

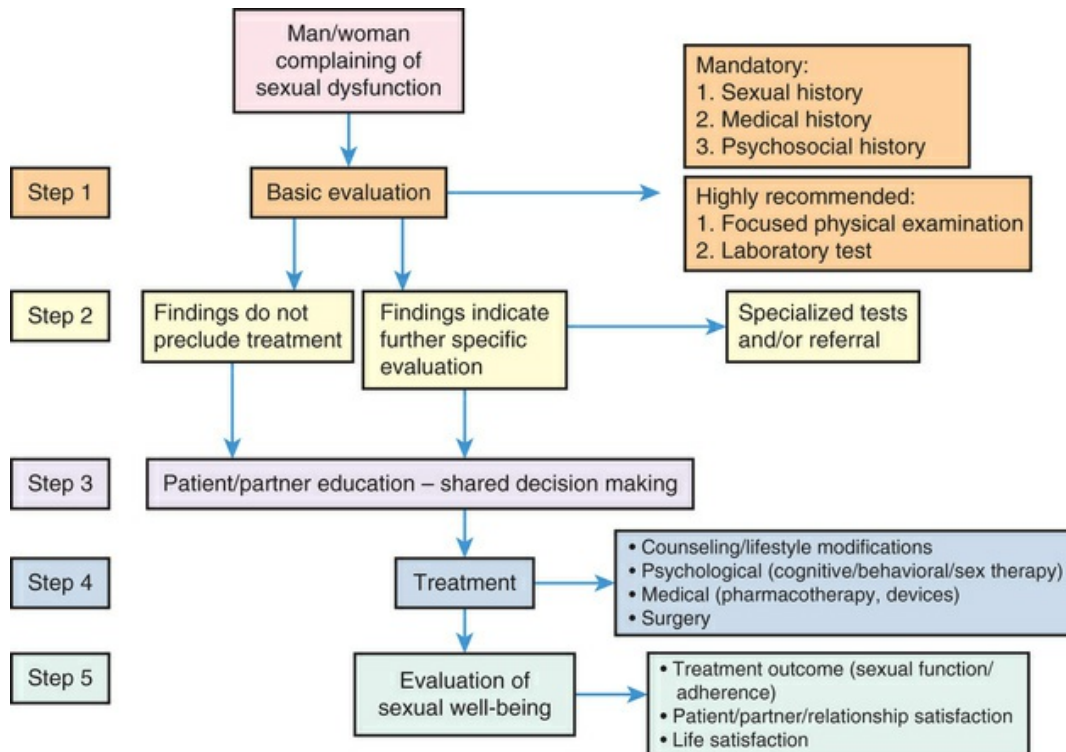

FIGURE 25.25 Diagnostic and Treatment Algorithm for Sexual Dysfunction. The International Consultation in Sexual Medicine stepwise diagnostic and treatment algorithm for sexual dysfunction in men and women. (From Hatzichristou D et al: *J Sex Med* 7[1pt2]:337–348, 2010.)

Disorders of desire (hypoactive sexual desire, decreased libido) are the most common sexual dysfunction in women.¹⁶³ The prevalence of hypoactive sexual desire increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency. β -Adrenergic blockers used for heart disease also may inhibit sexual desire. A promising medication, flibanserin, has emerged that activates dopamine and norepinephrine in the brain and has been shown to increase sexual desire. In addition, treatment with exogenous testosterone, the antidepressant bupropion, and sexual and psychologic therapy have all shown to increase sexual desire in women.¹⁶³

Anorgasmia, or orgasmic dysfunction, is the inability of the woman to reach or achieve orgasm. Dysfunction follows a continuum from difficulty in arousal to lack of orgasm. Any chronic illness may affect arousal. Diabetes, alcoholism, neurologic disturbances,

hormonal deficiencies, and pelvic disorders (such as infections, trauma, and surgical scarring) may block orgasm. Narcotics, tranquilizers, antidepressants (especially SSRIs), and antihypertensive medications also can inhibit orgasm.¹⁶⁰

Dyspareunia (painful intercourse) is common. Women may experience pain during arousal, at the initiation of intercourse, midway during intercourse, at the time of orgasm, or after intercourse. The pain may have a burning, sharp, searing, or cramping quality and may be described as external, vaginal, deep abdominal, or pelvic. A variety of psychosocial and organic causes have been identified.

Inadequate lubrication may make penetration or intercourse difficult or painful. Low estrogen levels, as are common with menopause and lactation, can decrease vaginal lubrication. Drugs with a drying effect, such as antihistamines, certain tranquilizers, and marijuana, can decrease lubrication. Infections and skin problems of the vulva and vagina are a frequent cause of acute onset dyspareunia. The use of products such as spermicides and fragrances on the sensitive vaginal mucosa may increase the risk of irritation. Disorders of the vaginal opening, such as scarring from female genital mutilation, episiotomy, or an intact hymen, also can be problematic. Deep pelvic disorders such as infection, tumors, and cervical or uterine abnormalities can cause pain with intercourse.

Vaginismus is an involuntary muscle spasm in response to attempted penetration. Vaginismus is often a response to previous painful penetration. Common causes include prior sexual trauma or fear of sex; organic causes are less common and are similar to those that cause dyspareunia, including vulvovestibulitis. Even after the underlying organic problem is detected and successfully treated, vaginismus may persist.

Sexual dysfunction may develop as a coping mechanism. Women with a history of sexual trauma—rape, incest, or molestation—often have problems of desire, arousal, or orgasm or experience pain with sexual activity. In extreme cases total sexual aversion may develop.¹⁶⁴ At other times, sexual dysfunction may be a symptom of marital or

relationship problems. Because sexual dysfunction has many causes, assessment and treatment should be holistic and culturally sensitive.

Impaired Fertility

Infertility affects approximately 15% of all couples and is defined as the inability to conceive after 1 year of unprotected intercourse with the same partner. However, many sources believe that medical intervention is indicated for women who are older than 35 years if they fail to conceive after 6 months of unprotected intercourse.¹⁶⁵ The rate of infertility may be increasing because of an increase in sexually transmitted disease and environmental exposures, and a delay in the start of childbearing; but the increase in incidence rates may also reflect the greater utilization of medical services for infertility.^{166,167} Fertility can be impaired by factors in the man or the woman or both partners. Causes include ovulatory disorder, abnormal semen, blockage of the fallopian tubes, endometriosis, and unexplained infertility.¹⁶⁸ The majority of cases of infertility involve the female, caused in part by the complexity of the female reproductive cycle and tract. Ovulatory factors account for 40% of female infertility.¹⁶⁷ Regular ovulation occurs as a result of a functioning hypothalamic/pituitary axis. Ovulation can be disrupted by a wide variety of factors, including imbalances in a diversity of hormones (e.g., TSH, estrogen, progesterone), chronic conditions, and stress. Age is a major factor in female fertility because the regularity of ovulation and the quality of ova decrease with age (Fig. 25.26). Abnormalities of the reproductive tract, including tubal pathologies, cause another 20% of cases of infertility.¹⁶⁷ Endometriosis and adhesions and scarring from PID are major contributors to blockages within the female reproductive tract. The remaining 20% of female infertility is caused by rare conditions or unknown etiology.¹⁶⁷

FIGURE 25.26 Relationship of Fertility and Miscarriage with Maternal Age. (From Heffner LJ: *N Engl J Med* 351[19]:1927–1929, 2004.)

Male infertility has a variety of causes, many of which can be corrected, and contributes to approximately 40% of cases of infertility.¹⁶⁷ Hormonal disorders, such as thyroid disturbances or low testosterone levels, can be diagnosed and corrected.¹⁶⁹ Throughout the 82 days of their creation and maturation, the sperm must be kept cooler than body temperature.¹⁶⁹ Elevations in temperature caused by illness, abnormal placement of the testes, varicoceles near the testes, or exposure to high temperatures in hot tubs or saunas may kill or disable sperm. Male infertility is also linked to abnormalities of the seminal tract and sexual dysfunction that disrupts ejaculation.¹⁶⁹ A number of diagnostic procedures are required in the routine investigation of the infertile couple¹⁶⁵ (see [Table 24.4](#)). In many instances no cause may be identified.

Fertility Tests

Before the performance of even basic fertility tests, a complete history should be obtained that includes (1) coital (sex) timing and frequency in relation to the menstrual cycle, (2) an in-depth assessment and charting of the menstrual cycle, (3) a reproductive history including

all previous pregnancies from both partners and their outcome, (4) a medical history of systemic disease, (5) current medications, (6) past surgeries, (7) a sexual history including any previous STIs, and (8) any exposure to toxins.¹⁶⁵ The history allows the clinician to focus on the most useful tests. Testing starts with the least invasive test or procedure and increases in invasiveness and complexity as the duration of infertility increases. The types of tests and their normal values are summarized in [Table 24.4](#).

The most common test for male infertility is the basic semen analysis. A sample of fresh semen is evaluated for volume and the concentration, morphology, and forward motility of sperm.¹⁶⁵ More advanced semen analysis also examines the function of the sperm including their ability to bind to and penetrate eggs. In-depth analysis also may analyze the sperm's DNA for number, fragmentation, and ability to merge with the egg's DNA.¹⁶⁹

Tests for women determine whether (1) ovulation occurs normally, (2) the endometrium is responding normally to hormones, (3) reproductive tissues are free of tumors or infections, (4) the woman does not have any chronic conditions interfering with fertilization or implantation, and (5) the reproductive tract (cervix, uterus, fallopian tubes) is adequately patent to allow for passage of ovum and sperm. Hormonal assays can be useful to detecting underlying abnormalities. The position and size of organs or the presence of tumors can be assessed by pelvic examination, ultrasound, or hysterosalpingogram that injects contrast dye into the reproductive tract to look for normal anatomy and fallopian/uterine tube patency. Chromosomal analysis of the couple may reveal mutations or translocations that result in very early embryo loss.¹⁶⁷

Treatment of infertility aims at correcting underlying pathologies or overriding the deficient system. Male infertility can be overcome through injection of the male DNA directly into the uterus or even the ovum. Anovulation in the female can be overcome with ovulation-inducing drugs. Blockages within the female reproductive tract can be bypassed with in vitro fertilization.

There has been a proliferation in assisted reproductive technologies

(ARTs) that enable women and couples to conceive and bear children. ART results in more than 50,000 live births (and more than 60,000 infants because of the higher incidence of multiple gestations) per year in the United States, and the rate is rising.¹⁷⁰ However, there are questions about the health and long-term safety of infants conceived with assisted reproduction, for instance, concerns about the high rate of twins and preterm births in pregnancies conceived with ARTs.¹⁷¹ In addition, children born through ART have a higher rate of birth defects, even when other variables are controlled.¹⁷² The many theories about the cause of this increase suggest that the birth defects may be the result of epigenetic changes when the expression of the embryo's DNA is affected by the very early environment of the blastocysts, though it is not clear if damage done through the fertilization and implantation procedures themselves is caused by an underlying medical condition contributing to the infertility.¹⁷² Research in this area and the field of epigenetics is ongoing.¹⁷²

Disorders of the Female Breast

Galactorrhea

Galactorrhea (inappropriate lactation) is the persistent and sometimes excessive secretion of a milky fluid from the breasts of a woman who is not pregnant or nursing an infant. It can occur in men, may involve one or both breasts, and is not associated with breast cancer.

Incidence is difficult to estimate because of differences among definitions of the condition, examination techniques, and populations of women who have been studied. Prevalence has been documented as 0.1% to 32% of all women.

◆Pathophysiology.

Galactorrhea is a manifestation of pathophysiologic processes in the body, rather than a breast disorder. These processes are chiefly hormone imbalances caused by hypothalamic/pituitary disturbances, pituitary tumors, or neurologic damage. Exogenous causes include drugs, estrogen, and manipulation of the nipples. When caused by hyperprolactinemia, it is manifested by the spontaneous appearance of a milky secretion from multiple duct openings, usually from both breasts. Galactorrhea caused by oral contraceptives (OCs) is more likely to occur with high-dose use; is characterized by clear, serous, or milky discharge from multiple ducts; and is noticeable during the drug-free interval between OC packets. In premenopausal women, unilateral or bilateral spontaneous multiple duct discharge that increases before menstruation often is caused by fibrocystic change. Unilateral, spontaneous, serous, or serosanguineous discharge from a single duct usually is caused by an intraductal papilloma. Bloody discharge suggests cancer; bilateral, sticky, multicolored discharge from multiple ducts is often caused by ductal ectasia; and purulent discharge indicates a subareolar abscess.¹⁷³

The most common cause of galactorrhea is **nonpuerperal**

hyperprolactinemia, or excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth. Nonpuerperal hyperprolactinemia can be caused by any factor that (1) stimulates or overstimulates the prolactin-secreting units of the pituitary gland; (2) interferes with production of **prolactin-inhibiting factor (PIF)**, a neurotransmitter (probably dopamine) that inhibits prolactin secretion; or (3) interferes with pituitary receptors for PIF. A variety of exogenous agents (such as drugs) and disorders can trigger one of these three mechanisms, thereby causing hyperprolactinemia ([Box 25.12](#)).

Box 25.12

Common Causes of Hyperprolactinemia

Physiologic Causes

- Exercise
- Idiopathic
- Pregnancy and postpartum period
- Sleep (rapid eye movement [REM] phase)
- Stress (trauma, surgery)
- Suckling

Drug Causes

- Amoxapine
- Amphetamines
- Anesthetic agents
- Butyrophenones
- Cimetidine
- Estrogens
- Hydroxyzine
- Methyldopa

Metoclopramide
Narcotics
Phenothiazines
Progestins
Reserpine
Tricyclic antidepressants
Verapamil

Pathophysiologic Causes

Acromegaly
Chronic chest wall stimulation (e.g., post-thoracotomy,
postmastectomy, herpes zoster)
Cirrhosis
Hypothalamic disease
Hypothyroidism
Pressure on pituitary stalk
Prolactin-secreting tumors
Pseudocyesis (false pregnancy)
Renal failure (especially with zinc deficiency)
Spinal cord lesions

Hypothyroidism causes increased secretion of hypothalamic TSH that stimulates prolactin release from the pituitary. Hypothyroidism also is associated with reduced metabolic clearance of prolactin, which prolongs its effects.

Many types of pituitary tumors cause hyperprolactinemia. Prolactinomas cause hyperprolactinemia by secreting prolactin, decreasing production of PIF, or putting pressure on the pituitary stalk such that delivery of PIF to the anterior pituitary is prevented. Growth hormone-secreting pituitary tumors may cause galactorrhea through the intrinsic lactogenic effect that growth hormone appears to have on mammary tissue. Prolactin-secreting lung and kidney tumors

also cause hyperprolactinemia.

Chronic stress may cause hyperprolactinemia by inhibiting PIF release. Cervical spinal injuries, head trauma, encephalitis, meningitis, herpes zoster, or thoracotomy scars may stimulate the afferent portion of the suckling reflex arc, which is carried in the second to sixth thoracic nerves. The suckling reflex increases prolactin secretion.

◆Clinical Manifestations.

A small amount of breast milk expressed from the nipples of parous women usually is not a concern, and normal breast milk color can be other than white. Inappropriate lactation is manifested by the appearance of a milky breast secretion in nonpregnant, nonlactating women from one or both breasts. Most women with galactorrhea also experience menstrual abnormalities. If a pituitary process is involved, the woman usually experiences hirsutism and infertility; if a hypothalamic lesion is present, she may report such CNS symptoms as intractable headache, visual field disturbances, sleep disturbances, and abnormal temperature, thirst, or appetite.

◆Evaluation and Treatment.

Galactorrhea requires evaluation when it (1) occurs in nulliparous women or in parous women who have not been pregnant or have not breast-fed for 12 months, or (2) is associated with amenorrhea, headache, visual field abnormalities, or other symptoms implying systemic illness. Evaluation includes a variety of diagnostic tests. When amenorrhea accompanies galactorrhea, the assessment is the same as that for amenorrhea. Breast secretions are examined for fat globules and neoplastic cells to verify their source. Serum prolactin levels are measured. Because such variables as eating, sleeping, stress, and breast examinations increase prolactin levels, at least two positive results are needed for a diagnosis of hyperprolactinemia. Prolactin levels greater than 25 to 30 ng/mL (by radioimmunoassay) are elevated. Those in the range of 75 to 100 ng/mL are considered to be caused by a pituitary tumor until proved otherwise. Serum thyroxine and TSH levels are measured to rule out hypothyroidism, and LH and

FSH levels are obtained if the individual is amenorrheic. MRI may assist in locating adenomas.

Treatment is specific to the underlying cause and occurs after identification of the cause. Medical therapy is usual and surgery or radiation therapy is rarely required.

Benign Breast Disease

Benign breast disease (BBD) is a range of noncancerous changes in the breast of different components of the breast (epithelial, stromal, adipocytes, or vascular). Numerous benign alterations in ducts and lobules occur in the breast, including irregular lumps, cysts, sensitive nipples, and itching. The most common symptoms reported by women are pain, palpable mass, or nipple discharge; the majority of these prove to have a benign cause. After a diagnosis of BBD, however, major determinants of breast cancer risk include degree of family history, histologic or biologic features (or both), and results of previous biopsy.¹⁷⁴ The College of American Pathologists has classified biopsy tissue according to breast cancer risk. Benign epithelial lesions can be broadly classified according to their risk of developing breast cancer as (1) nonproliferative breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia. The majority of nonproliferative benign lesions are not precursors of cancer and generally not associated with an increased risk of breast cancer.¹⁷⁵ Examples of other benign conditions are summarized in [Table 25.8](#).

TABLE 25.8

OTHER BENIGN BREAST CONDITIONS

TYPE	COMMENT
Developmental	
Milk-line remnants	Increase in number of nipples or breasts results from persistent epidermal thickening along the milk line
Accessory axillary breast tissue	Ductal system may extend into subcutaneous tissue of the chest wall and axillary region; this tissue can undergo lactational changes and give rise to tumors

Congenital nipple inversion	Is common and may be unilateral; can spontaneously correct during pregnancy; can be confused with retraction of nipple, which is sometimes part of invasive cancer or inflammation
Macromastia	Juvenile hypertrophy may be caused by unusual tissue response to hormonal stimulus
Iatrogenic	
Reconstruction or augmentation	Breast tissue can be replaced or augmented by skin and muscle flaps for synthetic prostheses; silicone implants, the most common, are rubbery silicone filled with either silicone gel or saline; a common complication of implants is formation of a thick fibrous capsule (i.e., chronic inflammatory responses) that can cause cosmetic deformity; the capsule can limit the spread of a ruptured implant but if the capsule ruptures, silicone gel can escape; long-term consequences of rupture are unknown
Inflammation	
Acute mastitis	Inflammatory diseases of the breast are rare; acute mastitis is confined to the lactating period of nursing; the nipples can become dry, cracked, and fissured, increasing risk of bacterial infection; infection may lead to abscess formation
Periductal mastitis	Women or men present with a painful subareolar mass thought to be infectious; not associated with lactation; 90% of individuals are smokers; vitamin A deficiency associated with smoking may alter the differentiation of the ductal epithelium; keratin is trapped within the ductal system causing dilation and rupture; antibiotic therapy and surgery are usually indicated
Mammary duct ectasia	Affects 50- and 60-year-olds, usually multiparous women, not associated with smoking; dilation of ducts with chronic granulomatous inflammatory reaction; fibrosis may eventually lead to skin and nipple retraction, thus mistaken for cancer; may have white nipple secretions
Fat necrosis	Painless, palpable mass, skin thickening or retraction; mammographic density or calcification; may have hemorrhage; most women will give a history of prior surgery or trauma; can be confused with breast carcinoma
Lymphocytic mastopathy	Single or multiple hard, palpable masses; can be so hard that interferes with biopsy; lesion includes collagenized stroma surrounding atrophic ducts and lobules; the breast membrane is frequently thickened; a prominent lymphocytic infiltrate surrounds epithelium and blood vessels; most common in women with type 1 diabetes or autoimmune thyroid disease

Data from Lester SC: The breast. In Kumar V, Abbas AK, Fausto N, editors: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

Nonproliferative Breast Lesions

Nonproliferative epithelial breast lesions are usually not associated with an increased risk of breast cancer. The nonproliferative lesions include: (1) simple breast cysts, (2) papillary apocrine change, and (3)

mild hyperplasia of the usual type. Terms such as **fibrocystic changes (FCCs)** (or physiologic nodularity and cysts), fibrocystic disease, chronic cystic mastitis, and mammary dysplasia refer to nonproliferative lesions that are not clinically definitive because they encompass a heterogeneous group of diagnoses.¹⁷⁴ Simple **cysts** (fluid-filled sacs) are the most common nonproliferative breast lesion and are a specific type of lump that commonly occurs in women in their 30s, 40s, and early 50s. Cysts feel “squishy” when they occur close to the surface of the breast but when deeply embedded they can feel hard (Fig. 25.27). An estimated 50% to 80% of women normally experience some of these changes. The prevalence of fibrocystic lesions is probably related to systemic factors, particularly hormones, through their receptors to produce signal pathways that result in cell regulation and stimulation. These events are affected by genetic background, age, parity, history of lactation, caffeine consumption, and use of exogenous hormones.¹⁷⁶ Calcifications, found in cysts and adenosis or an increase in the number of acini per lobule, can form mammographically suspicious alterations.¹⁷⁵ Cysts also can be associated with unilateral nipple discharge. A variety of substances are secreted into cyst fluid, including polypeptide hormones and male and female sex steroid hormones. Cysts often rupture with release of secretory material into the adjacent tissue. The resulting chronic inflammation and scarring fibrosis contribute to the palpable firmness of the breast.¹⁷⁵ Fibrous tissue increases progressively until menopause and regresses thereafter.

FIGURE 25.27 Benign Breast Disease. **A, Nonproliferative fibrocystic changes:** The architecture of the terminal-duct lobular unit is distorted by the formation of microcysts, associated with interlobular fibrosis. **B, Proliferative hyperplasia without atypia:** This is adenosis, a distinctive form of hyperplasia characterized by the proliferation of lobular acini, forming crowded glandlike structures. For comparison, a normal lobule is on the left side. **C, Proliferative hyperplasia without atypia:** There is moderate ductal hyperplasia, which is characterized by a duct that is partially distended by hyperplastic epithelium within the lumen. **D, Proliferative hyperplasia without atypia, which is florid ductal hyperplasia:** The involved duct is greatly expanded by a crowded, jumbled-appearing epithelial proliferation. **E, Atypical ductal hyperplasia:** These proliferations are complex and partially formed secondary lumens and mild nuclear hyperchromasia in the epithelial cell population. The peripheral spaces are irregular and slitlike. **F, Atypical lobular hyperplasia:** Monomorphic, small, rounded loosely cohesive cells fill the lumens of partially distended acini in this terminal-duct lobular unit (hematoxylin and eosin). (From Elmore JG, Gigerenzer G: *N Engl J Med* 353[3]:231, 2005.)

Papillary apocrine (glandular) change is an increase in ductal epithelial cells that has apocrine changes or an eosinophilic cytoplasm. **Mild hyperplasia of the usual type** is an increase in the number of epithelial cells within a duct that is more than two, but not more than four, cells in depth.¹⁷⁴

Proliferative Breast Lesions without Atypia

These disorders are characterized by proliferation of ductal epithelium or stroma, or both, without cellular signs of abnormality (**atypia** or deviation from normal). The following structurally diverse lesions are included: (1) usual ductal hyperplasia, (2) intraductal

papillomas, (3) sclerosing adenosis, (4) radial scar, and (5) simple fibroadenoma.¹⁷⁴

Criteria for the diagnosis of intraductal proliferative lesions have been the subject of much research and controversy and include the following structurally diverse lesions:

1. **Usual ductal hyperplasia (UDH)** is additional or proliferating epithelial cells that fill and distend the ducts and lobules. They retain features of benign cells, but the cells can vary in size and shape.¹⁷⁴ They are usually found as an incidental result from mammography. No additional treatment is needed and chemoprevention is not recommended.¹⁷⁴
2. **Intraductal papillomas** can occur as solitary or multiple lesions. *Solitary papillomas* are a monotonous (sameness) array of papillary cells that grow from the wall of a cyst into the lumen of the duct. Growth occurs within a dilated duct often near or beside the nipple, causing benign nipple discharge (Fig. 25.28). Epithelial hyperplasia and apocrine metaplasia are frequently present.¹⁷⁵ **Diffuse papillomatosis (multiple papillomas)** may present as breast masses (densities or calcifications on mammogram), nodules on ultrasound, or the cause of nipple discharge. Diffuse papillomatosis is defined as a minimum of five papillomas within a localized segment of breast tissue.¹⁷⁵ It is controversial whether papillary lesions require surgical excision after core needle biopsy.¹⁷⁷

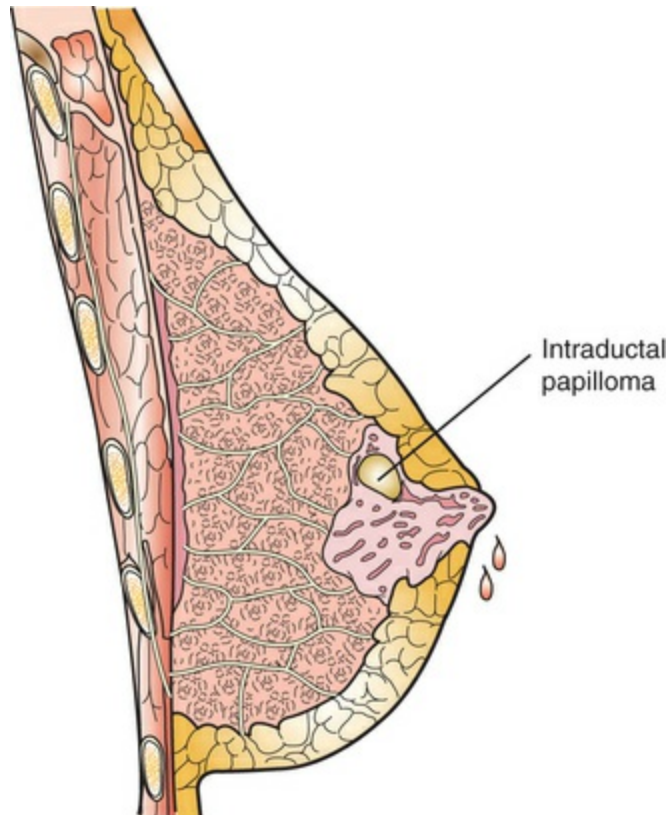

FIGURE 25.28 Intraductal Papilloma.

3. **Sclerosing adenosis** is a lobular lesion with increased fibrous tissue and scattered glandular cells.¹⁷⁴ Calcification is commonly present within the lumens; however, the normal lobular arrangement is maintained. It can present as a mass or suspicious finding from mammogram but requires no treatment. Occasionally, stromal fibrosis may mimic the appearance of invasive carcinoma.¹⁷⁵
4. **Radial scar (RS)** refers to an irregular, radial proliferation of ductlike small tubules entrapped in a densely fibrotic stroma (Fig. 25.29). The term *scar* refers to the structural appearance only because these lesions are not associated with scarring and fibrosis from a prior injury, biopsy, or surgery. RS also has been called *radial sclerosing lesions* and *sclerosing papillary proliferation*. RSs are usually discovered when a breast lesion or radiologic abnormality is biopsied or removed. Controversy exists about the need for surgical excision when RSs are found.

FIGURE 25.29 Radial Scar. Gross pathologic specimen of radial scar. (From the Armed Forces Institute of Pathology.)

5. **Simple fibroadenomas** are benign solid lumps or masses composed of both stromal and glandular tissue.¹⁷⁸ Fibroadenomas *usually* present as a well-defined mobile mass, smooth and hard like a marble on physical examination, or as a well-defined solid mass on ultrasound. Fibroadenomas are common, and regression or resolution is frequent. There is no increased risk of breast cancer in the majority of women with a simple fibroadenoma. If the fibroadenoma is *complex* with adjacent proliferative disease or if there is a family history of breast cancer, the risk of breast cancer is slightly elevated. Multiple fibroadenomas occur in the same breast or bilaterally in about 20% of cases.¹⁷⁸ Fibroadenomas are found most

commonly in women between the ages of 15 and 35 years but they can occur at any age, especially in older women receiving hormone therapy.¹⁷⁹ The etiology is unknown, but a hormonal role is likely because they persist during the reproductive years, increase in size during pregnancy or with estrogen therapy, and usually regress after menopause. Not all biopsy-proven lesions require surgical excision. Disadvantages of excisional surgery include scarring at the incision site, dimpling of the breast from the removal of the tumor, damage to the breast's duct system, and mammographic changes (e.g., architectural distortion, skin thickening, increased focal density).¹⁷⁵ If a biopsy-proven fibroadenoma is asymptomatic, then it can be left in place, although some women wish to have the mass excised so that they will not worry further.¹⁷⁵

Proliferative Breast Lesions with Atypia

Proliferative breast lesions with some abnormal structure or *atypia* include **atypical ductal hyperplasia (ADH)**, or abnormal proliferating cells in breast ducts (Fig. 25.30, A), and **atypical lobular hyperplasia (ALH)**, or abnormal proliferating cells in the lumen of lobular units (see Fig. 25.30, B).¹⁷⁵ ALH may lie between the ductal basement membrane and overlying normal luminal cells.¹⁷⁵ **Atypical hyperplasia (AH)** is an increase in the number of cells with some variation in cellular structure. Unlike ductal carcinoma in situ (DCIS), ADH only partially fills involved ducts.¹⁷⁵ Studies continue to indicate that women with atypical hyperplasia (AH) have an increased risk (about three- or fourfold) of breast cancer compared with women who have nonproliferative lesions.¹⁸⁰⁻¹⁸³ About 60% of the subsequent breast cancers in women with AH occur in the ipsilateral breast (same side) as the biopsy.^{180,184,185} As mentioned earlier from long-term follow-up studies, atypical hyperplasia has been shown to confer a relative risk of 4 for future breast cancer and recently the *absolute risk* has been better defined with a cumulative incidence of breast cancer about 30% at 25 years of follow-up.^{182,186} It appears that menopausal status at the time of benign breast biopsy influences the magnitude of

subsequent breast cancer risk. For women who were premenopausal at the time of their breast biopsy, the risk of breast cancer was greater in those with ALH than among women with ADH.¹⁸⁵ Overall, the younger a woman is when she receives a diagnosis of atypical hyperplasia the higher the risk that breast cancer will develop.^{180,182} Among women who were postmenopausal at the time of benign breast biopsy, the risk was similar with ALH and women with ADH.¹⁸⁵ Two independent cohorts of women found the *extent* of atypia stratified the long-term risk of breast cancer for ADH and ALH¹⁸⁷; however, from the Nurses' Health Study the extent of ADH or ALH did not significantly contribute to breast cancer risk.¹⁸⁸ The discrepant findings are important to clarify for breast cancer risk and because of concerns about overdiagnosis and overtreatment of high-risk breast lesions.^{189,190} Overall, ADH and ALH are viewed best as “markers” of a generalized bilateral increase in breast cancer risk.¹⁸⁵

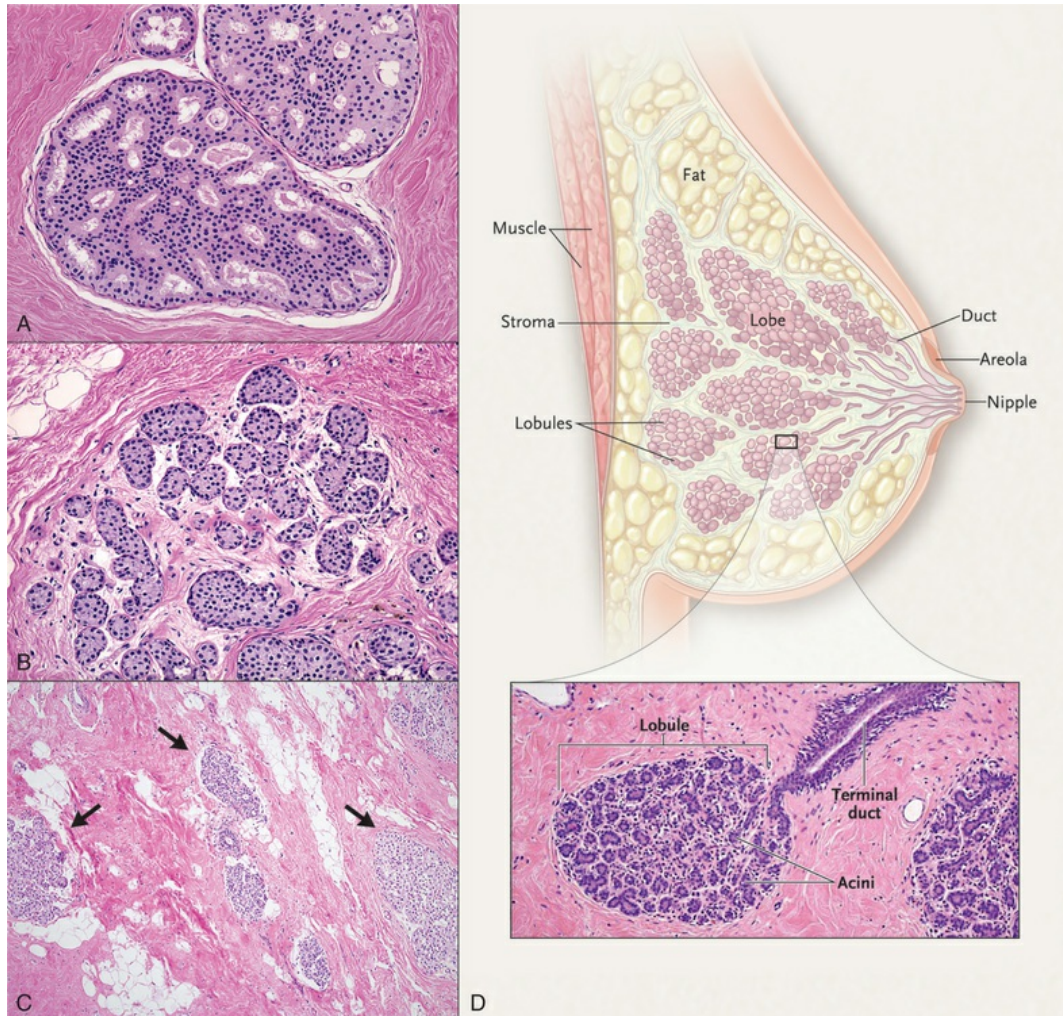

FIGURE 25.30 Anatomic and Histologic Features of Atypical Hyperplasias. A, shows atypical ductal hyperplasia with proliferation of monotonous cells in architecturally complex patterns, including secondary lumens and micropapillary formations. B, shows atypical lobular hyperplasia, with expanded acini filled with monotonous polygonal cells and a loss of acinar lumen. C, shows multifocal atypical hyperplasia (in this case atypical lobular hyperplasia). Atypical lobular hyperplasia is present in more than one terminal duct lobular unit, and units are clearly separated from one another by interlobular mammary stroma (*arrows*). D, is an illustration of the microanatomy of the breast, including a photomicrograph of a terminal duct lobular unit. (From Hartmann LC, Degnim AC, Santen RJ, et al: *N Engl J Med* 372[1]:1271–1272, 2015.)

◆Evaluation and Treatment.

Breast problems are diagnosed from a multimodal approach that combines physical examination, mammography, ultrasonography, thermography, possibly MRI, and biopsy. The dense breast tissue often seen in young women can make mammographic interpretation

extremely difficult ([What's New? Breast Cancer Screening Mammography](#)). Ultrasonography (ultrasound) is used to differentiate a solid mass from a cystic (fluid-filled) mass, which is generally benign.

What's New?

Breast Cancer Screening Mammography

Joann G. Elmore MD, MPH

Programs intended to screen the entire population of a country for disease usually require extensive resources. Possible harms of screening are important to consider, because screening at a population level involves testing healthy individuals. It must be made certain that the disease is not too rare, the test has a high level of accuracy, the potential costs and disadvantages are reasonable, and the treatment is effective for individuals who are diagnosed through screening.

Women have been encouraged to undergo breast cancer screening for many decades. The idea behind screening healthy women for breast cancer is to diagnose the disease early, when more treatment options are available and when they can positively impact their lives. Early screening programs encouraged women to perform breast self-examinations and also to have their clinician perform a breast examination in the office. Research has since shown that these screening techniques lead to false-positive examinations and are not associated with a reduction in mortality.

Most guidelines continue to recommend mammography screening for breast cancer, although the benefits of mammography are less than hoped, and more is being learned about potential harms. A mammogram is an x-ray examination that takes images of each breast (see [Figure](#)). The recommended age for a first mammogram and the suggested frequency of mammography screening vary among guidelines and between countries. The U.S. Preventive Services Task Force periodically reviews the evidence

and publishes mammography guidelines to aid discussions with women about screening.

Mammography, like any medical test, is imperfect. The benefits, harms, and accuracy of screening depend on numerous factors, including a woman's age, breast density, and time interval between mammograms. About 10% of screening mammograms in the United States are interpreted as “abnormal,” requiring additional testing. The great majority of women with an “abnormal” mammogram do not have breast cancer; this is called a *false-positive* mammogram. False-positive examinations lead to additional diagnostic testing, which may increase anxiety and morbidity. It is estimated that at least 50% of women who are screened annually for a decade will experience at least one false-positive mammogram. Most abnormal mammograms are evaluated with additional imaging and less frequently require biopsies. Some women think that a breast biopsy will provide an immediate and definitive diagnosis, but this is not always the case. For example, studies have shown that pathologists disagree on the diagnoses of breast atypia and ductal carcinoma in situ (DCIS).

As more women undergo mammography screening, there has been a sharp increase in the number of women *diagnosed* with DCIS and early-stage breast cancer. By definition, DCIS is confined to the breast milk duct and is *not* an immediately threatening, invasive carcinoma, although it is most often treated like an early-stage invasive breast cancer. Women with DCIS are at increased risk for a subsequent invasive breast cancer diagnosis, even though the majority of women with DCIS are never diagnosed with invasive cancer. Furthermore, treatment of DCIS does not alter mortality; women with DCIS have the same mortality rates as women without DCIS.

Another potential harm of screening mammography is *overdiagnosis*—a *diagnosis* of cancer that would never have harmed the woman during her lifetime. Overdiagnosis can lead to overtreatment. This can occur either with a preinvasive lesion, such as DCIS, or with invasive breast cancer. Unfortunately, it is not

possible to identify which individual women with a new diagnosis of DCIS or invasive breast cancer have a lesion that is so low-risk it will never harm them. Most women diagnosed with breast cancer undergo treatment with either mastectomy or with lumpectomy plus radiation therapy. This is considered *overtreatment* if the DCIS or invasive cancer was *overdiagnosed*. Published estimates of the prevalence of overdiagnosis range from <10% to 50%, and further research on this topic is needed.

Balancing the potential benefits and harms of breast cancer screening is not easy for women or their clinicians. Every woman should be encouraged to make informed decisions about participation in screening for breast cancer.

FIGURE Mammograms. Mammograms depicting varying breast densities from a craniocaudal view: A, almost entirely fat; B, scattered fibroglandular densities; C, heterogeneously dense; and D, extremely dense. (Images provided by Christoph I. Lee, MD, MSHS. From Fuller MS et al: *Med Clin North Am* 99[3]:451–468, 2015.)

Data from Elmore JG et al: *JAMA* 313(11):1122–1132, 2015; Fuller MS et al: *Med Clin North Am* 99(3):451–468, 2015; Katz DL et al: *Jekel's epidemiology, biostatistics, preventive medicine, and public health*, ed 4, Philadelphia, 2013, Elsevier Saunders; Welch HG et al: *N Engl J Med* 375(15), 2016; Elmore JG: *N Engl J Med* 375(15), 2016; U.S. Preventive Services Task Force: *Final update summary: breast cancer screening*, Jan 2016. Available at: <https://www.uspreventiveservicestaskforce.org/Page/Document/UpdateSummaryFinal/breast-cancer-screening>, accessed January 30, 2017; U.S. Preventive Services Task Force: *Ann Intern Med* 151(10):716–726, 2009.

Treatment consists largely of relieving symptoms. Reduction in the consumption of caffeinated beverages (e.g., cola) and chocolate, which can cause overstimulation for some women, may reduce pain and nodularity. Research for primary prevention of AH is weak. The roles of regular exercise, dietary factors, and sleep and the avoidance of psychologic stress are unknown. Given time, the cysts may disappear without treatment.

Certain selective estrogen modulators, such as tamoxifen and raloxifene, or an aromatase inhibitor may be considered for chemoprevention after a thorough discussion of risks and benefits. Although still controversial, isoflavone exposure was associated with a decreased risk of proliferative benign fibrocystic changes, nonproliferative changes, and breast cancer.^{191,192} Genistein, a soy isoflavone, has been reported to down-regulate an enzyme important in cancer progression (i.e., telomerase) and contributes to inhibition in both breast benign and cancer cells.¹⁹³ Toxicologists conclude soy supplement intake will not induce proliferation of normal breast tissue and may even inhibit proliferation.¹⁹⁴ The North American Menopause Society (NAMS) found that soy foods generally appear to be breast protective and recommended moderate lifelong soy consumption.¹⁹⁵ Another preventive factor may be iodine.¹⁹⁶ Investigators report that povidone-iodine (PVP-1), Lugol solution, and a combination of iodide and molecular iodine (I₂) may be potent agents for use in development of antitumor strategies.¹⁹⁷ Drugs used to treat severe breast pain are listed in [Table 25.9](#).

TABLE 25.9

DRUGS USED TO TREAT SEVERE BREAST PAIN (MASTALGIA)

AGENTS	COMMENTS
Definitely Effective	
Danazol	Causes a decrease in cyclic pain and nodularity believed to reduce estrogen; also used for endometriosis; some side effects include changes in menstrual cycle regularity, weight gain, acne, and flushing
Bromocriptine	Decreases cyclic pain, nodularity, and tenderness; decreases prolactin levels and may alter dopamine receptors; is also used to suppress lactation after childbirth; can

	cause nausea, vomiting, hypotension, and dizziness
Tamoxifen	As an antiestrogen it can decrease cyclic pain, increase clot formation (phlebitis, emboli, strokes), and cause hot flashes, amenorrhea, weight gain, and increased risk of uterine cancers
Evening primrose oil (linoleic acid)	Can decrease cyclic pain, nodularity, and tenderness; women with mastalgia believed to have low levels of breast linoleic acid; reduces PGE ₂ prostaglandins and inflammation; too much oil, however, has been associated with increasing inflammation (>1000 mg/day)
Possibly Effective	
Iodine	Can decrease cyclic pain and nodularity (see <i>Nutrition & Disease: Premenstrual Syndrome</i> , p. 813)
Vaginal progesterone	Decrease in cyclic pain and tenderness; not as effective for decreasing tenderness; antagonist to estrogen; can cause weight gain
Insufficiently Studied	
Progestins	May decrease estrogenic effects; however, related to endothelial vasospasms, weight gain, and increased risk of breast cancer

Cancer

Except for skin cancer, breast cancer is the most common cancer in American women.¹⁹⁸ It is estimated that 246,660 women and 2600 men will be diagnosed with breast cancer, and 40,450 women and 440 men will die from breast cancer in 2016.¹ Age and the chance of being diagnosed with breast cancer are presented in [Table 25.10](#). The age-adjusted death rate based on years 2009 to 2013 cases and deaths in the United States is 21.5 per 100,000 women per year.¹⁹⁹ Using Centers for Disease Control and Prevention (CDC) data from 2013 in the United States, white women had the highest rate of getting breast cancer followed by black, Hispanic, Asian/Pacific Islander, and American Indian/Alaska Native women. Dying from breast cancer varies by race and ethnicity. In 2013, black women were more likely to die of breast cancer than other groups, followed by white, Hispanic, Asian/Pacific Islander, and American Indian/Alaska Native women.²⁰⁰ Globally, breast cancer is the second most common cancer in the world.²⁰¹ It is the most frequent cancer of women with an estimated 1.67 million new cancer cases diagnosed in 2012.²⁰¹ Incidence rates vary nearly fourfold across the world regions with rates ranging from 27 per 100,000 in Middle Africa and Eastern Asia to 92 in North America.²⁰¹

TABLE 25.10

CHANCE OF BEING DIAGNOSED WITH BREAST CANCER*

BY AGE (YEARS)	BY RATIO
30–39	1 in 238
40–49	1 in 69
50–59	1 in 38
60–69	1 in 27
Ever [†]	1 in 8
Never	7 in 8

* **NOTE:** These calculations are averages. An individual's risk may be higher or lower

depending on several factors (e.g., family history, reproductive history, race/ethnicity, and others).

†Absolute lifetime risk.

Data from Reis LAG et al: *Cancer statistics review, 1975–2005*, Bethesda, MD, 2008, National Cancer Institute. Available at: http://seer.cancer.gov/csr/1975_2005. Based on November 2007 SEER data, posted SEER website, 2008.

More than two-thirds of breast cancer cases occur in women older than 55 years. From 2005 to 2009, the median age for breast cancer diagnosis was 61 years of age. The median age at death for breast cancer was 68 years of age.²⁰² Because ductal carcinoma in situ (DCIS) is almost exclusively detected by mammography, the large increase in incidence of DCIS over the past 20 years can be attributed to screening (see pp. 794 and 820). Some women younger than age 45 may have a higher risk for getting breast cancer compared with other women their age if they have the following risks factors: (1) close relatives (parents, siblings, or children) who were diagnosed with breast or ovarian cancer when they were younger than 45, especially if more than one relative was diagnosed or a male relative had breast cancer; (2) alterations in certain breast genes (*BRCA1* and *BRCA2*), or having close relatives with these alterations; (3) Ashkenazi Jewish heritage; (4) treatment with radiation therapy to the breast or chest during childhood or early adulthood; (5) have been diagnosed with breast cancer or other breast health problems, such as lobular carcinoma in situ (LCIS), DCIS, atypical ductal hyperplasia, or typical **lobular hyperplasia**; and (6) high breast density.²⁰³ A high-risk breast cancer condition is postpartum breast cancer with immune suppression and delayed involution (see [Reproductive Factors: Pregnancy](#)).²⁰⁴

Although breast cancer is a multifactorial disease involving a complex web of interacting factors, risk is related to timing, duration, and pattern of exposures. Risk factors and possible causes of breast cancer can be classified as reproductive, hormonal, environmental and lifestyle, and familial ([Table 25.11](#)). Two factors emerging as important are postpartum involution of the mammary gland, a reproductive factor, and breast density, which is not as easily classified.

TABLE 25.11**FACTORS ASSOCIATED WITH INCREASED RISK OF BREAST CANCER***

CATEGORY	RISK FACTOR	RELATIVE RISK [†]
Race	Blacks have higher incidence up to age 40 yr; whites have higher incidence after age 40 yr	1.1–1.9
Family history	Breast cancer in first-degree relative before age 60 yr	2–3
	Premenopausal or bilateral breast cancer	>4
	Postmenopausal in first-degree relative	≤2
	Breast cancer in two first-degree relatives,	4–6
	<i>BRCA1</i> or <i>BRCA2</i>	≤4
	<i>TP53</i> (Li-Fraumeni syndrome)	≤4
Previous medical history	Moderate or florid mammary hyperplasia	1.5–2
	Mammary papilloma	1.5–2
	Atypical mammary hyperplasia	4–5
	DCIS, LCIS [‡]	8–10
Estrogen exposure	Early menarche (before age 12 yr)	1.1–1.9
	Late menopause (after age 55 yr)	1.1–1.9
	Postmenopausal hormone therapy	1.4
	Oral contraceptive use	1.5
Pregnancy	Nulliparous or late first pregnancy (after age 35 yr)	1.1–1.9
Radiation	Atomic bomb	3
	Repeated fluoroscopy	1.5–2 [§]
Obesity and stature	Postmenopausal	1.2
	Tallness	≤2
Dietary/alcohol	High alcohol consumption	1.4–2
	High energy intake	≤2
	Advanced age	2–4
	Xenobiotics	≤2
Social	Smoking	2–4
	Higher socioeconomic status	≤2
	Low physical activity	≤2
Environmental	Excess radiation to breasts	?? [‡]
	Chemical carcinogens	≤2–??

Infectious agents	≤2-??
-------------------	-------

*Normal lifetime risk in white non-Hispanic women: 1 in 8.

†Relative risk is defined and discussed in [Chapter 5](#).

‡Data from Lester SC: The breast. In Kumar V, Abbas AK, Fausto N, editors: *Robbins & Cotran pathologic basis of disease*, ed 7, Philadelphia, 2005, Saunders.

§Currently debated.

DCIS, Ductal carcinoma in situ; LCIS, lobular carcinoma in situ.

Reproductive Factors: Pregnancy

A clearer understanding of mammary gland structure (morphology) and function from fetal development, to puberty, pregnancy, and aging will help elucidate fundamental changes to breast development and disease. A key element is “branching morphogenesis,” in which the mammary gland produces and delivers copious amounts of milk by forming a rootlike network of branched ducts from a rudimentary epithelial bud.²⁰⁵ Branching morphogenesis begins in fetal development, pauses after birth, starts again in response to estrogens at puberty, and is modified by cyclic ovarian hormonal action. This systemic hormonal action elicits local paracrine interactions between the developing epithelial ducts and their adjacent mesenchyme (embryonic) or postnatal stroma. The local cellular crosstalk then directs the tissue remodeling, ultimately producing a mature ductal tree.²⁰⁵ The gland is unique because it undergoes most of its branching during adolescence and not fetal development. This allows experimental manipulation of the gland not possible with any other organ.²⁰⁶

A woman's age when her first child is born affects her risk for developing breast cancer—the younger she is, the lower the risk. Overall, lifetime risk of breast cancer is reduced in parous women compared to nulliparous women, but pregnancy must occur at a young age²⁰⁷ (see [What's New? Potential Mechanisms Underlying Protective Effect of Pregnancy and Implications for Prevention of Breast Cancer](#)). The protective factor is especially observed in the

years of peak incidence, the postmenopausal years.²⁰⁸ The risk reduction is limited to hormone receptor–positive breast cancer.²⁰⁹ The influence of pregnancy on the risk of breast cancer also depends on family history, lactation postpartum, and overall parity.²¹⁰ Paradoxically, women of all ages have a transient *increase* in breast cancer risk with a recent pregnancy and after each subsequent pregnancy.^{210,211} **Pregnancy-associated breast cancer (PABC)** is defined as breast cancer diagnosed up to 5 years after a completed pregnancy; however, risk may persist for a decade.^{210,212} Delayed childbearing observed in the United States and all developing countries is expected to show a rise in diagnosed breast cancers.²¹⁰ (see [What's New? Potential Mechanisms Underlying Protective Effect of Pregnancy and Implications for Prevention of Breast Cancer](#)). The transient increase in breast cancer risk for all parous women includes events associated with pregnancy, including pregnancy-related hormones, such as estrogen, progesterone, and growth hormone, that promote or initiate cancer cells; immune suppressive effects of pregnancy; and breast tissue involution.²¹⁰ Breast gland *involution* after pregnancy and lactation uses some of the same tissue remodeling pathways activated during wound healing (i.e., proinflammatory pathways). The proinflammatory environment, although physiologically normal, promotes tumor progression. One mechanism identified links fibrillar collagen deposition, noted during normal involution, to high levels of COX-2 expression in tumor cells and subsequent tumor cell metastasis.²¹⁰ This alteration provides support to the tissue change in stroma for driving carcinogenesis.²¹³ The presence of macrophages in the involuting mammary gland contributes to carcinogenesis.^{212,214} Immature macrophages are capable of suppressing cytotoxic T-cell function, causing an immunosuppressive stroma conducive to tumor cell promotion (see [pp. 798 and 799](#)).

What's New?

Potential Mechanisms Underlying Protective Effect

of Pregnancy and Implications for Prevention of Breast Cancer

The most effective modifiable breast cancer prevention method is an early age (before 20 years) first-full-term birth (FFTB). An historic landmark case-control study of 17,022 women in 7 regions worldwide found that compared to nulliparous women, women who had their FFTB before the age of 20 had a risk reduction of 50%. Others have replicated this study with reproducible findings. From the same early study, women who gave birth for the first time older than age 33 were no longer protected against breast cancer compared to nulliparous women. These women were now at an increased risk compared to nulliparous women. The average age at FFTB in the United States has been increasing over time with those who gave birth for the first time between the ages of 30 and 34 rising 28% and those older than 35 years of age rising 23% between 2000 and 2014. The protective effect has been replicated in animal models including mice and rats. Ongoing research is needed to understand the stage of the pregnancy cycle (i.e., pregnancy, lactation, or involution) most important in reducing breast cancer risk. Investigators are concentrating on potential mechanisms of parity-induced protection against breast cancer (see text for discussion) and now include the insulin-like growth factor (IGF) system and effects of long-lasting reprogramming of the epigenome. Newer data on the genomic profile of parous women have shown pregnancy induces a long-lasting “genomic signature” that reveals chromatin remodeling derived from the early first pregnancy. The chromatin modifications are accompanied by higher expression of genes related to cell adhesion and differentiation, and genes only activated during the first 5 years after pregnancy may contribute to increased risk but the long-lasting genetic signature may explain pregnancy's preventive effect.

Data from Barton M et al: *Front Endocrinol (Lausanne)* 5:213, 2014; Horne HN et al: *Breast Cancer Res* 18(1):24, 2016; Katz TA: *Front Oncol* 6:228, 2016; MacMahon B et al: *Bull World Health Organ* 43:209–221, 1970; Mathews TJ, Hamilton BE: *NCHS Data Brief* 232:1–8, 2016.

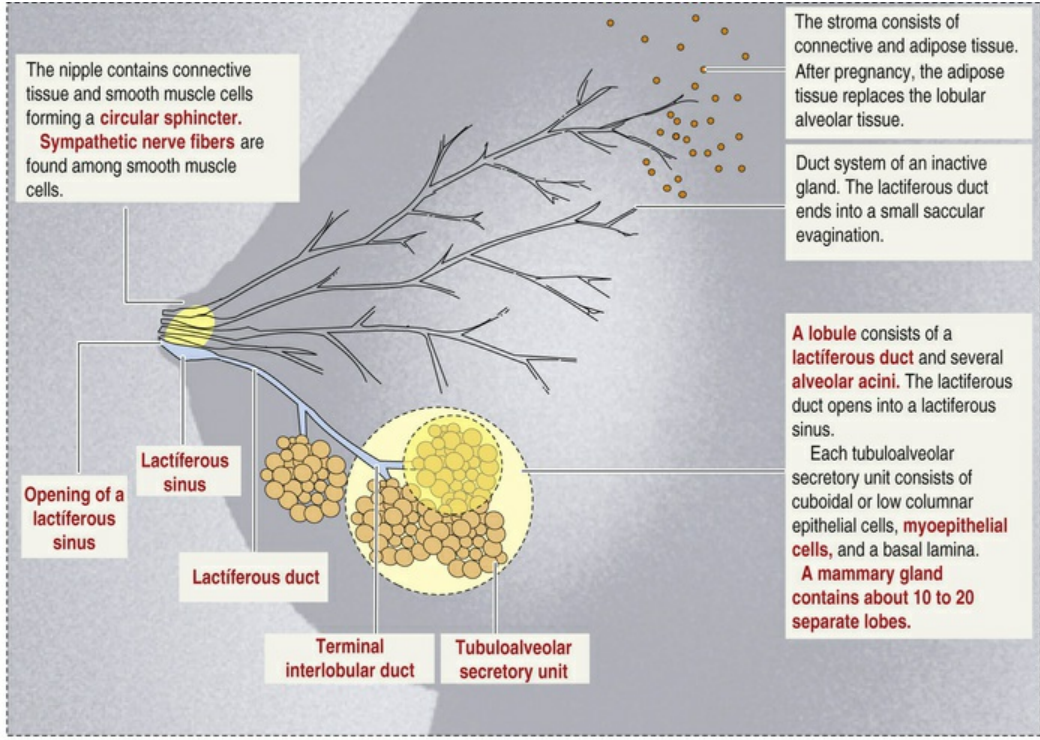

The main mechanisms for the *protective* effect of pregnancy are controversial including (1) induction of breast differentiation with lasting protective phenotypic (morphologic) changes; (2) altered cell fate with removal or modification of vulnerable cells, possibly stem cells; (3) enhancement of the ability for DNA repair or apoptosis, or both; (4) altered systemic hormonal regulation and possible persistent changes in intracellular pathways regulating proliferation; (5) decreased proliferation in the parous involuted gland; and (6) early-life hormonal and dietary exposures^{208,215} (see [What's New? Potential Mechanisms Underlying Protective Effect of Pregnancy and Implications for Prevention of Breast Cancer](#)).

Lobular Involution and Age and Postlactational Involution

Part of the uniqueness of the mammary gland is its profound physiologic changes throughout the phases of a woman's life: puberty, pregnancy, lactation, postlactational involution, and aging. The human breast is organized into 15 to 20 major lobes, each with terminal lobules containing milk-forming acini (see [Fig. 24.10](#)). **Terminal duct lobular units (TDLUs)**, also called *lobules*, are epithelial structures within the breast that produce milk during lactation and are the major source of most breast cancers ([Fig. 25.31](#)). With aging, breast lobules regress or involute with a decrease in the number and size of acini per lobule and replacement of the intralobular stroma with the denser collagen of connective tissue.²¹⁶ With time, the glandular elements and collagen are replaced with fatty tissue. This process is called **lobular involution**, and over many years the parenchymal elements progressively decrease in size and function and disappear. The first study of its kind found lobular involution was associated with reduced risk of breast cancer. Breast cancer risk decreased with increasing extent of involution in both high- and low-risk subgroups defined by family history of breast cancer, epithelial atypia, reproductive history, and age. Recent data

suggest breast cancer susceptibility from single nucleotide polymorphisms (SNPs) may not strongly influence TDLU involution.²¹⁷ Based on histologic and epidemiologic factors, investigators propose that *delayed* involution (persistent glandular epithelium) is a major risk factor for breast cancer.²¹⁶ Tissue involution involves massive epithelial cell death; recruitment and activation of fibroblasts; stromal remodeling; and immune cell infiltration, including macrophages with similarities to microenvironments present during wound healing and tumor progression.²¹⁸ **Post-lactational involution** is involution of the mammary gland that occurs at the end of every period of lactation and is essential to return the gland to a prepregnant state in readiness for the next pregnancy. For the first time, investigators, using murine postpartum mammary gland, showed involution is characterized by an influx of immune cells that reflect classic wound healing and mammary tumors exposed to the involution microenvironment are infiltrated by immature macrophages.²⁰⁴ These macrophages inhibit T-cell activation *ex vivo* and involution tumors have a growth edge that is interleukin-10 (IL-10) dependent.²⁰⁴ The immune cell composition across postpartum mammary gland involution resembles inflammation, proliferation, and remodeling/resolution phases associated with classic wound healing. Importantly, when apoptotic cells are phagocytosed by macrophages, macrophages are stimulated to an immune-suppressive phenotype, with transforming growth factor-beta (TGF- β) and IL-10 expression.²⁰⁴ Phagocytosis is crucial for the remodeling process, removal of cell debris, and residual milk in the second phase of involution.²¹⁹ Additionally, other investigators in a first study in rodent models demonstrated *Nucling*, a novel apoptosis-associated protein that plays an important role in involution by regulating NF- κ B STAT3 signaling pathways.²²⁰ An important transcriptional regulator of genes, **signal transducer and activator of transcription 3 (Stat3)** is associated with inflammation, wound healing, mammary macrophages, and mast cells. Stat3 appears to have an important role in modulating cell death and involution.²²¹ Regulatory T cells (Tregs) provide a checkpoint against inflammation during wounding by

suppressing multiple cell types including CD4+ and CD8+ T cells, B cells, natural killer cells, and antigen-presenting cells.²⁰⁴ All of these data are suggestive of classic wound resolution. The association between wound healing and tumor promotion has been recognized as a therapeutic target for decades.²²² This relevance with breast cancer has been recently obtained because mammary gland biopsies in rodents promote lung metastasis through recruitment of immune cells, and a skin wound adjacent to a mammary tumor stimulates tumor progression.²²³ Therefore studies support potential for tumor promotional effects of wound healing programs associated with normal gland involution. Investigators developed an immune-competent murine model of postpartum breast cancer. They demonstrated that tumor size is increased sixfold in the involution microenvironment compared to nulliparous hosts.²⁰⁴ In the postpartum group, mammary tumors have high levels of immature macrophages and reduced cytotoxic T-cell levels, a pattern predictive of poor prognosis in individuals with human breast cancer.²²⁴ Importantly, because involution macrophages have been proposed to be associated with the poor prognosis of postpartum breast cancer, macrophages may be a therapeutic target for blocking the tumor-promotional characteristics of the involuting gland (Fig. 25.32). Additionally, in rodents, circulating estrogens are responsible for recruiting estrogen receptor alpha (ER α) bone marrow cells that promote mammary tumor growth.^{225,226}

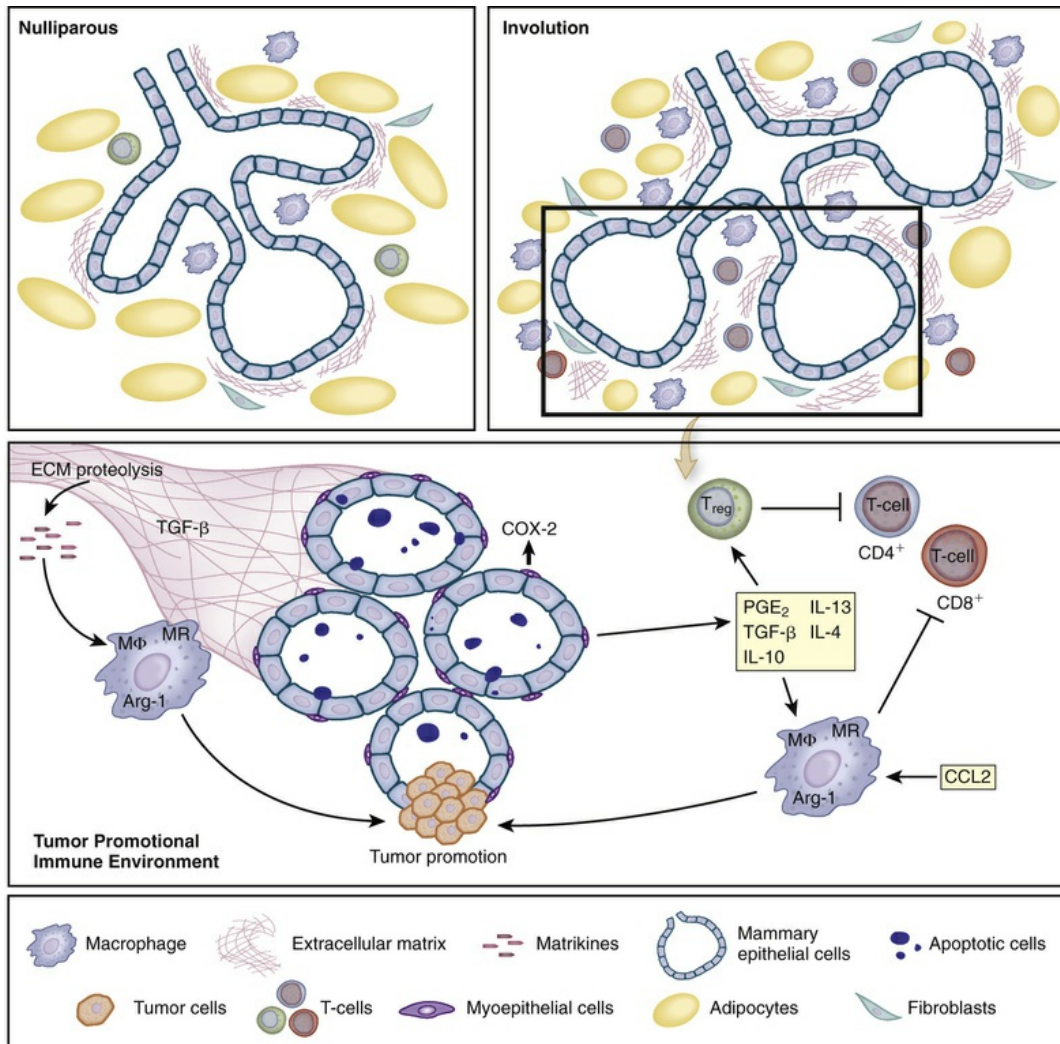

FIGURE 25.32 Macrophages as Instigators of a Tumor Promotional Immune Environment? Macrophages are proposed as the orchestrators of a tumor promotional immune environment during postpartum mammary involution. Also proposed is activated macrophages increase in the mammary gland during involution. Involution macrophages may contribute to tumor promotion through the production of growth factors, such as epidermal growth factor (EGF), and indirectly suppress antitumor immunity. Involution macrophage recruitment and activation are hypothesized as promoted by extracellular matrix (ECM) components, cytokines, growth factors, and prostaglandins, all of which may be immunotherapeutic targets. *Arg-1*, Arginase-1; *CD*, cluster of differentiation; *COX-2*, cyclooxygenase-2; *IL*, interleukin; *MR*, macrophage mannose receptor; *Mφ*, mouse; *PGE₂*, prostaglandin E2; *TGF-β*, transforming growth factor-beta. Widely appreciated is that as women age, their risk of breast cancer increases. But the *rate* of increase of breast cancer *slows* at about 50 years of age.²²⁷ This slowing has been attributed to a reduction in

ovarian hormone production. Milanese and colleagues²¹⁶ observed a definite increase in the process of involution at about 50 years of age with complete involution present in 5.8% of women ages 40 to 49 years and in 21.6% of women ages 50 to 59 years. Investigators propose that involution may contribute to this slowing in the rate of increase of breast cancer among women older than 50 years. Importantly, investigators found an inverse association between lobular involution and parity.²¹⁶ Other investigators have reported that the more children a woman has, the more likely she is to have persistent lobular tissue,²²⁸ which Milanese and colleagues²¹⁶ found was associated with increased risk of breast cancer. However, multiparity also has been found to reduce risk of breast cancer.^{229,230} This apparent contradiction may be explained by studies documenting that full-term pregnancies after 35 years of age are correlated with an increased risk of breast cancer.²³¹ In the Milanese study, the age of the mother at each child's birth was unknown.

Henson and colleagues²³² propose that late pregnancy with its concomitant increase in the proliferation of the ductal-alveolar epithelium is likely to interrupt the process of involution, which typically begins between 30 and 40 years of age. Failure to undergo TDLU involution among women with benign breast disease has been associated with progression to breast cancer, independent of other breast cancer risk factors.²³³ The activated stromal environment (with the influx of immune cells similar to that which occurs during wound healing) in the process of involution is the “ideal niche” for carcinogenesis.

Major signaling pathways involved in mammary gland involution also are involved in breast cancer.²³⁴ Certain proteases activated during involution modify the extracellular matrix and are implicated in loss of cell anchoring, providing a microenvironment for tumor growth.²³⁴ Further, the normal involuting gland may be in an immunosuppressed state with the transient presence of immune regulating cells that promote T-cell suppression.²⁰⁴

In summary, an increase in breast cancer risk following pregnancy may be caused by the *process* of mammary gland involution, which

returns the tissue back to its prepregnant state and is co-opted by processes of wound healing resulting in a proinflammatory environment that although physiologically normal can promote carcinogenesis.²¹⁴ The extracellular matrix (ECM) is very different between nulliparous, lactating, and involuting glands as shown in Fig. 25.33. Understanding the factors from the microenvironment that control cell function, differentiation, and stem cell renewal is the crux —the bottom line—of developmental and cancer biology²³⁵ (see *What's New? Mammary ECM Directs Differentiation of Testicular and Embryonic Stem Cells to Form Functional Mammary Glands In Vivo*).

FIGURE 25.33 Extracellular Matrix (ECM) Is Different in Nulliparous, Lactating, and Involuting Glands. Several ECM differences between nulliparous, lactational, and involuting mammary glands are related to collagen-fiber organization, cell motility and attachment, and cytokine regulation in a rodent model. Many protumorigenic ECM proteins are mediators of breast cancer progression specific to the involutorial window, and systemic ibuprofen experimental treatment during involution decreases its tumor promotional changes. (From O'Brien JH et al: *J Proteome Res* 11:4894–4905, 2012.)

What's New?

Mammary ECM Directs Differentiation of Testicular and Embryonic System Cells to Form Functional Mammary Glands In Vivo

Investigators tested whether acellular mammary extracellular matrix (mECM) preparations are sufficient to direct differentiation of testicular-derived cells and embryonic stem cells to form

functional mammary epithelial trees in vivo. Incredibly, they found that mECMs from mice and rats were sufficient to redirect testicular-derived cells to produce normal mammary epithelial trees within mammary fat-pads. This study, to the best of current knowledge, is the first to demonstrate tissue-specific ECM drives differentiation of cells to form functional tissue in vivo.

ECM, Extracellular matrix.

Data from Bruno RD et al: *Sci Rep* 7:40196, 2017.

Interestingly, oophorectomy, which is associated with a decrease in risk of breast cancer, leads to atrophy of breast parenchyma in young women as is noted in older women. Thus the risk reduction of oophorectomy may be caused by an accelerated involution.²³²

Hormonal Factors

The link between breast cancer and hormones is based on six factors that affect risk: (1) the protective effect of an early (i.e., in the 20s) first pregnancy; (2) the protective effect of removal of the ovaries and pituitary gland; (3) the increased risk associated with early menarche, late menopause, and nulliparity; (4) the relationship between types of fat, free estrogen levels, and oxidative changes in estrogen metabolism; (5) the hormone-dependent development and differentiation of mammary gland structures; and (6) the efficacy of anti-hormone therapies for treatment and prevention of breast cancer. Throughout its existence, the mammary gland epithelium proceeds through critical “exposure periods” of rapid growth or cycles of proliferation, including neonatal growth, pubertal development, pregnancy, lactation, and involution (after pregnancy and postmenopause; see the sections on Lobular Involution and Age and Postlactational Involution).^{214,236} Importantly, lack of TDLU involution has been associated with increased breast cancer risk, but the role of sex hormone levels and TDLU assessments is only beginning. Investigators suggest that hormone levels may act, in part, to delay

age-appropriate TDLU involution, resulting in a higher quantity of at-risk epithelium.²³³ These investigators found significant associations between higher TDLU counts, representing less involution with higher levels of prolactin and lower levels of progesterone among premenopausal women, and higher levels of estradiol, among postmenopausal women.²³³ Higher testosterone levels were suggestively associated with higher TDLU counts among postmenopausal women. From a cross-sectional study ($n = 94$ premenopausal; 92 postmenopausal women) investigators found higher levels of estrogen metabolites (premenopausal = unconjugated estradiol, 2-hydroxyestrone, and 4-hydroxyestrone; postmenopausal conjugated estrone and two to four pathway catechols) are generally associated with lower levels of TDLU involution.²³⁷

The understanding of the role of systemic hormones as powerful regulators of mammary gland development is shifting. Evidence is pointing to the wide-ranging effects of systemic hormones as possibly not due to their *direct* hormone action but rather their *induced* actions from multiple secondary paracrine effectors—thus the term *hierarchical*.²⁰⁵ Unraveling is a complex model of hormone, paracrine, possibly autocrine, and adhesion molecule–signaling pathways affecting epithelial and stromal cell fate in breast development and cancer. Despite differences between the organized process of development and the less, even chaotic, environment of invasive cancer, both processes share many identical mechanisms and signaling pathways. Key is *tissue remodeling* that applies to pubertal growth, immediately after pregnancy and during involution (see previous section).^{214,238,239}

The female reproductive hormones (estrogens, progesterone, and prolactin) have a major role and effect on mammary gland development and breast cancer (Fig. 25.34). Epidemiologic studies show that breast cancer risk increases with the number of menstrual cycles a woman has during her lifetime.²⁴⁰ Early menarche, late menopause, and short menstrual cycles all increase risk, and menopause (slows the *rate* of increase of breast cancer) and ovariectomy decrease the risk. A vast majority of breast cancers are

initially hormone dependent (estrogen receptor positive [ER+] and/or progesterone receptor positive [PR+]), with estrogens playing a crucial role in their development.²⁴¹ Estrogens control processes critical for cellular functions by regulating activities and expression of key signaling molecules. These processes include regulation of receptor activity and its interaction with other intracellular proteins and DNA.²⁴¹

FIGURE 25.34 Mammary Gland Development in the Mouse. Schematic representation of distinct stages of postnatal mammary gland development. (From Briskin C, Hess K, Jeitziner R: *Endocrinology* 156[10]:3442–3450, 2015.)

Endogenous Estrogen.

Substantial prospective data have accrued on endogenous circulating estrogens and breast cancer risk in postmenopausal women.²⁴²⁻²⁴⁴ From the EPIC study,²⁴⁵ increasing blood levels of estradiol also increased the risks for breast cancer. Updated analyses from two cohorts of the pooled analysis of nine prospective studies provide strong evidence that circulating hormones are an important marker of increased risk in postmenopausal women and not a result of the production of hormones by a tumor.²⁴⁶ Emerging data reveal estrogen acting on cells of hematopoietic origin.²²⁵ Coinjection of tumor cells and bone marrow isolated from estrogen-treated mice into nulliparous hosts was sufficient to promote tumor growth.²²⁵ In this model, despite the lack of estrogen receptor (ER) expression, tumors arising following pregnancy required circulating estrogens for their formation.²²⁵ Importantly, increasing the levels of circulating estrogens was sufficient to promote the formation and progression of ER-

negative cancers. This was accompanied by a systemic increase in host angiogenesis and coincided with the recruitment of bone marrow-derived stromal cells²²⁵ (see [What's New? Mammary ECM Directs Differentiation of Testicular and Embryonic Stem Cells to Form Functional Mammary Glands In Vivo](#)). Moreover, bone marrow cells from estrogen-treated mice were sufficient to promote tumor growth. The progression of normal mammary epithelium toward a cancerous state depends on diverse functions of the surrounding stromal cells. The many different mesenchymal cells appear to be recruited into developing tumor masses. Circulating levels of estrogen are at their highest in women during pregnancy, and the majority of breast cancers that develop during this time lack appreciable expression of either ERs or progesterone receptors (PRs).^{247,248} This significant observation suggests that estrogen is involved in promoting breast cancer following pregnancy and not through the direct binding of receptors expressed by breast epithelial cells.²²⁵ Recent work shows that estrogen may promote the progression of ER-negative breast cancer by stimulating cancer-associated fibroblasts (CAFs) to secrete stromal-derived factor-1 (SDF-1 α), which can recruit bone marrow myeloid-derived suppressor cells (MDSCs) to the tumor microenvironment, which exerts tumor promoting effects.²⁴⁹

Evidence for estrogens in modulating the immune environment of the mammary gland comes from studies showing changes in macrophage number and phenotype in the mammary gland across the estrous cycle and with treatment with estradiol and progesterone.²⁵⁰ In a wound-healing model, estradiol and progesterone promoted an alternative phenotype in macrophages.²⁵¹ Estradiol can promote a proinflammatory phenotype in macrophages.²⁵² In response to estrogen and progesterone, mast cells up-regulate chemokine receptors, maturation markers, and degranulate.^{253,254} T and B cells can be directly regulated by estrogen.²⁵⁵ Estrogen signaling drives the mobilization of MDSCs and enhances their immunosuppressive effects *in vivo*.²⁵⁶ More simply, estrogen promotes immunosuppression by promoting the mobilization and accumulation of the immunosuppressive action of MDSCs.²⁵⁶ Investigators found

that removing the ovaries, and thus estrogen production, from mice boosted the antitumor immune response and blocked malignant progression.²⁵⁶ Estrogen signaling is a critical mechanism underlying pathologic myelopoiesis in cancer.²⁵⁶

Endogenous Progesterone.

The role of progesterone receptor (PR) signaling in breast cancer is complex and controversial. See the section on Menopausal Hormone Therapy (MRT) and Breast Cancer Risk: Estrogen Plus Progesterone and Estrogen Only (ET) on treatment effects with progesterone. Several types of evidence show that repeated exposure to the luteal phase, and therefore endogenous increased serum progesterone (P) levels, increases breast cancer risk.²⁵⁷ Confusion exists about the term “proliferative” phase in the first part of the menstrual cycle, the follicular phase. The breast is quiet (quiescent) during the follicular phase. The term proliferative phase is based on changes that occur in the uterus; the endometrium proliferates before ovulation.²⁵⁷ Postovulatory secretion of P has antiproliferative effects on the endometrium and induces differentiation in the uterine lining.²⁵⁷ In the breast, cell proliferation occurs during the luteal phase and is accompanied by changes in the stroma, or microenvironment.^{258,259} Moreover, proliferation happens in the TDLUs where breast cancers originate.²⁵⁷ Data from cancer models show P is now recognized as a major proliferative hormone in both the mouse mammary gland and the normal human breast epithelium.²⁶⁰ The understanding of how P promotes proliferation in the human breast has grown over the years, mainly from animal studies (Fig. 25.35).

FIGURE 25.35 Working Model How Progesterone Promotes Proliferation in Human Breast Epithelium. After progesterone (P) exposure, P enters a PR+ luminal cell (blue) and binds to progesterone receptor (PR). PR moves laterally on the cell membrane (dimerizes) and transcribes target genes (e.g., RANKL, WNT-4, NOTCH ligands, GH). These signaling pathways then stimulate proliferation of neighboring PR- luminal cells (red), possibly also involving cells in the basal cell layer (purple). Not all of these pathways have been shown to be active in both mouse mammary gland and human breast. GHR, Growth hormone releaser; H, human gland; M, mouse gland; PR+, progesterone receptor positive; PR-, progesterone receptor negative; RANKL, receptor activator of nuclear factor kappa-β ligand; WNT, wingless-related integration site. (Adapted from Hilton HN, Graham JD, Clarke CL: *Mol Endocrinol* 29[9]:1230–1242, 2015.)

P is required to promote the wave of proliferation, which occurs in early pregnancy.²⁶⁰ Ovariectomy causes endogenous levels of estrogen and progesterone to decrease significantly. As a result, cell proliferation in mammary epithelium ceases and the epithelium becomes atrophic.²⁵⁷ Emerging from mouse studies is the mechanism by which progesterone triggers cell proliferation, activates progenitor cells, induces branching morphogenesis, affects immune cells, and controls the blood vessels to enable increased blood flow during the

luteal phase and pregnancy (Fig. 25.36).²⁵⁷

FIGURE 25.36 Working Model of Breast Carcinogenesis and Hormonal Involvement. Cross sections of a milk duct with luminal (*beige*) and outer myoepithelial cells (*green*) are surrounded by a basement membrane (*pink*). Although early stages of breast carcinogenesis are incompletely characterized, hormones impinge on all stages of breast cancer development. Progesterone signaling is important in determining whether preexisting lesions progress to invasive and metastatic breast cancer. Progesterone changes the microenvironment and activates a number of signaling pathways implicated in the development of different subtypes of breast cancer in the mouse model. Recently developed *ex vivo* models of the human breast have shown that progesterone promotes cell proliferation. Progesterone promotes stem cell activation in the adult mammary gland. Investigators hypothesize that repeated activation of these pathways during the luteal phase of the menstrual cycles promotes breast carcinogenesis. Some of the factors involved include amphiregulin, receptor activator of nuclear factor- κ B (NF- κ B) ligand (RANKL), and inhibitor of DNA binding 4 (ID4) have been implicated in distinct breast cancer subtypes. (From Brisken C: *Nat Rev Cancer* 13[6]:385–396, 2013; with data from Brisken C, Hess K, Jeitziner R: *Endocrinology* 156[10]:3442–3450, 2015; Tanos T et al: *Sci Transl Med* 5[182]:182ra55, 2013; Wang J et al: *Sci Trans Med* 5[215]:215le4, 2013.)

Endogenous Prolactin.

Prolactin, produced by the pituitary gland, travels through the blood and exerts multiple metabolic and reproductive effects, especially on the breast as the key regulator of lactation. Prolactin is also produced in other tissues, including the breast (known as *extrapituitary prolactin*).^{261,262} Recently, investigators reported that autocrine prolactin

is required for terminal mammary epithelial differentiation during pregnancy and production is regulated by the signaling pathway Pten-PI3K-Akt.²⁶¹ Although this finding is critical for normal breast development, differentiation, and lactation, it may also be important in breast carcinogenesis because the PI3K-Akt signaling pathway is commonly activated in human cancers. This suggests the important possibility that autocrine prolactin may play a role in breast cancer. A recent meta-analysis of seven studies supports a positive association between plasma prolactin levels and the risk of breast cancer.²⁶³ Prolactin may inhibit a major tumor-suppressive function of *BRCA1* by interfering with p21.²⁶⁴ From the Nurses' Health Study, the association with prolactin was more modest than with estradiol,²⁶⁵ the association was stronger among postmenopausal women and for ER-positive tumors.

Endogenous Testosterone: Androgen Receptor.

From the combination of prospective studies, case-control studies, and laboratory data the association between circulating testosterone in postmenopausal women and subsequent risk of breast cancer is now well established.²⁶⁶⁻²⁶⁹ Unclear is whether the association with testosterone is direct or indirect (i.e., enzyme conversion by aromatase of testosterone to estradiol) (Fig. 25.37).

FIGURE 25.37 Local Biosynthesis of Estrogens. Three main enzyme complexes (yellow) involved in estrogen formation in breast tissue, including aromatase, sulfatase, and 17 β -estradiol hydroxysteroid dehydrogenase (17 β -HSD). Thus despite low levels of circulating estrogens in postmenopausal women with breast cancer, the tissue levels are severalfold higher than those in plasma, suggesting tumor accumulation of these estrogens. Data suggest that most abundant is sulfatase in both premenopausal and postmenopausal women with breast cancer. Numerous agents can block the aromatase action. Exploration of progesterone and various progestins to inhibit sulfatase and 17 β -HSD or stimulate sulfotransferase (i.e., breast cancer cells cannot inactivate estrogens because they lack sulfotransferase) may provide new possibilities for treatment. LOH, Loss of heterozygosity (see Chapter 12); DHEA, dehydroepiandrosterone. (Adapted from Russo J, Russo I: *Molecular basis of breast cancer: prevention and treatment*, Berlin, Heidelberg, New York, 2004, Springer-Verlag.)

The androgen receptor (AR) has been implicated in prostate cancer, and now in the development and progression of breast cancer.²⁷⁰ The question of whether ARs are harmful or beneficial for individuals with breast cancer is complex and may differ by breast cancer subtype and menopausal status. Investigators used breast cancer cell lines and found that treatment of breast cancer cells with 5 α -dihydrotestosterone (DHT) promotes cell proliferation and decreases apoptosis.²⁷⁰ The reduction of testosterone levels in women with oophorectomy or hysterectomy may also be a protective factor.²⁷¹

Serum Estrogen, Progesterone, Androgens, and Prolactin.

Substantial evidence supports a positive association of circulating estrogens, androgens, and prolactin with postmenopausal breast cancer risk.²⁶⁸ From the Nurses' Health Study the inclusion of endogenous hormones (testosterone, estrone sulfate, and prolactin) to both the Gail score and the original Rosner-Colditz model significantly improved risk prediction for breast cancer among postmenopausal women.²⁶⁵ Measurements of endogenous hormones improve risk prediction for invasive breast cancer.²⁶⁸ A recent reanalysis of 13 prospective studies showed that circulating concentrations of sex hormones are associated with several of the established or suspected risk factors for breast cancer.²⁷² Data identify mammary stem cells (MaSCs) as critical targets for ovarian hormones, especially progesterone surges during the normal reproductive cycle and pregnancy increasing the proliferation of mammary stem cells.²⁷³⁻²⁷⁶ A key aspect of MaSCs is cytoskeletal function that facilitates cell shape and mobility.²⁷⁷

Local in Situ Estrogens (Paracrine).

The formation of estrogens in breast tumors may be significant for the growth and survival of estrogen-dependent breast cancer in postmenopausal women. The rationale is based on the following evidence: (1) estradiol (E_2) levels in breast tumors are equivalent to those in premenopausal women, despite plasma E_2 levels being lower after menopause; (2) E_2 concentrations in breast tumors of postmenopausal women are at least 10 times higher than serum levels; and (3) biosynthesis of estrogens in breast tumors occurs through two different routes: the aromatase pathway and the steroid sulfate (STS) pathway²⁴¹ (see Fig. 25.36).

Investigators measured levels of breast sex steroids in both benign and cancerous tissue.²⁷⁸ Estrogen and androgen concentrations varied greatly in both tissue and blood levels in benign and cancerous tissue.²⁷⁸ The estradiol/estrone ratio was lowest in premenopausal benign tissue and much higher in premenopausal cancerous tissue and postmenopausal benign and cancerous tissue. Estradiol and estrone levels were substantially higher in tissue than in plasma in

both premenopausal and postmenopausal women.²⁷⁸ Hormone levels in breast adipose tissue revealed high levels of androstenedione and testosterone and significant estrone and estradiol levels in breast adipocytes from postmenopausal breast cancer patients, consistent with an obesity-inflammation-aromatase axis (obesity with inflammation, COX elevation, and increased aromatase, which converts androgens to estrogen) occurring locally in breast tissue.²⁷⁸ Crown-like structures (CLSs; microscopic foci of dying adipocytes surrounded by macrophages) are proposed as sites of increased aromatization of androgens to estrogen. CLSs were more frequently identified in the breast fat of obese women and were associated with increased ratios of select estrogens/androgens in the blood and tissues but not with individual hormones.²⁷⁹

Evidence suggests that the site of conversion of androgens to estrogens in breast cancer is the stroma and not the malignant epithelial cells.²⁸⁰ Stromal fibroblasts adjacent to the tumor express aromatase and actively induce local estrogen production and signal crosstalk between estrogen and growth factors affecting the progression of breast carcinomas (Fig. 25.38). In the presence of estrogen in mice studies, fibroblasts provided cancer cells (MCF7S1 cell) additional growth capacity.²⁸¹ Breast tissue also contains high sulfatase activity and produces estrone through the hydrolysis of estrone sulfate (see Fig. 25.36). Thus quantitatively estrone sulfate may be the most important circulating estrogen in women; it increases the reservoir for the production of estrone and, ultimately, estradiol. It was found that E₂, itself, has antisulfatase action. This paradoxical effect of estradiol could be related to some studies that have found estrogen replacement therapy (ERT) either to have no effect or to decrease breast cancer mortality in postmenopausal women.^{282,283}

FIGURE 25.38 Breast Cancer Cells and Stromal Fibroblasts Produce Estrogen. In the microenvironment of breast carcinoma, breast cancer cells interact with different stromal cells through the secretion of growth factors and cytokines. Fibroblasts adjacent to cancer cells produce estrogen through the expression of the enzyme aromatase, which is induced by several factors including tumor necrosis factor- α ($TNF\alpha$), interleukin-1 ($IL-1$), and cyclooxygenase-2 ($COX-2$). EGF , Epidermal growth factor; ER , estrogen receptor; HGF , hepatocyte growth factor; $IGF-1$, insulin-like growth factor 1; $SDF-1$, stromal-derived factor 1 also known as $CXCL12$ or chemokine 12. These interactions lead to cancer cell proliferation, angiogenesis, and metastasis. (Adapted from Yamaguchi Y, Hayashi S: *Endocr J* 56[1], 2009.)

Estrogen metabolism from oxidation of the parent estrogens, estrone, and estradiol occurs at the 2, 4, or 16 position of the carbon skeleton to yield 2-hydroxylated, 4-hydroxylated, or 16-hydroxylated estrogens, respectively. The 4- and 16 α -hydroxylated pathways are potentially tumor promoting; conversely, the 2-hydroxylated pathway has been demonstrated to be less tumor promoting and, possibly, inhibiting.²⁸⁴ A recent prospective case-control study found nearly all estrogens, estrogen metabolites, and metabolic pathway groups were associated with an increased risk of breast cancer, especially unconjugated estradiol. These investigators found more extensive 2-

hydroxylation of estrogens is associated with lower risk and less methylation of the potentially genotoxic 4-hydroxylation pathway with a higher risk of breast cancer in postmenopausal women.²⁸⁵ From the Nurses' Health Study a comprehensive nested case-control study found that women who excrete more parent estrogens are at reduced breast cancer risk.²⁸⁶

Overall, two main mechanisms of carcinogenicity of estrogens involve (1) a receptor-mediated hormonal activity shown to stimulate cellular proliferation, resulting in increased opportunities for accumulation of genetic damage; and (2) oxidative catabolism of estrogens mediated by various cytochrome complexes (P450 [CYP] system) that eventually activate and generate reactive oxygen species (ROS) that can cause oxidative stress and genomic damage directly. Oxidative metabolites of estrogens can develop ultimate carcinogens that react with DNA to cause mutations leading to carcinogenesis. Thus imbalances in estrogen metabolites in breast tissue correlate with the development of tumors and suggest possible biomarkers related to the risk of developing breast cancer (see *Nutrition & Disease: Sustained Proliferation in Cancer and Dietary Substances to Block Cancer Proliferation*).

Nutrition & Disease

Sustained Proliferation in Cancer and Dietary Substances to Block Cancer Proliferation

Some of the leading natural compounds used in cancer therapy and in chemoprevention are presented below. Early steps in tumor development are associated with a fibrogenic response and hypoxic environment that favors the survival and proliferation of cancer stem cells. Once tumors appear, hormones support growth and metastases (in hormonally-dependent cancers) by promoting angiogenesis, by undergoing **epithelial to mesenchymal transition**, by triggering autophagy, and by taking cues from surrounding stroma. A number of natural compounds (e.g., curcumin,

resveratrol, indole-3-carbinaol, brassinin, sulforaphane, epigallocatechin-3-gallate, genistein, ellagitannins, lycopene, and quercetin) have been found to inhibit one or more pathways that contribute to proliferation (e.g., hypoxia-inducible factor 1, nuclear factor- $\kappa\beta$, phosphoinositide-3 kinase/Akt, insulin-like growth factor receptor 1, WNT, and cell cycle-associated proteins, as well as androgen and estrogen receptor signaling).

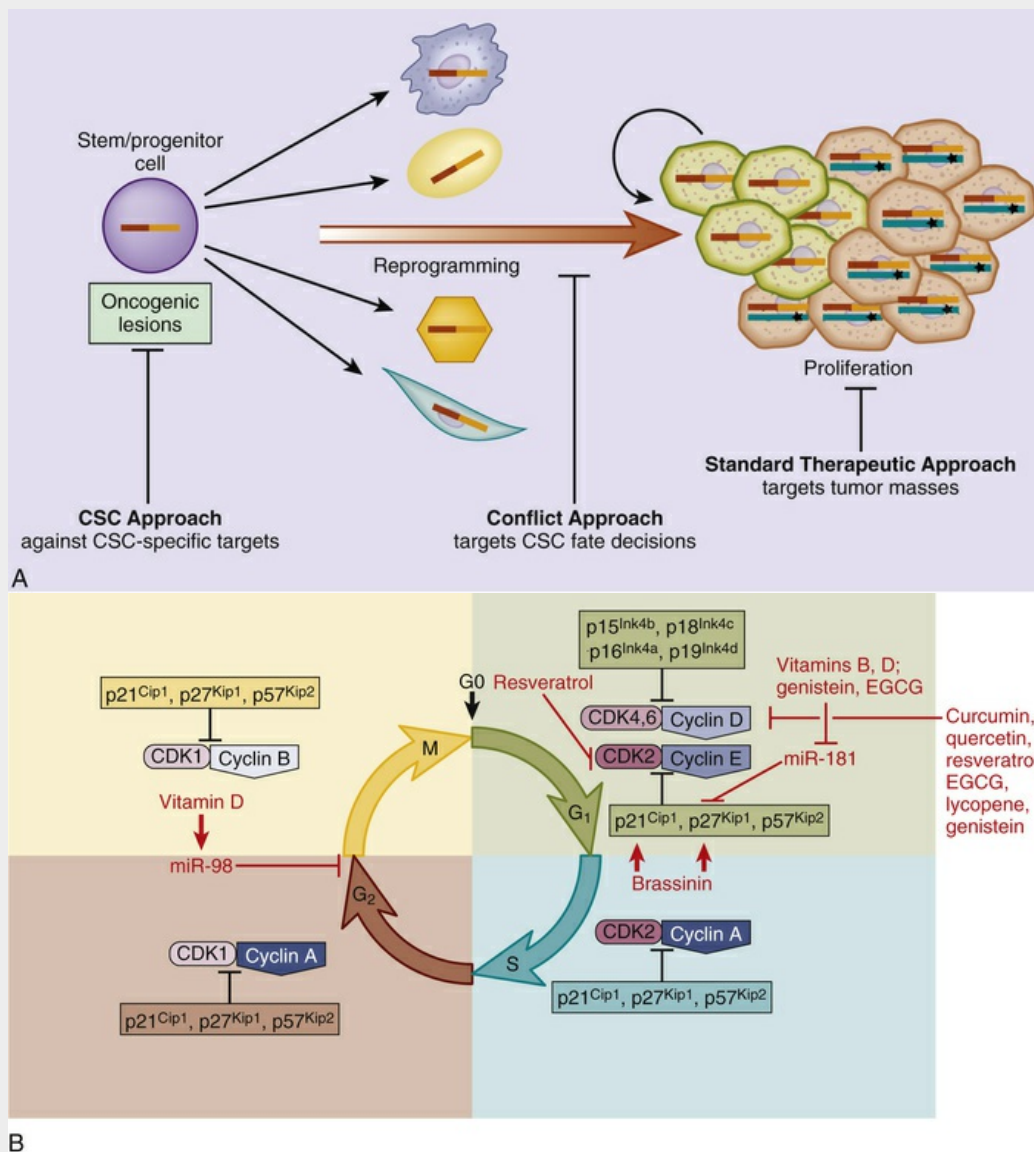

FIGURE Cancer Stem Cells, Proliferation, and Natural Products That Block Cell Cycle Progression. **A**, Cancer stem cells (CSCs) arise from tissue stem or progenitor cells that have undergone reprogramming or changes in gene expression as a result of epigenetic mechanisms or

oncogenic mutations. These CSCs proliferate and differentiate into tumor cells. CSCs are resistant to most therapies that are effective against the bulk of the tumor. Thus blocking the reprogramming and proliferation of stem cells will be essential to contribute to cancer chemoprevention. B, Selected natural products that block cell cycle progression. *CDK*, Cyclin-dependent kinase; *EGCG*, epigallocatechin gallate; *miR*, micron RNA; *p15*, *p16*, *p18*, *p19*, *p21*, *p27*, *p57*, cell cycle regulatory genes. Menopausal Hormone Therapy (MHT) and Breast Cancer Risk: Estrogen Plus Progesterone and Estrogen Only (ET).

The Nurses' Health Study (NHS) is one of the largest cohort studies with comprehensive knowledge on hormone therapy (HT) use for more than four decades.²⁸⁷ Table 25.12 summarizes postmenopausal hormone use and risk of cancer and cardiovascular disease from the NHS and NHSII from 1976 to 2016. Most epidemiologic studies have found an increase in breast cancer risk related to MHT with combined estrogen and progestogens²⁸⁷⁻²⁸⁹ (Table 25.13). Evidence comes from observational studies and clinical trials showing an increase in breast cancer risk with MHT current use, stronger among those with longer duration of use, and breast cancer risk disappearing a few years after treatment discontinuation.²⁹⁰⁻²⁹⁵

TABLE 25.12

POSTMENOPAUSAL HORMONE USE AND RISK OF CARDIOVASCULAR DISEASE AND CANCER: NHS AND NHS II, UNITED STATES 1976–2016

OUTCOME	EXPOSURE OR HORMONE FORMULATION	POPULATION	SUMMARY OF FINDINGS
Cardiovascular Disease			
CHD	Estrogen Estrogen + progestin	NHS 1976–2000	Initiation of HT near menopause (<4 yr since onset) associated with lower CHD risk; initiation of HT ≥10 yr after menopause onset not associated CHD risk; current use of estrogen + progestin not associated with risk
Stroke	Estrogen	NHS 1976–2004	Use associated with higher risk that does not

	Estrogen + progestin		appear to be related to timing of HT initiation
Recurrent CHD	Current postmenopausal HT use	NHS women with previous myocardial infarction or atherosclerosis 1976–1996	Short-term use appears to be associated with higher risk of recurrent major coronary events; longer-term use associated with lower risk
Pulmonary embolism	Postmenopausal HT use	NHS 1976–1992	Current but not past HT use associated with higher risk
Cancer			
Invasive breast cancer	Current HT use	NHS 1980–1996	Higher risk of breast cancer
Invasive breast cancer	Conjugated equine estrogens	NHS 1980–2002	Use associated with higher risk of breast cancer but only after longer-term use and only for estrogen receptor and progesterone receptor cancers
Invasive breast cancer	HT use	NHS 1976–1992	Use of conjugated estrogens alone or with progestins associated with higher risk
Invasive breast cancer	Estrogen + testosterone	NHS 1978–2002	Higher risk with use of testosterone alone or with estrogen
Ovarian cancer	Estrogen Estrogen + progestin	NHS 1976–2002	Use of unopposed estrogen, but not estrogen plus progestin, associated with significantly higher epithelial ovarian cancer risk
Endometrial cancer	Estrogen	NHS 1976–2004	Long-term use (≥ 5 yr) of estrogen and combined estrogen plus progesterone associated with higher risk
	Estrogen + progesterone		
Colorectal cancer	Postmenopausal HT use	NHS 1980–1994	Current use associated with lower risk but apparent lowering of risk disappeared on cessation
Colorectal cancer	Postmenopausal HT use	NHS 1980–2006	Current HT use associated with lower risk for CDKN1A-nonexpressed but not for CDKN1A-expressed tumors
Lung cancer	Postmenopausal HT use	NHS 1984–2006	HT may influence lung carcinogenesis although association is likely modest and altered by smoking status
Renal cell cancer	Postmenopausal HT use	NHS 1976–2004	Current use of estrogen alone or with progesterone not associated with risk
Bladder cancer	Postmenopausal HT use	NHS 1976–2002	Current use of estrogen or with progestin not associated with bladder cancer risk

TABLE 25.13

HORMONAL TREATMENTS ASSESSED BY THE IARC MONOGRAPH WORKING GROUP

GROUP 1 AGENT	CANCER ON WHICH SUFFICIENT EVIDENCE IN HUMANS IS BASED	SITES WHERE CANCER RISK IS REDUCED	ESTABLISHED MECHANISTIC EVENTS	OTHER LIKELY MECHANISTIC EVENTS
Diethylstilbestrol	Breast (exposure during pregnancy), vagina and cervix (exposure in utero); limited evidence: testis (exposure in utero), endometrium	–	Estrogen receptor-mediated events (vagina, cervix), genotoxicity	Epigenetic programming
Estrogen-only menopausal therapy	Endometrium, ovary; limited evidence: breast	–	Estrogen receptor-mediated events	Genotoxicity
Combined estrogen-progestogen menopausal therapy	Endometrium (risk decreases with number days/month of progestogen use), breast	–	Receptor-mediated events	Estrogen genotoxicity
Combined estrogen-progestogen oral contraceptives	Breast, cervix, liver	Endometrium, ovary	Receptor-mediated events	Estrogen genotoxicity, hormone-stimulated expression of human papillomavirus genes
Tamoxifen	Endometrium	Breast	Estrogen receptor-mediated events, genotoxicity

World Health Organization (WHO): A review of human carcinogens. B. Biological agents IARC monographs on the evaluation of carcinogenic risks to humans, *IARC Monographs*, vol 100(B), Geneva, Switzerland, 2015, Author.

From IARC Special Report: *Lancet* 10:13–14, 2009.

Similar to the findings of the intervention phase of the Women's Health Initiative (WHI), current use of unopposed estrogen therapy for 5.0 to 9.9 years was not associated with a higher risk of breast cancer in the NHS among postmenopausal women who had undergone a hysterectomy.^{290,296} However, longer duration of use, which could not be examined in the WHI, was associated with a trend toward higher risk: use for 20 years or more was associated with a 42% higher risk of breast cancer, especially for those positive for estrogen receptor and progesterone receptor.^{287,297} Longer use in animal studies has been linked with increasing cell proliferation, angiogenesis, and inhibition of apoptosis.²⁹⁸ Longer use of ET that may increase breast cancer risk was found in combined data of 16 studies and another analysis of 52,705 women with breast cancer.^{299,300} In these studies and the Million Women Study, leaner women had an even higher risk of breast cancer.³⁰¹

From the NHS, as with the WHI, current use of MHT was associated with a higher risk of invasive breast cancer.²⁸⁷ The NHS was one of the first studies to quantify the relationship between other types of HT formulations and breast cancer risk.²⁸⁷ During 14 years of follow-up studies, the use of estrogens (other than conjugated estrogens) or progestins alone was associated with adjusted relative risks for breast cancer.²⁹¹ These data from women in the United States confirm the data from European studies.²⁹¹ Moreover, with 10 additional years of follow-up, the risk of breast cancer was found to be nearly 2.5 times higher among current users of estrogen plus testosterone than among those who had never used these hormones.³⁰² Additional support for MHT to increase breast cancer risk was the *reduction* in risk reported by several countries with discontinuation of MHT use.^{289,303} The risks associated with transdermal, intranasal, or “natural” estrogens have insufficient data and hypotheses remain unsubstantiated.

The International Agency for Research on Cancer lists estrogen-progestogen menopausal therapy and estrogen-progestogen contraceptives as carcinogenic agents with sufficient evidence in humans for breast cancer (see [Table 25.13](#)). Evidence from the Agency for Healthcare Research and Quality (AHRQ, Rockville, MD) published a systematic review from 283 trials comparing effectiveness of treatments for menopausal symptoms.³⁰⁴ From this report, they state, “Over the long term, estrogen combined with progestogen has both beneficial effects (fewer osteoporotic fractures) and harmful effects (increased risk of breast cancer, gallbladder disease, venous thromboembolic events, and stroke). Estrogens given alone do not appear to increase breast cancer risk, although endometrial cancer risk is increased.”

Insulin and Insulin-Like Growth Factors.

IGFs regulate cellular functions involving cell proliferation, migration, differentiation, and apoptosis. IGF-1 is a protein hormone with a structure similar to that of insulin. IGF-1 is a potent mitogen after binding to the IGF-1R (receptor) triggers a signaling cascade leading to proliferation and antiapoptosis.³⁰⁵ The growth hormone–IGF-1 axis can stimulate proliferation of both breast cancer and normal breast epithelial cells.³⁰⁶ A pooled analysis of 17 studies showed a significant association of IGF-1 with breast cancer risk.³⁰⁷ Interestingly, no significant difference was found according to menopausal status. Joint associations of IGF-1 and estradiol together showed they were related to risk and those women in the top thirds of estradiol and IGF-1 levels had the highest risk. Estradiol increases IGF-1 activity in the breast.³⁰⁸ Agents to target IGF-1R in triple-negative breast cancer (TNBC) may induce cell protective autophagy.³⁰⁹ Investigators suggest that elevated IGF levels may define a subgroup of women with high mammographic density and limited TDLU involution, two markers related to increased breast cancer risk.³¹⁰ Insulin and IGF-1 receptor family are now known to have a role in macronutrient intake and cancer, diabetes and cancer, and obesity and cancer.³¹¹

Diabetes is associated with a complex physiology of insulin

resistance; increased insulin, estrogen, and growth hormone levels; increased inflammatory levels; and signaling pathways leading to an increased risk of breast cancer.³¹² Insulin therapy and sulfonylurea were found to be mildly associated with increased breast cancer risk.³¹² A United Kingdom study showed women treated with insulin glargine were not associated with breast cancer risk in the first 5 years; however, longer use may increase the risk.³¹³ Metformin appears to have a protective role. Much more investigation is needed to understand the role of insulin, insulin-like growth factors, and diabetes mellitus and their associated risk of breast cancer and recurrence of breast cancers. A recent study found women with multiple gestational diabetes mellitus (GDM) pregnancies had a higher incidence of breast cancer.³¹⁴

Melatonin as a regulator of circadian rhythm is the main focus of shift-work and light at night and breast cancer risk. However, tumor growth (in vivo) can be accelerated by light at night (LAN), in part from continuous activation of IGF-1 receptor (IGF-1R) signaling.³⁰⁸ A recent case-control study of 1679 women exposed to LAN during sleep was significantly associated with breast cancer risk.³¹⁵ This study was the first to identify bedroom light intensity and breast cancer risk. Although inconclusive, shift-work and its disruptive effects on circadian rhythms and sleep deprivation at night have been suggested as a risk factor for breast cancer.³¹⁶

Human Chorionic Gonadotropin.

Human chorionic gonadotropin (hCG) level increases during the first trimester and then rapidly declines to a steady state throughout pregnancy. Data from rat studies indicate that measurement of hCG levels may be useful in developing new therapies because it has antiproliferative and antiinvasive effects.³¹⁷ However, insufficient data exist on the safety of hCG; its role in carcinogenesis is complex and much research needs to be done.³¹⁸

Oral Contraceptives.

The International Agency for Research on Cancer (IARC) group

confirmed that combined estrogen-progestogen oral contraceptives (OCs) increase the risk for breast, cervix, and liver cancers.^{289,319} A recent meta-analysis of 66 studies showed current use of oral contraceptives, nulliparity, and maternal age of 30 years or older at first birth were associated with a 1–1.5-fold increased risk of breast cancer.³²⁰ Current OC use appears to be associated with a higher risk of invasive breast cancer, but risk differs by hormone fluctuations and age.²⁸⁷ From the NHS, older women's (40 years and older) use of OCs for 10 or more years and past OC use before a first full-term pregnancy were not associated significantly with breast cancer.³²¹ OC formulations were prescribed in the 1990s in the younger NHSII cohort but current OC use is associated with a 33% higher risk of breast cancer. A higher risk was not observed in past users.³²² Hormones are discussed further in the Pathophysiology section.

Mammographic Breast Density

Mammographic breast density (MBD) is the radiologic appearance of the breast (largely stromal and epithelial tissues) reflecting variations in breast tissue composition (Fig. 25.39). Mammographic breast density appears white or dense on a mammogram, is expressed as a percentage of the mammogram (percent mammographic density), and is a strong and consistent risk factor for breast cancer.^{265,323,324} A recent prospective study (sample size of 18,437 women) revealed breast density was the most prevalent risk factor for both premenopausal and postmenopausal women and had the largest effect on the population-attributable risk proportion (PARP).³²⁵ **Percent mammographic density (PMD)** estimates the proportion of stromal and epithelial tissues in relation to fat tissue in the breast. Internationally, studies done in the United States, Canada, and Europe all found that a significant increase in risk is associated with more extensive PMD; risk persisted for 8 to 10 years from the date of the mammogram, and increased with increasing PMD. Extensive PMD is associated with a markedly increased risk of invasive breast cancer.³²³ PMD is inversely associated with age, weight, age of menopause, and use of tamoxifen and directly associated with height, parity, family

history of breast cancer, and combined hormone therapy.³²⁶ High breast density correlates with collagen level.³²⁷ Investigators suggest that COX-2 has a direct role in modulating tumor progression in tumors arising within collagen-dense microenvironments.³²⁷ CC-chemokine ligand 2 (CCL2) is an inflammatory cytokine that recruits macrophages to sites of injury.³²⁸ CCL2 by mouse mammary epithelium induces a state of low-level chronic inflammation that increases stromal density.³²⁸ Investigators hypothesize that CCL2-driven inflammation contributes to the increased breast cancer in women with high MBD.³²⁸

FIGURE 25.39 Breast Density Varies Among Women. The sensitivity of mammography for detecting malignancy is significantly reduced if the breast consists of a high proportion of fibroglandular (dense) breast tissue (A) compared to a breast that is fatty (B). (From O'Malley FP, Pinder SE, Mulligan AM: *Breast pathology*, ed 2, Philadelphia, 2011, Saunders.)

Environmental Factors and Lifestyle

The environmental causes of breast cancer possibly affect the breast the most during critical phases or “windows” of development including early differential stages—that is, undifferentiated cells to

alveolar buds and then lobules, puberty, pregnancy and lactation, involution, and menopause. During early phases, mitotic activity and cell division are greater than later in life.

Radiation.

Ionizing radiation is a known mutagen and established carcinogen for breast cancer. To date, only accidentally or medically induced radiation has been demonstrated to exert a carcinogenic effect on the breast. The Institute of Medicine (IOM) reports that the two most strongly associated environmental factors are exposure to ionizing radiation and combined postmenopausal HT.³²⁹ There are many sources of ionizing radiation, including x-rays, CT scans, fluoroscopy, and other medical radiologic procedures. Although only about 10% of diagnostic radiologic procedures in large U.S. hospitals are CTs, they contribute an estimated 65% of the effective radiation dose to the public from all medical x-ray examinations.³³⁰ The IOM conclusion of a causal relationship between radiation exposure in the same range as CT and cancer is consistent from a large varied literature.³³¹ The IOM makes it clear that *avoidance* of medical imaging is an important and concrete step that women (girls) can take to reduce their risk of breast cancer.³³² Scientists and clinicians also have expressed concern about the increasing number of CT scans performed, including on children.^{332,333} Radiologic exposure of the upper spine, heart, ribs, lungs, shoulders, and esophagus also exposes breast tissue to radiation. Breast tissue may be exposed from abdominal CT scans. X-rays and fluoroscopy of infants may constitute whole-body irradiation. Epidemiologic studies have shown that adolescent and young women are at increased risk of developing breast cancer following exposure to ionizing radiation compared with older women, and the risk is dose-dependent.³³⁴ The duration of increased risk from radiation is unknown, but increased risk appears to have lasted at least 35 years in women treated for mastitis, those treated with fluoroscopy, and those who survived the atom bomb. Breast cancer rates in atomic bomb survivors in Japan were highest among women younger than 20 years of age at time of exposure; importantly,

those who had early full-term pregnancies were at significantly lower risk than those who had not.³³⁵ Thus interacting factors can modulate the risks from radiation. Similarly, young women exposed to high levels of diagnostic radiation have an elevated risk of breast cancer.³³⁴ In women treated with radiotherapy for Hodgkin lymphoma, there is a linear relationship between radiation exposure and breast cancer risk, and women younger than age 20 years at the time of exposure had the highest risk of developing subsequent breast cancer.³³⁶

Cancer induction and exposure to low doses and low-energy x-rays are controversial and the topic of much debate and research. Biologic understanding related to low doses of radiation is presented in [Chapters 2](#) and [13](#). Delivered dose and specific low-dose effects are main concerns in radiologic breast imaging.³³⁷ Conventional x-ray mammography is one of the most valuable diagnostic tools for imaging of the breast. Today much use is with full-field digital mammography (FFDM). Continuous technical development has led to several new imaging techniques, including digital breast tomosynthesis (DBT), phase-contrast x-ray imaging, computed tomography of the breast, as well as ultrasound and magnetic resonance imaging (MRI). Despite technical innovations, except for ultrasound and MRI, these modalities require exposure of breast tissue to ionizing radiation and the breast is considered the most radiosensitive organ in the body.^{337,338} Therefore it is critical to compare delivered radiation doses to the breast and measure x-ray-induced DNA damage, as well as other biologic effects. A technique for the detection and quantification of in vivo DNA damage has been developed. DNA double-strand breaks (DSBs) are the most relevant lesion induced by ionizing irradiation.³³⁸ After induction of DSBs, the phosphorylation of the histone variant H2AX, named γ -H2AX, is the second most source of DNA damage. γ -H2AX is a visible focus and a reliable and sensitive tool for the determination of DNA damage. Investigators found mammography induces a slight but significant increase of γ -H2AX foci in systemic blood lymphocytes. A clear induction of DNA lesions was found both by FFDM and by DBT.³³⁸ Investigators assessed in vitro mammographic radiation-induced

DNA damage in mammary epithelial cells from 30 women with low (LR) or high (HR) family risk of breast cancer.³³⁹ They found the existence of double-strand breaks (DSBs) induced by mammography and revealed by γ -H2AX assay with two radiobiologic effects: a low-dose effect and a low and repeated dose (LORD) effect.³³⁹ These effects were greater in high-risk patients.^{339,340} In agreement with these findings was a low and repeated dose effect and a lack of DNA repair of DNA damage.³⁴¹ Investigators from international studies have concluded that diagnostic chest irradiation or radiation therapy for benign or malignant diseases increases the risk of breast cancer for cumulative doses as low as 130 mGy. The breast cancer risk did not decrease when increasing the number of radiologic treatment fractions for delivering the same total dose, but the risk decreased greatly with increasing age of exposure to ionizing radiation.³³⁹ International agencies are assessing the utility of screening MRI and mammography in these high-risk populations. The risk of secondary lung malignancy (SLM) is an important concern for women treated with whole-breast radiation therapy after breast-conserving surgery for early-stage breast cancer.³⁴² According to a Cochrane review, radiation therapy as a treatment for breast cancer increases deaths from heart disease by more than 25% and much higher for deaths from lung cancer.³⁴³ Investigators studied SLM risk associated with several common methods of delivering whole-breast radiation therapy (RT). Compared with supine whole-breast irradiation (WBI), prone breast irradiation is associated with a significantly lower predicted risk of secondary lung malignancy.³⁴² These data will be important to compare different breast imaging techniques. The United States Preventive Services Task Force (USPSTF) has updated the recommendations for mammography because of overdiagnosis and overtreatment issues related to screening mammography (also see *What's New? Breast Cancer Screening Mammography*). [Table 25.14](#) presents benefits and harms of screening mammography from randomized controlled trials.

TABLE 25.14**BENEFITS AND HARMS OF SCREENING MAMMOGRAPHY: SUMMARY OF THE EVIDEN**

FROM THE NATIONAL CANCER INSTITUTE

Benefit					
<ul style="list-style-type: none"> Screening mammography in women ages 40 to 70 years decreases breast cancer mortality (see Magnitude of Effects below). The benefit is higher for older women, in part because their breast cancer risk is high 					
Evidence					
<ul style="list-style-type: none"> Study design: Meta-analysis of individual data from four randomized controlled trials (RCTs) and three additional RCTs. Internal validity: Validity of RCTs varies from poor to good; internal validity of meta-analysis is good. Overall consistency: Fair. Magnitude of effects on health outcomes: Relative breast cancer-specific mortality is decreased by 15% follow-up analysis and 20% for evaluation analysis. Absolute mortality benefit for women screened annually starting at age 40 is 4 per 10,000 women screened over 10.7 years. The comparable number for women screened annually starting at age 50 years is approximately 50 per 10,000. Overall, the absolute benefit is approximately 1%, but depends on inherent breast cancer risk, which increases with age. 					
HARM	STUDY DESIGN	INTERNAL VALIDITY	CONSISTENCY	MAGNITUDE OF EFFECTS	EXTERNAL VALIDITY
Treatment of insignificant cancers (overdiagnosis, true positives) can result in breast deformity, lymphedema, thromboembolic events, or chemotherapy-induced toxicities	Descriptive population based, autopsy series, and series of mammary reduction specimens	Good	Good	Approximately 33% of breast cancers detected by screening mammograms represent overdiagnosis	Good
Additional testing (false-positives)	Descriptive population based	Good	Good	Estimated to occur in 50% of women screened annually for 10 years, 25% of whom will have biopsies	Good
False sense of security, delay in cancer diagnosis (false-negatives)	Descriptive population based	Good	Good	6% to 46% of women with invasive cancer will have negative mammograms,	Good

				especially if young, with dense breasts, or with mucinous, lobular, or fast-growing cancers	
Radiation-induced mutations can cause breast cancer, especially if exposed before age 30 years; latency is more than 10 years, and the increased risk persists lifelong	Descriptive population based	Good	Good	Between 9.9 and 32 breast cancers per 10,000 women exposed to a cumulative dose of 1 Sv; risk is higher for younger women	Good

Data from National Cancer Institute: *Summary of evidence*. Available at: www.cancer.gov/cancertopics/pdq/screening/breast/healthprofessional/page1update03/30/2012; Nystrom L et al: *Lancet* 359(9310):909–919, 2002.

Investigators are looking for markers that are activated by DNA damage. One new marker may be caveolin-1 (CAV1) protein (see [Chapter 1](#) for a discussion on caveolin protein). Caveolin proteins acts as a sensor and early mediator in response to DNA damage and may be important as a biomarker for radiosensitivity.³⁴⁴

The pathogenesis of **radiogenic breast cancer** is unclear. Evidence shows that cancers that develop after radiation exposure have genotypic and phenotypic features that distinguish them from other breast cancers. Specific alterations have been implicated in radiogenic breast transformation.³³⁴ These cancers are more likely to be of the human epidermal growth factor receptor 2 (HER2) or basal-like subtypes.³⁴⁴ Radiogenic breast cancers have a higher degree of genetic instability, such as a higher frequency of allelic loss of chromosome bands 6q13 and 9p21.^{345,346} Investigators identified numerous alterations of c-MYC with high levels of c-MYC amplifications.³³⁴ c-MYC protein expression is significantly higher in breast cancers after radiotherapy exposure. Radiogenic breast cancers reveal extensive

intratumor heterogeneity with respect to c-MYC copy number, which suggests continuous evolution at this locus during pathogenesis and progression.³³⁴ These data implicate c-MYC as an oncogenic transcription factor in the etiology of radiogenic breast cancer. Elevated c-MYC expression drives cell proliferation and replicative stress (Fig. 25.40).

FIGURE 25.40 Working Model of Possible Mechanisms of Radiogenic Carcinogenesis in the Breast. Radiation-induced c-MYC amplifications (red arrows) in epithelial cells of the ductal/lobular tissue and in endothelial cells of the vascular tissue (blood/lymphatics) drive the evolving development of radiogenic adenocarcinoma and radiogenic angiosarcoma of the breast. c-MYC amplification of the breast suggests that dysregulation of this proto-oncogene is an early and necessary event in the development of radiogenic angiosarcoma. c-MYC amplification is an early event in the pathogenesis of radiogenic breast adenocarcinoma. (Adapted from Wade MA et al: *Mol Cell Oncol* 3[1]:e1010950, 2015.)

The interplay between two factors that together may increase breast

cancer risk is ionizing radiation and elevated estrogen levels.³⁴⁷ For the first time, a study was done in rat mammary gland tissue with ionizing radiation combined with elevated levels of estrogen. Combined exposures caused a significant induction of p24/44 MAPK (mitogen-activated protein kinase) and p38 signaling pathways that was paralleled by elevated levels of H3S10 phosphorylation, a well-established biomarker of genome and chromosome instability.³⁴⁷

Diet.

Prospective epidemiologic studies on diet and breast cancer risk fail to show an association that is consistent, strong, and statistically significant except for alcohol intake, being overweight, and weight gain after menopause (see following discussion).^{348,349} Diet has been postulated as important for breast cancer risk because of the international correlations of consumption of specific dietary factors (e.g., fats) and breast cancer incidence and mortality, and because migrant studies show greater incidence of breast cancer among descendants who relocated to another country compared with those in the country of origin. International variations also can occur because of differences in reproductive history, physical activity, obesity, and other factors. Animal models have identified the influence of diet on mammary carcinogenesis.³⁴⁸

Dietary Fat.

Dietary fat and breast cancer risk is the subject of much study, controversy, and debate. Potential biologic mechanisms between fat intake and breast cancer risk include: (1) that fat may stimulate endogenous steroid hormone production (also affect weight gain, age of menarche), (2) that fat interferes with immune or inflammatory function, and (3) that fat influences gene expression. Animal studies reveal obesity induced by high-fat diets increases the risk of several cancers, including breast cancer.³⁵⁰ Evidence from large, prospective cohort studies has been mostly unresponsive, and clinical trials have not supported a strong association with total fat intake.³⁵¹ Cohort studies, however, suggest a modest positive association between fat

intake and the risk of breast cancer;³⁵² but so far more than 70 studies of the consumption of dietary fat during midlife on risk of breast cancer show the relationship is likely to be small. After 8.1 years of follow-up, the largest randomized controlled dietary trial conducted in the United States showed no significant difference in the number of newly diagnosed breast cancer cases in the women in the treatment group (intervention of a low-fat diet) compared with the control group (usual fat intake).³⁵³ The World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) report indicated that although the evidence is limited, there was an increase in breast cancer risk among postmenopausal women consuming higher-fat diets.³⁵⁴ The hypothesis that exposures that occur between menarche and first pregnancy are especially important in determining subsequent risk of breast cancer is supported by several lines of evidence. A first prospective study of 39,268 premenopausal women observed a modest direct association between adolescent intake of fat and breast cancer.³⁵⁵ This association persisted after adjusting for adult fat intake. Subtypes of fat were not significantly related to invasive breast cancer. Additionally, from this same study, milk, dairy, and total carbohydrate intake in adolescence, as well as the quality of carbohydrate as assessed by glycemic load, glycemic index, and dietary fiber, was not associated with breast cancer. A large prospective study (90,655 subjects) with an 8-year follow-up found that dietary fat does increase the risk of breast cancer recurrence or death in premenopausal women.³⁵⁶ Concern also has been that any association with fat intake may be because of total energy intake.

A meta-analysis of 57 international and national studies indicates that saturated fat intake was associated with an increased risk for postmenopausal disease, polyunsaturated fats were associated with increased risk regardless of menopausal status, and monounsaturated fats had no significant correlation with risk.³⁵⁷ Breast cancer risk may be determined earlier in life before the period of investigations.

Red Meat.

Another area of study is how consumption of red meat could increase

breast cancer risk. The hypotheses range from available iron content, growth-promoting hormones used in the cattle industry, and carcinogenic heterocyclic amines released from cooking the fatty acid content. Case-control and cohort studies have shown a modest association of red meat intake with breast cancer incidence but no association in a pooled analysis of prospective studies.³⁵⁸ Researchers reported an increased risk with red meat consumption.³⁵⁹⁻³⁶¹ However, a 2010 meta-analysis supported the WCRF/AICR report that suggested there was no conclusive evidence that red meat or processed meat acts as an independent risk factor for breast cancer.^{354,362}

Fiber.

Fiber intake could affect breast cancer risk by several mechanisms, including stimulation of the intestinal microflora and reduction of the enterohepatic estrogen circulation that could reduce overall body estrogen concentrations.^{363,364} Dietary fiber has been shown to modify estrogen concentrations.³⁶⁵ A recent meta-analysis of prospective cohort studies showed that every 10-g/day increment in dietary fiber was associated with a significant reduction in breast cancer risk.³⁶⁶ A meta-analysis of prospective case-control studies also found an inverse association between dietary fiber intake and breast cancer risk.³⁶⁷ Data from the NHS support the hypothesis that higher fiber intake reduces breast cancer risk and suggests intake during adolescence and early adulthood may be especially important.³⁶⁸

Similar in structure to estrogens, lignans are biphenolic compounds in plant foods.³⁶⁹ Primarily found in fiber-rich foods (seeds, grains, vegetables, and fruits), lignans are the major source of phytoestrogens in Western populations.^{363,364} Plant lignans are converted in the human gut by intestinal bacteria to the enterolignans, enterolactone, and enterodiol, which are bioactive and are subsequently absorbed.³⁶³ Enterolignans may protect against cancer and several mechanisms have been proposed and include: (1) they have weak estrogenic activity, and therefore may bind to estrogen receptors (thus preventing other more powerful estrogens from binding to ERs); (2)

they inhibit tumor growth; (3) they stimulate apoptosis; and (4) they stimulate production of the carrier SHBG (which presumably lowers circulating free estrogen levels).³⁶⁹ Two meta-analyses found lignans to be associated with a small risk reduction in postmenopausal breast cancer but not premenopausal,^{370,371} and from a follow-up study those postmenopausal women with higher enterolignan levels may have better survival.³⁶⁹

Soy.

Soy products are a hot topic because of their consumption in Asian countries that have low rates of cancer. Soybeans are the main source of isoflavones. The isoflavone compounds, including daidzein and genistein, can bind estrogen receptors but are far less potent than estradiol. Soy may act like other antiestrogens, such as tamoxifen, by blocking the action of endogenous estrogens to reduce breast cancer risk. Thus depending on the estradiol concentration and the timing of administration, soy exhibits weak estrogenic or antiestrogenic activity. Isoflavones act through various mechanisms by which they may be cancer protective including antiproliferative effects, tyrosine kinase inhibition, induction of apoptosis, and inhibition of angiogenesis. They modulate enzyme activities, as well as signal transduction, and have antioxidant properties. Researchers found that rats fed genistein before puberty had activated T-cell immune response before they started treatment with tamoxifen. Genistein improved response of mammary tumors in rats by reduced activity of unfolded protein response (UPR), prosurvival autophagy signaling, and increased antitumor immunity.³⁷²

Soy is one of the few plant foods with all the amino acids to make necessary protein.³⁷³ In 2011 the North American Menopause Society held a symposium to review the latest evidence-based science on the role of soy and found that soy foods generally appear to be breast protective and recommended moderate lifelong soy consumption.¹⁹⁵ Specific recommendations for breast cancer survivors and soy or isoflavone consumption could not be reached, because animal studies indicate potential for risk and studies in humans imply a null or

protective effect.^{195,374} A recent large study of both American and Chinese women, however, suggested that moderate intake of soy (≥ 10 mg of isoflavones/day) had a significant reduction in breast cancer recurrence as well as a nonsignificant trend toward reduced all-cause mortality.³⁷⁵ In addition, soy may optimize extrarenal 1,25(OH)₂-cholecalciferol or vitamin D₃ (a prodifferentiating vitamin D metabolite), which could result in growth control and, conceivably, inhibition of tumor progression.³⁷⁶

Iodine deficiency is hypothesized as contributing to the development of breast pathology and cancer.^{377,378} Iodine plays a significant role in breast health.³⁷⁸⁻³⁸¹ Evidence reveals that iodine is an antioxidant and antiproliferative agent contributing to the integrity of normal mammary tissue.³⁸² Seaweed, which is iodine-rich, is an important dietary item in Asian communities and has been associated with the *low* evidence of benign and breast cancer disease in Japanese women.³⁸² Molecular iodine (I₂) supplementation exerts an inhibitory effect on the development and size of benign and cancerous tissue.³⁸³ A study in mice showed molecular iodine (I₂) with zoledronate (Zol) as a potent adjuvant therapeutic target for triple negative breast cancer. Combined therapy reduced metalloproteinases 2 and 9, inhibited invasion/migration of cells, and prevented growth of tumor in mice.³⁸⁴ Nutrition remains a critical area of study.

Data on *dietary patterns* are emerging. The Mediterranean diet includes high intake of vegetables, legumes, fruits, nuts, and minimally processed cereals; moderately high intake of fish; and high intake of monounsaturated lipids coupled with low intake of saturated fat, low to moderate intake of dairy products, low intake of meat products, and moderate intake of alcohol. The Mediterranean pattern was recently reported (EPIC study) to lower overall cancer risk.³⁸⁵ A case-control study among Greek-Cypriot women found the Mediterranean diet may favorably influence the risk of breast cancer.³⁸⁵ The Western pattern includes higher intake of red and processed meats, refined grains, sweets and desserts, and high-fat dairy products.

Evidence exists that alcohol consumption increases breast cancer

risk. In a report on carcinogens, the National Toxicology Program of the U.S. Department of Health and Human Services lists consumption of alcoholic beverages as a known human carcinogen. The IARC also lists alcohol with sufficient evidence in humans as a carcinogenic agent for cancer of the breast as well as other cancers. More than 100 epidemiologic studies have looked at the association between alcohol consumption and the risk of breast cancer in women.³⁸⁶ These studies have consistently found an increase in breast cancer risk with increasing alcohol intake. A meta-analysis of 53 studies with a large sample size found that woman who drank more than 45 grams of alcohol per day (approximately 3 drinks) had 1.5 times the risk of developing breast cancer as nondrinkers (a modest increased risk).³⁸⁷ The Million Women Study in the United Kingdom produced a slightly higher estimate of breast cancer risk at low to moderate levels of alcohol consumption: every 10 grams of alcohol consumed per day was associated with a 12% increase in the risk of breast cancer.³⁸⁸

The mechanisms by which alcohol intake increases the risk of breast cancer are unknown; however, proposed mechanisms include: (1) acetaldehyde is a toxic chemical and can damage DNA and proteins; (2) generation of ROS; (3) impaired nutrition decreasing absorption of certain vitamins (vitamin A; nutrients in vitamin B complex, such as folate; vitamins C, D, and E; and carotenoids); (4) alcoholic beverages may contain carcinogenic contaminants (nitrosamines, asbestos fibers, phenols, and hydrocarbons); and (5) physiologic studies have reported an estrogen level increase in women taking menopausal hormone therapy (MHT) and IGF-1 level increases with alcohol intake. Alcohol may increase breast cancer risk through increasing mammographic breast density especially in women at high risk.³⁸⁹ It is not known whether reducing or discontinuing alcohol consumption in midlife decreases the risk of breast cancer.

Obesity.

Excess body fatness is known to increase cancer risk from cellular pathways that involve hormonal regulation, cellular proliferation, and immunity.³⁹⁰ Obesity, measured as body mass index (BMI), has been

associated with a *reduced* risk of *premenopausal* breast cancer. Recently reported (from the Nurses' Health Studies I and II), however, was that weight gain or weight loss since age 18 did not significantly decrease the risk of premenopausal breast cancer.³⁹¹ Other data measuring adiposity using waist/hip ratio (WHR) have not found a reduced risk, but rather no association (null) nor an increased risk. Excess adiposity is positively associated with breast cancer recurrence and breast cancer specific mortality among both premenopausal and postmenopausal women.³⁹²

In 2002 the International Agency for Research on Cancer (IARC) concluded that excess body weight (EBW) increased the risk of developing postmenopausal breast, colorectum, endometrium, kidney, and esophageal adenocarcinoma.³⁹³ Numerous studies have observed increasing adult BMI and postmenopausal breast cancer, particularly for estrogen-receptor positive tumors.³⁹⁴ The World Cancer Research Fund (WCRF) concluded that evidence is convincing and that a probable association exists between body fat and postmenopausal breast cancer.³⁵⁴

Weight gain may be more strongly related to postmenopausal breast cancer risk than attained weight.³⁹³⁻³⁹⁹ A meta-analysis of 11 studies suggests that adult weight gain is predictive of a twofold increase in the risk for ER+, as well as ER+/PR+, breast tumors with a greater risk in postmenopausal women.⁴⁰⁰ Premenopausal and postmenopausal weight gain also is associated with higher estradiol and estrone levels and lower SHBG levels as a transporter protein; low levels cause higher bioavailable estrogen.³⁹⁵ This increase in estrogens, particularly estradiol, is from aromatization in the adipose tissue. Second, use of exogenous hormones postmenopausally obscures the variation in endogenous estrogens caused by adiposity and elevates breast cancer risk regardless of body weight.³⁹⁶ Excess body fat and weight gain are stronger risk factors for women who do not use hormone therapy. However, a prospective study found weight gained at multiple time points throughout adulthood of 44 to 63 lb was associated with a 56% higher risk of breast cancer, and weight gain of 88 to 108 lb doubled the risk of breast cancer among hormone users.⁴⁰¹ A recent animal

study showed obese animals deposited excess calories into the tumors themselves.⁴⁰² These tumors from obese animals had an increased expression of progesterone receptors.⁴⁰²

Obesity is associated with poor survival among women with breast cancer, and the association of obesity with mortality from breast cancer appears to be stronger than its association with incidence.^{396,398} The increase in breast cancer risk with increasing BMI among postmenopausal women is most likely the result of increases in levels of estrogens by aromatase activity in adipose tissue.³⁵⁴ However, studies of hormones secreted by adipose tissue, *leptin* and *adiponectin*, may underlie the association between obesity and breast cancer risk. Increasing BMI and central fat deposition are associated with increased risk for breast cancer in prospective studies, and in vitro studies have shown leptin-stimulated breast carcinogenesis.^{403,404} From molecular mechanism studies, leptin enhances breast cancer cell proliferation by inhibiting cell death (proapoptosis) signaling pathways and by increasing in vitro sensitivity to estrogens.⁴⁰⁵ Leptin secreted by adipocytes and fibroblasts in the microenvironment act on breast cancer cells in a paracrine manner.⁴⁰⁶ Adiponectin has been shown to exert antiproliferative effects in vitro on human breast cancer cells.⁴⁰⁵ Additionally, factors that may be related to recurrence of breast cancer in women with excess adiposity at the time of diagnosis include cytokines, IGF or immune function, or both.³⁹⁰

Synthetic Chemicals.

Evidence for linking synthetic chemicals to the cause of breast cancer is difficult to obtain. It is challenging because it is a life history of exposure that is important, not just a single chemical but also complex mixtures of chemicals and their interaction with endogenous hormones. The highest rates of breast cancer are found in superindustrialized countries—North America and Europe—and the lowest rates in central Africa and Asia. With industrial development, breast cancer rates increase. An estimated 100,000 synthetic chemicals are registered for use today in the United States, another 1000 or more are added each year, and toxicologic screening for these chemicals is

minimal—only about 7%.⁴⁰⁷ In 2006, more than 34 million metric tons of chemicals were produced or imported into the United States every day and chemical production is projected to double over the next 25 years.⁴⁰⁸ Current approaches to chemical screening are being reenvisioned. Several major federal research initiatives were instigated, including the EPA, ToxCast, the National Toxicology Program (NTP) High Throughput Screening Initiative, and the Interagency Tox21 Initiative.⁴⁰⁹ New important end points will include altered mammary gland development, Her2 activation, progesterone receptor activity, prolactin effects, and aspects of estrogen receptor β activity.⁴⁰⁹

Chemicals persist in the environment, accumulate in adipose tissue, interact with local adipose tissue physiology in an endocrine-paracrine manner, and remain in breast tissue for decades. Some of these chemicals are known human carcinogens and many have been linked to mammary tumors in animals. Women who emigrate to the United States from Asian countries experience an enormous percent increase in risk within one generation. A generation later their daughters' risk approaches that of women born in the United States. This change in risk suggests that in utero exposures affect subsequent disease risk. However, it is difficult to know whether these changes in risk are derived from nutritional content, pollutants, cosmetics, food additives, or other factors.

Xenoestrogens are synthetic chemicals that mimic the actions of estrogens and are found in many pesticides, fuels, plastics, detergents, and drugs. Because many factors correlated with breast cancer (e.g., early menarche, delayed pregnancy and breast-feeding, and late menopause) are associated with lifetime exposure to estrogens, investigators reasoned that environmental chemicals affect estrogen metabolism and contribute to breast cancer. The most significant chemicals may be polychlorinated biphenyls (PCBs), pesticides, BPA (pervasive in polycarbonate plastics), tobacco smoke (active and passive), dioxins (vehicle exhaust, incineration, contaminated food supply), alkylphenols (detergents and cleaning products), metals, phthalates (makes plastics flexible, some cosmetics), parabens

(antimicrobials), food additives (recombinant bovine somatotropin [rBST] and zeranol to enhance growth in cattle and sheep), MHT (i.e., HRT), and others. Bisphenol A treatment of breast epithelial cells cultured from premalignant biopsied tissue elicited a genetic expression profile associated with large, high-histologic-grade breast tumors.⁴¹⁰ Some chemicals are fat soluble and the estrogenic effect would require either that they bind to the nuclear estrogen receptor and then cause cell division or gene transcription or that they activate reactive oxygen species through oxidative catabolism of estrogens (see the section on [Hormonal Factors](#)) ([Table 25.15](#)).

TABLE 25.15

SELECTED CHEMICALS AND RISK OF BREAST CANCER

CHEMICAL	COMMENTS
Bisphenol-A (BPA)	Studies have shown altered reproductive systems and breast tissue when exposed to BPA in utero ¹
	BPA is commonly found in plastics ²
Polyvinyl chloride (PVC)	Used in food packaging, medical products, appliances, cars, toys, credit cards, rainwear ³
	Has been found in the air near waste sites, landfills, and tobacco smoke
	Has been linked to increased mortality from breast and liver cancer among manufacturing workers ^{4,5}
Pesticides: aldrin and dieldrin (organochlorines)	Used in crops like corn and cotton from 1950s to 1970s Banned by the EPA in 1975 except for termite control; completely banned in 1987
	In vitro assays showed estrogenic activity and dieldrin found in 78% of women diagnosed with breast cancer ⁶
	High incidence of breast cancer in Massachusetts study found associations with higher income and regular use of lawn services, termite treatments, and home pesticides ⁷
Household products: methylene chloride	Spray paints and paint removers may contain methylene chloride, documented breast cancer in laboratory animals ⁸
Diethylstilbestrol (DES)	Prescribed for women to avert miscarriages between 1941 and 1971
	Exposed daughters known to have higher rates of vaginal cancer; and in the mothers, slight increased risk of breast cancer ^{9,10}
	Daughters now known to have slight increased risk of breast

	cancer ¹¹
Solvents (e.g., benzene, toluene, trichloroethylene, chlorinated organic solvents)	Used in manufacture of computers, also some in cosmetics In 2003 a Taiwanese study documented increased risk of breast cancer among electronic workers exposed to chlorinated organic solvents ¹²
	A Danish study of women 22 to 55 years of age employed in industries (fabricated metal, lumber, furniture, printing, textiles) using solvents doubled the risk of breast cancer ¹³
Styrene, carbon tetrachloride, formaldehyde	A 1995 study suggested increased risk with occupational exposure – validation in Finland, Sweden, and Italy ¹⁴⁻¹⁷
Ethylene glycol methyl ether (EGME)	A Duke University study found it acts as a hormone sensitizer in vivo and in vitro. ^{18,19} Compounds are found in semiconductor industry, varnishes, paints, dyes, and fuel additives
Valproic acid (anticonvulsant medication)	Found to be hormone-sensitizing and prescribed for migraines and bipolar disorder ^{18,19}
1,3-butadiene	Air pollutant and synthetic rubber product and some fungicides and tobacco smoke Causes mammary and ovarian tumors in female mice and rats ^{20,21}
Aromatic amines (heterocyclic, polycyclic, monocyclic)	Found in plastics, tobacco smoke, grilled meats and fish, combustion of wood chips and rubber Exposure in adolescence before full-term pregnancy may increase risk ²²
Dichlorodiphenyltrichloroethane (DDT) and polychlorinated biphenyls (PCBs)	PCB used in manufacture of electrical equipment ²³ PCB and DDT are banned in the United States since 1970s but are still found in body fat, as well as breast milk ²⁴
	DDT was used as pesticide for insects on farms and swamps
	PCB deteriorates slowly in soil
	PCB is difficult to study because it is a diverse class of compounds
	A 1999 in vitro study showed PCBs proliferate in breast cancer cells ²⁵
	Conflicting results; several large studies failed to show relationship with PCBs
Polycyclic aromatic hydrocarbons (PAHs, including tobacco)	Found in soot and fumes from fuels Increased DNA damage (DNA adducts) implicated from the Long Island Breast Cancer Study Project ²⁶
	Tobacco smoke also contains PAHs
	Smokers who began smoking as adolescents have an increased risk of breast cancer ²⁷⁻²⁹

	In 2004 the California EPA concluded that environmental tobacco smoke (ETS) increases the risk of breast cancer, and the association appears stronger for premenopausal women ³⁰
	Tobacco smoke also contains the carcinogens polonium-210, vinyl chloride, benzene, and 1,3-butadiene ³¹
Dioxin	Products containing PVC, PCBs, or other chlorinated compounds release dioxin from incineration
	Declared a known carcinogen by the EPA in 2000
	It may be the most prevalent of all toxic chemicals
	Occurs in meat, poultry, dairy products, and human breast milk
	A United Kingdom study linked dioxin to the development of mammary tumors in mice ³²
	A study in Seveso, Italy, connected dioxin with breast cancer ³³
Ethylene oxide	Used to sterilize surgical instruments and in some cosmetics
	Linked to breast cancer in women exposed to ethylene oxide in commercial sterilization facilities ³⁴

Physical Activity.

Physically active individuals have lower rates of many cancers and improved cancer outcomes.^{411,412} Activity also may reduce the invasiveness of breast cancer.⁴¹³ A sedentary lifestyle may increase cancer risk through several mechanisms including increased insulin resistance, increased inflammation, and decreased immune function.⁴¹⁴ Epidemiologic studies demonstrated that physical activity lowered the risk of breast cancer mortality in breast cancer survivors and improved their physiologic and immune functions.⁴¹⁴ In a 2013 meta-analysis of 31 prospective studies, the average breast cancer risk reduction with physical activity was 12%.⁴¹⁵ Although the evidence is stronger for postmenopausal women, physical activity has been associated with reduced risk in both premenopausal and postmenopausal women.⁴¹⁶ Mechanisms for this protective effect are not known but include alterations in endogenous free radical formation and oxidative damage, effects on DNA repair capacity, changes in circulating insulin and insulin-related pathways, inflammation, alteration in carcinogen-metabolizing enzymes, increased intestinal transit times (i.e., reduced exposures to carcinogens), weight loss, and changes in endogenous sex hormone levels and possibly immune cell levels.

Inherited Cancer Syndromes, Genes, Epigenetic Considerations

The causes of breast cancer have been difficult to define because each woman has a different genetic profile called **genetic heterogeneity**.⁴¹⁷ Genetic heterogeneity is common among individuals but also at the level of the tumor itself, involving both genetic and epigenetic processes. **Phenotypic heterogeneity** is the result of tumor cell plasticity and together with the genetic background of the tumor determines whether cells resist environmental stress, such as microenvironmental stressors (for example, becoming hypoxic, entering dormancy [see [Chapter 12](#)]) and metastasizing.⁴¹⁸ The genetic factors interact with environmental factors. These facts are sobering and make the understanding of the genetic driving force behind tumor initiation, progression, and metastasis very complicated. Driver mutations are causally implicated in tumor development. Investigators examined the genomes of 100 tumors for somatic mutations and found they varied markedly between individual tumors.⁴¹⁷ Several new driver mutations were identified, including AKT2, ARID1B, CASP8, CDKN1B, MAP3K1, MAP3K13, NCOR1, SMARCD1, and TBX3 ([Fig. 25.41](#)). A novel 95-gene signature of residual breast cancer risk, which integrates lymph nodal status, has better clinical utility for early recurrence than the currently available multiparametric tests.⁴¹⁹

FIGURE 25.41 Driver Mutations and Copy Number Changes in Breast Cancer. The left side identifies each of the 40 cancer genes in which a driver mutation or copy number change has been identified. From investigation of 100 tumors, the number of mutations in each gene is shown (rows) as is the number of driver mutations in each breast cancer (columns). Point mutations are red and copy number changes are blue. (From Stephens PJ et al: *Nature* 486:400–404, 2012.)

A history of breast cancer in first-degree relatives (mother or sister) increases a woman's risk about 2 to 3 times. Risk increases even more if two first-degree relatives are involved, especially if the disease occurred before menopause and was bilateral. A small total proportion of breast cancers (5% to 10%, although the prevalence is significant) is the result of highly penetrant dominant genes (i.e., hereditary breast cancers). The most important of the dominant genes are the breast cancer susceptibility genes (*BRCA1*, *BRCA2*). *BRCA1* (breast cancer 1 gene), located on chromosome 17, is a tumor-suppressor gene; therefore any mutation in the gene may inhibit or retard its suppressor function, leading to uncontrolled cell proliferation. *BRCA2* (breast cancer 2 gene) is located on chromosome 13. A family history of both breast cancer and ovarian cancer increases the risk that an individual with breast cancer carries a *BRCA1* mutation.⁴²⁰ Carriers of the *BRCA1* gene also are at higher risk for ovarian cancer. The risks for breast or ovarian cancer, or both, however, are not equal in all mutation carriers and have been found to vary by several factors, including type of cancer, age at onset, and position of mutation.⁴²⁰ This observed variation in penetrance has led to the hypothesis that other genetic and/or environmental factors modify cancer risk in mutation carriers. Men who develop breast cancer are more likely to have a *BRCA2* mutation than a *BRCA1* mutation (see [Chapter 26](#)). Options for those who have a positive test for *BRCA1* or *BRCA2* mutation include surveillance to find cancers early, prophylactic surgery (i.e., bilateral salpingo-oophorectomy), risk factor avoidance, promotion of breast-feeding, and chemoprevention. Several other genetic alterations can increase the risk of breast cancer.

◆Pathophysiology.

Most breast cancers are adenocarcinomas and first arise from the ductal/lobular epithelium as carcinoma in situ. Carcinoma in situ is an early-stage, noninvasive, proliferation of epithelial cells that is confined to the ducts and lobules, by the basement membrane. (Ductal carcinoma in situ [DCIS] and lobular carcinoma in situ [LCIS] are

discussed next.) Breast cancer is a heterogeneous—not a single—disease with diverse molecular, genetic, phenotypic, and pathologic changes⁴²¹ (Table 25.16). Tumor heterogeneity results from the genetic, epigenetic, and microenvironmental influences (selective pressure) that tumor cells undergo during cancer progression. Cellular subpopulations from different sections of the same tumor vary in many ways including growth rate, immunogenicity, ability to metastasize, and drug response, demonstrating significant heterogeneity.⁴²² The biologic attributes of a tumor as a whole are strongly influenced by its subpopulation of cells with cellular populations communicating through paracrine or contact-dependent signaling (juxtacrine) from ligands and mediated from components of the microenvironment such as blood vessels, immune cells, and fibroblasts.⁴²² The rich microenvironment of breast tumors is highly dynamic and heterogeneous.⁴²²⁻⁴²⁴ Cancer cells behave as communities, and the cooperative behaviors of these subclones can influence cancer progression.⁴²² Recent research suggests that breast cancer is heterogeneous from its initial preinvasive stages⁴²⁵ and within the same tumor.

TABLE 25.16

TYPES OF BREAST CARCINOMAS AND MAJOR DISTINGUISHING FEATURES

HISTOLOGIC TYPE	DISTINGUISHING FEATURES
Carcinoma of Mammary Ducts	
Papillary	Well-delineated cystic masses in multiple areas; hemorrhage often present; majority appear in 40- to 60-year age group; often involves skin
Intraductal (comedo)	Often accompanied by evidence of inflammation; well-circumscribed tumors within duct; well-differentiated tumor cells; rarely ulcerates skin
Infiltrating Carcinoma	
Ductal (no specific type [NST])	Fibrous, firm, glistening, gray-tan mass with chalky streaks, mixture of patterns; may cause discharge from nipple; represents about 70%–80% of all breast cancers
Mucinous	Usually large (>3 cm in diameter), circumscribed, and encapsulated; glistening appearance; varies in color; two types: pure and mixed; pure tumor is surrounded by mucin; infrequent; found in lateral half of breast; tends to occur in women after

	age 70 years
Medullary	Encapsulated and grows very large (7–8 cm in diameter); commonly surrounded by lymphocytic inflammatory infiltrate; occurs after age 50 years
Tubular	Well-differentiated with orderly tubules in center (stroma) of mass; can be associated with noninfiltrating ductal carcinoma; occurs in women about 50 years of age; nodal metastasis infrequent; occurrence rare
Adenoid cystic	Very rare; well-circumscribed, painless mass arising from nipple and areola
Metaplastic	Involves cartilage or bone, mixed tumors or osteogenic sarcomas
Squamous cell	Frequent in blacks; originates in ductal epithelium
Carcinoma of Mammary Lobules	
Lobular carcinoma in situ	Found in individuals with fibrocystic disease; localized to upper breast quadrants; 15%–35% risk of becoming invasive; occurs frequently in mid-40s; infiltrating variety occurs in early 50s
Infiltrating lobular	Infiltrates from duct; firm mass with chalky streaks
Paget disease	Eczema of nipple that extends to areola; cancer usually found underneath nipple; poorly circumscribed; large Paget cells arise from duct and directly invade nipple; history of scaly, red rash spreading from nipple; lesion palpable beneath nipple, often bilateral; occurs in middle age
Inflammatory carcinoma	Not a histologic type; fairly diffuse within breast tissue, diffuse edema of overlying skin; extremely undifferentiated, very rare; most metastasize to axilla
Sarcoma of the Breast	
Cystosarcoma phyllodes	Usually large (>17 cm in diameter); mostly localized but can rupture through skin; rarely metastasizes to lymph nodes; history of painless nodule present for years before it forms a large mass; ulceration and bleeding of skin often present; occurs in wide age range (13–77 years)
Fibrosarcoma	Well-circumscribed, firm, and usually does not involve skin or nipple; well-differentiated to extremely undifferentiated; arises from connective tissue; extremely rare (e.g., liposarcoma, angiosarcoma)

Despite heroic efforts, this heterogeneity has greatly challenged the understanding of breast cancer evolution and the development of therapeutic strategies. Gene expression profiling studies have identified major subtypes classified as luminal A, luminal B, HER2+, basal-like, Claudin-low, and normal breast.⁴²⁶ These subtypes have different prognoses and responses to therapy.⁴²⁷ Tumors can be stratified with gene expression profiles such as Oncotype Dx, Prosigna, and MammaPrint on the basis of genomic profiles.⁴²⁷ This information helps personalize breast cancer treatment and determine

which women need aggressive systemic treatment for high-risk cancers versus close surveillance for indolent tumors.⁴²⁷

Many models of breast carcinogenesis have been suggested and the expanding themes include (1) gene addiction, (2) phenotype plasticity, (3) cancer stem cells, and (4) hormonal outcomes affecting cell turnover of mammary epithelium, stem cells, extracellular matrix, and immune function (see previous sections [Reproductive Factors: Pregnancy, Lobular Involution, and Age](#) and [Postlactational Involution and Hormonal Factors](#)).

Cancer gene addiction includes oncogene addiction, whereby these driver genes play key roles in breast cancer development and progression, and non-oncogene addiction, whereby these genes may not initiate cancer but play roles in cancer development and progression.⁴²⁸ Examples of key driver genes include *HER2* and *MYC*, and examples of tumor-suppressor genes include *TP53*, *BRCA1*, and *BRCA2*. Once a founding tumor clone is established, genomic instability may assist through the establishment of other subclones and contribute to both tumor progression and therapy resistance.¹⁷⁵

Phenotypic plasticity is exemplified by a distinctive phenotype called *epithelial-to-mesenchymal transition (EMT)* (see [Chapter 12](#)). EMT is involved in the generation of tissues and organs during embryogenesis, is essential for driving tissue plasticity during development, and is hijacked during cancer progression.⁴²⁹ The EMT-associated reprogramming is involved in many cancer cell characteristics, including suppression of cell death or apoptosis and senescence, is reactivated during wound healing, and is resistant to chemotherapy and radiation therapy.⁴³⁰ Remodeling or reprogramming of the breast during postpregnancy involution is important because it involves inflammatory and “wound healing-like” tissue reactions known as **reactive stroma** or **inflammatory stroma**. The reactive stroma releases various signals and interleukins that affect nearby carcinoma cells, inducing these cells to activate their previously silent EMT programs. The activation is typically reversible (i.e., plasticity) and those EMT programs may revert through mesenchymal-epithelial (MET) to the previous phenotypic state before

induction of the EMT program⁴²⁹ (see [Chapter 12](#)). Reactive stroma increases the risk for tumor invasion and may facilitate the transition of carcinoma in situ to invasive carcinoma. Activation of an EMT program during cancer development often requires signaling between cancer cells and neighboring stromal cells.⁴³¹ In advanced primary carcinomas, cancer cells recruit a variety of cell types into the surrounding stroma, including fibroblasts, myofibroblasts, granulocytes, macrophages, mesenchymal stem cells, and lymphocytes ([Fig. 25.42](#)). Overall, increasing evidence suggests that interactions of cancer cells with adjacent tumor-associated stromal cells induce malignant cell phenotypes ([Fig. 25.43](#)). Several types of carcinoma cells are reported to acquire tumor-initiating capability after induction of the EMT program.⁴²⁹ The tumor-initiating traits are depicted as cancer stem cells (CSCs). Tissues with residing carcinoma cells in the CSC state seem critical for progression through the invasion-metastasis cascade as founders of new metastatic colonies.⁴²⁹ With increasing acquisition of mesenchymal traits, as driven by an EMT program, it is reported to increase the resistance of carcinoma cells to both radiation and chemotherapy.⁴²⁹

FIGURE 25.42 Cells of the Tumor Microenvironment. **A**, Distinct cell types constitute most solid tumors including breast tumors. Both the main cellular tissue, called *parenchyma*, and the surrounding tissue, or stroma of tumors, contain cell types that enable tumor growth and progression. For example, the immune-inflammatory cells present in tumors can include both tumor-promoting and tumor-killing subclasses of cells. **B**, The microenvironment of tumors. Multiple stromal cell types create a succession of tumor microenvironments that change as tumors invade normal tissue, eventually seeding and colonizing distant tissues. The organization, numbers, and phenotypic characteristics of the stromal cell types and the extracellular matrix (*hatched background*) evolve during progression and enable primary, invasive, and metastatic growth. (Not shown are the premalignant stages.) (Data from Hanahan D, Weinberg R: *Cell* 144:646–674, 2011.)

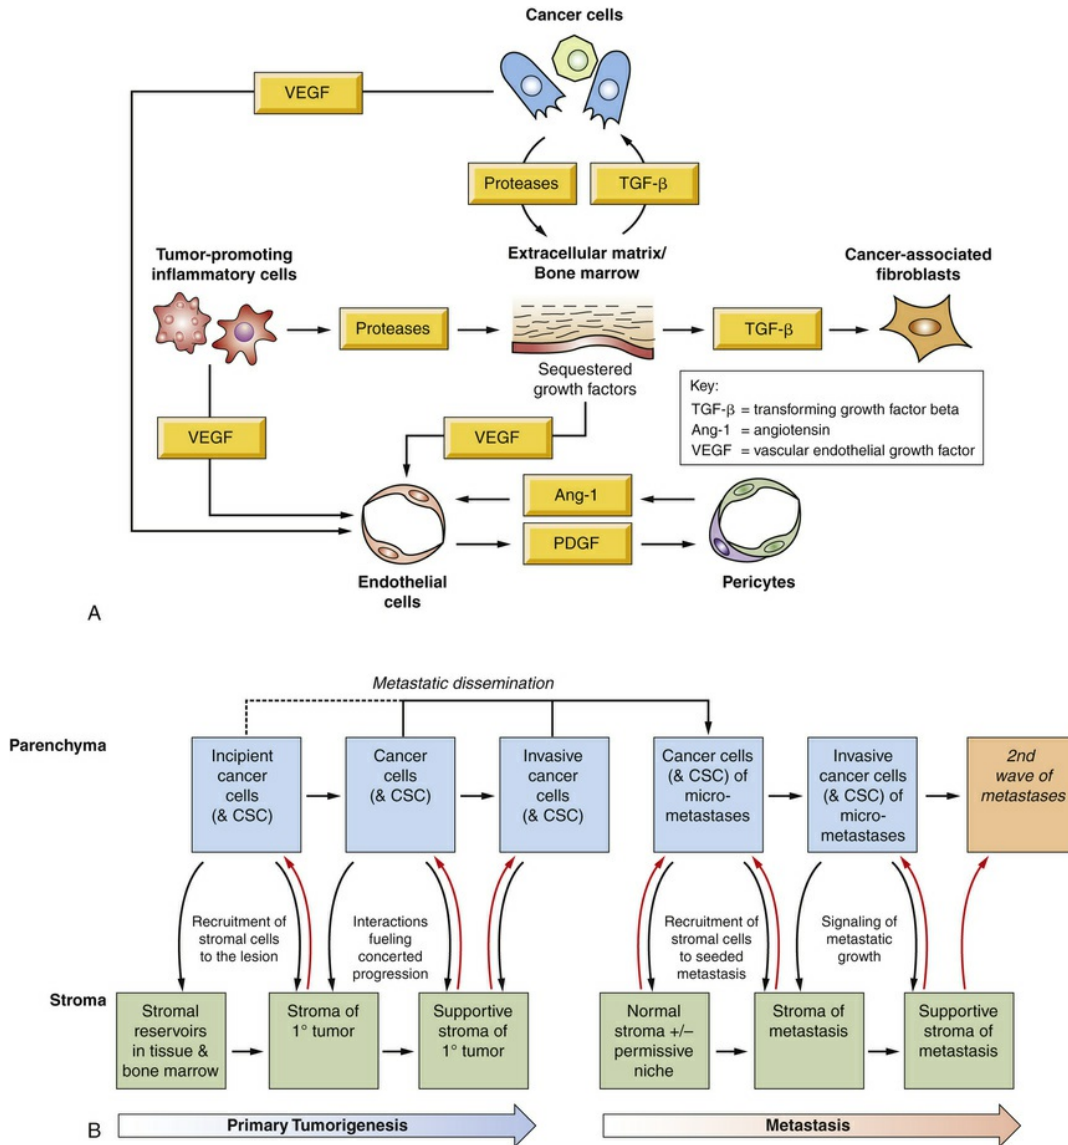

FIGURE 25.43 Signaling Interactions in the Tumor Microenvironment During Malignant Progression. A, Numerous cell types constitute the tumor microenvironment and are orchestrated and maintained by reciprocal interactions. B, The reciprocal interactions between the breast main tissue or parenchyma and the surrounding stroma are important for cancer progression and growth. Certain organ sites of “fertile soil” or “metastasis niches” facilitate metastatic seeding and colonization. Cancer stem cells are involved in some or all stages of tumor development and progression. CSC, Cancer stem cells. (Adapted from Hanahan D, Weinberg R: *Cell* 144:646–674, 2011.)

Invasion by primary tumor cells typically involves the collective migration of large, cohesive groups of cells into adjacent tissue rather than the scattering of individual carcinoma cells (Fig. 25.44).⁴³² Still unknown are the precise events occurring at the invasive edge.

Critical to understand is the process of invasion as it relates to treatment. The possibility of displacing tumor cells into the biopsy needle track is a concern.⁴³³ Although reported as a low incidence, mechanical disruption from surgery can lead to displacement and seeding of tumor cells. Dormant carcinoma cells appear to perpetuate carcinogenesis and form the precursors of eventual metastatic relapse and, sometimes, rapid cancer recurrence.^{434,435} These dormant cells are called **minimal residual disease (MRD)** and may remain after initial chemotherapy, radiotherapy, and surgery. Dormant cells have exited the cell cycle; thus they are not proliferating, and current treatments preferentially kill proliferating cells rendering dormant cells intrinsically more resistant to almost all current treatments.⁴²⁹ The benefit of surgery is reducing the numbers of cancer cells and diversity of neoplastic cells and perhaps increasing the chance of getting rid of therapy-resistant cells.⁴²⁹

FIGURE 25.44 Invasion. Invasion of carcinoma cells occurs through two

mechanisms: single cell dissemination through an epithelial-mesenchymal transition (EMT) (gray arrow), or the collective dissemination of a tumor cluster of cells. Emerging evidence suggests that the leader cells of tumor groups or clusters undergo EMT-associated phenotypic changes. Clusters of migrating cells are commonly noted at the borders of invasive carcinomas and are best documented in breast and lungs. (Adapted from Lambert AW, Pattabiraman DR, Weinberg RA: *Cell* 168[4]:670–691, 2017.)

A large number of reports identify the existence of the partial EMT state and its ability to enhance tumor progression and metastasis.⁴²⁹ The phenotypic plasticity associated with the epithelial-mesenchymal spectrum appears critical to the founding of metastatic colonies.⁴²⁹ Invasive clusters or individual invasive carcinoma cells eventually invade into the vasculature of either adjacent normal tissue or the neovasculature that has been assembled within the tumors themselves.⁴²⁹ The resulting intravasation is an avenue for circulating tumor cells (CTCs) to distant sites.

Using a mouse model of tumor heterogeneity, investigators demonstrate that different clones of mammary tumor cell lines possess different abilities to the formation of metastasis.⁴³⁶ More simply, different clones within the heterogeneous population had distinct properties, such as an ability to dominate the primary tumor, or to contribute to metastatic populations, or to enter the lymphatic or vascular systems.⁴³⁷ The expression of two proteins, Serpine2 and Slpi, correlates with lung metastases and similar associations were observed in human datasets. Serpine2 and Slpi act as anticoagulants and allow tumor cells to undergo *vascular mimicry*, whereby the tumor cells themselves form part of blood vessels and contribute to increased intravasation by building more leaky blood vessels.⁴³⁶ Vascular mimicry was first detailed in 1999 in aggressive melanomas, and involves the formation of vascular-like networks by aggressive tumor cells that have similar characteristics to the endothelial cells that line normal blood vessels. These networks are rich in extracellular matrix and allow perfusion of blood and fluid through tumor tissues (Fig. 25.45).

FIGURE 25.45 Vascular Mimicry Drives Metastasis. The steps to accomplish metastasis include *intravasation*, in which tumor cells escape from the primary tumor into the vasculature and move through the bloodstream; or *extravasation*, in which tumor cells escape from the vasculature to colonize in distant tissue. Metastasis is promoted by vascular mimicry, whereby tumor cells adopt characteristics similar to those of the endothelial cells that line blood vessels, and mimic vascular-like networks within tumors and between tumors and blood vessels. Wagenblast and colleagues found that two proteins, Serpine2 and Slpi, promoted metastasis by stimulating vascular mimicry. Tumor cells expressing these proteins (*green*) form the vascular-like network that allows other tumor cells (*purple, blue*) to move to secondary sites. (Adapted from Hendrix MJC: *Nature* 520:300–302, 2015; Wagenblast E et al: *Nature* 520:358–362, 2015.)

Carcinoma cells may promote the growth of lymphatic vessels through the process of lymphangiogenesis;⁴³⁸ this process is correlated with disease progression.⁴³⁹ It is not yet defined what specific factors determine the efficiency of clinical metastatic disease and why some patients present with metastasis and other patients experience years before a relapse and present with metastasis.⁴²⁹ The emergent evidence supports three main prerequisites that must be met in order for metastatic colonization to succeed:⁴²⁹ (1) the capacity to seed and maintain a population of tumor-initiating cancer stem cells; (2) the ability to create adaptive, organ-specific colonization programs; and (3) the development of a supportive microenvironmental niche (Fig. 25.46).

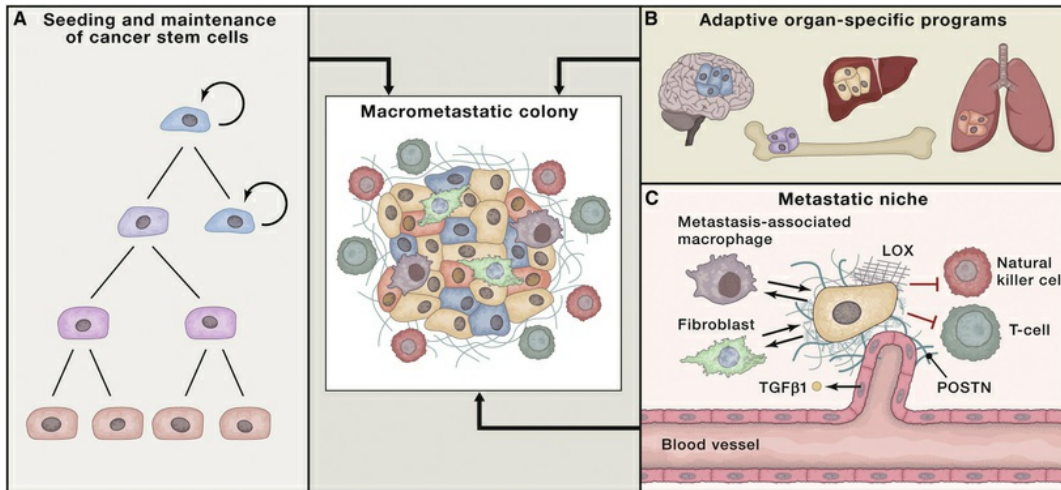

FIGURE 25.46 The Three Requirements for Metastatic Colonization. **A**, The necessity of cancer cells to seed (spread) and maintain a population of cancer stem cells. These cells can reinitiate tumor growth. Dormant disseminating tumor cells (DTCs) also exhibit key cancer stem cell competencies that possibly contribute to persistence in a quiescent (resting) state and can eventually develop a metastatic colony. **B**, Cancer stem cells must be capable to thrive in a foreign tissue microenvironment. **C**, During many stages of metastases, cancer cells have the ability to crosstalk with the microenvironment and stromal cells, including endothelial cell, fibroblasts, and cells of the immune system. The microenvironment is a component of the niche and can be modified to support the metastatic cascade. *LOX*, Lysyl oxidase; *POSTN*, periostin; *TGF*, transforming growth factor. (Data from Lambert AW, Pattabiraman DR, Weinberg RA: *Cell* 168[4]:670–691, 2017.)

Traditionally, metastases have been considered a late event in multistep tumor progression. Recent reports, however, suggest that dissemination can occur early during the process of neoplastic transformation.⁴²⁹ One explanation has been attributed to the presence of preneoplastic cells residing within inflammatory microenvironments that through signaling can activate EMT programs causing the development of invasive phenotypes.⁴⁴⁰ Additionally, from murine models of HER2+ breast cancer and in early stages of primary tumor formation, a migratory and stemlike program predominates before the proliferative pathways occur during the later stages of tumor growth.^{441,442} In other cases, however, metastases appear to be a late event.⁴²⁹

Ductal Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is a heterogeneous group of

proliferative lesions clinically, radiologically, morphologically, and genetically. DCIS is limited to breast ducts and lobules without invasion of the basement membrane (Fig. 25.47). When DCIS breaches the basement membrane and invades adjacent stroma to a depth of 1 mm or less, microinvasion (MI) is said to be present. About 84% of all in situ disease is DCIS; the remainder is mostly LCIS disease.⁴⁴³ DCIS occurs predominantly in women but can occur in men. DCIS has a wide spectrum of risk for invasive cancers.⁴⁴² Since 1980, the widespread adoption of screening mammography has led to an epidemic of diagnoses of DCIS.⁴⁴⁴ With the introduction of screening mammography, there has been a 500% increase in the diagnosis of DCIS, which represents about 25% of mammographically detected breast lesions.⁴⁴² Since 1983 there has been a 290% increase in DCIS among women younger than 50 years, and the incidence is still increasing.⁴⁴⁴ Because of the large numbers of cases diagnosed yearly in the United States, the debate is whether mammography is causing the overdiagnosis of potential pseudodisease; for example, the Canadian National Breast Screening Study-2 of women aged 50 to 59 years found a fourfold increase in DCIS cases in those screened by clinical breast examination (CBE) plus mammography compared with those screened by CBE alone, with no difference in breast cancer mortality.^{444,445}

FIGURE 25.47 Ductal Carcinoma in Situ (DCIS). Illustration showing the location of DCIS. Given the low breast cancer mortality, new approaches to managing DCIS are needed. (From National Cancer Institute: *Risk of breast cancer death is low after a diagnosis of ductal carcinoma in situ*, Bethesda, MD, 2015, Author. With permission from Terese Winslow.)

The perspectives on DCIS are changing. The cells of DCIS look like invasive cancer both pathologically and molecularly, and therefore the presumption was that these lesions were the precursors of cancer and that early removal and treatment would reduce cancer incidence and mortality.⁴⁴⁶ Long-term epidemiologic studies have demonstrated that the removal of 50,000 to 60,000 DCIS lesions annually has not been accompanied by a reduction in the incidence of invasive cancer.⁴⁴⁷ Contrarily, the removal of colonic polyps and of intraepithelial neoplasia lesions of the cervix and precursor lesions has led to a decrease in the incidence of colon and cervical cancer, respectively.⁴⁴⁸ It is now known that breast cancer has a range of behaviors, aggressive to indolent, and screening mammography increases the likelihood of indolent lesions surfacing.⁴⁴⁶

New data from Narod and colleagues⁴⁴⁹ add to the growing concern to rethink the strategy for the detection and treatment of DCIS. In a large observational study of 100,000 women with a diagnosis of DCIS, the risk of dying from breast cancer is low.^{449,450} Less than 1% of women in this 20-year study died of breast cancer (compared to 5% of women who died of other causes). Surprisingly, the overall death rate

for women with DCIS is lower than that for women in the population as a whole.^{175,451} Aggressive treatment of almost all DCIS does not lead to a reduction in breast cancer mortality, confirming the conclusions from the NSABP trials.⁴⁵² Because of these findings, some argue that the term DCIS is misleading and should be replaced by *ductal intraepithelial neoplasia*, similar to the term used in prostate cancer, and that breast cancer statistics should exclude those DCIS cases with invasive breast cancer statistics.⁴⁵¹ This very critical news suggests a treatment change as an alternative to surgery and radiation.⁴⁴⁶ A study of 6 months of letrozole therapy is one example of a new approach along with observation and may increase clinical trials of observation and endocrine risk-reducing therapy.⁴⁴⁶ Prevention or risk-reducing strategies are discussed next and need initiation and study. Stratification of risk is mandated to avoid overtreatment, unnecessary morbidity, and the same treatment as invasive cancer. Factors to help risk stratification of DCIS include grade and comedonecrosis; however, these factors are not predictive.⁴²⁷ Molecular tests, such as the Oncotype DCIS Score, have been shown to predict the 10-year risk of invasive cancer following surgical excision alone.⁴²⁷ Therefore some direction in solving the overtreatment dilemma is emerging. For example, if the emerging data suggest that it is safe to eliminate radiation for luminal A invasive tumors in postmenopausal women, then radiation should not be routine in low-grade or low-risk DCIS.⁴²⁷ The majority of DCIS is detected in women from screening and who are recalled for biopsy of calcifications. Importantly, to minimize risk of overdiagnosis or overtreatment, or both, reassessment of whether clustered amorphous calcifications should be a target for screening, recall, and biopsy, especially in older women.⁴⁵³

Increased mortality risk from DCIS is associated with risk factors: age at diagnosis; ethnicity; and DCIS characteristics, such as estrogen receptor status, grade, size (>5 cm), and comedonecrosis.⁴⁴⁶ DCIS lesions diagnosed before 35 or 40 years of age do pose an increased risk of breast cancer mortality.⁴⁴⁶ These lesions are likely different from those found from mammography, since screening before age 40 is rare, and may be associated with a symptomatic event, such as a

mass, or bloody nipple discharge. Black women (who have a higher risk for hormone receptor–negative, or HER2+, DCIS) should continue with today's aggressive standards.⁴⁴⁶ In total, these higher risk groups account for about 20% of the total population of women with DCIS.

Although DCIS may remain stable and never progress (or may regress), for invasive DCIS the cells within the DCIS *breach* the myoepithelial layer and the basement membrane, defining the moment when an invasive carcinoma is formed⁴⁵⁴ (Fig. 25.48). Importantly, the layer of myoepithelial cells is thought to be natural “tumor suppressors” and critical to maintaining tissue polarity (cell directional orientation) (see Fig. 1.10), a role that is lost in **invasive breast carcinomas**. Investigators and clinicians are intensely studying this key step, or breach, in terms of cellular alterations because of tumor biology or iatrogenic stimuli, or both.

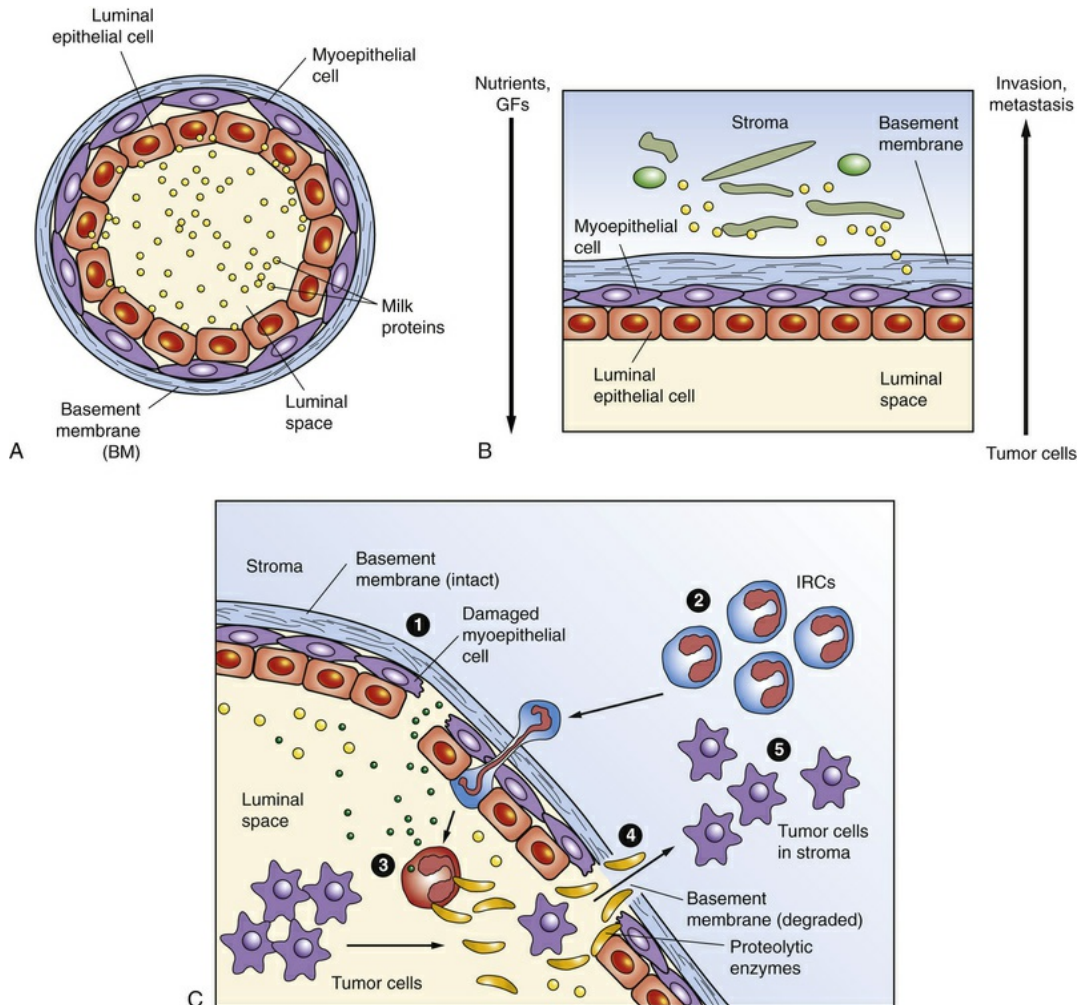

FIGURE 25.48 The Role of Myoepithelial Cells in Invasive Breast Cancer. **A**, Cross section of a normal mammary gland. **B**, Schematic of the anatomic relationship between mammary gland duct cells, basement membrane (BM), and stroma. **C**, With degradation of the normal “tumor-suppressing” basement membrane, tumor cells invade the stroma; (1) myoepithelial cells are damaged by various factors and release their inner contents (for example, diffusible molecules and chemoattractants); (2) immunoreactive cells (IRCs) are drawn to the luminal space by these chemoattractants; (3) IRCs become activated after contact with chemoattractants and secrete various proteolytic enzymes; (4) these enzymes then degrade the basement membrane resulting in gaps; and (5) tumor cells enter the stromal region through these gaps. *GF*, Growth factor. (Data and adapted figures from Pandey PR, Saidou J, Watabe K: *Front Biosci* 15:226–236, 2011.)

DCIS represents an opportunity to alter the breast environment. Alteration may be done with increased exercise, decreased alcohol intake, and avoidance of postmenopausal hormone therapy with progesterone-containing regimens.⁴⁴⁶ Stratification of DCIS lesions may be accomplished through available tools such as Oncotype DCIS;

unfortunately, according to one population-based study, only half of such women are tested with genetic testing.⁴⁵⁵

In summary, based on large numbers and long-term follow-up, given the low breast cancer mortality risk, DCIS is not an emergency. The detection and treatment of nonpalpable DCIS often represent overdiagnosis and overtreatment.⁴⁵¹ Data now suggest the following:

1. Much of DCIS should be considered a “risk factor” for invasive cancer and targeting for preventive strategies.
2. Radiation therapy should not be routinely offered after lumpectomy for DCIS lesions that are not high-risk because it does not affect mortality.
3. Low- and intermediate-grade DCIS does not need to be a target for screening or early detection.
4. Continuing study is needed both of the biologic nature of the highest-risk DCIS (large, high grade, hormone receptor negative, and HER2 positive, especially in very young and black women) and of target approaches to reduce death from breast cancer.⁴⁴⁶

Lobular Carcinoma in Situ

Lobular carcinoma in situ (LCIS) originates from the terminal duct-lobular unit (see Fig. 25.31, B). Unlike DCIS, LCIS has a uniform appearance (i.e., the cells expand but do not distort involved spaces); thus the lobular structure is preserved. The cells grow in noncohesive (discohesive) clusters, typically because of a loss of the tumor-suppressive adhesion protein **E-cadherin**.¹⁷⁵ Also unlike DCIS, LCIS is found as an incidental lesion from a biopsy and not from mammography because it is not associated with calcifications or stromal reactions that produce mammographic densities. LCIS has an incidence of about 1% to 6% of all carcinomas and did not increase with mammographic screening.¹⁷⁵ With biopsies in both breasts, LCIS is bilateral in 20% to 40% of cases, compared with 10% to 20% of cases of DCIS.¹⁷⁵ The cells of atypical hyperplasia, LCIS, and invasive lobular carcinoma are structurally identical.¹⁷⁵ Dysfunction of E-

cadherin results in loss of cellular adhesion, and lesions have a rounded shape without attachment to adjacent cells, increasing the risk of invasion.

Invasive carcinoma from LCIS develops in 25% to 35% of women over a period of 20 to 30 years. Unlike DCIS, the risk is almost as high in the contralateral breast as in the ipsilateral breast. Treatments include close clinical follow-up and mammographic screening, tamoxifen administration, and bilateral prophylactic mastectomy.

◆Clinical Manifestations.

The upper outer quadrant, where most of the glandular tissue of the breast is located, is where the majority of carcinomas of the breast occur. The lymphatic spread of cancer to the opposite breast, to lymph nodes in the base of the neck, and to the abdominal cavity is caused by obstruction of the normal lymphatic pathways or destruction of lymphatic vessels by surgery or radiotherapy (see [Fig. 24.11](#)). The less common inner quadrant tumors may spread to mediastinal nodes or Rotter nodes, which are located between the pectoral muscles (see [Fig. 24.11](#)). Other common sites of metastasis include the internal mammary chain nodes. Metastases from the vertebral veins can involve the vertebrae, pelvic bones, ribs, and skull. The lungs, kidneys, liver, adrenal glands, ovaries, and pituitary gland also are sites of metastasis.

The first sign of breast cancer is usually a painless lump. Lumps caused by breast tumors do not have any classic characteristics. Other presenting signs include palpable nodes in the axilla, retraction of tissue (dimpling) ([Fig. 25.49](#)), or bone pain caused by metastasis to the vertebrae. [Table 25.17](#) summarizes the clinical manifestations of breast cancers. Manifestations vary according to the type of tumor and stage of disease.

FIGURE 25.49 Retraction of Nipple Caused by Carcinoma. (From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer: diagnosis, treatment, and prognosis*, ed 6, St Louis, 1985, Mosby.)

TABLE 25.17

CLINICAL MANIFESTATIONS OF BREAST CANCER

CLINICAL MANIFESTATION	PATHOPHYSIOLOGY
Chest pain	Metastasis to the lung
Dilated blood vessels	Obstruction of venous return by a fast-growing tumor; obstruction dilates superficial veins
Dimpling of the skin	Can occur with invasion of the dermal lymphatics because of retraction of Cooper ligament or involvement of the pectoralis fascia
Edema	Local inflammation or lymphatic obstruction
Edema of the arm	Obstruction of lymphatic drainage in the axilla
Hemorrhage	Erosion of blood vessels
Local pain	Local obstruction caused by the tumor
Nipple/areolar eczema	Paget disease
Nipple discharge in a nonlactating woman	Spontaneous and intermittent discharge caused by tumor obstruction
Nipple retraction	Shortening of the mammary ducts

Pitting of the skin (similar to the surface of an orange [peau d'orange])	Obstruction of the subcutaneous lymphatics, resulting in the accumulation of fluid
Reddened skin, local tenderness, and warmth	Inflammation
Skin retraction	Involvement of the suspensory ligaments
Ulceration	Tumor necrosis

Data from Griffiths MJ, Murray KH, Russo PC: *Oncology nursing: pathophysiology, assessment, and intervention*, New York, 1984, Macmillan.

◆ Evaluation and Treatment.

Clinical breast examination, mammography, ultrasound, thermography, MRI, biopsy, hormone receptor assays, and gene expression profiling are used in evaluating breast alterations and cancer.

Treatment is based on the extent or stage of the cancer. The extent of the tumor at the primary site, the presence and extent of lymph node metastasis, and the presence of distant metastases are all evaluated to determine the stage of disease. Treatment includes surgery, radiation, chemotherapy, hormone therapy, and biologic therapy. Strategies for risk reduction of breast cancer are evolving and include implementation of a modified diet including decreased alcohol consumption, utilization of an exercise program, and avoidance of postmenopausal hormone therapy with progesterone-containing regimens, and possibly others.

Summary Review

Abnormalities of Reproductive Tract Development

1. Abnormalities of the female reproductive tract have multifactorial causes, including genetics and environmental factors. Common abnormalities include uterine agenesis or

structural malformations of the vagina, uterus, and fallopian tubes.

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, should begin in girls between ages 8 and 13 years. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is onset before these ages. The average age of puberty has been occurring earlier than in previous generations.
2. Alterations of sexual maturation can be idiopathic or caused by a disease or congenital anomaly. In most cases of delayed puberty, the hypothalamic-pituitary-gonadal (HPG) axis is intact but the surge of activity that stimulates puberty is delayed. Precocious puberty, more common in girls, also can be caused by mistiming of the stimulatory surge in a child whose HPG system is otherwise normal. Obesity is associated with younger pubertal age.
3. Precocious puberty can be complete (sex appropriate), mixed (not sex appropriate), or partial (development of one secondary sex characteristic only). Causes of delayed or incomplete puberty can be divided into categories based on gonadotropic secretion: hypergonadotropism (increased levels of FSH and LH) and hypogonadotropism (decreased LH and FSH levels).

Disorders of the Female Reproductive System

1. The female reproductive system can be altered by hormonal imbalances, infectious microorganisms, inflammation, structural abnormalities, and benign or malignant proliferative conditions.
2. Menstrual disorders usually involve some disruption of the HPG axis and subsequent alteration of hormone production,

reception by target organs, or feedback mechanisms.

3. Primary dysmenorrhea is painful menstruation not associated with pelvic disease. It often results from excessive synthesis of prostaglandins (or sensitivity to prostaglandins), which cause the myometrium to contract and constrict blood vessels, resulting in ischemic pain.
4. Primary amenorrhea is the continued absence of menarche and menstrual function by 13 years of age without the development of secondary sex characteristics, or by age 15 years if these changes have occurred.
5. Secondary amenorrhea is the absence of regular menses for 3 months, or 6 months of irregular menses in women who have previously menstruated. Secondary amenorrhea is usually associated with anovulation.
6. Amenorrhea is divided into compartments that reflect the underlying disorder: compartment I, disorders of the outflow tract or uterine target organ; compartment II, disorders of the ovary; compartment III, disorders of the anterior pituitary; and compartment IV, disorders of the CNS or hypothalamic factors.
7. Abnormal uterine bleeding (AUB) is bleeding that is abnormal in duration, volume, frequency, regularity, or some combination of these factors.
8. Polycystic ovary syndrome (PCOS) is a difficult syndrome to diagnose because several factors are involved. It is a syndrome in which at least two of the following are present: irregular ovulation or anovulation; elevated levels of androgens, or clinical signs of hyperandrogenism; and polycystic ovaries. Prolonged anovulation often leads to infertility, menstrual bleeding disorders, hirsutism, acne, endometrial hyperplasia, cardiovascular disease, and diabetes mellitus in women with hyperinsulinemia.
9. PMS is the cyclic recurrence of physical, psychologic, or behavioral changes distressing enough to disrupt normal activities or interpersonal relationships. Approximately 300

emotional, physical, and behavioral symptoms have been attributed to PMS. Emotional symptoms, particularly depression, anger, irritability, and fatigue, are reported as the most distressing; physical symptoms tend to be less problematic. Treatment is symptomatic and includes self-help techniques, lifestyle changes, counseling, and selective serotonin reuptake inhibitors (SSRIs).

10. Infection and inflammation of the female genitalia may result from exogenous pathogens, most often sexually transmitted, or from overproliferation of microorganisms that normally populate the genital tract.
11. Pelvic inflammatory disease (PID) is an acute ascending polymicrobial infection of the upper genital tract and is often caused by sexually transmitted pathogens that are allowed to ascend because of disruptions in the normal vaginal flora.
12. Vaginitis, or vaginal infection, can be caused by a variety of microorganisms or irritants, or disruptions in the vaginal pH, and involves vaginal irritation, itching, burning, odor, or abnormal discharge. The primary forms are vulvovaginal candidiasis, bacterial vaginosis, or trichomoniasis.
13. Cervicitis, which is inflammation of the cervix, can be acute (mucopurulent cervicitis) or chronic.
14. Vulvovestibulitis is an inflammation of the skin of the vulva. It can be caused by chemical and mechanical irritants, allergens, skin disorders, nerve problems, or vaginal infections, such as candidiasis.
15. Bartholinitis, also called Bartholin cyst, is an inflammation of the ducts that lead from the Bartholin glands to the surface of the vulva. Inflammation blocks the glands, preventing the outflow of glandular secretions, and is caused by trauma or infection.
16. Pelvic organ prolapse—uterine prolapse, cystocele, rectocele, and urethrocele—is caused by loss of support provided by the pelvic muscles and fascia. Age and pelvic trauma are associated. Women with a familial or genetic predisposition

have a higher risk.

17. Benign growths and proliferative conditions of the female reproductive tract tend to affect the ovaries (benign ovarian cysts) or uterine tissues (endometrial polyps, leiomyomas, and endometriosis).
18. Benign ovarian cysts develop from mature ovarian follicles that do not release their ova (follicular cysts) or from a corpus luteum that persists abnormally instead of degenerating (corpus luteum cyst). Cysts usually regress spontaneously.
19. Endometrial polyps are overgrowths of endometrial tissue and often cause abnormal bleeding.
20. Leiomyomas, also called *uterine fibroids*, are tumors arising from the muscle layer of the uterus, the myometrium. Prevalence increases in women between ages 30 and 50; most myomas remain small and asymptomatic.
21. Adenomyosis is the presence of endometrial glands and stroma within the uterine myometrium.
22. Endometriosis is the presence of functional endometrial tissue (i.e., tissue that responds to hormonal stimulation) at sites outside the uterus. Endometriosis causes an inflammatory reaction at the site of implantation and is a cause of pain and infertility.
23. Most cancers of the female genitalia involve the uterus (particularly the cervix) and the ovaries. Cancer of the vagina is rare.
24. Infection with high-risk HPV, a sexually transmitted infection, is a necessary precursor to developing CIN and cervical cancer. Smoking, immunosuppression, and poor nutrition are cofactors. HPV vaccination can substantially reduce the risk of cervical cancer.
25. Cervical cancer arises from the cervical epithelium. The progressively serious neoplastic alterations are: (1) cervical intraepithelial neoplasia (cervical dysplasia), (2) cervical carcinoma in situ, and (3) invasive cervical carcinoma.
26. Risk factors for vaginal cancer are in utero diethylstilbestrol

(DES) exposure and prior or concurrent cervical cancer. Like cervical cancers, vaginal cancers arise from the epithelium and are identified as intraepithelial neoplasia (dysplasia), carcinoma in situ, or invasive carcinoma. Most are secondary in nature.

27. The major risk for vulvar cancer is a history of HPV infection or squamous dysplasia of the vagina or cervix. Symptoms include chronic vulvar irritation, pruritus, bloody discharge, and a hard, ulcerated area of the vulva or large cauliflower-like lesions. Peak incidence is in postmenopausal women, but younger women can be affected.
28. Endometrial cancer is the most common cancer of the pelvic region. Risk factors for endometrial cancer include unopposed estrogen exposure, obesity, infertility, failure to ovulate, early menarche or late menopause, and tamoxifen. Oral contraceptive use protects against endometrial and ovarian cancers. Peak incidence occurs at 58 to 60 years of age.
29. Risk factors for ovarian cancer include an increased number of total lifetime ovulations including early menarche, late menopause, nulliparity, use of fertility drugs. *BRCA1*, *BRCA2*, and HNPCC gene abnormalities also are linked with ovarian cancer. Ovarian cancer causes more deaths than any other genital cancer in women.
30. Awareness of sexual dysfunction is relatively new. Chronic illness, medications, infection, sexual trauma, and a variety of psychosocial concerns have been implicated as causes.
31. Infertility, or the inability to conceive after 1 year of unprotected intercourse, affects approximately 15% of all couples. Women's fertility decreases with age, and older women may opt for intervention sooner than younger women. Fertility can be impaired by factors in the male, female, or both partners. Treatment depends on the cause of the infertility; ovulation disorders and tubal blockages are the most common pathologies.

Disorders of the Female Breast

1. Most disorders of the breast are disorders of the mammary gland, that is, the female breast.
2. Galactorrhea, or inappropriate lactation, is the persistent secretion of a milky substance by one or both breasts in nonpregnant, nonlactating women. It can occur in men. Its most common cause is nonpuerperal hyperprolactinemia, a rise in serum prolactin levels that is not associated with pregnancy and childbirth. Hyperprolactinemia can be caused by medications, pituitary tumors, hypothyroidism, chronic stress, or persistent and repeated suckling.
3. Numerous benign conditions occur in ducts and lobules in the breast. Benign breast disease is a spectrum of noncancerous changes in the breast. Benign lesions are broadly classified as (1) nonproliferating breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia.
4. The term *nonproliferative lesions* is used to discriminate such lesions from the “proliferative” changes associated with increased risk of breast cancer. The nonproliferative lesions include simple breast cysts, papillary apocrine change, and mild hyperplasia of the usual type.
5. Fibrocystic changes or physiologic nodularity and cysts are not clinically definitive because they include a heterogeneous group of disorders and refer to nonproliferative lesions. Symptoms affect women ages 30 to 50 and include cyclic bilateral breast tenderness and transient breast lumps.
6. Proliferative breast lesions without atypia are characterized by proliferation of ductal epithelium and/or stroma. Criteria for the diagnosis of intraductal proliferative lesions have been the subject of much research and controversy and include the following structurally diverse lesions: (1) usual ductal hyperplasia, (2) intraductal papillomas, (3) sclerosing adenosis, (4) radial scar, and (5) simple fibroadenoma.
7. Proliferative breast lesions with atypia include ADH and ALH.

ADH is abnormal proliferating cells in breast ducts. ALH is abnormal proliferating cells in the lumen of lobular units.

8. Except for skin cancer, breast cancer is the most common form of cancer in American women. Most breast cancer occurs in women older than 50 years. The major risk factors for breast cancer are classified as reproductive, such as nulliparity and pregnancy-associated breast cancer; familial, such as inherited gene syndromes; and environmental and lifestyle, such as hormonal factors and radiation exposure. Other important factors are delayed involution of the mammary gland and increased breast density.
9. Overall, lifetime risk of breast cancer is reduced in parous women compared to nulliparous women, but pregnancy must occur at a young age. The influence of pregnancy on the risk of breast cancer also depends on family history, lactation postpartum, and overall parity.
10. Breast gland involution after pregnancy and lactation uses some of the same tissue remodeling pathways activated during wound healing. The presence of macrophages in the involuting mammary gland contributes to carcinogenesis.
11. Most breast cancers are adenocarcinomas and first arise from the ductal/lobular epithelium as carcinoma in situ. Carcinoma in situ is an early stage, noninvasive proliferation of epithelial cells confined to the ducts and lobules by the basement membrane.
12. Breast cancer is a heterogeneous disease with diverse molecular, biologic, phenotypic, and pathologic changes. Breast cancer is heterogeneous *within* the same tumor. Cellular subpopulations from different sections of the same tumor vary in growth rate, immunogenicity, ability to metastasize, and drug response. Biologic attributes of a tumor are influenced by the surrounding neighborhood or microenvironment.
13. Cancer cells behave as communities, and the cooperative behaviors of subclones can influence cancer progression.
14. Epithelial-to-mesenchymal transition (EMT) is involved in the

generation of tissues and organs during embryogenesis, is essential for driving tissue plasticity during development, and is hijacked during cancer progression.

15. EMT-associated reprogramming is involved in many cancer cell characteristics, including suppression of cell death and senescence, and is reactivated during wound healing.
16. Invasion by primary tumor cells typically involves the collective migration of large, cohesive groups into adjacent tissue rather than the scattering of individual carcinoma cells. However, still unknown are the precise events occurring at the invasive edge.
17. Emerging evidence supports three main prerequisites that must be met for metastatic colonization to succeed: the capacity to seed and maintain a population of tumor-initiating stem cells; the ability to create adaptive, organ-specific colonization programs; and the development of a supportive microenvironmental niche.
18. Metastases also may occur early in the process of neoplastic transformation.
19. DCIS refers to a heterogeneous group of proliferative lesions limited to ducts and lobules without invasion to the basement membrane. Preinvasive lesions do not invariably progress to invasive malignancy. LCIS originates from the terminal duct-lobular unit.
20. The first clinical manifestation of breast cancer is usually a small, painless lump in the breast. Other manifestations include palpable lymph nodes in the axilla, dimpling of the skin, nipple and skin retraction, nipple discharge, ulcerations, reddened skin, and bone pain associated with bony metastases.
21. Treatment is based on the extent or stage of the cancer and includes surgery, radiation, chemotherapy, hormone therapy, and biologic therapy.

Cancer, 861

Alterations of the reproductive system span a wide range of concerns,

from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common male reproductive disorders carry potentially serious physiologic or psychologic consequences. Sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect sexual performance and fertility and may be risk factors for the development of some types of reproductive tract cancers. Prostate cancer is the second leading cause of cancer death in men and is the most frequently diagnosed cancer in men aside from skin cancer. About 6 in 10 cases of prostate cancer are diagnosed in men aged 65 or older; it is rare before age 40. Incidence rates for prostate cancer changed substantially between the mid-1980s and mid-1990s and have since fluctuated widely from year to year, in large part reflecting changes in prostate cancer screening with the prostate-specific antigen (PSA) blood test. The decline in rates since 2000 has accelerated in recent years, likely because of recommendations against routine PSA screening beginning in 2008. From 2009 to 2013, the rate decreased by about 8% per year.¹ Diagnosis and treatment of male reproductive system disorders are, like female reproductive system disorders, complicated because of the stigma and symbolism associated with the reproductive organs and the emotion-laden beliefs and behaviors related to reproductive health. Treatment and diagnosis for related problems may be delayed because of embarrassment, guilt, fear, or denial.

Alterations of Sexual Maturation

The process of sexual maturation, or puberty, is marked by the development of secondary sexual characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty, or sexual maturation. These disorders may cause puberty to occur too late

(delayed puberty) or too early (precocious puberty). Both types involve a disrupted onset of sex hormone production by the gonads. While the average age of pubertal onset appears to be decreasing for girls, the age of pubertal onset has remained essentially unchanged for boys.

Delayed Puberty

About 3% of children in North America experience delayed development of secondary sex characteristics.² Normally, boys tend to mature later than girls, around 14 to 14.5 years of age. In boys the first sign is enlargement of the testes and thinning of the scrotal skin. Puberty is considered delayed if there are no clinical signs of puberty by age 14 in boys (2 standard deviations [SDs] above the mean age of pubertal onset). Boys especially tend to be embarrassed by sexual immaturity³; therefore early diagnosis and treatment are recommended, as well as reassurance for boys as well as girls.

In 95% of cases delayed puberty is a physiologic delay; that is, hormonal levels are normal and the hypothalamic-pituitary-gonadal (HPG) axis is intact, but maturation is occurring slowly.⁴ This constitutional delay tends to be familial and is much more common in boys than in girls. Physiologic delay is difficult to distinguish from isolated gonadotropin deficiency and is usually diagnosed retrospectively once pubertal progression is complete.

Delayed puberty also may be related to consequences of any chronic condition that delays bone aging (e.g., lung disease, renal failure, cystic fibrosis) (Box 26.1).⁵ Many clinicians recommend intervention (e.g., exogenous sex steroid administration) in physiologic cases of delayed puberty to reduce the psychologic effects (e.g., self-esteem issues, embarrassment) often associated with delayed puberty.⁴

Box 26.1

Causes of Delayed or Absent Puberty

Chronic or Systemic Conditions

- Chronic renal disease
- Cystic fibrosis
- Diabetes mellitus
- Excessive exercise
- Hematologic diseases
- Hypothyroidism
- Irritable bowel diseases
- Poor nutrition (eating disorders, GI diseases, poverty)
- Gonadal dysgenesis
 - Turner syndrome (genetic karyotype 45,XO)
- Bilateral gonadal failure
 - Autoimmune
 - Congenital anorchia
 - Postsurgical, postirradiation, postchemotherapy
 - Traumatic or infectious

Hypogonadotropic Hypogonadism (Deficient FSH/LH)

- Central nervous system defects (GnRH deficiency)
 - Craniopharyngioma
 - GPR54 mutations
 - Hemochromatosis
 - Hypopituitarism
 - Kallmann syndrome, Bardet-Biedl syndrome, Prader-Willi syndrome
 - Marijuana use
 - Pituitary adenoma/tumor
 - Prolactinomas

Disordered Puberty

FSH, Follicle-stimulating hormone; *GI*, gastrointestinal; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone.

Data from Burchett MLR, Hanna CE, Steiner RD: Endocrine and metabolic diseases. In Burns CE, Brady MA, Dunn AM, editors: *Pediatric primary care*, ed 4, St Louis, 2009, Saunders; Jospe N: Disorders of pubertal development. In Osborne LM et al, editors: *Pediatrics*, Philadelphia, 2005, Mosby; Karagiannis A, Harsoulis F: *Eur J Endocrinol* 152(4):501–513, 2005.

The other 5% of cases of delayed puberty are caused by a disruption of the HPG axis of various etiologies (see [Box 26.1](#)).⁶ Human gonadal function is partially controlled by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), the release of which is regulated by the pulsatile secretion of hypothalamic gonadotropin-releasing hormone (GnRH).^{4,6} Most recently, the G-protein–coupled receptor 54 (GPR54) has been identified as the gatekeeper gene for activation of the GnRH axis based on loss of function studies in mice and humans. GPR54 is required for the normal function of this axis, and data suggest that the ligand kisspeptin-1 acts by stimulating neurons expressing gonadotropin-releasing hormone (GnRH).^{7,8} The mechanisms of childhood inhibition of GnRH release and activation are poorly understood but appear to involve feedback inhibition by sex steroids and presumably other central nervous system (CNS) pathways.⁹ Given the myriad etiologies contributing to the occurrence of delayed puberty, a thorough evaluation should be conducted that includes physical examination and medical and family history. Such evaluation should specifically target known contributors to delayed puberty.⁴ Laboratory workup generally consists of x-ray studies for determination of bone age; measurement of thyroid function and serum levels of prolactin and adrenal and gonadal steroids; radioimmunoassay of plasma gonadotropins; and screening for systemic disorders. Adolescents with high gonadotropin levels require a karyotype to rule out genetic causes, and those with low levels need skull imaging (lateral skull film, computed tomography [CT], or magnetic resonance imaging [MRI]) to rule out pituitary or other CNS infiltrate or tumor.⁵ Although several genes involved in the HPG maturation cascade have been characterized from familial or sporadic cases of primitive isolated hypogonadotropic hypogonadism, many genes regulating puberty onset remain undetermined.

Treatment of delayed puberty depends on the cause; the goal of treatment is the development of secondary sex characteristics and fertility, when possible. Insufficient sex hormone secretion can be corrected by hormone replacement therapy, such as testosterone for boys.¹⁰ Idiopathic hypogonadotropic hypogonadism is treated with synthetic GnRH or sex hormone administration, or both, and may be lifelong.^{4,5,10}

Precocious Puberty

Precocious puberty is a rare event in boys, affecting less than 1 in 50,000. Precocious puberty in boys has been redefined as sexual maturation before age 9.¹¹ One study has noted observed mean ages of beginning male genital and pubic hair growth and early testicular volumes tending toward younger ages than earlier studies have suggested, although this seems to be dependent on race and ethnicity.¹² For instance, black boys are showing significantly earlier mean ages for stages 2 to 4 genital development and stages 2 to 4 pubic hair than white and Hispanic boys. All cases of precocious puberty require thorough evaluation.

Precocious puberty may be partial, complete, or mixed (heterosexual) types ([Box 26.2](#)) and can be further categorized into central (GnRH-dependent) and peripheral (GnRH-independent) ([Box 26.3](#)). **Central precocious puberty** is GnRH-dependent and occurs when the HPG axis is working normally but prematurely. It mimics physiologic pubertal development, although at an inappropriate chronological age (before 8 years in girls and 9 years in boys).¹³ Besides the premature development of secondary sex characteristics, precocity causes premature closure of the epiphysis of long bones, which results in shorter stature. Central precocious puberty results from failure of central inhibition of the GnRH pulse generator (the gonadostat). The diagnosis of central precocious puberty is one of exclusion. Because of the possibility of a central nervous system (CNS) lesion, children with presumed central precocious puberty require long-term surveillance. Peripheral puberty is GnRH-independent and develops when sex hormones are produced by some mechanism other

than stimulation by the gonadotropins. Sex steroid–producing tumors such as gonadal tumors, testotoxicosis, and exposure to exogenous sex steroids (e.g., hormonal contraceptives and environmental endocrine disruptors) are some of the causes (see [Box 26.3](#)).

Box 26.2

Primary Forms of Precocious Puberty

Complete Precocious Puberty

Premature development of appropriate characteristics for the child's sex

Hypothalamic-pituitary-ovarian axis working normally but prematurely

In about 10% of cases, lethal central nervous system tumor may be the cause

Partial Precocious Puberty

Partial development of appropriate secondary sex characteristics

Premature thelarche (breast budding) seen in girls between 6 months and 2 years of age

Does not progress to complete puberty (ovulation and menstruation)

Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age

Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

Mixed Precocious Puberty

Causes the child to develop some secondary sex characteristics of the opposite sex
Common causes: adrenal hyperplasia or androgen-secreting tumors

Data from Burchette MLR, Hanna CE, Steiner RD: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Jospe N: Disorders of pubertal development. In Osborne LM et al, editors: *Pediatrics*, Philadelphia, 2005, Mosby.

Box 26.3

Causes of Precocious Puberty

Central (Gonadotropin-Releasing Hormone [GnRH] Dependent)

Idiopathic
Central nervous system (CNS) disorders
 Congenital anomalies (hydrocephalus)
 Hypothalamic hamartoma
 Postinflammatory/infectious condition
 Trauma
 Tumors (hypothalamic, pineal, other)
Hypothyroidism (severe)

Peripheral Puberty (GnRH Independent)

Adrenal hyperplasia or tumor
Environmental endocrine disruptors
Exogenous sex steroid exposure
Exogenous anabolic steroids
Familial Leydig cell hyperplasia
Gonadal tumors or cysts
Human chorionic gonadotropin (hCG)–secreting tumors

(hepatoblastomas, intracranial lesions)
McCune-Albright syndrome
Testotoxicosis

From Bhagavath B, Layman LC: *Semin Reprod Med* 25(4):272–286, 2007; Burchett MLR, Hanna CE, Steiner RD: Endocrine and metabolic diseases. In Burns CE et al, editors: *Pediatric primary care*, St Louis, 2009, Saunders; Caserta DL et al: *Hum Reprod Update* 14(1):59–72, 2008; Cesario SK, Hughes LA: *J Obstetr Gynecol Neonatal Nurs* 36(3):263–274, 2007; Jospe N: Disorders of pubertal development. In Osborne LM et al, editors: *Pediatrics*, Philadelphia, 2005, Mosby.

Complete precocious puberty refers to the onset and progression of all pubertal features. **Partial precocious puberty** is the partial development of appropriate secondary sexual characteristics alone or in combination. Premature pubarche tends to occur between ages 5 and 8 years. Premature pubarche is usually the consequence of an early increase in the adrenal androgens that leads to early growth of pubic hair and possibly a transient acceleration in growth and bone maturation that has no significant effect on timing of puberty or final height.

The diagnosis and cause of premature development are often obvious. A thorough history and physical examination is done to determine the velocity of the process and to rule out life-threatening CNS or adrenal neoplasms. Family occurrence helps exclude tumors. Children with precocious puberty also have a tendency toward obesity.⁹ In addition, excess body weight early in life can actually influence growth patterns. There is evidence suggesting that excess adiposity during childhood influences growth patterns and pubertal development.¹⁴

Treatment for all forms of precocious puberty includes identifying and removing the underlying cause (see [Boxes 26.2](#) and [26.3](#)) or administering appropriate hormones. In many cases precocious puberty can be reversed. Management goals include diagnosing and treating intracranial disease; arresting maturation until early teen years; maximizing eventual adult height; reducing emotional problems; and providing contraception, if necessary. The most

common form, central precocious puberty, is usually treated with potent GnRH agonist analogs, which induce reversible, selective suppression of the HPG axis. Treatment does not seem to affect body composition or increase obesity in children with central precocious puberty. Because many of these children are obese and childhood obesity is predictive of morbidity in adolescence and adulthood, it is important for clinicians to include assessment and management of obesity as part of the treatment for central precocious puberty.

Mixed precocious puberty, such as feminization of a boy, causes the child to develop some secondary sexual characteristics of the opposite sex. This condition is usually evident at birth and is rare in older children (Box 26.4).

Box 26.4

Causes of Mixed Precocious Puberty

Female (Virilization)

- Congenital adrenal hyperplasia
- Androgen-secreting tumors
 - Adrenal
 - Ovarian
 - Teratoma
- Exogenous androgens

Male (Feminization)

- Estrogen-producing tumors
 - Adrenal
 - Teratoma
 - Hepatoma
 - Testicular
- Exogenous estrogens

Increased peripheral conversion of androgens to estrogens

Data from Jospe N: Disorders of pubertal development. In Osborn LM et al, editors: *Pediatrics*, Philadelphia, 2005, Mosby.

Disorders of the Male Reproductive System

Disorders of the Urethra

Urethritis and urethral strictures are common disorders of the male urethra. Urethral carcinoma occurs in men older than 60 years, but it is an extremely rare form of cancer.

Urethritis

Urethritis is an inflammatory process of the urethra without concurrent bladder infection that is usually, but not always, caused by a sexually transmitted microorganism. Biologic agents associated with infectious urethritis in males include *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, *Ureaplasma urealyticum*, and other, less common, mycobacteria; parasites (e.g., *Trichomonas vaginalis*); and viruses (herpes simplex virus [HSV]).^{15,16} Infectious urethritis caused by *N. gonorrhoeae* often is called *gonococcal urethritis (GU)*; infection caused by other microorganisms is called *nongonococcal urethritis (NGU)*.¹⁷ (Sexually transmitted urethritis is described in [Chapter 27](#).) Nonsexual origins of urethritis include inflammation or infection as a result of urologic procedures, insertion of foreign bodies into the urethra, anatomic abnormalities, or trauma.

Noninfectious urethritis is rare and is associated with the ingestion of wood alcohol, ethyl alcohol, or turpentine. It is seen also with Reiter syndrome, which involves a number of mucocutaneous lesions.

Symptoms of urethritis include urethral tingling, itching, or burning sensation on urination (dysuria) and urinary frequency and urgency. The individual may note a purulent or clear mucous-like discharge

from the urethra. Nucleic acid detection amplification tests allow easy detection of *N. gonorrhoeae* and *C. trachomatis* in first-void urine.^{17,18} Treatment consists of appropriate antibiotic therapy for infectious urethritis and avoidance of future chemical or mechanical irritation.

Urethral Stricture

A **urethral stricture** is a fibrotic narrowing of the urethra caused by scarring. The scars may be congenital but can be present at any age and have a wide range of etiologic factors, including untreated urethral infection (e.g., from long-term use of indwelling urinary catheters), trauma, and urologic instrumentation. It can present at any age and has a wide range of etiologic factors, including infection, trauma, and instrumentation. Large catheters and instruments cause internal trauma and ischemia, whereas external trauma, such as pelvic fracture, can partially or completely sever the urethra and cause severe and complex strictures.¹⁹ In addition, a report has concluded that stricture may occur decades after initial hypospadias surgery.²⁰ Urethral carcinoma is a less common cause of urethral stricture. Prostatitis and infection secondary to urinary stasis are common complications. Severe and prolonged obstruction can result in hydronephrosis and renal failure. In addition, chronic, severe strictures may lead to urethral fistulae and periurethral abscesses.^{19,21}

The clinical manifestations of urethral stricture are caused by bladder outlet obstruction. Urethral stricture often manifests itself as lower urinary tract symptoms or urinary tract infections with significant impairment in the quality of life. The primary symptom is diminished force and caliber of the urinary stream; other symptoms include urinary frequency and hesitancy, mild dysuria, double urine stream or spraying, and postvoid dribbling. Symptoms of acute urinary retention may occur in the presence of infection or urinary obstruction. Induration at the stricture site may be palpable. Tender, enlarged masses along the urethra usually indicate periurethral abscesses. Urethral stricture often manifests itself as lower urinary tract symptoms or urinary tract infections with significant impairment in the quality of life.

Urethral stricture is diagnosed on the basis of history, physical examination, urinary flow rates, voiding cystourethrogram, and urethroscopy; biopsy confirms carcinoma. Treatment is usually surgical and may involve urethral dilation, urethrotomy, or a variety of open surgical techniques. The choice of surgical intervention depends on the age of the individual and the severity of the problem. Strictures may recur up to 1 year after treatment. Follow-up is necessary during this time; urinary flow measurements and a urethrogram help determine the extent of residual obstruction.

Disorders of the Penis

Phimosis and Paraphimosis

Phimosis and paraphimosis are disorders in which the foreskin (prepuce) is “too tight” to be moved easily over the glans penis. **Phimosis** is a condition in which the foreskin cannot be retracted back over the glans, whereas **paraphimosis** is the opposite: the foreskin is retracted and cannot be moved forward (reduced) to cover the glans (Fig. 26.1). Both conditions can cause penile pathologic conditions.

FIGURE 26.1 Phimosis and Paraphimosis. A, Phimosis: the foreskin has a narrow opening that is not large enough to permit retraction over the glans. B, Lesions on the prepuce secondary to infection cause swelling, and retraction of foreskin may be impossible. C, Paraphimosis: the foreskin is retracted over the glans but cannot be reduced to its normal position. Here it has formed a constricting band around the penis. D, Ulcer on the retracted prepuce with edema. (A and C From Monahan FD et al: *Phipp's medical-surgical nursing*, ed 8, St Louis, 2007, Mosby; B from Taylor PK: *Diagnostic picture tests in sexually transmitted diseases*, London, 1995, Mosby-Wolfe; D from Morse SA, Holmes KK, Ballard RC: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2011, Saunders.)

The inability to retract the foreskin is normal in infancy and is caused by congenital adhesions. During the first 3 years of life these adhesions separate naturally with penile erections and are not an indication for circumcision. Although most cases occur in uncircumcised males, stenosis and resultant phimosis can occur in

males with excessive skin remaining after circumcision.²¹ Phimosis can occur at any age and is caused most commonly by poor hygiene and chronic infection. Chronic balanoposthitis (inflammation of the glans and prepuce) predisposes older diabetic men to phimosis. It rarely occurs with normal foreskin.

Edema, erythema, and tenderness of the prepuce and purulent discharge are usually the reasons for seeking treatment; inability to retract the foreskin is a less common complaint. Circumcision, if needed, is performed after infection has been eradicated. Complications of phimosis include inflammation of the glans (balanitis) or prepuce (posthitis) and paraphimosis. There is a higher incidence of penile carcinoma in uncircumcised males, which is associated with morbidity and mortality, but chronic infection, most likely with human papillomavirus (HPV), is usually the underlying factor in such cases. HPV infection can result in a spectrum of genitourinary manifestations ranging from genital warts to cancer. Approximately 40% of invasive penile carcinomas are attributable to HPV.^{21,22}

Paraphimosis, in which the foreskin is retracted, can constrict the penis, causing edema of the glans. If edema is such that the foreskin cannot be reduced manually, surgery must be performed to prevent necrosis of the glans caused by constricted blood vessels. Severe paraphimosis is a surgical emergency, and phimosis may require immediate release if there is urinary obstruction.

Peyronie Disease

Peyronie disease (bent nail syndrome) is a fibrotic condition of the tunica albuginea of the penis resulting in varying degrees of curvature and sexual dysfunction. It is an underdiagnosed condition with prevalence in the male population as high as 9%²³ (Fig. 26.2). Peyronie disease develops slowly and is characterized by tough, fibrous thickening of the fascia in the erectile tissue of the corpora cavernosa. A dense fibrous plaque is usually palpable on the dorsum of the penile shaft. The problem usually affects middle-age men and is associated with painful erection, painful intercourse (for both

partners), and poor erection distal to the involved area. In some cases, impotence or unsatisfactory penetration occurs. There is no pain when the penis is flaccid.

FIGURE 26.2 Peyronie Disease. (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases*, London, 1995, Mosby-Wolfe.)

Although the exact cause is unknown, a local vasculitis-like inflammatory reaction occurs and decreased tissue oxygenation results in fibrosis and calcification. Peyronie disease is associated with Dupuytren contracture (a flexion deformity of the fingers or toes caused by shortening or fibrosis of the palmar or plantar fascia), diabetes, tendency to develop keloids, and, in rare cases, use of beta-blocker medications.

There is no definitive treatment for Peyronie disease. Spontaneous remissions occur in as many as 50% of cases. Treatment with pharmacologic therapies includes colchicine, aminobenzoate potassium (Potaba), L-carnitine, and liposomal superoxide dismutase. Men suffering with Peyronie disease who have significant penile deformity precluding successful coitus can be appraised for surgical correction. In men with adequate erectile function tunical plication or incision/partial excision, or both, and grafting can be offered

depending on the degree of curvature or the presence of destabilizing deformity, or both. Surgery is considered the gold standard and includes the measures mentioned in the previous sentence, in addition to penile prosthesis–related procedures.^{17,23}

Priapism

Priapism is an uncommon condition of prolonged penile erection, and is defined as a persistent and painful erection lasting longer than 4 hours without sexual stimulation (Fig. 26.3). Priapism is idiopathic in 60% of cases; the remaining 40% of cases are associated with spinal cord trauma, sickle cell disease, leukemia, pelvic tumors or infections, or penile trauma. Priapism also has been associated with cocaine use.^{24,25} Intracavernous injection therapy for impotence seems to be the most common cause. Prolonged sexual stimulation often is associated with initial development of the idiopathic type.²¹ The two corpora cavernosa within the erect penis are filled with blood and are tender to palpation; neither the corpus spongiosum nor the glans is engorged. The vascular congestion is thought to be associated with venous obstruction. If the erection remains over a period of days, edema and fibrosis develop, leading to erectile dysfunction (impotence).

FIGURE 26.3 Priapism. (From Lloyd-Davies RW, Gow JG, Davies DR: *Color atlas of urology*, ed 2, London, 1994, Mosby-Wolfe.)

Priapism is a urologic emergency. Treatment within hours is effective and prevents impotence. Conservative approaches include iced saline enemas, ketamine administration, and spinal anesthesia. Needle aspiration of blood from the corpus through the dorsal glans is often effective and is followed by catheterization and pressure dressings to maintain decompression. More aggressive surgical treatments include the creation of vascular shunts to maintain blood flow. Erectile dysfunction results in up to 50% of prolonged cases.

Balanitis

Balanitis is an inflammation of the glans penis (Fig. 26.4) and usually occurs in conjunction with posthitis, an inflammation of the prepuce. It is associated with poor hygiene and phimosis. The accumulation under the foreskin of glandular secretions (smegma), sloughed epithelial cells, and *Mycobacterium smegmatis* can irritate the glans directly or lead to infection. Skin disorders (e.g., psoriasis, lichen planus, eczema) and candidiasis must be differentiated from inflammation resulting from poor hygienic practices. Balanitis is seen most commonly in men with poorly controlled diabetes mellitus and

candidiasis. Antimicrobials are used to treat infection. Circumcision can prevent recurrences and can be considered after the inflammation has subsided.

FIGURE 26.4 Balanitis. (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases*, London, 1995, Mosby-Wolfe.)

Penile Cancer

In the United States, carcinoma of the penis is rare and affects about 1 in 100,000 men. The American Cancer Society estimates for penile cancer in the United States for 2017 are approximately 2120 cases and 360 deaths.²⁶ Although rare in North America and Europe, where it accounts for about 0.2% of cancers and 0.1% of cancer deaths in men, penile cancer may account for up to 10% of cancers in African and South American men.

In the United States, about four out of five cases of the disease are diagnosed in men older than age 55 years. Major risk factors include infection with HPV (mainly serotypes 16 and 18), smoking, and psoriasis treated with a combination involving the drug psoralen and ultraviolet (UV) light. Men circumcised at birth have less than half the chance of getting penile cancer than those who were not. Penile cancer is more common in men with phimosis and those with acquired immunodeficiency syndrome (AIDS). About two-thirds of men with

penile cancer are diagnosed at more than 65 years of age.²⁶

Before the development of penile cancer, signs of premalignant cancer or epidermal cancer in situ are present.²⁷ These include thick white plaque (leukoplakia) that typically involves the meatus; red, inflamed areas of Paget disease; red, velvety, ulcerative lesions of erythroplasia of Queyrat that usually involve the glans; large, invasive, scaly growths of Buschke-Löwenstein tumor; red plaque with encrustations of Bowen disease; and in situ carcinoma that generally affects the penile shaft. Men with leukoplakia or erythroplasia of Queyrat may have concurrent invasive penile carcinoma.^{28,29} Pain and bleeding are late signs of penile cancer. Condylomata (genital warts) caused by HPV may be involved in the development of precancerous lesions²² (see [Chapter 27](#) for a discussion of HPV). At times the penis might be the site of metastatic spread of solid tumors from the bladder, prostate, rectum, or kidney. Early squamous cell carcinoma and premalignant epidermal lesions are easily treated but are often ignored. Delays in seeking treatment are attributed to denial, embarrassment, failure to detect lesions under a phimotic foreskin, fear, guilt, and ignorance.

Penile cancer is mostly squamous cell carcinoma, which usually begins as a small, flat, ulcerative or papillary lesion on the glans or foreskin that grows to involve the entire penile shaft ([Fig. 26.5](#)). Extensive lesions are associated with metastases and a poor prognosis. These lesions are not as painful as the amount of tissue involvement would seem to indicate. The regional femoral and iliac nodes are common metastatic sites. Rarely the urethra and bladder are involved. Weight loss, fatigue, and malaise accompany chronic suppurative lesions. Untreated, progressive disease causes death within 2 years.²⁹

FIGURE 26.5 Squamous Cell Carcinoma Involving the Glans Penis. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders.)

The specific diagnosis is made by biopsy after examination to document the location, size, and fixation of the lesion. After a positive biopsy the extent of cancer spread is determined by imaging tests such as ultrasound, CT, or MRI. Fine-needle aspiration of lymph tissue confirms the absence or presence of regional adenopathy. About 30% of penile cancers spread to lymph nodes before diagnosis. Distant metastases occur in less than 10% of cases and may involve lung, liver, bone, or brain.²⁴ The following stages are used for penile cancer: stage 0 (carcinoma in situ), stage I, stage II, stage III, and stage IV.³⁰

Penile carcinoma is primarily managed with surgery. Newer, innovative surgical techniques can preserve as much penile tissue as possible without compromising cancer control. For invasive penile carcinoma, complete excision leaving adequate tumor-free margins is the goal. A simple circumcision may be sufficient for localized lesions of the prepuce. If the primary site is the glans and distal shaft, removal of the penis may be necessary. Although conventional radical surgery continues to be an effective approach, the emasculating nature of the treatment has serious psychologic and sexual consequences. Recent studies have challenged the conventional belief that a 2-cm margin was required for adequate cancer control.²⁷ Newer innovative surgical techniques can preserve as much penile tissue and functional integrity as possible without compromising cancer control.

Inguinal lymph nodes also are removed if metastasis to these structures is known or suspected. Palliative treatment with radiation or chemotherapy may be used when the disease is inoperable and bulky inguinal metastases have occurred. Options for individuals with carcinoma in situ include local excision, radiation, laser surgery, cryosurgery, chemosurgery, or chemotherapy with topical (5%) 5-fluorouracil (5-FU). Differentiation, tumor stage, and age influence prognosis.^{29,31} For cancers that are still confined to the penis (e.g., stage I and II cancers), the 5-year relative survival rate is around 85%. If the cancer has spread to nearby tissues or lymph nodes (e.g., stage III and some stage IV cancers), the 5-year relative survival rate is approximately 59%.²⁶

Disorders of the Scrotum, Testis, and Epididymis

Disorders of the Scrotum

Men may seek treatment for painful or painless scrotal masses. Masses may be serious (cancer or torsion) or benign (hydrocele or cyst) and may require immediate surgical intervention or allow for careful observation.³² Varicocele, hydrocele, and spermatocele are common intrascrotal disorders.³³⁻³⁵ A **varicocele** is an abnormal dilation of a vein within the spermatic cord and is classically described as a “bag of worms” (Fig. 26.6). Most (95%) occur on the left side and may be painful or tender. Varicocele occurs in 10% of males and is seen most often after puberty. Sudden development of a varicocele in an older man is a late sign of renal tumor.^{36,37} Unilateral right-sided varicoceles are rare and result from compression or obstruction of the inferior vena cava by a tumor or thrombus. Color Doppler ultrasonography is used to confirm the diagnosis.^{27,35}

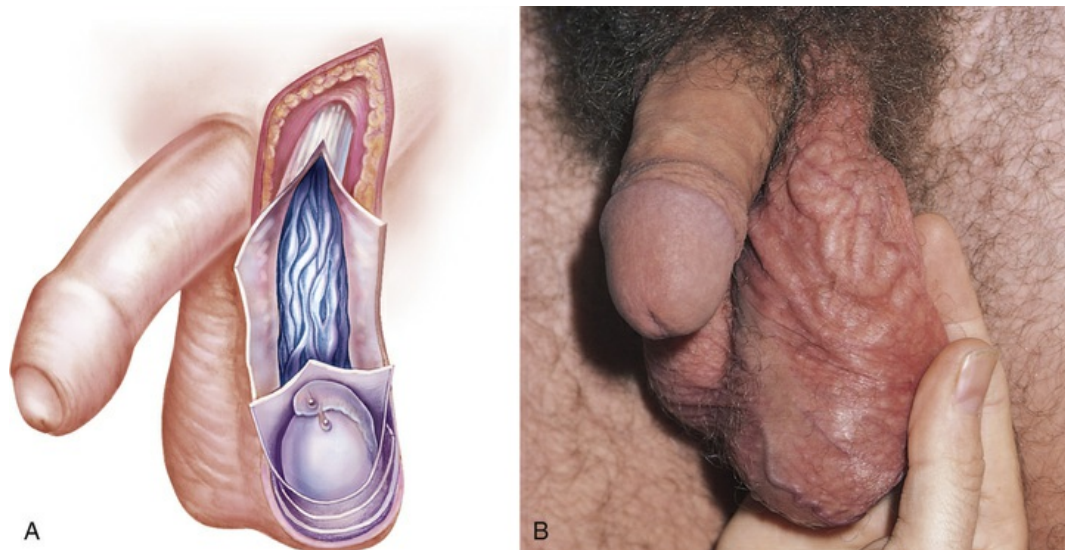

FIGURE 26.6 Varicocele. A, Dilation of veins within the spermatic cord. B, Varicocele on physical examination. (A From Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby. B From Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2010, Saunders.)

The cause of a varicocele is incompetent or congenitally absent valves in the spermatic veins. The valves that normally prevent backflow are absent or do not close adequately, permitting blood to pool in the veins rather than flow into the venous system. A varicocele decreases blood flow through the testis. This interferes with spermatogenesis and is a cause of infertility.^{35,38} If infertility is a problem, treatment consists of ligation of the spermatic vein or occlusion of the vein by percutaneous methods, such as balloon catheter and sclerosing fluids.³⁸ If the varicocele is mild and fertility is not an issue, a scrotal support usually is sufficient to relieve symptoms of scrotal heaviness or “dragging.”

A **hydrocele** is a collection of fluid within the tunica vaginalis^{39,40} (Fig. 26.7). It is the most common cause of scrotal swelling. Hydroceles occur in 6% of male newborns and are congenital malformations (patent processus vaginalis) that often resolve spontaneously in the first year of life. Surgical ligation is recommended if the hydrocele persists after age 1 year.³⁴ Hydroceles in adults may be caused by an imbalance between the secreting and absorptive capacities of scrotal tissues. Hydroceles range in size from slightly larger than the testes to the size of a grapefruit or larger and may be flaccid or tense.

Compression of testicular blood supply may lead to atrophy.

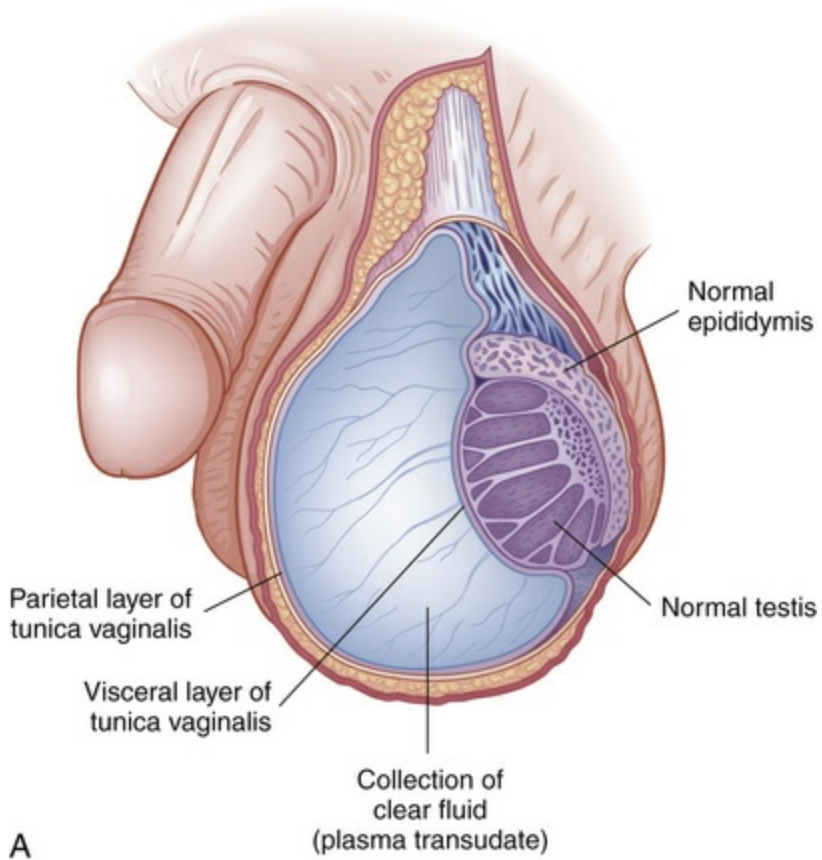

FIGURE 26.7 Depiction of a Hydrocele. A, Accumulation of clear fluid between the visceral (inner) and parietal (outer) layers of the tunica

vaginalis. B, The appearance of a hydrocele on ultrasound examination. (B From Adam A et al: *Grainger & Allison's diagnostic radiology*, ed 6, London, 2008, Churchill Livingstone.)

The exact mechanism of idiopathic hydrocele development is unknown. A secondary hydrocele may result from trauma or infection of the testis or epididymis or from a testicular tumor. Rapid accumulation of fluid occurs after local injury, radiotherapy, or infection (epididymitis or orchitis), or it may accompany testicular neoplasm. Chronic hydroceles are more common and occur in men older than 40 because of an imbalance between fluid secretion and reabsorption in the tunica vaginalis. A painless, extratesticular mass that easily transilluminates is found on physical examination. Ultrasonography of a large hydrocele, which may conceal a testicular tumor, is recommended. Treatment is usually not required unless a large, bulky hydrocele causes considerable physical discomfort or undesirable cosmetic appearance.³⁹ Treatment for uncomplicated hydrocele is aspiration of the fluid and injection of a sclerosing agent into the scrotal sac.⁴⁰⁻⁴² The goal of treatment is to remove the hydrocele and prevent recurrence by sclerosing or excising the tunica vaginalis.

Spermatoceles (epididymal cysts) are benign cystic collections of fluid of the epididymis located between the head of the epididymis and the testis. Efferent ducts of the epididymis have potential for cystic dilation to form a spermatocele⁴⁰⁻⁴² (Fig. 26.8). Spermatoceles are filled with milky fluid that contains sperm. A spermatocele is differentiated from a hydrocele in that aspiration of the hydrocele recovers a clear, yellow fluid, and unlike a hydrocele, a spermatocele does not cover the entire anterior surface of the testis.

FIGURE 26.8 Spermatocele. Retention cyst of the head of the epididymis or of an aberrant tubule or tubules of the rete testis. The spermatocele lies outside the tunica vaginalis; therefore, on palpation it can be readily distinguished and separated from the testis. (From Lloyd-Davies RW, Gow JG, Davies DR: *Color atlas of urology*, ed 2, London, 1994, Mosby-Wolfe.)

Spermatoceles manifest as discrete, firm, freely mobile masses distinct from the testis that may be transilluminated. Epididymal cysts do not require treatment.^{40,41} A spermatic cord tumor may feel like a tense spermatocele but does not contain fluid and will not transilluminate.³² Spermatoceles that cause pain or discomfort are excised. Usually, however, spermatoceles are asymptomatic or produce mild discomfort that is relieved by scrotal support.⁴² Neither hydroceles nor spermatoceles are associated with infertility.

Cryptorchidism and Ectopy

Cryptorchidism is a condition of testicular maldescent, whereas an **ectopic testis** has strayed from the normal pathway of descent. The etiology of cryptorchidism is considered to be multifactorial (genetic, maternal, and environmental factors) and it occurs most often as an isolated disorder with no obvious cause.⁴³ Ectopy may be caused by an abnormal connection at the distal end of the gubernaculum testis that leads the gonad to an abnormal position, usually at the superficial inguinal site. In cryptorchidism the descent of one or both testes is arrested, with unilateral arrest occurring more often than bilateral arrest.⁴² The testes may remain in the abdomen, or testicular descent

may be arrested in the inguinal canal or the penoscrotal junction. Cryptorchidism is a common pathologic condition that occurs in 3% of full-term newborns and it decreases to 0.8% to 1.2% at 1 year of age.⁴⁴ However, this rate increases significantly with low-birth-weight infants; for instance, the rate of cryptorchidism at 3 months has been found to be 7.7% for infants with birth weights less than 2000 g, 2.5% for birth weights of 2000 to 2500 g, and 1.41% for birth weights of 2500 g or more.^{42,45,46} The incidence of cryptorchidism in adults is 0.7% to 0.8%.³⁸ Cryptorchidism is commonly associated with vasal or epididymal abnormalities. These congenital anomalies affect about one-third to two-thirds of newborns with cryptorchidism. Other structural anomalies include posterior urethral valves (less than 5%), upper tract abnormalities (less than 5%), and hypospadias. The presence of hypospadias as well as cryptorchidism raises the suspicion of mixed gonadal dysgenesis (intersex infant). It has been hypothesized that cryptorchidism may result from an absence or abnormality of the gubernaculum, a cordlike structure that extends from the lower pole of the testis to the scrotum; a congenital gonadal or dysgenetic defect that makes the testes insensitive to gonadotropins (a likely explanation for unilateral cryptorchidism); or a lack of maternal gonadotropins (a likely explanation for bilateral cryptorchidism of prematurity).³⁸ Mechanical possibilities include a short spermatic cord, fibrous bands or adhesions in the normal path of the testes, or a narrowed inguinal canal. Chromosomal studies do not support a genetic component. Physiologic cryptorchidism, also called *retractile* or *migratory testis*, is an involuntary retraction of the testes out of the scrotum that occurs with excitement, physical activity, or exposure to cold and is caused by the small mass of prepubertal testis and the strength of the cremaster muscle. This is a common phenomenon that is self-limiting (descent occurs at puberty).

Physical examination discloses the absence of one or both testes in the scrotum and an atrophic scrotum on the affected side. If the undescended testis is in a vulnerable position, for example, over the pubic bone, an individual may complain of severe pain secondary to trauma. The adult male with bilateral cryptorchidism may be infertile.

Ultrasonography, CT, or MRI can be used to locate an intraabdominal or nonpalpable testis.

Testicular cancer is also a well-established complication of cryptorchidism. In men with a history of unilateral cryptorchidism, neoplasms also develop more commonly in the contralateral testis. This finding suggests cryptorchidism affects the testes and is a process more significant than simply the position of the testis in childhood.^{38,47} The risk of testicular cancer is 35 to 50 times greater for men with cryptorchidism or a history of cryptorchidism than for the general male population. Because definite histologic change (decreased Leydig cells, loss of germ cells, and peritubular fibrosis) occurs in the cryptorchid testis by 1 year of age, surgical correction is recommended earlier.^{43,48} Treatment often begins with administration of GnRH or human chorionic gonadotropin (hCG), hormones that may initiate descent, making surgery unnecessary. GnRH is given as a nasal spray in Europe and may enhance germ cell counts even when the testis does not descend.⁴⁸ If hormonal therapy is not successful, the testis is located and moved surgically (orchiopexy) in young children or removed (orchiectomy) in adults and children older than 10 years.^{43,48} The testis that is properly placed in the scrotum provides adequate hormonal function and gives the scrotum a normal appearance. A successful operation does not ensure fertility if the testis is congenitally defective. Approximately 20% of males with unilateral undescended testis remain infertile even though orchiopexy is performed by age 1 year; most individuals with treated or untreated bilateral testicular maldescent have poor fertility. In addition, placement of the cryptorchid testis into the scrotal sac does not decrease the potential for malignancy; it does facilitate examination and tumor detection.

Torsion of the Testis

Torsion of the testis is rotation of a testis, which twists blood vessels in the spermatic cord. It causes an acute scrotum, which is testicular pain and swelling (Fig. 26.9). Differentiation between testicular torsion and two other common causes of an acute scrotum is based on

physical examination and history⁴⁹ (Table 26.1). This event is most common among neonates and pubertal adolescents, but it can occur in males at any age.^{34,50} Onset may be spontaneous or follow physical exertion or trauma. Torsion twists the arteries and veins in the spermatic cord, reducing or stopping circulation to the testis. Vascular engorgement and ischemia develop, causing scrotal swelling and pain. These manifestations are not relieved by scrotal elevation (Prehn sign), rest, or scrotal support. On physical examination, men have a tender high-riding testis, a thickened spermatic cord, and an absent cremasteric reflex. Unlike epididymitis, the epididymis cannot be differentiated from the testis.⁴⁹ Diagnostic testing includes urinalysis (to rule out infection) and color Doppler ultrasonography.³⁸ Torsion of the testis is a surgical emergency. If the torsion cannot be reduced manually, surgery must be performed within 6 hours after the onset of symptoms to preserve normal testicular function. Surgery includes untwisting the spermatic cord and anchoring both testes in correct position within the scrotum to prevent recurrences. With successful manual detorsion, surgical fixation should be done within a few days.

FIGURE 26.9 Torsion of the Testes. A, Left testicular torsion in an adolescent with acute scrotum; the testis is necrotic. B, Late phase torsion in an adolescent with severe testicular pain 1 month previously. Note the absence of inflammation and the high position of the testis in the scrotum. C, The testes appear dark red and partially necrotic owing to hemorrhagic infarction. (A and B From Kliegman RM et al: *Nelson's textbook of pediatrics*, ed 19, Philadelphia, 2011, Saunders. C From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

TABLE 26.1

DIAGNOSIS OF SELECTED CONDITIONS RESPONSIBLE FOR THE ACUTE SCROTUM

CONDITION	ONSET OF SYMPTOMS	AGE	TENDERNESS	URINALYSIS	CREMASTERIC REFLEX
Testicular torsion	Acute	Early puberty	Diffuse	Negative	Negative
Appendiceal torsion	Subacute	Prepubertal	Localized to upper pole	Negative	Positive
Epididymitis	Insidious	Adolescence	Epididymal	Positive or negative	Positive

Orchitis

Orchitis is an acute infection of the testes (Fig. 26.10) and is uncommon except as a complication of systemic infection or as an extension of an associated epididymitis.⁵¹ Infectious microorganisms may reach the testes through the blood or the lymphatics or, most commonly, by ascent through the urethra, vas deferens, and epididymis. Most cases of orchitis are actually cases of epididymo-orchitis. Occasionally, in middle-age men, a nonspecific, apparently noninfectious, inflammatory process (called *granulomatous orchitis*) occurs. It seems to be an autoimmune disease that triggers a granulomatous response to spermatozoa.

FIGURE 26.10 Orchitis. Inflammation of the testicle with enlargement or swelling. (From Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby.)

Mumps is the most common infectious cause of orchitis and usually affects postpubertal males. The onset is sudden, occurring 3 to 4 days after the onset of parotitis. Signs and symptoms include high fever, reaching 40°C (104°F), marked prostration, bilateral or unilateral erythema, edema and tenderness of the scrotum, and leukocytosis. An acute hydrocele may develop. Urinary signs and symptoms, which accompany epididymitis, are absent. Atrophy with irreversible damage to spermatogenesis may result in 30% of affected testes. Bilateral orchitis does not affect androgenic function but may cause permanent sterility.

Treatment is supportive and includes bed rest, scrotal support, scrotal elevation, hot or cold compresses, and analgesic agents for relief of pain. If an acute hydrocele develops, it is aspirated. Testicular abscess usually requires orchiectomy (removal of the testis). Appropriate antimicrobial drugs should be used for bacterial orchitis, and corticosteroids are indicated in proved cases of nonspecific granulomatous orchitis.

Cancer of the Testis

Testicular cancer is a highly treatable, usually curable, cancer that most often develops in young and middle-aged men. For men with seminoma (all stages combined), the cure rate exceeds 90%. For those with low-stage seminoma or nonseminoma, the cure rate approaches 100%.⁵² Overall, testicular cancers are rare, yet they are the most common form of cancer in young men between ages 15 and 35. The American Cancer Society's estimates for testicular cancer in the United States for 2017 suggest approximately 8850 new cases of testicular cancer will be diagnosed, and about 410 deaths will result from testicular cancer.¹ In the United States, the lifetime probability of developing testicular cancer is 0.2% for white men, an incidence that is 4 times higher than that for blacks. Testicular tumors are slightly more common on the right side than on the left, a pattern that parallels the occurrence of cryptorchidism; about 1% to 2% of primary testicular cancers are bilateral (Fig. 26.11), and 50% of these tumors arise from treated or untreated cryptorchid testes.⁵³

FIGURE 26.11 Testicular Tumor. (From Wolfe J: *400 Self-assessment*)

◆Pathophysiology.

Ninety percent of testicular cancers are germ cell tumors arising from the male gametes. Germ cell tumors constitute 90% of testicular cancers and can be broadly classified into two types: seminomas and nonseminomas. Seminomas are the most common, are the least aggressive, and make up about 30% to 35% of testicular cancers. Nonseminomas include embryonal carcinomas, teratomas, and choriocarcinomas, which are the most aggressive but rare (less than 1%) form of testicular cancer. Testicular cancers can include a mix of types.⁵⁴ In addition, testicular tumors can arise from specialized cells of the gonadal stroma. These tumors, which are named for their cellular origins, are Leydig cell, Sertoli cell, granulosa cell, and theca cell tumors and constitute less than 10% of all testicular cancers.⁵⁵

The cause of testicular neoplasms is unknown. A genetic predisposition is suggested by the fact that the incidence is higher among brothers, identical twins, and other close male relatives. Genetic predisposition is supported further by statistics showing that the disease is relatively rare among black Africans, black Americans, Asians, and native New Zealanders. Familial testicular germ cell tumors may be associated with transgenerational inheritance of epigenetic events.⁵⁶ Risk factors include history of cryptorchidism, abnormal testicular development, human immunodeficiency virus (HIV) and AIDS, Klinefelter syndrome, and history of testicular cancer.⁵³

◆Clinical Manifestations.

Painless testicular enlargement is usually the first sign of testicular cancer. Enlargement is usually gradual and may be accompanied by a sensation of testicular heaviness or dull ache in the lower abdomen.⁵⁴ Occasionally, acute pain occurs because of rapid growth, resulting in hemorrhage and necrosis. Approximately 10% of affected men have epididymitis, 10% have hydroceles,⁴² and 5% have gynecomastia or hydroceles. The incidence of gynecomastia increases considerably

(30% to 45%) in men with Sertoli or Leydig tumors. Approximately 10% of individuals already have symptoms related to metastases at the time of initial diagnosis, which correlates with the typical delay of 3 to 6 months from initial recognition to definitive treatment. Lumbar pain may be present and usually is caused by retroperitoneal node metastasis. Signs of metastasis to the lungs include cough, dyspnea, and bloody sputum (hemoptysis). Supraclavicular node involvement may cause difficulty swallowing (dysphagia) and neck swelling. Alterations in vision or mental status, papilledema, and seizures may be experienced with metastasis to the CNS. Approximately 10% of affected individuals are asymptomatic; the tumor may be detected by the man's sexual partner or incidentally following trauma.

◆ Evaluation and Treatment.

An incorrect diagnosis at the initial examination occurs in as many as 25% of men with testicular cancer. Epididymitis and epididymo-orchitis are the most common misdiagnoses; others include hydrocele and spermatocele. Evaluation begins with careful physical examination, including palpation of the scrotal contents with the individual in the erect and supine positions. The abdomen and lymph nodes are palpated to rule out metastases. Signs of testicular cancer include abnormal consistency, induration, nodularity, or irregularity of the testis. A firm, nontender testicular mass or diffuse enlargement is found in the majority of cases. Primary testicular cancer can be assessed rapidly and accurately by scrotal ultrasonography. Tumor markers are higher than normal in the presence of a tumor and may help detect a tumor that is too small to be palpated during physical examination or seen on imaging.⁴⁹ Tumor type is identified after inguinal biopsy or orchiectomy. Scrotal incisions may cause dissemination of the tumor and increase the risk of local recurrence and therefore are avoided. Chest x-ray, lymphangiogram, intravenous pyelogram (IVP), abdominal ultrasound, and CT are used in clinical staging of the disease. Treatment is based on type of tumor, stage of disease, general health, and age. Besides surgery, treatment involves radiation and chemotherapy singly or in combination. A number of

factors influence the prognosis (Table 26.2). They include the histology of the tumor, the stage of the disease, and the selection of appropriate treatment. Serum markers, such as alpha fetoprotein (AFP), β -hCG, and lactate dehydrogenase, are useful for detecting metastases and assessing responses to therapy. With appropriate treatment survival rates from testicular cancer are excellent, although some affected men have persistent paresthesias, Raynaud phenomenon, or infertility. According to the National Cancer Institute, the overall 5-year survival rate from testicular cancer was 95.4% between 2006 and 2012. If the cancer was confined to the testis at the time of diagnosis, the survival rate was 99.3% and dropped only slightly to 96.1% with regional extension. For those with distant metastases, the survival rate was 73.9%.^{49,55} Orchiectomy does not affect sexual function, but infertility can result from chemotherapy or surgical removal of affected abdominal lymph nodes if the nerves necessary for ejaculation are severed. After orchiectomy, testicular silicone implants may be used to restore “normal” scrotal appearance.

TABLE 26.2

TESTICULAR TUMORS OF GERM CELL ORIGIN

CELL TYPES	OCCURRENCE	METASTATIC PATTERN	PROGNOSIS/REMISSION RATE
A. Seminoma (germinoma)	30%–35% of all testicular tumors	Rarely to retroperitoneal lymph nodes	Excellent; tumor usually remains localized and is responsive to radiation; cure rate stages I and II >95%; stages III and IV >80%
B. Nonseminomatous tumors	60% of all testicular tumors		
1. Single cell			
a. Embryonal carcinoma	20%–25% of all testicular tumors; most common testicular tumor in infants and children	Earlier to regional lymphatics; also lung, liver, bone	Good; complete remission rate stages I and II >95%; stages III and IV >70%–80%

b. Teratoma	5%–10% of all testicular tumors (occurs in children and adults)	Through lymphatics and bloodstream; affects same organ systems as embryonal type	Fair
c. Choriocarcinoma	<1% of all testicular tumors	Earliest and widest, initially through bloodstream	Poor; early metastasis
2. Mixed tumors	30%–40% of all testicular tumors		
a. Teratocarcinoma	20%–25% of all testicular tumors	Mixed pattern; depends on cell types	Variable; prognosis becomes that of the most malignant element
b. Other	10%–15% of all testicular tumors	Mixed pattern; depends on cell types	Variable; prognosis becomes that of the most malignant element
i. Teratocarcinoma with seminoma			
ii. Embryonal cancer with seminoma			
iii. Teratoma with seminoma			
iv. Any combination with choriocarcinoma			
3. Non-germ cell tumors (Leydig cell, Sertoli cell, granulosa cell, and thecal cell tumors)	<10%		

Data from American Cancer Society: *Cancer response system document #10029*, New York, 1995, The Society; Cancer Net: *Cancer facts: questions and answers about testicular cancer*, National Cancer Institute, 2000. Available at: <http://www.cancernet.nci.nih.gov>.

Epididymitis

Epididymitis, or inflammation of the epididymis, generally occurs in sexually active young males (younger than 35 years) and is rare before puberty (Fig. 26.12). In young men the usual cause is a sexually transmitted microorganism, such as *N. gonorrhoeae* or *C. trachomatis*. Men who practice unprotected anal intercourse may acquire sexually transmitted epididymitis because of *Escherichia coli*, *Haemophilus influenzae*, tuberculosis (especially in regions where the incidence of pulmonary tuberculosis is high), *Cryptococcus*, or *Brucella*.^{41,42} In men older than 35 years, Enterobacteriaceae (intestinal bacteria) and *Pseudomonas aeruginosa* associated with urinary tract infections and prostatitis also may cause epididymitis. Besides an infectious etiology, epididymitis may result from a chemical inflammation caused by the reflux of sterile urine into the ejaculatory ducts.⁴¹ It is associated with urethral strictures, congenital posterior valves, and excessive physical straining in which increased abdominal pressure is transmitted to the bladder. Chemical epididymitis is usually self-limiting and does not require evaluation or intervention unless it persists.

FIGURE 26.12 Epididymitis Secondary to Gonorrhea or Nongonococcal Urethritis. This infection spread to the testes, and rupture through the scrotal wall is threatened. (From Taylor PK: *Diagnostic picture tests in sexually transmitted diseases*, London, 1995, Mosby-Wolfe.)

The pathogenic microorganism usually reaches the epididymis by ascending the vasa deferentia from an already infected urethra or bladder. The presence of bacteria initiates the inflammatory response, causing symptoms of bacterial epididymitis. Epididymitis caused by heavy lifting or straining results from reflux of urine from the bladder into the vas deferens and epididymis. Urine is extremely irritating to the epididymis and initiates an inflammatory response called *chemical epididymitis*.

◆Clinical Manifestations.

Pain is the main symptom of epididymitis. Scrotal or inguinal pain is caused by inflammation of the epididymis and surrounding tissues. The pain is usually acute and severe. Flank pain may occur if, as the urethra passes over the spermatic cord, edematous swelling of the cord obstructs the urethra. The individual may have pyuria and bacteriuria and a history of urinary symptoms, including urethral discharge. The scrotum on the involved side is red and edematous as a result of inflammatory changes. The tail of the epididymis near the lower pole of the testes usually swells first; then swelling ascends to the head of the epididymis. The spermatic cord also may be swollen and tender.

Complications of epididymitis include abscess formation, infarction of the testis, recurrent infection, and infertility. Infarction probably is caused by thrombosis (obstruction by blood clots) of the prostatic vessels secondary to severe inflammation. Recurrent epididymitis may result from inadequate initial treatment or failure to identify or treat predisposing factors. Chronic epididymitis can cause scarring of the epididymal endothelium. Once scarring has occurred, treatment with antibiotics is ineffective because adequate antibiotic levels cannot be achieved within the epididymis.⁴¹

◆Evaluation and Treatment.

A history of recent urinary tract infection or urethral discharge suggests the diagnosis of epididymitis. The relief of pain when the inflamed testis and epididymis are elevated (Prehn sign) is also

diagnostic. Definitive diagnosis is based on culture or Gram stain of a urethral swab. Epididymal aspiration may be necessary to obtain a specimen, especially if the individual has been taking antibiotics and has sterile urine.

Treatment includes antibiotic therapy for the infection itself (see [Chapter 27](#)). Analgesics, ice, and scrotal elevation can provide symptomatic relief. If the individual does not steadily improve, he should be reevaluated for possible complications, such as abscess formation, sepsis, or continued infection.⁴¹ Bed rest and scrotal elevation are recommended until the scrotum is no longer tender. Scrotal elevation facilitates maximal lymphatic and venous drainage. Abscess formation is rare with antibiotic therapy. If an abscess occurs and persists, it is drained surgically and an orchiectomy may be indicated. Complete resolution of swelling and pain may take several weeks to months. The individual's sexual partner should be treated with antibiotics if the causative microorganism is a sexually transmitted pathogen.

Disorders of the Prostate Gland

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH), also called **benign prostatic hypertrophy**, is the enlargement of the prostate gland ([Fig. 26.13](#)). Because the major prostatic changes are caused by hyperplasia, not hypertrophy, benign prostatic hyperplasia is the preferred term. This condition becomes problematic as prostatic tissue compresses the urethra, where it passes through the prostate, resulting in frequency of lower urinary tract symptoms. The prevalence among U.S. men 60 years and older is about 50% and among men 70 years or older 90%.⁵⁷ BPH is common and involves a complex pathophysiology with several endocrine and local factors and a remodeled microenvironment. Its relationship to aging is well documented. At birth the prostate is pea sized, and growth of the gland is gradual until puberty. A period of rapid development continues until the third decade of life, when the prostate reaches adult size. Around 40 to 45

years of age, benign hyperplasia begins and continues slowly until death. Although dihydrotestosterone (DHT) is necessary for normal prostatic development, its role in BPH remains unclear. Among all androgen-metabolizing enzymes within the human prostate, 5 α -reductase is the most powerful. The level of this reductase positively corresponds to the age-dependent DHT level. Therefore although 5 α -reductase and DHT levels decrease with age in the epithelium, they remain relatively constant in the stroma of the prostate gland.

FIGURE 26.13 Prostate Zones, Benign Prostatic Hyperplasia (BPH), and Prostate Cancer Locations. BPH occurs in the peripheral zone of the prostate gland that can enlarge (not shown). BPH nodules and atrophy are associated with inflammation in the transition zone. Most cancer lesions

occur in the peripheral zone. Carcinoma can involve the central zone but rarely occurs in isolation, suggesting that prostatic intraepithelial neoplasia (PIN) lesions do not easily progress to carcinoma in this region. (Adapted from De Marzo AM et al: *Nat Rev Cancer* 7:256–269, 2007.)

◆Pathophysiology.

Current causative theories of BPH focus on levels and ratios of endocrine factors such as androgens, estrogens, gonadotropins, and prolactin and changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors. These factors include insulin-like growth factors (IGFs), epidermal growth factor, nerve growth factor, fibroblast factors, IGF binding proteins, and transforming growth factor-beta (TGF- β).⁵⁸

Aging and circulating androgens are associated with BPH and enlargement. These factors are predisposed as disrupting the *balance* of growth factor signaling pathways and stromal/epithelial interactions, creating a growth-promoting and tissue-remodeling microenvironment. However, BPH is a multifactorial disease, and not all men respond well to available treatments, suggesting factors other than androgens are involved. Testosterone, the primary circulating androgen in men, also can be metabolized through CYP19/aromatase into the potent estrogen, estradiol-17 β . The prostate is an estrogen target tissue, and estrogens directly and indirectly affect growth and differentiation of the prostate. The precise role of endogenous and exogenous estrogens in directly affecting prostate growth and differentiation in the context of BPH is an understudied area. Estrogens and selective estrogen receptor modulators have been shown to promote or inhibit prostate proliferation, illustrating their potential roles in the development of BPH as therapy.⁵⁹ Taken together, these interactions lead to an increase in prostate volume. The remodeled stroma promotes local inflammation with altered cytokine, reactive oxygen/nitrogen species, and chemoattractants.⁶⁰ The resultant increased oxygen demands of proliferating cells causes a local hypoxia that induces angiogenesis and changes to fibroblasts. Functional and phenotypic changes (transdifferentiation) of fibroblasts to the myofibroblasts is a hallmark of the remodeled

microenvironment.⁵⁸

BPH begins in the periurethral glands, which are the inner glands or layers of the prostate. The prostate enlarges as nodules form and grow (nodular hyperplasia) and glandular cells enlarge (hypertrophy). The development of BPH occurs over a prolonged period, and changes within the urinary tract are slow and insidious.

◆Clinical Manifestations.

Preclinical studies demonstrate that the activation of a chronic inflammatory prostatic response plays an important role in the pathogenesis and progression of BPH and prostate cancer. Approximately 40% to 70% of men with BPH-related lower urinary tract symptoms harbor chronic inflammation at the time of pathologic evaluation.⁵⁸ As nodular hyperplasia and cellular hypertrophy progress, tissues that surround the prostatic urethra usually compress it, but do not always cause **bladder outflow obstruction**. These symptoms are sometimes called the spectrum of lower urinary tract symptoms (LUTSs). Symptoms include the urge to urinate often, a delay in starting urination, and decreased force of the urinary stream. As the obstruction progresses, often over several years, the bladder cannot empty all the urine and the increasing volume leads to long-term urine retention. The volume of urine retained may be great enough to produce uncontrolled “overflow incontinence” with any increase in intraabdominal pressure. At this stage the force of the urinary stream is significantly reduced, and much more time is required to initiate and complete voiding. Hematuria, bladder or kidney infection, bladder calculi, acute urinary retention (hydronephrosis), hydronephrosis, and renal insufficiency are common complications.⁶¹

Some men initially have signs of uremia and renal failure. On digital rectal examination the hyperplastic prostate is a soft or firm enlargement with a smooth mucosal surface and no discernible distinction between lobes; asymmetry is common. The palpated prostate does not always reflect the degree of BPH because a substantial portion of the enlargement is intravesicular.⁶² Thirty

percent of men with mild to moderate symptoms improve with watchful waiting.

◆ Evaluation and Treatment.

Diagnosis is made from a medical history, physical examination, and laboratory tests including urinalysis. Careful review of symptoms is necessary. Digital rectal examination (DRE) and PSA are conducted to determine hyperplasia. Measurement of PSA level alone, however, cannot determine whether symptoms are caused by BPH because the level of PSA is elevated in both BPH and prostate cancer. Annual DREs are used to screen men older than 40 years of age for BPH, sooner in high-risk men.⁶³ If there is marked enlargement of the prostate or if moderate to severe symptoms or complications are present, transrectal ultrasound (TRUS) is used to determine bladder and prostate volume and the presence of residual urine. Urinalysis, measurements of serum creatinine and blood urea nitrogen levels, uroflowmetry, determination of postvoid residual (PVR) urine, pressure-flow study, cystometry, and cystourethroscopy are used to determine kidney and bladder function.⁶¹ BPH has been treated successfully with drugs. α_1 -Adrenergic blockers (prazosin and tamsulosin) are used to relax the smooth muscle of the bladder and prostate. Antiandrogen agents, such as finasteride (Proscar), selectively block androgens at the prostate cellular level and cause the prostate gland to shrink.⁶³ By shrinking the prostate, these drugs have been shown to improve BPH-related symptoms and reduce the risk of future urinary retention and BPH-related surgery. α_1 -Adrenergic blockers do not affect PSA level and have no effect on prostate cancer risk.⁶³

Newer minimally invasive procedures include interstitial laser therapy, transurethral radiofrequency procedure (TUNA), cooled Thermo Therapy, and prostate artery embolization. When necessary, the hyperplastic tissue may be removed surgically to prevent the serious consequences of urethral obstruction. A permanent indwelling catheter is inserted if the individual cannot tolerate surgery. It also should be noted that new techniques in genomics, proteomics, and

epigenetics have led to the discovery of aberrant signaling pathways, novel biomarkers, DNA methylation signatures, and potential gene-specific targets. As such, the ability to risk stratify men with symptomatic benign prostatic hyperplasia, identify those at higher risk for progression, and seek alternative therapies for those in whom conventional options are likely to fail will become the standard of targeted therapy in the future.⁶⁴

Prostatitis

Prostatitis is an inflammation of the prostate. Some degree of prostatic inflammation is present in 4% to 36% of the male population, increasing to 50% in older men. Inflammation is usually limited to a few of the gland's excretory ducts.

Prostatitis syndromes have been classified by the National Institutes of Health as (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory prostatitis (Box 26.5). ABP and CBP are caused mostly by gram-negative Enterobacteriaceae and *Enterococci* species, which originate in the gastrointestinal flora. The most common microorganism is *E. coli*, which is identified in the majority of infections.⁶⁵ *Klebsiella* species, *P. aeruginosa*, and *Serratia* species are common gram-negative cultured microorganisms. Nonbacterial prostatitis (CP/CPPS) syndromes are caused by a cascade of inflammatory, immunologic, neuroendocrine, and neuropathic mechanisms in which the initiating cause is unknown.

Box 26.5

National Institutes of Health Classification of Prostatitis Syndromes

This system, developed for clinical research purposes, can be simplified for use in primary care practice.

Category I, or acute bacterial prostatitis (ABP), is an acute

infection of the prostate and is manifested by systemic signs of infection and a positive urine culture.

Category II, or chronic bacterial prostatitis (CBP), is a chronic bacterial infection in which bacteria are recovered in significant numbers from a purulent prostatic fluid. These bacteria are thought to be the most common cause of recurrent urinary tract infection in men.

Category III, or chronic pelvic pain syndrome (CPPS), is diagnosed when no pathogenic bacteria can be localized to the prostate (culture of expressed prostatic fluid or postprostatic massage urine specimen) and is further divided into IIIa and IIIb. Category IIIa refers to inflammatory CPPS in which a significant number of white blood cells (WBCs) are localized to the prostate, whereas category IIIb is noninflammatory.

Category IV refers to asymptomatic inflammatory prostatitis in which bacteria or WBCs are localized to the prostate, but individuals are asymptomatic.

Bacterial Prostatitis.

Acute bacterial prostatitis (ABP, category I) is an ascending infection of the urinary tract that tends to occur in men between the ages of 30 and 50 years but also is associated with BPH in older men. Infection stimulates an inflammatory response in which the prostate becomes enlarged, tender, firm, or boggy. The onset of prostatitis may be acute and unrelated to previous illnesses or it may follow catheterization or cystoscopy.

Clinical manifestations of acute bacterial prostatitis are those of urinary tract infection or pyelonephritis. Sudden onset of malaise, low back and perineal pain, high fever (up to 40°C [104°F]), and chills is common, as are dysuria, inability to empty the bladder, nocturia, and urinary retention. The individual also may have symptoms of lower urinary tract obstruction, such as a slow, small, “narrowed” urinary stream, which may be a medical emergency. Acute inflammatory

prostatic edema can compress the urethra, causing urinary obstruction. Systemic signs of infection include sudden onset of a high fever, fatigue, arthralgia, and myalgia. Prostatic pain may occur, especially when the individual is in an upright position, because the pelvic floor muscles tighten with standing and the prostate gland is compressed. Some individuals experience low back pain, painful ejaculation, and rectal or perineal pain. Palpation discloses an enlarged, extremely tender and swollen prostate that is firm, indurated, and warm to the touch.

Because ABP is usually associated with a bladder infection caused by the same microorganism, urine cultures disclose its identity. Prostatic massage may express enough secretions from the urethra for direct bacterial examination, but massage may be painful and increases the risk that the infection will ascend to adjacent structures or enter the bloodstream and cause septicemia.

To resolve the infection and control its spread, individuals may require antibiotics. In severe cases, the individual is hospitalized and treated with intravenous antibiotics, followed by oral antibiotics. Analgesics, antipyretics, bed rest, and adequate hydration also are therapeutic. Complications include urinary retention that resolves with antibiotic therapy; prostatic abscess that may rupture into the urethra, rectum, or perineum; epididymitis; bacteremia; and septic shock. Urinary retention requiring drainage is best managed with a suprapubic catheter. Foley catheterization is contraindicated during acute infection.

Chronic bacterial prostatitis (CBP, category II) is characterized by recurrent urinary tract symptoms and persistence of pathogenic bacteria (usually gram negative) in urine or prostatic fluid. This form of prostatitis is the most common recurrent urinary tract infection in men. Symptoms may be similar to those of an acute bladder infection, such as frequency, urgency, dysuria, perineal discomfort, low back pain, myalgia, arthralgia, and sexual dysfunction. The prostate may only be slightly enlarged or boggy but it may be fibrotic because repeated infections can cause it to be firm and irregular in shape.

When the initial urine sample is bacteria-free, prostatic massage is

used to express secretions. Subsequently, the first 10 mL of voided urine is collected and examined microscopically. Prostatic secretions showing more than 10 white blood cells (WBCs) per high-power field and macrophages containing fat are indicative of bacterial infection; diagnosis is confirmed by culture. A pelvic x-ray or TRUS may show prostatic calculi.

Treatment of chronic bacterial prostatitis is difficult because it is often caused by prostatic calculi. Calculi are silent and are found in up to 50% of men with prostatitis, and infected calculi can serve as a source of bacterial persistence and relapsing urinary tract infection.⁶⁶ Calculi harbor pathogens within the stone, and consequently pathogens cannot be eradicated from the urinary tract. Permanent cure is achieved by surgical intervention.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome.

Chronic prostatitis/chronic pelvic pain syndrome (CPPS, category III) is diagnosed when no pathogenic bacteria can be localized to the prostate and is further divided into subcategories IIIa and IIIb (see [Box 26.5](#)). Category IIIa refers to inflammatory chronic pelvic pain syndrome where WBCs are elevated and localized to the prostate. Symptoms tend to be milder but are persistent and annoying. Presumably, noninfectious prostatitis or pain is caused by reflux of sterile urine into the ejaculatory ducts because of high-pressure voiding.⁶⁵ Reflux may be triggered by spasms of the external or internal sphincters. Category IIIb is noninflammatory; in category IV, individuals are asymptomatic but have an increase in the number of bacteria and WBCs localized to the prostate. Microorganisms suspected of causing CP/CPPS include *E. coli*, *Enterobacter*, *P. aeruginosa*, and *Helicobacter pylori*, a new suspect.⁶⁵

Men with **nonbacterial prostatitis** may complain of pain or a dull ache that is continuous or spasmodic in the suprapubic, infrapubic, scrotal, penile, or inguinal area. Other symptoms are pain on ejaculation and urinary symptoms, such as frequency of urination. The prostate gland generally feels normal on palpation.

Nonbacterial prostatitis is a diagnosis of exclusion. Digital

examination of the prostate, bacterial cultures of the urogenital tract, microscopic examination of expressed prostatic fluid, urethroscopy, and urodynamic studies are used to verify the diagnosis of nonbacterial prostatitis.

There is no generally accepted treatment for nonbacterial prostatitis. Hot sitz baths, bed rest, alpha-blockers, anticholinergics, and antiinflammatory drugs can relieve symptoms.

Cancer of the Prostate

Prostate cancer is the most commonly diagnosed non-skin cancer in men in the United States, with a lifetime risk for diagnosis currently estimated at 15.9%, according to the 2012 United States Preventive Services Task Force screening recommendation document.⁶⁷ The incidence varies greatly worldwide⁶⁸ (Fig. 26.14), but it is still considered to be the second most frequently diagnosed cancer and the sixth leading cause of death worldwide. Importantly, incidence rates vary by more than 25-fold worldwide, and the highest rates recorded mostly in developed countries include Oceania, Europe, and North America, largely because of the wide use or overuse of PSA testing.⁶⁹ Screening with PSA can amplify the incidence of prostate cancer by allowing detection of prostate lesions that although meeting the pathologic criteria for malignancy, may have low potential (e.g., latent, indolent, preclinical) for growth and metastasis. In countries with higher use of PSA testing, such as the United States, Canada, Australia, and the Nordic countries, trends in incidence rates follow similar patterns.⁶⁸

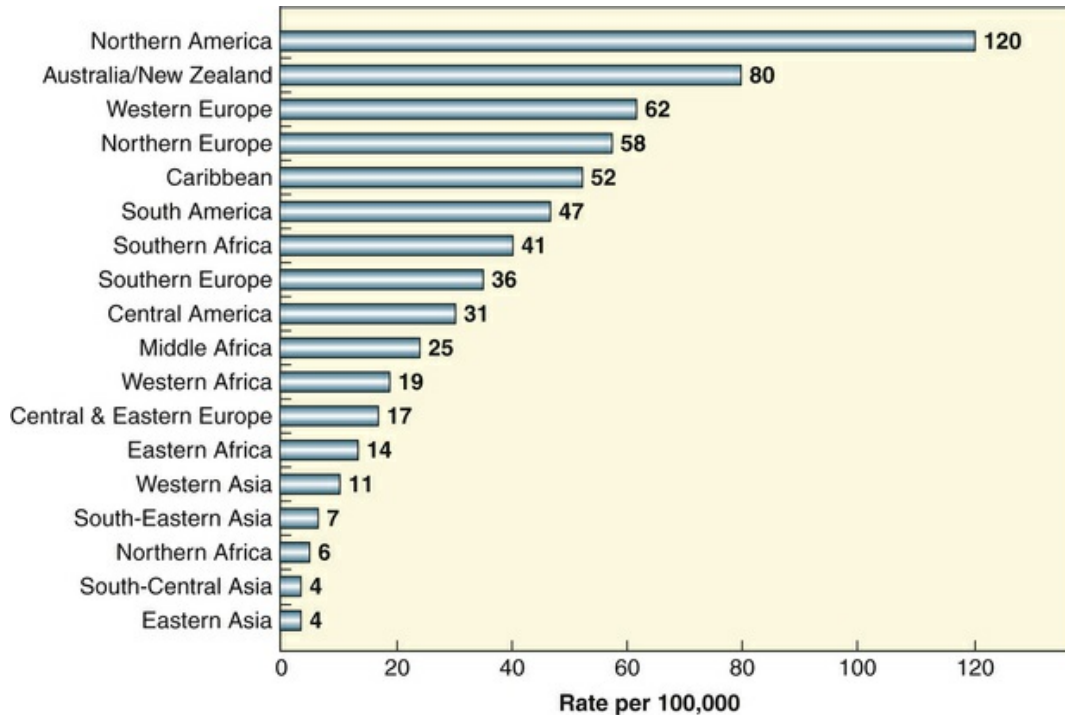

FIGURE 26.14 Selected World Population Age-Standardized (to the World Population) Incidence Rates of Prostate Cancer. (Modified from Jemal A et al: *Biomark Prev* 19:1893, 2010.)

Different from Western countries, incidence and mortality rates are rising in several Asian (including Japan) and Central and Eastern European countries.⁶⁹ Death rates have been decreasing in several countries including Australia, Canada, the United Kingdom, the United States, Italy, and Norway, in part from improved treatment. Males of African descent in the Caribbean have the highest mortality rates from prostate cancer in the world. Most cases of prostate cancer have a good prognosis even without treatment but some cases are aggressive; the lifetime risk for dying of prostate cancer is 2.8%. Prostate cancer is rare before age 50 years and very few men die from it before 60 years of age. Indeed, more than 75% of all prostate cancer is diagnosed in men older than 65.⁶⁷ With aging, most of the androgen-metabolizing enzymes undergo significant alteration and older age, race (black), and family history remain the well-established risk factors.⁶⁹

Dietary Factors.

Although evidence exists for a dietary role in prostate cancer, the

epidemiologic evidence is inconsistent. The problem has been confounded by a lack of biomarkers for certain nutrients, difficulties in measuring and quantifying diet, and a limitation of clinical trials to study diet over time. Important are the effects of diet on signaling pathways, hormones, oxidative stress, and reactive oxygen species (ROS). The nutrients in the epidemiology of prostate cancer that have received the most attention include carotenoids, fat, vitamin E, vitamin D/calcium, and selenium. Less studied are isoflavones, curcumin, lycopene, zinc, green tea, omega-3 polyunsaturated fats, and sulforaphane (see [Nutrition & Disease: Diet for Prostate Cancer](#)). Associations between obesity and prostate cancer are not clear, with some research inconsistencies, but obesity seems to be negatively associated with more indolent prostate cancer and positively associated with more aggressive disease and a worse outcome.^{70,71} In process is a randomized clinical trial of diet and early-stage prostate cancer, Men's Eating and Living Study (MEAL). The hypothesis for MEAL is that a change in diet from a high intake of animal products to the consumption of more fruits and vegetables will slow the progression of the indolent form to the aggressive form of prostate cancer.⁷¹ Likewise, a recent systematic review found that physical activity does not significantly reduce the risk of prostate cancer; however, the authors noted that vigorous exercise may reduce the risk of an aggressive tumor.⁷⁰ Because adipose tissue is increasingly being regarded as hormonally active tissue, high body fat and obesity need in-depth exploration to understand the associated risk of prostate problems. Adipose tissue is now known to affect circulating levels of several bioactive messengers and therefore could affect the risk of developing prostate problems in addition to several other well-recognized health problems.⁷² High energy intake (consumption of excess calories) indicates that this may indeed increase insulin levels and insulin-like growth factor 1 (IGF-1), a powerful carcinogenic agent⁷³ (see [Pathophysiology](#)). A meta-analysis found IGF-1 as a *potential* mechanism for the associations between milk intake and prostate cancer risk.⁷⁴ Investigators suggest a positive association between high-fat milk intake and prostate cancer progression among

individuals diagnosed with localized prostate cancer.⁷⁵ Although epidemiologic studies have revealed some dietary factors modulate the risk of advanced prostate cancer,⁷⁶ there is a lack of definitive evidence supporting the preventive role of diet against prostate cancer. More robust, high-quality research trials are needed to guide understanding of the complex relationship between diet and prostate cancer.

Nutrition & Disease

Diet for Prostate Cancer

- Epidemiologic studies have found total fat intake, animal and saturated fat, red meat, and dairy products are associated with an increase in prostate cancer risk.
- Obesity is linked to advanced and aggressive prostate cancer.
- High body mass index (BMI) is associated with more aggressive disease and a worse outcome.
- Calorie-dense or excessive carbohydrate intake and obesity, independent of dietary fat intake, may increase the risk of developing prostate cancer.
- Dietary fat may increase androgens, increase oxidative stress, and increase reactive oxygen species (ROS).
- Monounsaturated fats may decrease the risk of prostate cancer.
- High levels of linoleic acid (e.g., found in corn oil; safflower) tend to act as a proinflammatory eicosanoid, which is implicated in promotion of cell proliferation and angiogenesis as well as inhibition of apoptosis.
- The Western diet has increased omega-6/omega-3 ratios and therefore is proinflammatory.
- Cooking meat at high temperatures produces heterocyclic amines and aromatic hydrocarbons that are carcinogenic.
- A pooled analysis of 15 prospective cohort studies did not

support a strong role of fruits, vegetables (including cruciferous vegetables and tomato products [few studies assessed tomato sources of more bioavailable lycopene]) or mature beans in prostate cancer. The MEAL (The Men's Eating and Living) Study, a randomized trial of diet to alter disease, is assessing a diet-based intervention to increase vegetable and fruit consumption to see if it can slow prostate cancer progression for men with low-grade prostate cancer.

- A systematic review and meta-analysis concluded that IGF-1 is a potential mechanism underlying observed associations between milk intake and prostate cancer risk.
- Carcinogenic nitrosamines are formed after consumption of processed meat that contains nitrites and from heme iron present in large quantities of red meat.
- Vitamin E has long been considered a candidate for prostate cancer prevention from in vitro and in vivo animal studies. Vitamin E belongs to the family of tocopherols and tocotrienols that exist as α , β , γ , and δ isoforms. Among these, δ -tocopherol is the major dietary isoform, whereas supplements contain α -tocopherol. Vitamin E is a fat-soluble vitamin obtained from vegetable oils, nuts, and egg yolk. It is a potent intracellular antioxidant known to inhibit peroxidation and DNA damage. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) Study showed supplementation with vitamin E could reduce the incidence of prostate cancer among men who smoked. In vitro studies demonstrate that γ -tocopherol and δ -tocopherol induce cell cycle arrest in human prostate cancer cells (i.e., induce apoptosis) and inhibit the androgen receptor. Mouse studies show vitamin E can inhibit the growth-promoting effects of a high-fat diet; however, vitamin E in combination with selenium does not reduce the incidence of prostate cancer in lady mice models. In the prospective large clinical trial SELECT, the study found no apparent benefit of administering vitamin E.
- Selenium is a trace mineral and exists in food as

selenomethionine and selenocysteine. It is essential for the functioning of many antioxidant enzymes and proteins in the body. Humans receive selenium in their diet through plant (dependent on soil concentrations) and animal products. Several large prospective studies reported 50% to 65% reductions in prostate cancer risk with high levels versus low levels of selenium as measured in toenails and plasma. The Nutritional Prevention of Cancer (NPC) trial reported a 50% reduction in risk of developing prostate cancer. No potential benefit was found in the SELECT trial, whereas a small insignificant increase was noted for type 2 diabetes. From these two trials, two different forms of selenium were used—the NPC trial used selenized yeast and the SELECT trial used selenomethionine. A meta-analysis of 12 studies with 13,254 subjects and 5007 cases of prostate cancer showed that the risk of prostate cancer decreased with increasing plasma/serum selenium up to 170 ng/mL. Selenium has several modes of action depending on its form. Selenomethionine inhibits cell proliferation and induces cell cycle arrest of human prostate cells (i.e., apoptosis) and inhibits angiogenesis mediated in part by the androgen receptor. This also is true of methylseleninic acid. Sodium selenite's anticancer effects are mediated through cellular antioxidants, leading to increased apoptosis and sensitizing cells to radiation-induced killing. Selenium and its derivatives can activate both intrinsic and extrinsic pathways of apoptosis. Selenium intervention may depend on individual genotype.

- Vitamin D may play an important role in prostate cancer prevention.
- Soy contains isoflavones purported to have anticancer properties including inhibition of cell proliferation and angiogenesis and reduction in prostate-specific antigen (PSA) and androgen receptor levels.
- Tomatoes or tomato products ingested daily seem to reduce prostate cancer risk. In vitro studies show lycopene inhibits

DNA strand breaks. Unresolved is whether lycopene itself or a metabolic product is responsible for its biologic effect. In clinical studies, tomato paste, which is high in lycopene, reduced plasma PSA levels in those men with benign prostatic hyperplasia. Lycopene administration is associated with cell cycle arrest (apoptosis) and growth factor signaling. In 2007 the U.S. Food and Drug Administration (FDA) evaluated 13 available studies and found the relationship between lycopene and reduced risk of prostate cancer inadequate. A Cochrane review found that given only three randomized controlled trials were included in the analysis and a high risk of bias was found in two, there is insufficient evidence to support or refute lycopene for the prevention of prostate cancer.

- Vegetables including broccoli, cabbage, cauliflower, brussels sprouts, Chinese cabbage, and turnips (all crucifers) may be protective (several epidemiologic studies) against prostate cancer. In particular, a diet high in broccoli reduced cancer risk. By contrast, four studies revealed no cancer preventive effects. Crucifers have anticancer properties mediated by the phytochemicals phenethyl isothiocyanate, sulforaphane, and indole-3-carbinol. Sulforaphane is a naturally occurring isothiocyanate that was first isolated in broccoli. It protects against carcinogen-induced cancer in many rodents. Mice given 240 mg of broccoli sprouts per day showed a significant reduction in growth of prostate cancer cells. Sulforaphane treatment lowered androgen receptor protein and gene expression.
- Green tea contains polyphenols, including epigallocatechin gallate (EGCG). Green tea consumption has been associated with a reduced incidence of several cancers including prostate cancer. Green tea consumed within a balanced controlled diet in humans improved overall antioxidant potential. The anticancer effect potential of green tea from in vitro and experimental studies shows polyphenols bind directly to carcinogens and induce phase II enzymes that inhibit

heterocyclic amines. EGCG administration decreased NF- κ B activity. Green tea was shown to inhibit IGF-1 and increase IGFBP3, leading to inhibition of prostate cancer development and progression. Yet, in two small randomized studies in individuals with high-grade prostatic neoplasia, it showed no effects. In a population prospective large study ($n = 27,293$), green tea did not protect against prostate cancer and black tea showed a positive association with prostate cancer.

- Curcumin has anticarcinogenic potential with well-characterized antiinflammatory, antiangiogenic, and antioxidant properties. Recent studies report curcumin modulates the wingless signaling pathway (Wnt) that supports its antiproliferative potential.
- Overall, multiple signaling pathways are involved in prostate cancer development and progression, many of which are affected by dietary and lifestyle factors.

Data from Astorg P: *Cancer Causes Control* 15:367–386, 2004; Beier R et al: *EMBO J* 19(21):5813–5823, 2000; Dagnelie PC et al: *BJ Int* 98(8):1139–1150, 2004; Demark-Wahnefried W, Moyad MA: *Curr Opin Urol* 17:168–174, 2007; Freedland SJ, Aronson WJ: *Urology* 65:433–439, 2005; Giovannucci E et al: *Int J Cancer* 121:1571–1578, 2007; Greenwald P: *J Nutr* 234(12 suppl):3507S–3512S, 2004; Harrison S et al: *Cancer Causes Control* 28(6):497–528, 2017; Hill P et al: *Cancer Res* 39:5101–5104, 1979; Hurst R et al: *Am J Clin Nutr* 96(1):111–122, 2012; Khan N, Mukhtar H: *Biochem Pharmacol* 85(5):667–672, 2014; Kim DJ et al: *Cancer Causes Control* 11:65–77, 2000; Kobayashi N et al: *Clin Cancer Res* 12(15):4660–4670, 2006; Kolonel LN: *Epidemiol Rev* 23:72–81, 2001; Llic D, Forbes KM, Hased C: *Cochran Database Syst Rev* (11):CD008007, 2011; Lloyd JC et al: *J Urol* 183:1619–1624, 2010; Matsumura K et al: *Anticancer Res* 28:709–714, 2008; Montague JA et al: *Cancer Causes Control* 23(10):1635–1641, 2012; Ngo TH et al: *Cancer Causes Control* 13:929–935, 2002; Ngo TH et al: *Clin Cancer Res* 9:2734–2743, 2003; Ni J, Yeh S: *Vitam Horm* 76:493–518, 2007; Parsons JK et al: *BJU Int* 2017 Apr 24, [Epub ahead of print]; Petimar J et al: *Cancer Epidemiol Biomarkers Prev* 2017 Apr 26, [Epub ahead of print]; Rodriguez C et al: *Cancer Epidemiol Biomarker Prev* 16:63–69, 2007; Sinha R et al: *Am J Epidemiol* 170:1165–1177, 2009; Teiten M et al: *Int J Oncol* 38:603–611, 2011; Yang CD, Suh N, Kong AN: *Cancer Prev Res (Phil)* 5(5):701–705, 2012.

Hormones.

Prostate cancer develops in an androgen-dependent epithelium and is usually androgen sensitive. Androgens are synthesized not only in the

testis, accounting for 50% to 60% of the total testosterone in the prostate, but also in the prostate gland itself. In a process called **intraprostatic conversion**, the hormone dehydroepiandrosterone (DHEA) produced by the adrenal glands^{77,78} is converted to testosterone and then into DHT in the prostate (Fig. 26.15). Additionally, prostate cancer cells have been reported to make androgens from cholesterol (i.e., de novo).⁷⁹ However, these overall relative contributions from intratumoral sources remain to be determined. Population studies have not, however, provided clear and convincing patterns involving associations between circulating hormone concentrations (e.g., not tissue concentrations) and prostate cancer risk.⁸⁰⁻⁸² A recent case-control study found the risk of aggressive prostate cancer was strongly inversely associated with estradiol/testosterone ratios and positively associated with 2-hydroxyestrone/16 α -hydroxyestrone ratios.⁸³ These findings suggest that sex steroid hormones, specifically the estrogen-androgen balance, may be important in the development of aggressive prostate cancer.⁸³ Thus there is universal agreement that androgens are important for prostatic growth, development, and maintenance of tissue balance but their role in cancer is still controversial. As such, it also has been hypothesized that reducing the concentration of active hormones in the systemic circulation may be insufficient to block cancer progression, because this action selects for tumor cells that can generate active steroids from circulating precursors.^{77,84} Evidence for involvement of 5 α -reductase activity, which is critical in androgen activity in the prostate, is contradictory and inconsistent^{80,82} (see Fig. 26.15). A prevention study has provided some of the strongest hormonal data with the drug finasteride, which inhibits 5 α -reductase. The 7-year intervention study reduced prostate cancer risk in healthy men by about 25%.⁸⁵ Important, however, was that more high-grade tumors were found in those men who developed prostate cancer while taking the drug. In men younger than 50 years, circulating levels of androgens and estrogens appear to be higher in men of African descent than in European-American men.

FIGURE 26.15 Sources of Androgens and Aromatase and Estrogen Signaling in the Prostate. **A**, Body sources of androgens in the prostate gland. Hypothalamic GnRH causes the release of LH from the anterior pituitary gland. LH stimulates the testes to produce testosterone, which then accumulates in the blood. Pituitary ACTH release stimulates the adrenal glands, which secrete the androgen precursor DHEA into the blood. DHEA is converted into testosterone and then into DHT in the prostate. **B**, Aromatase and estrogen signaling in the prostate. In normal and benign tissue, aromatase is expressed within the stroma and regulated by promoter PII. Estrogen then exerts its effects in an autocrine fashion through the stromal ER- α receptor and also in a paracrine fashion through both ER- α and ER- β receptors. With prostate cancer, aromatase is now expressed within the tumor cells and in stromal cells, and regulated by aromatase promoters 1.3, 1.4, and PII. Thus estrogen exerts its effects in an autocrine way through stromal and epithelial ER- α and ER- β . Consequently, the increased levels of estrogen and abnormal ER- α signaling promote inflammation, which increases aromatase expression and the development of a positive feedback cycle. Inflammation drives aromatase expression, thus increasing estrogen, which in turn promotes further inflammation. *ACTH*, Adrenocorticotropic hormone; *DHEA*, dehydroepiandrosterone; *DHT*, dihydrotestosterone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone. (A Adapted from Labrie F: *Nat Rev Urol* 8:73–80, 2011; B from Ellem SJ, Risbridger GP: *J Steroid Biochem Mol Biol* 118[4–5]:246–251, 2010.)

Despite the well-documented importance of androgens, their pathophysiologic process in prostate diseases is incomplete.^{82,84} Identifying cellular signaling pathways that become corrupted and facilitate metastases in the presence of androgens is the focus of recent work. Investigators suggest that inhibition of CXCR7 (chemokine receptor 7) function might decrease metastatic potential by altering cell motility.⁸⁶ Androgens also are metabolized to estrogens (see [Figs.](#)

26.17 and 25.37) through the action of the enzyme aromatase, and a growing body of evidence implicates estrogens (estrogen receptor-mediated effects, estrogen metabolites, and estrogen genotoxicity) in the etiology of prostate disease (see [Pathophysiology under Prostate Cancer](#)). Importantly, the aberrant expression of aromatase has been implicated in other tissues, such as the breast and endometrium.⁸⁴

Only a few associations with prostate cancer risk have been observed consistently (in at least three studies), and their associations are weak: (1) slightly higher circulating testosterone and estrogen levels and lower DHEA (sulfate) levels in high-risk black men as compared with lower-risk European-American men; and (2) a cytosine-adenine-guanine (CAG) repeat-length polymorphism in the androgen receptor gene associated with increased risk and increased receptor activity (androgen receptor). Moreover, in a more recent collaborative analysis of existing worldwide epidemiologic data (18 prospective studies), the Endogenous Hormones and Prostate Cancer Collaborative Group found no associations between the risk of prostate cancer and serum concentrations of testosterone, calculated free testosterone, dihydrotestosterone, dehydroepiandrosterone sulfate, androstenedione, androstanediol glucuronide, estradiol, or calculated free estradiol.⁸⁷

As the results of the above-mentioned Endogenous Hormones and Prostate Cancer Collaborative Group suggest, investigations directed at understanding the hormonal basis of prostate carcinogenesis have numerous problems. Understanding the complexities of interacting hormones and differentiating the effects of a single hormone are profound. In addition, only single *blood* samples are generally available; *tissue* hormone samples important for paracrine signaling are not consistently measured, and within-subject variations over time and differences in circadian rhythms cannot be adequately measured. The results of several animal studies do support elevation of the levels of bioavailable and bioactive androgens in the circulation and in target tissue as an important risk factor. Animal studies also indicate that increased biologic activity of the androgen receptor may be associated with prostate cancer. See the [Pathophysiology](#) section for

prostate cancer for a more thorough discussion of the role of hormones in the pathogenesis of prostate cancer.

Vasectomy.

Vasectomy has been identified as a possible risk factor for prostate cancer in case-controlled and cohort studies.⁸⁸⁻⁹⁰ Three mechanisms by which vasectomy could increase risk are (1) elevation of the levels of circulating androgens; (2) immunologic mechanisms involving anti-sperm antibodies; and (3) reduction of seminal fluid levels of 5 α -dihydrotestosterone, the active metabolite of testosterone in the prostate, in vasectomized men. These results suggest an elevation of circulating free testosterone level following vasectomy. However, with these combined mechanisms it is unlikely that vasectomy plays a causal role.⁹¹ In fact, a recent systematic review and meta-analysis of cohort studies indicated that vasectomy may not contribute to the risk of prostate cancer.⁹²

Chronic Inflammation.

Data from the Medical Therapy of Prostatic Symptoms (MTOPS) study suggest the risk of BPH progression and acute urinary retention is greater in men with prostatic inflammation.^{93,94} Preclinical studies have claimed that inflammatory mediators are involved in prostate cancer development and, therefore, suggested these as attractive targets for intervention. However, among the many proinflammatory mediators, there is no consensus regarding the identity of the primary one(s).^{95,96} In a 5-year longitudinal study of the influence of chronic inflammation on prostate cancer, 33 of 144 men presented with chronic inflammation in their initial biopsy.⁹⁷ The investigators also found prostatic hyperplasia and proliferative inflammatory atrophy in those with chronic inflammation. Upon repeat biopsy, 29 new cancers were diagnosed, representing a new cancer incidence of 20%.⁹⁷ In contrast, of the 33 men initially showing no inflammation, 2 (6%) were found to have adenocarcinoma. Certain metabolic comorbidities, including obesity, diabetes, sleep apnea, and erectile dysfunction, may be linked to both BPH and inflammation.⁹⁸ The causes of chronic

inflammation are unknown (possible causes are shown in Fig. 26.16). Thus chronic inflammation may be an important risk factor for prostatic adenocarcinoma.

FIGURE 26.16 Possible Causes of Prostate Inflammation. A, Infection, including viruses, bacteria, fungi, and parasites. B, Hormones, for example, estrogen at key times during development. C, Physical trauma, any type of blunt physical injury. D, Urine reflux. E, Certain dietary factors (see text).

Genetic and Epigenetic Factors.

Other possible causes are genetic predisposition (familial and hereditary forms). Genetic studies suggest that strong familial predisposition may be responsible for 5% to 10% of prostate cancers.¹ Compared with men with no family history, those with one first-degree relative with prostate cancer have twice the risk and those with

two first-degree relatives have 5 times the risk.⁹⁹ Germline mutations in the breast cancer predisposition gene 2 (*BRCA2*) are the genetic events known to date that confer the highest risk of prostate cancer (8.6-fold in men ≤65 years). Although the role of *BRCA2* and *BRCA1* in prostate tumorigenesis remains unrevealed, deleterious mutations in both genes have been associated with more aggressive disease and poor clinical outcomes.¹⁰⁰ The strongest predictors are the *BRCA2* mutations and the highly penetrant G84E mutation in *HOXB13*.¹⁰¹ Men with *BRCA2* germline mutations have a 20-fold increase in risk for prostate cancer.¹⁰² Using previously estimated population carrier frequencies, investigators have recently found that deleterious *BRCA1* mutations confer a relative risk of prostate cancer of approximately 3.75-fold, translating to an 8.6% cumulative risk by age 65.¹⁰³ A common type of somatic mutation that gives rise to chromosomal rearrangements is the *ETS* gene. The most common epigenetic alteration in prostate cancer is hypermethylation of the glutathione S-transferase (*GST-P1*) gene. This gene is located on chromosome 11 and is part of the pathway that helps protect against carcinogen damage. More than 30 independent peer-reviewed studies have reported a consistently high sensitivity and specificity of *GST-P1* hypermethylation in prostatectomy or biopsy tissue.¹⁰⁴ A number of other epigenetic modifications found on tumor-suppressor genes include *PTEN*, *RB*, *p16/INK4α*, *MLH1*, *MSH21*, and *APC*.^{105,106} There is no clear evidence of a causal link between BPH and prostate cancer even though they may often occur together. Variations in several other genes related to inflammatory pathways might affect the probability of developing prostate cancer. The presence of multiple risk alleles is more highly predictive than a single allele.^{102,107}

◆Pathophysiology.

More than 95% of prostatic neoplasms are histologically similar to adenocarcinomas and rely on androgen-dependent signaling for their development and progression.¹⁰⁸⁻¹¹⁰ Most of these neoplasms occur in the periphery of the prostate. Prostatic adenocarcinoma is a heterogeneous group of tumors with a diverse spectrum of molecular

and pathologic characteristics, and therefore clinical behaviors and challenges.¹¹¹ The biologic aggressiveness of the neoplasm appears to be related to the degree of differentiation rather than the size of the tumor (Box 26.6).

Box 26.6

Determining the Grade of Prostate Cancer With the Gleason Score

Grade 1: The cancer cells closely resemble normal cells. They are small, uniformly shaped, evenly spaced, and well differentiated (i.e., they remain separate from one another).

Grade 2: The cancer cells are still well differentiated, but they are arranged more loosely and are irregular in shape and size. Some of the cancer cells have invaded the neighboring prostate tissue.

Grade 3: This is the most common grade. The cells are less well differentiated (some have fused into clumps) and are more variable in shape.

Grade 4: The cells are poorly differentiated and highly irregular in shape. Invasion of the neighboring prostate tissue has progressed further.

Grade 5: The cells are undifferentiated. They have merged into large masses that no longer resemble normal prostate cells. Invasion of the surrounding tissue is extensive.

Hormonal Levels.

Just as the testicles are the male equivalent of the female ovaries, the prostate is the male equivalent of the female uterus; in both situations, they originate from the same embryonic cells. This may be important in understanding the role of the associated hormones testosterone (T), DHT, and estrogens in prostate carcinogenesis. Testicular testosterone

synthesis and serum testosterone levels usually fall as men age, however, the levels of estradiol do not decline.¹¹² The relationship between hormones and the pathophysiology of prostate carcinogenesis is incomplete and controversial. The main issues and controversies include (1) the sources of androgen production outside of the testes, or extratesticular sources (e.g., from adrenal DHEA and from prostate cholesterol [de novo], itself); (2) the role of prostatic androgen receptor (AR); (3) the role of estrogens (e.g., genotoxicity), aromatase enzyme, and the estrogen receptors (ERs) ER- α and ER- β ; and (4) the role of the surrounding microenvironment or stroma.

The hormone concentrations in prostate tissue are important, and there is little evidence that circulating hormone levels are associated with future risk of prostate cancer.^{81,113,114} Testicular testosterone provides the main source of androgens in the prostate (see Fig. 26.15) and is the major circulating androgen, whereas DHT predominates in prostate tissue and binds to the AR with greater affinity than does T.^{115,116} The adrenal cortex contributes the far less potent DHEA that promotes synthesis of androgens in the prostate. In the target tissues and, to a lesser extent, in the testes themselves, testosterone is converted to DHT by the enzyme 5 α -reductase (Fig. 26.17). Thus DHT is the most potent intraprostatic androgen. About half of circulating testosterone is bound to sex hormone-binding globulin (SHBG), about half binds to albumin, and about 1% to 2% exists in a free state. Free testosterone, including testosterone disassociated from albumin and possibly SHBG, enters the prostate cell, where it is converted to DHT.^{115,116} DHT is a paracrine hormone because it affects the local environment or stroma. Several intraprostatic enzymes encoded by genes, *HSD3A* and *HSD3B*, are activated by DHT and are important components of intraprostatic androgen regulation.

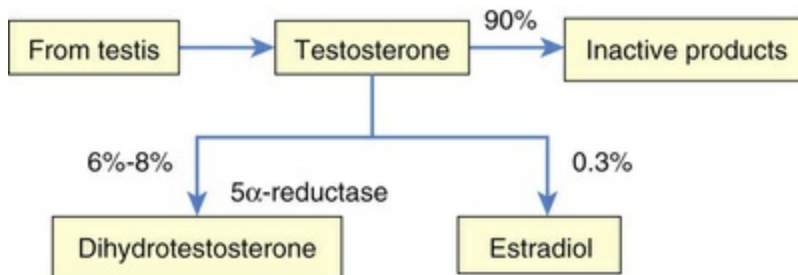

FIGURE 26.17 Testosterone and Conversion to Dihydrotestosterone (DHT).

One mechanistic effect of estrogen is determined by the two receptors ER- α and ER- β . ER- α leads to abnormal proliferation, inflammation, and the development of premalignant lesions. Increased expression of ER- α has been found to be associated with prostate cancer progression, metastasis, and the so-called castration-resistant (medical treatment that suppresses androgens) phenotype.¹¹⁷ A specific oncogene is regulated by ERs, and those hormones that stimulate the ER- α receptor–like (i.e., agonists) endogenous estrogens can stimulate oncogene expression.¹¹⁸ In contrast, ER- β leads to antiproliferative and antiinflammatory effects, differentiation and maturation of prostatic epithelial cells, and potentially anticarcinogenic effects that act in concert or balance the actions of ER- α and androgens.^{115,119}

Normally a small amount of estrogen is produced per day—estrone and estradiol—by the aromatization of androstenedione and testosterone, respectively. This reaction is catalyzed by the aromatase enzyme system. A small quantity of estradiol is released by the testes (see Fig. 26.17); the remainder of the estrogens in males is produced by adipose tissue, liver, skin, brain, and other nonendocrine tissue. Thus testosterone is a precursor of the two hormones DHT and estradiol.

Studies show aromatase is expressed in stromal tissue in the benign human prostate gland. Thus it appears that both normal prostate and benign prostate have the capacity to locally metabolize androgens to estrogens through aromatase. Investigators have demonstrated altered aromatase expression in prostate cancer^{120,121} (see Fig. 26.15, B). Data, mostly from animal studies, suggest that for androgens to cause

prostate cancer they must be aromatized to estrogen and act in concert with these estrogen metabolites. The androgen receptor–mediated activity of androgens and the estrogen receptor–mediated effects of estrogen metabolites are likely to be necessary, but estrogen genotoxicity appears to be a probable critical factor as well. Prostate carcinogenesis can occur only when all these mechanisms are active.⁸¹

The effects of progesterone are underinvestigated. Stromal progesterone/PR signaling may play a role in prostate cancer development and progression.¹²²

Chronic exposure to arsenic, as well as estrogen, is a known risk factor for prostate cancer. Though the evidence suggests that exposure to arsenic or estrogens can disrupt normal DNA methylation patterns and histone modifications, the mechanisms by which these chemicals induce epigenetic changes are not fully understood. Moreover, the epigenetic effects of coexposure to these two chemicals are not well-known. Investigators have revealed that exposure to arsenic, estrogen, and their combination alters the expression of epigenetic regulatory genes and changes global DNA methylation and histone modification patterns.¹²³

Most of the androgen-metabolizing enzymes undergo a significant age-dependent alteration. In epithelium, both the 5α -reductase activity and the DHT level decrease with age, whereas in stroma (prostate) not only the 5α -reductase activity but also the stromal DHT level is rather constant over the lifetime. In contrast to the relatively unaltered DHT level over time, the estrogen concentration follows an age-dependent increase. Thus the age-dependent decrease of the DHT accumulation in epithelium and the concomitant increase of the estrogen accumulation in stroma lead to a tremendous increase with age of the estrogen/androgen ratio in the human prostate. In animal studies, chronic exposure to testosterone plus estradiol is strongly carcinogenic, whereas testosterone alone is weakly carcinogenic.^{80,81} In mice studies elevated testosterone level in the absence of estrogen leads to the development of hypertrophy and hyperplasia but not malignancy. High estrogen and low testosterone levels have been shown to lead to inflammation with aging and the emergence of

precancerous lesions.¹²⁰ The mechanism is not clearly understood and may involve estrogen-generated oxidative stress and DNA toxicity, and it requires androgen-mediated and estrogen receptor-mediated processes, such as changes in sex steroid metabolism and receptor status.⁸⁰ In addition, there are changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors, such as the insulin-like growth factors (IGFs).¹²⁴ When exogenous estradiol is added to testosterone treatment of rats, prostate cancer incidence is markedly increased, and even a short course of estrogen treatment results in a high incidence of prostate cancer.⁸⁰

Androgen Receptor Signaling.

The androgenic hormone responses in the normal prostate and in prostate cancer are mediated by AR signaling. Exactly how AR drives the growth of prostate cancer cells is not fully known. Several mechanisms have been suggested,^{125,126} and specific pathways of signaling are important because they can provide novel therapeutic targets. A study using animal models found that loss of androgen receptor function prevented prostatic carcinogenesis, malignant transformation, and metastasis. Tissue-specific evaluation of androgen hormone action demonstrated that epithelial androgen receptor was not necessary for prostate cancer progression, whereas stromal androgen receptor was essential for prostate cancer progression, malignant transformation, and metastasis.¹²⁷⁻¹³⁰

Changes in AR signaling in the surrounding stroma can significantly affect tumor cell behavior.¹³¹ Emerging is the mechanism of AR function in prostate stroma. In the benign prostate, the chief stromal cells are smooth muscle cells and a majority express AR. In tumor stroma, the chief stromal cells are myofibroblasts.¹³¹ Recent work involves the identification of AR signaling in fibroblasts/myofibroblasts in prostate stroma.¹³¹ Key is the role of mesenchymal hormone signaling in the development of both male and female reproductive organs, with expression of the appropriate hormone receptors in adjacent stroma necessary for organ-specific

responses to estrogen, progesterone, and testosterone.¹³²⁻¹³⁴ Stromal AR activity has been investigated in animal models in early-stage cancer and AR signaling in tumor formation. Evidence supports stromal AR signaling to induce prostate cancer cell proliferation and the possibility of this signaling in early prostate carcinogenesis.¹³¹ Importantly, studies are ongoing to define the events (genetic, epigenetic, paracrine factors) and the potential role of loss or decreased stromal AR (lost stromal AR signaling is related to cancer progression) in cancer progression and metastases (Fig. 26.18).

FIGURE 26.18 Working Model Mechanism for Fibroblast Androgen Receptor (AR) on Prostate Cancer Outcomes. AR signaling in stromal fibroblasts regulates growth factors, chemoattractants, cytokines, and extracellular matrix (ECM) production. The regulation of growth factors by AR creates a favorable environment for cancer, and the loss of AR is hypothesized to drive cancer cells to metastasize elsewhere. Disruption of chemoattractant production regulated by AR may induce the migratory capacity of cancer cells. AR signaling in fibroblasts and regulation of cytokine production may influence immune responses that have important effects on tumor cells. AR signaling in fibroblasts regulates production of ECM, and with loss of AR it is hypothesized that ECM becomes dysregulated, enhancing the migratory potential of cancer cells. (Data and illustration adapted from Leach DA, Buchanan G: *Cancers [Basel]* 9[1], 2017.)

AR signaling in fibroblasts regulates growth factors,

chemoattractants (inflammatory mediators), cytokines, and extracellular matrix (ECM) production.¹³¹ AR regulates growth factors creating a favorable environment for cancer, and with loss of AR the local environment may drive cancer cells to metastasize elsewhere. One hypothesis is that by regulating cytokine production, AR signaling in fibroblasts influences immune responses that affect tumor cells. The declining mesenchymal AR signaling and decreased local availability of paracrine mediators could result in dedifferentiation or epithelial-mesenchymal transition (EMT), or both, and a less hospitable environment for epithelial cells driving pathways for cell mobility and metastases.¹³¹ The emerging significance of tumor stroma is shaping the understanding of prostate development, cancer, and metastases.

Prostate Epithelial Neoplasia.

A precursor lesion, prostatic epithelial neoplasia (PIN), has been described. PIN may be more concentrated in prostates containing cancer and is noted in proximity to cancer.¹⁰⁵ However, the final fate of PIN is unknown, including the possibilities of latency, invasion, and even regression. The current working model of prostate carcinogenesis suggests that repeated cycles of injury and cell death occur to the prostate epithelium as a result of damage (e.g., from oxidative stress) from inflammatory responses.¹³⁵ There is growing evidence that chronic inflammation is involved in the regulation of cellular events in prostate carcinogenesis, including disruption of the immune response and regulation of the tumor microenvironment.¹³⁶ The direct injury is hypothesized as a response to infections; autoimmune disease; circulating carcinogens or toxins, or both, from the diet; or urine that has refluxed into the prostate (see [Fig. 26.16](#)). The resultant manifestation of this injury is focal atrophy or prostatic intraepithelial atrophy (PIA). Biologic responses cause an increase in proliferation and a massive increase in the number of epithelial cells that possess a phenotype intermediate between basal cells and mature luminal cells ([Fig. 26.19](#)).^{135,136} In a small subset of cells, some may contain “stem cell” or tumor-initiating properties and telomere

shortening (see [Chapter 12](#)). A subset of PIN cells may activate telomerase enzyme, causing the cells to become immortal.¹³⁷ Molecular, genetic, and epigenetic changes can increase genetic instability that might progress to high-grade PIN and early prostate cancer formation. This model of prostate carcinogenesis needs much more research.

FIGURE 26.19 Cellular and Molecular Model of Early Prostate Neoplasia Progression. A, This stage includes infiltration of lymphocytes, macrophages, and neutrophils caused by repeated infections, dietary factors, urine reflux, injury, onset of autoimmunity (which triggers inflammation), and wound healing. B, Epigenetic alterations mediate telomere shortening. C, Genetic instability and accumulation of genetic alterations. D, Continued proliferation of genetically unstable cells leading to cancer progression. *PIN*, Prostatic intraepithelial neoplasia.

Stromal Environment.

The prostate gland is composed of secretory luminal epithelium, basal epithelium, neuroendocrine cells, and various cell types comprising supportive tissue or stroma. **Stroma**, or tissue microenvironment, produces autocrine/paracrine factors, as well as structural supporting molecules that help regulate normal cell behavior and organ homeostasis.^{138,139} **Fibroblasts** are the most important cells during the reconstructive phase of wound healing (see [Chapter 7](#)). The collagen and connective tissue proteins produced by fibroblasts are deposited in wounded areas after fibroblasts have entered the lesion. Thus their presence is a signature of alterations in the stroma. Reactive tumor stroma is associated with an increased number of fibroblasts, increased capillary density, and collagen and fibrin deposition. These findings suggest that alteration in the prostate microenvironment,

mediated by changes associated with aging or senescence, or both, promote epithelial responses that contribute to diseases. In animal studies, investigators have noted that the microenvironment has an increased number of cells that promote inflammation and a collapsed appearance of the smooth muscle cells within adjacent glandular stroma.^{138,139} Fibroblast spreading has been proposed as indicative of decreased mechanical tension because of a lack of direct association of the fibroblasts with aged fragmented collagen fibrils.^{140,141} These alterations in mechanical tension and cell shape are suggested as determinants in altering gene expression and cellular function. These alterations in aged prostate stroma for mice and men include significant enhancement for inflammation pathways (e.g., NF- κ B, collagens).^{140,141} Inflammation can induce cell stress, and stressed mesenchymal cells can secrete inflammatory mediators (chemoattractants); however, it remains to be determined whether inflammatory infiltrates are a cause of or response to the alterations of aged stroma.¹⁴² Evidence supports that inflammation has a role in the pathogenesis of prostate cancer.^{135,136,143} Investigators have found that disruption of fibroblast growth factor signaling pathways leads to strongly activated and atypical stroma that preceded the development of mice PIN (mPIN).

Epithelial-mesenchymal transition (EMT) was first described in embryonic development, and is observed in a number of solid tumors^{144,145} (also see [Chapter 12](#)). Cells that undergo EMT become more migratory and invasive and gain access to vascular vessels.¹⁴⁶ Numerous studies have shown that these transition states (EMT and mesenchymal-epithelial transition [MET]) are a consequence of tumor-stroma interactions.¹⁴⁶⁻¹⁴⁸

Investigators studying prostate cancer cells in vitro correlated EMT with increased growth, migration, and invasion. These investigators demonstrated that the microenvironment is a critical site for the transition of human prostate cancer cells from epithelial to mesenchymal structure, resulting in increased metastatic potential for bone and the adrenal gland.¹⁴⁹

Prostate cancer is known to be diverse and composed of multiple

genetically distinct cancer cell clones. Studies, however, indicate that most metastatic cancers arise from a single precursor cancer cell.¹⁵⁰ Various research models have been proposed to understand EMT (MET) and invasion and metastasis.¹⁵¹

In summary, the following multifactorial general hypothesis of prostate carcinogenesis emerges from all of these observations: (1) androgens act as strong tumor promoters through androgen receptor-mediated mechanisms to enhance the carcinogenic activity of strong endogenous DNA toxic carcinogens, including reactive estrogen metabolites and estrogen, and prostate-generated reactive oxygen species; (2) alterations in autocrine/paracrine growth-stimulating and growth-inhibiting factors between the prostate tumor cells and microenvironment influence cancer pathogenesis; and (3) possibly unknown environmental-lifestyle carcinogens may contribute to prostate cancer. All of these factors are modulated by diet and genetic determinants, such as hereditary susceptibility genes and polymorphic genes, which encode receptors and enzymes involved in the metabolism and action of steroid hormones.⁸⁰

The most common sites of distant metastasis are the lymph nodes, bones, lungs, liver, and adrenals. The pelvis, lumbar spine, femur, thoracic spine, and ribs are the most common sites of bone metastasis. Local extension is usually posterior, although late in the disease the tumor may invade the rectum or encroach on the prostatic urethra and cause bladder outlet obstruction (Fig. 26.20). The spread of cancer through blood vessels is illustrated in Fig. 26.21.

◆Clinical Manifestations.

Prostatic cancer often causes no symptoms until it is far advanced. The first manifestations of disease are those of bladder outlet obstruction: slow urinary stream, hesitancy, incomplete emptying, frequency, nocturia, and dysuria. Unlike the symptoms of obstruction caused by BPH, the symptoms of obstruction caused by prostatic cancer are progressive and do not remit. Local extension of prostatic cancer can obstruct the upper urinary tract ureters as well. If rectal obstruction occurs, a man may experience a large-bowel obstruction or difficulty in defecation. Symptoms of late disease include bone pain at sites of bone metastasis, edema of the lower extremities, enlargement of lymph nodes, enlargement of the liver, development of pathologic bone fractures, and mental confusion associated with brain metastases.

◆Evaluation and Treatment.

Screening for prostatic cancer includes DRE, PSA blood tests, and TRUS. The most significant test used in the diagnosis and management of prostate cancer is measurement of the level of **prostate-specific antigen (PSA)**. DRE may detect early prostatic

carcinomas but it has low sensitivity and specificity.¹⁰⁵ Cancer diagnosis is confirmed through tissue biopsy and microscopic examination of tissue. Lymphography, bone scans, MRI, and CT scans also may be used to determine metastasis to lymph, bone, or other adjacent tissue. Important for treatment is to accurately measure the size of the index (longest) tumor and its percentage Gleason grade of differentiation.^{152,153}

PSA screening for prostate cancer has led to considerable controversy. A review of the evidence from the 2012 U.S. Preventive Services Task Force (USPSTF) regarding screening for prostate cancer concluded that PSA-based screening results in small or no reduction in prostate cancer-specific mortality and is associated with harmful consequences related to subsequent evaluation and treatments, some of which may be unnecessary. However, additional evidence published since the 2012 recommendation statement suggests increased confidence in the benefits of screening: slightly more than 1 man per 1000 who is offered screening may avoid death from prostate cancer.¹⁵⁴ There also is new evidence that 3 men per 1000 offered screening may avoid metastatic disease.¹⁵⁵ The USPSTF assigned a grade of D (recommending against screening) for men aged ≥ 75 years in 2008 and for men of all ages in 2012; however, USPSTF *draft* recommendations in 2017 recommend against PSA-based screening for prostate cancer only in men age 70 years and older. Furthermore, the 2017 USPSTF draft recommendations now suggest that clinicians inform men ages 55 to 69 years about the potential benefits and detriments of PSA-based screening for prostate cancer; thus making the decision about whether to be screened for prostate cancer is an individual choice for each man. Choosing to screen (or not to screen) should be based on each man's values and preferences after an informed discussion with his clinician.¹⁵⁶ This approach may be particularly important for men who have had immediate family members diagnosed with prostate cancer. Nonetheless, convincing evidence used to formulate the 2012 U.S. Preventive Services Task Force guidelines demonstrated that the PSA test unfortunately often produces false-positive results. Men who have a false-positive test are

more likely to have additional testing, including one or more biopsies. Over a 10-year span, approximately 15% to 20% of men will have a PSA test result that triggers a biopsy, depending on the PSA threshold and testing interval used.⁶⁷ In addition, because PSA level is organ specific and not cancer specific, its measurement can increase and overlap with BPH, prostatitis, infarct, manipulation from instrumentation, and ejaculation.¹⁰⁵ Since the 2012 recommendation, rates of PSA screening decreased by 3% to 10% in all age groups and across most geographical regions of the United States. Rates of prostate biopsy and prostate cancer incidence have declined in unison, with a shift towards tumors being of higher grade and stage upon detection (i.e., reduced incidence of detecting early-stage prostate cancer). The implications of this are being considered as more data are obtained.^{157,158}

The annual rate by which PSA level rises is known as **PSA velocity** or doubling time (generally described as *PSA kinetics*). Its calculation has been judged to be far from straightforward. More than 20 different methods for calculation have been proposed, and many of these give divergent results. Evidence clearly shows that PSA kinetics are critical for understanding prognosis in advanced or relapsed prostate cancer. However, PSA kinetics have questionable value for men with an untreated prostate; neither PSA velocity nor doubling time has an established role in diagnosing prostate cancer or providing a prognosis for men before treatment.^{159,160} In fact, investigators recently evaluated guidelines on the use of PSA velocity in prostate cancer detection and found that change in PSA levels over time is such a poor predictor of prostate cancer (in a previously untreated prostate) that it is highly likely many unnecessary biopsies have been performed.¹⁶¹ It is thus somewhat doubtful at this juncture that PSA velocity adds any additional predictive accuracy to PSA level measurement alone or positive digital rectal examination, or both, for purposes of prostate cancer screening. For instance, a systematic review found that even when definitions are rigorously applied, PSA velocity calculation does not significantly enhance the clinical performance of PSA alone.¹⁵⁹ As such, it should be noted a recent study found that PSA levels in

midlife strongly predict future lethal prostate cancer in a U.S. cohort subjected to opportunistic screening.¹⁶²

Older age is the strongest risk factor for the development of prostate cancer. However, neither screening nor treatment trials show benefit in men older than 70 years. Given this knowledge, recent recommendations from a task force of the International Society of Geriatric Oncology suggest that older men should be managed according to their individual health status and not according to age. Fit elderly men should receive the same treatment as younger men on the basis of international recommendations.¹⁶³ Across age ranges, black men and men with a family history of prostate cancer have an increased risk of developing and dying of prostate cancer.¹⁶⁴ Black men are approximately twice as likely to die of prostate cancer compared with other men in the United States, and the reason for this disparity is unknown. Black men represent a very small minority of participants in randomized clinical trials of screening and, thus, no firm conclusions can be made about the balance of benefits and detriments of PSA-based screening in this population. As such, it is a questionable practice to selectively recommend PSA-based screening for black men in the absence of data that support a more favorable balance of risks and benefits.^{67,156} The ability to predict cancer rises significantly when TRUS is added to the annual DRE and PSA testing. Researchers are studying microRNAs as potential new biomarkers for prostate cancer.

Prostate cancer is now detected in greater numbers of men at lower stages of disease and is amenable to multiple forms of efficacious treatment. However, there is a lack of conclusive data demonstrating a definitive mortality benefit from this earlier diagnosis and treatment of prostate cancer. This is likely because of the treatment of a large proportion of indolent cancers that would have had little adverse effect on health or life span if left untreated (Box 26.7).

Box 26.7

Rethinking Screening for Prostate Cancer

and Breast Cancer

In essence, it has become necessary to rethink screening for both prostate cancer and breast cancer because since screening was introduced the incidence of both prostate cancer and breast cancer increased and never returned to prescreening levels; in addition, the absolute number of advanced prostate and breast cancers diagnosed during this period has not decreased as predicted. Furthermore, whereas colon and cervical cancer screening detects precancerous treatable conditions, prostate and breast cancer screening detects so-called early cancers that may not be destined to grow or become lethal. Thus it is possible that prostate and breast cancer screening may be increasing the burden of low-risk cancers without any significant reduction of burden associated with aggressive lesions, thereby not resulting in the anticipated reduction in breast and prostate cancer mortality.

Data from Esserman L, Shieh Y, Thompson I: *J Am Med Assoc* 302(15):1685–1920, 2000.

Because of this “over-treatment” phenomenon, active surveillance with delayed intervention is gaining traction as a viable management approach in contemporary practice. The ability to distinguish clinically insignificant cancers from those with a high risk of progression or lethality, or both, is critical to the appropriate selection of surveillance protocols versus immediate intervention¹⁶⁵ (Box 26.8). Mounting evidence also suggests that intermittent PSA testing may decrease the costs and detriments of screening while preserving the benefits of annual testing.¹⁶⁶ The most important observation for pathologists to make to facilitate cure of any man with prostate cancer is that of accurately measuring the size of the index (longest) tumor and determining the Gleason score (degree of differentiation) (see Box 26.6).¹⁶⁷

Box 26.8

Prostate Specific Antigen-Based Screening for Prostate Cancer*

Why not screen for prostate cancer?

Screening may benefit a small number of men but will result in harm to many others. A person choosing to be screened should believe that the possibility of benefit is more important than the risk for harm. The U.S. Preventive Services Task Force assessment of the balance of benefits and harms in a screened population is that the benefits do not outweigh the harms.

What are the benefits and harms of screening 1000 men ages 55 to 69 years⁺ with a prostate-specific antigen (PSA) test every 1 to 4 years for 10 years?

<i>Possible Benefits of Screening:</i>	Me n, >n
Reduced 10-year risk for dying of prostate cancer:	
Die of prostate cancer with no screening	5 in 1 0 0 0
Die of prostate cancer with screening	4-5 i n 1 0 0 0
Do not die of prostate cancer because of screening	0-1 i n 1 0 0 0

<i>Harms of Screening:</i>	
At least one false-positive screening PSA test result:	
Most positive test results lead to biopsy. Of men having biopsy, up to 33% will have moderate or major bothersome symptoms, including pain, fever, bleeding, infection, and temporary urinary difficulties; 1% will be hospitalized.	100–120000
Prostate cancer diagnosis:	
Although a diagnosis of prostate cancer may not be considered a harm, currently 90% of diagnosed men are treated and thus are at risk for the harms of treatment. A large majority of the men who are being treated would do well without treatment. A substantial percentage of these men would have remained asymptomatic for life.	110000
Complications of treatment (among persons who are screened) [‡] :	
Develop serious cardiovascular events because of treatment	2 in 10000
Develop deep venous thrombosis or pulmonary embolus because of treatment	1 in 10000
Develop erectile dysfunction because of treatment	29 in 10000
Develop urinary incontinence because of treatment	18 in 10000
Die because of treatment	<1 in 10000

*Calculations of the estimated benefits and harms rely on assumption and are, by nature, somewhat imprecise. Estimates should be considered in the full context of clinical decision making and used to stimulate shared decision making.

†The best evidence of possible benefit of PSA screening is in men ages 55 to 69 years.

‡The rate of complications depends on the proportion of men having treatment and the method of treatment. The preceding data reflect a distribution of 60% surgical treatment, 30% radiation treatment, and 10% observation. Other harms of radiation, such as bowel damage, are not shown.

Data from Moyer VA, U.S. Preventive Services Task Force: *Ann Intern Med* 157(2):120–124, 2012; also see Esserman L, Shieh Y, Thompson I: *J Am Med Assoc* 302(15):1685–1910, 2009, for further reading on this matter. A brief summary of the thinking of Esserman and colleagues is provided in the Prostate Cancer Evaluation and Treatment section.

Treatment of prostatic cancer depends on the stage of the neoplasm (see [Box 26.6](#)); the anticipated effects of treatment; and the age, general health, and life expectancy of the individual. Options include (1) no treatment; (2) surgical treatments, such as total prostatectomy, transurethral resection of the prostate (TURP), and cryotherapy; (3) nonsurgical treatments, such as radiation therapy, hormone therapy, or chemotherapy; (4) watchful waiting; and (5) any combination of these.⁶⁷ In addition, new approaches are using immunotherapy. Palliative treatment is aimed at relieving urinary, bladder outlet, or colon obstruction; spinal cord compression; and pain. Prognosis and survival rates have improved steadily since the early 1960s. According to the most recent data, 10- and 15-year relative survival rates are 98% and 95%, respectively.¹ A study examining 10-year outcomes after monitoring, surgery, or radiotherapy for localized prostate cancer found that at a median of 10 years, prostate cancer–specific mortality was low regardless of the treatment assigned, with no significant difference among treatments. Surgery and radiotherapy were associated with lower incidences of disease progression and

metastases than was active monitoring.¹⁶⁸

Treatment for prostate cancer may lead to loss of urinary control, which may or may not return to normal after several weeks or months. Stress incontinence can occur after surgery, and mild urge incontinence can occur after radiation therapy. Prostate cancer and its treatment can affect sexual functioning. Sensation of orgasm is not usually affected, but smaller amounts of ejaculate will be produced or men may experience a “dry” ejaculate because of retrograde ejaculation.

Sexual Dysfunction

In men the normal sexual response involves three processes: erection, emission, and ejaculation. **Sexual dysfunction** is the impairment of any or all of these processes. Impairment can be caused by a number of physiologic and psychologic factors.

Until the late 1970s, most cases of male sexual dysfunction were thought to be psychogenic. Studies of this problem indicate that in men older than 40 years, organic factors are involved in more than 50% of cases. The causes of organic sexual dysfunction include (1) vascular, endocrine, and neurologic disorders; (2) chronic disease, including renal failure and diabetes mellitus; (3) penile diseases and penile trauma; and (4) iatrogenic factors, such as surgery and pharmacologic therapies. Most of these disorders cause erectile dysfunction.

◆Pathophysiology and Clinical Manifestations.

Vascular disorders can prevent erection. Some arterial diseases diminish or interrupt circulation to the penis. This prevents engorgement of erectile tissues in the corpora cavernosa and corpus spongiosum. Rarely, excessive venous drainage of the corpora cavernosa prevents erection.

Endocrine disorders that reduce testosterone production affect sexual function and libido. The reduction may be caused by inadequate secretion of the gonadotropins caused by pituitary dysfunction or hyperprolactinemia. Feminizing tumors and estrogen

therapy reduce relative levels of testosterone. Testicular atrophy from any cause also decreases testosterone levels and contributes to sexual dysfunction.

Neurologic disorders can interfere with the important sympathetic, parasympathetic, and CNS mechanisms required for erection, emission, and ejaculation. They include spinal cord injury or tumor, multiple sclerosis, and disorders that cause peripheral neuropathies, such as diabetes mellitus and chronic renal failure. Spinal cord injuries or tumors can alter one or more components of the sexual response, depending on the location of the lesion. For example, in most men with upper motor neuron lesions, reflexogenic erection is possible, but emission and ejaculation (i.e., orgasm) are not possible. Lesions affecting the lower motor neurons usually prevent erection. In approximately 40% of such cases, emission and ejaculation are prevented.

Many chronic diseases are associated with sexual dysfunction. In some conditions the sexual dysfunction has a specific physiologic cause. Diabetes mellitus, for example, causes peripheral vascular and neurologic pathology that can lead to erectile dysfunction. Impotence occurs in about 50% of men undergoing dialysis because of decreased testosterone levels, autonomic neuropathy, accelerated vascular disease, multiple medications, worsening of primary disease, and psychologic stress. Potency may be restored by successful renal transplantation, except in bilateral transplantation if arterial flow is diminished or interrupted. Cirrhosis of the liver, scleroderma, chronic debilitation, and cachexia also are known to cause impotence. Emotional and psychologic response to chronic illness, such as anxiety, depression, and loss of self-esteem, can affect sexual functioning. In other chronic conditions, sexual dysfunction is associated with low energy levels and loss of libido. The pathophysiologic mechanisms responsible for such changes are not known.

Priapism causes fibrosis of trabeculae (erectile tissues) within the corpora cavernosa, making erection difficult. The penile curvature caused by Peyronie disease does not make erection impossible but

may make it extremely painful and intercourse impossible. Penile trauma can damage the erectile tissue, disrupt the posterior urethra, and disrupt the pudendal arteries or nerves.

Iatrogenic factors, including drugs and surgery, have a significant effect on erectile function. The following surgical procedures carry the risk of erectile dysfunction: radical pelvic surgery; radical prostatectomy; transurethral, suprapubic, or simple retropubic prostatectomy; and aortoiliac surgery. Erectile dysfunction is caused by the severing of small nerve branches that are essential for erection. Aortoiliac surgery, retroperitoneal lymphadenectomy, and sympathectomy cause the loss of ejaculation capacity in some individuals.

A few pharmacologic agents enhance the sexual response, but most have the opposite effect. Men who are taking antihypertensives, antidepressants, antihistamines, antispasmodics, sedatives or tranquilizers, barbiturates, diuretics, sex hormone preparations, narcotics, or psychoactive drugs may experience some degree of sexual dysfunction. Drug-induced sexual dysfunction consists of decreased desire, decreased erectile ability, or decreased ejaculatory ability. Ethyl alcohol may induce alcoholic neuropathy or increased levels of estrogens because of hepatic dysfunction; marijuana depresses testosterone levels; and cigarette smoking contributes to vasoconstriction and venous leakage. A number of pharmacologic agents also diminish the quality or quantity of sperm. A few may cause priapism. Drugs can assist in maintaining an erection.

◆Evaluation and Treatment.

Evaluation of sexual dysfunction includes a physical examination, with particular attention to the genitalia, prostate, and nervous system, and basic laboratory tests to identify the presence of endocrinopathies or other underlying disorders that can cause the dysfunction. If no physiologic cause is found and the condition does not improve with psychotherapy, the man is referred for further investigation of organic causes. Psychologic evaluation is indicated for younger men with a sudden onset of sexual dysfunction or men of

any age who are able to achieve but not maintain an erection.

Sophisticated diagnostic techniques can be used to assess penile blood flow, erectile tissue anatomy, nervous system function, and occurrence of erection or emission during sleep (nocturnal emission). Penile blood flow is measured by Doppler techniques and penile arteriography. Corpus cavernosography, in which contrast material is injected into the corpora cavernosa, provides anatomic information about the erectile tissue of the penis. Neuropathic causes of sexual dysfunction are evaluated by measuring the speed of the bulbocavernosus reflex. Nocturnal penile tumescence monitoring measures the frequency of nocturnal erections. Depending on the equipment used, this information may be correlated to rapid eye movement (REM) or non-REM sleep.

Treatments for organic sexual dysfunction include medical and surgical interventions. Nonsurgical interventions include correction of underlying disorders, particularly drug-induced dysfunction and endocrinopathy-related (e.g., reduced testosterone level associated with chronic renal failure) dysfunction. Use of vasodilators and cessation of smoking can benefit individuals with vasculogenic erectile dysfunction. Surgical interventions include penile implants, penile revascularization, and correction of other anatomic defects contributing to sexual dysfunction.

Impairment of Sperm Production and Quality

Spermatogenesis requires adequate secretion of FSH and LH by the pituitary; sufficient secretion of testosterone by the Leydig cells; sufficient function of the Sertoli cells, including secretion of androgen-binding protein, growth factors, inhibin B, and a number of other important (but poorly understood) peptides; and adequate spermatogonia.^{38,169} The Leydig cells are located in the testicular interstitium *between* the tubules, and the Sertoli cells and spermatogonia are located *within* the seminiferous tubules. The Sertoli cells extend from the basement membrane to the lumen, display tight junctions between adjacent cells, and form the blood-testis barrier. Inadequate secretion of gonadotropins may be caused by

hypothyroidism, hyperadrenocortisolism, hyperprolactinemia, or hypogonadotropic hypogonadism. In these situations, gonadotropin levels are low because of feedback inhibition or idiopathic hyposecretion. In the absence of adequate gonadotropin levels, the Leydig cells are not stimulated to secrete testosterone and sperm maturation is not promoted in the Sertoli cells. Spermatogenesis depends not only on appropriate stimulation by the gonadotropins but also on an appropriate response by the testes. Defects in testicular response to the gonadotropins result in decreased secretion of testosterone and inhibin B and, as a result of normal feedback mechanisms, high levels of circulating gonadotropins. In the absence of adequate testosterone levels, spermatogenesis is impaired. Newer research demonstrates the significance of inhibin B as an important marker of the competence of Sertoli cells and spermatogenesis. Inhibin B is strongly correlated with the severity of spermatogenic effects. A positive correlation exists between serum inhibin B levels and sperm concentration and testicular volume, and lower levels have been associated with azoospermia, testicular disorders, and infertility.¹⁶⁹

Impaired spermatogenesis also can be caused by genetic disorders (such as Klinefelter syndrome), myotonic dystrophy, or testicular trauma. Other conditions associated with impaired spermatogenesis include systemic illness, such as renal failure, hepatic disease, or sickle cell disease; exposure to gonadotoxins, such as chemotherapy or radiation; varicocele; and cryptorchidism.

Fertility is adversely affected if spermatogenesis is normal but the sperm are chromosomally or morphologically abnormal or are produced in insufficient quantities. Chromosomal abnormalities are caused by genetic factors and by external variables, such as exposure to radiation or toxic substances. Ongoing research using small ribonucleic acids (RNAs) is elucidating the molecular mechanisms regulating spermatogenesis.¹⁷⁰ A sperm count of 20 million sperm per milliliter of semen has been suggested as the minimum concentration required for fertility. Average fertile men have 50 to 100 million sperm per milliliter.³⁸

Sperm motility is another important variable affecting fertility.

Motility appears to be affected by the sperm's chemical environment, that is, the characteristics of semen. Prostatic dysfunction, excessive semen viscosity, presence of drugs or toxins in the semen, and presence of anti-sperm antibodies are associated with impaired sperm motility. Approximately 3% to 7% of infertile males have anti-sperm antibodies in their semen. Anti-sperm antibodies may develop as a result of epididymitis or other inflammation of the genitourinary tract, testicular injury or torsion, a previous vasectomy or biopsy, and cryptorchidism. Anti-sperm antibodies may be (1) cytotoxic antibodies, which attack sperm and reduce their number in the semen; or (2) sperm-immobilizing antibodies, which impair sperm motility and reduce their ability to traverse the endocervical canal. Intrinsic, biologic factors leading to the production of anti-sperm antibodies seem to play a greater role than extrinsic factors. The exact mechanism remains unclear.³⁸

A male factor contributes to the cause of up to 50% of cases of infertility. As understanding of the male factor in infertility increases, evaluation becomes more complex and essential to appropriate treatment (Box 26.9). Treatment for impaired spermatogenesis involves correction of any underlying disorders and avoidance of radiation or toxins. Androgens, human gonadotropins, and antiestrogens (e.g., clomiphene citrate, tamoxifen citrate) may enhance spermatogenesis. Semen can be modified to improve sperm motility. If conception is desired, the semen is obtained by masturbation (or mechanical device),³⁸ after which it can be diluted, concentrated, or washed to remove anti-sperm antibodies. These alterations are followed by artificial insemination.

Box 26.9

Evaluation of Male Partner of Infertile Couples

Thorough history and physical examination, including imaging

for varicocele
Two semen analyses and quantification of serum FSH, LH, testosterone levels, and prolactin if indicated
Semen and urethral cultures
Serum assays or monoclonal antibody testing for white blood cells
Immunobead monoclonal antibody test
Postcoital testing of semen activity and function
Sperm penetration assay
Inhibin B assays or testicular biopsy
Vasogram, TRUS, or other imaging studies

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone; *TRUS*, transrectal ultrasonography.

Disorders of the Male Breast

Gynecomastia

Gynecomastia is the overdevelopment of breast tissue in a male. Gynecomastia accounts for approximately 85% of all masses that develop in the male breast and affects 32% to 40% of the male population. If only one breast is involved, it is typically the left. Incidence is greatest among adolescents and men older than 50 years.

Gynecomastia results from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs, or neoplasms. It usually involves an imbalance of the estrogen/testosterone ratio, which can be altered in one of two ways. First, estrogen levels may be excessively high although testosterone levels are normal, as in drug-induced and tumor-induced cases of hyperestrogenism. Second, testosterone levels may be extremely low although estrogen levels are normal, as is the case in hypergonadism. Gynecomastia also can be caused by alterations in breast tissue responsiveness to hormonal stimulation. Breast tissue may have increased responsiveness to estrogen or decreased responsiveness to androgens. Alterations of

responsiveness may cause many cases of idiopathic gynecomastia.

Besides puberty and aging, estrogen-testosterone imbalances are associated with hypogonadism, Klinefelter syndrome, and testicular neoplasms. Hormone-induced gynecomastia is usually bilateral. Pubertal gynecomastia is a self-limiting phenomenon that usually disappears within 4 to 6 months. Senescent gynecomastia usually regresses spontaneously within 6 to 12 months.

Systemic disorders associated with gynecomastia include obesity, cirrhosis of the liver, infectious hepatitis, chronic renal failure, chronic obstructive lung disease, hyperthyroidism, tuberculosis, and chronic malnutrition. It may be that these disorders ultimately alter the estrogen/testosterone ratio, initiating gynecomastia.

Gynecomastia is often seen in men receiving estrogen therapy, in preparation either for a sex-change operation or for prostatic carcinoma. Other drugs that can cause gynecomastia include digitalis, cimetidine, spironolactone, reserpine, thiazide, isoniazid, ergotamine, tricyclic antidepressants, amphetamines, vincristine, and busulfan. Recent data reveal that the use of 5 α -reductase inhibitors for BPH increased the risk of gynecomastia.¹⁷¹

Malignancies of the testes, adrenals, or liver can cause gynecomastia if they alter the estrogen/testosterone ratio. Pituitary adenomas and lung cancer also are associated with gynecomastia.

◆Pathophysiology.

The breast enlargement consists of hyperplastic stroma and ductal tissue. Hyperplasia results in a firm, palpable mass, at least 2 cm in diameter located beneath the areola.

◆Evaluation and Treatment.

The diagnosis of gynecomastia is based on physical examination. Identification and treatment of the cause are likely to be followed by resolution of the gynecomastia. The man should be taught to perform breast self-examination and is examined at 6- and 12-month intervals if the gynecomastia persists. All unilateral breast enlargement in men warrants an evaluation for malignancy; workup includes fine-needle

aspiration, cytology, mammography, ultrasound, and biopsy.

Cancer

Male breast cancer (MBC) is rare. MBC accounts for 1% of all male cancers and less than 1% of all breast cancers. Global incidence rates were generally less than 1 per 100,000 man-years in contrast to much higher rates in females (see [Chapter 25](#)). The highest incidence rate for MBC is in Israel with 1.24 per 100,000, and the lowest incidence rates for males (0.16) and females (18.0) were observed in Thailand.¹⁷² The mean age of diagnosis is between 60 and 70 years, although men of all ages can be affected.¹⁷³ Risk factors for MBC include radiation exposure, estrogen administration, and diseases associated with hyperestrogenism, such as cirrhosis or Klinefelter syndrome.¹⁷³ An increased incidence is reported in men with a number of female relatives with breast cancer; there is an increased incidence in families with *BRCA2* mutations.¹⁷³

Similar to female breast cancer, infiltrating ductal cancer is the most common tumor type.¹⁷³ Intraductal cancer, inflammatory carcinoma, and Paget disease of the nipple have been diagnosed in men. Patterns of metastasis are similar to those in females.

The diagnosis of cancer is confirmed by biopsy, but because of delays in seeking treatment male breast cancer may be advanced at the time of diagnosis. Main treatments include chemotherapy and surgery.

Summary Review

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, should begin in boys between 9 and 14 years of age. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is onset before these ages. While the average age of pubertal onset appears to be decreasing for girls, the age of pubertal onset has remained

- essentially unchanged for boys.
2. Alterations of sexual maturation can be idiopathic or caused by a disease or congenital anomaly. In most cases of delayed puberty, the hypothalamic-pituitary-gonadal (HPG) axis is intact but the surge of activity that stimulates puberty is delayed. This situation is common in boys. Precocious puberty also can be caused by mistiming of the stimulatory surge in a child whose HPG system is otherwise normal.
 3. Precocious puberty can be complete (sex appropriate), mixed (not sex appropriate), or partial (development of one secondary sex characteristic only). Causes of delayed or incomplete puberty can be divided into categories based on gonadotropic secretion: hypergonadotropism (increased levels of FSH and LH) and hypogonadotropism (decreased LH and FSH levels).

Disorders of the Male Reproductive System

1. Disorders of the urethra include urethritis (inflammation of the urethra) and urethral strictures (narrowing or obstruction of the urethral lumen caused by scarring). Urethral stricture often manifests itself as lower urinary tract symptoms or urinary tract infections with significant impairment in the quality of life.
2. Although noninfectious urethritis can occur, most cases of urethritis result from sexually transmitted pathogens. Symptoms of urethritis include dysuria, frequency, urgency, urethral tingling or itching, and clear or purulent discharge. Treatment consists of appropriate antibiotic therapy and avoidance of future chemical or mechanical irritation.
3. Acquired or congenital scarring that causes urethral stricture can be caused by trauma or by severe or untreated urethral infection. The primary symptom is diminished force and caliber of the urinary stream; other symptoms include urinary frequency and hesitancy, mild dysuria, double urine stream or

spraying, and postvoid dribbling. Treatment is usually surgical.

4. Phimosis and paraphimosis are penile disorders involving the foreskin (prepuce). In phimosis the foreskin cannot be retracted over the glans. In paraphimosis the foreskin is retracted and cannot be returned to its normal anatomic position over the glans. Phimosis is caused by poor hygiene and chronic infection and can lead to paraphimosis. Paraphimosis can constrict the penile blood vessels, preventing circulation to the glans.
5. Peyronie disease consists of fibrosis that affects the corpora cavernosa, which causes penile curvature during erection. Fibrosis prevents engorgement on the affected side, causing a lateral curvature that can prevent intercourse. Peyronie disease is an underdiagnosed condition with a prevalence as high as 9% in the male population.
6. Priapism, a prolonged painful erection not stimulated by sexual arousal, is a urologic emergency. The corpora cavernosa (but not the corpus spongiosum) fills with blood that does not drain, probably because of venous obstruction. Priapism is associated with spinal cord trauma, sickle cell disease, leukemia, and pelvic tumors. It can also be idiopathic and can occur with cocaine use.
7. Balanitis is an inflammation of the glans penis and usually occurs in conjunction with posthitis. It is associated with phimosis, inadequate cleansing under the foreskin, skin disorders, and infections.
8. Cancer of the penis is rare; major risk factors include HPV, smoking, and consequences of treatment for psoriasis. Penile carcinoma in situ tends to involve the glans; invasive carcinoma of the penis involves the shaft as well.
9. A varicocele is an abnormal dilation of the veins within the spermatic cord caused by either congenital absence of valves in the internal spermatic vein or acquired valvular incompetence.

10. A hydrocele is a collection of fluid between the testicular and scrotal layers of the tunica vaginalis. Hydroceles can be idiopathic or caused by trauma or infection of the testes.
11. A spermatocele is a cyst located between the testis and epididymis that is filled with fluid and sperm.
12. Cryptorchidism is a condition in which one or both testes fail to descend into the scrotum. The etiology of cryptorchidism is considered to be multifactorial (genetic, maternal, and environmental factors) and occurs most often as an isolated disorder with no obvious cause. Uncorrected cryptorchidism is associated with infertility and a significantly increased risk of testicular cancer.
13. Testicular torsion is the rotation of a testis, which twists blood vessels in the spermatic cord. This interrupts blood supply to the testis, resulting in edema and, if not corrected within 4 to 6 hours, necrosis and atrophy of testicular tissues.
14. Orchitis is an acute infection of the testes. Pathogenic organisms may reach the testes through the blood or the lymphatics; most commonly, they reach the testes by ascending through the vas deferens and epididymis. Complications of orchitis include hydrocele and atrophy. Granulomatous orchitis, an autoimmune disease, is a nonspecific, noninfectious, inflammatory process that occurs in middle-aged men.
15. Testicular cancer is the most common malignancy in males 15 to 35 years of age. Although its cause is unknown, high androgen levels, genetic predisposition, and a history of cryptorchidism, trauma, or infection may contribute to tumorigenesis. Most testicular neoplasms are germ cell tumors.
16. Epididymitis, inflammation of the epididymis, is usually caused by a sexually transmitted pathogen that ascends through the vasa deferentia from an already infected urethra or bladder.
17. Benign prostatic hyperplasia (BPH) is enlargement of the

prostate gland. This condition becomes symptomatic as the enlarging prostate compresses the urethra, causing symptoms of bladder outlet syndrome and urine retention. Studies demonstrate that the activation of a chronic, inflammatory prostatic response plays an important role in the pathogenesis and progression of BPH and prostate cancer.

18. Prostatitis is inflammation of the prostate. Prostate syndromes have been classified by the National Institutes of Health as (a) acute bacterial prostatitis (ABP), (b) chronic bacterial prostatitis (CBP), (c) chronic pelvic pain syndrome (CPPS), and (d) asymptomatic inflammatory prostatitis.
19. Prostate cancer is the most common cancer in American men, and the incidence varies greatly worldwide. Possible causes include genetic predisposition, environmental and dietary factors, inflammation, and alterations in levels of hormones (testosterone, dihydrotestosterone, and estradiol) and growth factors. Incidence is greatest among northwestern European and North American men (particularly blacks) older than 65 years of age.
20. Most cancers of the prostate are adenocarcinomas that develop at the periphery of the gland.
21. Sexual dysfunction in males can be caused by any physical or psychologic factor that impairs erection, emission, or ejaculation.
22. Spermatogenesis (sperm production by the testes) can be impaired by disruptions of the HPG axis that reduce testosterone secretion and by testicular trauma or atrophy from any cause. Sperm production is also impaired by neoplastic disease, cryptorchidism, or any factor that causes testicular temperature to rise.
23. Sperm quality is impaired by chromosomal abnormalities resulting from genetic factors, irradiation, or toxins. Sperm motility can be impaired by unfavorable constituents or characteristics of semen.

Disorders of the Male Breast

1. Gynecomastia is the overdevelopment (hyperplasia) of breast tissue in a male resulting from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs, or neoplasms. It usually involves an imbalance of the estrogen/testosterone ratio.
2. Gynecomastia affects 32% to 40% of the male population. The incidence is greatest among adolescents and men older than 50 years.
3. Gynecomastia is caused by hormonal or breast tissue alterations that cause estrogen to dominate. These alterations can result from systemic disorders, drugs, neoplasms, or idiopathic causes.
4. Breast cancer is relatively uncommon in males, but it has a poor prognosis because men tend to delay seeking treatment until the disease is advanced. The mean age at diagnosis is between 60 and 70 years of age.
5. Most breast cancers in men are estrogen positive.

CHAPTER 27

Sexually Transmitted Infections

Julia C. Phillippi, Kathleen E. Danhausen

CHAPTER OUTLINE

Sexually Transmitted Urogenital Infections, 869

Bacterial Infections, 869

Viral Infections, 879

Parasitic Infections, 883

Sexually Transmitted Infections of Other Body Systems, 885

Hepatitis, 885

Acquired Immunodeficiency Syndrome, 886

Zika Virus, 886

Newly acquired sexually contracted infections affect more than 20 million Americans per year, and half of those individuals are younger than 25 years of age¹ (see [What's New? Sexually Transmitted Infection \[STI\] Statistical Summary from 2015 CDC](#)). **Sexually transmitted infections (STIs)** account for nearly \$16 billion dollars in healthcare costs in the United States. They have been called the *hidden epidemic* by the CDC¹ because they are so prevalent, yet rarely discussed. Complications of STIs include short- and long-term morbidity and even mortality that can affect physical, emotional, and financial well-

being.

What's New?

Sexually Transmitted Infection (STI) Statistical Summary From 2015 CDC Report

Each year in the United States:

- 20 million individuals contract a sexually transmitted infection; half of those infected are younger than 25 years.
- 16 billion dollars are spent on STIs, not including long-term healthcare costs.
- Only half of people who need STI screening receive needed services.

Chlamydia cases:

- 1.4 million cases were reported and treated, but an estimated 1 million of additional cases remain untreated.

Gonorrhea cases:

- 350,062 cases were reported in 2014, a 5% increase in 1 year.
- Increasing antibiotic resistance means that gonorrhea may soon become resistant to all known treatments.

Syphilis cases:

- There was a 15% overall increase in cases reported since 2013.
- The syphilis rate is highest among men who have sex with men.

Viral STIs affect more than 70 million people in the United States:

- The use of the HPV vaccine is already demonstrating positive effects on the rates of HPV acquisition in the United States.

- 50 million people are estimated to have genital herpes.
- 1.2 million adults in the United States live with an HIV infection.

Data from Centers for Disease Control and Prevention (CDC): *Sexually transmitted disease surveillance 2014*, Washington, DC, 2015, U.S. Department of Health and Human Services.

In the past, an infection transmitted through sexual intercourse was called a *venereal disease*. However, the term venereal disease has been replaced with STI. STIs are contracted by genital contact or through contact with infected blood or body fluids. Infections can be transmitted directly through touch or the infectious agent can be transmitted by an object, known as a **fomite**. STIs also can be transmitted from mother to child during pregnancy and birth, a process known as **vertical transmission**.

Many infected individuals are not screened for STIs because symptoms are absent, minor, or transient, or because health services are inaccessible, unaffordable, or culturally insensitive. When individuals do not know they have an STI, they often fail to prevent transmission to others. With adequate screening and early treatment and education, the prevalence and sequelae of STIs can be greatly reduced.

Behaviors are the greatest risk factor for STI acquisition. Individuals who have unprotected intercourse or genital/oral contact, especially with nonmonogamous or multiple partners, are at the greatest risk. Certain populations as defined by age, behaviors, geographic location, traits, or race/ethnicity have a higher incidence of STIs. This increase is usually a result of increased risky behaviors by individuals in this group, but it can also be due to physical or cultural characteristics that contribute to transmission. For example, rates of gonorrhea, chlamydia, vaginitis, cervical condyloma, genital warts, and pelvic inflammatory disease (PID) are highest in adolescents and decline exponentially with increasing age (Fig. 27.1). Adolescents more often engage in risky behaviors and have a greater number of sexual

partners than older adults. People entering correctional facilities, such as jails, also have higher rates of STI prevalence related to their risky behaviors before incarceration.¹

FIGURE 27.1 Incidence of Sexually Transmitted Infections by Age. (From Centers for Disease Control and Prevention [CDC]: *CDC fact sheet: sexually transmitted infections among young Americans, 2013*. Available at: <http://www.cdc.gov/std/products/infographics.htm>.)

Some populations are at greater risk because of the pathophysiology of STI transmission. Transmission of many STIs is enhanced when the infectious agent contacts mucous membranes, such as the mouth, oropharynx, vagina, rectum, and the inner foreskin, which provide a more favorable environment for transmission than skin. Therefore women, uncircumcised men, and men who are the receptive partner in oral or anal sex are at increased risk.¹ In addition, prolonged contact with infectious body fluids also

increases transmission, which occurs when semen is deposited in the vagina or rectum. Young women also are at greater risk for STI acquisition when compared with older women, which is related to the position of susceptible cells on the surface of their cervix.

STI transmission is enhanced when the infectious agent has contact with broken skin or blood vessels; therefore sexual contact that is damaging to the genitals increases STI acquisition. This is the case with rectal-penile sex, as well as forced genital contact. Broken or friable skin caused by genital infections or trauma also can increase the risk of STI acquisition. As a result, if an individual has one STI, he or she is more susceptible to acquisition when exposed to other STIs.

Race and ethnicity are not direct factors in STI acquisition. STIs are prevalent in all socioeconomic and racial/ethnic groups. Publicly available data suggest a greater prevalence in minority groups or among people with low socioeconomic status, which may be a reflection of greater STI reporting from public clinics that serve marginalized groups when compared with private providers who are not required to report all infections to authorities. Race and ethnicity alone do not alter STI risk, but rather act as risk markers that correlate with other more fundamental determinants of health status, such as (1) poverty, (2) access to quality care, and (3) health-seeking behavior. In some geographic areas racial, ethnic, or socioeconomic groups may be more or less likely to engage in at-risk behaviors such as intravenous drug use and unprotected sex. Healthcare providers should provide risk-appropriate screening based on behaviors and physiologic risk factors without racial profiling. To assist clinicians the CDC regularly publishes a comprehensive guideline detailing STI screening, evaluation, and treatment that specifies current at-risk groups. This guide and its corresponding smartphone app are the best sources of current information on STI screening and treatment since this area of clinical care changes rapidly.

An STI can be caused by bacteria, viruses, protozoa, parasites, or fungi ([Table 27.1](#)). Transmission rates and prevalence depend on the characteristics of the pathogen and complex factors associated with behavioral and societal factors. Bacterial, protozoan, parasitic, and

fungal STIs can be successfully treated once diagnosed, but viral STIs cannot be cured by pharmacologic means alone and, depending on the virus, affected individuals have the potential to carry or transmit the virus throughout their life.

TABLE 27.1

CURRENTLY RECOGNIZED SEXUALLY TRANSMITTED INFECTIONS

CAUSAL MICROORGANISM	INFECTION
Bacteria	
<i>Campylobacter</i>	Campylobacter enteritis
<i>Calymmatobacterium granulomatis</i>	Granuloma inguinale
<i>Chlamydia trachomatis</i>	Urogenital infections; lymphogranuloma venereum
Polymicrobial	
<i>Gardnerella vaginalis</i> interaction with anaerobes (<i>Bacteroides</i> and <i>Mobiluncus</i> spp.) and genital mycoplasmas	Bacterial vaginosis
<i>Haemophilus ducreyi</i>	Chancroid
<i>Mycoplasma</i>	Mycoplasmosis
<i>Neisseria gonorrhoeae</i>	Gonorrhea
<i>Shigella</i>	Shigellosis
<i>Treponema pallidum</i>	Syphilis
Viruses	
Cytomegalovirus	Cytomegalic inclusion disease
Hepatitis B virus (HBV)	Hepatitis
Hepatitis C virus (HCV)	Hepatitis
Herpes simplex virus (HSV)	Genital herpes
Human immunodeficiency virus (HIV)	Acquired immunodeficiency syndrome (AIDS)
Human papillomavirus (HPV)	Condylomata acuminata, cervical dysplasia, and cervical cancer
Molluscum contagiosum virus	Molluscum contagiosum
Zika virus	Zika virus disease
Protozoa	
<i>Entamoeba histolytica</i>	Amebiasis; amebic dysentery

<i>Giardia lamblia</i>	Giardiasis
<i>Trichomonas vaginalis</i>	Trichomoniasis
Ectoparasites	
<i>Pthirus pubis</i>	Pediculosis pubis
<i>Sarcoptes scabiei</i>	Scabies
Fungus	
<i>Candida albicans</i>	Candidiasis

Treatment or symptom management of STIs depends on the causative pathogen. Treatments change frequently based on drug resistance and availability of medications, and are personalized on the basis of the individual's medical needs and personal preferences. Treatment of the person and his or her sexual partner(s) is often complicated by inadequate access to medical care, drug cost, and privacy concerns.¹ Many states have enacted legislation to allow sexual partners to be treated without having to go to a clinic for an examination and prescription.²

Prevention of STI acquisition involves a multifaceted approach including encouraging behavioral changes to decrease transmission, such as decreasing the number of sexual partners or using condoms. Preexposure vaccines, including vaccines for hepatitis and human papillomavirus (HPV), have been used to protect populations against viral STIs before exposure.³ Medications also may be used to prevent acquisition of STIs as preexposure and postexposure prophylaxis, especially in the prevention of human immunodeficiency virus (HIV) acquisition.³ Early treatment of STIs prevents transmission to new hosts and decreases the risk of additional STI acquisition for the index person. Testing and treatment are especially helpful in preventing vertical transmission.

Sexually Transmitted Urogenital Infections

Bacterial Infections

Gonorrhea

Gonorrhea is caused by **gonococci** (singular, *gonococcus*), microorganisms of the species *Neisseria gonorrhoeae*. First identified in 1879, gonorrhea became the most widely reported STI in the United States before entering a decline because of widespread availability of testing and treatment. After reaching a record low in 2009, the rates for gonorrhea have increased 10.5% since 2010, in part because of widespread testing using more accurate nucleic acid amplification tests (NAATs).⁴

The risk of developing gonorrhea from intercourse with an infected male partner is 50% to 80% for women, and with an infected female partner, it is 20% to 30% for men. The risk increases threefold to fourfold for men after four exposures to an infected partner. Men who have sex with infected men have a greater risk of contracting gonorrhea if they are the receptive partner.⁵

Transmission of gonococcal infection generally requires contact of epithelial (mucosal) surfaces, such as occurs during vaginal, oral, or anal intercourse, and infection in adults can be maintained in the vagina, rectum, oropharynx, or urethra.⁴ A pregnant woman also can transmit gonorrhea to her fetus through infected cervical and vaginal secretions contacting the baby's mucosal surfaces during birth. Following vertical transmission, the newborn eyes can be infected and can result in blindness if untreated.

Treatment for gonorrhea is becoming more difficult because of rapidly developing resistance to available antibiotics. Both the CDC and the World Health Organization (WHO) advise dual drug treatment for gonorrhea to effectively treat infection and staunch increasing resistance.³ This antibiotic resistance is increased in populations that frequently have oral or anal receptive intercourse, such as men who have sex with men (MSM). The CDC states that it is reasonable to expect that gonorrhea may become resistant to all known antibiotics in the near future.³

◆ Pathophysiology

Humans are the only natural hosts for *N. gonorrhoeae*, an aerobic, non-spore-forming, oxidase-positive gram-negative coccal (round) microorganism that usually appears in pairs (diplococci), with adjacent, slightly-flattened sides. Hairlike filaments, called *pili*, appear to help the microorganisms attach themselves to host cells: the epithelial cells of mucous membranes (Fig. 27.2). Columnar, transitional, and stratified squamous epithelial cells are most often infected. First, the microorganisms become attached to the plasma membranes (cell walls) of these cells, and then they invade the cells and begin to damage the mucosa. Generally, a quick leukocytic (inflammatory) response and exudation at the site of infection occur.

FIGURE 27.2 Gonococci. Scanning electron microscopy showing gonococci attaching to the nonciliated cells of human uterine/fallopian tube mucosa. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 3, London, 2003, Mosby.)

In women, the endocervical canal (inner portion of the cervix) is a common site of initial gonococcal infection, although urethral colonization and infection of glands (paraurethral [Skene] glands and greater vestibular [Bartholin] glands) near the urethra and vagina also are common. Several factors facilitate ascent of gonococci into the

uterus and the fallopian tubes, where they can cause PID. Among these factors are (1) disintegration of the cervical mucous plug and an increase in vaginal pH to >4.5 during menstruation, (2) uterine contractions that may cause retrograde menstruation into the fallopian/uterine tubes, and (3) various microbes that possess virulent potentiating factors for chlamydia or gonococcal PID. Bacteria (*N. gonorrhoeae*, *Chlamydia trachomatis*) also may adhere to sperm and be transported to the fallopian/uterine tubes. Once gonococci are in the fallopian/uterine tubes, progressive mucosal and submucosal invasion of the tissues causes sloughing of normal, ciliated tubal epithelium and a marked inflammatory response causing the tubes to fill with exudate (see [Chapter 26](#) for more on PID).

In men, the gonococci typically infect the urethra or rectum. Untreated urethral infection can cause epididymitis in men, and potentially lead to urethral stricture, fistula formation, and sterility. However, a few men maintain asymptomatic infections for long periods of time.³

Concurrent or isolated oropharyngeal and anorectal infection can be found in infected men and women and may be difficult to detect with common testing mechanisms.⁵ These sites are associated with greater antibiotic resistance than urethral or vaginal infection and may need additional treatment and monitoring.⁵ One hypothesis for the increase in resistant strains in populations with a high prevalence of oral and anal intercourse is that the oral and rectal mucosae normally contain many nonpathogenic forms of *Neisseria* bacteria. These bacteria are often exposed to antibiotics used for other non-STI conditions; however, instead of being eliminated, they develop antibiotic resistance. Gonococci frequently share plasmids and DNA across species, facilitating the transfer of antibiotic resistance.⁴ When the oropharynx and the rectum are infected by *N. gonorrhoeae*, the pathogens come in contact with antibiotic-resistant bacteria that share plasmids and DNA. As the *N. gonorrhoea* proliferate, they can acquire antibiotic resistance before being spread to new individuals through orosexual contact.⁴

•Clinical Manifestations

The clinical manifestations of gonorrhea can be categorized as local or systemic and uncomplicated or complicated. Uncomplicated local infections include urethral infections in men and urogenital infections in women. While infection can initially be asymptomatic, the majority of infected men will develop painful urination or purulent penile discharge, or both, within a week of infection.³ These severe symptoms encourage most men in developed countries to seek treatment.³ However, some men only have a little discharge or urethral itching (pruritus), and 5% to 10% never have signs or symptoms. Most cases of untreated gonococcal urethritis resolve spontaneously after several weeks, and more than 95% of individuals are asymptomatic by 6 months after infection (although they may still be infectious).

In women, the incubation period varies but those who develop symptoms usually manifest within 10 days of exposure or 1 to 2 days after the next menstrual period. More than half of gonorrhea infections in women are initially asymptomatic. Symptoms often do not appear until the infection has spread to the upper reproductive tract (uterus, fallopian/uterine tubes, and ovaries). Symptoms can include dysuria, increased vaginal discharge, abnormal menses (increased flow or dysmenorrhea), dyspareunia, lower abdominal/pelvic pain, and fever. Physical examination may disclose cervical friability and erythema (redness) and mucopurulent discharge from the cervical os (Fig. 27.3). There may be discharge from the paraurethral (Skene) or greater vestibular (Bartholin) glands if these sites are involved.

FIGURE 27.3 Gonococcal Cervicitis. The cervix is involved in 85% to 90% of cases in women, but discharge is profuse enough to be recognized in only 10%. (From Centers for Disease Control and Prevention [CDC]: *STD clinical slides* [website]. Available at: www.cdc.gov/std/training/clinicalslides/slides-dl.htm. Accessed April 27, 2017.)

Anorectal gonorrhoea occurs more commonly in MSM, but also is found in women both as an isolated finding and with coexisting urogenital gonorrhoea.¹ Symptoms of anorectal gonorrhoea range from mild anal pruritus (itching), mucopurulent rectal discharge, and slight rectal bleeding to severe rectal pain, tenesmus (painful and ineffectual straining at stool), and constipation. Physical examination findings include anal erythema and discharge and evidence of mucosal damage to the anus and rectum, such as friability, edema, and purulent exudate.

Gonococcal pharyngitis occurs after oral sexual contact with an infected partner. Symptomatic pharyngitis is indistinguishable from any other bacterial pharyngitis and can include fever, lymphadenopathy, and tonsillitis. However, 60% of people with oropharyngeal infections are asymptomatic.³ In addition, many clinicians neglect to test for oropharyngeal gonorrhoea because they do not screen for unprotected oral sex. Cure rates for this type of gonorrhoea are much lower because of inadequate antibiotic concentrations in oral tissue.⁴ Other sites of uncomplicated local infections include the eyes, leading to conjunctivitis; this condition occurs almost exclusively in newborns born vaginally to infected mothers. Primary cutaneous infection also has been reported and is

usually manifested as a localized ulcer of the genitalia, perineum, proximal lower extremities, or fingers.

Complicated gonococcal infections include prostatitis, epididymitis, lymphangitis, and urethral stricture in men, and salpingitis, PID, and Bartholinitis in women. Infections spread from the site of infection further into the genital tract, causing severe inflammation and scarring. In women, infection of the uterus, uterine tubes, and eventually the peritoneum is known as *PID*. The onset of PID symptoms may be rapid and usually occurs during menses.⁶ Women may experience chills, fever, nausea, vomiting, and lower abdominal/pelvic pain that worsens with movement, such as walking, coughing, sneezing, or intercourse. Abdominal palpation often discloses bilateral lower quadrant tenderness and rebound tenderness from peritoneal irritation.³ Marked tenderness of the internal genitalia is often noted during pelvic examination.

PID resulting from any pathogen contributes to infertility through a variety of mechanisms. During infection, the delicate ciliated epithelium of the uterine tubes is permanently damaged and the lack of regular cilia movement can impair the transit of sperm and fertilized ova.⁶ Scarring and adhesions of the tubes may further impair fertility. Up to 18% of women who have been diagnosed with PID experience later infertility, and ectopic pregnancy rates in this population are as high as 9% because of slowed motility of the cilia in the fallopian tubes.⁶

Disseminated gonococcal infection (DGI) is a rare systemic complication caused by the spread of infection through the bloodstream. Symptoms of this life-threatening condition include a generalized rash, severe joint pain, and even meningitis and endocarditis.³ Gonococcal strains that can cause DGI may cause genital inflammation before systemic dissemination.³

If a mother has gonorrhea at the time of birth, she can transmit the infection to her child. Most states require that all infants receive prophylactic ophthalmic antibiotics to prevent gonococcal eye infection (**ophthalmia neonatorum**) (Fig. 27.4). Topical antibiotics may not be effective in eliminating neonatal infection, and systemic

treatment is indicated for all newborns with known exposure.³ Untreated infection causes bilateral corneal ulceration, with a profuse yellow or gray purulent exudate, and is followed by necrosis, scarring, and blindness. Newborns born to infected mothers also may develop gonorrheal rhinitis, anorectal infection, or an abscess at the site of electrode placement for fetal monitoring. Onset of symptoms generally occurs 1 to 12 days after birth.³

FIGURE 27.4 Gonococcal Ophthalmia Neonatorum. Examiner should be gloved. (From McMillan A, Scott GR: *Sexually transmitted infections*, ed 2, London, 2000, Churchill Livingstone.)

◆ Evaluation and Treatment

Because of the large percentage of infected women without symptoms, routine genital tract screening for at-risk women (i.e., those younger than age 25, pregnant, or with a new sexual partner) is recommended. Men should be screened according to risk factors and symptoms.³ Clinical signs and symptoms are not sufficient for the differential diagnosis. The test that is used should be selected on the

basis of the suspected site of infection. Nucleic acid hybridization tests can be used on samples collected from the vagina and urethra (of adult males and females; female children but not male children), as well as urine (except in boys).³ Culture should be used to diagnose infections of the rectum, oropharynx, and conjunctiva of both sexes and all ages, as well as any site on boys.³ Microscopic evaluation of Gram-stained slides of specimens from symptomatic men also can be used for diagnosis, and it is deemed positive for *N. gonorrhoeae* if gram-negative diplococci with typical “kidney bean” morphology are seen inside polymorphonuclear leukocytes.

N. gonorrhoeae has developed resistance to many antibiotics and has the real potential to become resistant to all current treatments.³ There is currently only one CDC recommended drug (ceftriaxone) to treat gonorrhea, although less-effective alternatives are available.³ To prevent further drug resistance, the CDC and the WHO recommend a multidrug treatment for gonorrhea that also is effective against chlamydia.³ The CDC is closely observing the drug resistance of gonorrhea through monitoring of samples obtained at clinics around the country. CDC treatment guidelines are updated regularly and the most recent edition, found on the CDC website or app, should be used. Current CDC treatment guidelines for uncomplicated gonorrheal infections are listed in [Box 27.1](#). Complicated infections require intravenous antibiotic therapy and possibly hospitalization.

Box 27.1

Outpatient Treatment for Uncomplicated Gonorrhea* Infection of the Cervix, Urethra, Rectum, and Pharynx

- One of the following:
 - Ceftriaxone, 250 mg IM in a single dose
- *AND* to prevent drug resistance and treat potential infection with chlamydia:

Azithromycin, 1 g PO in a single dose

IM, Intramuscularly; *PO*, orally.

* Antibiotic resistance is rapidly increasing for this pathogen; please check current guidelines at the Centers for Disease Control and Prevention website at <https://www.cdc.gov> and search “gonorrhea.”

Data from Workowski KA, Bolan GA: *MMWR Recommend Rep* 64(RR-03):1–137, 2015.

Sexual partners also are assessed and treated according to these protocols, and sexual contact is avoided until treatment is completed. Condoms for all genital contact, including oral sex, are strongly recommended to prevent future infection.

Syphilis

Syphilis, a disease with local and systemic manifestations that stretch over years, has been well-known throughout history. Many famous figures from the ancient world and royal families were thought or known to have had syphilis. With the advent of antibiotics and intensive public health efforts during and after World War II, the prevalence of syphilis declined sharply. Rates of syphilis reached a record low in 2000.⁷ However, since this all-time low, the rate of syphilis in the United States has doubled to 5.3 cases per 100,000. Men account for nearly 91% of all new cases of syphilis, whereas rates between sexes were equivalent two decades ago.⁷ Data suggest this increase is driven by transmission of syphilis among MSM and accounts for over 89% of new cases.¹

Congenital syphilis, caused by vertical transmission of the spirochete, also has experienced resurgence in the United States. After years of decline, the rate of congenital syphilis increased by 38% between 2012 and 2014 to 11.6 per 100,000 births.⁸ During pregnancy, untreated early syphilis results in perinatal death in as many as 40%

of cases and may lead to perinatal complications in more than 70% of cases because the spirochete can cross the placental membrane to infect the fetus.⁹ However, simple treatment with penicillin is 98% effective at preventing vertical transmission.⁸ Therefore all pregnant women should be screened at their first prenatal visit, and women at risk should be screened again in the third trimester and at the time of delivery.⁸

◀ Pathophysiology

Treponema pallidum, the cause of syphilis, is an anaerobic spirochete bacterium that can grow in any human organ or tissue but cannot be cultured in vitro. When viewed through dark-field microscopy, the *Treponema* (individual microorganism) resembles a corkscrew, with regular, tight spirals and a rotary motion.

Because the bacterium is present in exudate from moist mucosal or cutaneous lesions, the spirochete is usually transmitted to others during the first few years of infection.³ Transmission generally occurs through minor abrasions during sexual intercourse but can occur extragenitally as well. Although condoms can decrease the likelihood of infection, if lesions are present on areas not covered during intercourse, transmission can occur even with safer sex practices.

The course of untreated syphilis consists of four stages based on clinical findings: primary, secondary, latent, and tertiary (Box 27.2); the division between stages is not always apparent and the drug of choice is the same for all stages.³

Box 27.2

Progression of Untreated Syphilis

Stage I, primary syphilis—local invasion: *Treponema pallidum* multiplies in epithelium, producing granulomatous tissue reaction (chancre); lymph-containing microorganisms drain into adjacent lymph nodes and stimulate immune responses

Stage II, secondary syphilis—systemic disease: blood-borne bacteria spread to all major organ systems; immune system suppresses infection and symptoms regress spontaneously

Stage III, latent syphilis—silent infection: transmission of infection possible even though there are no clinical signs of infection

Stage IV, tertiary syphilis—noninfectious disease: significant morbidity and mortality occur; destructive skin, bone, and soft tissue lesions, or gummas, result from severe hypersensitivity; cardiovascular complications (aneurysms, heart valve insufficiency, heart failure) and neurosyphilis develop

Primary syphilis begins at the site of bacterial invasion (Fig. 27.5), where *T. pallidum* multiplies in the epithelium and produces a granulomatous tissue reaction called a **chancre**. Some microorganisms drain with lymph into adjacent lymph nodes. Within the nodes and at the site of the chancre, the cell-mediated and humoral immune responses are stimulated.

FIGURE 27.5 Primary Syphilis. A, Penile chancre. B, Vulval chancres; the labia and perineum show induration and edema of chancres. (A From McMillan A, Scott GR: *Sexually transmitted infections*, ed 2, London, 2000, Churchill Livingstone; B courtesy Barbara Romanowski, MD, from Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

Secondary syphilis is systemic. During this stage, blood-borne bacteria spread to all major organ systems. The secondary stage is followed by a period during which the immune system is able to suppress the infection. Even without treatment, spontaneous

resolution of the skin lesions occurs and the individual enters the latent stage of infection.

Latent syphilis may be subdivided into early and late stages; however, no specific criteria delineate one from the other.³ Medical history and serologic studies can show that syphilis is present, but the individual has no clinical manifestations. Transmission remains possible during this phase.

Tertiary syphilis is the most severe stage, involving significant morbidity and mortality. The pathogenesis of syphilitic manifestations at this stage remains unclear. The destructive skin, bone, and soft tissue lesions (called **gummas**) of tertiary syphilis probably are caused by a severe hypersensitivity reaction to the microorganism. Within the cardiovascular system, infection with *T. pallidum* may cause aneurysms, heart valve insufficiencies, and heart failure.

Congenital syphilis (CS) is caused by vertical transmission and is estimated to cause 500,000 fetal and neonatal deaths every year worldwide.⁹ Syphilis becomes a systemic disease shortly after maternal infection and can be transmitted to the fetus as early as the ninth week of gestation because the spirochete can pass through the placenta. Intrauterine infection causes fetal or perinatal death in 40% of affected infants, and many live-born infants have permanent, lifelong morbidity, including congenital abnormalities.⁹ The risk of CS is estimated at up to 80% in primary syphilis and declines with advancing stages of the disease.⁹ Penicillin is very effective in decreasing morbidity and mortality if the disease can be diagnosed early in fetal development.¹⁰

◀Clinical Manifestations

Primary Stage

In adults, the incubation period of syphilis ranges from 12 days to 12 weeks after exposure and averages 3 weeks. A sore, or *hard chancre*, develops at the site of treponemal entry. Typically the chancre is an eroded, painless, firm, and indurated (hard) ulcer up to 2 cm in diameter. Firm, enlarged, and nontender regional lymph nodes

accompany chancres. Typical chancres of the penis and vulva are shown in Fig. 27.5. Syphilitic chancres are not always typical and syphilis should be considered in the presence of any open lesion. Secondary infection can cause chancres to become necrotic and painful, and lesions on the fingers may be dry, scaly, and papular or moist and vegetative. If left untreated, the chancre of primary syphilis heals in 2 to 8 weeks and then spontaneously disappears, usually without leaving a scar.

Secondary Stage

Clinical manifestations of secondary syphilis usually develop 6 weeks after the first appearance of the chancre but may overlap with those of the primary stage. Systemic symptoms are variable and can include low-grade fever, malaise, sore throat, hoarseness, anorexia, generalized adenopathy, headache, joint pain, and skin or mucous membrane lesions or rashes. Cutaneous (skin) rashes are generally papulosquamous (raised and scaly), but any variation or combination of macular (flat), papular (raised), and pustular (pus-filled) lesions may be seen. Lesions are often widespread and bilateral, appearing on the palms and soles (Fig. 27.6). Some lesions become hypertrophied, flat, moist, and wartlike or vegetative (e.g., cauliflower-like). These lesions, called **condylomata lata**, are highly contagious and develop on the perineum, vulva, and groin of women (Fig. 27.7), and around the inner thigh and anal area in men and women. Besides skin sores, oral mucous membrane lesions (known as *mucous patches*), lymphadenopathy, pruritus, and alopecia are common. Some individuals develop anemia, leukocytosis, increased sedimentation rate, hepatitis, transitory proteinuria, arthritis, electrocardiographic abnormalities, and central nervous system (CNS) symptoms. Regardless of treatment, cutaneous lesions generally heal in 2 to 10 weeks. Within the CNS, the presence of *T. pallidum* in cerebrospinal fluid may cause the manifestations of neurosyphilis, including altered mental status and meningitis, which can occur within any stage of syphilis infection but are more common in early stages of infection.³

FIGURE 27.6 Secondary Syphilis. Secondary syphilis to the palms and plantar surfaces. (From Morse S et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

FIGURE 27.7 Condylomata Lata. Broad-based, moist, dark-field–positive condylomata lata of the perineum. (From McMillan A, Scott GR: *Sexually transmitted infections*, ed 2, London, 2000, Churchill Livingstone.)

Latent and Tertiary Stages

The asymptomatic, latent stage of syphilis may be as short as 1 year or as long as a lifetime. After the latent stage, tertiary syphilis may present with gummas, cardiovascular lesions, and neurosyphilis manifestations, including tabes dorsalis and general paresis.³ Tertiary syphilis is rare because of the widespread availability of antibiotics.

Congenital Syphilis

Congenital syphilis (CS) is caused by the passage of the spirochete across the placental membrane to affect any or all fetal tissues. The infection can cause fetal death or growth abnormalities, including changes in the fetal bones, teeth, and neurologic system. Affected newborns can have a variety of manifestations of the disease, including growth abnormalities, rashes, hepatosplenomegaly, jaundice, and CNS involvement, including blindness and deafness.⁸ A classically reported late manifestation of congenital syphilis is notched incisors. While now rare, this stigma is used in historical studies of syphilis.

◆ Evaluation and Treatment

Numerous dermatologic disorders can mimic the skin lesions of secondary syphilis, making differential diagnosis difficult. Laboratory confirmation is important. Two categories of serologic testing exist: nontreponemal antigen tests and treponemal antibody tests.³ Nontreponemal antigen tests, which demonstrate the presence of *reagin* (a group of antibodies present in syphilis) in serum, provide indirect evidence of infection. Examples of nontreponemal analysis are the Venereal Disease Research Laboratory (VDRL) antigen and the rapid plasma reagin (RPR) tests (Box 27.3). These tests yield a positive result (presence of reagin) in more than 50% of individuals with primary syphilis and in 100% of individuals in the secondary phase of disease and can be useful in screening and assessing response to treatment.³

Box 27.3

False-Positive Serologic Tests for Syphilis

Reasons for False-Positive, Nontreponemal Reactions (VDRL, RPR)

Transient Reactions (<6 Months)

- Technical error (low titer)
- Mycoplasma pneumoniae*
- Enterovirus infections
- Infectious mononucleosis
- Pregnancy
- Narcotic abuse
- Advanced tuberculosis
- Scarlet fever
- Viral and atypical pneumonia
- Brucellosis
- Rat-bite fever
- Leptospirosis
- Measles
- Mumps
- Lymphogranuloma venereum
- Malaria
- Trypanosomiasis
- Varicella

Chronic Reactions (>6 Months)

- Malaria
- Leprosy
- Systemic lupus erythematosus
- Narcotic abuse
- Other connective tissue diseases

Elderly population
Hashimoto thyroiditis
Rheumatoid arthritis
Reticuloendothelial malignancy
Familial false-positive reaction
Idiopathic

Reasons for False-Positive, Treponemal-Specific Reactions (FTA-ABS)

Technical error
Inefficient sorbents
Healthy individuals without syphilis
Genital herpes simplex
Pregnancy
Lupus erythematosus (skin only or systemic)
Alcoholic cirrhosis
Scleroderma
Mixed connective tissue disease

FTA-ABS, Fluorescent treponemal antibody absorption; *RPR*, rapid plasma reagin; *VDRL*, Venereal Disease Research Laboratory.

Because the VDRL and RPR tests have high rates of false positives, a treponemal test is performed if the screening test is positive. Treponemal tests are serologic-specific tests that are used to assess antibody response to *T. pallidum* and include enzyme immunoassays (EIAs), chemoluminescence immunoassays, the fluorescent treponemal antibody absorption (FTA-ABS) test, and the passive particle agglutination (TP-PA) assay.³

Preferred treatment for all stages of syphilis is parenteral injection of benzathine penicillin G, because other types of penicillin are not as effective. If the individual has manifested signs of the disease for less than 1 year, a single intramuscular dose is appropriate. If signs have

been present for more than 1 year or they are asymptomatic and assumed to be in late latent syphilis, the treatment is three weekly injections. The CDC is the best source for current information on treatment regimens.³ Penicillin therapy also is appropriate for pregnant women to prevent vertical transmission.³ There is no evidence to date that *T. pallidum* has developed resistance to penicillin. In fact, it is highly sensitive; but because of the slow replication time, serum levels must be maintained for 7 to 14 days. Men and nonpregnant women who are allergic to penicillin may receive oral doxycycline, 100 mg twice daily for 14 days, or tetracycline, 500 mg every day for 14 days. Pregnant women with a penicillin allergy should be desensitized and then treated with benzathine penicillin G as recommended by the CDC because the other available antibiotics cause lifelong discoloration of the forming teeth of the fetus.³

Repeated assessment of VDRL or RPR titers is used to determine effectiveness of treatment. Titers should decrease fourfold if treatment was successful. Sexual partners also are tested and treated, and the use of condoms is recommended until effective treatment is verified.

Newborns of mothers with documented syphilis need careful evaluation after birth. Definitive diagnosis of congenital syphilis is complicated by the presence of maternal antibodies in the newborn's blood. Treatment decisions are made based on maternal status, clinical symptoms of congenital syphilis, and also comparison of maternal and neonatal titers.³ If the infant requires treatment, penicillin is the drug of choice with carefully titrated dosing depending on fetal weight and the day of treatment, and the CDC is the best source of current information.³

Chancroid

Chancroid, or soft chancre, is an acute infectious disease that was first differentiated from syphilis in 1852. It is caused by *Haemophilus ducreyi*, a gram-negative bacillus. The incidence of chancroid is decreasing worldwide, and it is infrequently seen in the United States.¹ Sporadic outbreaks occur throughout the world and tend to be associated with prostitution and illicit drug use, when individuals

continue to engage in intercourse in spite of a painful genital lesion.¹¹ Chancroid is a risk factor for HIV acquisition, and existing HIV infection is a risk factor for chancroid infection with exposure.³

◀ Pathophysiology

H. ducreyi is a gram-negative bacillus with rounded ends. It is commonly observed in small chains or clusters along mucous strands under a microscope. Transmission can occur through sexual contact and autoinoculation, but there is no evidence for vertical transmission.³ Chancroid lesions are found throughout the genital area. Initially, the papule enlarges; it then erodes into a soft, circumscribed ulcer containing a superficial exudate of varying size and presentation.¹¹ Beneath the ulcer is a lesion characterized by edema, endothelial proliferation, and a base of granulation tissue. Adjacent lymph nodes are acutely inflamed and full of polymorphonuclear leukocytes and necrotic cells.

◀ Clinical Manifestations

Chancroid has an incubation period of 3 to 10 days.¹¹ Women are generally asymptomatic but, depending on the site of infection, can present with less obvious symptoms (dysuria, dyspareunia, vaginal discharge, pain on defecation, or rectal bleeding). Constitutional symptoms are unusual. An initial vesicopustule lesion forms at the site of inoculation and erodes into a soft ulcer with a necrotic base; surrounding erythema; and a ragged, serpiginous (spreading) border (Fig. 27.8). Unilateral, painful, local lymphadenopathy presents in about half of infected individuals. Inguinal **buboes** (unilocular abscess of the inguinal lymph nodes) develop 7 to 10 days after the initial chancre and fill with exudate. In 25% to 60% of cases, the buboes spontaneously rupture out onto the skin, spreading the infection through autoinoculation.

FIGURE 27.8 Chancroid. A, Ulcers on the penile shaft. B, Multiple vulvar lesions. C, Differences in clinical appearance among chancroid, syphilis, and genital herpes. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

Ulcers on the prepuce may lead to phimosis or paraphimosis. Other complications of chancroid include balanitis, secondary infections, necrosis, and fistula formation. Lesions may take months or years to heal and cause scarring.³

◆ Evaluation and Treatment

Chancroid is easily confused with other types of genital ulcers, particularly those of syphilis, genital herpes, and granuloma inguinale (see Fig. 27.8). Unlike the syphilitic ulcer, chancroidal ulcer is painful, tender, and nonindurated and inguinal lymphadenopathy is pronounced. Microscopic analysis of a Gram-stained smear from the chancroid helps to identify the microorganism. Definitive diagnosis depends on recovery of *H. ducreyi* from cultured specimens; however, the culture medium is not commercially available.³ Diagnosis depends

on the clinical presentation of a painful genital ulcer with inguinal lymphadenopathy and with negative testing for syphilis and herpes simplex virus.³ In addition, HIV testing is recommended because chancroid is a cofactor for transmission of HIV.

Resistance to recommended antibiotics has emerged in isolated instances worldwide. Recent treatment recommendations include a single intramuscular injection of ceftriaxone (250 mg) or a single dose of oral azithromycin (1 g). Effective oral multiple-dose regimens include ciprofloxacin, 500 mg orally twice daily for 3 days; or erythromycin, 500 mg 3 times daily for 7 days. Persons infected with HIV and uncircumcised men have higher rates of treatment failure and may require a longer treatment regimen. Treatment failure requires more intensive assessment for coinfection with other diseases.³ Simultaneous treatment of sexual partners and use of condoms are recommended to prevent reinfection.

Granuloma Inguinale

Granuloma inguinale (donovanosis) is a chronic, progressively destructive bacterial infection caused by *Klebsiella granulomatis*. Although sexually transmitted, granuloma inguinale has a low transmission rate between sexual partners.¹¹ Infection through fecal contamination and autoinoculation also is possible.¹¹ As with all genital ulcerative diseases, granuloma inguinale plays a role in HIV transmission.¹¹ Granuloma inguinale very rarely occurs in the United States¹¹; it is more prevalent in some tropical and subtropical parts of the world (India, New Guinea, Africa, central Australia, and to a lesser extent the Caribbean and Brazil).

◀ Pathophysiology

C. granulomatis is a gram-negative, nonsporing, nonmotile, encapsulated rod not easily cultured in the laboratory. After an individual is infected, bacteria survive and multiply within vacuoles of large histiocytic cells or polymorphonuclear leukocytes. The bacteria reproduce within these cells, and a vacuole may contain 20 to

30 microorganisms. These bacteria-filled vacuoles were identified by Donovan in 1905 and are termed **Donovan bodies**. The presence of Donovan bodies in tissue smears of material from the lesions is considered ideal for diagnosis, but this test is difficult even in well-equipped laboratories.³

The incubation period of granuloma inguinale is 8 to 80 days. As lesions begin to form, single lesions often coalesce with nearby lesions or form new lesions by autoinoculation of nearby skin surfaces. Progression from the initial nodule to a large, granuloma-heaped ulcer occurs slowly. These lesions are vascularized and bleed easily.³ Secondary infection may occur, increasing tissue damage and residual scarring. The disease may spread to the bones, joints, and liver.

◀Clinical Manifestations

The primary sites for development of the lesions are the distal penis in men and the introitus in women. The initial lesion is an indurated, sharply defined, painless, subcutaneous nodule that is often preceded and accompanied by itching. Nodules bleed easily and contain abundant red, beefy-looking granulation tissue. These lesions spread as the disease progresses. Secondary infection may occur, increasing tissue damage and residual scarring. Although systemic symptoms are rare, the disease may spread to the bones, joints, and liver. In some cases, infection spreads to the inguinal area and produces **pseudobuboes**. In these instances, the affected lymph nodes are not directly affected, but the surrounding area may be infected and abscessed.

◀Evaluation and Treatment

Although the clinical manifestations of this disease are important for diagnosis, confirmation involves microscopic examination for Donovan bodies in a smear or biopsy specimen. Currently, there is not an FDA-approved laboratory test for detection of *K. granulomatis*.³

Many antibiotics successfully treat *K. granulomatis*. With effective antibiotic treatment, lesions begin to heal in 7 days, but treatment is

continued for at least 3 weeks and until all lesions are healed. Oral therapy includes doxycycline, 100 mg twice a day; azithromycin, 1 g once a week for 3 weeks, and until lesions are healed; ciprofloxacin, 750 mg twice a day for at least 3 weeks; erythromycin base, 500 mg 4 times a day for at least 3 weeks; or trimethoprim-sulfamethoxazole, 160 mg/800 mg, double-strength tablet twice a day for at least 3 weeks.³ Relapses can occur 6 to 18 months later despite effective initial therapy; thus prolonged follow-up is necessary as is treatment of sexual partners. Because other STIs frequently coexist, individuals should be tested for chlamydia, gonorrhea, syphilis, hepatitis B, and HIV.

Bacterial Vaginosis

Bacterial vaginosis (BV) (previously called nonspecific vaginitis, nonspecific vaginosis, or *Haemophilus*, *Corynebacterium*, or *Gardnerella* vaginitis) is a sexually associated condition, but is not necessarily considered an STI. The condition is associated with sexual contact, including genital touching and digital penetration, oral sex, and penile penetration. Although BV occurs mostly in sexually active women of reproductive age, it can affect women, especially menopausal women, who are not sexually active. BV is diagnosed by the presence of characteristic symptoms and clinical findings. Prevalence rates vary from 17% among women in family planning clinics to 37% among some groups of pregnant women. Fifty percent of women clinically diagnosed with BV state they are asymptomatic.³

♦Pathophysiology

The exact etiology of BV is unknown but is thought to be a dysbiosis of normal vaginal flora that is associated with sexual contact. *Gardnerella vaginalis* and various anaerobes, including *Mycoplasma hominis*, *Bacteroides*, and *Mobiluncus*, interact and proliferate when lactobacilli (the normal predominant vaginal flora) are decreased or absent. Bacteria adhere to vaginal epithelium and form a scaffolding-like biofilm to which other bacteria can adhere, facilitating their

proliferation and causing a noninflammatory response in the surrounding tissues.¹² As the vaginal microbiome changes, catabolic enzymes degrade proteins into amines. In turn, amines elevate the vaginal pH and produce the characteristic fishy odor associated with BV. BV has been implicated in PID, chorioamnionitis, preterm labor, and postpartum endometritis. In addition, BV increases a woman's risk of contracting other STIs, such as HIV.³

◀Clinical Manifestations

BV is characterized by a thin, gray, homogeneous, and malodorous discharge that adheres to the vaginal walls but is often copious enough to drain from the vagina. Occasionally, the discharge is bubbly or frothy. The vaginal pH is usually 5 to 5.5, and women often complain of a strong, foul, fishy vaginal odor, particularly after intercourse and during menses. Odor is intensified by contact with alkaline secretions, including semen and menstrual discharge. Male and female partners of infected women may harbor the microorganisms responsible for BV but have no signs or symptoms.

◀Evaluation and Treatment

Diagnosis of BV can be made on the basis of the presence of three of four of the following criteria, known as *Amsel criteria*: (1) the presence of homogeneous, adherent gray or white vaginal discharge; (2) a vaginal pH greater than 4.5; (3) a positive amine odor in the presence of an alkali, such as potassium hydroxide, known as the *whiff test*; and (4) the presence of clue cells on wet mount.³ *Clue cells* are considered pathognomonic for BV. They are vaginal epithelial cells that are covered with bacteria, causing them to look as if they were sprinkled with pepper. The saline wet mount also may show the absence of lactobacilli and few or no leukocytes. There also is a commercially available test, Affirm VPIII, that uses DNA hybridization to detect *G. vaginalis*. Cultures for BV are not recommended; however, high-risk individuals should be screened for gonorrhea and chlamydia.³

The most commonly used treatment for BV is a course of oral

metronidazole (Flagyl), 500 mg twice daily for 7 days; 0.75% vaginal gel, once daily for 5 days; or clindamycin cream 2% applied vaginally for 7 days.³ Alternative regimens include tinidazole, 2 g orally once daily for 2 days or 1 g orally for 5 days; oral clindamycin, 300 mg twice daily for 7 days; or clindamycin ovules, 100 mg intravaginally for 7 days.³ Treatment for BV should be personalized based on the woman's needs and behaviors. For example, metronidazole and tinidazole strongly react with alcohol and should not be used by women who cannot or will not eliminate alcohol ingestion for the full duration of treatment plus an additional 24 hours. In addition, the ovules can weaken latex condoms and diaphragms.³

BV treatment in women infected with HIV is the same as that in individuals who are HIV-negative. The CDC currently recommends treatment of BV in pregnancy to reduce the risk of poor perinatal outcomes, including preterm birth.³

Chlamydia

Chlamydia is the common name for infections caused by *Chlamydia trachomatis* (CT). *C. trachomatis* is responsible for a variety of syndromes, including acute urethral syndrome, nongonococcal urethritis (NGU), mucopurulent cervicitis, and PID. Chlamydia is the most common reportable STI in the United States and is a leading cause of preventable infertility and ectopic pregnancy. In 2014, more than 1.4 million cases of chlamydial infections were reported,¹ the greatest number of cases ever reported in a single year. Rates of chlamydia infections are increasing in all age groups, areas of the country, and racial/ethnic groups. This increase probably reflects the continued expansion of screening efforts and the increased use of more sensitive diagnostic tests, as well as an actual increase in incidence.³ The majority of reported cases of chlamydia are in people younger than 26 years old, but the incidence in older adults is increasing.¹ Up to 90% of women with CT infection are asymptomatic, which can delay diagnosis and increase the risk of long-term health sequelae.³ Without timely treatment, 10% to 20% of women will have the infection spread to the uterus and uterine tubes.³

Risk groups for chlamydia include age younger than 26, recent new sexual partner, and drug use or other risky behaviors.¹ Like gonorrhea, *Chlamydia* infection can be transmitted from mother to infant during birth and can cause eye infections and pneumonia in affected newborns.³

◀ Pathophysiology

C. trachomatis is an obligate, gram-negative intracellular bacterium that lacks the ability to reproduce without a host cell. It is differentiated from other bacteria by its unique two-part growth cycle. The first part consists of an elementary body that is small and resilient and is able to survive extracellularly.¹³ Once this elementary body attaches itself to a receptor host cell, it is able to enter by endocytosis. Once inside the cell, the second part of the cycle begins and the microorganism becomes a metabolically active parasite, reproducing within the cell until the cell is destroyed and ruptures, disseminating up to 1000 new elementary bodies. Infection with *C. trachomatis* produces an inflammatory reaction that results in permanent scarring of tissues.¹³

Chlamydia microorganisms are always pathogens; they are not part of the normal flora of the urogenital tract, despite the fact that infection is often asymptomatic. Numerous serotypes, or strains, of *C. trachomatis* have been identified. Some cause urogenital infection; some, blindness; and others, lymphogranuloma venereum, which is discussed in the next section.¹³ The strains of *C. trachomatis* that cause urogenital infection require squamous-columnar and columnar-epithelial cells as hosts. *C. trachomatis* infects and disrupts superficial tissues, causing damage and scarring, but does not seem to invade or destroy deeper tissues.¹⁴

In newborns, several sites may be inoculated with *Chlamydia* during passage through the infected maternal cervix. These include the eye, nasopharynx, rectum, and vagina. The infant also may aspirate infected secretions with its first breaths, resulting in chlamydial pneumonitis and substantial newborn morbidity.³

•Clinical Manifestations

Chlamydial infections are asymptomatic in up to 90% of adults.³ Urogenital infections caused by *Chlamydia* closely parallel those caused by gonorrhea. Both microorganisms infect superficial genital tract tissues, such as mucosa of the urethra and cervix, and both can invade the epididymides, the fallopian/uterine tubes, and (rarely) the hepatic capsule. Table 27.2 lists the pathophysiologic similarities of chlamydial and gonococcal infections. Men and women have different responses to the infection.

TABLE 27.2

SIMILARITY OF CLINICAL SYNDROMES CAUSED BY *Neisseria gonorrhoeae* AND *Chlamydia trachomatis*

SITE OF INFECTION	CLINICAL SYNDROME	
	<i>N. gonorrhoeae</i>	<i>C. trachomatis</i>
Men		
Urethra	Urethritis	Urethritis
Epididymis	Epididymitis	Epididymitis
Rectum	Proctitis	Proctitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Systemic	Disseminated gonococcal infection	Reiter syndrome
Women		
Urethra	Acute urethral syndrome	Acute urethral syndrome
Bartholin gland	Bartholinitis	Bartholinitis
Cervix	Cervicitis	Cervicitis; cervical atypia
Fallopian tube	Salpingitis	Salpingitis
Conjunctiva	Conjunctivitis	Conjunctivitis
Liver capsule	Perihepatitis	Perihepatitis
Systemic	Disseminated gonococcal infection	Arthritis-dermatitis syndrome

Data from Stamm WE, Holmes KK: *Chlamydia trachomatis* infections in the adult. In Holmes KK et al, editors: *Sexually transmitted diseases*, ed 2, New York, 1990, McGraw-Hill.

The rate of chlamydial infection in men appears to be rising, with a

22% increase in diagnoses from 2010 to 2014. This increase may be an expression of increased testing as a result of easier screening methods. Rates of diagnosis are highest in adolescent men who have sex with women.¹

Although most men do not have symptoms even while contagious, chlamydial infection can cause nongonococcal urethritis. Clinically, urethritis caused by gonorrhea and chlamydia cannot be differentiated: both have a 7- to 21-day incubation period and cause dysuria. Although urethral discharge in men may be similar in the two infections, chlamydial discharge tends to be more clear and gonococcal discharge more purulent. Men might note a clear, mucous discharge or mild burning with urination.

Chlamydial epididymitis can accompany urethritis in men and is characterized by fever and a unilaterally painful, swollen scrotum. Chlamydial infection also causes proctitis (rectal inflammation) in people who have receptive anal intercourse. Chlamydial proctitis is generally mild, although it may, like gonorrheal proctitis, cause rectal bleeding, mucous discharge, and diarrhea. Reiter syndrome (urethritis, conjunctivitis, arthritis, and characteristic mucocutaneous lesions) is also associated with untreated urogenital tract infections.

C. trachomatis can cause asymptomatic urethral infection or **acute urethral syndrome** (dysuria, urinary frequency, and presence of sterile pus in the urine) in infected women. Chlamydial infection of Bartholin/greater vestibular glands can cause purulent discharge leading to a Bartholin cyst. Women with chlamydial cervicitis may be asymptomatic or may have a yellow mucopurulent discharge from the cervical os and a hypertrophic, edematous, and friable area of cervical ectopy. The woman also may report intermenstrual or postcoital spotting. Although ectopy alone does not indicate a pathologic condition, an erythematous, raw, and friable cervix is suggestive of chlamydial cervicitis (Fig. 27.9).

FIGURE 27.9 Chlamydial Cervicitis. Beefy red mucosa of columnar epithelium of cervix. (Courtesy Paul Weisner. From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

Chlamydia infection is the leading cause of tubal infertility in women because of infectious damage to the fallopian tubes similar to that which may occur with gonorrhea. Risk factors for infertility include the duration and severity of infection and the lifetime number of chlamydial infections. Even women with asymptomatic salpingitis have a risk of subsequent infertility.³

The most common manifestations of chlamydial infections in the newborn are conjunctivitis and pneumonia. Prophylactic treatment with antibiotic eye ointment at birth does not provide complete protection against neonatal conjunctivitis and does not protect against neonatal pneumonia. Intravenous (IV) antibiotics are needed for any child at risk of acquisition. Chlamydial conjunctivitis begins between 5 and 14 days after delivery when the infant's eyes begin to water. This discharge may become purulent, and both eyes may become red and swollen.

Scarring of the conjunctivae may result, but this infection does not cause blindness. Infants with chlamydial pneumonia develop staccato coughing spells, nasal congestion, and fever at 3 to 11 weeks of age.

◆ Evaluation and Treatment

Since most infections are asymptomatic, the CDC recommends widespread screening of at-risk groups. A complete detailing of groups needing annual screening can be found in their treatment guideline, on their website, or through their smartphone app. All sexually active women who are less than 26 years old should be screened annually. In addition, the CDC recommends that all women, regardless of age, be screened if they have a new sexual partner or their partner is not monogamous. Pregnant women should be routinely screened for *Chlamydia* at least once during pregnancy.³

Methods for diagnosing chlamydial infections include tissue culture, direct chlamydial enzyme immunoassay, fluorescein-labeled monoclonal antibody tests, and nucleic acid amplification testing (NAAT). Currently, tests using chlamydia-specific nucleic acid sequences are the most sensitive and cost-effective tests available. In addition, they are easy to use with a variety of specimen types.³ Concurrent testing for gonorrhea can be done using the same swab. NAAT can be performed on samples taken from the vagina, endocervix, or urethra; or urine specimens can be used. The person should be tested in all the locations of genital contact. The ease of NAAT testing means that screening can be performed without a clinician, if needed, because the individual can collect the specimen following basic instructions.³

C. trachomatis is susceptible to inexpensive, readily accessible antibiotics, and treatment should begin as soon as possible to prevent complications. Treatment includes antibiotic therapy for infected individuals and all sexual contacts; abstinence or use of condoms during treatment and for 7 days after treatment is recommended. The CDC recommends observed, on-site treatment for both partners when feasible.³

Azithromycin is given 1 g orally, as a single dose, or a 7-day course of oral doxycycline is administered, 100 mg twice daily. Single-dose azithromycin is preferred if adherence to a multiple-dose, multiple-day regimen is not feasible for the individual. Alternative regimens include a 7-day course of oral erythromycin, 500 mg 4 times a day; or

erythromycin E, 800 mg 4 times daily for 7 days. Ofloxacin, 300 mg twice daily; and levofloxacin, 500 mg once daily for 7 days, also are effective alternatives.³ Azithromycin is the drug of choice in pregnancy. A test of cure is only needed if there is concern that treatment of both partners was not successful. However, treatment failures are common, especially with multidose regimens and when the partner is not immediately provided with a prescription.³

Lymphogranuloma Venereum

C. trachomatis (invasive serovars of strains L1, L2, or L3) can cause a chronic STI known as **lymphogranuloma venereum (LGV)**, which may be confused with syphilis, herpes, or chancroid. LGV was previously rare in the developed world but now is increasingly found in men who have sex with men and may spread to other populations.¹ The infection is acquired during sexual intercourse or through contact with contaminated exudate from active lesions. HIV infection increases the likelihood of acquisition and the severity of symptoms.¹⁵

◀ Pathophysiology

The strain of *C. trachomatis* that causes LGV probably penetrates skin and mucous membranes through tiny abrasions. LGV spreads to genital and rectal lymphatic tissue, where it causes marked inflammation, necrosis, buboes, abscesses of inguinal lymph nodes, and infection of surrounding tissues. Healing occurs by fibrosis after several weeks or months and results in scarring and damaging the lymph nodes and disrupting their function. LGV can cause permanent lymphatic disruption and genital disfigurement. Affected nodes become chronically swollen, hardened, and enlarged. *C. trachomatis* also spreads systemically through the bloodstream and can enter the CNS.³

◀ Clinical Manifestations

The primary lesion of LGV appears after an incubation period of 5 to

21 days. The lesion is most commonly a herpetiform (multivesicular) ulcer, but it can assume various forms. The ulcer generally is asymptomatic and inconspicuous and heals rapidly, leaving no scar. However, when contracted through receptive anal intercourse (a common current mode of transmission), the ulcer is never visible. When rectal infection occurs, LGV can cause an inflammatory response that mimics inflammatory bowel disease or proctocolitis.³ Other signs of primary LGV include a large, tender lymphatic nodule (especially unilateral) or bubo; urethritis; and cervicitis. While historically this infection resulted in three clinical stages, anorectal infection has become the most common location of infection and results in symptoms that mimic other primary care conditions.¹¹

Clinical symptoms of anorectal infection mimic other inflammatory bowel conditions and include irregular bowel movements, multiple ulcerations of the rectal mucosa, mucopurulent rectal discharge, and rectovaginal fistulae in women. Individuals may have fever, rectal pain, and tenesmus. Rectal strictures, perirectal abscesses, and anal fissures may develop with untreated infection.³

◆ Evaluation and Treatment

Clinical manifestations, history of sexual intercourse, and laboratory tests are used for LGV diagnosis. LGV is diagnosed with NAAT testing at the suspected site of infection. If clinical symptoms match LGV presentation, pharmacologic treatment should begin while waiting definitive diagnosis with test results.³ LGV is treated with oral doxycycline, 100 mg twice daily for 21 days. A 21-day course of erythromycin (500 mg) also is effective. Sexual partners within the past 60 days should be treated.³

Viral Infections

Genital Herpes

Genital herpes, which causes painful blisters (cold sores), is the most common infectious cause of genital ulcerations in the United States. In fact, genital infection with herpes simplex virus (HSV) is an epidemic

in the United States. HSV is not a reportable disease so national statistics are not available. However, HSV infections are estimated to affect 1 million new individuals each year. Recurrent infections are mostly asymptomatic (50% to 70%) and affect an estimated 50 million Americans annually.¹ Eighty percent of infected individuals do not know they have herpes. Genital herpes can be caused by either of the two serotypes of HSV: HSV-1 or HSV-2. Historically, HSV-1 lesions were more common around the mouth while HSV-2 lesions were more frequently found in the genital area. However, HSV-1 is increasingly found in the anogenital area.¹ HSV-2 outbreaks are more frequent and more severe, so serologic testing to determine the HSV subtype is warranted at diagnosis to guide suppression efforts.³

HSV infection is transmitted through contact with HSV-infected fluids or skin as occurs with genital skin or mucosal contact with a person shedding the virus. There is even the possibility that saliva alone can transmit the virus when placed on mucous membranes or genitals for lubrication.¹⁶ Persons without symptoms probably transmit most infections. Asymptomatic viral shedding is common. Transmission rates are not well identified. However, women and men who are the receptive partner for men are more susceptible to contracting herpes related to prolonged semen contact with the vaginal or rectal mucosa. Any type of rough intercourse that causes breaks in the skin surface increases transmission as well. It is estimated that a woman has an 80% to 90% risk of developing genital herpes after being exposed to an infected man.

Condoms reduce the risk of transmission, especially from males to females.¹⁷ However, if lesions or shedding occur outside the area covered by the condom, transmission can still occur.¹⁷ Female condoms offer a bit more protection from HSV because they cover and protect the vulva, but they do not eliminate risk. HSV infection greatly increases the risk of HIV acquisition. People with HSV are 4 times more likely to contract HIV if exposed, potentially because of skin splits that occur as a result of HSV infection.³

Neonatal infections can begin in utero or, more commonly, during the intrapartum or postpartum period. The risk of transmission of

HSV to the neonate varies from <1% among women with recurrence of known herpes at term to up to 30% to 50% in women who acquire HSV near term.¹ Perinatal transmission can cause extensive morbidity and mortality. Intrauterine transmission is rare (only 5% of neonatal infections) but can occur through transplacental or ascending infection and can cause fetal malformations.¹⁸

Eighty-five percent of infections are transmitted during the intrapartum period.¹⁸ Infants are at greatest risk if the mother has a primary infection acquired near the time of delivery rather than a recurrent infection or an infection acquired during the first half of pregnancy.¹ Ruptured membranes have a role in the development of HSV. Rupture of membranes for more than 4 hours increases the risk of the fetus for contracting HSV. Internal fetal monitoring devices also increase the risk of vertical transmission because they break the fetal skin. Infants also may be exposed after birth through mouth-to-mouth kissing by family members; there have been several cases of infants exposed during ritual circumcision involving direct orogenital suction.¹⁹

◀ Pathophysiology

After initial exposure and entry of the virus at mucocutaneous sites or abraded skin, the virus undergoes replication locally in the dermis and epidermis. This leads to cell destruction, transudation, and vesicle formation. The virus spreads to contiguous cells and eventually into sensory nerves. This process often causes a systemic, inflammatory, immune response, especially with HSV-2 infection, that includes fever and malaise. In rare cases, the herpes can cause CNS manifestations. Painful lesions can last from days to weeks. Eventually, the virus is transported intraaxonally to the dorsal root, where it remains in a latent stage until it becomes reactivated. After oral infection, the latent virus resides in the trigeminal ganglion; after genital infection, it resides in the dorsal sacral nerve roots. During the latent period, the viral genome is maintained in the host cell nucleus without causing cell death.

Latent infections can become reactivated, often during times of

physical or emotional stress, and cause a recurrent infection. Compared to HSV-1 infections, reactivation of the HSV-2 infection is twice as common, and the likelihood of HSV-2 recurrent infections is 8 to 10 times that of HSV-1. Reactivation of HSV is not well understood but may be attributable to physical, hormonal, and immunologic stimuli. During reactivation, the viral genomes are transported through the peripheral sensory nerves back to the dermal surface.

Shedding of the virus occurs during outbreaks, and also may occur when the person is asymptomatic, increasing the likelihood of transmission. Antiviral medications decrease asymptomatic viral shedding and should be considered as an adjunct to safe sex practices.

•Clinical Manifestations

Three distinct syndromes associated with HSV infection are first-episode primary genital infection, first-episode non-primary HSV, and recurrent infections. The manifestations of each one depend on the individual's immune state. First-episode primary genital infection occurs when an individual has no antibodies to HSV-1 or HSV-2. Many primary infections with HSV are asymptomatic, or the symptoms are not severe enough to warrant medical attention. If symptoms occur, the individual may have small (1 to 2 mm), multiple, vesicular lesions at the site of infection, usually on the labia minora, fourchette, penis, or mouth (Fig. 27.10). They also may appear on the cervix, buttocks, and thighs and are often painful and pruritic. These lesions usually last about 10 to 20 days. The lesions of HSV-1 and HSV-2 can be very small and almost indistinguishable to the naked eye or fairly large and clustered into raw areas. These wet lesions actively shed virus for about 10 to 14 days, after which they heal by reepithelialization. Small lesions may coalesce into larger ulcers and become secondarily infected.

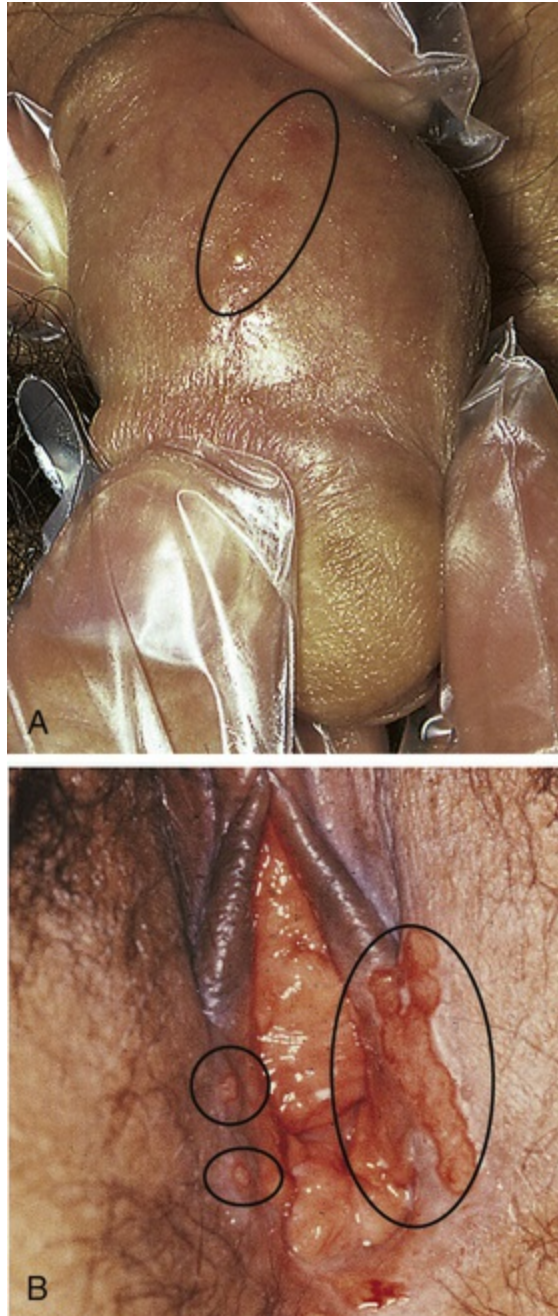

FIGURE 27.10 Herpes Lesions. A, Herpetic vesicles on the penis. B, Herpetic ulceration of the vulva. (A From McMillan A, Scott GR: *Sexually transmitted infections*, ed 2, London, 2000, Churchill Livingstone. B From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

Systemic manifestations often accompany primary HSV infection, and an individual may experience fever, malaise, myalgia, lymphadenopathy, and urinary retention. Pharyngitis, aseptic meningitis, and hepatitis also may accompany primary HSV infection.

Fig. 27.11 illustrates the clinical course of primary genital HSV.

FIGURE 27.11 Clinical Course of Primary Genital Herpes. (From Corey L: Genital herpes. In Holmes KK et al, editors: *Sexually transmitted diseases*, ed 2, New York, 1990, McGraw-Hill.)

First-episode non-primary HSV occurs in individuals who have preexisting antibodies. In some individuals, the primary infection may not have had any clinical manifestations, but the HSV virus has become latent in the nerve root and can reactivate later in life. Compared with primary infection, the first episode of non-primary HSV is often milder with fewer lesions that are less painful and heal faster. Fewer systemic manifestations occur and viral shedding is of shorter duration. However, the symptoms may be severe if the second infection occurs during a period of immunocompromised health status.

Recurrent infections usually produce mild local symptoms. The number of lesions is greatly reduced and the lesions are less painful. Lesions are often unilateral, with crusting within 4 to 5 days. Recovery and healing are usually complete within 10 days. Asymptomatic viral shedding can occur with both HSV-1 and HSV-2, but is more common with HSV-2.³

Individuals infected with HSV-2 are more likely to experience recurrent infections. Recurrent infections occur on an average of 5 to 8 times per year but may be more frequent in the first few years of

infection. Individuals may experience prodromal symptoms (e.g., pruritus, tingling, dysesthesias) a few hours to 2 days before the eruption of lesions. Women may experience a vaginal discharge and dysuria, and 44% of men have dysuria.

Symptomatic HSV infection of the newborn may occur any time in the first month of life. Manifestations range from a local infection of the eyes, skin, or mucous membranes to a severe disseminated infection with CNS involvement. About 70% of affected infants present with skin lesions. CNS involvement includes seizures and is associated with a mortality of more than 50% and extensive neurologic sequelae in survivors.¹⁸

◆ Evaluation and Treatment

Genital HSV infection is suggested if typical genital lesions are present; painful genital lesions alone are enough to begin treatment. The CDC recommends serologic testing for diagnosis and to determine the virus subtype because the prognosis and the risk of transmission differ.³ Viral cultures have been used in the past but their sensitivity is low, especially if lesions have crusted over and begun healing.

There is no cure for HSV, only symptom management and viral suppression treatments. All primary outbreaks should be treated with antiviral medications to prevent complications and speed healing.³ Oral acyclovir, valacyclovir, penciclovir, and famciclovir are used for primary and periodic outbreaks and to prevent recurrences. Acyclovir has a better safety profile for pregnant and nursing women, but there is ongoing research supporting the safety of valacyclovir as well. Intravenous acyclovir is reserved for very ill or severely immunocompromised individuals.³

Suppressive treatment is recommended for individuals with frequent or severe outbreaks³ and pregnant women at term with a history of herpes.²⁰ Suppressive treatment also may reduce asymptomatic viral shedding, decreasing transmission to sexual partners and vaginally-born infants. Although there are few side effects with suppression drugs, the decision to take daily medication

is complex for many individuals. Although male and female condoms offer some protection, individuals with HSV should refrain from all genital or oral contact when prodromal or symptomatic and understand that an undetermined risk of transmission exists even during asymptomatic periods.

Human Papillomavirus Infection

Human papillomavirus (HPV) infection is the most common symptomatic viral STI in the United States. Although more than 5.5 million cases are diagnosed yearly, the prevalence is considered underestimated because HPV infection is often subclinical. More sensitive measures of HPV indicate that 50% of all sexually active people are infected with the virus at some point in their lives, although these numbers are expected to decrease sharply in response to widespread vaccination. The virus is easily transmissible through direct contact with lesions or infected secretions. Vertical transmission in utero and during vaginal birth also is possible.²¹

More than 120 different types of HPV have been identified. More than 40 serotypes are unique to the stratified squamous epithelia of the anogenital area, although research is finding these same subtypes also may infect the oropharynx.²² These are divided into high-risk serotypes (which have a high risk of causing cancer) and low-risk serotypes (which are associated with benign genital lesions or warts: *condylomata acuminata* of the vulva, vagina, penis, and perianal areas).

Serotypes 6 and 11 are associated with 90% of genital warts. These low-risk, or **nononcogenic**, subtypes, can coexist with the high-risk types but do not cause cancer independently. Genital warts are very contagious, with transmission rates among individuals estimated to be between 38% and 95%. Such a wide range is attributable to the subclinical nature of some infections and various influencing factors that include number of exposures, HPV type, location of lesions, and cellular immunity response.

High-risk, or **oncogenic**, types 16 and 18 are the most common, causing up to 70% of anogenital cancers, and are highly associated with oropharyngeal cancers¹ (see [Chapters 12, 13, and 25](#)). HPV-

related cancers of the anogenital and oropharynx areas are more common than ovarian cancer in women and more common than brain cancer in men. In future generations, most of these cancers can be prevented through vaccination before HPV exposure.²²

HPV infection is closely associated with multiple sexual partners and early onset of sexual activity, and is most common in teens and young adults 16 to 25 years of age. Fortunately, most cases of HPV are transient and 70% of healthy individuals will spontaneously eliminate the virus.²³ The persistence of the virus and the immune response play a role in the development of cancer following HPV exposure. Behaviors and conditions that affect overall health status affect the body's ability to clear HPV infection. Alcohol use, smoking, and HIV infection are strongly correlated with persistent HPV infection.²⁴

Several vaccines are available to protect against HPV. All approved vaccines use noninfectious virus-like particles to induce an immune response, and newer vaccines protect against a greater number of subtypes. Approved vaccines induce protection against 2 (bivalent vaccine), 4 (quadrivalent vaccine), or 9 (9-valent vaccine) subtypes and increase in cost with greater protection. The CDC advises using the 9-valent vaccine because of greater prevention capability and cost-effectiveness.²⁵

HPV vaccination is recommended for females 11 to 26 years of age and for nonimmunocompromised males ages 11 to 21, but vaccination is recommended until 26 years of age for immunocompromised males and men who have sex with men. Originally released as a three-dose series, the CDC now advises two doses are sufficient for protection from the most dangerous HPV strains.^{25,26} Prevention of HPV acquisition in young adults is important because they are more likely than older adults to contract STIs and the cervixes of younger women are more vulnerable to HPV. Public health officials are hopeful that vaccination of boys and girls before they become sexually active will decrease the burden of HPV infection in the future. Preliminary data suggest the effects of widespread vaccination that began in 2006 are already becoming apparent²⁷ (see [What's New? Human Papillomavirus Vaccine](#)). There are even some reports that vaccination

of pregnant women can decrease vertical transmission during vaginal birth because maternal antibodies to HPV cross the placenta.²⁸

What's New?

Human Papillomavirus Vaccine

Every year in the United States:

- Nearly 1 in 4 adults have at least one strain of HPV.
- About 12,000 women are diagnosed with HPV-related cervical cancer.
- Almost 4000 women die from HPV-related cervical cancer.
- About 1900 men are diagnosed with HPV-related penile or anal cancer.

Vaccines are available in the United States to vaccinate 2, 4, or 9 strains of high-risk human papillomavirus (HPV):

- Vaccines are recommended for females and males beginning at age 11 years and up to age 26 depending on gender and risk factors.
- The CDC now recommends children ages 11 to 12 years receive two doses of HPV vaccine rather than the previously recommended three doses; the second dose should be given 6 to 12 months after the first dose.
- Vaccines are highly effective in preventing high-risk HPV types associated with cervical cancer; they have been proven safe and effective by the Centers for Disease Control and Prevention (CDC), with ongoing safety monitoring.
- Vaccines are not recommended for pregnant women because their safety is not yet established, but preliminary reports suggest that HPV vaccination in pregnancy may decrease vertical transmission during vaginal birth.

- Vaccinated women still need cervical cancer screening at regular intervals.
- The three-injection vaccine series is covered by most insurance plans, Medicaid, and the Vaccines for Children (VFC) program if individuals meet eligibility requirements, including age and financial need.

For more information, visit the Centers for Disease Control and Prevention (CDC) STD website at <http://www.cdc.gov/std/default.htm>. Data from Centers for Disease Control and Prevention (CDC): *Human papillomavirus (HPV)*, Atlanta, GA, 2017, U.S. Department of Health and Human Services. Available at: <https://www.cdc.gov/mmwr/volumes/65/wr/mm6549a5.html>, updated January 25, 2017; Centers for Disease Control and Prevention (CDC): *Multi-, routine-, & non-routine-vaccine VISs*, Atlanta, GA, 2016, U.S. Department of Health and Human Services. Available at: <http://www.cdc.gov/vaccines/hcp/vis/index.html>.

The immune system is prepared to eliminate the virus through the immune response when previously vaccinated. When an individual has not been vaccinated, he or she may or may not be able to clear this viral infection. Although most HPV subtypes are not associated with abnormal cellular growth, high-risk HPV subtypes cause cellular changes that can lead to cell proliferation, causing warts or cancer.

◆ Pathophysiology

HPV is a nonenveloped, circular, double-stranded DNA virus, one of the papovaviruses, that belongs to the Papovaviridae family.²⁴ Transmission of the virus occurs through close physical contact with infected skin, mucosa, or fluids; however, the exact transmissibility of the virus into the cell is unknown. The initial infection follows trauma to the epithelium that allows the virus to reach and infect the basal cells of the epithelium, which appear to be supportive of viral propagation. Such minor trauma may occur during sexual intercourse. HPV may enter the nuclear DNA and change the expression of cell proteins, leading either to increased but noncancerous cell growth (e.g., warts) or to unchecked cell growth (e.g., cancer). It is not known

exactly why some HPV serotypes are cleared from cells whereas other serotypes cause cellular transformations, but immune response and other cofactors play a role.²⁴ HPV infection may occur months to years before symptoms appear, such as warts or precancerous lesions.

◀Clinical Manifestations

Genital warts, **condylomata acuminata**, are soft, skin-colored, whitish pink to reddish brown discrete growths. They may occur singly or in clusters, may be broad at the base or pedunculated, and may be feathery or smooth. Sometimes the warts enlarge to form cauliflower-like masses on the male frenulum, glans, foreskin, urinary meatus, shaft, scrotum, or anus and on the female labia, clitoris, perineum, vagina, or anus (Fig. 27.12). Although the lesions are usually not painful, they may cause dyspareunia (painful intercourse) and may be friable and bleed easily. Some individuals complain of pruritus. Common locations for condylomata are the on the vaginal introitus, on the shaft of the penis, and under the foreskin. However, warts can be in any location infected by HPV along the reproductive tract, anus, and oropharynx.^{3,12} Laryngeal papillomas can occur in infants and children whose mothers had genital warts at the time of delivery. Clinical manifestations of laryngeal warts include stridor, hoarseness, abnormal cry, cough, and respiratory distress.²⁸

FIGURE 27.12 Condylomata Acuminata—Vulva and Perineum. The clinical diagnosis was giant condylomata. Such large and confluent lesions should be carefully examined and multiple biopsies obtained to rule out underlying malignancy. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

Precancerous changes related to HPV often do not have any visible manifestations and are not painful, hampering early detection. In addition, cervical and anal cancers may not cause symptoms until late into the disease process. Routine screening for cervical cancer (see below) was begun to increase early detection since clinical symptoms are minimal.

◆ Evaluation and Treatment

Generally, diagnosis of condylomata acuminata is made on the basis of clinical manifestations. Verrucous, fleshy pink lesions caused by HPV must be differentiated from condylomata lata (the whitish gray,

flat lesions) of secondary syphilis. Because HPV infection often accompanies other STIs, gonorrhea culture, chlamydia culture, serologic test for syphilis, and wet mount for other vaginal microorganisms also should be performed.

Treatments for external genital warts are considered cosmetic—not curative—and include patient-applied therapies (podofilox, imiquimod, and sinecatechins) and provider-administered therapies (cryotherapy, podophyllin resin, trichloroacetic acid [TCA], bichloroacetic acid [BCA], and surgery). Vaginal, urethral, or anal warts are treated in the clinic using topical medications, cryotherapy, or surgical excision; the CDC provides specific guidance on therapies based on wart location and pregnancy status. Cervical and anal warts require additional screening to exclude more extensive lesions.³ Success of treatment depends on response of the immune system. Surgical excision is the treatment for laryngeal warts in infants.

Evaluation of infection with oncogenic strains is more difficult since infection is often asymptomatic until cancer is advanced. This is especially true for cervical cancer because of poor innervation of the upper pelvis, allowing cancerous masses to grow large before causing symptoms. The development of the Papanicolaou, or “Pap,” smear helped reduce deaths related to cervical cancer by 80% since the 1950s.²⁹ Ideally, persistent HPV infections can be identified to encourage greater screening for abnormal cellular changes. The appropriate screening for HPV infection is controversial because there are no guidelines delineating who should be screened for anal and oropharyngeal infection. There are guidelines on screening for cervical cancer in women, and these guidelines change frequently in response to new evidence and testing techniques.

Following the development of the Pap smear, women were advised to have yearly Pap tests to detect cancer. Over time, however, it became apparent that while younger women often had abnormal Pap tests, they were often able to clear HPV infection and resolve cellular changes without treatment. Treatment of women less than 20 years of age provides little to no benefit in reducing later rates of cervical cancer but results in pain, anxiety, and increased healthcare costs.

Therefore the United States Preventive Services Health Task Force, the American College of Obstetricians and Gynecologists, and many other national cancer agencies recommended that Pap smear testing begin only after 21 years of age.^{30,31}

Women ages 21 to 29 should receive just Pap testing every 3 years, whereas women 30 to 65 years of age may receive Pap testing with HPV screening every 5 years (preferred) or Pap testing alone every 3 years. After 65 years of age, Pap testing and HPV screening are no longer recommended for women with previous normal testing results since the risk of new malignancy is low. Women who have had a hysterectomy with removal of the uterine cervix for a noncancerous condition do not need Pap smears or HPV testing for the rest of their lives. Although the HPV vaccine does reduce the risk for cervical cancer, it does not change the frequency or need for Pap and HPV testing at this time.

If the results of a Pap test are abnormal, the woman's cervix will be further evaluated using colposcopy, which involves applying acetic acid (vinegar) and using magnification to examine the cervix for changes indicative of cancer or precancerous lesions. HPV-infected cells will appear white when exposed to acetic acid. In some developing countries with limited laboratory facilities, this test alone is used to screen for cervical cancer (see [What's New? Cervical Cancer Screening in the Developing World in Chapter 25](#)). Following visual investigation of the cervix during colposcopy, the clinician biopsies suspicious areas for further investigation. Treatment of precancerous and cancerous lesions varies and involves removal or destruction of the affected cells through excision or ablation so they cannot continue to divide.

Although infection with high-risk HPV strains is a risk factor for development of anogenital cancers, as well as cervical cancer, there is not a consensus on screening for rectal and anal cancers.²² Anyone who engages in receptive anal intercourse is at risk for rectal acquisition of HPV and subsequent development of anal cancer. Women are about twice as likely as men to develop anal cancer, but men who have sex with men remain at risk.²² Hopefully, the need for

treatment of HPV-related genital conditions will decrease as more children and young adults receive the HPV vaccine before becoming sexually active.²⁵

Molluscum Contagiosum

Molluscum contagiosum is a benign viral infection of the skin in children and adults. For detailed information, see [Chapter 47](#). In adults, the disease is more commonly sexually transmitted and affects the lower abdomen, genitalia, and perianal area.¹¹ Molluscum contagiosum in adults is most common in men 20 to 29 years of age and in those with multiple sexual partners. Treatment for sexually transmitted molluscum contagiosum is the same as that for the nonsexually transmitted form of the disease; the CDC also includes information in their regularly updated guidelines.³

Parasitic Infections

Trichomoniasis

Trichomonas vaginalis, commonly known as *trich*, affects more than 3.5 million people in the United States and 11% of women older than 40, and is the most common non-viral STI in this region.¹ The high rate of asymptomatic infection aids the spread of this pathogen. Male-female vaginal intercourse is the most common route of transmission.¹ Although sexual transmission is clearly the most common means of disease spread, transmission through fomites is theoretically possible.

◆ Pathophysiology

T. vaginalis is an anaerobic, unicellular, flagellated, parasitic protozoan that adheres to and damages squamous epithelial cells ([Fig. 27.13](#)). It is primarily spread through penile-vaginal sex, although anal sex and oral sex could be potential routes of infection.³ Because this protozoan selectively affects squamous epithelia, the vaginal and urethral tissues in women are often infected, as are periurethral (Skene) and greater vestibular (Bartholin) glands. The endocervical canal is not affected

because it is lined with columnar epithelium. In men, the urethra is the most common site of infection, although the protozoa, called **trichomonads**, also can infect the epididymis and (rarely) the prostate. Uncircumcised men are more likely to become infected after exposure than circumcised men.³ There are no conclusive data that the rectum or the oropharynx is a reservoir for infection.³

FIGURE 27.13 *Trichomonas vaginalis*. (From CDC Public Health Information Library [PHIL].)

•Clinical Manifestations

Manifestations of vaginal trichomoniasis range from none to severe. Up to 85% of those infected have minimal or no symptoms.³ Vaginal discharge and internal pruritus are the most common manifestations of infection. Dyspareunia and dysuria also are fairly common. Some women report an increase in symptoms immediately after menses. Vaginal secretions can be copious, frothy, malodorous, and yellow-green to gray-green. On examination, the vaginal walls may appear erythematous and sore. Small, punctate red marks, sometimes called

strawberry spots, are sometimes visible on the vaginal walls and cervix. Most men with trichomoniasis are asymptomatic but may have scant intermittent discharge, slight pruritus, and mild dysuria.³

◀Evaluation and Treatment

All women reporting abnormal vaginal discharge should be tested for trichomoniasis.³ Nucleic acid amplification testing (NAAT) is the most sensitive and specific method for detection of *T. vaginalis* infection. Samples for testing can be obtained from the woman's endocervix, vagina, or urine. Samples for men ideally come from the penile meatus, but urine is acceptable as well. Self-collection of samples is acceptable; some tests have even been shown to be accurately used in self-testing,³ which can aid diagnosis, especially in cases of recurrence. A microscopic examination of vaginal fluid mixed with saline was previously widely used to detect the presence of this protozoan but, with a sensitivity of just greater than 50%, it is much less accurate than NAAT-based tests.³ However, this method can be used when other tests are unavailable or cost-prohibitive. On microscopic examination, the ovoid microorganism is slightly larger than a polymorphonuclear leukocyte and has one rounded, flagellated end and one slightly pointed, flagellated end. The flagella give the trichomonads their characteristic twisting motility. When women are infected, their vaginal secretions have a pH higher than 4.5 and when mixed with 10% potassium hydroxide (KOH) emit a “fishy” odor related to amine release, known as a positive *whiff test*.

The treatment of choice for trichomoniasis is a single 2-gram dose of tinidazole or metronidazole (Flagyl) with tinidazole, achieving better cure rates.³ These drugs have intense side effects when taken with alcohol; thus individuals must be able to abstain from all alcohol products for 3 days after treatment. Sexual partners, even if asymptomatic, also should be treated. There are high rates of reinfection and the CDC advises a 3-month follow-up after treatment for a test of cure.³

T. vaginalis infection in pregnant women is associated with an increased risk of preterm birth through unknown mechanisms that

may be linked with inflammation.³² The 2-gram single dose of metronidazole can be used to treat pregnant women. However, it is not clear if treatment improves outcomes and metronidazole therapy may actually increase the rate of preterm delivery.³³ An alternative dosing regimen is available for lactating women, or the woman can abstain from breast-feeding for 12 to 24 hours after taking the drug.

Scabies

Scabies is a common parasitic infection that can be spread by skin-to-skin and sexual contact.³⁴ Transmission of scabies requires close skin-to-skin contact, which occurs between sexual partners.³⁴ Scabies is more common in children and the elderly than in adults.³⁴ (Detailed information on scabies is contained in [Chapter 48](#).) However, sexual transmission is the most frequent cause of infection in adults.³

◆ Pathophysiology

The discussion of scabies is presented in [Chapter 48](#).

◆ Clinical Manifestations

The classic symptom of scabies is intense pruritus, which increases at night. Pruritus is a result of a reaction to the presence of the *Sarcoptes scabiei* mite. This reaction may take weeks with initial infection, but only 24 hours if the person has been previously infected. The groin and buttocks are common locations for sexually transmitted scabies. [Fig. 27.14](#) shows the typical sites of scabies burrows. The typical burrow of *S. scabiei* is a short, linear, curved, or S-shaped line ([Fig. 27.15](#)). There may be small, erythematous, excoriated larval papules near the burrows. Secondary infections are common and are caused by scratching. Even after successful treatment, some individuals will continue to experience pruritus for several weeks.³

FIGURE 27.14 Distribution of Skin Lesions of *Sarcoptes scabiei* Infestation. Unshaded areas are rarely affected in healthy adults. (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 3, London, 2003, Mosby.)

FIGURE 27.15 Scabies Burrow. An S-shaped burrow with a tiny vesicle at one end. (From Marks JG, Miller JJ: *Lookingbill and Marks' principles of dermatology*, ed 4, St Louis, 2006, Saunders.)

◆ Evaluation and Treatment

The diagnosis of scabies is often made clinically when risk factors are present. Microscopic identification of the mite, eggs, larvae, or feces is ideal because the symptoms of scabies can imitate many dermatologic conditions. Superficial scrapings from an intact papule or burrow can be observed under the microscope and KOH application facilitates mite visualization.

Preferred treatment is topical application of 5% permethrin massaged into the skin and left for 8 to 14 hours or ivermectin 1% dosed at 200 mcg/kg orally and repeated again in 2 weeks.³ Lindane (1%) lotion or cream also is effective if applied thinly to all areas of the body below the neck and washed thoroughly 8 hours after application.³ Close household and sexual contacts should be examined and treated if infected.³ Pregnant women should be treated with permethrin.³ To prevent reinfestation, clothing and bed linens should be washed and dried in a machine at high temperatures or kept away from body contact for 72 hours.³

Pediculosis Pubis

Pthirus pubis, the crab louse, is one of three species of lice that infest humans. *P. pubis* is commonly transmitted sexually and causes **pediculosis pubis**, or “crabs.” *P. pubis* is transmitted primarily by intimate sexual contact or by contact with infected linens. It is highly contagious; there is a 95% chance of contracting lice during a single sexual encounter. Fomites are a common method of infection because crabs can live away from the body for several days. The transfer of lice from pubic hair is probably mechanical, assisted by scratching, fingernails, and towels rather than by self-propulsion. Pubic lice usually infect the perineal and axillary hair and occasionally the hair of the trunk, beard, scalp, and eyelashes.

◆ Pathophysiology

The crab louse has a 25- to 30-day life cycle that consists of five stages: an egg (or nit) stage; three nymphal stages; and an adult stage, all of which occur on the host. The nits of crab lice are found “glued” to hairs; they are oval, 0.8 by 0.3 mm in length, and whitish, and they hatch in 5 to 10 days (Fig. 27.16). In the adult stage, pubic lice are grayish, are approximately 1 mm in length, and have a segmented body and claws to cling to hairs. They bite into the host's skin to feed on blood, causing itching and pain.

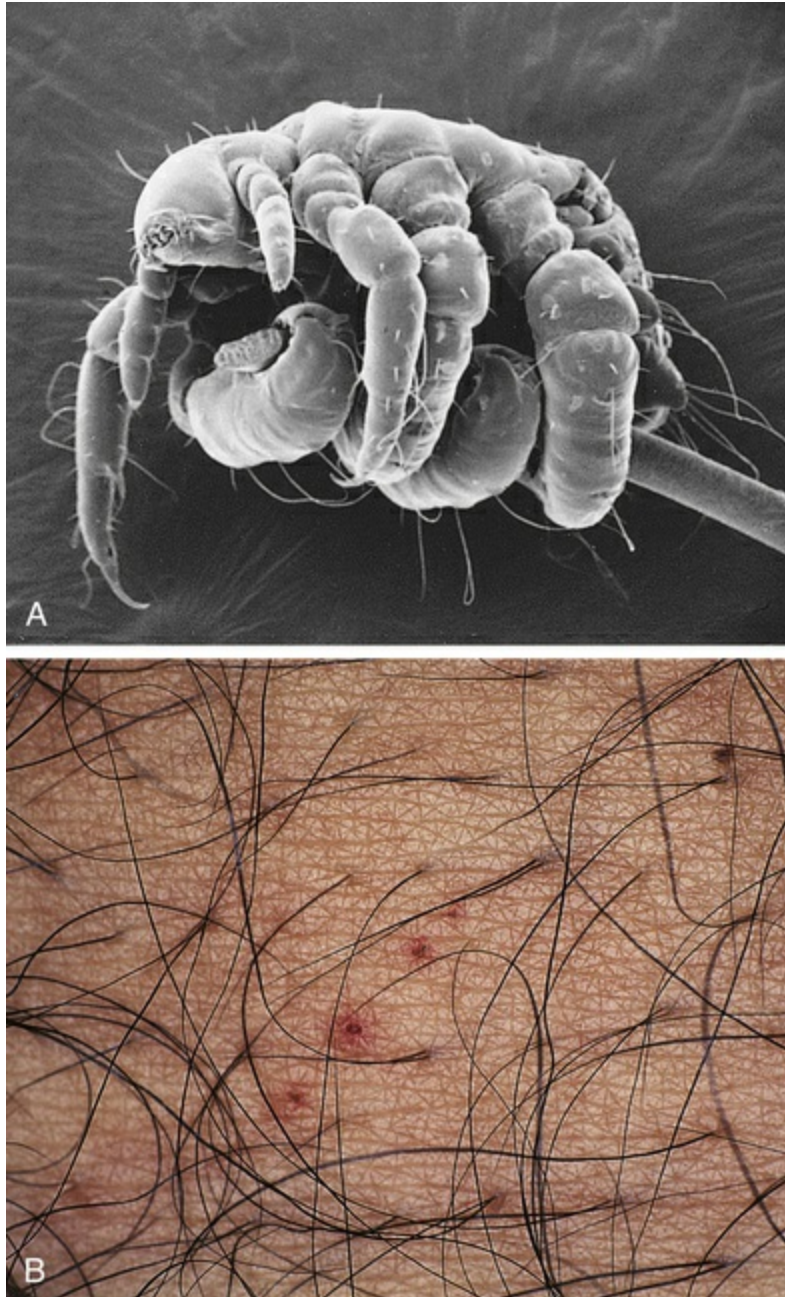

FIGURE 27.16 Pubic Louse and Crab Louse. A, Pubic louse (*Pthirus pubis*) encircling a pubic hair; the clawlike legs produce a firm grip. B, Crab louse bites (*P. pubis*). (From Morse SA et al, editors: *Atlas of sexually transmitted diseases and AIDS*, ed 4, London, 2013, Saunders.)

•Clinical Manifestations

The mites are visible, facilitating self-identification of infestation.³ Symptoms range from mild pruritus to severe, intolerable itching,

depending on the individual's sensitivity to louse bites. Allergic sensitization occurs in about 5 days, when itching, erythema, and inflammation may worsen. Excessive scratching may lead to secondary infection.

◆ Evaluation and Treatment

The individual usually presents with a history of itching in the infected area. Because the lice and nits are visible to the naked eye, a thorough clinical examination permits definitive diagnosis. Pediculosis pubis is treated either with 1% permethrin cream rinse and 1% lindane lotion, cream, or shampoo or with over-the-counter pyrethrin or piperonyl butoxide. For nonocular infections, the pediculicide is applied to infested and adjacent hairy areas and washed off after a specified time. Remaining nits can be removed with a fine-toothed comb. Permethrin is the first-line treatment. However, drug resistance is widespread and increasing. Malathion and ivermectin are alternative regimens, although ivermectin does not adequately kill the eggs and requires a second dose, and malathion has multiple contraindications.³ Lindane is a higher-level treatment and cannot be used by pregnant women because of risk of toxicity.³ Sexual contacts from the past month should be treated regardless of symptoms, and household contacts should be examined and treated if needed. Clothing and bed linens should be machine washed and dried at high temperatures or kept away from body contact for 72 hours.³

Sexually Transmitted Infections of Other Body Systems

The effects of some STIs extend beyond the urogenital tract. Many disorders have varied methods of transmission that may include nonsexual means. Although the major mode of transmission may be by oral ingestion or by direct contact with blood or body fluids (e.g., sharing of needles among drug users, blood transfusions, vertical

transmission from mother to baby, health worker exposures), infection can be transmitted through intimate sexual contact as well. Anal contact and physically damaging sex can increase the transmission of many of these infections.

Among the most serious of these infections are acquired immunodeficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV) and hepatitis (all types). Worldwide, the main mode of transmission of HIV and hepatitis B is through sexual intercourse (primarily male-female), but nonsexual exposure to infected blood and body fluids, especially through needle sharing, contributes to infection rates. The epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS and hepatitis are discussed in detail in [Chapters 10](#) and [42](#), respectively.

Sexual transmission of less serious but often debilitating infections, such as shigellosis and giardiasis, and systemic diseases, such as Epstein-Barr virus and cytomegalovirus infections, also can occur, although nonsexual transmission is more common. [Table 27.3](#) provides a list of several gastrointestinal and systemic infections that are known to be transmitted by intimate sexual contact, but in which the mode of transmission is primarily through other routes.

TABLE 27.3

INFECTIONS WITH KNOWN SEXUAL TRANSMISSIBILITY: MAIN MODE OF TRANSMISSION BY OTHER MEANS

INFECTION/DISEASE	MAIN ROUTE OF TRANSMISSION
Gastrointestinal Infections	
Shigellosis caused by <i>Shigella</i> bacteria	Contact with infected feces Hand-to-mouth
<i>Campylobacter</i> enteritis caused by <i>Campylobacter jejuni</i> bacteria	Primarily an animal pathogen Hand-to-mouth
Giardiasis caused by <i>Giardia lamblia</i> protozoa	Contaminated drinking water Hand-to-mouth
Amebiasis caused by <i>Entamoeba histolytica</i> protozoa	Contaminated drinking water Hand-to-mouth

Hepatitides A and C (liver infection and inflammation)	Hepatitis A: contact with infected feces; hand-to-mouth Hepatitis C: blood-borne pathogen; direct exposure to contaminated blood; sexual transmission very uncommon
Systemic Diseases	
Epstein-Barr virus	Mucous membrane (oral) exposure
Cytomegalovirus	Body fluids; exposure via close interpersonal contact or direct transfer
Zika virus	Primary spread through bites from infected mosquitos but may be transmitted sexually and across the placental membrane

Hepatitis

Hepatitis is a liver infection that can be caused by six types of viruses: hepatitis A, hepatitis B, hepatitis C, hepatitis D, hepatitis E, and hepatitis G. Each virus causes a syndrome of acute, icteric (jaundice-producing) liver inflammation. Additional information about hepatitis is found in [Chapter 42](#). Of the three most common types, A, B, and C, the **hepatitis B virus (HBV)** is most commonly sexually transmitted. Hepatitis A, like most other predominantly enteric infections, may be considered an STI because of anal-oral transmission, and vaccination is advised for men who have sex with men.³ Although hepatitis C virus (HCV) is not recognized as an STI, the CDC has listed sexual exposure, particularly for individuals with multiple partners, as a potential risk factor ([Fig. 27.17](#)).

*1982–1990 based on non-A, non-B hepatitis

FIGURE 27.17 Risk for Hepatitis C Exposure. Comparison of injecting drug use (blue), transfusions (purple), health-related work (green), and sexual exposure (red). Note the rise in sexually transmitted incidences. (From Centers for Disease Control and Prevention [CDC]: *Hepatitis C: what clinicians and other health professionals need to know*, 2000. Available at: www.cdc.gov/ncid/diseases/hepatitis/c_training/edu/intro.)

Hepatitis B prevalence varies dramatically worldwide with some geographic areas having more than 10% of the population infected with the virus.³⁵ There are an estimated 19,000 new cases of HBV infection in the United States each year, and more than 2.2 million people are chronically infected.³⁶ Those at risk for HBV infection in the United States are infants born to hepatitis-infected mothers, healthcare workers, individuals who have sex with HBV-infected persons, people with diabetes, and immigrants from areas of high HBV prevalence.³⁶ Widespread screening of pregnant women and vaccination of all infants since 1991 have decreased the rate of infection in the United States by more than 80% and are expected to have lasting effects into future decades.³⁷ Vaccination of healthcare workers also has decreased infection rates.³⁸

Transmission of HBV can occur through needle puncture, blood transfusion, cuts or abrasions in the skin, and absorption by mucosal surfaces. Direct contact with infected body fluids, such as semen and vaginal fluid, may transmit the infection. HBV can survive dry and outside the body for up to 1 week, making it easily infectious on

fomites.

In the United States, seropositivity generally increases with age.³⁶ This is a function of more time for exposure as well as the lack of routine vaccination before the 1990s. However, the younger a person is when he or she contracts the virus, the greater likelihood of chronic infection.³⁵ Perinatal transmission of HBV is relatively common, especially in developed countries without routine screening of pregnant women. Neonates whose mothers are infectious have a 90% chance of becoming chronically infected with HBV during labor or delivery if they do not receive treatment, but a 1% risk if they receive adequate treatment.³⁸ Infants of infected mothers should receive HBV vaccine and immunoglobulin against hepatitis within 12 hours of birth to reduce risk. The vaccine and immunoglobulin combination successfully prevents chronic carrier status in 99% of infants.³⁸ Although HBV is in many maternal body fluids, it is not found in breast milk and breast-feeding is still encouraged for mothers with HBV.³⁹ More information about the pathology, diagnosis, and treatment of hepatitis is covered in [Chapter 42](#).

Acquired Immunodeficiency Syndrome

Epidemiology, modes of transmission, pathophysiology, clinical manifestations, and evaluation and treatment of AIDS are discussed in detail in [Chapter 10](#).

Zika Virus

Zika virus is a single-stranded RNA virus from the Flaviviridae family, genus *Flavivirus*. The virus is predominantly transmitted through bites from infected mosquitos (see [Chapter 10](#) for additional information). However, vertical transmission easily occurs in infected women, and sexual transmission also has been confirmed. At this time, the exact mechanism of sexual transmission is not known, although shedding of the virus in semen is suspected.⁴⁰ The Centers for Disease Control and Prevention is investigating the issue and advises safer sex precautions for all sexual contact (including vagina,

anal, and oral sex) between an infected person and his or her partners, especially if a female partner is pregnant or plans on becoming pregnant.⁴⁰

Infection with zika virus during pregnancy has been associated with severe fetal infection and associated CNS abnormalities. The zika virus is able to infect human placental tissue and multiply within these tissues, spreading virus to the fetus, especially early in gestation.⁴¹ Although the exact pathophysiology is still unclear, postmortem studies of affected fetuses demonstrate a high level of zika virus within fetal brain tissue, even higher than levels found in other tissues or in adult serum.⁴² It is thought that the presence of zika virus within fetal central nervous system tissues disrupts normal cell developmental pathways, resulting in stunted brain and cranium formation and causing the characteristic microcephaly (abnormally small head) associated with this infection.⁴² Microcephaly is a permanent birth defect that results in lifelong disability because of an inadequately developed brain. The WHO and the CDC are actively studying the disease, and scientists are working to understand the exact mechanisms of zika transmission and cellular disruption.

Summary Review

Sexually Transmitted Urogenital Infections

1. Sexually transmitted diseases may be more common in certain populations related to increased physiologic risk for acquisition (such as with younger women or with men who have sex with men) or insufficient access to quality health care (such as with lower socioeconomic groups, racial/ethnic minorities, and marginalized groups).
2. Gonorrhea is a sexually transmitted communicable disease that can be local or systemic. Complications include PID, sterility, and disseminated infection.
3. Gonorrhea can be passed to the fetus from the mother and typically manifests as an eye infection 1 to 12 days after birth.

Ophthalmic antibiotic prophylaxis alone is not sufficient to prevent vertical transmission.

4. Gonorrhea is rapidly becoming resistant to available antibiotics. Multidrug therapy is now recommended to decrease drug resistance.
5. Syphilis is an STI that becomes systemic shortly after infection. The four stages of the disease are (a) primary syphilis with a chancre at the site of infection; (b) secondary syphilis with systemic spread to all body systems; (c) latent syphilis with minimal symptoms or the development of skin lesions; and (d) tertiary syphilis, the most severe stage, with destruction of bone, skin, and soft and neurologic tissues.
6. Congenital syphilis contributes to prematurity of the newborn with bone marrow depression, CNS involvement, renal failure, and intrauterine growth retardation.
7. Syphilis is diagnosed with serologic testing and is treated with injectable penicillin.
8. With chancroid infection, women are generally asymptomatic and men may develop inflamed, painful genital ulcers and inguinal buboes. The incubation period is 1 to 14 days. Single-dose therapy with injectable ceftriaxone or oral azithromycin for both partners is recommended. Persons with HIV may require a longer treatment regimen.
9. Granuloma inguinale (donovanosis) is rare in the United States. The bacteria are gram negative and survive within macrophages. Localized nodules coalesce to form granulomas and ulcers on the penis in men and on the labia in women. Antibiotics provide effective treatment.
10. Bacterial vaginosis (BV) is a sexually associated condition caused by an overgrowth of anaerobic bacteria that produce aromatic amines and raise the pH of the vagina, promoting further bacterial growth (without an inflammatory response) and a fishy odor. "Clue cells" are found on the wet mount. Metronidazole (Flagyl) provides effective treatment. BV has been associated with PID, chorioamnionitis, preterm labor,

and postpartum endometritis. Treatment of male sexual partners is not recommended.

11. Chlamydia is the most common bacterial STI in the United States and a leading preventable cause of infertility and ectopic pregnancy. The causative organism, *C. trachomatis*, localizes to epithelial tissue and can spread throughout the urogenital tract or pass from the infected mother to the eyes and respiratory tract of newborn infants during birth. *C. trachomatis* is susceptible to inexpensive, readily accessible antibiotics. Single-dose azithromycin is the drug of choice for infected individuals and all sexual contacts. Because of the asymptomatic nature of chlamydia and the potential sequelae of infection, widespread screening is recommended by the CDC.
12. Lymphogranuloma venereum is a chronic STI uncommon in the United States. The lesion begins as a skin infection and spreads to the lymph tissue, causing inflammation, necrosis, buboes, and abscesses of the inguinal lymph nodes. Primary lesions appear on the penis and scrotum in men and on the cervix, vaginal wall, and labia in women. Secondary lesions involve inflammation and swelling of the lymph nodes with formation of large buboes that rupture and drain. A 21-day or longer course of oral doxycycline or erythromycin is needed for treatment. Treatment of sexual partners is recommended.
13. Genital herpes is the most common genital ulceration in the United States and is caused by either HSV-1 or HSV-2. Lesions initially appear as groups of vesicles that progress to ulceration with pain, lymphadenopathy, and fever. Herpes simplex virus can pass from mother to fetus; thus women with active lesions should give birth by cesarean section to avoid vertical transmission.
14. Herpes simplex virus (HSV) infection is lifelong and can result in an initial outbreak and subsequent outbreaks. Individuals are contagious during outbreaks and episodes of asymptomatic viral shedding. Acyclovir reduces symptoms

but does not cure the disease. Recurrent infections are most often attributable to HSV-2 and are generally milder and of shorter duration.

15. Human papillomavirus (HPV) is associated with the development of cervical dysplasia and cancer as well as condylomata acuminata. The high-risk strains of HPV (HR-HPV) that are precursors to the development of cervical cancer do not cause genital warts. Testing is available to detect HR-HPV and a vaccine is now available for the HPV types with highest risk for cervical cancer.
16. Condylomata acuminata (genital warts) are sexually transmitted and highly contagious. The velvety cauliflower-like lesions occur in the genital and anal areas, vagina, and cervix and are painless. They can be transmitted to the infant at birth.
17. Molluscum contagiosum is a benign viral infection of the skin. It is transmitted by skin-to-skin contact in children and adults. In adults, it tends to occur on the genitalia and be transmitted by sexual contact.
18. Trichomoniasis (*T. vaginalis*) causes vaginitis in women and urethritis in men. Both partners usually are infected. Women usually have a copious, malodorous, gray-green discharge with pruritus. Men usually are asymptomatic. Metronidazole is the treatment for both sexes.
19. Scabies is a parasitic infection that spreads by skin-to-skin and sexual contact. The scabies mite burrows through the skin, depositing eggs, causing intense pruritus, especially at night. Treatment consists of topical application of a pediculicide.
20. Pediculosis pubis (crabs) is commonly transmitted sexually and is caused by the crab louse, *P. pubis*. The lice bite into the skin for nutrition. Symptoms include mild and severe pruritus. Topical application of prescription or over-the-counter pediculicides is effective treatment.

Sexually Transmitted Infections of Other Body

Systems

1. Systemic diseases known to be sexually transmitted include AIDS (see [Chapter 10](#)), cytomegalovirus infection, and Epstein-Barr virus.
2. Transmission of HBV can occur through needle puncture, blood transfusion, cuts in the skin, and contact with infected body fluids.
3. Hepatitis B infection poses significant health risks including chronic liver disease and hepatocellular cancer. Immunization against hepatitis B is the most effective means of preventing transmission. Universal vaccination of infants and children is recommended, as well as vaccination of high-risk adults.
4. The risk of perinatal transmission of HBV is high for infants of HBV-infected mothers unless they receive immunoglobulin and are vaccinated.
5. Hepatitis C is generally transmitted percutaneously but sexual transmission appears possible.
6. Although normally transmitted through mosquito bites, zika virus can be transmitted through sexual contact with infected body fluids or through vertical transmission. Zika virus sequesters in fetal brain tissue, disrupting brain growth and causing persistent, lifelong microcephaly.

Hematologic System, 917*

All the body's tissues and organs require oxygen and nutrients to survive. These essential needs are provided by the blood that flows through miles of vessels throughout the human body. The red blood cells provide the oxygen and remove carbon dioxide, and the fluid portion of the blood carries the nutrients and ions for proper acid-base balance. The blood also cleans discarded waste from the tissues; transports hormones; conveys white blood cells, platelets, and other ingredients that are necessary for protecting the entire body from injury and infection and initiating healing; and provides thermal regulation to maintain organs and tissues within an acceptable range of temperatures.

Components of the Hematologic System

Composition of the Blood

Blood consists of various cells that circulate in the cardiovascular system suspended in a solution of protein and inorganic materials (plasma), which is approximately 92% water and 8% dissolved substances (solutes) ([Fig. 28.1](#)). The blood volume amounts to about 6 quarts (5.5 L) in adults. The continuous movement of blood guarantees that critical components are available to all parts of the body to carry out their chief functions: (1) delivery of substances needed for cellular metabolism in the tissues, (2) removal of the wastes of cellular metabolism, (3) defense against invading microorganisms and injury, and (4) maintenance of acid-base balance. Fetal and neonatal hematopoiesis and blood composition are presented in [Chapter 30](#).

FIGURE 28.1 Composition of Whole Blood. Approximate values for the components of blood in a normal adult. (Adapted from Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Plasma and Plasma Proteins

In adults, plasma accounts for 50% to 55% of blood volume. **Plasma** is a complex aqueous liquid containing a variety of organic and inorganic elements (Table 28.1). The concentration of these elements varies depending on diet, metabolic demand, hormones, and vitamins. Plasma differs from serum in that **serum** is plasma that has been allowed to clot in the laboratory in order to remove fibrinogen and other clotting factors that may interfere with some diagnostic tests.

TABLE 28.1

ORGANIC AND INORGANIC COMPONENTS OF ARTERIAL PLASMA

CONSTITUENT	AMOUNT/CONCENTRATION	MAJOR FUNCTIONS

Water	91% of plasma weight	Medium for carrying all other constituents
Electrolytes	Total <1% of plasma weight	Maintain H ₂ O in extracellular compartment; act as buffers; function in membrane excitability
Na ⁺	142 mEq/L (142 mM)	
K ⁺	4 mEq/L (4 mM)	
Ca ⁺⁺	5 mEq/L (2.5 mM)	
Mg ⁺⁺	3 mEq/L (1.5 mM)	
Cl ⁻	103 mEq/L (103 mM)	
HCO ₃ ⁻	27 mEq/L (27 mM)	
Phosphate (mostly)	2 mEq/L (1 mM)	
Sulfate	1 mEq/L (0.5 mM)	
Proteins	7.3 g/dL (2.5 mM)	Provide colloid osmotic pressure of plasma; act as buffers; bind other plasma constituents (lipids, hormones, vitamins, minerals, etc.); clotting factors; enzymes; enzyme precursors; antibodies (immunoglobulins); hormones; transporters
Albumin	4.5 g/dL	
Globulins	2.5 g/dL	
Fibrinogen	0.3 g/dL	
Transferrin	250 mg/dL	
Ferritin	15–300 mcg/L	
Gases		
CO ₂ content	22–32 mmol/L plasma	Byproduct of oxygenation; most CO ₂ content is from HCO ₃ ⁻ and acts as a buffer
O ₂	PaO ₂ 80 torr or greater (arterial); PVO ₂ 30–40 torr (venous)	Oxygenation
N ₂	0.9 mL/dL	Byproduct of protein catabolism
Nutrients		Provide nutrition and substances for tissue repair
Glucose and other carbohydrates	100 mg/dL (5.6 mM)	
Total amino acids	40 mg/dL (2 mM)	
Total lipids	500 mg/dL (7.5 mM)	
Cholesterol	150–250 mg/dL (4–7 mM)	
Individual vitamins	0.0001–2.5 mg/dL	
Individual trace elements	0.001–0.3 mg/dL	

Iron	50–150 mcg/dL	
Waste products		
Urea (blood urea nitrogen [BUN])	7–18 mg/dL (5.7 mM)	End product of protein catabolism
Creatinine (from creatine)	1 mg/dL (0.09 mM)	End product from energy metabolism
Uric acid (from nucleic acids)	5 mg/dL (0.3 mM)	End product from protein metabolism
Bilirubin (from heme)	0.2–1.2 mg/dL (0.003–0.018 mM)	End product of red blood cell destruction
Individual hormones	0.000001–0.05 mg/dL	Functions specific to target tissue

P_{aO_2} , Partial pressure of oxygen in arterial blood.

Data from Vander AJ, Sherman JH, Luciano DS: *Human physiology: the mechanisms of body function*, ed 8, New York, 2001, McGraw-Hill.

The plasma contains a large number of proteins (**plasma proteins**) that constitute about 7% of the total plasma weight. These vary in structure and function and can be classified into two major groups, albumin and globulins. Most plasma proteins are produced by the liver. The major exception is antibodies (immunoglobulins), which are produced by plasma cells in the lymph nodes and other lymphoid tissues (see [Chapter 8](#)).

Albumin (about 57% of total plasma protein at a concentration of about 4 g/dL) serves as a carrier molecule for normal components of blood as well as drugs that have low solubility in water (e.g., free fatty acids, lipid-soluble hormones, thyroid hormones, bile salts). Its most essential role is regulation of the passage of water and solutes through the capillaries. Albumin molecules are large and do not diffuse freely through the vascular endothelium, and thus they maintain the critical colloidal osmotic pressure (or oncotic pressure) that regulates the passage of water and solutes into the surrounding tissues (see [Chapters 1](#) and [3](#)). Water and solute particles tend to diffuse out of the arterial portions of the capillaries because the blood pressure is greater in arterial than in venous blood vessels (see [Chapter 3](#)). Water and solutes move from tissue cells into the venous portions of the capillaries where the pressures are reversed, oncotic pressure being

greater than intravascular pressure or hydrostatic pressure. In the case of decreased production of albumin (e.g., cirrhosis, other diffuse liver diseases, protein malnutrition) or excessive loss of albumin (e.g., certain kidney diseases, extensive burns), the reduced oncotic pressure leads to excessive movement of fluid and solutes into the tissue and decreased blood volume.

The remaining plasma proteins, or **globulins**, are often classified by their properties in an electric field (serum electrophoresis). Under the normal conditions used to perform serum electrophoresis, albumin is the most rapidly moving protein. The globulins are classified by their movement relative to albumin: alpha (α) globulins (those moving most closely to albumin), beta (β) globulins, and gamma (γ) globulins (those with the least movement). Depending on the electrophoretic procedure, the α - and β -globulins may be subdivided into subregions (α_1 -, α_2 -, β_1 -, or β_2 -globulins). Fibrinogen is a major plasma protein (about 4% of total plasma protein) that would move between the beta and gamma regions but is removed during the formation of serum. The γ -globulin region consists primarily of immunoglobulin G (IgG) (see [Chapter 8](#)).

Plasma proteins can also be classified into groups by function: clotting, defense, transport, or regulation. The **clotting factors** promote coagulation and stop bleeding from damaged blood vessels (see [Function of Clotting Factors under Mechanisms of Hemostasis](#)). Fibrinogen is the most plentiful of the clotting factors and is the precursor of the fibrin clot (see [Fig. 7.9](#)). Proteins involved in defense, or protection, against infection include antibodies and complement proteins (see [Chapters 7 and 8](#)). Transport proteins specifically bind and carry a variety of inorganic and organic molecules, including iron (transferrin), copper (ceruloplasmin), steroid hormones, and vitamins (e.g., retinol-binding protein). The plasma lipids, triglycerides, phospholipids, cholesterol, and fatty acids are carried through the blood as complexes with plasma proteins; they are known as *lipoproteins* (see [Chapters 1 and 33](#)). Regulatory proteins include a variety of enzymatic inhibitors (e.g., α_1 -antitrypsin) that protect the tissues from damage, precursor molecules (e.g., kininogen) that are

converted into active biologic molecules when needed, and protein hormones (e.g., cytokines) that communicate between cells.

Plasma also contains several charged inorganic ions (electrolytes) that regulate cell function, osmotic pressure, and blood pH. (Electrolytes are described in [Chapters 1 and 3.](#))

Cellular Components of the Blood

The cellular elements of the blood are broadly classified as red blood cells (RBCs) (i.e., erythrocytes), white blood cells (WBCs) (i.e., leukocytes), and platelets (thrombocytes). The components of the blood are listed in [Table 28.2.](#)

TABLE 28.2

CELLULAR COMPONENTS OF THE BLOOD

CELL	STRUCTURAL CHARACTERISTICS*	NORMAL AMOUNTS OF CIRCULATING BLOOD	FUNCTION	LIFE SPAN
Erythrocyte (red blood cell)	Nonnucleated cytoplasmic disk containing hemoglobin	4.2–6.2 million/mm ³	Gas transport to and from tissue cells and lungs	80–120 days
Leukocyte (white blood cell)	Nucleated cell	5000–10,000/mm ³	Body defense mechanisms	See below
Lymphocyte	Mononuclear immunocyte	25%–33% of leukocyte count (leukocyte differential)	Humoral and cell-mediated immunity (see Chapter 7)	Days or years depending on type
Monocyte and macrophage	Large kidney-shaped mononuclear phagocyte	3%–7% of leukocyte differential	Phagocytosis; mononuclear phagocyte system	Months or years
Neutrophil	Segmented polymorphonuclear granulocyte with granules stainable by neutral staining	57%–67% of leukocyte differential	Phagocytosis, particularly during early phase of inflammation, bacterial killing	4 days

Basophil	Lobate nuclear granulocyte with granules stainable by basic dyes	0%–0.75% of leukocyte differential	Similar to mast cell; secretes inflammatory mediators (e.g., histamine, chemotactic factors for eosinophils and neutrophils); involved with allergic reactions	Few hours to days
Eosinophil	Segmented polymorphonuclear granulocyte with granules stainable by eosin dyes	1%–4% of leukocyte differential	Phagocytosis; response to parasites, control of allergic reactions	8–12 days
Platelet	Irregularly shaped cytoplasmic fragment (not a cell)	140,000–340,000/mm ³	Hemostasis following vascular injury; normal coagulation and clot formation/retraction	8–11 days

*See bottom row of [Fig. 28.12](#) for illustrations of cells.

Erythrocytes.

Erythrocytes (red blood cells [RBCs]) are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and about 42% in women. Erythrocytes are primarily responsible for tissue oxygenation. The erythrocyte contains hemoglobin, which carries the gases, and electrolytes, which regulate diffusion through a cell's plasma membrane. The mature erythrocyte lacks a nucleus and cytoplasmic organelles (e.g., mitochondria), so it cannot synthesize protein or carry out oxidative reactions. Because it cannot undergo mitotic division, the erythrocyte has a limited life span (approximately 100 to 120 days), ages, and is removed from the circulation, primarily in the spleen, to be replaced by new erythrocytes.

The erythrocyte's size and shape are ideally suited to its function as a gas carrier. An RBC is a small disk with two unique properties: (1) a *biconcave* shape and (2) the capacity to be *reversibly deformed* ([Fig. 28.2](#) and [Fig. 28.3](#)). The flattened, biconcave shape provides a surface area/volume ratio that is optimal for gas diffusion into and out of the

cell and for deformity. During its life span, the erythrocyte, which is 6 to 8 μm in diameter, repeatedly circulates through splenic sinusoids and capillaries that are only 2 μm in diameter (see [Fig. 28.3](#)). Reversible deformity enables the erythrocyte to assume a more compact torpedo-like shape, squeeze through the microcirculation, and return to normal shape.

FIGURE 28.2 Blood Cells. Leukocytes are spherical and have irregular surfaces with numerous extending pili (appear as yellow). Erythrocytes are flattened spheres with a depressed center. Activated platelets are green. (Copyright Dennis Kunkel Microscopy, Inc.)

FIGURE 28.3 Red Cells in the Spleen. Scanning electron micrograph of spleen demonstrating erythrocytes (numbered 1 through 6) squeezing through the fenestrated wall in transit from the splenic cord to the sinus. The view shows the endothelial lining of the sinus wall, to which platelets (*P*) adhere, along with “hairy” white cells, probably macrophages. The arrow shows a protrusion on a red blood cell ($\times 5000$). (From Weiss L: *Blood* 43:665, 1974; reprinted with permission.)

Leukocytes.

Leukocytes (white blood cells [WBCs]) defend the body against microorganisms that cause infection and remove debris, including dead or injured cells of all kinds (see [Fig. 28.2](#)). The leukocytes act primarily in the tissues but are transported in the circulation. The average adult has approximately 5000 to 10,000 leukocytes/ mm^3 of blood.

Leukocytes are classified according to structure as either granulocytes or agranulocytes and according to function as either **phagocytes** or **immunocytes**. **Granulocytes** include neutrophils, basophils, and eosinophils and all are phagocytes. (Phagocytic action is described in [Chapter 7](#).) Mast cells also are classified as granulocytes. Of the agranulocytes, the monocytes and macrophages are phagocytes, whereas the lymphocytes are immunocytes (cells that create immunity; see [Chapter 8](#)) ([Fig. 28.4](#)).

FIGURE 28.4 Leukocytes. Normal cells in peripheral blood: A, erythrocyte (red blood cell); B, neutrophil (segmented); C, neutrophil (banded); D, eosinophil; E, basophil; F, lymphocyte; G, monocyte; H, platelet. (From Keohane E, Smith L, Walenga J: *Rodak's hematology*, ed 5, St Louis, 2016, Saunders.)

Granulocytes.

Granulocytes have many membrane-bound granules in their cytoplasm. These granules contain enzymes capable of killing microorganisms and catabolizing debris ingested during phagocytosis. The granules also contain powerful biochemical mediators with inflammatory and immune functions. These mediators, along with the digestive enzymes, are released from granulocytes in response to specific stimuli. The biochemical mediators have vascular and intercellular effects, and the enzymes participate in the breakdown of debris from sites of infection or injury. Granulocytes are capable of amoeboid movement, by which they migrate through vessel walls (diapedesis) and then to sites where their action is needed (see [Chapter 7](#)).

The **neutrophil (polymorphonuclear neutrophil [PMN])** is the most numerous and best understood of the granulocytes (see [Fig. 28.4](#), [B and C](#), and [Table 28.2](#)). Neutrophils constitute about 57% to 67% of the total leukocyte count in adults. The cytoplasm of neutrophils

contains small lysosomal granules and a central nucleus with two to five distinct lobes.¹ Immature neutrophils are called *bands* or *stabs*. Mature neutrophils are called *segmented neutrophils* because of the characteristic appearance of their nucleus. Neutrophils reach a fully mature state in the bone marrow, and these mature neutrophils are called the *marrow neutrophil reserve*. Normally it takes about 14 days for neutrophils to develop from early precursors, but this process is accelerated by infection and treatment with colony-stimulating factors.

Neutrophils are the chief phagocytes of early inflammation. Soon after bacterial invasion or tissue injury, neutrophils migrate out of the capillaries and into the inflamed site, where they ingest and destroy microorganisms and debris and then die in 1 or 2 days. The dissolution of dead neutrophils releases digestive enzymes from their cytoplasmic granules. These enzymes dissolve cellular debris and prepare the site for healing. (This final function, called *débridement*, is described in [Chapter 7](#).)

Eosinophils have large, coarse granules and constitute only 1% to 4% of the normal leukocyte count in adults (see [Fig. 28.4, D](#), and [Table 28.2](#)). Like neutrophils, eosinophils are capable of amoeboid movement and phagocytosis. Using a spectrum of pattern-recognition receptors, eosinophils ingest antigen-antibody complexes and viruses and are induced by mast cell chemotactic factors to attack parasites and other pathogens.² Eosinophil secondary granules contain toxic chemicals (e.g., major basic protein, eosinophil cationic protein, eosinophil peroxidase, eosinophil-derived neurotoxin) that are highly destructive to parasites and viruses. The eosinophil granules contain a variety of enzymes (e.g., histaminase) that help to control inflammatory processes. (Their function in inflammation and defense against parasites and other pathogens is described in [Chapters 7](#) and [8](#).) Eosinophils process antigen and also release leukotrienes, prostaglandins, platelet-activating factor (PAF), and a variety of cytokines (e.g., interleukin-1 [IL-1], IL-6, tumor necrosis factor-alpha [TNF- α], granulocyte-macrophage colony-stimulating factor [GM-CSF]) and chemokines (e.g., IL-8) that augment the inflammatory

response. Type I hypersensitivity allergic reactions and asthma are characterized by high numbers of circulating eosinophils that may be involved in a dual role: regulation of inflammation and contribution to the destructive inflammatory processes observed in the lungs of persons with asthma (see [Chapters 9](#) and [36](#)).

Basophils, which comprise less than 1% (0.01% to 0.3%) of the leukocytes, contain cytoplasmic granules that have an abundant mixture of biochemical mediators, including histamine, chemotactic factors, proteolytic enzymes (e.g., elastase, lysophospholipase), and an anticoagulant (heparin) (see [Fig. 28.4, E](#)). Stimulation of basophils also induces synthesis of vasoactive lipid molecules (e.g., leukotrienes) and cytokines. Basophils produce IL-6, which induces IL-10 by T helper 1 (Th1) cells and also induces Th2 cells that favor B-cell differentiation.³ Basophils also are a particularly rich source of the cytokine IL-4,⁴ which preferentially guides B-cell differentiation toward plasma cells that secrete IgE (see [Chapter 8](#)).

The numbers of basophils are often increased at sites of allergic inflammatory reactions and parasitic infection, particularly ectoparasites (e.g., ticks). IgE receptors on the basophil would induce degranulation at sites of IgE-mediated hypersensitivity reactions and contribute to the local inflammatory response.

Mast cells are highly similar to basophils, but are generated from a different set of precursor cells in the bone marrow, from which they migrate in an immature form into tissues.⁵ They reside in vascularized connective tissues just beneath body epithelial surfaces, including the submucosal tissues of the gastrointestinal and respiratory tracts and the dermal layer that lies just below the surface of the skin. Mast cells play a central role in inflammation, and their activation and degranulation affect a great number of cells, including those involved in inflammation (e.g., vascular endothelial cells, smooth muscle cells, circulating platelets and leukocytes, nerves) and healing (e.g., fibroblasts), as well as glandular cells and cells of the immune system. Their activation contributes greatly to increased permeability of blood vessels and synthesis of mediators producing smooth muscle contraction (see [Fig. 7.11](#)).

Agranulocytes.

The **agranulocytes**—monocytes, macrophages, and lymphocytes—differ from the granulocytes in that they contain relatively fewer granules in their cytoplasm. Monocytes and macrophages make up the mononuclear phagocyte system.

The **mononuclear phagocyte system (MPS)**, also known as the *reticuloendothelial system* or *macrophage system*, consists of specialized endothelial cells in the bone marrow, spleen, and lymph nodes: promonocytes and their precursors in the bone marrow; monocytes in the peripheral blood; and a portion of macrophages that reside in the tissues, remaining there for months or perhaps years.⁶ Cells of the MPS ingest and destroy (by phagocytosis) unwanted materials, such as foreign protein particles, circulating immune complexes, microorganisms, debris from dead or injured cells, defective or injured erythrocytes, and dead neutrophils. Recently, the osteoclast was classified as a true member of the MPS. Macrophages stimulate formation of osteoclasts, multinucleated macrophage-like cells specialized for the function of lacunar bone resorptions and remodeling, in addition to phagocytosis.⁷ [Table 28.3](#) lists the various names given to macrophages localized in specific tissues.

TABLE 28.3

MONONUCLEAR PHAGOCYTE SYSTEM*

NAME OF CELL	LOCATION
Committed Stem Cells [†]	Bone marrow
Monoblasts	Bone marrow
Promonoblasts	Bone marrow
Monocytes	Bone marrow and peripheral blood
Macrophages	Tissue
Kupffer cells	Liver macrophages
Alveolar macrophages	Lung
Histiocytes	Connective tissue
Macrophages	Bone marrow
Fixed and free macrophages	Spleen and lymph nodes

Pleural and peritoneal macrophages Adipose macrophages	Serous cavities Adipose (fat) tissue
Microglial cells	Nervous system
Mesangial cells	Kidney
Osteoclasts	Bone
Langerhans cells	Skin
Dendritic cells	Lymphoid tissue, lining of respiratory and gastrointestinal tracts

*Formerly called the *reticuloendothelial system*.

†Development of blood cells from stem cells in the marrow is described on this page and illustrated in [Fig. 28.12](#).

Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015 Saunders.

Monocytes are the largest normal blood cell and have a horseshoe-shaped nucleus (see [Fig. 28.4, G](#)). They are formed and released by the bone marrow into the bloodstream. Monocytes migrate into a variety of tissues and fully mature into tissue macrophages and myeloid **dendritic cells** (see [Table 28.3](#)). Other monocytes may mature into macrophages in the circulation and migrate out of the vessels in response to infection or inflammation. Macrophages are generally larger and are more active as phagocytes than monocytes. Dendritic cells frequently extend projections (*dendrites*) into the tissue and assume a “neuron-like” appearance. The origin and turnover of many of the tissue macrophages are not precisely known. It seems clear that once monocytes leave the circulation, they do not return. They can survive many months or even years.

The normal role of **macrophages** is to remove old and damaged cells and large molecular substances from the blood. Cellular targets of macrophage phagocytosis include circulating senescent or damaged erythrocytes and platelets (removed primarily in spleen), dead neutrophils (in the circulation and at sites of inflammation), and cells undergoing apoptosis. Noncellular targets include antigen-antibody complexes, cellular debris, products of coagulation, and macromolecules (such as lipids and carbohydrates synthesized by the body as the result of faulty metabolism, as in storage diseases). Macrophages remove and kill contaminating microorganisms in the

blood (mostly in the liver and spleen) and at sites of infection. Macrophages and, particularly, dendritic cells are the major “antigen-processing” and “antigen-presenting” cells that initiate immune responses (see [Chapter 8](#)). Macrophages initiate wound healing and tissue remodeling and if activated by cytokines from T cells secrete a large array of biologically active chemicals that if uncontrolled result in chronic inflammation and tissue injury (see [Chapter 7](#)).

Lymphocytes constitute approximately 25% to 33% of the total leukocyte count and are the primary cells of the immune response (see [Fig. 28.4, F](#), and [Table 28.2](#); also see [Chapter 8](#)). Most lymphocytes transiently circulate in the blood and eventually reside in secondary lymphoid tissues as mature T cells, B cells, or plasma cells. The lymphocytes do not contain any enzyme-filled digestive vacuoles. The life span of the lymphocyte can be days, months, or years, depending on its type and subtype. (Lymphocyte function and dysfunction are described in detail in Unit III.)

Natural killer (NK) cells, which resemble large granular lymphocytes, kill some types of tumor cells (in vitro) and some virus-infected cells without being induced by previous exposure to these antigens (see [Chapters 7](#) and [8](#)). Hence they are named *natural killer cells* to differentiate them from T-cytotoxic cells, which are induced by antigen. NK cells also have the capacity to activate T cells and phagocytes and produce a variety of cytokines that can regulate immune responses. The predominant form of NK cells develops in the bone marrow and circulates in the blood, where it accounts for 5% to 10% of the circulating lymphoid pool, and is found mainly in the peripheral blood and spleen. NK cells develop independent of a thymus, although some NK precursors are found in the thymus and may develop into NK T cells that have markers of both NK and T cells.

Platelets.

Platelets (thrombocytes) are not true cells but irregularly shaped cytoplasmic fragments that are essential for blood coagulation and control of bleeding. They are formed in the bone marrow by

fragmentation of very large (40 to 100 μm in diameter) cells known as **megakaryocytes** (Fig. 28.5), a process that takes 7 to 10 days. They lack a nucleus and deoxyribonucleic acid (DNA), and are incapable of mitotic division. They do, however, contain cytoplasmic granules (i.e., dense granules, alpha granules, and lysosomes) capable of releasing biochemical mediators when stimulated by injury to a blood vessel. These mediators are generally proinflammatory (e.g., adenosine diphosphate [ADP], adenosine triphosphate [ATP], calcium, serotonin, and histamine). The alpha granules contain a mixture of coagulation factors, growth and angiogenic factors (e.g., platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], and basic fibroblast growth factor), and angiogenesis inhibitors (e.g., platelet factor 4, thrombospondin, and inhibitors of metalloproteinases). Depending upon the particular stimulus, platelets may selectively release promoters or inhibitors of angiogenesis.⁸ Activation also stimulates synthesis of arachidonic acid pathway products (e.g., thromboxane A_2) (see Chapter 7). Platelets can assume different shapes with pseudopodia and adhere to collagen fibers in damaged vascular walls, plugging vascular openings (the platelet plug) to control bleeding (Fig. 28.6).

FIGURE 28.5 Megakaryocyte and Platelets. Note the large number of platelets (*purple*) that have budded from the surrounding large megakaryocytes in the center. (From Miale JB: *Laboratory medicine: hematology*, ed 6, St Louis, 1982, Mosby.)

FIGURE 28.6 Colored Micrograph of Platelets. The platelet on the left is moderately activated, with a generally round shape and the beginning of formation of pseudopodia (footlike extensions from the membrane). The platelet on the right is fully activated, with extensive pseudopodia that

increase its surface area. (Copyright Dennis Kunkel, Microscopy, Inc.)

There are approximately 140,000 to 340,000 platelets/mm³ of circulating blood. An additional one-third of the body's available platelets are in a reserve pool in the spleen. A platelet circulates for approximately 8 to 11 days, ages, and is removed by macrophages of the MPS, mostly in the spleen.

Lymphoid Organs

The lymphoid system is closely integrated with the circulatory system. The lymphoid organs, some of which are merely aggregations of lymphoid tissue, are classified as primary or secondary. The **primary lymphoid organs** are the thymus and the bone marrow. The **secondary lymphoid organs** consist of the spleen, lymph nodes, tonsils, and Peyer patches in the ileum of the small intestine. All of the lymphoid organs link the hematologic and immune systems in that they are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes (monocytes and macrophages). (The liver, which also has hematologic functions, is primarily a digestive organ and is described in [Chapter 41](#).)

Spleen

The spleen is the largest of the secondary lymphoid organs. It is a site of fetal hematopoiesis, filters blood-borne antigens and cleanses the blood through the action of mononuclear phagocytes, initiates immune responses to blood-borne microorganisms (particularly bacteria), destroys aged erythrocytes, and serves as a reservoir for blood.⁹ The spleen is a concave, encapsulated organ that weighs approximately 150 g and is about the size of a fist. It is located in the left upper abdominal cavity, curved around a portion of the stomach (see [Fig. 8.3](#)). Strands of connective tissue (trabeculae) extend from the capsule, dividing the spleen into compartments ([Fig. 28.7](#)). The compartments contain masses of lymphoid tissue called *splenic pulp* (white and red) with the white pulp embedded within the red pulp. The spleen is interlaced with many blood vessels, some of which are

capable of distending to store blood. Blood that circulates through the spleen comes from the splenic artery, which branches from the descending aorta and reenters the circulatory system through the splenic vein and into the portal vein.

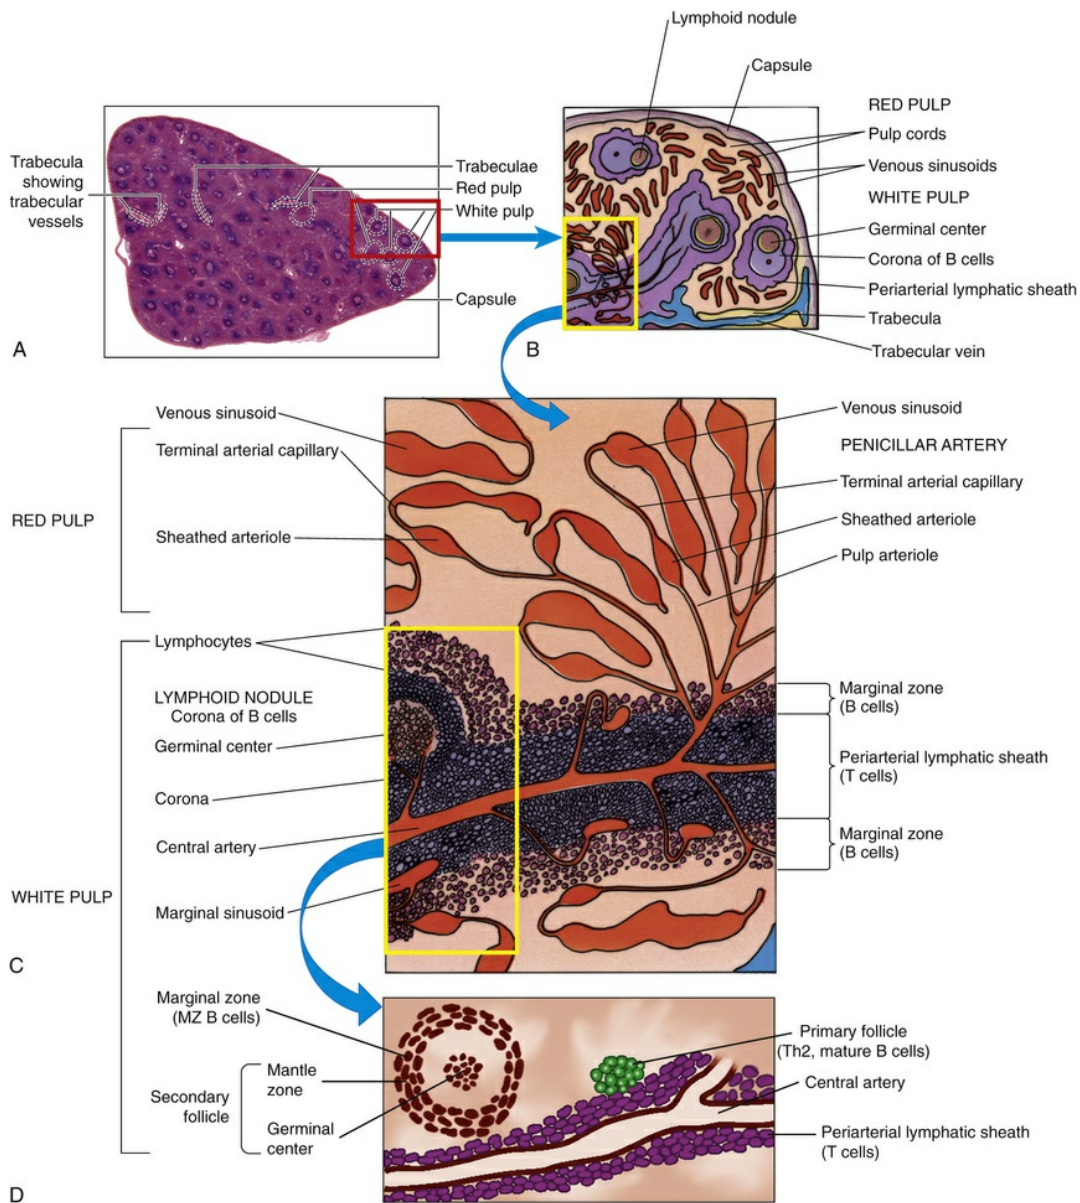

FIGURE 28.7 Splenic Architecture. A, Cross section of the spleen. The spleen is enclosed in a capsule with the interior pulp divided into compartments by strands of connective tissue. The splenic pulp contains regions that are rich in lymphocytes (white pulp) and those containing erythrocytes (red pulp). B, Subcapsular splenic structures. C, Magnified view of red and white pulp structures. D, The splenic artery branches into trabecular arteries and then to central arteries frequently surrounded by a

periarterial lymphoid sheath, primarily containing T cells. The secondary lymphoid follicles contain B cells that are proliferating in response to antigen. *Th2*, T-helper 2 cells. (A From Telser AG, Young JK, Baldwin KM: *Elsevier's integrated histology*, St Louis, 2007, Mosby; B and C from Gartner LP, Hiatt JL: *Color textbook of histology*, ed 3, Philadelphia, 2007, Elsevier; D from Hoffman R et al: *Hematology: basic principles and practice*, ed 6, Philadelphia, 2013, Churchill Livingstone.)

Arterial blood that enters the spleen first encounters the white splenic pulp, which consists of masses of lymphoid tissue containing macrophages and lymphocytes, primarily T lymphocytes in proximity to the arterioles (the periarterial lymphoid sheath) (see [Fig. 28.7](#)). Cellular clumps (lymphoid follicles) are formed in the white pulp around the splenic arterioles. The lymphoid follicles consist primarily of B lymphocytes. These are the chief sites of immune function within the spleen. Here blood-borne antigens encounter lymphocytes, initiating the immune response and the conversion of lymphoid follicles into germinal centers where B cells proliferate and differentiate during the humoral immune response (see [Chapter 8](#)).

Some of the blood that enters the terminal capillaries continues through the microcirculation and enters highly distensible storage areas called *venous sinuses* in the red pulp of the spleen. The venous sinuses are capable of storing more than 300 mL of blood. Passive dilation of the venous sinuses enables the spleen to increase its storage capacity as needed by the body. Sudden reductions in blood pressure cause the sympathetic nervous system to stimulate constriction of the sinuses, resulting in expulsion of as much as 200 mL of blood into the venous circulation, which helps restore blood volume and increases the hematocrit by as much as 4%.

The endothelial lining of the venous sinuses is discontinuous (having gaps between endothelial cells) and therefore extremely permeable so that blood cells are allowed to exit the circulation. The red pulp contains a system of loosely interconnected resident macrophages that provide the principal site of splenic filtration. Because of the slow circulation in the sinuses ([Fig. 28.8](#)), the macrophages easily phagocytose old, damaged, or dead blood cells of all kinds (but chiefly erythrocytes), microorganisms, macromolecules, and particles of debris. Hemoglobin from phagocytosed erythrocytes

is catabolized, and heme (iron) is stored in the cytoplasm of the macrophages or released back into the blood to support hemoglobin synthesis¹⁰ (see Fig. 28.18). The macrophages also can remove particulate inclusions containing denatured hemoglobin (Heinz bodies) from erythrocytes without harming the cells themselves. Blood that filters through the red pulp also finds its way into the venous sinuses and hence into the portal circulation.

FIGURE 28.8 Splenic Sinus. Transmission electron micrograph and schematic of erythrocytes in the process of squeezing from the red pulp cords into the sinus lumen. Note the degree of deformability required for red cells to pass through the wall of the sinus. *RBC*, Red blood cell. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby. Schematic from Kumar V, Fausto N, Abbas A: *Robbins & Cotran pathology basis of disease*, ed 7, St Louis, 2005, Saunders.)

The spleen is not absolutely necessary for life or for adequate hematologic function. However, splenic absence from any cause (atrophy, traumatic injury, or removal because of disease) has several secondary effects on the body. For example, leukocytosis (high levels of circulating leukocytes) often occurs after splenectomy, suggesting that the spleen exerts some control over the rate of proliferation of leukocyte stem cells in the bone marrow or their release into the bloodstream. Circulating levels of iron may also decrease, reflecting the spleen's role in the iron cycle. The immune response to encapsulated bacteria (e.g., *Streptococcus pneumoniae* [pneumococcus],

Neisseria meningitidis [meningococcus], *Haemophilus influenzae*), which is primarily an IgM response, may be severely diminished, resulting in increased susceptibility to disseminated infections and sepsis.¹¹ Loss of the spleen results in an increase in morphologically defective blood cells in the circulation, as well as senescent platelets, confirming the spleen's role in removing old or damaged red blood cells and platelets. Thrombocytosis and thrombosis are complications of splenectomy and can require anticoagulation therapy for 3 to 6 months.¹²

Lymph Nodes

Structurally, **lymph nodes** are part of the lymphatic system. Lymphatic vessels collect interstitial fluid from the tissues and transport it, as lymph, through vessels of increasing size to the thoracic duct, which drains into the superior vena cava and returns the lymph to the circulation. Lymph nodes are distributed throughout the body and provide filtration of the lymph during its journey through the lymphatics. Each lymph node is enclosed in a fibrous capsule, branches of which (trabeculae) extend inward to partition the node into several compartments (Fig. 28.9). Reticular fibers of connective tissue divide the compartments into a meshwork throughout the lymph node. The node consists of outer (cortex) and inner (paracortex) cortical areas and an inner medulla. Lymph enters through multiple small afferent lymphatic vessels into the subcapsular sinus, just beneath the capsule; drains into the cortical sinuses to the medullary sinuses, from which the lymph is collected; and leaves the node by way of the efferent lymphatic vessel. Blood flows into the lymph nodes through the lymphatic artery, which ends in groups of postcapillary venules distributed throughout the outer cortex. The blood is drained through the lymphatic vein.

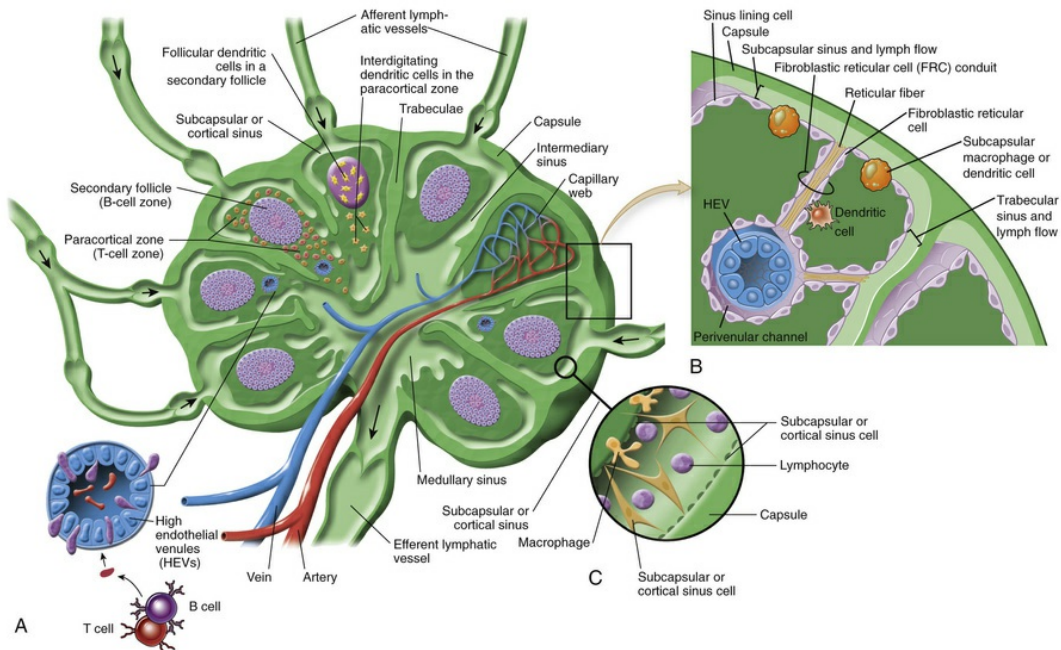

FIGURE 28.9 Lymph Node Architecture. **A**, Cross section showing ingoing and outgoing lymph vessels (afferent and efferent), blood supply, compartmentalization of the B-cell region (secondary follicle), T-cell region (paracortical zone) with precapillary or high endothelium venules, follicular interdigitating dendritic cells, medullary sinus, intermediate sinus, and subcapsular or cortical sinus. Naive B and T lymphocytes enter through the high endothelial venule (HEV), shown in cross section, and are drawn to different areas of the node by chemokines that are produced in these areas and bind selectively to either cell type. **B**, Cellular composition of the lymph node cortex depicting the route of lymph drainage from the subcapsular sinus, through fibroreticular cell conduits, to the perivenular channel around the high endothelial venule (HEV). Dendritic cells pick up antigen from peripheral sites of antigen entry and enter the lymph node through the afferent lymph vessels and migrate to the T-cell region of the node. **C**, Cellular composition of subcapsular sinus. (A and C From Paulsen F: *Sobotta atlas of human anatomy*, vol 1, ed 15, Philadelphia, 2013, Elsevier; B from Abbas AK, Pillai S: *Cellular and molecular immunology*, ed 9, Philadelphia, 2015, Saunders.)

Functionally, lymph nodes are part of the hematologic and immune systems and are the primary site for the first encounter between antigen and lymphocytes. Lymphocytes enter the lymph node from the blood through the postcapillary venules by means of diapedesis across the endothelial lining. B lymphocytes tend to migrate preferentially to nodes in the cortex and medulla, whereas T lymphocytes predominantly migrate to the paracortex (see Fig. 28.9). Macrophages reside in the lymph node; help filter the lymph of debris, foreign substances, and microorganisms; and provide antigen-

processing functions. The dendritic cells encounter and process antigens and microorganisms in other tissues, enter the lymph node through the afferent lymph vessels, and migrate throughout the nodes. The reticular network provides adhesive surfaces for trapping large numbers of phagocytes and lymphocytes and facilitating their organization into follicles or primary nodules. The presence of antigen, either removed from the lymph by macrophages or presented on the surface of dendritic cells, results in the production of secondary nodules containing germinal centers. In the germinal centers, lymphocytes, particularly B cells, respond to antigenic stimulation by undergoing proliferation and further differentiation, including class-switch, into memory cells and plasma cells (see [Chapter 8](#)). Plasma cells migrate to the medullary cords. The B-lymphocyte proliferation in response to a great deal of antigen (e.g., during infection) may result in lymph node enlargement and tenderness (reactive lymph node).

Development of Blood Cells

Hematopoiesis

The typical human requires about 100 billion new blood cells per day. Blood cell production, termed **hematopoiesis**, is constantly ongoing, occurring in the liver and spleen of the fetus and only in bone marrow (*medullary hematopoiesis*) after birth. These cells carry out functions including oxygen transport, immunity, and tissue remodeling. The process of hematopoiesis involves the biochemical stimulation of populations of relatively undifferentiated cells to undergo mitotic division (i.e., proliferation) and maturation (i.e., differentiation) into mature hematologic cells ([Table 28.4](#)). Although proliferation and differentiation are usually sequential, certain blood cells proliferate and differentiate simultaneously. Erythrocytes and granulocytes generally differentiate fully before entering the blood, but monocytes and lymphocytes continue to mature in the blood and in secondary lymphatic organs.

TABLE 28.4**HUMAN HEMATOPOIETIC GROWTH FACTORS (CYTOKINES, COLONY-STIMULATING FACTORS)**

FACTOR	CELL ORIGIN	PRIMARY CELL STIMULATED
M-CSF	Macrophage, lymphocyte, fibroblast, endothelial cell, osteoblast	Monocyte progenitor to monocyte
GM-CSF	Macrophage, T cell, endothelial cell, fibroblast, mast cell	Common myeloid progenitor to granulocyte progenitor and monocyte progenitor
G-CSF	Macrophage, fibroblast, endothelial cell	Granulocyte progenitor to neutrophil
IL-2	Th cell	T-cell progenitor to T cell
IL-3	T cell, monocyte/macrophage, stromal cell	Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series
IL-4	Th cell	B-cell progenitor to B cell
IL-5	Th cell, mast cell	Common myeloid progenitor to eosinophil
IL-7	Stromal cell, intestinal epithelium	Hematopoietic stem cell to common lymphoid progenitor Common lymphoid progenitor to progenitor B cell, pro NK cell, and progenitor T cell Progenitor T cell to T cell and progenitor B cell to B cell
IL-11	Stromal cell	Megakaryocyte progenitor to megakaryocyte
IL-15	Monocyte/macrophage	NK progenitor to NK cell
Erythropoietin	Peritubular kidney cell and Kupffer cell	Common myeloid progenitor to erythrocyte progenitor Erythrocyte progenitor to erythrocyte
Thrombopoietin	Liver, kidney, skeletal muscle	All cells in megakaryocyte lineage from common myeloid progenitor to platelet
Stem cell factor (steel factor)	Stromal cell in bone marrow and many other cells	Hematopoietic progenitor to common myeloid progenitor Common myeloid progenitor to progenitors for megakaryocyte, erythroid, granulocyte, and monocyte series

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IL*, interleukin; *M-CSF*, macrophage colony-stimulating factor; *NK*, natural killer; *pro*, progenitor; *Th*, T helper.

Hematopoiesis continues throughout life, increasing in response to a need to replenish aged RBCs or destroyed circulating cells (e.g., during hemorrhage, hemolytic anemia [peripheral destruction of erythrocytes], consumptive thrombocytopenia) or in response to infection. In general, long-term stimuli, such as chronic diseases, cause a greater increase in hematopoiesis than acute conditions, such as hemorrhage.

Various abnormalities in medullary hematopoiesis have been identified and are discussed in [Chapter 29](#). **Extramedullary hematopoiesis**—blood cell production in tissues other than bone marrow—of apparently normal blood cells has been reported in the spleen, liver, and, less frequently, lymph nodes, adrenal glands, cartilage, adipose tissue, intrathoracic areas, and kidneys. In adults, however, extramedullary hematopoiesis is usually a sign of disease, occurring in pernicious anemia, sickle cell anemia, thalassemia, hemolytic disease of the newborn (erythroblastosis fetalis), hereditary spherocytosis, and certain leukemias.

Bone Marrow

Bone marrow is confined to the cavities of bone and is the primary site of residence of hematopoietic stem cells ([Fig. 28.10](#)). Adults have two kinds of bone marrow: red marrow (active or hematopoietic marrow; also called **myeloid tissue**) and yellow marrow (inactive marrow). The large quantity of fat in marrow is responsible for its yellow appearance. Not all bones contain active marrow. In adults, active marrow is found primarily in the flat bones of the pelvis (34%), vertebrae (28%), cranium and mandible (13%), and sternum and ribs (10%), and in the extreme proximal portions of the humerus and femur (4% to 8%). Inactive marrow predominates in cavities of other bones. (Bones are discussed further in [Chapter 44](#).)

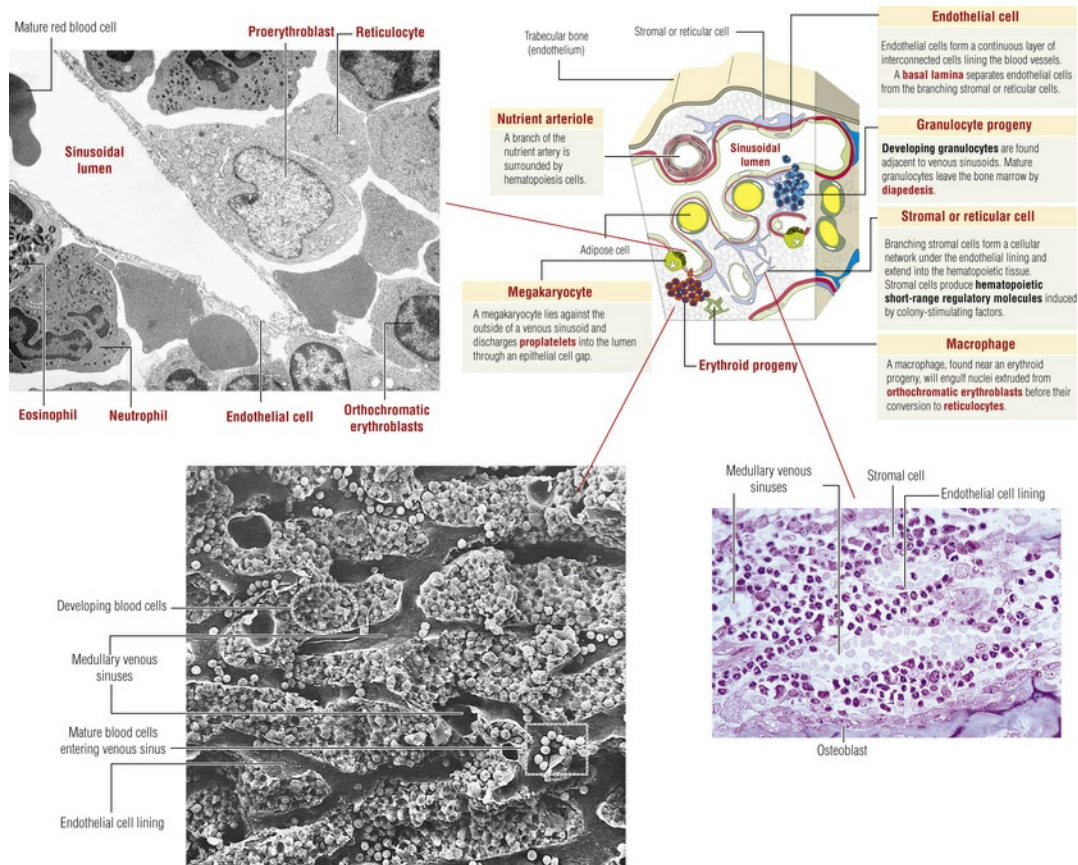

FIGURE 28.10 Bone Marrow: Structure and Vascularization. (From Kierszenbaum A, Tres L: *Histology and cell biology: an introduction to pathology*, ed 4, Philadelphia, 2016, Mosby. Scanning electron micrograph from Kessel RG, Kardon RH: *Tissues and organs*, New York, 1979, WH Freeman.)

At least two populations of stem cells are found in bone marrow niches. **Hematopoietic stem cells (HSCs)** are progenitors of all hematologic cells. Both populations of stem cells undergo continuous proliferation and self-renewal in the microenvironment of the bone marrow so that additional HSCs are produced to replace those undergoing differentiation. **Mesenchymal stem cells (MSCs)** are stromal cells and have a role in maintaining HSCs. They can differentiate into a variety of cells, including osteoblasts (produce bone), adipocytes (store fat), and chondrocytes (produce cartilage).

The hematologic compartment of the bone marrow consists of a variety of cellular and molecular microenvironments, called **niches**. Niches simultaneously contain stem cells, precursor cells, and terminally differentiated cells and provide a coordinated signaling

network necessary to regulate the self-renewal, differentiation, and maintenance of HSCs¹³ (Fig. 28.11). They protect HSCs by maintaining quiescence, limiting their entry into the cell cycle, and preventing exhaustion or errors in DNA replication. The niches of the bone marrow are commonly described as endosteal (at the interface of bone and bone marrow) and vascular (endothelial and perivascular cells), but this is an oversimplification of the complexity that is emerging with more investigation. There is more likely an array of niches that harbor the cells and cytokines that support hematopoiesis.¹⁴ Niches also have a role in metastasis related to the microenvironment of dormant disseminated cancer cells.¹⁵

FIGURE 28.11 Bone Marrow Stem Cell Niches. Stem cell niches are microenvironments where stem cells undergo hematopoiesis into all forms of blood cells. Stem cell niches retain and maintain adult quiescent hematopoietic stem cells (HSCs) and are activated to promote cell self-renewal, proliferation, and differentiation to form new cells. The fate of individual HSCs is determined by interactions (intercellular adhesion, cytokines, chemokines) with specialized cells within the niches. CAR, CXCL12-abundant reticular cells; CXCL4, chemokine ligand 4 (also known as *platelet factor 4*); CXCL12, chemokine ligand 12; MSC, mesenchymal stem cells; SCF, stem cell factor; TGF-β1, transforming growth factor-beta 1. (Adapted from Boulais PE, Frenette PS: *Blood* 125[17]:2621–2629; Schepers K, Campbell TB, Passegué E: *Cell Stem Cell* 16[3]:254–267, 2015.)

The cellular composition of niches includes osteoclasts, osteoblasts, sinusoidal endothelial cells, fibroblasts, adipocytes, and other stromal cells. Osteoblasts are derived from fibroblasts and are responsible for construction of bone. Osteoclasts are multinucleate cells of monocytic origin that remodel bone by resorption. Both cells are located near the endosteum and can produce cytokines that affect proliferation and maintenance of hematopoietic cells. Megakaryocytes and macrophages promote HSC migration and proliferation in the niches. Adipocytes suppress HSC numbers. The area is innervated through the sympathetic nervous system.

Hematopoietic marrow is vascularized by the primary arteries of the bones. Arterial vessels enter the bone, branch near the endosteum into smaller arterioles and capillaries, and drain into venous sinusoids (see [Fig. 28.11](#)). These sinuses coalesce into a large central sinus in the central cavity. Hematopoietic marrow and fat (yellow marrow) fill the spaces surrounding the network of venous sinusoids. Newly produced blood cells traverse narrow openings between endothelial cells in the venous sinus walls and thus enter the circulation. Dormant or quiescent HSCs localize near small arterioles of the endosteal region that are ensheathed by pericytes, which express high levels of nestin and act together with sympathetic nerves to promote HSC maintenance and retention. The low blood flow of the arteriole/sinusoid network limits gas exchange, creates a relatively hypoxic microenvironment, and maintains quiescence.¹⁶ Active HSCs are located near the sinusoids, which are likely more diverse in their influence for self-renewal, proliferation, and differentiation.¹⁷

Hematopoietic niches are affected by direct cell-to-cell signaling and by soluble mediators produced by cells within the niches. Niches contain two specialized MSCs: CXCL12-abundant sinusoidal reticular (CAR) cells and periarteriolar and sinusoidal nestin-expressing cells.¹⁸ These cells closely interact with HSCs and provide intercellular signaling through several HSC regulatory molecules important for retention, expansion, maintenance, and quiescence of HSCs. These molecules include chemokine ligand 12 (CXCL12, promotes retention and expansion of HSCs), stem cell factor (SCF, stimulates

hematopoiesis), vascular cell adhesion molecule 1 (VCAM-1, promotes HSC retention), and secreted protein angiopoietin 1 (ANG1, promotes quiescence or HSC stemness or ability to self-replicate). The CAR cell is the predominant cell in the sinusoids.¹³ The sympathetic nervous system regulates HSC mobilization through circadian release of β_3 -norepinephrine (adrenergic signaling), which down-regulates CXCL12 expression in the bone marrow. Nestin-expressing MSCs express large amounts of the protein nestin and, particularly, SCF and VCAM-1. Transforming growth factor-beta (TGF- β) also plays an important role in regulating HSC behavior, particularly quiescence and self-renewal.¹⁹

Cellular Differentiation

All humans originate from a single cell (the fertilized egg) that has the capacity to proliferate and eventually differentiate into the huge diversity of cells of the human body. After fertilization, the egg divides over a 5-day period to form a hollow ball (blastocyst) that implants on the uterus. Until about 3 days after fertilization, each cell (blastomere) is undifferentiated and retains the capacity to differentiate into any cell type. In the 5-day blastocyst, the outer layer cells have undergone differentiation and commitment to become the placenta. Cells of the inner cell mass (*embryonic stem cells*), however, continue to have unlimited differentiation potential (currently referred to as being *pluripotent*) and can grow into different kinds of tissue—blood, nerves, heart, bone, and so forth. After implantation, cells of the inner cell mass begin differentiation into other cell types. Differentiation is a multistep process and results in intermediate groups of stem cells (*multipotent stem cells*) with more limited, but still impressive, abilities to differentiate into many different types of cells²⁰ (Fig. 28.12).

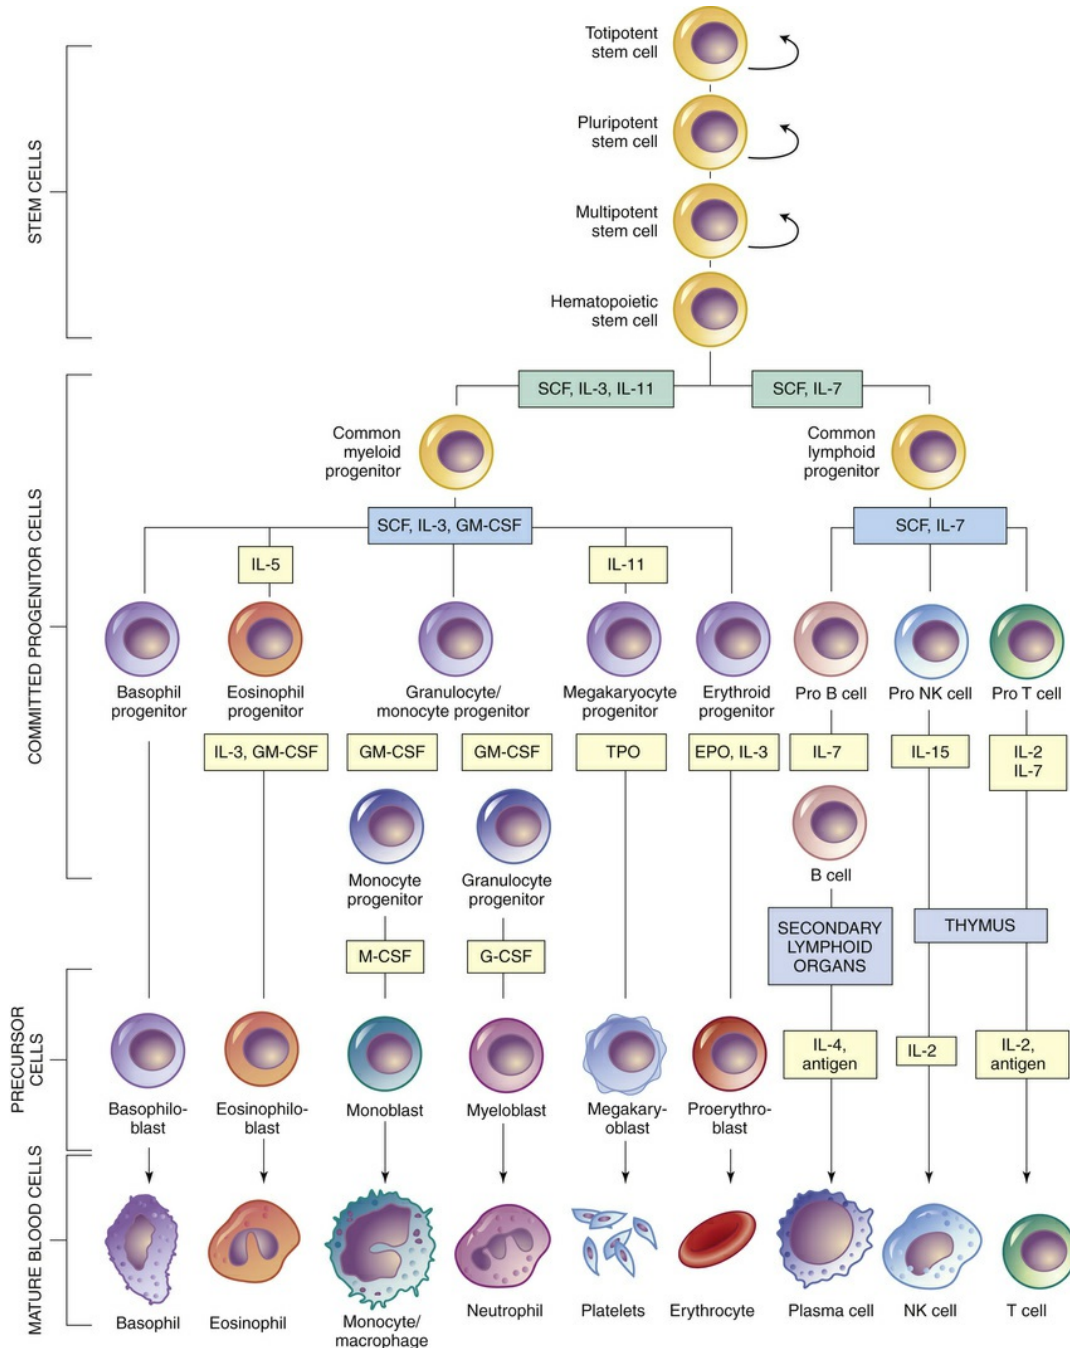

FIGURE 28.12 Differentiation of Hematopoietic Cells. Curved arrows indicate proliferation and expansion of prehematopoietic stem cell populations. *EPO*, Erythropoietin; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IL*, interleukin; *M-CSF*, macrophage colony-stimulating factor; *NK*, natural killer; *SCF*, stem cell factor; *TPO*, thrombopoietin.

Within the bone marrow niches, each type of blood cell originates from hematopoietic stem cells that proliferate and differentiate under the control of a variety of cytokines and growth factors (see [Fig. 28.12](#)

and [Table 28.4](#)). During this process some hematopoietic stem cells undergo alternative paths of differentiation into more differentiated stem cells that are committed to a particular line of blood cells.

As with all stem cells, the hematopoietic stem cells are self-renewing (they have the ability to proliferate without further differentiation) so that a relatively constant population of stem cells is available. Some hematopoietic stem cells will continue differentiation into hematopoietic progenitor cells. Progenitor cells retain proliferative capacity but are committed to possible further differentiation into particular types of hematologic cells: lymphoid (lymphocytes, NK cells), granulocyte-monocyte (granulocytes, monocytes, macrophages), and megakaryocyte-erythroid (platelets, erythrocytes) progenitor cells (see [Fig. 28.12](#)).

In addition to intercellular signaling events between HSCs and cells in the osteoblastic and vascular niches, several cytokines participate in hematopoiesis, particularly **colony-stimulating factors (CSFs or hematopoietic growth factors)**, which stimulate the proliferation of progenitor cells and their progeny and initiate the maturation events necessary to produce fully mature cells (see [Fig. 28.12](#)). Multiple cell types in the hematopoietic organs, including endothelial cells, fibroblasts, and lymphocytes, produce the necessary CSFs ([Box 28.1](#)).

Box 28.1

Clinical Uses of Colony-Stimulating Factor (CSF)

Neutrophils are normally present in the blood in the range of 4000 to 6000 cells/ μL , and in response to a bacterial infection, numbers usually increase to 10,000 to 20,000 cells/ μL . Susceptibility to infection develops when levels drop below 1000 cells/ μL , such as during congenital neutropenia or as a consequence of cytotoxic therapy for cancer. Similarly, normal levels of other hematologic cells may be suppressed (e.g., congenital or acquired immune deficiencies and anemia or myelodysplastic syndromes) (see

Chapters 9 and 29). The numbers of circulating hematologic cells are under the control of CSFs (see Table 28.4). CSF therapy can stimulate increases in circulating granulocyte-monocyte populations, but the degree of response depends on the available numbers of stem and progenitor cells that have survived chemotherapy or the effects of disease (see Figure).

FIGURE Morphologic Effects of Growth Factor. Marrow aspirate from a

patient receiving granulocyte colony-stimulating factor (G-CSF) showing an early neutrophil response. There is a marked shift toward immaturity in the neutrophils with the majority at the promyelocyte and early myelocyte stages of maturation (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Administration of CSFs has been approved for use when neutropenia is $<1500/\mu\text{L}$, and current guidelines recommend their use when the risk for febrile neutropenia is $>20\%$.¹ The results of CSF use to prevent neutropenia in individuals with cancer have been variable. In a review of 633 individuals receiving myelosuppressive chemotherapy and treated with granulocyte CSF (G-CSF) to prevent neutropenia for nonmyeloid malignancies, adverse events occurred in about 27% of individuals, including bone pain, myalgia, and asthenia.² A recent study reported improved prognosis using CSF therapy for prevention of febrile neutropenia associated with chemotherapy in adult acute lymphoblastic leukemia.³ Results of other studies using prophylactic granulocyte colony-stimulating factors to prevent febrile neutropenia in adult acute leukemia and stem cell transplants have been disappointing.⁴ An analysis of 19 trials in which CSFs were administered postchemotherapy to those with acute myelogenous leukemia detected no effect on overall survival or infections.⁵ Using CSF prophylactically to avoid neutropenia in individuals undergoing chemotherapy for breast cancer has shown low to modest benefit.⁶ An analysis of randomized trials of prophylactic use of GM-CSF and G-CSF in individuals undergoing chemotherapy for metastatic breast cancer indicated a significant effect on prevention of febrile neutropenia and a decrease of general mortality and need for hospital care.⁷ However, no effect was observed on the incidence of severe neutropenia, infections, or infection-related mortality. There is substantial lack of data to encourage the use of G-CSF and GM-CSF for the prevention of infection in cases of neutropenia associated with myelodysplastic syndromes.⁸ In severe congenital neutropenia, treatment with G-CSF increases the absolute neutrophil count but use of GM-CSF is not effective.⁹ CSF treatment can result in shorter periods of

intensive nursing and hospitalization but the cost of use must be considered in relation to outcome benefit and healthcare policy. Recombinant or biosimilar CSFs (e.g., G-CSF, GM-CSF, erythropoietin) are being mass-produced for therapeutic use.¹⁰

Hematopoiesis in the bone marrow occurs in two separate pools: the stem cell pool and the bone marrow pool (Fig. 28.13). The stem cell pool is the product of self-renewal that maintains the number of pluripotent stem cells and partially committed progenitor cells. The bone marrow pool contains cells that are proliferating and maturing in preparation for release into the circulation and mature cells that are stored for later release into the peripheral blood. The peripheral blood also contains two pools of cells: those in the circulation and those stored around the walls of the blood vessels (often called the **marginating storage pool**). The marginating storage pool primarily consists of neutrophils that adhere to the endothelium in vessels where the blood flow is relatively slow. These cells can rapidly move into tissues and mucous membranes when needed (i.e., during an inflammatory response).

FIGURE 28.13 Hematopoiesis. Hematopoiesis from the stem cell pool; activity occurs mainly in the bone marrow and in the peripheral blood. (Modified from Harmening DM, editor: *Clinical hematology and fundamentals of hemostasis*, ed 3, Philadelphia, 1997, FA Davis.)

Under certain conditions of rapid depletion of the circulating pool, the circulating hematologic cells need to be rapidly replenished. Medullary hematopoiesis can be accelerated by any or all of three mechanisms: (1) conversion of yellow bone marrow, which does not produce blood cells, to hematopoietic red marrow by the actions of **erythropoietin** (a hormone that stimulates erythrocyte production); (2) faster differentiation of progenitor cells; and (3) faster proliferation of stem cells into progenitor cells (see [Table 28.4](#)).

Development of Erythrocytes

For almost 100 years it was believed that erythrocytes developed from lymphocytes that were transformed in the spleen. It was not until the 1850s that the bone marrow was identified as the site of erythropoiesis.

Erythropoiesis

Erythropoiesis is the development of red blood cells. In the confines of the bone marrow, erythroid progenitor cells proliferate and differentiate into large, nucleated **proerythroblasts**, which are

committed into producing cells of the erythroid series (Fig. 28.14). All stages of erythroid development are referred to as the *erythron*. The proerythroblast, which has ribosomes and can produce protein, differentiates through several intermediate forms of **erythroblast** while synthesizing hemoglobin and progressively eliminating most intracellular structures, including the nucleus. Thus the maturing erythroblast becomes more compact and progressively assumes the shape and characteristics of an erythrocyte. Hemoglobin is readily apparent and increases in quantity as nuclear size shrinks throughout the basophilic and polychromatophilic stages. The orthochromatic erythroblast (**normoblast**) is the smallest of the nucleated erythrocyte precursors.

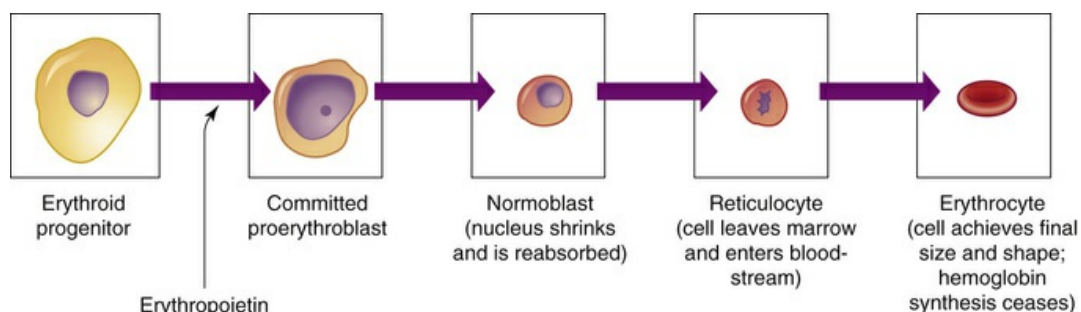

FIGURE 28.14 Erythrocyte Differentiation. Erythrocyte differentiation from large nucleated progenitor cells to small nonnucleated erythrocytes.

The last immature form of the erythroblast is the **reticulocyte**, which is anucleate and contains a meshlike (reticular) network of ribosomal ribonucleic acid (rRNA) that is visible microscopically after being stained with certain dyes. The reticulocyte contains polyribosomes (for globin synthesis) and mitochondria (for oxidative metabolism and heme synthesis). The reticulocyte matures into an erythrocyte within 24 to 48 hours. During this period, mitochondria and ribosomes disappear and the cell becomes smaller and more disklike. With these final changes, the erythrocyte loses its capacity for hemoglobin synthesis and oxidative metabolism. Reticulocytes remain in the marrow approximately 1 day and are released into the venous sinuses. They continue to mature in the bloodstream and may travel

to the spleen for several days of additional maturation. The normal reticulocyte count is 1% of the total red blood cell count. Approximately 1% of the body's circulating erythrocyte mass normally is generated every 24 hours. Therefore the reticulocyte count is a useful clinical index of erythropoietic activity and indicates whether new red cells are being produced.

Regulation of Erythropoiesis

In healthy individuals, the total volume of circulating erythrocytes remains surprisingly constant. Most steps of erythropoiesis are primarily under the control of a feedback loop involving the glycoprotein erythropoietin (see [Table 28.4](#)). In conditions of tissue hypoxia, erythropoietin is secreted by the liver and, primarily, by the peritubular cells of the kidney²¹ ([Fig. 28.15](#)). Rising levels of circulating erythropoietin cause a compensatory increase in proliferation and differentiation of proerythroblasts in the bone marrow. The density of cellular erythropoietin receptor decreases progressively during erythroid maturation to almost undetectable levels on reticulocytes. The normal steady-state rate of production of approximately 2.5 million erythrocytes per second can increase to 17 million per second during anemia or under conditions of low oxygen concentration, such as high-altitude environments or pulmonary disease. Thus the body responds to reduced oxygenation of blood in two ways: (1) stimulation of chemoreceptors of the carotid body and aortic arch that signals the brain to increase oxygen intake through increased ventilation; and (2) stimulation of receptors on the kidney peritubular cells to increase erythropoietin synthesis and release, thus increasing the oxygen-carrying capacity of the blood.

FIGURE 28.15 Role of Erythropoietin in Regulation of Erythropoiesis. (1) Decreased arterial oxygen levels result in (2) decreased tissue oxygen (hypoxia) that (3) stimulates the kidney to increase (4) production of erythropoietin. Erythropoietin is carried to the bone marrow (5) and binds to erythropoietin receptors on proerythroblasts, resulting in increased red cell production and maturation and expansion of the erythron (6). The increased release of red cells into the circulation frequently corrects the hypoxia in the tissues (7). (8) Perception of normal oxygen levels by the kidney causes (9) diminished production of erythropoietin (negative feedback) and return to normal levels of erythrocyte production. *EPO*, Erythropoietin; *O₂*, oxygen in the blood and tissue; *RBCs*, red blood cells.

Recombinant human erythropoietin (r-HuEPO) is used in individuals with anemia secondary to decreased erythropoietin production from chronic renal failure. An immediate effect of increased endogenous or exogenous erythropoietin is an increase in the blood reticulocyte count, followed by increasing levels of erythrocytes. The most significant side effect associated with r-HuEPO is increased blood pressure.

Hemoglobin Synthesis

Hemoglobin (Hb), the oxygen-carrying protein of the erythrocyte, constitutes approximately 90% of the cell's dry weight. Hemoglobin-packed blood cells take up oxygen in the lungs and exchange it for carbon dioxide in the tissues. A single erythrocyte can contain as many as 300 hemoglobin molecules. Hemoglobin increases the oxygen-carrying capacity of blood by 100-fold. Each hemoglobin molecule is composed of two pairs of polypeptide chains (the **globins**) and four colorful complexes of iron plus protoporphyrin (the hemes),

responsible for blood's ruby-red color and oxygen-carrying capacity (Fig. 28.16).

FIGURE 28.16 Molecular Structure of Hemoglobin. Hemoglobin is a spherical tetramer weighing approximately 64,500 daltons. It contains two α subunits, two β subunits, and an iron-containing heme group for each protein subunit. Each heme group can bind four oxygen molecules.

Several variants of hemoglobin exist, but they differ only slightly in primary structure based on the use of different polypeptide chains: alpha, beta, gamma, delta, epsilon, or zeta (α , β , γ , δ , ϵ , or ζ , respectively) (Table 28.5). Each polypeptide chain contains approximately 150 amino acids and is arranged in the knotted-sausage configuration shown in Fig. 28.16. The chains assemble to form a tetrahedron containing two pairs of identical chains. Hemoglobin A, the most common type in adults, is composed of two α - and two β -polypeptide chains ($\alpha_2\beta_2$). A normal variant, fetal hemoglobin (hemoglobin F), is a complex of two α - and two γ -polypeptide chains ($\alpha_2\gamma_2$) that binds oxygen with a much greater affinity than adult hemoglobin.

TABLE 28.5

STRUCTURE OF NORMAL HEMOGLOBIN MOLECULES

TYPE OF HEMOGLOBIN (Hb)	IDENTITY OF POLYPEPTIDE CHAIN	SIGNIFICANCE
HbA	$\alpha_2\beta_2$	92% of adult Hb
HbA _{1c}	α_2 (β -NH-glucose)	5% of adult Hb; increased in diabetes (see Chapter 22)
HbA ₂	$\alpha_2\delta_2$	2% of adult Hb; increased in β -thalassemia (see Chapter 31)
HbF	$\alpha_2\gamma_2$	Major fetal Hb from the third through ninth month of gestation; promotes oxygen transfer across platelets; increased in β -thalassemia
Hb Gower I	ϵ_4 or $\zeta_2\beta_2$	Present in early embryo; function unknown
Hb Gower II	$\alpha_2\epsilon_2$	Present in early embryo; function unknown
Hb Portland	$\zeta_2\gamma_2$	Present in early embryo; function unknown

NH, Amine.

Heme is a large, flat, iron-protoporphyrin disk that is synthesized in the mitochondria and can carry one molecule of oxygen (O₂). Thus an individual hemoglobin molecule with its four hemes can carry four oxygen molecules. If all four oxygen-binding sites are occupied by oxygen, the molecule is said to be saturated. Through a series of complex biochemical reactions, **protoporphyrin**, a complex four-ringed molecule, is produced and bound with ferrous iron (Fe⁺⁺). It is crucial that the iron be correctly charged; reduced ferrous iron (Fe⁺⁺) can bind oxygen in the lungs and release it in the tissues, where oxygen concentration is less, whereas ferric iron (Fe⁺⁺⁺) cannot. Binding of oxygen to ferrous iron (**oxyhemoglobin**) temporarily oxidizes Fe⁺⁺ to Fe⁺⁺⁺, but after the release of oxygen the body reduces the iron to Fe⁺⁺ (**deoxyhemoglobin** [reduced hemoglobin]) and reactivates the hemoglobin's capacity to bind oxygen. Without reactivation by methemoglobin reductase, the Fe⁺⁺⁺-containing hemoglobin (**methemoglobin**) cannot bind oxygen. An excess of ferric iron occurs with certain drugs and chemicals, such as nitrates and sulfonamides, and reduces oxygen-carrying capacity. Hemoglobin also undergoes a conformational change when binding oxygen. When one of the iron molecules binds oxygen, the porphyrin ring changes shape, increasing the exposure of the three remaining iron atoms to oxygen. This greatly increases the affinity for the oxygen-carrying

capacity of hemoglobin, as occurs in the lungs. When oxygen is unloaded from hemoglobin, the oxygen-carrying capacity of hemoglobin is low, facilitating the transport of carbon dioxide back to the lungs.

Several other molecules can competitively bind to deoxyhemoglobin. Carbon monoxide (CO) directly competes with oxygen for binding to ferrous ion with an affinity that is about 200-fold greater than that of oxygen. Thus even a small amount of CO can dramatically decrease the ability of hemoglobin to bind and transport oxygen. Hemoglobin also binds carbon dioxide (CO₂), but at a binding site separate from where oxygen binds. In the lungs, CO₂ is released, allowing hemoglobin to bind oxygen.

Erythrocytes may play a role in the maintenance of vascular relaxation. Nitric oxide (NO) produced by blood vessels is a major mediator of relaxation and dilation of the vessel walls. In the lungs, hemoglobin can concurrently bind oxygen to the ferrous ion and NO to cysteine residues in the globins. As hemoglobin transfers its oxygen to tissue, it may also shed small amounts of nitric oxide, contributing to dilation of the blood vessels and helping the oxygen gain access to tissues.

Nutritional Requirements for Erythropoiesis

Normal development of erythrocytes and synthesis of hemoglobin depend on an optimal biochemical milieu and adequate supplies of the necessary building blocks, including protein, vitamins, and minerals (Table 28.6). If these components are lacking for a prolonged time, erythrocyte production slows and anemia (insufficient numbers of functional erythrocytes) may result (see Chapter 29).

TABLE 28.6

NUTRITIONAL REQUIREMENTS FOR ERYTHROPOIESIS

NUTRIENT	ROLE IN ERYTHROPOIESIS	CONSEQUENCE OF DEFICIENCY
Protein (amino	Structural component of plasma	Decreased strength, elasticity, and flexibility of

acids)	membrane	membrane; hemolytic anemia
	Synthesis of hemoglobin	Decreased erythropoiesis and life span of erythrocytes
Cobalamin (vitamin B ₁₂)	Synthesis of DNA, maturation of erythrocytes, facilitator of folate metabolism	Macrocytic (megaloblastic) anemia
Folate (folic acid)	Synthesis of DNA and RNA, maturation of erythrocytes	Macrocytic (megaloblastic) anemia
Vitamin B ₆ (pyridoxine)	Heme synthesis	Microcytic-hypochromic anemia
Vitamin B ₂ (riboflavin)	Oxidative reactions	Normocytic-normochromic anemia
Vitamin C (ascorbic acid)	Iron metabolism; acts as a reducing agent to maintain iron in its ferrous (Fe ⁺⁺) form	Normocytic-normochromic anemia
Pantothenic acid	Heme synthesis	Unknown in humans*
Niacin	None, but needed for respiration in mature erythrocytes	Unknown in humans
Vitamin E	Heme synthesis (?); protection against oxidative damage in mature erythrocytes	Hemolytic anemia with increased cell membrane fragility; shortens life span of erythrocytes in individuals with cystic fibrosis
Iron	Hemoglobin synthesis	Iron deficiency anemia
Copper	Required for optimal mobilization of iron from tissues to plasma	Microcytic-hypochromic anemia

* **NOTE:** Although pantothenic acid is important for optimal synthesis of heme, experimentally induced deficiency *failed* to produce anemia or other hematopoietic disturbances.

DNA, Deoxyribonucleic acid; *RNA*, ribonucleic acid.

Data from Ames BN, Atamna H, Killilea DW: *Mol Aspects Med* 26(4–5):367–378, 2005; Strine-Martin EA, Lotspeich-Steininger CA, Koepke JA: *Clinical hematology: principles, procedures, correlations*, ed 2, Philadelphia, 1998, Lippincott.

Erythropoiesis cannot proceed in the absence of vitamins, especially B₁₂ (cobalamin), folate (folic acid), B₆, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E. Dietary vitamin B₁₂ is a large molecule that requires a protein secreted by parietal cells into the stomach (intrinsic factor [IF]) for transport across the ileum. Once

absorbed, vitamin B₁₂ is stored in the liver and used as needed in erythropoiesis. Defects in IF production lead to decreased B₁₂ absorption and pernicious anemia.

Folate is the second most important vitamin for erythrocyte production and maturation. Folate is necessary for DNA synthesis, being a component of three of the four DNA bases (thymine, adenine, and guanine), and RNA synthesis. Folate absorption occurs principally in the upper small intestine and it is stored in the liver. Folate deficiency is more common than vitamin B₁₂ deficiency and occurs more rapidly. Folate stores can be depleted within a few months, whereas vitamin B₁₂ depletion can take years. Folate supplements are prescribed for pregnant women because pregnancy increases the demand for folate and may cause anemia. Supplements can protect against neural tube defects and may prevent anemia.

Normal Destruction of Senescent Erythrocytes

After about 100 to 120 days in the circulation, old erythrocytes are removed by tissue macrophages, primarily in the spleen. Although mature erythrocytes lack nuclei, mitochondria, and the endoplasmic reticulum, they do have cytoplasmic enzymes capable of glycolysis (anaerobic glucose metabolism) and production of small quantities of ATP, which provides the energy needed to maintain cell function and membrane pliability. Metabolic processes diminish as the erythrocyte ages, so less ATP is available to maintain plasma membrane function. Disruption of the anchorage between the cytoskeleton and the plasma membrane results in the senescent red cell becoming increasingly fragile and losing its reversible deformability, and thus becoming susceptible to rupture while passing through narrowed regions of the microcirculation.

Additionally, the plasma membrane of senescent red cells undergoes phospholipid rearrangement (movement of the phospholipid phosphatidylserine from the cytoplasmic surface of the membrane to the external surface) that is recognized by receptors for phosphatidylserine on macrophages (primarily in the spleen) that

selectively remove and sequester the red cells.²² If the spleen is dysfunctional or absent, macrophages in the liver (Kupffer cells) become responsible for this process. The erythrocytes are digested by proteolytic and lipolytic enzymes in the phagolysosomes (digestive vacuoles) of the macrophage. The heme and globin of methemoglobin dissociate easily, and the globin is broken down into its component amino acids. The iron in hemoglobin is oxidized, forming Fe⁺⁺⁺ (methemoglobin), and recycled (see following section).

Porphyrin is reduced to bilirubin, which is transported to the liver, conjugated, and finally excreted in the bile as glucuronide (Fig. 28.17). Approximately 6 g of hemoglobin is catabolized daily, producing 200 mg of bilirubin. Bacteria in the intestinal lumen transform conjugated bilirubin into urobilinogen. Although a small portion is reabsorbed for further metabolism by the liver or excreted by the kidney into the urine, most urobilinogen is excreted in feces. Conditions causing accelerated erythrocyte destruction increase the load of bilirubin for hepatic clearance, leading to increased serum levels of unconjugated bilirubin and increased urinary excretion of urobilinogen. Gallstones (cholelithiasis) can result from a chronically elevated rate of bilirubin excretion.

FIGURE 28.17 Metabolism of Bilirubin Released by Heme Breakdown. *MPS*, Mononuclear phagocyte system.

Iron Cycle

Approximately 67% of total body iron is bound to heme in erythrocytes (hemoglobin) and muscle cells (**myoglobin**), and approximately 30% is stored in mononuclear phagocytes (i.e., macrophages) and hepatic parenchymal cells as either ferritin or hemosiderin. The remaining 3% (less than 1 mg) is lost daily by expelling urine, sweat, or bile; sloughing epithelial cells from the skin and intestinal mucosa; and minor bleeding. Approximately 25 mg of iron is required daily for erythropoiesis; only 1 to 2 mg of iron is dietary and the remainder is obtained from iron recycling of erythrocytes.

The methemoglobin released from the breakdown of senescent or damaged erythrocytes (see preceding section) is dissociated by the enzyme heme oxygenase, and the iron is released into the bloodstream, where it is free to bind again to transferrin or be stored in the macrophage's cytoplasm as ferritin or hemosiderin (Fig. 28.18). A minute amount of iron is stored in muscle cells by the heme-containing protein myoglobin. Unavailable stores of iron are present in cytochromes, catalases, and peroxidase enzymes.

FIGURE 28.18 Iron Cycle. Iron released from gastrointestinal epithelial cells circulates in the bloodstream associated with its plasma carrier, transferrin. It is delivered to erythroblasts in bone marrow, where most of it is incorporated into hemoglobin. Mature erythrocytes circulate for approximately 120 days, after which they become senescent and are removed by the mononuclear phagocyte system (MPS). Macrophages of MPS (mostly in spleen) break down ingested erythrocytes and return iron to the bloodstream directly or after storing it as ferritin or hemosiderin.

The protein ferritin is the major intracellular iron storage protein. **Apo ferritin**, which is ferritin without attached iron, can store thousands of atoms of iron. Several apoferritin complexes combine to form the micelle ferritin. Large aggregates of micelles (if a large amount of iron is present) produce numerous ferritin micelles, known as **hemosiderin**. Hemosiderin is visible as an iron-based pigment under a light microscope as cell inclusions. The iron within deposits of hemosiderin is poorly available to supply iron when needed. The most common cause of hemosiderin deposition is simple bruising. Hemosiderin in small amounts within iron-rich tissues (i.e., spleen, liver, bone marrow) is considered normal. Large aggregates or its presence in tissue such as the lungs or subcutaneous tissue suggests a pathologic condition.

Iron acquired by utilization of dietary sources, release of iron stores, or catabolism of erythrocytes is transported in the blood bound to **apotransferrin**, thus becoming **transferrin**. Under normal conditions, only one-third of the iron-binding sites on transferrin molecules are occupied. Apotransferrin is a glycoprotein synthesized primarily by hepatocytes in the liver but also produced in small quantities by tissue macrophages, submaxillary and mammary glands, and ovaries or testes. Iron for hemoglobin production is carried by transferrin to the bone marrow, where it binds to transferrin receptors on erythroblasts. Transferrin receptors are on the plasma membrane of all nucleated cells, although they are at particularly high levels on erythroid precursors and rapidly proliferating cells (e.g., lymphocytes), and are thought to be the only route of cellular entry for transferrin-attached iron. Transferrin is recycled (transferrin cycle) by intracellular dissociation of the iron with secretion of the resultant apotransferrin into the bloodstream.

The iron is transported to the erythroblast's mitochondria (the site

of hemoglobin production), where the enzyme heme synthetase inserts ferrous iron into protoporphyrin to form heme. Heme then is bound to globin to form hemoglobin. Iron not used in erythropoiesis is stored temporarily as ferritin or hemosiderin and later excreted.

Splenic red pulp macrophages are specialized for iron recycling with increased expression of proteins for the uptake of hemoglobin, the breakdown of heme, and the export of iron.²³ The body's iron homeostasis is primarily controlled by the hormone hepcidin. **Hepcidin** is synthesized in the liver and released as a 25–amino acid peptide, most of which is bound in the plasma with high affinity to α_2 -macroglobulin and relatively lower affinity to albumin. Hepatocellular hepcidin production is regulated physiologically by the body's dietary absorption of iron, rate of erythropoiesis, and level of oxygen saturation.²⁴ Hepatocytes sense levels of circulating iron by means of receptors for transferrin, the major transporter of iron in the plasma. Excess iron is stored in hepatocytes and macrophages. Hepatocytes sense these levels by means of bone morphogenetic protein (BMP), most likely BMP-6, which is a growth factor produced to a large extent by bone marrow sinusoid endothelial cells and the mother against the decapentaplegic (SMAD) protein pathway (BMP-SMAD pathway). Hepcidin production also can be induced by inflammation through IL-6.

Hepcidin regulates iron levels through its binding capacity to ferroportin, which is a transmembrane iron exporter found in the plasma membrane of cells that transport or store iron, including macrophages, hepatocytes, and enterocytes. The body's total iron balance is maintained through controlled absorption rather than excretion. Dietary iron (primarily as Fe^{++}) is transported directly across the membranes of epithelial cells (enterocytes) in the duodenum and proximal jejunum. (Transport mechanisms are described in [Chapter 1](#).) Hepcidin induces internalization and degradation of ferroportin, thus leading to increased intracellular iron stores, decreased dietary iron absorption, and decreased levels of circulating iron.²⁵ Decreased production of hepcidin leads to release of stored iron and increased dietary absorption. Thus if the body's iron stores are low or the

demand for erythropoiesis increases, dietary iron is transported rapidly through the epithelial cell and into the plasma. If body stores are high and erythropoiesis is not increased, iron transport is stopped, although iron can cross the plasma membranes of epithelial cells and be stored as ferritin.

Development of Leukocytes

Leukocytes consist of lymphocytes, granulocytes, and monocytes. Most of the leukocytes arise from stem cells in the bone marrow (their pathways of differentiation are shown in [Fig. 28.12](#)). Hematopoietic stem cells differentiate into two populations of progenitor cells: common lymphoid progenitors and common myeloid progenitors. Lymphoid progenitors that remain in the bone marrow undergo differentiation into the B-cell lineage, after which they are released into the circulation and undergo further maturation in the peripheral lymphoid organs (described in [Chapter 8](#); see [Fig. 8.3](#)). The common myeloid progenitors further differentiate into progenitors for basophils, mast cells, eosinophils, and megakaryocytes, and into granulocyte/monocyte progenitors. The granulocyte/monocyte progenitors further differentiate into monocyte progenitors and granulocyte progenitors, which develop into monocytes/macrophages and neutrophils, respectively. Development from hematopoietic stem cells to common granulocyte-monocyte progenitors primarily is under the control of stem cell factor, IL-3, and GM-CSF, whereas further differentiation into granulocytic and monocytic progenitors is controlled by G-CSF and M-CSF, respectively (see [Table 28.4](#)).

Monocytic progenitors undergo development into monocytes within 24 hours and are released into the circulation. Monocytes mature into various forms of macrophages, a process that is usually completed within 1 or 2 days after their release (see [Tables 28.3](#) and [28.4](#)).

Progenitor cells for granulocytes normally fully mature in the bone marrow into neutrophils, eosinophils, and basophils. The ultimate phenotype is determined by relative local bone marrow concentrations of early- and late-acting cytokines, including GM-CSF,

G-CSF, IL-3, IL-5, stem cell factor, and others (see [Table 28.4](#)). Granulocytes are released into the blood within 14 days of development. The bone marrow selectively retains immature granulocytes as a reserve pool that can be rapidly mobilized in response to the body's needs.

Most leukocytes exist in the body from days to years, depending on type. Maintenance of optimal levels of granulocytes and monocytes in the blood depends on the availability of pluripotent stem cells in the marrow, induction of these into committed stem cells, timely release of new cells from the marrow, and mobilization of the granulocyte reserve pool. Leukocyte production increases in response to infection, to the presence of steroids, and to reduction or depletion of reserves in the marrow. It is also associated with strenuous exercise, convulsive seizures, heat, intense radiation, paroxysmal tachycardias, pain, nausea and vomiting, and anxiety.

Development of Platelets

Platelets (thrombocytes) are derived from stem cells and progenitor cells that differentiate into megakaryocytes. During thrombopoiesis, the megakaryocyte progenitor is programmed to undergo an endomitotic cell cycle (**endomitosis**) during which DNA replication occurs, but anaphase and cytokinesis are blocked. Thus the megakaryocyte nucleus enlarges and becomes extremely polyploidy (up to 100-fold or more of the normal amount of DNA) without cellular division. Concurrently, the numbers of cytoplasmic organelles (e.g., internal membranes, granules) increase, and the cell develops cell surface proplatelet elongations into the sinusoidal blood vessels. These branches progressively fragment into platelets. A single large (30 to 100 μm) megakaryocyte may produce thousands of smaller platelets (2 to 3 μm). Like erythrocytes, platelets released from the bone marrow lack nuclei.

About two-thirds of platelets enter the circulation and the remainder reside in the splenic pool. Platelets circulate in the bloodstream for about 8 to 10 days before losing their ability to perform thrombogenic activity and biochemical reactions. Senescent

platelets are sequestered and destroyed in the spleen by mononuclear cell phagocytosis.

An adequate level of committed platelet precursors (megakaryoblasts) in the bone marrow and differentiation into circulating platelets are controlled by specific interactions between megakaryocyte progenitors and stromal cells in the bone marrow as well as **thrombopoietin** (TPO, a hormonal growth factor primarily produced by the liver) and various cytokines and colony-stimulating factors and interleukins (see [Table 28.4](#)). Platelets express high-affinity receptors for TPO, and when circulating platelet levels are normal, TPO is adsorbed onto the platelet surface and prevented from accessing the bone marrow and initiating further platelet production. TPO stimulates committed cells at further stages of differentiation to differentiate faster so that rates of megakaryocyte development, endomitosis, and platelet release are increased.²⁶ During inflammation, IL-6 induces increased synthesis of TPO, which increases production of newly formed platelets, which are more thrombogenic.

Mechanisms of Hemostasis

Hemostasis is the arrest of bleeding by the formation of blood clots at sites of vascular injury ([Fig. 28.19](#)). As a result of hemostasis, damaged blood vessels maintain a relatively steady-state of blood volume, pressure, and flow. Three equally important interactive components of hemostasis are the vasculature (endothelial cells and subendothelial matrix), platelets, and blood proteins (clotting factors). The general sequence of events in hemostasis is the following: (1) vascular injury leads to a transient arteriolar vasoconstriction to limit blood flow to the affected site; (2) damage to the endothelial cell lining of the vessel exposes prothrombogenic subendothelial connective tissue matrix, leading to platelet adherence and activation and formation of a *hemostatic plug* to prevent further bleeding (primary hemostasis); (3) tissue factor, produced by the endothelium, collaborates with secreted platelet factors and activated platelets to activate the clotting

(coagulation) system to form fibrin clots and further prevent bleeding (secondary hemostasis); and (4) the fibrin/platelet clot contracts to form a more permanent plug, and regulatory pathways are activated (fibrinolysis) to limit the size of the plug and begin the healing process. The relative importance of the hemostatic mechanisms clearly varies with vessel size. Damage to large vessels cannot easily be controlled by hemostasis but requires vascular contraction and dramatically decreased blood flow into the damaged vessels.

FIGURE 28.19 Hemostasis. Endothelium controls hemostasis by preventing platelet activation (1–3) and preventing activation of the clotting system (4–6). (1) *Prostacyclin production*: Injury activates inflammation (COX-1, [cyclooxygenase-1] arachidonic acid). Enzymes convert arachidonic acid into prostacyclin (prostaglandin I₂ [PGI₂]) in endothelial cells. PGI₂ eventually increases intracellular cyclic adenosine monophosphate (cAMP); cAMP inhibits platelet aggregation and induces vasodilation. Nitric oxide (NO) formation is induced by NO synthases (NOS) and NO causes increased cyclic guanosine monophosphate (cGMP). (2) *Nitric oxide system*: Endothelial cell NOS produces NO, which controls platelet activation through cGMP-mediated signaling. (3) *Adenosine diphosphatase (ADPase)*: Endothelial cells express a surface-bound ADPase (CD39) that converts circulating ADP (adenosine diphosphate) and ATP (adenosine triphosphate) to AMP (adenosine monophosphate). (4) *Antithrombin III–heparan sulfate system*: Antithrombin III (AT-III) inhibits thrombin slowly when heparan sulfate (HS) is absent. When HS is present, it quickly activates thrombin because it binds to a specific site on AT-III that causes an instant conformational change in AT-III, allowing it to quickly activate thrombin. (5) *Tissue factor inhibitor (TFI) system*: Expression of TFI on the endothelial cells and secreted into the circulation

complexes with factor IXa to form a competitive inhibitor of the tissue factor/factor VIIIa complex (*TF/VIIIa*) and prevent further activation of factor X to Xa. (6) *Protein C/protein S pathway (thrombomodulin)*: Thrombin in the circulation binds to thrombomodulin (TM) on the endothelial cell, creating a complex that can bind and activate protein C to activated protein C (*APC*) that complexes in the blood or on the surface of active platelets with protein S. This complex degrades circulating clotting factors Va and VIIIa to inactive forms (*iVa, iVIIIa*) to prevent further activation of clotting.

Function of Blood Vessels

The vessel walls consist of a layer of endothelial cells that adhere to an underlying matrix of connective tissue. The matrix contains a variety of proteins, including collagen, fibronectin, and laminins. Endothelial cells adhere to the matrix and to each other through receptors that are expressed only on the intercellular and basal surfaces.

Under normal conditions the endothelium actively regulates blood flow and prevents spontaneous activation of platelets and the clotting system (see [Fig. 28.19](#)). Endothelial cells produce **nitric oxide (NO)** from L-arginine and synthesize **prostacyclin (prostaglandin I₂ [PGI₂])** from arachidonic acid. Both NO, through cGMP, and PGI₂ are vasodilators that work in concert with endothelin (a vasoconstrictor) to modulate blood flow and pressure.²⁷ NO and PGI₂ also inhibit platelet adhesion and aggregation. Synergism between PGI₂ and NO is significant. PGI₂ production varies a great deal in response to stimuli, whereas NO is released continually to regulate vascular tone. NO has other biologic functions including cell signaling, free radical production, and possibly others. Endothelium also produces adenosine diphosphatase, which degrades adenosine diphosphate (ADP, a potent activator of platelets).

The endothelial cell surface contains antithrombotic molecules, such as glycosaminoglycans (e.g., heparan sulfate), thrombomodulin, and plasminogen activators. These limit platelet activation and fibrin deposition. Although thrombomodulin and plasminogen activators help control hemostasis in normal vessels, their effects are magnified during vascular damage and clot formation; therefore further information is provided on these molecules in the section [Control of](#)

Hemostatic Mechanisms.

As a result of damage to the vessels, the endothelial cell barrier is frequently compromised, the remaining endothelial cells are activated by products of tissue damage, and the underlying subendothelial matrix is exposed. Endothelial cells contain intracellular structures (Weibel-Palade bodies) that contain von Willebrand factor (vWF) that is released during vascular injury and activates platelets.²⁸

Function of Platelets

Platelets normally circulate freely, suspended in plasma, in an unactivated state. The roles of platelets are to (1) contribute to regulation of blood flow into a damaged site by induction of vasoconstriction (vasospasm); (2) initiate platelet-platelet interactions, resulting in formation of a platelet plug to stop further bleeding; (3) activate the coagulation (or clotting) cascade to stabilize the platelet plug; and (4) initiate repair processes including clot retraction and clot dissolution (**fibrinolysis**). The normal platelet count ranges from 140,000 to 340,000/mm³. Thrombocytopenia (abnormally low numbers of platelets) develops if the platelet count drops below 100,000/mm³. The individual may experience prolongation of normal clotting but is usually not at risk for spontaneous major bleeding episodes unless the platelet count falls below 20,000/mm³. If platelet numbers are elevated (thrombocytosis), the risk for spontaneous blood clots (thrombosis), stroke, or heart attack is increased.

The state of platelet activation is primarily under the control of endothelial cells lining the vessels. Damage to the vessel initiates a process of platelet activation: (1) increased platelet *adhesion* to the damaged vascular wall; (2) *activation* leading to platelet degranulation, which stimulates changes in platelet shape and biochemistry; (3) *aggregation* as platelet-vascular wall and platelet-platelet adherence increases;²⁹ and (4) activation of the clotting system and development of an immobilizing meshwork of platelets and fibrin (Fig. 28.20).

FIGURE 28.20 Platelet Activation. A, After endothelial denudation, platelets and leukocytes (*blue arrows*) adhere to the subendothelium in a monolayer fashion. B, Higher-power view showing leukocytes (*longer blue arrow*) and platelets (*shorter arrow*) adherent to the subendothelium. C, High magnification of a thrombus showing a mixture of red cells (*longer arrow*) and platelets (*shorter arrow*) incorporated into the fibrin meshwork. (A and B From Libby P et al: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 8, Philadelphia, 2007, Saunders, as reproduced from Faggiotto A, Ross R: *Arteriosclerosis* 4:341–356, 1984; C from Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Adhesion

Normally, platelets are generally observed “rolling” along the margins of vessels. At sites of vessel injury, however, platelets become adherent to the site of endothelial damage, where the subendothelial matrix is exposed and endothelial cells have released von Willebrand factor and decreased their antithrombotic activities (Fig. 28.21). **Platelet adhesion** is mostly mediated by the binding of platelet surface receptor glycoprotein Ib (GPIb) (in a complex with clotting factors IX and V) to **von Willebrand factor (vWF)**.³⁰ The vWF protein is found in the subendothelial matrix and is released by endothelial cells and platelets. Platelet adhesion narrows the diameter of the blood vessel, resulting in increasing shear forces that could strip platelets off the vessel surface. However, those same forces induce conformational changes in the vWF molecule that result in increased affinity with GPIb, thus stabilizing the adherent platelet.

FIGURE 28.21 Blood Vessel Damage, Platelet Activation, Blood Clot, and Clot Dissolution.

Platelet adhesion is also facilitated by other interactions between platelet receptors and exposed molecules of the subendothelial matrix. For instance, adhesion is increased through binding of the platelet collagen receptors GPVI and integrin $\alpha_2\beta_1$ to exposed collagen in the matrix.

Activation

As a result of interactions with the endothelium or the subendothelial matrix, as well as exposure to inflammatory mediators produced by the endothelium and other cells, the platelets are activated. Activation results in reorganization of the platelet cytoskeleton, leading to dynamic changes in platelet shape from smooth spheres to those with spiny projections (increases surface area) and degranulation (also called the **platelet-release reaction**) and resulting in the release of various potent biochemicals⁸ (see [Fig. 28.6](#)).

Platelets contain three types of granules: dense bodies, alpha granules, and lysosomes.³¹ The contents of the dense bodies and alpha granules are particularly important in hemostasis. The dense bodies contain ADP, serotonin, and calcium. ADP recruits and activates other platelets through specific receptors. During activation the platelet plasma membrane experiences several important changes, including becoming ruffled and sticky; undergoing cellular spreading to make tight contacts between neighboring platelets, causing the platelet plug to seal the injured endothelium; and externalizing the phospholipid phosphatidylserine, which provides a matrix for activation of clotting factors (see [Fig. 28.21](#)). Serotonin is a vasoactive amine that functions like histamine and increases vasodilation and vascular permeability. Calcium is necessary for many of the adhesive interactions as well as for intracellular signaling mechanisms that control platelet activation.

Alpha granules contain a mixture of clotting factors (e.g., fibrinogen, factor V), growth and angiogenic factors (e.g., platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], basic fibroblast growth factor), and angiogenesis inhibitors (e.g., platelet factor 4, thrombospondin, inhibitors of metalloproteinases). Platelet factor 4 also is a heparin-binding protein and enhances clot formation at the site of injury. Depending upon the particular stimulus, platelets may selectively release promoters or inhibitors of angiogenesis. Many of these mediators either promote or inhibit platelet activity and the eventual process of clot formation. PDGF stimulates smooth muscle cells and promotes tissue repair.

Platelet lysosomes have a role in the digestion of phagocytic and

cytosolic components, similar to that in nucleated cells. Lysosomal contents also may have important extracellular functions, such as supporting receptor cleavage, fibrinolysis and degradation of extracellular matrix components, and remodeling of the vasculature.⁸

Platelets also initiate production of the prostaglandin derivative **thromboxane A₂ (TXA₂)**, which counters the effects of PGI₂ produced by endothelial cells (see Fig. 28.21). TXA₂ causes vasoconstriction and promotes the degranulation of platelets, increases expression of platelet fibrinogen receptors, and stimulates platelet aggregation; whereas PGI₂ promotes vasodilation and inhibits platelet degranulation. An isoform of **cyclooxygenase (COX-1)** converts arachidonic acid to TXA₂ in platelets. Aspirin at low doses specifically and irreversibly inactivates COX-1, decreasing production of TXA₂ and decreasing platelet activation and aggregation.³² Daily intake of low doses of aspirin leads to more than 95% inhibition of TXA₂ in just a few days.

Other stimuli of platelet activation include epinephrine, thrombin, and collagen. Thrombin and collagen are particularly strong stimuli. Thrombin cleaves the extracellular domain of G-protein-coupled protease-activated receptors (PARs), thereby initiating transmembrane signaling.

Aggregation

Platelet aggregation is stimulated primarily by TXA₂ and ADP, which induce functional fibrinogen receptors on the platelet. The **glycoprotein IIb/IIIa (GPIIb/IIIa) complex** (also called *integrin αIIbβ₃*) undergoes a conformational change during activation to become a calcium-dependent receptor for fibrinogen (see Fig. 28.21). It is a member of the integrin receptor family and binds other matrix proteins (e.g., fibronectin, fibrinogen, thrombospondin). Defects in expression of the GPIIb/IIIa complex (Glanzmann thrombasthenia) result in a failure to aggregate and diminished clotting times.³³ Although the GPIIb/IIIa complex is the most abundant fibrinogen receptor on the platelet, receptors for vWF (GPIb) and collagen (GPVI)

also contribute to the process. Interplatelet aggregation and clot retraction, which forms the *primary hemostatic plug*, are facilitated by fibrinogen bridges between receptors on the platelets. The GPIIb/IIIa–fibrinogen pathway is essential for the formation of a thrombus and as such is an important therapeutic target for blockage by antiplatelet drugs. In addition, fibrin strands within the clot shorten and become denser and stronger, helping the clot to approximate the edges of the injured vessel wall and sealing the site of injury. Contraction of myosin and actin filaments in the platelet cytoskeleton mediates *platelet contraction* and fusion of the platelet mass into a *secondary hemostatic plug*. Contraction expels serum from the fibrin meshwork, resulting in greater packing and increased strength. This process usually begins within a few minutes after a clot has formed, and most of the serum is expelled within 20 to 60 minutes.³⁴

If blood vessel injury is minor, primary hemostasis is achieved by formation of the platelet plug within 3 to 5 minutes of injury. Platelet plugs seal the many minute ruptures that occur daily in the microcirculation, particularly in capillaries. With too few platelets, numerous small hemorrhagic areas called *purpuras* develop under the skin and throughout the tissues (see [Chapter 30](#)). If primary hemostasis is inadequate to prevent further bleeding, the process proceeds through secondary hemostasis to create a larger complex of more tightly interactive platelets within a matrix created by activation of the clotting system.

Function of Clotting Factors

A **blood clot** is a meshwork of protein strands that stabilizes the platelet plug and traps other cells, such as erythrocytes, phagocytes, and microorganisms. The strands are made of fibrin, which is produced by the **clotting (coagulation) system**. The clotting system was described in [Chapter 7](#) and consists of a family of proteins that circulate in the plasma of the blood in inactive forms (proenzymes). Initiation of the system results in sequential enzymatic activation (pathway) of multiple members of the system until a fibrin clot is created ([Table 28.7](#)).

TABLE 28.7**COAGULATION FACTORS AND SYNONYMS**

FACTOR	SYNONYM	PRIMARY FUNCTION
I	Fibrinogen	Source of fibrin to form clot
II	Prothrombin	Source of thrombin that activates fibrinogen, V, VII, VIII, XI, XIII, protein C, platelets
Tissue factor (thromboplastin)	Previously called <i>factor III</i>	Cofactor for factor VIIa
Calcium	Previously called <i>factor IV</i>	Cofactor for clotting factor binding to phosphatidylserine
V	Labile factor	Va is cofactor in prothrombinase complex
VII	Stable factor, proconvertin	VIIa forms complex with tissue factor and activates factors IX and X
VIII	Antihemophilic factor	VIIIa is component of tenase complex
IX	Christmas factor	IXa is component of tenase complex, activates factor X
X	Stuart-Prower factor	Xa is component of prothrombinase complex, activates prothrombin
XI	Plasma thromboplastin antecedent	XIa activates factor IX
XII	Hageman (contact) factor	XIIa activates factor XI
XIII	Fibrin-stabilizing factor	XIIIa cross-links fibrin

Based on laboratory evaluation, the clotting system is commonly presented as two pathways of initiation: the extrinsic pathway (also known as the *tissue factor pathway*) and the intrinsic pathway (also known as the *contact activation pathway* or the *plasma kallikrein-kinin system*). These pathways join in a common pathway with activation of factor X, which proceeds to thrombin, fibrin, and clot formation (Fig. 28.22). These pathways are controlled by anticoagulant proteins. The *in vivo* understanding of the clotting pathways has developed from the clinical disorders that result from deficiency of clotting factors. The extrinsic pathway is activated when there is vascular injury and blood escapes into tissue with activation of tissue factor. It is the normal mechanism of hemostasis and plug breaks in capillaries that occur with activities of daily living.³⁵ **Tissue factor (TF)** (also called

tissue thromboplastin) is abundant in vascular subendothelium and adventitial cells surrounding larger blood vessels and body organs, particularly the skin, brain, lungs, kidney, and placenta. There also are receptors for TF on activated monocytes. With vessel trauma and bleeding, TF binds with high affinity to circulating activated factor VII (TF/VIIa), initiating the clotting pathway. TF is a transmembrane protein that exists in an inactive form but is activated into an active enzyme with factors IX and X as substrates.³⁶ TF mediates a number of changes in disease-related activities, including inflammation, tumor angiogenesis metastasis, cell migration, and clotting associated with atherosclerosis (Fig. 28.23). The extrinsic pathway is evaluated in vitro by adding TF to a sample of plasma and measuring the prothrombin time (time to form a fibrin clot).

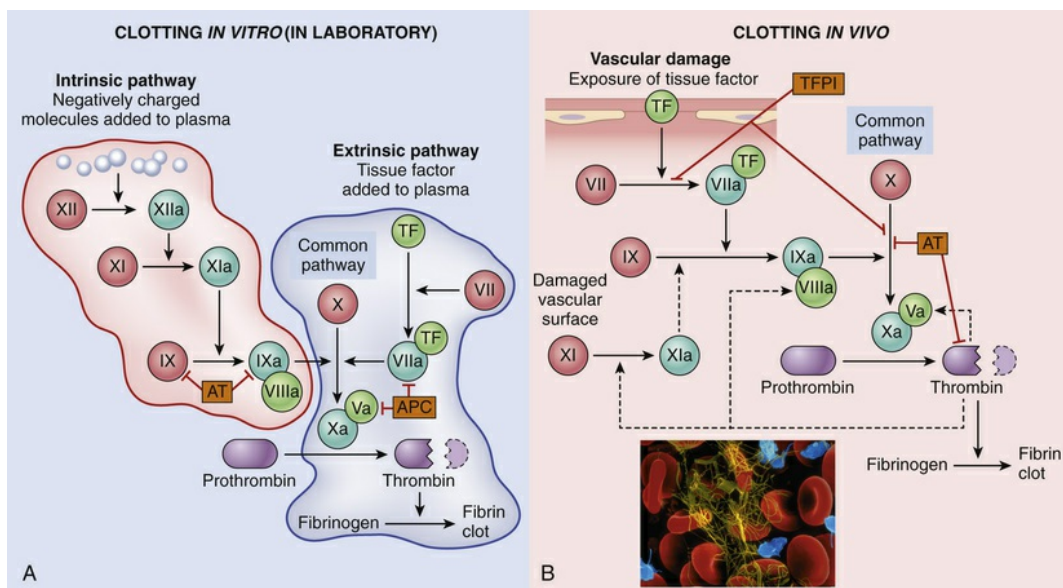

FIGURE 28.22 The Clotting Pathways and Control Proteins. The coagulation pathways in vitro (in the laboratory) and in vivo. **A**, Clotting evaluation of the intrinsic (contact) pathway (within the pink cloud) is initiated in the laboratory by adding phospholipids, calcium, and a negatively charged substance (such as silica or glass beads) and is measured as the activated partial thromboplastin time (aPTT, time for a fibrin clot to form). The extrinsic pathway (within the light blue cloud) is measured as prothrombin time (PT, time for a fibrin clot to form). **B**, In vivo, tissue factor is the major initiator of coagulation, which is amplified by feedback loops involving thrombin (*dotted lines*). The red polypeptides are inactive factors, the dark green polypeptides are active factors, and the light green polypeptides correspond to cofactors. The orange boxes represent control proteins. Electron micrograph *inset* shows entrapped red

blood cells (RBCs) and platelets (blue) in a fibrin clot (yellow strands). NOTE: Factor XII is not a clotting factor for maintaining normal hemostasis. In experiments, factor XI is thought to be involved in thrombus formation occurring with intrinsic vascular damage. Thrombin also can activate factor XI (as well as factors V and VIII), a feedback mechanism (dotted lines) that amplifies the coagulation cascade. APC, Activated protein C (protein C is activated by binding to the thrombomodulin-thrombin complex with protein S as a cofactor); AT, antithrombin; TF, tissue factor; TFPI, tissue factor pathway inhibitor. (Adapted from Kumar V, Abbas AK, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders. Inset Copyright Dennis Kunkel Microscopy, Inc.)

FIGURE 28.23 Factor VIIa Signaling Through Tissue Factor (TF) Expressed on the Surface of Cells Mediates Changes in Disease-Related Cellular Activities. EC, Endothelial cell; MC, monocyte/macrophage; SMC, smooth muscle cell. (Modified from Rao LV, Pendurthi UR: *Arterioscler Thromb Vasc Biol* 25[1]:47–56, 2005.)

Factor XIIa (Hageman factor), prekallikrein (PK), and high-molecular-weight kininogen (HK; activates factor XII) initiate the intrinsic coagulation pathway through activation of the downstream substrate factor XI. The terms *intrinsic* or *contact* mean that the pathway is activated within the blood vessel by contact with anionic

surfaces (i.e., exposure of subendothelial collagen from vessel damage) or other substances without the action of TF. The intrinsic pathway is not a significant pathway for normal hemostasis but is a pathophysiologic surface defense mechanism against foreign proteins, microbial pathogens, and artificial materials. Individuals with deficiencies in intrinsic pathway components (i.e., factor XI, factor XII) do not have disruption of hemostasis or prolonged bleeding with the exception of hemophilia C (deficiency of factor XI that usually causes mild bleeding). Consequently, factor XII and factor XI are being investigated for targeted anticoagulant strategies with lower risk for bleeding tendencies than anticoagulants that target thrombin and/or factor Xa.³⁷

The activation of the intrinsic pathway has been investigated using *in vitro* techniques. For example, in the laboratory negatively charged substances are introduced to activate factor XII (contact activation) for the diagnostic plasma clotting test known as the *activated partial thromboplastin time* (aPTT). Factor XIIa recruits HK that is complexed with prekallikrein (PK). Factor XIIa activates PK to kallikrein, which in turn generates more factor XIIa and amplifies the pathway. Factor XIIa also activates HK to release bradykinin (a proinflammatory mediator). This reaction is prevented from occurring in the plasma by the presence of C1 inhibitor (C1-INH) (see [Chapter 7](#) and [Figs. 7.8](#) and [7.9](#)). Other exogenous artificial surfaces also can activate factor XII (i.e., use of tubing for blood flow during hemodialysis, cardiopulmonary bypass, or extracorporeal membrane oxygenation) and require anticoagulation therapy. More recently it has been discovered that naturally occurring polyphosphates (i.e., RNA and DNA from injury in arterioles, such as ruptured plaque³⁸ or dying cells), activated platelets, neutrophil extracellular traps, and cell membranes from bacteria can activate the intrinsic pathway and promote thrombin formation and thrombosis. Factor XIa also is able to activate coagulation factors X, V, and VIII and inhibit the anticoagulant tissue factor pathway inhibitor (TFPI).³⁹ Thus factor XI may have a role in thrombus formation and is thought to be a risk factor for deep vein thrombosis and ischemic stroke. The role of

factors XII and XI in myocardial infarction is not clear.^{40,41} In mice factor XII or factor XI, deficiency results in fragmented unstable thrombi prone to embolization. Consequently, the intrinsic pathway also may be essential for stabilization of thrombi and prevention of embolism.⁴² It is important to recognize that factor XIa and factor IXa can be generated by routes independent of factor XIIa (i.e., thrombin also can activate factor XI, as well as factors V and VIII). Thrombin activation of XI and IX is a feedback mechanism that amplifies the coagulation pathway (see dotted lines in Fig. 28.22) and maintains the clot over time. Thus the older intrinsic pathway nomenclature has fallen out of use, to some extent, because of preference for contact activation pathway nomenclature.⁴¹

Activated platelets are important participants in clotting. The phosphatidylserine-rich surface produced during activation provides a matrix on which several important complexes of clotting factors are formed. These include the intrinsic pathway's *tenase complex* (factor X and activated factors VIII and IX) that activates factor X and the *prothrombinase complex* (prothrombin and activated factors X and V) that activates prothrombin into thrombin (see Fig. 28.22). Thrombin then converts fibrinogen into fibrin, which polymerizes into a fibrin clot. Thrombin has broad reactivity in the inflammatory response.⁴³ In addition to producing fibrin, thrombin is an activator of other coagulation proteins (e.g., factors V, VIII, XI, XIII), platelets (e.g., aggregation, degranulation), endothelial cells (e.g., upregulation of adhesion molecules for leukocytes, increased NO, PGI₂, PDGF), and monocytes (e.g., cytokine secretion, increased receptors for endothelial cells).

Vitamin K–dependent clotting factors include prothrombin (factor II) factors VII, IX, and X, and the anticoagulation proteins (C and cofactors S and Z). These proteins undergo vitamin K–dependent γ -carboxylation of glutamic acid residues that enables them to bind calcium and other divalent cations and participate in the clotting pathways. Vitamin K is antagonized by the anticoagulant drug warfarin.⁴⁴

Control of Hemostatic Mechanisms

The intact endothelium prevents thrombosis by inhibiting platelet aggregation, preventing coagulation activation and propagation, and enhancing fibrinolysis. Blood normally remains fluid despite the continual presence of clotting factors and platelets in the circulation. The major regulatory factors that control hemostasis reside where the greatest probability of clotting would occur: on the endothelial cell surface (see Fig. 28.19). The primary anticoagulant mechanisms include thrombin inhibitors (e.g., antithrombin III), tissue factor inhibitors (e.g., tissue factor pathway inhibitor), and mechanisms for degrading activated clotting factors (e.g., protein C). Antithrombotic mechanisms are listed in Table 28.8. When the endothelium is damaged, it transitions to the hemostatic action (vasoconstriction, platelet and clotting factor activation) described previously.

TABLE 28.8

ANTITHROMBOTIC MECHANISMS OF ENDOTHELIAL CELLS

FUNCTION REGULATED	SUBSTANCES INVOLVED
Clotting cascade	Tissue factor pathway inhibitor
	Antithrombin III Heparan sulfate
	Thrombomodulin/protein C/protein S/protein Z
Vessel and platelet activity	Covering of prothrombotic intercellular matrix molecules Prostacyclin (PGI ₂)
	Nitric oxide (NO) Adenosine diphosphate
Eliminate fibrin clot	Plasminogen activators

Antithrombin III (AT-III) is a circulating plasma serine protease inhibitor produced by the liver. Specifically, it inhibits thrombin and several activated clotting factors (e.g., VIIa, IXa, Xa, XIa, XIIa). AT-III is produced by the liver and binds with heparan sulfate found naturally on the surface of endothelial cells, or with heparin administered clinically to prevent thrombosis. Heparin induces a change in AT-III that greatly enhances its capacity to inhibit thrombin

and other activated clotting factors. Under normal conditions the presence of endothelial cell heparan sulfate and the available AT-III in the circulation cooperate to protect the vessels from the effects of spontaneously activated thrombin (see Fig. 28.19). Acquired AT-III deficiencies can result from infection with bacteria that produce AT-III inhibitors, sepsis, liver disease, and nephrotic syndrome and lead to venous thrombosis and pulmonary embolism.

Tissue factor pathway inhibitor (TFPI) is produced by endothelial cells and platelets and is the primary inhibitor of the initiation of blood clotting. TFPI forms complexes with and reversibly inhibits factor Xa. The resultant TFPI/Xa complex inhibits TF/VIIIa complex and prothrombinase (converts prothrombin to thrombin) and thus inhibits clotting⁴⁵ (see Fig. 28.19). Although the majority of TFPI remains associated with endothelial or platelet surfaces, about 20% circulates in plasma with lipoproteins. Heparin increases plasma levels of TFPI, which may contribute to heparin's antithrombotic effects.

Thrombomodulin is a transmembrane thrombin-binding protein on the surface of endothelial cells and a receptor for thrombin. When thrombin binds to thrombomodulin, it no longer serves as a procoagulant and cannot activate platelets, convert fibrinogen to fibrin, or amplify fibrin generation. **Protein C** in the circulation binds to the thrombomodulin-thrombin complex and is rapidly converted to activated protein C⁴⁶ (see Fig. 28.19). Activated protein C in association with a cofactor (**protein S**) inactivates factors Va and VIIIa, inhibits fibrin formation, and inhibits coagulation. Deficiencies of AT-III, protein C, or protein S are important inherited causes of hypercoagulation (increased clotting).⁴⁷ Expression of thrombomodulin and the endothelial cell protein C receptor is down-regulated by cytokines and other products of inflammation (e.g., IL-1 α , tumor necrosis factor-alpha [TNF- α], endotoxin). Decreased expression prevents protein C activation, thereby enhancing clot formation. Activated protein C inhibits the adhesion of neutrophils to the endothelium, but during inflammation neutrophil elastase enzymatically removes thrombomodulin from the endothelial cell

surface.⁴⁸ Protein Z is a cofactor for the inhibition of factor Xa through protein Z–dependent protease inhibitor.⁴⁹

Lysis of Blood Clots

Concurrent with activation of coagulation is the activation of pathways that limit the size of the clot and remove the clot after bleeding has ceased and repair has begun. The primary mechanism for lysis (breakdown) of blood clots is the **fibrinolytic system (plasminogen-plasmin system)**, a cascade of serine proteases that produce plasmin. The **plasmin** (also called *fibrinase* or *fibrinolysin*) degrades fibrin polymers in clots.⁵⁰ The inactive precursor of plasmin is **plasminogen**, which is produced in the liver (Fig. 28.24). Plasminogen activation may occur by several means, although the most physiologically important is by the action of **tissue plasminogen activator (t-PA)**. Endothelial cells at a site of vascular injury express t-PA, which is also a serine protease that reaches maximal enzymatic activity after binding to fibrin and proteolytically activates plasminogen to plasmin. Another activator of plasminogen is **urokinase-like plasminogen activator (u-PA)**. The u-PA is a serine protease that can bind to a specific cellular u-PA receptor (u-PAR), causing activation of plasminogen and resulting in plasmin generation. This urokinase is the major activator of fibrinolysis in the *extravascular* or tissue compartment, whereas t-PA is largely involved in *intravascular* fibrinolysis. Both t-PA and u-PA have been used clinically to treat diseases associated with a blood clot (e.g., pulmonary embolism, myocardial infarction, or stroke).

FIGURE 28.24 The Fibrinolytic System. Fibrinolysis is initiated by the binding of plasminogen to fibrin. Although tissue plasminogen activator (*t-PA*) initiates intravascular fibrinolysis, urokinase plasminogen activator (*u-PA*) is the major activator of fibrinolysis in tissue (extravascular). Inhibitors (indicated by red lines) of fibrinolysis include α_2 -antiplasmin (α_2 -AP), which inhibits plasmin, and plasminogen activator inhibitor 1 (*PAI-1*), which inhibits *t-PA*. Plasmin digests the fibrin into smaller soluble pieces (*Fibrin degradation products*). *u-PAR*, Urokinase-like plasminogen activator receptor.

As with most components of inflammation, plasmin interacts greatly with other factors. In addition to activation by *t-PA* and *u-PA*, plasminogen is activated to plasmin by thrombin, fibrin, factor XIIa, factor XIa, and kallikrein. Plasmin is proteolytic to several substrates, including activation of collagenases, complement components C1 and C3, and factor XII, and cleaves fibronectin, fibrin, thrombospondin, laminin, and vWF. Plasmin activity is usually controlled directly by the serine protease inhibitor α_2 -antiplasmin or by inhibiting plasminogen activation by specific plasminogen activator inhibitors (PAIs).

Cross-linked fibrin is deposited in tissues around wounds, inflammatory sites, and tumors. Fibrin removal is an important biologic process, for intravascular and extravascular spaces, with various controlling mechanisms that can lead to abnormalities of fibrin accumulation and thrombotic events and can be a structural barrier to tumor invasion.

Products of fibrinolysis include **fibrin degradation products (FDPs)**

(see Fig. 28.24). A major FDP is D-dimer. **D-dimer** is two D domains from adjacent fibrin monomers that are cross-linked by factor XIIIa and released as a result of enzymatic cleavage by plasmin. Measurement of levels of circulating D-dimer has been used for diagnosis of deep venous thrombosis (DVT) or pulmonary embolism (PE). Despite extensive literature, the diagnostic role of D-dimer is unclear because of the use of multiple D-dimer assays with different sensitivities and variabilities.⁵¹

Clinical Evaluation of the Hematologic System

Tests of Bone Marrow Function

The bone marrow is the soft spongy tissue found within bones, especially the sternum, pelvis, and femur. Several abnormal conditions in the numbers or morphology of circulating blood cells or suspected infection of the marrow may justify further investigation of the bone marrow.

Usually bone marrow is aspirated from the sternum or pelvis using a needle. In children a bone marrow aspirate can be obtained from the vertebrae or the femur. The aspirate is examined microscopically and may be cultured if infection (e.g., fungi, mycobacteria, brucellosis, typhoid fever) is suspected. Microscopic evaluation may also include flow cytometry, chromosome analysis, or polymerase chain reaction (PCR) related to the presence of atypical cells, the presence of atypical numbers of normal cells, and the absence of particular cell types. A normal bone marrow aspirate contains stromal cells (fibroblasts, macrophages, osteoblasts, adipocytes), stem cells (hematopoietic, mesenchymal, and endothelial), and immature and mature forms of blood cells (erythrocytes, leukocytes, platelets) (Fig. 28.25). The differential cell count of a bone marrow aspirate involves examining approximately 400 nucleated cells under oil-immersion magnification and counting populations of cells differentiated on the basis of morphology. The relative number of each type of stem cell is

expressed as a fraction of 400 (Table 28.9).

FIGURE 28.25 Bone Marrow Samples. Images A through D contain bone marrow aspirates; images E through I contain bone marrow biopsy specimens. A, Normal bone marrow aspirate stained by the May-Grünwald/Giemsa technique. B, Normal megakaryocyte with budding platelets at the plasma membrane (Wright stain). C, Osteoclasts containing multiple nuclei that are separated by cytoplasm. These cells may be confused with megakaryocytes. D, Metastatic adenocarcinoma of the breast. E, Normal bone marrow biopsy with paratrabecular space with immature myeloid cells (*two-headed arrow*) and circled erythron (site of erythrocyte production). F, Normal erythroid island in which several erythroid precursors cluster. G, Essential thrombocytopenia with normal cellularity, but increased numbers of large megakaryocytes. H, Bone marrow biopsies representing conditions of normal cellularity (*left*), hypocellularity (*middle*) as would be seen in conditions of bone marrow depletion such as aplastic anemia, and hypercellularity (*right*) as seen in malignant conditions. I, Advanced chronic idiopathic myelofibrosis marked by extensive replacement of the normal marrow stroma by fibrous tissue (stained pink; hematoxylin-eosin stain). (Sources for photographs: A, C from Hoffbrand V et al: *Color atlas of clinical hematology*, ed 4, Philadelphia, 2013, Mosby; B from Rodak BF et al: *Hematology*, ed 4, Philadelphia, 2012, Saunders; D–H from Jaffe E: *Hematology*, Philadelphia, 2010, Saunders; E from Young NS, Gerson SL, High KA: *Clinical hematology*, ed 1, St Louis, 2005, Mosby; I from Cleveland Clinic: *Current clinical medicine*, ed 2, Philadelphia, 2010, Saunders.)

TABLE 28.9**DIFFERENTIAL CELL COUNTS IN BONE MARROW WITH AGE***

DEVELOPING CELLS IN MARROW	BIRTH	1 Month–1 Year	1–4 Years	4–12 Years	ADULT
Erythrocytic series	14	8	19	21	20
Lymphocytic series	14	47	22	18	17
Eosinophilic series	3	3	6	3	3
Neutrophilic series	60	33	50	52	57
Myeloid/erythroid ratio	4:3	4:0	1:3	2:5	1:3

* **NOTE:** Values are percentages of cell types counted during examination of a marrow specimen containing approximately 400 nucleated cells.

Bone marrow iron stores, primarily in macrophages, can be examined using special stains (e.g., Prussian blue) for iron-containing granules. A direct measure of iron stores also can be obtained only from liver biopsy specimens, although bone marrow is preferred because it is a safer procedure and because bone marrow is the immediate source of iron destined for erythrocyte production.

Bone marrow aspiration is an important diagnostic test for severe central defects in hematopoiesis (e.g., aplastic anemia, metabolic anemias arising from insufficient iron or inadequate erythropoietin, thrombocytopenia, neutropenia; see [Chapters 29](#) and [31](#).) Examination of the bone marrow is also useful to diagnose B-lymphocyte immune deficiencies (see [Chapter 9](#)), nonmalignant myeloproliferative disorders (e.g., polycythemia vera), and lymphoid/monocytic malignancies (e.g., leukemias, myelomas, lymphomas; see [Chapters 30](#) and [31](#)). This test can also be used to monitor the effects of chemotherapy on malignancies that have invaded the bone marrow (see [Fig. 28.25](#)). A marrow aspirate that is richly cellular implies normal or increased hematopoiesis but does not indicate whether marrow activity is effective.

Results from bone marrow aspiration are sometimes limited because this technique disturbs the architecture of the marrow and only provides an analysis of the general cellularity (numbers of

constituent cells) of the marrow. On occasion, analysis of an aspirate may only suggest the presence of a malignancy or a central defect in hematopoiesis without being clearly confirmatory, or the sample may be inadequate for diagnosis of bone marrow fibrosis. In these cases the need for a bone marrow biopsy may be indicated.

During a biopsy, a special needle is used to obtain a “core” or cylindrical sample of bone and marrow in which the three-dimensional structure of the marrow is preserved. The biopsy specimens provide the most reliable and complete information about marrow cellularity (see Fig. 28.25). Obtaining a bone marrow biopsy is, however, usually more painful and expensive than aspiration. Therefore biopsy is not performed unless insufficient information is obtained from aspiration.

Blood Tests

Blood tests provide information about the absolute and relative numbers of blood cells in a specimen of blood, as well as various structural and functional characteristics of the cells, and usually provide the initial justification for performing a bone marrow aspiration. Deviations from the normal differential distribution and the presence of abnormal or immature cells can reflect disease, physiologic states (e.g., pregnancy, infancy, old age), injury, or dysfunction in almost any part of the body. Blood tests that reflect chiefly hematologic disorders are listed in Table 28.10.

TABLE 28.10

BLOOD TESTS FOR HEMATOLOGIC DISORDERS

CELL TYPE AND TEST	PROPERTY EVALUATED BY TEST	POSSIBLE HEMATOLOGIC CAUSE OF ABNORMAL FINDINGS
Erythrocytes		
Red cell count	Number (in millions) of erythrocytes/ μ L of blood	Altered erythropoiesis, anemias, hemorrhage, Hodgkin disease, leukemia
Mean corpuscular volume	Size of erythrocytes	Anemias, thalassemias

Mean corpuscular hemoglobin (MCH)	Amount of hemoglobin in each erythrocyte (by weight)	Anemias, hemoglobinopathy
Mean corpuscular hemoglobin concentration (MCHC)	Concentration of hemoglobin in each erythrocyte (percentage of erythrocyte occupied by hemoglobin)	Anemias, hereditary spherocytosis
Hemoglobin determination	Amount of hemoglobin (by weight)/dL of blood	Anemias
Hematocrit determination	Percentage of a given volume of blood that is occupied by erythrocytes	Hemorrhage, polycythemia, erythrocytosis, anemias, leukemia
Reticulocyte count	Number of reticulocytes/ μ L of blood (also expressed as percentage of reticulocytes in total red cell count)	Hyperactive or hypoactive bone marrow function
Erythrocyte osmotic fragility test	Cellular shape (biconcavity), structure of plasma membrane	Anemias, hemolytic disease caused by ABO or Rh blood group incompatibility, Hodgkin disease, polycythemia vera, thalassemia major
Hemoglobin electrophoresis	Relative percentage of different types of hemoglobin in erythrocytes	Sickle cell disease, sickle cell trait, hemoglobin C disease, hemoglobin C trait, thalassemias
Sickle cell test	Presence of hemoglobin S in erythrocytes	Sickle cell trait, sickle cell anemia
Glucose-6-phosphate dehydrogenase (G6PD) deficiency test	Deficiency of G6PD in erythrocytes	Hemolytic anemia
Hemoglobin Metabolism		
Serum ferritin determination	Depletion of body iron (potential deficiency of heme synthesis)	Iron deficiency anemias
Total iron-binding capacity (TIBC)	Amount of iron in serum plus amount of transferrin available in serum (mcg/dL)	Hemorrhage, iron deficiency anemia, hemochromatosis, hemosiderosis, iron overload, anemias, thalassemias
Transferrin saturation	Percentage of transferrin that is saturated with iron	Acute hemorrhage, hemochromatosis, hemosiderosis, sideroblastic anemia, iron deficiency anemia, iron overload, thalassemias
Porphyrin analysis (protoporphyrin)	Concentration of protoporphyrin in	Megaloblastic anemia, congenital erythropoietic porphyria

analysis)	erythrocytes (mcg/dL); an indicator of iron-deficient erythropoiesis	
Direct antiglobulin test (DAT)	Antibody binding to erythrocytes	Hemolytic disease of the newborn, autoimmune hemolytic anemia, drug-induced hemolytic anemia, transfusion reaction
Antibody screen (indirect Coombs test)	Detection of antibodies to erythrocyte antigens (other than the ABO antigens)	Same as for DAT
Leukocytes		
Differential white cell count (absolute number of a type of leukocyte/ μ L of blood)	See below	See below
Neutrophil count	Neutrophils/ μ L	Myeloproliferative disorders, hematopoietic disorders, hemolysis, infection, immune deficiency
Lymphocyte count	Lymphocytes/ μ L	Infectious lymphocytosis, infectious mononucleosis, hematopoietic disorders, anemias, leukemia, lymphosarcoma, Hodgkin disease, primary immune deficiency
Plasma cell count	Plasma cells/ μ L	Infectious mononucleosis, lymphocytosis, plasma cell leukemia, primary immune deficiency
Monocyte count	Monocytes/ μ L	Hodgkin disease, infectious mononucleosis, monocytic leukemia, non-Hodgkin lymphoma, polycythemia vera, primary immune deficiency
Eosinophil count	Eosinophils/ μ L	Hematopoietic disorders
Basophil count	Basophils/ μ L	Chronic myelogenous leukemia, hemolytic anemias, Hodgkin disease, polycythemia vera
Platelets and Clotting Factors*		
Platelet count	Number of circulating platelets (in thousands)/ μ L of blood	Anemias, multiple myeloma, myelofibrosis, polycythemia vera, leukemia, disseminated intravascular coagulation (DIC), hemolytic disease of the newborn, idiopathic thrombocytopenic purpura, transfusion reaction, lymphoproliferative disorders
Bleeding time	Duration of bleeding following	Leukemia, anemias, DIC, fibrinolytic activity,

	a standardized superficial puncture wound of the skin, integrity of the platelet plug; measured in minutes following puncture	purpuras, hemorrhagic disease of the newborn, infectious mononucleosis, multiple myeloma, clotting factor deficiencies, thrombasthenia, thrombocytopenia, von Willebrand disease
Clot retraction test	Platelet number and function, fibrinogen quantity and use; measured in hours, which is required for expression of serum from a clot incubated in a test tube	Acute leukemia, aplastic anemia, factor XIII deficiency, increased fibrinolytic activity, Hodgkin disease, hyperfibrinogenemia or hypofibrinogenemia, idiopathic thrombocytopenic purpura, multiple myeloma, polycythemia vera, secondary thrombocytopenia, thrombasthenia
Platelet adhesion studies	Ability of platelets to adhere to foreign surfaces	Anemia, macroglobulinemia, Bernard-Soulier syndrome, multiple myeloma, myeloid metaplasia, plasma cell dyscrasias, thrombasthenia, thrombocytopathy, von Willebrand disease
Platelet aggregation tests	Ability of platelets to adhere to one another	Afibrinogenemia, Bernard-Soulier syndrome, thrombasthenia, hemorrhagic thrombocytopenia, myeloid metaplasia, plasma cell dyscrasias, platelet-release defects, polycythemia vera, preleukemia, sideroblastic anemia, von Willebrand disease, Waldenström macroglobulinemia, hypercoagulability
Whole blood clotting time (Lee-White coagulation time)	Overall ability of blood to clot; measured in minutes in a test tube	Afibrinogenemia, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia, hypoprothrombinemia, leukemia
Circulating anticoagulants (immunoglobulin G [IgG] or M [IgM] antibodies that inhibit coagulation)	Presence of antibodies that neutralize clotting factors and inhibit coagulation, as indicated by prolonged clotting time, prothrombin time, or partial thromboplastin time	Afibrinogenemia, presence of fibrin-fibrinogen degradation products, macroglobulinemia, multiple myeloma, DIC, plasma cell dyscrasias
Partial thromboplastin time (PTT)	Effectiveness of clotting factors (except factors VII and VIII), effectiveness of intrinsic pathway of coagulation cascade; measured in seconds in a test tube	Presence of circulating anticoagulants, DIC, clotting factor deficiencies, excessive fibrinolysis, hemorrhagic disease of the newborn, hypofibrinogenemia and afibrinogenemia, prothrombin deficiency, von Willebrand disease, acute hemorrhage
Prothrombin time (PT)	Effectiveness of activity of prothrombin, fibrinogen, and factors V, VII, and X;	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; DIC; deficiency of factors V,

	effectiveness of vitamin K–dependent coagulation factors of the extrinsic and common pathways of the coagulation cascade; measured in seconds in a test tube	VII, or X; presence of fibrin degradation products, increased fibrinolytic activity, hemolytic jaundice, hemorrhagic disease of the newborn; acute leukemia, polycythemia vera, prothrombin deficiency, multiple myeloma
Thrombin time	Quantity and activity of fibrinogen; measured in seconds in a test tube	Hypofibrinogenemia, dysfibrinogenemia, and afibrinogenemia; presence of circulating anticoagulants; hemorrhagic disease of the newborn, polycythemia vera; increase in fibrin-fibrinogen degradation products; increased fibrinolytic activity
Fibrinogen assay	Amount of fibrinogen available for fibrin formation	Acute leukemia, congenital hypofibrinogenemia or afibrinogenemia, DIC, increased fibrinolytic activity, severe hemorrhage
Fibrin-fibrinogen degradation products (fibrin-fibrinogen split products)	Fibrinogenic activity as measured by levels of fibrin-fibrinogen degradation products (in mcg/mL of blood)	Transfusion reactions, DIC, internal hemorrhage in the newborn, deep vein thrombosis, pulmonary embolism

* **NOTE:** See [Fig. 28.23](#) and [Table 28.7](#) for information about clotting factors and their sequence of activation in the coagulation cascade.

Data from Garrels M, Oatis CS: *Laboratory and diagnostic testing in ambulatory care: a guide for health care professionals*, ed 3, St Louis, 2015, Saunders; Hudnall D: *Hematology: a pathophysiologic approach*, St Louis, 2012, Mosby.

Pediatrics and the Hematologic System

Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. [Table 28.11](#) lists normal ranges during infancy and childhood. The immediate rise in values is the result of accelerated hematopoiesis during fetal life, increased numbers of cells that result from the trauma of birth, and cutting of the umbilical cord.

TABLE 28.11

HEMATOLOGIC VALUES DURING INFANCY AND CHILDHOOD

AGE	DIFFERENTIAL COUNTS*				
	HEMOGLOBIN (g/dL)	HEMATOCRIT (%)	RETICULOCYTES (%)	LEUKOCYTES (WBCs/mm ³)	NEUTRO (%)
Cord blood	16.8	55	5.0	18,000	61
2 wk	16.5	50	1.0	12,000	40
3 mo	12.0	36	1.0	12,000	30
6 mo–6 yr	12.0	37	1.0	10,000	45
7–12 yr	13.0	38	1.0	8000	55
Adult	13.0	40	1.0	8000	55
Female	14	41	0.8–4.1	7400	54–62
Male	16	47	0.8–2.5	7400	54–62

*All values are means except for platelets.

WBCs, White blood cells.

Average blood volume in the full-term neonate is 85 mL/kg of body weight. The premature infant has a slightly larger blood volume of 90 mL/kg of body weight, with the mean increasing to 150 mL/kg during the first few days after birth. In both full-term and premature infants, blood volume decreases during the first few months. Thereafter the average blood volume is 75 to 77 mL/kg, which is similar to that of older children and adults.

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus and accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) of the newborn. After birth the oxygen from the lungs saturates arterial blood, and more oxygen is delivered to the tissues. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease.

The very active rate of fetal erythropoiesis results in a large number of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. After birth the number of reticulocytes decreases about 50% every 12 hours so that it is rare to find an elevated reticulocyte count after the first week of life. During this period of

rapid growth, the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, normal erythrocyte life span is 60 to 80 days; in premature infants, it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—100 to 120 days.

The postnatal decrease in hemoglobin and hematocrit values is more marked in premature infants than in the full-term infant. In the preschool and school-age child, hemoglobin, hematocrit, and red blood cell counts gradually rise. Metabolic processes within the erythrocytes of neonates differ significantly from those of erythrocytes in the normal adult. Among other differences, the relatively young population of erythrocytes in the newborn consumes greater quantities of glucose than do erythrocytes in adults.

Most coagulation factors (both procoagulants and anticoagulants) in children reach adult levels by 6 months of age, and some not until adolescence. Children have quantitative and qualitative differences in clotting factors that result in decreased risk for thrombosis without increased risk for bleeding (developmental hemostasis) because the reduction of procoagulant and anticoagulant proteins is balanced.⁵² Laboratory values for hemostasis (i.e., prothrombin time and activated partial thromboplastin time) are referenced by the testing laboratory.⁵³

At birth, the lymphocyte count is high and continues to rise during the first year of life, and then steadily declines until lower adult values are reached. The lymphocytes of children also tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. A possible explanation is that children tend to have more frequent viral infections, some of which are subclinical, and are receiving vaccinations, both of which are associated with atypical lymphocytes.

The neutrophil count, like the lymphocyte count, is high at birth and rises during the first days of life. After 2 weeks the neutrophil count falls to within or below the normal adult range. By approximately 4 years of age, the neutrophil count is the same as that of an adult. The eosinophil count is high in the first year of life and higher in children than in teenagers or adults. Monocyte counts also

are high in the first year of life but then decrease to adult levels. Platelet counts in full-term neonates are comparable with platelet counts in adults and remain so throughout infancy and childhood.

Aging and the Hematologic System

Blood composition changes little with age. Erythrocyte life span in older adults is normal, although erythrocytes are replenished more slowly after bleeding, probably because of iron depletion. Values of total serum iron, total iron-binding capacity, and intestinal iron absorption are all decreased in older adults. Iron deficiency is often responsible for the low hemoglobin levels noted in older adults. The plasma membranes of erythrocytes become increasingly fragile, presumably because of physical trauma inflicted during circulation. Chronic inflammation and the presence of chronic disease, including diabetes mellitus, chronic heart disease, chronic renal insufficiency, and Parkinson disease, are associated with suppressed erythropoiesis and anemia occurring in older adults.⁵⁴

Lymphocyte function decreases with age (see [Chapters 8](#) and [9](#)), causing changes in cellular immunity with some decline in T-cell function. The humoral immune system is less able to respond to antigenic challenge and to vaccination.⁵⁵ No changes in platelet numbers or structure have been observed in elderly persons, yet platelet adhesiveness probably increases and may be related to oxidative stress.⁵⁶ Levels of fibrinogen and factors V, VII, and IX and also levels of vWF tend to be increased in older adults. In addition, thrombin generation and platelet activation are enhanced in older adults. Consequently, there is an increased incidence of venous thromboembolism.⁵⁷

Summary Review

Components of the Hematologic System

1. Blood consists of cells suspended in a solution of about 91% water and 8% solutes. In adults the total blood volume is approximately 5.5 L.
2. Plasma, the liquid portion of the blood (50% to 55% of blood volume), contains two major groups of proteins: albumins and globulins.
3. The cellular elements of blood are the erythrocytes (red blood cells), leukocytes (white blood cells), and platelets (thrombocytes).
4. Erythrocytes are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and approximately 42% in women. Erythrocytes are responsible for tissue oxygenation.
5. Leukocytes are fewer in number than erythrocytes and constitute approximately 5000 to 10,000 mm^3 of blood. Leukocytes defend the body against infection and remove dead or injured host cells.
6. Leukocytes are classified as either granulocytes (neutrophils, basophils, eosinophils) or agranulocytes (monocytes, macrophages, lymphocytes).
7. Macrophages remove old and damaged cells and large molecular substances from the blood by phagocytosis.
8. The neutrophil is the most abundant leukocyte (approximately 55% of the leukocytes) and is the primary granulocyte that defends against infections.
9. Lymphocytes are the primary cells of the immune response.
10. Platelets are not cells—they are disk-shaped cytoplasmic fragments. Platelets are essential for blood coagulation and control of bleeding.
11. The lymphoid organs are classified as primary (thymus and bone marrow) or secondary (spleen, lymph nodes, tonsils, and Peyer patches of the small intestine).
12. The lymphoid organs are sites of residence, proliferation, differentiation, and function of lymphocytes and mononuclear phagocytes.

13. The spleen is the largest of the secondary lymphoid organs and functions as the site of hematopoiesis in the fetus, filters and cleanses the blood, and is a reservoir for lymphocytes and other blood cells.
14. The lymph nodes are the site of development or activity of large numbers of lymphocytes, monocytes, and macrophages.
15. The MPS is composed of macrophages in tissue and lymphoid organs.
16. The MPS is the main line of defense against bacteria in the bloodstream and cleanses the blood by removing old, injured, or dead blood cells; antigen-antibody complexes; and macromolecules.

Development of Blood Cells

1. Hematopoiesis, or blood cell production, occurs in the liver and spleen of the fetus and in the bone marrow after birth.
2. Hematopoiesis involves two stages: (a) proliferation and (b) maturation.
3. Hematopoiesis continues throughout life to replace blood cells that grow old and die, are killed by disease, or are lost through bleeding.
4. Bone marrow consists of red (hematopoietic) marrow (blood vessels, mononuclear phagocytes, stem cells, blood cells in various stages of differentiation, stromal cells) and yellow marrow (fatty tissue).
5. The bone marrow contains multiple populations of *stem cells*; mesenchymal stem cells develop into fibroblasts, osteoclasts, and adipocytes; and hematopoietic stem cells develop into blood cells.
6. Regulation of hematopoiesis occurs in specialized microenvironments (niches) in the bone marrow (an osteoblastic niche and a vascular niche) in which hematopoietic stem cells are signaled to undergo differentiation through the effects of multiple cytokines and

chemokines and through direct contact with osteoblasts (osteoblastic niche) or vascular endothelial cells (vascular niche), as well as several other specialized cells, including CAR cells and nestin-expressing cells.

7. Specific hematopoietic growth factors (e.g., colony-stimulating factors) are necessary for the adequate production of myeloid, erythroid, lymphoid, and megakaryocytic lineages.
8. Erythropoiesis (production of erythrocytes) is regulated by erythropoietin. Erythropoietin is secreted by the kidneys in response to tissue hypoxia and causes a compensatory increase in erythrocyte production if the oxygen content of the blood decreases because of anemia, high altitude, or pulmonary disease.
9. Hemoglobin, the oxygen-carrying protein of the erythrocyte, enables the blood to transport 100 times more oxygen than could be transported dissolved in plasma alone.
10. The iron cycle reutilizes iron released from old or damaged erythrocytes. Iron binds to transferrin in the blood, is transported to macrophages of the MPS, and is stored in the cytoplasm as ferritin.
11. Iron homeostasis is controlled by hepcidin, a small hormone produced by hepatocytes, which regulates ferroportin, the principal transporter of iron from stores in hepatocytes and macrophages and from intestinal cells that take up dietary iron.
12. Granulocytes and monocytes in the blood develop from common myeloid progenitor cells in the bone marrow under the direction of several growth factors, including stem cell factor, IL-3, and GM-CSF.
13. Platelets develop from megakaryocytes by a process called *endomitosis*, which is controlled by thrombopoietin. During endomitosis the megakaryocytes undergo mitosis but not cell division and the cytoplasm and plasma membrane fragment into platelets.

Mechanisms of Hemostasis

1. Hemostasis, or arrest of bleeding in damaged vessels, involves (a) vasoconstriction, (b) damage to the endothelium and exposure of connective tissue resulting in formation of a platelet plug, (c) activation of the clotting cascade, (d) formation of a blood clot, and (e) activation of fibrinolysis for clot retraction and clot dissolution.
2. Platelet activation involves three linked processes: (a) adhesion, (b) activation, and (c) aggregation.
3. A blood clot is a meshwork of protein strands that stabilizes the platelet plug. The strands are made of fibrin. Fibrin is the end product of the coagulation cascade.
4. The pathways of hemostasis include the intrinsic pathway (also known as the *contact pathway*) and extrinsic pathway. The extrinsic pathway is the major pathway of normal hemostasis initiated by TF that forms a complex with the TF/VIIa complex. The intrinsic (contact) pathway is activated by artificial negative surfaces and also functions in thrombotic states.
5. The endothelium prevents the formation of spontaneous clots in normal vessels by several anticoagulant mechanisms, including production of NO and PGI₂, thrombin inhibitors (antithrombin III), and tissue factor inhibitors (tissue factor pathway inhibitors); and degradation of activated clotting factors (thrombomodulin–protein C).
6. Fibrinolysis (breakdown of blood clots) is the function of the plasminogen-plasmin system. Plasmin is a degrading enzyme of fibrin clots. It is produced from plasminogen by activation of plasminogen activators (t-PA, u-PA), thrombin, fibrin, factor XIIa, factor XIa, and kallikrein.
7. Products of fibrinolysis include fibrin degradation products, such as D-dimer.

Clinical Evaluation of the Hematologic System

1. Tests of bone marrow function include bone marrow aspiration and bone marrow biopsy.
2. Cells contained in the marrow specimen are assessed with respect to (a) relative numbers of stem cells and their developing daughter cells, and (b) morphologic structure.

Pediatrics and the Hematologic System

1. Blood cell counts rise above adult levels at birth and then gradually decline throughout childhood.
2. The average blood volume of an infant is 75 to 77 mL/kg, which is similar to that of older children and adults.
3. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease.
4. The normal erythrocyte life span is 60 to 80 days in full-term infants, 20 to 30 days in premature infants, and 120 days in children, adolescents, and adults.
5. The lymphocyte count is high at birth, rises further during the first year of life, and steadily declines until lower adult volumes are reached.
6. The neutrophil count is very high at birth, falls to adult ranges after 2 weeks, and is the same as that for adults by 4 years of age.
7. The eosinophil count is high in the first year of life and is higher in children than in adolescents and adults. Monocyte counts are high in the first year of life and decrease to adult levels.
8. Platelet counts in full-term infants are comparable with those in adults and remain so throughout childhood.

Aging and the Hematologic System

1. Blood composition changes little with age. A delay in

- erythrocyte replenishment may occur after bleeding, presumably because of iron deficiency.
2. Lymphocyte function appears to decrease with age. Particularly affected is a decrease in cellular immunity.
 3. Platelet adhesiveness probably increases with age, as do clotting factors increasing risk for thromboembolism.

Disorders of Platelets, 947

Disorders of Coagulation, 952

Alterations of erythrocyte function involve either insufficient or excessive numbers of red blood cells (RBCs) in the circulation or normal numbers of cells with abnormal components. Anemias occur when there is an inadequate number of RBCs or an insufficient volume or mass of RBCs in the blood, while polycythemias develop when the number or volume of RBCs is excessive. Each of these

conditions has many causes and is a pathophysiologic manifestation of a variety of disease states.

The primary role of clotting (hemostasis) is to stop bleeding through an interaction among vascular endothelium, platelets, and the clotting system. Many disease states are associated with clinically significant aberrations in any of these three necessary components of clotting. This chapter discusses alterations of platelets and various components of clotting and their control systems.

Anemia

Anemia is a reduction in the total circulating red cell mass or a decrease in the quality or quantity of hemoglobin. Anemias commonly result from (1) blood loss (acute or chronic), (2) impaired erythrocyte production, (3) increased erythrocyte destruction, or (4) a combination of these factors. Total circulating red blood cell mass is reflected by changes in plasma volume caused by dehydration and fluid retention. For example, decreased plasma volume from dehydration (less water intake, prolonged vomiting, diarrhea, excessive use of diuretics) with a normal red blood cell mass may indicate a *relative polycythemia* or abnormally elevated red cell count because of hemoconcentration. Severe dehydration can correlate with increased hematocrit and hemoglobin levels. Fluid retention is associated with hemodilution rather than a true decrease in red blood cell mass.

Classification and General Characteristics

There are several ways to classify anemias. A useful way is by the underlying main mechanism (Table 29.1). Another way to classify anemias is based on changes that affect the erythrocyte's size or hemoglobin content. The terminology reflects these characteristics: terms that end in “-cytic” refer to cell size, whereas “-chromic” refers to hemoglobin content. Microcytic-hypochromic anemias are caused by disorders of hemoglobin synthesis, particularly iron deficiency.

Macrocytic anemias arise commonly from abnormalities that hinder the maturation of erythroid precursors in the bone marrow. Various etiologies occur in normocytic-normochromic anemias, and the specific shapes of the red blood cell can help determine the cause. Additional descriptors of erythrocytes associated with some anemias include **anisocytosis** (assuming various sizes) or **poikilocytosis** (assuming various shapes) (Fig. 29.1).

TABLE 29.1

CLASSIFICATION OF ANEMIA ACCORDING TO UNDERLYING MECHANISM

MECHANISM	SPECIFIC EXAMPLES
Blood Loss	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances*
Increased Red Cell Destruction (Hemolysis)	
<i>Inherited Genetic Defects</i>	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
Deficient globin synthesis	Thalassemia syndromes
Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
<i>Acquired Genetic Defects</i>	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-induced, autoimmune disorders
Mechanical trauma	
Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura
Cardiac traumatic hemolysis	Defective cardiac valves
Repetitive physical trauma	Bongo drumming, marathon running, karate chopping

Infections of red cells	Malaria, babesiosis
Toxic or chemical injury	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	Hypersplenism
Decreased Red Cell Production	
<i>Inherited Genetic Defects</i>	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
<i>Nutritional Deficiencies</i>	
Deficiencies affecting DNA synthesis	B ₁₂ and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency anemia
Erythropoietin deficiency	Renal failure, anemia of chronic disease
Immune-mediated injury of progenitors	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	Anemia of chronic disease
Primary hematopoietic neoplasms	Acute leukemia, myelodysplasia, myeloproliferative disorders
Space-occupying marrow lesions	Metastatic neoplasms, granulomatous disease
Infections of red cell progenitors	Parvovirus B19 infection
Unknown mechanisms	Endocrine disorders, hepatocellular liver disease

*The usual cause of anemia is iron deficiency, not actual bleeding.

G6PD, Glucose-6-phosphate dehydrogenase.

N, Basophil stippling in case of unexplained anemia. O, Howell-Jolly bodies (after splenectomy). (From Wintrobe MM et al: *Clinical hematology*, ed 8, Philadelphia, 1981, Lea & Febiger.)

The main physiologic manifestation of anemia is a reduced oxygen-carrying capacity of the blood resulting in tissue hypoxia. Symptoms

of anemia vary, depending on the body's ability to compensate for reduced oxygen-carrying capacity (Fig. 29.2). Anemia that is mild and develops gradually is usually easier to compensate and may cause problems for the individual only during physical exertion. As the reduction in the number of red blood cells (RBCs) continues, symptoms become more pronounced and alterations of specific organs and compensatory effects become more apparent. Compensation generally involves the cardiovascular, respiratory, and hematologic systems. (Hematologic findings associated with various anemias are listed in Table 29.2 and progression and manifestations of anemias are shown in Fig. 29.2.)

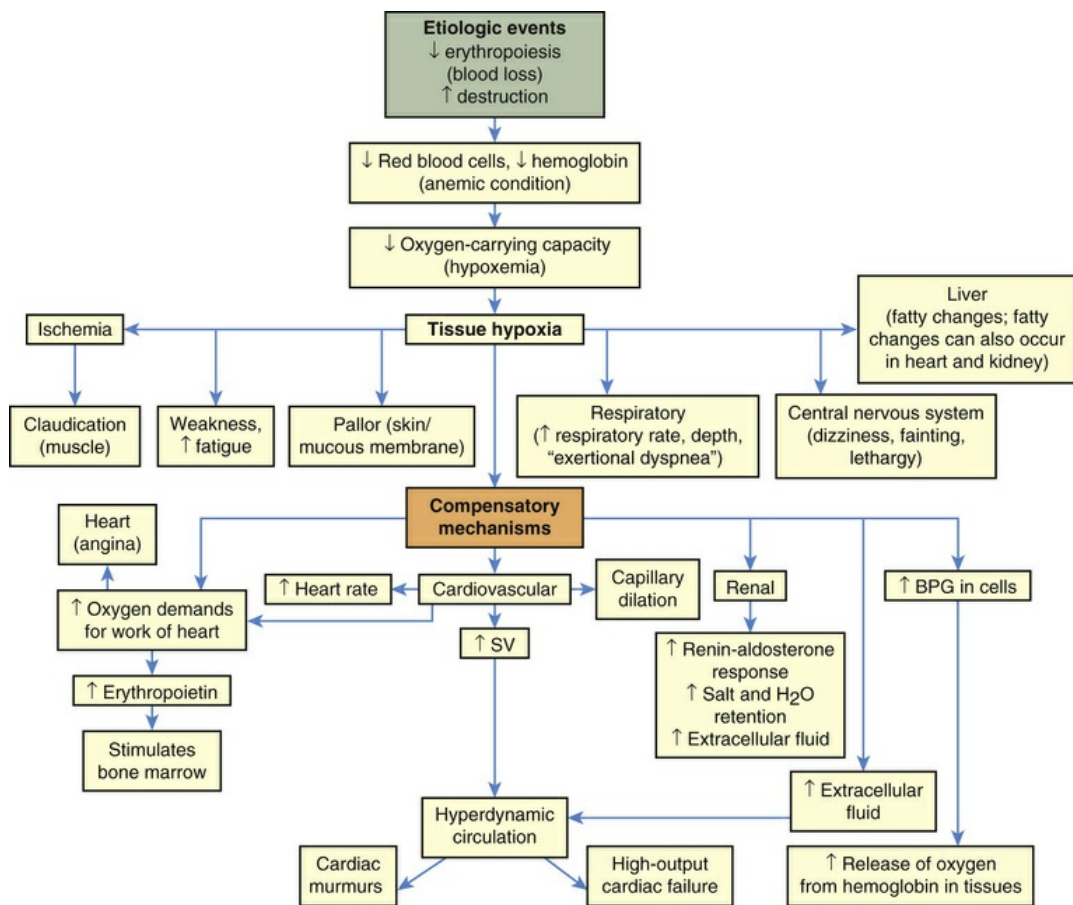

FIGURE 29.2 Progression and Manifestations of Anemia. *BPG*, Bisphosphoglycerate; *SV*, stroke volume.

TABLE 29.2**LABORATORY FINDINGS FOR VARIOUS ANEMIAS**

TEST	PERNICIOUS ANEMIA	FOLATE DEFICIENCY ANEMIA	IRON DEFICIENCY ANEMIA	SIDEROBLASTIC ANEMIA	APLAS ANEM
Hemoglobin	Low	Low	Low	Low	Low or norm
Hematocrit	Low	Low	Low	Low	Low or norm
Reticulocyte count	Low	Low	Normal or slightly high or low	Normal or slightly high	Low
Mean corpuscular volume	High	High	Low	Low	Normal or slight high
Plasma iron	High	High	Low	High	High
Total iron-binding capacity	Normal	Normal	High	Normal	Normal
Ferritin	High	High	Low	High	Normal
Serum B ₁₂	Low	Normal	Normal	Normal	Normal
Folate	Normal	Low	Normal	Normal	Normal
Bilirubin	Slightly high	Slightly high	Normal	High	Normal
Free erythrocyte protoporphyrin	Normal	Normal	High	Increased or normal	High
Transferrin	Slightly high	Slightly high	Low	High	Normal

A reduction in the number of blood cells in the blood causes a reduction in the consistency and volume of blood. Compensation for a reduced blood volume causes interstitial fluid to move into the intravascular space, expanding plasma volume. This movement maintains adequate blood volume, but the viscosity (thickness) of the blood decreases. The diluted blood flows faster and more turbulently than normal blood, causing a hyperdynamic circulatory state. This hyperdynamic state creates cardiovascular changes—increased stroke volume and heart rate. These changes may lead to cardiac dilation and

heart valve insufficiency if the underlying anemic condition is not corrected.

Hypoxemia, reduced oxygen levels in the blood, further contributes to cardiovascular dysfunction by causing dilation of arterioles, capillaries, and venules, thus leading to decreased vascular resistance and increased flow. Increased peripheral blood flow and accelerated venous return further contribute to an increase in heart rate and stroke volume in a continuing effort to meet normal oxygen demand and prevent cardiopulmonary congestion. These compensatory mechanisms may lead to heart failure.

Tissue hypoxia creates additional demands and compensatory actions on the pulmonary and hematologic systems. The rate and depth of breathing increase in an attempt to increase the availability of oxygen. These demands are accompanied by an increase in the release of oxygen from hemoglobin. (Mechanisms of oxygen transport and release by hemoglobin are described in [Chapter 28](#).) All of these compensatory mechanisms may cause individuals to experience shortness of breath (dyspnea); a rapid, pounding heartbeat (palpitations); dizziness; and fatigue. In mild, chronic conditions, these symptoms might be present only when the demand for oxygen is increased (e.g., during physical exertion), but in severe conditions they may be experienced at rest.

Manifestations of anemia may be observed in other parts of the body. The skin, mucous membranes, lips, nail beds, and conjunctivae become pale as a result of reduced hemoglobin concentration. If anemia is caused by RBC destruction (hemolysis), the skin may become yellowish because of accumulation of the products of hemolysis. Tissue hypoxia of the skin results in impaired healing and loss of elasticity, as well as thinning and early graying of the hair. Nervous system manifestations can occur if the anemia is caused by a vitamin B₁₂ deficiency. Myelin degeneration may occur, causing a loss of nerve fibers in the spinal cord and producing paresthesias (numbness), gait disturbances, extreme weakness, spasticity, and reflex abnormalities. Decreased oxygen supply to the gastrointestinal (GI) tract often produces abdominal pain, nausea, vomiting, and

anorexia. A low-grade fever of less than 38.5°C (less than about 101°F) occurs in some anemic individuals and may result from the release of leukocyte pyrogens from ischemic tissues.

When the anemia is severe or acute in onset (e.g., hemorrhage), the initial compensatory mechanism is peripheral blood vessel constriction, diverting blood flow to vital organs. Decreased blood flow detected by the kidneys activates the renal renin-angiotensin response, causing salt and water retention in an attempt to increase blood volume. These situations are emergencies and require immediate intervention to correct the underlying problem that caused the acute loss of blood; therefore long-term compensatory mechanisms do not develop.

Therapeutic interventions for slowly developing anemic conditions require treatment of the underlying disorder and palliation of associated symptoms. Therapies include provision of transfusions, correction of dietary imbalances, and administration of supplemental vitamins or iron. Effective management of an individual's blood is described in [What's New? Patient-Centered Blood Management](#).

What's New?

Patient-Centered Blood Management

Red blood cell transfusion is the main treatment to correct anemia; however, it is one of the top five overused procedures and carries its own risk and economic burdens. In an effort to improve patient outcomes, patient blood management (PBM) is a patient-centered and multidisciplinary approach to effectively manage anemia, reduce iatrogenic blood loss, and improve outcomes for those with anemia. Some hospitals are implementing PBM in practice.

Data from Meybohm P et al: *Perioper Med* 6:5, 2017.

Anemias of Blood Loss

Acute Blood Loss

Posthemorrhagic anemia is a **normocytic-normochromic anemia (NNA)** caused by acute blood loss. Acute blood loss is mainly a loss of intravascular volume and the effects depend on the rate of hemorrhage that can lead to cardiovascular collapse, shock, and death. A major cause of acute blood loss is **trauma**. Severe trauma is a rising global problem.¹ Traumatic injury results in an annual worldwide death of more than 5.8 million people, or 1 in 10 mortalities.^{1,2} Uncontrolled posttraumatic bleeding is the leading cause of potentially preventable death among injured individuals.¹ The pathophysiologic mechanisms associated with traumatic injury is an evolving field of study (see *What's New? Traumatic Injury, Bleeding, and Coagulopathy*). [Table 29.3](#) presents classification of estimated blood loss for a 70-kg man based on initial presentation, as developed by the American College of Surgeons Advanced Trauma Life Support (ATLS).¹ The overall reliability and validity of the ATLS classification are still undergoing study.

TABLE 29.3

CLASSIFICATION OF ESTIMATED BLOOD LOSS*

	CLASS I	CLASS II	CLASS III	CLASS IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15	15–30	30–40	>40
Pulse rate (beats/min)	<100	100–120	120–140	>140
Systolic blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14–20	20–30	30–40	>35
Urine output (mL/hr)	>30	20–30	5–15	Negligible
Central nervous system/mental state	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Initial fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

*For a 70-kg man.

What's New?

Traumatic Injury, Bleeding, and Coagulopathy

Emerging is the understanding that about one-third of all persons with bleeding trauma are already showing signs of coagulopathy upon hospital admission. The presence of coagulopathy is related to an increased risk of multiple organ failure and death (see [Chapter 49](#)). Acute coagulopathy associated with traumatic injury is now recognized as a multifactorial condition caused by bleeding-induced shock, tissue-related thrombin-thrombomodulin complex generation, and activation of anticoagulant and fibrinolytic pathways (see [Figure](#)). The severity of the coagulopathy disorder is impacted by preexisting and treatment factors that contribute to acidosis, hypothermia, hemodilution, hypoperfusion, and coagulation factor consumption. Coagulopathy is modified by brain injury, age, genetic background, comorbidities, inflammation, medications (especially oral anticoagulants), and prehospital fluid administration. New terms for trauma-associated coagulopathic physiology include acute traumatic coagulopathy, early coagulation of trauma, acute coagulopathy of trauma-shock, trauma-induced coagulopathy, and trauma-associated coagulopathy. New guidelines recommend that individuals be transferred directly to trauma centers to improve outcomes.

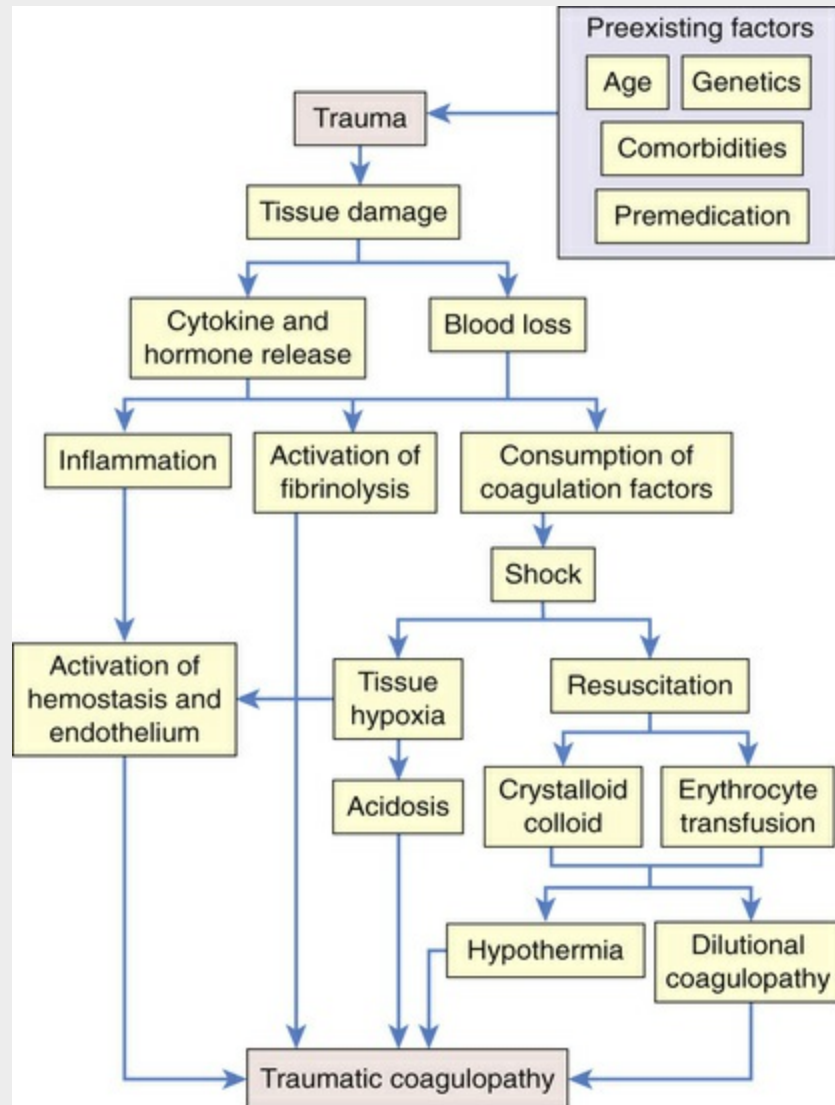

FIGURE Traumatic Coagulopathy. Preexisting and trauma-related factors contribute to coagulopathy. (Box data from Firth D et al: *J Thromb Haemost* 8(9):1919–1925, 2010; MacLeod JB et al: *J Trauma* 55(1):39–44, 2003; Maegele M et al: *Injury* 38(3):298–304, 2007; Rossaint R et al: *Crit Care* 20:100, 2016. Figure adapted from Rossaint R et al: *Crit Care* 20:100, 2016.)

Volume loss reduces mean systemic filling pressure, resulting in decreased venous return. The initial manifestations (increased sympathetic nerve activation and a reduction in blood pressure, cardiac output, and central venous pressure) are caused by cardiovascular adaptations to blood volume depletion. Indexes to predict the risk of hemorrhagic shock are proposed as useful to

provide prompt and appropriate treatment.¹

If the acute blood loss is not severe (does not cause the preceding manifestations), complete recovery is possible. Within 24 hours of blood loss, lost plasma is replaced by mobilizing water and electrolytes from tissues and interstitial spaces into the vascular system. The hemodilution that results lowers the hematocrit value; concurrently, there is often a rapid elevation of circulating neutrophils and platelets. Neutrophils can rise to levels between 10,000 and 30,000/ μL within a few hours as a result of a shift of marginated leukocytes into the circulation and a release of leukocytes from the bone marrow. The platelet count can rise to levels of about 1 million/ μL . In severe blood loss, more immature cells—metamyelocytes, myelocytes, and nucleated red blood cells—may enter the circulation. Reduction in tissue oxygenation stimulates production of erythropoietin and increasing production of erythrocytes (reticulocytes) in the bone marrow. Iron recovery from destroyed erythrocytes may occur if the acute blood loss is internal; however, if blood is lost externally, iron stores may be depleted and erythropoiesis may be impeded. Hemorrhage that is chronic (occult [i.e., bleeding ulcer or neoplasm]) produces adaptations that are less prominent, but the individual may experience an iron deficiency anemia (IDA) when iron reserves become depleted. Initial treatment for acute blood loss is restoration of blood volume by intravenous administration of saline, dextran, albumin, or plasma. Large volume losses may require transfusion of fresh whole blood.

Successful therapy is first indicated by a return of erythrocytes to their normal size and shape. As the bone marrow begins to produce more erythrocytes, an increase in the number of reticulocytes (10% to 15% after 7 days) is seen. Changes in the appearance of erythrocytes (polychromatophilia and macrocytosis) associated with reticulocytosis may give the impression that an underlying hemolytic process is occurring. A normal erythrocyte count is usually noted in 4 to 6 weeks, but hemoglobin restoration may take 6 to 8 weeks.

Chronic Blood Loss

Anemia from chronic blood loss only occurs if the loss is greater than the replacement capacity of the bone marrow. If iron stores are depleted, iron deficiency anemia can occur.

Anemias of Diminished Erythropoiesis

The anemias of diminished red cell production are heterogeneous and can be classified according to the underlying mechanism (see [Table 29.1](#)). The most common anemias of diminished red cell production are the result of ineffective erythrocyte DNA synthesis, commonly caused by nutritional deficiencies of vitamin B₁₂ (cobalamin) or folate (folic acid), coenzymes that are required for nuclear maturation and DNA synthesis.³ These anemias, also called **macrocytic (megaloblastic) anemias**, are characterized by abnormally large erythroid precursors (megaloblasts) in the marrow that mature into large erythrocytes (macrocytes). [Box 29.1](#) lists the various causes of megaloblastic anemia. Other anemias from underproduction of red cells are secondary to renal failure and chronic inflammation.

Box 29.1

Causes of Megaloblastic Anemia

Vitamin B₁₂ Deficiency

Decreased Intake

Inadequate diet, vegetarianism

Impaired Absorption

Intrinsic factor deficiency
 Pernicious anemia
 Gastrectomy
Malabsorption states

Diffuse intestinal disease (e.g., lymphoma, systemic sclerosis)
Ileal resection, ileitis
 Competitive parasitic uptake
 Fish tapeworm infestations
Bacterial overgrowth in blind loops and diverticula of bowel

Folic Acid Deficiency

Decreased Intake

Inadequate diet, alcoholism, infancy
Impaired absorption
Malabsorption states
Intrinsic intestinal disease
Anticonvulsants, oral contraceptives
Increased loss
Hemodialysis

Increased Requirement

Pregnancy, infancy, disseminated cancer, markedly increased hematopoiesis

Impaired Utilization

Folic acid antagonists

Unresponsive to Vitamin B₁₂ or Folic Acid Therapy

Metabolic inhibitors of DNA synthesis and/or folate metabolism (e.g., methotrexate)

Megaloblastic Anemias

With megaloblastic anemias the cells are challenged to make DNA; however, RNA production proceeds normally. The cells have slow-maturing nuclei but have normal maturing cytoplasm. Therefore megaloblastic erythroid precursors grow large before the larger nuclei become mature enough to signal division (causing the cell to be larger than normal). Examination shows the nucleus to be more immature than the cytoplasm, hence the term “*nuclear-cytoplasmic asynchrony*.” The overall nuclear-cytoplasmic asynchrony from the ineffective DNA synthesis produces megaloblastic changes in the bone marrow with resulting anemia. These defective erythrocytes die prematurely, called **eryptosis**, which decreases their numbers in the circulation and causes anemia. Damaged erythrocytes undergo cell shrinkage, membrane changes (blebbing), and rearrangement of plasma membrane phospholipid distribution with efflux of phosphatidylserine (PS). Macrophages have receptors that recognize surface PS and remove the damaged erythrocytes from the circulation.

Dietary cause of vitamin B₁₂ deficiency is decreased intake. Vitamin B₁₂, known as *cobalamin*, is dependent on dietary vitamin B₁₂ intake. Plants and vegetables contain little cobalamin and strictly vegetarian and macrobiotic diets do not provide adequate amounts.⁴ Another important cause that results in megaloblastic anemia is pernicious anemia, caused by autoimmune destruction of parietal cells that make intrinsic factor.³ **Intrinsic factor (IF)** is a protein transporter necessary for absorption of vitamin B₁₂ in the intestine. The prevalence of folate deficiency has decreased because of food fortification with folate; however, it does occur among the poor, elderly, and alcoholics, especially in countries without folate fortification. Vitamin B₁₂ deficiency also can result from malabsorption or increased cell turnover and increased demand.³

Abnormal asynchronous maturation may affect the neutrophil series. Neutrophil precursors create giant metamyelocytes with a tendency to have more nuclear lobes (hypersegmented) than normal.

The reason for this transformation is unknown. Other cells throughout the body also may demonstrate enlargement and nuclear abnormalities.

Pernicious Anemia.

Pernicious anemia (PA) is a type of megaloblastic anemia and is caused by vitamin B₁₂ deficiency, which is often associated with the end stage of type A chronic atrophic (autoimmune) gastritis⁵ (see [Fig. 29.1, C](#); and [Fig. 29.3](#)). Autoimmune gastritis impairs the production of IF, which is required for vitamin B₁₂ uptake from the gut. *Pernicious* means highly injurious or destructive and reflects the fact that this condition was once fatal. It most commonly affects individuals older than age 30 (60 being the median age of diagnosis) who are of Northern European descent; however, it has now been recognized in all populations and ethnic groups.

FIGURE 29.3 Bone Marrow Aspirate from Individual with Pernicious Anemia. Bone marrow aspirate smear from an individual with megaloblastic red blood cell precursors and giant metamyelocytes. The chromatin in the red blood cell nuclei is more dispersed than that in normal red blood cell precursors at comparable stages of maturation; the giant metamyelocytes have dispersed nuclear chromatin in contrast to a normal metamyelocyte, which has condensed chromatin (Wright-Giemsa stain). (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

◆Pathophysiology.

The principal disorder in PA is an absence of intrinsic factor (IF). IF is secreted by gastric parietal cells and complexes with dietary vitamin B₁₂ in the small intestine. The B₁₂-IF complex binds to cell surface receptors in the ileum and is transported across the intestinal mucosa.

Deficiency in IF secretion may be congenital; however, it is often considered an autoimmune (and possibly innate) process directed against gastric parietal cells. Congenital IF deficiency is a genetic disorder that demonstrates an autosomal recessive inheritance pattern.⁶ The autoimmune form of the disease may have a genetic component, but no genetic pattern of transmission has been identified.⁴ PA is also frequently a component of autoimmune polyendocrinopathy, which is a cluster of autoimmune diseases of endocrine organs (e.g., chronic autoimmune thyroiditis [Hashimoto thyroiditis], type 1 diabetes mellitus, Addison disease, primary hypoparathyroidism, Graves disease, and myasthenia gravis) that frequently present as comorbidities. Autoimmune thyroiditis and type 1 diabetes mellitus, in particular, are associated with PA. Other causes include surgical removal of the stomach, resection of the ileum, and infestation with tapeworms; in addition, various conditions related to increased demand for vitamin B₁₂, such as pregnancy, hyperthyroidism, chronic infection, and disseminated cancer, are associated with PA (see [Box 29.1](#)). Environmental conditions also may contribute to chronic gastritis. These include excessive alcohol or hot tea ingestion and smoking. Drugs known as *proton pump inhibitors (PPIs)* are used to decrease gastric acidity, but also may decrease cobalamin absorption, although it is not believed that they actually cause PA. Although PA is a benign disorder, individuals with type A chronic gastritis also are at risk for developing gastric adenocarcinoma and gastric carcinoid type I. The incidence of carcinoma in these individuals is 2% to 3%.

The presence of PA with autoimmune gastritis (type A chronic gastritis) leads to gastric atrophy from destruction of parietal and zymogenic cells. Individuals with PA commonly have autoantibodies against the gastric H⁺-K⁺ ATPase, which is the major protein

constituent of parietal cell membranes. Early in the disease process the gastric submucosa becomes infiltrated with inflammatory cells, including autoreactive T cells. It appears that the T-cell response initiates gastric mucosal injury and triggers the formation of autoantibodies.⁴ The susceptibility to develop PA (as well as other autoimmune disorders) is linked to genetic variants involving the inflammasome, which suggests a relationship to innate immunity.⁴ Eventually, the parietal and zymogenic cells are destroyed and replaced by mucous-containing cells (intestinal metaplasia). Gastric mucosal atrophy, in which gastric parietal cells are destroyed, results in a deficiency of all secretions of the stomach—hydrochloric acid, pepsin, and IF.

Initiation of the autoimmune process may be secondary to a past infection with *Helicobacter pylori*.⁷⁻⁹ Although active infection with *H. pylori* is rare in individuals with PA, more than half of these individuals possess circulating antibodies against this microorganism, suggesting a history of infection. The current opinion is that in genetically prone individuals, antigens expressed by *H. pylori* mimic the parietal cell H⁺-K⁺ ATPase, resulting in production of an antibody that binds and damages the parietal cell (see [Chapter 9](#) for a discussion of antigenic mimicry and autoimmune disease).

◆Clinical Manifestations.

PA develops slowly (possibly over 20 to 30 years); 60 years of age is the median age at time of diagnosis. Because of the slow onset of symptoms, PA is usually severe by the time the individual seeks treatment. Early symptoms are often ignored because they are nonspecific and vague and include infections, mood swings, and gastrointestinal, cardiac, or kidney ailments. When the hemoglobin level has decreased significantly (7 to 8 g/dL), the individual experiences the classic symptoms of anemia—weakness, fatigue, paresthesias of the feet and fingers, difficulty walking, loss of appetite, abdominal pains, weight loss, and a sore tongue that is smooth and beefy red secondary to atrophic glossitis. The skin may become “lemon yellow” (sallow) as a result of a combination of pallor and

icterus. Hepatomegaly, indicating right-sided heart failure, may be present in the elderly along with splenomegaly, which is nonpalpable.

Neurologic manifestations result from nerve demyelination that may produce neuronal death. The posterior and lateral columns of the spinal cord also may be affected, causing a loss of position and vibration sense, ataxia, and spasticity. The cerebrum also may be involved with manifestations of affective disorders, most commonly of the depressive types. Low levels of vitamin B₁₂ have been associated with neurocognitive disorders. Overall, the consequences of vitamin B₁₂ deficiency can include encephalopathy, myelopathy, and peripheral and optic neuropathy. An increased prevalence of serum vitamin B₁₂ deficiency has been reported among individuals with Alzheimer disease. Individuals with atrophy and metaplasia of the gastric mucosa associated with PA have an increased risk of gastric carcinoma.⁴

◆ Evaluation and Treatment.

Diagnosis of PA is based on clinical manifestations and a variety of test results (see [Table 29.2](#)), including blood tests, bone marrow aspiration, serologic studies, and gastric biopsy. The following tests are used to diagnose PA: (1) moderate to severe megaloblastic anemia, (2) leukopenia with hypersegmented granulocytes, (3) low levels of serum vitamin B₁₂, (4) elevated serum levels of homocysteine and methylmalonic acid, and (5) an outpouring of reticulocytes and an increase in hematocrit level after about 5 days of parenteral administration of vitamin B₁₂.⁴ The presence of circulating antibodies against parietal cells and intrinsic factor is also useful in diagnosis.¹⁰ Gastric biopsy reveals total achlorhydria (absence of hydrochloric acid), which is diagnostic for PA because it occurs only in the presence of this gastric lesion.

Replacement of vitamin B₁₂ (cobalamin) is the treatment of choice. Initial injections of vitamin B₁₂ are administered weekly until the deficiency is corrected, followed by monthly injections for the remainder of the individual's life. The effectiveness of cobalamin

replacement therapy is determined by a rising reticulocyte count. Conventional wisdom and practice assumed that oral preparations were ineffective because there was no IF to facilitate absorption of vitamin B₁₂. However, recent experience has shown that higher doses of orally administered vitamin B₁₂ are absorbed across the small bowel and are beneficial.

Untreated PA is fatal, usually because of heart failure. Death occurs after a course of remissions and exacerbations lasting from 1 to 3 years. Since 1926, when replacement therapy began, mortality has been reduced significantly. Today, death from PA is rare, and any relapses that occur are usually the result of noncompliance with therapy.

Folate Deficiency Anemia.

A deficiency of folic acid results in a megaloblastic anemia having the same pathologic consequences as those caused by vitamin B₁₂ deficiency.⁴ **Folate (folic acid)** is an essential vitamin for RNA and DNA synthesis within the maturing erythrocyte. Folates are coenzymes required for the synthesis of thymine and purines (adenine and guanine) and the conversion of homocysteine to methionine. Deficient production of thymine, in particular, affects cells undergoing rapid division (e.g., bone marrow cells undergoing erythropoiesis). Humans are totally dependent on folate dietary intake to meet the daily requirement of 50 to 200 mcg/day. Increased amounts are required for pregnant and lactating females. Absorption of folate occurs primarily in the upper small intestine and does not depend on the presence of any other facilitating factor, such as IF. After absorption, folate circulates through the liver, where it is stored. Folate deficiency is more common than B₁₂ deficiency, particularly in alcoholics and individuals with chronic malnourishment. Alcohol interferes with folate metabolism in the liver, causing a profound depletion of folate stores. Fad diets and diets low in vegetables also may cause folate deficiency because of the absence of plant sources of folate. It is estimated that at least 10% of North Americans have a folate deficiency, although the incidence has been on the decrease in

the United States since the fortification of foods with folate and the increased use of folate supplements. [Box 29.1](#) lists the various causes of folic acid deficiency including (1) decreased intake, (2) increased requirement, and (3) impaired utilization.

◆Pathophysiology.

Impaired DNA synthesis secondary to folate deficiency results in megaloblastic cells with clumped nuclear chromatin. Anemia may result from apoptosis of erythroblasts in the late stages of erythropoiesis. In addition to anemia, folate deficiency in pregnant women is associated with neural tube defects of the fetus. Folate is necessary for the reduction of circulating levels of homocysteine, a risk factor for the development of atherosclerosis (see [Chapter 33](#)); thus a folate deficiency increases the risk for developing coronary artery disease. A deficiency of folate also is implicated in the development of cancers, specifically colorectal cancers.

◆Clinical Manifestations.

Clinical manifestations are similar to the cachectic, malnourished appearance of individuals with PA. Specific symptoms include severe cheilosis (scales and fissures of the lips and corners of the mouth), stomatitis (inflammation of the mouth), and painful ulcerations of the buccal mucosa and tongue, characteristic of burning mouth syndrome. Burning mouth syndrome may be secondary to a large number of disorders (e.g., extremely dry mouth, infection, autoimmune disease, nutritional deficiencies, and other conditions). The mechanisms underlying folate deficiency as a cause remain unknown. Gastrointestinal (GI) symptoms may be present and include dysphagia (difficulty swallowing), flatulence, and watery diarrhea, as well as histologic and roentgenographic changes of the GI tract suggestive of sprue (a chronic malabsorption syndrome). Undiagnosed inflammatory bowel disease (e.g., Crohn disease, ulcerative colitis) may be the underlying cause of folate malabsorption in some individuals, and folate deficiency may suppress proliferation of the intestinal mucosa, leading to exacerbation of gastrointestinal

damage. Neurologic manifestations, such as those that occur in PA, are generally not seen in folate deficiency anemia. Any neurologic symptoms are usually caused by a thiamine deficiency, which often accompanies folate deficiency.

◆ Evaluation and Treatment.

Evaluation of folate deficiency is based on measurement of serum folate levels and documentation of symptoms. Treatment requires daily oral administration of folate preparations until adequate blood levels are obtained and clinical symptoms are reduced or eliminated; 1 mg daily is sufficient for most individuals, although persons with alcoholism may require 5 mg/day. Prophylactic dosages of 0.1 to 0.4 mg/day are sometimes given during pregnancy. Parenteral administration of folic acid (citrovorum factor or leucovorin) generally is not used except in situations in which an individual has been using drugs that inhibit dihydrofolate reductase. After administration of folate, the manifestations of anemia disappear within 1 to 2 weeks.

After the folate deficiency has been corrected, long-term treatment with folate is not necessary if the appropriate dietary adjustments are made to maintain adequate intake. An intake of folate (400 mcg/day) is recommended as a measure to reduce the risk of heart disease and stroke. The symptoms of vitamin B₁₂ deficiency also respond to folate therapy; however, it is essential to exclude vitamin B₁₂ deficiency as the cause of anemia because folate does not prevent the neurologic deficits (and may even exacerbate symptoms) found with vitamin B₁₂ deficiency.⁴

Microcytic-Hypochromic Anemias

The **microcytic-hypochromic anemias** are characterized by abnormally small erythrocytes that contain unusually reduced amounts of hemoglobin (see [Fig. 29.1, B](#)). The most common nutritional disorder of microcytic-hypochromic anemia—iron deficiency anemia—is discussed here; others are discussed in [Chapter 31](#).

Iron Deficiency Anemia.

Iron deficiency anemia (IDA) is the most common type of nutritional disorder worldwide, occurring in both developing and developed countries and affecting as many as one-fifth of the world population. The prevalence of IDA is higher in developing countries, but IDA is common in the United States, particularly in toddlers, adolescent girls, and women of childbearing age.⁴ Populations also at increased risk for IDA include individuals living in poverty; infants consuming cow's milk, which has poor bioavailability of iron; older individuals ingesting restricted diets; and teenagers eating poor (junk-food) diets. The daily requirement of iron is 7 to 10 mg for adult men and 7 to 20 mg for adult women. The bioavailability of iron is especially important because only about 10% to 15% of ingested iron is absorbed.⁴ Men typically ingest more iron than women, and premenopausal women, particularly during pregnancy, have an increased requirement. Increased requirement is an important cause of iron deficiency in growing infants, children, and adolescents. The causes of IDA include (1) dietary deficiency, (2) impaired absorption, (3) increased requirement, and (4) chronic blood loss. Impaired absorption can occur in sprue, disorders involving alterations of fat absorption, and chronic diarrhea.⁴ Other causes for both genders include use of medications that cause GI bleeding (such as aspirin or nonsteroidal antiinflammatory drugs [NSAIDs]); surgical procedures that decrease stomach acidity, intestinal transit time, and absorption (e.g., gastric bypass); and eating disorders, such as pica, which is the craving and eating of nonnutritional substances, such as dirt, chalk, and paper. The clinical manifestations are mostly related to the reduction in adequate levels of hemoglobin.

Females have a higher incidence of hypoferrremia (13.9%) than do males (8.3%), as well as IDA (4% to 6% in females and 4% in males). The incidence peaks in females during their reproductive years and decreases after menopause. Those at highest risk are black females living in urban poverty.¹¹ Males have a higher incidence during childhood and adolescence, with a decrease occurring during young adulthood and an increase during late adulthood. An increased

prevalence of iron deficiency has been observed in overweight children, adolescents, women, and those undergoing bariatric surgery.¹²

In developed countries, pregnancy and a continuous loss of blood are the most common causes of IDA. A blood loss of 2 to 4 mL/day (1 to 2 mg of iron) is enough to cause IDA. Menorrhagia (excessive menstrual bleeding) causes primary IDA in females. Males may experience bleeding as a result of ulcers, hiatal hernia, esophageal varices, cirrhosis, hemorrhoids, ulcerative colitis, or cancer. An occult bleeding source, such as gastrointestinal cancer or other lesion, can lead to IDA; the astute clinician who understands the cause of IDA may be a cancerous lesion can save a life.

Children in developing countries often are affected by chronic parasite infestations that result in intestinal blood and iron loss that outpaces dietary intake.¹³ Treatment of helminth infections results in an improvement in the anemia as well as in appetite and growth. *H. pylori* infections also have been found to cause IDA of unknown origin, although *H. pylori* impairs iron uptake. Iron deficiency anemia is associated with an increased absorption of other elements such as lead (Pb) and cadmium (Cd).¹⁴ Heavy exposure to Pb and Cd causes hypochromic-microcytic anemia.¹⁵ Treatment of the iron deficiency is associated with a decrease in lead levels. Deficiencies in vitamins C, B₁, and B₆ may enhance sensitivity toward Cd and Pb toxicity.¹⁶

◆Pathophysiology.

IDA is a hypochromic-microcytic anemia. Anemia occurs when iron stores are depleted. With inadequate dietary intake or excessive blood loss, there is no intrinsic dysfunction in iron metabolism; however, both conditions deplete iron stores and reduce hemoglobin synthesis. With metabolic or functional iron deficiency, various metabolic disorders lead to either insufficient iron delivery to bone marrow or impaired iron use within the marrow. Paradoxically, iron stores may be sufficient but delivery is inadequate to maintain heme synthesis, thus producing a functional or relative iron deficiency.

Iron in the form of hemoglobin is in constant demand by the body.

Iron is recyclable; therefore the body maintains a balance between iron that is contained in hemoglobin and iron that is in storage and available for future hemoglobin synthesis (see [Chapter 28](#)). Blood loss disrupts this balance by creating a need for more iron, thus depleting the iron stores more rapidly to replace the iron lost from bleeding.

Iron also contributes to immune function by regulating immune effector mechanisms (i.e., cytokine activities [interferon-gamma (IFN- γ)], nitric oxide formation, and T-cell proliferation). Acquired hypoferremia may be part of the body's response to infection. Anemia can be part of the nonspecific acute phase response to any type of inflammation of sufficient degree. Many pathogens require iron for survival; thus hypoferremia would hamper their growth. However, the precise benefits or detriments of iron deficiency and immunity are still controversial.

IDA occurs when the demand for iron exceeds the supply and develops slowly through three overlapping stages. In stage I, the body's iron stores are depleted. Erythropoiesis proceeds normally, with the hemoglobin content of erythrocytes remaining normal. In stage II, iron transportation to bone marrow is diminished, resulting in iron-deficient erythropoiesis. Stage III begins when the small hemoglobin-deficient cells enter the circulation to replace the normal aged erythrocytes that have been removed from the circulation. The manifestations of IDA appear in stage III when there is depletion of iron stores and diminished hemoglobin production.

◆Clinical Manifestations.

Symptoms of IDA begin gradually, and individuals usually do not seek medical attention until hemoglobin levels have decreased to about 7 to 8 g/dL. Early symptoms are nonspecific and include fatigue, weakness, shortness of breath, and pale earlobes, palms, and conjunctivae ([Fig. 29.4, A](#)).

FIGURE 29.4 Manifestations of Iron Deficiency Anemia. A, Pallor and iron deficiency. Pallor of the skin, mucous membranes, and palmar creases in an individual with a hemoglobin level of 9 g/dL. Palmar creases become as pale as the surrounding skin when the hemoglobin level approaches 7 g/dL. B, Koilonychia. The nails are concave, ridged, and brittle. C, Glossitis. Tongue of individual with iron deficiency anemia has bald, fissured appearance caused by loss of papillae and flattening. (From Hoffbrand AV, Pettit JE, Vyas P: *Color atlas of clinical hematology*, ed 4, London, 2009, Mosby; B courtesy Dr. S.M. Knowles.)

As the condition progresses and becomes more severe, structural and functional changes occur in epithelial tissue (see [Fig. 29.4](#)). The fingernails become brittle, thin, coarsely ridged, and “spoon-shaped” or concave (koilonychia) as a result of impaired capillary circulation ([Fig. 29.4, B](#)). IDA also is associated with unexplained burning mouth syndrome, as was discussed for folate deficiency. Tongue papillae atrophy and cause soreness along with redness and burning (glossitis) ([Fig. 29.4, C](#)). The degree of pain experienced is directly associated

with the amount of iron deficiency, and these changes can be reversed within 1 to 2 weeks of iron replacement therapy. Individuals also experience dryness and soreness in the epithelium at the corners of the mouth, known as *angular stomatitis*. Difficulty in swallowing is associated with an esophageal “web,” a thin, concentric, smooth extension of normal esophageal tissue consisting of mucosa and submucosa at the juncture between the hypopharynx and esophagus. The duration of iron deficiency required for web formation is uncertain. Dysphagia also is exacerbated by hyposalivation. The pathophysiology associated with these epithelial lesions is not well understood, but the lesions have the potential to become cancerous.

Nonheme iron is a component of many enzymes in the body (e.g., cytochromes, myoglobin, catalases, peroxidases), particularly those involved in the metabolism of amine neurotransmitters, the reduction of nucleotides, and the biosynthesis of methionine. Abnormalities and deficiencies of iron-dependent enzymes may account for many of the clinical manifestations of IDA. Individuals with IDA also exhibit gastritis, neuromuscular changes, irritability, headache, numbness, tingling, and vasomotor disturbances. Gait disturbances are rare. The pathogenesis of neurologic symptoms is unknown but may be caused by hypoxia in already compromised cerebral vessels. In the elderly, mental confusion, memory loss, and disorientation are often associated with anemia and may be wrongly perceived as “normal” events related to aging.

Iron deficiency in children is associated with numerous adverse health-related manifestations, especially cognitive impairment, which may be long-lasting and even irreversible (see [Chapter 31](#)). Teens with a history of iron deficiency as infants are likely to score lower on cognitive and motor tests, even if the iron deficiency was identified and treated in infancy.

◆ **Evaluation and Treatment.**

Initial evaluation is based on clinical symptoms and decreased levels of hemoglobin and hematocrit. Anemia appears only when iron stores are depleted and is accompanied by lower than normal serum iron,

ferritin, and transferrin saturation levels.⁴ Laboratory findings for IDA are included in [Table 29.2](#). Iron stores may be measured directly by bone marrow biopsy and iron staining or indirectly by laboratory tests for serum ferritin level, transferrin saturation, or total iron-binding capacity. Serum ferritin is a widely accepted and available measurement of iron status that has been used for the past 25 years; 1 mcg/L serum ferritin corresponds to 8 to 10 mg or 120 mcg of storage iron per kilogram body weight. A limitation on interpretation of serum ferritin levels is that values may be elevated independently of iron status during acute or chronic inflammation, malignancy, liver disease, or alcoholism. A sensitive indicator of heme synthesis is the amount of free erythrocyte protoporphyrin (FEP) within erythrocytes. A test that determines the concentration of soluble fragment transferrin receptor differentiates primary IDA from IDA that is associated with chronic disease.

An indicator of iron levels is the level of serum transferrin receptor (sTfR). Transferrin receptors are membrane glycoproteins that bind circulating transferrin for transport into cells. Soluble forms of the receptor are found in serum. The ratio of serum levels of transferrin receptor to ferritin (R/F) estimates body iron stores and differentiates primary IDA from anemia secondary to chronic disease. A major drawback, however, is the lack of proper standardization for the sTfR assay.

The first step in treatment of IDA is to identify and eliminate sources of blood loss.¹⁷ With ongoing bleeding, any replacement therapy is likely to be ineffective. Iron replacement therapy is required and very effective. Initial doses are 150 to 200 mg/day. Hematocrit levels should improve within 1 to 2 months of therapy; however, the serum ferritin level is a more precise measurement of improvement and total body stores of iron. Once the serum ferritin level reaches 50 mcg/L, adequate replacement of iron has occurred. A rapid decrease in fatigue, lethargy, and other associated symptoms is generally seen within the first month of therapy. Replacement therapy usually continues for 6 to 12 months after the bleeding has stopped but may continue for as long as 24 months. Menstruating females may

need daily oral iron replacement therapy (325 mg/day) until menopause.

Parenteral iron replacement is used in instances of uncontrolled blood loss, intolerance to oral iron, intestinal malabsorption, or poor adherence to oral therapy. Iron dextran has been the only parenteral agent available in the United States. Intramuscular injection is the recommended method; however, intravenous (IV) administration is generally preferred because of the ability to administer larger doses. A significant concern in the use of IV dextran is the potential for severe anaphylactic reaction. Delayed allergic reactions are also major concerns.

Medications that have recently been approved for parenteral therapy in treating IDA are sodium ferric gluconate complex in sucrose (Ferrlecit) and iron sucrose injection (Venofer). Iron dextran is recommended as the first choice in spite of its higher rate of adverse reactions. For individuals who are intolerant of iron dextran, the two newer agents are safe and effective alternatives. Drawbacks to their use include higher cost and the need for multiple infusions.

Anemia of Chronic Disease

Anemia of chronic disease (ACD, also called anemia of inflammation [AI]) is a mild to moderate anemia resulting from decreased erythropoiesis and impaired iron utilization in individuals with conditions of chronic systemic disease or inflammation (e.g., infections, cancer, and chronic inflammatory or autoimmune diseases). ACD is a common type of anemia in hospitalized individuals. [Table 29.4](#) lists the possible causes of ACD. This form of anemia also is commonly noted in the presence of congestive heart failure (CHF). The anemia develops after 1 to 2 months of disease activity. The initial severity is related to that of the underlying disorder but, although persistent, it usually does not progress. Individuals may be asymptomatic or the anemia may be a coincidental clinical finding. ACD shares features observed in individuals with chronic obstructive pulmonary disease; in persons with critical illnesses after acute events such as major surgery, severe

trauma, myocardial infarction, and sepsis; and in the elderly. It shares some features with anemia noted in multiple myeloma and malignant lymphoma.¹⁸

TABLE 29.4

UNDERLYING CAUSES OF ACD

ASSOCIATED DISEASES	ESTIMATED PREVALENCE (%)
Infections	18–95
Acute and chronic; viral infections including HIV infection, bacterial, parasitic, fungal	
Cancer	30–77
Hematologic, solid tumor	
Autoimmune	8–71
Rheumatoid arthritis, systemic lupus erythematosus and connective tissue diseases, vasculitis, sarcoidosis, inflammatory bowel disease	
Chronic rejection after solid-organ transplantation	8–70
CKD and inflammation	25–30

ACD, Anemia of chronic disease; *CKD*, chronic kidney disease.

Data from Weiss G, Goodnough LT: *N Engl J Med* 352(10):1011–1023, 2005.

ACD is one of the most common conditions encountered in medicine and is probably only secondary to IDA in overall incidence. In individuals older than age 65, anemia is present in 10% of those who live in the community and in more than 50% of those who reside in nursing homes, with two-thirds of these cases being ACD or unexplained anemia. The elderly may be predisposed to ACD related to age-associated hematopoietic restriction and generally have increased concentrations of inflammatory cytokines, which play a significant role in the development of ACD. The elderly who present with characteristics of ACD without an underlying malignancy or inflammatory condition are described as having primary defective iron utilization syndrome.

◆ Pathophysiology.

ACD results from a combination of (1) decreased erythrocyte life span, (2) suppressed production of erythropoietin, (3) ineffective bone marrow erythroid progenitor response to erythropoietin, and (4) altered iron metabolism and iron sequestration in macrophages.¹⁹ During chronic inflammation a large variety of cytokines are released by lymphocytes, macrophages, and the affected tissue.²⁰ These include tumor necrosis factor-alpha (TNF- α), IFN- γ , interleukin-1 β (IL-1 β), IL-3, and IL-6²¹ (also see [Chapters 7](#) and [8](#)).

Impaired iron metabolism is partially the result of iron sequestration.²² IL-6 in particular affects hepatocytes and increases the release of the peptide hepcidin, which regulates the activity of ferroportin. Ferroportin is the primary transporter for the export of iron from macrophages to the plasma, and increased levels of hepcidin result in decreased ferroportin activity and suppression of iron release ([Fig. 29.5](#)).

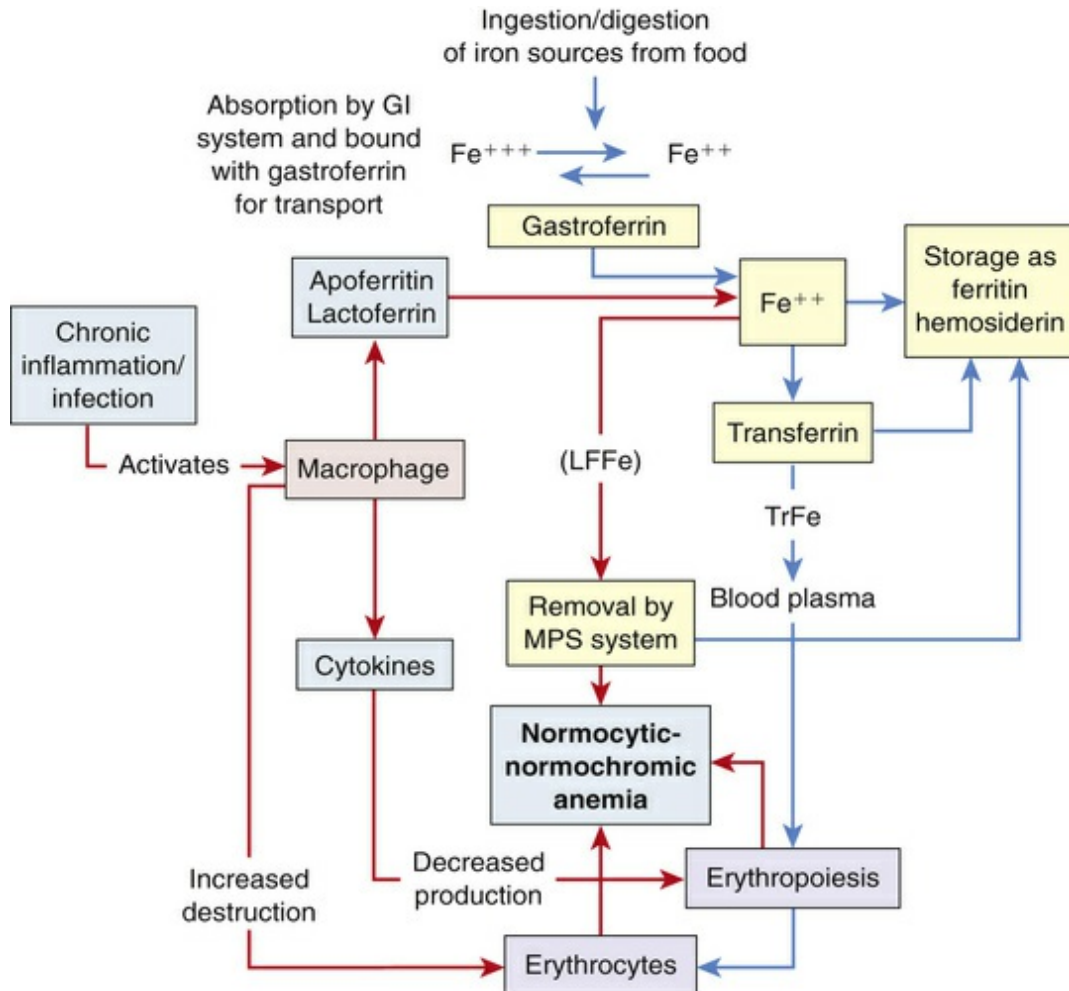

FIGURE 29.5 Pathophysiology of Anemia of Chronic Disease. Normal iron metabolism is indicated by the blue arrows. Abnormal mechanisms that are instrumental in the development of anemia of chronic inflammation are indicated by red arrows. See discussion in text. *GI*, Gastrointestinal; *LFFe*, lactoferrin bound to iron; *MPS*, mononuclear phagocyte system; *TrFe*, transferrin bound to iron.

Erythrocyte destruction is the result of eryptosis (described earlier in this chapter). Most of the diseases responsible for ACD damage erythrocytes, resulting in increased efflux of plasma membrane phosphatidylserine and susceptibility to removal by macrophages. Normal iron transport by transferrin also may be decreased as a result of competitive iron binding by inflammation-related increases in the levels of circulating lactoferrin and apoferritin. **Lactoferrin** is a member of the transferrin family of nonheme iron-binding glycoproteins, and under normal conditions is present in the blood in only small amounts. During inflammation neutrophils release

lactoferrin to bind iron and reduce its availability for bacteria. However, the affinity of iron for lactoferrin is 260 times greater than that for transferrin. Lactoferrin-bound iron is removed by the mononuclear-phagocyte system and converted into ferritin, the storage form of iron. **Apoferritin** also has a higher affinity for iron and affects available iron in a similar manner.

The erythropoietic defect in ACD is failure to increase erythropoiesis in response to decreased numbers of erythrocytes. In part, decreased erythropoiesis results from diminished production of erythropoietin by the kidneys. The kidney is frequently affected by chronic inflammatory processes caused by circulating immune complexes and other factors that deposit in the kidney and activate secondary inflammatory mechanisms. In addition, the failure in erythropoiesis may reflect decreased responsiveness of erythroid progenitors to erythropoietin. Decreased availability of iron would diminish the rate of erythropoiesis. Proliferation of erythroid cells is also inhibited by proinflammatory cytokines, especially TNF- α , IFN- γ , and IL-1 β . TNF- α also directly induces apoptosis of erythroid progenitors, thus diminishing the number of responsive cells. In individuals who had anemia secondary to rheumatoid arthritis, the bone marrow contained elevated levels of IL-3, which correlated with diminished expression of integrins on the surface of cells of the erythroid series.²³ Loss of integrins may prevent adequate interaction with stromal cells and matrix proteins and inhibit erythropoiesis.

Anemia associated with chronic renal failure may result from a variety of simultaneous mechanisms. Damage to the kidney affects the secretion of erythropoietin, a necessary hormone for production of erythrocytes in the bone marrow, thus resulting in diminished bone marrow erythropoiesis.²⁴ Uremic toxins (e.g., uric acid, sulfates, phosphates) that increase in the blood secondarily to renal failure may suppress bone marrow function and damage erythrocytes, which undergo eryptosis. Platelet function also may be defective in these individuals, which results in chronic bleeding and loss of erythrocytes.

Anemia may arise from the direct action of bacterial toxins. For

example, *Clostridium perfringens* (gas gangrene and a cause of food poisoning) produces an alpha toxin. This toxin has enzymatic activity (phospholipase C, sphingomyelinase) that disrupts the membrane of cells. If the cells are erythrocytes, hemolysis will result.

◆Clinical Manifestations.

The anemia of ACD is usually in the mild to moderate range, with few additional complications. If hemoglobin levels drop significantly, clinical manifestations of IDA appear.

◆Evaluation and Treatment.

Morphologically, ACD is initially normocytic-normochromic, but as the condition persists it becomes hypochromic and microcytic. ACD is characterized by abnormal iron metabolism with low levels of circulating iron (less than 60 mcg/dL) and reduced levels of transferrin. The most significant finding of ACD is very high total body iron storage, although inadequate iron is released from the bone marrow for erythropoiesis. Very often the first indication of ACD is a failure to respond to conventional iron replacement therapy. Levels of erythropoietin are generally lower than expected for the degree of anemia. The affected individuals also frequently present with low or normal total iron-binding capacity (TIBC), normal or high serum ferritin levels, and low concentrations of soluble transferrin receptor (blood test findings are listed in [Table 29.2](#)). Occasionally it may be difficult to differentiate ACD from IDA; however, measurement of sTfR (key receptor for iron acquisition by erythroid cells) may be useful. Levels of sTfR do not respond to iron supplementation in ACD but do so in IDA.

Use of erythropoietin in treatment of ACD associated with arthritis, malignancies, and acquired immunodeficiency syndrome (AIDS) has met with limited success. Individuals with severe anemia secondary to chronic kidney disease (CKD) can be treated successfully with erythropoietin and treatments to increase iron stores.²⁵ However, the optimal degree of restoration of hemoglobin levels (a measure of anemia) has not been determined; achievement of normal levels

increases the risk of hypertension, stroke, and death.²⁶ Transfusion of critically ill individuals may worsen the outcome and increase morbidity and mortality.²⁷ The principal treatment is alleviation of the underlying disorder. Individuals who have ACD but demonstrate no evidence of inflammatory or infectious conditions are screened for the presence of malignancies.

Aplastic Anemia

Aplastic anemia (AA) is a hematopoietic failure or bone marrow aplasia characterized by reduction in the effective production of mature cells by the bone marrow, causing peripheral **pancytopenia** (anemia, neutropenia, and thrombocytopenia), which is a reduction or absence of all three blood cell types (Fig. 29.6). Although the pathogenesis is not clearly defined, mechanisms include immune-mediated destruction of hematopoietic stem cells or their progenitors at various stages of differentiation.²⁸

FIGURE 29.6 Aplastic Anemia. A, Normal bone marrow of an adult. Hematopoietic cells account for approximately 40% of marrow's cellularity. B, There is a marked reduction in hematopoietic cells with expansion of fat cells. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

The known causes of AA are from chemicals and drugs, physical agents, or unpredictable exposures; AA can be inherited or idiosyncratic (Box 29.2). The incidence of AA is relatively rare (annual rate of two to five new cases per million per year). The incidence in developing countries is somewhat higher and may be related to greater exposure to certain chemicals known to cause AA. The incidence is bimodal, with one peak occurring between 15 and 25 years of age and a second peak occurring in individuals older than age

60. AA is equally distributed between genders.

Box 29.2

Major Causes of Aplastic Anemia

Acquired

- Idiopathic
- Acquired stem cell defects
- Immune mediated

Chemical Agents

Dose Related

- Alkylating agents
- Antimetabolites
- Benzene
- Chloramphenicol
- Inorganic arsenicals

Idiosyncratic

- Chloramphenicol
- Phenylbutazone
- Organic arsenicals
- Methylphenylethylhydantoin
- Carbamazepine
- Penicillamine
- Gold salts

Physical Agents

Whole-body irradiation
 Viral infections
 Hepatitis (unknown virus)
 Cytomegalovirus infections
 Epstein-Barr virus infections
 Herpes zoster (varicella zoster)

Inherited

Fanconi anemia
 Telomerase defects

From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.

AAs are the most common type of bone marrow aplasia, with *idiopathic AA* (primary acquired) accounting for approximately 75% of all confirmed cases and being an autoimmune disease. *Secondary AA*, which accounts for approximately 15% of cases, is caused by a variety of known chemical agents and ionizing radiation. Chemical agents and drug effects are included in [Table 29.5](#). The development of AA with use of these agents is generally dose related, and the effect can be controlled with diminished dosages. In other instances, AA might develop after the use of small amounts of these drugs (idiosyncratic), with the anemia following a severe, rapid, irreversible progression. Liver disease (seronegative hepatitis) is also recognized as a cause of AA.

TABLE 29.5

ANEMIAS SECONDARY TO DRUG EFFECTS

DRUG	HEMOLYTIC	MEGALOBLASTIC	SIDEROBLASTIC	APLAST
Antibiotics				
Amphotericin B				X

Trimethoprim-sulfamethoxazole (Bactrim)		X		
Chloramphenicol (Chloromycetin)			XX	XXXX
Erythromycin	X			X
Sulfisoxazole (Gantrisin)				X
Penicillin	XXX			X
Sulfanilamide/Sulfonamides	XX			X, X*
Streptomycin	X			X
Anticonvulsants				
Phenytoin (Dilantin)		XXX		XXX, X*
Mephenytoin		XXX		XXX
Primidone (Mysoline)		XX		
Phenobarbital		XX		
Trimethadione (Tridione)				XXX
Antiinflammatories				
ASA (aspirin)				X*
Colchicine		X?		
Gold compounds				XX
Ibuprofen (Motrin)	X			X
Indomethacin (Indocin)				X
Phenacetin	XXX			X
Phenylbutazone				XX, X*
Antihypertensives/Diuretics				
Methyldopa (Aldomet)	XXX			
Acetazolamide (Diamox)				X
Thiazides	X			
Tranquilizers				
Chlordiazepoxide (Librium)				X
Chlorpromazine (Thorazine)	XX			X
Meprobamate				X
Oral Hypoglycemics				
Chlorpropamide (Diabinese)	X			

Tolbutamide (Orinase)				X, X*
Immunosuppressants				
Azathioprine (Imuran)			X	X*
Cyclosporine	X			
Miscellaneous Agents				
Benzene	XX			XX
Cimetidine (Tagamet)				X
Heparin				X*
Potassium perchlorate				XX
Quinine/quinidine	XX			
Acetaminophen (Tylenol)	X			X
Antituberculosis Agents				
INH (isoniazid)	XX			
PASA (<i>para</i> -aminosalicylic acid)	XX	X		
Pyridium (phenazopyridine HCl)				XX

ASA, Acetylsalicylic acid; X, rare number of reported cases; XXXX, substantial number of reported cases; XX and XXX, intermediate number of reported cases; X*, “pure red cell” aplasia; X?, uncertain.

AA is constitutional or familial in origin or is associated with one or more somatic abnormalities in approximately 5% to 10% of affected individuals. A subset of these is found to have defective telomerase RNA, resulting in shortened telomeres. This abnormality also is found in some individuals with idiopathic AA.

Total body irradiation also causes AA and in certain instances may be used therapeutically for this effect. Infections are also known to cause AA, with viruses being the most common agent. These include infections with the human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), and hepatitis (non-A, non-B, non-C, and non-G forms of the virus). Persistent parvovirus B19 infection also has been identified as producing bone marrow failure resulting in AA. Parvovirus B19 has been identified as the cause of aplastic crisis in children who have sickle cell hemoglobinopathies and hereditary spherocytosis.

Another condition associated with AA is **pure red cell aplasia (PRCA)**, in which only the erythrocytes are affected. PRCA is a rare disorder and has been associated with autoimmune, viral, and neoplastic (leukemias) disorders; infiltrative disorders of the bone marrow (myelofibrosis); renal failure; hepatitis; mononucleosis; and systemic lupus erythematosus. It also is a well-recognized but infrequent complication of allogeneic bone marrow transplantation, particularly when there is donor-recipient ABO mismatch. A thymoma often is found in association with PRCA and is also present in Diamond-Blackfan syndrome, a congenital disorder.

A very small percentage of AA cases are linked to genetic alterations. **Fanconi anemia** is a rare genetic anemia characterized by pancytopenia resulting from defects in DNA repair.²⁹ This anemia develops early in life and is accompanied by multiple congenital anomalies.

◆Pathophysiology.

The characteristic lesion of AA is a hypocellular bone marrow that has been replaced with fat. The pathogenesis of AA is not certain. Two etiologies and mechanisms are observed: an extrinsic immune-mediated suppression of bone marrow progenitor cells and an intrinsic abnormality of stem cells.⁴ The primary mechanism of acquired AA involves immune-mediated destruction directed against hematopoietic stem cells (HSCs).^{28,30} Several immune abnormalities are found in individuals including dysregulated CD4+, CD8+, and Th-17 T-cell responses and reduced numbers of regulatory T cells.²⁸ Additionally, many people have elevations of circulating levels of inflammatory or myelosuppressive cytokines, such as interferon-gamma (IFN- γ), tumor necrosis factor-alpha (TNF- α), and transforming growth factor-beta (TGF- β).^{28,31} Although efforts have identified circulating antibodies in acquired AA individuals, the identification of autoantigens capable of eliciting cytotoxic T-cell responses and causing stem cell destruction has been challenging.²⁸ Laboratory studies have focused on a working model where activated T cells suppress HSCs. Stem cells may be altered from exposure to

drugs, infectious agents, or other unknown environmental factors. In many cases no initiating factor can be identified and therefore this type of AA belongs in the idiopathic category. A genetic predisposition may involve polymorphisms in human leukocyte antigens (HLAs) and inhibitory cytokines (e.g., TNF- α , TGF- β , and IFN- γ).³¹ An emerging understanding suggests that the initial immune response may be triggered by pathogens, drugs, or chemicals, or by neoantigens through epigenetic mechanisms.^{28,32-34} It is interesting that transient and persistent bone marrow hypoplasia has been linked to many microorganisms, and the interaction and alterations between the gut microbiota and immune system is hypothesized as an initial insult in the development of bone marrow failure syndromes such as AA²⁸ (Fig. 29.7).

FIGURE 29.7 Working Model: Microbes, Microbiota, Hematopoiesis, and Immune Response. Microbes can participate in a symbiotic relationship (commensal) with hosts to maintain hematopoietic stem cells (HSCs) and precursor myeloid cells. Defects in innate immune cell populations, including neutrophils, monocytes, and macrophages, can occur with deficient commensal microbes. Experiments feeding mice diets rich in fiber changed the ratio of firmicutes to bacteroidetes and bifidobacteriaceae. Gut microbiota metabolize fiber, increasing short-chain fatty acids (SCFAs) and promoting the growth of bone marrow myeloid precursors (not affecting lymphoid progenitors). With dysbiosis (disrupted microbiosis; microbial imbalance or maladaptation) pathogenic microbes may increase and provide a source of chronic low-grade inflammation mediated by lipopolysaccharides (LPSs) and other pathogen-associated molecular patterns (PAMPs). These factors continuously stimulate hematopoietic

stem progenitor cells (HSPCs) through pathogen recognition receptors like TLRs, resulting in hematopoiesis inhibition. The LPS stimulation of toll-like receptors (TLRs) on monocytes causes tumor necrosis factor-alpha (TNF- α) secretion and with continuous stimulation of HSPCs may eventually inhibit hematopoiesis through exhaustion. (Adapted from Espinoza JL, Kotecha R, Nakao S: *Front Immunol* 8:186, 2017.)

The evidence supporting an autoimmune process includes the response of AA to immunosuppressive therapy including depletion of T cells by antithymocyte antibodies. Cytotoxic T cells (Tc cells) appear to be the main culprits, although the causative antigen has yet to be identified. Th1 cytokines (involved in the differentiation of Tc cells), such as IFN- γ and TNF- α , as well as cellular contact with Tc cells through FasL, induce apoptosis of CD34+ target cells, which includes most of the hematopoietic progenitors. The presence of stem cell abnormalities is supported by the existence of abnormal karyotypes, short telomeres, and the low incidence of transformation of AA into myeloid neoplasms.⁴

◀Clinical Manifestations.

The onset of symptoms is insidious and related to the rapidity with which the bone marrow is destroyed and replaced. AA affects both males and females at any age. Approximately 50% of AA cases progress rapidly, with a high risk of death from overwhelming infection or bleeding. In some cases the rate of decline is slow and the individual may adapt progressively to a new level of hematologic function. This condition is referred to as *hypoplastic anemia* rather than aplastic anemia.

Initial symptoms depend on which cell line is affected. Rapidly progressing disease is usually associated with hypoxemia, pallor (occasionally with a brownish pigmentation of the skin), and weakness along with fever and dyspnea with rapidly developing signs of hemorrhaging if platelets are affected (e.g., unexplained bruising, nosebleeds, bleeding gums, bleeding in the GI tract, prolonged bleeding at sites of minor injury). A slower onset over weeks or months is characterized by progressive weakness and fatigue with developing signs of hemorrhaging. Major hemorrhage may occur from any organ; however, it is generally observed in the

late stages and is often secondary to other events. Menorrhagia and purpura also may be evident; however, purpura is not necessarily a classic indication of AA and may not be representative of the degree of thrombocytopenia. In both rapid onset and slow onset AA, diminished leukocyte production may result in a progressive frequency and prolongation of infections.

Late manifestations of the condition include ulcerations of the mouth and pharynx or a low-grade cellulitis in the neck. Splenomegaly is extremely rare; if it is present, however, other conditions that may imitate AA should be excluded. Neurologic changes are only evident when hemorrhages have occurred within the system; however, some individuals have complained of paresthesias.

◆Evaluation and Treatment.

Diagnosis is made by blood tests and bone marrow biopsy. AA is suspected if levels of circulating erythrocytes, leukocytes, and platelets are diminished: a granulocyte count less than $500/\mu\text{L}$, a platelet count less than $20,000/\mu\text{L}$, and an absolute reticulocyte count less than or equal to $40 \times 10^9/\text{L}$. The diagnosis is confirmed by bone marrow biopsy. The bone marrow usually has reduced cellularity (i.e., less than 25% normal cellularity). The morphology of the few remaining hematopoietic cells is usually normal. Occasionally the erythrocytes are macrocytic, with anisocytosis and poikilocytosis, and may appear immature.

Marrow biopsied from individuals with typical AA contains yellowish white material consisting mainly of fat, fibrous tissue, and lymphocytes. Pancytopenia is usually characterized by decreased stem cell and progenitor cell populations to approximately 1% or less of normal.

Up until 20 years ago, treatment involved determination of the cause, removal of the potential causative agent, implementation of transfusions, and prevention and treatment of infection and hemorrhage. Stimulation of blood cell production also was used, and in some instances splenectomy was recommended. The prognosis with these forms of treatment was extremely poor. In acute cases, 25%

of individuals succumbed within 4 months, and approximately 70% died within 5 years; only about 10% experienced complete recovery. Newer forms of treatment, such as bone marrow transplant (BMT), immunosuppression, and identification of high-risk individuals, have decreased mortality significantly.³⁵

Bone marrow and, most recently, peripheral blood stem cell transplantation from a histocompatible sibling often cures the underlying bone marrow failure.³⁶ Survival rates of 75% to 80% have been reported, and death rates within the first 100 days have decreased. Before transplantation the recipient usually receives radiation or chemotherapy to deplete the bone marrow of disease-causing lymphocytes. Thus an unsuccessful transplantation may leave the recipient with a depleted immune system and an increased vulnerability to infection. Graft-versus-host (GVH) disease remains a risk and is a major contributor to premature death.³⁷ Children demonstrate higher survival rates than adults.

For those individuals unable to undergo bone marrow transplantation or who lack a suitable sibling donor, immunosuppression remains the treatment of choice. Antithymocyte globulin (ATG) specifically suppresses lymphocytes, including those autoreactive lymphocytes destroying the bone marrow cells. Drugs like cyclosporine, which is often used in combination with ATG, broadly suppress the activity of immune cells. Response rates (i.e., increased blood cell counts) of 40% to 50% may occur in individuals who receive ATG. The addition of cyclosporine has increased the response and survival rates to as much as 70% to 80%, with a 5-year survival rate between 80% and 90%. Cyclosporine as a single therapeutic agent is not as effective. Corticosteroids are often used concurrently with ATG and cyclosporine. Cyclophosphamide also has been used as an immunosuppressive agent and has produced the same effects as ATG; however, its use has been discontinued because of its toxicity. The addition of recombinant hematopoietic growth factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-6, and epoetin, to immunosuppressive therapy has produced significant additional benefit in both children and adults.

Immunosuppressive therapy is not without risk. Individuals receiving immunosuppressive therapy are at risk of experiencing treatment failure or late clonal/malignant conditions, or both. Late clonal/malignant conditions include paroxysmal nocturnal hemoglobinuria (PNH), myelodysplasia (MDS), acute leukemia, or solid tumor. Although quite rare (less than 3%), administration of ATG may cause an anaphylactic reaction in some individuals.

Hemolytic Anemia

The predominant event in **hemolytic anemias** is premature accelerated destruction of erythrocytes, either episodically or continuously. A large majority of hemolytic anemias occur within phagocytes in lymphoid tissue, called *extravascular hemolysis*. The destruction of senescent erythrocytes takes place within macrophages typically abundant in the spleen, bone marrow, and liver. Less common is *intravascular* (blood vessels) *hemolysis* caused by mechanical injury, complement fixation, intracellular parasites, or exogenous toxic factors (e.g., clostridial sepsis, snake venom, lead poisoning). The consequences of the anemia are elevated levels of erythropoietin to induce accelerated production of erythrocytes and an increase in the products of hemoglobin catabolism.

Hemolytic anemias may be either congenital or acquired. Congenital hemolytic anemias result from intrinsic defects in erythrocytes, including the red cell membrane (e.g., hereditary spherocytosis, paroxysmal nocturnal hemoglobinuria), enzymatic pathways (e.g., glucose-6-phosphate dehydrogenase deficiency), and hemoglobin synthesis (e.g., the thalassemia syndromes, sickle cell anemia). (Glucose-6-phosphate dehydrogenase deficiency, thalassemia, and sickle cell disease are discussed in [Chapter 31](#).) Acquired hemolytic anemias are usually immunologic (immune hemolytic anemias), such as erythrocyte destruction caused by autoantibodies against erythrocyte antigens (e.g., autoimmune hemolytic anemia), isohemagglutinins (e.g., mismatched erythrocyte transfusions), or allergic reactions against drug antigens adsorbed onto the erythrocyte surface (drug-induced hemolytic anemia).

(Isohemagglutinins, erythrocyte antigens, autoantibodies, and allergic reactions are discussed in [Chapter 9](#).) Acquired hemolytic anemia may also be secondary to erythrocyte damage caused by cardiac valve prostheses or by increased shear stresses in narrowed small vessels (e.g., during disseminated intravascular coagulation). Causes of acquired and hereditary hemolytic anemias are listed in [Table 29.6](#).

TABLE 29.6

CAUSES OF HEMOLYTIC ANEMIAS

TYPE OF HEMOLYTIC DISORDER	PRIMARY CAUSE OR ASSOCIATED DISORDER	MECHANISMS OF ERYTHROCYTE DESTRUCTION
Acquired Forms		
Immune system–mediated hemolysis	Transfusion reaction Hemolytic disease of the newborn (see Chapter 31) Autoimmune hemolytic anemia (see text)	Antibody-mediated: intravascular hemolysis by activation of complement system; extravascular hemolysis by phagocytosis of antibody-coated erythrocytes in spleen (see Chapter 9)
Traumatic hemolysis	Presence of prosthetic heart valves Structural abnormalities of the heart Hemolytic uremic syndrome Disseminated intravascular coagulation Hemodialysis	Physical destruction of erythrocytes by “mechanical” means (trauma)
Infectious hemolysis	Bacterial infection Viral infection Protozoal infection Helminthic infection	Bacterial hemolysins (e.g., <i>Escherichia coli</i> 0157:H7 shiga toxin; <i>Clostridium perfringens</i> toxin) Initiates autoimmune hemolysis (e.g., <i>Mycoplasma pneumoniae</i> : cold agglutinin) Affects erythrocytes (e.g., parvovirus B19: infects erythroid progenitors) Infects erythrocytes (e.g., malaria) Causes intestinal bleeding (e.g., hookworm)
Drug or toxic	Exposure to toxic	Chemical injury of erythrocytes (see Chapter 2)

(chemical) hemolysis	chemical agents Hemodialysis or uremia Venoms	
Physical hemolysis	Burns Radiation	Heat or radiation injury (see Chapter 2)
Hypophosphatemic hemolysis	Hypophosphatemia (phosphate deficiency in plasma; see Chapter 3)	Diminished cellular production of substances required for erythrocyte life and function
Hereditary Forms		
Structural defects	Plasma membrane defects	Fragility of the erythrocyte
Plasma membrane protein mutation	Deficient complement regulatory proteins (i.e., paroxysmal nocturnal hemoglobinuria)	Complement activation on erythrocyte surface, intravascular lysis
Enzyme deficiencies	Deficiency of glycolytic enzymes Deficiency of metabolic enzymes (i.e., glucose-6-phosphate dehydrogenase deficiency)	Diminished cellular function
Defects of globin synthesis or structure	Sickle cell anemia	Increased membrane fragility and deformation during sickle crises
	Thalassemia	Defective hemoglobin structure and function
	Miscellaneous hemoglobin defects	Defective hemoglobin structure and function

From Lee GR et al: *Wintrobe's clinical hematology*, ed 9, Philadelphia, 1993, Lea & Febiger.

◆Pathophysiology.

Extravascular hemolysis appears to be initiated by age-related changes in erythrocyte surface proteins leading to their recognition and phagocytosis. Erythrocytes continuously circulate through the

spleen, passing through the thin-walled splenic cords into the splenic sinusoids, a spongelike labyrinth of macrophages. Normally, erythrocytes are able to alter their shape to allow passage through openings in the splenic cords. Macrophages will phagocytose erythrocytes with structural alterations of the membrane surface, or erythrocytes may become more rigid and therefore incapable of maneuvering through this network. In some cases, IgG antibodies or complement component C3b can coat erythrocytes without causing hemolysis, but can function as opsonins that are recognized by macrophages.

Intravascular hemolysis is caused by physical destruction of erythrocytes in the circulation, frequently by antibody and complement. As mentioned earlier, other forms of destruction include mechanical injury, such as shear stresses in narrowed microcirculation; repetitive physical trauma (karate chopping, bongo drumming, marathon running); or trauma caused by cardiac valves. Intracellular parasites such as *Plasmodium falciparum* malaria can cause intravascular hemolysis because infection may generate early elimination of normal or nonparasitized RBCs, lysis of parasitized RBCs, and impairment of erythropoiesis.³⁸ Toxic injury, such as from snake venom, contains hemolytic toxins and clostridial sepsis results in the release of enzymes that digest the erythrocyte membrane.

Paroxysmal nocturnal hemoglobinuria, although rare, is the only hemolytic anemia caused by an acquired genetic defect that is manifested by complement-mediated hemolysis. It may be congenital or acquired secondarily to acquired aplastic anemia. The disease results from a mutation in the X-linked gene for phosphatidylinositol glycan—class A (*PIG-A*), which results in a defect in expression of glycosylphosphatidylinositol (GPI) in hematologic stem cells.³⁹ GPI is a lipid anchor that is necessary for attachment of a large number of proteins to the plasma membrane. Several GPI-anchored proteins on erythrocytes are complement regulatory proteins, including CD55 (decay-accelerating factor) and CD59 (membrane attack complex [MAC] inhibitory protein). Normally low levels of complement are activated on cell surfaces through the alternative pathway (see

[Chapter 7](#)). Erythrocytes are protected from complement-mediated damage by CD55, which accelerates the degradation of any C3 convertase that forms on the cell surface, and by CD59, which prevents C9 aggregation and pore formation by the membrane attack complex. Thus erythrocytes deficient in CD55 and CD59 undergo complement-mediated intravascular lysis and release of hemoglobin.⁴⁰ Peptide inhibitors of C3 activation that may prevent hemolysis are under investigation.⁴¹ In addition to anemia and hemoglobinuria, affected individuals also present with severe fatigue, abdominal pain, and thrombosis.⁴² The cause of death is usually thrombosis of the abdominal or cerebral veins.⁴³ Thrombosis most likely results from a depletion of vascular nitric oxide (NO) by free hemoglobin, which has a high affinity for NO. The result is dysregulation of normal hemostasis and increased platelet vascular adherence and clot formation (see [Chapter 28](#)).

Immuno-hemolytic anemias, also called **autoimmune hemolytic anemias (AIHAs)**, are acquired disorders caused by autoantibodies or complement, or both, on red cells against antigens normally on the surface of erythrocytes.^{4,44} Immuno-hemolytic anemia is the preferred term because in some instances the immune reaction is initiated by an ingested drug.⁴ Three types of AIHAs have been described: (1) warm reactive antibody type, (2) cold agglutinin type, and (3) cold hemolysin type (paroxysmal cold hemoglobinuria). This classification is based on the optimal temperature at which the antibody binds to erythrocytes and the mechanism of erythrocyte destruction.

Warm autoimmune hemolytic anemia is uncommon (incidence of about 1 per 80,000 population annually), although it is the most common form of AIHA (80% to 90% of cases), and generally occurs in individuals older than the age of 40.⁴⁵ Approximately half of the cases are secondary to other diseases, especially lymphomas but also chronic lymphocytic leukemia, other neoplastic disorders, or systemic lupus erythematosus (SLE). The anemia is caused by IgG that binds optimally to erythrocytes at normal body temperature (37°C [98.6°F]). Most cases are related to antibody against Rh-related antigens other than the D epitope (Rh antigens are discussed in [Chapter 9](#)). The

spectrum of antibody specificities includes antibodies against the e, E, or c antigens of the Rh complex. Other cases are caused by IgG antibodies against erythrocyte antigens outside the Rh complex and include antibodies against Wr^b , En^a , the Kell blood group, and many others. The warm reactive IgG antibodies usually do not activate complement because of the rather sparse distribution of antigens on the erythrocyte surface. (Activation of complement by antibody is discussed in [Chapters 7, 8, and 9](#).) Erythrocyte destruction is caused by extravascular processes. The IgG-coated erythrocytes bind to the Fc receptors on monocytes and splenic macrophages and are removed by phagocytosis.

Cold agglutinin autoimmune hemolytic anemia is mediated by immunoglobulin M (IgM) antibodies and occurs less often than warm antibody hemolysis, affecting mostly middle-aged and older adults. Cold antibodies optimally bind to erythrocytes at colder temperatures (lower than 31°C [87.8°F]) with maximal binding capacity at 4°C (39.2°F). Cold agglutinin autoantibodies may appear acutely during recovery of certain infectious disorders, particularly infectious mononucleosis, *Mycoplasma pneumoniae*, and disseminated tuberculosis.⁴⁶ Individuals with these conditions are usually younger than those with primary disease; the anemia may be severe but may be self-limiting. Chronic cold agglutinin AIHAs also can occur in association with lymphoid neoplasm and other unknown or idiopathic conditions.⁴⁷

The IgM autoantibody is usually monoclonal and directed against erythrocyte carbohydrate antigens of the I system (i.e., i, I) or the P system (i.e., Pr).⁴⁸ In the colder areas of the body (e.g., fingers, toes, nose, ears, exposed skin), particularly during cold weather, the IgM autoantibodies bind to circulating erythrocytes. The IgM is rapidly released when the blood recirculates and warms. IgM is an extremely efficient activator of complement, resulting in the stable deposition of C3b on the cell surface. If an adequate amount of complement is deposited, the erythrocytes become vulnerable to recognition and rapid phagocytosis by mononuclear phagocytes in the liver and spleen (also see [Chapter 9](#)). The severity of hemolysis is variable and

may result in a progressive chronic anemia. If the level of antibody is high or has particularly strong binding, hemagglutination may occur in the capillaries of exposed sites, such as fingers, toes, and ears, when temperatures are below 30°C (86°F). Obstruction of blood flow caused by erythrocyte agglutination may lead to a bluish discoloration of the skin (acrocyanosis) that resolves as the skin is warmed. Prolonged exposure to the cold may lead to gangrene.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) is a disorder in which exposure to cold initiates acute and severe intravascular hemolysis that, unlike cold agglutinin anemia, results in hemoglobinuria. The chronic form of this anemia is extremely rare, but an acute form of paroxysmal cold hemoglobinuria is frequently observed (30% to 40% of cases) in AIHA of childhood. The acute form occurs primarily in children younger than the age of 10 years and is usually preceded by an upper respiratory tract infection or flulike symptoms. Infections with measles, mumps, *Mycoplasma* (pneumonia), and *Varicella* have also been linked to an onset of paroxysmal cold hemoglobinuria. The anemia may be rapidly progressing and severe and associated with fever, reddish brown urine, hemoglobinuria, jaundice, abdominal pains, and pallor, with about 25% of individuals presenting with hepatomegaly and splenomegaly.

Paroxysmal cold hemoglobinuria is generally caused by IgG autoantibodies against the P blood group antigen. Antibody binding occurs in the colder portions of the body. As the erythrocyte recirculates, enzymes of the complement cascade are activated, and cells are destroyed in the vasculature by complement-mediated lysis. The involved antibody, also called *Donath-Landsteiner antibody*, was first recognized in individuals with anemia secondary to chronic syphilis infection. A transfusion reaction is an example of alloimmune hemolytic anemia (also see [Chapter 9](#)). Transfused blood that is mismatched for ABO antigens is destroyed by preexisting isohemagglutinins in the recipient. Isohemagglutinins, which are generally IgM antibodies, activate complement, resulting in a rapid intravascular hemolysis. The individual may immediately experience

fever, chills, dyspnea, and hypotension and may progress to shock. In some cases the hemolytic reaction may be delayed and develop 3 to 10 days after transfusion. The delayed reaction is caused by a low titer of preexisting antibodies to minor erythrocyte antigens.

Drug-induced hemolytic anemia is a form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics)⁴⁹ (also see [Chapter 9](#)). Usually the drug is low molecular weight, functions as a hapten, and binds to proteins on the surface of erythrocytes. This is sometimes called the *hapten model* and is based on anemia caused by penicillin, cephalosporins (more than 90% of cases), and hydrocortisone⁵⁰ ([Fig. 29.8, A](#)). IgG antibody against the drug or against the unique antigen formed by the interface of the drug and erythrocyte protein is formed and binds to the erythrocyte at normal body temperature. Hemolysis is usually extravascular because the opsonized erythrocytes are removed by phagocytes in the spleen and liver, although complement-dependent intravascular hemolysis may occur in some individuals. This form of drug-induced anemia usually follows a large intravenous infusion of an antibiotic and occurs 1 to 2 weeks after the initiation of therapy. Cessation of administration of the drug results in rapid resolution of the anemia.

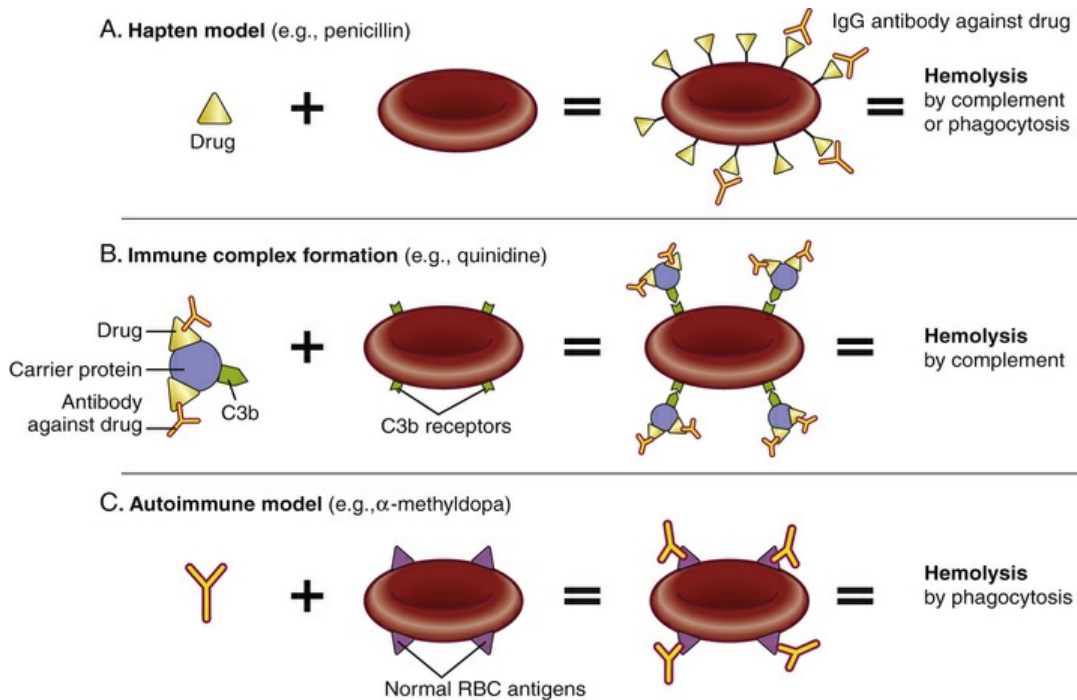

FIGURE 29.8 Models of Drug-Induced Hemolytic Anemia. See discussion in text. *IgG*, Immunoglobulin G; *RBC*, red blood cell.

The erythrocyte plasma membrane contains receptors of components of the complement system, such as C3b, and can bind circulating immune complexes that have activated the complement cascade (see [Chapter 9](#) for a discussion of immune complexes). This forms the basis for the *immune complex model* of drug-induced hemolytic anemia and was first described for anemia resulting from administration of the drug quinidine ([Fig. 29.8, B](#)). The drug or a metabolite of the drug, both of which are haptens, initially binds to plasma proteins and becomes immunogenic (see [Chapter 8](#)). The circulating drug-protein complex reacts with the resultant antibody (usually IgM, although IgG complexes have also been described) and activates the complement system, resulting in the deposition of C3b into the complex. Binding of the immune complexes to the erythrocyte surface results in further complement activation and intravascular hemolysis. This mechanism also may explain some of the anemia observed in other immune complex conditions, such as SLE.

In at least one instance, administration of the drug α -methyl dopa induces an immune response against normal erythrocyte antigens and

thus initiates a true AIHA (*autoimmune model*) (Fig. 29.8, C). The autoantibody is usually against Rh blood group antigens. It is estimated that 20% of individuals taking α -methyldopa develop detectable antibodies, but only 1% actually develop clinically significant anemia. The mechanism by which α -methyldopa induces autoantibodies against the erythrocytes is unknown.

◆Clinical Manifestations.

The presence and severity of signs and symptoms of hemolytic anemia depend on the degree of anemia and hemolysis and the success of compensatory erythropoiesis. Adaptation to red cell destruction is facilitated by increased red cell production. Bone marrow is capable of increasing red cell production up to eight times its normal rate. Accelerated erythrocyte production that is incapable of keeping up with destruction develops into a true hemolytic anemia.

The severity of anemia varies widely among individuals, even in those who have the same illness. Severe disease is commonly diagnosed shortly after birth or within the first year of life. Mild to moderate anemia is more common because the shortened erythrocyte survival time is offset by increased erythropoiesis. Some individuals have no symptoms of anemia, and the underlying hemolytic process remains undetected unless some other complications develop during the course of the disease.

Jaundice (icterus) is present when heme destruction exceeds the liver's ability to conjugate and excrete bilirubin. Jaundice is first noticed in the neonatal period. Children and adults with congenital hemolytic anemia may not have icterus, or it may be mild enough that it remains unnoticed. In some individuals, faint scleral icterus may be the only indication of hemolytic disease.

Acute conditions that disrupt the delicate equilibrium of accelerated erythropoiesis and erythrocyte destruction may precipitate a crisis. The most common type of crisis is aplastic and results from failure of bone marrow erythrocyte production. The most common cause of aplastic crisis is human parvovirus B19 infection.

Commonly, individuals with congenital hemolytic disorders

demonstrate splenomegaly, which is often only mild in nature. In some cases the spleen may become quite enlarged and may cause discovery of the underlying hemolytic disorder. Another underlying condition that may be the cause of inadvertently determining the presence of the anemic disorder is the development of gallstones.

Children who have hemolytic anemia often demonstrate skeletal abnormalities caused by expansion of erythroid bone marrow during the active phase of growth and development. These alterations are more pronounced in the bony structures of the face and skull and may result in pathologic fractures (see [Chapter 31](#)). Cardiovascular and respiratory manifestations vary with the degree of anemia. In spite of the disorder being characterized as hemolytic in nature, thromboembolism may occur. Pulmonary embolism is a common finding during autopsies of individuals with immune hemolytic anemia.

◆Evaluation and Treatment.

Diagnosis is based on clinical manifestations, bone marrow studies, and blood tests (see [Table 29.2](#)). Abnormally increased numbers of erythrocyte stem cells are found in the marrow, a finding termed *erythroid hyperplasia*. Accelerated erythropoiesis causes large numbers of fragile and immature erythrocytes (stem cells and reticulocytes) to be released prematurely into the circulation. These cells are observed in blood smears. If the bone marrow is able to consistently maintain adequate compensation, the hemoglobin may remain stable. The mean corpuscular volume, however, may be decreased in the presence of reticulocytes. A blood smear is helpful in determining the presence of spherocytes or schistocytes, as well as examining white blood cells and platelets for coexisting hematologic or malignant conditions.

Acquired hemolytic anemias are treated by removing the cause or treating the underlying disorder. Corticosteroids are used for initial treatment. Approximately 75% of individuals initially respond to treatment with corticosteroids, but many of these patients relapse within a year. The most commonly used second-line treatments are

splenectomy and administration of rituximab. Splenectomy is performed if the spleen is the major site of hemolysis and splenomegaly is significant. Analysis of multiple studies confirms that some response (complete or partial) is achieved in between 59% and 100% of individuals.⁵¹ Although some individuals relapse after splenectomy, most achieve long-term remission.

The therapeutic use of monoclonal antibody has proven beneficial in individuals who relapse or are resistant to the effects of corticosteroids. Rituximab is a monoclonal antibody directed against the CD20 antigen and specifically depletes or suppresses B cells throughout the body. CD20 is expressed on most cells in the B-cell lineage, except hematopoietic stem cells and plasma cells. Rituximab is used to treat a variety of leukemias and lymphomas and autoimmune diseases (e.g., rheumatoid arthritis, idiopathic thrombocytopenia, multiple sclerosis, type 1 diabetes mellitus, systemic lupus erythematosus). It is used successfully in several types of immune hemolytic anemias. Eculizumab is a monoclonal antibody against complement protein C5, which blocks the enzymatic activation of C5 to C5a and C5b, and thus may be useful to treat paroxysmal nocturnal hemoglobinuria. Treatment with eculizumab prevents the formation of the membrane attack complex and complement-mediated cell lysis.

Acute fulminating hemolytic anemia (hemolytic crisis) is treated with fluid and electrolyte replacement to prevent shock and renal damage, which may be caused by erythrocyte debris clogging the kidney tubules. Transfusions of blood products sometimes are given. Folate also is used in treating chronic hemolytic disease to prevent megaloblastic crisis because long-term erythrocyte turnover increases folate requirements.

Myeloproliferative Red Blood Cell Disorders

Hematologic dysfunction results from an overproduction of cells as

well as a deficiency. One or more hematopoietic lines may be overproduced in the marrow in response to exogenous (e.g., exposure to radiation, drugs) or endogenous (e.g., physiologic compensatory responses, immune disorders) signals. Excessive red blood cell production is classified as **polycythemia**. Polycythemia exists in two forms: relative and absolute. **Relative polycythemia** results from hemoconcentration of the blood associated with dehydration that may be caused by decreased water intake, diarrhea, excessive vomiting, or increased use of diuretics. Its development is usually of minor consequence and resolves with fluid administration or treatment of the underlying condition.

Absolute polycythemia consists of two forms: primary or secondary. *Secondary polycythemia*, the more common type, is a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia. This hypoxia is noted in individuals who live at higher altitudes (i.e., higher than 10,000 feet), smokers with increased levels of carbon monoxide (CO), and individuals with chronic obstructive pulmonary disease or congestive heart failure, or both. Abnormal types of hemoglobin (e.g., hemoglobin San Diego or hemoglobin Chesapeake), which have a greater affinity for oxygen, also can cause secondary polycythemia, as does secretion of erythropoietin by certain tumors (e.g., renal cell carcinoma, hepatoma, and cerebral hemangioblastoma).

Polycythemia Vera

Polycythemia vera (PV) (also known as *primary polycythemia*) is one of several disorders collectively known as *chronic myeloproliferative disorders* (CMPDs).⁵² Others in this group include essential thrombocytosis, chronic idiopathic myelofibrosis, chronic myeloid leukemia, chronic neutrophilic leukemia, and chronic eosinophilic leukemia. All result from abnormal regulation of the multipotent hematopoietic stem cells. The major characteristics shared by these disorders are (1) involvement of a multipotent hematopoietic progenitor cell, (2) overproduction of one or more of the formed elements of the blood in the absence of a defined stimulus, (3)

dominance of a transformed progenitor cell over the nontransformed progenitor cells, (4) marrow hypercellularity or fibrosis, (5) cytogenetic abnormalities, (6) predisposition to thrombus formation and hemorrhage, and (7) spontaneous transformation to acute leukemia.

PV is quite rare with an estimated incidence of 2.3 per 100,000 individuals; peak incidence is between the ages of 60 and 80 years, with a median incidence in individuals ages 55 to 60. However, PV has been observed in individuals younger than the age of 40. Males are twice as likely as females to develop PV. PV is more common in whites than in blacks, particularly in whites of Eastern European Jewish ancestry. PV is rarely found in children or in multiple members of a single family; however, an autosomal dominant form exists that is characterized by increased production of erythropoietin.

◆Pathophysiology.

PV is a chronic neoplastic, nonmalignant condition characterized by overproduction of red blood cells (frequently with increased levels of white blood cells [leukocytosis] and platelets [thrombocytosis]) and splenomegaly. Erythrocytosis is the essential component of PV. Clonal proliferation of erythroid progenitors occurs in the bone marrow independent of erythropoietin, although the cells express a normal erythropoietin receptor. However, more than 95% of individuals with PV possess an acquired point mutation (e.g., V617F) in the *Janus kinase 2 gene (JAK2)*, a cytoplasmic tyrosine kinase, on chromosome 9.⁵³ *JAK2* increases the activity of the erythropoietin receptor and is self-regulatory so that *JAK2* activity diminishes over time. The mutation associated with PV negates the self-regulatory activity of *JAK2* so that the erythropoietin receptor is constitutively active regardless of the level of erythropoietin.⁵⁴ These red blood cell precursors also demonstrate sensitivity to other growth factors, such as interleukin-3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), or insulin-like growth factor. Very recent data suggest that erythropoietin could stimulate the proliferation of cells expressing *JAK2* and that phosphorylation of three tyrosine residues

in the erythropoietin receptor underlie *JAK2* point mutation (V617F) induced tumorigenesis.⁵⁵

◆Clinical Manifestations.

Almost every individual initially presents with an enlarged spleen, frequently with abdominal pain and discomfort. As the disease progresses many of the symptoms are related to the increased blood cellularity and viscosity. Increased viscosity, as well as thrombocytopenia and increased platelet dysfunction, leads to a hypercoagulable state with formation of venous and arterial thrombosis and vessel occlusion.⁵⁶ Endothelial cells carrying the *JAK2*^{V617F} mutation suggest that endothelial cells are involved in the pathogenesis of the myeloproliferative neoplasms.⁵⁷ Thrombi with occlusion of major and minor blood vessels lead to tissue and/or organ injury (ischemia) and death (infarction). Extreme thrombocytopenia (greater than 1,500,000/mm³ of blood) increases the risk for excessive bleeding, rather than thrombosis.

Increased blood viscosity results in a variety of circulatory alterations in PV, such as plethora (ruddy, red color of the face, hands, feet, ears, and mucous membranes) and engorgement of the retinal and cerebral veins. Individuals also may experience headache, drowsiness, delirium, mania, psychotic depression, chorea, and visual disturbances. Death from cerebral thrombosis is increased approximately fivefold in individuals with PV.

Cardiac workload and output remain essentially unchanged; however, increased blood volume may lead to elevated blood pressure. Coronary blood flow may be affected, precipitating angina, although cardiovascular infarctions are relatively rare. Other evidence of cardiovascular involvement is the development of Raynaud phenomenon and thromboangiitis obliterans.

Additionally, gastrointestinal gastric and duodenal thrombosis may occur with resultant hemorrhaging. The development of mesenteric thrombosis requires immediate medical intervention. Splenomegaly and hepatomegaly result from pooling of blood in these organs; consequently, individuals may develop portal hypertension. The

respiratory system is generally not affected by PV, unless thrombosis and embolization occur.

A unique feature of PV, one helpful in diagnosis, is the development of intense, painful itching that is intensified by heat or exposure to water (aquagenic pruritus), particularly warm water when bathing or showering. The intensity of the itching is related to the concentration of mast cells in the skin and is generally not responsive to antihistamines or topical lotions.

◆Evaluation and Treatment.

PV is frequently suspected on the basis of clinical features, such as a thrombotic event, splenomegaly, or aquagenic pruritus. Diagnosis of PV is made from blood and laboratory findings. An absolute increase in the number of red blood cells and in total blood volume confirms the diagnosis. The hemoglobin concentration ranges from 14 to 28 g/dL, and the hematocrit is usually 60% or higher.⁴ Erythrocytes appear normal but anisocytosis may be present. A bone marrow examination may be done but is not very valuable unless performed in association with cytogenetic and molecular studies for relevant mutations in *JAK2*.⁵⁸ The presence of a *JAK2* mutation confirms the diagnosis.⁵⁹ Typically the marrow is hypercellular but not in such a manner as to differentiate it from other myeloproliferative disorders. Additional observations of abnormal megakaryocyte morphologies, formation of clusters of abnormal cells, and increased fibrosis add more specificity and usefulness to bone marrow analysis. Elevated serum levels of erythropoietin are not helpful because most individuals with PV have normal or low levels.

Treatment of PV is challenging and directed toward minimizing the risk of thrombosis and preventing progression to myelofibrosis and acute leukemia. In low-risk individuals (e.g., those younger than age 60 or with no history of thrombosis and without risk factors for cardiovascular disease), the recommended therapy is phlebotomy (300 to 500 mL at a time to reduce erythrocytosis and blood volume) and low-dose aspirin. Initial phlebotomies are done 2 or 3 times a week until the hematocrit drops sufficiently and repeated every 3 to 4

months to maintain a safe hematocrit level (less than 45%). Aspirin is used for its antithrombotic (decrease in thromboxane) properties.

Hydroxyurea, an antimetabolite that blocks DNA synthesis and reduces vascular cellularity, is the drug of choice for myelosuppression. Unlike other similar drugs, hydroxyurea reduces the risk of thrombotic complications, but does not increase the risk for developing leukemia.⁶⁰ Radioactive phosphorus (³²P) has been used to suppress erythropoiesis. Its effects may last up to 18 months. Side effects of ³²P treatment include suppression of hematopoiesis resulting in anemia, leukopenia, or thrombocytopenia. Acute leukemia also is a side effect, although most often it occurs after 7 or more years of treatment, making this therapy more useful in the elderly.

Interferon-alpha (IFN- α) has been used when other forms of treatment have failed. Interferon inhibits the growth of the abnormal progenitors and inhibits the actions of cytokines that may lead to the development of myelofibrosis. Therapy with IFN- α is complicated by its proinflammatory activities; thus fever, flulike symptoms, and more severe complications are common. IFN- α is not consistently effective in high-risk adult cases, but is considered in individuals who are intolerant to hydroxyurea, younger individuals, and individuals who are pregnant.

Treatment with inhibitors of the *JAK2* pathway has resulted in the reduction of many associated disease symptoms (e.g., thrombosis) and a significant improvement in the quality of life.⁶¹ However, the optimal target defining successful treatment (hematocrit level) and the effects on life span have not yet been determined. Recent studies comparing the effects of phlebotomy or hydroxyurea, or both, concluded that a goal of maintaining a hematocrit of less than 45% was preferable to the goal of 45% to 50%.⁶² The lower target goal resulted in a significantly lower rate of death from cardiovascular causes or major thrombotic events.

Survival for 10 to 15 years is common. However, without proper treatment, 50% of individuals with PV die within 18 months of the onset of initial symptoms. The primary cause of death is thrombosis, which is more prevalent in elderly individuals and those with prior

vascular complications. Death because of hemorrhage is rare but more common in individuals with high platelet counts and those taking antiplatelet drugs. Conversion to acute myeloid leukemia (AML) occurs spontaneously in 10% of individuals within 15 years, increasing to 50% within 20 years. This leukemia is generally refractory to conventional treatment. Conversion to AML is most likely related to treatment with cytotoxic myelosuppressive agents, such as chlorambucil.⁵⁹ Those individuals treated only with IFN- α or hydroxyurea had the same incidence of conversion as those who received no treatment. Although PV is a chronic disorder, appropriate therapy results in remissions and prevention of significant morbidity.

Iron Overload

Iron overload can be primary, as in hereditary hemochromatosis, or secondary. The secondary causes of iron overload include parenteral iron overload in conditions such as anemias with inefficient erythropoiesis (e.g., aplastic anemia), dietary iron overload, or other conditions that require repeated blood transfusions or iron dextran injections.

Hereditary hemochromatosis (HH) is a common inherited, autosomal recessive disorder of iron metabolism and is characterized by increased gastrointestinal iron absorption with subsequent tissue iron deposition. Excess iron is deposited in the liver, pancreas, heart, joints, and endocrine glands, causing tissue damage that can lead to diseases such as cirrhosis, diabetes, heart failure, arthropathies, and impotence.⁶³

HH is caused by two genetic base pair alterations, C282Y and H63D. These are mutations in the *HFE* gene on chromosome 6. Homozygosity of C282Y is the most common genotype and accounts for 82% to 90% of HH cases. The remaining cases appear to be caused by environmental factors or other genotypes. *HFE* mutations are common in the United States with 1 in 10 white individuals heterozygous for the *HFE* C282Y mutation and 4.4 in 1000 homozygous for the C282Y mutation. C282Y homozygosity is much lower among Hispanics (0.27 in 1000), Asian Americans (<0.001 per

1000), Pacific Islanders (0.12 per 1000), and blacks (0.14 per 1000).

◆Pathophysiology.

Studies in mice have confirmed that the *HFE* gene (high Fe gene) is responsible for the majority of adult form HH. HFE protein, found in the crypt cells of the duodenum, facilitates transferrin receptor-dependent iron uptake into crypt cells. The HFE protein regulates the production of the protein hepcidin, considered the “master” regulator of iron.⁶⁴ The C282Y mutation prevents the altered HFE protein from reaching the cell surface, preventing interaction with hepcidin and transferrin receptors. The deficiency results in an increase in the expression of an iron transport protein, divalent metal ion transporter 1 (DMT-1), which is responsible for dietary iron absorption in the villus cells of the small intestine. This inappropriate intestinal iron absorption leads to iron overload and, eventually, end-organ damage that can result in cirrhosis, diabetes mellitus, hypothyroidism, cardiomyopathies, and arthritis.

Although the natural history of HH is emerging, there appears to be a long latent period with individual variation in biochemical expression modified by environmental factors, such as blood loss from menstruation or donation, alcohol intake, and diet. Cirrhosis is a late-stage development of HH that can shorten life expectancy. Cirrhosis also is a risk factor for hepatocellular carcinoma that occurs in individuals between the ages of 40 and 60 years. Cirrhosis prevention is a major goal of HH screening and treatment.

◆Clinical Manifestations.

Clinical manifestations of HH include symptoms such as fatigue, malaise, abdominal pain, arthralgias, and sometimes amenorrhea in women and loss of libido or impotence in men. Clinical findings of HH include hepatomegaly, abnormal levels of liver enzymes, bronzed skin, altered glucose homeostasis or diabetes, and cardiac dysfunction (dysrhythmias, cardiomegaly). Many individuals are diagnosed as a result of serum iron studies as part of a health-screening panel. Most individuals (>75%) are asymptomatic and have a low frequency

(<25%) of cirrhosis, diabetes, or skin pigmentation.

◆Evaluation and Treatment.

Laboratory findings in individuals with HH show elevations in serum iron levels, transferrin saturation, and ferritin levels. Documentation of iron overload relies on quantitative phlebotomy with calculation of the amount of iron removed, or liver biopsy with determination of quantitative hepatic iron. With the advent of genetic testing, no further workup is necessary in individuals who are C282Y homozygous or compound heterozygous, are less than 40 years old, and have normal liver function.

Treatment of HH is simple and consists of phlebotomy of 550 mL of whole blood, which is equivalent to 200 to 250 mg of iron. Frequency of phlebotomy depends on ferritin levels and should continue until the ferritin level is between 20 and 50 ng/mL. Initially, phlebotomy may be needed weekly but once therapeutic ferritin levels are reached, phlebotomy may only be needed every 2 to 3 months. Blood banks now accept blood donations from persons with documented HH. Iron chelating agents are sometimes used in addition to phlebotomy, but this is not the mainstay of treatment. Individuals with HH should be instructed to refrain from taking iron and vitamin C supplements and consuming raw shellfish; in addition, alcohol should be used in moderation. Family screening is recommended and necessary for all first-degree relatives of a person with HH.

Alterations of Platelets and Coagulation

Hemostasis is dependent on adequate numbers of platelets and levels of coagulation factors. Diminished or excessive levels may lead to defective hemostasis or spontaneous and unnecessary activation of clotting. (Hemostasis is described in [Chapter 28](#).) Diminished hemostasis results in either internal or external hemorrhage. Diffuse hemorrhage into skin tissues that is visible through the skin causes a

red-purple discoloration identified as a **purpura**. Purpuric disorders occur when there are not enough normal platelets to plug damaged vessels or prevent leakage from the many minute tears that occur daily in normal capillaries. Disorders of the clotting system tend to result in more serious internal bleeding than platelet defects and are usually caused by a deficiency of one or several clotting factors. Disorders that result in spontaneous clotting can result from genetic disorders of clotting system components or from acquired diseases that activate clotting. These disorders are known collectively as **thromboembolic disease**.

Disorders of Platelets

Quantitative or qualitative abnormalities of platelets can interrupt normal blood coagulation and prevent hemostasis.⁶⁵ The quantitative abnormalities are thrombocytopenia (a decrease in the number of circulating platelets) and thrombocythemia (an increase in the number of platelets). Qualitative disorders affect the structure or function of individual platelets and can coexist with the quantitative disorders. Qualitative disorders usually prevent platelet adherence and aggregation, preventing formation of a platelet plug.

Thrombocytopenia

Thrombocytopenia is defined as a platelet count less than 150,000 platelets/mm³ of blood, although most healthcare providers do not consider the decrease of significance unless the count falls to less than 100,000 platelets/mm³.⁴ Hemorrhage resulting from minor trauma does not usually occur until the count falls below 50,000/mm³. Spontaneous bleeding without apparent trauma can occur with counts between 10,000 and 15,000/mm³, resulting in petechiae, ecchymoses, larger purpuric spots, or frank bleeding from mucous membranes. Severe spontaneous bleeding may result if the count is less than 10,000/mm³ and can be fatal if it occurs in the gastrointestinal tract, respiratory system, or central nervous system (CNS).

Before the diagnosis of thrombocytopenia is made,

pseudothrombocytopenia must be ruled out. This phenomenon occurs in approximately 1 in 1000 to 1 in 10,000 laboratory samples and is an in vitro artifact that may occur when a blood sample is analyzed by an automated cell counter. Platelets in the sample may become nonspecifically agglutinated by immunoglobulins in the presence of ethylenediaminetetraacetic acid (EDTA), a preservative in banked blood. The agglutinated platelets are not counted, thus giving an apparent, but false, thrombocytopenia. Thrombocytopenia also may be falsely diagnosed because of a dilutional effect observed after massive transfusion of platelet-poor packed cells to treat a hemorrhage. This occurs when more than 10 units of blood have been transfused within a 24-hour period. The hemorrhage that necessitated the transfusion also accelerates the loss of platelets, which further contributes to the pseudothrombocytopenic state. Splenic sequestering of platelets secondary to hypersplenism (congestive) induces an apparent thrombocytopenia, as does hypothermia (less than 25°C [77°F]), which is reversed when temperatures return to normal, suggesting an increased platelet sequestration in response to chilling.

◆ Pathophysiology.

Thrombocytopenia results from decreased platelet production, increased consumption, or both. The condition also may be congenital or acquired and primary or secondary to other acquired or congenital conditions. Thrombocytopenia secondary to congenital conditions occurs in a large number of different diseases, although each is relatively rare. These include thrombocytopenia with absence of radius (TAR) syndrome, Wiskott-Aldrich syndrome (see [Chapter 9](#)), various forms of *MYH9* gene mutation (e.g., May-Hegglin syndrome), X-linked thrombocytopenia, and many other examples.

Acquired thrombocytopenia is more common and may occur as a result of decreased platelet production secondary to viral infections (e.g., EBV, rubella, cytomegalovirus [CMV], HIV), drugs (e.g., thiazides, estrogens, quinine-containing medications, chemotherapeutic agents, ethanol), nutritional deficiencies (vitamin B₁₂ or folic acid in particular), chronic renal failure, bone marrow

hypoplasia (e.g., aplastic anemia), radiation therapy, or bone marrow infiltration by cancer. Most common forms of thrombocytopenia are the result of increased platelet consumption. Examples include heparin-induced thrombocytopenia, idiopathic (immune) thrombocytopenic purpura, and thrombotic thrombocytopenic purpura.

Heparin-Induced Thrombocytopenia.

Heparin is a common cause of drug-induced thrombocytopenia. Approximately 4% of individuals treated with unfractionated heparin develop **heparin-induced thrombocytopenia (HIT)**. The incidence is lower (about 0.1%) with the use of low-molecular-weight heparin. HIT is an immune-mediated, adverse drug reaction caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation through platelet Fc γ IIa receptors (Fig. 29.9).⁶⁶ The release of additional platelet factor 4 from activated platelets and activation of thrombin lead to increased platelet consumption and a decrease in platelet counts beginning 5 to 10 days after administration of heparin.

FIGURE 29.9 Pathogenesis of Heparin-Induced Thrombocytopenia (HIT). (1) Activated platelets release procoagulant proteins from α -granules, including platelet factor 4 (PF4). Administered heparin binds PF4 (2), which

undergoes a conformational change and expresses a new antigen (neopeptide). Individuals with HIT produce an immunoglobulin G (IgG) antibody that specifically reacts (3) with multiple identical neopeptides on the heparin-PF4 complex. The reaction forms heparin-PF4-IgG immune complexes. Platelets express FcγRIIa receptors (Fcγ receptor) that react (4) with the Fc portion of IgG in immune complexes. Cross-linking of Fc receptors (5) results in FcγRIIa-dependent platelet activation. The activated platelets mediate a series of events that lead to further activation of the coagulation cascade, resulting in thrombin generation. Further release of PF4 from newly activated platelets leads to a cycle of continuing platelet activation and (6) formation of a primary clot. The reaction can be enhanced by the release of platelet-derived microparticles that are rich in surface phosphatidylserine and increase activation of coagulation and by the binding of heparin-PF4 complexes and HIT-IgG to the vascular endothelium (not shown).

◀Clinical Manifestations.

The hallmark of HIT is thrombocytopenia. A decrease of approximately 50% in the platelet count is seen in more than 95% of individuals. However, 30% or more of those with thrombocytopenia also are at risk for venous or arterial thrombosis.⁶⁶ Venous thrombosis is most common and results in deep venous thrombosis and pulmonary emboli. Arterial thromboses affect the large arteries of the lower extremities, causing acute limb ischemia. Arterial thrombosis also may lead to cerebrovascular accidents and myocardial infarctions. Other major arteries (renal, mesenteric, upper limb) also may be affected. Bleeding is uncommon in HIT, even with low platelet counts.

◀Evaluation and Treatment.

Diagnosis is primarily based on clinical observations.⁶⁷ The individual presents with dropping platelet counts after 5 days or longer of heparin treatment. On average, platelet counts may reach 60,000/mm³. Because most individuals are postsurgery and the onset of symptoms, including thrombosis, may be delayed until after release from the hospital, other possible causes of thrombocytopenia (e.g., infection, other drug reactions) must be considered.

Tests are available to measure antibodies against heparin–platelet factor 4.⁶⁸ The test sensitivity is extremely high (more than 90%), but the specificity is less because of false-positive reactions (e.g., those on

dialysis). HIT antibody titers may be measured, but the titers must be evaluated in the context of the clinical presentation. If HIT is not recognized and treated, intravascular aggregation of platelets causes rapid development of arterial and venous thrombosis. Although rare, heparin antibodies have caused anaphylactic shock.

Treatment is the withdrawal of heparin and use of alternative anticoagulants. A switch to low-molecular-weight heparin is not indicated, and warfarin should not be used until the symptoms of HIT have resolved because of an increased risk of initiating skin necrosis. The thrombocytopenia should progressively resolve. The chance of spontaneous blood clots can be diminished using thrombin inhibitors (e.g., lepirudin, argatroban).⁶⁷

Immune Thrombocytopenic Purpura.

The most common cause of thrombocytopenia secondary to increased platelet destruction is **immune thrombocytopenic purpura (ITP)**. The incidence of ITP is estimated to be 5.8 to 6.6 per 100,000 in the general population. ITP was formerly known as *idiopathic thrombocytopenic purpura*; however, it is widely recognized now as an immune process, hence the change from idiopathic to immune.⁶⁹ ITP may be acute or chronic. The acute form is frequently observed in children and typically lasts 1 to 2 months with a complete remission. In some instances it may last for up to 6 months, and some children (7% to 28%) may progress to the chronic condition. Acute ITP is usually secondary to infections (particularly viral) or other conditions that lead to large amounts of antigen in the blood, such as drug allergies or systemic lupus erythematosus (SLE) (see [Chapter 9](#)). Under these conditions the antigen usually forms immune complexes with circulating antibody, and it is thought that the immune complexes bind to Fc receptors on platelets, leading to their destruction in the spleen. The acute form of ITP usually resolves as the source of antigen is removed (e.g., the viral infection resolves).

Chronic ITP is associated with autoantibodies against platelet-specific antigens. This form is more commonly observed in adults, with the highest prevalence in women between 20 and 40 years old,

although it can develop at most any age. The chronic form tends to get progressively worse.

The autoantibodies are generally of the IgG class, although IgA and IgM antibodies also have been identified. They react against one or more of several platelet glycoproteins (e.g., GPIIb/IIIa, GPIb/IX, GPIa/IIa)⁷⁰ (see [Chapter 28](#)). The antibody-coated platelets are removed from the circulation by mononuclear phagocytes in the spleen through the Fc receptor.

◆Clinical Manifestations.

Initial manifestations are usually minor bleeding problems (development of petechiae and purpura) that occur over the course of several days and progress to major hemorrhage from mucosal sites (epistaxis, hematuria, menorrhagia, bleeding gums). Rarely will an individual present with intracranial bleeding or internal bleeding at other sites.

During pregnancy, an individual with ITP may have a newborn that is also thrombocytopenic. In most individuals the antiplatelet antibody is an IgG that readily crosses the placenta (see [Chapters 8](#) and [9](#)). If the fetal platelets express the same antigen as the mother, the maternal antibody will coat the platelets, potentially resulting in thrombocytopenia in utero. A variant of neonatal thrombocytopenia (neonatal alloimmune thrombocytopenia) occurs when the mother does not have ITP, but makes IgG antibodies against an antigen inherited from the father and found on fetal platelets but not on maternal platelets.⁷⁰ Alloimmune neonatal thrombocytopenia occurs in 1 of 2000 pregnancies. The most common antibody in this condition is against the human platelet antigen-a (HPA-a) antigen on the GPIIIa protein. Neonatal thrombocytopenia, either secondary to maternal autoimmune thrombocytopenia or as alloimmune thrombocytopenia, may occur to various degrees. The most severe form results in fetal platelet counts below 20,000/mm³ with a high associated risk of intracranial hemorrhage.

◆Evaluation and Treatment.

Diagnosis of ITP is based on a history of bleeding and associated symptoms, such as weight loss, fever, and headache. Physical examination includes notations on the types of bleeding, location, and severity. Assessment includes determination of a history of infections (bacteria, HIV, and other viruses) as well as medication history and family history; evidence of thrombosis also is assessed. Diagnostic tests include complete blood count (CBC) and peripheral blood smear. Unlike some other forms of thrombocytopenia, splenectomy is rarely observed. Testing for antiplatelet antibodies is usually not helpful. Although most cases of ITP are associated with elevated levels of IgG on platelets, other forms of thrombocytopenia also have a high incidence of platelet-associated antibodies; thus the specificity is low (50% to 65%).⁷¹ In addition, some cases of ITP will not present with elevated platelet-associated antibodies; the sensitivity is 75% to 94%, so that a negative test does not completely rule out ITP.

The acute form of ITP usually resolves without major clinical consequences. As with most autoimmune diseases, the course of the chronic form is variable, with multiple remissions and exacerbations. For many individuals the platelet count may remain adequate enough to avoid clinically serious bleeding. However, the presence of spontaneous bleeding suggests more severe disease and requires immediate attention. Treatment is initiated when platelet counts are less than 30,000/mm³ or less than 50,000/mm³ with evidence of bleeding from mucous membranes or when the individual is at high risk to develop bleeding.

Treatment is palliative, not curative, focusing on prevention of platelet destruction. Initial therapy for ITP is infusion of glucocorticoids (e.g., prednisone), which suppresses the production of antiplatelet antibodies and prevents sequestering and further destruction of platelets. If platelet counts do not increase appropriately, other medications may be tried. Treatment with intravenous immunoglobulin (IVIG) is used to prevent major bleeding. The response rate is 80%, but the effects are transient, lasting only days or a few weeks. Anti-Rh_o(D) immune globulin (anti-D), which is a preparation of antibody against the D antigen of the Rh

blood group, has been used with limited success to treat individuals who are Rh-positive.

Newer treatments include romiplostim (trade name Nplate) and eltrombopag (trade name Promacta in the United States, Revolade in the European Union). Both drugs are thrombopoiesis-stimulating Fc-peptide fusion proteins (peptibody). Romiplostim is administered subcutaneously and eltrombopag is taken orally. These drugs increase platelet counts and decrease bleeding. Romiplostim is often used as a second-line treatment after IVIG or in individuals who experience relapse postsplenectomy.

If all other therapies are ineffective, splenectomy is considered to remove the primary site of platelet destruction.⁷² The response rate (resolution of the thrombocytopenia) is 60% to 70%; however, the procedure is not without risk. Approximately 10% to 20% of individuals who undergo splenectomy suffer a relapse and require further treatment. It is thought that other reticuloendothelial organs, particularly the liver, can become major sites for platelet destruction. If splenectomy is unsuccessful and life-threatening thrombocytopenia persists, more aggressive immunosuppressive medications (e.g., azathioprine, cyclophosphamide) may be used. Because of potential major complications, these medications are reserved for individuals who are severely thrombocytopenic and refractive to other therapies.

Thrombotic Thrombocytopenic Purpura.

Thrombotic thrombocytopenic purpura (TTP; also known as Moschcowitz disease) is characterized by the concomitant occurrence of often severe thrombocytopenia and thrombotic **microangiopathy** in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation^{73,74} (Fig. 29.10). Aggregation may lead to increased platelet consumption and organ ischemia, particularly in the brain, heart, and kidneys.⁷³

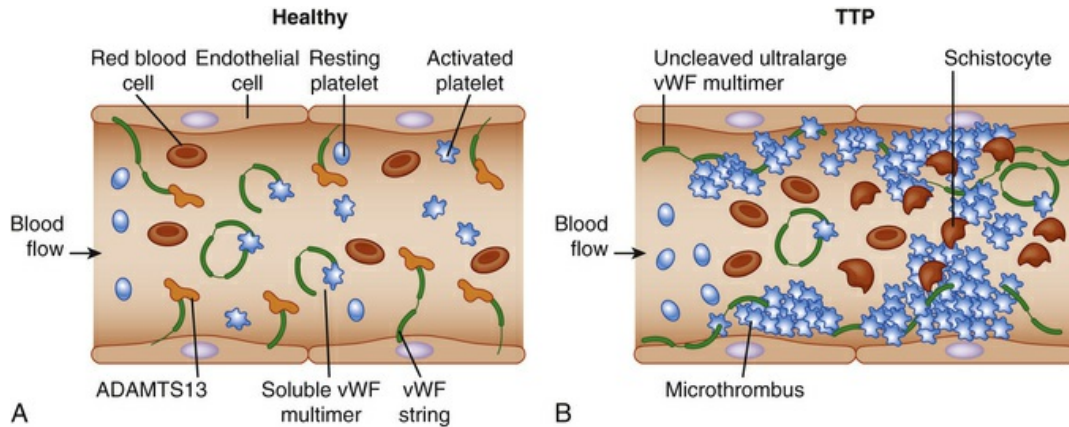

FIGURE 29.10 Thrombotic Thrombocytopenic Purpura. **A**, A microvessel (arteriole or capillary) in a healthy individual. Normal proteolysis by ADAMTS13 of ultralarge von Willebrand factor (vWF) strings anchored to or secreted from stimulated microvascular endothelial cells. **B**, A microvessel in thrombotic thrombocytopenic purpura (TTP). Cleavage of secreted or anchored ultralarge vWF is severely reduced when ADAMTS13 activity is less than 10% of normal level. The results include excessive microthrombi formation, shear stress injury to red blood cells (schistocytes) flowing through microvessels that are partially occluded by platelet clumps (producing hemolysis), and perhaps damage from activation of the alternative complement pathway on the uncleaved ultralarge vWF strings. (From Kremer Hovinga JA et al: *Nat Rev Dis Primers* 3:17020, 2017.)

TTP is relatively uncommon, occurring in about 5 per 1 million individuals per year. The incidence is increasing, which appears to be an actual increase in the number of affected individuals rather than a result of improved recognition. There are two forms of TTP: familial or acquired idiopathic. The familial form is more rare and is usually chronic, relapsing, and is seen in children. The child experiences predictable recurring episodes at approximately 3-week intervals that are responsive to treatment. Acquired TTP is more common, as well as more acute and severe. It occurs mostly in females in their thirties and is rarely observed in infants or older adults.

Platelet aggregation and microthrombi formation are found throughout the entire vascular system, causing damage to multiple organs. Although the organs most susceptible to damage are the kidney, brain, and heart, other organs often affected are the pancreas, spleen, and adrenal glands. The thrombi are primarily composed of platelets with minimal fibrin and red cells, differentiating them from thrombi secondary to intravascular coagulation. Most cases of TTP are related to a decrease or dysfunction of the plasma disintegrin and

metalloprotease ADAMTS13⁷³ (see Fig. 29.10). This enzyme is responsible for digesting large precursor molecules of von Willebrand factor (vWF), which is produced by endothelial cells, into smaller molecules. A lack of ADAMTS13 enzyme activity alters the balance between bleeding and clotting.⁷⁵ Decreases or defects in ADAMTS13 result in expression of large-molecular-weight vWF on the endothelial cell surface and formation of large aggregates of platelets. The aggregates may detach and form occlusions in smaller vessels. Most individuals with TTP (about 80%) have less than 5% of normal plasma ADAMTS13 levels. TTP also is commonly associated with an IgG autoantibody against ADAMTS13 that is able to neutralize the enzyme's activity and accelerate its clearance from the plasma.

◆Clinical Manifestations.

The rare familial **chronic relapsing TTP** observed in children is usually recognized and successfully treated. The acquired **acute idiopathic TTP** is much more common and more severe.⁷⁴ Early diagnosis and treatment are important because the disease may be fatal within 90 days of onset. TTP is clinically related to and must be distinguished from other thrombotic microangiopathic conditions, including hemolytic uremic syndrome, malignant hypertension, preeclampsia, or the pregnancy-induced HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome. Hemolytic uremic syndrome (HUS) shares many of the clinical characteristics of TTP; however, HUS often follows a hemorrhagic, diarrheal illness.

◆Evaluation and Treatment.

Acute idiopathic TTP is characterized by a “pathognomonic pentad” of symptoms. However, only 20% to 30% of people present with the classic pentad. These include extreme thrombocytopenia (less than 20,000 platelets/mm³), intravascular hemolytic anemia, ischemic signs and symptoms most often involving the CNS (about 65% present with memory disturbances, behavioral irregularities, headaches, or coma), kidney failure (affecting about 65% of individuals), and fever (present in about 33% of individuals with TTP).⁷⁴ It is not mandatory that all

five be present to begin treatment. A routine blood smear usually reveals fragmented red cells (*schizocytes; schistocytes*) produced by shear forces when red cells are in contact with the fibrin mesh in clots that form in the vessels. As a result of tissue injury, serum levels of lactate dehydrogenase (LDH) may be very high, and low-density lipoprotein (LDL) levels may be elevated. Tests for antibody on red cells are negative, excluding immune hemolytic anemia.

Untreated acute TTP has a death rate of 90%, which can be reduced to 10% to 20% with prompt treatment. Plasma exchange with fresh frozen plasma replenishes functional ADAMTS13 and is the treatment of choice, achieving a response rate of 70% to 85%. Additionally, steroids (glucocorticoids) are administered. In the absence of major organ damage, this approach may lead to complete recovery with no long-term complications. The anti-CD20 monoclonal antibody rituximab has shown some activity in people who are refractory to plasma exchange.⁷⁶ Caplacizumab, an anti-vWF, has demonstrated platelet-protective effects and an increased tendency toward bleeding as compared to placebo.⁷⁷ Relapses do occur at a rate of 13% to 36%, and recurrences have been reported, some as far out as 9 years. Individuals who do not respond to conventional treatment may be candidates for splenectomy; however, postoperative hemorrhage remains a dangerous complication. Immunosuppressive (azathioprine) therapy has been successful in some individuals.

Thrombocythemia

Thrombocythemia (also called **thrombocytosis**) is defined as a platelet count greater than 450,000/mm³ of blood.⁷⁸ Thrombocythemia may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/mm³ of blood. Then intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

◆Pathophysiology.

Secondary thrombocythemia may occur after splenectomy because platelets that normally would be stored in the spleen remain in

circulating blood. The increase in platelets may be gradual, with thrombocythemia not occurring for up to 3 weeks after splenectomy. Reactive thrombocythemia may occur from infections and during some inflammatory conditions, such as rheumatoid arthritis and cancers. In these conditions, excessive production of some cytokines (e.g., IL-6, IL-11) may induce increased production of thrombopoietin in the liver, resulting in increased megakaryocyte proliferation. Reactive thrombocythemia also may occur during a variety of physiologic conditions, such as after exercise. Because of the relatively self-resolving nature of secondary thrombocythemia, the remaining discussion will focus on the more severe primary form.

Essential (primary) thrombocythemia (ET) is a chronic myeloproliferative disorder characterized by excessive platelet production resulting from a defect in bone marrow megakaryocyte progenitor cells.⁷⁹ The overall incidence of ET is 0.8 per 100,000 in the United Kingdom, 2.53 in the United States, and 0.59 in Denmark. It is more common in middle-age individuals, with the majority of cases occurring between ages 50 and 60 years. There is no known gender preference. There also is a rare hereditary type of ET called *familial essential thrombocythemia (FET)* that is inherited in an autosomal dominant pattern.

The thrombocythemia is secondary to increased plasma thrombopoietin levels resulting from defects in the thrombopoietin receptor. The defective receptor cannot adequately bind and remove thrombopoietin from the blood; thus circulating levels remain high. Along with increased platelet levels, there may be a concomitant increase in the level of red cells, indicating a myeloproliferative disorder; however, the increase in red cell level is not to the extent seen in polycythemia vera. The bone marrow of affected individuals with ET is characterized by hyperplasia of megakaryocytes. The platelets of affected individuals appear to have a normal survival time, compatible with a defect in production rather than an increase in platelet life span.

RBCs in ET tend to aggregate and contribute to the blockage of flow in the microvasculature and altered interactions between platelets and

the vascular endothelium.⁸⁰ Increased adherence of erythrocytes to the endothelium appears to result from a mutation in an erythrocyte Janus kinase 2 gene (*JAK2*) that is responsible for phosphorylation of the erythrocyte receptor for endothelial laminin.^{81,82} The frequency of *JAK2* mutations in ET is about 30%. Increased platelet aggregation arises from several mutations that result in altered platelet membrane glycoproteins, particularly resulting in increased expression of GPIV, and increased secretion of thromboxane.

◆Clinical Manifestations.

Clinical manifestations vary significantly among individuals. Those with ET are at risk for large-vessel arterial or venous thrombosis, although the most common complication is **microvasculature thrombosis** leading to ischemia in the fingers, toes, or cerebrovascular regions.⁸⁰ The primary presenting symptoms of microvasculature thrombosis are erythromelalgia, headache, and paresthesias. **Erythromelalgia** is characterized by unilateral or bilateral warm, congested, red hands and feet with painful burning sensations, particularly in the forefoot sole and one or more toes. The lower extremities are affected more often, and only one side may be involved. The pain is initiated by standing, exercise, or warmth and relieved by elevation and cooling. In extreme situations, acrocyanosis and gangrene may result.

Arterial thrombosis is more common than venous thrombosis and may involve the coronary and renal arteries. The carotid, mesenteric, and subclavian arteries also may be affected. Myocardial ischemia and infarction have occurred without clear evidence of coronary artery disease. Deep venous thrombosis of the lower extremities and pulmonary embolism are the major sites for venous involvement. Common sites of intraabdominal venous thrombosis are in the portal and hepatic circulation. People older than 60 years of age or those with prior history of thrombotic events have as much as a 25% chance of developing a cerebral, cardiac, or peripheral arterial thrombus. Conversion to acute leukemia is found in less than 10% of affected individuals.⁸³

Microvascular thrombosis in the CNS is usually associated with headache and dizziness, with paresthesias, transient ischemic attacks, strokes, visual disturbances, and seizures also being reported. Major thrombotic events, not directly related to the platelet count, occur in about 20% to 30% of individuals with ET. Prior history of thrombotic events, advanced age, and duration of thrombocytosis are predictors of future thrombotic complications. Individuals older than age 60 are at greatest risk.

Although thrombosis is the most common symptom, hemorrhage can also occur. Sites for bleeding include the GI tract, skin, mucous membranes, urinary tract, gums, tooth sockets (after extraction), joints, eyes, and brain. GI bleeding may be mistaken for a duodenal ulcer. Hemorrhage is not severe and generally occurs in the presence of very high platelet counts, occasionally requiring transfusion. It is important to recognize that bleeding and clotting may exist simultaneously and individuals will not necessarily be “bleeders” or “clotters.”

◆Evaluation and Treatment.

Initial diagnosis is not difficult; as many as two-thirds of affected individuals are diagnosed from a routine CBC. Secondary thrombocytosis may present as a moderate rise in the platelet count that resolves with treatment or resolution of the underlying condition. The World Health Organization (WHO) criteria for the diagnosis of ET require the following four conditions be met: (1) sustained platelet count of at least $450 \times 10^9/L$; (2) bone marrow biopsy showing proliferation of enlarged mature megakaryocytes and no increase of granulocyte or erythrocyte precursors; (3) person does not meet the criteria of polycythemia vera, myelofibrosis, chronic myeloid leukemia (CML), or other myelodysplastic syndrome; and (4) presence of $JAK2^{V617F}$ or another clonal marker or evidence of reactive thrombocytosis.⁸⁴

After diagnosis, these individuals may recall events related to thrombosis or hemorrhage. Manifestations of ET may be mistaken for CML; therefore differentiation of the two is important because

treatment varies significantly. Identification of the Philadelphia chromosome is recommended in all cases of ET.

Treatment of ET is directed toward preventing thrombosis or hemorrhage.⁸⁵ The reduction of platelet count remains a significant treatment issue. Historically, treatment of ET relied on the use of alkylating agents (busulfan) or radiophosphorus (³²P) to suppress platelet production. Hydroxyurea, a nonalkylating myelosuppressive agent, has been the drug of choice to suppress platelet production; however, long-term use may cause progression to other myelodysplastic disorders, particularly AML or myelofibrosis.⁸⁵ Conversion to myelofibrosis occurs approximately 8% of the time and conversion to AML occurs approximately 3.5% of the time when treated with hydroxyurea as a single cytotoxic agent, but increases to 14% when more than one cytotoxic agent is used.

Interferon (IFN) also may be used and has a response rate of 80%. IFN may not work for everyone because it has many side effects and 20% of individuals may be intolerant. Anagrelide is now considered to be the drug of choice. Anagrelide specifically interferes with platelet maturation rather than production, thus not affecting erythropoiesis or leukopoiesis.

Aspirin also is used in the treatment of ET; however, its action is not to reduce the platelet count but to prevent adherence of platelets to each other and prevent thrombus formation. Early studies with aspirin found hemorrhage to be a major contraindication for its use; however, in lower doses (80 to 160 mg/daily) it effectively alleviates erythromelalgia and transient neurologic manifestations. Vitamin K antagonists (VKAs) are used for secondary prevention of thrombosis in those with ET.⁸⁶

Prognosis and survival of individuals with ET have been somewhat difficult to establish. ET is not necessarily considered life-threatening; however, in persons who are older than age 60 and have a history of previous incidences of thrombosis, complications are more common and have a higher risk of mortality.

Alterations of Platelet Function

Qualitative alterations in platelet function occur with an increased bleeding time in the presence of a normal platelet count. Associated clinical manifestations include spontaneous petechiae and purpura and bleeding from the GI tract, genitourinary tract, pulmonary mucosa, and gums. Congenital alterations in platelet function (thrombocytopathies) are quite rare and may be categorized into several types of disorders: (1) platelet–vessel wall adhesion, (2) platelet-platelet interactions, (3) platelet granules and secretion, (4) arachidonic acid pathways, and (5) membrane phospholipid regulation (coagulation protein–platelet interactions).⁸⁷

Disorders of platelet–vascular wall adhesion result from aberrations of the platelet membrane glycoprotein GPIb/IX/V (Bernard-Soulier syndrome), anomalies of the collagen receptor GPVI, or deficiencies of vWF. The GPIb protein is the most commonly mutated protein in individuals with Bernard-Soulier syndrome. Lack of these proteins prevents platelets from adhering to collagen, resulting in impaired hemostasis and clinical hemorrhage.

Disorders of platelet-platelet interactions result in failure of platelets to aggregate in response to adenosine diphosphate (ADP), collagen, epinephrine, or thrombin because of a deficiency in the glycoprotein (α IIb β ₃) that acts as a receptor for fibrinogen, vWF, and fibronectin (Glanzmann thrombasthenia). Lack of this glycol protein results in a failure to build “fibrinogen bridges” between platelets (see [Fig. 28.21](#)). Defects also can occur in platelet receptors for platelet activators. These include mutations in the receptors for thromboxane or ADP.

Disorders of platelet granules and secretion and disorders of arachidonic pathways are characterized by initial normal platelet aggregation with collagen or ADP; however, subsequent processes fail, specifically secretion of prostaglandins and release of granules. Defective α -granule numbers or release (gray platelet syndrome) results from mutations in several aspects of granule function, including biosynthesis or loading of proteins normally found in these granules. Defects in dense granules include Hermansky-Pudlak syndrome, Chédiak-Higashi syndrome, and delta-storage pool disease. These usually result from mutations in proteins involved in

formation of dense granules or their movement to the plasma membrane. Defects in the thromboxane pathway prevent the release of this mediator.

Externalization of plasma membrane phosphatidylserine (PS) is necessary for effective platelet function. In Scott syndrome, the enzyme responsible for PS efflux is defective; thus platelets are unable to support the activation of factor X and prothrombin. The reverse of Scott syndrome is Stormorken syndrome, in which platelets constitutively externalize PS.

Acquired disorders of platelet function are more common than the congenital disorders and may be categorized into three principal causes: (1) drug effects, (2) systemic inflammatory conditions, and (3) hematologic conditions.

Multiple drugs are known to affect platelet function in several ways: inhibition of platelet membrane receptors, inhibition of prostaglandin pathways, and inhibition of phosphodiesterase activity. Aspirin is the most commonly used drug that affects platelets and the only drug specifically used for its platelet effects. It irreversibly inhibits cyclooxygenase function for several days after administration. Nonsteroidal antiinflammatory drugs also affect cyclooxygenase, although in a reversible fashion.

Systemic disorders that affect platelet function are chronic renal disease, liver disease, cardiopulmonary bypass surgery, severe deficiencies of iron or folate, and the presence of antiplatelet antibodies associated with autoimmune disorders. Hematologic disorders that cause platelet dysfunction are chronic myeloproliferative disorders, multiple myeloma, leukemias, myelodysplastic syndromes, and dysproteinemias.

Disorders of Coagulation

Disorders of coagulation usually are caused by defects or deficiencies of one or more of the clotting factors. (Normal function of the clotting factors is described in [Chapter 28](#).) Qualitative or quantitative abnormalities of clotting factors interfere with or prevent the enzymatic reactions that transform circulating clotting proteins into a

stable fibrin clot (see [Fig. 28.22](#)).

Some clotting factor defects are inherited and usually involve a single factor, such as hemophilias and von Willebrand disease, caused by deficiencies of specific clotting factors (see [Chapter 31](#)). Other coagulation defects are acquired and tend to result from deficient synthesis of clotting factors by the liver. Causes include liver disease and dietary deficiency of vitamin K.

Other coagulation disorders are attributed to pathologic conditions that trigger coagulation inappropriately. For example, any cardiovascular abnormality that alters normal blood flow by accelerating, decelerating, or obstructing it can result in spontaneous coagulation within the vessels. Coagulation is also stimulated by the presence of tissue factor, which is released by damaged or dead tissues. **Vasculitis**, or inflammation of the blood vessels, as well as vessel damage, activates platelets, which in turn activates the coagulation cascade. In extensive or prolonged vasculitis, blood clot formation can suppress mechanisms that normally control clot formation and breakdown, leading to clogging of the vessels. In each of these acquired conditions, normal hemostatic function proves detrimental to the body by consuming coagulation factors excessively or by overwhelming the normal control of clot formation and breakdown (fibrinolysis).

Impaired Hemostasis

Impaired hemostasis, or the inability to promote coagulation and the development of a stable fibrin clot, is commonly associated with liver disorders, resulting either from the lack of vitamin K or from specific diseases of the liver.

Vitamin K Deficiency.

Vitamin K, a fat-soluble vitamin, is necessary for synthesis and regulation of prothrombin, procoagulant factors (VII, IX, X), and anticoagulant regulators (proteins C and S) within the liver.⁸⁸ Vitamin K is found in green leafy vegetables, which is its primary dietary source. Vitamin K also is synthesized by intestinal flora, but its

contribution to the overall supply of vitamin K is uncertain. The most common cause of vitamin K deficiency is parenteral nutrition in combination with broad-spectrum antibiotics that destroy normal gut flora. Rarely is a deficiency caused by lack of dietary intake; however, bulimia can suppress vitamin K-dependent activity. Clinical manifestations of vitamin K deficiency are caused by a reduction of vitamin K-dependent proteins. The severity of manifestations is related to the degree of deficiency and ranges from laboratory abnormalities to significant hemorrhage.

Parenteral administration of vitamin K is the treatment of choice and usually results in correction of the deficiency. Improvement of clotting tests is usually noted within 8 to 12 hours. Fresh frozen plasma may be administered but usually is reserved for individuals with life-threatening hemorrhages or who require emergency surgery.

Liver Disease.

Individuals who have liver disease (e.g., acute or chronic hepatocellular diseases, cirrhosis, vitamin K deficiency) or major liver surgery present with a broad range of hemostasis derangements that may be characterized by defects in the clotting or fibrinolytic systems or in platelet function.⁸⁸ The hepatic parenchymal cells produce most of the factors involved in hemostasis. Thus damage to the liver frequently results in diminished production of factors involved in clotting, usually in proportion to the degree of hepatic parenchymal cell damage. For instance, factor VII is most sensitive to liver damage because of its rapid turnover. Factor IX levels are less affected and do not decline until liver destruction is well advanced. The liver is also a major site for production of plasminogen and α_2 -antiplasmin of the fibrinolytic system, as well as thrombopoietin and the metalloprotease ADAMTS13. Diminished levels of thrombopoietin may lead to thrombocytopenia from decreased platelet production. Decreased production of ADAMTS13 results in increased levels of large precursor molecules of vWF, which leads to the formation of large aggregates of platelets.

In conditions of severe liver disease (e.g., cirrhosis), circulating

levels of most clotting factors are significantly depressed. Concurrently, production of clotting system regulators (e.g., antithrombin, protein C, protein S) and of fibrinogen is diminished. The fibrinolytic system is commonly active because of decreased levels of plasmin inhibitor and unaffected levels of fibrinolytic activators (e.g., tissue plasminogen activator [tPA], urokinase-like plasminogen activator [uPA]). The affected individuals also are thrombocytopenic because of diminished production of thrombopoietin and ADAMTS13, as well as increased platelet sequestration in the spleen, which is frequently enlarged in cirrhosis and is associated with portal hypertension. Thus individuals with cirrhosis may appear to have a condition similar to DIC (see [Consumptive Thrombohemorrhagic Disorders](#)).

Treatment of hemostatic alterations in liver disease must be comprehensive to cover all aspects related to platelet, clotting, and fibrinolytic dysfunctions. Fresh frozen plasma administration is the treatment of choice, but not all individuals tolerate the volume needed to adequately replace all deficient factors. Alternative modalities include the addition of exchange transfusions and platelet concentration to plasma administration.

Consumptive Thrombohemorrhagic Disorders

Consumptive thrombohemorrhagic disorders are a heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions. Symptoms range from subtle to devastating and generally are considered to be intermediary disease processes that complicate many primary disease states. These disorders also are characterized by confusion and controversy regarding diagnosis, treatment, and management. No one definition can cover all possible varieties of these disorders; however, disseminated intravascular coagulation is the most common term used in the clinical setting to describe a pathologic condition associated with hemorrhage and thrombosis.

Disseminated Intravascular Coagulation.

Disseminated intravascular coagulation (DIC) is an acquired clinical syndrome characterized by widespread activation of coagulation resulting in formation of fibrin clots in medium and small vessels (microvasculature) throughout the body. Disseminated clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The magnitude of clotting may result in consumption of platelets and clotting factors leading to severe bleeding. The Subcommittee on DIC of the International Society on Thrombosis and Haemostasis (ISTH) defined DIC as “An acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction.”⁸⁹ The ISTH has contributed to defining better criteria and clinical management strategies.⁹⁰

The clinical course of DIC largely is determined by the intensity of the stimulus, host response, and comorbidities, and it ranges from an acute, severe, life-threatening process that is characterized by massive hemorrhage and thrombosis to a chronic low-grade condition. The chronic condition is characterized by subacute hemorrhage and diffuse microcirculatory thrombosis. DIC may be localized to one specific organ or generalized, involving multiple organs.

Because of the complexity and wide variations in manifestations of DIC, diagnosis has been challenging. Diagnostic criteria have been established and include a systemic thrombohemorrhagic disorder with laboratory evidence of (1) clotting activation, (2) fibrinolytic activation, (3) coagulation inhibitor consumption, and (4) biochemical evidence of end-organ damage or failure.

DIC is secondary to a wide variety of well-defined clinical conditions, specifically those capable of activating the clotting cascade (Box 29.3). These include (1) arterial hypotension, frequently accompanying shock; (2) hypoxemia; (3) acidemia; and (4) stasis of capillary blood flow.

Box 29.3

Clinical Conditions Associated With Disseminated Intravascular Coagulation

SEPSIS OR SEVERE INFECTION

Potentially from any microorganism, including malaria

TRAUMA

Serious head injury
Head injury
Fat metabolism
Burns

LIVER DISEASES

Fulminant hepatitis
Severe liver cirrhosis

HEAT STROKE ORGAN DESTRUCTION

Severe pancreatitis

MALIGNANCY

Solid tumors
Hematologic cancers

OBSTETRIC CALAMITIES

Preeclampsia or eclampsia
Placental abruption
Amniotic fluid embolism
HELLP (hemolysis, elevated liver enzymes, and low platelet

count) syndrome
Acute fatty liver
Sepsis during pregnancy

VASCULAR ABNORMALITIES

Hemangioma
Leaking or ruptured aneurysm (such as in the aorta)
Aortic aneurysm
Kasabach-Merritt syndrome
Other vascular malformations

SEVERE TOXIC OR IMMUNOLOGIC REACTIONS

Snake bite
Recreational drug use
Severe transfusion reaction
Transplant rejection

Data from Gando S, Levi M, Toh CH: *Nat Rev Dis Primers* 2:16037, 2016.

Sepsis is the most common condition associated with DIC. Gram-negative microorganisms (as well as some gram-positive microorganisms), fungi, protozoa (malaria), and viruses (influenza, herpes) are capable of precipitating DIC by causing damage to vascular endothelium. Gram-negative endotoxins are the primary cause of endothelial damage; DIC may occur in up to 50% of individuals with gram-negative sepsis. DIC occurs in approximately 10% to 20% of individuals with metastatic cancer or acute leukemia. Direct tissue damage (ischemia and necrosis, surgical manipulation, crushing injury) also results in release of tissue factor (TF) by the endothelium. Severe trauma, especially to the brain, can induce DIC. DIC occurs in about two-thirds of individuals with a systemic inflammatory response to trauma. Some complications of pregnancy

also are associated with DIC; incidence ranges from 50% for women with placental abruptions to less than 10% for severe preeclampsia. Other causes of DIC have been identified, most notably blood transfusion. Transfused blood dilutes the clotting factors, as well as circulating naturally occurring antithrombins. In hemolytic transfusion reactions, the endothelium is damaged by complement-mediated reactions.

◆Pathophysiology.

The coagulation system is designed to function at local areas of vascular damage, resulting in cessation of bleeding and activation of repair to the vessels. DIC results from abnormally widespread and ongoing activation of clotting (Fig. 29.11). A variety of conditions are associated with DIC (see Box 29.3). The common pathway for DIC appears to be excessive and widespread exposure of TF.⁹¹ This may occur by several mechanisms. Widespread damage to the vascular endothelium results in exposure of subendothelial TF. Several types of cells, either produced after stimulation by cytokines or occurring constitutively, express TF on their surfaces. Normally, endothelial cells and monocytes do not express surface TF unless stimulated by inflammatory cytokines (particularly IL-6 and TNF- α).⁹² Many tumors express surface TF or produce cytokines that stimulate TF expression by the endothelium or monocytes, or both.⁹³ These cytokines are abundantly produced during many of the conditions listed in Box 29.3. Endotoxin, in particular, triggers the release of multiple cytokines that play a significant role in the development and maintenance of DIC. Proinflammatory cytokines (TNF- α , interleukins [IL-1, IL-6, IL-8], and platelet-activating factor [PAF]) are responsible for the clinical signs and symptoms associated with sepsis. They also contribute to the development of DIC by activating endothelial cells, causing release of TF and vWF, increasing plasminogen activator inhibitor-1 (PAI-1) synthesis and tissue factor activity, and decreasing thrombomodulin expression, thereby promoting development of thrombi. TF also may be released directly into the bloodstream from circulating white blood cells (monocyte/endotoxin interaction).⁹¹

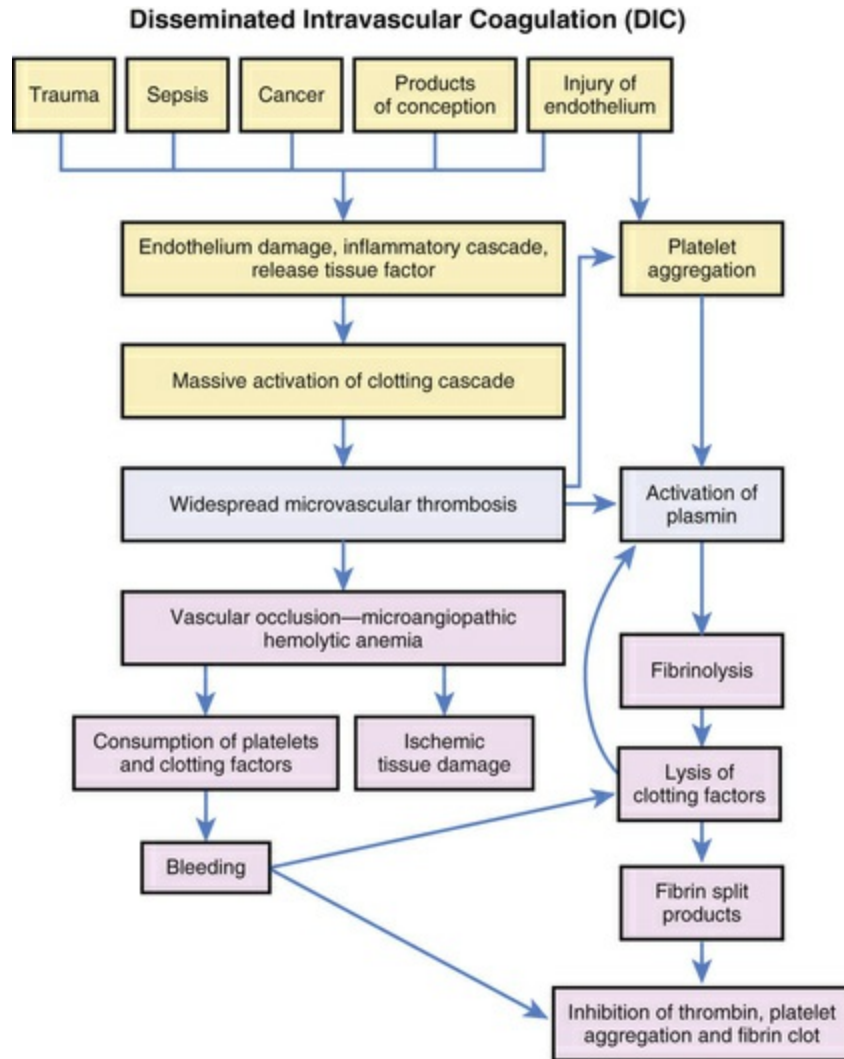

FIGURE 29.11 Pathophysiology of Disseminated Intravascular Coagulation. See text.

TF binds clotting factor VII, which leads to conversion of prothrombin to thrombin and formation of fibrin clots (see Fig. 28.22). This pathway appears to be the primary route by which DIC is initiated; inhibition of TF or factor VIIa completely prevents the generation of thrombi by gram-negative bacterial endotoxin in animal models of DIC.

Not only is the clotting system extensively activated in DIC, but levels of the predominant natural anticoagulants (tissue factor inhibitor, antithrombin III [AT-III], protein C) are also greatly diminished (see Fig. 28.19). During DIC the activation of clotting is prolonged both by the increased rate of consumption of clotting

factors and platelets, because of persistent thrombin production as well as decreased synthesis of the natural anticoagulants and protein S, and by the cytokine-mediated decreased expression of thrombomodulin on the endothelial cell surface. Hepatic dysfunction in sepsis results in decreased antithrombin synthesis and extravascular leakage of this protease inhibitor because of capillary leakage. Additionally, antithrombin is degraded by elastase released by activated neutrophils, and clotting is initiated concurrently with loss of regulation of the extent of thrombosis; thus the amount of thrombin produced during DIC exceeds the ability of the body's naturally occurring anticoagulants to regulate it.

The rate of fibrinolysis is also diminished in DIC. The primary component of fibrinolysis is plasmin, which exists in the circulation as an inactive precursor, plasminogen (see [Fig. 28.24](#)). Plasminogen is activated to plasmin that digests fibrin clots, thus controlling the extent of fibrin deposition in the vessels. During DIC the activity of plasmin is diminished by increased production of its natural inhibitor, PAI-1. Although some fibrinolytic activity remains, the level is inadequate to control the systemic deposition of fibrin. The slow breakdown of fibrin by plasmin produces fibrin degradation products (FDPs) that are released into the blood. These are potent anticoagulants that are normally removed from blood by fibronectin and macrophages. FDPs, along with thrombin, induce further cytokine release from monocytes, contributing to endothelial damage and TF release. During DIC the presence of fibrin degradation products is prolonged, probably because of diminished production of fibronectin. Fibronectin is a glycoprotein with adhesive properties that mediate removal of particulate matter (e.g., fibrin clumps). Low levels of fibronectin suggest a poor prognosis.

Although thrombosis is generalized and widespread, individuals with DIC are paradoxically at risk for hemorrhage. Hemorrhage is secondary to the abnormally high consumption of clotting factors and platelets, as well as the anticoagulant properties of FDPs, which interfere with polymerization of fibrin monomers. Both thrombin and FDPs have a high affinity for platelets and cause platelet activation

and aggregation—an event that occurs early in the development of DIC and that facilitates microcirculatory coagulation and obstruction in the initial phase. However, platelet consumption exceeds production, resulting in a thrombocytopenia that increases bleeding.

Activation of clotting also leads to activation of other inflammatory pathways, including the kallikrein-kinin and complement systems (see [Chapter 7](#)). Factor XIIa, generated in DIC, converts prekallikrein to kallikrein, ultimately resulting in conversion to circulating kinins. Activation of these systems contributes to increased vascular permeability, hypotension, and shock. Activated complement components also induce platelet destruction, further contributing initially to the thrombosis and later to the thrombocytopenia.

The deposition of fibrin clots in the circulation interferes with blood flow, causing widespread organ hypoperfusion. This condition may lead to ischemia, infarction, and necrosis, further potentiating and complicating the existing DIC process by causing additional release of TF and eventually organ failure.

In addition to initiation of clotting by TF, DIC may be precipitated by direct proteolytic activation of factor X. This has been described as “thrombin mimicry” and is the result of activated factor X directly converting fibrinogen to fibrin. The proteases that activate factor X may come from snake venom, some tumor cells, or the pancreas and liver, where they are released during episodes of pancreatitis and various stages of liver disease. Direct proteolytic activity appears to be independent of any type of damage to the endothelium or tissue.

Vascular obstruction results from circulatory deposition of thrombin and clot formation that impedes blood flow, causing widespread organ hypoperfusion that can lead to tissue ischemia, infarction, and necrosis. The resulting tissue damage further potentiates and complicates the existing DIC process. Because organ perfusion is drastically impaired, manifestations of multisystem organ dysfunction and failure ultimately result. Multisystem organ dysfunction and failure are discussed in [Chapter 49](#). Whatever initiates the process of DIC, the cycle of thrombosis and hemorrhage persists until the underlying cause of the DIC is removed or

appropriate therapeutic interventions are used.

◆Clinical Manifestations.

Clinical signs and symptoms of DIC present a wide spectrum of possibilities, depending on the underlying disease process that initiates DIC and whether the DIC is acute or chronic (Box 29.4). Most symptoms are the result of either hemorrhage or thrombosis. Acute DIC presents with rapid development of hemorrhaging, such as oozing from venipuncture sites, arterial lines, and surgical wounds, or development of ecchymotic lesions (purpura, petechiae) and hematomas. Other sites of bleeding include the eyes (sclera and conjunctiva), the nose (epistaxis), and the gums. Most individuals with DIC demonstrate bleeding at three or more unrelated sites, and any combination may be observed. Shock of variable intensity, out of proportion to the amount of apparent blood loss, also may be observed. Hemorrhaging into closed compartments of the body also can occur and may precede the development of shock.

Box 29.4

Clinical Manifestations Associated With Disseminated Intravascular Coagulation (DIC)

Integumentary System

- Widespread hemorrhage and vascular lesions
- Oozing from puncture sites, incisions, mucous membranes
- Acrocyanosis (irregularly shaped cyanotic patches)
- Gangrene

Central Nervous System

- Subarachnoid hemorrhage

Altered state of consciousness (from slight confusion to convulsions and coma)

Gastrointestinal System

Occult bleeding to massive gastrointestinal bleeding

Abdominal distention

Malaise

Weakness

Pulmonary System

Pulmonary infarctions

Acute respiratory distress syndrome (ARDS)

Cyanosis

Tachypnea

Hypoxemia

Renal System

Hematuria

Oliguria

Renal failure

Modified from Bailes BK: *AORN J* 55(2):517–529, 1992.

DIC has been conceptualized as a systemic hemorrhagic disorder because bleeding, sometimes very extensive, is usually the initial observation. Symptoms of thrombosis are not always as evident, even though it is often the first pathologic alteration to occur and ultimately determines the degree of morbidity and risk for death. A large amount of microvascular and macrovascular occlusion may occur that is not clinically obvious. Several organ systems are susceptible to

microvascular thrombosis that affects their function; these include the cardiovascular, pulmonary, central nervous, renal, and hepatic systems. Quick and accurate clinical diagnosis is critical to preventing further progression of DIC that may lead to multisystem organ dysfunction or failure. Indicators of multisystem failure include changes in level of consciousness, behavior, and mentation; confusion; seizure activity; oliguria; hematuria; hypoxia; hypotension; hemoptysis; chest pain; and tachycardia. Symmetrical cyanosis of the fingers and toes (“blue finger/toe syndrome”) and, in some instances, of the nose and breasts may be present. Symmetrical parts are often affected and are indicative of microvascular thrombosis. This may progress to infarction and gangrene, requiring amputation. Jaundice also may be present and is believed to result from red blood cell destruction rather than hepatic dysfunction.

Individuals with chronic or low-grade DIC do not present with overt manifestations of hemorrhaging and thrombosis but instead have subacute bleeding and diffuse thrombosis and are described as having a **compensated DIC**, or non-overt DIC. The major characteristic of this state is an increased turnover and decreased survival time of the components of hemostasis: platelets and clotting factors. Occasionally, diffuse or localized thrombosis develops, but this is infrequent.

◆ **Evaluation and Treatment.**

No single laboratory test can be used to effectively diagnosis DIC. Diagnosis is based primarily on clinical symptoms and confirmed by a combination of laboratory tests. The individual must present with a clinical condition that is known to be associated with DIC. The most commonly used combination of laboratory tests usually confirms thrombocytopenia or a rapidly decreasing platelet count on repeated testing, prolongation of clotting times, the presence of fibrin degradation products, and decreased levels of coagulation inhibitors. The relationships among these criteria are summarized in [Box 29.5](#). Platelet counts less than $100,000/\text{mm}^3$ or a progressive decrease in platelet counts is very sensitive for DIC, although not greatly specific.

These changes usually indicate consumption of platelets.

Box 29.5

Laboratory Diagnostic Criteria for Disseminated Intravascular Coagulation (DIC)*

Group I Tests (Indicators of Procoagulant Activation)

1. Elevated prothrombin fragment 1+2
2. Elevated fibrinopeptide A
3. Elevated fibrinopeptide B
4. Elevated thrombin-antithrombin (TAT) complex
5. Elevated D-dimer

Group II Tests (Indicators of Fibrinolytic Activity)

1. Elevated D-dimer
2. Elevated fibrin degradation products (FDPs)
3. Elevated plasmin
4. Elevated plasmin-antiplasmin (PAP) complex

Group III Tests (Indicators of Inhibitor Consumption)

1. Decreased antithrombin III
2. Decreased α_2 -antiplasmin
3. Decreased heparin cofactor II
4. Decreased protein C or S
5. Elevated TAT complex
6. Elevated PAP complex

Group IV Tests (Indicators of End-Organ Damage/Failure)

1. Elevated lactic dehydrogenase (LDH)
2. Elevated creatinine
3. Decreased pH
4. Decreased PaO₂

*Satisfactory criteria for laboratory diagnosis of DIC require one abnormality in each of groups I through III and at least two abnormalities in group IV.

Data from Bick RL: *Semin Thromb Hemost* 24(1):3, 1998.

The standard coagulation tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]) also have a high degree of sensitivity, but they are not highly specific for DIC. As a result of consumption of circulating clotting factors, these tests are usually abnormal, ranging from shortened to prolonged times. However, conditions other than DIC may prolong clotting times. Assays of specific clotting factors do not contribute meaningful diagnostic information.

Detection of various fibrin degradation products is more specific for DIC; of these tests the detection of D-dimers is the most widely used, reliable, and specific test.⁹⁴ A **D-dimer** is a molecule produced by plasmin degradation of cross-linked fibrin in clots. D-dimers in the blood can be quantified using enzyme-linked immunosorbent assay (ELISA) tests that include commercially available and highly specific monoclonal antibody against the D-dimer. Agglutination tests for other fibrin degradation products are available. Levels of fibrin degradation products, in general, are elevated in the plasma in 95% to 100% of cases; however, concentrations of FDPs are less specific and only document the presence of plasmin and its action on fibrin, whereas detection of D-dimers measures a specific DIC-related

product.

ELISAs for markers of thrombin activity are sometimes used. Normal conversion of prothrombin to thrombin produces an inactive prothrombin fragment 1.2 (PF1+2).⁹⁴ This fragment is released from the prothrombin molecule, generating an intermediate factor, prethrombin 2. Once generated, prethrombin 2 can either split to produce thrombin, which can then proteolyze fibrinogen and thus liberate fibrinopeptide A (FPA), or can combine with its major antagonist (antithrombin) and form a stable inactive enzyme–inhibitor complex, the thrombin-antithrombin (TAT) complex. Assays of these factors (PF1+2, FPA, TAT) are now generally available to quantify their blood levels, providing evidence of excessive factor Xa (PF1+2) and thrombin (FPA) generation.

Levels of coagulation inhibitors (e.g., AT-III, protein C) can be measured by assays that rely on function or by ELISAs that quantify the amount of the specific inhibitor. AT-III levels can provide key information for diagnosing and monitoring therapy for DIC. Initial levels of functional AT-III are low in DIC because thrombin is irreversibly complexed with activated clotting factors and AT-III.

Treatment of DIC is directed toward (1) eliminating the underlying pathology, (2) controlling ongoing thrombosis, and (3) maintaining organ function. Elimination of the underlying pathology is the initial intervention in the treatment phase in order to eliminate the trigger for activation of clotting. Once the stimulus is gone, production of coagulation factors in the liver leads to restoration of normal plasma levels within 24 to 48 hours.

Control of thrombosis is more difficult to attain. Heparin has been used for this; however, its use is controversial because its mechanism of action is binding to and activating AT-III, which is deficient in many types of DIC. Currently heparin is indicated only in certain situations related to DIC. For instance, heparin seems to be effective in DIC caused by a retained dead fetus or associated with acute promyelocytic leukemia. Organ function is compromised by microthrombi, and there is a risk of losing an extremity because of vascular occlusion; thus heparin is also indicated in these conditions.

Heparin's usefulness, however, for DIC that is precipitated by septic shock has not been established and so is contraindicated in that instance; heparin is also contraindicated when there is evidence of postoperative bleeding, peptic ulcer, or CNS bleeding.

Replacement therapy (interventions based on restoring the balance of coagulation factors, deficient coagulation factors, platelets, and other coagulation elements) is gaining recognition as an effective treatment modality. Components used in replacement therapy include platelets, fresh frozen plasma, and cryoprecipitate. Platelets are given for thrombocytopenia, plasma provides volume and replaces clotting factors, and cryoprecipitate replaces fibrinogen. Their use is not without controversy, however, because of the possible risk of adding components that will increase the rate of thrombosis. Clinical judgment is the key factor in determining whether replacement is to be used as a treatment modality.

Several clinical trials are evaluating replacement of anticoagulants (i.e., AT-III, protein C). Studies assessing the use of anticoagulants are presented in the review by Gando and colleagues.⁹¹ Antifibrinolytic drugs also are used in treatment but are limited to instances of life-threatening bleeding that have not been controlled by blood component replacement therapy. Maintenance of organ function is achieved by fluid replacement to sustain adequate circulating blood volume and to maintain optimal tissue and organ perfusion. Fluids may be required to restore blood pressure, cardiac output, and urine output to normal parameters.

Thromboembolic Disease

Certain conditions within the blood vessels predispose an individual to develop clots spontaneously.⁹⁵ A stationary clot attached to the vessel wall is called a **thrombus** (Fig. 29.12). A thrombus is composed of fibrin and blood cells and can develop in either the arterial or the venous system. **Arterial thrombi** form under conditions of high blood flow and are composed mostly of platelet aggregates held together by fibrin strands. **Venous thrombi** form in conditions of low flow and are composed mostly of red cells with larger amounts of fibrin and

few platelets.

FIGURE 29.12 Thrombus. Thrombus arising in valve pocket at upper end of superficial femoral vein. Postmortem clot on the right is shown for comparison. (From McLachlin J, Paterson JC: *Surg Gynecol Obstet* 93:1, 1951.)

A thrombus may eventually grow large enough to reduce or obstruct blood flow to tissues or organs, such as the heart, brain, or lungs, depriving them of essential nutrients critical to survival. A thrombus also has the potential of detaching from the vessel wall and circulating within the bloodstream (referred to as an **embolus**). The embolus may become lodged in smaller blood vessels, blocking blood flow into the local tissue or organ and leading to ischemia. The potential for episodes of thromboembolism to become life-threatening depends on the site of vessel occlusion.

Therapy consists of removal or breakdown of the clot and provision of supportive measures. Anticoagulant therapy is effective in treating or preventing venous thrombosis; it is not as useful in treating or preventing arterial thrombosis. Parenteral heparin is the major

anticoagulant used to treat thromboembolism. Oral coumarin drugs also are widely used, particularly for individuals not hospitalized. More aggressive therapy may be indicated for such conditions as pulmonary embolism, coronary thrombosis, or thrombophlebitis. Streptokinase and urokinase activate the fibrinolytic system and are administered to accelerate the lysis of known thrombi. Thrombolytic therapy has limited uses and is prescribed with a high degree of caution because it can cause hemorrhagic complications.

The risk for developing spontaneous thrombi is related to several factors, referred to as the **Virchow triad**: (1) injury to the blood vessel endothelium, (2) abnormalities of blood flow, and (3) hypercoagulability of the blood.

Vascular endothelial injury can result from atherosclerosis (plaque deposits on arterial walls). Atherosclerosis initiates platelet adhesion and aggregation, promoting the development of atherosclerotic plaques that enlarge, causing further damage and occlusion. Other causes of vessel endothelial injury may be related to hemodynamic alterations associated with hypertension and turbulent blood flow. Injury also is caused by radiation injury, exogenous chemical agents (toxins from cigarette smoke), endogenous agents (cholesterol), bacterial toxins or endotoxins, or immunologic mechanisms. Whatever the precipitating cause of endothelial injury, it is a potent thrombogenic agent.

Turbulent blood flow in the arteries and stasis of blood flow in the veins are at-risk conditions for thrombus formation. In areas of turbulence, platelets and endothelial cells may be activated, leading to thrombosis. In sites of stasis, platelets may remain in contact with the endothelium for prolonged times, and clotting factors that would normally be diluted with fresh-flowing blood are not diluted and may become activated. The most common clinical conditions that predispose to venous stasis and subsequent thromboembolic phenomena are major surgery (e.g., orthopedic surgery), acute myocardial infarction, congestive heart failure, limb paralysis, spinal injury, malignancy, advanced age, the postpartum period, and bed rest longer than 1 week. Turbulence and stasis occur with ulcerated

atherosclerotic plaques (myocardial infarction), hyperviscosity (polycythemia), and conditions with deformed red cells (sickle cell anemia).

Hypercoagulability, or **thrombophilia**, is the condition in which an individual is at risk for thrombosis. Hypercoagulability is differentiated according to whether it results from primary (hereditary) or secondary (acquired) causes. Primary causes include defects in proteins involved in hemostasis. Secondary causes include a variety of clinical disorders or conditions ([Box 29.6](#)). It is not well understood why there is not a greater incidence of thrombosis formation in hypercoagulable states associated with various disease states and conditions.

Box 29.6

Hypercoagulable States

Primary (Genetic)

Common

Factor V mutation (Arg to Glu substitution in amino acid residue 506 leading to resistance to activated protein C; factor V Leiden)

Prothrombin mutation (G20210A noncoding sequence variant leading to increased prothrombin levels)

Increased levels of factors VIII, IX, XI, or fibrinogen (genetics unknown)

Rare

Antithrombin III deficiency

Protein C deficiency

Protein S deficiency

Very Rare

Fibrinolysis defects

Homozygous homocystinuria (deficiency of cystathionine β -synthetase)

Secondary (Acquired)

High Risk for Thrombosis

Prolonged bed rest or immobilization

Myocardial infarction

Atrial fibrillation

Tissue injury (surgery, fracture, burn)

Cancer

Prosthetic cardiac valves

Disseminated intravascular coagulation

Heparin-induced thrombocytopenia

Antiphospholipid antibody syndrome

Lower Risk for Thrombosis

Cardiomyopathy

Nephrotic syndrome

Hyperestrogenic states (pregnancy and postpartum)

Oral contraceptive use

Sickle cell anemia

Smoking

From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.

Hereditary Thrombophilias.

A large number of inherited conditions have been identified that

increase the risk of developing thrombosis. Most are autosomal dominant; thus individuals who are homozygous for the mutation are at greatest risk for thrombosis. These include mutations in coagulation proteins, fibrinolytic proteins, platelet receptors, and other factors. The mutations most strongly linked as risk factors for venous thrombosis or for arterial thrombosis leading to coronary artery disease or stroke include those that affect prothrombin (G20210A variant) and factor V (factor V Leiden) of the coagulation system. Other inherited thrombophilias are reviewed in [Box 29.6](#).

Factor V Leiden results from a single nucleotide mutation of guanine to adenine at nucleotide 1691 (G1691A). Activated factor V (Va) is usually inactivated by protein C, but this single mutation results in a change in amino acid 506 from arginine to glutamine. The change alters the site where protein C would cleave factor Va and confers partial resistance, resulting in prolonged high levels of Va and prolongation of clot formation.⁹⁶ Although this mutation increases the risk for thrombosis, most individuals with factor V Leiden do not have clinically relevant thrombotic events. It is the most common hereditary thrombophilia and is found in about 30% of individuals presenting with deep venous thrombosis (DVT) or pulmonary embolism. It is primarily observed in individuals of European ancestry and in about 5% of whites in the United States and Europe.

The second most common inherited form of thrombophilia (after factor V Leiden) is a mutation in the *F2* gene. The mutation that causes prothrombin thrombophilia results in an overactive *F2* gene that causes too much prothrombin to be produced.⁹⁷ An increase in prothrombin levels leads to more thrombin which promotes the formation of blood clots.⁹⁷ Other factors that increase the risk of blood clots include increasing age, obesity, trauma, surgery, smoking, use of oral contraceptives or hormone replacement therapy, and pregnancy. Other mutations in genes involved in blood clotting also can influence risk.⁹⁷

Acquired Hypercoagulability.

The acquired thrombophilias are often multifactorial ([Box 29.7](#)). An

example of an acquired hypercoagulable state is antiphospholipid syndrome (APS), an autoimmune syndrome characterized by autoantibodies against plasma membrane phospholipids and phospholipid-binding proteins. As with most autoimmune diseases, the predominantly affected individual is female and of reproductive age. Those with APS are at risk for arterial and venous thrombosis and a variety of obstetric complications, including pregnancy loss and preeclampsia or eclampsia (Fig. 29.13).⁹⁸ In severe cases the person may die from recurrent major thrombus formation.⁹⁹ The pathophysiology is related to autoantibodies directly reacting with platelets or endothelial cells (increasing the risk for thrombosis) or the placental surface (resulting in damage to the placenta). The predominant diagnostic tests measure prolongation of laboratory blood coagulation tests related to an antibody inhibitor (lupus anticoagulant) and specific ELISAs for antibodies against phospholipids (e.g., anticardiolipin antibody) or proteins that bind to phospholipids (e.g., β_2 -glycoprotein I).^{100,101} Highly effective therapy (i.e., unfractionated or low-molecular-weight heparin with low-dose aspirin) is available to prevent the obstetric complications.¹⁰²

Box 29.7

Clinical Conditions Associated With High Risk for Thrombosis or Thromboembolism

ARTERIAL	VENOUS
Atherosclerosis	General surgery
Cigarette smoking	Orthopedic surgery
Hypertension	Arthroscopy
Diabetes mellitus	Trauma
LDL cholesterol	Malignancy
Hypertriglyceridemia	Immobility
Positive family history	Sepsis
Left ventricular failure	Congestive heart failure

Oral contraceptives	Nephrotic syndrome
Estrogens	Obesity
Lipoprotein A	Varicose veins
Polycythemia	Postphlebitic syndrome
Hyperviscosity syndrome	Oral contraceptives
Leukostasis syndrome	Estrogens
Thrombocythemia	Thrombocythemia

LDL, Low-density lipoprotein.

FIGURE 29.13 Arterial Thrombosis Associated with Antiphospholipid Antibodies. A 12-year-old girl with systemic lupus erythematosus and antiphospholipid antibodies with painful cutaneous vasculitis of the right foot. Arterial thrombosis documented by angiography resulted in cyanosis of the large toe. Symptoms resolved with treatment with heparin and corticosteroids. (From Kliegman R et al: *Nelson textbook of pediatrics*, ed 18, Philadelphia, 2007, Saunders.)

Summary Review

Anemia

1. Anemia is defined as a reduction in the total circulating red cell mass or a decrease in the quality or quantity of hemoglobin. Polycythemias are excessive levels or volumes of RBCs.
2. Anemias can result from blood loss, impaired erythrocyte production, increased erythrocyte destruction, and a combination of these factors.
3. Total circulating red blood cell mass is reflected by changes in plasma volume caused by dehydration and fluid retention.
4. Anemias can be classified in several ways and a useful way is by the main underlying mechanism.
5. Clinical manifestations of anemia may be demonstrated in all organs and tissues (tissue hypoxia) throughout the body. Decreased oxygen delivery to tissues causes fatigue, dyspnea, syncope, angina, compensatory tachycardia, and organ dysfunction.
6. Posthemorrhagic anemia is a normocytic-normochromic anemia caused by acute blood loss. A major cause of acute blood loss is trauma, a rising global problem.
7. Anemia from chronic blood loss occurs if the loss is greater than the replacement capacity of the bone marrow. If iron stores are depleted, iron deficiency anemia can occur.
8. Macrocytic (megaloblastic) anemias are characterized by larger than normal erythroid precursors (megaloblasts) in the bone marrow that mature into large erythrocytes. They most commonly are caused by deficiency of vitamin B₁₂ or folate.
9. PA results from inadequate vitamin B₁₂ absorption because autoimmune gastritis impairs the production of IF, which is required for vitamin B₁₂ uptake from the gut. Folate deficiency anemia is caused by inadequate dietary intake of folate. Both anemias respond to replacement therapy.
10. Microcytic-hypochromic anemias are characterized by

abnormally small erythrocytes with insufficient hemoglobin content. The anemias result from disorders of (a) iron metabolism (IDA), (b) porphyrin and heme synthesis (SAs), or (c) globin synthesis (thalassemia).

11. IDA is the most common type of nutritional disorder worldwide. It is usually a result of dietary deficiency. Other major causes are impaired absorption, increased requirement, and chronic blood loss. IDA usually develops slowly, with a gradual insidious onset of symptoms, which include fatigue, weakness, dyspnea, alteration of various epithelial tissues, and vague neuromuscular complaints result.
12. Individuals at highest risk for developing IDA include older adults, women, infants, teenagers eating poor diets, and those living in poverty. Once the source of blood loss is identified and corrected, oral iron replacement therapy can be initiated.
13. ACD, also called *anemia of inflammation*, results from decreased erythropoiesis and impaired iron utilization in people with chronic systemic disease or inflammation. ACD is common among hospitalized individuals.
14. Examples of mechanisms associated with ACD include (1) decreased erythrocyte life span, (2) reduced production of erythropoietin, (3) ineffective bone marrow response to erythropoietin, and (4) iron sequestration in macrophages. In particular, the proinflammatory cytokine IL-6 increases hepatocyte release of hepcidin which suppresses ferroportin transport of iron out of macrophages.
15. AA is a critical condition characterized by a reduction or absence of all three blood cell types (pancytopenia). Unless the cause is determined, bone marrow aplasia results in death.
16. Hemolytic anemia is a result of excessive destruction of erythrocytes and may be acquired or hereditary. Common, acquired forms are autoimmune reaction (immuno-hemolytic) and drug-induced hemolysis.
17. AIHAs include (a) warm reactive antibody type, (b) cold agglutinin type, and (c) cold hemolysin type (paroxysmal cold

hemoglobinuria).

18. Examples of mechanisms associated with ACD include (a) decreased erythrocyte life span, (b) reduced production of erythropoietin, (c) ineffective bone marrow response to erythropoietin, and (d) iron sequestration in macrophages. In particular, the proinflammatory cytokine IL-6 increases hepatocyte release of hepcidin, which suppresses ferroportin transport of iron out of macrophages.

Myeloproliferative Red Blood Cell Disorders

1. Polycythemia vera is a myeloproliferative disorder characterized by excessive proliferation of erythrocyte precursors, frequently with increased levels of white blood cells and platelets, in the bone marrow and splenomegaly. Signs and symptoms result directly from increased blood volume and viscosity and a predisposition to thrombosis.
2. Therapeutic phlebotomy to remove excessive blood volume and the use of hydroxyurea have been helpful in decreasing the excessive erythrocyte population.

Alterations of Platelets and Coagulation

1. Thrombocytopenia is characterized by a platelet count less than $150,000/\text{mm}^3$ of blood; a count less than $50,000/\text{mm}^3$ increases the potential for hemorrhage associated with minor trauma.
2. Thrombocytopenia may be congenital or acquired and primary or secondary to other acquired or congenital conditions. Acquired thrombocytopenia is associated with autoimmune diseases, viral infections, nutritional deficiencies, chronic renal failure, bone marrow hypoplasia, radiation therapy, and bone marrow infiltration by cancer. Most common forms of thrombocytopenia are the result of increased platelet

consumption

3. Heparin-induced thrombocytopenia develops in approximately 4% of individuals receiving unfractionated heparin.
4. Immune thrombocytopenic purpura (ITP) is a major cause of platelet destruction, often affecting females, and results in hemorrhaging that ranges from petechiae to bleeding from mucosal sites.
5. Thrombotic thrombocytopenic purpura (TTP) causes platelet aggregation leading to microcirculatory occlusion.
6. Thrombocythemia is characterized by a platelet count more than $450,000/\text{mm}^3$ of blood and is symptomatic when the count exceeds 1 million/ mm^3 , which increases the risk for intravascular clotting (thrombosis).
7. Essential or primary thrombocythemia is caused by excessive platelet production in the bone marrow secondary to increased plasma thrombopoietin levels resulting from defects in the thrombopoietin receptor.
8. Qualitative alterations in normal platelet adherence or aggregation prevent platelet plug formation and may result in prolonged bleeding times.
9. Prolonged bleeding can result from alterations in platelet function, including adhesion between platelets and the vessel wall, platelet-platelet adhesion, platelet granule secretion, arachidonic acid pathway activity, and membrane phospholipid regulation.
10. Disorders of coagulation are usually caused by defects or deficiencies of clotting factors.
11. Coagulation is impaired when there is a deficiency of vitamin K because of insufficient production of prothrombin and synthesis of clotting factors II, VII, IX, and X, often associated with liver diseases.
12. DIC is a complex syndrome that results from a variety of clinical conditions that release tissue factor, causing an increase in fibrin and thrombin activity in the blood and

- producing augmented clot formation and accelerated fibrinolysis. Sepsis is often associated with DIC.
13. DIC is characterized by a cycle of intravascular clotting followed by active bleeding caused by the initial consumption of coagulation factors and platelets and diffuse fibrinolysis.
 14. Diagnosis of DIC is based on dysfunctional coagulation activity. Treatment is complex, nonstandardized, and focused on removing the primary cause, restoring hemostasis, and preventing further organ damage.
 15. Thromboembolic disease results from a fixed (thrombus) or moving (embolus) clot that blocks flow within a vessel, denying nutrients to tissues distal to the occlusion; death can result when clots obstruct blood flow to the heart, brain, or lungs.
 16. Hypercoagulability is the result of deficient anticoagulation proteins. Secondary causes are conditions that promote venous stasis.
 17. The term *Virchow triad* refers to three factors that can cause thrombus formation: (1) vessel wall injury, (2) blood flow abnormalities, and (3) altered blood constituents leading to hypercoagulability.
 18. Autoantibodies against phospholipids result in a state of acquired hypercoagulability, an increased risk for venous or arterial thrombosis, and a higher incidence of pregnancy complications.

CHAPTER 30

Alterations of Leukocyte and Lymphoid Function

Kathryn L. McCance, Neal S. Rote

CHAPTER OUTLINE

Alterations of Leukocyte Function, 963

Quantitative Alterations of Leukocytes, 963

Infectious Mononucleosis, 966

Lymphoid Neoplasm: Leukemias, 968

Alterations of Lymphoid Function, 976

Lymphadenopathy, 976

Malignant Lymphomas, 976

Plasma Cell Malignancies, 983

Alterations of Splenic Function, 988

Disorders involving leukocytes range from deficiencies in the quality and quantity of leukocytes (leukopenia) to increased numbers of leukocytes (leukocytosis) in response to infections or proliferative disorders, such as leukemia. Many hematologic disorders are malignancies, and many nonhematologic malignancies act like malignancies and can metastasize to bone marrow, affecting leukocyte production. Because of the complexity of hematologic disorders a

large portion of this chapter is devoted to malignant disease.

Alterations of Leukocyte Function

Leukocyte function is affected if too many or too few white cells are present in the blood or if the cells that are present are structurally or functionally defective. **Quantitative leukocyte disorders**, such as infections and leukemias, result from decreased production in the bone marrow or accelerated destruction of cells in the circulation. Other quantitative alterations, however, occur in response to infections.

Qualitative leukocyte disorders consist of disruptions of leukocyte function. Phagocytic cells (granulocytes, monocytes, macrophages) may lose their phagocytic capacity to function. Lymphocytes may lose their capacity to respond to antigens. (Qualitative disruptions of inflammatory and immune processes caused by leukocyte disorders are described in [Chapter 9](#).) Other leukocyte alterations include infectious mononucleosis and cancers of the blood—leukemia and multiple myeloma.

Quantitative Alterations of Leukocytes

Leukocytosis is a leukocyte count that is higher than normal; conversely, **leukopenia** is a count that is lower than normal. Leukocytosis or leukopenia may affect all cell types or only a specific type of leukocyte and may result from a variety of physiologic conditions and alterations.

Leukocytosis occurs as a normal protective response to physiologic stressors, such as infection, strenuous exercise, emotional changes, temperature changes, anesthesia, surgery, pregnancy, and some drugs, hormones, and toxins. It is also caused by pathologic conditions, such as malignancies and hematologic disorders. Leukopenia is never normal and is defined as an absolute blood cell count less than 4000 cells/ μL . Leukopenia is associated with a decrease in the number of neutrophils, which increases the risk for

infection. The absolute neutrophil count (ANC) is calculated by multiplying the white blood cell count by the percent of band and segmented neutrophils. The ANC is classified as mild (1000 to 1500 cells/ μL), moderate (500 to 1000 cells/ μL), or severe (<500 cells/ μL). When the ANC is less than 500/ μL , the possibility for life-threatening infections is high. Leukopenia can be caused by radiation, anaphylactic shock, autoimmune disease (e.g., systemic lupus erythematosus), immune deficiencies (see [Chapter 9](#)), and exposure to certain drugs such as glucocorticoids and chemotherapeutic agents.

Granulocytes and Monocytes

Increased numbers of circulating granulocytes (neutrophils, eosinophils, basophils) and monocytes are primarily a response to infection. Increased numbers also occur as a result of myeloproliferative disorders (i.e., polycythemia vera, chronic myelogenous leukemia, chronic neutrophilic leukemia, chronic eosinophilic leukemia) that increase stem cell proliferation in bone marrow.

Decreased numbers occur when infectious processes exhaust the supply of circulating granulocytes and monocytes by drawing them out of the circulation and into infected tissues faster than they can be replaced. Decreases also can be caused by disorders that suppress marrow function.

Granulocytosis—an increase in the number of granulocytes (neutrophils, eosinophils, basophils)—begins with the release of stored leukocytes from the venous sinuses of the marrow. **Neutrophilia** is another term that may be used to describe *granulocytosis* because neutrophils are the most numerous of the granulocytes ([Table 30.1](#)). Neutrophilia occurs in the early stages of infection or inflammation and is established when the absolute neutrophil count exceeds 7500/ μL . Stored neutrophils are approximately 20 to 40 times greater in number than circulating neutrophils. On rare occasions when the neutrophil count increases significantly—more than 100,000/ μL (usually seen only in those with myelocytic leukemia)—the blood viscosity may increase considerably

so that thrombosis or occlusion of blood vessels occurs. Release and depletion of stored neutrophils from the venous sinuses stimulate granulopoiesis to replenish neutrophil reserves. Specific conditions associated with neutrophilia are identified in [Table 30.1](#).

TABLE 30.1

OTHER CONDITIONS ASSOCIATED WITH NEUTROPHILS, EOSINOPHILS, BASOPHILS, MONOCYTES, AND LYMPHOCYTES

CONDITION	CAUSE	EXAMPLE
Neutrophil		
Neutrophilia (granulocytosis)	Inflammation or tissue necrosis	Surgery, burns, MI, pneumonitis, rheumatic fever, rheumatoid arthritis
	Infection	Bacterial: gram positive (staphylococci, streptococci, pneumococci), gram negative (<i>Escherichia coli</i> , <i>Pseudomonas</i> species)
	Physiologic	Exercise, extreme heat or cold, third-trimester pregnancy, emotional distress
	Hematologic	Acute hemorrhage, hemolysis, myeloproliferative disorder, chronic granulocytic leukemia
	Drugs or chemicals	Epinephrine, steroids, heparin, histamine, endotoxin
	Metabolic	Diabetes (acidosis), eclampsia, gout, thyroid storm
	Neoplasm	Liver, GI tract, bone marrow
Neutropenia	Decreased marrow production	Radiation, chemotherapy, leukemia, aplastic anemia, abnormal granulopoiesis
	Increased destruction	Splenomegaly, hemodialysis, autoimmune disease
	Infection	Gram negative (typhoid), viral (influenza, hepatitis B, measles, mumps, rubella), severe infections, protozoal infections (malaria)
Eosinophil		
Eosinophilia	Allergy	Asthma, hay fever, drug sensitivity
	Infection	Parasites (trichinosis, hookworm), chronic (fungal, leprosy, TB)
	Malignancy	CML, lung, stomach, ovary, Hodgkin disease
	Dermatosis	Pemphigus, exfoliative dermatitis (drug-induced)
	Drugs	Digitalis, heparin, streptomycin, tryptophan (eosinophilia-myalgia syndrome), penicillins, propranolol

Eosinopenia	Stress response	Trauma, shock, burns, surgery, mental distress
	Drugs	Steroids (Cushing syndrome)
Basophil		
Basophilia	Inflammation	Infection (measles, chickenpox), hypersensitivity reaction (immediate)
	Hematologic	Myeloproliferative disorders (CML, polycythemia vera, Hodgkin lymphoma, hemolytic anemia)
	Endocrine	Myxedema, antithyroid therapy
Basopenia	Physiologic	Pregnancy, ovulation, stress
	Endocrine	Graves disease
Monocyte		
Monocytosis	Infection	Bacterial (subacute bacterial endocarditis, TB), recovery phase of infection
	Hematologic	Myeloproliferative disorders, Hodgkin disease, agranulocytosis
	Physiologic	Normal newborn
Monocytopenia	Rare	
Lymphocyte		
Lymphocytosis	Physiologic	4 months to 4 years
	Acute infection	Infectious mononucleosis, CMV infection, pertussis, hepatitis, mycoplasma pneumonia, typhoid
	Chronic infection	Congenital syphilis, tertiary syphilis
	Endocrine	Thyrotoxicosis, adrenal insufficiency
	Malignancy	ALL, CLL, lymphosarcoma cell leukemia
Lymphocytopenia	Immunodeficiency syndrome	AIDS, agammaglobulinemia
	Lymphocyte destruction	Steroids (Cushing syndrome), radiation, chemotherapy, Hodgkin lymphoma, CHF, renal failure, TB, SLE, aplastic anemia

AIDS, Acquired immunodeficiency syndrome; *ALL*, acute lymphocytic leukemia; *CHF*, congestive (left) heart failure; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myelogenous leukemia; *CMV*, cytomegalovirus; *GI*, gastrointestinal; *MI*, myocardial infarction; *SLE*, systemic lupus erythematosus; *TB*, tuberculosis.

When the demand for circulating mature neutrophils exceeds the supply, the marrow begins to release immature neutrophils (and other leukocytes) into the blood. Premature release of the immature white cells is responsible for the phenomenon known as a **shift-to-the-left** or

leukemoid reaction. This refers to the microscopic detection of disproportionate numbers of immature leukocytes in peripheral blood smears. Many diagrams present cellular differentiation and maturation progressing from left to right within the drawing, instead of vertically as shown in Fig. 28.12. When immature leukocytes are released prematurely they cause a shift in the distribution of cells in the blood toward the left side, or immaturity side, of the diagram. This phenomenon is also seen in the blood smear of individuals with leukemia as well, hence the term *leukemoid reaction*. As infection or inflammation diminishes and as granulopoiesis replenishes circulating granulocytes, a shift back to normal occurs.

Neutropenia is a condition associated with a reduction in the number of circulating neutrophils. Clinically, neutropenia exists when the neutrophil count is less than $2000/\mu\text{L}$.¹ The absolute neutrophil count reflects not only the degree of neutropenia but also the risk for infection (see preceding discussion of leukocytosis). A reduction in the number of neutrophils can occur in severe, prolonged infections when production of granulocytes cannot keep up with demand. Severe neutropenia, **granulocytopenia** (less than $500/\mu\text{L}$) or **agranulocytosis** (complete absence of granulocytes in blood), is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation. Chemotherapeutic agents used to treat hematologic and other malignancies cause generalized bone marrow suppression. Several other drugs and large doses of ionizing radiation cause agranulocytosis, which occurs rarely but carries a high death rate (10% to 50%). Clinical manifestations of agranulocytosis include recurrent and persistent life-threatening infection (particularly of the respiratory system) leading to septicemia, general malaise, fever, tachycardia, and ulcers in the mouth and colon. If untreated, sepsis caused by agranulocytosis results in death within 3 to 6 days.

Other causes of neutropenia, in the absence of infection, may be (1) decreased neutrophil production or ineffective granulopoiesis, (2) reduced neutrophil survival, and (3) abnormal neutrophil distribution and sequestration. Neutropenia also is categorized as primary or secondary; primary disorders are further identified as congenital or

acquired (Box 30.1).

Box 30.1

Classification of Neutropenia

Congenital

- Severe infantile agranulocytosis (Kostmann syndrome)
- Shwachman-Diamond-Oski syndrome
- Myelokathexis/neutropenia with tetraploid nuclei
- Cyclic neutropenia
- Chédiak-Higashi syndrome
- Reticular dysgenesis
- Dyskeratosis congenita

Acquired

- Postinfectious neutropenia
- Drug-induced neutropenia
- Complement activation (hemodialysis, leukapheresis, ARDS)
- Immune neutropenia
 - Isoimmune neonatal neutropenia
 - Alloimmune neutropenia (transfusion reaction)
 - Autoimmune neutropenia – primary
 - Beginning of childhood
 - Adult chronic form
 - Autoimmune neutropenia – secondary
 - Autoimmune diseases
 - Large granular lymphocyte
 - Pure white cell aplasia
- Chronic idiopathic neutropenia
- Hypersplenism
- Nutritional deficiency (vitamin B₁₂ or folate deficiency)

Diseases affecting the bone marrow

Postchemotherapy

Aplastic anemia

Fanconi anemia

Myelodysplastic syndrome

Acute and chronic leukemias

ARDS, Acute respiratory distress syndrome.

Data from Capsoni F, Sarzi-Puttini P, Zanella A: *Arthritis Res Ther* 7(5):208–214, 2005.

Congenital defects in neutrophil production include cyclic neutropenia and neutropenia with congenital immunodeficiency diseases, as well as multiple syndromes (e.g., Kostmann, Shwachman-Diamond, Diamond-Blackfan, Griscelli, Chédiak-Higashi, and Barth syndromes). Primary acquired neutropenia is associated with multiple conditions, for example, hypoplastic anemia or aplastic anemia, leukemia (acute myelogenous leukemia [AML]/chronic lymphocytic leukemia [CLL]), lymphomas (Hodgkin, non-Hodgkin), and myelodysplastic syndrome (MDS). The megaloblastic anemias (vitamin B₁₂ and folate deficiency) as well as starvation and anorexia nervosa cause neutropenia because of an inadequate supply of vitamins and nutrients for protein production.

Reduced neutrophil survival and abnormal distribution and sequestration are usually secondary to other disorders. Neutropenia occurs in a variety of immunologic disorders, particularly systemic lupus erythematosus, rheumatoid arthritis, Felty and Sjögren syndromes, splenomegaly, and drug-related causes.

Eosinophilia is an absolute increase (more than 450/μL) in the total numbers of circulating eosinophils. Allergic disorders (type I hypersensitivity) associated with asthma, hay fever, and drug reactions, as well as parasitic infections (particularly with metazoal parasites), are often cited as causes. Hypersensitivity reactions and the normal defense against parasites trigger the release of eosinophil chemotactic factor of anaphylaxis (ECF-A) from mast cells, attracting

eosinophils to the area. (These processes are described and illustrated in [Chapters 8](#) and [9](#).) Tissues with abundant mast cells, such as the respiratory and gastrointestinal tracts, are particularly common sites for eosinophil invasion. Mast cells also release interleukin-5 (IL-5), which stimulates the bone marrow to produce and release more eosinophils into the blood. Eosinophilia may also be associated with dermatologic disorders, such as atopic dermatitis, eczema, and pemphigus. Various types of eosinophilic scleroderma-like diseases also have been reported to occur in association with hematologic disorders (i.e., eosinophilic cellulitis [Wells syndrome] and eosinophilic fasciitis [Shulman syndrome]). Increased numbers of eosinophils have been observed in individuals with eosinophilia-myalgia syndrome (EMS), which is associated with ingestion of the supplement L-tryptophan. EMS may develop in individuals with fibromyalgia syndrome as an allergic reaction to L-tryptophan.²

Eosinopenia, a decrease in circulating numbers of eosinophils, generally is caused by migration of eosinophils into inflammatory sites. It also may be seen in Cushing syndrome and as a result of stress caused by surgery, shock, trauma, burns, or mental distress. Other conditions causing eosinopenia are detailed in [Table 30.1](#).

Basophilia, an increase in circulating numbers of basophils, is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basophils contain histamine that is released during an allergic reaction. An increase in the levels of basophils is seen also in myeloproliferative disorders, such as chronic myeloid leukemia and myeloid metaplasia. Other conditions associated with basophilia are listed in [Table 30.1](#).

Basopenia (also known as *basophilic leukopenia*), a decrease in circulating numbers of basophils, is seen in hyperthyroidism, acute infection, and long-term therapy with steroids. A decrease in the number of basophils may be seen during ovulation and pregnancy. Other conditions associated with basopenia are listed in [Table 30.1](#).

Monocytosis is an increase (generally greater than 800/ μ L) in numbers of circulating monocytes. The condition is often transient and not related to a dysfunction of monocyte production. When

present, it most commonly occurs with neutropenia associated with bacterial infections, particularly in the late stages or recovery stage, when monocytes are needed to phagocytize surviving microorganisms and debris. Monocytosis often is seen in chronic infections, usually with intracellular bacteria, such as tuberculosis (TB), brucellosis, listeriosis, and subacute bacterial endocarditis (SBE). Peripheral monocytosis has been found to correlate with the extent of myocardial damage following myocardial infarction. Increased numbers of monocytes also may indicate marrow recovery from agranulocytosis. Other conditions associated with monocytosis are identified in [Table 30.1](#).

Monocytopenia, a decrease in numbers of circulating monocytes, is rare, and not much is known about this condition because of the small numbers of monocytes generally present in the blood. Monocytopenia, however, has been identified with hairy cell leukemia and prednisone therapy.

Lymphocytes

Quantitative alteration of lymphocytes occurs when lymphocytes are activated by antigenic stimuli, usually microorganisms (see [Chapter 8](#)). **Lymphocytosis (absolute lymphocytosis)** is an increase in the number or proportion of lymphocytes in the blood. It is rare in acute bacterial infections and occurs most commonly in acute viral infections, particularly those caused by the Epstein-Barr virus (EBV), a causative agent in infectious mononucleosis. Other specific disorders associated with lymphocytosis are listed in [Table 30.1](#).

Lymphocytopenia is a decrease in the number of circulating lymphocytes in the blood. It may be attributable to (1) abnormalities of lymphocyte production associated with neoplasias and immune deficiencies and (2) destruction by drugs, viruses, or radiation. It also can occur in individuals for no apparent reason. Other conditions associated with lymphocytopenia are identified in [Table 30.1](#). The lymphocytopenia associated with heart failure and other acute illnesses may be caused by elevated levels of cortisol. Lymphocytopenia is a major problem in acquired immunodeficiency

syndrome (AIDS) in which the human immunodeficiency virus (HIV) is cytopathic for T helper lymphocytes. (For a more detailed discussion of AIDS, see [Chapter 10](#).)

Infectious Mononucleosis

Infectious mononucleosis (IM) is a benign, acute, self-limiting, lymphoproliferative clinical syndrome characterized by acute viral infection of B lymphocytes (B cells). It is associated with several human tumors, most commonly specific lymphomas and nasopharyngeal carcinoma.³ The most common etiologic agent is EBV, a ubiquitous, lymphotropic, gamma-group herpesvirus, which was first recognized as the causative agent of IM in the late 1960s. EBV accounts for approximately 85% of all IM cases. Other etiologic agents that may cause symptoms resembling IM are viruses (cytomegalovirus [CMV], adenovirus, HIV, hepatitis A, influenzas A and B, and rubella), as well as the bacteria *Toxoplasma gondii*, *Corynebacterium diphtheriae*, and *Coxiella burnetii*. IM caused by CMV is generally noted in older individuals, with fever and malaise the major complaints; the major manifestations of EBV-induced IM are the classic triad of symptoms of pharyngitis, lymphadenopathy, and fever.

Approximately 50% to 85% of children are infected with EBV by age 4, and more than 90% of adults have indications of subclinical EBV infections. These early infections are usually asymptomatic and provide immunity to EBV; thus early EBV infections rarely develop into IM. IM may arise when the initial infection occurs during adolescence or later, but still only results in IM in 35% to 50% of these individuals. Symptomatic IM usually affects young adults between ages 15 and 35 years, with the peak incidences occurring between 15 and 24 years; males have a later peak (18 to 24 years) than females. The overall incidence rate for the 15- and 24-year age group is 6 to 8 cases per 1000 persons per year. Children from low socioeconomic environments are particularly susceptible to infections with EBV. IM is uncommon in individuals older than age 40; but if it does occur, it is more commonly caused by CMV.

Transmission of EBV is usually by saliva through personal contact (e.g., kissing, hence the term “kissing disease”). The virus also may be present in other mucosal secretions of the genitalia, rectum, and respiratory tract, as well as blood. No evidence of aerosol transmission through sneezing or coughing has been documented. The disease begins with widespread infection of B lymphocytes, all of which possess receptors for EBV. The virus initially infects the oropharynx, nasopharynx, and salivary epithelial cells with later spread to the lymphoid tissue and B cells. Infection of B cells permits the virus to enter the bloodstream, which spreads the infection systemically.

◆Pathophysiology.

In the immunocompetent individual, unaffected B cells produce antibodies (IgG, IgM, IgA) against the virus. Concomitantly, there is a massive activation and proliferation of cytotoxic T cells (CD8) directed against EBV-infected cells; CD8 lymphocytes can account for greater than 50% of the total circulating lymphocytes. The immune response against EBV-infected cells (cellular infiltration, cytokine production) is largely responsible for the cellular proliferation in the lymphoid tissues (lymph nodes, spleen, tonsils, occasionally liver). Sore throat and fever, two of the earliest manifestations, are caused by inflammation at the site of viral entry and initial infection (the mouth and throat). Outcomes of EBV infection are presented in [Fig. 30.1](#).

FIGURE 30.1 Outcomes of Epstein-Barr Virus (EBV). In individuals with normal immune function, infection is typically asymptomatic or leads to mononucleosis. With immunodeficiency, proliferation of B cells may be uncontrolled and progress to the development of B-cell neoplasms. Individuals without evidence of immunodeficiency can also develop EBV-positive neoplasms. In Burkitt lymphoma, the individual's susceptibility to EBV causes B cells to undergo genetic alterations (usually an 8;14 chromosomal translocation). EBV also is implicated in Hodgkin lymphoma, nasopharyngeal carcinoma, and other rare non-Hodgkin lymphomas. (From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

◀ Clinical Manifestations.

The incubation period of IM is approximately 30 to 50 days (4 to 8 weeks) followed by a 3- to 5-day prodrome of fever, malaise, and arthralgias that are often attributed to viral infection, although some individuals remain asymptomatic. These symptoms may vary in severity for the next 7 to 20 days. At the time of diagnosis the individual usually has the classic triad of symptoms: fever, pharyngitis, and lymphadenopathy of the cervical lymph nodes. The pharyngitis is usually diffuse and often accompanied by a whitish or grayish green, thick exudate. It also is quite painful and is the symptom that most often causes the individual to seek treatment. IM is usually self-limiting, and recovery occurs in a few weeks. Fatigue may last for 1 to 2 months after resolution of the infection.

Although severe clinical complications are rare, as the condition progresses generalized lymph node enlargement may develop and enlargement of the spleen and liver also may occur. Splenomegaly is clinically evident 50% of the time and is demonstrated radiologically 100% of the time. Difficulty in detecting splenomegaly with physical examination contributes to the underestimation of actual enlargement. Splenic rupture is rare (only 0.1% to 0.5% of all cases) and can occur spontaneously as a result of mild trauma, occurring primarily in men younger than 25 years of age and between days 4 and 21 after the onset of symptoms. It is the most common cause of death related to IM. Other causes of fatalities are hepatic failure, extensive bacterial infection, or viral myocarditis.

Other organ systems are rarely involved, but such involvement may result in additional symptoms, such as meningitis, encephalitis, Guillain-Barré syndrome, Bell palsy, optic neuritis, mental impairment, transverse myelitis, cerebellar ataxia, and demyelinating diseases. Ocular manifestations may include eyelid and periorbital edema, dry eyes, keratitis, uveitis, conjunctivitis, retinitis, oculoglandular syndrome, choroiditis, papillitis, and ophthalmoplegia. In children, Reye syndrome also has been associated with EBV infection.

Pulmonary involvement is rare, but when present may include hilar and mediastinal lymphadenopathy, interstitial pneumonitis, and

pleural effusion. Pneumonia and respiratory failure have been documented; however, they are more likely to develop in immunocompromised individuals. Approximately 3% to 10% of adults older than 40 years of age have never been infected with EBV and are susceptible to IM later in life. In these individuals the classic symptoms are not generally present, making diagnosis more difficult. If an older individual has an elevated temperature that cannot be explained and persists for more than 2 weeks, EBV infection should be suspected, particularly in the presence of abnormal liver function tests with hepatomegaly and jaundice. Other neurologic manifestations that may be present include peripheral neuropathy and Guillain-Barré syndrome.

◆ Evaluation and Treatment.

Children commonly present with fever, sore throat, lymphadenitis, and the manifestations discussed earlier. The presentation in young adults includes malaise, fatigue, and lymphadenopathy and often a fever of unknown origin. The blood of affected individuals contains an increased number of atypical lymphocytes (Fig. 30.2). Diagnosis of IM is commonly based on Hoagland's criteria of at least 50% lymphocytes and at least 10% atypical lymphocytes in the blood in the presence of fever, pharyngitis, and adenopathy confirmed by a positive serologic test. Serologic tests are used to determine a heterophile antibody response.⁴ **Heterophile antibodies** are a heterogeneous group of immunoglobulin M (IgM) antibodies that are agglutinins against nonhuman red blood cells (e.g., sheep, horse) and are detected by qualitative (Monospot) or quantitative methods (heterophile antibody test).

FIGURE 30.2 Peripheral Blood Smear in Infectious Mononucleosis. Low power (A) shows moderately high white blood cell count and a high number of reactive, or “atypical,” lymphocytes. Higher power (B–G) illustrates the spectrum of lymphoid morphology, including small resting lymphocytes (B) for comparison, large granular lymphocytes (C), atypical forms (D–F) (also referred to as *reactive lymphs*), and circulating plasma cells (G). (From Hoffman R et al: *Hematology: basic principles and practice*, ed 6, Philadelphia, 2013, Churchill Livingstone.)

The Monospot test is limited because other infections (e.g., CMV, adenovirus) and toxoplasmosis also produce heterophilic antibodies. Thus 5% to 15% of Monospot tests yield false-positive results. Levels of heterophilic antibodies in the blood increase as the condition progresses, although some individuals and children younger than age 4 years do not produce them. These individuals give a false-negative result. Specificity for diagnosis of EBV infection may be increased with viral-specific serologic tests that identify EBV-specific antibodies (e.g., IgG or IgM against the viral capsid antigen [VCA], or IgG against the EBV nuclear antigen [EBNA]). These tests are more expensive and labor intensive; therefore they are reserved for instances in which the Monospot test is not appropriate.

Because IM is usually self-limiting, medical intervention is rarely required. Treatment of IM is supportive and includes rest and alleviation of symptoms with analgesics and antipyretics. Ibuprofen, *not aspirin*, is used with children and adolescents because of the reported incidence of Reye syndrome associated with EBV infection. Pharyngitis of streptococcal origin, which occurs in 20% to 30% of cases, is treated with penicillin or erythromycin. Ampicillin is contraindicated because it causes a rash in most individuals with IM.

Bed rest and avoidance of strenuous activity should be included in the therapy. Steroids may be used, but only in the presence of severe complications (e.g., impending airway obstruction) or other organ

system involvement (e.g., nervous system manifestations, thrombocytopenic purpura, myocarditis, pericarditis). Acyclovir has been used with immunosuppressed individuals; however, clinical improvement has been minimal and therefore it is not recommended for standard treatment.

In the rare event of splenic rupture, the treatment has been removal of the spleen and continues to be the choice in hemodynamically unstable individuals. However, new research is suggesting that it may be better to repair the spleen to avoid overwhelming postsplenectomy infection (OPSI). Children are at greater risk of OPSI than adults. Postsplenectomy vaccinations for *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Meningococcus* are essential because these microorganisms are responsible for 92% of fatal infections. Treatment may also be necessary for airway obstruction from massive edema of the Waldeyer ring or for autoimmune hemolytic anemia, which occurs in approximately 3% to 5% of cases.

Fatal IM also is expressed with the inherited X-linked lymphoproliferative (XLP) syndrome (Duncan disease). Duncan disease is a rare disorder characterized by severe dysregulation of the immune system, often in response to EBV. The underlying cause leading to death is the absence of a functional SAP protein that allows for the unregulated proliferation of cytotoxic T cells and the concomitant production and release of cytokines.

Lymphoid Neoplasm: Leukemias

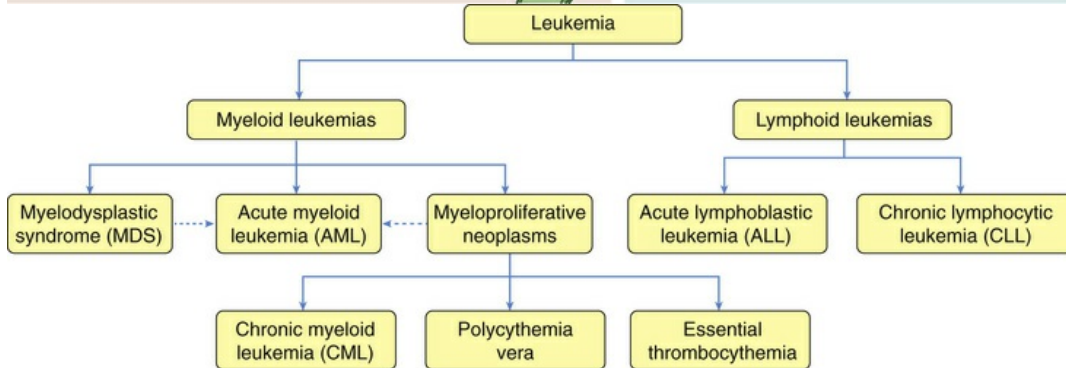

Leukemia is a clonal malignant disorder of leukocytes in the bone marrow and usually, but not always, of the blood. The common feature of all forms of leukemia is an uncontrolled proliferation of malignant leukocytes, causing an overcrowding of bone marrow and decreased production and function of normal hematopoietic cells. Thus leukemia has been termed an *accumulation* disorder, as well as a *proliferation* disorder. In the majority of cases, leukemic cells are ejected into the blood where they accumulate. These cells also may infiltrate and accumulate in the liver, spleen, lymph nodes, and other organs throughout the body. The presentation of large numbers of

leukemic cells in the blood may be one of the most dramatic indicators of leukemia; however, leukemia is still a primary disruption of the bone marrow.

The first description of a “leukemic” individual was written by Velpeau in 1827.⁵ Virchow, a pathologist, coined the term *white blood* (*Weissus blut*) and later originated the term *leukemia*. Since Virchow's initial discovery, the overall classification of leukemia has become increasingly complex and undergone several permutations. With increased understanding, the *distinct* divisions between *leukemia* and *lymphoma* has become indistinct or blurred. Many entities known as “lymphoma” that arise as a discrete tissue mass sometimes have “leukemic” presentations, and evolution to leukemia is not unusual during the progression of incurable lymphomas.³ The current World Health Organization (WHO) classification scheme uses morphologic, immunophenotypic, genotypic, and clinical features to group the lymphoid neoplasms into five broad categories, which are sorted according to the cell of origin³:

1. Precursor B-cell neoplasms (immature B cells)
2. Peripheral B-cell neoplasms (mature B cells)
3. Precursor T-cell neoplasms (immature T cells)
4. Peripheral T-cell and NK-cell neoplasms (mature T cells and NK cells)
5. Hodgkin lymphoma (Reed-Sternberg cells and variants)

Most lymphoid neoplasms relate to stages of differentiation of B-cell or T-cell differentiation (Fig. 30.3, A). Fig. 30.3, B provides a simple schematic overview of the main types of leukemia.

B

FIGURE 30.3 Origin of Lymphoid Neoplasms. A, Specific lymphoid tumors emerge from stages of B- and T-cell differentiation. B, Overview of main types of leukemia. Acute myeloid lymphoma (AML) may arise *de novo* or be preceded by myelodysplastic phase. Not all cases of myelodysplastic syndrome (MDS) evolve to AML (dashed line). Some myelodysplastic neoplasms can transform into AML, although very rarely (dotted line). *BLB*, Pre-B lymphoblast; *CLP*, common lymphoid precursor; *DN*, CD4/CD8 double-negative pro-T cell; *DP*, CD4/CD8 double-positive pre-T cell; *GC*, germinal-center B cell; *MC*, mantle B cell; *MZ*, marginal zone B cell; *NBC*, naïve B cell; *PTC*, peripheral T cell. (A, From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders; B, from Khwaja A et al: Acute myeloid leukemia, *Nat Rev Dis Pimers* 2:16010, 2016.)

Acute leukemia is characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid with a short survival time. In **chronic leukemia** the predominant cell is more differentiated but does not function normally, with a relatively slow progression. There are four general types of leukemia: acute lymphocytic (ALL), acute myelogenous (AML), chronic lymphocytic (CLL), and chronic myelogenous (CML).

Leukemia occurs with varying frequencies at different ages and is more common in adults than children (Fig. 30.4). Worldwide, the number of new leukemia cases is estimated at 351,965 and deaths of 265,471 for 2012.⁶ In the United States it is estimated that more than 62,100 new cases of leukemia were diagnosed and 24,500 deaths occurred in 2017,⁷ with males having a slightly higher incidence than females. In all types of leukemia males have a higher incidence rate as do Americans of European descent. White children have higher rates of leukemia than children of other groups. ALL is the least common type overall, but is the most common in children (approximately 66% of ALL cases are diagnosed before the age of 20). Leukemia accounts for about 29% of all childhood cancers, and ALL accounts for a majority of all new cases of leukemia in children. CLL and AML are the most common types in adults. CML is found mostly in adults.

FIGURE 30.4 Age-Related Incidence at Diagnosis of Leukemias. The incidences of acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML) are relatively stable until middle age and then increase dramatically. The incidence of acute lymphocytic leukemia (ALL) peaks in childhood, and then diminishes until middle age when the incidence begins rising slowly with age. (Data obtained from Howlander N et al, editors: *SEER cancer statistics review, 1975-2009 [vintage 2009 populations]*, Bethesda, MD, 2012, National Cancer Institute. Available at http://seer.cancer.gov/csr/1975_2005/pops09/.)

Risk factors for the onset of leukemia include environmental factors, genetic factors, as well as other diseases. See discussions under sections [Acute Leukemias](#) and [Chronic Leukemias](#).

Over the past two decades, the rates of induced remission and survival in most forms of leukemia have increased, sometimes dramatically. This progress is the result of more effective chemotherapeutic agents, improved blood product and antimicrobial support, and specialized nursing care. Chemotherapy and bone marrow transplants have significantly increased the survival time for individuals with acute leukemia.

◆Pathophysiology.

All leukemias have certain pathophysiologic features in common. Most lymphoid neoplasms arise from B-cell and T-cell differentiation pathways (see [Fig. 30.3](#)). Thus the hypothesis of origin for leukemias is “clonal disorders driven by genetically abnormal progenitor cells or stemlike cancer cells (SLCC).”⁸ The majority (85% to 90%) of lymphoid neoplasm are of B-cell origin, followed by T-cell tumors, and NK-cell tumors rarely.³ Abnormal immature white blood cells, called **leukemic blasts**, fill the bone marrow and can spill into the blood. The leukemic blasts literally “crowd out” the bone marrow and cause cellular proliferation of the other cell lines to cease. Normal granulocytic-monocytic, lymphocytic, erythrocytic, and megakaryocytic progenitor cells can cease to function, leading to **pancytopenia** (a reduction in all cellular components of the blood). Almost 90% of ALLs have chromosomal changes that correlate with immunophenotyping and sometime confer prognostic significance. Genetic translocations (mitotic errors) are observed in leukemic cells. The most common genetic abnormality is the reciprocal translocation

between chromosomes 9 and 22—t(9;22)(q34;q11), the **Philadelphia chromosome**.⁹

The Philadelphia chromosome was first observed in persons with CML, and is present in 95% of those with CML, 3% of individuals with AML, and 25% to 30% of adults with ALL and 2% to 10% of children with ALL.¹⁰ This translocation results in the novel fusion of the *BCR1* gene region from chromosome 22 and the proto-oncogene *ABL1* from chromosome 9 (Fig. 30.5). The *BCR-ABL1* joining results in the expression of a unique fused oncoprotein, BCR-ABL1.⁹ The ABL1 protein is a tyrosine kinase in the signaling pathway that promotes cell proliferation. The BCR-ABL1 variant possesses greater tyrosine kinase activity and proves to be essential for transformation into leukemic cells. BCR-ABL1 appears to excessively activate intracellular pathways, leading to increased proliferation, decreased sensitivity to apoptosis, and premature release of immature cells into the circulation. In most leukemias and lymphomas a single major genetic abnormality, such as the t(9;22) translocation, does not lead to an aggressive malignancy. The initial event is usually followed by a series of secondary genetic changes.¹¹ Thus the original tumor becomes genetically unstable and diverse.

FIGURE 30.5 Philadelphia Chromosome. The Philadelphia chromosome is an example of a reciprocal chromosomal translocation that results in an abnormal gene product responsible for a clinical disorder. **A,** An exchange occurs between the long arm of chromosome 9 (black chromosome) and the long arm of chromosome 22 (blue chromosome); $t(9;22)(q34;q11)$. **B,** Mechanism of action of imatinib. By occupying the ATP-binding pocket of the ABL kinase domain, imatinib prevents substrate phosphorylation and downstream activation of signals, thus inhibiting the leukemogenic effects of BCR-ABL1 on cells in chronic myelogenous leukemia. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *BCR-ABL*, Breakpoint cluster region-Abelson; *P*, phosphate group. (A, Top portion from Rakel R, Bope E: *Conn's current therapy 2008*, Philadelphia, 2008, Saunders; lower portion

from Yanoff M, Duker J: *Ophthalmology*, ed 3, Edinburgh, 2009, Mosby. B
From Goldman L, Schafer AI: *Goldman's Cecil medicine*, ed 24,
Philadelphia, 2012, Saunders.)

In the majority of cases, leukemic cells are ejected into the blood, where they accumulate. These cells also may infiltrate and accumulate in the liver, spleen, lymph nodes, and other organs throughout the body. The presentation of large numbers of leukemic cells in the blood may be one of the most dramatic indicators of leukemia; however, leukemia is still a primary disruption of the bone marrow.

Acute Leukemias

Acute leukemias consist of two types: **acute lymphocytic leukemia (ALL)** and **acute myelogenous leukemia (AML)**. ALL is an aggressive fast-growing leukemia with too many lymphoblasts (i.e., immature white blood cells) found in blood and bone marrow. It is also called *acute lymphoblastic leukemia*. AML is an aggressive fast-growing leukemia with an excessive number of myeloblasts (i.e., immature white blood cells that are not lymphoblasts) found in the bone marrow and blood. It is also called *acute myeloblastic leukemia*, *acute myeloid leukemia*, or *acute nonlymphocytic leukemia (ANLL)*. Acute leukemias are seen in both genders and in all ages. AML is the more common acute leukemia in adults with the median age at diagnosis around 70 years, a rise in the age-related incidence around 40 to 50 years of age, and a steep increase from 60 to 64 years of age.¹² Mortality for all acute leukemias in the United States is about 7 per 100,000. In children younger than 15 years, leukemia accounts for one-third of all deaths from cancer. North American and Scandinavian countries have the highest mortality; Eastern European countries, Asia (except Japan), and Central America have the lowest mortality. Japan's higher mortality is the result of the atomic bombs dropped in World War II. Blacks have consistently shown a lower mortality than whites. More than 5970 new cases of ALL and 21,380 cases of AML are estimated in 2017, with more than 1440 deaths attributed to ALL and 10,590 to AML.⁷

Although the exact cause of leukemia is unknown, several risk

factors and related genetic aberrations are associated with the onset of malignancy. There is a statistically significant tendency for leukemia to reappear in families. There also is an increased incidence of leukemia in association with other hereditary abnormalities, such as Down syndrome, Fanconi aplastic anemia, Bloom syndrome, trisomy 13 (Patau syndrome), and some immune deficiencies (i.e., ataxia-telangiectasia, Wiskott-Aldrich syndrome, and congenital X-linked agammaglobulinemia) (see [Chapter 9](#)). Increased risk in adults has been linked to exposure to cigarette smoke, benzene, and ionizing radiation. Large doses of ionizing radiation particularly result in an increased incidence of myelogenous leukemia. There is growing concern about the effect of low-dose radiation on subsequent risk of leukemia.¹³ Infections with HIV or hepatitis C virus increase the risk for lymphoid neoplasms, and it is now widely accepted that some types of leukemia are caused by infection with the human T-cell leukemia/lymphoma virus-1 (HTLV-1). Drugs that cause bone marrow depression (e.g., chloramphenicol, phenylbutazone, and certain alkylating agents, such as cytoxan) also can predispose an individual to leukemia. AML is the most frequently reported secondary cancer after high doses of chemotherapy for Hodgkin lymphoma, non-Hodgkin lymphoma, multiple myeloma, ovarian cancer, and breast cancer. Acute leukemia also may develop secondary to certain acquired disorders, including CML, CLL, polycythemia vera, myelofibrosis, Hodgkin lymphoma, multiple myeloma, ovarian cancer, and sideroblastic anemia. A unique characteristic of ALL, unlike other forms, is that ALL develops at different rates in different geographic locations, although the reason for this is unclear. Individuals in developed countries and in higher socioeconomic categories have an increased incidence of ALL.

◆Pathophysiology.

Chromosomal alterations in ALL cause alterations of expression and function of transcription factors necessary for normal B- and T-cell development.³ All of the varied mutations present in B- and T-cell development interrupt the normal differentiation of lymphoid

precursors and stop (arrest) maturation, causing an increased proliferation or self-renewal of a stem cell–like phenotype.³ A similar process occurs in AML. ALL of B-cell origin occurs mainly in children and has diverse chromosomal translocations, such as translocation [t(12;21)] involving gene mutations required for B-cell development, including *ETV6* and *RUNX1*. ALL of T-cell origin involves diverse chromosomal translocations with, for example, mutations in *NOTCH1*, a gene required for T-cell development found in approximately 50% to 70% of cases, mostly in adolescent males. Adult ALL is a mixture of cancers of precursor B- and T-cell origin. The identity of mutations found in ALL is ongoing and includes mutations that drive cell growth (e.g., *RAS* signaling) and mutations that increase tyrosine kinase activity. ALL is a progressive neoplasm defined by the presence of greater than 30% lymphoblasts in the bone marrow or blood.

Genetic aberrations in AML alter genes encoding transcription factors needed for normal myeloid differentiation; consequently, differentiation becomes arrested. These mutations affect the epigenome, suggesting that epigenetic alterations are key in AML.³ Mutations may lead to proliferation by activating growth factor signaling, as well as a decreased rate of apoptosis. Therefore, the bone marrow and peripheral blood are characterized by leukocytosis and a predominance of blast cells. As the immature blasts increase in number, they replace normal myelocytic cells, megakaryocytes, and erythrocytes. This displacement eventually leads to complications of bleeding, anemia, and infection. AML subtypes are classified on the basis of the developmental stage that myeloblasts have reached at the time of diagnosis. The incidence of AML increases with age, peaking in the sixth decade of life.

◆Clinical Manifestations.

More prevalent with ALL, within days to a few weeks, is an abrupt stormy onset. The clinical manifestations of all the varieties of acute leukemia are generally similar. (Mechanisms associated with common manifestations are summarized in [Table 30.2](#).) Signs and symptoms

related to bone marrow depression include fatigue caused by anemia, bleeding resulting from thrombocytopenia (reduced numbers of circulating platelets), and fever caused by infection. Sites of infection include the oral cavity, throat, respiratory tract, lower colon, urinary tract, and skin. Common organisms include the gram-negative bacilli *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Fever is an early sign, often accompanied by chills. Bleeding can occur in skin, gums, mucous membranes, and gastrointestinal and genitourinary tracts. Visible signs of bleeding include petechiae and ecchymosis, as well as discoloration of the skin, gingival bleeding, hematuria, and midcycle or heavy menstrual bleeding.

TABLE 30.2

CLINICAL MANIFESTATIONS AND RELATED PHYSIOLOGY IN LEUKEMIA

CLINICAL MANIFESTATIONS	LABORATORY ABNORMALITIES	CAUSE	COMMENTS
Anemia	Key is the relative <i>proportion</i> of erythroblasts to total count (decreased in anemia)	Decreased stem cell input or ineffective erythropoiesis, or both	In acute leukemia, anemia is usually present from the beginning, often the first symptom noticed, and severe; mild form without symptoms is common in CML and CLL; hemorrhage common in acute forms, occasional in CML, and rare in CLL
Bleeding (purpura, petechiae, ecchymosis, hemorrhage)	Decreased and possibly abnormal platelets	Reduction in megakaryocytes leading to thrombocytopenia	Bleeding more common in acute than in chronic leukemia
Infection	Increased multisegmented neutrophils	Opportunistic organisms; decreased protection resulting from granulocytopenia or immune deficiency secondary to chemotherapy,	Major sites of infection: oral cavity, throat, lower colon, urinary tract, lungs, and skin; prevention of infection focuses on restoring host defenses, decreasing invasive procedures, and reducing colonization of organisms

		corticosteroids, and the disease process	
Weight loss	Decreased 24-hr urinary creatinine excretion; hypoalbuminemia	Condition can be attributed to pain, depression, chemotherapy, radiation therapy, loss of appetite, and alterations in taste	Severe weight loss may be related to excess production of TNF- α
Bone pain	Often no radiographic evidence of bone problems	Result of bone infiltration by leukemic cells or intramedullary infection	If combination drug regimens are ineffective, radiation therapy is used
Liver, spleen, and lymph node enlargement	Biopsy abnormal for liver and spleen	Leukemic cell infiltration; lymph nodes also undergo leukemia proliferation in CLL	
Elevated uric acid	Normal excretion of uric acid is 300–500 mg/day; leukemic individual can excrete 50 times more	Increased catabolism of protein and nucleic acid; urate precipitation increased from dehydration caused by anorexia or fever and drug therapy	Hyperuricemia is present in both acute leukemia and CML; increasing urine pH or decreasing acid production with the drug allopurinol

CLL, Chronic lymphocytic leukemia; *CML*, chronic myelogenous leukemia; *TNF- α* , tumor necrosis factor-alpha.

Anorexia can occur in all varieties of acute leukemia and is associated with weight loss, diminished sensitivity to sour and sweet tastes, muscle atrophy, and difficulty in swallowing. Liver, spleen, and lymph node enlargement is more common in ALL than in AML (Fig. 30.6). Splenomegaly and hepatomegaly usually occur together. The leukemic individual often experiences abdominal pain and tenderness and breast tenderness. Pain in the bones and joints is thought to result from leukemia infiltration with secondary stretching

of the periosteum.

FIGURE 30.6 Lymphadenopathy. Individual with lymphocyte leukemia with extreme but symmetric lymphadenopathy. (Courtesy Dr. A.R. Kagan, Los Angeles. From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer*, ed 2, St Louis, 1985, Mosby.)

Central nervous system (CNS) involvement is common and may be caused by either leukemic infiltration or cerebral bleeding. Headache, vomiting, papilledema, facial palsy, blurred vision, auditory disturbances, and meningeal irritation can occur if leukemic cells infiltrate the cerebral or spinal meninges. CNS involvement at the time of diagnosis is rare, and less than 5% of children and less than 10% of adults are affected. Without CNS prophylaxis, approximately

one-third of individuals will develop CNS complications. Interventions associated with CNS prophylaxis include cranial irradiation, chemotherapy, and high doses of systemic chemotherapy. Specific treatment modalities or combinations of treatment vary and are determined by age and risk status.

◆Evaluation and Treatment.

The diagnosis is made through examination of blood cells and bone marrow. A stained peripheral blood smear will exhibit low red blood cell and platelet counts along with the presence of leukemic blast cells (Fig. 30.7). Examination of bone marrow demonstrates hypercellularity with 60% to 100% blast cells, an occasional normal myeloid, precursor and erythroid precursors, and few to no megakaryocytes. For ALL, diagnostic confusion with AML, hairy cell leukemia, and malignant lymphoma is not uncommon.¹⁴ It is critical to obtain an accurate diagnosis because of the differences in both the treatment and prognosis of ALL and AML.¹⁴ The examination of bone marrow aspirates should be done by an experienced oncologist, hematologist, hematopathologist, or general pathologist experienced in interpreting conventional and specially stained specimens.¹⁴

FIGURE 30.7 Morphologic Aspects of Leukemia Cells. *Acute lymphoblastic leukemia (ALL)* (A–C). A, Typical uniform lymphoblasts with intermediate-sized nuclei, fine but “smudgy” chromatin, absence of nucleoli, and scant cytoplasm. B, Lymphoblasts with more cytologic variation, including variability in size, number of nucleoli, and amount of cytoplasm. C, Histologic features of ALL in bone core biopsy. *Acute myeloid leukemia (AML)* (D–G). D, Acute myeloblastic leukemia with minimal or no maturation. The cells are myeloblasts with dispersed chromatin and variable amounts of agranular cytoplasm. Some display medium-sized, poorly defined nucleoli. E, Acute monoblastic leukemia; characteristic monoblasts with round nuclei and delicate chromatin and prominent nucleoli. Cytoplasm is abundant. F, Acute monocytic leukemia with most of the cells in this field being promonocytes. Monoblasts and an abnormal monocyte also are present. G, Marrow biopsy of acute megakaryoblastic leukemia containing large and small blasts and atypical megakaryocytes. *Chronic lymphocytic leukemia (CLL)* (H–K). H, Peripheral blood smear typically shows lymphocytosis. Cytologic features of CLL cells differ. I, Classic cells have a small nucleus with a “soccer ball” chromatin pattern. J, Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent “punched-out” nucleoli (prolymphocyte, right side). K, The bone marrow can show nodular infiltrates of CLL cells. *Chronic myelogenous leukemia (CML)* (L–N). L, Peripheral smear shows marked leukocytosis attributable to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. M, Bone core biopsy illustrates markedly hypercellular marrow attributable to granulocytic proliferation and increased small hypolobated megakaryocytes. N, Bone marrow aspirate shows granulocytic proliferation and small, “dwarf” megakaryocyte. (A–C, H–N

from Hoffman R et al: *Hematology: basic principles and practice*, ed 6, Philadelphia, 2013, Churchill Livingstone. D–G from Abeloff M et al: *Abeloff's clinical oncology*, ed 4, Philadelphia, 2008, Churchill Livingstone.)

Successful treatment of AML depends on control of bone marrow and systemic disease.¹⁴ Treatment is divided into two phases: remission induction (to attain remission) and postremission (to maintain remission). Historically, maintenance therapy for AML was administered for several years but is not included in most current treatment clinical trials in the United States, except for promyelocytic leukemia.¹⁴ Standard treatment during the remission induction phase depends on the subtype of AML. Postremission therapy appears to be more effective when given immediately after remission is achieved.¹⁴ Since only 5% of individuals with AML develop CNS disease, prophylactic treatment is not indicated.¹⁴

Chemotherapy, used in varying combinations, is the treatment of choice for leukemia.¹⁵⁻¹⁷ Supportive measures include blood transfusions, antibiotics, antifungals, and antivirals. Stem cell transplantation is now considered standard therapy for selected individuals with leukemia. It is critical that stem cell transplants be done at hospitals with very experienced staff for both the procedure and the recovery phase.

All-trans-Retinoic acid (ATRA;atRA) is made in the body from vitamin A and helps cells grow and differentiate (e.g., differentiation therapy). In the leukemia arena, experiments with retinoic acid propels cells to develop into functional cells and thereby alleviate the disease. It is a chemotherapeutic agent used to treat some forms of leukemia. Although there were five deaths in a study performed by Hu and colleagues, the 5-year event-free survival rate was 89%, a remarkable improvement over historically bleak survival rates.¹⁸ A recent study showed the rate of relapse in those administered ATRA+As₂O₃ was significantly lower than in those administered ATRA+chemotherapy maintenance.¹⁹ The relative effectiveness of ATRA may depend on the microenvironment's ability to inactivate ATRA.²⁰

The 5-year survival rate for those with leukemia is 38%, largely because of poor survival rates of individuals with certain types of

leukemia (e.g., acute myelogenous). Since the 1970s, 5-year survival rates for those with ALL have increased from 38% to 65% for adults and from 53% to 85% for children. Factors influencing increased survival rate include the use of combined and multimodality treatment methods, improvement in supportive services such as blood banking and nutritional support, and implementation of antimicrobial treatment. The presence of the Philadelphia chromosome (observed in about 5% of children with ALL, in 30% of adults with ALL, and occasionally in AML) is a poor prognostic indicator.

Myelosuppression is both a consequence of leukemia and its treatment. Hematologic support with blood products and granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) has effectively shortened the time of neutropenia and improved survival by reducing the risk for infection.

Chronic Leukemias

The two main types of chronic leukemia are (1) **chronic myelogenous leukemia (CML)** and (2) **chronic lymphocytic leukemia (CLL)**. In adults, CLL is the most common leukemia in the western world.³ CLL is a slow-growing cancer in which too many immature lymphocytes are found mostly in the blood and bone marrow. CLL and **small lymphocytic lymphoma (SLL; also CLL/SLL)** differ only in the degree of proliferation of peripheral blood lymphocytes.³ Several forms of CML can occur, depending on the lineage of the malignant cells (e.g., chronic neutrophilic leukemia [CNL], chronic eosinophilic leukemia [CEL]). Unlike cells in acute leukemia, chronic leukemic cells are well differentiated and can be readily identified. CML is mostly a disease of adults but can occur in children or adolescents. The peak incidence is in the fifth to sixth decades. Individuals with chronic leukemia have a longer life expectancy, usually extending several years from the time of diagnosis.

It is estimated that in 2017 more than 20,110 cases of CLL and 8950 cases of CML will be newly diagnosed in the United States.⁷ CML is a member of the family of myeloproliferative disorders that also

includes polycythemia vera (see [Chapter 29](#)), essential thrombocythemia, chronic idiopathic myelofibrosis (invasion of bone marrow by fibrous tissue), chronic neutrophilic leukemia, and chronic eosinophilic leukemia.

The etiology of CLL is unknown. A familial tendency suggests a genetic linkage; first-degree relatives have a three times greater risk of developing the disease. It is rare in individuals younger than 45 years of age and, when diagnosed, 95% of individuals are older than age 50. Genetic anomalies occur in approximately 90% of cases, frequently as deletions, although none have been linked to the etiology of CLL. The only known cause of CML is exposure to ionizing radiation.

◆Pathophysiology.

CML is clonal and thought to arise from a hematopoietic stem cell. The cells observed in CML are heterogeneous in differentiation, depending on the stage of the disease. During the chronic phase, the predominant cell is a long-lasting hematopoietic stem cell. A leukemic granulocyte-monocyte progenitor cell is seen. The Philadelphia chromosome is present in more than 95% of persons diagnosed with CML, and the presence of the BCR-ABL1 protein is responsible for initiation of CML ([Fig. 30.8](#)). The presence of the chimeric *BCR-ABL* fusion gene distinguishes CML from other myeloproliferative disorders. In advanced disease, the accumulation of additional mutations leads to the more aggressive leukemic phenotype.

FIGURE 30.8 Pathogenesis of Chronic Myeloid Leukemia. The breakage and joining of *BCR* and *ABL* creates the chimeric fusion gene *BCR-ABL*. *BCR-ABL* genetically encodes an active *BCR-ABL* intracellular tyrosine kinase (an enzyme that controls intracellular “on-off” switches). The *ABL* kinase in turn induces signaling through the same pro-growth and pro-survival pathways that are activated by normal hematologic growth factors. Altogether the activation of many downstream pathways drives growth factor–independent proliferation and survival of bone marrow progenitors. *der chromosome* is a structurally rearranged chromosome. *AKT*, Serine/threonine kinases; *BCR-ABL*, breakpoint cluster region-Abelson; *RAS*, rat sarcoma; *STAT*, signal transducer and activator of transcription. (From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

CLL involves malignant transformation and progressive accumulation of monoclonal B lymphocytes; rarely (less than 5%) are CLL malignancies of T-cell origin. The characteristic immunophenotype is expression of CD5, CD19, and CD23 molecules

and low amounts of surface membrane Ig, CD20, and CD22 molecules.²¹ CD5 is a signal transduction molecule linked to the B-cell receptor (BCR); CD19 is a low-affinity antigen receptor expressed on maturing B cells, but is lost in plasma cells; and CD23 is a low-affinity receptor for the Fc portion of IgE. CLL is derived from a transformation of a partially mature B cell that has not yet encountered antigen. The gene for the variable region of the antibody heavy chain (*IGHV*) is frequently mutated (30% to 40% of persons). (See [Chapter 8](#) for discussion of immunoglobulin heavy-chain structure.) Individuals with a mutated *IGHV* gene tend to have a more benign condition with a more slowly developing and less malignant disease. Significant numbers of this mutation are associated with a median survival in excess of 20 to 25 years, whereas the absence of mutations is associated with a poorer survival rate (median survival 8 to 10 years).²²

CLL cells that accumulate in the marrow do not interfere with normal blood cell production to the extent found in acute leukemias. This is a significant feature explaining the reduced severity in the beginning stage of disease. Accumulation of malignant B cells is the result of cell cycle arrest in the G₀/G₁ phase. CLL cells tend to express increased levels of proapoptotic proteins (e.g., BCL2) and suppress antiapoptotic proteins (e.g., BCL2L1), which reduces their sensitivity to apoptosis. Because the major pathophysiologic deficit in CLL is the failure of B cells to mature into plasma cells that synthesize immunoglobulin, this often results in hypogammaglobulinemia (60% of individuals).

◆Clinical Manifestations.

Chronic leukemia advances slowly and insidiously. Approximately 70% of individuals with CLL are asymptomatic at the time of diagnosis. When symptoms do appear, the most common finding is lymphadenopathy. The most significant effect of CLL is suppression of humoral immunity and increased infection with encapsulated bacteria. Frequently the level of neutrophils is depressed, which adds to the risk of infection. Invasion of most organ cells is uncommon but

infiltration does occur in lymph nodes, liver, spleen, and salivary glands. CNS involvement is rare. Approximately 10% of individuals develop a more aggressive malignancy, usually a diffuse, large B-cell lymphoma. In these individuals, extreme fatigue, weight loss, night sweats, low-grade fever, elevated levels of the enzyme lactic dehydrogenase, hypercalcemia, anemia, and thrombocytopenia are common.

Individuals with CML may progress through three phases of the disease: a chronic phase lasting 2 to 5 years during which symptoms may not be apparent; an accelerated phase of 6 to 18 months during which the primary symptoms develop; and a terminal blast phase ("blast crisis") with a survival of only 3 to 6 months. The accelerated phase is characterized by excessive proliferation and accumulation of malignant cells. Splenomegaly is the most common finding, which may be prominent and painful, but lymphadenopathy generally is not present. Liver enlargement also occurs, but liver function is rarely altered. Hyperuricemia is common and produces gouty arthritis. Infections, fever, and weight loss also are frequent. The terminal blast phase is characterized by rapid and progressive leukocytosis with an increase in the number of basophils. In the later stages of the terminal phase, which then resembles AML, blast cells or promyelocytes predominate, and the individual experiences a blast crisis.

The acute effects of CML resemble those of acute leukemia but with more prominent and painful splenomegaly. Liver function rarely is altered despite enlargement, and lymphadenopathy generally is found only in the acute phase of the disease. Hyperuricemia invariably is present and produces gouty arthritis. Infections, fever, and weight loss are common findings in individuals with CML.

◆ Evaluation and Treatment.

Diagnosis of chronic leukemia depends on laboratory analyses of peripheral blood and bone marrow samples. Diagnosis of CLL is based on detection of a monoclonal B-cell lymphocytosis in the blood. The cells must have the immunophenotype characteristic of CLL (CD5+, CD19+, CD20 [weak], CD23+), at levels in excess of 5000 cells/

μL , over a sustained period of time (usually 4 weeks). Bone marrow may contain more than 30% lymphocytes and be normocellular or hypercellular.

Treatment is frequently based on prognostic indicators and ranges from observation with treatment of infection, hemorrhage, or immune complications; to a variety of drug options, including steroids, alkylating agents, purine analogs, and monoclonal antibodies; to combination chemotherapy and transplant options.²³ Because this disease typically occurs in the elderly and the rate of progression is slow, it is often simply observed until the disease progresses. Meta-analysis of randomized trials shows no survival advantage for immediate versus delayed treatment of those individuals with early stage disease.²⁴ For individuals with progressing CLL, treatment with conventional doses of chemotherapy is not curative; selected individuals treated with allogeneic stem cell transplantation have achieved prolonged disease-free survival.²³ Antileukemic therapy is frequently unnecessary in uncomplicated early disease.²³ From older clinical trials (1970s to 1990s), the median survival for all individuals ranges from 8 to 12 years.²³ A large variation in survival, however, exists among individuals, ranging from several months to a normal life expectancy. Treatment must be individualized based on the clinical behavior of the disease.²³ Complications of pancytopenia, including hemorrhage and infection, are a major cause of death.

Typically, individuals with CLL survive 10 years or more. However, those with certain risk markers have a more aggressive disease that shortens survival to less than 3 years. Markers of high risk include anemia, thrombocytopenia, and absence of mutations in the *IGHV* gene. Mutations in *IGHV* correlate very closely with levels of intracellular ZAP-70, detection of which may be substituted for tests of *IGHV* mutation. ZAP-70 is a tyrosine kinase that is linked to the T-cell receptor (see [Chapter 8](#)). ZAP-70 negativity is associated with improved mean survival.²⁵ It is not normally detected in CLL cells with mutated *IGHV*, but is easily detectable by immunohistologic studies in cells with an unmutated *IGHV*.

Current treatment modalities for CML do not cure the disease or

prevent blastic transformation. Standard treatment consists of combined chemotherapy, biologic response modifiers, and allogeneic stem cell transplantation. Although transplantation is potentially curative, its use is limited by donor availability and high toxicity in older adults, thus limiting use to those older than 65 years. Traditional chemotherapy agents used are hydroxyurea and busulfan. The development and introduction of the first tyrosine kinase inhibitor imatinib mesylate (Gleevec) as a treatment modality lead to changes in the management of CML. Other tyrosine kinase inhibitors have been developed; however, concerns regarding disease persistence and resistance still exist.²⁶ Imatinib mesylate is highly specific for CML and suppression of BCR-ABL kinase activity and produces a complete cytogenetic response in more than 80% of newly diagnosed persons; however, it does not cure CML because it does not kill leukemia stem cells (LSCs) both in vitro and in vivo.²⁷⁻³⁰ New targets or drugs have been reported to inhibit LSCs in cultured CD34+ CML cells or in mouse models. These drugs include the Alox5 pathway inhibitor, Hsp90 inhibitors, omacetaxine, hedgehog inhibitor, and BMS-214662. Some suggest targeting LSCs but not normal stem cells is a correct strategy for anticancer therapies in the future.²⁸

Alterations of Lymphoid Function

Lymphadenopathy

Lymphadenopathy is characterized by enlarged lymph nodes. Lymph node enlargement is caused by an increase in size and number of its germinal centers caused by proliferation of lymphocytes and monocytes or invasion by malignant cells. Normally, lymph nodes are not palpable or are barely palpable. Enlarged lymph nodes are characterized by being palpable and often also may be tender or painful to touch, although not in all situations (see [Fig. 30.6](#)).

Localized lymphadenopathy usually indicates drainage of an area associated with an inflammatory process or infection (reactive lymph nodes). Generalized lymphadenopathy is usually a result of malignant

or nonmalignant disease, particularly in adults. Palpable nodes, however, do not always indicate serious disease and may indicate only a reaction to minor trauma or infection of a specific structure. The location and size of the enlarged nodes are important factors in diagnosing the cause of the lymphadenopathy, as are the individual's age, gender, and geographic location. Generalized lymphadenopathy occurs with non-Hodgkin lymphomas, chronic lymphocytic leukemia, histiocytosis, and disorders that produce lymphocytosis. In general, lymphadenopathy results from one of four types of conditions: (1) neoplastic disease, (2) immunologic or inflammatory conditions, (3) endocrine disorders, or (4) lipid storage diseases. Diseases of unknown cause, including reactions to drugs, also may lead to generalized lymphadenopathy.

Malignant Lymphomas

Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system. The classification of lymphomas was published by the WHO and is derived from the Revised European-American Lymphoma (REAL) classification. This classification is based on the cell type from which the lymphoma probably originated (Box 30.2). The basic groups include *Hodgkin lymphoma* and *non-Hodgkin lymphoma*. Two groups that were previously classified as *non-Hodgkin lymphoma* are now classified as B-cell neoplasms, T-cell neoplasms, and natural killer (NK) cell neoplasms. With the new classification, multiple myeloma, which was previously classified independently, is included as a B-cell lymphoma. Non-Hodgkin lymphoma can be further divided into cancers that have an *indolent* or slow-growing course and those with an *aggressive* or fast-growing course. These different subtypes progress and respond to treatment differently. Both Hodgkin lymphoma and non-Hodgkin lymphoma occur in children and adults, and the overall treatment and prognosis depend on the stage and type of lymphoma.

Box 30.2

World Health Organization Classification of Lymphoid Neoplasms

B-Cell Neoplasms

Precursor B-Cell Neoplasms

Precursor B-lymphoblastic leukemia/lymphoma
Precursor B-cell acute lymphoblastic leukemia

Mature (Peripheral) B-Cell Neoplasms

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytoid lymphoma
Splenic marginal zone B-cell lymphoma (with/without villous lymphocytes)
Hairy cell leukemia
Plasma cell myeloma/plasmacytoma
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid (MAL type) tissue
Nodal marginal zone B-cell lymphoma (with/without monocytoid B cells)
Follicular lymphoma
Mantle-cell lymphoma
Diffuse large B-cell lymphoma
 Mediastinal large B-cell lymphoma
 Primary effusion lymphoma
Burkitt lymphoma/Burkitt cell leukemia

T-Cell and NK-Cell Neoplasms

Precursor T-Cell Neoplasms

Precursor T-lymphoblastic lymphoma/leukemia
Precursor T-cell acute lymphoblastic leukemia

Mature (Peripheral) T-Cell Neoplasms

T-cell prolymphocytic leukemia
T-cell granular lymphocytic leukemia
Aggressive NK-cell leukemia
Adult T-cell lymphoma/leukemia (HTLV-1 positive)
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-type T-cell lymphoma
Hepatosplenic gamma-delta T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides/Sézary syndrome
Anaplastic large-cell lymphoma, T/null cell, primary cutaneous type
Peripheral T-cell lymphoma, not otherwise characterized
Angioimmunoblastic T-cell lymphoma
Anaplastic large-cell lymphoma, T/null cell, primary systemic type

Hodgkin Lymphoma (Hodgkin Disease)

Nodular lymphocyte predominant Hodgkin lymphoma
Classic Hodgkin lymphoma

- Nodular sclerosis Hodgkin lymphoma (grades 1 and 2)
- Lymphocyte-rich classic Hodgkin lymphoma
- Mixed cellularity Hodgkin lymphoma
- Lymphocyte depletion Hodgkin lymphoma

HTLV, Human T-cell leukemia virus; *NK*, natural killer.

End Results (SEER) Program. Available at:

http://training.seer.cancer.gov/module_coding_primary/table_who_class_hemo_2.html.

Globally, the incidence of lymphoma exhibits a significant geographic variation; it is more prevalent in North America, Australia/New Zealand, and Europe whereas it is less common in Asia and Africa, except where Burkitt lymphoma is endemic.³¹ Lymphoma is the most common blood cancer in the United States. Incidence rates of lymphoma differ with respect to age, gender, geographic location, and socioeconomic class. The estimated number of new cases of lymphoma for 2017 is more than 80,500 individuals with estimated deaths at 21,210.⁷ Since the early 1970s, the incidence of non-Hodgkin lymphoma has nearly doubled. The exact reason for this increase remains a mystery; however, a modest portion of the increase is attributed to lymphomas developing in association with immune deficiencies, including AIDS and organ transplants. Conversely, the incidence of Hodgkin lymphoma has declined over the same time period, especially among older adults.

Factors associated with country development and economic improvement include changes in diet (e.g., overnutrition), increases in anthropometric measurements (e.g., metabolic syndrome), improvements in hygiene, changes in family size (i.e., smaller families), adoption of sedentary lifestyles, advancements in medical access and care, increases in life span, and exposure to environmental carcinogens associated with industrialization.³¹ In general, lymphomas are the result of genetic mutations or viral infection. These factors are related to an aging world population and increasing adoption of cancer-causing behaviors.³¹ Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses. Lymphomas usually start in the lymph nodes or lymphoid tissues of the stomach or intestines.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a malignant lymphoma first characterized by Thomas Hodgkin in 1832. HL progresses from one group of lymph nodes to another and includes the development of systemic symptoms and the presence of B cells called **Reed-Sternberg (RS) cells** (Fig. 30.9). It is estimated that more than 8260 individuals will be newly diagnosed with HL in 2017 with estimated deaths of 1070.⁷ The incidence of HL is higher in males, and the median age of diagnosis is 64 years. Incidence rates for HL have declined, especially among older adults. The decrease in incidence in older adults is attributed to improved diagnostic accuracy. The incidence is greater in whites than blacks. Denmark, the Netherlands, and the United States have the highest incidence of HL, and Japan and Australia have the lowest incidence. HL peaks at two different ages: early in life in the second and third decades and later in life during the sixth and seventh decades.

FIGURE 30.9 Reed-Sternberg Cell. A large, multinucleated or multilobed cell (center of photograph) with inclusion body–like nucleoli surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

It is widely accepted that the RS cell represents the malignant transformed lymphocyte. RS cells are often large and binucleate, with occasional mononuclear variants; these cells are the hallmark of HL and are necessary for the diagnosis of HL. However, they are not specific to HL. In rare instances, cells resembling RS cells can be found in benign illnesses, as well as in other forms of cancer, including non-Hodgkin lymphomas and solid tissue cancers and in infectious mononucleosis.

The triggering mechanism for the malignant transformation of cells remains unknown. Classic HL appears to be derived from a B cell in the germinal center that has not undergone successful immunoglobulin gene rearrangement (see [Chapter 8](#)) and would normally be induced to undergo apoptosis. Survival of this cell may be linked to infection with EBV. Laboratory and epidemiologic studies have linked HL with EBV infections and EBV DNA. RNA and proteins are frequently observed in HL cells. The RS cells secrete and release cytokines (e.g., IL-10, transforming growth factor-beta [TGF-β]) that result in the accumulation of inflammatory cells that produces the local and systemic effects. HL is subcategorized into two main types: classic Hodgkin and nodular lymphocyte–predominant Hodgkin. Classic HL is subclassified into four types ([Table 30.3](#)) based on the morphology of RS cells, and the characteristics of the inflammatory cell infiltrate in the tumor. Nodular lymphocyte–predominant HL presents with earlier stage disease, longer survival, and fewer treatment failures than classic HL.³² However, despite a more favorable prognosis, in approximately 10% of people nodular lymphocyte–predominant HL has a tendency to histologically transform into diffuse large B-cell lymphoma.³³

TABLE 30.3

SUBTYPES OF HODGKIN LYMPHOMA

SUBTYPE	INCIDENCE	PRESENTATION
Nodular sclerosis Hodgkin	Most common subtype in developing countries Found in all ages but most	Large tumor nodules with RS cells surrounded by collagen and fibrous bands

lymphoma (HL)	common in adolescents and young adults (median age of onset is about 28 years) Incidence in females exceeds that in males	
Mixed cellularity HL	Second most common subtype Incidence in males exceeds that in females	RS cells with mixed inflammatory cell (lymphocytes, monocytes/macrophages, eosinophils, plasma cells) infiltrates
Lymphocyte-rich classic HL	Uncommon subtype Found in all ages but most common in adults Incidence in males exceeds that in females	Few RS cells and predominantly lymphocytic infiltration Usually localized at diagnosis Survival is long with or without treatment
Lymphocyte depletion HL	Uncommon subtype Most common type in older adults, HIV-positive individuals, and persons in nonindustrialized countries Incidence in males exceeds that in females	Large number of RS cells with less additional cellular infiltrate Usually widespread disease: abdominal lymphadenopathy; spleen, liver, and bone marrow involvement, without peripheral lymphadenopathy Stage is usually more advanced at diagnosis

HIV, Human immunodeficiency virus; *RS*, Reed-Sternberg.

The molecular events causing malignant transformation remain controversial; although RS cells are apparently from B-cell lineage, they express very few B-cell markers and express markers normally not found on B cells. For instance, RS cells do not express immunoglobulin, but do express CD15 (a carbohydrate adhesion molecule found on neutrophils), TARC (a Th2-cell-specific chemokine), and T-cell-associated antigens (e.g., β -chain of the T-cell receptor).³⁴ The precise genetic defects leading to development of HL are unknown, although several have been suggested. These generally include defects in immunoglobulin variable region gene rearrangement or defects in other B-cell-specific differentiation genes.

◆Clinical Manifestations.

Many of the characteristic clinical features (Box 30.3) of HL can be explained by the complex action of cytokines and other growth factors that are secreted by the malignant cells. These substances induce infiltration and proliferation of inflammatory cells, resulting in an enlarged, painless lymph node in the neck (often the first sign of HL)

(Fig. 30.10). The discovery of an asymptomatic mediastinal mass on routine chest x-ray is not uncommon and is often an initial sign of HL. The cervical, axillary, inguinal, and retroperitoneal lymph nodes are commonly affected in HL (Fig. 30.11). Local symptoms caused by pressure and obstruction of the lymph nodes are the result of the lymphadenopathy.

Box 30.3

Clinical Manifestations of Hodgkin Lymphoma

Physical Findings

- Adenopathy
- Mediastinal mass
- Splenomegaly
- Abdominal mass

Symptoms

- Fever, weight loss, night sweats
- Pruritus

Laboratory Findings

- Thrombocytosis
- Leukocytosis
- Eosinophilia
- Elevated erythrocyte sedimentation rate (ESR)
- Elevated alkaline phosphatase
- Paraneoplastic syndromes

FIGURE 30.10 Hodgkin Lymphoma and Enlarged Cervical Lymph Node. Typical enlarged cervical lymph node in the neck of a man with Hodgkin lymphoma. The scar of a previous biopsy incision is well healed. (From Hoffbrand AV, Petit JE, Vyas P: *Color atlas of clinical hematology*, ed 4, Philadelphia, 2009, Mosby Elsevier.)

FIGURE 30.11 Common and Uncommon Involved Lymph Node Sites for Hodgkin Lymphoma.

About one-third of individuals will have some degree of systemic symptoms.³⁵ Intermittent fever, without other symptoms of infection, drenching night sweats, itchy skin (pruritus), and fatigue are relatively common. These constitutional symptoms accompanied by weight loss are associated with a poor prognosis. The Cotswold staging classification system used for HL is able to establish a correlation between the anatomic extent of the disease and the prognosis (Table 30.4). This classification system is based on the individual's medical history and physical examination (presence of symptoms and palpable lymph nodes) as well as other radiologic and hematologic results. Prognostic indicators include clinical stage, histologic type, tumor cell concentration and tumor burden,

constitutional symptoms, and age.

TABLE 30.4

COTSWOLD STAGING CLASSIFICATION SYSTEM

STAGE	CRITERIA
I	Involvement of a single lymph node region or single extranodal organ or site
II	Involvement of two or more lymph node regions on the same side of the diaphragm or a single extranodal organ or site and its regional lymph nodes
III	Involvement of lymph node regions or structures on both sides of the diaphragm
IV	Disseminated involvement of one or more extralymphatic organs or an isolated extralymphatic organ with distant nodal involvement
	Modifying characteristics for all four stages:
	A: No B symptoms
	B: Unexplained fever of >38°C (100.4°F), drenching night sweats, unexplained loss of >10% of body weight in the 6 months preceding diagnosis
	E: Large mediastinal mass with direct extension into extranodal sites

Data from Lister TA, Crowther D: *Semin Oncol* 17:696, 1990.

Although HL rarely arises in the lung, mediastinal and hilar node adenopathy can cause secondary involvement of the trachea, bronchi, pleura, or lungs. Retroperitoneal nodes can involve vertebral bodies and nerves, causing displacement of ureters. Spinal cord involvement is more common in the dorsal and lumbar regions than in the cervical region. Although uncommon, skin manifestations include psoriasis and eczematoid lesions, causing itching and scratching.

As a result of direct invasion from mediastinal lymph nodes, pericardial involvement can cause pericardial friction rub, pericardial effusion, and engorgement of the neck veins. The gastrointestinal (GI) tract and urinary tract rarely are involved. Anemia often is found in individuals with HL, accompanied by a low serum iron level and decreased iron-binding capacity. Other laboratory findings include elevated sedimentation rate, leukocytosis, and eosinophilia. Leukopenia occurs in advanced states of HL.

Splenic involvement of HL depends on histopathologic type (see [Table 30.3](#)). The spleen is involved in 60% of cases of mixed cellularity

and lymphocytic depletion types. With lymphocyte predominance and nodular sclerosis types, only 34% of cases reveal splenic involvement.

◆Evaluation and Treatment.

Because of the variability in symptoms, early definitive detection may be difficult. Asymptomatic lymphadenopathy can progress undetected for several years. Careful evaluation, including chest x-rays, lymphangiography, and biopsy, should be carried out for individuals with fever of unknown origin and peripheral lymphadenopathy.³⁵ A lymph node biopsy with scattered RS cells and a cellular infiltrate is highly indicative of HL. The effectiveness of treatment is related to the age of the individual and the extent of the disease. Approximately 75% of individuals diagnosed with HL are cured, largely because of successful combined treatment with radiation therapy and chemotherapy (Fig. 30.12). Over the past 50 years, the death rate has fallen more rapidly for HL than for any other malignancy. More recent treatments include high-dose chemotherapy in conjunction with bone marrow or stem cell transplantation. Monoclonal antibodies also are being developed and nonmyeloablative allogeneic stem cell transplantation has been found to help certain individuals, even though this treatment is still under development.

FIGURE 30.12 Cervical Hodgkin Lymphoma (Extreme Case). A, Young boy

with extensive cervical Hodgkin lymphoma. B, Appearance several years later and after treatment, when axillary manifestations developed. C, Appearance 23 years after initial treatment with radiation. (From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer*, ed 2, St Louis, 1985, Mosby.)

The 5-year survival rate varies depending on the stage that is identified at diagnosis. The 5-year survival rate for stages I and II is 90% to 95%, 80% to 85% for stage III, and 75% for stage IV. Those with stage I or II disease are candidates for chemotherapy, radiation therapy, or a combination of these treatment modalities. Individuals with stage III or IV disease, bulky disease (more than 10-cm mass or mediastinal disease with a transverse diameter exceeding 33% of the transthoracic diameter), or the presence of B symptoms require combined chemotherapy with or without additional radiation treatment. Other factors, if present, have an influence on survival. Poorer survival is related to a high white blood cell count (greater than 15,000/ μ L) or a low hemoglobin (Hb) level (less than 10.5 g/dL); low lymphocyte count (less than 600/ μ L); and male gender. Cure for HL can be achieved in 75% of cases with current therapies.

Non-Hodgkin Lymphoma

The **non-Hodgkin lymphomas (NHLs)** are a heterogeneous group of neoplasms arising from lymphoid tissue, with varied biologic and clinical features. Worldwide, NHLs account for about 3% of the cancer burden with global variations in patterns of occurrence.³⁶ NHL incidence in developed countries was 8.6/100,000 compared to 3.6/100,000 in less developed countries, whereas HL incidence in developed countries was 2.1/100,000 compared to 0.6/100,000 in less developed countries.⁶ In the United States, NHLs account for 4.3% of all new cancer cases and HLs account for about 0.5% of all new cancer cases.³⁷ NHL incidence rates increased worldwide from 1950 to 2000, tripling in adults older than 65 years.³⁸ The previously used generic classification of non-Hodgkin lymphoma (NHL) has been reclassified in the WHO/REAL scheme into (1) **B-cell neoplasms**, which include a variety of lymphomas including myelomas that originate from B cells at various stages of differentiation, and (2) **T-cell and NK-cell**

neoplasms, which include lymphomas that originate from either T cells or NK cells. These cancers are differentiated from HL by lack of RS cells and other cellular changes not characteristic of HL.

More than 72,240 cases of NHL with 20,140 deaths are predicted in the United States for 2017.⁷ The median age of diagnosis is 67 years. The highest incidence of NHL is in North America, Europe, Oceania, and several African countries.³⁹ NHL affects more men than women. For unknown reasons, the incidence increased in many high-income countries between the 1950s and 1990s and no further increase has been observed during the last decade.³⁹ Part of the increased incidence has been attributed to diagnostic improvements as well as increases in the number of AIDS-related cancers following the HIV epidemic.³⁹ Mortality from NHL has declined since 1997.⁴⁰ It is thought that newer treatment modalities are improving survival rates.

Risk factors include a family history of the disease, exposure to a variety of mutagenic chemicals (e.g., certain occupations) or to irradiation, infection with certain cancer-related viruses (e.g., EBV, human herpesvirus-8, HIV, HTLV-1, hepatitis C), and immune suppression related to organ transplantation. Gastric infection with *Helicobacter pylori* increases the risk for gastric lymphomas. NHL is a disease of middle age, usually found in individuals more than 50 years old.

◆Pathophysiology.

NHL is best described as a progressive clonal expansion of B cells, T cells, or NK cells. B cells account for 85% to 90% of NHLs, with most of the remaining cases of NHL attributable to T cells and, rarely, NK cells. A very small percentage originates from macrophages. Chromosomal translocations may activate oncogenes, or the tumor-suppressor loci may be inactivated by deletion or mutation of chromosomes. Certain subtypes may have altered genomes by oncogenic viruses. The genetic lesions affecting proto-oncogenes or tumor-suppressor genes result in cell immortalization and the resultant increase in the number of malignant cells. The various subtypes of NHL may be identified by specific diagnostic markers

related to various cytogenic lesions.

Lymphomas most likely originate from mutations in cellular genes (many of which are environmentally induced) in a single cell that lead to loss of control of proliferation and other aspects of cell growth. The most common type of chromosomal alteration in NHL is translocation, which disrupts the genes encoded at the breakpoints.

NHL tumors are categorized by the level of differentiation, cell of origin, and rate of cellular proliferation. Tumor aggressiveness of many B-cell NHLs may be predicted by the pattern of cell growth and size. Tumors with a characteristic nodular pattern, vaguely resembling lymphoid follicular structures, are generally less aggressive than lymphomas, with a diffuse pattern of proliferation. Small lymphocyte lymphomas are less aggressive than large-cell lymphomas, which are generally intermediate to high grade in aggressiveness. However, small cells are characteristic of some subtypes of high-grade lymphomas.

◆Clinical Manifestations.

Clinical manifestations of NHL usually begin as localized or generalized lymphadenopathy, similar to HL. The cervical, axillary, inguinal, and femoral chains are the most commonly affected sites. Generally, the swelling is painless and the nodes have enlarged and transformed over a period of months or years. Other sites of involvement are the nasopharynx, GI tract, bone, thyroid, testes, and soft tissue. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), and leg swelling.

Lymphomas are classified as low, intermediate, or high grade. A low-grade lymphoma, which also may be termed *indolent*, has a slow progression. Individuals with low-grade lymphoma commonly present with a painless, peripheral adenopathy. Spontaneous regression of these nodes may occur, mimicking the presence of an infection. Night sweats with an elevated temperature (more than 38°C [100.4°F]) and weight loss, as well as extranodal involvement, are not typically present in the early stages but are common in advanced

or end stages of the disease. Cytopenia, reflective of bone marrow involvement, is often observed. Hepatomegaly is common; however, splenomegaly is present in approximately 40% of individuals. Fatigue and weakness are more prevalent with advanced stages.

Intermediate- and high-grade lymphomas, which are more aggressive, have a more varied clinical presentation. A high-grade lymphoma also may be termed *aggressive*. Adenopathy is common with more than one-third of individuals having extranodal involvement. Common sites are the GI tract, skin, bone marrow, sinuses, genitourinary (GU) tract, thyroid, and CNS. Night sweats, with an increased temperature (more than 38°C [100.4°F]), as well as weight loss (more than 10% from baseline within 6 months) are present in approximately 30% to 40% of individuals. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), and leg swelling. Hepatomegaly and splenomegaly are often present. Differences in clinical features are noted in [Table 30.5](#).

TABLE 30.5

CLINICAL DIFFERENCES BETWEEN NON-HODGKIN LYMPHOMA AND HODGKIN LYMPHOMA

CHARACTERISTIC	NON-HODGKIN LYMPHOMA	HODGKIN LYMPHOMA
Nodal involvement	Multiple peripheral nodes	Localized to single axial group of nodes (i.e., cervical, mediastinal, paraaortic)
	Mesenteric nodes and Waldeyer ring commonly involved	Mesenteric nodes and Waldeyer ring rarely involved
Spread	Noncontiguous	Orderly spread by contiguity
B symptoms*	Uncommon	Common
Extranodal involvement	Common	Rare
Extent of disease	Rarely localized	Often localized

*Fever, weight loss, night sweats.

◀ **Evaluation and Treatment.**

Biopsy is considered the primary means for diagnosis of NHL. Staging of NHL is necessary to identify treatment and make a prognosis. In addition to biopsy, computed tomography (CT) scans of the neck, chest, abdomen, and pelvis, as well as bilateral bone marrow aspirate examination, are performed. Data from all three procedures are necessary for appropriate staging. A common finding in NHL is noncontiguous lymph node involvement, which is not common in HL. The Ann Arbor staging system is most commonly used to stage NHL (Table 30.6).

TABLE 30.6

ANN ARBOR STAGING FOR HODGKIN LYMPHOMA

STAGE CRITERIA	
I	Involvement of single lymph node
II	Involvement of two or more lymph node regions
III	Involvement of lymph nodes on both sides of diaphragm
IV	Diffuse involvement of one or more extralymphatic organs with or without associated lymph node involvement
SUBCLASSIFICATIONS	
E	Involvement of adjacent extralymphatic site
S	Involvement of spleen
A	Asymptomatic
B	Fever, night sweats, weight loss

Treatment for NHL is quite diverse and depends on cell type (B or T), tumor stage, histologic status (low, intermediate, or high grade), symptoms, age, and presence of comorbidities. Depending on the cell type (B or T) of the tumor, the stage of the disease, and the aggressiveness of the tumor, treatment is usually initiated at the time of diagnosis. However, because treatment is not curative for some low-grade indolent lymphomas that are widely disseminated, observation without treatment may be the most appropriate choice. These indolent tumors are often asymptomatic for the individual and this approach improves quality of life. In some cases the disease may be so slow growing that treatment is not needed for an extended

period of time.

Success of treatment is dependent on several parameters, including the type of lymphoma, stage of disease, type of cell, involvement of organs outside the lymph nodes, age of the person, and severity of the body's reaction to the disease (e.g., fever, night sweats, weight loss). Treatment with chemotherapy alone may be adequate in many cases, although radiation therapy is frequently included. Low-dose chemotherapy has been followed by autologous stem cell transplantation in some NHLs or for recurrent disease. Treatment of B-cell lymphomas with rituximab has proven effective. Rituximab is a commercial monoclonal antibody against antigen CD20, which is expressed on the surface of all B cells, including those that are malignant. Administration of rituximab depletes most B cells and allows the replenishment of normal B cells from the lymphoid stem cell pool. It has also proven useful in a variety of autoimmune diseases, including immune thrombocytopenic purpura, autoimmune anemias, systemic lupus erythematosus, and rheumatoid arthritis.

Radioimmunotherapy, a newer treatment approach, combines radiation therapy with monoclonal antibody therapy and is used to improve rates of complete remission both in indolent forms of lymphoma (follicular and marginal zone) and in aggressive forms, including large B-cell and mantle cell lymphomas. Studies suggest improved complete remission rates and longer disease-free survival in persons with these types of lymphomas.

Individuals with NHL can survive for extended periods.⁴¹ A partial remission may be achieved in some cases in which evidence of the disease remains but the disease does not progress. Survival with nodular lymphoma ranges up to 15 years, but those with diffuse disease generally do not survive as long. Overall, the survival rates of NHL are less than those for Hodgkin lymphoma. For NHL, the survival rates are 1 year, 77%; 5 years, 59%; and 10 years, 42%. Many investigators believe that more aggressive treatment increases the cure rate. High-grade NHL is seen with increasing frequency in persons with AIDS and has an extremely poor prognosis.

Burkitt Lymphoma

Burkitt lymphoma is a B-cell non-Hodgkin lymphoma with unique clinical and epidemiologic features and it accounts for 30% of childhood lymphomas worldwide. It is highly aggressive and is the fastest growing human tumor. There are three main types of Burkitt lymphoma (*endemic, sporadic, and immunodeficiency-related*). *Endemic* Burkitt lymphoma commonly occurs in Africa and is linked to the EBV, and *sporadic* Burkitt lymphoma occurs worldwide.⁴¹ *Immunodeficiency-related* Burkitt lymphoma is most often seen in individuals with AIDS. Burkitt lymphoma occurs most often in children and young adults. *Endemic* cases, usually from Africa, involve a rapidly growing tumor of the jaw and facial bones (Fig. 30.13). In the United States, Burkitt lymphoma is rare, usually involves the abdomen, and is characterized by extensive bone marrow invasion and replacement.

FIGURE 30.13 Burkitt Lymphoma. Burkitt lymphoma involving the jaw in a young African boy. (Courtesy I. Mcgrath, MD, Bethesda, MD. From Zitelli BJ, McIntire SC, Norwalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, Philadelphia, 2012, Saunders.)

◀Pathophysiology.

EBV is associated with almost all cases (more than 90%) of Burkitt lymphoma. It is suspected that suppression of the immune system by other illnesses (e.g., HIV infection, chronic malaria) increases the individual's susceptibility to EBV. B cells are particularly sensitive because of specific surface receptors for EBV. As a result, the B cell undergoes chromosomal translocations that result in overexpression of the *C-MYC* proto-oncogene and loss of control of cell growth (Fig. 30.14). The most common translocation (75% of individuals) is between chromosomes 8 (containing the *C-MYC* gene) and 14 (containing the immunoglobulin heavy-chain genes). Other translocations have been reported between chromosome 8 and chromosomes 2 or 22, which contain genes for immunoglobulin light chains.

FIGURE 30.14 Burkitt Lymphoma Cells. **A**, A case of Burkitt lymphoma illustrated at low power showing the “starry sky” appearance. This is due to the dense proliferating cells producing the dark sky, and the scattered lighter-staining tingible body macrophages (*stars*) phagocytizing dying cells. **B**, Higher magnification illustrating the syncytia of intermediate-sized cells with coarse chromatin and multiple nucleoli. Note the tingible body macrophage with abundant light cytoplasm and ingested debris (*center bottom*). **C**, Burkitt cells as seen on a Wright-stained bone marrow aspirate in a person with Burkitt leukemia. Note the deep blue cytoplasm with numerous vacuoles. **D**, Fluorescence in situ hybridization (FISH) with

probes to MYC and IGH illustrates the IGH/MYC fusion. E, The 8;14 chromosomal translocation and associated oncogenes in Burkitt lymphoma. *IGH*, Immunoglobulin heavy chain loci; *MYC*, protooncogene. (A–D Courtesy Dr. Y. Zhang, University of Chicago. From Hoffman R et al: *Hematology: basic principles and practice*, ed 6, Philadelphia, 2013, Churchill Livingstone. E From Kumar V, Abbas A, Aster JC: *Robbins & Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

◆Clinical Manifestations.

In non-African Burkitt lymphoma the most common presentation is abdominal swelling. Manifestations of most tumors occur at extranodal sites. More advanced disease may involve the eye, ovaries, kidneys, or glandular tissue (breast, thyroid, tonsils), and presents with type B symptoms (night sweats, fever, weight loss). Common manifestations may include nausea and vomiting; loss of appetite or change in bowel habits, or both; gastrointestinal bleeding, symptoms of an acute abdominal condition; intestinal perforation; and renal failure.

◆Evaluation and Treatment.

The presence of tumors in the jaw and facial bones, enlarged lymph nodes, and bone marrow containing malignant B cells is usually indicative of Burkitt lymphoma. The mainstay of treatment is aggressive multidrug regimens, such as combination chemotherapy. Adjuvant monoclonal antibody therapy with rituximab (anti-CD20) may be a promising agent for improving outcomes.⁴²

Lymphoblastic Lymphoma

Lymphoblastic lymphoma (LL) is a relatively rare variant of NHL (2% to 4%) but accounts for about 20% of cases of NHL in children and adolescents, with a male predominance. It is a fast-growing type of NHL in which increased numbers of lymphoblasts are found in the lymph nodes and the thymus gland. Lymphoblasts also can spread to other areas of the body. The vast majority of cases of LL (more than 85%) are of T-cell origin, and the remainder of LL cases arise from B cells. LL is similar to acute lymphoblastic leukemia and may be

considered a variant of that disease.

◆Pathophysiology.

The disease arises from a clone of relatively immature T cells that becomes malignant in the thymus. As with most lymphoid tumors, LL is frequently associated with translocations, primarily of the chromosomes that encode for the T-cell receptor (chromosomes 7 and 14). These aberrations result in increased expression of a variety of transcription factors and loss of growth control.

◆Clinical Manifestations.

The first sign of LL is usually a painless lymphadenopathy in the neck. Peripheral lymph nodes in the chest become involved in about 70% of individuals, mostly above the diaphragm. LL is a very aggressive tumor that presents as stage IV in most people. T-cell LL is associated with a unique mediastinal mass (up to 75%) because of the apparent origin of the tumor in the thymus.

The mass results in chest pain and may cause compression of bronchi or the superior vena cava. The tumor may infiltrate the bone marrow in about half of those affected, and suppression of bone marrow hematopoiesis leads to increased susceptibility to infections. Other organs, including the liver, kidney, spleen, and brain, may also be affected. Many individuals express type B symptoms (fever, night sweats, and significant weight loss).

◆Evaluation and Treatment.

The most common therapeutic approach is combined chemotherapy with multiple drugs. In early stages of the disease, the response rate is high with increased survival; the 5-year survival in children is 80% to 90%, and 45% to 55% in adults. Although LL is easily treated, there is a high relapse rate: 40% to 60% of adults.

Conditions That Mimic Lymphomas

Certain other clinical conditions mimic the malignant lymphomas. These conditions include tuberculosis (TB), syphilis, systemic lupus

erythematosus, lung cancer, and bone cancer. An important distinction between lymphomas and other conditions is that lymphomas usually involve localized lymphadenopathy. Infectious precursors of malignant lymphomas are characterized by more generalized lymphadenopathy with systemic signs and symptoms.

Plasma Cell Malignancies

The plasma cell is the end-stage cell of the humoral immune response (see [Chapter 8](#)). Immunocompetent B cells presented with antigen and stimulated with cytokines from T helper cells will undergo proliferation and differentiation into antibody-producing plasma cells. Antigen-reactive B cells have undergone rearrangement of immunoglobulin heavy-chain variable region genes (*V*, *D*, *J*) and express surface IgM or IgD, or both. After stimulation with antigen, the B cells may not undergo any further genetic rearrangement; instead, they may develop into plasma cells that secrete IgM or selectively rearrange the immunoglobulin heavy-chain genes to irreversibly switch to secretion of IgG, IgA, or IgE. During this process some cells may undergo malignant transformation, leading to one of several types of plasma cell malignancies ([Fig. 30.15](#)). The most common and most aggressive plasma cell tumor is multiple myeloma. Examples of other diseases in this classification include precursors to malignant myeloma (smoldering myeloma, monoclonal gammopathy of undetermined significance [MGUS]), solitary plasmacytoma of the bone, and Waldenström macroglobulinemia. A common characteristic of these tumors is secretion of complete or partial immunoglobulin molecules.

FIGURE 30.15 Distribution of Monoclonal Gammopathy Types. **A**, Distribution of serum monoclonal proteins in 1485 patients seen at the Mayo Clinic during 2008. **B**, Diagnoses in 1612 cases of monoclonal gammopathy seen at the Mayo Clinic during 2008. *Ig*, Immunoglobulin; *MGUS*, monoclonal gammopathy of undetermined significance; *SMM*, smoldering multiple myeloma. (From Goldman L, Schafer AI: *Goldman's Cecil medicine*, ed 24, Philadelphia, 2012, Saunders.)

Multiple Myeloma

Multiple myeloma (MM; plasma cell myeloma) is a clonal plasma cell cancer characterized by the slow proliferation of tumor cell masses in the bone marrow associated with lytic bone lesions. Uncommon variants include *solitary myeloma (plasmacytoma)* with a single mass in bone or soft tissue and *smoldering myeloma*, which is defined by a lack of symptoms and a high plasma abnormal antibody called the **M protein**. Most MMs secrete large amounts of monoclonal proteins that resemble intact immunoglobulins. MM is the third most common blood cancer (after lymphoma and leukemia) in the United States. For unknown reasons, the reported incidence of myeloma has doubled in the past two decades. The number of new cases in the United States is estimated at greater than 30,280 with more than 12,590 deaths for 2017.⁷ Multiple myeloma occurs in all races, but the incidence in blacks is about twice that of whites. It rarely occurs before the age of 40 years—the peak age of incidence is between 65 and 70 years. It is slightly more common in men than women. Other risk factors include exposure to radiation or certain chemicals including pesticides, and a history of monoclonal gammopathy of undetermined significance

(MGUS, see [Clinical Manifestations](#)) or plasmacytoma.^{43,44} Neoplastic cells of multiple myeloma reside in the bone marrow and are usually not found in the peripheral blood. Occasionally it may spread to other tissues, especially in very advanced stages of the disease.

◆Pathophysiology.

Multiple myeloma is a biologically complex disease with significant heterogeneity reflected by a wide range of genetic alterations and individual differences in clinical response and survival of individuals receiving the same treatment.⁴⁵ The genetic mutations in different pathways alter the intrinsic biology of the plasma cell, generating the features of myeloma.⁴⁶ The genetic mutations may affect genes that impact cell growth and division, causing excessive proliferation of plasma cells. Many myelomas are aneuploidy, with chromosomal numbers ranging from 44 chromosomes to near tetraploid. Chromosomal translocations (breakpoints) are responsible for development of myeloma in most individuals. The primary translocation involves the immunoglobulin heavy chain on chromosome 14 that relocates to sites containing genes that cell-cycle (cyclins) on chromosomes 11(q13), 12(p13), and 6(p21); oncogenes on chromosomes 16(q23), 8(q24), and 20; and fibroblast growth factor receptor on chromosome 4(p16).¹⁰ A progression of further secondary genetic alterations causes development to an aggressive MM ([Fig. 30.16](#)). The molecular pathogenesis of multiple myeloma also involves proto-oncogene mutations and, more rarely, inactivation of tumor-suppressor genes. The precise timing and reason for the genetic alteration and accumulation are unknown, but probably occur initially late in B-cell development after exposure to antigen. Investigators are studying various epigenetic alterations in multiple myeloma, for example, microRNAs and global changes in chromatin.⁴⁷ Epigenetic aberrations play an important role in the pathogenic events leading to MM, and further studies are warranted to identify the precise mechanisms.⁴⁵

FIGURE 30.16 Myeloma Cell Proliferation and Disease Progression. Development of malignant myeloma results from multiple genetic changes, initially a translocation involving the immunoglobulin heavy-chain genes on chromosome 14 or a deletion in chromosome 13. The intermediate phenotype is frequently genetically unstable, leading to further mutations that result in a myeloma. Interactions between myeloma cells and extracellular matrix proteins further increase adhesion molecule expression, antiapoptotic pathways, angiogenesis, bone resorption, and cytokine secretion. *IL-6*, Interleukin-6; *KRAS*, V-Ki-ras Z Kirsten rat sarcoma viral oncogene homolog; *MGUS*, monoclonal gammopathy of undetermined significance; *MIP-1 α* , macrophage inflammatory protein-1 α ; *NRAS*, neuroblastoma RAS viral (v-ras) oncogene homolog; *OPG*, osteoprotegerin; *RANKL*, receptor activator of nuclear factor- κ B ligand; *VEGF*, vascular endothelial growth factor. (From Abeloff M et al: *Abeloff's clinical oncology*, ed 4, Philadelphia, 2008, Churchill Livingstone.)

Malignant plasma cells arise from one clone of B cells that produce abnormally large amounts of one class of immunoglobulin (usually IgG, occasionally IgA, and rarely IgD or IgE). The malignant transformation may begin early in B-cell development, possibly before encountering antigen in the secondary lymphoid organs. The myeloma cells return either to the bone marrow or to other soft tissue sites. Cell adhesion molecules help them target favorable sites that promote continued expansion and maturation.

Myeloma cells in the bone marrow directly secrete hepatocyte growth factor and parathyroid hormone-related peptide and adhere to stromal cells, inducing their production of several cytokines (e.g., IL-6, IL-1, TNF- α , TNF- β , IL-11, macrophage inflammatory protein).

(Lymphocytes and cytokines are described in [Chapter 8](#).) These factors, particularly IL-6, act as an osteoclast-activating factor and stimulate osteoclasts to reabsorb bone. This process results in bone lesions and hypercalcemia attributable to release of calcium from the breakdown of bone.

The antibody produced by the transformed plasma cell is usually defective, containing truncations, deletions, and other abnormalities, and is frequently referred to as a *paraprotein* (abnormal protein in the blood). Because of the large number of malignant plasma cells, M protein becomes the most prominent protein in the blood in 80% of individuals with myeloma ([Fig. 30.17](#)). Suppression of normal plasma cells by the myeloma results in diminished or absent normal antibodies. The excessive amount of M protein also may contribute to many of the clinical manifestations of the disease. The myeloma may produce free immunoglobulin light chain (**Bence Jones protein**) that is present in the blood and urine in approximately 80% of individuals and contributes to damage of renal tubular cells.

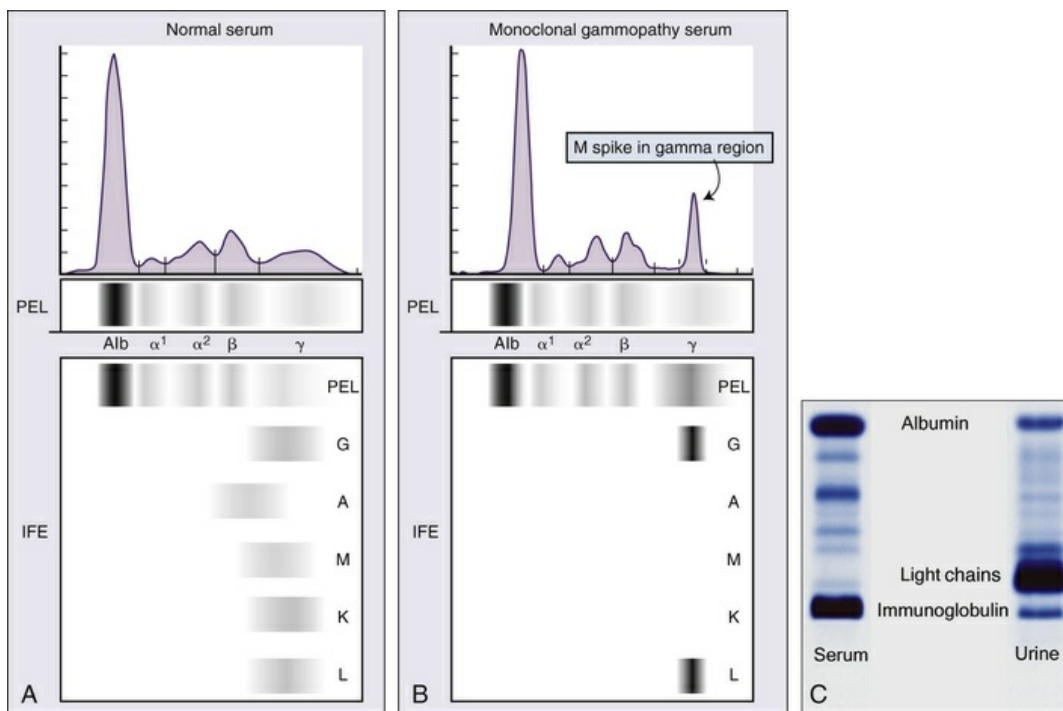

FIGURE 30.17 M Protein. Serum protein electrophoresis (PEL) is used to screen for M proteins in multiple myeloma. A, In normal serum the proteins

separate into several regions between albumin (*Alb*) and a broad band in the gamma (γ) region, where most antibodies (gamma globulins) are found. Immunofixation (*IFE*) can identify the location of IgG (*G*), IgA (*A*), IgM (*M*), and kappa (*K*) and lambda (*L*) light chains. B, Serum from an individual with multiple myeloma contains a sharp M protein (*M spike*). The M protein is monoclonal and contains only one heavy chain and one light chain. In this instance the IFE identifies the M protein as an IgG containing a lambda light chain. C, Serum and urine protein electrophoretic patterns in a client with multiple myeloma. Serum demonstrates an M protein (*Immunoglobulin*) in the gamma region, and the urine has a large amount of the smaller-sized light chains with only a small amount of the intact immunoglobulin. (A and B From Abeloff M et al: *Abeloff's clinical oncology*, ed 4, Philadelphia, 2008, Churchill Livingstone. C From McPherson R, Pincus M: *Henry's clinical diagnosis and management by laboratory methods*, ed 22, Edinburgh, 2012, Saunders.)

◆Clinical Manifestations.

The common presentation of MM is characterized by elevated levels of calcium in the blood (hypercalcemia) (13% of persons), renal failure (19%), anemia (72% of persons), and bone lesions (80% of persons).⁴⁸ The hypercalcemia and bone lesions result from infiltration of the bone by malignant plasma cells and stimulation of osteoclasts to reabsorb bone. This process results in the release of calcium (hypercalcemia) and the development of “lytic lesions” (round, “punched-out” regions of bone) (Fig. 30.18). Destruction of bone tissue causes pain, the most common presenting symptom, and pathologic fractures. The pain may be felt in a single bone of the entire skeleton, and the bones most commonly involved, in decreasing order of frequency, are the vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula. Spinal cord compression, because of the weakened vertebrae, occurs in about 10% of individuals. The pain is initially aching and intermittent, and is aggravated by weightbearing activities. As the disease progresses, pain becomes severe and prolonged. It is common for those with myeloma to be treated for a slipped vertebral disc or arthritis before the correct diagnosis of myeloma is established. The individual may complain of weakness, fatigue, weight loss, anorexia, easy bruising or bleeding, and trouble breathing in addition to pain.

FIGURE 30.18 Osteolytic Lesions in Individuals with Multiple Myeloma. A, Radiograph showing skull lesions in a client with myeloma. B, Roentgenogram of femur showing extensive bone destruction caused by tumor. Note absence of reactive bone formation. (A From Abeloff M et al: *Abeloff's clinical oncology*, ed 4, Philadelphia, 2008, Churchill Livingstone. B From Kissane JM, editor: *Anderson's pathology*, ed 9, St Louis, 1990, Mosby.)

Antibody proteins can increase in number and stick together, called *amyloidosis*, in peripheral nerves and organs, such as the heart and kidneys. Amyloidosis causes the nerves and organs to become stiff, and the manifestations include extreme exhaustion, purple spots on the skin, enlarged tongue, diarrhea, edema, and tingling and numbness in the legs and feet.

Proteinuria is observed in 90% of individuals. Renal failure may be either acute or chronic and is usually secondary to the hypercalcemia. Bence Jones protein may lead to damage of the proximal tubules. Anemia is usually normocytic and normochromic and results from inhibited erythropoiesis caused by tumor cell infiltration of the bone marrow.

The high concentration of paraprotein in the blood may lead to hyperviscosity syndrome. The increased viscosity interferes with blood circulation to various sites (brain, kidneys, extremities). Hyperviscosity syndrome is observed in up to 20% of individuals with MM. Additional neurologic symptoms (e.g., confusion,

headaches, blurred vision) may occur secondary to hypercalcemia or hyperviscosity.

Suppression of the humoral (antibody-mediated) immune response results in repeated infections, primarily pneumonias and pyelonephritis. The most commonly involved organisms are encapsulated bacteria that are particularly sensitive to the effects of antibody, such as pneumonia caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, or *Klebsiella pneumoniae* or pyelonephritis caused by *Escherichia coli* or other gram-negative organisms. Cell-mediated (T-cell) function is relatively normal. Overwhelming infection is the leading cause of death from MM.

MM is a progressive disorder and is often preceded by a condition known as **monoclonal gammopathy of undetermined significance (MGUS)**. MGUS is diagnosed by the presence of an M protein in the blood or urine without additional evidence of MM.⁴⁸ MGUS is present in approximately 1% of the general population and in 3% of individuals older than 70 years. The herbicide Agent Orange contains 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a human carcinogen, and was sprayed during the Vietnam War. Operation Ranch Hand veterans have a significantly increased risk of MGUS, supporting an association between Agent Orange exposure and multiple myeloma.⁴⁹ From occupational studies, pesticides (i.e., insecticides, herbicides, fungicides) are associated with increased risk of MM and MGUS.⁴⁹

Although MGUS is considered nonpathologic and requires no treatment, about 2% of individuals with MGUS progress to malignant plasma cell disorders. When MM is preceded by MGUS, it advances first to asymptomatic MM and then to symptomatic MM. Asymptomatic MM also may be referred to as **smoldering myeloma** and indolent myeloma.⁴⁸ Smoldering myeloma is usually characterized by the presence of an M protein and clonal bone marrow plasma cells, but with no indication of end-organ damage.

Most cases of symptomatic plasma cell tumors are multiple myeloma (about 94%). The remaining 6% of cases are divided equally between solitary plasmacytomas and extramedullary plasmacytomas.⁵⁰ **Solitary plasmacytoma** is characterized by a

solitary tumor of malignant plasma cells that may result in a single lytic bone lesion or may develop in the tissues (extramedullary plasmacytoma).⁴⁸ Extramedullary plasmacytoma can be found in a variety of soft tissues, but commonly in those of the upper respiratory tract (e.g., tonsils, nasopharynx, sinuses). Additionally, MM is staged to help determine prognosis and appropriate treatment (Table 30.7).

TABLE 30.7

INTERNATIONAL STAGING SYSTEM FOR MULTIPLE MYELOMA

STAGE	CRITERIA
I	Serum β_2 -microglobulin <3.5 mg/L
	Serum albumin \geq 3.5 g/dL
II	Not stage I or III*
III	Serum β_2 -microglobulin \geq 5.5 mg/L

*There are two categories for stage II: serum β_2 -microglobulin <3.5 mg/L but serum albumin <3.5 g/dL; or serum β_2 -microglobulin 3.5 to <5.5 mg/L irrespective of the serum albumin level.

From Greipp PR et al: *J Clin Oncol* 23(15):3412–3420, 2005.

◆ Evaluation and Treatment.

Diagnosis of MM is made by symptom assessment, radiographic and laboratory studies, and bone marrow biopsy. The International Myeloma Working Group consensus updated the disease definition of MM to include validated biomarkers and the existing requirements of CRAB features (hypercalcemia, renal failure, anemia, and bone lesions).⁵¹ The revised criteria for MM and smoldering MM are presented in Box 30.4.

Box 30.4

Revised International Myeloma Working Group Diagnostic Criteria for Multiple

Myeloma and Smoldering Multiple Myeloma

Definition of Multiple Myeloma

Clonal bone marrow plasma cells $\geq 10\%$ or biopsy-proven bony or extramedullary plasmacytoma* and any one or more of the following myeloma-defining events:

Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:

Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)

Renal insufficiency: creatinine clearance >40 mL/min[†] or serum creatinine >177 μ mol/L (>2 mg/dL)

Anemia: hemoglobin value of >20 g/L below the lower limit of normal, or hemoglobin value <100 g/L

Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or PET-CT[‡]

Any one or more of the following biomarkers of malignancy:

Clonal bone marrow plasma cell percentage* $\geq 60\%$

Involved/uninvolved serum-free light-chain ratio[§] ≥ 100

>1 focal lesion on MRI studies[¶]

Definition of Smoldering Multiple Myeloma

Both criteria must be met:

Serum monoclonal protein (IgG or IgA) ≥ 30 g/L or
urine monoclonal protein ≥ 500 mg/24 hr and/or
clonal bone marrow plasma cells 10% to 60%
Absence of myeloma-defining events or amyloidosis

PET-CT, ^{18}F -Labeled fluorodeoxyglucose PET with CT.

*Clonality should be established by showing κ/λ -light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence. Bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen; in case of disparity between the aspirate and core biopsy, the highest value should be used.

†Measured or estimated by validated equations.

‡If bone marrow has less than 10% clonal plasma cells, more than one bone lesion is required to distinguish from solitary plasmacytoma with minimal marrow involvement.

§These values are based on the serum Freelite assay (The Binding Site Group, Birmingham, U.K.). The involved free light chain must be ≥ 100 mg/L.

¶Each focal lesion must be 5 mm or more in size.

From Rajkumar SV et al: *Lancet Oncol* 15(12):e538–e548, 2014.

Quantitative measurements of immunoglobulins (IgG, IgM, IgA) are usually performed. Typically, one class of immunoglobulin (the M protein produced by the myeloma cell) is significantly expressed whereas the other classes are suppressed. Serum electrophoretic analysis reveals increased levels of M protein. Because the M protein is monoclonal, each molecule has the same electric charge and migrates to about the same site during electrophoresis, resulting in a highly concentrated protein (M spike). Bence Jones protein is observed in the urine or serum by using immunoelectrophoretic analysis or in the serum by using enzyme-linked immunosorbent assay (ELISA). Usually individuals with Bence Jones protein also have M protein in their blood. However, variants of MM include individuals in which

only free light chain is produced and a rare variant that produces only free heavy chain, and approximately 1% of variants are nonsecretory so that neither M protein nor Bence Jones protein is produced. The amount of M protein in the blood may be used as a measure of the extent of the disease or as a measure of response to therapy. The serum level of another protein, free β_2 -microglobulin, is a useful indicator of prognosis or effectiveness of therapy.

A bone marrow biopsy is performed to confirm the presence of myeloma cells in the marrow (Fig. 30.19). Radiographic studies include x-ray, CT scans, and magnetic resonance imaging (MRI) to document the presence of bone lesions and areas of destruction. Diagnosis is based on findings and the degree of involvement (see Box 30.4).

FIGURE 30.19 Myeloma Cells. The typical myeloma type has fairly mature appearing plasma cells with eccentric nuclei on bone marrow aspirate (A) and biopsy (B). C, Osteosclerotic myeloma in which the left side of the photograph shows bone sclerosis and the marrow cavity replaced by

myeloma. (From Hoffman R et al: *Hematology: basic principles and practice*, ed 6, Philadelphia, 2013, Churchill Livingstone.)

Treatment options include combinations of chemotherapy, other drug therapy, targeted therapy, high-dose chemotherapy with stem cell transplant, biologic therapy, radiation therapy (bone lesions of the spine), and sometimes surgery. Supported therapy includes plasmapheresis (exchange) if the blood becomes thick with increased antibody proteins and interferes with circulation. Conventional combinations of chemotherapeutic agents have included melphalan and prednisone (MP); MP with vincristine, carmustine, and cyclophosphamide; vincristine, doxorubicin, and dexamethasone; and thalidomide and dexamethasone. The drug thalidomide disrupts the stromal marrow–MM cell interaction by modulating cell surface adhesion molecules and inhibiting angiogenesis. In addition, it increases apoptosis and G₁ growth arrest (i.e., the cell cycle gap 1; see [Chapter 1](#)) of MM cells. New therapies called *proteasome inhibitors* are emerging. Myeloma cells are sensitive to inhibitors of the proteasome because the proteasome degrades unwanted and misfolded proteins and myeloma cells are prone to the accumulation of misfolded, unpaired Ig chains. Proteasome inhibitors induce cell death and retard bone resorption through effects on stromal cells.³

Dose intensification improves the outcomes in younger persons; however, long-term remissions are obtained in a minority of individuals. Thus intensive research measuring the effect of novel new therapies is the objective of ongoing trials.

Gene expression profiling (GEP) helps improve the treatment of MM because it identifies prognostic subgroups and defines the molecular pathways associated with these subgroups. Newer agents (e.g., bortezomib, lenalidomide) have broadened the therapeutic regimens for end-stage myeloma. Lenalidomide is related to thalidomide; however, it increases treatment efficacy while avoiding the adverse effects associated with thalidomide. In combination with dexamethasone, lenalidomide is now an approved second-line treatment for MM. The FDA has approved daratumumab for people who have received at least three prior treatments. Ixazomib has been

approved for the treatment of relapsed multiple myeloma in individuals who have received at least one prior treatment, and elotuzumab has been approved for those who have received one to three prior therapies.

High-dose chemotherapy followed by blood-forming stem cell transplantation (SCT) has become standard treatment for younger individuals (up to 70 years old in some trials).^{50,52} Survival is increased with SCT compared with chemotherapy alone. SCT uses the client's own blood-forming stem cells (autologous) or a donor's cells (allogeneic). Survival may be prolonged by performing a second autologous transplant, called a *tandem transplant*, within 6 to 12 months after the first transplant.

Radiation with high-energy x-rays is used more for a localized, rather than system, effect. It is most often used to treat areas of the bone that have been damaged and are not responding to chemotherapy. In addition, it may be used to treat sites where tumor has led to collapse of vertebrae and spinal cord compression.

Additional interventions are used to prevent and treat complications arising from progression of the disease. Drugs that inhibit bone resorption—bisphosphonates—reduce the incidence of skeletal damage, which also reduces hypercalcemia and decreases bone pain. Hydration and diuretics may be used to maintain a high urine output, and antibiotics to treat recurring infections.

The median survival for all stages of MM is 3 years. Individuals with multiple bone lesions, if untreated, rarely survive more than 6 to 12 months. Individuals with inactive (indolent) myeloma, however, can survive for many years. With chemotherapy and aggressive management of complications, median survival may increase to 24 to 30 months, with a 10-year survival rate of 3%. With the approval of new drugs, the management of MM has changed and research for survival improvement is ongoing.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia (WM), also called lymphoplasmacytic lymphoma, is a rare type of slow-growing

plasma cell tumor that secretes a monoclonal IgM molecule. Approximately 1500 new cases are diagnosed yearly in the United States; the median age of diagnosis is 63 years of age.⁵³ WM shares a great deal of similarity with multiple myeloma regarding its plasma cell origin, diagnosis, and treatment. However, the overproduction of the macromolecule IgM leads to certain unique clinical characteristics.

◆Pathophysiology.

WM arises from plasma cells that have undergone genetic rearrangement of the variable region genes (*V*, *D*, *J*), but have not undergone class-switch. Therefore, the principal secretory product of the tumor is IgM. Although no definitive genetic defect has been identified, WM may originate from aberrant B-cell maturation and class-switch.

Most of the pathology is associated with the production of large amounts of IgM, a high-molecular-weight protein (about 900,000 daltons). Excessive production leads to thickening of the blood and abnormally high blood viscosity (hyperviscosity syndrome). The increased viscosity interferes with circulation to various sites (e.g., eyes, brain, kidneys, extremities). IgM paraprotein may also result in the formation of cryoglobulins (i.e., proteins that precipitate from the blood at lower than body temperature). Hyperviscosity syndrome is observed in up to 20% of individuals with WM.

◆Clinical Manifestations.

Many individuals with WM are asymptomatic. The most common symptoms include weakness and fatigue, bleeding (from gums and nose), weight loss, and bruising. Bleeding may result secondary to formation of complexes among the macroglobulin, clotting factors, and platelets that diminish hemostatic capacity. If hyperviscosity syndrome occurs, the individual may develop neurologic problems (e.g., blurred vision, loss of vision, headaches, dizziness, vertigo). The macromolecules may also precipitate in colder regions of the body (cryoglobulins), leading to Raynaud phenomenon.

Although the malignant plasma cells invade the bone marrow,

erosion of the bone is not commonly observed; less than 5% of individuals have lytic bone lesions. The tumor often disseminates to other organs, including the spleen, lymph nodes, and liver. Anemia occurs in about 10% of individuals, secondary to tumor infiltration of the bone marrow. Peripheral hemolysis can also result from production of cold agglutinins.

◆Evaluation and Treatment.

Diagnosis is made on the basis of high levels of monoclonal IgM in the blood and the identification of malignant cells in bone marrow aspirates. Other hematologic abnormalities may be observed, especially anemia (80% of people with symptomatic WM) but also thrombocytopenia and leukopenia. Bence Jones protein may be observed in almost half of individuals with WM.

Therapy includes combined chemotherapy with nucleoside analogs, alkylating agents, and monoclonal antibody (e.g., rituximab). Bone marrow stem cell transplantation has also proven effective in some individuals.

Alterations of Splenic Function

The spleen has been an organ of mystery and perplexity in the study of medicine. Its relationship to other organs and disease processes, particularly the immune and hematologic systems, was not identified until the eighteenth century. The complexities of splenic function are not totally understood, and its mysteries are still being explored. The spleen is a useful organ, but its functions overlap those of other organs so that one is capable of living a normal, healthy life without the spleen. The relationship between asplenia and a higher risk for infection was not recognized until the early 1950s.

In the past, **splenomegaly** (enlargement of the spleen) was associated with various disease states. It is now recognized that splenomegaly is not necessarily pathologic; an enlarged spleen may be present in certain individuals without any evidence of disease. However, splenomegaly may be one of the first physical signs of

underlying conditions, and its presence should not be ignored. In conditions in which splenomegaly is present, the normal functions of the spleen may become overactive, producing a condition known as **hypersplenism**.

Current criteria indicating the presence of hypersplenism include (1) cytopenias (anemia, leukopenia, thrombocytopenia, or combinations of these); (2) cellular bone marrow; (3) splenomegaly; and (4) improvement after splenectomy. Some individuals may seek treatment for problems even though they have not met all these clinical criteria; therefore, the relevance and significance of hypersplenism are still uncertain. Primary hypersplenism is recognized when no etiologic factor has been identified; secondary hypersplenism occurs in the presence of another condition.

◆Pathophysiology.

Splenomegaly without a specific etiology is seen in 7% to 15% of individuals who are being evaluated for primary splenomegaly and is generally a diagnosis of exclusion. Specific conditions causing secondary splenomegaly and resulting hypersplenism are numerous and are related to all other categories of disease that affect individuals. Secondary splenomegaly may be classified according to the underlying cause. Specific conditions related to these various classifications of splenomegaly are detailed in [Box 30.5](#). Different pathologic processes that produce splenomegaly are described briefly.

Box 30.5

Diseases Related to Classification of Splenomegaly

Inflammation or Infection

Acute: viral (hepatitis, infectious mononucleosis, cytomegalovirus), bacterial (*Salmonella*, gram negative),

parasitic (typhoid)

Subacute or chronic: bacterial (subacute bacterial endocarditis, tuberculosis), parasitic (malaria), fungal (histoplasmosis), Felty syndrome, systemic lupus erythematosus, rheumatoid arthritis, thrombocytopenia

Congestive

Cirrhosis, heart failure, portal vein obstruction (portal hypertension), splenic vein obstruction

Infiltrative

Gaucher disease, amyloidosis, diabetic lipemia

Tumors or Cysts

Malignant: polycythemia vera, chronic or acute leukemias, Hodgkin lymphoma, metastatic solid tumors

Nonmalignant: hamartoma

Cysts: true cysts (lymphangiomas, hemangiomas, epithelial, endothelial); false cysts (hemorrhagic, serous, inflammatory)

Acute inflammatory or infectious processes cause splenomegaly because of an increased demand for defensive activities. Acutely enlarged spleens secondary to infection may become so filled with erythrocytes that their natural rubbery resilience is lost and they become fragile and vulnerable to blunt trauma. Splenic rupture is a complication associated with infectious mononucleosis; rupture occurs mostly in males between the fourth and twenty-first day of acute illness.

Congestive splenomegaly is accompanied by ascites, portal hypertension, and esophageal varices and is most commonly seen in

those with hepatic cirrhosis. Splenic hyperplasia develops in disorders that increase splenic workload and is associated most commonly with various types of anemia (hemolytic) and chronic myeloproliferative disorders (i.e., polycythemia vera).

Infiltrative splenomegaly is caused by engorgement by the macrophages with indigestible materials associated with various “storage diseases.” Tumors and cysts cause actual growth of the spleen. Metastatic tumors in the spleen are rare and may result from primary tumors of the skin, lung, breast, and cervix.

◆Clinical Manifestations.

Overactivity of the spleen results in hematologic alterations that affect all blood components. Sequestering of red blood cells, granulocytes, and platelets causes a reduction in the number of all circulating blood cells. The spleen may sequester up to 50% of the red blood cell population, thereby upsetting the normal physiologic concentration of red blood cells in the circulation. The rate of splenic pooling is directly related to the size of the spleen and the degree of increased blood flow through it. Sequestering exposes the red blood cells to splenic conditions that accelerate destruction, further contributing to the decreased red blood cell concentration. Anemia is the result of these combined activities. Anemia may be further potentiated by an increase in blood volume, which produces a dilutional effect on the already reduced concentration of red blood cells. The dilutional effect, as well as the removal and destruction of red blood cells, depends primarily on the degree of splenomegaly.

White blood cells and platelets also are affected by sequestering, although not to the same degree as the red blood cell. Again, the size of the spleen is the determining factor in the number of cells sequestered.

◆Evaluation and Treatment.

Treatment for hypersplenism is splenectomy; however, it is not always the treatment of choice. A splenectomy should be performed when its removal is considered necessary to alleviate the destructive

effects on red blood cells. Clinical indicators should determine the need for splenectomy, not necessarily the specific condition. Splenectomy for splenic rupture no longer is considered mandatory in light of the possibility of overwhelming sepsis after removal. Repair and preservation of the ruptured spleen are now considered before the decision to remove the spleen. Splenectomy also may be performed as treatment for hairy cell leukemia, Felty syndrome, agnogenic myeloid metaplasia, thalassemia major, Gaucher disease, hemodialysis, splenomegaly, splenic venous thrombosis, and thrombotic thrombocytopenic purpura (TTP).

Individuals are able to lead normal lives after splenectomy, but hematologic abnormalities often exist after removal of the spleen. The red blood cells become thinner, broader, and wrinkled as a result of increases in surface area and membrane lipids. The white blood cell count increases dramatically 1 week after removal and then stabilizes to approximately 40% greater than normal. Platelet numbers also rise immediately after surgery and then equilibrate to above-normal levels for the duration of the individual's life. Increased platelet levels have been implicated in ischemic heart disease in males because of increased thrombocytosis and hypercoagulability.

A major postoperative complication following splenectomy is overwhelming postsplenectomy infection (OPSI). Unless treated in time, OPSI may rapidly progress to septic shock and possibly disseminated intravascular coagulation (DIC). Initial statistics indicate a death rate of 50% to 70%, with most deaths occurring within the first 48 hours after hospitalization. Prompt medical attention can reduce the death rate to 10%.

Summary Review

Alterations of Leukocyte Function

1. Quantitative alterations of leukocytes (too many or too few) can be caused by bone marrow dysfunction or premature destruction of cells in the circulation. Many quantitative

changes in leukocytes occur in response to invasion by microorganisms.

2. Leukocytosis is a leukocyte count higher than normal and is usually a response to physiologic stressors, malignancies and hematologic disorders, and invasion of microorganisms.
3. Leukopenia is a leukocyte count lower than normal, is associated with neutropenia and infection, and is caused by physiologic stressors and by pathologic conditions such as malignancies and hematologic disorders.
4. Granulocytosis (particularly as a result of an increase in the number of neutrophils) occurs in response to infection. The marrow releases immature cells, causing a shift-to-the-left when responding to an infection that has created a demand for neutrophils that exceeds the supply in the circulation.
5. Eosinophilia results most commonly from parasitic invasion and ingestion or from inhalation of toxic foreign particles.
6. Basophilia is seen in hypersensitivity reactions because of the high content of histamine and subsequent release.
7. Monocytosis occurs during the late or recuperative phase of infection when macrophages (mature monocytes) phagocytose surviving microorganisms and debris. Monocytosis is often seen in chronic infections, usually with intracellular bacteria, such as tuberculosis (TB), brucellosis, listeriosis, and subacute bacterial endocarditis (SBE). Peripheral monocytosis has been found to correlate with the extent of myocardial damage following myocardial infarction. Increased numbers of monocytes also may indicate marrow recovery from agranulocytosis.
8. Granulocytopenia, a significant decrease in the number of neutrophils, can be a life-threatening condition if sepsis occurs; it is often caused by chemotherapeutic agents, severe infection, and radiation.
9. The number of lymphocytes is decreased (lymphocytopenia) in most acute infections and in some immunodeficiency syndromes.

10. Lymphocytosis occurs in viral infections (IM and infectious hepatitis, in particular), leukemia, lymphomas, and some chronic infections.
11. Infectious mononucleosis is an acute infection of B lymphocytes most commonly associated with EBV, a type of herpesvirus. Transmission of EBV is by personal contact, commonly through saliva (e.g., kissing, hence its nickname "kissing disease").
12. Two of the earliest manifestations of mononucleosis are sore throat and fever caused by inflammation at the primary site of viral entry. It is self-limiting and treatment consists of rest and relief of symptoms.
13. EBV is associated with several tumors including lymphomas and nasopharyngeal carcinoma.
14. Leukemia is a clonal disorder of leukocytes in the bone marrow, and usually of the blood. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of leukocytes and overcrowding of the bone marrow, causing a decreased production and function of the other blood cell lines.
15. All leukemias are classified by the cell type involved: B cells, T cells, and NK cells. They are differentiated by onset: acute or chronic. Overall, there are four major types of leukemia: ALL, CLL, AML, and CML. With increased understanding, the distinct divisions between leukemia and lymphoma have become indistinct and blurred. Conditions known as "lymphoma" that arise as a discrete tissue mass sometimes have "leukemic" presentations and progression to leukemia is not unusual during the progression of incurable lymphomas.
16. Although the exact cause of leukemia is unknown, it is considered a clonal disorder. A higher incidence of acute leukemias and CLL is reported in certain families, suggesting a possible genetic predisposition. Risk factors have been linked to exposure to cigarette smoke, benzene, and ionizing radiation.

17. The most common genetic abnormality in adult ALL is the Philadelphia chromosome.
18. Genetic aberrations in AML alter genes encoding transcription factors needed for normal myeloid differentiation and arrest differentiation. These mutations affect the epigenome, suggesting that epigenetic alterations are key in AML.
19. The major clinical manifestations of leukemia include fatigue caused by anemia, bleeding caused by thrombocytopenia, fever secondary to infection, anorexia, and weight loss. Chronic leukemias progress differently than acute leukemias, advancing slowly and without warning. The presence of the Philadelphia chromosome is a diagnostic marker for CML.
20. Chemotherapy is the treatment of choice for leukemia. New targets or drugs have been reported to inhibit leukemia stem cells both in vitro and in vivo.

Alterations of Lymphoid Function

1. The number of lymphocytes is decreased (lymphocytopenia) in most acute infections and in some immunodeficiency syndromes.
2. Lymphocytosis occurs in viral infections (IM and infectious hepatitis, in particular), leukemia, lymphomas, and some chronic infections.
3. Lymphomas are tumors of primary lymphoid tissue (thymus, bone marrow) or secondary lymphoid tissue (lymph nodes, spleen, tonsils, intestinal lymphoid tissue). The two major types of malignant lymphomas are Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).
4. Reed-Sternberg (RS) cells in lymph nodes are classically associated with HL. The RS cell is derived from a malignant B cell that usually becomes binucleate.
5. A virus might be involved in the pathogenesis of HL. Some familial clustering suggests an unknown genetic mechanism.
6. An enlarged painless mass or swelling, most commonly in the

- neck, is an initial sign of HL. Local symptoms are produced by lymphadenopathy, usually caused by pressure or obstruction.
7. Treatment of HL includes radiation therapy and chemotherapy.
 8. The cause of lymph node enlargement and cancerous transformation in NHL is unknown. Factors associated with industrialization and economic improvement may be linked to the incidence of lymphoma, geographically. In general, lymphomas are the result of genetic mutations or viral infection. Immunosuppressed persons have a higher incidence of NHL, suggesting an immune mechanism.
 9. Generally, with NHL the swelling of lymph nodes is painless, and the nodes enlarge and transform over months or years.
 10. Individuals with NHL can survive for long periods. Treatment is chemotherapy.
 11. Burkitt lymphoma involves the jaw and facial bones and occurs in children from east-central Africa and New Guinea. In the United States, Burkitt lymphoma is rare, usually involves the abdomen, and is characterized by extensive bone marrow invasion and replacement.
 12. Multiple myeloma (MM) is a neoplasm of B cells (immature plasma cells) and mature plasma cells. It is characterized by multiple malignant tumors of plasma cells scattered throughout the skeletal system and occasionally in soft tissue.
 13. Myeloma cells usually secrete monoclonal protein (M protein) that is an abnormal antibody molecule. The myeloma cell may also secrete free antibody light chain that is excreted in the urine (Bence Jones protein).
 14. The exact cause of MM is unknown. Risk factors include exposure to radiation or certain chemicals and a history of monoclonal gammopathy of undetermined significance (MGUS).
 15. The major clinical manifestations for MM include recurrent infections caused by suppression of the humoral immune response and renal disease as a result of Bence Jones

- proteinuria.
16. Chemotherapy is the treatment of choice for MM. Other therapies include stem cell transplantation, biologic therapy, radiation therapy, and sometimes surgery.
 17. Waldenström macroglobulinemia is a rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule.

Alterations of Splenic Function

1. Splenomegaly (enlargement of the spleen) may be considered normal in certain individuals, but its presence should not be ignored.
2. Splenomegaly results from (1) acute inflammatory or infectious processes, (2) congestive disorders, (3) infiltrative processes, and (4) tumors or cysts.
3. Splenomegaly causes hypersplenism (overactivity of the spleen). Hypersplenism results in blood cell sequestration, causing destruction of red blood cells and development of anemia.

Lymphomas, 1012

This chapter briefly explains fetal and neonatal hematopoiesis and postnatal changes in blood as a foundation for understanding the

pathophysiology of specific blood disorders in childhood. Among the diseases that affect erythrocytes are acquired disorders, such as iron deficiency anemia, hemolytic disease of the newborn, and anemia of infectious disease; and inherited disorders, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, hereditary spherocytosis, sickle cell disease, and the thalassemias. Disorders of coagulation and platelets include inherited hemorrhagic diseases, such as the hemophilias, and antibody-mediated hemorrhagic diseases, which include immune thrombocytopenia, autoimmune neonatal thrombocytopenias, and autoimmune vascular purpuras. Finally, leukocyte disorders, such as leukemia and the lymphomas (non-Hodgkin lymphoma as well as Hodgkin lymphoma), are discussed.

Fetal and Neonatal Hematopoiesis

As the developing embryo becomes too large for oxygenation of tissues by simple diffusion, the production of erythrocytes begins within the vessels of the yolk sac. Shortly after 2 weeks of gestation, circulating erythrocytes play a major role in delivering oxygen to the tissues. At approximately the eighth week of gestation, the site of erythrocyte production shifts from the vessels to the liver sinusoids, and the production of leukocytes and platelets begins in the liver and spleen. Erythropoiesis in the liver and, to a lesser extent, in the spleen and lymph nodes, reaches a peak at approximately 4 months. Hepatic blood formation declines steadily thereafter but does not disappear entirely during the remainder of gestation. By the fifth month of gestation, hematopoiesis begins to occur in the bone marrow and increases rapidly until hematopoietic (red) marrow fills the entire bone marrow space. By the time of delivery, the marrow is the only significant site of hematopoiesis.

In neonates and young infants, hematopoietic marrow progressively fills the bony cavities of the entire axial skeleton (skull, vertebrae, ribs, sternum), the long bones of the limbs, and many intramembranous bones. (These structures are described in [Chapter](#)

46.) Fatty (yellow) marrow gradually replaces hematopoietic marrow in some bones. During childhood, hematopoietic tissue retreats centrally to the vertebrae, ribs, sternum, pelvis, scapulae, skull, and proximal ends of the femur and humerus.

In diseases characterized by hemolysis, erythrocyte production can increase as much as eight times the normal level because erythropoietin causes hematopoietic marrow to increase in volume. Initially, hematopoietic marrow expands from the ends of the long bones toward the middle of the shafts, replacing fatty marrow. Next, blood cell production begins to occur outside the marrow cavities, especially in the liver and spleen. Extramedullary hematopoiesis is more likely to occur in children than in adults because the bony cavities of children already are filled with red marrow ([Fig. 31.1](#)). This is why hemolytic disease causes especially pronounced enlargement of the spleen and liver in children.

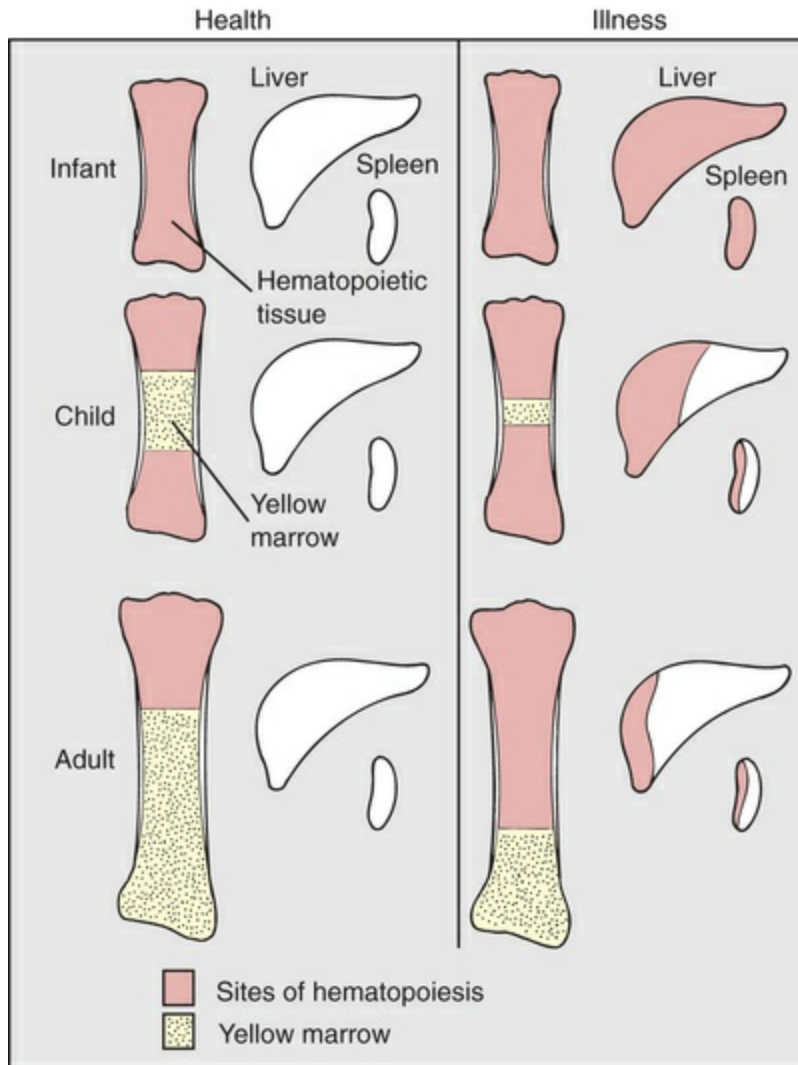

FIGURE 31.1 Sites of Hematopoiesis in Health and Illness. With normal maturation, red marrow is partly replaced by yellow marrow in the shafts of the long bones. In adults, red marrow is largely restricted to the proximal ends of the femur and humerus. In response to hemolysis, red marrow replaces yellow marrow in the long bones. In infants, whose long bones already are filled with red marrow, additional hematopoiesis takes place in the liver and spleen. In children and adults, red marrow can replace yellow marrow in response to hemolysis, necessitating less hematopoiesis in the liver and spleen.

The erythrocytes undergo striking changes during gestation, particularly during the first two trimesters, at which time they nearly double in numbers and in hemoglobin content. A proportionate increase in hematocrit level also occurs. By the end of gestation the erythrocyte count has more than tripled but the size of each erythrocyte has decreased.

A biochemically distinct type of hemoglobin is synthesized during fetal life. The three **embryonic hemoglobins (Gower 1, Gower 2, and Portland)** and the **fetal hemoglobin (HbF)** are composed of two α and two γ chains of polypeptides, whereas the adult hemoglobins (HbA and HbA₂) are composed of two α chains and two β chains. (The structure of an adult hemoglobin molecule is illustrated in [Fig. 28.16](#), and types of hemoglobin are defined in [Table 28.5](#).) Some unknown regulatory mechanism promotes γ -chain synthesis and inhibits β - and δ -chain synthesis in utero. This results in production of embryonic or fetal hemoglobin. After birth, γ -chain synthesis is inhibited, whereas β - and δ -chain synthesis is facilitated, resulting in production of adult hemoglobins.

Fetal hemoglobin has greater affinity for oxygen than does adult hemoglobin because it interacts less readily with an enzyme (2,3-diphosphoglycerate [2,3-DPG]) that inhibits hemoglobin-oxygen binding. The decreased inhibitory effects of 2,3-DPG enable fetal blood to transport oxygen despite the relative lack of oxygen in the uterine environment. The increased affinity for oxygen enables HbF to bind with maternal oxygen in the placental circulation.

During the first trimester nearly all of the hemoglobin in the fetus is embryonic, but some HbA can be detected. Therefore it is possible to identify as early as 16 to 20 weeks of gestation some disorders of adult hemoglobin, such as sickle cell anemia and thalassemia major. In the 6-month fetus, HbF constitutes 90% of the total. This percentage then begins to decline. At birth, neonatal hemoglobin consists of 70% HbF, 29% HbA, and 1% HbA₂. Between 6 and 12 months of age, normal adult hemoglobin percentages are established (see [Chapter 28](#)).

Postnatal Changes in the Blood

Blood cell counts tend to rise higher than adult levels at birth and then decline gradually throughout childhood. [Table 31.1](#) lists normal ranges during infancy and childhood. The immediate rise in values is the result of the accelerated hematopoiesis during fetal life, the increased numbers of cells that result from the trauma of birth, and

the cutting of the umbilical cord. These events surrounding the birth also are accompanied by the presence of large numbers of immature erythrocytes and leukocytes (particularly granulocytes) in peripheral blood (see [Chapter 28](#)). As the infant develops over the first 2 to 3 months of life, the numbers of these immature blood cells decrease.

TABLE 31.1

HEMATOLOGIC VALUES DURING INFANCY AND CHILDHOOD

AGE	HEMOGLOBIN (g/dL)		HEMATOCRIT (%)		RETICULOCYTES (%) MEAN	MCV (fl) LOWEST	LEUKOCYTES (WBC/mm ³)	
	MEAN	RANGE	MEAN	RANGE			MEAN	RANGE
Cord blood	16.8	13.7–20.1	55	45–65	5	110	18,000	(900–3000)
2 wk	16.5	13–20	50	42–66	1		12,000	(500–2000)
3 months	12	9.5–14.5	36	31–41	1		12,000	(600–1500)
6 months to 6 yr	12	10.5–14	37	33–42	1	70–74	10,000	(600–1500)
7–12 yr	13	11–16	38	34–40	1	76–80	8,000	(450–1500)
Adult								
Female	14	12–16	42	37–47	1.6	80	7,500	(500–1500)
Male	16	14–18	47	42–52		80		

*Relatively wide range.

fl, Femtoliters; MCV, mean corpuscular volume; WBC, white blood cells.

From Behrman R et al, editors: *Nelson textbook of pediatrics*, ed 17, Philadelphia, 2004, Saunders.

Average blood volume in the full-term neonate is 85 mL/kg of body weight. The premature infant has a proportionately larger blood volume of 90 to 100 mL/kg of body weight. In both full-term and premature infants, blood volume relative to body weight decreases during the first few months. By 3 years of age, a child's average blood volume is 75 to 77 mL/kg, which is similar to that of older children

and adults.

Erythrocytes

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus. This accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) of the newborn. After birth the oxygen from the lungs saturates arterial blood, and the amount of oxygen delivered to the tissues increases. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease. The very active rate of fetal erythropoiesis is reflected by the large numbers of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. The number of reticulocytes decreases abruptly during the first few days after birth, which is associated with decreased erythropoietin production.¹ Finding an elevated reticulocyte count after the first week of life is rare. A decrease in extramedullary hematopoiesis also occurs at this time. In the peripheral blood the erythrocyte count drops for 6 to 8 weeks after birth. During this period of rapid growth the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, the normal erythrocyte life span is 60 to 80 days; in premature infants it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—120 days. (Mechanisms of hemolysis are described in [Chapter 28](#).)

In the premature infant, the postnatal decrease in hemoglobin and hematocrit values is more marked than in the full-term infant. In the preschool and school-age child, hemoglobin, hematocrit, and red blood cell (RBC) count values rise gradually. In males and females, these values first begin to diverge in adolescence. In the female, the gradual hemoglobin level increase continues into early puberty, at which time it stabilizes. In the male, the hemoglobin level increase keeps pace with growth and maturation and eventually surpasses that of the female. This higher value of hemoglobin level in the mature male is related to androgen secretion.

Metabolic processes within the erythrocytes of neonates differ significantly from those of erythrocytes in the normal adult. The relatively young population of erythrocytes in the newborn consumes greater quantities of glucose than do erythrocytes in adults. Several enzymes that regulate glucose consumption are increased in the erythrocytes of neonates, with a subsequent increase in the rate of glycolysis.

Leukocytes and Platelets

The lymphocytes of children tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. The significance of these differences is unknown. One possible explanation is that children tend to have more frequent viral infections, which are associated with atypical lymphocytes. Even minor infections, in which the child fails to exhibit clinical manifestations of illness, or administration of immunizations may result in lymphocyte changes.²

The lymphocyte count is high at birth and continues to rise in some healthy infants during the first year of life. A steady decline occurs throughout childhood and adolescence until lower adult values are reached. Whether these developmental variations are physiologic or are a pathologic response to frequent viral infections and immunizations in children is not known.

In healthy neonates, the neutrophil count peaks at 6 to 12 hours after birth and then declines over the next few days of life.³ Neutrophil counts also are slightly higher in female neonates compared with males. After 2 weeks of life, neutrophil counts fall to within or below normal adult ranges. By approximately 4 years of age, the neutrophil count is similar to that of an adult. White children have slightly higher counts than black children.⁴

The eosinophil count is elevated in the first year of life relative to children, teenagers, or adults.^{5,6} Monocyte counts are elevated through the preschool years and then decrease to adult levels. No relationship between age and basophil count has been found. Platelet counts in full-term neonates are comparable to platelet counts in adults and remain so throughout infancy and childhood.⁵

Disorders of Erythrocytes

Anemia is the most common blood disorder in children. Although not a disease state in and of itself, the presence of anemia may be associated with an underlying pathophysiologic process. Like anemia in adults, the anemias of childhood are caused by ineffective erythropoiesis or premature destruction of erythrocytes. The most common cause of insufficient erythropoiesis is iron deficiency, which may result from insufficient dietary intake or chronic loss of iron caused by bleeding. The hemolytic anemias of childhood may be divided into two large categories. The first category consists of disorders that result from premature destruction caused by intrinsic abnormalities of the erythrocytes, and the second category consists of disorders that result from damaging extra-erythrocytic factors. The hemolytic anemias can be inherited, congenital, or both.

The most dramatic form of acquired congenital hemolytic anemia is *hemolytic disease of the fetus and newborn (HDFN)* an alloimmune disorder in which maternal blood and fetal blood are antigenically incompatible, causing the mother's immune system to produce antibodies against fetal erythrocytes. Fetal erythrocytes that have been bound to maternal antibodies are recognized as foreign or defective by the fetal mononuclear phagocyte system and are removed from the circulation by phagocytosis, usually in the fetal spleen. (For a complete discussion of HDFN, see [Hemolytic Disease of the Fetus and Newborn](#).) Other acquired hemolytic anemias—some of which begin in utero—include those caused by infections or the presence of toxins.

The inherited forms of hemolytic anemia result from intrinsic defects of the child's erythrocytes, any of which can lead to erythrocyte destruction by the mononuclear phagocyte system. Structural defects include abnormal red blood cell size and abnormalities of plasma membrane structure (spherocytosis). Intracellular defects include enzyme deficiencies, the most common of which is G6PD deficiency; and defects of hemoglobin synthesis, which manifest as sickle cell disease or thalassemia, depending on which component of hemoglobin is defective. These and other causes of

childhood anemia, some more common than others, are listed in [Table 31.2](#).

TABLE 31.2

ANEMIAS OF CHILDHOOD

CAUSE	ANEMIC CONDITION
Deficient Erythropoiesis or Hemoglobin Synthesis	
Decreased stem cell population in marrow (congenital or acquired pure red cell aplasia)	Normocytic-normochromic anemia
Decreased erythropoiesis despite normal stem cell population in marrow (infection, inflammation, cancer, chronic renal disease, congenital dyserythropoiesis)	
Deficiency of a factor or nutrient needed for erythropoiesis	
Cobalamin (vitamin B ₁₂), folate	Megaloblastic anemia
Iron	Microcytic-hypochromic anemia
Increased or Premature Hemolysis	
Alloimmune disease (maternal-fetal Rh, ABO, or minor blood group incompatibility)	Hemolytic disease of the newborn (HDN)
Autoimmune disease (idiopathic autoimmune hemolytic anemia, symptomatic systemic lupus erythematosus, lymphoma, drug-induced autoimmune processes)	Autoimmune hemolytic anemia
Inherited defects of plasma membrane structure (spherocytosis, elliptocytosis, stomatocytosis) or cellular size or both (pyknocytosis)	Hemolytic anemia
Infection (bacterial sepsis, congenital syphilis, malaria, cytomegalovirus infection, rubella, toxoplasmosis, disseminated herpes)	Hemolytic anemia
Intrinsic and inherited enzymatic defects (deficiencies of glucose-6-phosphate dehydrogenase [G6PD], pyruvate kinase, 5'-nucleotidase, glucose phosphate isomerase)	Hemolytic anemia
Inherited defects of hemoglobin synthesis	Sickle cell anemia Thalassemia
Disseminated intravascular coagulation (see Chapter 29)	Hemolytic anemia
Galactosemia	Hemolytic anemia
Prolonged or recurrent respiratory or metabolic acidosis	Hemolytic anemia
Blood vessel disorders (cavernous hemangioma, large vessel thrombus, renal	Hemolytic anemia

Acquired Disorders

Iron Deficiency Anemia

Iron is *critical* to the developing child, especially for normal brain development, and without it the damage from the periods of iron deficiency anemia (IDA) in children is irreversible. IDA is the most common nutritional disorder worldwide with the highest incidence occurring between 6 months and 2 years of age. IDA is common in the United States where prevalence is higher in toddlers, adolescent girls, and women of childbearing age, and causes clinical manifestations mostly related to inadequate hemoglobin synthesis.⁷ Its incidence is not related to gender or race; however, socioeconomic factors are important because they affect nutrition.

IDA can result from (1) dietary insufficiencies, (2) absorption problems, (3) blood loss, and (4) increased requirement of iron. Inadequate intake is the most common cause of IDA during the first few years of life and blood loss is the most common cause during childhood and adolescence, and for adults in the Western world. Chronic IDA from occult (hidden) blood loss may be caused by a gastrointestinal lesion, parasitic infestation, or hemorrhagic disease. A reasonable hypothesis for infants and young children who develop IDA is they have chronic intestinal blood loss induced by exposure to a heat-labile protein in cow's milk. Such exposure causes an inflammatory gastrointestinal reaction that damages the mucosa and results in diffuse microhemorrhage. Growing evidence indicates that cellular components of both innate and adaptive immunity play significant roles during the pathogenesis of cow's milk allergy.⁸ Dietary lack is not common in developed countries where iron is in the readily absorbed form from heme that comes from meat. IDA has declined in the United States; however, a recent study in the United States found toddlers are vulnerable to IDA, especially those consuming excessive quantities of whole cow's milk.⁹ Increased consumption of iron-fortified infant foods, including formula, is

hypothesized to have contributed to the overall decline in IDA.¹⁰ However, bioavailability of iron from breast milk is higher than that from cow's milk. At this point, only low-quality evidence for use of micronutrient powders in pregnant women is available.¹¹ Impaired absorption is found in chronic diarrhea, fat malabsorption, and celiac disease. Evidence also is emerging regarding genetic polymorphisms that may contribute to altered iron absorption in cases of refractory IDA with a familial component.¹²

Children in developing countries are often affected by chronic parasite infestations that result in blood and iron loss greater than dietary intake.¹³ Treatment of helminth infections results in improvement in appetite, growth, and in the anemia. Controversial is the association of IDA with lead (Pb) poisoning. Newer areas of investigation include iron deficiency in overweight children and the association of *H. pylori* infection with IDA.¹⁴

◆Pathophysiology.

Regardless of the cause, a deficiency of iron produces a hypochromic-microcytic anemia.⁷ Progressive depletion of blood and low serum levels of ferritin and transferrin saturation eventually lead to a lowering of hemoglobin and hematocrit values. In early stages an adaptive increase in red blood cell activity in the bone marrow may prevent the development of anemia. Anemia develops when the iron stores are depleted with accompanying important laboratory indicators. (Mechanisms of iron depletion are described in [Chapter 28](#).)

◆Clinical Manifestations.

The symptoms of mild anemia—lethargy and listlessness—usually are not clearly evident in infants and young children, who are unable to describe these symptoms. Therefore parents usually do not notice any change in the child's behavior or appearance until moderate anemia has developed. General irritability, decreased activity tolerance, weakness, and lack of interest in play are nonspecific indications of anemia. In mild to moderate IDA (hemoglobin level of 6 to 10 g/dL),

compensatory mechanisms of tissue oxygenation, such as increased amounts of 2,3-DPG within erythrocytes and a shift of the oxyhemoglobin dissociation curve, may be so effective that few clinical manifestations are apparent. When the hemoglobin level falls below 5 g/dL, however, pallor, tachycardia, and systolic murmurs often occur.

Clinical manifestations of chronic IDA include splenomegaly; widened skull sutures; decreased physical growth and developmental delays; and *pica*, a behavior in which non-food substances such as clay, paper, or ice are eaten. Weight is not necessarily an indicator of IDA because children may be obese, underweight, or of normal weight. Consequences of IDA are significant and may include altered neurologic and intellectual function, especially involving attention span, alertness, and learning ability.

◆ Evaluation and Treatment.

Laboratory tests confirm the diagnosis of IDA. Laboratory tests include measurements of hemoglobin, hematocrit, serum iron, ferritin, and the total iron-binding capacity. A thorough history of present illness, a dietary history, and a physical examination are essential. Evaluation and treatment of IDA in children are similar to evaluation and treatment in adults (see [Chapter 29](#)). Oral administration of simple ferrous salts usually is satisfactory, and additional vitamin C helps promote absorption.¹⁵ Iron in a liquid form should be administered through a straw because it can stain teeth. Iron therapy is continued for at least 2 months after erythrocyte indexes have returned to normal in order to replenish iron stores.¹⁶

Dietary modification is required to prevent recurrences of IDA. Intake of iron-rich foods is increased and the intake of cow's milk may be restricted, with the exact amount restricted to 16 to 32 ounces per day depending on the child's age. Limiting milk intake makes the child hungrier for other iron-rich foods and prevents gastrointestinal blood loss in children whose anemia is aggravated or caused by inflammatory reactions to proteins in cow's milk.

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) can occur only if antigens on fetal erythrocytes differ from antigens on maternal erythrocytes. The antigenic properties of erythrocytes are determined genetically: they may be type A, B, or O and may or may not include Rh antigen D. Erythrocytes that express Rh antigen D are Rh-positive; those that do not are Rh-negative. The frequency of Rh negativity is higher in whites (15%) than in blacks (5%), and is rare in Asians. Maternal-fetal incompatibility exists if mother and fetus differ in ABO blood type or if the fetus is Rh-positive and the mother is Rh-negative. (The antigenic properties of erythrocytes are described in [Chapter 9](#).)

ABO incompatibility occurs in about 20% to 25% of all pregnancies, but only 1 in 10 cases of ABO incompatibility results in HDFN. Rh incompatibility occurs in less than 10% of pregnancies and rarely causes HDFN in the first incompatible fetus. Even after five or more pregnancies, only 5% of women have babies with hemolytic disease. Typically, erythrocytes from the first incompatible fetus cause the mother's immune system to produce antibodies that affect the fetuses of subsequent incompatible pregnancies. Most cases of HDFN are caused by ABO incompatibility, and only one in three cases is caused by Rh incompatibility.

◆Pathophysiology.

HDFN will result from the following: (1) if the mother's blood contains preformed antibodies against erythrocytes or produces antibodies on exposure to fetal erythrocytes, (2) if sufficient amounts of antibody (usually immunoglobulin G [IgG]) cross the placenta and enter fetal blood, and (3) if IgG binds with sufficient numbers of fetal erythrocytes to cause widespread antibody-mediated hemolysis or splenic removal. (Antibody-mediated red blood cell destruction is discussed in [Chapter 9](#).)

Maternal antibodies may be formed against type B fetal erythrocytes if the mother is type A or against type A fetal erythrocytes if the mother is type B. Usually, however, the mother is type O and the fetus is A or B. ABO incompatibility can cause HDFN

even if fetal erythrocytes do not escape into the maternal circulation during pregnancy. This occurs because the blood of most adults already contains anti-A or anti-B antibodies, which are produced on exposure to certain foods or infection by gram-negative bacteria. (Anti-O antibodies do not exist because type O erythrocytes are not antigenic.) Therefore IgG against type A or B erythrocytes is usually preformed in maternal blood and can enter the fetal circulation throughout the first incompatible pregnancy.

Anti-Rh antibodies, on the other hand, are formed *only* in response to the presence of incompatible (Rh-positive) erythrocytes in the blood of an Rh-negative mother. Sources of exposure include fetal blood that is mixed with the mother's blood at the time of delivery, transfused blood, and, rarely, previous sensitization of the mother by her own mother's incompatible blood (Fig. 31.2).

FIGURE 31.2 Hemolytic Disease of the Fetus and Newborn (HDFN). A, Before or during delivery, Rh-positive erythrocytes from the fetus enter the

blood of an Rh-negative woman through a tear in the placenta. B, The mother is sensitized to the Rh antigen and produces Rh antibodies. Because this usually happens after delivery, there is no effect on the fetus in the first pregnancy. C, During a subsequent pregnancy with an Rh-positive fetus, Rh-positive erythrocytes cross the placenta, enter the maternal circulation, and (D) stimulate the mother to produce antibodies against the Rh antigen. The Rh antibodies from the mother cross the placenta, using agglutination and hemolysis of fetal erythrocytes, and HDFN develops. (Modified from Seeley RR, Stephens TD, Tate P: *Anatomy and physiology*, ed 3, St Louis, 1995, Mosby.)

The first Rh-incompatible pregnancy usually presents no difficulties because very few fetal erythrocytes cross the placental barrier during gestation. However, when the placenta detaches at birth, large numbers of fetal erythrocytes usually enter the mother's bloodstream. If the mother is Rh-negative and the fetus is Rh-positive, the mother produces anti-Rh antibodies. The capacity of the mother's immune system to produce anti-Rh antibodies depends on many factors, including her genetic capacity to make antibodies against the Rh antigen D, the amount of fetal-to-maternal bleeding, and the occurrence of any bleeding earlier in the pregnancy. Anti-Rh antibodies persist in the bloodstream for a very long time, and if the next offspring is Rh-positive, the mother's anti-Rh antibodies can enter the fetus's bloodstream and destroy the erythrocytes. Antibodies against Rh antigen D are of the IgG class and easily cross the placenta.

IgG-coated fetal erythrocytes are destroyed through extravascular hemolysis, primarily by mononuclear phagocytes in the spleen. As hemolysis progresses, the fetus becomes anemic. Erythropoiesis accelerates, particularly in the liver and spleen, and immature nucleated cells (erythroblasts) are released into the bloodstream, hence the name **erythroblastosis fetalis** (Fig. 31.3). The degree of anemia depends on the length of time the antibody has been in the fetal circulation, the concentration of antibody, and the ability of the fetus to compensate for increased hemolysis. Unconjugated (indirect) bilirubin, which is formed during breakdown of hemoglobin, is transported across the placental barrier into the maternal circulation and is excreted by the mother. **Hyperbilirubinemia**, an increase in bilirubin concentration in the blood, occurs in the neonate after birth because excretion of lipid-soluble unconjugated bilirubin through the

placenta no longer is possible.

FIGURE 31.3 Rh Incompatibility in Hemolytic Disease of the Newborn. This micrograph shows immature red blood cells not normally found in blood. Large purple cells are erythroblasts; nucleated red blood cells are normoblasts. Normal red blood cells also are shown ($\times 500$). (Copyright Ed Reschke.)

The pathophysiologic effects of HDFN are more severe in Rh incompatibility than in ABO incompatibility. ABO incompatibility may resolve after birth without life-threatening complications. Maternal-fetal incompatibility in which a mother with type O blood has a child with type A or B blood usually is so mild that it does not require treatment.

Rh incompatibility is more likely than ABO incompatibility to cause severe or even life-threatening anemia, death in utero, or damage to the central nervous system (CNS). Severe anemia alone can cause death as a result of cardiovascular complications (see [Chapter 29](#)). Extensive hemolysis also results in increased levels of unconjugated bilirubin in the circulation. If bilirubin levels exceed the liver's ability to conjugate and excrete bilirubin, some of it is deposited in the brain, causing cellular damage and eventually death, if exchange transfusions are not administered.

Fetuses that do not survive anemia in utero usually are stillborn, exhibiting gross edema throughout the entire body, a condition called

hydrops fetalis. Death can occur as early as 17 weeks of gestation and results in spontaneous abortion.

◆Clinical Manifestations.

Neonates with mild HDFN may appear healthy or slightly pale, with slight enlargement of the liver and spleen. Pronounced pallor, splenomegaly, and hepatomegaly indicate severe anemia, which predisposes the neonate to cardiovascular failure and shock. Life-threatening Rh incompatibility is rare today, largely because of maternal testing and the routine use of Rh immune globulin.

Because maternal antibodies remain in the neonatal circulation after birth, erythrocyte destruction can continue. This causes hyperbilirubinemia and **icterus neonatorum (neonatal jaundice)** that occurs shortly after birth. Without replacement transfusions, in which the child receives Rh-negative erythrocytes, the bilirubin is deposited in the brain, causing a condition termed **kernicterus**. Kernicterus produces cerebral damage and usually causes death (**icterus gravis neonatorum**). Infants who do not die may have significant developmental delay, cerebral palsy, or high-frequency deafness.¹⁷

◆Evaluation and Treatment.

Routine evaluation for HDFN includes the Coombs test. The indirect Coombs test measures antibody in the mother's circulation and indicates whether the fetus is at risk for HDFN. The direct Coombs test measures antibody already bound to the surfaces of fetal erythrocytes and is used primarily to confirm the diagnosis of antibody-mediated HDFN. Determining prior history of fetal hemolytic disease, as well as diagnostic tests, may help predict the severity of the disorder. Diagnostic measures include maternal antibody titers, fetal blood sampling, amniotic fluid spectrophotometry, and ultrasound fetal assessment.¹⁸

The key to treatment of HDFN resulting from Rh incompatibility lies in prevention (immunoprophylaxis). Rh immune globulin (RhoGAM), a preparation of antibody against Rh antigen D (anti-D Ig) administered within 72 hours of exposure to Rh-positive erythrocytes,

ensures that the mother will not produce antibody against the D antigen, and that the next Rh-positive baby will be protected (see Fig. 31.2). Updated recommendations also state that if anti-D Ig is not given within 72 hours every effort should still be made to administer the anti-D Ig within 10 days. The newer updates on the use of anti-D Ig as prophylaxis to prevent sensitization to the D antigen *during* pregnancy or at *delivery* for the prevention of HDFN can be found at the National Guideline Clearinghouse at <http://www.guideline.gov/content.aspx?id=34964#Section420> for the use of anti-D immunoglobulin for rhesus D prophylaxis and from the British Committee for Standards in Haematology (BCSH) guidelines.¹⁹

The injected (anti-D Ig) antibodies remain in the mother's bloodstream long enough to prevent her immune system from producing its own anti-Rh antibodies but not long enough to affect subsequent offspring. The mother must be given Rh immune globulin injections after the birth of each Rh-positive baby and after a miscarriage. The mother also must be especially careful not to receive a transfusion containing Rh-positive blood, because this would stimulate production of anti-Rh antibodies.

If antigenic incompatibility of the mother's erythrocytes is not discovered in time to administer Rh immune globulin and a child is born with HDFN, treatment consists of exchange transfusions in which the neonate's blood is replaced with new Rh-positive blood that is not contaminated with anti-Rh antibodies. This treatment is instituted during the first 24 hours of extrauterine life to prevent kernicterus. Phototherapy also is used to reduce the toxic effects of unconjugated bilirubin.

Jaundice and indirect hyperbilirubinemia are reduced when the infant is exposed to high-intensity light in the visible spectrum from 460 to 490 nm.²⁰ Bilirubin in the skin absorbs light energy, which, by photoisomerization, converts the toxic unconjugated bilirubin into conjugated isomers that are excreted in the bile. Phototherapy also causes autosensitization that results in oxidation reactions. Breakdown products from the oxidation reactions are excreted by the liver and kidney without need for conjugation. The therapeutic effect

of phototherapy depends on the light energy emitted in the effective wavelengths, the distance between the infant and the light source, and the amount of skin exposed; the rate of hemolysis and the infant's ability to excrete bilirubin also are factors in determining the effectiveness of phototherapy in lowering serum bilirubin levels.

Anemia of Infectious Disease

Infections of the newborn, often initially acquired by the mother and transmitted to the fetus, may result in a hemolytic anemia with clinical manifestations similar to those of HDFN. Congenital syphilis, toxoplasmosis, cytomegalic inclusion disease, rubella, coxsackievirus B infection, herpesvirus infection, and bacterial sepsis can cause hemolytic anemia in the neonate.

The exact mechanism of anemia caused by congenital infections is unclear. In some instances, it is related to direct injury of erythrocyte membranes or erythrocyte precursors by the infectious microorganism. In other instances, it results from traumatic destruction of erythrocytes during their passage through inflamed capillaries.

Anemia in Critically Ill Children

Anemia is a common occurrence in critically ill children (see [Chapter 50](#)). The causes are numerous and include decreased erythropoietin activity, poor iron use by the body, and blood loss from diverse conditions and consequences of treatment. A topic of ongoing discussion is whether transfusion of blood products, particularly packed RBCs, improves outcomes in critically ill children because of problems related to blood storage. New research is ongoing and needed to understand these problems, the development of new blood transfusion strategies, and blood substitutes.²¹

Inherited Disorders

A number of inherited and intrinsic erythrocyte defects are known to

cause hemolytic disease or increased hemolysis (see [Table 31.2](#)). These defects may result from enzymatic abnormalities that disrupt metabolic processes and prevent normal biochemical balance within the cell, alterations of hemoglobin structure or synthesis, or plasma membrane defects accompanied by changes in erythrocyte size or shape.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited disorder caused by a genetic defect in the RBC enzyme G6PD, which is involved in the normal processing of carbohydrates. The enzyme G6PD is responsible for the first step in a pathway that converts glucose to ribose-5-phosphate. The chemical reactions usually produce nicotinamide adenine dinucleotide phosphate (NADPH), which helps in protecting cells from oxidative stress from reactive oxygen species (ROS). G6PD deficiency is the most common disorder of RBCs, estimated to affect 200 to 400 million people worldwide. The enzyme deficiency leads to damaged RBCs that can rupture and break down prematurely, causing hemolysis. The deficiency occurs most often in tropical and subtropical regions of the Eastern Hemisphere including Europe, Africa, and Asia. G6PD deficiency is an X-linked recessive disorder, most fully expressed in homozygous males, although partial expression is possible in heterozygous females because of mosaicism resulting from X-inactivation. (X-linked inheritance is discussed in [Chapter 4](#).) Several genetic variants of G6PD are identified but most are harmless.⁷ Two variants, G6PD and G6PD Mediterranean, cause most of the significant hemolytic anemias.⁷ The deficiency is present in 10% of American blacks, and the G6PD Mediterranean variant is prevalent in Middle East populations.

◆Pathophysiology.

Deficient or abnormal enzyme function can cause abnormalities in the hexose monophosphate shunt or glutathione metabolism that impairs the ability of RBCs to protect themselves against oxidative stress

injuries that lead to hemolysis. One of the most important enzymes is G6PD. Oxidants cause both an intravascular and an extravascular hemolysis in G6PD-deficient individuals. G6PD enables erythrocytes to maintain normal metabolic processes despite injury from oxidative stressors, such as exposure to certain classes of drugs (sulfonamides, nitrofurantoin, antimalarial agents, salicylates, or naphthoquinones), ingestion of fava beans (a dietary staple in some Mediterranean areas), hypoxemia, infection, fever, or acidosis. Therefore G6PD deficiency is usually asymptomatic unless one of these events occurs. Commonly, infections can initiate hemolysis, especially viral hepatitis, pneumonia, and typhoid fever. The fava bean is often ingested in Mediterranean cultures, causing “favism,” and in some parts of Africa. Erythrocyte damage in affected children begins after intense or prolonged exposure to one of these stressors (substances or conditions) and ceases when the stressors are removed. In black males, the G6PD defect becomes more pronounced as the erythrocyte ages, and in other populations the defect is profound even in young erythrocytes. A pregnant woman may cause an episode of hemolysis in a fetus with G6PD deficiency by ingesting a substance with oxidant properties, such as a salicylate (aspirin).

In the absence of G6PD, oxidative stressors damage hemoglobin and the plasma membranes of erythrocytes and possibly interfere with the activities of other enzymes within the cell. Hemoglobin is oxidized progressively to methemoglobin, sulfmethemoglobin, and denatured globin-glutathione complexes. Exposure to oxidizing substances results in the precipitation of insoluble hemoglobin inclusions, called *Heinz bodies*, within the cell. Plasma damage and the presence of Heinz bodies cause hemolysis, primarily in the spleen.

◆Clinical Manifestations.

In infants, G6PD deficiency may present as icterus neonatorum. The most common clinical manifestation of G6PD deficiency is acute hemolytic anemia, usually after infections or the ingestion of certain oxidative drugs. The fava bean produces a severe hemolytic reaction in children with G6PD deficiency.

Hemolytic episodes are characterized by pallor, icterus, dark urine, back pain, and, in severe cases, shock, cardiovascular collapse, and death. Between hemolytic episodes, the child does not have anemia and erythrocyte survival is normal.

◆Evaluation and Treatment.

Reduced G6PD activity in erythrocytes is required for diagnosis. Immediately after a hemolytic episode, reticulocytes and young erythrocytes are evident. Because young erythrocytes have significantly higher enzyme activity than do older cells, laboratory evaluation should be performed shortly after a crisis so that a low level of enzyme activity can be demonstrated. G6PD activity that is within the low normal range in the presence of a high reticulocyte count suggests G6PD deficiency. G6PD deficiency also can be detected by electrophoretic analysis.

Prevention of hemolysis is the most important therapeutic measure. Prevention includes avoiding medications and dietary substances associated with hemolysis. Because of the high frequency of G6PD deficiency in areas of the world that are endemic for malaria, the World Health Organization currently recommends testing for G6PD deficiency before administration of antimalarial medications in these regions.²² When hemolysis occurs, supportive treatment may include blood transfusions and oral iron therapy. Spontaneous recovery generally follows treatment.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is an inherited disorder caused by defects in the membrane skeleton of RBCs. The changes cause RBCs to become spherical, less deformable, and vulnerable to destruction. HS is caused by genetic mutations in at least five genes (*ANK1*, *EPB42*, *SLC4A1*, *SPTA1*, and *SPTB*). These genes provide proteins for producing RBC membranes. These proteins act as transporters for molecules in and out of the cells, attach to other proteins, and maintain cell shape. Thus these proteins help the cells to be flexible for RBC mobility from large blood vessels to capillaries. Mutations in

RBC membranes result in changes in shape, becoming more spherical instead of a flattened disc shape, and rigid. The misshapen cells, or **spherocytes**, are removed from circulation and end in the spleen for destruction. In the spleen, the spherocytes break down and undergo hemolysis.

◆Pathophysiology.

HS is transmitted as an autosomal dominant trait in about 75% of cases. The defect results from properties of its specialized membrane skeleton, which lies close to the internal surface of the plasma membrane.⁷ The affected proteins include spectrins and ankyrin, and their intrinsic defects in the membrane cause less deformability and increased vulnerability to splenic sequestration and destruction.

The spleen is intimately involved in the hemolytic process. The spherocyte is relatively rigid and passes with difficulty through the small openings between the splenic cords and sinuses initiating macrophage response. Circulation of blood to the spleen creates repeated circulation through a metabolic environment that results in sequestration and destruction of spherocytes.

◆Clinical Manifestations.

The presenting signs of HS are anemia, jaundice, and splenomegaly. Anemia may be mild or absent in some cases depending on the individual's physiologic compensation. In these cases, the reticulocyte count will be elevated. Splenomegaly is usually mild. HS can present at any age, from the neonatal period until older adulthood. If HS presents during the newborn period, it is typically more severe with the infant developing signs of hemolytic anemia and hyperbilirubinemia.²³ These children, therefore, may have life-threatening anemia with clinical symptoms ranging from difficulty feeding, circumoral pallor, tachycardia, nasal flaring, and diaphoresis to lethargy. They also are at increased risk for gallstones because of the presence of extra bile pigment. Infection (specifically parvovirus),²⁴ fever, and stress stimulate the spleen to destroy more RBCs than usual, leading to a worsening anemia in a child with baseline anemia.

◆ Evaluation and Treatment.

Ascertaining a family history of spherocytosis is important. Laboratory findings include spherocytes in the peripheral blood smear (*spherocytosis*), elevated reticulocyte count (with or without anemia), indirect hyperbilirubinemia, and a positive osmotic fragility test. An osmotic fragility test is performed by placing RBCs in a saline solution for 24 hours. Spherocytes do not tolerate saline solutions; as a result, they burst more readily than normal RBCs. Treatment of HS is based on disease severity. Although some children with HS will have severe anemia, blood transfusions are rarely required. Treatment before the age of 5 years consists of daily folic acid supplementation to increase production of healthy RBCs. In the past, splenectomy was the first line of treatment. Currently, however, splenectomy is only recommended for those children more than 5 years of age with severe disease or those who develop symptomatic gallstones. Partial splenectomy, in which only a portion of the spleen is removed, is being performed on children with HS in an attempt to decrease the risk of postsplenectomy complications.²⁵

Sickle Cell Disease

Sickle cell disease (SCD) is a group of disorders that affects hemoglobin characterized by the presence of an atypical form of hemoglobin—*hemoglobin S* (*HbS*; *sickle hemoglobin*)—within the erythrocytes. It is a common hereditary hemoglobinopathy where HbS is formed by a genetic point mutation (missense) in **β -globin** that leads to the replacement of one glutamate amino acid with a valine amino acid (Fig. 31.4). Abnormal versions of β -globin can distort erythrocytes into a sickle shape. Hemoglobin consists of four protein subunits called α -globin and two subunits called β -globin. The hemoglobin B (*HbB*) gene provides instructions for making protein β -globin. Other mutations in the *HbB* gene lead to other versions of β -globin, such as hemoglobin C (*HbC*) and hemoglobin E (*HbE*). *HbB* gene mutations also can affect the quantity of β -globin, such as low levels of β -globin found in β -thalassemia. Sickle cell disease affects millions of people worldwide and is most common among individuals

with ancestors from Africa and less so from the Mediterranean countries, such as Greece, Turkey, and Italy; the Arabian peninsula; India; and Spanish-speaking regions in South America, Central America, and parts of the Caribbean.²⁶ Most infants with SCD born in the United States are now identified by routine neonatal screening. Between 1 and 3 million Americans and more than 100 million individuals worldwide are estimated to be heterozygous carriers for the sickle cell trait (HbAS).²⁷ It is estimated that between 70,000 and 100,000 Americans have SCD.²⁸

FIGURE 31.4 Sickle Cell Hemoglobin. Brief summary of sickle cell. (From Kierzenbaum AL, Tres LL: *Histology and cell biology: an introduction to pathology*, ed 4, Philadelphia, 2015, Saunders.)

Cycles of deoxygenation and oxygenation cause the HbS molecule to polymerize and stiffen. These polymers can damage the RBC structure, leading to sickle-shaped RBCs. This change causes a variety of pathologic consequences; the sickle-shaped RBCs die prematurely leading to hemolytic anemia, microvascular obstruction, and ischemic tissue damage. SCD is inherited in an autosomal recessive pattern where each parent carries one copy of the mutated gene. **Sickle cell anemia (SCA; HbSS)**, a homozygous form, is the most severe. **Sickle cell trait (HbAS)**, in which the child inherits HbS from one parent and normal hemoglobin (HbA) from the other, is a heterozygous carrier state and not a form of SCD. The most prevalent SCD genotypes include homozygous hemoglobin SS (HbSS, or sickle cell anemia) and

the compound heterozygous conditions hemoglobin S β^0 -thalassemia (Hb β^0 -thalassemia), hemoglobin S β -thalassemia (HbS β^+ -thalassemia), and hemoglobin SC disease (HbSC).²⁸ HbSS and HbS β^0 -thalassemia are clinically similar and are, therefore, commonly referred to as *sickle cell anemia (SCA)*; these genotypes are associated with the most severe clinical manifestations.²⁸ All forms of SCD are lifelong conditions. Two effective disease therapies for SCD are hydroxyurea and chronic transfusion.²⁸ Hope for a cure is use of hematopoietic stem cell transplantation (HSCT); however, it is infrequently performed and needs significant investigation.²⁸

◆Pathophysiology.

Pathogenesis of sickling includes erythrocyte derangement, chronic hemolysis (hemolytic anemia), microvascular occlusions, and tissue damage. Deoxygenation is probably the most important variable in determining the occurrence of sickling. Other significant variables that affect sickling include interaction of HbS with other types of hemoglobin in the cell, mean cell hemoglobin concentration (MCHC), intracellular pH, and transit times of erythrocytes through the microcirculation.⁷ In heterozygotes with sickle cell trait, the presence of other types of Hb prevents sickling except under conditions of severe hypoxia. Intracellular dehydration increases the MCHC, which increases sickling. A decrease in pH reduces the oxygen affinity of hemoglobin, resulting in an increase in the quantity of deoxygenated HbS at any oxygen tension and increasing sickling. Inflammation in the microcirculation will slow erythrocyte transit times because blood flow is sluggish with adhesion of leukocytes to activated endothelial cells. Increased osmolality of the plasma draws water out of the erythrocytes. This promotes sickling by raising the relative HbS content in erythrocytes. Investigators are studying the optimal intravenous fluid to increase erythrocyte deformability and biomechanical properties.²⁹ To simplify, sickling as an occasional, intermittent phenomenon can be triggered or sustained by one or more of the following stressors: decreased oxygen tension (PO₂) of the blood (i.e., hypoxemia), acidosis (decreased pH), increased plasma

osmolality, decreased plasma volume, and low temperature (Fig. 31.5). Low temperatures precipitate sickle crisis, presumably because of vasoconstriction.³⁰

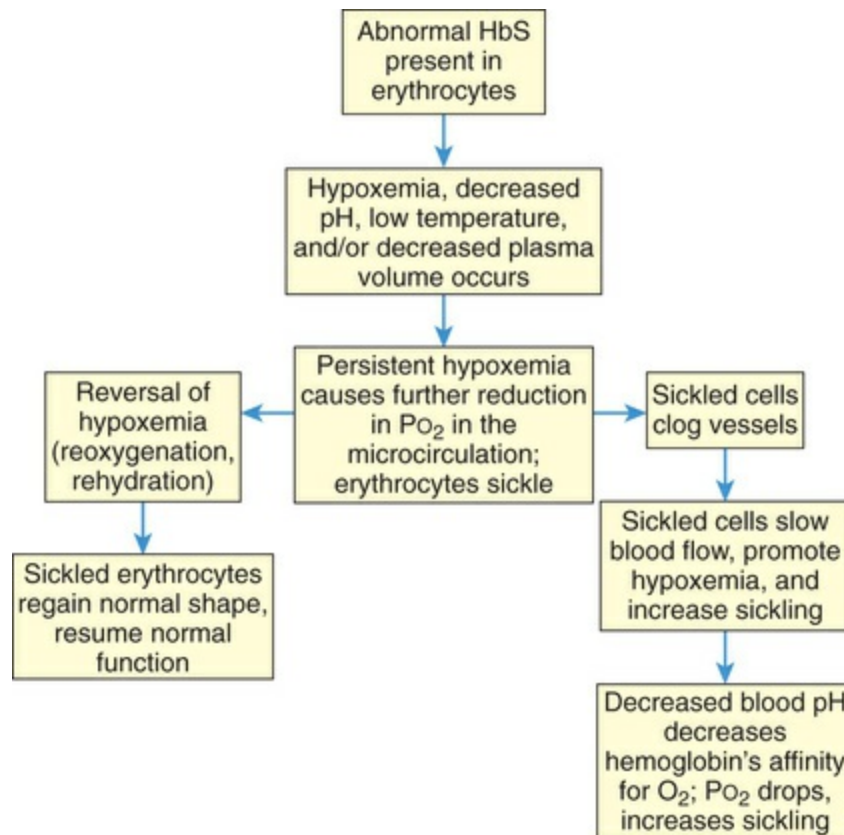

FIGURE 31.5 Sickling of Erythrocytes.

Sickling causes damage to erythrocytes through several mechanisms, including (1) *membrane derangements* occur because as HbS units (polymers) grow they protrude through the membrane skeleton by only the lipid layer, causing changes in membrane structure: (2) membrane derangement leads to *changes in ionic flow* with an influx in Ca^{++} ions, which induces cross-linking of membrane proteins and activation of an ion channel that induces the efflux of K^{+} and H_2O ; and (3) with time the damaged *cells are converted to end-stage*, nondeformable or stiff and irreversibly sickled cells (Fig. 31.6). Recent studies have shown that elevated red cell levels of the enzyme *sphingosine kinase 1 (SPH1)* underlie sickling and disease progression

by increasing *sphingosine 1-phosphate (S1P)* production in the blood.³¹ **S1P level**, a bioactive lipid enriched in red cells, is elevated in red cells and plasma of mice and humans with SCD.³¹ S1P also is a signaling molecule that regulates diverse biologic functions including inflammation.³² Additionally, investigators demonstrated that the compound 5C can inhibit *SPHK1* and, thus, has antisickling properties.³³ These data are important for identifying the structure of the sickling process to assess potential new therapeutics.

FIGURE 31.6 Sickle Cell Disease Pathogenesis. See text for discussion. (B adapted from Kumar V, Abbas AK, Aster JC: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Elsevier Saunders.)

The cells remain sickled even with full oxygenation and some cells are vulnerable to hemolysis. Polymerization of sickled hemoglobin is central to the disorder. **Polymerization** stiffens the sickled erythrocyte, changing it from a flexible, beneficial cell to an inflexible one where HbS molecules stack into polymers that starve and damage tissues. The pathogenesis of SCD totally derives from the tendency of

HbS molecules to stack into polymers when deoxygenated and assemble into needle-like fibers within cells, producing the distorted crescent-like sickle or holly-leaf shape (Fig. 31.7). Sickled cells undergo hemolysis in the spleen or become sequestered there, causing blood pooling and infarction of splenic vessels. The anemia that follows triggers erythropoiesis in the marrow and, in extreme cases, in the liver.^{34,35}

FIGURE 31.7 Normal and Sickle-Shaped Blood Cells. A, Color-enhanced electron micrograph shows normal erythrocytes and sickled blood cell. B, Scanning electron micrograph of normal and sickle-shaped red blood cells together. The irregularly shaped cells are the sickle cells; the circular cells are the normal blood cells. (From Raven PH, Johnson GB: *Biology*, ed 3, St Louis, 1992, Mosby.)

However, the pathogenesis of **microvascular occlusions**, a main feature of SCD not fully understood, is responsible for the most serious and urgent manifestations. Microvascular occlusions are not

related to the quantity of irreversibly sickled cells in the blood but are dependent on understated RBC membrane damages and other local factors, such as inflammation or vasoconstriction, that tends to decrease blood flow or arrest red cells through the microcirculation.⁷ Investigators are studying the microvasculature from a developed model and mathematics of the microvasculature to allow the understanding of the rheology of sickle cell blood.^{36,37} Sickle RBCs express higher than normal amounts of adhesion molecules and are sticky. During inflammatory reactions, leukocyte release of mediators increases the expression of adhesion molecules on endothelial cells. These reactions further promote sickled erythrocytes to become arrested during movement through the microvasculature.⁷ The sluggish and stagnant red cells within the inflamed vascular vessels result in extended exposure to low oxygen tension, sickling, and vascular obstruction.⁷ Lysed sickle erythrocytes release hemoglobin and free hemoglobin can bind and inactivate nitric oxide (NO), which is a powerful vasodilator and inhibitor of platelet aggregation. Decreased blood pH reduces hemoglobin's affinity for oxygen leading to an increasing fraction of deoxygenated HbS at any oxygen tension and predisposition to sickling. As less oxygen is taken up by hemoglobin in the lungs, the PO₂ drops promoting additional sickling.

Once sickling begins, it tends to continue until the PO₂ returns to normal; then it ceases spontaneously. The extent, severity, and clinical manifestations of sickling depend to a great extent on the percentage of hemoglobin that is HbS. That is why homozygous inheritance of HbS produces the severest form of SCD—sickle cell anemia. Heterozygous inheritance of SCD results in less sickling because the individual's erythrocytes contain other forms of abnormal hemoglobin that, although defective, do not contribute to sickling to any great degree. Heterozygous inheritance (sickle cell trait), in which abnormal hemoglobin is inherited from one parent and normal hemoglobin from the other, rarely results in sickling because normal HbF and HbA do not contribute to sickling at all. Anemia persists because HbF does not live 120 days.

◀Clinical Manifestations.

There is much variation in the clinical manifestations of sickle cell disease. Some individuals have mild symptoms and others suffer from repeated vaso-occlusive crises.⁷ Clinical manifestations of SCD may first be seen at 6 to 12 months of age as fetal hemoglobin is replaced by HbS. Two characteristics of SCD determine presentation: the first is its nature to be a chronic disease with acute exacerbations; the second is that it is a condition affecting RBCs that supply oxygen to all cells of the body. Therefore SCD can affect any part of the body. When sickling occurs, the general manifestations of hemolytic anemia—pallor, fatigue, jaundice, and irritability—sometimes are accompanied by acute manifestations called *crises*. Extensive sickling can precipitate four types of crises: (1) vaso-occlusive crisis, (2) aplastic crisis, (3) sequestration crisis, or rarely (4) hyperhemolytic crisis. Sites of specific dysfunction are shown in [Fig. 31.8](#).

FIGURE 31.8 Clinical Manifestations of Sickle Cell Disease.

Vaso-occlusive crises (pain crises) are events of hypoxic injury and infarction that can cause severe pain in affected areas. However, the specific cause of sensory pain lacks sufficient characterization.^{38,39} The most common sites include bones, lungs, spleen, liver, brain, and penis. Painful bone crises are very common in children and are

difficult to distinguish from acute osteomyelitis.⁷ These bone alterations can manifest as painful swelling of the hands and feet (*hand-foot syndrome* or *dactylitis*).

A high-risk type of vaso-occlusive crisis involves the lungs known as **acute chest syndrome**. It typically presents with fever, cough, chest pain, and accumulations of lung infiltrates. The complications in the lungs create a worsening cycle of hypoxemia, sickling, and vaso-occlusion.⁷ Acute chest syndrome is the cause of death in approximately 25% of all deaths in people with SCD.^{40,41} *Priapism*, or prolonged erection of the penis, can lead to hypoxic damage and erectile dysfunction. Vaso-occlusion in vessels to the brain can result in stroke. Chronic vaso-occlusion in vessels to the kidneys results in end-stage renal disease. Vaso-occlusive crisis is extremely painful and may last for days or even weeks. The frequency of this type of crisis is variable and unpredictable because it may develop spontaneously or be precipitated by infection, exposure to cold, dehydration, low PO₂, acidosis (low pH), or localized hypoxemia.

Aplastic crisis, a transient cessation in RBC production resulting in acute anemia, occurs as a result of a viral infection, almost always infection with parvovirus B1. The virus causes temporary shutdown of RBC production in the bone marrow but hemolysis continues. The outcome is a sudden drop in hemoglobin level with an extremely low reticulocyte count.

In **sequestration crisis**, large amounts of blood become pooled in the spleen. Massive large amounts of sickle red cells lead to a rapid splenic enlargement, hypovolemia, and sometimes shock.⁷ Sequestration crisis and acute chest syndrome may be fatal and can require prompt treatment with exchange transfusions.

Hyperhemolytic crisis, an accelerated rate of RBC destruction, is unusual but may occur in association with certain drugs or infections. It is characterized by anemia, jaundice, and reticulocytosis. The concomitant presence of G6PD deficiency (see [Glucose-6-Phosphate Dehydrogenase Deficiency](#)) contributes to hyperhemolytic episodes, especially when combined with infections.

A significant cause of morbidity and mortality is infection,

especially for those with impaired splenic function. Splenic function is severely altered in children with splenic congestion and poor blood flow, and severe splenic damage in adults occurs from splenic infarction. In children, infections from *Pneumococcus pneumoniae* and *Haemophilus influenzae* are common.

Glomerular disease, characterized by damage to the glomeruli allowing protein and often RBCs to leak into the urine, is caused by sickling of RBCs in the kidneys. Extensive damage to the glomeruli results in nephropathy that may progress to renal failure. The earliest manifestation of SCD in the kidney is hyposthenuria, or the inability of the tubules of the kidneys to concentrate urine. Very low urine specific gravity occurs and in young children this often results in bed-wetting. Proteinuria also is an early manifestation of sickle nephropathy.

Cholecystitis, inflammation of the gallbladder that occurs when a gallstone blocks the cystic duct, can be caused by hemolysis resulting in an increase of bilirubin concentration, which in turn causes the formation of gallstones in the gallbladder. The presence of gallstones can cause right upper quadrant pain, nausea, vomiting, and an elevated white blood cell count and alkaline phosphatase level. Cholecystectomy may be required.

Sickle cell-hemoglobin C (HbC) disease is usually milder than sickle cell anemia. HbC results when lysine is substituted for glutamic acid in the amino acid chain. HbC is less soluble than HbA; however, it does not polymerize under conditions of decreased oxygen tension as does HbS. The main clinical problems are related to vaso-occlusive crises and are proposed to result from higher hematocrit values and viscosity. In older children, sickle cell retinopathy, renal necrosis, and aseptic necrosis of the femoral heads occur along with obstructive crises.

Sickle cell-thalassemia has the mildest clinical manifestations of all the SCDs. Individuals with sickle cell-thalassemia have mutations in each allele coding for hemoglobin. One mutation results in HbS formation and the other is associated with β -thalassemia and results in decreased production of hemoglobin. Even though most of the

child's hemoglobin is HbS (60% to 90%), normal hemoglobins (HbA and HbF) also are present. The normal hemoglobins, particularly HbF, inhibit sickling. In addition, the erythrocytes tend to be small (microcytic) and to contain relatively little hemoglobin (hypochromic). Their small size makes them less likely than normal-size cells to clog the microcirculation, even when in a sickled state.

◆Evaluation and Treatment.

The parents' hematologic history and clinical manifestations may suggest that a child has SCD, but hematologic tests and the presence of irreversibly sickled cells are necessary for diagnosis. If the sickle solubility test confirms the presence of HbS in blood, hemoglobin electrophoresis provides information about the amount of HbS in erythrocytes. Prenatal diagnosis can be made by chorionic villus sampling as early as 8 to 10 weeks of gestation or amniotic fluid analysis at 15 weeks of gestation. Newborn screening for SCD should be performed according to state law.

Health maintenance as early interventions in populations identified by screening is beneficial.²⁸ Young children with SCA have a very high risk of infection, septicemia, and meningitis. The fatality is high and the risk is greatest in young people who lack immunity against pneumococcal serotype causing infection. These infections arise because of abnormal or absent splenic function.²⁸ A recent proposal has been presented as a prevention strategy to use prophylactic antibiotics (penicillin), vaccination against pneumococcus and other encapsulated microorganisms, and education to those with SCD, parents, and caregivers to seek immediate medical attention in the event of fever.²⁸ Other recommendations for treatment and health maintenance are available at <https://www.nhlbi.nih/sites/www.nhlbi.nih.gov/files/sickle-cell-disease-report.pdf>.

Treatment advances since the late 1980s have significantly decreased morbidity and mortality in children with SCD. Aggressive management of fever, early diagnosis of *acute chest syndrome* (hypoxia, anemia, progressive multilobar pneumonia, fat emboli), RBC

transfusions, and proper pain management can improve quality of life and prognosis for these children. Treatment of SCD consists of supportive care aimed at preventing consequences of anemia and avoiding crises. Crises can be prevented by avoiding fever, infection, acidosis, dehydration, constricting clothes, and exposure to cold. Immediate correction of acidosis and dehydration with appropriate intravenous fluids is imperative. Infections require aggressive antibiotic therapy and infections can be reduced by vaccination. Oxygen is not needed unless the child becomes hypoxic. Pain associated with SCD is very complex, requiring accurate assessment and multimodal management.⁴²

A common treatment is hydroxyurea, an inhibitor of DNA synthesis. It increases HbF synthesis, which decreases the proportion of HbS. Transfusion or exchange transfusion also can achieve these changes. Genetic counseling and psychologic support are important for the child and family.

Thalassemias

The α - and β -thalassemias are inherited autosomal recessive disorders that cause an impaired synthesis of one of the two chains— α or β —of adult hemoglobin (HbA). The disorder was named **thalassemia**, which is derived from the Greek word for *sea*, because it was initially described in people with origins near the Mediterranean Sea. β -Thalassemia, in which synthesis of the β -globin chain is slowed or defective, is prevalent among Greeks, Italians, and some Arabs and Sephardic Jews. α -Thalassemia, in which the α chain is affected, is most common among Chinese, Vietnamese, Cambodians, and Laotians. Both α - and β -thalassemias are common among blacks. Anemia associated with thalassemia is microcytic-hypochromic hemolytic anemia.

◆Pathophysiology.

The **β -thalassemias** are classified into two types depending on the severity of symptoms: thalassemia major and thalassemia intermedia. Thalassemia major is more severe. The β -thalassemias are caused by

mutations in the *HBB* gene that decrease the synthesis of β -globin chains. **Thalassemia major (Cooley anemia)** and **thalassemia intermedia** are inherited in an autosomal recessive pattern where both copies of the *HBB* gene in each cell have mutations. In a small percentage of families, the *HBB* gene mutation is inherited in an autosomal dominant manner.⁴³ The mutations are classified as (1) β^0 mutations or absent β -globin synthesis and (2) β^+ mutations with reduced amounts of β -globin synthesis. Genetic studies have identified more than 100 different causative mutations, and most are point (missense) mutations. Clinical classification of β -thalassemias is based on the severity of the anemia, which is dependent on the type of mutation (β^0 or β^+ allele) and gene dosage (homozygous or heterozygous).⁷ β -Chain production is depressed in the heterozygous form, thalassemia minor (β^0 or β^+ allele); and anemia, if present, is mild; however, anemia is severe in the homozygous form, β -thalassemia major. β -Thalassemia major may lack HbA (β^0/β^0 genotype) or contain small amounts (β^+/β^+ or β^0/β^+ genotypes). The main type of hemoglobin is HbF and sometimes HbA₂ is high and often normal or low.⁷ Depression of β -chain synthesis results in erythrocytes having a reduced amount of hemoglobin and accumulations of free α chains. The free α chains are unstable and easily precipitate in the cell (Fig. 31.9). Most erythroblasts that contain precipitates are destroyed by mononuclear phagocytes in the marrow, resulting in ineffective erythropoiesis and anemia. Some of the precipitate-carrying cells do mature and enter the bloodstream, but they are destroyed prematurely in the spleen, resulting in mild hemolytic anemia.

FIGURE 31.9 Pathogenesis of β -Thalassemia Major. The aggregates of unpaired α -globin chains are a hallmark of the disease. Blood transfusions can diminish the anemia but they add to the systemic iron overload. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Saunders.)

The **α -thalassemias** result from deletions involving the *HBA1* and *HBA2* genes. These genes provide instructions for making a protein called **α -globin**, a subunit of hemoglobin. The different types of α -thalassemia result from the loss of some or all of the alleles (two copies of the *HBA1* gene and two copies of the *HBA2* gene in each cell; for each gene, one allele is inherited from the father and the other from the mother). Characteristic features of α -thalassemia are anemia, weakness, fatigue, and other more severe complications (see [Clinical Manifestations](#)). Types of α -thalassemia include:

1. *Hb Bart syndrome* is the most severe form of α -thalassemia and is caused by the loss of all four α -globin alleles. In the fetus,

hydrops fetalis is the most severe form of α -thalassemia caused by the deletion of all four α -globin genes. Excess γ -globin chains do have a high affinity for oxygen but deliver small quantities to tissue. Signs of fetal distress may become evident in the third trimester of pregnancy, and intrauterine transfusions may save the baby.

2. HbH disease is caused by a loss of three of the four α -globin alleles. In both Hb Bart syndrome and *HbH disease*, the decrease in α -globin prevents cells from making normal hemoglobin. Instead, cells produce abnormal forms of hemoglobin called *Bart* (Hb Bart) or *hemoglobin H* (HbH). These abnormal forms of hemoglobin do not carry oxygen effectively, which causes anemia and other related consequences.⁴⁴
3. Two other variants of α -thalassemia are related to reduced amounts of α -globin. These variants still produce some normal hemoglobin and therefore cause few or no health problems.⁴⁴
4. α -Thalassemia trait results from a loss of two of the four α -globin alleles. These individuals may have small, pale erythrocytes and mild anemia. A loss of one α -globin allele is found in α -thalassemia silent carriers, meaning these individuals have no related clinical manifestations.⁴⁴

β -Thalassemia occurs more frequently than does α -thalassemia. Occasionally synthesis of γ - or δ -polypeptide chains is defective, resulting in γ - or δ -thalassemia. (Hemoglobin chains are described in [Chapter 28](#).)

◆Clinical Manifestations.

β -Thalassemia minor causes mild to moderate microcytic-hypochromic hemolytic anemia. The degree of reticulocytosis depends on the severity of the anemia. Hemolysis of immature (and therefore fragile) erythrocytes may cause a slight elevation in serum iron and indirect bilirubin levels. Although persons with β -thalassemia minor may be asymptomatic, mild splenomegaly, bronze

coloring of the skin, and hyperplasia of the bone marrow resulting in skeletal changes can occur.

Persons with β -thalassemia major may become quite ill with impaired physical growth and development. The severe anemia resulting from this condition can cause significant cardiovascular burden with high-output congestive heart failure. Historically, death results from cardiac failure by 5 or 6 years of age. Today, blood transfusions can increase life span by one to two decades, and death usually is caused by hemochromatosis (from transfusions).⁴⁵ (Hemosiderosis and hemochromatosis are described in [Chapters 28](#) and [29](#).) Liver enlargement occurs as a result of progressive hemosiderosis, whereas enlargement of the spleen is caused by extramedullary hematopoiesis and increased destruction of RBCs. Skeletal changes include spinal impairment that starts in infancy and retards linear growth and subsequent upper and lower limb-length discrepancy. Bone marrow hyperplasia causes a characteristic deformity of the facial bones, as the nasal bridge, mandible, and maxilla widen. Osteopenia, osteochondrosis, or both also may develop.

People who inherit the mildest form of α -thalassemia, the **α trait**, usually are symptom free, having, at most, mild microcytosis. **α -Thalassemia minor** has clinical manifestations that are virtually identical to those of β -thalassemia minor: mild microcytic-hypochromic reticulocytosis, bone marrow hyperplasia, increased serum iron concentrations, and moderate splenomegaly.

α -Thalassemia major causes hydrops fetalis and fulminant intrauterine congestive heart failure. In addition to edema and massive ascites, the fetus has a grossly enlarged heart and liver. Most affected babies are stillborn or die shortly after birth. Diagnosis usually is made postmortem. Prenatal screening for this disorder can be performed by use of chorionic villus sampling. These cells can be analyzed, and a deoxyribonucleic acid (DNA) genetic map can be constructed and evaluated for the characteristic abnormalities associated with hydrops fetalis.

◆ Evaluation and Treatment.

The diagnosis of thalassemia is based on familial disease history, clinical manifestations, and blood tests. Laboratory tests reveal microcytic-hypochromic anemia and nucleated RBCs on peripheral blood smear, whereas hemoglobin analysis shows decreased amounts of HbA and increased amounts of hemoglobin F (HbF) after age 12 months, and severity of anemia. Treatment involves a regular transfusion program and chelation therapy to reduce transfusion iron overload. Milder forms of thalassemia rarely require transfusion, and these individuals are at risk for iron overload secondary to increased intestinal absorption of iron from ineffective erythropoiesis.⁴⁶ The only available definitive cure for thalassemia major is by allogeneic hematopoietic stem cell transplantation (HSCT) from a matched family or unrelated donor or cord blood transplantation from a related donor.⁴⁶ Optimal clinical management may decrease the need for splenectomy. For less severe thalassemia (sometimes called *intermedia*), splenectomy may be done for those with the most affected symptoms, as well as sporadic red cell transfusions for some, folic acid supplementation, and iron chelation.⁴⁶

Prenatal diagnosis is sometimes done and families are referred for genetic counseling. Molecular genetic testing of at-risk siblings should be offered to allow for early diagnosis and appropriate treatment. Women with thalassemia intermedia who have never received a blood transfusion or who received a minimal quantity of blood are at risk for severe alloimmune anemia if blood transfusions are required during pregnancy.⁴⁶

Disorders of Coagulation and Platelets

Inherited Hemorrhagic Disease

Hemophilias

Awareness of a serious bleeding disorder in males was documented nearly 2000 years ago in the Babylonian Talmud, which exempted those boys having male relatives prone to excessive bleeding from the rite of circumcision. In 1803 the first description of this disorder

appeared in the medical literature, where it was noted to be X-linked and associated with joint bleeding and crippling.

Table 31.3 lists the coagulation factors. Until 1952 the term *hemophilia* was reserved for deficiency of factor VIII (antihemophilic factor). Since then two additional coagulation proteins, factor IX (plasma thromboplastin component [PTC]) and factor XI (plasma thromboplastin antecedent [PTA]), have been identified and their deficiency associated with similar clinical manifestations. Congenital deficiencies of these three plasma clotting factors—VIII, IX, XI—account for 90% to 95% of the hemorrhagic bleeding disorders collectively called *hemophilia*.

TABLE 31.3

THE COAGULATION FACTORS

CLOTTING FACTORS	SYNONYM	DISORDER
I	Fibrinogen	Congenital deficiency (afibrinogenemia) and dysfunction (dysfibrinogenemia)
II	Prothrombin	Congenital deficiency or dysfunction
V	Labile factor, proaccelerin	Congenital deficiency (parahemophilia)
VII	Stable factor or proconvertin	Congenital deficiency
VIII	Antihemophilic factor (AHF)	Congenital deficiency is hemophilia A (classic hemophilia)
IX	Christmas factor	Congenital deficiency is hemophilia B
X	Stuart-Power factor	Congenital deficiency
XI	Plasma thromboplastin antecedent	Congenital deficiency, sometimes referred to as hemophilia C
XII	Hageman factor	Congenital deficiency is <i>not</i> associated with clinical symptoms
XIII	Fibrin-stabilizing factor	Congenital deficiency

Types of Hemophilia.

Hemophilia is a bleeding disorder with a wide range of clinical

severity. The major types of hemophilia are **hemophilia A (classic hemophilia or factor VIII deficiency)** and **hemophilia B (Christmas disease or factor IX deficiency)**. Hemophilia A is the most common hereditary disease associated with life-threatening bleeding, with an incidence of 1 in 4000 to 5000 male births and an incidence of hemophilia B of 1 in 20,000 newborn males worldwide.⁴⁷ Hemophilia A is caused by changes in the *F8* gene, and mutations in the *F9* gene cause hemophilia B. The *F8* gene provides instructions for making the protein called coagulation VIII. The *F9* gene produces coagulation factor IX.⁴⁷ These factors are important for blood clotting. Factor VIII is an essential cofactor for factor IX in the coagulation cascade. The alterations or deficiencies of the coagulation factors decrease the ability to form blood clots in response to injury. The decreased or ineffective blood clotting leads to continuous bleeding. The most severe types of hemophilia are derived from mutations that eliminate factor VIII or coagulation factor IX. Mutations that reduce but do not eliminate the activity of these proteins are responsible for mild and moderate hemophilia.⁴⁷ Hemophilia A and hemophilia B are inherited as an X-linked recessive pattern. The genes associated with the disorders are located on the X chromosome; in males one altered copy of the disorder causes the condition, which is why it affects mainly males (females are carriers) and very rarely homozygous females. In about 30% of individuals with no family history, their disease is caused by acquired new mutations.⁷

Hemophilias A and B occur with varying degrees of clinical severity, depending on concentrations of clotting factor VIII or IX in the blood. Severe hemophilia (concentration of clotting factors less than 1% of normal) is associated with spontaneous bleeding. In moderate hemophilia (1% to 5% of normal), bleeding usually occurs only after trauma; in the mild form (6% to 50% of normal), bleeding occurs only after severe trauma or surgery.

◆Pathophysiology.

Multiple types of genetic mutations are associated with hemophilias A and B with more than 2000 unique mutations identified for

hemophilia A⁴⁸ and more than 1000 mutations described for hemophilia B.⁴⁹ The type of mutation also affects the phenotype of the disease. Mutations tend to be identical among affected members of a given family; however, mutations often differ across families.^{50,51}

Inversions in introns 1 and 22 of the factor VIII gene are the most frequently observed mutations and account for the majority of severe cases of hemophilia A.⁵⁰ Point mutations, in which a single base in the DNA is inserted in the place of another base, are another type of mutation that causes hemophilia. Point mutations comprise the majority of unique mutations associated with hemophilia.⁵² When a point mutation gives rise to a de novo stop codon (nonsense mutation), translation of the protein ceases and a shortened version of the protein is synthesized. Usually the protein is destroyed intracellularly and never reaches the plasma. This type of defect also is associated with severe hemophilia, that is, with coagulant activity levels below 1%. Point mutations resulting in the substitution of one amino acid for another can cause phenotypes of varying severity. The altered amino acid chain can destroy protein function, activation, or folding; inhibit intracellular processing; or cause protein clearance.⁵²

Table 31.3 summarizes the types of coagulation disorders. Not all the disorders are discussed in this chapter because some are extremely rare (congenital dysfibrinogenemias) and others have no clinical significance. For example, Hageman factor deficiency is a condition with profound laboratory deficiency of factor XII yet is associated with no clinical defects in humans.

◆Clinical Manifestations.

Children with severe hemophilia manifest prolonged bleeding times at different ages. Many boys with hemophilia are circumcised without excessive bleeding. Normal hemostasis is achieved in these infants because clotting is activated through the extrinsic coagulation cascade, which does not involve factors VII, IX, or XI.

During the first year of life spontaneous bleeding often is minimal, but hematoma formation may result from immunizations and from firm holding (e.g., under the arms). Many children are diagnosed

around the time they become mobile (i.e., crawling, pulling to stand) and become easily injured (i.e., increased bruising, swelling, redness at joints, mouth bleeding). By 3 to 4 years of age, 90% of children with hemophilia have had episodes of persistent bleeding from relatively minor traumatic lacerations (e.g., to the lip or tongue). These episodes are often the first clinical manifestations of hemophilia. Hemorrhage into the joints, elbows, knees, and ankles causes pain and limited joint mobility and predisposes the child to degenerative joint changes. Spontaneous hematuria and epistaxis are troublesome but minor complications. Oral bleeding can occur with dental surgery.

Recurrent bleeding—spontaneous and after minor trauma—is a lifelong problem. Many affected individuals experience cycles of spontaneous bleeding episodes. Intracranial bleeds; bleeding of internal organs; and bleeding into the tissues of the neck, chest, or abdomen are life-threatening. Delayed or suboptimal treatment of these bleeds may lead to permanent brain injury, loss of organ function, or death.

◆Evaluation and Treatment.

Since hemophilia is most often an inherited disease, a positive family history may expedite a diagnosis of hemophilia. When a suspected carrier mother is expecting, genetic testing in utero through amniocentesis or chorionic villus sampling (CVS) may reveal a hemophilia diagnosis before birth. In the absence of a positive family history, when a bleeding disorder is suspected, personal bleed history, laboratory testing, family history, and physical assessment contribute to a thorough evaluation and accurate diagnosis. In general, those with hemophilia A or B will have a prolonged partial thromboplastin time (PTT) and the **prothrombin time (PT)** will be normal. An accurate diagnosis is made from factor VIII (hemophilia A) and factor IX (hemophilia B) levels.

The majority of children with hemophilia A (factor VIII deficiency) can be treated with recombinant factor VIII, and the majority of children with hemophilia B (factor IX deficiency) can be treated with recombinant factor IX. Recombinant factor is reconstituted in a small

volume of diluent and administered by slow intravenous push, which raises the factor level almost immediately.

Primary prophylaxis consists of regular infusions of factor VIII or IX with the goal of preventing joint bleeding. It is usually given to children with severe hemophilia. A 5-year, multicenter trial, which has now become the standard of care,⁵³ found prophylaxis initiated in children between 6 and 30 months of age to be effective in the prevention of joint bleeding, structural joint damage, and frequency of bleeding in boys with factor VIII deficiency. Recent multisite trials have demonstrated the safety and efficacy of pegylated, recombinant factors VIII and IX. These pegylated products have extended half-lives and require less frequent dosing.^{54,55}

von Willebrand Disease

von Willebrand disease results from an inherited trait with variable clinical manifestations and hematologic findings resulting from a deficiency or dysfunction in von Willebrand factor. von Willebrand factor binds factor VIII and platelets to the blood vessel wall as part of the clotting process. As a result, factor VIII activity is decreased in individuals with von Willebrand disease. Most cases of von Willebrand disease demonstrate an autosomal dominant pattern of inheritance; however, some cases demonstrate an autosomal recessive or compound heterozygous pattern. The pattern of inheritance depends on the type of mutation that is present.⁵⁶

Congenital Hypercoagulability and Thrombosis

Hereditary bleeding disorders, such as hemophilia, have been recognized and treated for centuries; however, the counterpart of these disorders, **thrombophilia**, has not been recognized until the past 50 years. The inherited thrombophilic conditions generally are caused by defects in the clotting factors that inhibit clot formation; thus the balance between bleeding and clotting is directed toward the clotting aspects of hemostasis. Although the majority of thrombotic events occurring in children, adolescents, and young adults are believed to

be spontaneous, studies are investigating the role of mutations in multiple genes that may contribute to an increased risk of thrombosis. A recent study investigating genetic mutations in 115 adolescents and young adults presenting with thrombotic events identified single gene mutations in two-thirds of this sample, and some individuals had more than one mutation.⁵⁷ Ongoing studies are needed to further investigate the specific roles of these mutations.

Defects in specific proteins (C and S) and antithrombin (AT), as well as resistance to activated protein C (APC) and hyperhomocysteinemia, are the major recognized causes of inherited thrombophilia. Both proteins C and S are inhibitors of coagulation and depend on vitamin K for synthesis in the hepatocytes of the liver. Decreased levels of either of these proteins interfere with the normal homeostatic balance of procoagulant and anticoagulant activity at the endothelial level. Protein C and S deficiency states predispose affected individuals to thrombosis, especially venous thrombosis of the lower extremities.

Inheritance of **protein C deficiency** is autosomal dominant and results from mutations in the *PROC* gene. Its prevalence is approximately 0.2% to 0.4% in the general population. Genetic mutations may result in quantitative (type I) or qualitative (type II) deficiencies of protein C. *Type I deficiencies* involve a reduction in both biologic and immunologic activity of protein C. Type I is caused by deletion of the entire gene. *Type II deficiencies* are less common and result in decreased functional levels of protein C activity despite the presence of a normal level of protein C.⁵⁸

Heterozygotes have protein C levels 50% to 60% of normal and may develop superficial thrombophlebitis, deep venous thrombosis, or pulmonary embolism in their late teens and early 20s. Homozygotes have less than 1% of normal levels of protein C and tend to develop thrombosis of the cutaneous vessels with large areas of skin necrosis. Arterial thrombosis is rare among individuals with protein C deficiency.

Neonatal purpura fulminans is a fatal syndrome found in neonates who are homozygous or double heterozygous for types I and II

protein deficiency. Ecchymosis becomes apparent on the first day of life and develops around the head, trunk, and extremities and often is accompanied by cerebral thrombosis and infarction. The ecchymotic areas often coalesce, and ulceration and necrosis develop. Treatment includes administration of fresh frozen plasma (FFP) and heparinization, although the infant rarely survives.

Treatment for protein C deficiency depends on the clinical manifestations. Individuals who are asymptomatic may not require therapy unless a strong family history of thrombosis is present. Heparin is the treatment for acute episodes of thrombosis caused by protein C deficiency. Long-term therapy is required and consists of either oral warfarin sodium (Coumadin) or subcutaneous heparin. Supplemental protein C concentrates (human) also are available and have been approved for use in children.⁵⁹

Protein S deficiency results from mutations in the *PROS1* gene and is similar to protein C deficiency. The inheritance pattern (autosomal dominant) also is similar. The severity of the clinical manifestations can vary, and many affected individuals never develop an abnormal blood clot.⁵⁸

Protein S deficiency exists in three forms: type I, type II, and type III.⁶⁰ *Type I* deficiency is identified as a quantitative deficiency and manifests as low levels of total protein S antigen and free protein S antigen. *Type II* deficiency is identified as a qualitative deficiency with normal levels of free and total protein S antigen but reduced protein S activity. *Type III deficiency* results in low free protein S levels; however, the total plasma concentration of protein S is normal. Type III deficiency has not been established as a risk factor for venous or arterial thromboembolism.

Heterozygotes with a more severe deficiency demonstrate a strong tendency for deep venous thrombosis, with the first incidence often occurring before age 25 years. Other manifestations include superficial thrombophlebitis and pulmonary emboli. Although clots may occur spontaneously in individuals with protein S deficiency, risk factors, such as increasing age and immobility, can raise the risk of thrombus formation.

Homozygotes demonstrate severe manifestations of the condition and may develop a form of purpura fulminans in the neonatal period. The homozygous state also may lead to intrauterine death. Treatment with heparin, warfarin (Coumadin), and protein C concentrate is similar to that for protein C deficiency.

Antithrombin III (AT III) deficiency is inherited as an autosomal dominant condition—the heterozygous state is the most common. AT III deficiency results from mutations in the *SERPINC1* gene and exists in forms type I and type II. Type I is a quantitative deficiency of the AT III antigen resulting from decreased production. Type II is characterized by decreased functional activity; normal levels of AT III are present, however, activity is reduced.

Individuals with AT III deficiency are at risk for early development of venous thrombosis and pulmonary embolism. These events often occur in the middle to late teens, but can occur as early as 10 years of age. The deep veins of the lower extremities are usually involved, most commonly the iliofemoral vein. Other sites include the mesenteric veins, vena cava, renal veins, and retinal veins. Cerebral thromboses also have been described, and arterial thrombotic events are rare. In some cases thrombosis is precipitated by surgery, trauma, pregnancy, oral contraceptives, and infection.

The treatment of choice for AT III deficiency is heparin. Antiplatelet agents (e.g., aspirin, dipyridamole) may be used, as well as AT III concentrates.

Antibody-Mediated Hemorrhagic Disease

The antibody-mediated hemorrhagic diseases are a group of disorders caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues. The thrombocytopenic purpuras may be intrinsic or idiopathic, or they may be transient phenomena transmitted from mother to fetus. The inflammatory, or “allergic,” purpuras occur in response to allergens in the blood. All these disorders first appear during infancy or childhood.

Primary Immune Thrombocytopenia

Primary **immune thrombocytopenia (ITP)** (previously referred to as **idiopathic thrombocytopenic purpura**) is the most common of the thrombocytopenic purpuras of childhood. It is a disorder of platelet consumption in which antiplatelet autoantibodies bind to the plasma membranes of platelets, causing platelet sequestration and destruction by mononuclear phagocytes in the spleen and other lymphoid tissues at a rate that exceeds the ability of the bone marrow to produce them. The destruction of platelets is triggered by drugs, infections, lymphomas, or an unknown cause.

An international working group of experts updated definitions and terminology for ITP in 2007. The goal of this effort was to reduce heterogeneity across studies and support standardization of reporting patient outcomes.⁶¹ Key outcomes of this effort included distinguishing between primary and secondary ITP, defining the phases of the illness, and establishing criteria for evaluating the response to therapy. Specific phases include *newly diagnosed ITP*, within 3 months of diagnosis; *persistent ITP*, describing individuals with 3 to 12 months of diagnosis who have not achieved remission or complete response off therapy; *chronic ITP*, symptoms lasting longer than 12 months; and *severe ITP*, the presence of bleeding that requires treatment either at diagnosis or following initiation of treatment.

◆Pathophysiology.

The autoantibodies that produce the destruction are often of the IgG class and are usually against the platelet membrane glycoproteins (IIb–IIIa or Ib–IX). Approximately 70% of cases of ITP are preceded by a viral disease (e.g., cytomegalovirus [CMV], Epstein-Barr virus [EBV], HIV, parvovirus, or viral respiratory infection), suggesting that viral sensitization has occurred. The typical interval between infection and onset of purpura is 1 to 3 weeks.

◆Clinical Manifestations.

One to 3 weeks after a viral infection, bruising and a generalized petechial rash often occur with acute onset. Petechiae can develop into

ecchymoses. Asymmetric bleeding is typical and is found most often on the legs and trunk. Hemorrhagic bullae of the gums, lips, and other mucous membranes may be prominent. Epistaxis (nosebleed) may be severe and difficult to control. Except for the signs of bleeding, the child appears well. The principal changes are found in the spleen, bone marrow, and blood.⁷ The acute phase of the disease associated with spontaneous hemorrhages lasts 1 to 2 weeks, but thrombocytopenia often persists. Intracranial hemorrhage is the most serious complication of ITP, although the incidence is less than 1%. In some cases, the onset is more gradual and clinical manifestations consist of moderate bruising and scattered petechiae.

◆Evaluation and Treatment.

Laboratory examination reveals an isolated low platelet count, and the few platelets observed on a peripheral blood smear are large in size, reflecting increased bone marrow production. The Ivy bleeding time is prolonged. Bone marrow aspiration is not recommended for children with typical features of ITP. The primary treatment for children with ITP is observation regardless of platelet count. When bleeding is present, primary treatment is with an infusion of intravenous immune globulin (IVIG) or a short course of corticosteroids only if thrombocytopenia is severe (suppresses immune attack).

Even without treatment the prognosis for children with ITP is excellent—75% recover completely within 3 months. After the initial acute phase, clinical manifestations typically subside. By 6 months after onset, 80% to 90% of affected children have regained normal platelet counts.⁶² ITP that persists longer than 12 months in children is considered chronic and immunosuppressive therapies are utilized.^{63,64}

Parents should be instructed to discourage activities that might cause trauma that could result in bleeding (e.g., contact sports, skateboarding, skiing, bicycle riding). Splenectomy should be reserved for chronic cases that fail to respond to nonsurgical intervention.

Autoimmune Neonatal Thrombocytopenias

Antibody-mediated thrombocytopenic purpura occurs in neonates in either autoimmune or alloimmune form. Both forms are characterized by the immunologic destruction of platelets by autoantibodies (IgG) against tissue-specific antigens expressed by the platelets (i.e., platelet-specific antigens).

Autoimmune neonatal thrombocytopenia was first noted in the early 1950s, when it was observed that mothers with ITP often delivered infants who were transiently thrombocytopenic. Neonatal thrombocytopenia was observed in approximately 50% of infants at risk and lasted an average of 1 month. As platelet counts returned to normal, a concomitant drop in the level of maternal antiplatelet antibody on the child's platelets occurred. The antibody is directed against antigens common to maternal and neonatal platelets. The prognosis generally is favorable and the frequency of intracranial hemorrhage is rare (1% to 3% of cases). Medical management of affected infants is to prevent the severe thrombocytopenia that can cause significant morbidity by administering intravenous immunoglobulins.

Neonatal alloimmune thrombocytopenic purpura (NATP) is less common, estimated to occur in 1 to 2 per 1000 live births. NATP is caused by maternal immunization against fetal paternally derived platelet-specific antigens (similar to rhesus [Rh] disease). The mother has a normal platelet count, whereas the fetus can be severely thrombocytopenic.

The diagnosis of NATP is confirmed by detection in the maternal serum of antibody that reacts with platelets from the infant and father but not with platelets from the mother. In approximately 75% to 85% of cases, NATP recurs in subsequent pregnancies. Purpura usually develops in the affected infant shortly after delivery, and intracranial, renal, and gastrointestinal hemorrhages are possible. The mortality rate from intracranial hemorrhage has been estimated at 10% to 15%. Management of the newborn with NATP includes an immediate cranial ultrasound because of the significant risk of intracranial hemorrhage. Severely thrombocytopenic newborns ($<10,000/\mu\text{L}$) or newborns with intracranial or visceral hemorrhages should receive a

matched platelet transfusion (maternal or homozygous human platelet antigen 1b [HPA-1b] donor) as soon as possible. If maternal platelets are used, they must be processed to remove platelet alloantibodies. Newborn thrombocytopenia is difficult to predict because newborn platelet counts do not correlate with maternal platelet counts or antiplatelet antibody titers.⁶⁵

Most of the life-threatening clinical manifestations of transient neonatal thrombocytopenia and NATP can be avoided through cesarean delivery. If the mother has antiplatelet disease, however, surgery can result in hemorrhage and serious maternal morbidity. Maternal morbidity resulting from NATP during pregnancy is low (less than 5%): the principal maternal risk is bleeding from surgical incisions during cesarean delivery. The incidence of transient thrombocytopenia in infants born to mothers with NATP is about 50%. If all deliveries were cesarean, half the mothers would undergo cesarean delivery unnecessarily. Conversely, if all deliveries were vaginal, half the infants—those with thrombocytopenia—would be at risk for intracranial bleeding. Therefore in the absence of any clear benefit to the neonate (given the low rate of intracranial hemorrhage in infants born to mothers with ITP), cesarean delivery should be reserved for the usual obstetric indications.

Autoimmune Vascular Purpura

Autoimmune vascular purpura (allergic purpura) is caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The inflammatory reaction is to foreign proteins or chemicals in the blood (microorganisms, drugs, or other chemicals).

Autoimmune vascular purpura usually is seen in young children, with the incidence decreasing in adolescents and adults and occurring only rarely in older adults. The average age at onset is 5 years, with a slightly higher proportion of males affected. Purpura occurs as vessel integrity is disrupted by inflammatory processes, causing effusion of serosanguineous exudate to perivascular tissues.

Clinical manifestations include headache, anorexia, fever, abdominal pain, constipation, arthralgias and urticaria, and erythema

that are located symmetrically on the proximal portions of the extremities, particularly on the legs and buttocks, and may be accompanied by itching or paresthesias. Abdominal pain results from hemorrhage into the bowel, which may lead to colic, nausea, and vomiting. These symptoms may precede the appearance of skin lesions. The pain usually is midabdominal but may radiate to other parts of the abdomen. Joint pain and tenderness may be present, but hemarthrosis does not occur. Periarticular swelling and edema of the hands and feet are common and may precede the onset of abdominal pain and purpura. Subacute glomerulonephritis occurs in some cases but usually is reversible.

The characteristic skin lesions (purpura and cutaneous manifestations of allergy), accompanied by a history of joint and abdominal pain, are suspicious for diagnosis. Laboratory test results often reveal no major abnormalities. Attacks may last several weeks and may recur at odd intervals and with changing manifestations with each episode. Treatment, if necessary, consists of symptom management.

Neoplastic Disorders

Leukemia

Leukemia is cancer of the blood-forming tissues, such as the bone marrow, that most often produce abnormal white blood cells called *leukemic cells*. Once in the blood, leukemic cells can spread to other organs, such as the lymph nodes, spleen, and brain. Leukemia is the most common malignancy of children and adolescents. Of the varieties of acute childhood leukemia, 75% to 80% of leukemias in children are *acute lymphoblastic leukemia (ALL)* or *acute leukemia of ambiguous lineage*. The remaining 20% to 25% are classified as *acute myeloid leukemia (AML)* and *related neoplasms*. The related neoplasms include acute promyelocytic, myelomonocytic, and myelomonoblastic leukemias, as well as the very rare RBC leukemia erythroid leukemia.⁶⁶ Chronic leukemias are rare in children and account for

fewer than 5% of cases. Leukemia accounts for 25% of cases of cancer in black children and 34% of cases of cancer in white children.

In the United States, 75% of all cases of ALL are diagnosed in individuals less than 20 years of age, and the peak incidence for childhood ALL is between 2 and 6 years of age.^{67,68} A sharp peak in ALL incidence is reported among children aged 2 to 3 years (>90 cases per 1 million per year), and rates decrease to fewer than 30 cases per million by age 8 years. Since 1975, there has been a gradual increase in the incidence of ALL.⁶⁸ New leukemia cases have been rising on average 0.3% a year in the last 10 years.⁶⁹ ALL affects more white and Hispanic than black children and more males than females. The incidence of ALL also is higher in Western and industrialized nations.⁶⁷

Types of Leukemia

A number of different classifications are used for the leukemias. First, acute leukemia is differentiated from chronic leukemia. Second, the cell line determines whether lymphoid cells or myeloid cells are involved. In acute leukemia this difference separates ALL from AML and vice versa. Within each of these categories, further subdivisions have been developed. (See [Chapter 30](#) for a discussion of leukemias in adults.)

Cytogenetic studies of leukemic cells are performed routinely at most major treatment centers during the diagnostic process. Abnormal morphologic characteristics, as well as abnormalities in the number of copies of chromosomes, are often found in leukemic cells. **Hyperdiploidy** (the presence of greater than the diploid [46] number of chromosomes) is associated with a good prognosis. Common translocations associated with ALL are TEL-AML1, MLL rearrangements, and BCR-ABL. TEL-AML1 is the most common abnormality (in 20% to 30% of cases) and occurs when the *TEL* gene on chromosome 12p13 fuses with the *AML1* gene on chromosome 21q22. TEL-AML1 is associated with a favorable outcome. MLL rearrangements are translocations between the *MLL* gene on chromosome 11q23 and other partner chromosomes. One of the most

noted MLL rearrangements involves chromosome 4 as the partner chromosome t(4;11). This specific MLL rearrangement occurs most frequently among leukemia in infants less than 1 year of age and is associated with a poor prognosis despite intensive therapy.⁷⁰ A translocation involving the long arms of chromosomes 9 and 22, t(9;22)(q34;q11), also described as the **Philadelphia chromosome**, occurs in more than 95% of cases of chronic myeloid leukemia (CML) and in only 2% to 3% of cases of ALL.⁶⁶ The specific breakpoint varies in CML and ALL. The translocation results in the generation of the *BCR-ABL* fusion gene and the bcr-abl protein results in unregulated tyrosine kinase activity.

Classification of childhood leukemia has become a complex but essential process to determine treatment. Previous classification by the French-American-British Cooperative Group (FAB) was based primarily on the morphologic and biochemical system. A classification scheme developed by the World Health Organization (WHO) is based on a more comprehensive system that uses morphology, immunophenotyping, and cytogenetic and clinical features.⁶⁶

Flow cytometric immunophenotyping has made distinguishing between lymphoblastic and nonlymphoblastic leukemia much easier than in the past, when the degree of immaturity of the cell sometimes made such distinction difficult. Molecular cytogenetic techniques, such as fluorescence in situ hybridization (FISH), allow for further detection of specific genetic abnormalities associated with leukemia subtypes.

Immunologic classification has been used on identification of various surface markers. Categories of ALL have been identified on the basis of their presumed origin from thymic cells (T cells) and bursa-equivalent cells (B cells) of normal lymphocytes:

1. T-cell ALL—characterized by the presence of abnormal T lymphocytes and found more commonly in adolescent boys whose initial presentation often includes mediastinal masses, high white blood cell counts, and hepatosplenomegaly (15% to 20% of ALL)

2. Mature B-cell ALL—also called *Burkitt leukemia*; characterized by the presence of abnormal B lymphoblasts and associated with a poor prognosis (5% of ALL)
3. B-precursor ALL—characterized by the presence of pre-B lymphoblasts (80% to 85% of ALL); this category includes the pro-B (3% to 4%), early pre-B (60% to 70%), and pre-B (20% to 30%)
4. Acute leukemia of ambiguous lineage—includes acute undifferentiated leukemia and mixed phenotype acute leukemia (less than 5% of ALL)

◀Etiology.

The cause of most childhood cancer is unknown. About 5% of all childhood cancers are caused by inherited mutations. Genetic mutations can occur during fetal development. Examples of genetic diseases that predispose a child to ALL include Down syndrome, neurofibromatosis, Fanconi anemia, Bloom syndrome, Li-Fraumeni syndrome, and ataxia-telangiectasia.⁷¹ Genetic disorders associated with AML include Down syndrome, Fanconi anemia, neurofibromatosis type 1, Noonan syndrome, and Shwachman-Diamond syndrome. AML in children is sometimes associated with loss or deletion of chromosome 7 in the leukemia cells. AML can develop from preexisting myeloproliferative disorders that also are preleukemia syndromes (i.e., myelodysplastic syndrome). Epigenetic modifications, including DNA methylation, have been proposed as mediating events between environmental exposures and subsequent disease development.⁷²

Many studies have shown that exposure to ionizing radiation (prenatal exposure to x-rays and postnatal exposure to high doses of radiation) can lead to the development of childhood leukemia.⁷¹ There is recent concern about performing computed tomography (CT) scans in children because increased use combined with wide variability in radiation doses has resulted in many children receiving a high dose of radiation.⁷³ Studies of other possible environmental risk factors, including parental exposure to cancer-causing chemicals, prenatal

exposure to pesticides, childhood exposure to common infectious agents, and environmental exposure to a nuclear power plant, have so far produced inconsistent results. Higher risks of cancer have not been seen in children of individuals treated for sporadic cancer (cancer not caused by an inherited mutation).^{74,75}

The occurrence of leukemia in monozygotic twins is estimated as being as high as 25%. In 2006, the Office of the U.S. Surgeon General suggested evidence of a causal relationship between childhood leukemia, lymphoma, and brain tumors and prenatal or postnatal environmental tobacco smoke exposure.⁷⁶ A French case-control study failed to identify an association between maternal smoking and childhood leukemia; however, paternal preconception smoking was associated with an increased risk of both ALL and AML.⁷⁷ Likewise, an Italian case-control study demonstrated an association between paternal smoking and AML; however, an increased risk was not demonstrated for ALL. An association between maternal smoking and an increased risk of leukemia was not observed.^{78,79} The pooled analysis of the Childhood Leukemia International Consortium (CLIC1974-2012) suggests an association between paternal smoking and childhood AML.⁸⁰ Exposure to both alcohol and cigarette smoke is associated with AML. Being Hispanic increases the risk of AML.⁸¹

Prenatal exposure to pesticides is hypothesized to increase the risk of childhood leukemia by resulting in oxidative stress leading to the generation of free radicals that induce breaks in the DNA of early hematopoietic stem cells.⁸² Results of recent meta-analyses support associations between parental exposure to pesticides and other potential environmental toxins before or during pregnancy and subsequent development of childhood leukemia.^{83,84}

Chemicals such as benzene have been associated with the development of AML in adults. A recent meta-analysis provides evidence of a possible association between benzene exposure and childhood leukemia.⁸⁵ Previous treatment with chemotherapy is a risk factor for developing ALL.⁷¹

Leukemic “clusters” that represent a greater number of leukemia cases occurring in a particular geographic location have raised

speculation about environmental factors or infectious patterns of transmission. Careful follow-up, however, has failed to document the abnormal clustering.⁸⁶⁻⁸⁸

◆Pathophysiology.

Acute lymphoblastic leukemia (ALL) is composed of immature B (pre-B) or T (pre-T) cells called *lymphoblasts*. The bone marrow is dense with lymphoblasts, considered hypercellular, that replace the normal marrow and disrupt normal function. Many of the chromosomal abnormalities documented in ALL cause dysregulation of the expression and function of transcription factors required for normal B-cell and T-cell development.⁷ The mutations can include both gain of function and loss of function that are required for normal development.

Acute myeloid leukemia (AML) is caused by acquired oncogenic mutations that impair differentiation, resulting in the accumulation of immature myeloid blasts in the marrow and other organs. Epigenetic alterations are frequent in AML and have a central role. The bone marrow crowding by blasts produces marrow failure and complications, including anemia, thrombocytopenia, and neutropenia. AML is very heterogeneous because myeloid cell differentiation is very complex. To be called *acute*, the bone marrow usually must include greater than 20% leukemic blasts.

◆Clinical Manifestations.

The onset may be abrupt or insidious, but the most common symptoms reflect the consequences of bone marrow failure: decreased levels of RBCs and platelets and changes in white blood cells. Pallor, fatigue, petechiae, purpura, bleeding, and fever generally are present. Approximately 45% of children have a hemoglobin level less than 7 g/dL; in contrast to adults, children seem to demonstrate fewer symptoms. If acute blood loss occurs, however, characteristic symptoms of tachycardia, air hunger, restlessness, and thirst may be present. Epistaxis, excessive bruising, and hematuria may occur in children with severe thrombocytopenia. Three-quarters of children

with ALL have platelet counts less than $100,000/\text{mm}^3$ at diagnosis, and 28% have platelet counts less than $20,000/\text{mm}^3$. Half of all children newly diagnosed with AML have platelet counts less than $50,000/\text{mm}^3$. Disseminated intravascular coagulation occurs more commonly with AML, particularly with promyelocytic leukemia. The granules in the leukemic promyelocytes likely possess thromboplastin activity.

Fever usually is present as a result of two causes: (1) infection associated with the decrease in functional neutrophils and (2) hypermetabolism associated with the ongoing rapid growth and destruction of leukemic cells. In most children with ALL, the total white blood count at diagnosis is less than $10,000/\text{mm}^3$, and with AML most present with white cell counts less than $50,000/\text{mm}^3$. In a few children, however, the peripheral white blood count at presentation may be greater than $100,000/\text{mm}^3$. White blood cell counts greater than $200,000/\text{mm}^3$ can cause leukostasis, an intravascular clumping of cells that results in infarction and hemorrhage, usually in the brain and lung. The three most important favorable prognostic factors are age at diagnosis (2 to 10 years), initial leukocyte count ($<50,000/\text{mm}^3$), and initial response to treatment.

Renal failure as a result of hyperuremia (high uric acid levels) can be associated with ALL, particularly at diagnosis or during active treatment. Uric acid levels rise as an end product of purine metabolism from cellular destruction. Because the major excretory pathway is through the kidney, urates can precipitate in renal tubules or ureters and can lead to oliguria and acute renal failure. Renal failure is preventable if uric acid levels are monitored and treatment is aimed at optimal hydration, alkalinization of urine to assist with the excretion of soluble urates, and blockage of further uric acid formation by administration of the drug allopurinol.

Extramedullary invasion with leukemic cells can occur in nearly all body tissue. Most children with ALL have some extramedullary involvement at diagnosis. Leukemic invasion of tissue other than bone marrow is believed to represent metastatic infiltration. Hepatosplenomegaly and lymphadenopathy, resulting from

extramedullary hematopoiesis, occur in nearly half of children with ALL, but they are less common in children with AML.

The central nervous system (CNS) is a common site of infiltration of extramedullary leukemia, although less than 10% of children with ALL have CNS involvement at diagnosis. CNS infiltration manifests later in the course of the disease. Because successful chemotherapy prolongs the time of remission, the incidence of CNS involvement has increased. The most common symptoms of CNS involvement relate to increased intracranial pressure, causing early morning headaches, nausea, vomiting, irritability, and lethargy.

Gonadal involvement, with testicular and ovarian infiltration, has been demonstrated in postmortem examination in 57% and 35% of children, respectively. Clinical detection of gonadal involvement is much less frequent. The incidence of testicular involvement, like CNS involvement, has increased with lengthened duration of remission.

Leukemic infiltration into bones and joints is common in children. Reports of bone or joint pain actually lead to the diagnosis of leukemia in some children. In most children bone pain is characterized as migratory, vague, and without areas of swelling or inflammation. If joint pain is the primary symptom and some swelling is associated with the pain, however, misdiagnoses of rheumatoid arthritis may occur.

Other organs reported to be sites of leukemic invasion include the kidneys, heart, lungs, thymus, eyes, skin, and gastrointestinal tract. Of these, the kidneys, lungs, and gastrointestinal tract are the most frequently reported sites. Skin involvement is more common in AML than in ALL.

◆ Evaluation and Treatment.

The diagnosis of leukemia is made from blood tests and examination of peripheral blood smears. A bone marrow aspiration is usually performed to further characterize the leukemia. The **blast cell** is the hallmark of acute leukemia (see Fig. E 31.1 on Evolve). The blast cell is a relatively undifferentiated cell characterized by diffusely distributed nuclear chromatin, with one or more nucleoli and basophilic

cytoplasm (see Fig. E 31.2 on Evolve).

Healthy children have less than 5% blast cells in the bone marrow and none in the peripheral blood. The bone marrow is categorized on the basis of blast percentage. In ALL the bone marrow often is replaced by 80% to 100% blast cells, with a reduction in normally developing RBCs and granulocytes. The marrow, which is considered hypercellular, is composed of a homogeneous population of cells. Occasionally, however, the marrow appears hypocellular, making the diagnosis difficult to differentiate from aplastic anemia. When this occurs, bone marrow biopsy or biopsy of extramedullary sites is necessary to confirm the diagnosis.

Remarkable success has occurred with treatment of ALL in children. Chemotherapy is the treatment of choice for acute leukemia. Radiation has special considerations for use. In ALL, identification of various risk groups has led to the development of different intensities of drug protocols. Thus treatment is tailored specifically for a particular risk group.

Treatment of the CNS, usually with intrathecal medication, is part of most pediatric acute leukemia protocols.^{71,81} CNS irradiation is used only in selected cases of ALL. For children with AML, CNS irradiation is not necessary either as prophylaxis or for those presenting with cerebrospinal fluid leukemia that clears with intrathecal and systemic chemotherapy.⁷¹

Chronic myelogenous leukemia accounts for less than 5% of childhood leukemia. Biologically targeted therapies, specifically tyrosine kinase inhibitors, are becoming the mainstay of treatment, specifically for individuals with the BCR/ABL translocation.⁸⁹

Lymphomas

Lymphomas are malignant proliferations that arise from discrete tissue masses.⁷ These neoplasms involve some recognizable stage of lymphocyte B- or T-cell differentiation. Emerging is the understanding that some lymphomas occasionally have leukemic presentations and evolution to “leukemia” is not unusual during the progression of incurable “lymphomas.” Therefore the terms merely reflect the usual

tissue distribution.⁷ Much controversy has surrounded the classifications of lymphoma and a consensus has been reached with the current World Health Organization (WHO) classification scheme found at www.cancer.gov/cancertopics/pdq/treatment/adult-non-hodgkins/HealthProfessional/page3. Non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL) constitute approximately 11% of all cases of childhood cancer. Approximately 2200 cases of lymphoma are diagnosed in children and adolescents less than 20 years of age in the United States annually.⁶⁷ Either group of diseases is rare before age 5 years, and the relative incidence increases throughout childhood and adolescence. NHL (including Burkitt lymphoma) occurs more often than HL in children. Boys are more likely to be diagnosed with a malignant lymphoma than are girls. The incidence of lymphoma is increased in children with congenital immunodeficiency syndromes such as Wiskott-Aldrich syndrome, severe combined immunodeficiency (SCID), X-linked lymphoproliferative disease, and ataxia-telangiectasia. An increased incidence of NHL also is associated with immunosuppression after solid organ and stem cell transplants, particularly T-cell-depleted stem cell transplantation. The strongest association between viruses and the development of cancer in children has been the EBV, Burkitt lymphoma, and HL. Children with AIDS have an increased risk of developing NHL. However, with the use of highly active antiretroviral therapy in the developed world, the incidence of AIDS-related malignancies has declined dramatically.⁹⁰

Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas (NHLs) are neoplasms of immune cells. NHLs are diverse and include a large group of tumors; some are slow growing (indolent) and others are fast growing and aggressive. Almost without exception, childhood NHL becomes evident as a diffuse disease and can be further subdivided into three major types: (1) mature B-cell NHL (Burkitt and Burkitt-like lymphoma, Burkitt leukemia, and diffuse large B-cell lymphoma), (2) lymphoblastic lymphoma, and (3) anaplastic large cell lymphoma.⁹¹ The common types of NHL in children are different than those in adults. The most

common types of NHL in children are Burkitt lymphoma (40%), lymphoblastic lymphoma (25% to 30%), and large cell lymphoma (10%). Little data have been published on the etiology of childhood NHL. Known risk factors include Epstein-Barr virus (EBV) with most cases in the immunodeficient population, congenital and acquired immunodeficiency, and after a previous (subsequent to treatment) neoplasm (is rare in the child population).

◆Pathophysiology.

Burkitt lymphoma will be discussed as an example of pathogenesis of NHL in children. All forms of Burkitt lymphoma are associated with translocations of the MYC gene on chromosome 8 that lead to increased MYC protein levels.⁷ MYC is a transcriptional regulator that increases the expression of genes required for aerobic glycolysis, called the *Warburg effect* (see [Chapter 12](#)). Most Burkitt lymphomas are latently infected with the Epstein-Barr virus (EBV).⁷ EBV also is present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases.⁷ There is increased evidence of NHL in children with congenital immunodeficiency syndromes, such as Wiskott-Aldrich syndrome, ataxia-telangiectasia, and Bloom syndrome.

◆Clinical Manifestations.

NHL has been found to arise from any lymphoid tissue. Signs and symptoms therefore are specific for the site involved. Some children have such widespread involvement that no original site can be determined. Because some childhood NHL is rapidly progressive, symptoms are typically present only a few weeks before diagnosis is made. Rapidly enlarging lymphoid tissue and painless lymphadenopathy are common in about one-third of children with abdominal sites of involvement, usually representing a gastrointestinal origin for the disease. Symptoms often include abdominal pain and vomiting, but a palpable mass is not always present. The other common site of childhood NHL is the chest region. Overall, associated signs of NHL include swelling of the lymph nodes in the neck, underarm, stomach, or groin; trouble swallowing;

painless lump or swelling in a testicle; weight loss for unknown reason; night sweats; and possibly trouble breathing. Involvement of facial bones, particularly the jaw, is common in African Burkitt lymphoma.

◆Evaluation and Treatment.

Diagnosis is made by physical examination and health history, followed by biopsy of disease sites, usually the involved lymph nodes, tonsils, bone marrow, spleen, liver, bowel, or skin. Burkitt lymphoma is very aggressive and responds well to treatment. Most children and young adults can be cured with intensive chemotherapy.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a group of lymphoid neoplasms that, unlike NHL, arises in a single chain of lymph nodes and spreads first in a contiguous way to lymphoid tissue. NHL typically arises at extranodal sites and spreads in a noncontiguous or unpredictable manner. HL is characterized by the presence of Reed-Sternberg cells, which are large cells that come from the germinal center of B cells (Fig. 31.10). HL is a common type of cancer in young adults and adolescents but rare in childhood. The World Health Organization (WHO) has identified five types of HL: (1) nodular sclerosis, (2) mixed cellularity, (3) lymphocyte rich, (4) lymphocyte depletion, and (5) lymphocyte predominance. Similar expression of Reed-Sternberg cells occurs in the first four types; therefore they are considered the *classic* types. In the lymphocyte predominance type, the Reed-Sternberg cell is distinctive but different than the others. Risk factors for HL include having EBV, being infected with HIV or other immunologic disorders (immunodeficiencies, autoimmune lymphoproliferative syndrome), having a personal history of mononucleosis, and having a parent or sibling with a personal history of HL.⁹² HL accounts for 6% of all childhood cancers with a significant male-to-female dominance of 4 : 1 in young children. HL occurs infrequently among children younger than 2 years with relatively few cases observed before age 5 years. A gradual rise in incidence occurs through age 11 years, with a marked

increase through adolescence that continues into the 30s.

FIGURE 31.10 Diagnostic Reed-Sternberg Cell. A large multinucleated or multilobated cell with inclusion body–like nucleoli (*arrow*) surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

Individuals typically have painless supraclavicular or cervical adenopathy. These nodes are firm and rubbery and may be sensitive to palpation if they have grown rapidly. At least two-thirds of individuals have mediastinal involvement that may cause symptoms ranging from a nonproductive cough to tracheal or bronchial compression leading to airway obstruction. Systemic symptoms may include fatigue, anorexia, weight loss, fever, drenching night sweats, and pruritus.

The Ann Arbor staging system considers extent and location of disease, as well as substage classifications that consider systemic symptoms (presence of fever of 38°C [100.4°F] for 3 consecutive days, drenching night sweats, or unexplained loss of 10% or more of body weight in the 6 months preceding diagnosis), extranodal manifestations, or bulky disease. Combination chemotherapy used with or without low-dose radiation has been shown to be an effective treatment, with long-term cure rates reported from 90% to 95%.⁶⁷

Summary Review

Fetal and Neonatal Hematopoiesis

1. After 2 weeks of gestation, circulating erythrocytes play a major role in delivering oxygen to embryonal tissues.
2. Erythropoiesis in the liver and, to a lesser extent, in the spleen and lymph nodes reaches a peak at about 4 months of gestation.
3. By the fifth month of gestation, hematopoiesis begins to occur in the bone marrow, and by the time of delivery it is the only significant site of hematopoiesis.
4. Embryonal (Gower 1, Gower 2, and Portland) and fetal (HbF) hemoglobins are biochemically distinct from adult hemoglobin (HbA and HbA₂). They are composed of two α - and two γ -chains of polypeptides and have a greater affinity for oxygen.
5. Production of adult hemoglobin begins at approximately 16 to 20 weeks of gestation. Hemoglobin in the average term neonate is approximately 70% HbF, 29% HbA, and 1% HbA₂.

Postnatal Changes in the Blood

1. Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood.
2. The immediate postnatal rise in blood cell counts is the result of increased hematopoiesis during fetal life, trauma of birth, and cutting of the umbilical cord.
3. Polycythemia in the term neonate is the result of accelerated erythropoiesis during fetal life that is stimulated by the hypoxic intrauterine environment.
4. Erythrocyte values are age-dependent, and differences in values between males and females are apparent in adolescence.
5. The lymphocyte count is high at birth, and continues to rise in

- some healthy infants during the first year of life.
6. Platelet counts in full-term neonates are comparable to platelet counts in children and adults.

Disorders of Erythrocytes

1. Iron deficiency anemia (IDA) is the most common blood disorder of infancy and childhood; the highest incidence occurs between 6 months and 2 years of age.
2. Hemolytic disease of the fetus and newborn (HDFN) results from incompatibility between the maternal and the fetal blood, which may involve differences in Rh factors or blood type (ABO). Maternal antibodies enter the fetal circulation and cause hemolysis of fetal erythrocytes. Because the immature liver is unable to conjugate and excrete the excess bilirubin that results from the hemolysis, icterus neonatorum, or kernicterus, or both can develop.
3. Kernicterus, which may result from other causes of hyperbilirubinemia as well as HDFN, is the deposition of excess bilirubin in the brain.
4. Infections of the newborn, often acquired by the mother and transmitted to the infant, may result in hemolytic anemia; the mechanism is unclear.
5. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an inherited enzyme deficiency in erythrocytes that impairs the ability of RBCs to protect themselves against oxidative stress injuries that lead to hemolysis.
6. Hereditary spherocytosis is the most common of the hereditary hemolytic states in which there is no abnormality of hemoglobin. The basic defect is an undefined abnormality of the proteins or spectrins of the erythrocyte membrane in which affected cells are unduly permeable to sodium and acquire a characteristic structure.
7. Sickle cell disease (SCD) is an autosomal recessive condition resulting in defects in the β -globin units of the hemoglobin

molecule. Conditions resulting in decreased oxygen tension result in polymerization of the abnormal hemoglobin, causing the RBC to take on the characteristic sickled shape. SCD is most common among Africans, blacks, and those of Mediterranean descent.

8. The thalassemias are a heterogeneous group of hereditary microcytic-hypochromic anemias of varying severity. The genetic defects cause an impaired synthesis of one of the two chains— α or β —of adult hemoglobin (HbA). The thalassemias are further classified based on the severity of the anemia, type of mutation present, and whether the individual is heterozygous or homozygous for the given mutation.

Disorders of Coagulation and Platelets

1. Hemophilias A and B are characterized by hereditary deficiencies in coagulation factors resulting in a decreased ability to form blood clots in response to injury. Because transmission is X-linked recessive, hemophilia occurs almost exclusively in males.
2. von Willebrand disease is an autosomal dominant condition characterized by prolonged bleeding, resulting from a deficiency or dysfunction in von Willebrand factor, which binds factor VIII and platelets to the blood vessel wall as part of the clotting process.
3. Hereditary disorders of congenital hypercoagulability and thrombosis include protein C deficiency, protein S deficiency, and antithrombin III deficiency. Genetic mutations may result in quantitative (type I) or qualitative (type II) deficiencies of the given clotting factor.
4. Immune thrombocytopenia (ITP), the most common of the childhood antibody-mediated hemorrhagic diseases, is a disorder of platelet consumption in which antiplatelet antibodies bind to the plasma membranes of platelets. This results in platelet sequestration and destruction by

mononuclear phagocytes at a rate that exceeds the ability of the bone marrow to produce them.

5. Antibody-mediated neonatal thrombocytopenia can occur as either an autoimmune or an alloimmune disorder.
6. The autoimmune vascular purpuras (allergic purpuras) occur as an inflammatory reaction to foreign proteins or chemicals in the blood.

Neoplastic Disorders

1. Leukemia is the most common malignancy of childhood and adolescence, with a peak incidence in children between 2 and 6 years of age. More than 95% of childhood leukemia cases are acute leukemia.
2. Although the cause of childhood leukemia is not known, it is probably the result of multiple interactions between hereditary or genetic predisposition and environmental influences.
3. Acute lymphoblastic leukemia is a potentially curable disease, with more than 85% of cases cured.
4. The lymphomas of childhood are non-Hodgkin lymphoma and Hodgkin lymphoma.
5. Non-Hodgkin lymphoma is a diverse group of tumors. Factors that have been implicated in the development of non-Hodgkin lymphoma include defective host immunity, a viral agent, chronic immunostimulation, and genetic predisposition.
6. The risk of Hodgkin lymphoma is associated in part with infectious diseases, immune deficits, and genetic susceptibility.
7. The incidence of Hodgkin lymphoma increases during adolescence. Approximately 90% to 95% of individuals who develop Hodgkin lymphoma will be cured.

The functions of the circulatory system include delivery of oxygen, nutrients, hormones, cells of the immune system, and other substances to body tissues and removal of the waste products of cellular metabolism. Delivery and removal are achieved by an extensive array of tubing—the blood and lymphatic vessels—connected to a pump—the heart. The heart continuously pumps blood through the blood vessels in collaboration with other systems, particularly the nervous and endocrine systems, which are intrinsic regulators of the heart and blood vessels. Immune system cells, nutrients, and oxygen are supplied by the immune, digestive, and respiratory systems; gaseous wastes of cellular metabolism are blown off by the lungs; and other wastes are removed by the kidneys and digestive tract.

A critical component of the circulatory system is the vascular endothelium, which is considered by some to be a separate endocrine organ. The endothelium is a multifunctional tissue whose health is essential to normal vascular, immune, and hemostatic system function. Endothelial dysfunction is a critical factor in the pathogenesis of vascular and other diseases.

Circulatory System

The heart is comprised of two conjoined pumps moving blood through two separate circulatory systems; one to the lungs and one to all other parts of the body. Structures on the right side of the heart, or **right heart**, pump blood through the lungs. This system, termed the **pulmonary circulation**, is described in [Chapter 35](#). The left side of the heart, or **left heart**, sends blood throughout the **systemic circulation**, which supplies all of the body except the lungs ([Fig. 32.1](#)). These two systems are serially connected so that the output of one pump becomes the input of the other.

B

FIGURE 32.1 Diagram Showing Serially Connected Pulmonary and Systemic Circulatory Systems and How to Trace the Flow of Blood. A, Right heart chambers propel unoxygenated blood through the pulmonary

circulation, and the left heart propels oxygenated blood through the systemic circulation. B, The direction of blood flow begins at the left ventricle of the heart; flows to the arteries, arterioles, capillaries of each body organ, venules, veins, right atrium, right ventricle, pulmonary artery, lung capillaries, pulmonary veins, and left atrium; and then returns to the left ventricle. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SL, semilunar. (A From Patton KT, Thibodeau GA, Douglas MM: *Essentials of anatomy & physiology*, St Louis, 2012, Mosby. B From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Arteries carry blood from the heart to all parts of the body, where they branch into arterioles and even smaller vessels until they become a fine meshwork of capillaries. Capillaries allow the closest contact and exchange between the blood and the interstitial space, or interstitium—the environment in which the cells live. Venules and then veins then carry blood from capillaries back to the heart. Some of the plasma or liquid component of the blood passes through the walls of the capillaries into the interstitial space. This fluid, called *lymph*, is returned to the cardiovascular system by vessels of the lymphatic system. The lymphatic system is also a critical component of the immune system as described in [Chapters 7](#) and [8](#).

The Heart

The adult heart is about the size of a fist and weighs between 200 and 350 grams. It lies obliquely (diagonally) in the **mediastinum**, the area above the diaphragm and between the lungs. Heart structures can be categorized by function:

1. *Structural support of heart tissues and circulation of pulmonary and systemic blood through the heart.* This category includes the heart wall and fibrous skeleton, which enclose and support the heart and divide it into four chambers; the valves that direct flow through the chambers; and the great vessels that conduct blood to and from the heart.
2. *Maintenance of heart cells.* This category comprises vessels of the coronary circulation—the arteries and veins that serve the metabolic needs of all the heart cells—and the heart's

lymphatic vessels.

3. *Stimulation and control of heart action.* Among these structures are the nerves and specialized muscle cells that direct the rhythmic contraction and relaxation of the heart muscles, propelling blood throughout the pulmonary and systemic circulatory systems.

Structures That Direct Circulation Through the Heart

Heart Wall

The heart wall has three layers—the epicardium, **myocardium**, and **endocardium**—and is enclosed in a double-walled membranous sac, the **pericardium** (Fig. 32.2). The **pericardial sac** has several functions: it prevents displacement of the heart during gravitational acceleration or deceleration, serves as a physical barrier that protects the heart against infection and inflammation from the lungs and pleural space, and contains pain receptors and mechanoreceptors that can cause changes in blood pressure and heart rate. The two layers of the pericardium, the *parietal* and *visceral* pericardia (see Fig. 32.2), are separated by a fluid-containing space called the **pericardial cavity**. The **pericardial fluid** (about 20 mL) is secreted by cells of the mesothelial layer of the pericardium and lubricates the membranes that line the pericardial cavity, allowing them to slide smoothly over one another with minimal friction as the heart beats. The amount and character of the pericardial fluid are altered if the pericardium is inflamed (see Chapter 33).

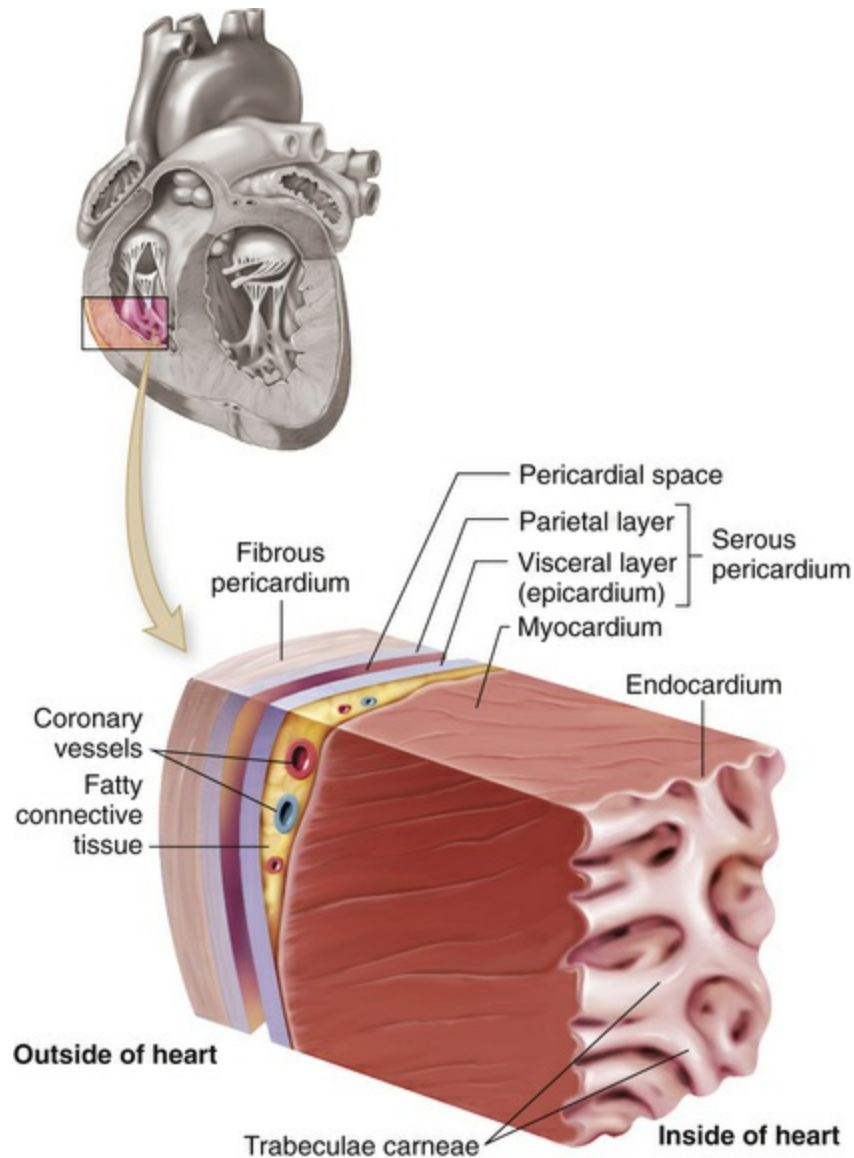

FIGURE 32.2 Wall of the Heart. The cutout section of the heart wall shows the outer fibrous pericardium and the parietal and visceral layers of the serous pericardium (with the pericardial space between them). Note that a layer of fatty connective tissue is located between the visceral layer of the serous pericardium (epicardium) and the myocardium. Note also that the endocardium covers beamlike projections of myocardial muscle tissue, called *trabeculae carneae*. (Modified from Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

The outer layer of the heart, the epicardium, provides a smooth surface that allows the heart to contract and relax within the pericardium with a minimal amount of friction. The thickest layer of the heart wall, the myocardium, is composed of cardiac muscle and is anchored to the heart's fibrous skeleton. The heart muscle cells,

cardiomyocytes, provide the contractile force needed to propel blood through the heart and into the pulmonary and systemic circulations. About 0.5% to 1% of cardiomyocytes are replaced annually; thus over a lifetime about one-half of these muscle cells are replaced.¹⁻³ The limited myocyte turnover is insufficient for restoration of contractile function. The capacity to generate cardiomyocytes in the adult human heart has created great interest and investigation for potential cardiomyocyte replacement for persons with cardiac pathologies (see [What's New? Myocardial Regeneration](#)).

What's New?

Myocardial Regeneration

Myocardial infarction causes the loss of some of the muscle cells needed to maintain cardiac output, thus increasing the risk of heart failure in survivors. Given that heart failure is a growing problem with a poor prognosis in both the United States and internationally, finding an effective therapy is a critical need.

To replace the approximately 1 billion cardiomyocytes that are estimated to be lost with a myocardial infarction, researchers have identified four possible approaches: (1) accelerating the rate of heart cell division, (2) inserting new cells into the heart, (3) stimulating the heart muscle precursor cells already in the heart, and (4) reprogramming other cells so that they will become cardiomyocyte precursor cells. To stimulate adult heart cells to enter the cell cycle and thus accelerate cell division, various signaling molecules, such as neuregulin and fibroblast growth factor 1, have been used with some success. Currently the most promising cell types that have been injected into the heart include cells from the bone marrow, cardiac-derived cells taken from myocardial biopsies, and human pluripotent stem cells. Although there are cardiac progenitor or precursor cells in the heart, their rate of division is not adequate to replace lost tissue after an infarction. Some of the methods being investigated to stimulate these cardiomyocytes or other progenitor

cells in the heart include treatment with peptides that act as paracrines and some types of modified ribonucleic acids (RNAs) for vascular endothelial growth factor (VEGF). Reprogramming from one cell type into a pluripotent stem cell has been attempted with fibroblasts with some success. Each of these four approaches to replacing cardiomyocytes after injury comes with its own set of risks and challenges. Associated risks include increasing the chances for tumor development, damage to other organs, and myocardial scarring.

Portello and colleagues demonstrated that removal of up to 15% of the heart apex of the left ventricle of postnatal day 1 (P1) mice results in complete regeneration within 3 weeks without any measurable fibrosis and cardiac dysfunction. This response involved vigorous proliferating myocytes and gradual restoration of normal cardiac structure. Genetic studies confirmed that the majority of newly formed cardiomyocytes are derived from proliferation of preexisting cardiomyocytes. Using an injury model, investigators found the response similar to the resection model; however, the regenerative capacity was lost by postnatal day 7 (P7). By P7, injury results in typical cardiomyocyte hypertrophy and scar formation of the adult mammalian heart. Importantly, why does the loss of the regenerative capacity occur? The investigators hypothesized that oxidative damage might increase in cardiomyocytes postnatally and play a role in postnatal cell cycle arrest (i.e., stop proliferation). From their study, they found that oxidative base damage modification of DNA was undetectable at P1 but significantly increased at P7 and P14.

Overall, the factors that mediate increased mitochondrial reactive oxygen species (ROS) production and eventual oxidative damage are not well-known. Compared to the oxygenation state, energy metabolism of the embryonic and adult heart is quite distinct. During embryonic development, when cardiomyocytes rapidly proliferate, the relatively hypoxic embryonic heart utilizes anaerobic glycolysis as a main source of energy, whereas adult cardiomyocytes utilize the oxygen-dependent mitochondrial

oxidative phosphorylation as an energy source. Therefore to further advance this field, it is necessary to study changes in oxygenation of cardiomyocytes. Eulalio and colleagues report, that in rodents, exogenous administration of selected microRNAs stimulates cardiomyocyte proliferation and promotes cardiac repair. Morrison and colleagues, studying a similar approach in large mammals (sheep), found some inconsistency and differences in sheep, potentially highlighting differences between species.

Data from Elhelaly WM et al: *Front Cell Dev Biol* 4:137, 2016; Eulalio A et al: *Nature* 492(7429):376–381, 2012; Fisher DJ, Heymann MA, Rudolph AM: *Am J Physiol* 238:H399–H405, 1980; Gerbin KA, Murray CE: *Cardiovasc Pathol* 24(3):133–140, 2015; Laflamme AM, Murry CE: *Nat Biotechnol* 23(7):845–856, 2005; Lin Z, Pu WT: *Sci Transl Med* 6(239):239rv1, 2014; Lopaschuk GD, Collins-Nakai RL, Itoi T: *Cardiovasc Res* 26,1172–1180, 1992; Morrison JL et al: *BMC Genomics* 16(1):541, 2015; Ounzain S, Pedrazzini T: *Trends Cardiovasc Med* 25(7):592–602, 2015; Porrello ER et al: *Science* 331(6020):1078–1080, 2011; Porrello ER et al: *Proc Natl Acad Sci U S A* 110(1):187–192, 2012.

The thickness of the myocardium varies tremendously from one heart chamber to another. Thickness is related to the amount of resistance the muscle must overcome to pump blood from the different chambers. The internal lining of the myocardium is composed of connective tissue and a layer of squamous cells called the *endocardium* (see [Fig. 32.2](#)). The endocardial lining of the heart is continuous with the endothelium that lines all the arteries, veins, and capillaries of the body, creating a continuous, closed circulatory system.

Chambers of the Heart

The heart has four chambers: the **right atrium**, **left atrium**, **right ventricle**, and **left ventricle**. These chambers form two pumps in series: the right heart, a low-pressure system pumping blood through the lungs; and the left heart, a high-pressure system pumping blood through the rest of the body. (Blood flow through these chambers is illustrated in [Fig. 32.3](#).) The atria are smaller than the ventricles and have thinner walls. The ventricles have a thicker myocardial layer and

make up much of the bulk of the heart. The wall of the right ventricle is about 4 to 5 mm thick, and that of the left ventricle, the most muscular chamber, is about 12 to 15 mm thick.⁴ The ventricles are formed by a continuum of muscle fibers that originate from the fibrous skeleton at the base of the heart (chiefly around the aortic orifice).

FIGURE 32.3 Structures That Direct Blood Flow Through the Heart. Arrows indicate path of blood flow through chambers, valves, and major vessels.

The wall thickness of each cardiac chamber depends on the amount of pressure or resistance it must overcome to eject blood. The two atria have the thinnest walls because they are low-pressure chambers that serve as storage units and conduits for blood that is emptied into the ventricles. Normally, there is little resistance to flow from the atria to the ventricles. The ventricles, on the other hand, must propel blood all the way through the pulmonary or systemic circulation. The ventricular myocardium must be strong enough to pump against

pressures in the pulmonary or systemic vessels. The mean pulmonary capillary pressure, the force the right ventricle must overcome, is only 15 mmHg whereas the mean arterial pressure, the force the left ventricle must overcome, is about 92 mmHg. Because the pressure is markedly higher in the systemic circulation, the wall of the left ventricle is several times thicker than that of the right ventricle.

The right ventricle is shaped like a crescent, or triangle, enabling it to function like a bellows and efficiently eject large volumes of blood through the pulmonary semilunar valve into the low-pressure pulmonary system. The left ventricle is larger and bullet shaped, helping it to eject blood through the larger aortic semilunar valve into the high-pressure systemic circulation.

The ventricles are structurally more complex than the atria. Each ventricle contains muscle fibers that divide it roughly into an **inflow tract**, which receives blood from the atrium, and an **outflow tract**, which sends blood to the circulation (see [Fig. 32.3](#)).

Normally blood does not flow between the chambers of the right side of the heart and the chambers of the left side of the heart except in the fetus before delivery. The atria are separated by the interatrial septum and the ventricles by the interventricular septum. There is an opening between the right and left atria before birth called the *foramen ovale*; however, this opening closes shortly after birth in most individuals (see [Chapter 34](#)). The interventricular septum is an extension of the fibrous skeleton of the heart. Indentations of the endocardium form valves that separate the atria from the ventricles and the ventricles from the aorta and pulmonary arteries.

Fibrous Skeleton of the Heart

Four rings of dense fibrous connective tissue provide a firm anchorage for the attachments of the atrial and ventricular musculature, as well as the valvular tissue. The fibrous rings are adjacent and form a central, fibrous supporting structure collectively termed the *annuli fibrosi cordis*.

Valves of the Heart

One-way blood flow through the heart is ensured by the four heart valves as well as the pressure gradients that they maintain. During ventricular relaxation the two **atrioventricular valves** open and blood flows from the relatively higher pressure in the atria to the lower pressure in the relaxed ventricles. With increasing ventricular pressure these valves close and prevent backflow into the atria as the ventricles contract. The **semilunar valves** of the heart open when intraventricular pressure exceeds aortic and pulmonary pressures and blood flows out of the ventricles and into the systemic and pulmonary circulations, respectively. After ventricular contraction and ejection, intraventricular pressure decreases and the **pulmonic** and **aortic semilunar valves** close when the pressure in the vessels is greater than the pressure in the ventricles, thus preventing backflow into the right and left ventricles, respectively ([Fig. 32.4](#); also see [Fig. 32.3](#)).

FIGURE 32.4 Chambers and Valves of the Heart. Chambers and valves of the heart. **A**, During atrial contraction cardiac muscle in the atrial wall contracts, forcing blood through the atrioventricular (AV) valves and into the ventricles. Bottom illustration shows superior view of all four valves, with semilunar (SL) valves closed and AV valves open. **B**, During ventricular contraction that follows, the AV valves close and the blood is forced out of the ventricles through the SL valves and into the arteries. Bottom illustration shows superior view of SL valves open and AV valves closed. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

The atrioventricular (AV) (tricuspid and mitral) valve openings are composed of tissue flaps called *leaflets* or *cusps* that are attached at the upper end to one of the rings in the fibrous skeleton of the heart and at the lower end to papillary muscles by the **chordae tendineae** (see [Fig. 32.3](#)). The **papillary muscles** are extensions of the myocardium that help hold the cusps together and downward at the onset of

ventricular contraction, thus preventing their backward expulsion, or **prolapse**, into the atria.

The right AV valve is called the **tricuspid valve** because it has three cusps. The tricuspid opening (orifice) has the largest diameter of all the heart valves. The left AV valve is a bicuspid (two cusps) valve called the **mitral valve**. The tricuspid and mitral valves function as a unit because the atria, fibrous rings, valvular tissue, chordae tendineae, papillary muscles, and ventricular walls are connected. Collectively, these six structures are known as the **mitral and tricuspid complex**. Damage to any one of the six components of this complex can significantly alter function and contribute to heart failure.

Blood leaves the right ventricle through the pulmonic semilunar valve, and it leaves the left ventricle through the aortic semilunar valve (see [Figs. 32.3](#) and [32.4](#)). Both the pulmonic and aortic semilunar valves have three cup-shaped cusps that arise from the fibrous skeleton. The pulmonic cusps are slightly thinner than the aortic cusps. The lower edges of each cusp are suspended from the root of the pulmonary artery or aorta, with the upper valve edges freely projecting into the vessel lumen. When the ventricles contract, the cusps behave like one-way swinging doors. The force of the blood propels the cusps outward against the vessel wall. When the ventricles relax, blood fills the cusps and causes their free edges to meet in the middle of the vessel, closing the valve and preventing any backflow.

Great Vessels

Blood moves in and out of the heart through several large vessels (see [Fig. 32.3](#)). The right heart receives venous deoxygenated blood from the systemic circulation through the **superior vena cava** and the **inferior vena cava**, which enter the right atrium. Blood leaves the right ventricle and enters the pulmonary circulation through the pulmonary artery. The **pulmonary artery** divides into **right** and **left pulmonary arteries** to transport deoxygenated blood from the right heart to the right and left lungs. The pulmonary arteries branch

further into the pulmonary capillary bed, where oxygen enters the blood and carbon dioxide leaves it as each gas moves from its higher to lower concentration gradient.

Four **pulmonary veins**, two from the right lung and two from the left lung, carry oxygenated blood from the lungs to the left side of the heart. The oxygenated blood moves through the left atrium and ventricle and out into the **aorta**, which delivers it to systemic vessels that supply the body.

Blood Flow During the Cardiac Cycle

The pumping action of the heart consists of contraction and relaxation of the heart muscle or myocardium. Each ventricular contraction and the relaxation that follows it constitute one **cardiac cycle**. (Blood flow through the heart during a single cardiac cycle is illustrated in [Fig. 32.4](#).) During the period of relaxation, termed **diastole**, blood fills the ventricles. The ventricular contraction that follows, termed **systole**, propels the blood out of the ventricles and into the pulmonary and systemic circulations. Contraction of the left ventricle occurs slightly earlier than contraction of the right ventricle.

During ventricular systole, blood from the veins of the systemic circulation enters the thin-walled right atrium from the superior and inferior venae cavae (see [Figs. 32.3](#) and [32.4](#)). Venous blood from the coronary circulation enters the right atrium through the *coronary sinus*. The right atrium fills, which, along with the falling right ventricular pressures, allows the right AV (tricuspid) valve to open and fill the right ventricle during ventricular diastole (occasionally called *atrial systole*). The same sequence of events occurs a split second earlier in the left heart. The four pulmonary veins, two from the right lung and two from the left lung, carry blood from the pulmonary circulation to the left atrium. As the left atrium fills and left ventricular pressure falls, the mitral valve opens and blood flows into the left ventricle. Left atrial contraction, termed *atrial kick*, provides significant increases in the volume of blood entering the left ventricle at the end of diastole. Filling of the right and left ventricles occurs during one period of diastole. Five phases of the cardiac cycle can be identified ([Figs. 32.5](#)

and 32.6). As blood is pushed through the inflow and outflow tracts of the ventricles, it flows around the **crista supraventricularis**—the muscle that separates the inflow from the outflow tracts—and is mixed by passing through the strands of the **trabeculae carneae**.

FIGURE 32.5 Composite Chart of Heart Function. This chart is a composite of several diagrams of heart function (blood pressure, blood flow, volume, heart sounds, venous pulse, and electrocardiogram [ECG]), all adjusted to the same time scale.

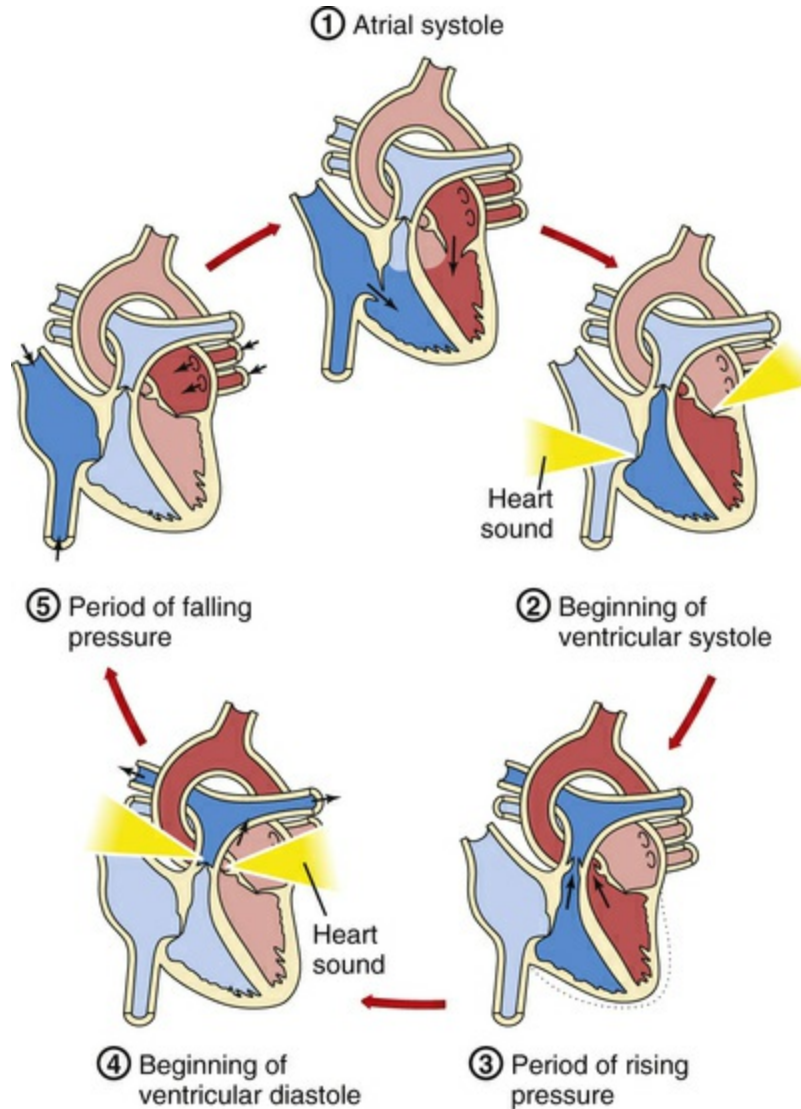

FIGURE 32.6 The Five Phases of the Cardiac Cycle. 1, Atrial systole: Atria contract, pushing blood through the open tricuspid and mitral valves into the ventricles. Semilunar valves are closed. 2, Beginning of ventricular systole: Ventricles contract, increasing pressure within the ventricles. The tricuspid and mitral valves close, causing the first heart sound. 3, Period of rising pressure: Semilunar valves open when pressure in the ventricle exceeds that in the arteries. Blood spurts into the aorta and pulmonary arteries. 4, Beginning of ventricular diastole: Pressure in the relaxing ventricles drops below that in the arteries. Semilunar valves snap shut,

causing the second heart sound. 5, Period of falling pressure: Blood flows from veins into the relaxed atria. Tricuspid and mitral valves open when pressure in the ventricles falls below that in the atria. (Adapted from Solomon E: *Introduction to human anatomy and physiology*, ed 4, St Louis, 2016, Saunders.)

Normal Intracardiac Pressures

Normal intracardiac pressures are shown in [Table 32.1](#) and [Fig. 32.7](#). Atrial pressure (see venous pulse in [Fig. 32.5](#)) curves are composed of the **a wave**, which is generated by atrial contraction, and the **v wave**, which is an early diastolic peak caused by filling of the atrium from the peripheral veins. A smaller pressure increase, the **c wave**, occurs after the a wave in early systole and may represent bulging of the mitral valve into the left atrium during early systole. Two aspects of falling atrial pressure have also been named. The **x descent** follows the a wave and is produced by the descent of the tricuspid valve ring and by the ejection of blood from both ventricles. The **y descent** that follows the v wave reflects the rapid flow of blood from the great veins and right atrium into the right ventricle. Left ventricular pressures are illustrated by a peak systolic pressure and an end-diastolic pressure, which is the ventricular pressure immediately before the onset of systole. The minimal left ventricular pressure occurs in early diastole.

TABLE 32.1

NORMAL INTRACARDIAC PRESSURES

	MEAN (mmHg)	RANGE (mmHg)
Right atrium	4	0–8
Right ventricle		
Systolic	24	15–28
End-diastolic	4	0–8
Left atrium	7	4–12
Left ventricle		
Systolic	130	90–140

Structures That Support Cardiac Metabolism: The Coronary Vessels

The myocardium and other heart structures are supplied with oxygen and nutrients by the coronary circulation, which is part of the systemic circulation. The **coronary arteries** originate just beyond the aortic semilunar valve cusps and receive blood through openings in the aorta called the **coronary ostia**. The **cardiac veins** empty into the right atrium through another ostium, the opening of a large vein called the **coronary sinus** (Fig. 32.8). (Regulation of the coronary circulation is described in a later section.)

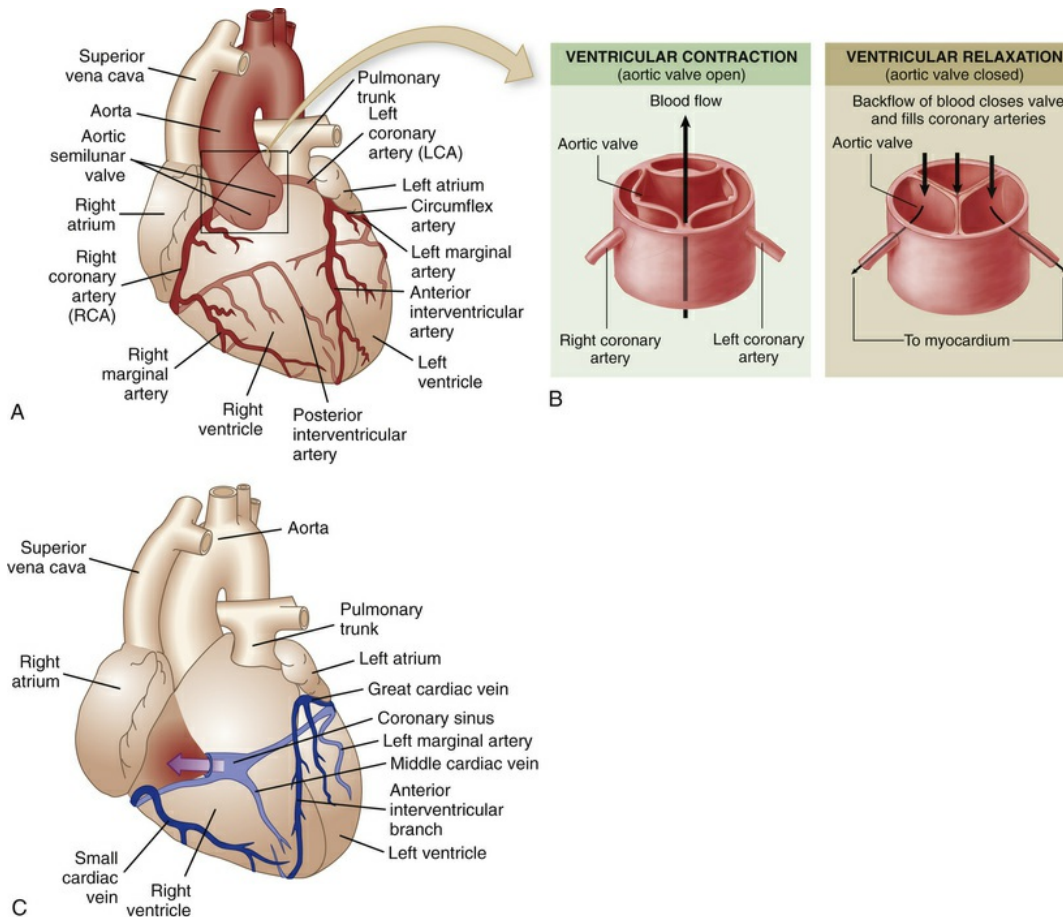

FIGURE 32.8 Coronary Circulation. A, Arteries. B, Coronary artery openings from the aorta. C, Veins. Both (A) and (C) are anterior views of the heart. Vessels near the anterior surface are more darkly colored than vessels of the posterior surface seen through the heart. B, Placement of the coronary artery opening behind the leaflets of the aortic valve allows the coronary arteries to fill during ventricular relaxation. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Coronary Arteries

The major coronary arteries are the **right coronary artery (RCA)** and the **left coronary artery (LCA)** (see [Fig. 32.8](#)). They traverse the epicardium, myocardium, and endocardium and branch to become arterioles and then capillaries. Their main branches are outlined in [Box 32.1](#). Because women's hearts weigh proportionately less than men's hearts, the coronary arteries are smaller in women.

Box 32.1

Main Branches of the Coronary Arteries

Left coronary artery. Arises from a single ostium behind the left cusp of the aortic semilunar valve; ranges from a few millimeters to a few centimeters long; passes between left arterial appendage and pulmonary artery and generally divides into two branches: the left anterior descending (LAD) artery and the circumflex artery; other branches are distributed diagonally across the free wall of the left ventricle.

Left anterior descending (LAD) artery (or anterior interventricular artery). Delivers blood to portions of the left and right ventricles and much of the interventricular septum; travels down the anterior surface of the interventricular septum toward the apex of the heart.

Circumflex artery. Travels in a groove (*coronary sulcus*) that separates the left atrium from the left ventricle and extends to the left border of the heart; supplies blood to the left atrium and the lateral wall of the left ventricle; often branches to posterior surfaces of the left atrium and left ventricle.

Right coronary artery. Originates from an ostium behind the right aortic cusp, travels from behind the pulmonary artery, and extends around the right heart to the heart's posterior surface, where it branches to the atrium and ventricle; three major branches are the conus (supplies blood to upper right ventricle), right marginal branch (supplies right ventricle to the apex), and posterior descending branch (lies in posterior interventricular sulcus and supplies smaller branches to both ventricles).

Collateral Arteries

The **collateral arteries** are connections, or anastomoses, between

branches of the same coronary artery or connections of branches of the right coronary artery with branches of the left. The epicardium contains more collateral vessels than the endocardium. New collateral vessels are formed through two processes: **arteriogenesis** (new artery growth branching from preexisting arteries) and **angiogenesis** (growth of new capillaries within a tissue).⁵ This collateral growth is stimulated by **shear stress**, an increased blood flow speed near an area of **stenosis**, or narrowing, and the production of growth factors and cytokines, including monocyte chemoattractant protein-1 (MCP-1) and vascular endothelial growth factor (VEGF).⁶ Investigators, using a murine model, show that the mixed lineage kinases-Jun amino-terminal kinases (MLK-JNK) signaling pathway is required for formation of native collateral arteries that can restore circulation following arterial occlusion.⁷ The collateral circulation assists in supplying blood and oxygen to myocardium that has become ischemic following stenosis of one or more coronary arteries (coronary artery disease [CAD]). Unfortunately, diabetes, which predisposes to coronary artery disease, also impedes collateral formation because of increased production of antiangiogenic factors, such as endostatin and angiostatin. Current research is focused on identifying whether some factors that stimulate collateral growth might be useful treatments for myocardial ischemia.

Coronary Capillaries

The heart has an extensive capillary network. Blood travels from the arteries to the arterioles and then into the capillaries, where exchange of oxygen and other nutrients takes place.

Alterations of the cardiac muscles dramatically affect blood flow in the capillaries. For example, in ventricular hypertrophy (enlargement of the ventricular myocardium), the capillary network does not expand along with muscle fiber size. Therefore the same number of capillaries must now perfuse a larger area. This results in decreased exchange of oxygen and nutrients. At rest, the heart extracts 70% to 80% of the oxygen delivered to it and coronary blood flow is directly correlated with myocardial oxygen consumption.⁸ Investigators are

studying the microcirculation—capillaries and arterioles—and not just the main coronary arteries in congestive heart failure.⁹

Coronary Veins and Lymphatic Vessels

After passing through the extensive capillary network, blood from the coronary arteries drains into the cardiac veins, which travel alongside the arteries. Most of the venous drainage of the heart occurs through veins in the **visceral pericardium**. The veins then feed into the **great cardiac vein** (see [Fig. 32.8, C](#)) and coronary sinus on the posterior surface of the heart, between the atria and ventricles, in the coronary sulcus.

The myocardium has an extensive system of lymphatic capillaries and collecting vessels within the layers of the myocardium and also in the valves. Impairment of cardiac lymphatic function has been hypothesized to impact cardiac conduction, protection from infection, and the development of myocardial fibrosis and atherosclerosis.¹⁰

Structures That Control Heart Action

People's lives depend on the continuous repetition of the cardiac cycle (systole and diastole) that occurs because of the transmission of electrical impulses, termed **cardiac action potentials**, through the myocardium (action potentials are described in [Chapters 1](#) and [3](#)). As an electrical impulse passes from cell to cell (fiber to fiber) in the myocardium, it stimulates an intracellular process that results in fiber shortening—that is, muscular contraction or systole. Between action potentials, the fibers relax and return to their resting length, causing diastole. The muscle fibers of the myocardium are electrically coupled so that action potentials pass from cell to cell very rapidly and efficiently. The myocardial structures that allow the action potentials to move so rapidly through the heart are the gap junctions in the intercalated disks. In the intercalated disks, the channel-forming proteins, called **connexins**, form pores in the gap junctions.¹¹ As a result of these structures plus the heart's conduction system, an action potential generated in one part of the myocardium passes very

quickly throughout the heart, causing rapid, organized, sequential contraction of the atria and then the ventricles.

The myocardium contains its own pacemakers and **conduction system**—specialized cells that enable it to generate and transmit action potentials without input from the nervous system (Fig. 32.9). The pacemaker cells are concentrated at two sites in the myocardium called **nodes**, the sinoatrial (SA) node and the atrioventricular (AV) node. Although the heart is innervated by the autonomic nervous system (sympathetic and parasympathetic fibers), neural impulses are not needed to maintain the cardiac cycle. Thus the heart will beat in the absence of any nervous connection, one of the many factors that allow heart transplantation to be successful. The cardiac cycle is stimulated by the nodes of specialized cells and then adjusted to the physical needs of the body by the autonomic fibers. The sympathetic and parasympathetic nerves affect the speed of the cardiac cycle (**heart rate**, or beats per minute), the force of contraction, and the diameter of the coronary vessels (Fig. 32.10 and *What's New? More Understanding on the Heart-Brain Axis*). The sympathetic nervous system increases heart rate and conduction through the nodes, the parasympathetic nervous system slows heart rate and prolongs intranodal conduction time, and both systems cause coronary vasodilation.¹²

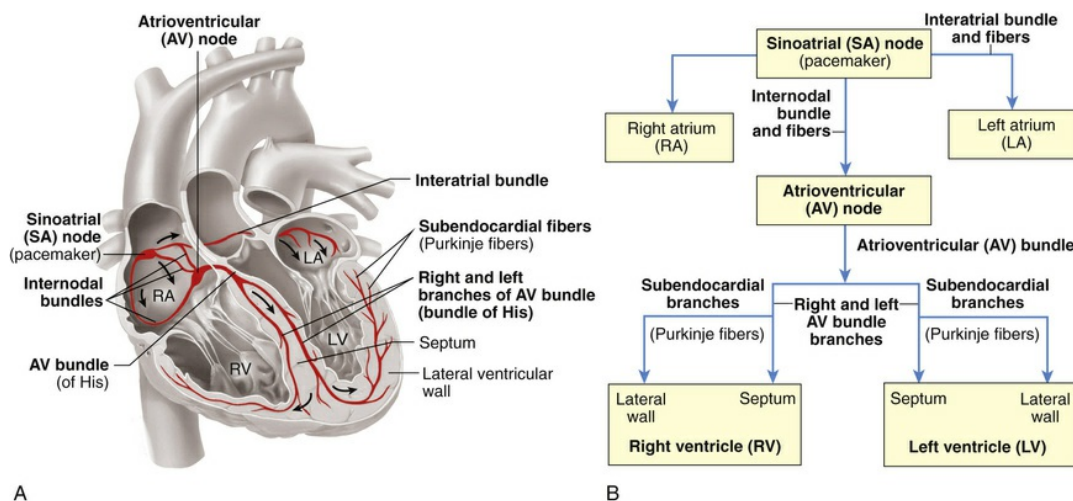

FIGURE 32.9 Conduction System of the Heart. Specialized cardiac muscle cells (**boldface type**) in the wall of the heart rapidly initiate or conduct an

electrical impulse throughout the myocardium. Both the sketch of the conduction system (A) and the flowchart (B) show the origin and path of conduction. The signal is initiated by the SA node (pacemaker) and spreads to the rest of the right atrial myocardium directly, to the left atrial myocardium by way of a bundle of interatrial conducting fibers, and to the AV node by way of three internodal bundles. The AV node then initiates a signal that is conducted through the ventricular myocardium by way of the AV bundle (of His) and subendocardial branches (Purkinje fibers). (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

What's New?

More Understanding on the Heart-Brain Axis

Some of the effects of cardiovascular disease on the nervous system have been known for a long time; however, effects of neurologic disorders on the cardiovascular system are now expanding. Many pathologies of the nervous system can lead to several alterations in function and structure of the cardiovascular system including changes in the electrocardiogram (ECG), myocardial injury, cardiomyopathy, and cardiac death. The effects of neurologic injury on cardiac function and structure include electrocardiographic alterations, both benign and fatal after brain injury; and cardiac conduction disturbances from central nervous system (CNS) injury because of released enzymes that can alter automaticity, refractoriness, and repolarization. Neurologic injury and psychologic stressors (see [Chapter 11](#)) can affect cardiac structure by rapid (within minutes) development of subendocardial infarctions, calcification, and myofibrillar degeneration or *myocytolysis*. Paroxysmal sympathetic hyperactivity (PSH) can develop in pathologies of the autonomic nervous system (ANS), such as ischemia, inflammation, and trauma. The problems associated with PSH include aneurysmal subarachnoid hemorrhage (SAH), postcardiac arrest, cerebral ischemia, severe traumatic brain injury (TBI), and, less frequently, brain tumors. The prevalence of neuropsychiatric disorders including SAH, TBI, stroke, seizure, depression, and intense emotions, such as loss of a loved one, is related to stress-induced cardiomyopathy, especially in postmenopausal women. Emotional stressors are linked to sudden cardiac death (SCD), such as anger, fear, grief, and natural disasters. Neurologic injury can result in SCD by inducing fatal dysrhythmias, massive myocytolysis, and myocardial infarction. These changes are hypothesized as a result of catecholamines (see [Chapter 11](#)). More data are emerging related to the interaction between the nervous and cardiovascular systems. Dysfunction in one system may lead to changes in function in the other system.

Data from Tahsili-Fahadan P, Geocadin RG: *Circ Res* 120(3):559–572, 2017.

Heart action also is influenced by substances delivered to the myocardium in coronary blood. Nutrients and oxygen are needed for cellular survival and normal function, and hormones and biochemical substances, including medications, can affect the strength and duration of myocardial contraction and the degree and duration of myocardial relaxation. Normal or appropriate function depends on the availability of these substances, which is why coronary artery disease can seriously disrupt heart function.

The Conduction System

Electrical impulses normally arise in the **sinoatrial (SA) node**, the usual *pacemaker of the heart*. The SA node is located at the junction of the right atrium and superior vena cava, just above the tricuspid valve (see [Fig. 32.9](#)). The SA node sits only about 1 mm beneath the visceral pericardium, making it vulnerable to injury and disease, especially pericardial inflammation. The SA node is nourished by the sinus node artery, which passes through the center of the node. The SA node is heavily innervated by both sympathetic and parasympathetic nerve fibers.

In the resting adult the SA node generates about 60 to 100 action potentials per minute depending on age and physical condition. Each action potential travels rapidly from cell to cell and through the atrial myocardium, onward to the **atrioventricular node (AV node)**, as well as causing both atria to contract and begin systole. The AV node, located in the right atrial wall superior to the tricuspid valve and anterior to the ostium of the coronary sinus, conducts the action potentials onward to the ventricles. It is innervated by nerves from the autonomic parasympathetic ganglia that serve as receptors for the vagus nerve and cause slowing of impulse conduction through the AV node.

From the AV node, conducting fibers converge to form the **bundle of His (atrioventricular bundle)** within the posterior border of the interventricular septum. The bundle of His then gives rise to the right and left **bundle branches**. The **right bundle branch (RBB)** is thin and travels without much branching to the right ventricular apex. The

thinness and relative lack of branches of the RBB make it susceptible to interruption of impulse conduction by damage to the endocardium. The **left bundle branch (LBB)** in some hearts divides into two branches, or fascicles. The **left anterior bundle branch (LABB)** passes the left anterior papillary muscle and the base of the left ventricle and crosses the aortic outflow tract. The LABB is susceptible to damage from the aortic valve or the left ventricle. The **left posterior bundle branch (LPBB)** travels posteriorly, crossing the left ventricular inflow tract to the base of the left posterior papillary muscle. This branch spreads diffusely through the posterior inferior left ventricular wall. Because of relatively nonturbulent blood flow through this portion of the left ventricle, the LBB is somewhat protected from injury caused by wear and tear.

Terminal branches of the RBB and LBB are the **Purkinje fibers**. They extend from the ventricular apexes to the fibrous rings and penetrate the heart wall to the outer myocardium. Portions of the interventricular septum of the ventricles are the first areas to be excited. Both the RBB and the LBB activate the septum. The rapid spread of the impulse to the ventricular apexes is accomplished from the extensive network of Purkinje fibers. Last to be activated are the basal and posterior portions of the ventricles.

Cardiac Excitation.

From the SA node, the impulse that begins systole spreads throughout the right atrium at a conduction velocity of about 35 cm/sec.¹² Because impulses from the SA node arrive at the AV node very quickly, investigators have proposed that these nodes are connected by internodal pathways, called the *anterior, middle, and posterior internodal pathways*. However, the existence of these pathways is controversial; not all experts agree that they exist.¹²

The action potential is delayed in the region of the AV node, possibly because of electrophysiologic differences in the cells that comprise the AV region. Conduction velocity within the node is about 10 cm/sec, markedly slower than conduction through the atria.¹² The delay between atrial and ventricular excitation permits an additional

boost to ventricular filling by atrial contraction (atrial kick). From the AV node the impulse travels from the AV bundle and through the bundle branches to the Purkinje fibers. Conduction velocities in the AV and Purkinje fibers are the most rapid in the heart.

Ventricular activation occurs sequentially in three phases: (1) septal activation, (2) apical activation, and (3) basal (upper) and posterior activation. The first areas of the ventricles to be excited are portions of the interventricular septum. The septum is activated from both the RBB and the LBB, although the impulse travels from left to right. The extensive network of Purkinje fibers promotes the rapid spread of the impulse to the ventricular apexes. Activation traverses the heart wall from the inside outward (from the endocardium to the epicardium; see [Fig. 32.2](#)). The basal and posterior portions of the ventricles are the last to be activated. Deactivation, which begins in diastole, occurs in the opposite direction, spreading from the outside inward (epicardium to endocardium). All areas of the ventricle recover at about the same time.

Propagation of Cardiac Action Potentials.

Electrical activation of the muscle cells, termed **depolarization**, is caused by the movement of ions, including sodium, potassium, calcium, and chloride, across cardiac cell membranes. Deactivation, called **repolarization**, occurs the same way. (Movement of ions across cell membranes is described in [Chapter 1](#); electrical activation of muscle cells is described in [Chapter 44](#).)

Movement of ions into and out of the cell creates an electrical (voltage) difference across the cell membrane called the *membrane potential*. The resting membrane potential of myocardial cells is between -80 and -90 millivolts, whereas that of the SA node is between -50 and -60 millivolts and that of the AV node is between -60 and -70 millivolts.¹² During depolarization the inside of the cell becomes less negatively charged as positive ions move inside. In cardiac cells the difference between resting membrane potential (in millivolts) and the decreased negative charge caused by depolarization is the cardiac action potential. [Table 32.2](#) summarizes

the intracellular and extracellular ionic concentrations of cardiac muscle. The various phases of the cardiac action potential are related to changes in the permeability of the cell membrane to sodium, potassium, chloride, and calcium. Threshold is the point at which the cell membrane's selective permeability to these ions is temporarily disrupted, leading to depolarization. If the resting membrane potential becomes more negative as a result of a decrease in extracellular potassium concentration (hypokalemia), it is termed *hyperpolarization*.

TABLE 32.2

INTRACELLULAR AND EXTRACELLULAR ION CONCENTRATIONS IN THE MYOCARDIUM

ION	INTRACELLULAR CONCENTRATION	EXTRACELLULAR CONCENTRATION
Sodium (Na ⁺)	15 mM	145 mM
Potassium (K ⁺)	150 mM	4 mM
Chloride (Cl ⁻)	5-30 mM	120 mM
Calcium (Ca ⁺⁺)	10 ⁻⁷ M	2 mM

M, Moles; *mM*, millimoles per kilogram.

From Bonow RO et al, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 9, Philadelphia, 2012, Elsevier Saunders.

Normal myocardial cell depolarization and repolarization occur in five phases numbered 0 through 4 (Fig. 32.11). Phase 0 consists of depolarization. This phase lasts 1 to 2 milliseconds (ms) and represents rapid sodium entry into the cell. Phase 1 is early repolarization, in which calcium slowly enters the cell. Phase 2, also called the *plateau*, is a continuation of repolarization, with slow entry of calcium and sodium into the cell. Potassium is moved out of the cell during phase 3, with a return to resting membrane potential in phase 4.¹² The time between action potentials corresponds to diastole.

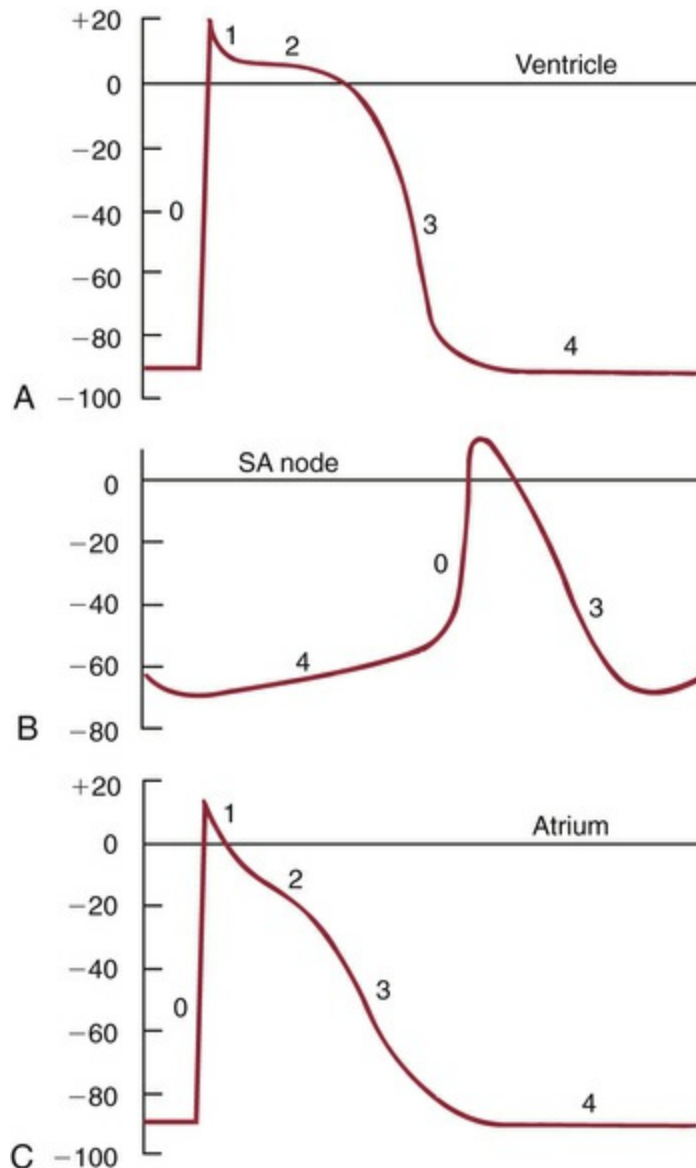

FIGURE 32.11 Cardiac Action Potentials. A, Ventricle. B, Sinoatrial (SA) node. C, Atrium. Sweep velocity in B is half that in A or C. (Modified from Koeppen BM, Stanton BA: *Berne and Levy physiology*, ed 6, Philadelphia, 2010, Mosby.)

The phases of depolarization and repolarization occur somewhat differently in the SA and AV node cells, a difference that enables these cells to generate cardiac action potentials independently. The cells of the Purkinje fibers, atria, and ventricles begin with a negative resting membrane potential and proceed to a rapid upstroke, or depolarization (phase 0), a rapid early repolarization (phase 1), a plateau (phase 2), and a rapid later repolarization (phase 3) (see Fig.

32.11, A and C). The fast inward current of phase 0 is mediated by sodium ions flowing through “fast channels” in the cell membrane and causes the rapid upstroke of the action potential in Purkinje fibers, atria, and ventricles. In contrast, the cells of the SA and AV nodes begin with a less negative resting membrane potential, proceed to a slow upstroke (phase 0), and usually lack a plateau (phase 2) (see Fig. 32.11, B). The slow inward current, mediated by calcium through transient and long-lasting channels and sodium ions flowing through “slow channels” of the cell membrane, is responsible for the action potential of the SA node and the AV node. Hence, drugs that block calcium have profound effects on the slow inward current and can alter heart rate. Slow channel-blocking drugs, such as verapamil, are used to treat a variety of cardiovascular disorders.

A refractory period, during which no new cardiac action potential can be initiated by a stimulus, follows depolarization. This effective or absolute refractory period corresponds to the time needed for the reopening of channels that permit sodium and calcium influx (phase 0 through half of phase 3). A relative refractory period occurs near the end of repolarization, following the effective refractory period. During this time the membrane can be depolarized again but only by a greater than normal stimulus. Abnormal refractory periods as a result of disease can cause abnormal heart rhythms, or dysrhythmias, including ventricular fibrillation and cardiac arrest (see Chapter 33).

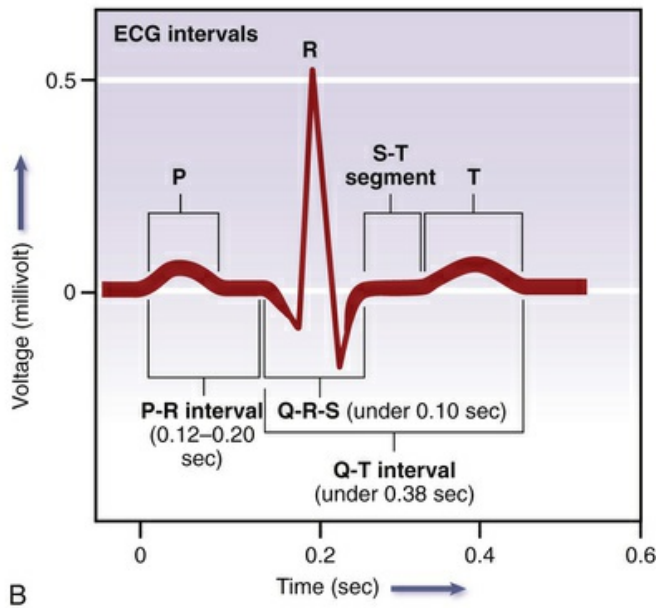

Normal Electrocardiogram.

The genesis of the normal electrocardiogram is from electrical activity recorded by skin electrodes, that is, the sum of all cardiac action potentials (Fig. 32.12). The **P wave** represents atrial depolarization. The **PR interval** is a measure of time from the onset of atrial activation to the onset of ventricular activation; it normally ranges from 0.12 to 0.20 second. The PR interval represents the time necessary to travel from the sinus node through the atrium, AV node, and His-Purkinje system to activate ventricular myocardial cells. The **QRS complex** represents the sum of all ventricular muscle cell depolarizations. The configuration and amplitude of the QRS complex vary considerably

among individuals. The duration is normally between 0.06 and 0.10 second. During the **ST interval** the entire ventricular myocardium is depolarized. The **QT interval** is sometimes called the *electrical systole* of the ventricles. It lasts about 0.4 second, but it varies inversely with the heart rate.

Automaticity.

Automaticity, or the property of generating spontaneous depolarization to threshold, enables the SA and AV nodes to generate cardiac action potentials without any stimulus. Cells capable of spontaneous depolarization are called **automatic cells**. The automatic cells of the cardiac conduction system can stimulate the heart to beat even when the heart is transplanted and, thus, has no innervation. Spontaneous depolarization is possible in automatic cells because the membrane potential does not “rest” during phase 4. Instead, it slowly creeps toward threshold during the diastolic phase of the cardiac cycle. Because threshold is approached during diastole, phase 4 in automatic cells is called **diastolic depolarization**. The electrical impulse normally begins in the SA node because its cells depolarize more rapidly than other automatic cells.

Rhythmicity.

Rhythmicity is the regular generation of an action potential by the heart's conduction system. The SA node sets the pace because normally it has the fastest rate of depolarization. The SA node depolarizes spontaneously 60 to 100 times per minute. If the SA node is damaged, the AV node can become the heart's pacemaker at a rate of about 40 to 60 spontaneous depolarizations per minute. Eventually, however, conduction cells in the atria usually take over from the AV node. Purkinje fibers also are capable of spontaneous depolarization but at a slower rate. Therefore the Purkinje fibers only function as pacemakers when the SA and AV nodes are diseased or there is interruption to movement of electrical current through the heart.

Cardiac Innervation

Although the heart's nodes and conduction system generate cardiac action potentials independently, the autonomic nervous system influences the rate of impulse generation (firing), depolarization, and repolarization of the myocardium and the strength of atrial and ventricular contraction. Autonomic neural transmission produces changes in the heart and circulatory system faster than metabolic or humoral agents (see [Fig. 32.10](#)). Speed is important, for example, in stimulating the heart to increase its pumping action during times of stress and fear, the *fight-or-flight response*, or with increased physical activity. Although increased delivery of oxygen, glucose, hormones, and other blood-borne factors sustains increased cardiac activity, the rapid initiation of increased activity depends on the sympathetic and parasympathetic fibers of the autonomic nervous system. (The autonomic nervous system is described and illustrated in [Chapter 15](#).)

Sympathetic and Parasympathetic Nerves.

Sympathetic and parasympathetic nerve fibers innervate all parts of the atria and ventricles and the SA and AV nodes. In general, sympathetic stimulation increases electrical conductivity and the strength of myocardial contraction, and vagal parasympathetic nerve activity does the opposite, slowing the conduction of action potentials through the heart and reducing the strength of contraction. Therefore the sympathetic and parasympathetic nerves affect the speed of the cardiac cycle (**heart rate**, or beats per minute). The sympathetic nerves also influence the diameter of the coronary vessels (see [Fig. 32.10](#)) and overall myocardial performance. Stimulation of the SA node by the sympathetic nervous system rapidly increases heart rate. In addition, neurally released **norepinephrine** or circulating catecholamines interact with β -adrenergic receptors on the cardiac cell membranes. The final effect is an increased influx of Ca^{++} , which increases the contractile strength of the heart and increases the speed of electrical impulses through the heart muscle and the nodes.¹³ Finally, increased sympathetic discharge dilates the coronary vessels by causing the release of vasodilating metabolites resulting from increased

myocardial contraction.¹⁴

Efferent sympathetic fibers originate in the thoracic spinal cord and branch into the superior middle and inferior cardiac nerves. They join at the **cardiac plexus**, a neural junction located at the root of the aorta in front of the trachea. The efferent parasympathetic fibers originate in the medulla oblongata and travel by way of the vagus nerves to join the sympathetic nerves in the cardiac plexus.

Parasympathetic (vagal) activity causes the release of acetylcholine. Receptors for these neurotransmitters are found in the myocardium and coronary vessels of the heart. Acetylcholine decreases heart rate, slows conduction through the AV nodes, and reduces myocardial contraction strength.¹²

Adrenergic Receptor Function.

Sympathetic neural stimulation of the myocardium and coronary vessels depends on the presence of G-protein-coupled adrenergic receptors, which bind specifically with neurotransmitters of the sympathetic nervous system. (Receptor physiology is discussed in [Chapter 1](#).) The effects of sympathetic stimulation depend on whether (1) the α - or β -adrenergic receptors are most plentiful on cells of the effector tissue, (2) the neurotransmitter is norepinephrine or epinephrine, and (3) the extent to which the individual variations in receptor structure caused by single nucleotide polymorphisms (SNPs) influence receptor responsiveness.^{15,16}

There are five types of adrenergic receptors: β_1 , β_2 , β_3 , α_1 , and α_2 (see [Table 15.7](#)). Each of the α -adrenergic receptors also has three subtypes, so some sources indicate that there are nine types of adrenergic receptors.^{16,17} Overall, cardiovascular structures have more β - than α -receptors; therefore effects mediated by the β -receptors predominate. Norepinephrine is released by postsynaptic sympathetic nerve endings in the heart, whereas epinephrine is mainly released by the adrenal medulla and reaches the heart through the bloodstream.

The β_1 -receptors are found mostly in the heart, specifically the conduction system (AV and SA nodes, Purkinje fibers) and the atrial and ventricular myocardium. The β_2 -receptors are found in the heart

and also on vascular smooth muscle. Stimulation of both the β_1 - and β_2 -receptors results in an increase in heart rate (chronotropy) and force of myocardial contraction (inotropy).¹⁸ In addition, stimulation of the β_2 -receptors results in vasodilation because of the location of the receptors on vascular smooth muscle. Overall β_1 and β_2 stimulation enables the heart to pump more blood and β_2 stimulation also increases coronary blood flow, and β_3 -receptors are also found in the myocardium and coronary vessels. In the heart, stimulation of these receptors opposes the effects of β_1 - and β_2 -receptor stimulation and decreases myocardial contractility (negative inotropic effect).¹⁸ Thus β_3 -receptors may provide a “safety mechanism” to prevent overstimulation of the heart by the sympathetic nervous system.

Norepinephrine binding with α_1 -receptors, all of which are postsynaptic in the systemic and coronary arteries, causes smooth muscle contraction and thus vasoconstriction. One of the three subtypes of α_2 -receptors, α_{2a} , is located on the sympathetic ganglia and nerve terminals. The effect of norepinephrine on these receptors is to inhibit release of more norepinephrine, which promotes vasodilation, thus providing another safety mechanism to prevent excess blood pressure elevation.¹⁸ Dysfunction of α - and β -adrenergic receptors can occur in many conditions (e.g., diabetes, hypertension) and has been implicated in the pathogenesis of many cardiac diseases, including heart failure, myocardial ischemia, and dysrhythmias.^{15,16,18}

Myocardial Cells

Cardiomyocytes are composed of long, narrow fibers that contain bundles of longitudinally arranged myofibrils; a nucleus; mitochondria; an internal membrane system (the sarcoplasmic reticulum); cytoplasm (sarcoplasm); and a plasma membrane (the sarcolemma), which encloses the cell. Cardiac and skeletal muscle cells also have an “external” membrane system made up of transverse tubules (T tubules) formed by inward pouching of the sarcolemma. The sarcoplasmic reticulum forms a network of channels that

surrounds the muscle fiber.

Myofibrils in both cardiac and skeletal fibers consist of alternating light and dark bands of protein, causing the fibers to appear striped, or striated. The dark and light bands of the myofibrils create repeating longitudinal units, called *sarcomeres*, which are between 1.6 and 2.2 μm long (Fig. 32.13, A). The length of these sarcomeres determines the limits of myocardial stretch at the end of diastole and subsequently the force of contraction during systole. Alterations in sarcomere size occur in both physiologic and pathologic myocardial hypertrophy.

FIGURE 32.13 Structure of a Sarcomere, Myofilaments, and Myosin. **A**, The sarcomere is the basic contractile unit of a muscle cell. The Z disk is the anchor for the contractile elements actin and myosin. Actin attaches directly to the Z disk, whereas myosin is attached to it by elastic titin filaments. The myosin filaments are connected to each other by M-protein at the M line. The A, H, and I bands refer to parts of the sarcomere as they were originally seen by light microscopy. **B**, Thin myofilaments and thick myofilament. **C**, Each myosin molecule is a coil of two chains wrapped around each other. At the end of each chain is a globular region, much like a golf club, called the *head*. Myosin molecules usually are combined into filaments, which are stalks of myosin from which the heads protrude at regular intervals.

There are differences between skeletal and cardiac muscle, which reflect cardiac function. Skeletal muscle cells tend to be arranged in parallel units throughout the length of the muscle, whereas cardiac cells are arranged in branching networks throughout the myocardium. Skeletal muscle cells have many nuclei, but cardiac fibers have only one nucleus. Other differences enable cardiac fibers to accomplish the following:

1. *Transmit action potentials quickly from cell to cell.* Electrical impulses are transmitted rapidly from cardiac fiber to cardiac fiber because the network of fibers connects at **intercalated disks**, which are thickened portions of the sarcolemma. The intercalated disks contain three junctions: desmosomes or macula adherens; fascia adherens, which mechanically attach one cell to another; and gap junctions (tight junctions), which allow the electrical impulse to spread from cell to cell through a low-resistance pathway (see [Chapter 1](#)). Changes in the function of these junctional elements may cause an increased risk of dysrhythmias.¹³
2. *Maintain high levels of energy synthesis.* Unlike skeletal muscle, the heart cannot rest and is in constant need of energy, which is supplied by molecules such as adenosine triphosphate (ATP). Therefore the cytoplasm surrounding the bundles of myofibrils in each cardiomyocyte contains a large number of mitochondria (25% to 33% of cell volume). Cardiac muscle cells have more mitochondria than do skeletal muscle cells to

provide the necessary respiratory enzymes for aerobic metabolism and supply quantities of ATP sufficient for the constant action of the myocardium.¹⁹

3. *Gain access to more ions, particularly sodium and potassium, in the extracellular environment.* Cardiac fibers contain more T tubules than do skeletal muscle fibers (Fig. 32.14). This increased closeness to the T tubules gives each myofibril in the myocardium faster access to molecules needed for the transmission of action potentials, a process that involves transport of sodium and potassium through the walls of the T tubules. Because the T tubule system is continuous with the extracellular space and the interstitial fluid, it facilitates the rapid transmission of the electrical impulses from the surface of the sarcolemma to the myofibrils inside the fiber. This rapid transmission activates all the myofibrils of one fiber simultaneously. The sarcoplasmic reticulum is located around the myofibrils. As an action potential is transmitted through the T tubules, it induces the sarcoplasmic reticulum to release its stored calcium, thus activating the contractile proteins actin and myosin.

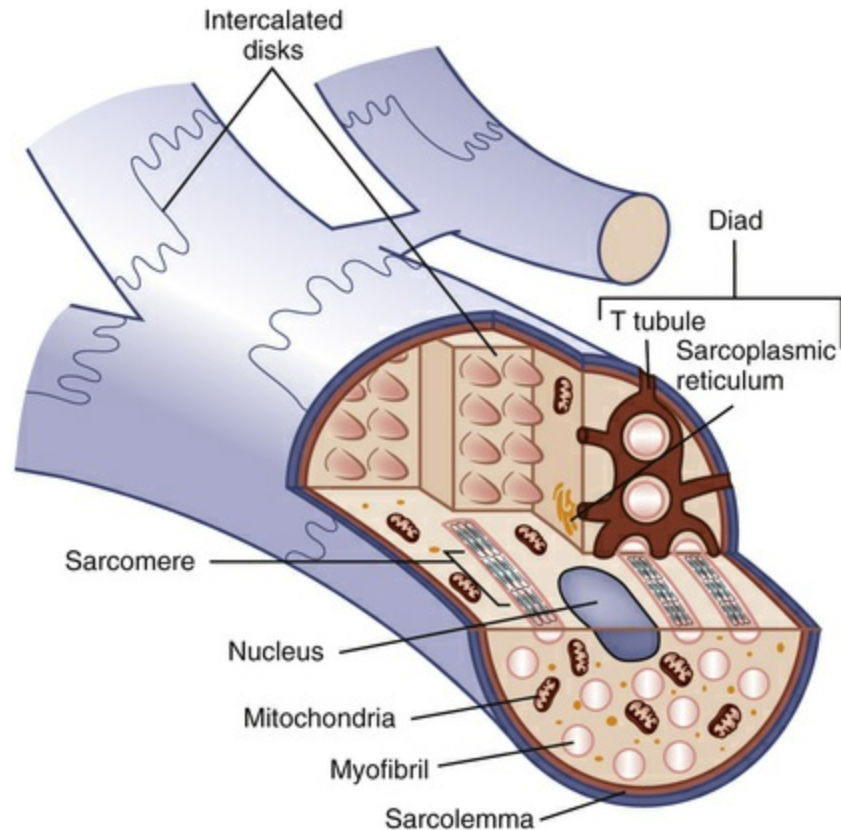

FIGURE 32.14 Cardiac Muscle Fiber. Unlike other types of muscle fibers, cardiac muscle fibers are typically branched with junctions, called *intercalated disks*, between adjacent myocytes. Like skeletal muscle cells, cardiac muscle cells contain sarcoplasmic reticula and T tubules, although these structures are not as highly organized as in skeletal muscle fibers.

Actin, Myosin, Troponin-Tropomyosin Complex, and Titin.

Within each myocardial sarcomere, thick filaments of **myosin** constitute the central dark band called the **anisotropic band**, or **A band** (see Fig. 32.13, B). The myosin molecule resembles a golf club with two large bulbous heads protruding from one end of a straight shaft (Fig. 32.13, C). The bilobed heads contain an actin-binding site and a site of ATPase activity. A thick filament called *myosin microfilament* is composed of about 200 myosin molecules bundled together with outward-facing molecule heads called *cross-bridges* because with activation of contraction they will form force-generating bridges with exposed actin molecules (see Fig. 32.13, A, C). **Actin** molecules are part of the thin filaments (Fig. 32.15). The light bands,

called **isotropic bands**, or **I bands**, of the sarcomere contain only actin molecules and no myosin (see Fig. 32.13, A). The thin filaments of actin extend from the **Z line**, a dense fibrous line that crosses the center of each I band. The area from one dark Z line to the next Z line defines one sarcomere. In the center of a sarcomere is the H zone, a somewhat less dense region. A thin, dark **M line** travels the center of the H zone. A single **tropomyosin molecule** (a relaxing protein) lies alongside seven actin molecules. **Troponin**, another relaxing protein, associates with the tropomyosin molecule, forming the **troponin-tropomyosin complex** (see Fig. 32.15). The troponin complex itself has three components. **Troponin T** aids in binding of the troponin complex to actin and tropomyosin; **troponin I** inhibits the ATPase of actomyosin; and **troponin C** contains binding sites for the calcium ions involved in contraction. Troponin T and I molecules are released into the bloodstream during myocardial injury. They are measured to evaluate if a myocardial infarction or other damage has occurred. Once troponin and tropomyosin cover the myosin-binding sites on actin, the cross-bridges release calcium and the myocardium relaxes. A giant elastic sarcomere protein (**titin** or connectin), which attaches myosin to the Z line, acts as a spring and influences myocardial stiffness.¹⁹ Titin structure affects myocardial diastolic filling and has been found to play a role in heart failure.²⁰

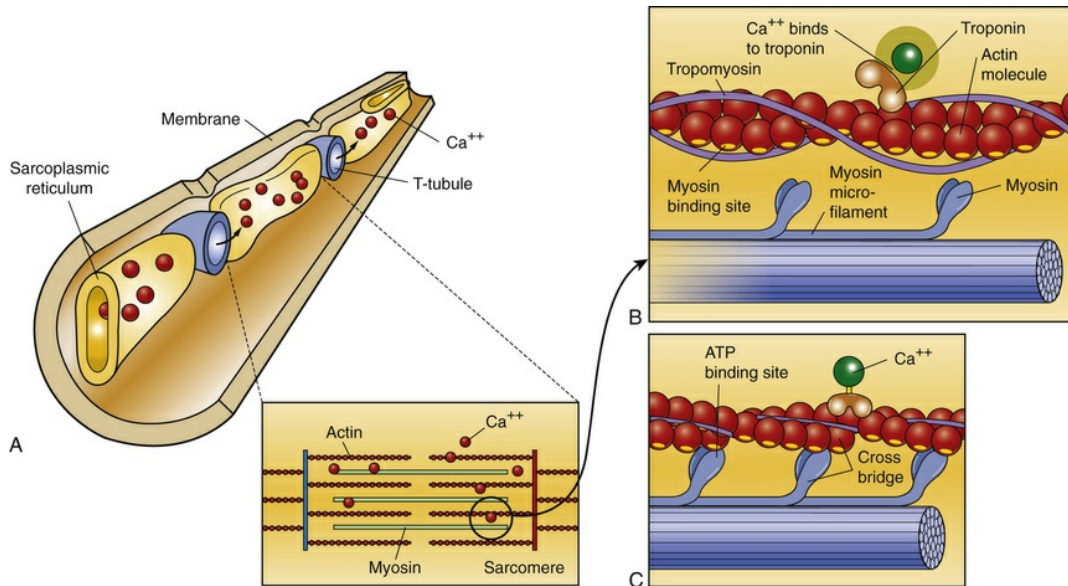

FIGURE 32.15 Myofilaments and Mechanisms of Muscle Contraction. **A,** Thin and thick myofilaments. In resting muscle, calcium ions are stored in the sarcoplasmic reticulum. When an action potential reaches the muscle cell, the T tubules carry the action potential deep into the sarcoplasm. The action potential causes the sarcoplasmic reticulum to release the store of calcium ions. **B,** In resting muscle the myosin-binding sites are covered by troponin and tropomyosin. The calcium ions released into the sarcoplasm as a result of the action potential bind to the troponin. This binding causes the tropomyosin and troponin to move out of the way of the myosin-binding sites, leaving the myosin heads free to bind to the actin microfilament. **C,** ATP is used as an energy molecule to the myosin cross-bridge. (Adapted from Raven PH, Johnson GB: *Understanding biology*, ed 3, Dubuque, IA, 1995, Brown.)

Myocardial Metabolism.

Cardiomyocytes depend on the constant production of ATP, which is synthesized within the mitochondria mainly from glucose, fatty acids, and lactate. If the myocardium is underperfused because of coronary artery disease, anaerobic metabolism must be used as a source of energy (see [Chapter 1](#)). Energy produced by metabolic processes sustains muscle contraction and relaxation, electrical excitation, membrane transport, and synthesis of large molecules. Normally, the amount of ATP produced supplies sufficient energy to pump blood systemically.

Cardiac work often is expressed as **myocardial oxygen consumption (MVO₂)**, which is correlated with total cardiac energy requirements. MVO₂ is determined by three major factors: (1) the

amount of wall stress during systole, estimated by measuring the systolic blood pressure; (2) the duration of systolic wall tension, measured indirectly by the heart rate; and (3) the contractile state of the myocardium, which is not measured clinically.

The coronary arteries deliver oxygen (O_2) to the myocardium. From 70% to 75% of this O_2 is used immediately by cardiac muscle, leaving little O_2 in reserve. Therefore increased energy needs can be met only by increasing coronary blood flow. MVO_2 can increase with exercise and decreases with hypotension and hypothermia. As myocardial metabolism and consumption of O_2 increases, the concentration of local vasoactive metabolic factors increases. Some of these, such as adenosine, nitric oxide, and prostaglandins, dilate coronary arterioles, thus increasing coronary blood flow.²¹

Myocardial Contraction and Relaxation

Myocardial contractility is a change in developed tension at a given resting fiber length, which is simply the ability of the heart muscle to shorten. At the molecular level, thin filaments of actin slide over thick filaments of myosin, called the **cross-bridge cycle of muscle contraction**. Anatomically, contraction occurs when the sarcomere shortens, causing adjacent Z lines to move closer together (Fig. 32.16). The width of the A band, which contains the thick myosin filaments, is unchanged whereas the I band becomes narrower as the overlap between the thick and thin filaments increases. The degree of shortening of the muscle fibers depends on how much the thin filaments overlap the thick filaments. Maximal contraction occurs when the sarcomere length is 2.2 mm. At 2.2 mm the number of cross-bridge attachments between actin and myosin is maximal.

FIGURE 32.16 Cross-Bridge Theory of Muscle Contraction. **A**, Each myosin cross-bridge in the thick filament moves into a resting position after an adenosine triphosphate (ATP) molecule binds and transfers its energy. **B**, Calcium ions released from the sarcoplasmic reticulum bind to troponin in the thin filament, allowing tropomyosin to shift from its position blocking the active sites of actin molecules. **C**, Each myosin cross-bridge then binds to an active site on a thin filament, displacing the remnants of ATP hydrolysis—adenosine diphosphate (ADP) and inorganic phosphate (P_i). **D**, The release of stored energy from step A provides the force needed for each cross-bridge to move back to its original position, pulling actin along with it. Each cross-bridge will remain bound to actin until another ATP molecule binds to it and pulls it back into its resting position (A). (Adapted from Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 4, St Louis, 1999, Mosby.)

Cross-Bridge Cycling.

The globular head-end of the myosin contains a binding site for actin and a separate enzymatic site that catalyzes the breakdown of ATP to adenosine diphosphate (ADP) and inorganic phosphate (P_i) (see Fig. 32.16). This reaction releases the chemical energy stored in ATP. Magnesium is required for the binding of ATP to the myosin site. The splitting of ATP occurs on the myosin molecule before it attaches to actin, but the ADP and inorganic phosphate released remain bound to the active site on myosin. The chemical energy released is transferred to myosin (m), producing a high-energy form of myosin (M):

The binding of this high-energy myosin-actin form to a cross-bridge releases the energy stored in myosin (e.g., ADP and P_i), producing the force necessary for movement of the cross-bridge. With the attachment of actin to myosin at the cross-bridge, the myosin head molecule undergoes a position change, exerting traction on the rest of

the myosin bridge, causing the thin filaments to slide past the thick filaments (see Fig. 32.16). During contraction each cross-bridge undergoes several cycles of attachment, movement, and dissociation from the thin filaments.²²

Calcium and Excitation-Contraction Coupling.

Excitation-contraction coupling is the process by which an action potential arriving at the plasma membrane of the muscle fiber triggers the cycle, leading to cross-bridge activity and contraction. Activation of this cycle depends on the availability of calcium, and the amount of force developed is regulated by how much the concentration of calcium ion increases within the cardiomyocytes.

Calcium is stored in the tubule system and the sarcoplasmic reticulum. It enters the myocardial cell from the interstitial fluid after electrical excitation, which increases the membrane permeability to calcium. Two types of calcium channels (L-type and T-type) are identified in cardiac tissues. The L-type, or long-lasting, channels are the predominant type of calcium channels and are the channels blocked by **calcium channel–blocking drugs** (verapamil, nifedipine, diltiazem).¹⁹ The major effect of these medications is to decrease the strength of cardiac contraction. The T-type, or transient, channels are much less abundant in the heart and are not blocked by currently available calcium channel–blocking drugs and are being investigated. Calcium entering the cell from the interstitial fluid triggers release of calcium from the storage sites within the sarcomere. Calcium from these sites diffuses toward the myofibrils, where it binds with troponin.

Myocardial Relaxation

Relaxation is as vital to optimal cardiac function as contraction, and calcium, troponin, and tropomyosin also facilitate relaxation. After contraction, free calcium ions are actively pumped out of the cell back into the interstitial fluid or taken up again by the sarcoplasmic reticulum and stored. As the concentration of calcium within the sarcomere subsequently falls, troponin releases its bound calcium. The

tropomyosin complex blocks the active sites on the actin molecule, preventing cross-bridges with the myosin heads. Impairment of myocardial relaxation can lead to increased diastolic filling pressures and eventually heart failure.²³

Factors Affecting Cardiac Output

Cardiac capability can be evaluated by measuring the cardiac output. **Cardiac output** is calculated by multiplying heart rate in beats per minute (beats/min) by stroke volume in liters per beat. Normal adult cardiac output at rest is about 5 L/min. The at-rest heart rate is about 70 beats/min with a normal stroke volume of about 70 mL.¹⁴ With each heartbeat, the ventricles eject much of their blood volume; the amount ejected per beat is called the **ejection fraction**. The ejection fraction is calculated by dividing the stroke volume by the end-diastolic volume. The end-diastolic volume (EDV) of the normal ventricle is about 70 to 80 mL/m², and the normal ejection fraction of the resting heart measured with gated myocardial perfusion imaging was 66% ± 8% for women and 58% ± 8% for men.²⁴ The ejection fraction is increased by factors that increase contractility, for example, sympathetic nervous system activity. A decrease in ejection fraction may indicate ventricular failure. The effects of aging on cardiovascular function are summarized in [Table 32.3](#).

TABLE 32.3

CARDIOVASCULAR FUNCTION IN OLDER ADULTS

DETERMINANT	RESTING CARDIAC PERFORMANCE	EXERCISE CARDIAC PERFORMANCE
Cardiac index	Unchanged or slightly decreased in women only	Declines because of a decrease in heart rate and stroke volume
Heart rate	Slight decrease	Increases less than in younger people, possibly because of decreased cardiovascular response to catecholamines; overall slight decrease
Stroke volume	Slight increase	Slight increase

Ejection fraction	Unchanged	Increases less from rest to exercise in older people than in younger people
Afterload	Increased	Uncertain
End-diastolic volume	Unchanged	Unchanged
End-systolic volume	Unchanged	Higher in older people than in younger people
Contraction	Increased because of prolonged relaxation	Decreases with vigorous exercise*
Cardiac dilation	No change	Increases at end-diastole and end-systole
O ₂ max	Not applicable	Declines because of a decline in skeletal muscle mass and increase in body fat

* As measured by end-systolic volume/systolic blood pressure (ESV/SBP), an index of contractility.

Data from Najjar SS, Gerstenblith G, Lakatta EG: Aging and the cardiovascular system. In Willerson JT et al, editors: *Cardiovascular medicine*, ed 3, London, 2007, Springer-Verlag.

Four factors affect cardiac output directly: preload, afterload, myocardial contractility, and heart rate (Fig. 32.17). **Preload** is the volume inside the ventricle at the end of diastole (ventricular end-diastolic volume [VEDV] and pressure [VEDP]). Preload is determined by two major factors: (1) the amount of venous blood returning to the ventricle during diastole and (2) the amount of blood left in the ventricle after systole (end-systolic volume). Blood volume and flow through the venous system and the atrioventricular valves determine *venous return*. The strength of ventricular contraction and the resistance to ventricular emptying determine *end-systolic volume*. Clinically, preload is estimated by measuring the central venous pressure (CVP) for the right side of the heart and the pulmonary artery wedge pressure for the left side. Normal values for these two estimates are 1–5 and 4–12 mmHg, respectively.²⁵ Heart failure can occur because of an increase in preload (VEDV), which causes a decline in stroke volume and also increases VEDP. Increased VEDP causes pressures to increase or “back up” into the pulmonary or systemic venous circulation, increasing plasma outflow through the vessel walls, causing pulmonary edema (see Chapter 36).

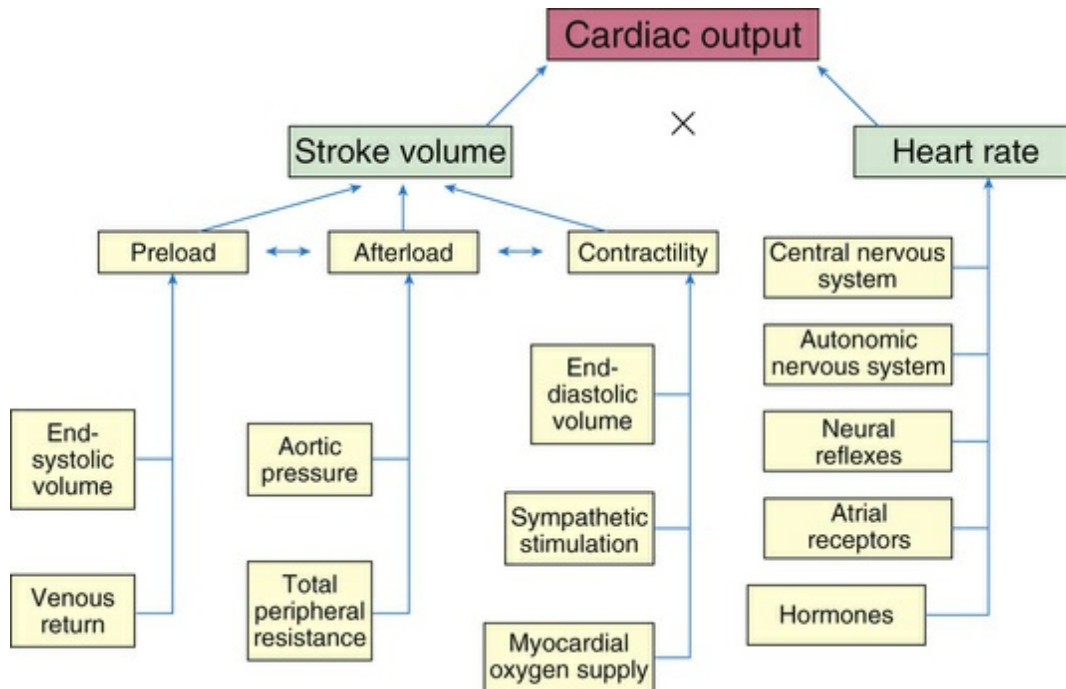

FIGURE 32.17 Factors Affecting Cardiac Performance. Cardiac output, which is the amount of blood (in liters) ejected by the heart per minute, depends on heart rate (beats per minute) and stroke volume (milliliters of blood ejected during ventricular systole).

Left ventricular **afterload** is the resistance to ejection of blood from the left ventricle (see p. 1035). More simply, it is the load the muscle must move during contraction. An index of afterload is aortic systolic pressure. To understand the role of these factors in cardiac performance, it is first necessary to understand two physical laws that explain the mechanisms of heart action: the Frank-Starling law of the heart and Laplace's law.

Frank-Starling Law of the Heart

Cardiac muscle, like other muscle, increases its strength of contraction when it is stretched. This relationship was described in 1914 by a British physiologist, Ernest Starling, and was based on the earlier work of a German physiologist, Otto Frank. The **Frank-Starling law of the heart**, or the length-tension relationship of cardiac muscle, relates resting sarcomere length, expressed as the volume of blood in the heart at the end of diastole (**end-diastolic volume**), to tension generation, described as development of left ventricular pressure.

Thus the volume of blood in the heart at the end of diastole (the length of its muscle fibers) is directly related to the force of contraction during the next systole. Although the change in pressure is related to the volume of the ventricle and, consequently, to the length of the ventricular muscle fibers, preload (i.e., filling pressure) is commonly used as an index of ventricular volume. The length-tension mechanism is the main mechanism by which the normal right and left ventricles maintain equal minute outputs even though their stroke outputs may vary considerably during normal respiration. For example, changes in volume occur when an individual assumes a reclining position after being in a standing position; the volume of blood returning to the heart temporarily increases. The right ventricle stretches to accommodate this increase in volume and thereby increases its force of contraction. A larger stroke volume (i.e., the amount of blood ejected per beat) is pumped to the lungs, generating higher pressures. Pulmonary vascular pressure increases, causing a rise in the left ventricular filling pressure or preload. Left ventricular volume and pressure increase. The left ventricle pumps a larger stroke volume, and arterial vascular pressure rises.

The mechanical function of the heart is characterized by a number of length-tension curves (Fig. 32.18). Factors that increase contractility (i.e., positive inotropic), such as sympathetic nerve stimulation, cause the heart to operate on a higher length-tension curve (curve A in Fig. 32.18). A higher tension or increase in ventricular stroke volume is generated without a necessary change in **left ventricular end-diastolic volume (LVEDV)** or fiber length. Heart failure (curve C in Fig. 32.18) is characterized by a lower length-tension curve (see Chapter 33). The Frank-Starling law of the heart may not apply to dilated or failing hearts because their fibers are already stretched beyond their optimal length. The failing heart responds to increased filling or stretch with a progressive decline in the force of contraction. Thus at the same left ventricular end-diastolic volume (LVEDV) as curves A and B (see Fig. 32.18), the force of contraction of stroke volume is decreased.

FIGURE 32.18 Frank-Starling Law of the Heart. Relationship between length and tension in the heart. End-diastolic volume determines end-diastolic length of ventricular muscle fibers and is proportional to tension generated during systole, as well as to cardiac output, stroke volume, and stroke work. A change in myocardial contractility causes the heart to perform on a different length-tension curve. (See text.) A, Increased contractility; B, normal contractility; C, heart failure or decreased contractility.

The cross-bridge arrangement with the sarcomere partially accounts for the length-tension mechanism of cardiac muscle. According to the Frank-Starling law, the longer the initial resting length of the cardiac muscle fiber (optimal length is between 2.2 and 2.4 mm), the greater the strength of contraction. At 2.2 mm an optimal number of active cross-bridges exist between actin and myosin. However, if the fibers are stretched beyond 2.2 to 2.4 mm, the force of contraction decreases because actin and myosin become partially disengaged, disrupting many of the cross-bridges. Excessive stretching, to about 3.65 mm, causes actin and myosin to become completely disengaged so that tension (force of contraction) drops to zero. The relationship between stretch and contraction can be compared with that of a rubber band. Up to a certain point, the more the rubber band is stretched the farther it will fly when one end is released; beyond that point, however, the rubber band will break but, of course, the myocardium does not actually break.

Laplace's Law

Laplace's law states that wall tension is related directly to the product of intraventricular pressure and internal radius and inversely related to the wall thickness as shown in the Laplace equation:

$$T = (p \times r) / \mu m$$

where T = wall tension, p = intraventricular pressure, r = internal radius of the sphere, and μm = wall thickness. In other words, the amount of tension generated in the ventricular wall (or any chamber or vessel) to produce a given intraventricular pressure depends on the size (radius and wall thickness) of the ventricle.

Laplace's law is useful for understanding aneurysm formation, distensibility in blood vessels, and the effects of ventricular dilation on myocardial contraction. Dilation is an important factor in heart failure (see [Chapter 33](#)). With a dilated ventricle, myocardial fibers in the wall must develop greater tension to produce a given pressure within the ventricle. The disadvantage of dilation is that the increased force, or tension, in the myocardial fibers required to develop a given pressure inside a dilated ventricle decreases the rate of fiber shortening, thereby decreasing the ability of the ventricle to eject blood.

Afterload

Ventricular afterload is the resistance to ejection of blood from the ventricle. Low aortic pressures (decreased afterload) enable the heart to contract more rapidly, whereas high aortic pressures (increased afterload) slow contraction and cause higher workloads against which the heart must function to eject blood. Pressure in the ventricle must exceed aortic pressure before blood can be pumped out during systole. Increased aortic pressure is usually the result of increased **systemic vascular resistance (SVR)**, also called **total peripheral resistance (TPR)**. In individuals with hypertension, increased TPR means that afterload is chronically elevated, resulting in increased ventricular workload and hypertrophy of the myocardium. In some individuals, changes in afterload are the result of aortic valvular disease (see [Fig. 32.17](#)).

Myocardial Contractility

Stroke volume, or the volume of blood ejected per beat during

systole, depends on the *force* of contraction, the myocardial contractility, or the degree of myocardial fiber shortening. Three major factors determine the force of contraction (see [Fig. 32.17](#)):

1. *Changes in the stretching of the ventricular myocardium caused by changes in VEDV (preload)*. These changes were discussed earlier and an excessive increase in preload leads to decreased stroke volume.
2. *Alterations in the inotropic stimuli of the ventricles*. **Inotropic agents** affect contractility and include hormones, neurotransmitters, or medications. The sympathetic nervous system neurotransmitters, epinephrine and norepinephrine, are the most important endogenous positive inotropic agents. The most important negative inotropic agent is acetylcholine released from the vagus nerve. Many medications have positive or negative inotropic properties that can have significant effects on cardiac function. Cytokines released during sepsis, such as tumor necrosis factor- α (TNF- α) and interleukin-1 β , are known to impair myocardial contractility.²⁶ Emerging is the understanding of mitochondrial dysfunction in sepsis and impaired myocardial function.²⁷
3. *Adequacy of myocardial oxygen supply*. Both oxygen and carbon dioxide levels (tensions) in the coronary blood influence contractility. With oxygen saturation less than 50% (severe hypoxemia) myocardial contractility is decreased. Circulating catecholamines can increase contractility with moderate degrees of hypoxemia.²⁸

Preload, afterload, and contractility all interact with one another to determine stroke volume and cardiac output. Changes in any one of these factors can result in deleterious effects on the others, resulting in heart failure (see [Chapter 33](#)).

Heart Rate

The SA node activity is the primary determinant of the heart rate. The

control of heart rate includes activity of the CNS, autonomic nervous system, neural reflexes, atrial receptors, hormones (e.g., catecholamines [norepinephrine and epinephrine]), thyroid hormones, and growth hormones. Although these are principal factors, heart rate varies naturally with respiration, exercise, neuropsychologic factors (e.g., stressors, depression), cardiovascular disease, alcohol and drug consumption, air pollution, meditation, and others²⁹ (Figure E 32.1 [on Evolve]). This variability in heart rate is called **heart rate variability (HRV)**; see Figure E 32.1(on Evolve) reveals physiologic, environmental, and psychologic elements linked with HRV.

In addition to HRV related to nervous system and hormonal factors, other factors include cardiovascular disease (CVD), depression, and proinflammatory cytokines, which can lead to immune dysfunction and inflammation.²⁹ Neurologic diseases linked with a HRV decrease include parkinsonian syndrome, spinocerebellar degeneration, Shy-Drager syndrome, multiple sclerosis, and Guillain-Barré syndrome. Temperature affects HRV; temperature decrease can induce bradycardia and temperature increase can increase heart rate. Estrogen levels correlated with HRV measures in healthy women and androgens have a parasympathetic effect (higher HPV with high testosterone levels).²⁹ Occupational settings can influence HRV, such as particulate matter, chemicals, electromagnetic fields (EMFs), vibrating tools, psychosocial environment, working time, fatigue, and others. A chronic exposure to these factors was linked to a decrease in HRV.²⁹ A high level of work stress also was associated with a low HRV.²⁹

Heart rate varies naturally with respiration, the rate increasing with inspiration and decreasing with expiration. This normal alteration in rhythm pattern, called **sinus arrhythmia**, is caused by changes that occur within the chest cavity because of respiration. Inspiration results in stretch and an associated increase in firing of the SA node that increases heart rate. The stretch is reduced with expiration and the SA node firing rate slows, resulting in a decrease in heart rate.³⁰

The average heart rate in healthy adults is about 70 beats/min. The average heart rate is typically greater in children. Heart rate diminishes by 10 to 20 beats/min during sleep and can accelerate to

more than 100 beats/min during muscular activity or emotional excitement. In well-conditioned athletes the resting heart rate is about 50 to 60 beats/min. In highly trained or elite athletes, the resting heart rate can be less than 50 beats/min; these athletes have a greater stroke volume and lower peripheral resistance in active muscles than they had before training.

Cardiovascular Control Centers in the Brain.

The **cardiovascular vasomotor control center** is in the medulla and pons of the brainstem with additional areas in the hypothalamus, the cerebral cortex, and the thalamus. The hypothalamic centers regulate cardiovascular responses to changes in temperature; the cerebral cortex centers adjust cardiac reaction to a variety of emotional states; and the medullary control center regulates heart rate and blood pressure (see [Fig. 32.10](#)).

The nerve fibers from the **cardiovascular control center** synapse with the autonomic neurons that control the rate of firing of the SA node. As discussed earlier, sympathetic (adrenergic) stimulation increases heart rate. When the parasympathetic nerves to the heart are stimulated (primarily vagus nerve), the heart slows and the sympathetic nerves to the heart, arterioles, and veins are inhibited.

The resting heart rate in healthy individuals is primarily under the control of parasympathetic stimulation. While the individual is at rest, parasympathetic effects from the vagus nerves override sympathetic effects in the SA node. Interruption of the vagus nerves causes significant tachycardia (abnormally fast heart rate) because the inhibitory parasympathetic influence is lost.

Neural Reflexes.

The **baroreceptor reflex** is important in blood pressure control and is mediated by stretch receptors (baroreceptors or pressoreceptors) in the aortic arch and carotid arteries. (Because the receptors respond to mechanical factors, they are also called *aortic and carotid mechanoreceptors*.) When blood pressure falls, the baroreceptor reflex accelerates heart rate, increases myocardial contractility, and causes

constriction of arterioles in the systemic circulation. These responses raise blood pressure back toward normal and are critical to maintaining adequate tissue perfusion. Aging is associated with dysfunction of the baroreceptor reflex (baroreflex) and can result in postural hypotension³¹ (orthostatic hypotension, see [Chapter 33](#)).

The baroreflex also can reduce high blood pressure. The mechanoreceptors increase their rate of discharge when stretched by blood pressure elevations. Neural impulses are then transmitted over the glossopharyngeal nerve (ninth cranial nerve) from the carotid artery and through the vagus nerve from the aorta to the cardiovascular control centers in the medulla. These centers initiate an increase in parasympathetic activity and a decrease in sympathetic activity, causing blood vessels to dilate and heart rate to decrease. Responses to the baroreceptor reflex return the blood pressure to its previous level, which may or may not have been normal.

Atrial Receptors.

Mechanoreceptors that influence heart rate exist in both atria.³² They are located where the veins, venae cavae, and pulmonary veins enter their respective atria. **Bainbridge reflex** is the name for the changes in the heart rate that occur after intravenous infusions of blood or other fluids.³³ The change in heart rate is thought to be caused by a reflex mediated by these atrial volume receptors that are innervated by the vagus nerves (volume receptors are thought to respond to increased plasma volume). Although this reflex can be elicited in humans, its relevance is uncertain at this time.³³

Stimulation of these atrial receptors also increases urine volume, presumably because of a neurally mediated reduction in antidiuretic hormone. Peptides of the atrial natriuretic family also are released from atrial tissue in response to the increases in blood volume. These peptides have diuretic and natriuretic (salt excretion) properties, resulting in decreased blood volume and pressure. The atrial natriuretic peptides can relax vascular smooth muscle and oppose myocardial hypertrophy, leading to measurement of blood levels to evaluate clinical status and raising interest in their use as therapeutic

agents.³⁴

Hormones and Biochemicals.

Hormones and biochemicals affect the arteries, arterioles, venules, capillaries, and contractility of the myocardium. Norepinephrine increases heart rate, enhances myocardial contractility, and constricts blood vessels. Epinephrine dilates vessels of the liver and skeletal muscle and causes an increase in myocardial contractility. Some adrenocortical hormones, such as hydrocortisone, potentiate the effects of the catecholamines.

Thyroid hormone, specifically triiodothyronine, causes increases in both heart rate and contractility, resulting in an increase in cardiac output; it also decreases systemic vascular resistance. Triiodothyronine acts directly on the cardiac myocytes to cause gene transcription and cellular changes that result in more calcium release from the sarcoplasmic reticulum.³⁵ Awareness of these changes helps to understand the cardiovascular changes that occur with thyroid diseases. Growth hormone, working together with insulin-like growth factor 1 (IGF-1), also has been shown to increase myocardial contractility.³⁶ Decreases in levels of growth hormone or thyroid hormone may result in bradycardia, reduced cardiac output, and low blood pressure.

The Systemic Circulation

The arteries and veins of the systemic circulation are illustrated in [Fig. 32.19](#). Oxygenated blood from the left side of the heart flows through the aorta and into the systemic arteries. These **arteries** branch into small **arterioles** that branch into the smallest vessels, the capillaries, where nutrient exchange between the blood and tissues occurs. Blood from the capillaries then enters tiny **venules** that join to form the larger **veins**, which return venous blood to the right heart. **Peripheral vascular system** is the term used to describe the part of the systemic circulation that supplies the skin and the extremities, particularly the legs and feet.

A

FIGURE 32.19 Circulatory System. A, Principal arteries of the body. B, Principal veins of the body. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Mosby.)

Structure of Blood Vessels

Blood vessel walls are composed of three layers: (1) the **tunica intima** (innermost or intimal layer); (2) the **tunica media** (middle or medial layer); and (3) the **tunica externa** or **adventitia** (outermost or external layer), which also contains nerves and lymphatic vessels. These layers are illustrated in [Fig. 32.20](#). Blood vessel walls vary in thickness depending on the thickness or absence of one or more of these three layers. Cells of the larger vessels are nourished by the **vasa vasorum**, small vessels located in the tunica externa, and innervated by perivascular nerves. The vasa vasorum arises from the blood vessel itself or from other vessels nearby.

A

B

FIGURE 32.20 Structure of Blood Vessels, and an Artery and Vein. **A**, Structure of blood vessels. The tunica externa of the veins are color-coded blue and the arteries red. **B**, Artery and vein. Light micrograph of a cross section of similar-sized artery (*left*) and vein (*right*). Notice the thick muscular wall of the artery as compared to the thin-walled vein. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Adults are capable of growing new blood vessels through three processes, all of which are important in wound healing but also

contribute to tumor growth. The three processes are angiogenesis, arteriogenesis, and vasculogenesis. Both angiogenesis and arteriogenesis occur by growth of new vessels that branch from existing vessels. Angiogenesis is branching of small vessels, such as capillaries, whereas arteriogenesis occurs by branching from larger vessels, such as arterioles. **Vasculogenesis** is a term that refers to the growth of vessels from progenitor or stemlike cells that originate in the bone marrow and other body tissues.³⁷

Arterial Vessels

Arterial walls are composed of elastic connective tissue, fibrous connective tissue, and smooth muscle. There are two types of arteries: elastic and muscular. The **elastic arteries** have a very thick tunica media that contains more elastic fibers than smooth muscle fibers. Elastic arteries include the aorta and its major branches and the pulmonary trunk. Elasticity enables the vessel to absorb energy imparted to the blood by ventricular contraction and they stretch as blood is ejected from the heart during systole. During diastole, elasticity promotes recoil of the arteries, which is important for maintaining blood pressure within the vessels, and retransfers the energy from the elastic artery walls to the blood.

The **muscular arteries** are medium and small size arteries farther from the heart than the elastic arteries. They contain fewer elastic fibers and more muscle fibers than the elastic arteries and their function is to distribute blood to arterioles throughout the body. Because their smooth muscle can be stimulated to contract or relax, they play a role in controlling blood flow and in directing flow to the parts of the body with the highest need at any time. During exercise more blood is sent to the skeletal muscles, while after a meal more blood is directed to the gut and liver. Contraction narrows the vessel **lumen** (the internal cavity of the vessel), which diminishes flow through the vessel. This condition is termed **vasoconstriction**. When the smooth muscle layer relaxes, more blood flows through the vessel lumen, a state called **vasodilation**.

An artery becomes an arteriole at the point where the diameter of its

lumen narrows to less than 0.5 mm. The arterioles are composed almost exclusively of smooth muscle, with little elastic tissue. Arterioles regulate the flow of blood into the capillaries by vasoconstriction, which retards the flow of blood into the capillaries, and vasodilation, which permits blood to enter the capillaries freely (Fig. 32.21). The thick, smooth muscle layer of the arterioles is a major determinant of the resistance blood encounters as it flows through the systemic circulation.

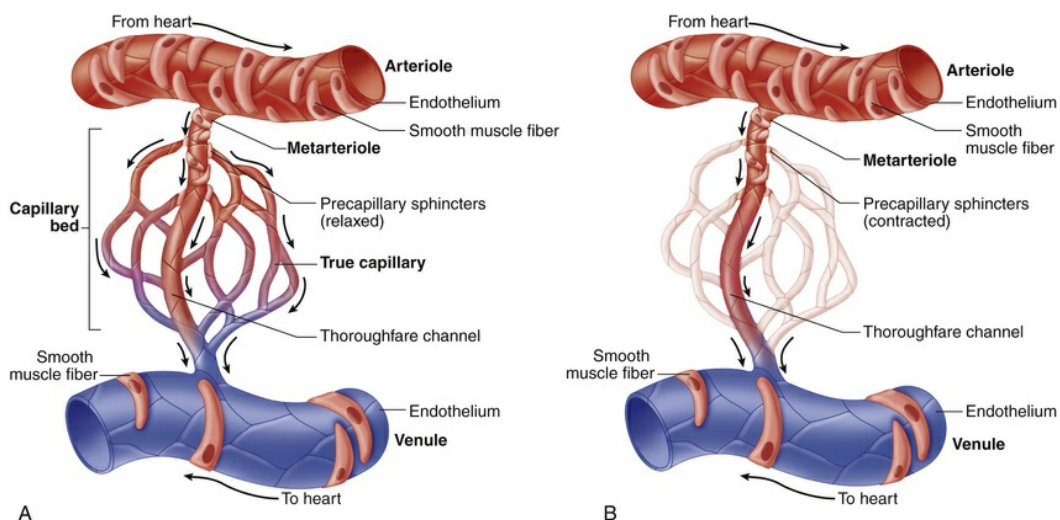

FIGURE 32.21 Capillary Wall and Microcirculation. Control of blood flow through a capillary network is regulated by the relative contraction of precapillary sphincters surrounding arterioles and metarterioles. **A**, Sphincters are relaxed, permitting blood flow to enter the capillary bed. **B**, With sphincters contracted, blood flows from the metarteriole directly into the thoroughfare channel, bypassing the capillary bed. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

The capillary network is composed of connective channels called **metarterioles**, and “true” capillaries (see Fig. 32.21). Metarterioles have discontinuous smooth muscle cells in their tunica media whereas capillaries lack any smooth muscle cells. The capillaries branch from the metarterioles, meeting at a ring of smooth muscle called the **precapillary sphincters**. As the sphincters contract and relax, they regulate blood flow through the capillaries. Appropriately stimulated, the precapillary sphincters help maintain arterial pressure and regulate selective flow to vascular beds.

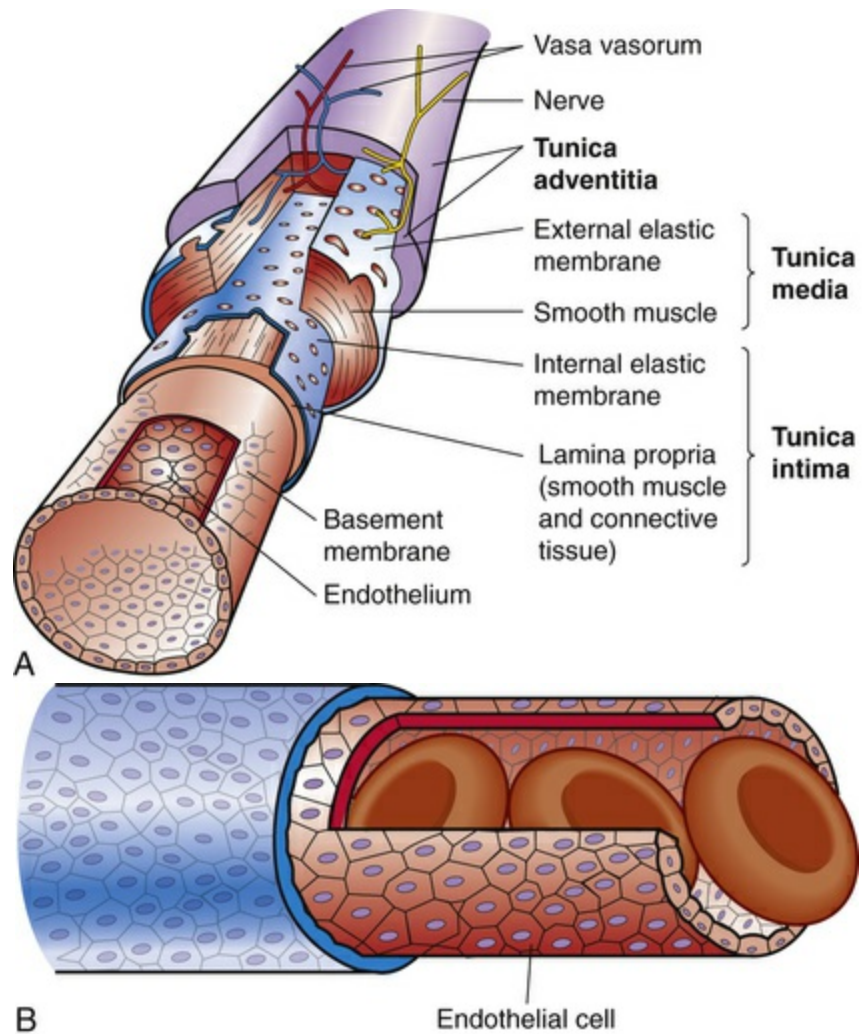

Capillaries are composed solely of a layer of endothelial cells surrounded by a basement membrane. Their thin walls and unique structure make possible the rapid exchange of water, small (low-molecular-weight) soluble molecules, some larger molecules (such as albumin), and cells of the innate and adaptive immune system between the blood and the interstitial fluid.³⁸ Based on their structure, three types of capillaries have been described: continuous, sinusoid, and fenestrated. In the renal glomerulus, for example, the endothelial cells contain oval windows or pores termed **fenestrations**, which are covered by a thin diaphragm.³⁹ Sinusoid capillaries are found in the liver and bone marrow.

Substances pass between the capillary lumen and the interstitial fluid in several ways: (1) through junctions between endothelial cells, (2) through fenestrations in endothelial cells, (3) in vesicles moved by active transport across the endothelial cell membrane, or (4) by diffusion through the endothelial cell membrane. (Movement across cell membranes is described in [Chapter 1](#).) A single capillary may be only 0.5 to 1 mm in length and 0.01 mm in diameter, but the capillaries are so numerous that their total surface area may be more than 600 m².

Endothelium

The vascular **endothelium**, or blood vessel lining, is important to several body functions and is considered by some to be a separate endocrine organ ([Fig. 32.22](#)). All tissues depend on blood supply and the blood supply depends on **endothelial cells**, which form the lining, or endothelium of the blood vessel (see [Fig. 32.22](#)). In addition to substance transport, the vascular endothelium has important roles in coagulation, antithrombogenesis, and fibrinolysis; immune system function; tissue growth and wound healing; and **vasomotion**, the contraction and relaxation of vessels. The endothelium performs these vital functions through synthesis and release of vasoactive chemicals ([Table 32.4](#)). Because of its varying roles, the actual structure of the endothelium may vary in different vascular beds. For example, within lymph nodes the endothelial cells of specialized venules, called *high endothelial venules*, are uniquely structured to support the movement

of lymphocytes from the blood into the lymph node.⁴⁰ Endothelial injury and dysfunction are central processes in many of the most common and serious cardiovascular disorders including hypertension and atherosclerosis (see [Chapter 33](#)).

C

FIGURE 32.22 Endothelium. A, This schematic shows the endothelium in context with the entire blood vessel. Practically imperceptible, the endothelial cells arrange themselves as a fine lining that has numerous life support functions. B, The inset shows more clearly the endothelial cells. C, The endothelium supports numerous functions through synthesis and release of vasoactive fibers.

TABLE 32.4

FUNCTIONS OF THE ENDOTHELIUM

FUNCTION	ACTIONS INVOLVED
Filtration and permeability	Facilitates transport of large molecules via vesicular transport movement through intercellular junctions
	Facilitates transport of small molecules via movement of vesicles, through opening of tight junctions, and across cytoplasm
Vasomotion	Stimulates vascular relaxation through production of nitric oxide, prostacyclin, and other vasodilators
	Stimulates vascular constriction through production of endothelin-1 and of angiotensin II by the action of endothelial angiotensin-converting enzyme on

	angiotensin I
Hemostatic balance	Endothelial surface is normally antithrombotic and maintains a balance between pro- and anti-coagulant factors, as well as pro- and anti-fibrinolytic factors
	Anticoagulant factors include prostacyclin, nitric oxide, antithrombin, thrombomodulin, tissue factor pathway inhibitor, and heparins Procoagulant factors include tissue factor (factor VII), factor VIII, factor V, and plasminogen activator inhibitor-1 (PAI-1)
	Profibrinolytic factors are tissue- and urokinase-type plasminogen activating factor and plasminogen activator inhibitor-1 (PAI-1) Antifibrinolytic factor is tissue plasminogen activator
Inflammation/immunity	Expresses chemotactic agents and adhesion molecules that support white blood cells (including monocytes, neutrophils, and lymphocytes) moving into tissues Expresses receptors for oxidized lipoproteins, allowing them to enter vascular intima
Angiogenesis/vessel growth	Releases growth factors such as endothelin-1 and heparins for vascular smooth muscle cells
Lipid metabolism	Expresses receptors for lipoprotein lipase and low-density lipoproteins (LDLs)

From Griendling KK et al: *Biology of the vessel wall*. In Fuster et al, editors: *Hurst's the heart*, ed 13, Philadelphia, 2011, McGraw-Hill; Rajendran P et al: *Int J Biol Sci* 9(10):1057–1069, 2013.

Veins

The smallest venules downstream from the capillaries have an endothelial lining surrounded by fibrous tissue. The largest venules, those farthest from the capillaries, are surrounded by a few smooth muscle fibers comprising a thin tunica media.

Compared with arteries, veins are thin walled and fibrous with a larger diameter (see [Fig. 32.20](#)). A given vein is larger than the artery that lies within the same sheath. Veins are more numerous than arteries. In veins the tunica externa has less elastic tissue than that in arteries, so veins do not recoil after distention as quickly as arteries. Like arteries, veins receive nourishment from the tiny vasa vasorum. Some veins, typically in the legs, contain valves that regulate the one-way flow of blood toward the heart ([Fig. 32.23](#)). These valves are folds of the tunica intima and are structurally similar to the semilunar valves of the heart. Backflow in veins of the legs is stopped as the

flaps of the valves fill with blood and block the vessel. The position of the valves also facilitates blood flow in the proper direction during venous compression. When a person stands up, contraction of the skeletal muscles of the legs compresses the deep veins of the legs and assists the flow of blood toward the heart. This important mechanism of venous return is called the *muscle pump* (see Fig. 32.23).

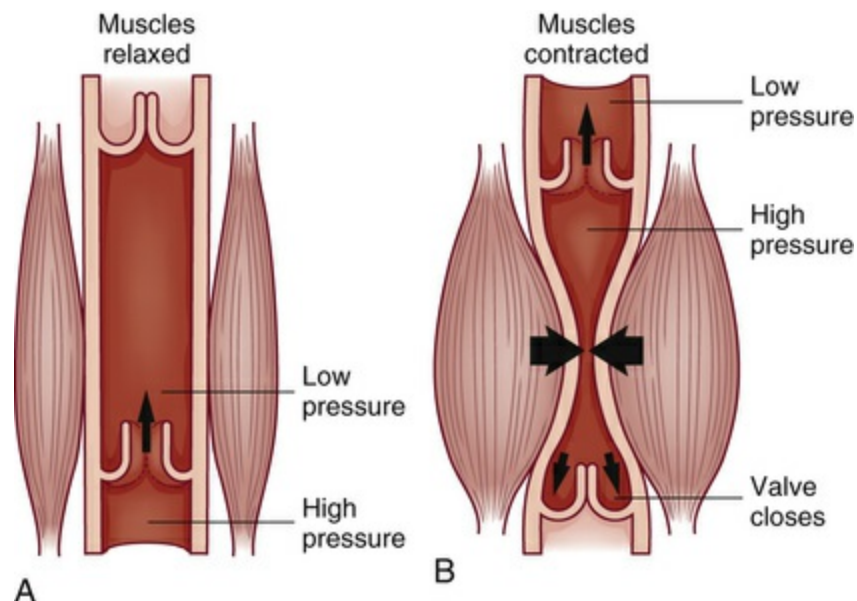

FIGURE 32.23 Venous Valves and the Muscle Pump. In veins, one-way valves aid circulation by preventing backflow of venous blood when pressure in a local area is low. A, Blood is moved toward the heart as valves in the veins are forced open by pressure from the volume of blood downstream and the neighboring muscles are relaxed. B, When pressure below the valve drops, blood begins to flow backward but fills the “pockets” formed by the valve flaps, pushing the flaps together and thus blocking further backward flow. Contraction in the adjacent muscles and the valves of the systemic veins assists in the return of unoxygenated blood to the right heart.

Factors Affecting Blood Flow

Blood flow, the amount of fluid moved per unit of time, is usually expressed as liters or milliliters per minute (L/min or mL/min). The most important factors that influence blood flow are pressure and resistance, followed by velocity, turbulent versus laminar flow, and compliance.

Pressure and Resistance

Pressure in a liquid system is the force exerted on the liquid per unit area and is expressed clinically as millimeters of mercury (mmHg), or torr (1 torr = 1 mmHg). Blood flow to a specific organ depends partly on the pressure difference between the arterial and venous vessels supplying that organ. Fluid moves from the arterial “side” of the capillaries, a region of greater pressure, to the venous side, a region of lesser pressure.

Resistance is the opposition to blood flow. Most opposition to blood flow results from the diameter and length of the blood vessels. Changes in blood flow through an organ result from changes in the vascular resistance within the organ because of increases or decreases in vessel diameter and the opening or closing of vascular channels. Resistance in a vessel is inversely related to blood flow; that is, increased resistance leads to decreased blood flow. **Poiseuille's law** indicates that resistance is directly related to tube length and fluid viscosity (blood viscosity) and inversely related to the radius of the tube to the fourth power (r^4). Blood flow is inversely related to resistance so that the greater the resistance in a vascular bed or tissue, the lower the blood flow. Resistance to flow cannot be measured directly but it can be calculated if the pressure difference and flow volumes are known. Resistance to blood flow in a single vessel is determined by the radius and length of the blood vessel and by the blood viscosity.

Clinically the most important factor determining resistance *in a single vessel* is the **radius** (diameter) of the vessel's lumen. Small changes in the lumen's radius lead to large changes in vascular resistance. Clinically, vasoconstriction will contribute to an increase in resistance whereas vasodilation will cause a decrease in resistance that may be reflected by a fall in blood pressure. Because vessel length is relatively constant and lumen size is quite variable, length is not as important as lumen size in determining flow through a single vessel. Because viscosity is relatively constant, blood vessel radius is usually the key factor in determining total peripheral resistance. An exception to this rule is when red blood cell volume, measured as hematocrit, is

elevated, which is relatively rare. Conditions with elevated hematocrits include a lack of body water, cyanotic congenital heart disease (see [Chapter 34](#)), or polycythemia (see [Chapter 28](#)) and can lead to increased cardiac work as a result of increased vascular resistance.

Resistance to flow through a *system of vessels*, or **total resistance**, depends not only on characteristics of individual vessels but also on whether the vessels are arranged in *series* (end-to-end) or in *parallel* (side-to-side) and on the total cross-sectional area of the system. Vessels arranged in parallel provide less resistance than vessels arranged in series. Blood flowing through the distributing arteries, beginning with branches off the aorta and ending at arterioles in the capillary bed, encounters more resistance than blood flowing through the capillary bed itself, where flow is distributed among many short, tiny branches arranged in parallel ([Fig. 32.24](#)). The total cross-sectional area of the arteriolar system is greater than that of the arterial system, yet the greater number of arterioles arranged in series leads to great resistance to flow in the arteriolar system. In contrast, the capillary system has a larger number of vessels arranged in parallel than the arteriolar system, and the total cross-sectional area is much greater; thus there is lower resistance overall through the capillary system. The resulting slow velocity of flow in each capillary is optimal for capillary-tissue exchange.

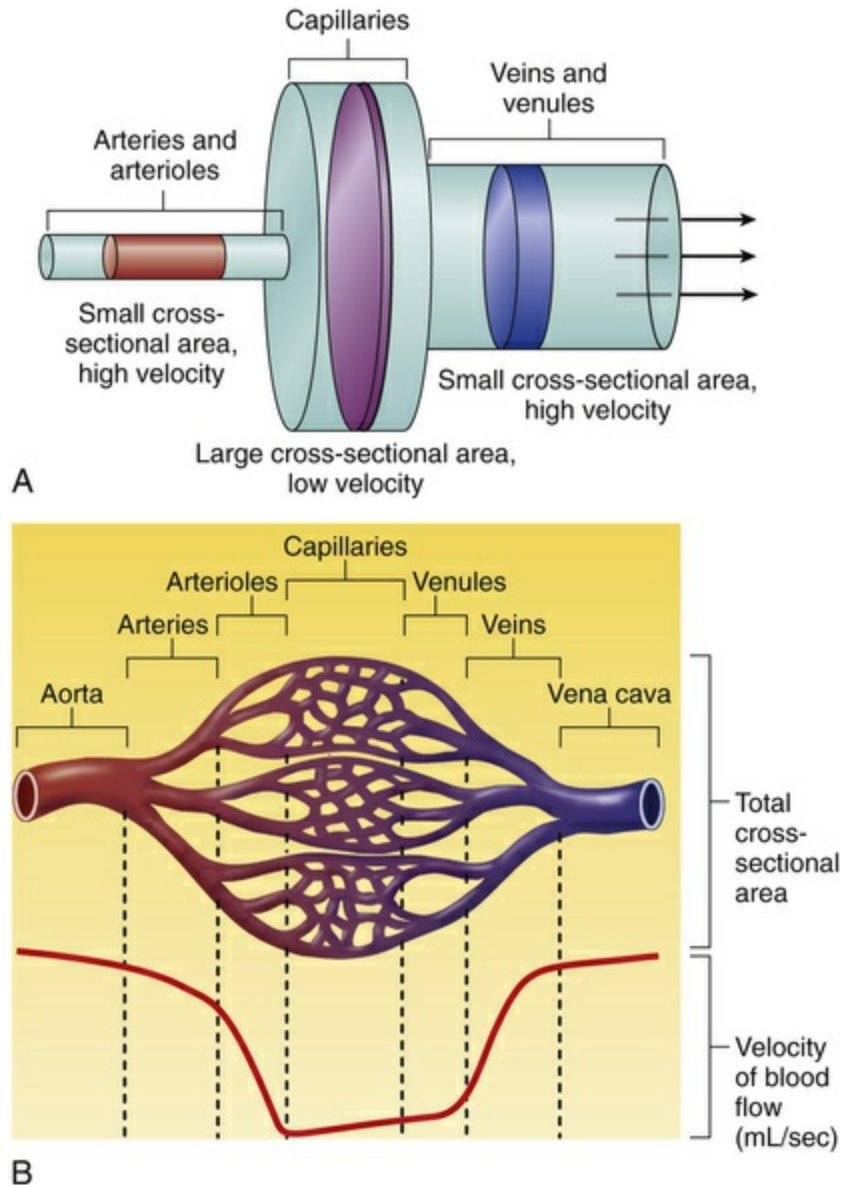

FIGURE 32.24 Relationship Between Cross-Sectional Area and Flow Rate of Blood. As can be seen in the simple diagram (A) and the blood vessel chart (B), blood flows with great speed in the large arteries. However, branching of arterial vessels increases the total cross-sectional area of the arterioles and capillaries, reducing the flow rate. When capillaries merge into venules and venules merge into veins, the total cross-sectional area decreases, causing the flow rate to increase. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Velocity

Blood velocity, or *speed*, is the *distance* blood travels in a unit of time, usually centimeters per second (cm/sec). Blood velocity is directly

related to blood flow (*amount* of blood moved per unit of time) and inversely related to the cross-sectional area of the vessel in which the blood is flowing (see [Fig. 32.24](#)). As blood moves from the aorta to the capillaries, the total cross-sectional area of the vessels increases and the velocity decreases.

Viscosity

Flow varies inversely with the **viscosity**—thick, sticky consistency of the fluid. Thick fluids move more slowly and cause greater resistance to flow than thin fluids—just think of honey as compared to water. The viscosity of blood depends on red cell content. The greater the percentage of red cells in the blood, the more viscous the blood. This relationship is expressed as the **hematocrit**—the ratio of the volume of more red blood cells to the volume of whole blood (see [Chapter 28](#)). A high hematocrit value reduces flow through the blood vessels, particularly the microcirculation (arterioles, capillaries, venules).

Laminar Versus Turbulent Flow

Flow through any tubular system can be either laminar or turbulent. Blood flow through the vessels, except where vessels split or branch, is mainly laminar. In **laminar flow**, concentric layers of molecules move “straight ahead.” Each concentric layer flows at a different velocity ([Fig. 32.25](#)). The cohesive attraction between the fluid and the vessel wall prevents the molecules of blood that are in contact with the wall from moving. The next thin layer of blood is able to slide slowly past the stationary layer and so on until, at the center, the blood velocity is greatest. The centermost concentric layer of fluid is not slowed by friction against the vessel wall. Large vessels have room for a large center layer; therefore they have less resistance to flow and greater flow and velocity than smaller vessels.

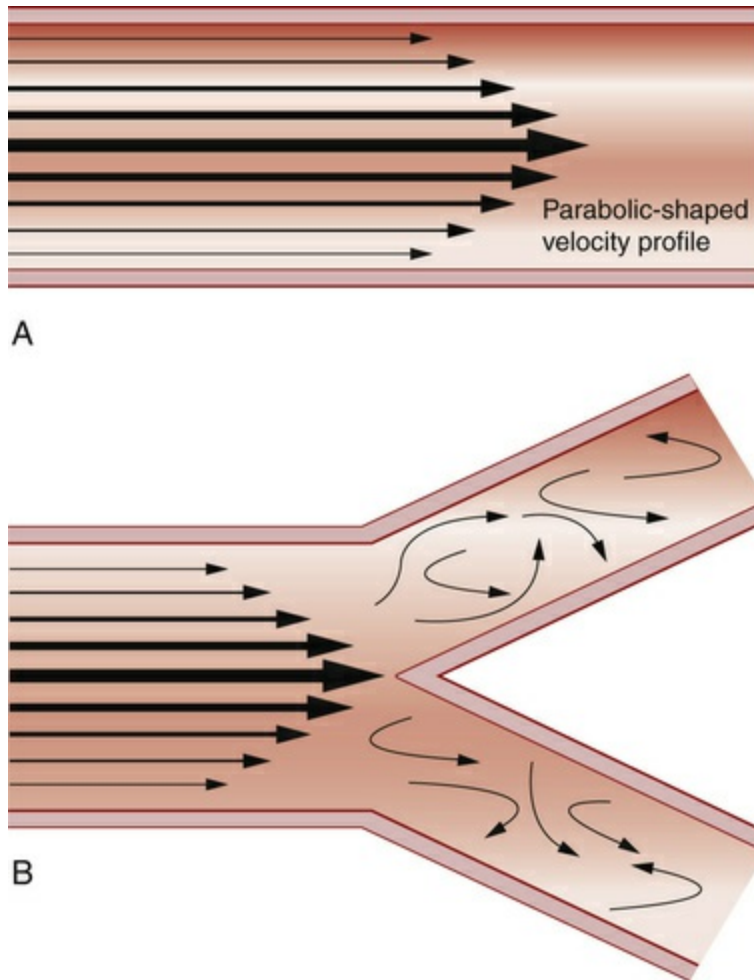

FIGURE 32.25 Laminar and Turbulent Flow. A, Laminar flow. Fluid flows in long smooth-walled tubes as if it is composed of a large number of concentric layers. B, Turbulent flow is caused by numerous small currents flowing crosswise or oblique to the long axis of the vessel, resulting in flowing whorls and eddy currents. (Adapted from Seeley RR, Stephens TD, Tate P: *Anatomy and physiology*, ed 3, St Louis, 1995, Mosby.)

Where flow is obstructed, the vessel turns, or blood flows over rough surfaces; it becomes **turbulent** with whorls or eddy currents that produce noise, causing a murmur to be heard on auscultation. Resistance increases with turbulence, which frequently occurs in areas with atherosclerotic plaques. **Wall shear stress (WSS)** is the complex interaction between the vessel wall's endothelial layer and blood hemodynamics. Much investigation is on the consequences of lower WSS and the promotion of plaque development distal to an induced stenosis.⁴¹ Clarifying WSS and the perivascular changes with inflammation, macrophage activation, medial thinning, and plaque

disruption is critical.

Vascular Compliance

Vascular compliance is the increase in volume a vessel is able to accommodate for a given increase in pressure. Compliance depends on the factors related to the nature of a vessel wall, such as the ratio of elastic fibers to muscle fibers in the vessel wall. Elastic arteries are more compliant than muscular arteries; the veins are more compliant than either type of artery because they have less smooth muscle. Because they are more compliant, veins serve as storage areas for the circulatory system.

Compliance determines a vessel's response to pressure changes. For example, with a very small increase in pressure, a large volume of blood can be accommodated by the venous system. In the less compliant arterial system, where smaller volumes and higher pressures are normal, small variations in pressure cause little or no change in the volume of blood within the arterial vessels.

Stiffness is the opposite of compliance. Several conditions and disorders can increase vascular stiffness, with the most common being aging and arteriosclerosis (see [Chapter 33](#) and section on aging at the end of this chapter). Arteriosclerosis increases the rigidity or stiffness of arterial walls, which in turn increases peak arterial pressure at a given volume of blood.

Regulation of Blood Pressure

Arterial Pressure

Arterial pressure is determined by the cardiac output multiplied by the peripheral resistance ([Fig. 32.26](#)). The **systolic blood pressure** is the highest arterial blood pressure following ventricular contraction or systole. The **diastolic blood pressure** is the lowest arterial blood pressure that occurs during ventricular filling or diastole. The **mean arterial pressure (MAP)**, which is the average pressure in the arteries throughout the cardiac cycle, depends on the elastic properties of the arterial walls and the mean volume of blood in the arterial system.

MAP can be approximated from the measured values of the systolic (P_s) and diastolic (P_d) pressures as follows:

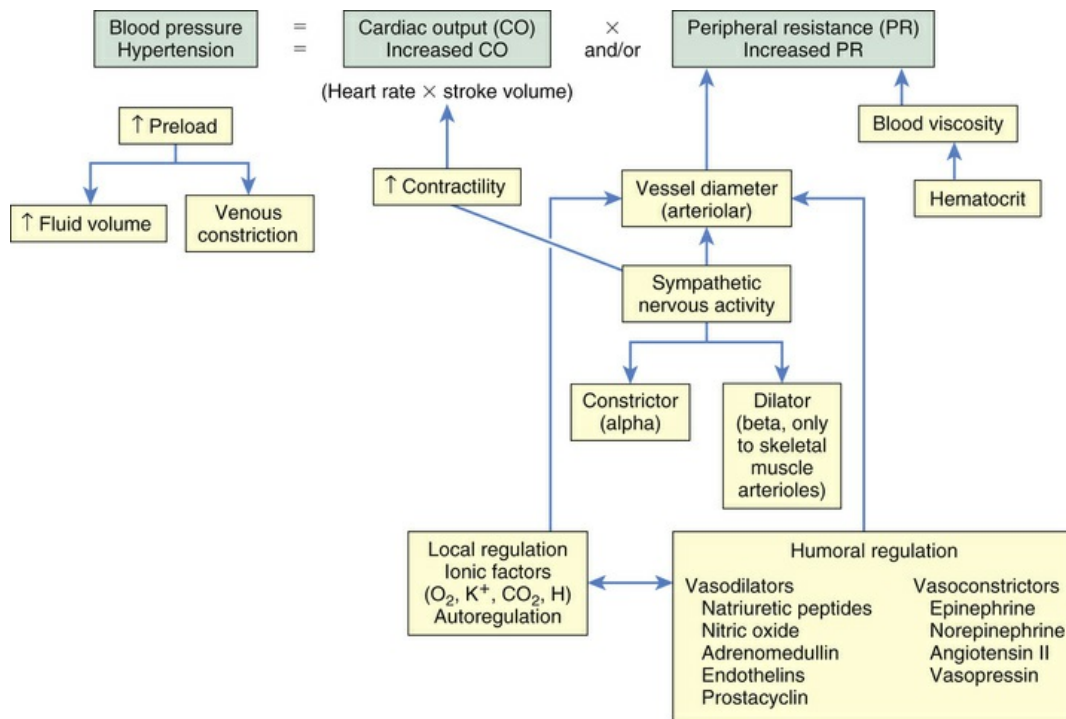

FIGURE 32.26 Factors Regulating Blood Pressure.

$$MAP = P_d + \frac{1}{3}(P_s - P_d)$$

The normal range for the MAP is 70 to 110 mmHg.⁴² The difference between the systolic pressure and diastolic pressure ($P_s - P_d$) is called the **pulse pressure** and typically is between 40 and 50 mmHg.⁷ Pulse pressure is directly related to arterial wall stiffness and stroke volume.

During a wide range of physiologic conditions, including changes in body position, muscular activity, and circulating blood volume, arterial pressure is regulated within a fairly narrow range to maintain tissue **perfusion**, or blood supply to the capillary beds. The major factors and relationships that regulate arterial blood pressure are summarized in Fig. 32.26.

Effects of Cardiac Output

The cardiac output (minute volume) of the heart can be changed by alterations in heart rate, stroke volume (volume of blood ejected during each ventricular contraction), or both. An increase in cardiac output without a decrease in peripheral resistance will cause mean blood pressure and flow rate to increase. The higher arterial pressure increases blood flow through the arterioles. On the other hand, a decrease in the cardiac output causes an immediate drop in mean arterial blood pressure and flow rate (Table 32.5).

TABLE 32.5

FACTORS THAT AFFECT MEAN ARTERIAL PRESSURE AND CAPILLARY FLOW

From Little RC: *Physiology of the heart and circulation*, ed 3, St Louis, 1985, Mosby.

Effects of Total Peripheral Resistance and Blood Volume

Total resistance in the systemic circulation, often referred to as either

systemic vascular resistance (SVR) or total peripheral resistance (TPR), is primarily a function of the diameter of the arterioles. If cardiac output remains constant, arteriolar constriction raises mean arterial pressure by reducing the flow of blood into the capillaries and arteriolar dilation has the opposite effect. Reflex control of total cardiac output and peripheral resistance includes (1) sympathetic stimulation of heart, arterioles, and veins; and (2) parasympathetic stimulation of the heart ([Fig. 32.27](#)). The cardiovascular center in the medulla receives input from arterial baroreceptors and chemoreceptors throughout the vascular system and then modifies vagal and sympathetic output to control heart rate and contractility, plus vascular diameter. Vasoconstriction is regulated by an area of the brainstem that maintains a constant (tonic) output of norepinephrine from sympathetic fibers in the peripheral arterioles. This tonic activity is essential for maintenance of blood pressure.

A

B

FIGURE 32.27 Baroreceptor and Chemoreceptor Reflex Control of Blood Pressure. **A**, Baroreceptor reflexes. Baroreceptors located in the carotid sinuses and aortic arch detect changes in blood pressure. Action potentials are conducted to the cardiorespiratory and vasomotor centers. The heart rate can be decreased by the parasympathetic system; the heart rate and stroke volume can be increased by the sympathetic system. The sympathetic system also can constrict or dilate blood vessels. **B**, Chemoreceptor reflexes. Chemoreceptors located in the medulla oblongata and in the carotid and aortic bodies detect changes in levels of blood oxygen, carbon dioxide, or pH. Action potentials are conducted to the medulla oblongata. In response, the vasomotor center can cause vasoconstriction or dilation of blood vessels by the sympathetic system,

and the cardiorespiratory center can cause changes in the pumping activity of the heart through the parasympathetic and sympathetic systems. (From Seeley RR, Stephens TD, Tate P: *Anatomy & physiology*, ed 3, St Louis, 1995, Mosby.)

Baroreceptors.

As discussed earlier, baroreceptors are stretch receptors located mainly in the aorta and the carotid sinus (see Fig. 32.27, A). They respond to changes in smooth muscle fiber length by altering their rate of discharge and supply sensory information to the cardiovascular center in the brainstem. When activated (stretched), the baroreceptors decrease cardiac output by lowering heart rate and stroke volume and peripheral resistance, and thus lower blood pressure.

Arterial Chemoreceptors.

Specialized areas within the medulla oblongata and aortic and carotid arteries are sensitive to concentrations of arterial oxygen (PaO_2), arterial carbon dioxide (PaCO_2), and arterial hydrogen ions (pH) in the blood. Although these *chemoreceptors* are most important for respiratory control, they also transmit impulses to the medullary cardiovascular centers that regulate blood pressure. A decrease in arterial oxygen concentration (hypoxemia), an increase in arterial PaCO_2 concentration, or to a lesser extent a decrease in arterial blood pH causes a reflexive increase (by a dominance of sympathetic impulses) in heart rate, stroke volume, and blood pressure.

Effects of Hormones.

Hormones influence blood pressure regulation through their effects on vascular smooth muscle and blood volume. By constricting or dilating arterioles in organs, hormones can (1) increase or decrease the blood flow in response to the body's needs, (2) redistribute blood volume during hemorrhage or shock, and (3) regulate heat loss. The key **vasoconstrictor hormones** include angiotensin II, **vasopressin** (or antidiuretic hormone), epinephrine, and norepinephrine. The main vasodilator hormones are the atrial natriuretic hormones.

Aldosterone, vasopressin, and the natriuretic hormones can influence stroke volume and thus blood pressure by causing fluid retention or loss.

A variety of other factors, including adipokines and insulin, may be related to the hypertension that occurs with chronic conditions, such as adiposity and diabetes mellitus; but these factors have not been clearly demonstrated to play a role in blood pressure regulation in healthy individuals.⁴³ Adiposity may increase cardiovascular disease (CVD) risk in part through effects on vascular stiffness.⁴⁴ Some research has suggested that the risk of cardiovascular disease and hypertension that often co-occurs with diabetes mellitus is more closely related to insulin resistance than to insulin levels.⁴⁵

Adrenomedullin (ADM) is a vasodilating peptide present in cardiovascular, pulmonary, renal, and other tissues. Because increases in ADM levels are associated with heart failure and myocardial infarction, ADM levels may be useful for risk categorization in people with these conditions.⁴⁶

Vasoconstrictor Hormones.

The vasoconstrictor hormones include epinephrine; norepinephrine; **angiotensin II (Ang II)**, which is part of the renin-angiotensin-aldosterone system (RAAS); and vasopressin (also known as *antidiuretic hormone*). **Epinephrine**, the catecholamine hormone released from the adrenal medulla, causes vasoconstriction in most vascular beds except the coronary, liver, and skeletal muscle circulations. Norepinephrine mainly acts as a neurotransmitter; however, some also is released from the adrenal medulla. When released into the circulation, it is a more potent vasoconstrictor than epinephrine. Under normal circumstances, as vasoconstrictors—angiotensin II and vasopressin—are not thought to have a major role in blood pressure control. Vasopressin and aldosterone, however, affect blood pressure by increasing blood volume through their influence on fluid reabsorption in the kidney and by stimulating thirst. Vasopressin causes the reabsorption of water from tubular fluid in the distal tubule and collecting duct of the nephron. Aldosterone,

the end product of the renin-angiotensin-aldosterone system, stimulates the reabsorption of sodium, chloride, and water from the same locations in the kidney (Fig. 32.28; also see Chapters 3 and 21).

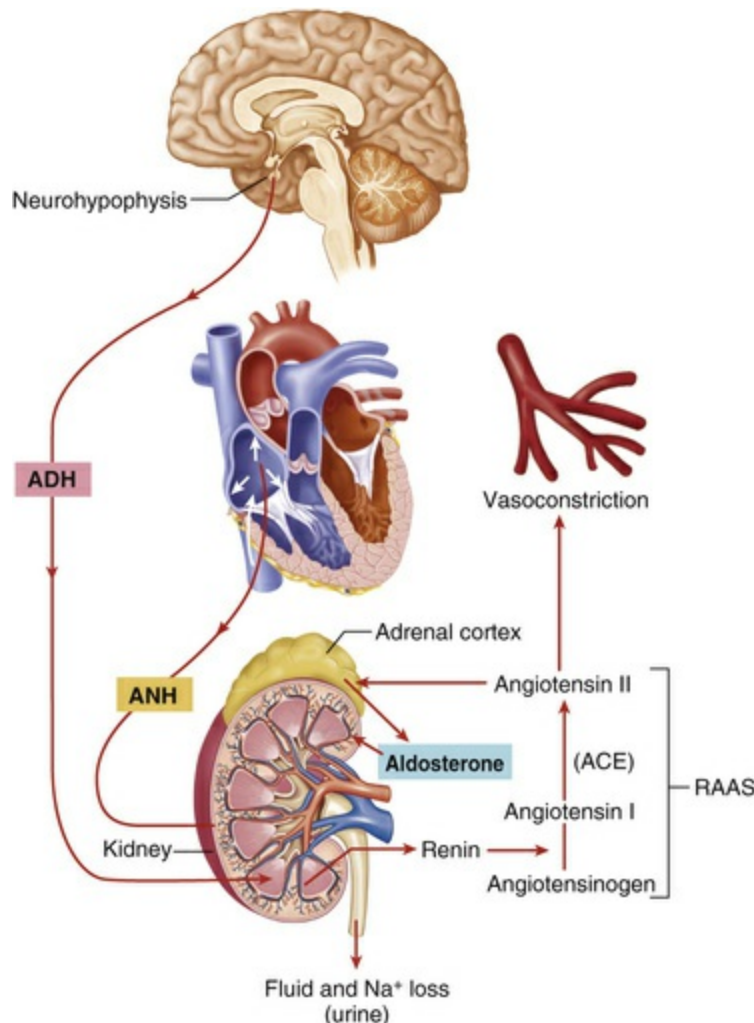

FIGURE 32.28 Three Mechanisms That Influence Total Plasma Volume. The antidiuretic hormone (*ADH*) mechanism and renin-angiotensin-aldosterone system (*RAAS*) tend to increase water, sodium, and chloride retention and thus increase total plasma volume. The atrial natriuretic hormone (*ANH*) mechanism antagonizes these mechanisms by promoting water, sodium, and chloride loss, thus promoting a decrease in total plasma volume. *ACE*, Angiotensin-converting enzyme. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Elsevier.)

Vasodilator Hormones.

The natriuretic peptides (NPs) or hormones, including atrial

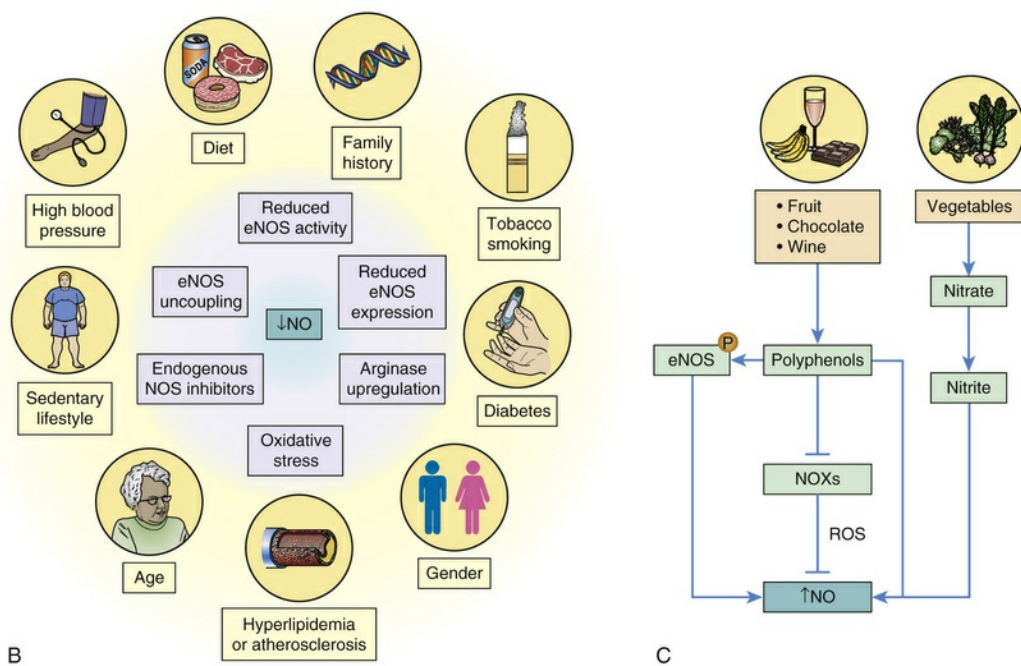

natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin, function as both vasodilators and regulators of sodium and water excretion (natriuresis and diuresis). Increased pressure or diastolic volume in the heart stimulates the release of these peptide hormones. Increased levels of BNP predict increased risk of a poor outcome in heart failure, pulmonary embolism, valvular heart disease, and chronic coronary artery disease.³⁹

Effects of Other Mediators.

Several mediators produced by the vascular endothelium have been demonstrated to cause arteriolar vasodilation or vasoconstriction. Examples of vasodilating mediators include nitric oxide (NO), ADM, the endothelins, and prostacyclin. **Nitric oxide (NO)** is a soluble gas continuously synthesized from the amino acid L-arginine in endothelial cells by the calcium-calmodulin–dependent enzyme nitric oxide synthase (NOS).⁴⁷ NO has a wide range of biologic properties that maintain vascular homeostasis, including modulation of vascular dilator tone, regulation of local cell growth, and protection of the vessel from injurious consequences of platelets and cells circulating in blood ([Fig. 32.29](#)).

A

B

C

FIGURE 32.29 Importance of Nitric Oxide in Health and Disease and Lifestyle Factors Associated with Nitric Oxide Bioavailability. **A**, Nitric oxide in a healthy blood vessel and one with an altered or dysfunctional endothelium. **B**, Lifestyle factors associated with reduced bioavailability of

nitric oxide. C, Dietary polyphenols can increase bioavailable nitric oxide. *BH4*, (6R) 5,6,7,8-tetrahydrobiopterin; *cGMP*, cyclic guanosine monophosphate; *eNOS*, endothelial nitric oxide synthase; *GTP*, guanosine triphosphate; *sGC*, soluble guanylate cyclase. (Adapted from Lundberg JO, Gladwin MT, Weitzberg E: *Nat Rev Drug Discov* 14:623–641, 2015.)

Therefore NO plays a crucial role in the normal endothelial function. An emerging list of conditions, including those commonly associated as risk factors for atherosclerosis such as hypertension, hypercholesterolemia, smoking, diabetes mellitus, and heart failure, is associated with diminished release of nitric oxide into the arterial wall because of impaired synthesis or excessive oxidative degradation.⁴⁷ The decreased production of NO in these pathologic states causes serious problems in endothelial stability.

The velocity of blood movement within the arterioles causes shear stress at the vascular endothelial surface that in turn is the stimulus that causes the endothelial cells to produce these vasodilator substances. The flow-mediated dilation (FMD) test is used to evaluate endothelial function and to predict the risk of cardiovascular disease. A reduction in FMD is predictive of increased risk.⁴⁸

ADM, a peptide with strong vasodilatory activity, is present in numerous tissues. It is a member of the calcitonin gene-related peptide family. Its exact role in adult human cardiovascular function and disease is unclear, but it has been found to have numerous cardiovascular effects, including a role in fetal cardiovascular system development and vasodilation

The *endothelins* are a family of three structurally similar peptides (ET-1, ET-2, and ET-3) and four receptors produced in cells in the vascular smooth muscle, the endothelium, the kidneys, and other organs. Because endothelin binding to the type A receptor causes vasodilation and natriuresis whereas binding to type B receptor causes the opposite response—vasoconstriction plus sodium and water retention, the understanding of the physiologic and pathologic roles has been complex.⁴⁹ Inhibitors to endothelin-1 have been approved for the treatment of pulmonary hypertension.⁵⁰

Prostacyclin is a vasodilator that is produced by the actions of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. It also has

the additional properties of opposing clot formation (antithrombotic), decreasing platelet activity, and inhibiting the release of growth factors from macrophages and the endothelial cells.⁵¹ Nonsteroidal antiinflammatory drugs (NSAIDs) that inhibit these cyclooxygenases have been associated with cardiovascular disease risk in healthy people and in those with a known cardiovascular disease.^{52,53}

Nattokinase (NK) activates multiple fibrinolytic and antithrombotic pathways simultaneously, either directly or indirectly (see [Nutrition & Disease: Nattokinase for the Prevention of Thrombosis](#)). In summary, NK intake could be an exceptional fibrinolytic/anticoagulant agent to reduce the risk of thrombosis in humans.

Nutrition & Disease

Nattokinase for the Prevention of Thrombosis

Nattokinase (NK) is an enzyme found in natto, a traditional food made of soybeans fermented with *Bacillus subtilis*. Nattokinase has strong fibrinolytic properties. It has been consumed for more than 1000 years, especially in the Eastern Kanto region of Japan. Natto (whole food) has a cheeselike appearance, is sticky, and has a strong smell. Nattokinase is available as an oral capsule and is stable in the gastrointestinal tract. Other names for the enzyme nattokinase include natto extract, NK, subtilisin NAT, and fermented soybeans. For the first time, investigators provide evidence of NK's (nattokinase) ability to enhance fibrinolysis and antithrombosis at the same time, after a single dose of oral NK administration in humans. Ero and colleagues presented the first bioavailability data of NK in humans by enzyme-linked immunosorbent assay. From both studies the dosage used was 2,000 fibrinolytic units NK administration, with NK serum activity between 2 through 24 hours in healthy subjects, and an increase in fibrinolysis and anticoagulant indicators between 2 and 8 hours. Other data from animal and human studies have evaluated the actions of nattokinase. Using a clot lysis assay in vitro, the cleavage of cross-linked fibrin by NK

was six times more efficient than that by plasmin. In rats, NK was four times more effective than plasmin at dissolving a thrombus.

Data from Cesarone MR et al: *Angiology* 54(5):531–539, 2003; Dabbagh F et al: *Appl Microbiol Biotechnol* 98(22):9199–9206, 2014; Ero MP et al: *Altern Ther Health Med* 19(3):16–19, 2013; Fujita M et al: *Biochem Biophys Res Commun* 197:1340–1347, 1993; Fujita M et al: *Biol Pharm Bull* 18(10):1387–1391, 1995; Fujita M et al: *Fibrinolysis* 9:157–164, 1995; Kurosawa Y et al: *Sci Rep* 5:11601, 2015; Natural Database: *Nattokinase. Venous Pressure

The main determinants of venous blood pressure are (1) the volume of fluid within the veins and (2) the compliance (distensibility) of the vessel walls. Typically, the venous system accommodates approximately 66% of the total blood volume with venous pressure averaging less than 10 mmHg. The systemic arteries accommodate about 11% of the total blood volume, with an average arterial pressure (blood pressure) of about 100 mmHg; the remainder of the blood volume is within the heart, capillaries, and pulmonary circulation.⁴²

The sympathetic nervous system controls compliance. The walls of the veins are highly innervated by sympathetic fibers that control venous smooth muscle. Sympathetic innervation to the veins results in an increase in smooth muscle tone rather than vasoconstriction, which occurs in arteries. This increased smooth muscle tone stiffens the walls of the veins, reducing distensibility and increasing venous blood pressure, thus forcing more blood through the veins and into the right heart.

Two other mechanisms that increase venous pressure and venous return to the heart are (1) the skeletal muscle pump and (2) the respiratory pump. During skeletal muscle contraction the veins within the muscles are partially compressed, causing a decrease in venous capacity and increased return to the heart. The respiratory pump acts during inspiration, when the veins of the abdomen are partially

compressed by the downward movement of the diaphragm. Increased abdominal pressure moves blood toward the heart.

Regulation of Coronary Circulation

Coronary blood flow is directly proportional to the perfusion pressure and inversely proportional to the vascular resistance of the coronary bed. **Coronary perfusion pressure** is the difference between pressure in the aorta and pressure in the coronary vessels. Thus aortic pressure is the driving pressure that propels the perfusion of myocardial vessels. Vasodilation and vasoconstriction maintain coronary blood flow despite stresses imposed by the constant contraction and relaxation of the heart muscle and despite shifts (within a physiologic range) of coronary perfusion pressure.

Several unique anatomic factors influence coronary blood flow. Because of their location, the aortic valve cusps can obstruct coronary blood flow by pushing against the openings of the coronary arteries during systole. Also during systole, the coronary arteries are compressed by ventricular contraction. The resulting **systolic compressive effect** is particularly evident in the subendocardial layers of the left ventricular wall and can greatly increase resistance to coronary blood flow. Therefore most coronary blood flow in the left ventricle occurs during diastole. During the period of systolic compression, when flow is slowed or stopped, oxygen is supplied by **myoglobin**, a protein in heart muscle that binds oxygen during contraction and supplies oxygen to the myocardium.

Autoregulation

Autoregulation (automatic self-regulation) enables organs to regulate blood flow by altering the resistance (diameter) in their arterioles. Autoregulation in the coronary circulation maintains the blood flow at a nearly constant rate at perfusion pressures (mean arterial pressure) between 60 and 140 mmHg when other influencing factors are held constant. Thus autoregulation helps to ensure constant coronary blood flow despite shifts in the perfusion pressure within the stated range.

Given that blood flow is directly related to pressure and inversely related to resistance, for flow to stay constant as pressure decreases, resistance also has to decrease; thus the mechanism(s) underlying autoregulation must relate to control of smooth muscle contraction in the arteriolar walls. Although the exact mechanisms underlying autoregulation are not known, research has indicated that factors influencing calcium release with the myocardium are involved and perhaps also the accumulation of vasodilatory products of metabolism, such as adenosine.^{32,53}

Lymphatic System

The **lymphatic system** is a one-way network of lymphatic vessels and lymph nodes (Figs. 32.30 and 32.31) that is important for fluid balance, immune function, and transport of lipids, hormones, and cytokines. Every day about 3 liters of fluid filters out of venous capillaries in body tissues and is not reabsorbed. This fluid becomes the lymph that is carried by the lymphatic vessels to the chest where it enters the venous circulation. The lymphatic vessels run in the same sheaths with the arteries and veins. (Lymph nodes and lymphoid tissues are described in Chapters 7 and 28.) In this pumpless system a series of valves ensures one-way flow of the excess interstitial fluid (then called *lymph*) toward the heart. The lymphatic capillaries are closed at the distal ends (Fig. 32.32).

FIGURE 32.30 Role of the Lymphatic System in Fluid Balance. Fluid from plasma flowing through the capillaries moves into interstitial spaces. Although most of this interstitial fluid is either absorbed by tissue cells or reabsorbed by blood capillaries, some of the fluid tends to accumulate in the interstitial spaces. This lymph then diffuses into the lymphatic vessels that carry it to the lymph nodes and then into the systemic venous blood. Green is used to diagram the lymphatic vessels although the lymphatic vessels, particularly the smaller ones, are almost transparent. (Modified from Thibodeau GA, Patton KT: *Structure & function of the body*, ed 13, St Louis, 2008, Elsevier.)

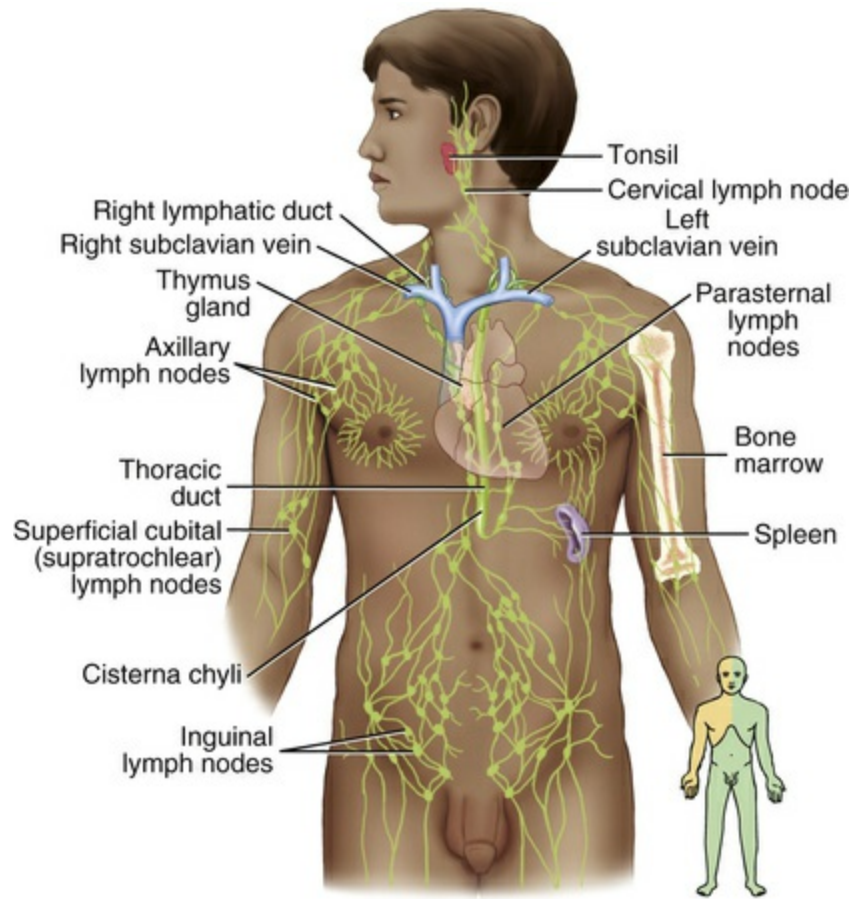

FIGURE 32.31 Principle Organs of the Lymphatic System. (From VanMeter KC, Hubert RJ: *Microbiology for the healthcare professional*, St Louis, 2010, Mosby.)

FIGURE 32.32 Lymphatic Capillaries. A, Schematic representation of lymphatic capillaries. B, Anatomic components of microcirculation.

Lymph consists primarily of water and small amounts of dissolved proteins, mostly albumin, which are too large to be reabsorbed into the less permeable blood capillaries. Lymph also carries two types of cells—lymphocytes and antigen-presenting cells. The antigen-presenting cells are carried to the next lymph node in the system whereas lymphocytes traffic between lymph nodes. Once within the

lymphatic system, lymph travels through **lymphatic venules** and **veins** that drain into one of two large ducts in the thorax—the right lymphatic duct and the thoracic duct. The **right lymphatic duct** drains lymph from the right arm and the right side of the head and thorax, whereas the larger **thoracic duct** receives lymph from the rest of the body (see [Fig. 32.31](#)). The right lymphatic duct and the thoracic duct drain lymph into the right and left subclavian veins, respectively.

Lymphatic veins are thin walled, like the veins of the cardiovascular system. In the larger lymphatic veins, endothelial flaps form valves similar to those in the blood-carrying veins (see [Fig. 32.32](#)). The valves permit lymph to flow in only one direction because lymphatic vessels are compressed intermittently by contraction of skeletal muscles, pulsatile expansion of an artery in the same sheath, and contraction of the smooth muscles in the walls of the lymphatic vessel.

As lymph is transported toward the heart, it is filtered through thousands of bean-shaped lymph nodes clustered along the lymphatic vessels (see [Fig. 32.31](#)). Lymph enters the nodes through several **afferent lymphatic vessels**, filters through the sinuses in the nodes, and leaves by way of **efferent lymphatic vessels**. Lymph flows slowly through a node, which facilitates the phagocytosis of foreign substances within the node by antigen-presenting cells and the entry of mature but naïve B and T lymphocytes, which then circulate through the body, moving from one lymph node to the next while waiting for a chance encounter with the antigen to which they are programmed to respond. (Phagocytosis is described in [Chapter 7](#).)

Tests of Cardiovascular Function

Assessment of the individual with suspected cardiovascular disorders begins with a thorough history for determination of risk factors and symptoms. A careful physical examination looking for evidence of tissue ischemia, pulmonary congestion, and cardiac dysfunction is next. Blood samples are taken and sent for a variety of tests. For many individuals, these basic steps will be complemented with methods that measure heart and vascular function with greater specificity.

Cardiac function can be evaluated using indicators calculated from pressures and flow rates in the heart and vessels. [Table 32.6](#) defines the indicators most often used in the clinical setting. The normal values for several testing methods are different for men and women.^{54,55} This textbook's inside back cover includes normal blood values for common laboratory tests.

TABLE 32.6

INDICATORS OF CARDIAC FUNCTION

INDICATOR	DEFINITION*	COMMON CAUSE OF ABNORMALITY
Heart rate (HR)	Number of heartbeats (cardiac cycles) per minute	Ischemia, electrolyte disturbances, drug toxicity
	Normal adult value: 70 beats/min	
Cardiac output (CO)	Amount of blood (in L) moved by the heart in 1 min	Decrease indicates heart failure
	Normal range: 4–8 L/min	Increase indicates decreased systemic vascular resistance, common in sepsis
Cardiac index (CI)	Relationship between cardiac output and body surface area (BSA, in m ²)	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 2.8–4.2 L/min/m ²	
Stroke volume (SV)	Amount of blood (in mL) ejected by the left ventricle during systole (i.e., per beat)	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 60–100 mL/beat	
Stroke volume index (SVI)	Relationship between stroke volume and body surface area	Decrease indicates heart failure Increase indicates decreased systemic vascular resistance, common in sepsis
	Normal range: 33–47 mL/beat/m ²	
Oxygen consumption index (VO ₂)	Amount of oxygen (in mL) consumed per minute in relation to BSA	Decrease: sedation, anesthesia, hypothermia Increase: elevated temperature, sepsis, seizures
Stroke work index (SWI)	Amount of work (expressed as done) by the left or right ventricle per systole per square meter of BSA	Decreases within specific ranges indicate cardiogenic or hypovolemic shock (see Chapter 49)
	Normal value: 35 g/m ²	Increase: elevated systemic vascular resistance

Systemic mean arterial pressure (MAP)	Mean blood pressure (in mmHg) in the systemic arteries	Elevated: epinephrine release, diseases of arteries, primary hypertension Decreased: cardiac failure, decreased vascular resistance of sepsis
	Normal range: 70–100 mmHg	
Pulmonary vascular resistance (PVR)	Relationship among cardiac output, preload, and afterload, expressed as units of force of resistance per second per centimeter of water	Increased: acute respiratory distress syndrome (ARDS), pneumonia, primary pulmonary hypertension, congestive heart failure Decreased: late shock
	Normal value: less than 250 dynes/sec/cm ⁻⁵	
Systemic vascular resistance (SVR)	Same definition as for PVR Normal range: 770–1500 dynes/sec/cm ⁻⁵	Increased: epinephrine release Decreased: inflammatory response

*Values given are for adults at rest.

Cardiac and Coronary Artery Evaluation

Many sophisticated tests are used to evaluate and diagnose cardiac or coronary artery diseases, and new ones are being tested each year. Some of the more commonly used modalities include chest x-ray, electrocardiography, echocardiography, stress testing, computed tomography (CT) and magnetic resonance imaging (MRI), technetium scanning, electrophysiology studies, and catheterization with angiography.

Chest Radiograph Examination

Chest x-rays allow for the examination of the size and contour of the heart and related structures. Evidence of chamber enlargement, pericardial disease, pulmonary edema, valvular calcification, ventricular hypertrophy, and pathology of the great vessels may be visualized. Chest x-ray also is useful to assess for appropriate placement of invasive cardiac conduction devices and for any complications caused by these devices (e.g., pneumothorax or hemothorax; see [Chapter 36](#)). A chest x-ray examination is a routine

part of a cardiac examination. The most commonly obtained views are posteroanterior (PA) and lateral, with the individual standing upright and the lungs fully expanded. In those individuals confined to bed, an anteroposterior (AP) view may be obtained but is usually of lesser quality than the PA view.

Electrocardiography

Electrocardiography, typically a 12-lead electrocardiogram (ECG), gives information about heart rate and rhythm; the effects of activities of daily life, exercise, electrolytes, drugs, and disease on electrical activity in the heart; and the electrical orientation of the cardiac muscle. An ECG provides no direct information about the contractile state or mechanical performance of the heart.

Serial 12-lead ECGs are of primary importance in establishing the presence of myocardial ischemia and infarction or conduction defects and dysrhythmias. This examination has become part of the routine hospital preadmission/admission assessment, even when the admitting diagnosis is not cardiac in nature, because it establishes baseline information about the electrical function of the heart. Also, recent ECGs can be compared with ECGs obtained from the same individual in the past. Changes in the ECG over time assist in determining the cause, amount, or nature of changes in cardiac anatomy and physiology. Ambulatory electrocardiographic or Holter monitoring is used to evaluate rhythm changes that may occur in persons during activities of daily living. Cell phone technology also is rapidly advancing to enable ECG recording and relaying to healthcare providers.

Echocardiography

Echocardiography is the most effective and widely used noninvasive modality for evaluating the structures of the heart. Ultrasound beams reflected by cardiovascular structures produce shapes that can be visualized and allow for recognition of altered cardiac anatomy.⁵⁶ It is used to evaluate for suspected coronary artery disease, heart failure,

valvular disease, infective endocarditis, cardiomyopathies, pericardial disease, prosthetic valve function, congenital heart disease, and aortic diseases. Through the use of M-mode, two- and three-dimensional techniques with Doppler and color flow imaging, accurate assessments of cardiac output, ejection fraction, and valvular function can be obtained.^{56,57} Advances in technology now allow both intracardiac and transesophageal echocardiography for evaluation of the heart anatomy, although anesthesia is required for the transesophageal technique.⁵⁸

Exercise or Stress Testing

Cardiac activity during exercise is examined during a stress test when an intervention is used to increase myocardial work. Stress testing elicits signs and symptoms of heart disease and coronary artery disease that may not appear at rest. Echocardiography or continuous 12-lead ECG and blood pressure measurements are obtained before, during, and after the study. Cardiac stress from exercise is usually induced by having the individual walk on a treadmill. Other, less frequently used forms of exercise include static exercise (hand ergometry or chemical stress), stair climbing (the Stairmaster's double two-step), arm ergometry, and bicycle ergometry. The individual exercises until the maximal heart rate for gender and age is reached or until other subjective or objective indicators of cardiac dysfunction or distress appear. Subjective indicators include chest pain, extreme fatigue, extreme dyspnea, leg pain, or the individual's request to stop the test. Objective criteria are ST-segment elevation or depression, SA node or atrial dysrhythmias, AV node dysrhythmias, ventricular dysrhythmias, elevated or decreased blood pressure, signs of cerebral hypoxia, and signs of circulatory insufficiency. One limitation of this test is that it cannot be used in persons whose capacity for exercise is limited.

Stress testing also may be used to evaluate either fitness for noncardiac surgery or progress in recovery after myocardial infarction or cardiac surgery. Graded exercise in individuals with low- to moderate-risk chest pain evaluated in an emergency department can

be used as a prognostic indicator of adverse cardiac events. When a differential diagnosis for chest pain has been difficult to determine, stress testing may help distinguish coronary artery insufficiency from other causes of pain. The risks associated with stress testing include dysrhythmias, myocardial infarction, and death. The risk is greater when the test is performed soon after an acute ischemic event.

Stress testing with ECG monitoring may not be sensitive enough to detect and localize areas of the myocardium at risk for ischemia and infarction. Currently, most stress testing includes the injection of a radiotracer that is absorbed by active heart cells. When the heart is scanned, during and after stress testing, areas where the radiotracer is not taken up by ischemic cells can be seen and those locations indicate areas of myocardial damage.

Single-Photon Emission Computed Tomography

Single-photon emission computed tomography (SPECT) is typically used to evaluate individuals for coronary artery disease and myocardial ischemia during stress testing. A radiotracer (usually thallium-201) is injected intravenously and is absorbed and retained for a while by healthy myocytes.⁵⁹ Photons are emitted from the radiotracer in the myocardium in proportion to perfusion of the tissue. A gamma camera visualizes the photons, and views are taken from 360 degrees by CT, which digitizes the information and provides a three-dimensional view of myocardial perfusion. Data about where the myocardium absorbs the tracer normally, slowly, or not at all can be correlated with existing myocardial disease and can help quantify ischemic risk. A new development, high-speed SPECT, has the advantage of taking less time and, thereby, requiring less radiotracer, which decreases radiation exposure for the person being examined.⁵⁹

Computed Tomography (CT) and Magnetic Resonance Imaging (MRI)

Computed tomography (CT) and magnetic resonance imaging (MRI) are used to evaluate cardiac anatomy and physiology. New

techniques, including ECG gating (timing of data gathering to the cardiac cycle), electron beam CT, and spiral CT, have improved the ability of tomography to visualize cardiac structures. The high resolution of CT can provide information about calcification of coronary vessels and cardiac valves. Information about coronary artery calcification is being used to improve risk classification for coronary artery disease.⁶⁰ It also is a tool for evaluating large-vessel disease. Concerns and debate continue, however, about the radiation risks and use of variable protocols. The International Commission on Radiological Protection (ICRP) recently released a report on radiological protection in cardiology.⁶¹

MRI is based on the principle that the frequency of energy (resonant frequency) given up by a nucleus is exactly proportional to the surrounding magnetic field (see [Chapter 15](#)). The anatomy and physiology of the great blood vessels and myocardium are depicted in three dimensions with excellent resolution. Ventricular function can be evaluated using indexes of ventricular function, such as ejection fraction. Rapidly moving sequences (MRI) can determine regional wall motion and myocardial deformation. Flow direction and velocity also can be quantitatively determined. Stress testing also can be done with MRI using the drug dobutamine to increase the cardiac workload instead of exercise.⁶²

Technetium Scanning

Radiopharmaceuticals labeled with ^{99m}technetium preparations, such as sestamibi, teboroxime, and tetrofosmin, are used to image the coronary arteries and myocardium. Technetium pyrophosphate (^{99m}TcPYP) is injected intravenously into a resting individual during a “hot spot” imaging examination. Two hours after injection the distribution pattern of the radioactive solution is recorded by nuclear scan. During the 2-hour delay, the injected material will have been taken up by infarcted areas of the myocardium, particularly 1 to 3 days after the onset of symptoms. This type of scanning also is done with stress testing using exercise or dobutamine.⁶³ Study results are not definitive during the first 12 hours after an infarct.

Technetium scanning is used when (1) there is a conflicting history for myocardial infarction, (2) there are equivocal ECG abnormalities, or (3) an individual's cardiac enzymes have been elevated because of surgery or trauma. Ongoing research is determining any risks associated with radioactive substances.

Electrophysiology Studies

In-depth evaluation of electrical conduction within the heart can provide important information about the nature and causes of dysrhythmias, such as atrial and ventricular tachycardias and heart block. This evaluation is often referred to as *electrophysiologic mapping* of the myocardium. There are many types of electrophysiology studies that are specific to certain conduction disorders but they have the common goal of documenting abnormal conduction pathways. Furthermore, the techniques used may also allow for ablation of unwanted pathways or the appropriate placement of pacemakers and implantable defibrillators. Mapping can include the use of echocardiography and CT scanning.⁶⁴

One example of an electrophysiology study is AV bundle electrocardiography. Two electrode-tipped catheters are inserted percutaneously into the femoral vein, floated up the inferior vena cava, and positioned in or near the right atrium during AV bundle (His bundle) electrocardiography. AV bundle electrocardiography can detect secondary sites of impulse generation (ectopic foci), as well as accessory pathways of conduction. Other conduction defects and the effects of drugs on conduction also can be illuminated. Risks related to this procedure can be grave and include dysrhythmias, death, vessel or heart perforation, clot or plaque embolization, and kidney failure.

Cardiac Catheterization and Angiography

One or both sides of the heart can be examined using **cardiac catheterization**. This invasive procedure requires the use of fluoroscopy and strict sterile techniques and takes place in a specially equipped catheterization laboratory. Local anesthetic is administered,

and a catheter is introduced percutaneously into the vasculature and passed caudally into the atrium and ventricle. For a right-heart catheterization, the catheter is placed in either the jugular, subclavian, brachial, or femoral veins. The femoral artery is commonly used for a left-heart study. Once the catheter has been guided into the heart chambers, pressures are recorded, blood samples are obtained to examine oxygen content, and a contrast medium is injected to visualize chamber function and valve patency.

Cardiac catheterization provides a means to visualize the chambers of the heart continuously, although for a short time. A great deal of information can be obtained about heart structure and function. Pressures in each chamber and across heart valves can be precisely measured, along with timing of events in the cardiac cycle. Of particular value is the ability to compare the oxygen content of blood in each heart chamber. Risks for this procedure that have decreased over time include the development of dysrhythmias. Death can occur secondary to cardiac arrest after ventricular fibrillation.

Fluoroscopic visualization of the coronary arteries and left-heart structures using contrast dye is called **coronary angiography** or arteriography. Like cardiac catheterization, this study takes place in a catheterization laboratory using local anesthesia and a sterile field. A catheter is threaded into the left ventricle through the femoral artery. A ventriculogram generally is performed first. Contrast dye is injected into the apex of the ventricle, and the next few cardiac cycles are visualized and filmed. Like cardiac catheterization, coronary angiography is used to gain information about the structure and function of the ventricles and related valves. After the ventriculogram, catheters are introduced individually into the ostia of the coronary arteries. When the catheter is in position, a small volume of contrast dye is mechanically and rapidly injected into the artery and the results are visualized and filmed. Dye injection is repeated with the individual tilted at various angles to afford views of the artery other than the anteroposterior view.

The risks of for coronary angiography are similar to those of cardiac catheterization, with exceptions. As the blood supply to the cardiac

muscle is briefly interrupted when dye is introduced into the coronary arteries, angina (chest pain) caused by ischemia (lack of oxygen) is much more common. Coronary artery spasms also can occur. Interrupted flow also causes decreased heart rate (bradycardia), as well as some tachydysrhythmias, hypotension, and ST-segment depression.

Systemic Vascular Evaluation

The systemic vascular system can be studied by a variety of techniques in order to evaluate for adequate flow rates, vascular obstruction, and structural defects. These techniques include Doppler ultrasonography, CT and MRI, venography, and arteriography.

Arterial Pressure Pulse Waveform Analysis

Pulsation, described by the flow of blood through an artery during the cardiac cycle, can be drawn as a waveform plotting pressure against time (Fig. 32.33). The waveform can be obtained noninvasively by placing a transducer on the skin over the carotid artery while the individual's head is turned slightly away from the transducer. The amplitude and shape of arterial waveforms can provide information about the elasticity of the arterial wall, or its inverse—the stiffness of the wall.

FIGURE 32.33 Arterial Pressure Pulse Waveforms.

Doppler Ultrasonography Studies

A Doppler study is done using a microphone that amplifies and records the sounds made by blood flowing in peripheral vessels. The Doppler microphone is placed over the vessel to be studied, and sounds related to obstructions to flow, vessel wall mobility, and heart murmurs are transmitted through a lubricating gel to the microphone. The audio findings can be digitized into visual findings that can be analyzed for flow velocity and volume. These studies are useful in the evaluation for abnormalities of venous flow (e.g., deep venous thrombosis) and arterial flow (e.g., embolism). Ultrasound also is used to calculate the thickness of arterial walls, yielding a reading called *intimal-medial thickness*. Carotid intimal-medial thickness is used to assess for atherosclerosis.⁶⁵ Many people are familiar with ultrasound measurements because they are commonly used to assess fetal growth and development.

Computed Tomography and Magnetic Resonance Imaging

CT and MRI are used to evaluate the systemic circulation, providing information about the structure of the great vessels. Either can be used

to evaluate for aneurysms and dissections of the thoracic or abdominal aorta. CT also is used to assess for vessel calcification and provide some insights into the risk for stroke and myocardial infarction through evaluation of the carotid and coronary vessels.

Venography and Arteriography

Radiopaque dye can be injected through intravenous or intraarterial catheters to allow for visualization of the internal structure, diameter, and patency of veins and arteries. Venography is performed primarily in the lower extremity to assess for the presence of thrombi in the large veins of the leg. Arteriography (angiography) can be used in almost any vascular system, including the great vessels and the pulmonary, coronary (see previously in this chapter), cerebral, mesenteric, renal, hepatic, and peripheral arteries. Risks include rupture, dissection, thrombosis, embolization, or organ infarction involving the arterial system being studied.

Aging and the Cardiovascular System

Cardiovascular disease is the most common cause of morbidity and mortality in older adults in Western society and in much of the rest of the world.⁶⁶ In addition, age is a key driver of cardiovascular risk, which explains why it is the primary cause of death in persons older than age 65.⁶⁷ The most common cardiovascular disease condition is hypertension followed by coronary atherosclerosis for which hypertension is a risk factor.

It is challenging to determine the normal physiologic changes in cardiac function with aging because many pathologic changes are usually present and physical fitness is variable in older people as well. Studies of the effect of age on cardiovascular function must be rigorous in their distinction between persons who are free of disease and those who have disease that may be evident only during testing. There is a wide range in the older population for nearly every cardiovascular variable. These variations are related to an increase in

the prevalence of hypertension and coronary disease with advancing age; the growth in the segment of the population older than age 65; and major age-associated changes in lifestyle (e.g., fitness status).⁶⁷ The most relevant age-associated physiologic changes in cardiovascular performance include myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, increased occurrence of atrial fibrillation, and loss of exercise capacity plus left ventricular hypertrophy and fibrosis.^{67,68} These changes pose considerable consequences with increased demand for flow, with changes in posture, or with disease.

Arterial stiffening occurs with aging even in the absence of clinical hypertension. It can, however, be an important contributor to systolic hypertension and its associated risks for cardiovascular events, dementia, and death. These changes result from alterations within the vascular media, including age-associated changes in cross-linking of collagen, an increase in the amount of collagen, deposition of calcium, and changes in the nature of elastin, the extracellular matrix, inflammatory molecules, endothelial cell function, and reactive oxygen species.³⁷ The increased arterial stiffness may not be related strictly to an age-associated change in vascular structure but may be caused by changes in **baroreceptor** activity. Baroreceptor activity may decrease with age, slowing physiologic adjustment to changes in blood pressure, and posture. In persons older than age 60, pulse pressure, which is directly influenced by arterial stiffness, is a better predictor of cardiovascular disease than either diastolic or systolic blood pressure.⁶⁹

Left ventricular hypertrophy and fibrosis also are more common in the aging population, even in the absence of high blood pressure. As the arterial system becomes stiffer the ventricles must work harder to pump blood throughout the body, thus contributing to hypertrophy. Fibrosis, calcification, and increase in stiffness also impact valvular function, particularly the function of the atrioventricular valves. These changes make valvular disease a greater risk for the elderly, along with an increased risk of heart failure related to the left ventricular hypertrophy and stiffness.

The advent of genomic medicine and a deeper exploration of molecular changes with aging continue to enhance understanding of the myriad changes in people's bodies as they age.^{67,68} The ongoing hope is that as understanding of the causative factors related to cardiovascular decline with aging improves, therapeutics that arrest or slow these changes may be developed.

Stress testing is used to uncover functional capacity losses that are not apparent at rest. In contrast to the subtle age effects on resting cardiac tests, more dramatic changes occur during exercise. [Table 32.3](#) summarizes age-associated changes at rest and during exercise. Overall, long-term exercise conditioning in older individuals increases aerobic capacity and decreases arterial stiffness and left ventricular function so that cardiovascular diseases may be prevented or delayed in older adults. Although the risks and benefits of pharmacologic and invasive strategies must always be assessed carefully, many older adults can live longer and healthier lives if appropriate preventive and treatment regimens are offered, even quite late in life.

Summary Review

Circulatory System

1. The circulatory system is the body's transport system and a part of its communication system. It delivers oxygen, nutrients, hormones, blood cells, immune cells, and others throughout the body and carries metabolic wastes to the kidneys and lungs for excretion.
2. The circulatory system consists of the heart, blood vessels, and the lymphatic vessels and is made up of two separate but conjoined, serially connected pump systems: the pulmonary circulation and the systemic circulation, plus the lymphatics.
3. The low-pressure pulmonary circulation is driven by the right side of the heart. The function of the pulmonary circulation is to deliver blood to the lungs for oxygenation.
4. The higher pressure systemic circulation is driven by the left

side of the heart, and its function is to move oxygenated blood to body tissues and to deliver waste products to the lungs, kidneys, and liver.

5. The lymphatic vessels collect fluids from the interstitium and return the fluids to the circulatory system. Another important function of the lymphatic system is the movement of lymphocytes and leukocytes between different components of the immune system.

The Heart

1. The heart consists of four chambers (two atria and two ventricles), four valves (two AV valves and two semilunar valves), a muscular wall, a fibrous skeleton, a conduction system, nerve fibers, systemic vessels (the coronary circulation), and openings where the great vessels enter the atria and ventricles.
2. The heart wall, which encloses the heart and divides it into chambers, is made up of three layers: the epicardium (outer layer), the myocardium (muscular layer), and the endocardium (inner lining). The heart is contained within the pericardium, a double-walled sac.
3. The myocardial layer of the two atria, which receive blood entering the heart, is thinner than the myocardial layer of the ventricles, which is stronger because it generates the pressure that causes the blood to circulate through the lungs or the systemic circulation.
4. The right and left sides of the heart are separated by portions of the heart wall called the *interatrial septum* and the *interventricular septum*.
5. Unoxygenated (venous) blood from the systemic circulation enters the right atrium through the superior and inferior venae cavae. From the right atrium the blood passes through the right AV (tricuspid) valve into the right ventricle. In the ventricle the blood flows from the inflow tract to the outflow

tract and then through the pulmonic semilunar valve (pulmonary valve) into the pulmonary artery, which delivers it to the lungs for oxygenation.

6. Oxygenated blood from the lungs enters the left atrium through the four pulmonary veins (two from the left lung and two from the right lung). From the left atrium the blood passes through the left AV valve (mitral valve) into the left ventricle. In the ventricle the blood flows from the inflow tract to the outflow tract and then through the aortic semilunar valve (aortic valve) into the aorta, which delivers it to systemic arteries of the entire body.
7. The heart valves that ensure the one-way flow of blood from the atria to the ventricles are called the *atrioventricular valves*. The valves that ensure one-way flow from the ventricles to either the pulmonary artery or the aorta are called *semilunar valves*.
8. Oxygenated blood enters the coronary arteries through openings within the semilunar valves at the entrance to the aorta, and deoxygenated blood from the coronary veins enters the right atrium through the coronary sinus.
9. The pumping action of the heart consists of two phases: diastole, during which the myocardium relaxes and the chambers fill with blood; and systole, during which the myocardium contracts, forcing blood out of the ventricles. A cardiac cycle consists of one systolic contraction and the diastolic relaxation that follows it. Each cardiac cycle makes up one heartbeat.
10. The sinoatrial (SA) node generates electrical impulses, and the conduction system of the heart transmits these electrical impulses (cardiac action potentials) that stimulate systolic contraction. The autonomic nerves (sympathetic and parasympathetic fibers) can adjust heart rate and systolic force, but they do not stimulate the heart to beat.
11. Collateral arteries are connections between branches of the same coronary artery or connections of branches of the right

coronary artery with branches of the left. New collateral vessels are formed through two processes: arteriogenesis and angiogenesis. This collateral growth is stimulated by shear stress, an increased blood flow speed near an area of stenosis, or narrowing, and the production of growth factors and cytokines.

12. The heart has an extensive capillary network.
13. The normal ECG is the sum of all cardiac action potentials. The P wave represents atrial depolarization; the QRS complex is the sum of all ventricular cell depolarizations. The ST interval occurs when the entire ventricular myocardium is depolarized.
14. Cardiac action potentials are generated by the SA node at the rate of between 60 and 100 impulses per minute. The impulses travel through the conduction system of the heart, stimulating myocardial contraction as they travel.
15. Cells of the cardiac conduction system possess the properties of automaticity and rhythmicity. Automatic cells return to threshold and depolarize rhythmically without an outside stimulus. The cells of the SA node depolarize faster than other automatic cells, making it the natural pacemaker of the heart. If the SA node is disabled, the next fastest pacemaker, the AV node, assumes control.
16. Each cardiac action potential travels from the SA node to the AV node to the bundle of His (AV bundle), through the bundle branches, and finally to the Purkinje fibers and the ventricular myocardium. There the impulse is stopped. It is prevented from reversing its path by the refractory period of cells that has just been polarized. The refractory period ensures that diastole (relaxation) will occur, thereby completing the cardiac cycle.
17. Adrenergic receptor number, type, and function govern autonomic (sympathetic) regulation of heart rate, contractile force, and dilation or constriction of coronary arteries. The presence of specific receptors (α_1 , α_2 , β_1 , β_2 , β_3) in the

myocardium and coronary vessels determines the effects of the neurotransmitters norepinephrine and epinephrine.

18. Unique features that distinguish myocardial cells from skeletal cells enable myocardial cells to transmit action potentials faster (through intercalated disks), synthesize more ATP (because of a large number of mitochondria), and have readier access to ions in the interstitium (because of an abundance of transverse tubules). These combined differences enable the myocardium to work constantly, which is not required of skeletal muscle.
19. Cross-bridges between actin and myosin enable contraction to occur. Calcium and its interaction with the troponin complex facilitate the contraction process. With troponin release of calcium, myocardial relaxation begins.
20. Cardiac performance is affected by preload, afterload, heart rate, and myocardial contractility.
21. Preload, or pressure generated in the ventricles at the end of diastole, depends on the amount of blood in the ventricle. Afterload is the resistance to ejection of the blood from the ventricle. Afterload depends on pressure in the aorta.
22. Contractility is the potential for myocardial fiber shortening during systole. It is determined by the amount of stretch during diastole (i.e., preload) and by sympathetic stimulation of the ventricles.
23. The Frank-Starling law of the heart states that the myocardial stretch determines the force of myocardial contraction (the greater the stretch, the stronger the contraction).
24. Laplace's law states that the amount of contractile force generated within a chamber depends on the radius of the chamber and the thickness of its wall (the smaller the radius and the thicker the wall, the greater the force of contraction).

The Systemic Circulation

1. Blood flows from the left ventricle into the aorta and from the

aorta into arteries that eventually branch into arterioles and capillaries, the smallest of the arterial vessels. Oxygen, nutrients, and other substances needed for cellular metabolism pass from the capillaries into the interstitium, where they are available for uptake by the cells. Capillaries also absorb products of cellular metabolism from the interstitium.

2. Venules, the smallest veins, receive capillary blood. From the venules the venous blood flows into larger and larger veins until it reaches the venae cavae, through which it enters the right atrium.
3. Vessel walls consist of three layers: the tunica intima (inner layer), the tunica media (middle layer), and the tunica externa (outer layer).
4. Layers of the vessel wall differ in thickness and composition from vessel to vessel, depending on the vessel's size and location within the circulatory system. In general, the tunica media of arteries close to the heart contains a greater proportion of elastic fibers because these arteries must be able to distend during systole and recoil during diastole. Distributing arteries farther from the heart contain a greater proportion of smooth muscle fibers because these arteries must be able to constrict and dilate to control blood pressure and volume within specific capillary beds.
5. Blood flow into the capillary beds is controlled by the contraction and relaxation of smooth muscle bands (precapillary sphincters) at junctions between metarterioles and capillaries. The endothelium is probably a source of prostaglandins that control vasomotion.
6. Blood flow through the veins is assisted by the contraction of skeletal muscles (the muscle pump), and backwards flow in the lower body is prevented by one-way valves, particularly in the deep veins of the legs.
7. Blood flow is affected by blood pressure; resistance to flow within the vessels; blood consistency (which affects velocity); anatomic features that may cause turbulent or laminar flow;

and compliance (distensibility) of the vessels.

8. Poiseuille's law describes the relationship of blood flow, pressure, and resistance as the difference between pressure at the inflow end of the vessel and pressure at the outflow end divided by resistance within the vessel.
9. Resistance to blood flow depends on vessel length and radius and on the viscosity of the blood. The greater a vessel's length and the blood's viscosity and the narrower the radius of the vessel's lumen, the greater the resistance within the vessel.
10. Total peripheral resistance, or the resistance to flow within the entire systemic circulatory system, depends on the combined lengths and radii of all the vessels within the system and on whether the vessels are arranged in series (greater resistance) or in parallel (lesser resistance).
11. Blood flow is influenced also by neural stimulation (of vasoconstriction or vasodilation) and by autonomic features that cause turbulence within the vascular lumen (e.g., protrusions from the vessel wall, twists and turns, bifurcations).
12. Arterial blood pressure is influenced and regulated by factors that affect cardiac output (heart rate and stroke volume), total resistance within the system, and blood volume.
13. Many hormones and other endothelial mediators alter vasomotion including epinephrine, norepinephrine, antidiuretic hormone, renin-angiotensin system, natriuretic peptides, adrenomedullin, nitric oxide, prostaglandins, and endothelium-derived relaxing factor.
14. Venous pressure is influenced by blood volume within the venous system and compliance of the venous walls.
15. Blood flow through the coronary circulation is governed not only by the same principles as flow through other vascular beds but also by two adaptations dictated by cardiac dynamics. First, blood flows into the coronary arteries during diastole rather than systole because during systole, the cusps of the aortic semilunar valve block the openings of the

- coronary arteries. Second, systolic contraction inhibits coronary artery flow by compressing the coronary arteries.
16. Autoregulation enables the coronary vessels to maintain optimal perfusion pressure despite systolic effects, and myoglobin in heart muscle stores oxygen for use during the systolic phase of the cardiac cycle.

Lymphatic System

1. The vessels of the lymphatic system run in the same sheaths as those of the arteries and veins.
2. Lymph (interstitial fluid plus cells of the immune system) is absorbed by lymphatic venules in the capillary beds and travels through ever larger lymphatic veins until it empties into the right lymphatic duct and the thoracic duct, which drain into the right and left subclavian veins, respectively.
3. As lymph travels toward the thoracic ducts, it passes through lymph nodes clustered around the lymphatic vessels. The lymph nodes are sites of immune function and are ideally placed to sample fluid and cells moving from the periphery into the central circulation.

Tests of Cardiovascular Function

1. The evaluation of an individual with known or suspected cardiovascular disease must include a careful history and physical examination including assessment of risk factors, symptoms, vital signs, level of consciousness, mucous membrane color, and cardiopulmonary functioning.
2. Important tests for cardiac disorders are ECG and Holter monitoring, which detect disturbances of impulse generation or conduction.
3. Stress tests elicit clinical manifestations of cardiovascular disease that might not be present at rest.

4. The sensitivity of stress testing is improved by the use of radiotracer imaging techniques such as SPECT.
5. Echocardiography detects structural and functional cardiac abnormalities over time.
6. Cardiac catheterization is used to measure the oxygen content and pressure of blood in the heart's chambers and to inject contrast media for x-ray examination of the size and shape of the chambers and valves. Injection of contrast medium into the coronary arteries (coronary angiography), on the other hand, permits visualization of the coronary circulation and every tissue perfused by the coronary arteries.
7. Evaluation of the systemic vascular system can include arterial pressure pulse waveform analysis, Doppler ultrasonography, venography, and arteriography.

Aging and the Cardiovascular System

1. Cardiovascular disease is the most common cause of morbidity and mortality in older adults in Western society and in much of the rest of the world. In addition, age is a key driver of cardiovascular risk, which explains why it is the primary cause of death in persons older than age 65.
2. The most common cardiovascular disease condition is hypertension followed by coronary atherosclerosis, for which hypertension is a risk factor.
3. It is challenging to determine the normal physiologic changes in cardiac function with aging because many pathologic changes are usually present and physical fitness is variable in older people as well.
4. The most relevant age-associated physiologic changes in cardiovascular performance include myocardial and blood vessel stiffening, changes in neurogenic control over vascular tone, increased occurrence of atrial fibrillation, and loss of exercise capacity plus left ventricular hypertrophy and fibrosis.

5. With active risk reduction, physical activity, and disease management, older adults can have markedly improved cardiovascular health.

Dysrhythmias, 1103

Cardiovascular disease is the leading cause of death, in both the United States and worldwide.¹ Disorders of the veins, arteries, and heart wall comprise the scope of cardiovascular disease. Current understanding of the pathophysiology of cardiovascular disease is focused on genetic, neurohumoral, inflammatory, and metabolic mechanisms that underlie tissue and cellular alterations.

Diseases of the Veins

Varicose Veins and Chronic Venous Insufficiency

Chronic venous disease manifests along a continuum from asymptomatic telangiectasias to varicose veins to chronic vascular insufficiency. Telangiectasias are small, widened blood vessels visible in the skin. A **varicose vein** refers to a condition in which venous blood has pooled, producing distortion of the veins, leakage, increased intravascular hydrostatic pressure, and inflammation (Fig. 33.1). Varicose veins result from incompetent valves, venous obstruction, muscle pump dysfunction, or a combination of these conditions. The increase in venous hydrostatic pressure is associated with an increase in transforming growth factor beta (TGF- β) and basic fibroblast growth factor (bfgf) in vessel walls resulting in permanent remodeling of the vessels. An altered ratio of prostacyclin to thromboxane A₂ with potential for clotting also occurs.² Risk factors for developing varicose veins include gender (women are at a much

higher risk), pregnancy, increased weight, increased age, leg trauma, sitting or standing for long periods of time, and family history. Symptoms include visible distended veins; itching, burning, or throbbing around lower leg veins; and muscle cramping or pain in the lower legs.

FIGURE 33.1 Varicose Veins of the Leg (*arrow*). (Courtesy Dr. Magruder C. Donaldson, Brigham and Women's Hospital, Boston. From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2010, Saunders.)

Varicose veins can progress to **chronic venous insufficiency (CVI)**, which is defined as persistent ambulatory lower extremity venous hypertension. Venous hypertension, circulatory stasis, and tissue hypoxia lead to an inflammatory reaction in vessels and tissue. These processes cause lower extremity edema, pain, skin changes (hyperpigmentation and lipodermatosclerosis), and necrosis (**venous stasis ulcers**)³ (see [Fig. 33.1](#)). Infection can occur because poor circulation limits immune and inflammatory responses, especially as a complication of reparative surgery.

Treatment across the spectrum of chronic venous disease may

include recommendations to lose weight and decrease time spent standing or sitting, leg elevation, physical exercise, and use of compression stockings. If conservative treatment is not successful, endovenous ablation or foam sclerotherapy may be recommended. Both are associated with less pain and faster recovery compared to endovenous laser therapy and surgical stripping.⁴

Deep Venous Thrombosis

Venous thromboembolism (VTE) includes **deep venous thrombosis (DVT)** and pulmonary embolism (PE) (see [Chapter 36](#)). DVT is a blood clot that remains attached to a vessel wall, usually in a single side of a lower extremity ([Fig. 33.2](#)). A detached thrombus is a **thromboembolus**. Venous thrombi are more common than arterial thrombi because flow and pressure are lower in the veins than in the arteries. The American Heart Association (AHA) estimates that about 2 million people in the United States will have VTE annually with approximately 44,000 deaths.⁵ Three factors (termed the triad of Virchow) promote venous thrombosis: (1) **venous stasis** (associated with immobility, obesity, prolonged leg dependency, age, congestive heart failure [CHF]), (2) **venous intimal damage** (related to trauma, venipuncture, IV medications), and (3) **hypercoagulable states** (from inherited disorders, smoking, malignancy, liver disease, pregnancy, oral contraceptives, hormone replacement, hyperhomocysteinemia, antiphospholipid syndrome).⁶ Virtually everyone who is hospitalized is at significant risk for DVT, especially those with orthopedic trauma or surgery, spinal cord injury, age older than 60 years, and obstetric/gynecologic conditions. Individuals with malignancy (especially ovarian and pancreatic cancer), and women who are pregnant are also at significant risk. The most common heritable hypercoagulable states are abnormal factor V Leiden and prothrombin gene variant 20210A, both of which predispose patients to DVT.⁶ Other less common causes are deficiencies of the endogenous anticoagulants protein C, protein S, and antithrombin.

FIGURE 33.2 Multiple Venous Thrombi. (From Rosai J: *Ackerman's surgical pathology*, ed 8, vol 2, St Louis, 1996, Mosby.)

Accumulation of clotting factors and platelets leads to thrombus formation in the vein, often near a venous valve. Inflammation around the thrombus promotes further platelet aggregation, and the thrombus grows proximally. Most thrombi eventually dissolve without treatment, but untreated DVT is associated with a high risk of **thromboembolization** of a part of the clot from the leg traveling to the lung resulting in a pulmonary embolism⁷ (see [Chapter 36](#)). In up to one-third of individuals with DVT, persistent venous outflow obstruction may lead to **post-thrombotic syndrome (PTS)** characterized by chronic, persistent pain; edema; and ulceration of the affected limb.⁸

Clinical manifestations of DVT are often absent. If a symptom is present, it is typically pain. Other signs of DVT include unilateral leg swelling, dilation of superficial veins, calf tenderness, and skin that is mottled or cyanotic. Because DVT is usually asymptomatic and difficult to detect clinically, prevention of DVT is a high priority. Prevention strategies are dependent upon the condition of the individual and prior history of DVT. In general, individuals should be

mobilized as soon as possible after illness, injury, or surgery. Additional prophylactic treatment for individuals at low risk can include aspirin or pneumatic devices.⁹ People at higher risk are treated prophylactically with low-molecular-weight heparin or, in some cases, direct thrombin inhibitors.

Diagnosis is made by combining measurement of serum D-dimer concentration plus lower extremity compression Doppler ultrasonography. D-dimer is an indirect measure of the presence of thrombosis that is very sensitive but is not specific. If the D-dimer is negative, DVT is ruled out. If it is positive, the diagnosis must be confirmed with ultrasonography. Because of its high rate of sensitivity and specificity, use of digital photoplethysmography is becoming more widespread.¹⁰

Management of deep venous thrombosis is based on the risk of extension of the clot or embolization. For low-risk individuals, serial imaging of the deep veins may be indicated. For individuals at high risk for clot extension or pulmonary embolism, anticoagulation with low-molecular-weight heparin is indicated.^{11,12} Other options include direct thrombin inhibitors, such as fondaparinux, apixaban, argatroban, or dabigatran.^{7,13} Catheter-directed thrombolytic therapy may be used to dissolve the clot more quickly and reduce the risk of postphlebotic syndrome, especially when a large clot is located in a proximal vein; however, bleeding risk is increased and many people have contraindications to the use of thrombolytics.¹⁴ Pharmacomechanical treatment involves catheter-directed thrombolysis in combination with catheter-mediated removal of clots and can be used in selected individuals.¹⁵ DVT has a high recurrence rate after discontinuation of anticoagulant therapy. In people with proximal DVT or pulmonary embolism, at least 3 months of therapy is indicated. Recent updated guidelines suggest that for long-term therapy of individuals with DVT without underlying cancer, direct thrombin inhibitors are recommended. For those with DVT and cancer, continued low-molecular-weight heparin is indicated.¹⁶ If the individual is active and no identifiable underlying condition is discovered, aspirin therapy alone may be indicated.⁹

Superior Vena Cava Syndrome

Superior vena cava syndrome (SVCS) is a clinical manifestation of progressive compression of the superior vena cava (SVC) that leads to venous distention in the upper extremities and head. The leading causes of SVCS are nonsmall cell lung cancer, small cell lung cancer, and lymphoma. Nonmalignant causes of SVCS include thrombosis; infection, such as tuberculosis or histoplasmosis; mediastinal fibrosis; cystic fibrosis; and retrosternal goiter. Pacemaker wires, central venous catheters, and pulmonary artery catheters also can lead to SVCS.¹⁷

The SVC is a thin-walled and relatively low-pressure vessel that lies in the closed thoracic compartment; therefore tissue expansion can easily compress the SVC. The right main stem bronchus abuts the SVC so that cancers occurring in the bronchus may press on the vessel and obstruct venous return to the right atrium. Additionally, the SVC is surrounded by lymph nodes and lymph chains that commonly become involved in infection and thoracic cancers. If the onset of SVCS is slow, surrounding collateral vessels may enlarge in response to the increased pressure and symptoms may occur more gradually.

The most common clinical manifestations of SVCS include edema and venous distention in the face, neck, trunk, and upper extremities. More rarely, cyanosis may be observed. Individuals may complain of dyspnea, dysphagia, hoarseness, stridor, cough, and chest pain. Central nervous system (CNS) edema may cause malaise, headache, visual disturbances, vertigo, awareness or memory disorders, and impaired consciousness. The skin of the face and arms may become purple and taut, and capillary refill time can be prolonged. Respiratory distress may be present because of edema of bronchial structures or compression of the bronchus by a carcinoma.

Diagnosis is made by chest x-ray, Doppler ultrasound studies, computed tomography (CT), and contrast-enhanced magnetic resonance imaging (MRI). If laryngeal constriction or cerebral edema is present, emergency intervention may be required to address the underlying cause of SVCS. Similarly, if a rapidly growing malignancy is found, immediate treatment is indicated, including radiation or

chemotherapy. With a slow-growing malignancy, stenting of the SVC may be considered for immediate symptom relief, followed by appropriate chemotherapy. For an infectious cause of SVCS, antibiotics are used. Fluid restriction, diuretics, supplemental oxygen, and elevation of the head also can provide symptomatic relief.¹⁷

Diseases of the Arteries

Hypertension

Hypertension (HTN) is consistent elevation of systemic arterial blood pressure. Hypertension was defined in 2014 as a sustained systolic blood pressure (SBP) of 140 mmHg or greater or a diastolic blood pressure (DBP) of 90 mmHg or greater.¹⁸ In 2017 hypertension was redefined as a SBP of 130 or greater or a DBP of 80 or greater ([Table 33.1](#)).^{18a} Hypertension is the most common primary diagnosis in the United States—approximately one in three adults older than 20 years of age has hypertension; this increases to nearly two in three in those older than age 60. In individuals younger than age 45, the prevalence of hypertension is higher in men than in women; from ages 45 to 65 prevalence is the same in men and women; and after age 65 the prevalence of hypertension is greater in women than in men.⁵ The prevalence of HTN is higher in blacks and in those with diabetes. Those who fall into the prehypertension category (which includes between 25% and 37% of the U.S. population) are at risk for developing hypertension unless lifestyle modification and treatment are instituted. Some individuals have isolated systolic hypertension. **Isolated systolic hypertension (ISH)** is elevated systolic blood pressure accompanied by normal diastolic blood pressure (less than 90 mmHg). ISH is becoming more prevalent in all age groups and is strongly associated with cardiovascular and cerebrovascular events.⁵

TABLE 33.1

CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS*

--

CATEGORY	SYSTOLIC (mmHg)		DIASTOLIC (mmHg)
Normal	<120	AND	<80
Elevated	120–129	OR	<80
Hypertension			
Stage 1 hypertension	130–139	OR	80–89
Stage 2 hypertension	≥140	OR	≥90
Hypertensive crisis	>180	AND/OR	>120

* Individuals with systolic blood pressure and diastolic blood pressure in two categories should be designated to the higher blood pressure category. Blood pressure indicates an average of more than two careful readings obtained on more than two occasions.

Data from Whelton PK, Carey RM, Aronow WS, et al: *Hypertension*. 2017 Nov 13. doi: 10.1161/HYP.0000000000000065.

Approximately 95% of cases of hypertension have no known cause and therefore are diagnosed as primary hypertension (also commonly called *essential hypertension*). Secondary hypertension accounts for 5% of cases and is associated with an underlying primary disorder, such as renal disease. Hypertension is a complex disorder that affects the entire cardiovascular system, and all types and stages of hypertension are associated with increased risk for target organ disease events, such as myocardial infarction (MI), kidney disease, and stroke.

Factors Associated with Primary Hypertension

A combination of genetic and environmental factors is thought to be responsible for the development of primary hypertension. Genetic predisposition to hypertension is polygenic, including polymorphisms associated with renal sodium excretion, insulin and insulin sensitivity, activity of the sympathetic nervous system (SNS) and renin-angiotensin-aldosterone system (RAAS), and cell membrane sodium or calcium transport.¹⁹ Epigenetic links between environmental factors, such as diet, exercise, and smoking, with gene expression also are being defined.^{20,21}

Risk factors associated with primary hypertension include age, ethnicity, family history of hypertension and genetic factors, lower

education and socioeconomic status, tobacco use, psychosocial stressors, sleep apnea, and dietary factors (including dietary fats, higher sodium intake, lower potassium intake, and excessive alcohol intake).⁵ Glucose intolerance (diabetes mellitus) and obesity also are significant risk factors. Many of these factors also are risk factors for other cardiovascular disorders. In fact, hypertension, dyslipidemia, and glucose intolerance are often found together in a condition called *metabolic syndrome* (see [Chapter 22](#)).

◆Pathophysiology.

Hypertension is caused by increases in cardiac output, total peripheral resistance, or both. Cardiac output is increased by any condition that increases heart rate or stroke volume, whereas peripheral resistance is increased by any factor that increases blood viscosity or reduces vessel diameter (vasoconstriction). (The many factors affecting cardiac output and peripheral resistance are described in [Chapter 32](#).)

Primary Hypertension

Primary hypertension is the result of a complicated interaction between genetics and the environment that increases vascular tone (increased peripheral resistance) and blood volume, thus causing sustained increases in blood pressure. Multiple pathophysiologic mechanisms mediate these effects including the sympathetic nervous system (SNS), the RAAS, and natriuretic peptides. Inflammation, endothelial dysfunction, obesity-related hormones, and insulin resistance also contribute to both increased peripheral resistance and increased blood volume. Increased vascular volume is related to a decrease in renal excretion of salt, often referred to as a shift in the **pressure-natriuresis relationship**. This means that for a given blood pressure, individuals with hypertension tend to secrete less salt in their urine. The pathophysiology of primary hypertension is summarized in [Fig. 33.3](#).

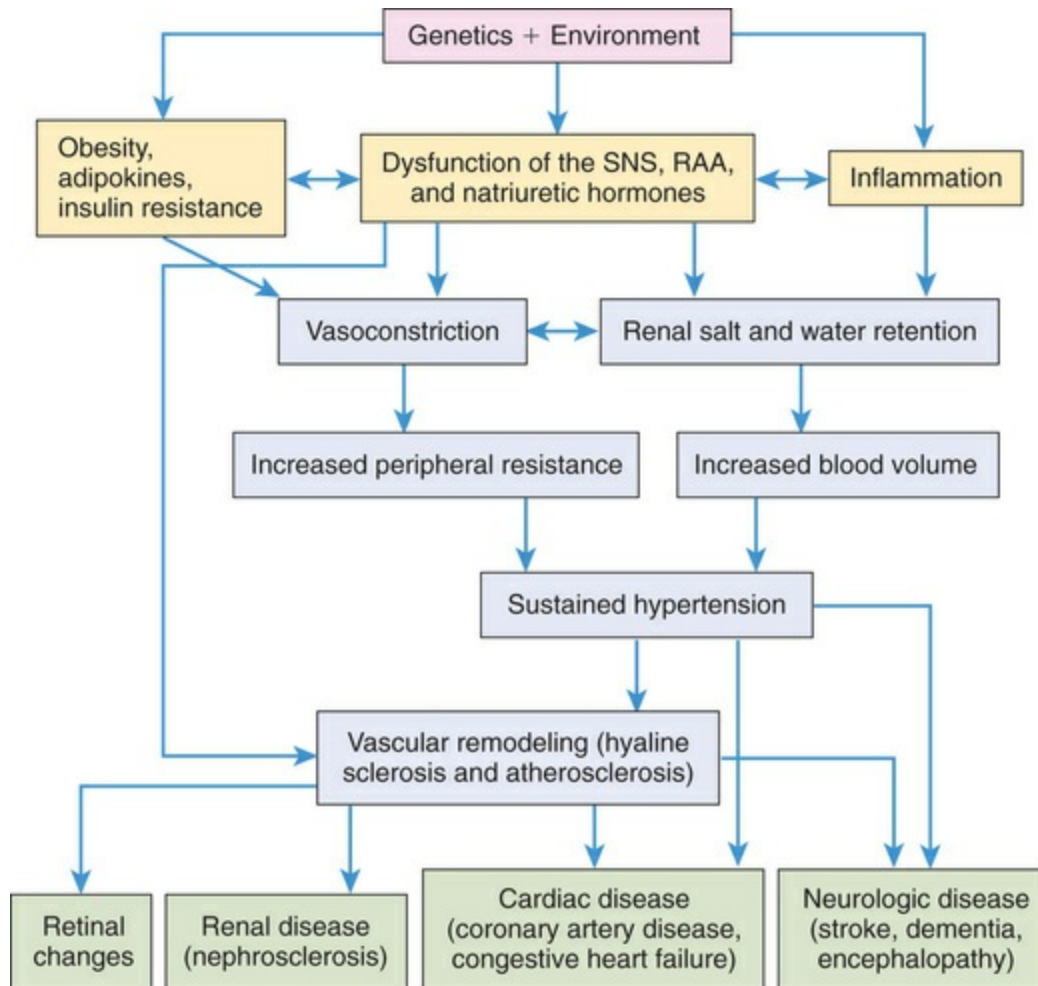

FIGURE 33.3 Pathophysiology of Hypertension. Numerous genetic vulnerabilities have been linked to hypertension and these, in combination with environmental risks, cause neurohumoral dysfunction (sympathetic nervous system [SNS], renin-angiotensin-aldosterone [RAA] system, and natriuretic hormones) and promote inflammation and insulin resistance. Insulin resistance and neurohumoral dysfunction contribute to sustained systemic vasoconstriction and increased peripheral resistance. Inflammation contributes to renal dysfunction, which, in combination with the neurohumoral alterations, results in renal salt and water retention and increased blood volume. Increased peripheral resistance and increased blood volume are two primary causes of sustained hypertension.

The SNS contributes to the pathogenesis of hypertension in many people. In the healthy individual, the SNS contributes to the maintenance of adequate blood pressure and tissue perfusion by promoting cardiac contractility and heart rate (maintenance of adequate cardiac output) and by inducing arteriolar vasoconstriction (maintenance of adequate peripheral resistance). In individuals with hypertension, overactivity of the SNS can result from increased

production of catecholamines (epinephrine and norepinephrine) or from increased receptor reactivity involving these neurotransmitters.²² Increased SNS activity causes increased heart rate and systemic vasoconstriction, thus raising the blood pressure. Efferent sympathetic outflow stimulates renin release, increases tubular sodium reabsorption, and reduces renal blood flow. Additional mechanisms of SNS-induced hypertension include structural changes in blood vessels (vascular remodeling), insulin resistance, increased renin and angiotensin levels, and procoagulant effects.²² The SNS is implicated in the cardiovascular and renal complications of hypertension. Beta-blocking medications oppose the effects of the SNS and have been used for decades in the treatment of hypertension. However, because of their side effects, these medications are no longer considered first-line treatment. The role of the SNS in the pathogenesis of cardiovascular disease is summarized in Fig. 33.4.

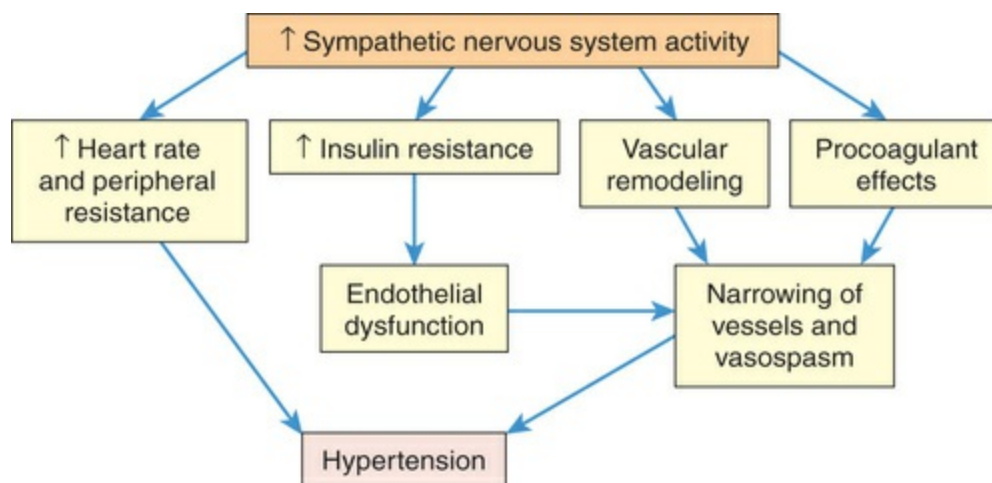

FIGURE 33.4 Role of the Sympathetic Nervous System in the Pathogenesis of Hypertension. Increased activity of the sympathetic nervous system (SNS) not only increases heart rate and peripheral resistance but also causes vascular remodeling with narrowing and vasospasm of arteries. The SNS contributes to insulin resistance, which is associated with endothelial dysfunction and decreased production of vasodilators, such as nitric oxide. The SNS also has procoagulant properties, making vascular spasm and thrombosis more likely. All of these factors contribute to sustained increases in blood pressure.

In the healthy individual, the RAAS provides an important homeostatic mechanism for maintaining adequate blood pressure and

therefore tissue perfusion (see [Chapter 32](#)). In hypertensive individuals, overactivity of the RAAS contributes to salt and water retention and increased vascular resistance. In the brain, angiotensin (ang) II enhances sympathetic neural outflow and alters the release of hormones that contribute to endothelial dysfunction, insulin resistance, dyslipidemia, and platelet aggregation.²³ Further, ang II mediates arteriolar remodeling, which is a structural change in the vessel wall that results in permanent increases in peripheral resistance²⁴ (see [Figs. 33.5](#) and [32.28](#)). Ang II is associated with end-organ effects of hypertension, including atherosclerosis, renal disease, and cardiac hypertrophy. Finally, aldosterone not only contributes to sodium retention by the kidney but also has other deleterious effects on the cardiovascular system.²⁴ Medications, such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin-receptor blockers (ARBs), oppose the activity of the RAAS and are effective in reducing blood pressure and protecting against target organ damage, including the synthesis of angiotensins III and IV, which also are hypothesized to contribute to hypertension.²⁴ Another RAAS system has been identified that is proposed to be protective. This system uses ACE2 to create angiotensin (ang) 1-7, which reduces the blood pressure and has cardiovascular protective effects. Its discovery may lead to new and more effective medications.²⁴⁻²⁶ Other RAAS pathways also have been described (see [What's New? The Renin-Angiotensin-Aldosterone System \[RAAS\] and Cardiovascular Disease](#)).

FIGURE 33.5 Angiotensins and the Organs Affected. **A**, The shaded blue area is the classical pathway of biosynthesis that generates the renin and angiotensin (ang) I. Ang is synthesized in the liver and is released into the blood where it is cleaved to form ang I by renin secreted by cells in the kidneys. Angiotensin-converting enzyme (ACE) in the lung catalyzes the formation of ang II from ang I, and destroys the potent vasodilator bradykinin. Further cleavage generates ang III and IV. The reddish shading shows the organs affected by ang II including the brain, heart, adrenals,

kidney, and the kidney's efferent arterioles. The dashed line (on the left) shows the inhibition of renin by ang II. B, Summary of ang II effects on blood vessel structure and function leading to arteriosclerosis. (Redrawn from Goodfriend TL et al: *N Engl J Med* 334:2649–2654, 1996.)

What's New?

The Renin-Angiotensin-Aldosterone System (RAAS) and Cardiovascular Disease

The RAAS has multiple effects on the cardiovascular system. There are four known RAA systems. The first and best known pathway includes the release of renin, the synthesis of angiotensin II (ang II) through angiotensin-converting enzyme (ACE), and stimulation of the AT1 receptor with secretion of aldosterone. Activation of the AT1 receptor causes systemic vasoconstriction and renal salt and water retention, and stimulates tissue growth and inflammation. AT1 activation also contributes to insulin resistance; remodeling of blood vessels, glomeruli, and the myocardium; atherogenesis and dysrhythmias; and decreased release of endothelial vasodilators and anticoagulants. Drugs that block this RAA pathway include ACE inhibitors, direct renin inhibitors, Ang II receptor blockers (ARBs), and aldosterone inhibitors. The second RAA pathway involves activation of a second ACE (ACE2) leading to the synthesis of angiotensin (1-7) from ang II. Ang (1-7) stimulates Mas receptors in the brain, blood vessels, heart, kidney, gut, pancreas, and inflammatory cells and has vasodilatory, antiproliferative, antifibrotic, and antithrombotic effects. These protective effects lead to lower blood pressure, less vascular inflammation and clotting, improved insulin sensitivity, and decreased tissue remodeling and damage to target organ tissues. Research is underway to develop pharmacologic interventions, such as synthetic Mas agonists, Ang (1-7) formulations, and ACE2 activators that will stimulate these protective RAA pathways. More recently, additional RAA pathways have been identified. The third RAA system involves activation of the AT2 receptor by Ang II and by Ang III (derived

from Ang II through the action of aminopeptidase). This pathway is up-regulated in brain, heart, and kidney injury and is antifibrotic, neuroprotective, and antiinflammatory but has no effect on blood pressure. AT2 agonists are being explored. Finally, the fourth RAA pathway is mediated by Ang IV which is derived from Ang III and activates the insulin-responsive aminopeptidase (IRAP) receptor. This pathway contributes to target organ damage in hypertension, and inhibitors of IRAP are under investigation. It may not be long before a fifth RAA pathway is described since a new homolog of ACE called ACE3 is now being identified in animal models.

Data from de Silva AR et al: *Eur J Clin Invest* 45:274–287, 2015; Mavtaveli LC, Siragy HM: *J Cardiovasc Pharm* 65:226–232, 2015; Oparil S, Schmieder, RE: *Circ Res* 116:1074–1095, 2015; Patel VB et al: *Circ Res* 118:1313–1326, 2016; Te Riet L et al: *Circ Res* 116(6):960–975, 2015; Romero CA, Orias M, Wier MR: *Nat Rev Endocrinol* 11:242–252, 2015; Santos RA: *Hypertension* 63:1138–1147, 2014; Yu CJ et al: *J Am Heart Assoc* 5(2):e002680, 2016; Zhang YH et al: *Inflamm Res* 64:253–260, 2015.

Populations with high dietary sodium intake have long been shown to have an increased incidence of hypertension.²⁷ Low levels of dietary potassium, calcium, and magnesium also are risk factors because sodium is retained without their intake. The natriuretic hormones modulate renal sodium (Na⁺) excretion and require adequate potassium, calcium, and magnesium to function properly. The natriuretic hormones include atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. These hormones induce diuresis; enhancement of renal blood flow and glomerular filtration rate, systemic vasodilatation, and suppression of aldosterone; and inhibition of the SNS. Dysfunction of these hormones, along with alterations in the RAAS and the SNS, cause an increase in vascular tone and a shift in the pressure-natriuresis relationship. When there is inadequate natriuretic function, serum levels of the natriuretic peptides rise in an attempt to compensate. In hypertension, increased ANP and BNP levels are linked to an increased risk for ventricular hypertrophy, atherosclerosis, and heart failure.²⁸ Salt retention leads to water

retention and increased blood volume, which contributes to an increase in blood pressure. Subtle renal injury results, with renal vasoconstriction and tissue ischemia. Tissue ischemia causes inflammation of the kidney and contributes to dysfunction of the glomeruli and tubules and promotes additional sodium retention. Increasing dietary intake of potassium, calcium, and magnesium can enhance natriuretic peptide function. New natriuretic peptide agonists are being studied.²⁹

Inflammation also plays a role in the vascular dysfunction of hypertension. Endothelial injury and tissue ischemia result in the release of vasoactive inflammatory cytokines. Although many of these cytokines (e.g., histamine, prostaglandins) have vasodilatory actions in acute inflammatory injury, chronic inflammation contributes to vascular remodeling and smooth muscle contraction.³⁰ Endothelial injury and dysfunction in primary hypertension are further characterized by decreased production of vasodilators, such as nitric oxide, and increased production of vasoconstrictors, such as endothelin.³¹

Obesity is recognized as an important risk factor for hypertension in both adults and children and contributes to many of the neurohumoral, metabolic, renal, and cardiovascular processes that cause hypertension.³² Obesity causes changes in what are called the *adipokines* (leptin, resistin, and adiponectin) and is associated with increased activity of the SNS and the RAAS.^{33,34} Obesity is linked to inflammation, small artery remodeling, endothelial dysfunction, insulin resistance, and an increased risk for cardiovascular complications from hypertension.^{35,36} The association between obesity and hypertension begins in adolescence and can have lifelong effects on health.

Finally, insulin resistance is common in hypertension, even in individuals without clinical diabetes. Insulin resistance is associated with endothelial injury and affects renal function, causing renal salt and water retention.³⁷ Insulin resistance is associated with overactivity of the SNS and the RAAS. It is interesting to note that in many individuals with diabetes treated with drugs that increase insulin

sensitivity, blood pressure often declines, even in the absence of antihypertensive drugs. The interactions between obesity, hypertension, insulin resistance, and lipid disorders in the metabolic syndrome result in a high risk of cardiovascular disease.^{38,39}

It is likely that primary hypertension is an interaction between many of these factors leading to sustained increases in blood volume and peripheral resistance. The role of these mechanisms in increasing blood volume in the pathophysiology of primary hypertension is summarized in Fig. 33.6.

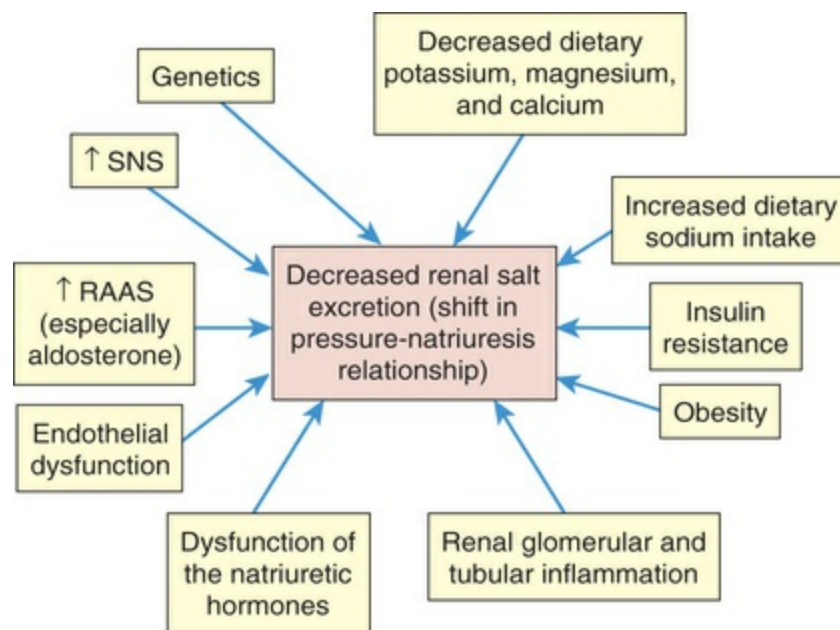

FIGURE 33.6 Shift in the Pressure-Natriuresis Relationship. Numerous factors have been implicated in the pathogenesis of sodium retention in individuals with hypertension. These factors cause less renal excretion of salt than would normally occur with increased blood pressure. This is called a *shift in the pressure-natriuresis relationship* and is believed to be a central process in the pathogenesis of primary hypertension. RAAS, Renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

Secondary Hypertension

Secondary hypertension is caused by an underlying disease process that raises peripheral vascular resistance or cardiac output. Examples include renal vascular or parenchymal disease, adrenocortical tumors,

adrenomedullary tumors (pheochromocytoma), and drugs (oral contraceptives, corticosteroids, antihistamines). Blood pressure returns to normal if the cause is identified and removed before permanent structural changes occur.

Complicated Hypertension

Complicated hypertension is chronic hypertension that damages the walls of systemic blood vessels. Within the walls of arteries and arterioles, smooth muscle cells undergo hypertrophy and hyperplasia with associated fibrosis of the tunica intima and media in a process called *vascular remodeling* (Fig. 33.7). Endothelial dysfunction, ang II, catecholamines, insulin resistance, and inflammation contribute to this process. Once significant fibrosis has occurred, reduced blood flow and dysfunction of the organs perfused by these affected vessels are inevitable. Target organs include the kidney, brain, heart, extremities, and eyes (these effects are summarized in Table 33.2).

FIGURE 33.7 Dramatic Hypertension Change in Small Arterioles. Fibrous intimal proliferation (*I*) with reduction in lumen vessel caliber (radius) (*L*) and normal media (*M*). (From Stevens A, Lowe JS, Scott I: *Core pathology*, ed 3, London, 2009, Mosby.)

TABLE 33.2

PATHOLOGIC EFFECTS OF SUSTAINED, COMPLICATED PRIMARY HYPERTENSION

PATHOLOGIC EFFECTS OF SUSTAINED, COMPLICATED PRIMARY HTN EXTENSION

SITE OF INJURY	MECHANISM OF INJURY	POTENTIAL PATHOLOGIC EFFECT
Heart		
Myocardium	Increased workload combined with diminished blood flow through coronary arteries	Left ventricular hypertrophy, myocardial ischemia, heart failure
Coronary arteries	Accelerated atherosclerosis (coronary artery disease)	Myocardial ischemia, myocardial infarction, sudden death
Kidneys	Reduced blood flow, increased arteriolar pressure, renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system (SNS) stimulation, and inflammation	Glomerulosclerosis and decreased glomerular filtration, end-stage renal disease
Brain	Reduced blood flow and oxygen supply; weakened vessel walls, accelerated atherosclerosis	Transient ischemic attacks, cerebral thrombosis, aneurysm, hemorrhage, acute brain infarction
Eyes (retinas)	Retinal vascular sclerosis, increased retinal artery pressures	Hypertensive retinopathy, retinal exudates and hemorrhages
Aorta	Weakened vessel wall	Dissecting aneurysm
Arteries of lower extremities	Reduced blood flow and high pressures in arterioles, accelerated atherosclerosis	Intermittent claudication, gangrene

Cardiovascular complications include angina pectoris, left ventricular hypertrophy leading to CHF (left heart failure, congestive heart failure), coronary heart disease (CAD), MI, and sudden death. Myocardial hypertrophy is mediated by several neurohormonal substances, including the SNS and ang II.⁴⁰ Hypertrophy is characterized by changes in the myocyte proteins, apoptosis of myocytes, and deposition of collagen in heart muscle, which causes it to become thickened, scarred, and less able to relax during diastole, leading to heart failure with preserved ejection fraction.⁴¹ In addition, the increased size of the heart muscle increases demand for oxygen delivery over time, contractility of the heart is impaired, and the individual is at increased risk for systolic heart failure. Vascular complications include the formation, dissection, and rupture of aneurysms (outpouchings in vessel walls); intermittent claudication;

and gangrene resulting from vessel occlusion. Renal complications are parenchymal damage, nephrosclerosis, renal arteriosclerosis, and renal insufficiency or failure. Microalbuminuria (small amounts of protein in the urine) is an early sign of impending renal dysfunction and significantly increased risk for cardiovascular events.⁴²

Changes in the vascular beds can be estimated by viewing the arterioles of the retina. Complications specific to the retina include retinal vascular sclerosis, exudation, and hemorrhage. Cerebrovascular complications are similar to those of other arterial beds and include transient ischemia, stroke, cerebral thrombosis, aneurysm, and hemorrhage. Chronic hypertension also has been linked to cognitive decline with aging.^{43,44}

Hypertensive crisis (or malignant hypertension) is rapidly progressive hypertension in which diastolic pressure is usually greater than 140 mmHg. It can occur as an uncommon complication of primary hypertension. Other causes include complications of pregnancy, cocaine or amphetamine use, reaction to certain medications, adrenal tumors, and alcohol withdrawal. High arterial pressure renders the cerebral arterioles incapable of regulating blood flow to the cerebral capillary beds. High hydrostatic pressures in the capillaries cause vascular fluid to exude into the interstitial space. If blood pressure is not reduced, cerebral edema and cerebral dysfunction (encephalopathy) increase until death occurs. Besides encephalopathy, hypertensive crisis can cause papilledema, cardiac failure, uremia, retinopathy, and cerebrovascular accident and is considered a medical emergency. Treatment must be initiated rapidly to avoid these serious complications.⁴⁵

◆Clinical Manifestations.

The early stages of hypertension have no clinical manifestations other than elevated blood pressure; for this reason, hypertension is called a *silent disease*. Some hypertensive individuals never have signs, symptoms, or complications, whereas others become very ill, and hypertension can be a cause of death. Still other individuals have anatomic and physiologic damage caused by past hypertensive

disease, despite current blood pressure measurements being within normal ranges. If elevated blood pressure is not detected and treated, it becomes established, setting the stage for the complications of hypertension that begin to appear during the fourth, fifth, and sixth decades of life.

Most clinical manifestations of hypertensive disease are caused by complications affecting the target organs. Evidence of heart disease, renal insufficiency, central nervous system dysfunction, impaired vision, impaired mobility, vascular occlusion, or edema can all be caused by sustained hypertension.

◆ Evaluation and Treatment.

A single elevated blood pressure reading does not mean that a person has hypertension. Diagnosis requires the measurement of blood pressure on at least two separate occasions averaging two readings at least 2 minutes apart, with the individual seated, the arm supported at heart level, after 5 minutes rest, with no smoking or caffeine intake in the past 30 minutes. Some individuals benefit from 24-hour ambulatory blood pressure monitoring because of better correlation with end-organ damage and the ability to screen out “white coat hypertension” (elevated blood pressure that occurs only in a clinic setting) and “masked hypertension” (normal blood pressure in the clinic setting but elevated elsewhere).⁴⁶ Ambulatory measurement also detects those who fail to have a nocturnal decrease in blood pressure and who may be at higher cardiovascular risk. It is especially recommended for individuals with drug resistance, hypotensive symptoms with medications, episodic hypertension, and autonomic dysfunction.⁴⁷

Evaluation of the hypertensive individual should include a complete medical history and assessment of lifestyle and other risk factors for hypertension and cardiovascular disease, as well as evidence of possible secondary causes of hypertension. Physical examination should include examination of the optic fundi; calculation of body mass index; auscultation for carotid, abdominal, and femoral bruits; examination of the heart and lungs; palpation of

the abdomen; assessment of lower extremity pulses and edema; and neurologic examination. Diagnostic tests include complete blood count, urinalysis, biochemical blood profile (measures levels of plasma glucose, sodium, potassium, calcium, magnesium, creatinine, cholesterol, and triglycerides), and an electrocardiogram (ECG). Individuals who have elevated blood pressure are assumed to have primary hypertension unless their history, physical examination, or initial diagnostic screening indicates secondary hypertension. Once the diagnosis is made, a careful evaluation for other cardiovascular risk factors and for target organ damage should be done.

Treatment of primary hypertension depends on its severity. [Fig. 33.8](#) illustrates an overview of the 2017 recommendations.^{18a} Treatment begins with reducing or eliminating risk factors. Lifestyle modification can prevent hypertension from developing in those individuals who fall into the elevated category, may control the blood pressure in stage I hypertension, and can enhance the effects of drug treatment for those with more significant blood pressure elevation. Dietary modifications, such as the Dietary Approaches to Stop Hypertension (DASH) diet, are recommended⁴⁸ (also see [Nutrition & Disease: Mediterranean Diet and Cardiovascular \[CV\] Disease and Recent Findings on Sugar](#)). Physical training increases stroke volume, which has the effect of lowering heart rate and hence systolic blood pressure, and should consist of regular aerobic physical activity. Individuals are counseled to stop smoking to eliminate vasoconstrictor effects of nicotine.

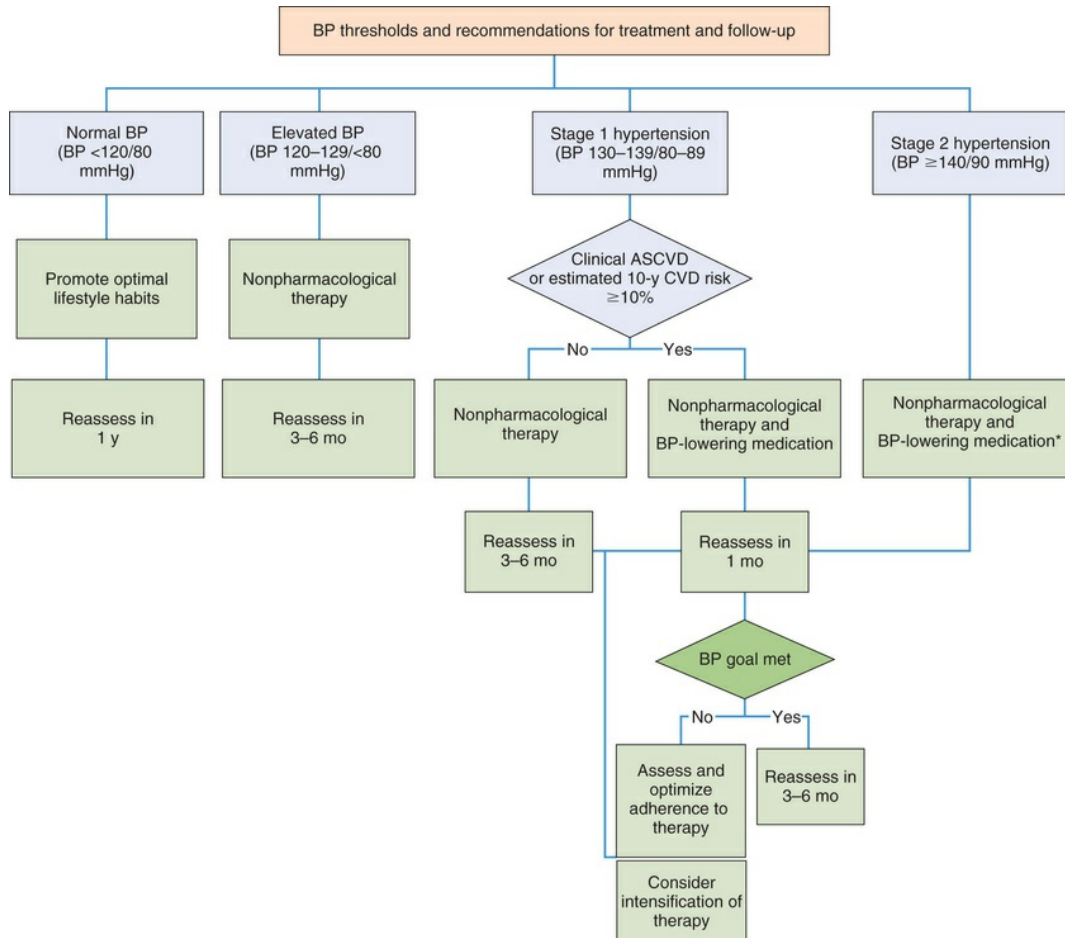

FIGURE 33.8 Blood Pressure Thresholds and Recommendations for Treatment and Follow-Up. Note: Patients with diabetes mellitus (DM) or chronic kidney disease (CKD) are automatically placed in the high-risk category. For initiation of renin-angiotensin system or diuretic therapy, assess blood tests for electrolytes and renal function 2 to 4 weeks after initiating therapy. *Consider initiation of pharmacological therapy for stage 2 hypertension with 2 antihypertensive agents of different classes. Patients with stage 2 hypertension and BP $\geq 160/100$ mmHg should be promptly treated, carefully monitored, and subject to upward medication dose adjustment as necessary to control BP. Reassessment includes BP measurement, detection of orthostatic hypotension in selected patients (e.g., older or with postural symptoms), identification of white coat hypertension or a white coat effect, documentation of adherence, monitoring of the response to therapy, reinforcement of the importance of adherence, reinforcement of the importance of treatment, and assistance with treatment to achieve BP target. ASCVD, Atherosclerotic cardiovascular disease; BP, blood pressure; CVD, cardiovascular disease. Data from Whelton PK, Carey RM, Aronow WS, et al: ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA guideline for the prevention, detection, evaluation, and management of high blood pressure in adults: A report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Hypertension*. 2017 Nov 13. doi: 10.1161/HYP.000000000000065. [Epub ahead of print.]

Pharmacologic treatment of hypertension reduces the risk of end-organ damage and prevents major diseases, such as myocardial ischemia and stroke. Recent recommendations describe specific target blood pressure outcomes and medication choices for individuals based on age, ethnicity, and comorbidities, such as diabetes and renal disease.^{18a} Commonly recommended medications include thiazide diuretics, ACE inhibitors or ARBs, and calcium channel blockers. Additional considerations are necessary for those with coronary artery disease.⁴⁹ Some individuals require two or more drugs for blood pressure control. Treatment of hypertension with a SBP treatment goal of less than 130 mmHg is recommended for noninstitutionalized ambulatory community-dwelling adults (≥65 years of age) with an average SBP of 130 mmHg or higher. For older adults (≥65 years of age) with hypertension and a high burden of comorbidity and limited life expectancy, clinical judgment, patient preference, and a team-based approach to assess risk/benefit is reasonable for decisions regarding intensity of BP lowering and choice of antihypertensive drugs.^{18a,50} Attempts to treat hypertension with techniques, such as renal denervation, have not been consistently successful to date; however, the use of invasive procedures for resistant hypertension continues to be explored.^{51,52} Many new approaches to the treatment of hypertension are being explored that address the complex neurohumoral interactions that contribute to this disorder, and pharmacogenetic research is leading to more personalized treatment regimes.^{53,54} Nutrition is significant for influencing the risk for cardiovascular disease (CVD) and other chronic diseases (see [Nutrition and Disease: Mediterranean Diet and Cardiovascular Disease \[CVD\] and Recent Findings on Sugar](#)).

Orthostatic (Postural) Hypotension

The term **orthostatic (postural) hypotension (OH)** refers to a decrease in systolic blood pressure of at least 20 mmHg or a decrease in diastolic blood pressure of at least 10 mmHg within 3 minutes of moving to a standing position.⁵⁵ Primary OH is often called *neurogenic* and is usually the result of neurologic disorders that affect autonomic

function. Compensatory changes during standing normally increase sympathetic activity mediated through stretch receptors (baroreceptors) in the carotid sinus and the aortic arch (see [Chapter 32](#)). This reflex response to shifts in volume caused by postural changes leads to a prompt increase in heart rate and constriction of the systemic arterioles, which maintains a stable blood pressure. These compensatory mechanisms are not effective in maintaining a stable blood pressure in individuals with orthostatic hypotension. Primary OH is often chronic. Older adults are susceptible to this type of OH because of slowing of postural reflexes as part of the aging process. It also occurs in neurologic diseases, such as Parkinson disease, multiple system atrophy, and inherited neurologic disorders. Multiple system atrophy is a severe form of chronic autonomic failure in which there are multiple central nervous system degenerative changes, and Parkinson disease. Individuals with this disorder also may exhibit supine hypertension, altered drug sensitivity, hyperresponsiveness of blood pressure to hypo/hyperventilation, sleep apnea, and other neurologic disturbances.⁵⁶ Primary OH is a significant risk factor for falls and associated injury. It also is associated with an increased risk of death, coronary artery disease, heart failure, and stroke.⁵⁷

Secondary OH is often acute and associated with (1) altered body chemistry, (2) drug action (e.g., antihypertensives or antidepressants), (3) prolonged immobility caused by illness, (4) starvation, (5) physical exhaustion, (6) any condition that produces volume depletion (e.g., massive diuresis, potassium or sodium depletion), and (7) any condition that results in venous pooling (e.g., pregnancy, extensive varicosities of the lower extremities). Other more chronic forms of secondary OH are seen with adrenal insufficiency, diabetes mellitus, cardiovascular diseases, and paraneoplastic syndromes.⁵⁷

Orthostatic hypotension often is accompanied by dizziness, blurring or loss of vision, and syncope or fainting. To assess hypotensive episode frequency, severity, and correlation with symptoms, 24-hour blood pressure monitoring is recommended. Basic diagnostic tests include ECG and blood electrolyte measurements. Other tests in selected individuals may include autonomic testing, serum

catecholamine measurements, and heart rate variability testing.

Treatment for secondary OH is focused on correcting the underlying disorder. No curative treatment is available for primary orthostatic hypertension. Management includes liberalizing salt intake; raising the head of the bed; wearing thigh-high stockings; and administering erythropoietin, somatostatin, volume expansion with mineralocorticoids, and vasoconstrictors, such as midodrine and pyridostigmine.^{56,57}

Aneurysm

An **aneurysm** is a localized dilation or outpouching of a vessel wall or cardiac chamber. Laplace's law can provide an understanding of the hemodynamics of an aneurysm (Fig. 33.9). (Laplace's law is discussed in detail in Chapter 32.) **True aneurysms** involve all three layers of the arterial wall and are best described as a weakening of the vessel wall. Most are fusiform and circumferential (Fig. 33.10). **False aneurysm** is an extravascular hematoma that communicates with the intravascular space. A common cause of this type of lesion is a leak between a vascular graft and a natural artery.

FIGURE 33.9 Pressure-Tension and Wall Thickness Relations in Blood

Vessels or Cardiac Chambers (Laplace's Law).

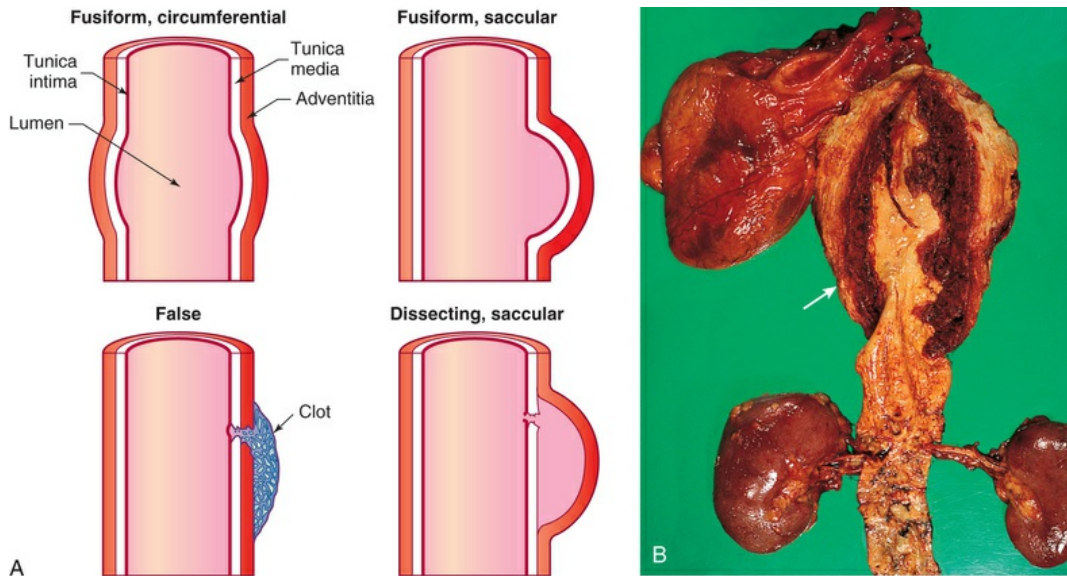

FIGURE 33.10 Longitudinal Sections Showing Types of Aneurysms. A, The fusiform circumferential and fusiform saccular aneurysms are true aneurysms, caused by weakening of the vessel wall. False and saccular aneurysms involve a break in the vessel wall, usually caused by trauma. B, Dissecting aneurysm of thoracic aorta (arrow). (B From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Aneurysms most commonly occur in the thoracic or abdominal aorta. The aorta is particularly susceptible to aneurysm formation because of constant stress on the vessel wall and the absence of penetrating vasa vasorum in the media layer (Fig. 33.11, A). Chronic inflammation of the wall of the aorta causes weakening of the intima and medial layers.⁵⁸ Arteriosclerosis and hypertension are found in more than half of all individuals with aneurysms. Chronic hypertension results in mechanical and shear forces that contribute to remodeling and weakening of the vessel wall. Atherosclerosis is a common cause of aneurysms because plaque formation erodes the vessel wall. From studies of abdominal aortic aneurysm (AAA) the main pathologic features include extracellular matrix remodeling, loss of vascular smooth muscle cells, and accumulation of inflammatory cells. The inflammatory process has a critical role in AAA influencing aortic wall remodeling, possibly as the result of *distinct* subsets of

monocytes and macrophages.⁵⁹ Infections, such as syphilis, collagen disorders (such as Marfan syndrome), and traumatic injury to the chest or abdomen, also can cause aortic aneurysms. Genetic susceptibilities have been identified including gene polymorphisms for the production of growth factors, myosin, and proteases. Inflammation (with the production of toxic oxygen radicals) and changes in cytokines, such as TGF- β , activate matrix-degrading proteins and smooth muscle cell apoptosis, resulting in loss of medial elastic lamellae and thinning of the tunica media.⁶⁰

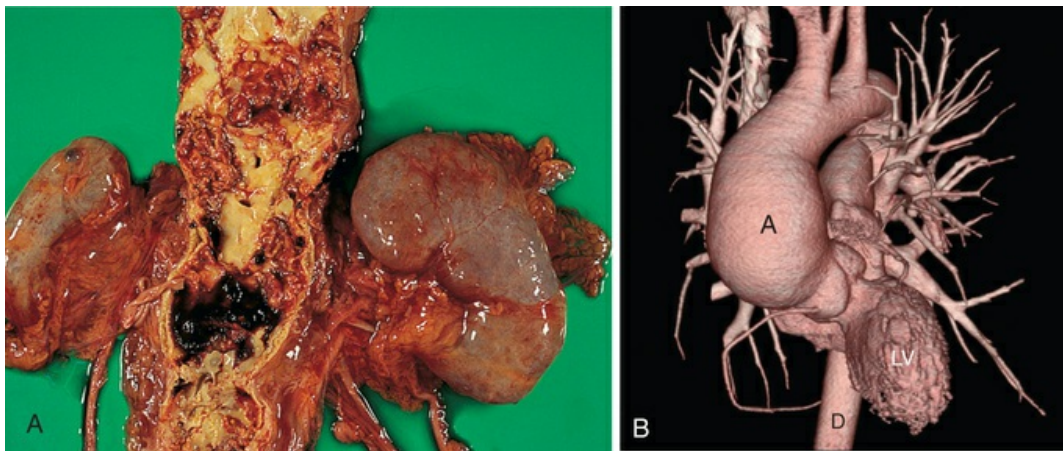

FIGURE 33.11 Aneurysms. A, Abdominal aortic atherosclerotic aneurysm. B, Thoracic aortic aneurysm. A three-dimensional CT scan shows the aneurysm. A, Ascending thoracic aorta; D, descending aorta; LV, left ventricle. (A From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Formation of a ventricular wall aneurysm most often occurs when intraventricular tension stretches noncontracting infarcted muscle (see [Fig. 33.11, B](#)). The stretching produces infarct expansion, a weak and thin layer of necrotic muscle, and fibrous tissue that bulges with each systole. With time the aneurysm becomes more fibrotic but continues to bulge with each systole, thus acting as a “reservoir” and reducing stroke volume.

Clinical manifestations depend on where the aneurysm is located. Aneurysms in the heart present with dysrhythmias, heart failure, and embolism of clots to the brain or other vital organs. Aortic aneurysms often are asymptomatic until they rupture, when they become painful.

Symptoms of dysphagia (difficulty in swallowing) and dyspnea (breathlessness) are caused by the pressure of a thoracic aneurysm on surrounding organs. An abdominal aneurysm can impair flow to an extremity and cause symptoms of ischemia. Aneurysms that occur elsewhere in the body have variable symptoms and signs related to the size of the aneurysm and the potential for rupture and hemorrhage.

The diagnosis of an aneurysm is usually confirmed by ultrasonography, CT, MRI, or angiography.⁶¹ The goals of medical treatment of aneurysms are to maintain a low blood volume and low blood pressure to decrease mechanical forces thought to contribute to vessel wall dilation. Medical treatment is indicated for slow-growing aortic aneurysms, particularly in early stages, and includes smoking cessation, reducing blood pressure and blood volume, and administering β -adrenergic blockage medications. Aortic aneurysms can be complicated by the acute aortic syndromes that include vessel rupture and aortic dissection.⁶² Rapidly expanding aneurysms are prone to rupture, and urgent surgical treatment often is indicated. New endovascular surgical techniques with placement of a stent make aneurysm repair possible even in those individuals with acute symptoms or complications.⁶³ **Aortic dissection** is a devastating complication that can involve any part of the aorta. Dissection of the ascending aorta is called *Type A*, and in any other part of the aorta it is called *Type B*. Dissection can disrupt flow through arterial branches, thus creating a surgical emergency. The risk is increased in individuals with hypertension, congenital heart disorders, atherosclerosis, and Marfan syndrome. Dissection of the layers of the arterial wall occurs when there is inflammation and release of enzymes that damage the vessel wall followed by a tear in the intima and blood that enter the wall of the artery (see [Fig. 33.10](#)). Individuals with acute aortic dissection complain of severe pain in the neck, jaw, chest, back, or abdomen; and diagnosis is made emergently with CT, echocardiography, or MRI. Although medical therapy may be indicated for Type B dissection, Type A is considered an emergency needing immediate surgical intervention.⁶⁴

Arterial Thrombus Formation

As in venous thrombosis, arterial thrombi tend to develop wherever intravascular conditions promote activation of the coagulation, or clotting, cascade. In the arteries, activation of the coagulation cascade is most often caused by roughening of the tunica intima by atherosclerosis. Another important cause is anatomic changes of an artery (such as an aneurysm) that can stimulate thrombus formation, particularly if the change results in pooling of arterial blood. Thrombi also form on heart valves altered by calcification or bacterial vegetation. Valvular thrombi are associated most commonly with inflammation of the endocardium (endocarditis) and rheumatic heart disease. Widespread arterial thrombus formation can occur in shock, particularly shock resulting from septicemia. In septic shock, systemic inflammation activates the intrinsic and extrinsic pathways of coagulation, resulting in microvascular thrombosis throughout the systemic arterial circulation (see [Chapters 29](#) and [49](#)).

Arterial thrombi pose two potential threats to the circulation. First, the thrombus may grow large enough to occlude the artery, causing ischemia in tissue supplied by the artery. Second, the thrombus may dislodge, becoming a thromboembolus that travels through the vascular system until it occludes flow into a distal systemic vascular bed.

Diagnosis of arterial thrombi is usually accomplished through the use of Doppler ultrasonography and angiography. Pharmacologic treatment involves the administration of heparin, warfarin derivatives, thrombin inhibitors, or thrombolytics. A balloon-tipped catheter also can be used to remove or compress an arterial thrombus. Various combinations of drug and catheter therapies are sometimes used concurrently.

Embolism

Embolism is the obstruction of a vessel by an **embolus**—a bolus of matter that is circulating in the bloodstream. The embolus may consist of a dislodged thrombus; an air bubble; an aggregate of amniotic fluid;

an aggregate of fat, bacteria, or cancer cells; or a foreign substance. An embolus travels in the bloodstream until it reaches a vessel through which it cannot fit. No matter how tiny it is, an embolus eventually will lodge in a systemic or pulmonary vessel. The source of the embolus determines whether the embolus will lodge in a vessel of the pulmonary or systemic circulation. Embolism causes ischemia or infarction in tissues distal to the obstruction. A limb that is ischemic because of arterial occlusion is characterized by an almost waxy whiteness of the skin because the vasculature is devoid of erythrocytes, and by numbness and pain resulting from neural ischemia. Embolism to a central organ causes organ dysfunction and pain and can be life threatening. For example, pulmonary artery embolism causes chest pain and dyspnea; renal artery embolism causes abdominal pain and oliguria; and mesenteric artery embolism causes abdominal pain and a paralytic, ischemic bowel. Embolism to a coronary or cerebral artery can result in MI or stroke.

Thromboembolism

Thromboembolism is a vascular obstruction resulting from a dislodged thrombus. Pulmonary emboli originate in the venous circulation (mostly from the deep veins of the legs) or in the right heart (also see [Chapter 36](#)). Arterial emboli most commonly originate from thrombi in the left heart that form as the result of MI, valvular disease, left heart failure, endocarditis, and dysrhythmias. More than half of these thromboemboli lodge in the lower extremities (in the femoral and popliteal arteries). Others lodge in the coronary arteries and the cerebral vasculature.

Air Embolism

Room air that enters the circulation through intravenous lines is a common cause of air embolism. Air also can be introduced into the bloodstream if trauma to the chest causes air from the lungs to enter the vascular space. For example, gunshot wounds and puncture wounds of the thorax sometimes introduce air emboli. Room air is

about 70% nitrogen. Although nitrogen dissolves quickly in blood, large amounts of air cannot be dissolved rapidly enough to prevent the displacement of blood in the arterioles and capillary beds. Ischemia and necrosis occur when air totally blocks a vessel. Treatment for air embolism is supportive, including bed rest and supplemental oxygen, once the connection between the source of air and the vascular system is eliminated.

Amniotic Fluid Embolism

The great intraabdominal pressures generated during labor and delivery may force amniotic fluid into the mother's bloodstream through the highly vascular uterine wall. Amniotic fluid not only displaces blood, reducing oxygen, nutrient, and waste exchange, but also introduces antigens, cells, and protein aggregates that trigger inflammation, coagulation, and the immune response within the bloodstream. Capillary beds usually are affected by amniotic fluid emboli, especially the capillary beds of the lungs and kidneys. Treatment is supportive and may include dialysis, particularly after a cesarean delivery or hysterectomy.

Bacterial Embolism

Isolated bacteria in the bloodstream do not cause embolism, but aggregates of bacteria may be large enough to do so. The most common cause of bacterial embolism is infectious endocarditis, during which clumps of bacterial vegetations are dislodged from infected cardiac valves and ejected into the pulmonary or systemic circulation. A less common cause is erosion of an artery or vein by bacteria at a source of infection, such as an abscess. Treatment for bacterial embolism includes bed rest, supplemental oxygen, and antibiotics to eradicate the source of infection.

Fat Embolism

Trauma to the long bones is associated with fat embolism, particularly

to the lungs. Two mechanisms have been proposed to account for the generation of fat emboli after skeletal trauma. The first is that trauma to the bones initiates defective fat metabolism, causing globules of fat to form in the blood. Platelets adhere to these globules until the conglomerate is large enough to lodge in a capillary bed. The second possible explanation is that globules of fat are released from fatty bone marrow exposed by fracture. Again, platelets adhere to the fat globules, and embolism occurs. Treatment for fat embolism consists of prompt immobilization of fractures and supportive measures that include administration of supplemental oxygen and steroids. Steroid administration may decrease the inflammation that occurs with vascular occlusion. Inflammation in the pulmonary bed is especially dangerous because it can cause acute respiratory distress syndrome (ARDS) (see [Chapter 36](#)).

Foreign Matter

Foreign matter can enter the bloodstream during trauma or through an intravenous or intraarterial line. Small particles, such as drug precipitates, small glass shards, or fibers from linen, are sometimes introduced unintentionally into a vessel through intravenous injections or manipulation of monitoring lines. Once in the blood, these small particles initiate the coagulation cascade. The thromboemboli that form around the particles are large enough to occlude a vessel and result in ischemia. Treatment is aimed at prevention of thrombus formation around the particle, dissolution of the particle, and supportive measures to alleviate ischemia. If the bolus of foreign matter is relatively large, it usually is removed surgically.

Peripheral Vascular Diseases

Thromboangiitis Obliterans (Buerger Disease)

Thromboangiitis obliterans (Buerger disease) is an idiopathic autoimmune condition strongly associated with smoking that is characterized by the formation of thrombi filled with inflammatory

and immune cells that disrupt flow in the peripheral arteries.⁶⁵ Inflammatory cytokines and toxic oxygen radicals contribute to accompanying vasospasm. Over time, these thrombi become organized and fibrotic and result in permanent occlusion and obliteration of portions of small- and medium-sized arteries in the feet and sometimes in the hands. Typically affected are the digital, tibial, and plantar arteries of the feet and the digital, palmar, and ulnar arteries of the hands.

The chief symptoms of thromboangiitis obliterans are pain and tenderness of the affected part. Clinical manifestations are caused by sluggish blood flow and include rubor (redness of the skin caused by dilated capillaries) and cyanosis (blueness of the skin caused by blood that remains in the capillaries after its oxygen has diffused into the interstitium). Chronic ischemia causes the skin to thin and become shiny and the nails to become thickened and malformed. In advanced disease, ischemia can cause gangrene, which may require amputation.

Diagnosis of thromboangiitis obliterans is made by identification of common features, such as age younger than 45 years, smoking history, and evidence of peripheral ischemia; and by exclusion of other causes of arterial insufficiency. The most important part of treatment is cessation of cigarette smoking. Vasodilators are prescribed to alleviate vasospasm, and the individual receives instruction in exercises that use gravity to improve blood flow. If vasospasm persists, sympathectomy may be performed. Newer therapies include immunomodulation, spinal cord stimulation, and bone marrow transplantation.⁶⁶

Raynaud Phenomenon and Disease

Raynaud phenomenon and Raynaud disease are characterized by attacks of vasospasm in the small arteries and arterioles of the fingers and, less commonly, the toes. Although the clinical manifestations of the phenomenon and the disease are the same, their causes differ.

Raynaud disease (or primary Raynaud's) is a primary vasospastic disorder of unknown origin. It is estimated to affect nearly 5% of the general population and is associated with female gender, family

history, smoking, manual occupation, migraine, and cardiovascular disease.⁶⁷ Blood vessels in affected individuals demonstrate endothelial dysfunction with an imbalance between endothelium-derived vasodilators (e.g., nitric oxide) and vasoconstrictors (e.g., endothelin-1). Platelet activation may play a role and vasospastic attacks triggered by brief exposure to cold or by emotional stress.

Raynaud phenomenon (or secondary Raynaud's) is secondary to systemic diseases, such as collagen vascular disease (e.g., scleroderma), chemotherapy, cocaine use, hypothyroidism, pulmonary hypertension, thoracic outlet syndrome, serum sickness, vasculitis, or malignancy. Vascular inflammation and vasospasm may reflect progression of the underlying disease.

The clinical manifestations of the vasospastic attacks of either disorder are pallor, numbness, and the sensation of cold in the digits. Attacks tend to be bilateral, and manifestations usually begin at the tips of the digits and progress to the proximal phalanges. Sluggish blood flow resulting in ischemia may cause the skin to appear cyanotic. Rubor follows as vasospasm ends and the capillaries become engorged with oxygenated blood. Rubor often is accompanied by throbbing and paresthesias. Skin color returns to normal after the attack, but frequent, prolonged attacks may cause the skin of the fingertips to thicken and the nails to become brittle. In severe, chronic Raynaud phenomenon or disease, ischemia eventually can cause ulceration and gangrene.

Once evident, the clinical manifestations confirm the diagnosis of Raynaud phenomenon; however, nailfold capillaroscopy is a more sensitive method of diagnosis and can improve management and follow-up of individuals with associated collagen-vascular disorders. The diagnostic criteria for Raynaud disease include not only the characteristic clinical manifestations described previously but also the absence of necrosis, no detectable underlying cause, normal digital photoplethysmography and pulse contour analysis, normal laboratory tests for inflammation, and negative tests for antinuclear factors.⁶⁸

Treatment of Raynaud disease consists of avoidance of stimuli that trigger attacks (e.g., emotional stress, cold) and use of arm exercises,

vasodilators, and biofeedback. Treatment for Raynaud phenomenon consists of removing the stimulus or treating the primary disease process. When Raynaud phenomenon is associated with malignancy, surgical removal of the tumor may resolve the ischemia. For Raynaud phenomenon not associated with malignancy, management includes arm exercises, vasodilators, sympathectomy, or botulinum toxin.⁶⁹

Atherosclerosis

Atherosclerosis is a form of arteriosclerosis in which thickening and hardening of the vessel are caused by the accumulation of lipid-laden macrophages within the arterial wall, which leads to the formation of a lesion called a **plaque**. Atherosclerosis is not a single disease but rather a pathologic process that can affect vascular systems throughout the body, resulting in ischemic syndromes that can vary widely in their severity and clinical manifestations. It is the leading cause of coronary artery and cerebrovascular disease. (Atherosclerosis of the coronary arteries is described in the Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndrome section; atherosclerosis of the cerebral arteries is discussed in [Chapter 18](#).)

◆Pathophysiology.

Atherosclerosis is a chronic inflammatory condition that results from the interaction of numerous pathophysiologic processes culminating in damage to arterial walls.⁷⁰ Pathologically, the lesions progress from endothelial injury and dysfunction to fatty streak fibrotic plaque to complicated lesions ([Fig. 33.12](#)).

FIGURE 33.12 Progression of Atherosclerosis. A, Damaged endothelium. B, Fatty streak and lipid core formation. C, Fibrous plaque (raised plaques are visible: some are yellow; others are white). D, Complicated lesion (thrombus is red; collagen is blue).

Atherosclerosis begins with injury to the endothelial cells that line artery walls.⁷¹ There are many possible causes of endothelial injury

such as aging, smoking, hypertension, and diabetes. The risk factors for atherosclerosis are discussed in more detail in the following section on coronary artery disease. Injured endothelial cells become inflamed and cannot make normal amounts of antithrombotic and vasodilating cytokines. The adventitia also plays an important role through production of reactive oxygen species and activation of endothelial inflammation.⁷² Low-density lipoprotein (LDL) penetrates into the subintima of arterial walls, where it is trapped by proteoglycans (Fig. 33.13). Inflammation, oxidative stress, and activation of macrophages cause the aggregated LDL to become oxidized. Hypertension, increased levels of LDL, oxidative stress, and activation of the renin-angiotensin-aldosterone system all contribute to an acceleration of this step in atherogenesis.⁷³ Inflammation and oxidized LDL cause endothelial cells to express adhesion molecules that bind monocytes and other inflammatory and immune cells. Monocytes penetrate the vessel wall becoming macrophages. Several types of receptors on these macrophages (toll-like receptors [TLRs] and LDL receptor-related protein [LRP]) enable detection and engulfment of the oxidized LDL.⁷⁴ These lipid-laden macrophages are now called *foam cells*, and when they accumulate in significant amounts, they form a lesion called a *fatty streak* and numerous inflammatory cytokines are released (e.g., tumor necrosis factor-alpha [TNF- α], interferons, interleukins, and C-reactive protein), as well as enzymes that further injure the vessel wall.⁷⁵ Growth factors also are released, including ang II, fibroblast growth factor, TGF- β , and platelet-derived growth factor, which stimulate smooth muscle cell proliferation in the affected vessel. These smooth muscle cells produce collagen and migrate over the fatty streak forming a fibrous plaque (see Fig. 33.12).⁷¹ The fibrous plaque may calcify, protrude into the vessel lumen, and obstruct blood flow to distal tissues, especially during exercise, which may cause symptoms (e.g., angina or intermittent claudication).

FIGURE 33.13 Low-Density Lipoprotein Oxidation. (1) LDL enters the arterial intima through an intact endothelium. (2) and (3) Inflammation and oxidized LDL cause endothelial cells to express adhesion molecules that bind monocytes and other inflammatory and immune cells. Monocytes penetrate the vessel wall, becoming macrophages. (4) Lipid-laden macrophages are called “foam cells.” (5) Foam cells accumulate and form the fatty streak, and many inflammatory cytokines and enzymes are released that injure the vessel wall. (Modified from Crawford MH, DiMarco JP, Paulus WJ: *Cardiology*, ed 3, London, 2010, Mosby.)

Many plaques, however, are “unstable,” meaning they are prone to rupture even before they affect blood flow and are clinically silent until they rupture. Plaque rupture occurs because of the inflammatory activation of proteinases (matrix metalloproteinases and cathepsins), apoptosis of cells within the plaque, and bleeding within the lesion (plaque hemorrhage).^{76,77} Plaques that have ruptured are called **complicated plaques** (see Fig. 33.12). Once rupture occurs, exposure of underlying tissue results in platelet adhesion, initiation of the clotting cascade, and rapid thrombus formation that may suddenly occlude the affected vessel, resulting in ischemia and infarction. Aspirin or other antithrombotic agents are used to prevent this complication of atherosclerotic disease.

◆Clinical Manifestations.

Atherosclerosis presents with symptoms and signs that result from inadequate tissue perfusion because of obstruction of the vessels that supply them. Partial vessel obstruction may lead to transient ischemic events, often associated with exercise or stress. Once the lesion becomes complicated, increasing obstruction with superimposed

thrombosis may result in tissue infarction. Obstruction of peripheral arteries can cause significant pain and disability. CAD caused by atherosclerosis is the major cause of myocardial ischemia and is one of the most important health issues in the United States. Atherosclerotic obstruction of the vessels supplying the brain is the major cause of stroke. Often more than one vessel is involved with this disease process; consequently, an individual may present with symptoms from several ischemic tissues at the same time, and disease in one area may indicate that the individual is at risk for ischemic complications elsewhere.

◆Evaluation and Treatment.

In evaluating individuals for the presence of atherosclerosis, a complete health history (including risk factors and symptoms of ischemia) is essential. Physical examination may reveal arterial bruits and evidence of decreased blood flow to tissues. Laboratory tests include measurement of lipids, blood glucose, and high-sensitivity CRP (hs-CRP). Judicious use of x-ray films, electrocardiography, ultrasonography, nuclear scanning, CT, MRI, and angiography may be necessary to identify affected vessels, particularly coronary vessels.

Prevention of atherosclerosis encompasses a broad range of nonpharmacologic and pharmacologic approaches to reducing risk factors such as dyslipidemia, hypertension, diabetes, smoking, and obesity. (Management of atherosclerotic risk factors for coronary artery disease is discussed further in the Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes section.) Current management of atherosclerosis is focused on detecting and treating preclinical lesions with drugs aimed at stabilizing and reversing plaques before they rupture. Once a lesion obstructs blood flow, the primary goal in managing atherosclerosis is to restore adequate blood flow to the affected tissues. If an individual has presented with acute ischemia (e.g., MI, stroke), interventions are specific to the diseased area and are discussed further under those topics. In situations in which the disease process does not require immediate intervention, management focuses on reducing risk factors,

removing the initial causes of vessel damage, and preventing lesion progression. This includes exercise, smoking cessation, and control of hypertension and diabetes when appropriate while reducing LDL cholesterol by diet or medications or both. (Management of atherosclerotic risk factors is discussed further in the Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes section.)

Peripheral Artery Disease

Peripheral artery disease (PAD) refers to atherosclerotic disease of arteries that perfuses the limbs, especially the lower extremities. PAD affects 10% to 15% of those who are 60 years of age or older, and is associated with significant morbidity and mortality.⁵ Prevalence increases with age, and PAD disproportionately affects blacks. The risk factors for PAD are the same as those for atherosclerotic disease, and it is especially prevalent in individuals who smoke and those with diabetes. PAD is a significant predictor of systemic atherosclerotic disease such that those with documented PAD have nearly double the risk of coronary artery disease than those without PAD.

Lower-extremity ischemia, resulting from arterial obstruction in PAD, can be gradual or acute. In many individuals, gradually increasing obstruction to arterial blood flow to the legs caused by atherosclerosis in the iliofemoral vessels results in pain with ambulation called **intermittent claudication**; however, ischemia may not be painful and may go undetected for years. If a thrombus forms over the atherosclerotic lesion, perfusion can cease acutely with severe pain, loss of pulses, and skin color changes in the affected extremity.

Evaluation for PAD requires a careful history and physical examination that focuses on evidence of atherosclerotic disease (e.g., bruits), ankle-brachial index, and noninvasive Doppler measurement of blood flow. Treatment includes risk factor reduction (smoking cessation and treatment of diabetes, hypertension, and dyslipidemia) and antiplatelet therapy. Symptomatic PAD should be managed with vasodilators in combination with antiplatelet or antithrombotic medications (aspirin, cilostazol, ticlopidine, or clopidogrel),

cholesterol-lowering medications, and exercise rehabilitation. If acute or refractory symptoms occur, emergent percutaneous or surgical revascularization may be indicated.^{78,79} Newer treatment modalities that are being explored include autologous stem cell and gene therapies.^{80,81}

Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes

CAD, myocardial ischemia, and MI form a pathophysiologic continuum that impairs the pumping ability of the heart by depriving the heart muscle of blood-borne oxygen and nutrients. The earliest lesions of the continuum are those of **coronary artery disease (CAD)** in which atherosclerosis occludes the coronary arteries (Fig. 33.14). CAD can diminish the myocardial blood supply until deprivation impairs myocardial metabolism enough to cause **ischemia**, a local state in which the cells are temporarily deprived of blood supply. They remain alive but cannot function normally. Persistent ischemia or the complete occlusion of a coronary artery causes **acute coronary syndromes**. **Infarction** (irreversible myocardial injury) constitutes the often-fatal event known as a *heart attack*.

FIGURE 33.14 Histologic Features of Atheromatous Plaque in the Coronary Artery. A, Overall architecture demonstrating fibrous cap (F) and a central necrotic (largely lipid) core (C). The lumen (L) has been moderately narrowed. Note that a segment of the wall is plaque free (arrow), so that there is an eccentric lesion. In this section, collagen has been stained blue (Masson's trichrome stain). B, Higher power photograph of a section of the plaque shown in (A), stained for elastin (black),

demonstrating that the internal and external elastic membranes are destroyed and the media of the artery is thinned under the most advanced plaque (*arrow*). C, Higher magnification photomicrograph at the junction of the fibrous cap and core, showing scattered inflammatory cells, calcification (*arrowhead*), and neovascularization (*small arrows*). (From Kumar V et al: *Robbins basic pathology*, ed 9, St Louis, 2007, Saunders.)

Development of Coronary Artery Disease

The American Heart Association estimates that the percentage of the U.S. population older than age 20 years with CAD ranges from 3.3% to 6.9% with the lowest prevalence among Asian Americans and the highest among native Hawaiians or other Pacific Islanders. Non-Hispanic whites and blacks have approximately the same CAD prevalence rates at 5.5% to 5.6%.⁵ CAD and associated myocardial infarction is the number one cause of death in both men and women, resulting in a death every 1 minute and 20 seconds in the United States.

Risk factors for CAD are the same as those for atherosclerosis and can be categorized as conventional (major) and nontraditional (novel) and modifiable versus nonmodifiable. It is estimated that 65% of whites and 90% of blacks with CAD events have one or more of these risk factors, and avoidable death rates are nearly twice as high among blacks as compared with whites.⁵

Conventional or major risk factors for CAD that are nonmodifiable include (1) advanced age, (2) male gender or women after menopause, and (3) family history. Aging and menopause are associated with increased exposure to risk factors and poor endothelial healing. Family history may contribute to CAD through genetics and shared environmental exposure.⁸² Many gene polymorphisms have been associated with CAD and its risk factors.⁸³

Major modifiable conventional risks include (1) dyslipidemia, (2) hypertension, (3) cigarette smoking, (4) diabetes and insulin resistance, (5) obesity and sedentary lifestyle, and (6) an atherogenic diet. If individuals receive appropriate preventive care, modification of these factors can significantly reduce the risk for CAD.

Dyslipidemia.

The link between CAD and abnormal plasma lipoprotein concentrations is well documented.⁵ The term **lipoprotein** refers to lipids, phospholipids, cholesterol, and triglycerides bound to carrier proteins. Lipids (cholesterol in particular) are required by most cells for the manufacture and repair of plasma membranes. Cholesterol is also a necessary component for the manufacture of such essential substances as bile acids and steroid hormones. Although cholesterol can easily be obtained from dietary fat intake, most body cells also can manufacture cholesterol.

The cycle of lipid metabolism is complex. Dietary fat is packaged into particles known as **chylomicrons** in the small intestine that transport exogenous lipid from the intestine to the liver and peripheral cells. Chylomicrons are the least dense of the lipoproteins and primarily contain triglyceride. Some of the triglyceride may be removed and either stored by adipose tissue or used by muscle as an energy source. The chylomicron remnants, composed mainly of cholesterol, are taken up by the liver. A series of chemical reactions in the liver results in the production of several lipoproteins that vary in density and function. These include **very-low-density lipoproteins (VLDLs)**, primarily triglyceride and protein; **low-density lipoproteins (LDLs)**, mostly cholesterol and protein; and **high-density lipoproteins (HDLs)**, mainly phospholipids and protein.

Dyslipidemia (or **dyslipoproteinemia**) refers to abnormal concentrations of serum lipoproteins as defined by the *Third Report of the National Cholesterol Education Program* (Table 33.3).⁸⁴ It is estimated that nearly half of the U.S. population has some form of dyslipidemia.⁵ These abnormalities are the result of a combination of genetic and dietary factors. Primary or familial dyslipoproteinemias result from genetic defects that cause abnormalities in lipid-metabolizing enzymes and abnormal cellular lipid receptors (Table 33.4). Secondary causes of dyslipidemia include several common systemic disorders, such as diabetes, hypothyroidism, pancreatitis, and renal nephrosis, as well as the use of some medications such as certain diuretics, beta-blockers, glucocorticoids, interferons, and antiretrovirals.

TABLE 33.3**CRITERIA FOR DYSLIPIDEMIA**

	OPTIMAL	NEAR OPTIMAL	DESIRABLE	LOW	BORDERLINE	HIGH	VERY HIGH
Total cholesterol			<200		200–239	≥240	
LDL	<100	100–129			130–159	160–189	≥190
Triglycerides			<150		150–199	200–499	≥500
HDL				<40		≥60	

HDL, High-density lipoprotein; *LDL*, low-density lipoprotein.

Data from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults: *J Am Med Assoc* 285:2486–2497, 2001.

TABLE 33.4**FAMILIAL DYSLIPOPROTEINEMIAS**

NAME	LABORATORY FINDINGS	CLINICAL FEATURES	THERAPY
Type I: exogenous hyperlipidemia; fat-induced hypertriglyceridemia	Cholesterol normal Triglycerides increased three times Chylomicrons increased	Abdominal pain Hepatosplenomegaly Skin and retinal lipid deposits Usual onset: childhood	Low-fat diet
Type IIa: hypercholesterolemia	Triglycerides normal LDL increased Cholesterol increased	Premature vascular disease Xanthomas of tendons and bony prominences Common Onset: all ages	Low-saturated-fat and low-cholesterol diet Cholestyramine ^a Colestipol ^b Lovastatin ^c Nicotinic acid ^d Neomycin ^e Intestinal bypass
Type IIb: combined hyperlipidemia; carbohydrate-induced	LDL, VLDL increased Cholesterol	Same as IIa	Same as IIa; <i>plus</i> carbohydrate restriction

hypertriglyceridemia	increased Triglycerides increased		Clofibrate ^f Gemfibrozil ^g Lovastatin
Type III: dysbetalipoproteinemia	IDL or chylomicron remnants increased Cholesterol increased Triglycerides increased	Premature vascular disease Xanthomas of tendons and bony prominences Uncommon Onset: adulthood	Weight control Low- carbohydrate, low- saturated-fat, and low- cholesterol diet Alcohol restriction Clofibrate Gemfibrozil Lovastatin Nicotinic acid Estrogens ^h Intestinal bypass
Type IV: endogenous hyperlipidemia; carbohydrate-induced hypertriglyceridemia	Glucose intolerance Hyperuricemia Cholesterol normal or increased VLDL increased Triglycerides increased	Premature vascular disease Skin lipid deposits Obesity Hepatomegaly Common onset: adulthood	Weight control Low- carbohydrate diet Alcohol restriction Clofibrate Nicotinic acid Intestinal bypass
Type V: mixed hyperlipidemia; carbohydrate and fat- induced hypertriglyceridemia	Glucose intolerance Hyperuricemia Chylomicrons increased VLDL increased LDL increased Cholesterol increased Triglycerides increased three times	Abdominal pain Hepatosplenomegaly Skin lipid deposits Retinal lipid deposits Onset: childhood	Weight control Low- carbohydrate and low-fat diet Clofibrate Lovastatin Nicotinic acid Progesterone ⁱ Intestinal bypass

^a*Cholestyramine* (Questran), anion exchange resin; binds bile acids; enhances cholesterol excretion.

^b*Colestipol* (Colestid), same as cholestyramine.

^c*Lovastatin*, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase

inhibitor; decreases cholesterol synthesis in the liver.

^d*Nicotinic acid* (niacin), decreases release of free fatty acids from adipose tissue; increases lipogenesis in liver; decreases glucagon release; most effective for type V disorder.

^e*Neomycin*, experimental medication; questionable mode of action; decreases LDLs.

^f*Clofibrate* (Atromid-S), decreases release of free fatty acids from adipose tissue; decreases hepatic secretion of VLDL and increases catabolism of VLDL.

^g*Gemfibrozil* (Lopid), similar to clofibrate but increases HDLs more.

^h*Estrogens*, decrease IDL levels in type III disorders; experimental.

ⁱ*Progesterone*, decreases plasma triglycerides in type V disorders; experimental.

IDL, Intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *VLDL*, very-low-density lipoprotein.

An increased serum concentration of LDL is an indicator of coronary risk; however, the relative risk of elevated LDL depends on the presence of other risk factors such as age, diabetes, and chronic kidney disease. Thus new guidelines from the American Heart Association and the American College of Cardiology focus on treating dyslipidemia in the context of other risk factors.⁸⁵ LDL is responsible for the delivery of cholesterol to the tissues. Serum levels of LDL are normally controlled by hepatic receptors that bind LDL and limit liver synthesis of this lipoprotein. High dietary intake of cholesterol and fats, often in combination with a genetic predisposition to accumulations of LDL in the serum (e.g., dysfunction of the hepatic LDL receptor), results in high levels of LDL in the bloodstream. LDL oxidation, migration into the vessel wall, and phagocytosis by macrophages are key steps in the pathogenesis of atherosclerosis (see [Fig. 33.13](#)). The term LDL actually describes several types of LDL molecules. Measurement of LDL subfractions allows for better prediction of coronary risk. For example, low density lipoprotein-cholesterol (LDL-C) measurements allow for detection of the small dense LDL particles that are the most atherogenic, and apolipoprotein B (structural protein found in both LDL and VLDL) levels are a strong predictor of future coronary events.⁸⁶ Lowering serum levels of LDL

can reduce the risk for CAD. For example, recent studies found that for every 1% reduction in LDL-C, there is a 1% reduction in coronary risk in both men and women.^{87,88} Although the 3-hydroxy-3-methylglutaryl-CoA reductase medications (statins) continue to be used for many people with elevated LDL levels and other risk factors for CAD,⁸⁵ new and future medications aimed at lowering LDL levels, such as the proprotein convertase subtilisin/kexin 9 (PCSK9) inhibitors, are being developed⁸⁹ (see [What's New? New and Future Drugs for Treatment of Dyslipidemia](#)).

What's New?

New and Future Drugs for Treatment of Dyslipidemia

A new guideline for the treatment of blood cholesterol was released by the American College of Cardiology (ACC) and the American Heart Association (AHA) in 2014. This guideline linked decisions about treatment of dyslipidemia to the presence of other cardiovascular risks, such as diabetes. Statins have been shown to be effective in reducing low density lipoprotein (LDL) and overall cardiovascular risk but there continue to be considerable concerns about potential side effects of their use and their lack of effect on high density lipoprotein (HDL). The PCSK9 inhibitors are a new class of drugs that are now being used to treat increased LDL. These drugs prevent the breakdown of the LDL receptor, thus reduce hepatic synthesis of LDL. Early studies suggest that these drugs are safe and effective in lowering serum LDL levels in selected individuals. The FDA currently approves the use of two PCSK9 inhibitors (alirocumab and evolocumab) for individuals on maximally-tolerated statin therapy, who have familial hypercholesterolemia, or who have clinical coronary artery disease and require additional LDL lowering. Low levels of HDL also are a significant risk factor for cardiovascular disease. Unfortunately, most new drugs aimed at increasing HDL levels (e.g., cholesterol

ester transfer protein [CETP] inhibitors) have been ineffective in reducing cardiovascular risk. Recent studies suggest that high density lipoprotein-cholesterol (HDL-C) is the most important HDL particle, and that this molecule becomes dysfunctional independent of serum levels in inflammatory conditions, such as atherosclerosis. Diet and exercise appear to improve HDL functionality. Assays to evaluate dysfunctional HDL and new drugs to improve HDL function are in development.

Data from Gadi R, Figueredo VM: *J Cardiovasc Med* 16(1):1–10, 2015; Leander K et al: *Circulation* 133:1230–1239, 2016; McKenney JM: *J Clin Lipidol* 9(2):170–186, 2015; Nofer JR: *Handb Exp Pharmacol* 224:229–256, 2015; Rosenson RS et al: *Nat Rev Cardiol* 13(1):48–60, 2016; Sattar N et al: *Lancet Diabetes Endocrinol* 4:403–410, 2016; Shapiro MD, Fazio S, Tavori H: *Curr Atheroscler Rep* 17(4):499, 2015; Siddiqi HK, Kiss D, Rader D: *Curr Opin Cardiol* 30(5):536–542, 2015; Waters DD, Hsue PY, Bangalore S: *J Am Med Assoc* 2315:1571–1572, 2016.

Low levels of HDL cholesterol also are a strong indicator of coronary risk. HDL is responsible for “reverse cholesterol transport,” which returns excess cholesterol from the tissues to the liver, where it binds to hepatic receptors (including the LDL receptor) and is processed and eliminated as bile or converted to cholesterol-containing steroids. HDL can remove excess cholesterol from the arterial wall through several pathways, including mediating the efflux of cholesterol from lipid-laden macrophages (foam cells) through the activation of adenosine triphosphate (ATP)–binding cassette transporter proteins (ABC proteins). Additional actions of HDL include protecting LDL from oxidation, preserving endothelial function, and also promoting antiinflammatory and antithrombotic effects.⁹⁰ As HDL cholesterol is transported, it progresses through three subtypes of HDL: pre- β HDL, HDL3, and HDL2. Apolipoprotein (ApoA-I) on the pre- β HDL binds cholesterol where it is converted to cholesteryl ester creating HDL3. HDL3 then increases in size to form HDL2, which is fully loaded with cholesterol. The smaller HDL3 molecule is the most protective in preventing atherosclerosis, and research continues to explore the best approach to increasing this type

of HDL. These various types of HDL exert both distinct and overlapping activities, which may be compromised by inflammatory conditions, obesity, and diabetes resulting in HDL dysfunction.^{91,92} Drugs aimed at increasing HDL have not been effective to date, but new therapies are being explored that address HDL dysfunction (see [What's New? New and Future Drugs for Treatment of Dyslipidemia](#)).

Other lipoproteins associated with increased cardiovascular risk include elevated levels of serum VLDL (triglycerides) and increased lipoprotein(a). Triglycerides are associated with an increased risk for CAD, especially in combination with other risk factors such as diabetes. Because of this, the measurement of “non-HDL cholesterol” (LDL plus VLDL) is frequently used to assess cardiovascular risk rather than just LDL or HDL levels alone. **Lipoprotein(a) (Lp[a])** is a genetically determined molecular complex between LDL and a serum glycoprotein called *apoprotein(a)* that has been shown to be an important risk factor for coronary atherosclerosis, especially in women.⁹³

Hypertension.

Hypertension is responsible for a two- to threefold increased risk of atherosclerotic cardiovascular disease including MI.⁵ It contributes to endothelial injury, a key step in atherogenesis and causes myocardial hypertrophy, which increases myocardial demand for coronary flow. The overactivity of the SNS and RAAS commonly found in hypertension also contributes to the genesis of coronary artery disease. Drugs that block the effects of the SNS and RAAS to treat hypertension have many positive effects on the vasculature.⁹⁴

Cigarette Smoking.

In the United States, approximately 17% of adults are active cigarette smokers, and direct and passive (environmental) smoking account for approximately one-third of all deaths related to CAD.⁵ Smoking has a direct effect on endothelial cells and the generation of oxygen radicals that contribute to atherogenesis.⁹⁵ Nicotine stimulates the release of catecholamines (epinephrine and norepinephrine), which increases

heart rate and causes peripheral vascular constriction. As a result blood pressure increases, as do cardiac workload and oxygen demand. Cigarette smoking is associated with an increase in LDL and a decrease in HDL levels, and contributes to vessel inflammation and thrombosis. The risk of CAD increases with heavy smoking and decreases when smoking is stopped.

Diabetes Mellitus.

Diabetes mellitus and insulin resistance are extremely important risk factors for CAD.⁵ Insulin resistance, hyperinsulinemia, and hyperglycemia have multiple effects on the cardiovascular system. These effects can include endothelial damage, thickening of the vessel wall, increased inflammation and leukocyte adhesion, increased thrombosis, glycation of vascular proteins, and decreased production of endothelial-derived vasodilators such as nitric oxide⁹⁶ (diabetes is discussed in [Chapter 22](#)). Diabetes is also associated with dyslipidemia, and aggressive management of this additional risk factor can significantly improve CAD risk in individuals with diabetes.⁸⁵

Obesity and Sedentary Lifestyle.

It is estimated that approximately one-third of children and two-thirds of adults in the United States are overweight or obese, resulting in a much increased risk for CAD and stroke. An estimated 47 million U.S. residents have a combination of obesity, dyslipidemia, and hypertension (called **metabolic syndrome**) (see [Chapter 22](#)), which is associated with an even higher risk for CAD events.⁵ Obesity is caused by genetics, diet, and inadequate physical exercise. Abdominal obesity (also known as **android obesity**) has the strongest link with increased CAD risk and is related to insulin resistance, decreased HDL levels, increased blood pressure, and inflammation. Obesity is associated with changes in the adipokines (see the following) and is associated with the deposition of perivascular adipose tissue that contributes to atherogenesis.⁹⁷ A sedentary lifestyle not only increases the risk of obesity but also has an independent effect on increasing CAD risk. It

is estimated that physical inactivity is responsible for approximately 12% of myocardial infarctions.⁵ Physical activity and weight loss offer substantial reductions in risk for CAD.⁹⁸ There is emerging evidence that bariatric surgery procedures can provide sustained improvement in risk factors for cardiovascular disease such as hypertension, dyslipidemia, and diabetes.⁵

Atherogenic Diet.

Diet plays a complex role in atherogenic risk. Diets high in salt, fats, trans fats, and carbohydrates have all been implicated. There are many recommendations regarding diet modification to reduce coronary risk; one of the most studied dietary patterns is the Mediterranean diet.⁹⁹ A recent randomized control trial in high-risk individuals suggested that following a Mediterranean diet over a 5-year period, compared with a control diet, was related to a 29% lower risk of CVD¹⁰⁰ (see [Nutrition & Disease: Mediterranean Diet and Cardiovascular \[CV\] Disease and Recent Findings on Sugar](#)).

Nutrition & Disease

Mediterranean Diet and Cardiovascular (CV) Disease and Recent Findings on Sugar

The Mediterranean diet comprises a high intake of fruits, vegetables, legumes, whole-grain products, fish, and unsaturated fatty acids (especially olive oil), with low consumption of red meat, dairy products, and saturated fatty acids. Included in this dietary pattern is moderate consumption of alcohol (mostly wine, consumed with meals). However, investigators from a recent mendelian randomization study, including 59 epidemiologic studies, reported that the lowest risks for CV outcomes were in abstainers and that any amount of alcohol is associated with elevated blood pressure and body mass index (BMI).

The proportion of calories derived from carbohydrates has been associated with risk of diabetes and cardiovascular disease in

observational studies and clinical trial. Some studies have shown that a diet higher in glycemic index (GI) is associated with higher levels of C-reactive protein, a marker of inflammation associated with risk for diabetes or cardiovascular disease. This observation has led to the hypothesis that inflammation may mediate the association of GI with cardiovascular disease. Ongoing studies are identifying these interactions. Investigators report that the oral glucose tolerance test does not represent the overall glycemic effects of dietary patterns that vary in both amount and type of carbohydrate. Glycated albumin and fructosamine, markers of 2- to 3-week cumulative exposure to blood glucose, may be especially suited for evaluating the effects of dietary carbohydrates on glycemia. Both glycated albumin and fructosamine are formed by glycation reactions, where glucose binds with intravascular proteins, including albumin, and are associated with risk of diabetes and cardiovascular disease events. Using an isocaloric feeding study (OmniCarb trial) in adults without diabetes, investigators found that reducing dietary carbohydrates lowered markers of 2- to 3-week glycemia (i.e., glycated albumin and fructosamine). Additionally, changes to GI had no effect on glycated albumin or fructosamine and neither reducing dietary carbohydrates or modifying glycemic index affected C-reactive protein. Overall, this study suggests that reducing carbohydrate content, rather than GI, is a better strategy for lowering glycemia in adults at risk for diabetes and, therefore, cardiovascular disease. The largest single food source of calories in the United States and Europe is sugar-sweetened soft drinks.

Data from Holmes MV et al: *BMJ* 349:g4164, 2014; Juraschek SP et al: *BMJ Open Diabetes Res Care* 4(1):e000276, 2016.

Nontraditional Risk Factors.

Nontraditional, or novel, risk factors for CAD include (1) increased serum markers for inflammation, ischemia, and thrombosis; (2) adipokines; (3) chronic kidney disease; (4) air pollution and ionizing

radiation; (5) medications; (6) coronary artery calcification and carotid wall thickness; and (7) the microbiome. The amount of risk conferred by these relatively newly identified factors is still being explored.

Markers of Inflammation, Ischemia, and Thrombosis.

Of the numerous markers of inflammation that have been linked to an increase in CAD risk, **highly sensitive C-reactive protein (hs-CRP)** has been explored in the greatest depth. hs-CRP is an acute phase reactant or protein mostly synthesized in the liver and is an indirect measure of atherosclerotic plaque-related inflammation and plaque progression.¹⁰¹ Elevated levels of hs-CRP are associated with numerous other CAD risk factors including smoking, obesity, and diabetes and, while they have been found to be an independent risk factor for coronary disease, the risk is highest when there is an associated elevation in LDL-C.¹⁰² Current recommendations suggest that hs-CRP should be used as a part of overall cardiovascular risk assessment in selected individuals.¹⁰³ Troponin I (TnI) is a serum protein whose measurement is used as a sensitive and specific diagnostic test to help identify myocardial ischemia during acute coronary syndromes. Highly sensitive TnI assays are used in individuals without a history of CAD to assess risk for future CHD events, mortality, and heart failure.¹⁰⁴ Markers of thrombosis associated with CAD include fibrinogen and protein C.

Adipokines.

Adipokines are a group of hormones released from adipose cells. The two that are most studied are adiponectin and leptin. Increased serum leptin is primarily implicated because of its contributions to the complications of obesity, hypertension, and diabetes but it is also being implicated in autoimmunity and decreased endothelial angiogenesis.¹⁰⁵ Decreased adiponectin (hypoadiponectinemia) in obese individuals has been linked to a significant increase in cardiovascular risk. Antiatherogenic effects of adiponectin include antiinflammatory, insulin-sensitizing enhancement of nitric oxide generation, attenuation of reactive oxygen species production in

endothelial cells, and reduced vascular smooth muscle cell proliferation.¹⁰⁶ A more recently described adipokine is resistin, which has been linked to inflammation, endothelial dysfunction, thrombosis, and smooth muscle cell dysfunction. Emerging evidence suggests that adipokine changes occurring in perivascular adipose cells may play a significant role in metabolic and vascular disorders.¹⁰⁷ Weight loss and exercise improve adipokine levels and are correlated with improved cardiovascular risk, and new therapies, such as peroxisome proliferator-activated receptor (PPAR) gamma agonists, upregulation of adiponectin receptors, and direct infusions of adiponectin, are being explored.¹⁰⁶

Chronic Kidney Disease.

People with chronic kidney disease (CKD) are at increased risk for CAD events, and risk increases as glomerular filtration rate declines. In CKD, dyslipidemia, endothelial dysfunction, vascular calcification, elevated levels of growth factors, and toxic oxygen radicals all contribute to atherogenesis and CAD.^{108,109}

Air Pollution and Ionizing Radiation.

Exposure to air pollution is strongly correlated with coronary risk. It is postulated that toxins in pollution contribute to macrophage activation, oxidation of LDL, autonomic imbalance, thrombosis, and inflammation of vessel walls.¹¹⁰ Ionizing radiation is most often linked to cancer risk, but there is emerging evidence that even low doses of radiation may contribute to CAD.¹¹¹ A recent hypothesis is somatic mutations in hematopoietic cells contribute to the development of human atherosclerosis.¹¹²

Medications.

An increase in CAD-related ischemic events can occur within weeks of beginning NSAID use.¹¹³ The likelihood of MI or stroke is greatest among those with preexisting disease, and risk increases at higher doses and with longer duration of use. There also is evidence that NSAIDs decrease the effectiveness of aspirin in preventing clot

formation on atherosclerotic plaques (see [What's New? Nonsteroidal Antiinflammatory Drugs and Coronary Artery Disease](#)). Antirejection drugs and protease inhibitors also increase the risk for CAD.

What's New?

Nonsteroidal Antiinflammatory Drugs and Coronary Artery Disease

Nonsteroidal antiinflammatory drugs (NSAIDs) are some of the most widely used medications in the world, and approximately 13% of Americans take them regularly. The first NSAIDs linked to cardiovascular disease were the cyclooxygenase-2 (COX-2) inhibitors that were designed to protect the gastrointestinal tract from ulceration, but were found to increase the risk of acute coronary syndromes. Since then, all NSAIDs have been found to be linked to coronary risk, and no NSAID is considered “safe,” especially in those with underlying coronary artery atherosclerosis. Pathophysiologically, all NSAIDs have effects on the mitochondria in myocytes, including generation of toxic reactive oxygen species through pathways, such as nicotinamide adenine dinucleotide phosphate (NADPH), cytochrome 450, and lipoxygenase. Furthermore, NSAIDs alter the thromboxane/prostacyclin balance contributing to platelet aggregation. More recently, they have been shown to block the anti-platelet effects of aspirin. Finally, NSAIDs may contribute to hypertension, heart failure, and chronic kidney disease which have significant associated cardiovascular complications. The FDA has added label warnings, and high-risk individuals are recommended to avoid their use when possible.

Data from Campbell CL, Moliterno DJ: *J Am Med Assoc* 313(8):801–802, 2015; Danelich IM et al: *Pharmacotherapy* 35(5):520–535, 2015; Ghosh R, Alajbegovic A, Gomes AV: *Oxid Med Cell Longev* 2015:536962, 2015; Schjerning Olsen AM et al: *J Am Med Assoc* 313(8):805–814, 2015; Yoemans ND: *BMC Med* 13:56–59, 2015.

Coronary Artery Calcification and Carotid Artery Wall Thickness.

Coronary risk related to changes in vessel walls can be assessed using various types of vascular imaging techniques. Coronary artery calcification (CAC), as detected by CT scanning, carotid intima-media thickness test (CIMT), and ultrasonography, are two important imaging modalities in widespread use for determining coronary heart disease risk. CAC is likely to be the most useful of the current approaches to improving risk assessment among individuals found to be at intermediate risk after formal risk assessment.¹⁰³

The Microbiome.

The effects of diet and other lifestyle measures on the microbiome and CVD risk increasingly are being explored. These effects may be mediated through their impact on other risk factors, such as diabetes and autoimmunity, or through more direct effects on microbiota function. For example, hyperhomocysteinemia has been linked to cardiovascular risk, yet the addition of folate (which increases homocysteine breakdown) has not improved risk. It is now postulated that the microbiome may be an important modulator of lipid and homocysteine metabolism, as well as many other atherosclerotic risk factors.^{114,115}

In coronary artery disease, atherosclerotic plaques that form in the coronary circulation can develop in two primary ways. **Stable plaques** gradually increase in size and may partially occlude the vessel lumina, thus limiting coronary flow and causing ischemia especially during exercise. **Unstable plaques** are prone to ulceration or rupture even if there has been no significant impairment of coronary blood flow before the event (see [Fig. 33.19](#)). When this ulceration or rupture occurs, underlying tissues of the vessel wall are exposed, resulting in platelet adhesion and thrombus formation. Thrombus formation can suddenly cut off blood supply to the heart muscle, resulting in acute myocardial ischemia, and if the vessel obstruction cannot be reversed rapidly, ischemia will progress to infarction.

Transient Myocardial Ischemia

As described previously, CAD can diminish the myocardial blood supply causing ischemia. The process of atherosclerotic plaque progression can be gradual, which usually results in transient myocardial ischemic syndromes when demand for blood supply exceeds supply, but perfusion is restored before there is permanent damage to the heart muscle. Ischemia also can occur with coronary vasospasm even in the absence of atherosclerosis. Transient myocardial ischemia can result in unstable angina, Prinzmetal angina, or silent ischemia.

◆Pathophysiology.

The coronary arteries normally supply blood flow sufficient to meet the demands of the myocardium because it labors under varying workloads. Oxygen extraction from these vessels occurs with maximal efficiency. If efficient exchange does not meet myocardial oxygen needs, healthy coronary arteries are able to dilate to increase the flow of oxygenated blood to the myocardium. Narrowing of a major coronary artery by more than 50% impairs blood flow sufficiently to hamper cellular metabolism under conditions of increased myocardial demand (see [Fig. 33.14](#)).

Myocardial ischemia develops if the supply of coronary blood cannot meet the demand of the myocardium for oxygen and nutrients. Imbalances between myocardial demand and coronary blood supply can result from a number of conditions. Common causes of increased myocardial demand for blood include tachycardia, exercise, hypertension (hypertrophy), and valvular disease. Myocardial ischemia also can result from other causes of decreased blood and oxygen delivery to the myocardium, such as coronary spasm, hypotension, dysrhythmias, decreased oxygen-carrying capacity of the blood (anemia, hypoxemia), and aortic valvular disease.

Myocardial cells become ischemic within 10 seconds of coronary occlusion. After several minutes the heart cells lose the ability to contract, and cardiac output decreases. Ischemia also causes conduction abnormalities that lead to changes in the

electrocardiogram and may initiate dysrhythmias. Anaerobic processes take over, and lactic acid accumulates. Cardiac cells remain viable for approximately 20 minutes under ischemic conditions. If blood flow is restored, aerobic metabolism resumes, contractility is restored, and cellular repair begins. If the coronary artery occlusion persists beyond 20 minutes, MI occurs (Fig. 33.15).

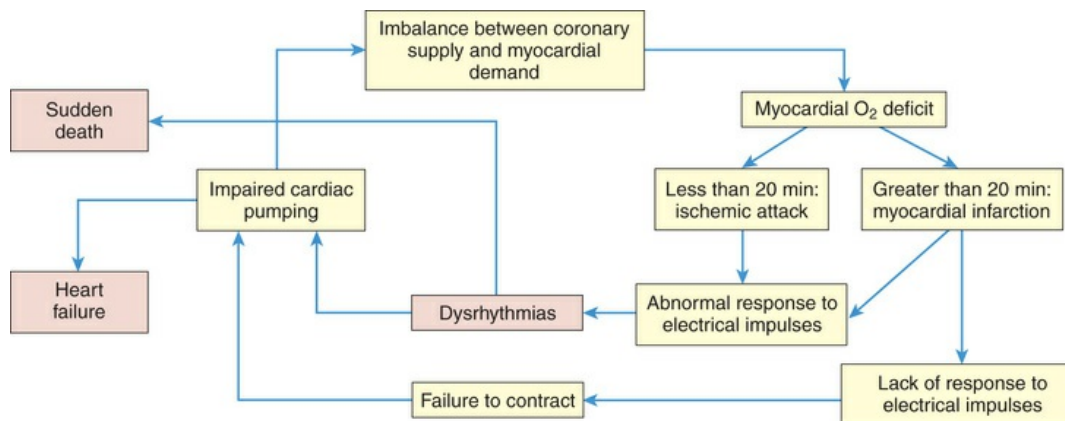

FIGURE 33.15 Cycle of Ischemic Events.

◀Clinical Manifestations.

Individuals with reversible myocardial ischemia present clinically in several ways. Chronic atherosclerotic coronary obstruction usually results in recurrent predictable chest pain called **stable angina**. Abnormal vasospasm of coronary vessels results in unpredictable chest pain called **Prinzmetal angina**. Myocardial ischemia that does not cause detectable symptoms is called **silent ischemia**.

Stable Angina

Angina pectoris is chest pain caused by myocardial ischemia. Stable angina is caused by gradual luminal narrowing and hardening of the arterial walls, so that affected vessels cannot dilate in response to increased myocardial demand associated with physical exertion or emotional stress. With rest, blood flow is restored and no necrosis of myocardial cells results. **Angina pectoris** is typically experienced as

transient substernal chest discomfort, ranging from a sensation of heaviness or pressure to moderately severe pain. Individuals often describe the sensation by clenching a fist over the left sternal border. The discomfort may be mistaken for indigestion. The pain is caused by the buildup of lactic acid or abnormal stretching of the ischemic myocardium that irritates myocardial nerve fibers. These afferent sympathetic fibers enter the spinal cord from levels C3 to T4, accounting for the variety of locations and radiation patterns of anginal pain. Pain may radiate to the neck, lower jaw, left arm, and left shoulder or occasionally to the back or down the right arm. Pallor, diaphoresis, and dyspnea may be associated with the pain. The pain is usually relieved by rest and nitrates.

Myocardial ischemia in women may not present with typical angina. Common symptoms in women include atypical chest pain, palpitations, sense of unease, and severe fatigue. In addition, it is estimated that half of women with stable angina do not have obstructive coronary artery disease, but rather have *microvascular angina* that results from vasoconstriction of small coronary arterioles deep in the myocardium¹¹⁶ (see [What's New? Women and Microvascular Angina](#)). Similarly, in individuals who have autonomic nervous system dysfunction, such as older adults or those with diabetes, angina may be mild, atypical, or even silent (see the following).

What's New?

Women and Microvascular Angina

Women with myocardial ischemia often have either no or atypical symptoms, such as palpitations, anxiety, weakness, and fatigue. Additionally, many women with angina are found to have cardiac ischemia, yet no evidence of obstructive coronary artery disease on cardiac catheterization. Evidence is accumulating that nearly half of women with myocardial ischemia suffer from coronary microvascular disease, a condition often called *microvascular angina*

(MVA). Small intramyocardial arterioles constrict in MVA causing ischemic pain that is less predictable than with typical epicardial coronary artery disease (CAD). The pathophysiology is complex and still being elucidated, but there is strong evidence that endothelial dysfunction, decreased endogenous vasodilators, inflammation, changes in adipokines, and platelet activation are contributing factors. The diagnosis of MVA may require catheterization during which there is assessment of the microcirculatory response to adenosine or acetylcholine and measurement of coronary and fractional flow reserve. New techniques include positron emission tomography (PET) scanning, cardiac magnetic resonance imaging (MRI), and transthoracic Doppler echocardiography. Managing MVA can be challenging, for example, women with this condition have less coronary microvascular dilation in response to nitrates than do those without MVA. Women with MVA often have traditional risk factors for CAD such as obesity, dyslipidemia, diabetes, and hypertension. Aggressive interventions to reduce modifiable risk factors are an important component of management, especially smoking cessation, exercise, and diabetes management. The combination of nonnitrate vasodilators, such as calcium channel blockers and angiotensin converting enzyme (ACE) inhibitors along with 3-hydroxy-3-glutaryl-coenzymeA (HMG-CoA) reductase inhibitors (statins), also has been shown to be effective in many women, and new drugs, such as Ranolazine and Ivabradine, have shown promise in the treatment of MVA. Other approaches include spinal cord stimulators, adenosine receptor blockade, and psychiatric intervention.

Data from Cattaneo M et al: *Int J Cardiol* 181:376–381, 2015; Celik T et al: *Int J Cardiol* 218:233–234, 2016; Lanza GA et al: *Circ J* 2016 May 27 [Epub ahead of print]; Marinescu MA et al: *JACC Cardiovasc Imaging* 8(2):210–220, 2015; Selthofer-Relatic K, Boxnjak I, Kibel A: *Cardiol Res Pract* 2016:8173816, 2016; Titterington JS, Hung OY, Wenger NK: *Future Cardiol* 11(2):229–242, 2015.

Prinzmetal Angina

Prinzmetal angina (also called *variant angina*) is chest pain attributable to transient ischemia of the myocardium that occurs unpredictably and almost exclusively at rest. This form of angina often occurs at night during rapid eye movement sleep and may have a cyclic pattern of occurrence. Pain is caused by vasospasm of one or more major coronary arteries with or without associated atherosclerosis. The angina may result from decreased vagal activity, hyperactivity of the sympathetic nervous system, and decreased nitric oxide activity. Other causes include altered calcium channel function in arterial smooth muscle and endothelial dysfunction with release of inflammatory mediators, such as serotonin, histamine, endothelin, or thromboxane.¹¹⁷ The level of hs-CRP may be elevated in individuals with this form of angina. Prinzmetal angina is usually a benign condition, but can occasionally cause serious dysrhythmias especially if treatment is withdrawn; therefore calcium channel blockers or long-acting nitrates, or both, should be continued even if clinical remission is achieved. If the spasm persists long enough, infarction or serious dysrhythmias may occur.¹¹⁸

Silent Ischemia and Mental Stress (Induced Ischemia)

Myocardial ischemia does not always cause angina and may be associated only with nonspecific symptoms such as fatigue, dyspnea, or feeling of unease. Some individuals only have silent ischemia, whereas episodes of silent myocardial ischemia may occur in individuals who also experience angina. Global or regional abnormalities in left ventricular sympathetic afferent innervation have been implicated in diabetes mellitus, following surgical denervation during coronary artery bypass grafting (CABG) or cardiac transplantation, or following ischemic local nerve injury by MI. There also is evidence that individuals with silent ischemia produce less lactate than those with angina.¹¹⁹ Silent ischemia also may occur in some individuals during mental stress and anger.¹²⁰ Mental stress results in the release of catecholamines and an increase in heart rate,

blood pressure, and vascular resistance, as well as electrical instability (see Fig. 33.16). In addition, it has been linked to increased hs-CRP level, decreased activity of vasodilators such as nitric oxide, and a hypercoagulable state that may contribute to acute ischemic events.

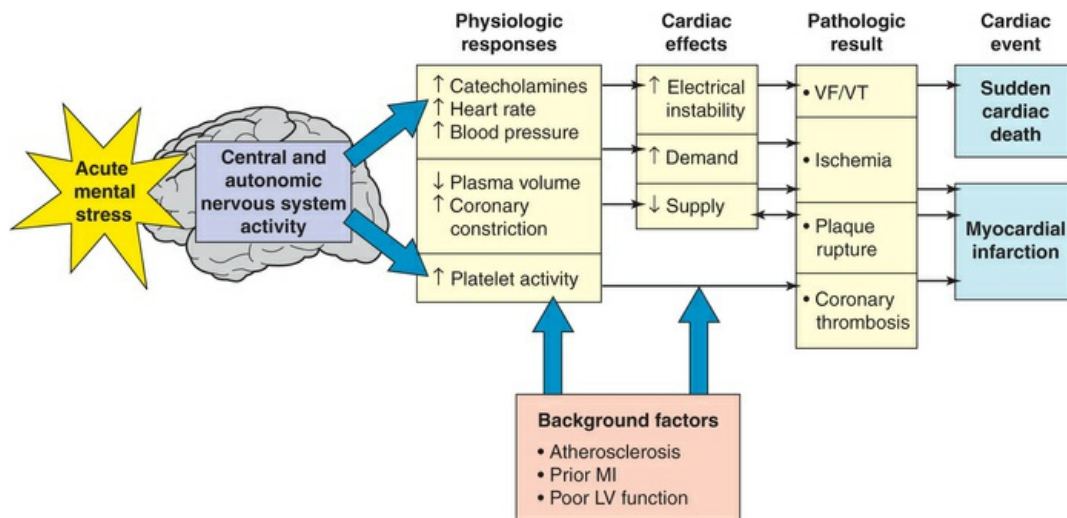

FIGURE 33.16 Pathophysiologic Model of Acute Stress Effects Triggering Cardiac Clinical Events. Acting via the central and autonomic nervous systems, stress can produce a cascade of physiologic responses that may lead to myocardial ischemia, potentially fatal dysrhythmia, plaque rupture, or coronary thrombosis. *LV*, Left ventricle; *MI*, myocardial infarction; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia. (From Kranz DS et al: Mental stress as a trigger of myocardial ischemia and infarction. In Deedwania PC, Tofler GH, editors: *Triggers and timing of cardiac events*, ed 2, London, 1996, Saunders.)

◆ Evaluation and Treatment.

Many individuals with reversible myocardial ischemia exhibit a normal physical examination between episodes. Physical examination of an individual experiencing myocardial ischemia may disclose tachycardia, extra heart sounds (gallops or murmurs), and pulmonary congestion indicating impaired left ventricular function. The presence of **xanthelasmas** (small fat deposits) around the eyelids or **arcus senilis** of the eyes (a yellow lipid ring around the cornea) suggests dyslipidemia and possible atherosclerosis. The presence of peripheral or carotid arterial bruits suggests probable atherosclerotic disease and increases the likelihood that CAD is present.

Electrocardiography is a critical tool for diagnosing myocardial ischemia. Because many individuals have normal ECGs in the absence of pain, diagnosis may require that electrocardiography be performed during an attack of angina. Transient ST-segment depression and T-wave inversion are characteristic signs of subendocardial ischemia frequently seen in angina. ST elevation, indicative of transmural ischemia, can be seen in individuals with Prinzmetal angina but is more common in infarction (Fig. 33.17). The ECG also can give some indication of which coronary artery is involved. Approximately 30% of individuals with angina have nondiagnostic ECG tracings and require other diagnostic studies.

FIGURE 33.17 Electrocardiogram (ECG) and Ischemia. A, Normal ECG. B, Electrocardiographic alterations associated with ischemia.

Stress radionuclide imaging is indicated to detect ischemic changes in asymptomatic individuals with multiple risk factors for coronary disease, such as diabetes and dyslipidemia, and for older individuals who plan to start vigorous exercise. Stress testing is made more sensitive when radioisotope imaging is added to the ECG as an indicator of myocardial ischemia. Currently, the modality of choice for the diagnosis of myocardial ischemia is single-photon emission computed tomography (SPECT), which is effective at identifying ischemia and estimating risk for coronary events.¹²¹ Radioisotope imaging with thallium-201 and stress echocardiography also are used. Unfortunately, although all of these tests are helpful in documenting coronary obstruction, they cannot detect the presence of unstable plaques, which are the cause of the majority of acute coronary

syndromes.

Imaging the coronary arteries for the evaluation of atherosclerotic plaques involves the use of CT with and without angiography, MRI, or intravascular ultrasound.¹²² Coronary angiography is useful in determining the anatomic extent of CAD. The procedure is expensive and carries some risk; thus it is used primarily to evaluate for possible percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) surgery for individuals whose noninvasive studies suggest severe disease.

The primary aims of therapy for myocardial ischemia and angina are to increase delivery of oxygen by improving coronary artery blood flow and to reduce myocardial oxygen consumption. Recommendations for appropriate diet, exercise, and risk reduction strategies have been widely distributed. Coronary blood flow is improved by reversing vasoconstriction, preventing clotting, and reducing plaque growth and rupture. Myocardial oxygen consumption is reduced by manipulation of blood pressure, heart rate, contractility, and left ventricular volume. Many different classes of drugs are available to manage stable angina, including nitrates, β -adrenergic receptor blockers, and calcium channel blockers.¹²³ Statins are indicated for primary prevention in high-risk individuals and for all those with known CAD.⁸⁵ Antithrombotics, such as aspirin or clopidogrel, reduce the risk of clot formation. Angiotensin-converting enzyme (ACE) inhibitors or ang II receptor blockers are indicated for all people with coronary artery disease who also have diabetes, hypertension, and/or left ventricular systolic dysfunction. Ranolazine represents a relatively new class of antianginal drugs known as *sodium ion channel inhibitors* and has been found to improve exercise tolerance, lessen anginal symptoms, and reduce the need for nitrates in many individuals with chronic stable angina.¹²⁴

Coronary revascularization is indicated for those individuals who do not respond adequately to antianginal drugs or who have high-risk atherosclerotic lesions.^{123,125} **Percutaneous coronary intervention (PCI)** is a procedure whereby stenotic (narrowed) coronary vessels are dilated with a catheter. Several different types of catheters can be used

to open the blocked vessel. PCI is most often used to treat single-vessel disease, but it can be effective with multiple-vessel disease or restenosis of a coronary artery bypass graft in selected individuals. Restenosis of the artery is the major complication of the procedure; however, placement of a coronary stent can reduce this risk and antithrombotic treatment, such as aspirin, clopidogrel, or glycoprotein IIb/IIIa receptor antagonists, after stenting can improve outcomes. Severe CAD can be surgically treated by CABG, usually using the saphenous vein from the lower leg. In selected individuals, a modified CABG procedure called *minimally invasive direct coronary artery bypass (MIDCAB)* can be used with much less surgical morbidity and more rapid recovery. Investigational treatment for refractory angina includes gene and stem therapies for myocardial angiogenesis and spinal cord stimulation.^{126,127}

Acute Coronary Syndromes

When there is sudden coronary obstruction caused by thrombus formation over a ruptured or ulcerated atherosclerotic plaque, acute coronary syndromes result (Fig. 33.18). The acute coronary syndromes (ACS) include unstable angina and myocardial infarction. **Unstable angina** is the result of reversible myocardial ischemia and is a harbinger of impending infarction. **Myocardial infarction (MI)** results when prolonged ischemia causes irreversible damage to the heart muscle. MI can be further subdivided into non-ST-elevation MI (non-STEMI) and ST-elevation MI (STEMI) (see [the Pathophysiology section](#)). Sudden cardiac death can occur as a result of any of the acute coronary syndromes.

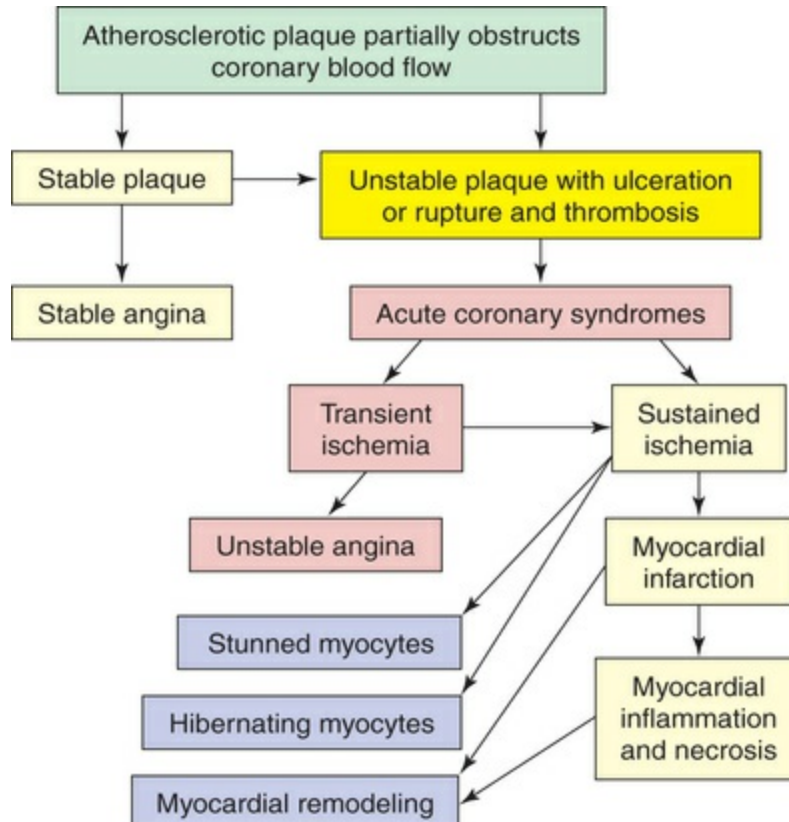

FIGURE 33.18 Pathophysiology of Acute Coronary Syndromes. The atherosclerotic process can lead to stable plaque formation and stable angina or can result in unstable plaques that are prone to rupture and thrombosis. Thrombus formation on a ruptured plaque that disperses in less than 20 minutes leads to transient ischemia and unstable angina. If the vessel obstruction is sustained, myocardial infarction with inflammation and necrosis of the myocardium result. In addition, myocardial infarction is associated with other structural and functional changes, including myocyte stunning and hibernation and myocardial remodeling.

An unstable atherosclerotic plaque is prone to rupture. It has a core that is especially rich in deposited oxidized LDL and a thin fibrous cap (Fig. 33.19). These unstable plaques may not extend into the lumen of the vessel and may be clinically silent until they rupture. Plaque disruption (ulceration or rupture) occurs because of shear forces, inflammation with release of multiple inflammatory mediators, secretion of macrophage-derived degradative enzymes, and apoptosis of cells at the edges of the lesions. Exposure of the plaque substrate activates the clotting cascade. In addition, platelet activation results in the release of coagulants and exposure of platelet glycoprotein IIb/IIIa surface receptors, resulting in further platelet aggregation and adherence. The resulting thrombus can form very quickly (Fig. 33.20,

A). Vessel obstruction is further exacerbated by the release of vasoconstrictors, such as thromboxane A₂ and endothelin. The thrombus may break up before permanent myocyte damage has occurred (unstable angina) or it may cause prolonged ischemia with resultant MI (see Fig. 33.20, B). Diagnostic tests aimed at identifying unstable plaques before they rupture include intravascular ultrasound or MRI, angiography, and spectroscopy. Medications such as statins, ACE inhibitors, and beta-blockers can help stabilize plaques and prevent rupture.

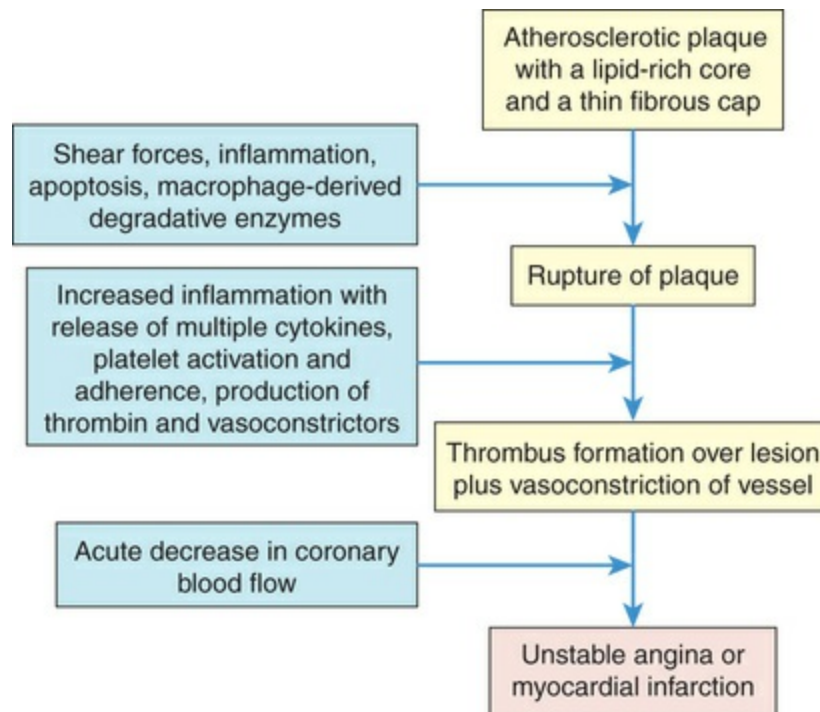

FIGURE 33.19 Pathogenesis of Unstable Plaques and Thrombus Formation.

FIGURE 33.20 Plaque Disruption and Myocardial Infarction. **A**, Plaque disruption. The cap of the lipid-rich plaque has become torn with the formation of a thrombus, mostly inside the plaque. **B**, Myocardial infarction. This infarct is 6 days old. The center is yellow and necrotic with a hemorrhagic red rim. The responsible coronary artery occlusion is probably in the right coronary artery. The infarct is on the posterior wall. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Unstable Angina.

Unstable angina is a form of acute coronary syndrome that results in reversible myocardial ischemia. It is important to recognize this syndrome because it signals that the atherosclerotic plaque has ruptured, and infarction may soon follow.

◆Pathophysiology.

Unstable angina occurs when fissuring or superficial erosion of the plaque leads to transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage. This thrombus is labile and occludes the vessel for no more than 10 to 20 minutes, with return of perfusion before significant myocardial necrosis occurs.

◆Clinical Manifestations.

Unstable angina presents as new-onset angina, angina that is occurring at rest, or angina that is increasing in severity or frequency (Box 33.1). Individuals may experience increased dyspnea, diaphoresis, and anxiety as the angina worsens.

Box 33.1

Three Principal Presentations of Unstable Angina

Rest angina* — angina occurring at rest and prolonged, usually >20 minutes

New-onset angina — new-onset angina of at least Canadian Cardiovascular Society (CCS) class III severity (CCS class III indicates “marked limitations of ordinary physical activity”)

Increasing angina — previously diagnosed angina that has become distinctly more frequent, longer in duration, or lower in threshold (i.e., increased by ≥ 1 CCS class to at least CCS class III severity)

*Individuals with non-ST-elevation myocardial infarction (non-STEMI) usually present with angina at rest.

From Anderson J et al: *J Am Coll Cardiol* 50:e1–e157, 2007. Originally adapted from Braunwald E: *Circulation* 80:410–414, 1989.

◆ Evaluation and Management.

Physical examination may reveal evidence of ischemic myocardial dysfunction such as tachycardia or pulmonary congestion. The ECG most commonly reveals ST-segment depression and T-wave inversion during pain that resolves as the pain is relieved. The serum cardiac biomarkers (troponins, creatine phosphokinase-myocardial bound [CPK-MB]) remain normal. Management of unstable angina is the same as the management for non-STEMI and requires immediate hospitalization. Administration of nitrates, antithrombotics (aspirin, ticagrelor, and/or GP IIb/IIIa platelet receptor antagonists), and anticoagulants (heparin, low-molecular-weight heparin, or direct thrombin inhibitors, such as fondaparinux) is recommended. If the

individual stabilizes, then continued anticoagulation plus beta-blockers and ACE inhibitors are indicated. If the patient is refractory to medical treatment, then emergent PCI is indicated.¹²⁸

Myocardial Infarction

When coronary blood flow is interrupted for an extended period, myocyte necrosis occurs. This results in MI. Pathologically there are two major types of MI: subendocardial infarction and transmural infarction. Clinically, however, MI is categorized as STEMI or non-STEMI.

◆Pathophysiology.

Plaque progression, disruption, and subsequent clot formation are the same for myocardial infarction as they are for unstable angina (see Figs. 33.18, 33.19, and 33.20). In this case, however, the thrombus is less labile and occludes the vessel for a prolonged period, such that myocardial ischemia progresses to myocyte necrosis and death (Fig. 33.21). The duration of ischemia determines the size and character of the infarction. If the thrombus breaks up before complete distal tissue necrosis has occurred, the infarction will involve only the myocardium directly beneath the endocardium (subendocardial MI). This infarction usually presents with ST depression and T-wave inversion and is termed **non-STEMI**. It is especially important to recognize this form of acute coronary syndrome because recurrent clot formation on the disrupted atherosclerotic plaque is likely to occur unless some intervention is undertaken as soon as possible. If the thrombus lodges permanently in the vessel, the infarction will extend through the myocardium all the way from endocardium to epicardium (transmural MI), resulting in severe cardiac dysfunction. Transmural infarction usually causes marked elevations in the ST segments on ECG, called **STEMI**. Clinically it is important to identify those with STEMI because they are at highest risk for serious complications and require immediate intervention.

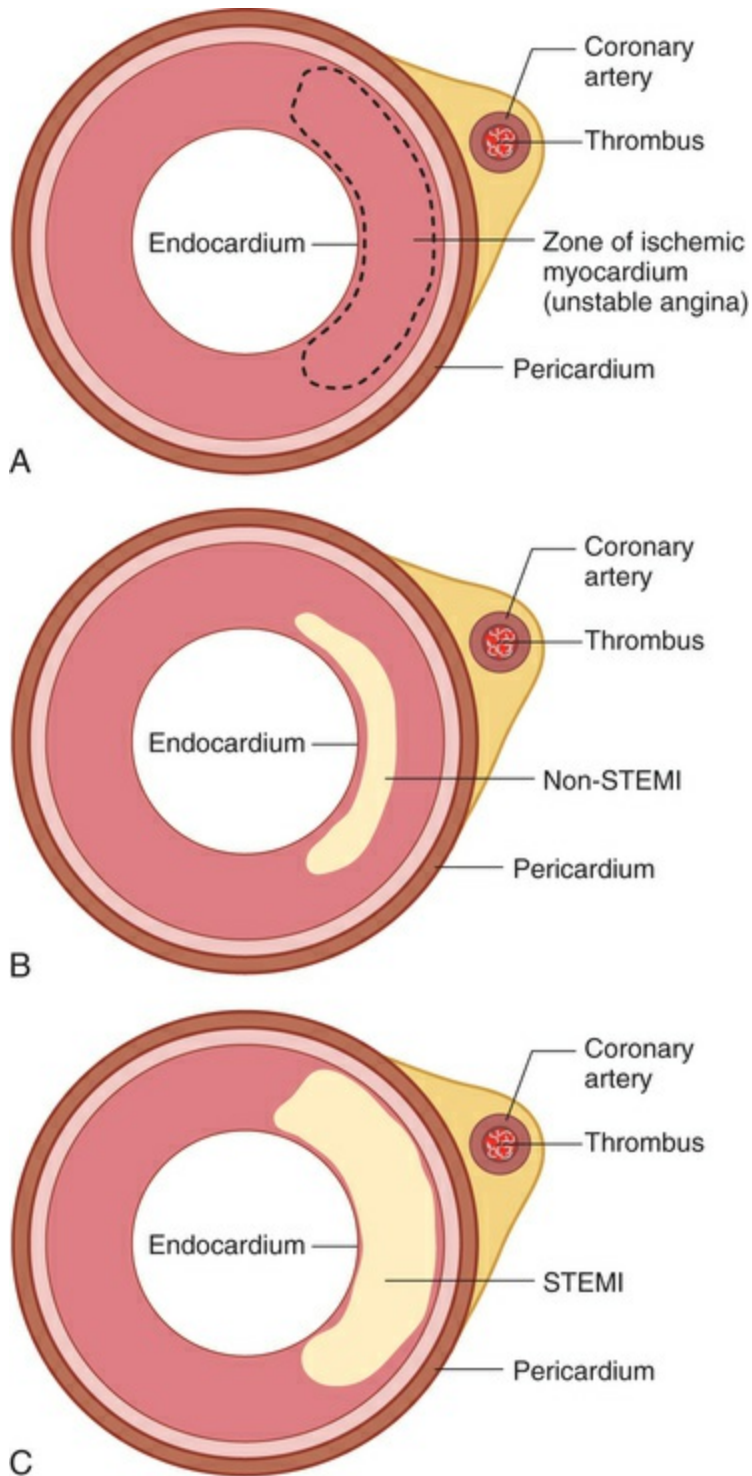

FIGURE 33.21 Unstable Angina, Non-STEMI, and STEMI. **A**, Unstable angina. Coronary thrombosis leads to myocardial ischemia. **B**, Non-ST-segment elevation myocardial infarction (Non-STEMI). Persistent coronary occlusion leads to infarction of the myocardium closest to the endocardium. **C**, ST-segment elevation myocardial infarction (STEMI). Continued coronary occlusion leads to transmural infarction extending from endocardium to pericardium.

Cellular Injury

Cardiac cells can withstand ischemic conditions for about 20 minutes before cellular death takes place. After only 30 to 60 seconds of hypoxia, ECG changes are visible. Yet even if cells are metabolically altered and nonfunctional, they can remain viable if blood flow returns within 20 minutes. Reports suggest previous recurrent episodes of myocardial ischemia can result in myocyte adaptation to oxygen deprivation and preservation of myocardium. This process, termed **ischemic preconditioning**, results in changes in reactive oxygen species, calcium ions, adenosine, bradykinin, catecholamines, and opioids that exert protective effects on the myocardium.¹²⁹ Therapeutic ischemic preconditioning has been used in individuals undergoing elective CABG or valvular replacement and in individuals with STEMI before emergent PCI; however, more studies are needed to determine the best use of this modality.¹³⁰

After 8 to 10 seconds of decreased blood flow, the affected myocardium becomes cyanotic and cooler. Myocardial oxygen reserves are used very quickly (within about 8 seconds) after complete cessation of coronary flow. Glycogen stores decrease as anaerobic metabolism begins. Unfortunately, glycolysis can supply only 65% to 70% of the total myocardial energy requirement and produces much less ATP than aerobic processes. Hydrogen ions and lactic acid accumulate. Because myocardial tissues have poor buffering capabilities and myocardial cells are very sensitive to low cellular pH, accumulation of these products further compromises the myocardium. Acidosis may make the myocardium more vulnerable to the damaging effects of lysosomal enzymes and may suppress impulse conduction and contractile function, thereby leading to heart failure.

Oxygen deprivation also is accompanied by electrolyte disturbances, specifically loss of potassium, calcium, and magnesium from cells. Myocardial cells deprived of necessary oxygen and nutrients lose contractility, thereby diminishing the heart's pumping ability. Ischemic myocardial cells release catecholamines (epinephrine

and norepinephrine), predisposing the individual to serious imbalances of sympathetic and parasympathetic function, irregular heartbeats (dysrhythmia), and heart failure. Catecholamines mediate the release of glycogen, glucose, and stored fat from body cells. Therefore plasma concentrations of free fatty acids and glycerol rise within 1 hour after onset of acute MI. Excessive levels of free fatty acids can have a harmful detergent effect on cell membranes. Norepinephrine elevates blood glucose levels through stimulation of liver and skeletal muscle cells. It also suppresses pancreatic B-cell activity, which reduces insulin secretion and elevates blood glucose level further.

Ang II is released during myocardial ischemia and contributes to the pathogenesis of MI in several ways. First, it results in the systemic effects of peripheral vasoconstriction and fluid retention. These homeostatic responses are counterproductive in that they increase myocardial work and thus exacerbate the effects of the loss of myocyte contractility. Ang II is also released locally, where it is a growth factor for vascular smooth muscle cells, myocytes, and cardiac fibroblasts promoting catecholamine release and coronary artery spasm.

Ischemic injury can be exacerbated by what is termed **reperfusion injury** once blood flow is restored. This process involves the release of toxic oxygen radicals, calcium flux, and pH changes that cause a sustained opening of mitochondrial permeability transition pores (mPTPs) and contribute to resultant cellular death.¹³¹ Infiltration of inflammatory cells contributes to tissue injury. Therapies aimed at reducing reperfusion injury are being explored, including targeted temperature management, use of adenosine or atrial natriuretic peptide, and ischemic postconditioning.^{132,133}

Cellular Death

After about 20 minutes of myocardial ischemia, irreversible hypoxic injury causes cellular death and tissue necrosis. (Types of necrosis are described in [Chapter 2](#).) Necrosis of myocardial tissue results in the release of intracellular enzymes, such as troponin, through the

damaged cell membranes into the interstitial spaces. The lymphatics pick up the enzymes and transport them into the bloodstream, where they can be detected by serologic tests. Recent evidence has found that, along with necrosis, myocardial tissue is also destroyed by apoptosis and autophagy. An increased understanding of these processes in MI may lead to new therapies aimed at limiting infarct size.¹³⁴

Structural and Functional Changes

As a result of an MI, structural and functional changes occur within cardiac tissue (Fig. 33.22). Gross tissue changes in the area of infarction may not become apparent for several hours, despite almost immediate onset (within 30 to 60 seconds) of ECG changes. The infarcted myocardium is surrounded by a zone of hypoxic injury, which may progress to necrosis, undergo remodeling (scarring), or return to normal.

FIGURE 33.22 Myocardial Infarction. A, Local infarct confined to one region. B, Massive large infarct caused by occlusion of three coronary arteries. (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby.)

Myocardial stunning is a temporary loss of contractile function that persists for hours to days after perfusion has been restored. This pathophysiologic state can occur both with MI and in individuals who suffer ischemia during cardiovascular procedures such as cardiac surgery. Stunning is caused by the alterations in electrolyte pumps,

calcium homeostasis, and the release of toxic oxygen radicals. It is characterized by decreased contraction and conduction and can contribute to heart failure, shock, and dysrhythmias. **Hibernating myocardium** refers to tissue that is persistently ischemic and undergoes metabolic adaptation to prolong myocyte survival until perfusion can be restored. Restoring adequate perfusion to the myocardium with revascularization therapies can improve myocardial function; however, future therapies aimed specifically at maintaining myocyte viability are needed.¹³⁵ **Myocardial remodeling** is a process mediated by ang II, aldosterone, catecholamines, adenosine, oxidative stress, and inflammatory cytokines, which causes myocyte hypertrophy, scarring, and loss of contractile function in the areas of the heart distant from the site of infarction. These changes can be limited and even reversed (reverse remodeling) through rapid restoration of coronary flow and the use of ACE inhibitors, beta-blockers, statins, sequential pacemakers, and ventricular assist devices after MI.

Repair

MI causes a severe inflammatory response that ends with wound repair (see [Chapter 7](#)). Repair consists of degradation of damaged cells, proliferation of fibroblasts, and synthesis of scar tissue. Many cell types, hormones, and nutrient substrates must be available for optimal healing to proceed. Within 24 hours, leukocytes infiltrate the necrotic area and proteolytic enzymes from scavenger neutrophils degrade necrotic tissue. A collagen matrix is deposited and is initially weak, mushy, and vulnerable to reinjury. Unfortunately it is at this time in the recovery period (10 to 14 days after infarction) that individuals feel more capable of increasing activities and thus may stress the newly formed scar tissue. After 6 weeks the necrotic area is completely replaced by scar tissue, which is strong but unable to contract and relax like healthy myocardial tissue.

The severity of functional impairment depends on the size of the lesion and the site of infarction. Functional changes can include (1) decreased cardiac contractility with abnormal wall motion, (2) altered

left ventricular compliance, (3) decreased stroke volume, (4) decreased ejection fraction, (5) increased left ventricular end-diastolic pressure and volume, and (6) sinoatrial node malfunction. Life-threatening dysrhythmias and heart failure often follow myocardial infarction.

With infarction, ventricular function is abnormal and the ejection fraction falls, resulting in increases in ventricular end-diastolic volume (VEDV). If the coronary obstruction involves the perfusion to the left ventricle, pulmonary venous congestion ensues; if the right ventricle is ischemic, increases in systemic venous pressures occur.

◆Clinical Manifestations.

The first symptom of acute MI is usually sudden, severe, chest pain. It is not possible to distinguish between angina and MI by symptoms alone, although the pain associated with MI tends to be more severe and prolonged. It may be described as heavy and crushing, such as an “elephant sitting on my chest.” Radiation to the neck, jaw, back, shoulder, or left arm is common. Some individuals (especially older adults or those with diabetes) experience no pain, thereby having a “silent” infarction. Infarction often simulates a sensation of unrelenting indigestion. Nausea and vomiting may occur because of reflex stimulation of vomiting centers by pain fibers. Vasovagal reflexes from the area of the infarcted myocardium also may affect the gastrointestinal tract. Various cardiovascular changes are found on physical examination:

1. The sympathetic nervous system (SNS) is reflexively activated to compensate, resulting in a temporary increase in heart rate and blood pressure, although severe myocardial damage may cause hypotension despite elevated catecholamine activity.
2. Abnormal extra heart sounds reflect left ventricular dysfunction.
3. Cardiac murmurs may indicate acute valvular insufficiency.
4. Pulmonary findings of congestion including dullness to percussion and inspiratory crackles at the lung bases can occur if the individual develops heart failure.

5. Peripheral vasoconstriction may cause the skin to become cool and clammy.

◆ Evaluation and Treatment.

The diagnosis of acute MI is made on the basis of history, physical examination, ECG, and serial cardiac biomarker alterations (Box 33.2). It is important to note that nearly half of MIs are not preceded by any previous angina symptoms and up to one-third present with STEMI as the first symptomatic manifestation of coronary disease. MI can occur in various regions of the heart wall and may be described as anterior, inferior, posterior, lateral, subendocardial, or transmural depending on its location and extent of tissue damage from infarction. Twelve-lead ECGs help localize the affected area through identification of changes in ST segments and T waves (Fig. 33.23). In STEMI, a characteristic Q wave often develops on ECG some hours later.

Box 33.2

The Universal Definition of Myocardial Infarction

The term *myocardial infarction* should be used when there is evidence of myocardial necrosis in a clinical setting with myocardial ischemia. Under these conditions any one of the following criteria meets the diagnosis for myocardial infarction (MI):

- Detection of rise and/or fall of cardiac biomarkers (preferably cardiac troponin [cTn]) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia with at least one of the following:
 - Symptoms of ischemia
 - New or presumed new significant ST-segment-T wave

(ST-T) changes or new left bundle branch block (LBBB)
Development of pathologic Q waves in the
electrocardiogram (ECG)
Imaging evidence of new loss of viable myocardium or
new regional wall motion abnormality
Identification of an intracoronary thrombus by
angiography or autopsy

- Cardiac death with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes or new LBBB, but death occurring before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased.
- Percutaneous coronary intervention (PCI)–related MI is arbitrarily defined by an elevation of cTn values ($>5 \times 99$ th percentile URL) in patients with normal baseline values (≤ 99 th percentile URL) or a rise of cTn values $>20\%$ of the baseline values are elevated and are stable or falling. In addition, either (i) symptoms suggestive of myocardial ischemia, (ii) new ischemic ECG changes, (iii) angiographic findings are consistent with a procedural complication, or (iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required.
- Stent thrombosis–associated MI when detected by coronary angiography or autopsy in the setting of myocardial ischemia and with a rise and/or fall of cardiac biomarker values with at least one value over the 99th percentile URL.
- Coronary artery bypass grafting (CABG)–related MI is arbitrarily defined by an elevation of cardiac biomarker values ($>10 \times 99$ th percentile URL) in patients with normal baseline cTn values (≤ 99 th percentile URL). In addition, either (i) new pathologic Q waves or new LBBB, (ii) angiographically documented new graft or new native coronary artery occlusion, or (iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

FIGURE 33.23 Electrocardiographic Alterations Associated with the Three Zones of Myocardial Infarction.

Cardiac troponin I (cTnI) is the most specific indicator of MI and should be obtained on admission to the emergency department. cTnI elevation is detectable 2 to 4 hours after onset of symptoms. Additional measurements within 6 to 9 hours and again at 12 to 24 hours are recommended if clinical suspicion is high and previous samples were negative. Troponin levels also can be used to estimate infarct size and therefore the likelihood of complications. Other biomarkers released by myocardial cells include CPK-MB and LDH. Additional laboratory data may reveal leukocytosis and elevated CRP, both of which indicate inflammation. The individual's blood glucose level is usually elevated and the glucose tolerance level may remain abnormal for several weeks. Individuals with acute coronary syndromes require admission to the hospital. The individual should be placed on supplemental oxygen and given an aspirin immediately (clopidogrel or prasugrel if intolerant to aspirin). Pain is treated with morphine sulfate, which also has vasodilatory effects on the coronaries. Continuous monitoring of cardiac rhythms and biomarker changes is essential because the first 24 hours after onset of symptoms is the time of highest risk for sudden death. Non-STEMI is treated in the same way as unstable angina including antithrombotics, anticoagulation or PCI, or both.¹²⁸ STEMI is best managed with emergent PCI and antithrombotics.^{136,137} Careful monitoring for dysrhythmias, heart failure, and shock is essential. Hyperglycemia is treated with insulin. Once the person is stabilized, further management includes ACE inhibitors, beta-blockers, and statins.

Bed rest, followed by gradual return to activities of daily living, reduces the myocardial oxygen demands of the compromised heart. Individuals not receiving thrombolytic or heparin infusion must receive deep venous thrombosis (DVT) prophylaxis as long as their activity is significantly limited. Stool softeners are given to eliminate the need for straining. Education on diet, caffeine, smoking cessation, exercise, and other aspects of risk factor reduction is crucial for secondary prevention of recurrent myocardial ischemia.

Approximately 1% to 2% of people initially diagnosed with STEMI do not have myocardial infarction, but rather have a stress-induced syndrome known as the *broken heart syndrome* or *Takotsubo cardiomyopathy*.¹³⁸ These individuals present with the acute onset of chest pain, ST elevation, and elevated troponins after emotional stress, but generally do not have coronary artery disease and must be managed differently (see [What's New? The Broken Heart Syndrome](#)).

What's New?

The Broken Heart Syndrome

Episodes of extreme mental stress, like the loss of a loved one, have been linked to sudden onset of myocardial ischemia, arrhythmias, heart failure, shock, and even death. This has been called the *broken heart syndrome*. This phenomenon, now called *Takotsubo cardiomyopathy*, was first described in Japan in 1990, where it was found to occur most often in postmenopausal women at times of acute stress. Since then it has been found to occur in women and men of all ages, and many other stressful triggers have been identified such as earthquakes, lightning strikes, noncardiac surgery, seizures, trauma, anesthesia, and alcohol withdrawal to name just a few. Although the manifestations are variable, it has been found that many individuals have weakening and ballooning of the left ventricular apex during systole that begins within minutes to hours after the stressful episode. Although the pathophysiology is still being explored, catecholamines play an

important role in the pathogenesis causing coronary artery spasm, coronary microvascular abnormalities, direct myocardial damage, and neurogenic myocardial stunning. Intracellular calcium overload, oxidative stress, and estrogen deficiency also are implicated. Postmenopausal women may be especially vulnerable because of estrogen deficiency–mediated effects on the microvasculature. On myocardial biopsy, most people have inflammation without necrosis. People with Takotsubo cardiomyopathy present clinically with the same symptoms as acute ST-elevation myocardial infarction (STEMI), including chest pain, dyspnea, ST-segment elevation, and moderately elevated cardiac biomarkers, such as troponins and brain natriuretic peptide. Echocardiography and MRI are often used to make the diagnosis, along with cardiac catheterization in selected individuals. The American Heart Association Criteria for the diagnosis describe transient dyskinesis of the left ventricle in the absence of acute coronary artery disease, acute head trauma, myocarditis, or other forms of cardiomyopathy. Management usually includes aspirin, beta-blockers, angiotensin-converting enzyme inhibitors, and statins, although targeted emotional support and standard psychologic counseling have the greatest effect on recovery and reducing the risk for recurrence. An interprofessional team that includes a social worker, pastor, and mental health care providers has been found beneficial for those suffering from this cardiomyopathy. While many individuals recover without complication, recent population studies indicate that there is significant mortality with 30-day and 1-year mortality rates of 2.5% and 6.9%, respectively, in the United States.

Data from Akashi YJ, Nef HM, Lyon AR: *Nat Rev Cardiol* 12(7):387–397, 2015; Dastidar AG et al: *Heart Fail Rev* 20(4):415–421, 2015; Madias JE: *Int J Cardiol* 188:19–21, 2015; Peters S: *Int J Cardiol* 218:284, 2016; Stiermaier T, Thiele H, Eitel I: *JACC Heart Fail* 4(6):519–520, 2016; Yoshikawa T: *Int J Cardiol* 182:297–303, 2015.

◆Complications.

The number and severity of postinfarction complications depend on the location and extent of necrosis, the individual's physiologic condition before the infarction, and the availability of swift therapeutic intervention.

Dysrhythmias (arrhythmias), which are disturbances of cardiac rhythm, are the most common complication of acute MI. Dysrhythmias can be caused by ischemia, hypoxia, autonomic nervous system (ANS) imbalances, lactic acidosis, electrolyte abnormalities, alterations of impulse conduction pathways or conduction defects, drug toxicity, or hemodynamic abnormalities. Dysrhythmias may originate from the atria, ventricles, nodal regions, or conduction tissues. The seriousness of dysrhythmias depends on the hemodynamic consequences. (Dysrhythmias are described in [Tables 33.9](#) and [33.10](#).) Prophylactic use of antiarrhythmics, such as lidocaine and amiodarone, does not improve mortality; however, individuals at high risk should be considered for implantable cardioverter-defibrillators (ICDs).

Acute MI is accompanied by functional impairment of the myocardium. Many infarctions result in some degree of heart failure, which is characterized by pulmonary congestion, reduced myocardial contractility, and abnormal heart wall motion. Anterior infarction is associated with more severe left heart failure than is inferior infarction. If cardiac output is insufficient to maintain normal arterial pressure and to perfuse the kidneys and other organs adequately, **cardiogenic shock** develops. (Cardiogenic shock is discussed in [Chapter 49](#).)

Inflammation of the pericardium (**pericarditis**) is a common complication of acute MI. Pericardial friction rubs often are noted 2 to 3 days after MI and are associated with anterior chest pain that worsens with respiratory effort. Specific treatment is not required; however, corticosteroids dramatically relieve symptoms.

Cardiac complications of MI can include rupture of heart structures and aneurysm formation. Tissue necrosis in or around the papillary muscles can cause rupture of these muscles or of the chordae tendineae. Weakening of the wall of the infarcted ventricle can cause

ventricular aneurysm formation. Left ventricular aneurysm is a late complication of MI, occurring months or years after the acute event. The ventricle wall bulges with systole, resulting in impaired pump function and a significant risk for dysrhythmias. Although rare, rupture may occur when the tension becomes too great.

Thromboembolism is found during postmortem examinations of many individuals who have died of MI. Thromboemboli may disseminate from debris and clots that collect inside dilated aneurysmal sacs or from the infarcted endocardium and travel to the pulmonary or systemic vascular systems. Pulmonary emboli also may result from the breaking loose of deep venous thrombi of the legs in individuals who are confined to bed (see the Thromboembolism section and [Chapter 36](#)). Early mobilization and prophylactic anticoagulation therapy are essential to reduce the incidence of this complication.

Several factors contribute to the risk of death during acute infarction or reduce the chances of long-term survival, despite the best possible treatment. They are (1) the degree of left ventricular dysfunction, (2) the degree of left ventricular ischemia, (3) the potential for ventricular dysrhythmias, and (4) the individual's age.

Disorders of the Heart Wall

Disorders of the Pericardium

Pericardial disease is often a manifestation of another disorder, such as infection (bacterial, viral, fungal, rickettsial, parasitic); trauma or surgery; neoplasm; or a metabolic, immunologic, or vascular disorder (uremia, rheumatoid arthritis, systemic lupus erythematosus, periarteritis nodosa). The pericardial response to injury from these diverse causes may consist of acute pericarditis, pericardial effusion, or constrictive pericarditis.

Acute Pericarditis

Acute pericarditis is acute inflammation of the pericardium. The etiology of acute pericarditis is most often idiopathic (autoimmune) or caused by viral infection. Other causes include MI, trauma, neoplasm, surgery, uremia, bacterial infection (especially tuberculosis), connective tissue disease (especially systemic lupus erythematosus and rheumatoid arthritis), or radiation therapy. The pericardial membranes become inflamed and roughened, and a pericardial effusion may develop that can be serous, purulent, or fibrinous ([Fig. 33.24](#)). Possible sequelae of pericarditis include recurrent pericarditis, pericardial constriction, and cardiac tamponade.

FIGURE 33.24 Acute Pericarditis. Note shaggy coat of fibers covering surface of heart. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

Symptoms may follow several days of fever and usually begin with the sudden onset of severe, retrosternal chest pain that worsens with respiratory movements and when assuming a recumbent position. The pain may radiate to the back as a result of irritation of the phrenic nerve (innervates the trapezius muscles) as it traverses the pericardium. Individuals with acute pericarditis also report dysphagia, restlessness, irritability, anxiety, weakness, and malaise.

Physical examination often discloses low-grade fever ($<38^{\circ}\text{C}$) and sinus tachycardia. A friction rub—a scratchy, grating sound—may be heard at the cardiac apex and left sternal border and is caused by the roughened pericardial membranes rubbing against each other. Friction rubs are not always present and may be intermittently heard and transient. Serum measures of inflammation, such as hs-CRP, are elevated. Electrocardiographic changes may reflect inflammatory processes through PR-segment depression and diffuse ST-segment elevation without Q waves, and they may remain abnormal for days or even weeks. Ultrasound, CT scanning, and MRI may be used as diagnostic modalities. Acute pericarditis requires at least two of the following four criteria for diagnosis: (1) chest pain characteristic of

pericarditis, (2) pericardial rub, (3) characteristic electrocardiographic (ECG) changes, and (4) new or worsening pericardial effusion.

Treatment for uncomplicated acute pericarditis relies on the use of antiinflammatory medications. Combined nonsteroidal antiinflammatory medications and colchicine (prevents fibrosis) is a highly effective regimen.¹³⁹ The level of hs-CRP in the blood should be followed to determine resolution before discontinuation of treatment. Additional analgesics may be given to relieve pain. Exploring the underlying cause is important. If pericardial effusion develops, aspirating the excessive fluid may be necessary.

Pericardial Effusion

Pericardial effusion, the accumulation of fluid in the pericardial cavity, can occur in all forms of pericarditis. Most are idiopathic (20%) but other causes, such as neoplasm and infection, must be considered. The fluid may be a transudate, such as the serous effusion that develops with left heart failure, overhydration, or hypoproteinemia. More often, however, the fluid is an exudate, which indicates pericardial inflammation like that seen with acute pericarditis, heart surgery, chemotherapeutic agents, infections, and autoimmune disorders, such as systemic lupus erythematosus. (Types of exudate are described in [Chapter 7](#).) If the fluid is serosanguineous, the underlying cause is likely to be tuberculosis, neoplasm, uremia, or radiation. Effusions of frank blood are generally related to aneurysms, trauma, or coagulation defects. If chyle leaks from the thoracic duct, it may enter the pericardium and lead to cholesterol pericarditis.

Pericardial effusion may create sufficient pressure to cause cardiac compression, which is a serious condition known as **tamponade**. If an effusion develops gradually, the pericardium can stretch to accommodate large quantities of fluid without compressing the heart. If the fluid accumulates rapidly, however, even a small amount (50 to 100 mL) may cause serious tamponade. The danger is that pressure exerted by the pericardial fluid will eventually equal diastolic pressure within the heart chambers, which will interfere with right atrial filling during diastole. This causes increased venous pressure,

systemic venous congestion, and signs and symptoms of right heart failure (distention of the jugular veins, edema, hepatomegaly). Decreased atrial filling leads to decreased ventricular filling, decreased stroke volume, and reduced cardiac output.

Individuals with cardiac tamponade most often present with dyspnea, tachycardia, jugular venous distention, cardiomegaly, and pulsus paradoxus. Pulsus paradoxus means that the arterial blood pressure during expiration exceeds the arterial pressure during inspiration by more than 10 mmHg. This clinical finding reflects impairment of diastolic filling of the left ventricle plus reduction of blood volume within all four cardiac chambers. Other clinical manifestations of pericardial effusion are distant or muffled heart sounds, poorly palpable apical pulse, dyspnea on exertion, and dull chest pain. A chest x-ray may disclose a “water-bottle” configuration of the cardiac silhouette. An echocardiogram can detect an effusion as small as 20 mL and is considered the most accurate and reliable method of diagnosis, although CT or MRI also are used.¹⁴⁰

Treatment of pericardial effusion or tamponade generally consists of pericardiocentesis (aspiration of excessive pericardial fluid). Pericardiocentesis is diagnostic and therapeutic: the fluid is analyzed to identify the cause of the effusion, and its removal alone may bring dramatic relief from symptoms. Removal of large amounts of fluid may be associated with pericardial decompression syndrome, a potentially fatal condition complicated by pulmonary edema and cardiovascular shock.¹⁴¹ Persistent pain may be treated with analgesics, antiinflammatory medications, or steroids. Surgery may be required if the underlying cause of tamponade is trauma or aneurysm. If an effusion is neoplasm induced, sclerosing agents may be injected into the pericardial space. Recurrent pericardial effusions may require surgical creation of a pericardial “window” that allows for continual drainage and prevents tamponade.

Constrictive Pericarditis

Constrictive pericarditis, or restrictive pericarditis (chronic pericarditis), was once synonymous with tuberculosis. In the United

States this form of pericardial disease is more often idiopathic or associated with radiation exposure, heart surgery (including transplantation), acute pericarditis, rheumatologic disease, trauma, or malignancy.¹⁴² In constrictive pericarditis, fibrous scarring with occasional calcification of the pericardium causes the visceral and parietal pericardial layers to adhere, obliterating the pericardial cavity. The fibrotic lesions encase the heart in a rigid shell (Fig. 33.25). Like tamponade, constrictive pericarditis compresses the heart, which impairs ventricular relaxation during diastole, reduces ventricular filling, and eventually reduces cardiac output.

FIGURE 33.25 Constrictive Pericarditis. The fibrotic pericardium encases the heart in a rigid shell. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

Because the onset of constrictive pericarditis is gradual, clinical manifestations develop slowly. Symptoms include exercise intolerance, dyspnea on exertion, fatigue, and anorexia. Approximately two-thirds of individuals present with heart failure.¹⁴² Clinical assessment shows edema, jugular vein distention, and hepatic

congestion. Restricted ventricular filling may cause a pericardial knock (early diastolic sound). ECG findings include T-wave inversions and atrial fibrillation. Chest x-ray often discloses prominent pulmonary vessels and calcification of the pericardium. CT, MRI, and transesophageal echocardiography (TEE) are used to detect pericardial thickening and constriction. Pericardial biopsy may be needed to determine the etiology.

Initial treatment for chronic constrictive pericarditis consists of dietary sodium restriction and diuretics. Management also may include use of antiinflammatory drugs and treatment of any underlying disorder. If these modalities are not successful, surgical excision of the restrictive pericardium (pericardiectomy) is indicated.¹⁴²

Disorders of the Myocardium: The Cardiomyopathies

The **cardiomyopathies** are a diverse group of diseases that affect the myocardium. Most are the result of remodeling caused by the effect of the neurohumoral responses to ischemic heart disease or hypertension on the heart muscle. Cardiomyopathies also can be secondary to inherited disorders, infectious disease, exposure to toxins, systemic connective tissue disease, infiltrative and proliferative disorders, or nutritional deficiencies. Many cases of cardiomyopathy are idiopathic. The cardiomyopathies are categorized as dilated, hypertrophic, or restrictive depending on their tissue characteristics, genomics, and hemodynamic effects (Fig. 33.26 and Table 33.5). An individual may display characteristics of more than one type.

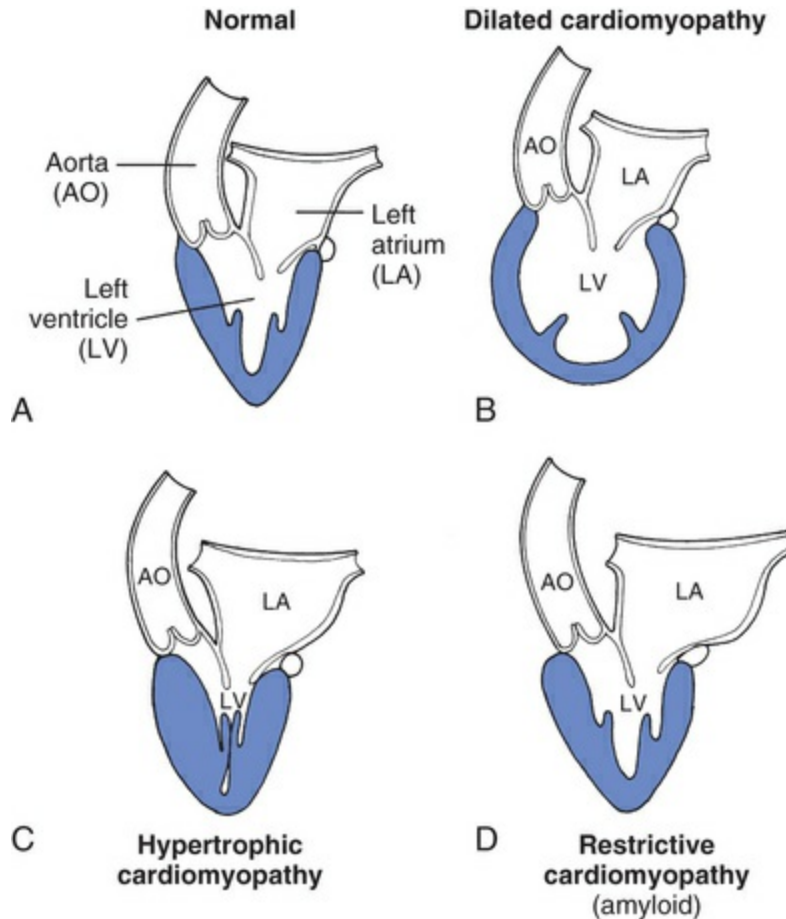

FIGURE 33.26 Diagram Showing Major Distinguishing Pathophysiologic Features of the Types of Cardiomyopathy. A, The normal heart. B, In the dilated type of cardiomyopathy, the heart has a globular shape, and the largest circumference of the left ventricle is not at its base but midway between apex and base. C, In the hypertrophic type of cardiomyopathy, the wall of the left ventricle is greatly thickened; the left ventricular cavity is small, but the left atrium may be dilated because of poor diastolic relaxation of the ventricle. D, In the restrictive type the left ventricular cavity is of normal size, but again, the left atrium is dilated because of the reduced diastolic compliance of the ventricle. (From Kissane JM, editor: *Anderson's pathology*, ed 9, St Louis, 1990, Mosby.)

TABLE 33.5

PATHOPHYSIOLOGIC EFFECTS OF THE CARDIOMYOPATHIES

PATHOPHYSIOLOGY	TYPE OF CARDIOMYOPATHY		
	DILATED	HYPERTROPHIC	RESTRICTIVE
Associated conditions	Ischemic heart disease, alcoholism, pregnancy, infection, nutritional	Untreated hypertension and inherited defect of muscle growth	Infiltrative disease

	deficiency, exposure to toxins	and development	
Alterations of chamber volume	Volume increased	Volume decreased, particularly in left ventricle	Volume normal to decreased
Alterations of chamber compliance	Compliance increased	Compliance decreased, particularly in left ventricle	Compliance decreased, particularly in left ventricle
Alterations of myocardial contractility	Contractility decreased in left ventricle	Contractility normal	None
Dysrhythmias	Sinoatrial tachycardia; atrial and ventricular dysrhythmias	Atrial and ventricular dysrhythmias	Tachydysrhythmias
Eventual cardiovascular event	Left heart failure	Left heart failure	Right heart failure

Dilated Cardiomyopathy

Dilated cardiomyopathy is usually the result of ischemic heart disease, valvular disease, diabetes, renal failure, alcohol or drug toxicity, hyperthyroidism, nutritional deficiencies (niacin, vitamin D, and selenium), or infection. Peripartum cardiomyopathy occurs in previously healthy women in the final month of pregnancy and up to 5 months after delivery and can lead to shock.¹⁴³ Dilated cardiomyopathy also can be associated with inherited disorders.^{144,145} This form of cardiomyopathy is characterized by impaired systolic function leading to increases in intracardiac volume, ventricular dilation, and heart failure with reduced ejection fraction (Fig. 33.27). Arrhythmias also are common. (Pathophysiologic effects of the cardiomyopathies are summarized in Table 33.5.)

FIGURE 33.27 Dilated Cardiomyopathy. The dilated left ventricle has a thin wall (V). (From Stevens A, Lowe JS, Scott I: *Core pathology*, ed 3, London, 2009, Mosby.)

Individuals complain of dyspnea, fatigue, and pedal edema. Findings on examination include a displaced apical pulse, S_3 gallop, peripheral edema, jugular venous distention, and pulmonary congestion. Diagnosis is confirmed by chest x-ray and echocardiogram, and management is focused on reducing blood volume, increasing contractility, and reversing the underlying disorder if possible.¹⁴⁶ Heart transplant is required in severe cases.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy refers to two major categories of thickening of the myocardium: (1) hypertrophic obstructive cardiomyopathy (asymmetrical septal hypertrophic cardiomyopathy or idiopathic hypertrophic subaortic stenosis [IHSS]) and (2) hypertensive or valvular hypertrophic cardiomyopathy. These two categories are very different in their etiology, pathophysiology, and clinical presentation.

Hypertrophic obstructive cardiomyopathy is the most common inherited heart defect associated with left ventricular hypertrophy, occurring in 1 of 500 individuals through autosomal dominant inheritance.^{147,148} It is characterized by thickening of the septal wall (Fig. 33.28), which may cause outflow obstruction to the left ventricle outflow tract. Additional changes include abnormalities of collagen deposition and altered contractile proteins in the myocytes. The thickening of the septum results in a hyperdynamic state, especially with exercise. Obstruction of left ventricular outflow can occur when heart rate is increased and intravascular volume is decreased. Individuals complain of angina, syncope, palpitations, and symptoms of MI and left heart failure. Sudden death may occur. Examination may reveal extra heart sounds and murmurs. Echocardiography and MRI are used to confirm the diagnosis and determine the best therapeutic approach.¹⁴⁹ Management includes beta-blockers to slow the heart rate, ACE inhibitors to reverse hypertrophic changes, and surgical resection or ablation of the hypertrophied myocardium.¹⁴⁸ Placement of an implantable cardioverter-defibrillator significantly decreases the risk of arrhythmia-related sudden death.¹⁵⁰

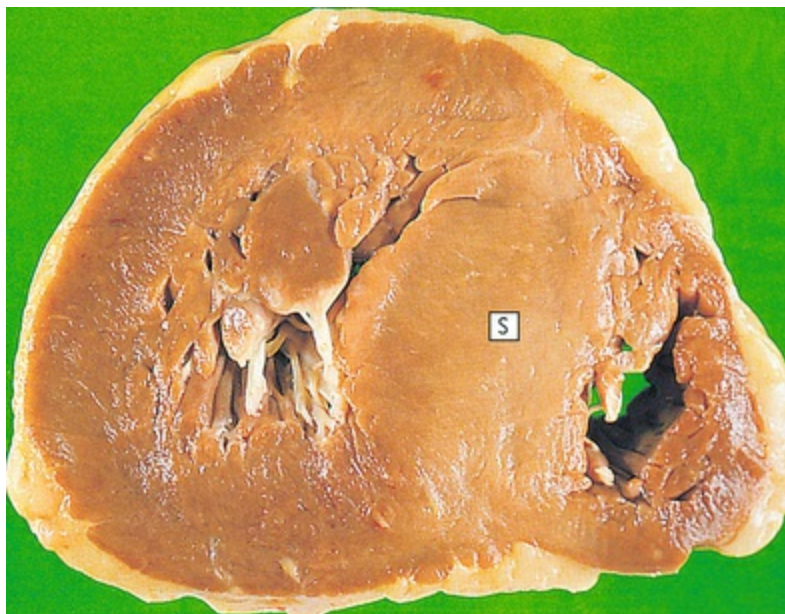

FIGURE 33.28 Hypertrophic Cardiomyopathy. There is marked left ventricular hypertrophy. This often affects the septum (S). (From Stevens

Hypertensive or valvular hypertrophic cardiomyopathy occurs because of increased resistance to ventricular ejection; it is commonly seen in hypertension or in valvular stenosis (usually aortic). In this case, hypertrophy of the myocytes is an attempt to compensate for increased myocardial workload. Long-term dysfunction of the myocytes develops over time, with first diastolic dysfunction leading eventually to systolic dysfunction of the ventricle (see [Heart Failure](#)). Individuals with hypertrophic cardiomyopathy may be asymptomatic or may complain of angina, syncope, dyspnea on exertion, and palpitations. Examination may reveal extra heart sounds and murmurs. Echocardiography and cardiac catheterization can confirm the diagnosis.

Restrictive Cardiomyopathies

Restrictive cardiomyopathy is characterized by restrictive filling and reduced diastolic volume of either or both ventricles with normal or near-normal systolic function and wall thickness. It may occur idiopathically or as a cardiac manifestation of systemic diseases, such as scleroderma, amyloidosis, sarcoidosis, lymphoma, and hemochromatosis, or a number of inherited storage diseases. The myocardium becomes rigid and noncompliant, impeding ventricular filling and raising filling pressures during diastole. The overall clinical and hemodynamic picture mimics and may be confused with that of constrictive pericarditis.

The most common clinical manifestation of restrictive cardiomyopathy is right heart failure with systemic venous congestion. Cardiomegaly and dysrhythmias are common. A thorough evaluation for the underlying cause should be initiated (and may include myocardial biopsy). Treatment is aimed at the underlying cause; however, many individuals require placement of left ventricular assist devices (LVADs) followed by heart transplantation.¹⁵¹

Disorders of the Endocardium

Valvular Dysfunction

Disorders of the endocardium (the innermost lining of the heart wall) damage the heart valves, which are made up of endocardial tissue. Endocardial damage can be either congenital or acquired. Congenital valvular disease is discussed in [Chapter 34](#). The acquired forms result from inflammatory, ischemic, traumatic, degenerative, or infectious alterations of valvular structure and function. Structural alterations of the heart valves result from remodeling changes in the valvular extracellular matrix and lead to stenosis, regurgitation, or both. Although all four heart valves may be affected, those of the left heart (mitral and aortic valves) are more commonly affected than those of the right heart (tricuspid and pulmonic valves).

In **valvular stenosis** the valve orifice is constricted and narrowed, impeding the forward flow of blood and increasing the workload of the cardiac chamber proximal to the diseased valve ([Fig. 33.29](#)). Intraventricular or atrial pressure increases in the chamber to overcome resistance to flow through the valve. Increased pressure causes the myocardium to work harder, causing myocardial hypertrophy. In **valvular regurgitation** (also called *insufficiency* or *incompetence*) the valve leaflets, or cusps, fail to shut completely, permitting blood flow to continue even when the valve is supposed to be closed (see [Fig. 33.29](#)). During systole or diastole some blood leaks back into the chamber proximal to the incompetent valve, producing a murmur on auscultation. Valvular regurgitation increases the volume of blood the heart must pump and increases the workload of the affected heart chamber. Increased volume leads to chamber dilation, and increased workload leads to hypertrophy.

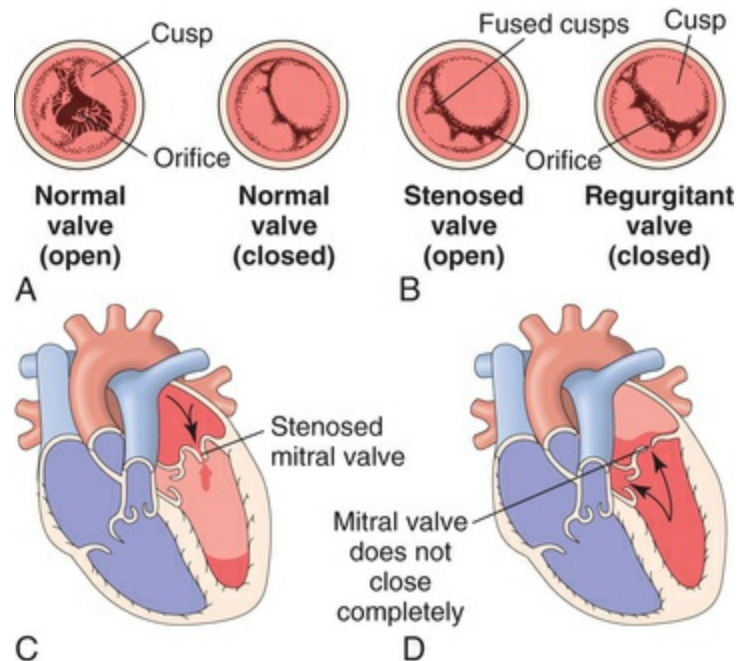

FIGURE 33.29 Valvular Stenosis and Regurgitation. A, Normal position of the valve leaflets, or cusps, when the valve is open and closed. B, Open position of a stenosed valve (*left*) and open position of a closed regurgitant valve (*right*). C, Hemodynamic effect of mitral stenosis. The stenosed valve is unable to open sufficiently during left atrial systole, inhibiting left ventricular filling. D, Hemodynamic effect of mitral regurgitation. The mitral valve does not close completely during left ventricular systole, permitting blood to reenter the left atrium.

Valvular dysfunction stimulates chamber dilation and/or myocardial hypertrophy, both of which are compensatory mechanisms intended to increase the pumping capability of the heart. Eventually, myocardial contractility is diminished, the ejection fraction is reduced, diastolic pressure increases, and the affected heart chamber fails from overload. Depending on the severity of the valvular dysfunction and the capacity of the heart to compensate, valvular alterations cause a range of symptoms and some degree of incapacitation ([Table 33.6](#)). In general, valvular disease is diagnosed by transthoracic echocardiography (TTE), which can be used to assess the severity of valvular obstruction or regurgitation before the onset of symptoms. CT or MRI may be indicated in certain settings. Valvular lesions are staged using four general categories: (1) at risk, (2) progressive, (3) asymptomatic severe, and (4) symptomatic severe, which determine the appropriate management. Management almost always includes careful medical management, valvular repair, or

valve replacement followed by long-term anticoagulation therapy and prophylaxis for endocarditis as needed.¹⁵² The purpose of valvular intervention is to improve symptoms and prolong survival, as well as to minimize complications such as asymptomatic irreversible ventricular dysfunction, pulmonary hypertension, stroke, and atrial fibrillation (AF).¹⁵²

TABLE 33.6

CLINICAL MANIFESTATIONS OF VALVULAR STENOSIS AND REGURGITATION

MANIFESTATION	AORTIC STENOSIS	MITRAL STENOSIS	AORTIC REGURGITATION	MITRAL REGURGITATION
Most common cause	Congenital bicuspid valve, degenerative (calcification) changes with aging, rheumatic fever	Rheumatic heart disease	Infective endocarditis; aortic root disease (connective tissue diseases, Marfan syndrome); dilation of the aortic root due to hypertension and aging	Myxomatous degeneration (mitral valve prolapse)
Cardiovascular outcome (untreated)	Left ventricular hypertrophy followed by left heart failure; decreased coronary blood flow with myocardial ischemia	Left atrial hypertrophy and dilation with fibrillation, followed by right ventricular failure	Left ventricular hypertrophy and dilation, followed by heart failure	Left atrial hypertrophy and dilation, followed by left heart failure
Pulmonary effects	Pulmonary edema: dyspnea on exertion	Pulmonary edema: dyspnea on exertion, orthopnea, paroxysmal, nocturnal dyspnea, predisposition to respiratory	Pulmonary edema with dyspnea on exertion	Pulmonary edema with dyspnea on exertion

		infections, hemoptysis, pulmonary hypertension, and edema		
Central nervous system effects	Syncope, especially on exertion	Neural deficits only associated with emboli (e.g., hemiparesis)	Syncope	None
Pain	Angina pectoris	Atypical chest pain	Angina pectoris	Atypical chest pain
Heart sounds	Systolic murmur heard best at the right parasternal second intercostal space and radiating to the neck	Low rumbling diastolic murmur heard best at the apex and radiating to the axilla, accentuated first heart sound, opening snap	Diastolic murmur heard best at the right parasternal second intercostal space and radiating to the neck	Murmur throughout systole heard best at the apex and radiating to the axilla

Data from Braunwald E, editor: *Heart disease: a textbook of cardiovascular medicine*, ed 7, Philadelphia, 2005, Saunders; Carabello BA, Paulus WJ: Valvular heart disease. In Crawford MH, DiMarco JP, editors: *Cardiology*, London, 2001, Mosby-Wolfe.

Stenosis

Aortic Stenosis.

Aortic stenosis (AS) is the most common valvular abnormality, affecting approximately 5% of adults older than 75 years.¹⁵³ The three common causes are (1) calcific degeneration related to aging (aortic sclerosis), (2) congenital bicuspid valve, and (3) inflammatory damage caused by rheumatic heart disease (RHD). Aortic sclerosis affects up to 40% of those older than age 75 with about 2% per year progressing to hemodynamically significant AS, whereas congenital bicuspid aortic valve occurs in 0.5% to 0.8% of the population.¹⁵³ RHD is a less

frequent cause of AS.

The pathophysiology of AS is complex and numerous gene abnormalities have been implicated, including polymorphisms of genes that code for LDL.⁵ AS results from lipoprotein deposition in the valve tissue with chronic inflammation and leaflet calcification. Autoimmunity disorders in calcium transport, apoptosis of endocardial cells, and decreased nitric oxide synthesis have been implicated.^{154,155} In AS from any cause, the orifice of the aortic semilunar valve narrows, causing diminished blood flow from the left ventricle into the aorta (Fig. 33.30). Outflow obstruction increases pressure within the left ventricle as it tries to eject blood through the narrowed opening. Left ventricular hypertrophy develops to compensate for the increased workload.¹⁵⁶ Eventually hypertrophy increases myocardial oxygen demand that the coronary arteries may not be able to supply. If this occurs, ischemia may cause attacks of angina. Untreated aortic stenosis can lead to dysrhythmias, myocardial infarction, and heart failure.

FIGURE 33.30 Aortic Stenosis. Mild stenosis in valve leaflets of a young adult. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

Aortic stenosis tends to develop gradually. The classic manifestations of aortic stenosis are angina, syncope, and heart

failure. Clinical manifestations include decreased stroke volume, reduced systolic blood pressure, and narrowed pulse pressure (difference between systolic and diastolic pressure). Heart rate is often slow, and pulses are faint. Resistance to flow through the stenotic valve gives rise to a crescendo-decrescendo systolic heart murmur heard best at the second intercostal space and may radiate to the neck. Echocardiography is used to follow valve orifice and cardiac functioning. Medical management with careful monitoring for complications, such as heart failure and myocardial ischemia, may be indicated for selected individuals. Surgical valve replacement with either a mechanical or a bioprosthetic valve is indicated for both symptomatic and asymptomatic individuals with severe stenosis.^{152,154} Transcatheter aortic valve replacement (TAVR) is used increasingly to avoid major heart surgery in selected individuals.¹⁵⁷ The prognosis is poor once an individual becomes symptomatic from aortic stenosis.¹⁵⁴

Mitral Stenosis.

Mitral stenosis impairs the flow of blood from the left atrium to the left ventricle. Mitral stenosis is the most common form of rheumatic heart disease (see [the Acute Rheumatic Fever and Rheumatic Heart Disease section](#)). Autoimmune activation of lymphocytes and macrophages leads to inflammatory damage and subsequent scarring of the valve leaflets.¹⁵⁸ Scarring causes the leaflets to become fibrous and fused, and the chordae tendineae cordis becomes shortened ([Fig. 33.31](#)). Impedance to blood flow results in incomplete emptying of the left atrium and elevated atrial pressure as the chamber tries to force blood through the stenotic valve. Continued increases in left atrial volume and pressure cause chamber dilation and hypertrophy and eventually result in pulmonary hypertension. The outcomes of untreated chronic mitral stenosis are pulmonary hypertension and right ventricular failure. The risk of developing atrial dysrhythmias (especially fibrillation) and dysrhythmia-induced thrombi is high.

FIGURE 33.31 Mitral Stenosis with Classic “Fish Mouth” (Arrows) Orifice. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, St Louis, 2015, Elsevier.)

Clinical manifestations depend on the size of the valvular orifice. As mitral stenosis progresses, symptoms of decreased cardiac output occur, especially during exertion. Blood flow through the stenotic valve gives rise to a rumbling decrescendo diastolic murmur heard best over the cardiac apex and radiating to the left axilla. If the mitral valve is forced open during diastole, it may make a sharp noise called an *opening snap*. The first heart sound (S_1) is often accentuated and somewhat delayed because of increased left atrial pressure. Other signs and symptoms, such as jugular venous distension and peripheral edema, result from pulmonary congestion and right heart failure. Atrial enlargement is demonstrated by chest x-rays and electrocardiography. Mitral stenosis can often be repaired with percutaneous balloon commissurotomy, but valve replacement may be required in advanced cases.¹⁵² New minimally invasive procedures for mitral valve replacement are being explored, including percutaneous transcatheter techniques.¹⁵⁹

Regurgitation

Aortic Regurgitation.

Aortic regurgitation results from an inability of the aortic valve

leaflets to close properly during ventricular diastole, resulting from abnormalities of the leaflets or the aortic root, or both. It can be primary, caused by congenital bicuspid valve disease or degeneration or secondary, caused by chronic hypertension, rheumatic heart disease, bacterial endocarditis, syphilis, connective tissue disorders (e.g., Marfan syndrome and ankylosing spondylitis), appetite-suppressing medications, trauma, or atherosclerosis. More than one-third of cases of aortic regurgitation are idiopathic. The hemodynamic repercussions depend on the size of the “leak.” During systole, blood is ejected from the left ventricle into the aorta. During diastole, some of the ejected blood flows back into the left ventricle through the leaking valve. Volume overload occurs in the ventricle because it receives blood from the left atrium and the aorta during diastole. As the end-diastolic volume of the left ventricle increases, myocardial fibers stretch to accommodate the extra fluid. Compensatory dilation permits the left ventricle to increase its stroke volume and maintain cardiac output. Ventricular hypertrophy also occurs as an adaptation to the increased volume and increased afterload created by the high stroke volume and resultant systolic hypertension. Ventricular dilation and hypertrophy eventually cease to compensate for aortic incompetence, and heart failure develops.

Clinical manifestations include widened pulse pressure resulting from increased stroke volume and diastolic backflow. Turbulence across the aortic valve produces a diastolic decrescendo murmur heard best in the second, third, or fourth intercostal spaces parasternally and may radiate to the neck. Large stroke volume and rapid runoff of blood from the aorta cause prominent carotid pulsations and bounding peripheral pulses (Corrigan pulse). Other symptoms are usually associated with heart failure that occurs when the ventricle can no longer pump adequately. Dysrhythmias and endocarditis are common complications of aortic regurgitation. The severity of regurgitation can be estimated by echocardiography, and surgical or transcatheter valve replacement may be delayed for many years through careful use of vasodilators and inotropic agents.^{152,160}

Mitral Regurgitation.

Mitral regurgitation occurs in approximately 1.7% of the U.S. population.⁵ It can be primary because of mitral valve prolapse, rheumatic heart disease, infective endocarditis, MI, connective tissue diseases (Marfan syndrome), and dilated cardiomyopathy. It can also be secondary because of ischemic or nonischemic myocardial disease that damages the chordae tendineae or the mitral annulus.¹⁵² Mitral regurgitation permits backflow of blood from the left ventricle into the left atrium during ventricular systole, giving rise to a loud pansystolic (throughout systole) murmur heard best at the apex that radiates into the back and axilla. The volume of backflow reentering the left atrium gradually increases, causing atrial dilation and associated atrial fibrillation. As the left atrium enlarges, the valve structures stretch and become deformed, leading to further backflow. The increased volume in the left atrium increases the volume that enters the ventricle; the left ventricle becomes dilated and hypertrophied to maintain adequate cardiac output. As mitral valve regurgitation progresses, left ventricular function may become impaired to the point of failure. Eventually, increased atrial pressure also causes pulmonary hypertension and failure of the right ventricle. Mitral incompetence is usually well tolerated—often for years—until ventricular failure occurs. Most clinical manifestations are caused by heart failure. The severity of regurgitation can be estimated by echocardiography, and surgical repair or valve replacement may become necessary.^{152,161} In acute mitral regurgitation caused by MI, surgical repair or replacement must be done emergently.¹⁶²

Tricuspid Regurgitation.

Tricuspid regurgitation is more common than tricuspid stenosis and usually is associated with dilation and failure of the right ventricle secondary to pulmonary hypertension. Rheumatic heart disease and infective endocarditis are less common causes. Tricuspid valve incompetence leads to volume overload in the right atrium and ventricle, increased systemic venous blood pressure, and right heart failure. Pulmonic valve dysfunction can have the same consequences as tricuspid valve dysfunction.

Mitral Valve Prolapse Syndrome.

Mitral valve prolapse syndrome is a condition in which the anterior and posterior cusps of the mitral valve billow upward (prolapse) into the atrium during systole (Fig. 33.32). To maintain competency, the mitral valve must be supported by what is called the *mitral valve complex*, which includes the annulus, leaflets, chordae tendineae, papillary muscles, and the left ventricular wall; dysfunction of any of these elements can lead to prolapse of the valve.¹⁶³ The most common cause of mitral valve prolapse is myxomatous degeneration of the leaflets in which the cusps are redundant, thickened, and scalloped because of changes in tissue proteoglycans, increased proteinases, and infiltration by myofibroblasts. The chordae tendineae may be elongated, permitting the valve cusps to stretch upward. Mitral regurgitation occurs if the ballooning valve permits blood to leak into the atrium.

FIGURE 33.32 Mitral Valve Prolapse. A, Prolapsed mitral valve. Prolapse permits the valve leaflets to billow back (arrow) into the atrium during left ventricular systole. The billowing causes the leaflets to part slightly, permitting regurgitation into the atrium. B, Looking down into the mitral valve, the ballooning (arrows) of the leaflets is seen. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 9, St Louis, 2015, Mosby.)

Mitral valve prolapse (MVP) is the most common valve disorder in the United States, with a prevalence estimated at 3%. MVP tends to be most prevalent in young women. Genetic studies suggest several candidate genes that influence cardiac fibroblast and endothelial cell function.¹⁶⁴ Because mitral valve prolapse often is associated with other inherited connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta), it is thought to result from a genetic or environmental disruption of valvular development during the fifth or sixth week of gestation. There may be a relationship between symptomatic mitral valve prolapse and hyperthyroidism.

Many cases of mitral valve prolapse are completely asymptomatic. Cardiac auscultation on routine physical examination may disclose a regurgitant murmur or midsystolic click in an otherwise healthy individual. Echocardiography may demonstrate the condition in the absence of auscultatory findings. Symptomatic mitral valve prolapse can cause palpitations related to dysrhythmias, tachycardia, lightheadedness, syncope, fatigue (especially in the morning), lethargy, weakness, dyspnea, chest tightness, hyperventilation, anxiety, depression, panic attacks, and atypical chest pain. Many symptoms are vague and puzzling and are unrelated to the degree of prolapse. Most individuals with mitral valve prolapse have an excellent prognosis, do not develop symptoms, and do not require any restriction in activity or medical management. Occasionally, beta-blockers are needed to alleviate syncope, severe chest pain, or palpitations. Surgical repair is only necessary if significant mitral regurgitation develops.

Acute Rheumatic Fever and Rheumatic Heart Disease

Rheumatic fever is a systemic, inflammatory disease caused by an immune and inflammatory response to infection by group A beta-hemolytic streptococci in genetically predisposed individuals.¹⁶⁵ In its acute form, rheumatic fever is a febrile illness that occurs approximately 2 to 3 weeks after infection and is characterized by

inflammation of the joints, skin, nervous system, and heart. If untreated, rheumatic fever can cause scarring and deformity of cardiac structures resulting in **rheumatic heart disease (RHD)**.

The incidence of acute rheumatic fever declined in the United States during the 1960s, 1970s, and early 1980s because of medical and socioeconomic improvements, as well as changes in the virulence of group A streptococci.¹⁵³ It occurs most often in children between 5 and 15 years of age. Appropriate antibiotic therapy given within the first 9 days of infection usually prevents rheumatic fever. Individuals who have experienced one attack of acute rheumatic fever are more susceptible to recurrent attacks.

◆Pathophysiology.

Acute rheumatic fever can develop *only* as a sequela to pharyngeal infection by group A beta-hemolytic streptococci. Streptococcal skin infections do not progress to acute rheumatic fever because the strains of the microorganism that infect the skin do not have the same antigenic molecules in their cell membranes as do those that cause pharyngitis and therefore do not elicit the same kind of immune response. Acute rheumatic fever is the result of an abnormal humoral and cell-mediated immune response to the M proteins on the microorganisms that cross-react with normal tissues (Fig. 33.33). Antibodies against streptococci bacterial antigens display cross-reactivity against laminin, a protein present in extracellular tissues around heart cells and in the valves. Cardiac myosin and vimentin are other target antigens.¹⁵³

FIGURE 33.33 Pathogenesis and Structural Alterations of Acute Rheumatic Heart Disease. Beginning usually with a sore throat, rheumatic fever can develop only as a sequela to pharyngeal infection by group A beta-hemolytic streptococcus. Suspected as a hypersensitivity reaction, it is proposed that antibodies directed against the M proteins of certain

strains of streptococci cross-react with tissue glycoproteins in the heart, joints, and other tissues. The exact nature of cross-reacting antigens has been difficult to define, but it appears that the streptococcal infection causes an autoimmune response against self antigens. Inflammation is found in various sites including (1) endocardium, (2) myocardium, and (3) pericardium. The most distinctive inflammatory lesions within the heart are called *Aschoff bodies*. The chronic sequelae result from progressive fibrosis because of healing of the inflammatory lesions and the changes induced by valvular deformities. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

Autoimmunity and associated intense inflammation result in diffuse, proliferative, and exudative lesions in the connective tissues, especially in the heart, joints, and skin.¹⁶⁵ Repeated attacks of acute rheumatic fever cause chronic proliferative changes with resultant scarring, granulomas, and thromboses. Approximately 10% of cases of rheumatic fever develop RHD.¹⁵³ RHD begins as **carditis**, or inflammation of the heart. Although rheumatic fever can cause carditis in all three layers of the heart wall (endocardium, myocardium, pericardium) (see [Chapter 32, Fig. 32.2](#)), the primary lesion usually involves the endocardium, which includes the heart valves. Endocardial inflammation causes swelling of the valve leaflets, with secondary erosion along the lines of leaflet contact. Small beadlike clumps of vegetation containing platelets and fibrin are deposited on eroded valvular tissue and on the chordae tendineae ([Fig. 33.34](#)). The valves lose their elasticity, and the leaflets may adhere to each other. Scarring and shortening of the involved structures occur over time.

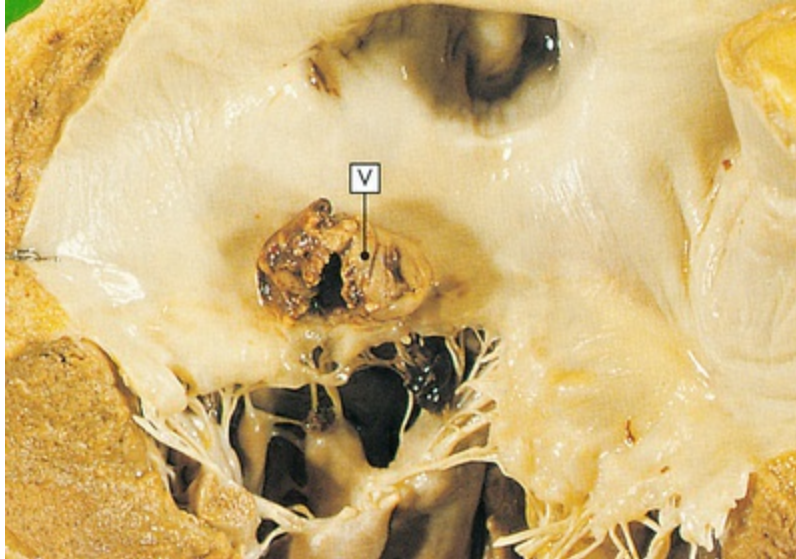

FIGURE 33.34 Valvular Vegetations in Mitral Stenosis. Mitral stenosis and clumps of vegetation (V) containing platelets and fibrin. Mitral leaflets are thickened and fused and have clumps of vegetation containing platelets and fibrin. (From Stevens A, Lowe JS, Scott I: *Core pathology*, ed 3, London, 2009, Mosby.)

If inflammation penetrates the myocardium, localized fibrin deposits develop that are surrounded by areas of necrosis. These fibrinoid necrotic deposits are called *Aschoff bodies*. Pericardial inflammation is usually characterized by serofibrinous effusion within the pericardial cavity. Cardiomegaly and left heart failure may occur during episodes of untreated acute or recurrent rheumatic fever. Conduction defects and atrial fibrillation often are associated with rheumatic heart disease.

◆Clinical Manifestations.

The common symptoms of acute rheumatic fever are fever, lymphadenopathy, arthralgia, nausea, vomiting, epistaxis (nosebleed), abdominal pain, and tachycardia. The major clinical manifestations of acute rheumatic fever (carditis, acute migratory polyarthritis, subcutaneous nodules, chorea, and erythema marginatum) usually occur singly or in combination 1 to 5 weeks after streptococcal infection of the pharynx.

Carditis

Carditis occurs a few weeks after the initial infection in about 50% of patients with acute rheumatic fever with the mitral valve being the most affected structure.¹⁶⁵ Cardiac manifestations of acute rheumatic fever may be a previously undetected murmur caused by mitral or aortic valve dysfunction, chest pain, and pericardial rub caused by pericardial inflammation or unexplained cardiomegaly with heart failure.¹⁶⁶

Polyarthriti

Acute migratory asymmetrical polyarthriti (inflammation of more than one joint) occurs in the majority of individuals with rheumatic fever, although a severe monoarthriti also is a presenting feature in high-risk populations.¹⁶⁵ Although all of the synovial joints may be involved, the large joints of the extremities are most often affected. Two or more joints are usually involved simultaneously or in succession, with each joint being symptomatic for approximately 2 to 3 days while the overall polyarthriti continues for up to 3 weeks. Exudative synoviti causes heat, redness, swelling, severe pain, and tenderness but no permanent disability.

Subcutaneous Nodules

Palpable subcutaneous nodes occur in less than 5% of cases of acute rheumatic fever.¹⁶⁵ They develop over bony prominences and along extensor tendons of elbows, wrists, knees, and ankles. They do not interfere with joint function and often go unnoticed.

Chorea

Sydenham chorea, or **St. Vitus dance**, is a disorder of the CNS characterized by sudden, aimless, irregular, involuntary movements. (Chorea is described in [Chapter 17](#).) It affects up to 15% of people with rheumatic fever, and is the most common acquired chorea in children.¹⁶⁵ The chorea is self-limiting, although severe cases may require the use of dopamine receptor blockers and antiepileptic

medications. It resolves within 1 to 6 months and has no permanent neural sequelae.

Erythema Marginatum

Erythema marginatum is an uncommon manifestation and presents as a distinctive truncal rash that often accompanies acute rheumatic fever. It consists of an annular erythema with the appearance of nonpruritic, pink, erythematous macules that spread outwards. The rash is transitory and may change in appearance within minutes or hours.

◆ Evaluation and Treatment.

The original Jones Criteria for the diagnosis of rheumatic fever have been updated by the American Heart Association¹⁶⁷ (Table 33.7). Supportive evidence for group A beta-hemolytic streptococci includes positive throat cultures and measurement of serum antibodies against the hemolytic factor streptolysin O. Cultures may be negative when the rheumatic attack begins, however. Several other antibody tests are sensitive prognosticators of streptococcal infection, including antideoxyribonuclease B (anti-DNase B), antihyaluronidase, and antistreptozyme (ASTZ). Elevated measurements of white blood cell count, erythrocyte sedimentation rate, and C-reactive protein indicate inflammation. All three are usually increased at the time cardiac or joint symptoms begin to appear.

TABLE 33.7

MAJOR AND MINOR DIAGNOSTIC CRITERIA FOR ACUTE RHEUMATIC FEVER ACCORDING TO THE JONES CRITERIA

For all patient populations with evidence of preceding group A streptococcal infection: one major plus two minor manifestations	
MAJOR CRITERIA IN LOW-RISK POPULATIONS	MAJOR CRITERIA IN MODERATE- AND HIGH-RISK POPULATIONS
Carditis (clinical and/or subclinical) Arthritis (polyarthritis only) Chorea	Carditis (clinical and/or subclinical) Arthritis (monoarthritis or polyarthritis; polyarthralgia) Chorea

Erythema marginatum Subcutaneous nodules	Erythema marginatum Subcutaneous nodules
MINOR CRITERIA IN LOW-RISK POPULATIONS	MINOR CRITERIA IN MODERATE- AND HIGH-RISK POPULATIONS
Polyarthralgia Fever ($\geq 38^{\circ}\text{C}$; 100.4°F) ESR ≥ 60 mm/hr and/or CRP >3.0 mg/dL Prolonged PR interval	Monoarthralgia Fever ($\geq 38^{\circ}\text{C}$; 100.4°F) ESR ≥ 30 mm/hr and/or CRP >3.0 mg/dL Prolonged PR interval

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

From Gewitz MH et al: *Circulation* 131:1806–1818, 2015.

Therapy for acute rheumatic fever is aimed at eradicating the streptococcal infection using a 10-day regimen of antibiotics. NSAIDs are used as antiinflammatory agents for rheumatic carditis and arthritis and help relieve symptoms, but do not prevent complications. Serious carditis may require diuretics and vasodilators, and recovery can take up to 12 months. Surgical repair of damaged valves may be necessary in cases of chronic recurrent rheumatic fever or carditis. Persistent chorea requires psychosocial support, protection against falls and injury, and treatment with antiepileptic or neuroleptic medications. NSAIDs or paracetamol may provide symptomatic relief from arthralgias.¹⁶⁵ Because recurrent rheumatic fever occurs in more than half of affected children, continuous prophylactic antibiotic therapy may be necessary for as long as 5 years.

Infective Endocarditis

Infective endocarditis (IE) is a general term used to describe infection and inflammation of the endocardium, especially the cardiac valves. The incidence of IE is increasing in the United States, in large part because of the increase in the implantation of prosthetic valves¹⁶⁸ (Box 33.3). Bacteria are the most common cause of IE with *Staphylococcus aureus* the most common causative agent worldwide.¹⁶⁹ Other causes include streptococci, enterococci, viruses, fungi, rickettsia, and parasites.¹⁶⁸

Box 33.3

Risk Factors for Infective Endocarditis

- Implantation of prosthetic heart valves
- Congenital lesions associated with highly turbulent flow (e.g., ventricular septal defect)
- Acquired valvular heart disease (especially mitral valve prolapse)
- Previous attack of infective endocarditis
- Intravenous drug use
- Long-term indwelling intravenous catheterization (e.g., for pressure monitoring, feeding, hemodialysis)
- Implantable cardiac pacemakers
- Heart transplant with defective valve

◆ Pathophysiology.

The pathogenesis of IE requires at least three critical elements ([Fig. 33.35](#)):

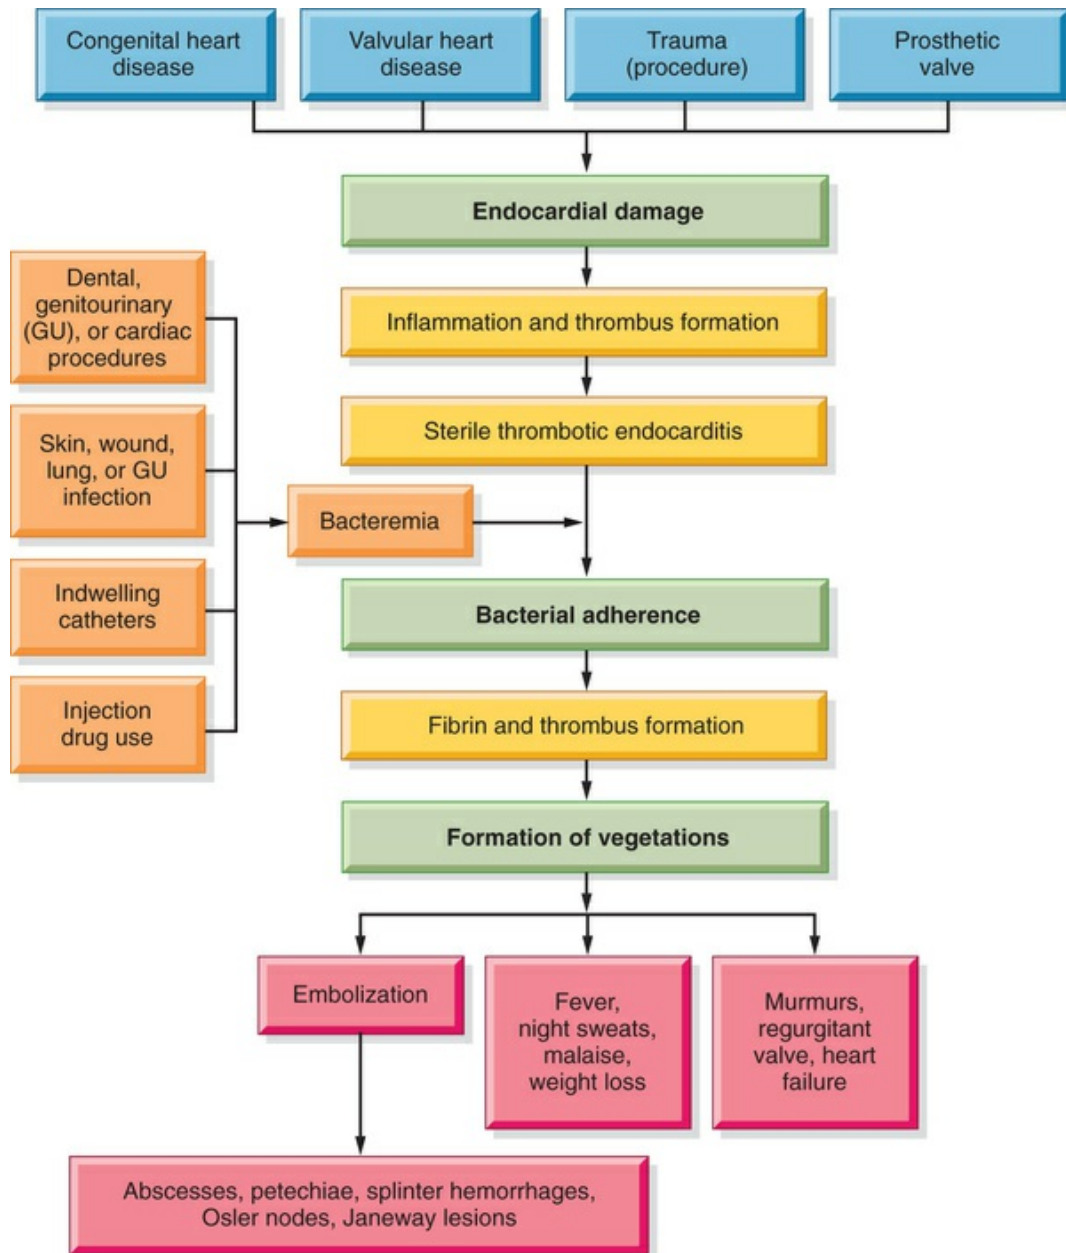

FIGURE 33.35 Pathogenesis of Infective Endocarditis.

1. Trauma, congenital heart disease, valvular heart disease, and the presence of prosthetic valves are the most common risk factors for endocardial damage that leads to IE. Turbulent blood caused by these abnormalities usually affects the atrial surface of atrioventricular valves or the ventricular surface of semilunar valves. Endocardial damage exposes the endothelial

basement membrane, which contains a type of collagen that attracts platelets and thereby stimulates sterile thrombus formation on the membrane. This causes an inflammatory reaction (nonbacterial thrombotic endocarditis).

2. Blood-borne microorganism adherence to the damaged endocardial surface. Bacteria may enter the bloodstream during injection drug use, trauma, dental procedures that involve manipulation of the gingiva, cardiac surgery, genitourinary procedures and indwelling catheters in the presence of infection, or gastrointestinal instrumentation, or may spread from uncomplicated upper respiratory tract or skin infections. Bacteria adhere to the damaged endocardium using adhesins.
3. Formation of infective endocardial vegetations ([Fig. 33.36](#)). Bacteria infiltrate the sterile thrombi and accelerate fibrin formation by activating the clotting cascade. These vegetative lesions can form anywhere on the endocardium but usually occur on heart valves and surrounding structures. Although endocardial tissue is constantly bathed in antibody-containing blood and is surrounded by scavenging monocytes and polymorphonuclear leukocytes, bacterial colonies are inaccessible to host defenses because they are embedded in the protective fibrin clots. Embolization from these vegetations can lead to abscesses and characteristic skin changes, such as petechiae, splinter hemorrhages, and Janeway lesions (nonpainful hemorrhagic lesions on the palms and soles).

FIGURE 33.36 Bacterial Endocarditis of Mitral Valve. Lesion (*arrow*) in combination with old rheumatic valvulitis. (From Damjanov I, Linder J: *Pathology: a color atlas*, St Louis, 2000, Mosby.)

◆Clinical Manifestations.

IE may be acute, subacute, or chronic. It causes varying degrees of valvular dysfunction and may be associated with manifestations involving several organ systems (lungs, eyes, kidneys, bones, joints, CNS). Signs and symptoms of IE are caused by infection and inflammation, systemic spread of microemboli, and immune complex deposition. The “classic” findings are fever, new or changed cardiac murmur, and petechial lesions of the skin, conjunctiva, and oral mucosa. Characteristic physical findings include Osler nodes (painful erythematous nodules on the pads of the fingers and toes) and Janeway lesions. Other manifestations include weight loss, back pain, night sweats, and heart failure. CNS, splenic, renal, pulmonary peripheral arterial, coronary, and ocular emboli may lead to a wide variety of signs and symptoms.

◆Evaluation and Treatment.

The widely accepted Duke criteria for the diagnosis of IE include the two major criteria of positive blood cultures (at least 2 positive cultures drawn >12 hours apart) and evidence for endocardial

involvement (echocardiographic findings of vegetations and valvular dysfunction or damage), plus minor criteria including predisposing conditions, fever, evidence of emboli (e.g., Janeway lesions), and immunologic phenomena (e.g., Osler nodes).¹⁶⁹ The diagnosis of IE must be made as soon as possible to initiate appropriate empirical antibiotic therapy and to identify patients at high risk for complications. Antimicrobial therapy should begin as soon as possible, and it is generally continued for several weeks. Surgical intervention to repair or replace the valve may be required, especially in individuals with heart failure, abscess, infection with highly resistant microorganisms, and large vegetations.¹⁶⁹ Antibiotic prophylaxis to prevent IE is indicated for those with prosthetic valves, a history of IE, unrepaired cyanotic congenital heart disease, and heart transplant with valvular defect in the setting of gingival procedures or in the presence of documented acute gastrointestinal or genitourinary infection.¹⁵²

Manifestations of Heart Disease

Heart Failure

Heart failure (HF) is defined as the pathophysiologic condition in which the heart is unable to generate an adequate cardiac output such that inadequate perfusion of tissues or increased diastolic filling pressure of the left ventricle, or both, occurs; consequently, pulmonary capillary pressures are increased. It is estimated that 5.7 million Americans ≥ 20 years of age have HF and it causes 1 in 9 deaths in the United States.⁵ HF is a pressing, world-wide problem with millions of people experiencing worsening heart failure.¹⁷⁰ Ischemic heart disease and hypertension are the most important predisposing risk factors with 75% of HF cases occurring in individuals with hypertension. Other risk factors include age, smoking, obesity, diabetes, renal failure, valvular heart disease, cardiomyopathies, myocarditis, congenital heart disease, and excessive alcohol use. Numerous genetic polymorphisms have been linked to an increased

risk for heart failure, including genes for cardiomyopathies, sarcomere proteins, and neurohumoral receptors.¹⁴⁴ Most causes of heart failure result in dysfunction of the left ventricle (systolic and diastolic heart failure). The right ventricle also may be dysfunctional, especially in pulmonary disease (right ventricular failure). Finally, some conditions cause inadequate perfusion despite normal or elevated cardiac output (high-output failure). A current area of investigation is mitochondrial dysfunction.¹⁷⁰ Mitochondrial abnormalities include impaired mitochondrial electron transport chain activity, increased formation of reactive oxygen species, altered metabolic substrate usage, abnormal mitochondrial dynamics, and altered ion hemostasis.¹⁷⁰ Abnormal mitochondrial energy production is involved in many symptoms found in individuals with heart failure and include skeletal muscle dysfunction and renal pathologies.¹⁷⁰

Types

Left Heart Failure.

Left heart failure (congestive heart failure) is categorized as heart failure with reduced ejection fraction, or HFrEF (systolic heart failure), or heart failure with preserved ejection fraction, or HFpEF (diastolic heart failure). These two types of heart failure can occur together in one individual or singly.

Heart Failure with Reduced Ejection Fraction (HFrEF) (Systolic Heart Failure).

Heart failure with reduced ejection fraction, or HFrEF (systolic heart failure), is defined as an ejection fraction of <40% and an inability of the heart to generate an adequate cardiac output to perfuse vital tissues. Cardiac output depends on the heart rate and stroke volume. Stroke volume is influenced by three major factors: contractility, preload, and afterload (see [Chapter 32](#)). Contractility is reduced by diseases that disrupt myocyte activity. Myocardial infarction is the most common cause of decreased contractility; other causes include myocarditis and cardiomyopathies. These diseases contribute to

inflammatory, immune, and neurohumoral changes (activation of the SNS and RAAS) that mediate a process called *ventricular remodeling*. **Ventricular remodeling** results in disruption of the normal myocardial extracellular structure with resultant dilation of the myocardium and causes progressive myocyte contractile dysfunction over time (Fig. 33.37). When contractility is decreased, stroke volume falls, and left ventricular end-diastolic volume (LVEDV) increases. This causes dilation of the heart and an increase in preload.

FIGURE 33.37 Pathophysiology of Ventricular Remodeling. Myocardial dysfunction activates the renin-angiotensin-aldosterone and sympathetic nervous systems, releasing neurohormones (angiotensin [ang] II, aldosterone, catecholamines, and cytokines). These neurohormones contribute to ventricular remodeling. (Redrawn from Carelock J, Clark AP: *Am J Nurs* 101[12]:27, 2001.)

Preload, or LVEDV, increases with decreased contractility or when there is an excess of plasma volume (intravenous fluid administration, renal failure, mitral valvular disease). Increases in LVEDV can actually improve cardiac output up to a certain point, but as preload

continues to rise, it causes a stretching of the myocardium that eventually can lead to dysfunction of the sarcomeres and decreased contractility. This relationship is described by the Frank-Starling law of the heart (see Fig. 32.18).

Increased afterload is most commonly a result of increased peripheral vascular resistance (PVR), such as that seen with hypertension (Fig. 33.38). Although much less common, it also can be the result of aortic valvular disease. With increased PVR, there is resistance to ventricular emptying and more workload for the left ventricle, which responds with hypertrophy of the myocardium. This process differs from the physiologic myocyte response to increased workload (exercise) in which the workload is intermittent rather than sustained, resulting in an increase in muscle mass but no distortion of the cardiac architecture. Sustained afterload leads to pathologic hypertrophy which is characterized by myocyte death, fibrosis, inflammation, and alterations in cardiac energetics and is mediated by ang II, catecholamines, and changes in intracellular signaling within the myocytes¹⁷¹ (see Fig. 33.37). This pathologic increase in muscle mass results in an increase in oxygen and energy demand. When demand for energy is greater than the ability of these systems to supply the necessary ATP, contractility of the myocardium is compromised. An energy-starved state develops that further contributes to changes in the myocytes themselves and ventricular remodeling that significantly impairs contractility and therefore ventricular function. Remodeling also results in the deposition of collagen between the myocytes, which can disrupt the integrity of the muscle, decrease contractility, and make the ventricle more likely to dilate and fail.¹⁷² Weakness of the cardiac muscle due to hypertension-induced hypertrophy is called *hypertensive hypertrophic cardiomyopathy*.^{173,174}

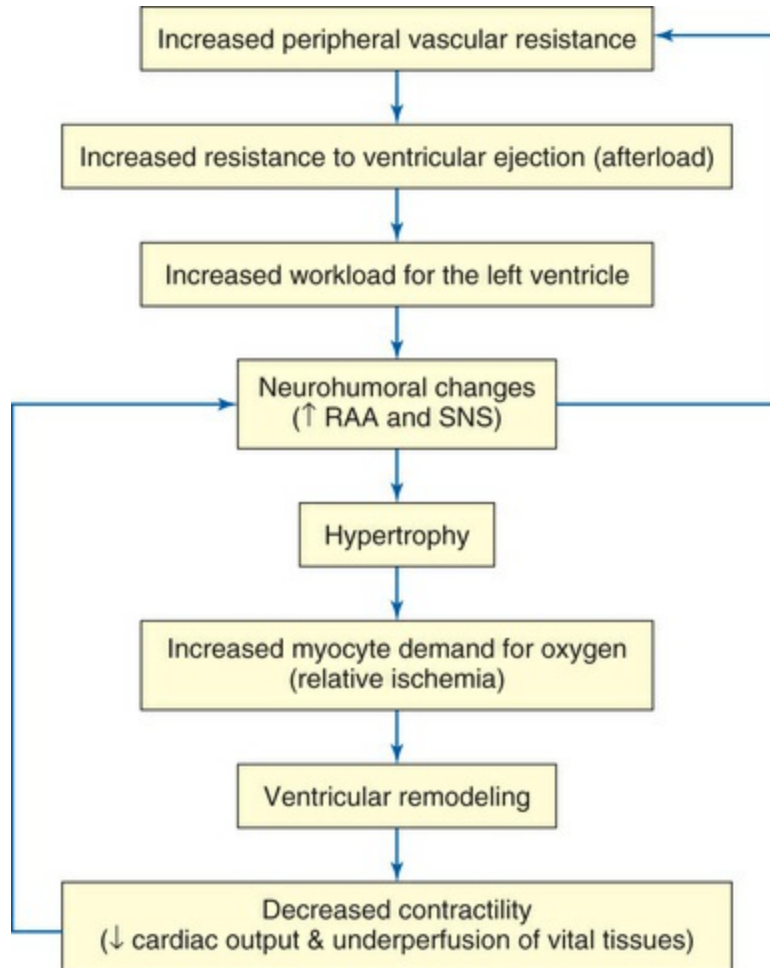

FIGURE 33.38 The Role of Increased Afterload in the Pathogenesis of Heart Failure. RAA, Renin-angiotensin-aldosterone, SNS, sympathetic nervous system.

As cardiac output falls, renal perfusion diminishes with activation of the RAAS, which acts to increase PVR and plasma volume, thus increasing afterload and preload further. In addition, baroreceptors in the central circulation detect the decrease in perfusion and stimulate the SNS to cause yet more vasoconstriction and to cause the hypothalamus to produce antidiuretic hormone. This vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening of left heart failure (Fig. 33.39).

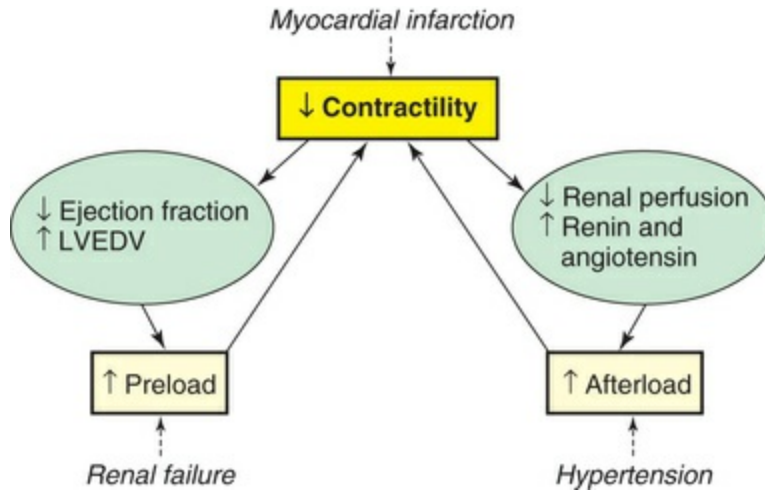

FIGURE 33.39 The Vicious Cycle of Systolic Heart Failure. Although the initial insult may be one of primary decreased contractility (e.g., myocardial infarction), increased preload (e.g., renal failure), or increased afterload (e.g., hypertension), all three factors play a role in the progression of left heart failure. *LVEDV*, Left ventricular end-diastolic volume.

In addition to these hemodynamic interactions, systolic congestive heart failure is characterized by a complex constellation of neurohumoral, inflammatory, and metabolic processes:

1. *Catecholamines*. Sympathetic nervous system activation initially compensates for a decrease in cardiac output by increasing heart rate and peripheral vascular resistance. However, catecholamines cause numerous deleterious effects on the myocardium, including direct toxicity to myocytes, induction of myocyte apoptosis, myocardial remodeling, downregulation of adrenergic receptors, facilitation of dysrhythmias, and potentiation of autoimmune effects on the heart muscle.
2. *RAAS*
 - a. Angiotensin II (Ang II). Activation of the RAAS causes not only increases in preload and afterload, but also causes direct toxicity to the myocardium (see [Fig. 33.37](#)). Ang II mediates remodeling of the ventricular wall, contributing to sarcomere death, loss of the normal collagen matrix, and interstitial fibrosis. This leads to decreased contractility,

changes in myocardial compliance, and ventricular dilation.¹⁷⁵

- b. Aldosterone. Aldosterone not only causes salt and water retention by the kidney but also contributes to myocardial fibrosis, autonomic dysfunction, and dysrhythmias. It also has been implicated in endothelial dysfunction and prothrombotic effects.
3. *Arginine vasopressin*. Arginine vasopressin is also known as *antidiuretic hormone* and causes both peripheral vasoconstriction and renal fluid retention. These actions exacerbate hyponatremia and edema in heart failure. The arginine vasopressin type 2 antagonist tolvaptan is indicated for the treatment of heart failure that is resistant to conventional diuretics.¹⁷⁶
4. *Natriuretic peptides*. Atrial natriuretic peptides (ANPs) and B-type natriuretic peptides (BNPs) are increased and may have some protective effect by decreasing preload; however, their compensatory mechanisms are inadequate in heart failure.¹⁷⁷
5. *Inflammatory cytokines*
 - a. Endothelial hormones. Endothelin is a potent vasoconstrictor and is associated with a poor prognosis in individuals with heart failure.
 - b. TNF- α and IL-6. TNF- α is elevated in heart failure and contributes to myocardial hypertrophy and remodeling. It down-regulates the synthesis of the vasodilator nitric oxide (NO), induces myocyte apoptosis, and may contribute to weight loss and weakness in individuals with heart failure (cardiac cachexia). IL-6 also is elevated in individuals with severe heart failure and cardiogenic shock and may contribute to further deleterious immune activation.¹⁷⁸
6. *Myocyte calcium transport*. Calcium transport into, out of, and within myocytes is critical to normal contractile function. Changes in calcium ion channels, intracellular transport

mechanisms in the sarcoplasmic reticulum, and calcium cycling have all been implicated in decreased myocardial contractility and heart failure.¹⁷⁹

7. *Insulin resistance and diabetes.* Insulin resistance is a likely contributor to, as well as complication of, heart failure.¹⁸⁰ Insulin resistance causes abnormal myocyte fatty acid metabolism and generation of ATP, which contributes to decreased myocardial contractility and remodeling (see [What's New? Metabolic Changes in Heart Failure](#)). Heart failure activates the SNS and RAAS, which contribute to insulin resistance. Diabetes contributes to heart failure through disturbed calcium metabolism, oxidative stress, changes in fatty acid and glucose metabolism, and mitochondrial dysfunction.¹⁸¹ In addition, receptors on myocytes for damaging advanced glycation end-products (RAGE) (see [Chapter 22](#)) are up-regulated in injuries to the heart, including ischemia and reperfusion injury. Measurement of levels of RAGE in plasma or serum may correlate with the degree of heart failure. Unfortunately, many of the new medications used to treat diabetes and insulin resistance have deleterious side effects on cardiac functioning. Newer agents, such as the sodium/glucose cotransporter 2 (SGLT2) inhibitors and the incretin-based drugs (see [Chapter 22](#)), are safer and may even reduce hospitalization and mortality from heart failure.^{182,183}

What's New?

Metabolic Changes in Heart Failure

Although the use of medications that block the renin-angiotensin-aldosterone and sympathetic nervous systems reduce remodeling and improve outcomes in heart failure, morbidity and mortality from this condition are still high. The heart is the largest consumer of energy in the body and relies on the efficient production of adenosine triphosphate (ATP) yet it has very little capacity for

energy storage. Normally, fatty acids supply approximately 80% of energy for myocardium. In the failing heart, increased demand for oxygen and energy is coupled with a decreased ability to use fatty acids as an energy source. This causes the myocytes to favor glucose metabolism. Glycolysis rises and there is reduced mitochondrial oxidative metabolism. Energy starvation and high levels of catecholamines associated with heart failure lead to altered fatty acid oxidation and decreased effective ATP generation and use. This results in decreased myocardial contractility and structural changes in the myocardium (remodeling). The peroxisome proliferator-activated receptor (PPAR) family of genes controls fatty acid oxidation and is of particular importance in heart failure associated with insulin resistance and diabetes. Increasing knowledge of these mechanisms has led to the exploration of potential new therapies for heart failure. Although currently available PPAR- γ agonists (thiazolidinediones) are contraindicated in worsening heart failure because of increased fluid retention at the renal tubule, new insulin sensitizers are being explored that may improve myocardial metabolic function. In addition, inhibitors of fatty acid oxidation (e.g., trimetazidine and perhexiline) have been tried in several small studies with some improvement in cardiac function. Other metabolic abnormalities in the failing heart are being discovered, including changes in the AMP (adenosine monophosphate)-activated protein kinase (AMPK) pathway, pentose phosphate pathway, ketone bodies, acylcarnitines, uncoupled electron transfer, and lipotoxins. Investigation into drugs that activate cardiac myosin, inhibit phosphodiesterase, and alter the nitrate/nitrite/NO pathway is underway. Mechanical supports, such as left ventricular assist devices, are promising in reversing these metabolic changes.

Data from Ahmad T et al: *J Am Coll Cardiol* 67:291–299, 2016; Czarnowska E et al: *PPAR Res* 2016:7508026, 2016; Horton JL et al: *JCI Insight* 1(2), 2016; Kim TT, Dyck JR: *Trends Endocrinol Metab* 26(1):40–48, 2015; Loudon BL et al: *Br J Pharmacol* 173(12):1911–1924, 2016; Rame JE: *J Am Coll Cardiol* 67:300–302, 2016.

The interaction of these metabolic, neurohumoral, and inflammatory processes results in a gradual decline in myocardial function. Pathologically, the heart muscle exhibits progressive changes in myocyte myofilaments, decreased contractility, myocyte apoptosis and necrosis, abnormal fibrin deposition in the ventricle wall, myocardial hypertrophy, and changes in the ventricular chamber geometry. Remodeling, endothelial dysfunction, venous congestion, and worsening renal function all contribute to the pathophysiology of acute heart failure.¹⁷⁵ These changes reduce myocardial function and cardiac output and lead to increased morbidity and mortality. These discoveries have led to the routine use of ACE inhibitors, aldosterone blockers, and beta-blockers in the management of heart failure, which has resulted in significant decreases in morbidity and mortality.¹⁸⁴

◆Evaluation.

The clinical manifestations of HFrEF are the result of pulmonary vascular congestion and inadequate perfusion of the systemic circulation. Individuals experience dyspnea, orthopnea, cough of frothy sputum, fatigue, decreased urine output, and edema. Physical examination often reveals pulmonary edema (cyanosis, inspiratory crackles, pleural effusions), hypotension or hypertension, an S₃ gallop, and evidence of underlying CAD or hypertension. An ECG and serum troponin should be obtained to evaluate for acute ischemia. A chest x-ray should be obtained to assess heart size and evidence of pulmonary congestion, and echocardiography, to confirm decreased cardiac output and cardiomegaly.¹⁸⁴ Invasive catheterization to monitor hemodynamics or to document underlying coronary disease may be needed. Serum BNP levels should be measured to assist in diagnosing heart failure and to monitor its severity and response to treatment.¹⁸⁴ Other biomarkers that may aid in the diagnosis and management of heart failure include cardiac troponins and soluble suppression of tumorigenicity 2 (ST2).¹⁸⁵

Management of HFrEF is aimed at interrupting the worsening cycle of decreasing contractility, increasing preload, and increasing

afterload, as well as blocking the neurohormonal mediators of myocardial toxicity. The acute onset of left heart failure is often the result of acute myocardial ischemia and must be managed in conjunction with the underlying coronary disease. Oxygen, nitrates, and morphine administration improve myocardial oxygenation and help relieve coronary spasm while lowering preload through systemic venodilation. Diuretics reduce preload and are the mainstay of therapy. Intravenous inotropic drugs, such as dobutamine and milrinone, increase contractility and can help raise the blood pressure in hypotensive individuals. Calcium-sensitizing inotropic drugs (e.g., levosimendan) have shown promise for acute heart failure in selected individuals. ACE inhibitors (which reduce preload and afterload) and intravenous beta-blockers (which reduce myocardial demand) have been found to reduce mortality but must be used with caution in hypotensive individuals. Intravenous administration of nesiritide (recombinant BNP) also improves preload and contractility; however, results of this therapy have been mixed. Individuals with severe systolic failure because of myocardial ischemia may benefit from acute coronary bypass or PCI. Those with refractory hypotension may be supported with the intraaortic balloon pump (IABP) until they can be taken safely to the operating room; the IABP is positioned in the aorta just distal to the aortic valve and is inflated during diastole to improve coronary perfusion and deflated during systole to reduce afterload. Left ventricular assist devices (LVADs) also can be lifesaving.

Management of **chronic left heart failure** also relies on increasing contractility and reducing preload and afterload. In all patients with reduced ejection fraction, ACE inhibitors and beta-blockers are indicated to reduce mortality.¹⁸⁴ Salt restriction, loop diuretics, and aldosterone-blockers such as spironolactone and eplerenone are effective in reducing preload and improving outcomes. ACE inhibitors reduce preload and afterload and have been shown to significantly reduce mortality in chronic left heart failure. ARBs do not improve morbidity or mortality in individuals with heart failure and should be used only in those who do not tolerate ACE inhibitors. Renin inhibitors, such as aliskiren, can be effective in selected

individuals.¹⁸⁶ Beta-blockers improve symptoms and increase survival. A new class of medications, called *neprilysin (NEP) inhibitors*, has been developed and, when combined with ARBs, can improve HF outcomes.¹⁷⁷ Pharmacogenetics may improve the individualization of therapies.¹⁸⁷ Anticoagulants and antithrombotics may be indicated in selected individuals, particularly those with intracardiac thrombi or atrial fibrillation. Although many individuals with left heart failure die suddenly from dysrhythmias, prophylactic administration of antidysrhythmics has not been shown to improve survival. In individuals with sustained ventricular tachycardia, amiodarone or ICDs are indicated. Cardiac resynchronization therapy is proving to be an important modality in selected individuals. Coronary bypass surgery or PCI may improve perfusion to ischemic myocardium (hibernating myocardium) and improve cardiac output. Other types of surgical intervention that improve ventricular geometry may be considered. Left ventricular assist devices have lengthened survival significantly for those with end-stage heart failure.¹⁸⁸ Heart transplant may be the only remaining option. Experimental therapies, including gene and stem cell therapies, are being explored^{189,190} (see [What's New? Gene Therapy for Heart Failure](#)).

What's New?

Gene Therapy for Heart Failure

The effectiveness and safety of recent gene therapy trials for heart failure have led to an explosion of interest in innovative methods for restoring cardiac function. Multiple components of cardiac contractility have been identified as targets for gene therapy, including calcium channel cycling, beta adrenergic functioning, and cellular proliferation. The most studied of the potential gene targets include sarcoendoplasmic reticulum calcium ATPase (SERCA2a) and S100A1, which affect intracellular myocyte calcium handling. Another exciting target is adenylyl cyclase 6 (AC6), the enzyme catalyzing cyclic adenosine monophosphate (cAMP) formation and

beta-adrenergic receptor function. Other targets include SDF1/CXCR4 complex, which promotes homing of stem cells to infarcted myocardium; microRNAs; and genes that code for critical neurohumoral factors, including insulin-like growth factor-1 (IGF-1), growth hormone, and B-type natriuretic peptide. Viruses are the most widely used vectors for cardiovascular gene transfer, especially adeno-associated virus (AAV). These viruses exhibit fairly good cardiotropism, and various methods are being explored for delivering these gene vectors most efficiently to the myocardium, including antegrade or retrograde coronary infusion, intravenous infusion, direct myocardial injection, and pericardial injection. Intracoronary infusion of AAV with SERCA2a for individuals with severe heart failure significantly improved mortality and heart failure outcomes with positive effects and no reported safety concerns reported at 3 years. Unfortunately, a follow-up study by the same author provided less positive results. Most recently, a study reported that gene transfer of AC6 improved LV function and reduced hospitalizations for individuals with moderate to severe heart failure with preserved ejection fraction (HFpEF). Another avenue for gene therapy uses drugs to inhibit microRNAs that block essential gene expression and protein translation. It is clear that the future will reveal many new and potentially lifesaving gene therapies for those with intractable heart failure.

Data from Braunwald E: *Lancet* 385(9970):812-824, 2015; Donahue JK: *Lancet* 387(10024):1137-1139, 2016; Fish KM, Ishikawa K: *Dis Med* 19(105):285-291, 2015; Greenberg B: *J Cardiol* 66(3):195-200, 2015; Greenberg B et al: *Lancet* 387(10024):1178-1186, 2016; Hammond HK et al: *J Am Med Assoc Cardiol* 1(2):163-171, 2016.

Heart Failure with Preserved Ejection Fraction (Diastolic Heart Failure)

Heart failure with preserved ejection fraction, or HFpEF (diastolic heart failure), can occur singly or along with systolic heart failure. Isolated diastolic heart failure is defined as pulmonary congestion

despite a normal stroke volume and cardiac output. It is the cause of approximately 50% of all cases of left heart failure and is more common in women.¹⁹¹ The major causes of HFpEF include hypertension-induced myocardial hypertrophy and myocardial ischemia with resultant ventricular remodeling. Hypertrophy and ischemia cause a decreased ability of the myocytes to actively pump calcium from the cytosol, resulting in impaired relaxation. Other causes include aortic valvular disease, mitral valve disease, pericardial diseases, and cardiomyopathies.¹⁹² Diabetes also increases the risk for diastolic dysfunction.¹⁹¹

Two areas of pathophysiologic changes in the ventricle have been identified in diastolic dysfunction: decreased compliance of the left ventricle and abnormal diastolic relaxation (lusitropy). Decreased ventricular compliance has been linked to changes in myocardial structure such as that seen with molecular alterations in collagen, which forms the extracellular matrix for myocytes. Another recently identified structural change is because of abnormalities in an intracellular protein component of the myocyte cytoskeleton called *titin*. Abnormal lusitropy is caused by changes in calcium transport from myocytes and may be related to the activity of sarcoplasmic reticulum–calcium adenosine triphosphatase (ATPase). Other pathophysiologic processes implicated include autonomic and endothelial dysfunction.¹⁹³ The resultant noncompliant and poorly lusitropic ventricle cannot accept filling with blood without significant resistance and an increase in wall tension. Thus HFpEF occurs because a normal LVEDV is associated with an increased LVEDP. The resultant increase in left atrial pressure is then reflected proximally into the pulmonary circulation and results in pulmonary edema. The increase in pressure is made worse when ventricular filling is rapid so symptoms worsen with tachycardia (e.g., with exercise).

Individuals with HFpEF most often present with dyspnea on exertion and fatigue. If diastolic dysfunction is severe, there may be evidence of pulmonary edema (inspiratory crackles on auscultation, pleural effusions). Pulmonary hypertension and right ventricular failure may develop. Late in diastole, atrial contraction with rapid

ejection of blood into the noncompliant ventricle may give rise to an S_4 gallop. Electrocardiography often reveals evidence of left ventricular hypertrophy, and chest x-ray shows pulmonary congestion without cardiomegaly (Table 33.8). There also may be evidence of underlying coronary disease, hypertension, or valvular disease. Diagnosis is based on three factors: signs and symptoms of heart failure, normal left ventricular ejection fraction, and evidence of diastolic dysfunction. The diagnosis is initially made by echocardiography, which demonstrates poor ventricular filling, abnormal relaxation, hypertrophy, and/or left atrial enlargement with normal ejection fractions.¹⁹¹ Management is aimed at improving ventricular relaxation and prolonging diastolic filling times to reduce diastolic pressure. Physical training (aerobic and weight training) improves endurance and quality of life. Nitrates, beta-blockers, ACE inhibitors, ARBs, and aldosterone blockers have been used with varying success, however current guidelines focus on treating hypertension, ischemia or valvular disease.^{184,193} Outcomes for individuals with HFpEF can be as poor as those with systolic heart failure, and there has been little improvement in prognosis despite numerous new treatment trials.

TABLE 33.8

COMPARISON OF SYSTOLIC AND DIASTOLIC HEART FAILURE

CHARACTERISTIC	SYSTOLIC HEART FAILURE	DIASTOLIC HEART FAILURE
Gender	Male > female	Female > male
Left ventricular ejection fraction	Decreased	Normal
Left ventricular chamber size	Increased	Decreased
Left ventricular hypertrophy on electrocardiogram	Possible	Probable
Chest radiography	Pulmonary congestion with cardiomegaly	Pulmonary congestion without cardiomegaly
Gallop	S_3	S_4

Adapted from Jessup M, Brozena S: *N Engl J Med* 348(20):2007–2018, 2003.

Right Heart Failure

Right heart failure is defined as the inability of the right ventricle to provide adequate blood flow into the pulmonary circulation at a normal central venous pressure. It most often results from severe left heart failure when the increased left ventricular filling pressure is reflected back into the pulmonary circulation. As pressure in the pulmonary circulation rises, the resistance to right ventricular emptying increases. The right ventricle hypertrophies in response to this increased workload, however it undergoes progressive diastolic and systolic deterioration and will dilate and fail. When this happens, pressure will rise in the systemic venous circulation, resulting in jugular venous distention, peripheral edema, and hepatosplenomegaly. Treatment relies on management of the left ventricular dysfunction as just outlined. When right heart failure occurs in the absence of left heart failure, it is caused most commonly by pulmonary hypertension resulting from diffuse hypoxic pulmonary disease, such as chronic obstructive pulmonary disease (COPD) and cystic fibrosis, or from primary pulmonary arterial hypertension (Fig. 33.40). The mechanisms for this type of right ventricular dysfunction (*cor pulmonale*) are discussed in Chapter 36. Finally, right heart failure can result from right ventricular MI, cardiomyopathies, and pulmonic valvular disease. Management relies on treating the underlying condition, managing intravascular volume, and assisting right ventricular contractility.¹⁹⁴ Vasodilators may improve outcomes in primary pulmonary arterial hypertension (see Chapter 36).

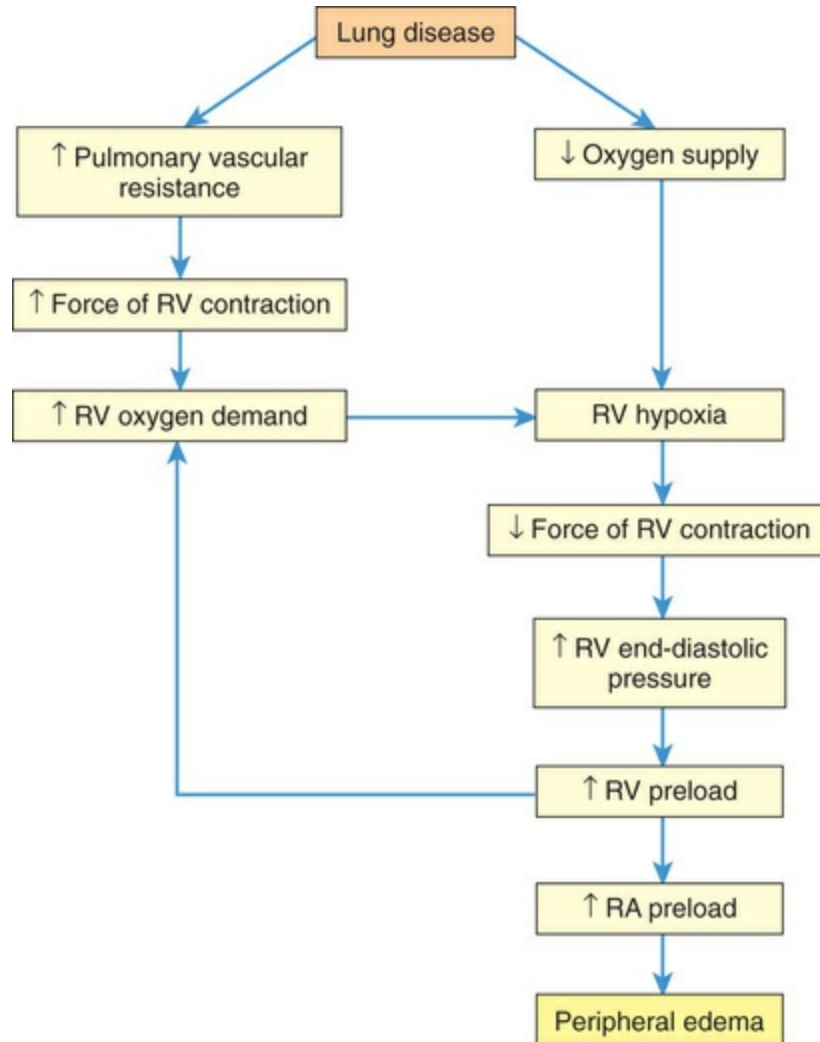

FIGURE 33.40 Right Heart Failure (Cor Pulmonale) Caused by Lung Disease. The presence of peripheral edema in cor pulmonale is caused by lung disease. RA, Right atrial; RV, right ventricular.

High-Output Failure

High-output failure is the inability of the heart to adequately supply the body with blood-borne nutrients, despite adequate blood volume and normal or elevated myocardial contractility. In high-output failure the heart increases its output but the body's metabolic needs are still not met. Common causes of high-output failure are anemia, septicemia, hyperthyroidism, and beriberi (Fig. 33.41).

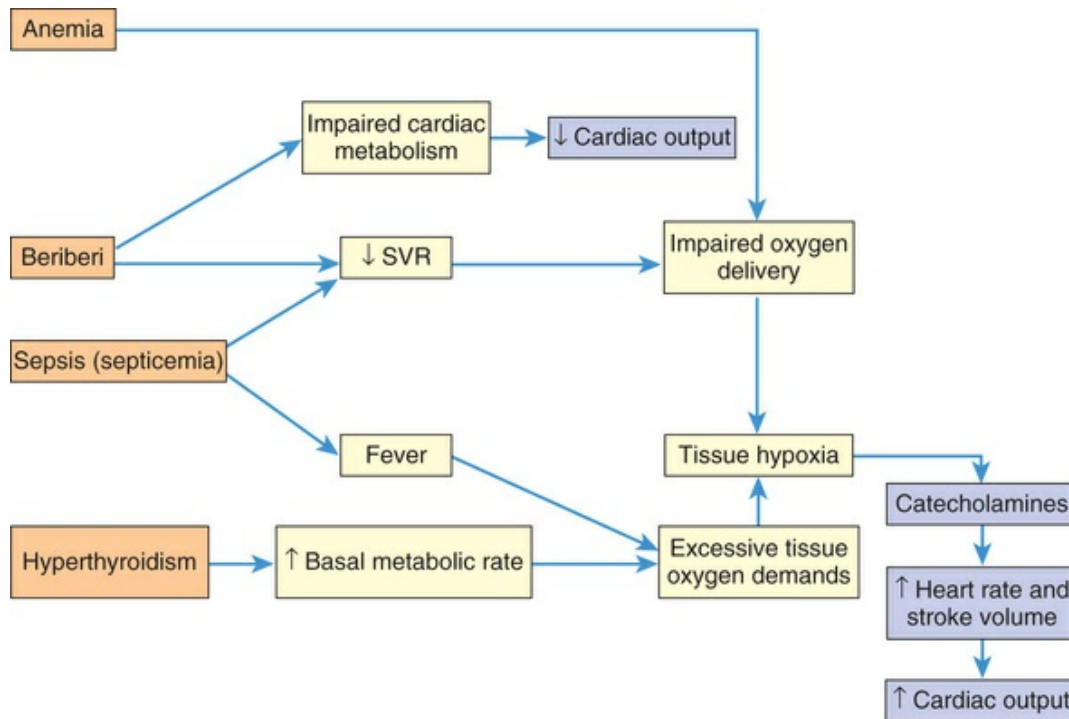

FIGURE 33.41 High-Output Failure. SVR, Systemic vascular resistance.

Anemia decreases the oxygen-carrying capacity of the blood (see [Chapter 29](#)). Metabolic acidosis occurs as the body's cells switch to anaerobic metabolism (see [Chapter 3](#)). In response to metabolic acidosis, heart rate and stroke volume increase in an attempt to circulate blood faster. If anemia is severe, however, even maximum cardiac output does not supply the cells with enough oxygen for metabolism.

In septicemia, disturbed metabolism, bacterial toxins, and the inflammatory process cause systemic vasodilation and fever. Faced with a lowered systemic vascular resistance (SVR) and an elevated metabolic rate, cardiac output increases to maintain blood pressure and prevent metabolic acidosis. In overwhelming septicemia, however, the heart may not be able to raise its output enough to compensate for vasodilation (septic shock). Body tissues show signs of inadequate blood supply despite a very high cardiac output.

Hyperthyroidism accelerates cellular metabolism through the actions of elevated levels of thyroxine from the thyroid gland. This may occur chronically (thyrotoxicosis) or acutely (thyroid storm). Because the body's increased demand for oxygen threatens to cause

metabolic acidosis, cardiac output increases. If blood levels of thyroxine are high and the metabolic response to thyroxine is vigorous, even an abnormally elevated cardiac output may be inadequate.¹⁹⁵

In the United States, beriberi (thiamine deficiency) usually is caused by malnutrition secondary to chronic alcoholism. Beriberi actually causes a mixed type of heart failure. Thiamine deficiency impairs cellular metabolism in all tissues, including the myocardium. In the heart, impaired cardiac metabolism leads to insufficient contractile strength. In blood vessels, thiamine deficiency leads mainly to peripheral vasodilation, which decreases SVR. Heart failure ensues as decreased SVR triggers increased cardiac output, which the impaired myocardium is unable to deliver. The strain of demands for increased output in the face of impaired metabolism may deplete cardiac reserves until low-output failure begins.

Dysrhythmias

A dysrhythmia, or arrhythmia, is a disturbance of heart rhythm. Normal heart rhythms are generated by the SA node and travel through the heart's conduction system, causing the atrial and ventricular myocardium to contract and relax at a regular rate that is appropriate to maintain circulation at various levels of physical activity (see [Chapter 32](#)). Dysrhythmias range in severity from occasional “missed” or rapid beats to serious disturbances that impair the pumping ability of the heart, contributing to heart failure and death. Dysrhythmias can be caused by either an abnormal rate of impulse generation ([Table 33.9](#)) by the SA node or other pacemaker, or by the abnormal conduction of impulses ([Table 33.10](#)) through the heart's conduction system, including the myocardial cells themselves. The pathophysiology, diagnosis, and treatment of dysrhythmias are highly complicated. Atrial fibrillation provides an example of the many factors that must be considered ([Box 33.4](#)).

TABLE 33.9

DISORDERS OF IMPULSE FORMATION

DISORDERS OF IMPULSE FORMATION

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY
Sinus bradycardia	P rate 60 or less PR interval normal QRS for each P	Increased preload Decreased mean arterial pressure	Hyperkalemia: slow depolarization Vagal hyperactivity unknown Digoxin toxicity common Late hypoxia: lack of adenosine triphosphate
Simple sinus tachycardia	P rate 100-150 PR interval normal QRS for each P	Decreased filling times Decreased mean arterial pressure Increased myocardial demand	Catecholamines; resting potential calcium influx Fever: unknown Early failure and disease: hypocalcemia Hypercalcemia
Premature atrial contractions (PACs) or beats*	Early P waves that may have changed morphology PR interval normal QRS for each P	Occasional decreased filling time and mean arterial pressure	Electrolyte disturbances: decrease in all phases Hypoxia and elevated preload: cell membrane disturbances Hypercalcemia
Sinus dysrhythmias	Rate varies P-P regularly irregular, short with inspiration, long with exhalation PR interval normal QRS for each P	Variable filling times Variable mean arterial pressures Variable oxygen demand	Unknown Common in young children and young adults
Atrial tachycardia (includes premature atrial tachycardia if onset is abrupt)	P rate 151-250; morphology may differ from sinus PR interval normal P:QRS ratio variable	Decreased filling time Decreased mean arterial pressure Increased myocardial demand	Same as PACs: lack of increased atrial automaticity, reentry Digoxin toxicity: common

		demand	
Atrial flutter*	P rate 251-300; morphology may vary from sinus P PR interval usually not observable P:QRS ratio variable	Decreased filling time Decreased mean arterial pressure	Same as atrial tachycardia Aging
Atrial fibrillation*	P rate >300 and usually not observable No PR interval QRS rate variable and rhythm irregular	Same as atrial flutter	Same as atrial tachycardia Aging
Idiojunctional rhythm	P absent or independent QRS normal, rate 41-59, regular	Decreased cardiac output from loss of atrial contribution to ventricular preload Decreased mean atrial pressure as a result of bradycardia	Atrial and sinus bradycardia, stand or block
Junctional bradycardia	P absent or independent QRS normal, rate 40 or less	Same as idiojunctional rhythm	Same as idiojunctional rhythm Vagal hyperactivity
Premature junctional contractions (PJCs) or beats	Early beats without P waves QRS morphology normal	Decreased cardiac output from loss of atrial contribution to ventricular preload for that beat	Hyperkalemia (6.5-8.0 mEq/L) Hypercalcemia, hypoxia, and elevated preload (see PACs)
Accelerated junctional rhythm	P absent or independent QRS morphology normal, rate 60-99	Decreased cardiac output from loss of atrial contribution to ventricular preload	Same as PJCs
Junctional tachycardia	P absent or independent QRS morphology normal, rate 100 or more	Decreased cardiac output from loss of atrial	Same as PJCs

		<p>contribution to ventricular preload</p> <p>Increased myocardial demand because of tachycardia</p>	
Idioventricular rhythm [†]	P absent or independent QRS >0.11 and rate 20-39	Same as idiojunctional rhythm	Sinus, atrial, and junctional bradycardia, standstill or block
Ventricular bradycardia [†]	P absent or independent QRS >0.11 and rate 60-21	Same as idiojunctional rhythm	Same as idiojunctional rhythm
Agonal rhythm/electromechanical dissociation [†]	P absent or independent QRS >0.11 and rate 20 or less	Absent or barely present cardiac output and pulse Not compatible with life	Depolarization and contraction not coupled: electrical activity present with little or no mechanical activity Usually caused by profound hypoxia
Ventricular standstill or asystole [†]	P absent or independent QRS absent	No cardiac output Not compatible with life	Profound ischemia, hyperkalemia, acidosis
Premature ventricular contractions (PVCs) or depolarizations [*]	Early beats with P waves QRS occasionally opposite in deflection from usual QRS	Same as PJs	Same as PJs, including agonal and induced by anesthesia Impulse originates in cell outside normal conduction system and spreads through intercalated disc
Accelerated ventricular rhythm	P absent or independent QRS >0.11 and rate 41-99	Same as accelerated junctional rhythm	Same as PVCs
Ventricular tachycardia [†]	P absent or independent QRS >0.11 and rate 100 or more	Same as junctional tachycardia	Same as PVCs
Ventricular fibrillation [†]	P absent	Same as ventricular	Same as PVCs

	QRS >300 and usually not observable	standstill	Rapid infusion of potassium
--	-------------------------------------	------------	-----------------------------

*Most common in adults.

†Life threatening in adults.

TABLE 33.10

DISORDERS OF IMPULSE CONDUCTION

TYPE	ELECTROCARDIOGRAM	EFFECT	PATHOPHYSIOLOGY	T
Sinus block	Occasionally absent P, with loss of QRS for that beat	Occasional decrease in cardiac output Increase in preload for the following beat	Local hypoxia, scarring of intraatrial conduction pathways, electrolyte imbalances Increased atrial preload	
First-degree block*	PR interval >0.2	None	Same as sinus block Hyperkalemia (>7 mEq/L) Hypokalemia (<3.5 mEq/L) Formation of myocardial abscesses in endocarditis	
Second-degree block, Mobitz I, or Wenckebach*	Progressive prolongation of PR interval until one QRS is dropped Pattern of prolongation resumes	Same as sinus block	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism in atrioventricular (AV) node Severity increases as heart rate increases Supports theory that AV node is fatiguing Digoxin toxicity, beta-blockade Coronary artery disease (CAD), myocardial	S

			infarction (MI), hypoxia, increased preload, valvular surgery and disease, diabetes
Second-degree block or Mobitz II	Same as sinus block	Same as sinus block	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism below AV node Antidysrhythmics, cyclic antidepressants CAD, MI, hypoxia, increased preload, valvular surgery and disease, diabetes
Third-degree block [†]	P waves present and independent of QRS No observed relationship between P and QRS Always AV dissociation	Same as idiojunctional rhythm	Hypokalemia (<3.5 mEq/L) Faulty cell metabolism low in bundle of His MI, especially inferior wall, as nodal artery interrupted; results in ischemia of AV node
Atrioventricular dissociation	P waves present and independent of QRS, but not always because of block (e.g., ventricular tachycardia) AV dissociation not always third-degree block	Decreased cardiac output from loss of atrial contribution to ventricular preload Variable effect on myocardial demand, depending on ventricular rate	May result from third-degree block or accelerated junctional or ventricular rhythm, or be caused by sinus, atrial, and junctional bradycardias
Ventricular block	QRS >0.11 R-S-R' in V ₁ , V ₂ , V ₅ , V ₆	None	Faulty cell metabolism in right and left bundle branches

			<p>RBBB more common than LBBB because of dual blood supply to left bundle branch</p> <p>Congestive heart failure, mitral regurgitation, especially anterior MI, because of infarct of fascicles</p> <p>Left anterior hemiblock more common than left posterior hemiblock, since posterior fascicles have dual blood supply</p>	
Aberrant conduction	QRS >0.11	None unless ventricular rate abnormalities present	Conduction of impulse through intercalated disks because conduction system transiently blocked because of hypoxia, electrolyte imbalances, digoxin toxicity, excessively rapid rates of discharge	C
Preexcitation syndromes (Wolff-Parkinson-White and Lown-Ganong-Levine)	<p>P present with QRS for each P</p> <p>PR interval >0.12 and QRS >0.11 because of presence of delta wave in PR interval</p>	None	<p>Congenital presence of accessory pathways (bundle of Kent and fiber of Mahaim) that conduct very rapidly and bypass the AV node, causing early ventricular depolarization in relation to atrial depolarization</p> <p>Prone (reason unknown) to tachycardias and atrial fibrillation that can result in</p>	

			very rapid ventricular rates
--	--	--	---------------------------------

*Most common in adults.

†Life threatening in adults.

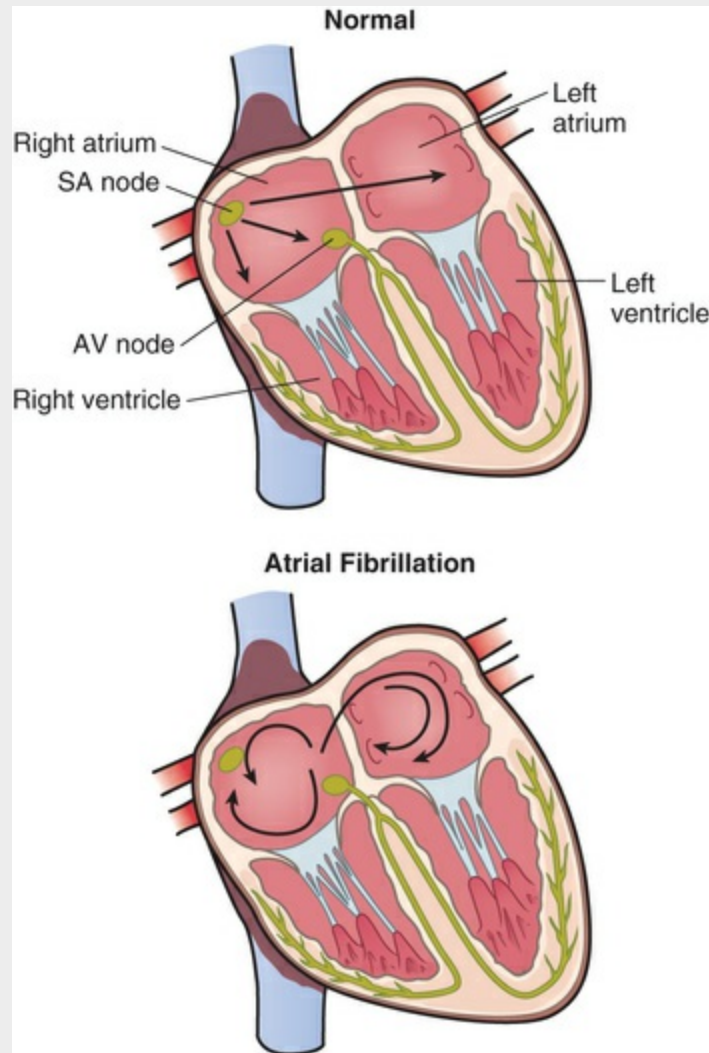

Box 33.4

Atrial Fibrillation

Atrial fibrillation (AF) is the most common cardiac rhythm disorder. It occurs when electrical impulses in the heart become disorganized leading to a rapid and irregular heart rhythm. People with AF have a four- to fivefold increased risk of stroke and a two- to threefold increased risk of heart failure.

Mechanisms

Efficient pumping of blood by the heart relies on the coordinated activity of the atria and ventricles, which involves contraction of cardiomyocytes in response to membrane depolarization. Electrical impulses begin in the sinoatrial (SA) node and first propagate through the atria, then pass through atrioventricular (AV) node (which delays their transit) and enter the ventricles, causing sequential cardiomyocyte contraction. In AF, the electrical activity in the atria is rapid and irregular. As a result, there is no coordinated atrial contraction and, depending on the filtering effect of the SA node, the response of the ventricles can also be rapid and irregular. Although several explanations have been put forward for this disordered atrial activity, AF fundamentally involves atrial remodeling that generates ectopic foci or ‘triggers’—additional sources of electrical impulses—and mechanisms that act to maintain inappropriate conduction within vulnerable ‘substrates’.

Diagnosis

Symptoms of AF include palpitations, fatigue, dizziness, lightheadedness and dyspnea. They are nonspecific and are often not present. Diagnosis of AF is made by first checking a patient's pulse and then confirming it with a 12-lead electrocardiogram (ECG), which detects the electrical activity of the heart through electrodes placed on the skin. In AF, the space between the activation of the ventricles (QRS complexes) is "irregularly irregular" and there is often an absence of coordinated atrial contractions (P waves) prior to ventricular contraction.

12-Lead Electrocardiogram (ECG). Because 12-lead ECG is not cost-effective on a large scale, future population screening for AF might involve oscillometry, smartphone cameras, or hand-held ECG rhythm strips.

Management

Treatment of AF involves strategies to achieve a normal heart rate, restore normal rhythm and reduce the risk of stroke, which is the most important priority for AF management. Rate-controlling drugs such as β -blockers usually act to modulate the activity of the SA and AV nodes. Rhythm control can be achieved either using antiarrhythmic drugs or the catheter-based introduction of lesions to ablate AF triggers and modify AF substrates. Finally, patients with AF commonly have comorbid conditions, the risk factors for which must also be appropriately addressed.

NOTE: Ineffective blood pumping raises the likelihood of coagulation and thrombosis. As a result, patients with AF have an increased risk of stroke and often require oral anticoagulant therapy.

Epidemiology

Globally, in 2010 an estimated 20.9 million men and 12.6 million

women had AF, and in developed countries AF is thought to be present in 3%-6% of those admitted to hospital with acute conditions. Risk factors for developing AF include conditions that have been found to promote atrial remodeling, such as heart failure, ischemic heart disease, hypertension, obesity, and obstructive sleep apnea. In addition, AF is associated with other classic cardiovascular disease risk factors such as diabetes, advanced age, male sex, alcohol consumption, and smoking. In developing countries, rheumatic heart disease often contributes to AF.

Outlook

Improved understanding of the mechanisms that trigger and maintain AF—such as changes in intracellular calcium ion handling, subtle alterations in atrial structure, and genetic factors—might lead to better strategies to prevent or treat the condition, whereas advances in catheter ablation will likely broaden the subset of patients who are eligible to undergo this procedure. In addition, although rates of stroke in patients in AF are declining owing to improved management, the identification of asymptomatic patients remains a challenge that might be addressed through new approaches to community-based screening.

Summary Review

Diseases of the Veins

1. Varicosities are areas of veins in which blood has pooled, usually in the saphenous veins. Varicosities may be caused by damaged valves as a result of trauma to the valve or by chronic venous distention involving gravity and venous constriction.
2. Chronic venous insufficiency is inadequate venous return over

- a long period that causes pathologic ischemic changes in the vasculature, skin, and supporting tissues.
3. Superior vena cava syndrome most often results from compression of the SVC by tumors.
 4. DVT occurs in individuals who have venous stasis (immobility, age, left heart failure), spinal cord injury, vein wall damage (trauma, intravenous medications), or hypercoagulable states (pregnancy, oral contraceptives, malignancy, genetic coagulopathies).
 5. DVT is often asymptomatic but may lead to fatal pulmonary emboli; prevention and careful assessment in individuals at risk are crucial.

Diseases of the Arteries

1. Hypertension is a sustained elevation of the systemic arterial blood pressure resulting from increases in cardiac output or total peripheral resistance, or both. Hypertension can be primary (without known cause) or secondary (caused by disease or drugs). Systolic hypertension is the most significant factor in causing target organ damage.
2. The risk factors for hypertension include a positive family history; male gender; advanced age; black race; obesity; high sodium intake; low potassium, calcium, and magnesium intake; diabetes mellitus; labile blood pressure; cigarette smoking; and heavy alcohol consumption.
3. Primary hypertension is the result of extremely complicated interactions of genetics and the environment mediated by a host of neurohumoral effects. These genes interact with diet, smoking, age, and the other risk factors to cause chronic changes in vasomotor tone and blood volume.
4. The most frequently cited theories of the pathogenesis of primary hypertension include overactivity of the SNS; overactivity of the RAAS; alterations in other neurohumoral mediators of blood volume and vasomotor tone such as ANP,

BNP, and adrenomedullin; inflammation; a complex interaction involving insulin resistance and endothelial function; and obesity-related hormonal changes.

5. Clinical manifestations of hypertension result from damage of organs and tissues outside the vascular system. These include heart disease, renal disease, CNS problems, and retinal changes.
6. Hypertension is managed pharmacologically, using diuretics, adrenergic blockers, calcium channel blockers, ACE inhibitors, and Ang II receptor blockers. Nonpharmacologic methods include cessation of smoking, dietary modifications, and exercise.
7. Orthostatic hypotension is a drop in blood pressure that occurs on standing. The compensatory vasoconstriction response to standing is altered by a marked vasodilation and blood pooling in the muscle vasculature.
8. Orthostatic hypotension may be primary or secondary. The primary form is caused by neurologic changes that affect the autonomic reflexes that control blood pressure upon standing.
9. The clinical manifestations of orthostatic hypotension include fainting and may result in falls and significant injury.
10. An aneurysm is a localized dilation of a vessel wall to which the aorta is particularly susceptible.
11. A thrombus is a clot that remains attached to a vascular wall.
12. An embolus is a mobile aggregate of a variety of substances that occludes the vasculature. Sources of emboli include thrombi, air, amniotic fluid, bacteria, fat, and foreign matter.
13. The most common sources of arterial thrombotic emboli from the heart are mitral and aortic valvular disease and atrial fibrillation. Tissues affected include the lower extremities, the brain, and the heart.
14. Emboli to the central organs cause tissue death in lungs, kidneys, and mesentery.
15. The generation of air emboli requires a connection between the vascular compartment and a source of air. These emboli cause

- ischemia and necrosis when a vessel is totally blocked.
16. Amniotic fluid may be forced into the bloodstream and generate an embolus during the labor and delivery of pregnancy.
 17. Aggregates of bacteria in the vasculature may be large enough to form an embolus.
 18. Fat emboli are caused mainly by trauma to the long bones, either through defective fat metabolism after trauma or through the release of fat globules from bone marrow exposed by fracture.
 19. The introduction of foreign matter into the vasculature can occur with trauma and also can occur in a hospital setting in which intravenous and intraarterial lines are being used.
 20. Vasospastic disorders include thromboangiitis obliterans and Raynaud disease, involving arterioles of the extremities.
 21. Atherosclerosis is a form of arteriosclerosis and is the leading cause of coronary artery and cerebrovascular disease.
 22. Atherosclerosis is an inflammatory disease that begins with endothelial injury and progresses through several stages to become a fibrotic plaque.
 23. Once a plaque has formed it can rupture, resulting in thrombosis and vasoconstriction that leads to obstruction of the lumen and inadequate perfusion of distal tissues.
 24. PAD is atherosclerosis of arteries that perfuse the limbs, especially the lower extremities.
 25. PAD is often asymptomatic but can present with intermittent claudication (pain in leg on walking). Treatment includes risk factor reduction and antiplatelet therapy.
 26. CAD is occlusion of the coronary arteries and is most often the result of atherosclerotic lesions that limit the flow of blood to the heart.
 27. Many risk factors contribute to the onset and escalation of CAD, including advanced age, gender, hypertension, dyslipidemia, diabetes mellitus, smoking, obesity, sedentary lifestyle, elevated hs-CRP, chronic kidney disease, and

environmental exposures, such as air pollution and ionizing radiation.

28. CAD results in an imbalance between coronary supply of blood and myocardial demand for oxygen and nutrients such that reversible myocardial ischemia or irreversible infarction may result.
29. Reversible myocardial ischemia presents clinically in several ways. Chronic coronary obstruction results in recurrent predictable chest pain called *stable angina*. Abnormal vasospasm of coronary vessels results in unpredictable chest pain called *Prinzmetal angina*. Myocardial ischemia that does not cause detectable symptoms is called *silent ischemia*.
30. Stable angina is evaluated by noninvasive techniques of assessing coronary flow with or without exercise (stress ECG, thallium, or SPECT). Management may include lifestyle changes, vasodilators, antithrombotics, PCI, or CABG surgery.
31. When there is sudden coronary obstruction because of thrombosis formation over a ruptured atherosclerotic plaque, the acute coronary syndromes result. Unstable angina causes reversible myocardial ischemia and is a harbinger of impending infarction. MI results when prolonged ischemia causes irreversible damage to the heart muscle. Sudden cardiac death can occur in any of the acute coronary syndromes.
32. Unstable angina occurs because of transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage, with return of perfusion before significant myocardial necrosis occurs. This must be managed aggressively with antithrombotic agents to prevent MI.
33. When coronary blood flow is interrupted for an extended period, myocyte necrosis occurs; this is called *MI*. Pathologically, there are two major types of myocardial infarction: subendocardial infarction and transmural infarction. In addition to myocyte necrosis, other changes in the heart with MI include hibernating, stunning, and

remodeling of the myocardium.

34. Acute coronary syndromes are assessed by measuring serum enzymes, such as troponins, as well as looking for characteristic changes in the ECG. Those individuals at highest risk for complications present with ST-segment elevations on the ECG (STEMI) and require immediate intervention. Smaller subendocardial infarctions are not associated with ST-segment elevations (non-STEMI) but suggest that additional myocardium is still at risk for recurrent ischemia and infarction. Management may include thrombolytic drugs, antithrombotic drugs, vasodilators, PCI, or immediate surgery.
35. Dysrhythmias, congestive heart failure, and sudden death are the most common complications of the acute coronary syndromes.

Disorders of the Heart Wall

1. Inflammation of the pericardium (pericarditis) may result from innumerable sources (infection, drug therapy, tumors). Pericarditis presents with symptoms that are physically troublesome, but in and of themselves they are not life threatening.
2. Fluid may collect within the pericardial sac (pericardial effusion). Cardiac function may be severely impaired if a large volume of fluid accumulates rapidly.
3. Cardiomyopathies are a diverse group of primary myocardial disorders that are poorly understood. The cardiomyopathies are categorized as dilated (congestive), restrictive (rigid and noncompliant), and hypertrophic (asymmetrical).
4. Hemodynamic integrity of the cardiovascular system depends to a great extent on properly functioning cardiac valves. Congenital or acquired disorders that structurally alter the valves result in stenosis or regurgitation, or both.
5. Characteristic heart sounds, cardiac murmurs, and systemic

complaints assist in determining which valve is abnormal. If severely compromised function exists, a prosthetic heart valve may be surgically implanted to replace the faulty one.

6. Mitral valve prolapse is a common finding, especially in young women. Although not grossly abnormal, the mitral valve leaflets do not position themselves properly during systole. Mitral valve prolapse may be a completely asymptomatic condition or may progress to mitral regurgitation.
7. Rheumatic fever is an inflammatory disease that results from a delayed autoimmune response to a streptococcal infection. The disorder usually resolves without sequelae if treated early.
8. Untreated cases of rheumatic fever may progress to rheumatic heart disease, a potentially disabling cardiovascular disorder primarily affecting the heart valves.
9. Infective endocarditis is a general term for infection and inflammation of the endocardium, especially the cardiac valves. A wide range of conditions predisposes one to the development of this disorder. If infective endocarditis is left unchecked, severe valve abnormalities, chronic bacteremia, and systemic emboli may occur as vegetations break off the valve surface and travel through the bloodstream. Antibiotic therapy is essential to prevent serious complications.

Manifestations of Heart Disease

1. Heart failure is an inability of the heart to supply the metabolism with adequate circulatory volume and pressure.
2. Left heart failure can be categorized as heart failure with reduced ejection fraction (systolic) or heart failure with preserved ejection fraction (diastolic).
3. Heart failure with reduced ejection fraction is defined as an inability of the heart to generate an adequate cardiac output to perfuse vital tissue.
4. Cardiac output depends on the heart rate and stroke volume. Stroke volume is influenced by contractility, preload, and

afterload. MI is the most common cause of decreased contractility. Myocardial ischemia results in ventricular remodeling that causes progressive myocyte contractile dysfunction over time.

5. Preload LVEDV is increased when there is decreased contractility or excess plasma volume.
6. Increased afterload is most commonly the result of increased peripheral vascular resistance. This increase in resistance decreases ventricular emptying and makes more workload for the left ventricle, resulting in hypertrophy and ventricular remodeling. The vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening.
7. Neurohumoral mechanisms of congestive heart failure (CHF) include abnormalities in the SNS, RAAS, arginine vasopressin, natriuretic peptides, inflammatory cytokines, and myocyte metabolism.
8. The clinical manifestations of left heart failure are the result of pulmonary vascular congestion and inadequate systemic perfusion.
9. Management of left heart failure relies on increasing contractility and reducing preload and afterload.
10. Heart failure with preserved ejection fraction can occur singly or with systolic heart failure. The major causes of diastolic dysfunction include hypertension-induced myocardial hypertrophy and ischemia with resultant ventricular remodeling.
11. Right heart failure can result from left heart failure and/or diffuse hypoxic pulmonary disease, such as COPD, cystic fibrosis, and ARDS.
12. High output failure is the inability of the heart to adequately supply the body with blood-borne nutrients despite adequate volume and normal or elevated myocardial contractility. Common causes are anemia, septicemia, hyperthyroidism, and beriberi.

13. A dysrhythmia (arrhythmia) is a disturbance of heart rhythm. Dysrhythmias range in severity from occasional missed beats or rapid beats to disturbances that impair myocardial contractility and are life threatening.
14. Dysrhythmias can occur because of an abnormal rate of impulse generation or the abnormal conduction of impulses.

Cardiovascular disease in children can be classified as congenital or acquired heart disease. Congenital heart disease is the most common. The diagnosis and management of congenital heart defects continue to improve with the use of fetal echocardiography, early interventional catheterization, and refined surgical repair or palliation. Acquired heart disease in children continues to present challenges to the practitioner; guidelines for diagnosis are available; standards of treatment and long-term follow-up are in progress.

Development of The Cardiovascular System

Developmental Anatomy

Embryology

Cardiogenesis begins at approximately 3 weeks' gestation; however, most cardiovascular development occurs between the fourth and seventh weeks.¹ The heart arises from the mesenchyme and begins development as an enlarged blood vessel with a large lumen and a muscular wall (Fig. 34.1, A). Initially, two lateral endocardial heart tubes fuse to form a single structure (see Fig. 34.1, B). During the fifth week of gestation, the midsection of this tube begins to grow faster than its ends. This single heart tube elongates and rotates to the right (D-loop formation), creating a bulboventricular loop by approximately the 28th day¹ (see Fig. 34.1, C). Also at this time the first fetal heart contractions occur. At this stage the primitive heart structures include a common atrium; a common ventricle; the sinus venosus, which eventually evolves into the superior and inferior venae cavae; the bulbus cordis, which eventually evolves into the ventricular outflow tracts; and the truncus arteriosus, which eventually yields the main pulmonary artery (PA) and aorta (see Fig. 34.1, D). By the fourth week of gestation, cardiovascular septation, ventricular development, aortic arch evolution, and circulation begin.

FIGURE 34.1 Embryologic Development of the Heart. A, The earliest heart structure consists of a muscular tube with a large lumen. About the fifth week of gestation, the tube, B, bulges and, C, twists until, D, the ends come together and fuse.

Cardiac Septation

Separation first begins when collections of mesenchymal cells cause the endocardial lining of the heart to bulge into the internal lumen. These changes, known as **endocardial cushions**, are instrumental in closing the lower portion of the atrial septum, dividing the atrioventricular (AV) canals into the right and left AV orifices and forming the upper portion of the interventricular septum. Altered formation of the endocardial cushions can result in atrial septal defects (ASDs), inlet ventricular septal defects (VSDs), malformation of the AV valves, or a complete AV defect (also known as *atrioventricular septal defect*).²

Atrial septation begins when two thin membrane-like structures, known as the **septum primum** and the **septum secundum**, grow toward the area of the endocardial cushions (Fig. 34.2). The septum primum forms along the posterior wall of the common atrium and grows downward toward the center portion of the heart. The gap between the two structures, known as the **ostium primum**, normally closes by extensions from the endocardial cushions. At the time of closure, fenestrations or openings develop in the superior portion of the septum primum, creating the **ostium secundum**. Failure of the septum primum to fuse with the endocardial cushions results in an ostium primum defect in the atrial septum near the AV valve area.

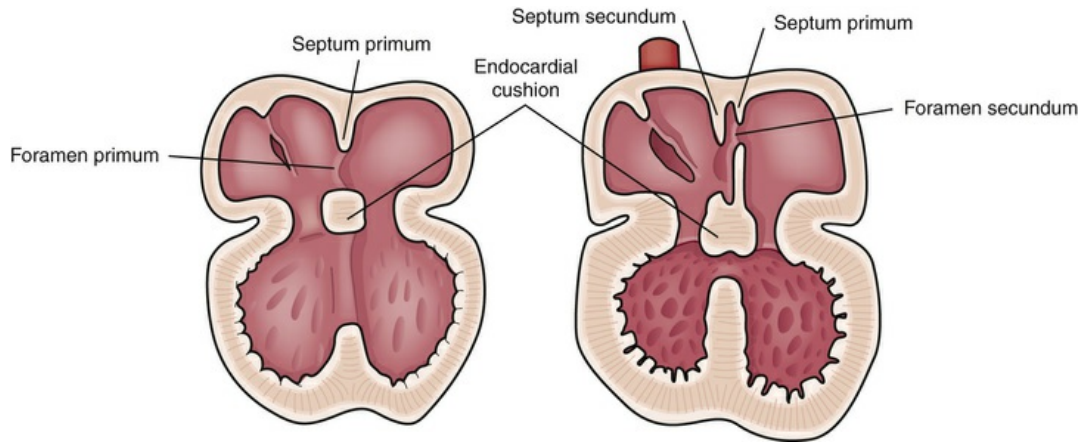

FIGURE 34.2 Development of the Cardiac Septa.

The septum secundum is also a fenestrated, membrane-like structure located anteriorly that grows toward the endocardial cushions. During fetal development this structure does not completely fuse with the endocardial cushions to achieve complete atrial septal closure. The nonfused septum secundum and ostium secundum result in the formation of a flapped orifice known as the *foramen ovale*, which allows the right-to-left shunting necessary for fetal circulation. Altered development in any of these structures can lead to an ASD.

Ventricular septation develops when the muscular ridge located at the apex, endocardial tissue, and the bulbar ridges in the bulbus cordis fuse together (Fig. 34.3). Closure of the interventricular septum ensures communication between the right ventricle (RV) and the PA and between the left ventricle (LV) and the aorta. Further evolution of the endocardial tissue gives rise to the membranous ventricular septum and the AV valves. The conal portion of the ventricular septum that separates the aorta from the PA forms from the **bulbus cordis**.

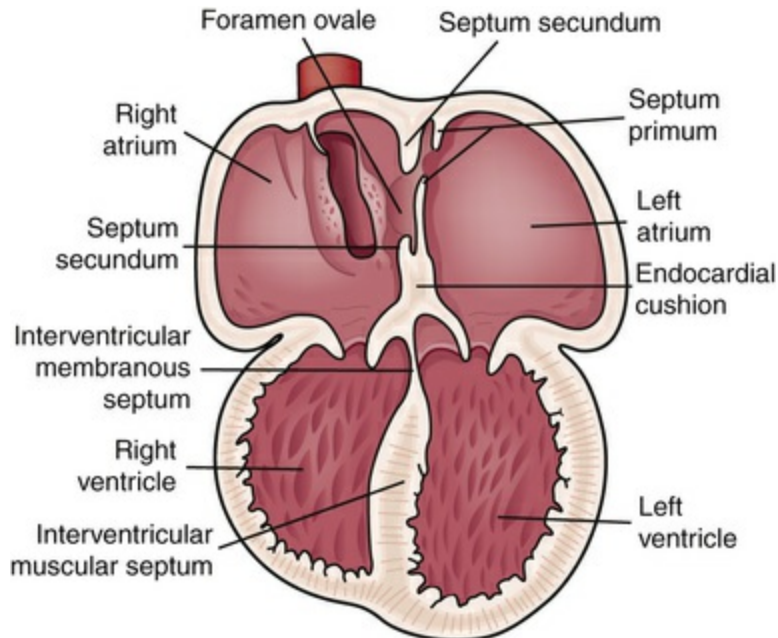

FIGURE 34.3 Septal Development of the Heart.

When the single primitive heart tube begins to form the D-loop, the venous and arterial poles of the heart are fixed, resulting in torsion within the anterosuperior region of the loop, known as the *truncus arteriosus*. This torsion creates a spiral ridgelike structure or septum within the truncus arteriosus that divides it into the PA and the aorta. The semilunar valves evolve from tubercles after this division is complete.

Before this division occurs, however, two large arteries form at the distal end of the truncus arteriosus. Over time they give rise to a series of arterial vessels, collectively called the *six aortic arches*. By the fifth week of gestation, the first two pairs disappear and the third eventually evolves into the common carotid artery, the external carotid artery, and part of the internal carotid artery. The fourth pair of aortic arches will form part of the true aortic arch and the proximal segment of the right subclavian artery. The fifth pair disappears; however, the sixth pair yields the proximal and branch pulmonary arteries within the lung parenchyma and the ductus arteriosus.

Swellings in the conal region at the base of the main trunk separate the right ventricular outflow (pulmonary outflow) tract from the left ventricular outflow (aortic outflow) tract. The conus also contributes

to complete closure of the interventricular septum, and normal reabsorption of the subaortic conal region ensures rotation of the great arteries so that the aorta is positioned posterior and to the right of the PA. Despite division of the truncus arteriosus and separation of the right and left outflow tracts, a communication exists between the aorta and the PA known as the *ductus arteriosus*.

Fetal Circulation

In order to deliver maximally oxygenated blood to the developing brain, fetal circulation differs from the adult pattern by the presence of alternate pathways known as *fetal shunts* (Fig. 34.4). Fetal shunts include the foramen ovale, ductus arteriosus, and ductus venosus. Fetal oxygenation occurs in the placenta instead of the fetal lungs. Therefore fetal lungs are not aerated despite the fetus making breathing motions.

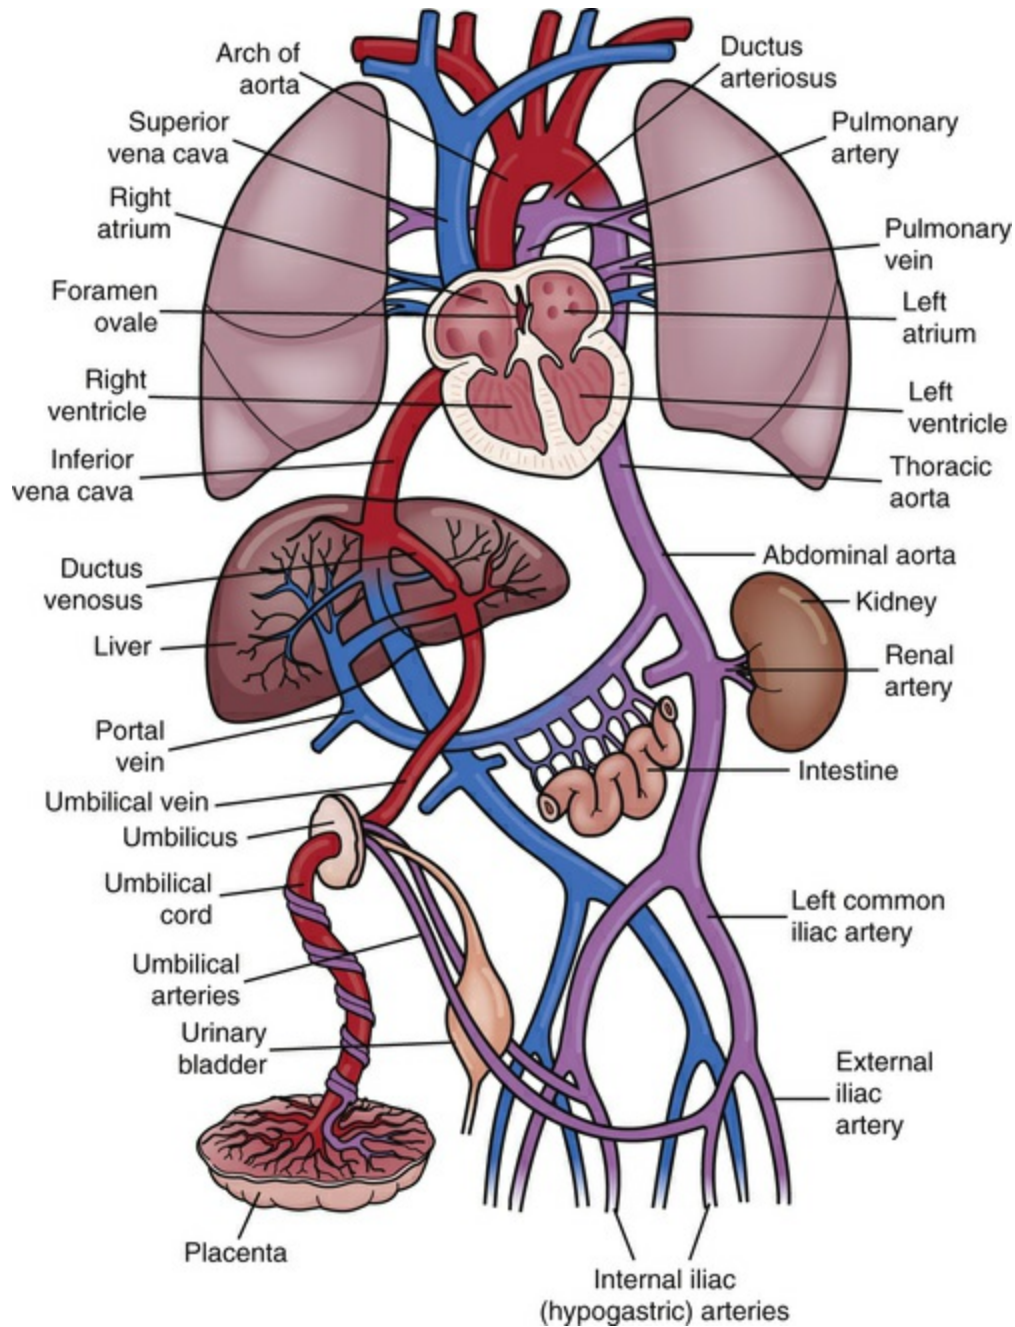

FIGURE 34.4 Fetal Circulation. Circulation of the fetus reflects the fact that oxygenation of fetal blood does not take place in the lungs, but rather in the placenta. Therefore the pulmonary circulatory system is essentially “bypassed.” Instead of traveling from the right heart to the lungs, as occurs after birth, the majority of blood entering the right heart is shunted into systemic circulation through the ductus arteriosus.

In utero the fetus receives oxygenated blood and nutrients from the placenta through the umbilical vein. The blood travels to the liver, where a portion enters the portal and hepatic circulation;

approximately half the flow is diverted away from the liver through the **ductus venosus** and into the inferior vena cava. Because the blood received from the inferior vena cava yields a higher pressure, blood entering the right atrium (RA) from the inferior vena cava is shunted through the **foramen ovale** and into the left atrium (LA) and is then pumped through the LV and into the aorta. Approximately two-thirds of the blood flows to the head and upper extremities. The brain and coronary arteries receive the blood with the highest oxygen concentration, and the remaining blood flows into the descending aorta to perfuse distal organs.

Less-saturated blood, with an oxygen tension of 15 to 19 torr, returns from the upper body, head, neck, and arms and travels from the superior vena cava into the RA. A small portion of this blood flows into the RV and out the PA, entering the nonfunctioning lungs. Most of the blood, however, bypasses the lungs by flowing through the **ductus arteriosus** and into the descending aorta. Blood from the descending aorta returns to the placenta through two umbilical arteries.¹

The nonaerated lungs and low oxygen tension induce vasoconstriction, creating high pulmonary vascular resistance (PVR). This is transmitted to the right side of the heart and the PAs. Conversely, fetal systemic resistance is low because of the large-volume placenta and ductus arteriosus. Therefore, because blood flow follows the path of least resistance, high PVR diverts most of the blood flow into the PA, through the ductus arteriosus, and into the aorta. From there it perfuses distal organs before traveling into the low-resistance placenta. Of clinical note, prenatal ultrasounds performed at 18 to 20 weeks' gestation can reveal up to 50% of all complex congenital heart disease with rates varying depending on provider training³ ([What's New? Fetal Intervention for Complex Congenital Heart Disease](#)).

What's New?

Fetal Intervention for Complex Congenital Heart

Disease

It is now possible to diagnose many types of CHD prenatally (as early as 16 to 18 weeks' gestation) through the use of fetal echocardiography. Fetal cardiac dysrhythmias are commonly treated by medication administration to the mother; the drugs are then transferred to the fetus through the placenta. Some types of CHD can progress in severity during fetal development—for example, severe aortic valve stenosis can sometimes progress to hypoplastic left heart syndrome (HLHS), because of reduced blood flow through the left ventricle. In some large centers, fetal balloon aortic valvuloplasty is available for some types of aortic valve stenosis. In this procedure, the apex of the fetal left ventricle is punctured with a needle placed through the mother's abdominal wall. A catheter can then be placed through the fetal aortic valve and a balloon inflated to dilate the valve. In HLHS, some fetuses have an intact or restrictive atrial septum, which can cause fetal lung damage or early death postnatally because of obstructed pulmonary venous return. Fetal intervention for intact atrial septum in HLHS involves direct puncture of the fetal heart through the mother's abdominal wall, and a catheter is then placed across the atrial septum to perform a balloon atrial septostomy. The intent of these procedures is to improve postnatal hemodynamic stability and potentially to allow a two-ventricle repair, rather than a single-ventricle treatment pathway. Although fetal intervention for severe CHD is in early stages of development, the potential to reduce CHD morbidity and mortality is great.

Data from Moon-Grady AJ, et al: *J Am Coll Cardiol* 66(4):388-399, 2015.

Transitional Circulation and Closure of Fetal Shunts

At birth a series of circulatory changes occur that affect blood flow, vascular resistance, and oxygen tension. The most important change

that takes place in the circulation is the shift of gas exchange from the placenta to the lungs. In addition, alterations in pressure and volume of blood flowing through the heart chambers functionally close the ductus arteriosus, ductus venosus, and foramen ovale. A decrease of PVR and an increase of systemic vascular resistance (SVR) lead to changes in the size and shape of the heart chambers.

Clamping of the umbilical cord and expansion of the lungs at birth shift gas exchange from the placenta to the lungs. Removal of the low-resistance placenta from circulation also causes an immediate increase in SVR to about twice that before birth. Conversely, PVR decreases because of expansion of the lungs, which result from the infant's respirations and exposure to more oxygen-rich blood.

Once the umbilical cord is clamped, the umbilical arteries and vein, which comprise the cord, vasoconstrict and undergo fibrous changes. Therefore blood flow through the ductus venosus falls instantly; absence of fetal shunting through this vessel usually occurs within the first 7 days of life. Once the ductus venosus closes, its remnants form the **ligamentum venosum**, or round ligament of the liver.

Increased pulmonary venous return and decreased inferior vena cava return cause functional closure of the foramen ovale within the first month of life. In the fetus the foramen ovale is held open by the blood flow from the higher-pressure right side, reflecting the increased PVR, to the lower-pressure area on the left side of the heart, reflecting the decreased SVR. At birth the pressure gradients reverse (left atrial pressure exceeds right atrial pressure by a small degree), causing the valve flaps of the foramen ovale to close. Functional closure occurs by the adherence of these flaps to the atrial septum. Anatomic closure occurs within the first month of life after deposition of fibrin tissue and cell products permanently seals the flaps closed. Until this occurs, any condition that stimulates an increase in the right-sided pressures or causes dilation of the RA can reopen the foramen ovale. Conditions in which a patent foramen ovale (PFO) may continue past the first month of life include pulmonary hypertension, RV failure, and tricuspid atresia.

The ductus arteriosus closes more gradually. Increased oxygen

saturation in the systemic arterial blood is thought to be the major stimulus causing vasoconstriction of the ductus arteriosus. In addition, a decrease in the amount of endogenous prostaglandins promoting dilation and the release of vasoactive substances stimulate further ductal closure. Vasoconstriction of the ductal medial smooth muscle shortens and thickens the intima of the ductal wall within 15 hours after birth. Permanent closure is complete several weeks after birth. Fibrous tissue adheres to the remaining structure, and the ductus arteriosus eventually evolves into the ligamentum arteriosum. Conditions that involve low arterial oxygen saturations, such as cyanotic heart disease, decreased medial muscle layer within the ductus, or increased levels of circulating vasodilating substances in the blood, may delay or prevent ductal closure.⁴

Postnatal Development

Compared to the adult, the infant's cardiopulmonary system is proportionally larger in relation to body surface area. The infant's heart points at a transverse angle, but as the lungs and heart mature, the heart shifts lower in the chest and is rotated at a more oblique angle. Unlike the adult heart, the newborn heart has RV dominance with a thickened RV wall. This is because of the high PVR during fetal circulation that exposed the RV to a high afterload, which in turn causes the right ventricular myocardial mass to become similar to the adult LV myocardium.

After birth the RV myocardium becomes less dominant as PVR drops. As SVR increases, the LV myocardium becomes thicker. By 1 month of age, the newborn's ventricles are approximately equal in weight. As the child grows, the heart size increases accordingly. The weight of the heart doubles during the first year of life and increases to six times that by 9 years of age.⁴

Postnatal changes involve a rise in arterial oxygen tension and an increase in alveolar oxygenation that stimulates vasodilation, resulting in a decrease in PVR. During the first 2 to 9 weeks of life, the inner medial linings of the small pulmonary arterioles become thinner in response to decreased pulmonary arterial pressure. This increased

diameter of the pulmonary vessels, along with further development of the pulmonary bed in response to lung growth, results in a decrease in PVR. By 2 months of age, pulmonary resistance may approximate adult levels. During the neonatal period the pulmonary vascular bed remains hyperactive. Adverse conditions, such as alveolar hypoxia, acidosis, and hypothermia, may trigger pulmonary vasoconstriction and lead to pulmonary hypertension.

Postnatal Hemodynamics

As stated, SVR begins to rise once the placenta is removed from the circulation. Normal levels in the infant range from approximately 10 to 15 Wood units \times body surface area (in square meters) and gradually increase to 15 to 30 Wood units \times body surface area (in square meters) by childhood.⁵ Likewise, the systolic pressure is low in the full-term newborn (approximately 39 to 59 mmHg), reflecting the low SVR. As the SVR increases, the LV becomes more developed and the systolic pressure rises steadily until it equals adult levels once the child reaches puberty.

The heart rate of the newborn ranges from 100 to 180 beats per minute, which gradually decreases as the child grows. Similarly, the newborn's cardiac output is high, which is a reflection of the fetal circulation described earlier. Oxygen consumption doubles at birth; to maintain adequate oxygen delivery, the cardiac output also remains high. These changes, however, cause minimal cardiac reserve in the newborn. Additional stressors could increase oxygen demands and result in acute deterioration. For example, stroke volume is fixed because of a decreased myocardial compliance; however, bradycardia may result in severely decreased cardiac output.² As the newborn grows, stroke volume steadily increases while the heart rate decreases, thus maintaining cardiac output.² By 2 months of age, oxygen consumption decreases by half.

Postnatal Circulation

Postnatal circulation allows the lungs to oxygenate the venous blood

and allows fully saturated blood to be delivered to the systemic circulation. Desaturated blood returning from the superior vena cava, inferior vena cava, and coronary veins enters the RA and is pumped to the RV through the tricuspid valve. The RV then pumps the blood through the pulmonic valve to the PA; the blood flows to the lungs, where it is oxygenated. The oxygenated blood returns from the lungs through the pulmonary veins and enters the LA, which pumps blood to the LV through the mitral valve. The LV then pumps blood through the aortic valve and into the aorta. The coronary arteries receive the saturated blood along with delivery to the systemic circulation.

Congenital Heart Defects

Congenital heart disease (CHD) is the leading cause of death, excluding prematurity, during the first year of life³ (Box 34.1). There are more than 35 documented types of congenital heart defects, and the frequency of occurrence in the United States continues to rise. Although researchers have not determined the reason for this increase, one explanation is that it may be the result of improved methods for early detection ([What's New? Screening for Critical Congenital Heart Disease](#)).

Box 34.1

Endocarditis Risk

Children with congenital heart disease are at risk for developing endocarditis. Although the risk is low, a transient bacteremia has been noted to follow dental and surgical procedures and instrumentation involving mucosal surfaces. A blood-borne pathogen can inhabit areas of the heart where there is high turbulence (such as an abnormal valve or vessel) or reside on artificial material (such as a valve or homograft). *Streptococcus viridans* (α -hemolytic streptococci) is the most commonly found pathogen following dental or oral procedures. *Enterococcus faecalis*

(enterococci) is the most common bacterium found following genitourinary and gastrointestinal tract surgery or instrumentation. The American Heart Association has provided updated guidelines for the prevention of bacterial endocarditis. The type and dose of antibiotic prophylaxis recommended depend on the procedure and the cardiac classification of risk for endocarditis. Good dental hygiene with daily brushing and flossing is critically important along with regular dental check-ups.

Data from the American Heart Association. Available at: www.americanheart.org.

What's New?

Screening for Critical Congenital Heart Disease

Some newborn infants with severe congenital heart disease (CHD) may appear to be physically normal, without cyanosis or a significant heart murmur, but may become critically ill or even die when fetal shunts close, usually after discharge home. In 2011, the U.S. Department of Health and Human Services added pulse oximetry screening for critical congenital heart disease (CCHD) to the *Recommended Uniform Screening Panel* for all newborn infants. The requirement is a pulse oximeter recording from the right hand (preductal) and one foot (postductal) 24 hours after birth or prior to hospital discharge. A pulse oximeter reading less than 95% in either site or more than 3% difference between hand and foot means a positive (or failed) screen. If failed, the screen is repeated and if failed again, the infant should be evaluated and undergo a diagnostic echocardiogram prior to discharge. As of 2015, 43 states had enacted legislation, regulations, or hospital guidelines for CCHD screening. Studies are underway to evaluate the effect of this screening on CHD morbidity and mortality.

Data from Glidewell J, et al: *MMWR Morb Mortal Wkly Rep* 64(23):625-630, 2015.

The underlying cause of CHD is known in only 10% of cases. Several factors place the fetus at risk for developing CHD, including prenatal, environmental, and genetic factors. Among the prenatal factors are maternal rubella, maternal insulin-dependent diabetes, maternal lupus, maternal alcohol or illicit drug use, maternal age (older than 40 years), maternal phenylketonuria, and maternal hypercalcemia (Table 34.1). The use of some drugs during pregnancy is associated with an above-average incidence of CHD. Examples of these drug teratogens include anticonvulsants, angiotensin-converting enzyme (ACE) inhibitors, lithium, retinoic acid, and warfarin. The incidence of heart defects also has been found to be higher in stillbirths, spontaneous abortions, and low-birth-weight or small-for-gestational-age infants.² In general, the likelihood of unaffected parents having a child with CHD is about 1%. The risk of recurrence in a sibling is approximately 3%; however this may vary depending on the type of CHD (e.g., the risk may be up to 10% with hypoplastic left heart syndrome).²

TABLE 34.1

ENVIRONMENTAL FACTORS ASSOCIATED WITH HEART DISEASE

CAUSE	TYPE OF CONGENITAL HEART DEFECT
Infection	
Intrauterine	Patent ductus arteriosus (PDA), pulmonary stenosis (PS), coarctation of aorta (COA)
Systemic viral	PDA, PS, COA
Rubella	PDA, PS, COA
Coxsackie B5	Endocardial fibroelastosis
Herpesvirus Cytomegalovirus (HCMV)	Can infect endothelial cells and vascular endothelium
Radiation	Studies of cancer survivors reveal radiation can cause atherosclerosis; myocardial, endocardial, and pericardial disease; conduction disturbances; and endothelial vessel disease
Metabolic Disorders	
Diabetes	Ventricular septal defect (VSD), ventricular hypertrophy, cardiomegaly,

	transposition of the great vessels
Phenylketonuria (PKU)	COA, PDA
Hypercalcemia	Supravalvular aortic stenosis, PS; aortic hyperplasia
Drugs	
Alcohol	Tetralogy of Fallot (TOF), atrial septal defect (ASD), VSD
Lithium	Exact effect not known
Phenytoin	Embryonic dysrhythmia and valvular heart disease
Warfarin	ASD and PDA
Peripheral Conditions	
Increased maternal age	VSD, TOF (relationship unclear)
Antepartal bleeding	Various defects (relationship unclear)
Prematurity	PDA, VSD
High altitude	PDA, ASD (increased incidence)

Genetic factors also have been implicated in the development of CHD, although the mechanism of causation is often multifactorial. Recent progress, accelerated through the Human Genome Project, has resulted in the rapid identification of many genes causing CHD.³

◆ Etiology.

The etiology of most CHD is unknown. Early epidemiologic studies report a multifactorial influence to be the cause of up to 90% of cardiac anomalies.² Associated risk factors include maternal, gestational, and familial conditions. (Maternal risk factors are discussed in the previous section.) Exposure to teratogens in utero also may be a risk factor. Likewise, fetal exposure to active maternal infections, such as rubella, herpesvirus, coxsackievirus B5, and cytomegalovirus, may be a risk.

Chromosomal aberrations account for about 6% of all CHD (Table 34.2). Many genetic and hereditary diseases are associated with CHD, although the mechanism of causation is unknown (Table 34.3). As many as 50% of infants with trisomy 21 have a CHD, usually either an AV canal defect or a VSD. Noncardiac defects are noted in as many as 35% of infants with cardiac lesions. Prospective studies using chromosomal analysis have suggested that congenital cardiac malformations may be the result of a single gene defect.³

TABLE 34.2**CONGENITAL HEART DISEASE IN SELECTED FETAL CHROMOSOMAL ABERRATIONS**

CONDITIONS	INCIDENCE OF CHD (%)	COMMON DEFECTS (IN DECREASING ORDER OF FREQUENCY)
5p (cri du chat syndrome)	25	VSD, PDA, ASD
Trisomy 13 syndrome	90	VSD, PDA, dextrocardia
Trisomy 18 syndrome	99	VSD, PDA, PS
Trisomy 21 (Down syndrome)	50	AVSD, VSD
Turner syndrome (XO)	35	COA, AS, ASD
Klinefelter variant (XXXXY)	15	PDA, ASD

AS, Aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; COA, coarctation of the aorta; PDA, patent ductus arteriosus; PS, pulmonary stenosis; VSD, ventricular septal defect.

TABLE 34.3**DISORDERS COEXISTENT WITH CONGENITAL OR ACQUIRED HEART DISEASE**

DISORDER	ASSOCIATED CARDIOVASCULAR DEFECT
Connective Tissue Disorders	
Marfan syndrome	Aortic or mitral regurgitation, aortic aneurysm
Hurler syndrome (mucopolysaccharidosis type I)	Aortic or mitral regurgitation, pseudoatherosclerosis
Hunter syndrome (mucopolysaccharidosis type II)	Aortic or mitral regurgitation, pseudoatherosclerosis
Osteogenesis imperfecta	Incompetent aortic valve
Complex Syndromes	
Alagille syndrome	Peripheral pulmonary artery stenosis, complex cardiac defects

CHARGE syndrome	Tetralogy of Fallot (TOF), truncus arteriosus, interrupted aortic arch (IAA), vascular ring
DiGeorge syndrome	TOF, IAA, truncus arteriosus
Ellis-von Creveld syndrome	Defect or absence of atrial septum
Goldenhar syndrome	Ventricular septal defect (VSD), TOF
Holt-Oram syndrome	Atrial septal defect (ASD), VSD
Kartagener syndrome	Dextrocardia
Pierre Robin	VSD, patent ductus arteriosus (PDA)
Thrombocytopenia Absent Radius (TAR) syndrome	TOF, ASD, dextrocardia
Tuberous sclerosis	Cardiac rhabdomyoma
VATER syndrome	VSD, other defects
Velocardiofacial syndrome (VCFS)	TOF, truncus arteriosus, pulmonary atresia with VSD, IAA, VSD, D-transposition of the great arteries
Williams syndrome	Supravalvar aortic stenosis, pulmonary artery stenosis
Inborn Errors of Metabolism	
Pompe disease (glycogen storage disease II)	Cardiomegaly, left heart failure, supraventricular tachycardia
Homocystinuria	Thromboembolic episodes, pulmonic and aortic regurgitation

CHARGE, Coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities; **VATER**, vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies.

Data from Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

Because of improved screening methods, surgical interventions, and management, children with congenital heart defects are now surviving into adulthood and bearing children of their own. Studies report up to 15% incidence of CHD in offspring of a parent having a congenital heart lesion.² Subsequent siblings could have as high as a 50% chance of having a cardiac malformation.

Classification of Congenital Heart Defects and Associated Conditions

There are more than 35 different types of congenital anomalies that can be classified into 4 categories based on blood flow pattern: (1)

lesions increasing pulmonary blood flow; (2) lesions decreasing pulmonary blood flow; (3) obstructive lesions, in which right- or left-sided outflow tract obstructions curtail or prohibit blood flow out of the heart; and (4) mixing lesions, in which desaturated blood and saturated blood mix within the chambers or great arteries of the heart (Table 34.4). By classifying lesions in this way, the clinical manifestations, as well as associated sequelae, are more predictable.

TABLE 34.4

CLASSIFICATION OF CONGENITAL HEART DEFECTS

CLASSIFICATION	SHUNT DIRECTION	PRESENTATION	SPECIFIC DEFECTS
Lesions increasing pulmonary blood flow	Left to right	Acyanotic congestive heart failure	Patent ductus arteriosus, atrial septal defect, ventricular septal defect, complete atrioventricular canal defect
Lesions decreasing pulmonary blood flow	Right to left	Cyanotic	Tetralogy of Fallot, tricuspid atresia
Obstructive lesions*	None	Low cardiac output Shock	Coarctation of the aorta, aortic stenosis, pulmonary stenosis
Mixed lesions†	Variable	Variable	Transposition of the great arteries, total anomalous pulmonary venous connection, truncus arteriosus, hypoplastic left heart syndrome*

*If patent ductus arteriosus closes, newborns with hypoplastic left heart syndrome, coarctation of the aorta, or critical aortic stenosis will present with shock. Newborns with aortic stenosis or pulmonary stenosis may have only mild symptoms depending on severity of stenosis.

†Transposition of the great arteries, truncus arteriosus, and hypoplastic left heart syndrome will present with cyanosis as patent ductus arteriosus starts to close. Total anomalous pulmonary venous connection usually presents with heart failure, but may present with severe hypoxemia if pulmonary venous return is obstructed.

Associated conditions and their clinical manifestations are lesion dependent. The two most common conditions associated with CHD are heart failure and hypoxemia. Lesions increasing pulmonary blood

flow include defects that allow blood flow to shunt from the high-pressure left side to the lower-pressure right side, resulting in pulmonary congestion. Lesions that cause decreased pulmonary blood flow are generally complex and result in cyanosis. Obstructive lesions increase the pressure needed to eject the blood from the ventricles. The two types of obstructive lesions are right-sided lesions that may result in hypoxemia and cyanosis, and left-sided lesions that may result in HF. Mixing lesions are variable in their physiology and clinical manifestations.

Heart Failure

Heart failure (HF) is classified as an acquired condition. HF occurs when the heart is unable to maintain sufficient cardiac output to meet the metabolic demands of the body. HF can occur as the result of decreased myocardial function or excessive metabolic demands. The most common causes of HF in infancy and childhood are cardiomyopathy or the result of poor ventricular function. [Table 34.5](#) lists the congenital heart defects that cause HF by age. Pulmonary overcirculation from large left-to-right shunts (mixing) is often called *congestive heart failure (CHF)* but is not usually associated with decreased cardiac output and failure to meet metabolic demands. However, the clinical manifestations are similar, such as failure to thrive (FTT), tachypnea, tachycardia, and respiratory tract infections.

TABLE 34.5

CONGENITAL HEART DEFECTS CAUSING HEART FAILURE

AGE	CONGENITAL HEART DEFECT
Time of birth	Hypoplastic left heart syndrome
	Volume overload caused by tricuspid regurgitation (rare)
	Arteriovenous fistula
Birth to 1 week	Hypoplastic left heart syndrome
	Aortic atresia
	Transposition of the great vessels with ventricular septal defect (VSD)

	Coarctation of the aorta
	Total anomalous pulmonary venous connection (TAPVC) with obstruction
	Patent ductus arteriosus (PDA) in premature infants
First 4 weeks	Coarctation of the aorta
	TAPVC
	Large left-to-right shunt caused by VSD, PDA in premature infants
	Tricuspid atresia
	Persistent truncus arteriosus with large left-to-right shunt
	All previously mentioned defects
4 to 6 weeks	Transposition of the great vessels with VSD
	Large left-to-right shunt caused by endocardial cushion defect
6 weeks to 6 months	VSD
6 months	Endocardial fibroelastosis

◆Pathophysiology.

In general, the pathophysiologic mechanisms of HF in infants and children are very similar to those in adults. The same compensatory mechanisms are activated in the face of inadequate cardiac output. An acute decrease in blood pressure stimulates stretch receptors and baroreceptors in the aorta and carotid arteries, which in turn stimulate the sympathetic nervous system. With the release of catecholamines and the stimulation of β receptors, heart rate and the force of myocardial contraction increase. Venous smooth muscle tone also increases, which increases return of venous blood to the heart. Sympathetic stimulation also decreases blood flow to the kidneys, skin, spleen, and extremities so that maximum flow to the brain, heart, and lungs can be maintained. Decreased blood flow to the kidneys causes the release of renin, angiotensin, and aldosterone. If chronic, this cycle results in retention of sodium and fluid by the kidneys, which in turn increases volume in the circulatory system.

These neurohumoral and hemodynamic changes create abnormal ventricular wall stress and cause the myocardium to hypertrophy. After excessive hypertrophy, the myocardial fibers begin to stretch to accommodate the increased volume. Hypertrophy and fiber stretch temporarily increase contractility and hence the force of ventricular

contraction. However, these mechanisms eventually fail to maintain cardiac output as HF progresses. A review of the Frank-Starling law of the heart (see [Chapter 32](#)) is useful for an understanding of the cycle of compensation and decompensation that occurs in HF.

◆Clinical Manifestations.

Symptomatic HF in children has many causes. It is not usually necessary to determine if it is right- or left-sided HF. When assessing a child with HF, a combination of symptoms generally is present. Pulmonary overcirculation is the predominant cause associated with congenital defects.

HF in infants is manifested as poor feeding and sucking, often leading to failure to thrive (FTT). Dyspnea, tachypnea, and diaphoresis may be accompanied by retractions, grunting, and nasal flaring. Wheezing, coughing, and rales are rare even with significant HF. Common skin changes, such as pallor or mottling, are often present.

Hepatomegaly (enlargement of the liver) is atypically attributable to systemic venous congestion. In infants the normal liver is soft, sharp-edged, and palpable 1 to 2 cm below the costal margin. However, the absence of hepatomegaly does not rule out HF.

Periorbital edema and weight gain without caloric increase are uncommon manifestations of right ventricular failure in infants. Peripheral edema, which is a common finding in adults, is rare in infants and young children and more often signifies renal disease rather than cardiac disease. The clinical manifestations of HF are listed in [Box 34.2](#).

Box 34.2

Clinical Manifestations of Heart Failure

IMPAIRED MYOCARDIAL FUNCTION	PULMONARY CONGESTION	SYSTEMIC VENOUS CONGESTION
Tachycardia	Tachypnea	Weight gain

Sweating (inappropriately)	Dyspnea	Hepatomegaly
Decreased urinary output	Retractions (infants)	Peripheral edema (rare)
Fatigue	Flaring nares	Ascites
Weakness	Exercise intolerance	Neck vein distention (rare in children)
Restlessness	Orthopnea	
Anorexia	Cough, hoarseness	
Pale, cool extremities	Cyanosis	
Weak peripheral pulses	Wheezing (rare)	
Decreased blood pressure	Grunting	
Gallop rhythm		
Cardiomegaly		

From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.

◆ Evaluation and Treatment.

A thorough physical examination with an emphasis on cardiac and pulmonary findings often will reveal the degree of HF. Plotting the child's growth (height, weight, head circumference) is an important method for monitoring a child's health. Infants with HF and pulmonary overcirculation usually have low weight with normal length and head circumference. FTT is usually the result of increased metabolic expenditure relative to caloric intake. Increasing caloric density or nasogastric feeding, or both, may be necessary to optimize caloric intake to promote weight gain. An electrocardiogram (ECG) should be performed to determine the presence of dysrhythmias or hypertrophy. A chest radiograph is useful in assessing the presence of cardiomegaly and signs of increased pulmonary circulation. However, echocardiography is the gold standard for definitive diagnosis of structural and functional cardiac disease.

Treatment is aimed at decreasing cardiac workload and increasing the efficiency of heart function. Medical management initially consists of diuretics, such as furosemide. Depending on the degree of HF, other diuretics can be used in combination with furosemide to

counteract potassium losses. Agents that reduce afterload, such as ACE inhibitors, angiotensin receptor blockers, and beta-blockers, are used to further manage severe HF. In severe cases of HF, anticoagulation and mechanical circulatory support may be indicated to support the failing myocardium.⁶

Hypoxemia
