1. Benign tumors are usually encapsulated and contain fairly well-differentiated cells and well-organized stroma, and they do not spread to distant locations.
2. Malignant tumors, compared with benign tumors, have more rapid growth rates, specific microscopic alterations (anaplasia, loss of differentiation), absence of normal tissue organization, and no capsule. They invade blood vessels and lymphatics and have distant metastases.
3. Carcinomas arise from epithelial tissue, and leukemias are cancers of blood-forming cells. Carcinoma in situ (CIS) refers to preinvasive epithelial tumors of glandular or squamous cell origin. These early-stage cancers are localized to the

epithelium and have not penetrated the local basement membrane or invaded the surrounding stroma.

The Biology of Cancer Cells

1. Genetic changes are the basis of cancer. These changes include small and large DNA mutations that alter genes, chromosomes, and non-coding RNAs, as well as epigenetic changes because of altered chemical modifications of DNA and histones.
2. Mutations include point mutations that alter a few nucleotide base pairs, which has a profound effect on the activity of resultant proteins. Other genetic alterations include chromosome translocations, gene amplification, DNA methylation, histone acetylation, or altered expression of non-coding RNA.
3. Some mutations, referred to as driver mutations, drive the progression of cancer and some are just random events, referred to as passenger mutations, and are just along for the ride.
4. Each cancer cell may develop its own set of mutations resulting in a genomically heterogeneous mixture of cancer cells with subsets that have accumulated more and more mutations increasing the cell's malignant potential.
5. The processes occurring during the development of cancer are in many ways analogous to wound healing. The initial proliferation of cancer cells and enlargement of the tumor elicit the synthesis of proinflammatory mediators by the cancer cells and adjacent nonmalignant cells.
6. As with wound healing, mediators recruit inflammatory/immune cells and cells normally associated with tissue repair. These cells form the stroma that surrounds and infiltrates the tumor.
7. Extensive paracrine signaling among the stromal and cancer cells affects both populations; cancer cells increase

proliferation and become more heterogenous during tumor growth and stromal cells undergo evolution to phenotypes that promote cancer progression and metastatic potential.

8. Cancer heterogeneity arises from ongoing proliferation and mutation.
9. Many of the hallmarks of cancer are consequences of cancer-stromal interactions.
10. Several of the hallmarks/enablers are mostly genomic alterations that initiate and maintain development of cancer. These hallmarks include sustained proliferative signaling, evading growth suppression, genomic instability, and replicative immortality.
11. Other hallmarks/enablers are cellular adaptations secondary to genomic change and include inducing angiogenesis and reprogramming energy metabolism. A third group of hallmarks/enablers are the host's protective mechanisms including apoptotic cell death, promoting tumor inflammation, and avoiding immune destruction. The last hallmark is the culmination of the previous nine: activating invasion and metastasis.
12. Cancerous cells characteristically express mutated or overexpressed proto-oncogenes, referred to as oncogenes, which are independent of normal regulatory mechanisms and signal uncontrolled proliferation.
13. Some oncogenes, such as *RAS*, result from point mutations.
14. Oncogenes can result from genetic translocations. The Philadelphia chromosome in chronic myeloid leukemia (CML) results from a translocation that creates a novel protein fusion of the *BCR* and *ABL* genes and expression of an unregulated promoter of cell growth.
15. Tumor-suppressor genes must be inactivated in cancer cells by mutations to each allele, one from each parent.
16. A common mutation in cancer cells is inactivation of the tumor-suppressor gene tumor protein p53 (TP53), which controls expression of many genes that repair DNA damage,

suppression of cellular proliferation during genomic repair, and initiation of apoptosis. Inactivation of p53 results in increased mutation rates and cancer.

17. In rare families, an initial inheritable mutation in a tumor-suppressor gene, such as TP53, the retinoblastoma gene (*RB*), or the breast cancer genes (*BRCA1* and *BRCA2*), may lead to a greatly increased risk for developing particular cancers.
18. Caretaker genes are responsible for maintaining genomic integrity. Inherited mutations can disrupt caretaker genes and cause genomic instability.
19. Abnormal gene silencing is emerging as a major factor in cancer progression. Gene expression can be regulated in a heritable manner (i.e., passed from a parent to a child or from a single cell to its progeny) by an “epigenetic” mechanism called silencing.
20. Changes in gene regulation can affect not just single genes, but entire networks of signaling. Gene expression networks can be regulated by changes in microRNAs (miRNAs or miRs) and other non-coding RNAs (ncRNAs).
21. Cancer cells are immortal.
22. When they reach a critical age, cancer cells activate telomerase to restore and maintain their telomeres, thereby allowing cancer cells to divide repeatedly or become immortal.
23. Like many normal adult tissues, cancers can contain rare stem cells that provide a source of immortal cells. To fully eradicate a cancer, it may be necessary to target the cancer stem cell.
24. Most of the genetic and epigenetic alterations that cause cancer occur within the somatic tissues during the lifetime of the individual.
25. Access to the vascular system is essential for tumor growth.
26. Stromal cells and cancer cells can secrete multiple factors, such as vascular endothelial growth factor (VEGF), that stimulate new blood vessel growth (called neovascularization or angiogenesis).
27. The successful cancer cell divides rapidly, with the consequent

requirement for the building blocks of new cells; cancer cell division often occurs in a hypoxic and acidic environment. Many cancer genes also encourage aerobic glycolysis and promote high glucose utilization of a cancer.

29. In cancer, defects in the intrinsic or extrinsic pathways, or both, provide resistance to apoptotic cell death.
30. Overexpression of BCL-2 blocks apoptosis in most follicular B-cell lymphomas.
31. Some conditions of chronic inflammation increase the risk of developing cancer. A prime example is the association between gastric cancer and infection with *Helicobacter pylori*. Additionally, some organs appear to be more susceptible to the oncogenic effects of chronic inflammation.
32. One of the key cells that promote tumor survival is the tumor-associated macrophage, or TAM. The classic proinflammatory macrophage (M1) is the primary macrophage in the acute inflammatory response. During tissue healing, the M2 macrophage phenotype produces antiinflammatory mediators to suppress ongoing inflammation and induce cellular proliferation, angiogenesis, and wound healing. TAMs appear to mimic the M2 phenotype.
33. Cancer-associated fibroblasts (CAFs) synthesize the extracellular matrix that surrounds and permeates the tumor. Molecules secreted by CAFs contribute greatly to cancer progression, local spread, and metastasis.
34. The most clearly documented effective immune response is prophylactic and directed against oncogenic viruses. Viruses are associated with about 15% of all human cancers worldwide. Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of virus-linked cancer cases.
35. Antibodies induced by vaccines against oncogenic viruses, such as human papillomavirus (HPV) and hepatitis B virus (HBV), are expected to protect against initial infection and development of cervical and liver tumors, respectively.
36. Unique antigens and other markers on tumor cells can be

- recognized by T cells and NK cells of the immune system, leading to destruction of the tumor cell.
37. Cancer cells can evade rejection by the immune system by production of immunosuppressive factors, induction of immunosuppressive T-regulator cells, evolution of tumor-antigen negative variants, or suppressed expression of antigen-presenting MHC class I molecules.
 38. Metastasis is the major cause of death from cancer.
 39. Metastasis is a complex process that requires cells to have many new abilities, including the ability to invade, survive, and proliferate in a new environment.
 40. Invasion consists of loss of cell-to-cell contact, degradation of the extracellular matrix (ECM), and migration of tumor cells to the vascular or lymphatic systems. Stromal cells, particularly TAMs, are essential to this process.
 41. Carcinomas undergo a process of epithelial-mesenchymal transition (EMT) during which many epithelial-like characteristics are lost (e.g., polarity, adhesion to basement membrane), resulting in increased migratory capacity, increased resistance to apoptosis, and a dedifferentiated stem cell-like state that favors growth in foreign microenvironments and establishment of metastatic disease.
 42. Some cancers appear to selectively move or home to particular metastatic sites, which may be a result of expression of particular receptors for ligands expressed by cells at the site.

Clinical Manifestations of Cancer

1. Paraneoplastic syndromes are rare symptom complexes, often caused by biologically active substances released from a tumor or by an immune response triggered by a tumor, that manifest as symptoms not directly caused by the local effects of the cancer.
2. Clinical manifestations of cancer include pain, cachexia, anemia, leukopenia, thrombocytopenia, and infection.

3. Pain is generally associated with the late stages of cancer. It can be caused by pressure, obstruction, invasion of a structure sensitive to pain, stretching, tissue destruction, and inflammation.
4. Fatigue is the most frequently reported symptom of cancer and cancer treatment.
5. Cachexia is a multiorgan syndrome with many clinical manifestations including anorexia; muscle wasting; thermogenesis; altered heart and liver function; gut malabsorption; early satiety; taste alterations; and altered protein, lipid, and carbohydrate metabolism. Two factors are most significant: muscle loss and inflammation. Muscle wasting involves many protein signaling pathways and inflammatory mediators. Profoundly altered are both appetite-stimulating and appetite-suppressing brain pathways.
6. Anemia associated with cancer usually occurs because of malnutrition, chronic bleeding and resultant iron deficiency, chemotherapy, radiation, and malignancies in the blood-forming organs.
7. Leukopenia is usually a result of chemotherapy (which is toxic to bone marrow) or radiation (which kills circulating leukocytes).
8. Thrombocytopenia is usually the result of chemotherapy or malignancy in the bone marrow.
9. Infection may be caused by leukopenia, immunosuppression, or debility associated with advanced disease. It is the most significant cause of complications and death.
10. The gastrointestinal tract relies on rapidly growing cells to provide an absorptive surface for nutrients. Both chemotherapy and radiation therapy may cause decreased cell turnover, thereby leading to oral ulcers (stomatitis), malabsorption, and diarrhea.
11. Alopecia (hair loss) results from chemotherapy effects on hair follicles. Alopecia is usually temporary, although hair may initially regrow with a different texture. Not all

chemotherapeutic agents cause alopecia. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection.

Diagnosis, Characterization, and Treatment of Cancer

1. The diagnosis of cancer requires examination of tumor tissue by a pathologist. Cancer classification is established by a variety of tests.
2. Tumor staging involves the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread. A standard scheme for staging is the T (tumor spread), N (node involvement), and M (metastasis) system.
3. The classification, and hence the treatment decisions, of cancers was originally based on gross and light microscopic appearance, and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive molecular analysis of the tumors.
4. Tumor markers are substances (i.e., hormones, enzymes, genes, antigens, antibodies) found in cancer cells and in blood, spinal fluid, or urine. They are used to screen and identify individuals at high risk for cancer, to help diagnose specific types of tumors, and to follow the clinical course of cancer.
5. Cancer therapy is now in a process of rapid evolution. Although cancer is treated routinely with surgery, radiation therapy, chemotherapy, and combinations of these modalities, they have many limitations.
6. Surgical therapy is used for nonmetastatic disease and as a palliative measure to alleviate symptoms.
7. Ionizing radiation causes cell damage; therefore the goal of radiation therapy is to damage the tumor without causing excessive toxicity or damage to nondiseased structures.

8. The theoretic basis of chemotherapy is the vulnerability of tumor cells in various stages of the cell cycle.
9. Modern chemotherapy uses combinations of drugs with different targets and different toxicities.
10. Immunotherapy attempts to modify the immune system from a cancer-protective state to a destructive condition.
11. Future treatment of tumors will, most likely, use a careful histologic and genetic analysis of individual cancers that prescribes a combination of tumor-targeting drugs to simultaneously disrupt multiple hallmarks of that particular cancer.
12. Prevention of cancer has become increasingly urgent with researchers studying lifestyle changes to lower the risks of cancers including diet, exercise, cessation of smoking, air pollution, occupational hazards, synthetic chemicals, sunlight and ionizing radiation, and many other factors. These factors are discussed in [Chapter 13](#).

**Chemicals and Occupational Hazards as Carcinogens,
414**

Although cancer arises from a complicated and an interacting web of multiple etiologies, avoiding high-risk behaviors and exposure to **individual carcinogens**, or cancer-causing substances, will prevent many types of cancer (Fig. 13.1). In fact, estimates as high as 80% to 90% for smoking-related cancers, such as lung and oropharyngeal cancer, and as high as 60% for other common lifestyle cancers, such as colorectal and bladder cancer, are preventable.¹ Lifestyle behaviors, dietary and environmental factors (such as exposure to ultraviolet radiation and infections), and occupational exposure contribute to cancer cases and deaths. In this context, any of the following factors can contribute to the development of cancer²⁻⁴:

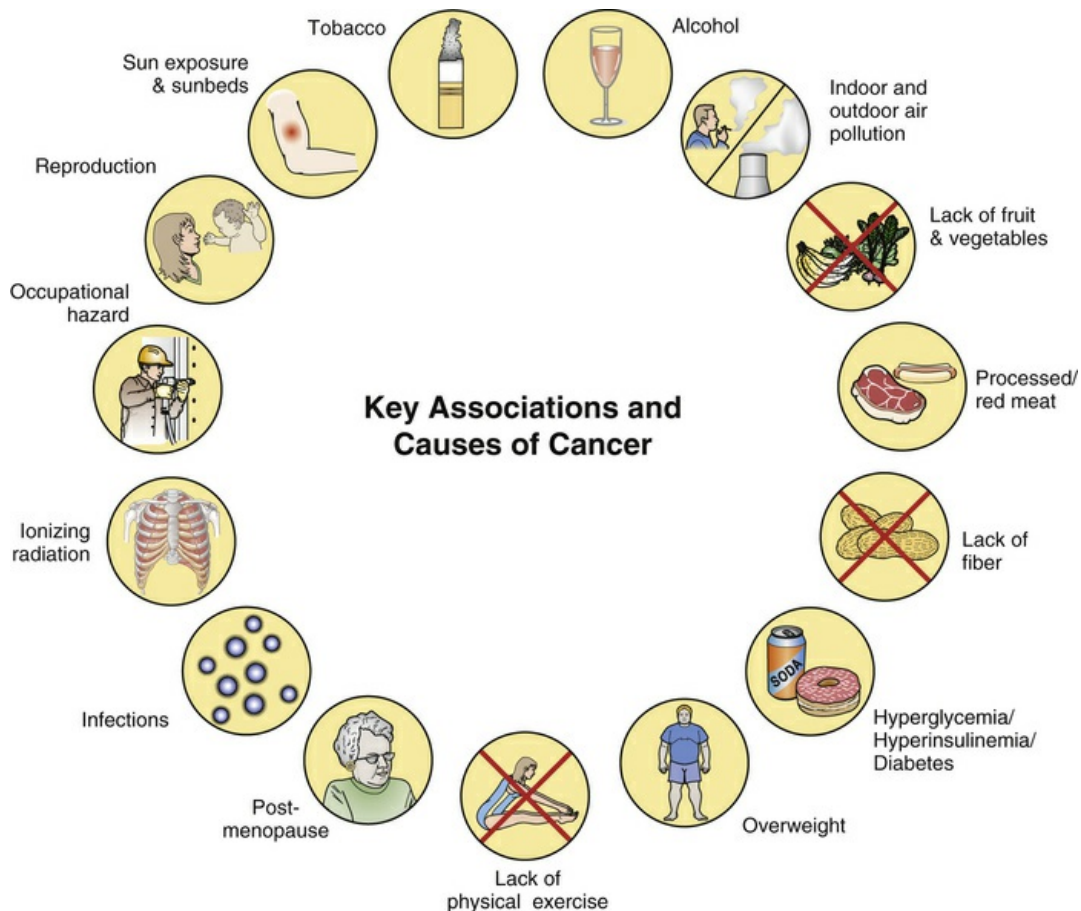

FIGURE 13.1 Key Associations and Causes of Cancer. Tobacco, diet and alcohol, obesity, lack of physical activity, air pollution, hormones, infections, ionizing radiation, occupational hazards, reproductive factors, and ultraviolet light are key associations and causes of cancer. Although diet is key and known to affect cancer risk, determining specific dietary

factors has been very difficult and is emerging.

- Lifestyle choices, such as smoking, alcohol use, nutritional intake
- Lack of physical exercise and overweight/obesity
- Infections, sexual practices
- Environmental conditions, air pollution, sunlight, natural and medical radiation, workplace exposures, and involuntary or unknown exposures
- Prescribed and illicit medications
- Socioeconomic factors that affect exposures and susceptibility
- Carcinogenic substances present in air, water, and soil

Estimates of environmental factors and their attributable risk for cancer vary. The International Agency for Research on Cancer (IARC) is part of the World Health Organization (WHO). A major goal for the IARC is to identify causes of cancer. The IARC has evaluated more than 900 candidate carcinogens and placed them into the following groups: Group 1: Carcinogenic to humans, Group 2A: Probably carcinogenic to humans, Group 3: Unclassifiable as to carcinogenicity in humans, and Group 4: Probably not carcinogenic to humans. Because it is difficult to test candidate carcinogens, most are listed as probable, possible, or unknown risk. About 100 chemicals, occupations, physical agents, biologic agents, and other agents are classified as carcinogenic to humans.² Simplified tables with a list of classifications by cancer sites with sufficient or limited evidence in humans are contained in [Table 13.1](#).

TABLE 13.1

LIST OF CLASSIFICATIONS BY CANCER SITES WITH SUFFICIENT OR LIMITED EVIDENCE IN HUMANS

CANCER SITE	CARCINOGENIC AGENTS WITH SUFFICIENT EVIDENCE IN HUMANS	AGENTS WITH LIMITED EVIDENCE IN HUMANS
-------------	--	--

Lip, Oral Cavity, and Pharynx

Lip		Solar radiation
Oral cavity	Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Human papillomavirus type 16 Tobacco, smokeless Tobacco smoking	
Salivary gland	X-radiation, γ -radiation	Radioiodines, including iodine-131
Tonsil	Human papillomavirus type 16	
Pharynx	Alcoholic beverages Betel quid with tobacco Human papillomavirus type 16 Tobacco smoking	Asbestos (all forms) Mate drinking, hot Printing presses Tobacco smoke, secondhand
Nasopharynx	Epstein-Barr virus Formaldehyde Salted fish, Chinese-style Wood dust	
Digestive tract, upper	Acetaldehyde associated with consumption of alcoholic beverages	
Digestive Organs		
Esophagus	Acetaldehyde associated with consumption of alcoholic beverages Alcoholic beverages Betel quid with tobacco Betel quid without tobacco Tobacco, smokeless Tobacco smoking X-radiation, γ -radiation	Dry cleaning Mate drinking, hot Pickled vegetables (traditional Asian) Rubber production industry Tetrachloroethylene
Stomach	<i>Helicobacter pylori</i> Rubber production industry Tobacco smoking X-radiation, γ -radiation	Asbestos (all forms) Epstein-Barr virus Lead compounds, inorganic Nitrate or nitrite (ingested) under conditions that result in endogenous nitrosation Pickled vegetables (traditional Asian) Salted fish (Chinese style)
Colon and rectum	Alcoholic beverages Tobacco smoking X-radiation, γ -radiation	Asbestos (all forms) <i>Schistosoma japonicum</i>
Anus	Human immunodeficiency virus type 1	Human papillomavirus types 18, 33

	Human papillomavirus type 16	
Liver and bile duct	Aflatoxins Alcoholic beverages <i>Clonorchis sinensis</i> Estrogen-progestogen contraceptives Hepatitis B virus Hepatitis C virus <i>Opisthorchis viverrini</i> Plutonium thorium-232 and its decay products Tobacco smoking (in smokers and in smokers' children) Vinyl chloride	Androgenic (anabolic) steroids Arsenic and inorganic arsenic compounds Betel quid without tobacco Human immunodeficiency virus type 1 Polychlorinated biphenyls <i>Schistosoma japonicum</i> Trichloroethylene X-radiation, γ -radiation
Gallbladder	Thorium-232 and its decay products	
Pancreas	Tobacco, smokeless Tobacco smoking	Alcoholic beverages Thorium-232 and its decay products X-radiation, γ -radiation
Digestive tract, unspecified		Radioiodines, including iodine-131
Respiratory Organs		
Nasal cavity and paranasal sinus	Isopropyl alcohol production Leather dust Nickel compounds Radium-226 and its decay products Radium-228 and its decay products Tobacco smoking Wood dust	Carpentry and joinery Chromium (VI) compounds Formaldehyde Textile manufacturing
Larynx	Acid mists, strong inorganic Alcoholic beverages Asbestos (all forms) Tobacco smoking	Human papillomavirus type 16 Mate drinking, hot Rubber production industry Sulfur mustard Tobacco smoke, secondhand
Lung	Aluminum production Arsenic and inorganic arsenic compounds Beryllium and beryllium products Bis(chloromethyl) ether; chloromethyl methyl ether (technical grade) Cadmium and cadmium compounds Chromium (VI) compounds Coal, indoor emissions from household combustion Coal gasification	Acid mists, strong inorganic Art glass, glass containers, and pressed ware (manufacture of) Biomass fuel (primarily wood), indoor emissions from household combustion of Bitumens, oxidized, and their emissions during roofing Bitumens, hard, and their emissions during mastic asphalt work Carbon electrode manufacture α -Chlorinated toluenes and benzyl

	<p>Coal-tar pitch Coke production Hematite mining (underground) Iron and steel founding MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture) Nickel compounds Painting Plutonium Radon-222 and its decay products Rubber production industry Silica dust, crystalline Soot Sulfur mustard Tobacco smoke, secondhand Tobacco smoking X-radiation, γ-radiation</p>	<p>chloride (combined exposure) Cobalt metal with tungsten carbide Creosotes Engine exhaust, diesel Frying, emissions from high-temperature Insecticides, nonarsenical (occupational exposures in spraying and application) Printing processes 2,3,7,8-Tetrachlorodibenzo-<i>para</i>-dioxin Welding fumes</p>
Bone, Skin, and Mesothelium, Endothelium, and Soft Tissue		
Bone	<p>Plutonium radium-224 and its decay products Radium-226 and its decay products Radium-228 and its decay products X-radiation, γ-radiation</p>	Radioiodines, including iodine-131
Skin (melanoma)	<p>Solar radiation Ultraviolet-emitting tanning devices</p>	
Skin (other malignant neoplasms)	<p>Arsenic and inorganic arsenic compounds Azathioprine Coal-tar distillation Coal-tar pitch Cyclosporine Methoxsalen plus ultraviolet A Mineral oils, untreated or mildly treated Shale oils Solar radiation Soot X-radiation, γ-radiation</p>	<p>Creosotes Human immunodeficiency virus type 1 Human papillomavirus types 5 and 8 (in individuals with epidermodysplasia verruciformis) Nitrogen mustard Petroleum refining (occupational exposures) Ultraviolet-emitting tanning devices Merkel cell polyomavirus (MCV)</p>
Mesothelium (pleura and peritoneum)	<p>Asbestos (all forms) Erionite Painting</p>	
Endothelium (Kaposi sarcoma)	<p>Human immunodeficiency virus type 1 Kaposi sarcoma herpesvirus</p>	

Soft tissue		Polychlorobiphenols or their sodium salts (combined exposures) Radioiodines, including iodine-131 2,3,7,8-Tetrachlorodibenzo- <i>para</i> -dioxin
Breast and Female Genital Organs		
Breast	Alcoholic beverages Diethylstilbestrol Estrogen-progestogen contraceptives Estrogen-progestogen menopausal therapy X-radiation, γ -radiation	Estrogen menopausal therapy Ethylene oxide Shift work that involves circadian disruption Tobacco smoking
Vulva	Human papillomavirus 16	Human immunodeficiency virus type 1
Vagina	Diethylstilbestrol (exposure in utero) Human papillomavirus 16	Human immunodeficiency virus type 1
Uterine cervix	Diethylstilbestrol (exposure in utero) Estrogen-progestogen contraceptives Human immunodeficiency virus type 1 Human papillomavirus types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59 Tobacco smoking	Human papillomavirus types 26, 53, 66, 67, 68, 70, 73, 82 Tetrachloroethylene
Endometrium	Estrogen menopausal therapy Estrogen-progestogen menopausal therapy Tamoxifen	Diethylstilbestrol
Ovary	Asbestos (all forms) Estrogen menopausal therapy Tobacco smoking	Talc-based body powder (perineal use) X-radiation, γ -radiation
Male Genital Organs		
Penis	Human papillomavirus type 16	Human immunodeficiency virus type 1 Human papillomavirus type 18
Prostate		Androgenic (anabolic) steroids Arsenic and inorganic arsenic compounds Cadmium and cadmium compounds Rubber production industry Thorium-232 and its decay products X-radiation, γ -radiation
Testis		Diethylstilbestrol exposure in utero
Urinary Tract		
Kidney	Tobacco smoking X-radiation, γ -radiation	Arsenic and inorganic arsenic compounds

		Cadmium and cadmium compounds Printing processes
Renal pelvis and ureter	Aristolochic acids, plants containing phenacetin Phenacetin, analgesic mixtures containing Tobacco smoking	Aristolochic acids
Urinary bladder	Aluminum production 4-Aminobiphenyl Arsenic and inorganic arsenic compounds Auramine production Benzidine Chlornaphazine Cyclophosphamide Magenta production 2-Naphthylamine	4-Chloro- <i>ortho</i> -toluidine Coal-tar pitch Coffee Dry cleaning Engine exhaust, diesel Hairdressers and barbers (occupational exposure) Printing processes Soot Textile manufacturing
	Painting Rubber production industry <i>Schistosoma haematobium</i> Tobacco smoking <i>ortho</i> -Toluidine X-radiation, γ -radiation	
Eye, Brain, and Central Nervous System		
Eye	Human immunodeficiency virus type 1 Ultraviolet-emitting tanning devices Welding	Solar radiation
Brain and central nervous system	X-radiation, γ -radiation	Radiofrequency electromagnetic fields (including from wireless phones)
Endocrine Glands		
Thyroid	Radioiodines, including iodine-131 X-radiation, γ -radiation	
Lymphoid, Hematopoietic, and Related Tissue		
Leukemia and/or lymphoma	Azathioprine Benzene Busulfan 1,3-Butadiene Chlorambucil Cyclophosphamide Cyclosporine Epstein-Barr virus Etoposide with cisplatin and	Bis(chloroethyl)nitrosourea (BBCNU) Chloramphenicol Ethylene oxide Etoposide Hepatitis B virus Magnetic fields, extremely low frequency (childhood leukemia) Mitoxantrone Nitrogen mustard

Genetics, Epigenetics, and Tissue

Cancers are caused by environmental-lifestyle and genetic factors. Cancer is *driven* by genetic alterations and changes in epigenetic regulation⁵⁻⁷ (see [Chapter 12](#)). Critical cancer genes include oncogenes

and tumor-suppressor genes. These genes become altered by a combination of genetic and epigenetic alterations to drive cancer progression.⁸ Critical genes for cancer regulate when cells grow, divide, differentiate, or die. A subclass of tumor-suppressor genes helps maintain genome integrity.⁸ Although driver and passenger genetic alterations are key, a wealth of data now indicate the importance of epigenetic processes, especially those with resultant gene silencing (not broken, but mute) of key regulatory genes (see [Chapters 6 and 12](#)). Different combinations of mutations and epigenetic changes are found in different types of cancers.⁸ Neoplastic cells undergo dynamic and reversible transitions between multiple phenotypic states, including epithelial-mesenchymal plasticity in cancer (see [Chapter 12](#)). This plasticity is enabled by changes in epigenetic regulation.^{7,9} Interacting factors that influence cancer risk include detoxifying enzymes, DNA repair genes, immune/inflammation systems, and the cell's immediate environment. The biologic environment surrounding cells includes metabolic and hormonal factors, for example, excess estrogen production, inflammation, and disordered glucose and lipid metabolism. The cell's biologic environment is modified by metabolic requirements, physical activity, infections, nutrition, occupational carcinogens, air pollution, and many other environmental factors. Investigators are challenged to connect the complex web between genotype, phenotype, and environment-lifestyle factors to understand a person's chances of developing cancer (see [What's New? New Models to Understand Intrinsic and Extrinsic Cancer Risk](#)).

What's New?

New Models to Understand Intrinsic and Extrinsic Cancer Risk

Vigorous debate has surrounded two possibly opposing explanations of why cancers are distributed unevenly among organs. Some organs are more likely to develop malignant tumors

than others, and children and adults develop very different types of cancers. These biases in cancer formation, adult versus child and organ specificity, are explained, in part, by organ-specific susceptibilities to carcinogens or inherited oncogenic mutations. The specific contributions, however, to these or other factors are unknown. The understanding of these factors that lead to cancer development is crucial for prevention and treatment. Thus investigators have proposed recent hypotheses. The “bad luck” hypothesis states that many cancers arise following the generation of mutations that occur by chance in highly-replicative stem cell populations, rather than following exposure to environmental factors. The implication of this hypothesis is that these cancers are not preventable. This hypothesis has undergone a great deal of scrutiny and is strongly contested. Importantly, recent mathematical modeling estimated that 70% to 90% of the causal factors driving the most common cancers are extrinsic or environmental factors.

The controversy from these studies has occurred because of the use of different mathematical approaches to correlate selected human cancer incidence data with various metrics of stem cell proliferation data. Investigators, therefore, approached the problem using experimental *in vivo* studies with defined populations of both neonatal and adult mice. These investigators found that tumor incidence is determined by the lifelong generative capacity of mutated cells, supporting the hypothesis that *stem cells dictate organ cancer risk*. Damage-induced activation of stem cell function significantly increases cancer risk. Therefore a combination of stem cell mutagenesis and environmental (extrinsic) factors that damage tissue and increase the proliferation of these cells creates the “perfect storm” and ultimately determines organ cancer risk. Tissue damage and inflammation are well-recognized determinants of cancer risk. The risk of an organ developing cancer following the introduction of oncogenic mutations into a stem cell population is significantly associated with their lifelong generative capacity and this holds true regardless of the developmental stage, supporting

the finding that the mutation of stem cells dictates cancer risk. Chronic tissue injury plays a critical role in tumor development and progression because it can reactivate generative and tumorigenic capacity in stem cells. In this model, damaging the liver reactivated a neonatal-like stem cell program promoting their proliferation and liver repair. The reactivation increases their susceptibility to transformation providing direct evidence that *cell generative capacity* can be a major determinant of organ cancer risk (see [Figures A and B](#)).

1. Normal stem cells

Stem cells can be asleep

When needed, for example to repair damage, they replicate to make more stem cells or other cells the body needs.

2. DNA mistakes in stem cells

Sometimes stem cells acquire random mistakes in their DNA as they replicate

Things in the environment can increase DNA mistakes

3. What happens to stem cells with DNA mistakes?

If stem cells with DNA mistakes are sleeping, no cancer develops

But if stem cells with DNA mistakes are replicating, cancer can develop

FIGURE A New research has demonstrated how cancers can start in stem cells.

FIGURE B Investigators propose that extrinsic (environmental) factors impact stem cells to induce mutations or tissue damage, or both, that stimulate proliferative repair. Tissue-specific susceptibility of stem cells to induce mutations and their intrinsic or damage-induced proliferative capacity create a “perfect storm” that ultimately determines organ cancer risk. Stem cells can regulate immune cells that may enable early transforming cells to escape immune protection or cause immunosuppression.

Data from Ashford NA et al: *Science* 347:727, 2015; Gotay C, Dummer T, Spinelli J: *Science* 347:728, 2015; Howlader N et al: *SEER cancer statistics review, 1975-2009*, Bethesda, MD, 2012, National Cancer Institute; O'Callaghan M: *Science* 347:729, 2015; Potter JD, Prentice RL: *Science* 347:727, 2015; Song M, Giovannucci EL: *Science* 347:728–729, 2015; Wild C et al: *Science* 347:728, 2015; Wu S et al: *Nature* 529:43–47, 2016; Zhu L et al: *Cell* 166(5):1132–1146, 2016.

Cancer development and progression involve the tissue microenvironment or stroma (see [Chapter 12](#)). The microenvironment participates in a complex signaling process that facilitates tumor promotion and metastasis because stromal tissue has various immune cells that can promote inflammation. Extensive clinical and experimental evidence shows that infiltrating immune cells cause chronic inflammation and, therefore, create a permissive tumor-progressing environment. Chronic inflammation also can *precede* and presumably initiate malignant change, as for example in inflammation-induced colon cancer.¹⁰ It is well documented that chronic inflammation induced by bacteria, viruses, autoimmune processes, and toxins promotes common types of cancer, including colon, liver, and lung cancer. Inflammation can be caused by numerous environmental factors, for example, inhaling tobacco smoke, asbestos fibers, or fine particles in the air from diesel engine exhaust and industrial sources. These sources are major factors in lung and other respiratory tract cancers.^{11,12} Cancer development in the presence of chronic inflammation involves the continuous presence of cytokines, chemokines, reactive oxygen species (ROS), oncogenes, cyclooxygenase-2 (COX-2), 5-lipoxygenase (5-LOX), and matrix metalloproteinases (MMPs), as well as the activation of essential transcription factors, such as nuclear factor κ B (NF- κ B).

Incidence and Mortality Trends

Cancer is reported to become a major cause of morbidity and mortality in the coming decades in all regions of the world. According to a report by GLOBACAN, an estimated 14.1 million new cancer cases and 8.2 million cancer deaths were reported and 32.6 million people were found to be living with cancer (diagnosed in the past 5 years) worldwide in 2012.¹³ The age-standardized rate for all cancers (excluding nonmelanoma skin cancer) for men and women combined was 182 per 100,000 in 2012; the rate was higher for men (205 per 100,000) than women (165 per 100,000). The highest cancer rate for men and women together was found in Denmark with 338 people per

100,000 being diagnosed in 2012. The age-standardized rate was at least 300 per 100,000 for 9 countries (Denmark, France, Australia, Belgium, Norway, United States, Ireland, Republic of Korea, and The Netherlands). The countries in the top 10 come from Europe, Oceania, Northern America, and Asia.¹³

In the 2016 annual report to the nation, the National Cancer Institute, the American Cancer Society, the Centers for Disease Control and Prevention, and the North American Association of Central Cancer registries collaborated to provide updates on cancer incidence, death rates, and trends in these rates for the United States from 2003 to 2012.¹⁴ The overall incidence rates (new cases per 100,000 persons in the United States) decreased for men and stayed about the same for women. During this period, 7 of the 17 more common cancers in men showed decreases in incidence, including colorectal, lung and bronchus, prostate, stomach, larynx, bladder, and brain cancers. Six of the more common cancers in women showed decreases in incidence, including cancers of the colorectum, cervix, lung and bronchus, bladder, ovary, and stomach. Importantly, the decline in the incidence of lung cancer corresponded with a decrease in tobacco use. During this same period, cancer incidence increased among people ages 0 to 19 years. The annual report's highlight included a special section on liver cancer. In all racial and ethnic populations, men had about a threefold higher liver cancer incidence rate than women. In 2012, the most recent year for which data are available, 28,012 people were diagnosed with liver cancer in the United States (excluding Nevada). Of this total, 20,207 were men and 7805 were women.¹⁴ Liver cancer incidence rates were higher among people born between 1945 and 1965 than among those born in other periods because of higher rates of hepatitis C virus (HCV) infection. Among persons born in this cohort, HCV infection was highest among nonHispanic whites, nonHispanic blacks, and Hispanics. Cirrhosis or scarring of the liver also is a precursor to liver cancer. Risk factors for cirrhosis include a history of liver disease, a history of heavy alcohol use, and some rare genetic disorders. In the United States, alcohol overuse contributes to about 8% to 16% of liver cancer deaths.¹⁴

Researchers found continued declines in cancer death rates or mortality rates for men, women, and children. Deaths caused by liver cancer, however, increased at the highest rate of all reported cancer sites, and liver cancer incidence rates increased sharply. The mortality rates for men from liver cancer were more than double the rate of those from women, with 15,563 deaths among men and 7409 deaths among women.

In Utero and Early Life Conditions

From studies of the etiology of certain cancers, it is widely accepted that a long latency period precedes the onset of adult cancers. Accumulating data suggest early life events influence later susceptibility to certain chronic diseases (Fig. 13.2).¹⁵ **Developmental plasticity** is the degree to which an organism's development is contingent on its environment. Specifically, the developmental origins' hypothesis postulates that nutrition and other environmental factors affect cellular pathways during gestation, enabling a single genotype to produce a broad range of adult phenotypes.¹⁶ *Plasticity* refers to the ability of genes to organize physiologically or structurally in response to environmental conditions during fetal development. The hypothesis also postulates that persistent epigenetic adaptations that occur early in development in response to maternal and paternal nutrition and the environment are associated with increased susceptibility to cancer and other adult-onset chronic diseases.^{17,18} Throughout in utero development, the placenta plays a major role in controlling growth and development.¹⁹ Because the placenta is a regulator of the intrauterine environment and can be influenced by exposures throughout pregnancy,^{19,20} research is being done with DNA methylation linking environmental cues to placental pathologies and adult life. The Dutch Famine Birth Cohort is a well-known study of the effects of prenatal undernutrition in humans. Undernutrition was linked to increased heart disease, metabolic disorders, and a possible link with breast cancer decades later.²¹ Early versus late undernutrition in pregnancy indicated that the first trimester of

pregnancy is particularly vulnerable to disease outcome in adulthood.²² A striking experiment in mice demonstrated how extra vitamin doses during pregnancy in the mother's diet changed the fur color of her pups.²³ This was the first study to show maternal nutrition and subsequent phenotype changes. The nutrients (B₁₂, folic acid, choline, and betaine) silenced the gene that rendered mice fat and yellow but did not alter its DNA sequence. Silencing, or switching the gene off, linked prenatal diet to such diseases as diabetes, obesity, and cancer. More research is needed to understand nutrition in pregnancy and child vulnerabilities later in life (Fig. 13.3).

FIGURE 13.2 Fetal Vulnerability to External and Internal Environments. The fetus is particularly vulnerable to changes in the external and internal environments, which can have immediate and lifelong consequences. Such environmentally induced changes can occur at multiple levels, including molecular and behavioral. Ultimately these alterations may be epigenetic, inducing mitotically heritable alterations in gene expression without changing the DNA. (Adapted from Crews E, McLachlan JA: *Endocrinology* 147[6 Suppl]:S4–S10, 2006.)

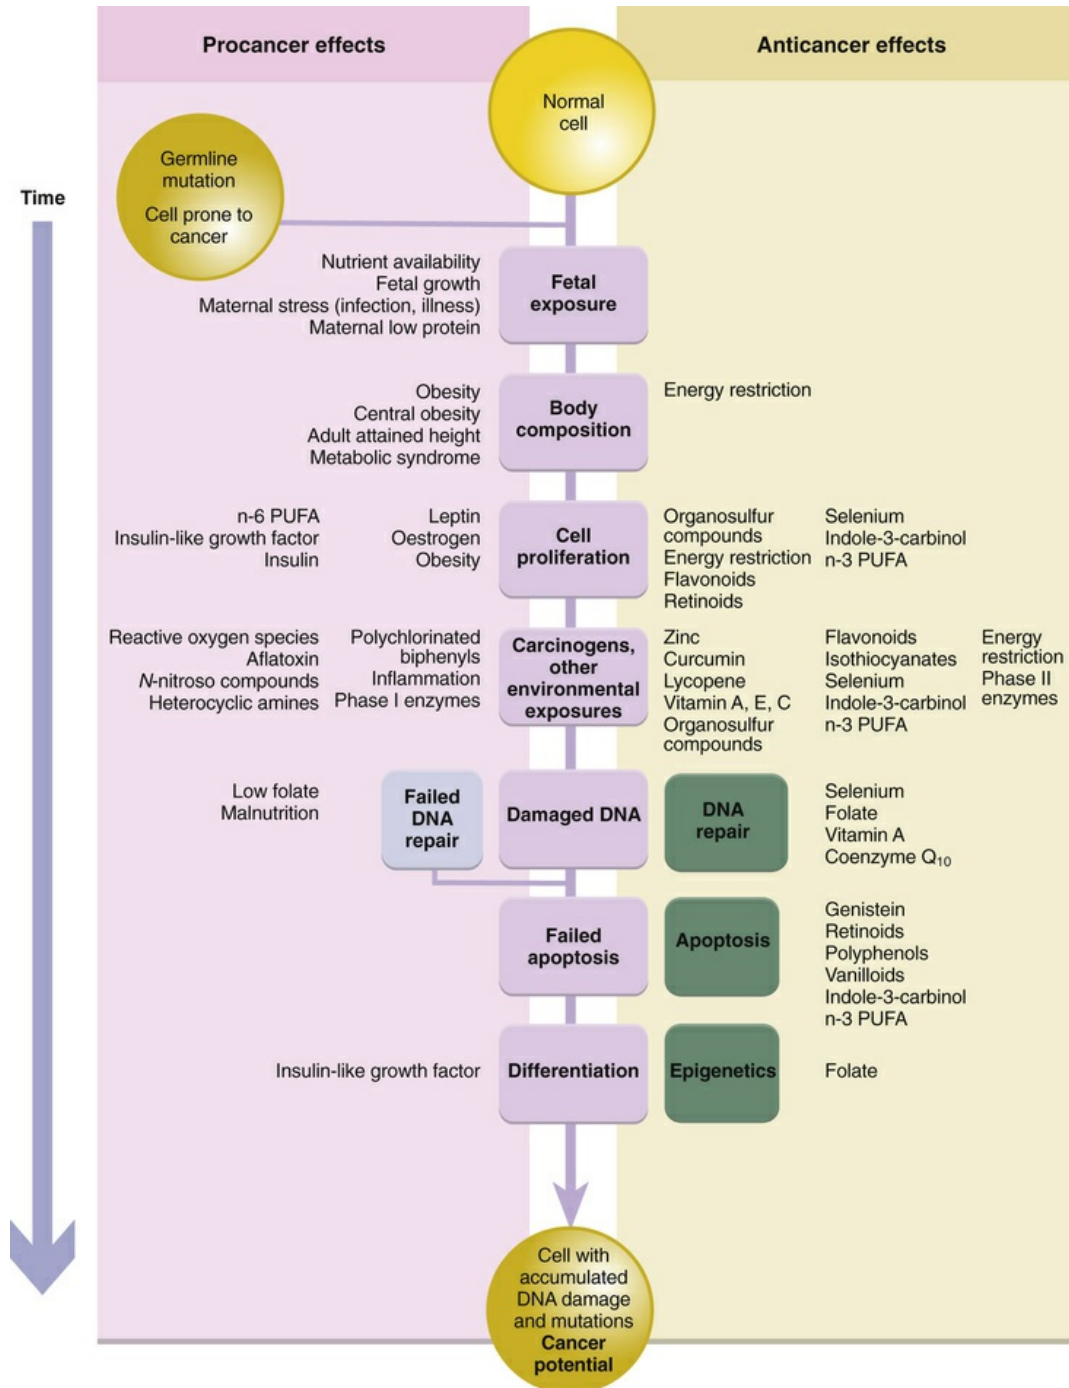

FIGURE 13.3 Pro- and Anticancer Effects. *PUFA*, Polyunsaturated fatty acids. (From World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective*, Washington, DC, 2007, AICR.)

Perhaps one of the best examples of early life events and future cancer is the chemical exposure to diethylstilbestrol (DES), a synthetic estrogen. This medication was prescribed between 1938 and 1971 to

attempt to prevent multiple pregnancy-related problems, such as miscarriage, premature birth, and abnormal bleeding.²⁴ By the 1950s it became clear that DES interfered with the *development* of the reproductive system in the fetus and it did not prevent miscarriage. Recent data suggest that the DES-associated increase in clear cell adenocarcinoma is elevated throughout a woman's reproductive years.²⁵ Other studies have revealed that daughters of women who took DES during pregnancy may have a slightly increased risk of breast cancer before age 40 (i.e., 1.9 times the risk compared with unexposed women at age 40).²⁶ For every 1000 DES-exposed women ages 45 to 49 it is estimated that 4 will be diagnosed with breast cancer.

Research from animal studies has demonstrated a relationship between DES exposure and an increased rate of a rare type of testicular cancer (rete testis) and prostate cancer.^{27,28} In terms of in utero exposures, testicular cancer has been linked to exposure to abnormal levels of estrogen,²⁹ and testicular cancer is a risk factor for men with undescended testicles, a factor in some studies correlated with DES exposure. However, studies in humans determining the risk of testicular or prostate cancer and DES exposure are unclear and continuing. Investigators from a recent study reported early life exposure to endocrine disrupting chemicals (EDCs), including DES, can increase the incidence, multiplicity, and overall size of uterine fibroids in the Eker rat model.³⁰

In summary, epidemiologic and animal studies reveal that small changes in the developmental environment can alter phenotypic changes, resulting in individual responses in adulthood. Continuing evidence indicates that epigenetic mechanisms are responsible for tissue-specific gene expression during cellular differentiation and that these mechanisms modulate developmental phenotypic changes. The phenotypic effects of epigenetic modifications during development may need long latency periods, such as in cancer, thus manifesting later in life. In addition, epigenetic effects may help explain transgenerational effects (Tables 13.2 and 13.3).

TABLE 13.2**DIFFERENCES BETWEEN MULTIGENERATIONAL AND TRANSGENERATIONAL PHENOTYPES**

PHENOTYPE	EXPOSURE	DEFINITION
Multigenerational	Direct	Simultaneous exposure of multiple generations to an environmental factor
Transgenerational	Initial germline exposure (ancestral)	Transgenerational phenotype is transmitted to future generations through germline inheritance

TABLE 13.3**SOMATIC VS. GERM CELL INHERITANCE**

CELL TYPE	BIOLOGIC RESPONSE
Somatic cells	Critical for adult-onset disease in exposed individual; not transmitted to future generations as transgenerational effect
Germ cells	Allow transmission between generations; promote transgenerational phenotype

Lifestyle habits are modifiable, and changing them can translate to reduced cancer risk and prevention of cancer. Examples of environmental factors on cancer risk are abundant.^{1,31,32} A critical question is whether individuals are intervening early enough in life to achieve cancer prevention.³³ Protective measures in very young and young people—for example, avoiding sun exposure during peak hours (10 AM to 3 PM), covering the skin whenever possible, increasing physical exercise, and avoiding high-risk sexual practices—will reduce cancer incidence. Understanding that it takes years to develop tumors, cancer prevention beginning early in life will help reduce the burden of cancer on individuals and society.³³

Environmental-Lifestyle Factors

Tobacco Use

Cigarette smoking is carcinogenic and remains the most important cause of cancer and death from cancer.³⁴ Close to 40 million adults in the United States still smoke cigarettes and about 4.7 million high school and middle school students use at least one tobacco product, including electronic cigarettes.³⁵ In the United States, cigarette smoking is the leading cause of preventable disease and death and accounts for more than 480,000 deaths each year, or 1 of every 5 deaths.^{35,36} More than 16 million Americans live with a smoking-related disease.³⁶ Worldwide, tobacco use is a major preventable cause of premature death and disease in which 5.4 million people die each year from tobacco-related illnesses.³⁷ The risk is greatest in those who begin to smoke when young and continue throughout life, but tobacco smoking is pandemic, affecting all ages. Current cigarette smoking was higher among persons aged 18 to 24 years, 25 to 44 years, and 45 to 64 years than among those 65 years and older.³⁸ The eradication of tobacco use can only be achieved by preventing children and adolescents from starting tobacco use. Men are more likely to smoke (16.7%) than women (13.6%).³⁸ According to race and ethnicity, smoking occurs more often in nonHispanic American Indians/Alaska Natives (29.2%), nonHispanic whites (18.2%), nonHispanic blacks (17.5%), nonHispanic multiple race individuals (27.9%), and nonHispanic Asians (9.5%). Cigarettes remained the most commonly used tobacco product, and young adults aged 18 to 24 years reported the highest prevalence of use of emerging tobacco products, including water pipes/hookahs and e-cigarettes.³⁹ Globally, tobacco use is greatest in developing countries, where 84% of 1.3 billion current smokers live.⁴⁰ Asia is now considered the largest tobacco producer and consumer in the world.⁴¹

Smoking affects nearly every organ of the body^{42,43} (Fig. 13.4). Since the first Surgeon General's report on smoking and health in 1964, more than 20 million Americans have died as a result of smoking.⁴³

Most of these deaths were adults with a history of smoking, but about 2.5 million were nonsmokers who died from lung cancer and heart disease from secondhand smoke⁴³ (see [Fig. 13.4](#)). Secondhand smoke, also called **environmental tobacco smoke (ETS)**, is the combination of sidestream smoke (burning end of a cigarette, cigar, or pipe) and mainstream smoke (exhaled by the smoker). More than 7000 chemicals have been identified in mainstream tobacco smoke. Nonsmokers who live with smokers are at greatest risk for lung cancer as well as numerous noncancerous conditions.⁴⁴ Additionally, another 100,000 fatalities were babies who died of sudden infant death syndrome (SIDS) or complications from low birth weight or other conditions as a result of parental smoking, particularly from the mother.⁴³

FIGURE 13.4 Health Consequences Linked to Smoking. **NOTE:** The conditions in red are new diseases that have causally been linked to smoking. See text for discussion. Stroke is a new disease causally linked to secondhand smoke. (From U.S. Department of Health and Human Services [USDHHS]: *The health consequences of smoking—50 years of progress: a report of the Surgeon General*, Atlanta, 2014, U.S. Department of Health and Human Services, Centers for Disease Control and Prevention,

Smoking tobacco is linked to cancers of the lung, upper aerodigestive tract (oral cavity, pharynx, larynx, nasal cavity, paranasal sinuses, esophagus), stomach, lower urinary tract (renal pelvis, penis, and bladder), kidney, pancreas, cervix, and uterus, as well as myeloid leukemia (see Fig. 13.4). The new list of disease risks includes liver cancer and colorectal cancer. Secondhand smoke is a cause of stroke; it increases the risk of death in people with cancer and cancer survivors as well as those with age-related macular degeneration, tuberculosis, ectopic pregnancy, and diabetes mellitus; increases inflammation; impairs immunity; and is a cause of rheumatoid arthritis. Smoking causes even more deaths from vascular, respiratory, and other diseases than from cancer. The epidemic of smoking ranks among the greatest health catastrophes of the century and has caused an enormous avoidable public health tragedy.⁴⁴

Cigars have the same toxic and carcinogenic compounds found in cigarettes; they are not a safe alternative to cigarettes.^{45,46} Cigars have a much higher concentration of nicotine (100 to 200 mg or higher [444 mg]) than cigarettes (about 8 mg), and cigarettes deliver about 1 to 2 mg of nicotine to the smoker.⁴⁷ Full-size cigars can have as much nicotine as an entire pack of cigarettes.⁴⁷ Regular cigar smoking is associated with increased risk for cancers of the lung, esophagus, larynx, and oral cavity (lip, tongue, mouth, throat). Cigar smoking is linked to gum disease and tooth loss. Heavy cigar smoking increases the risk for lung diseases, including emphysema and chronic bronchitis.⁴⁸ Heavy cigar smokers and those who inhale deeply may be at increased risk for developing coronary heart disease.⁴⁶

Hookahs are water pipes used to smoke specialized tobacco that comes in different flavors, including apple, mint, cherry, chocolate, coconut, licorice, cappuccino, and watermelon.⁴⁹ Hookah smoking has many of the same health risks as cigarette smoking, but is often assumed by users to be less harmful.⁴⁹ Other names for Hookahs include *narghile*, *argileh*, *shisha*, *hubble-bubble*, and *goza*. Hookah pipes

vary in size, shape, and style and typical smoking is done in groups with the same mouthpiece passed from person to person. Hookah use is increasing worldwide, including Britain, France, Russia, the Middle East, and the United States, and in young people and college students.⁴⁹ Data from Monitoring the Future survey found that, among high school seniors in the United States, about 1 in 5 boys (17%) and 1 in 6 girls (15%) had used a hookah in the past year.⁵⁰ Compared to smoking a cigarette where it involves about 20 puffs, an hour-long hookah smoking session involves 200 puffs. The smoke inhaled during a typical hookah session is about 90,000 milliliters (mL), compared with 500 to 600 mL inhaled when a cigarette is smoked.⁴⁹ Hookah smokers may be at risk for some of the same diseases as cigarette smokers, including oral cancer, lung cancer, stomach cancer, esophageal cancer, reduced lung function, and decreased fertility. Secondhand smoke from hookahs is a health risk for nonsmokers.

Pipe smokers have an increased risk of dying from cancers of the lung, throat, esophagus, larynx, pancreas, and colorectum.⁵¹ Smoking *bidi*, a small amount of tobacco wrapped in the leaf of another plant (used in South Asia), delivers higher amounts of nicotine per gram of tobacco and comparable or greater amounts of tar compared with cigarettes.⁵² Bidi smokers have the same risks of cancers and higher risks of heart attacks and chronic bronchitis than those found in nonsmokers.⁵¹ *Kreteks*, or clove cigarettes, are a tobacco product with the same health risks as cigarettes.

Electronic cigarettes (e-cigarettes) are a type of electronic nicotine delivery system (ENDS). ENDS include e-pens, e-pipes, e-hookahs, and e-cigars. Over 3 million high school and middle school students were current users of e-cigarettes in 2015.⁵³ As a small battery-operated device, e-cigarettes look like a cigarette. When a smoker puffs on the e-cigarette, the system delivers a vapor (aerosol) of nicotine, flavorings, and other chemicals.⁵¹ The vapor is inhaled just like smoke from a regular cigarette and absorbed into the lungs. Colorful “vape pens” or “e-hookahs” are marketed to appeal to youth with flavors like candy and fruit.⁵¹ These products contain liquid

nicotine, flavorings, propylene glycol, glycerin, and other ingredients.⁵³ Since 2016, the Food and Drug Administration (FDA) regulates the manufacture, import, packaging, labeling, advertising, promotion, sale, and distribution of ENDS.⁵³ Beginning in 2018, all newly regulated covered tobacco products must have the following statement “WARNING: This product contains nicotine. Nicotine is an addictive chemical.”⁵³

A recent genetics study found the total mutation burden is elevated in smokers versus nonsmokers with lung adenocarcinoma, larynx, liver, and kidney cancers.⁵⁴ United Kingdom researchers reported for the first time that starting smoking results in epigenetic changes or DNA methylation associated with the development of cancer.⁵⁵ Investigators are studying the genetic and epigenetic effects of secondhand smoke and smoking (both maternal and paternal) during pregnancy on prenatal exposure and subsequent chronic diseases. [Fig. 13.5](#) illustrates a working model of carcinogenesis by cigarette smoke. Measures that prevent young adults from starting smoking would substantially avoid future disease burden. A strong public health approach is one that *prevents* young people from *starting* smoking and helps others *stop* smoking.

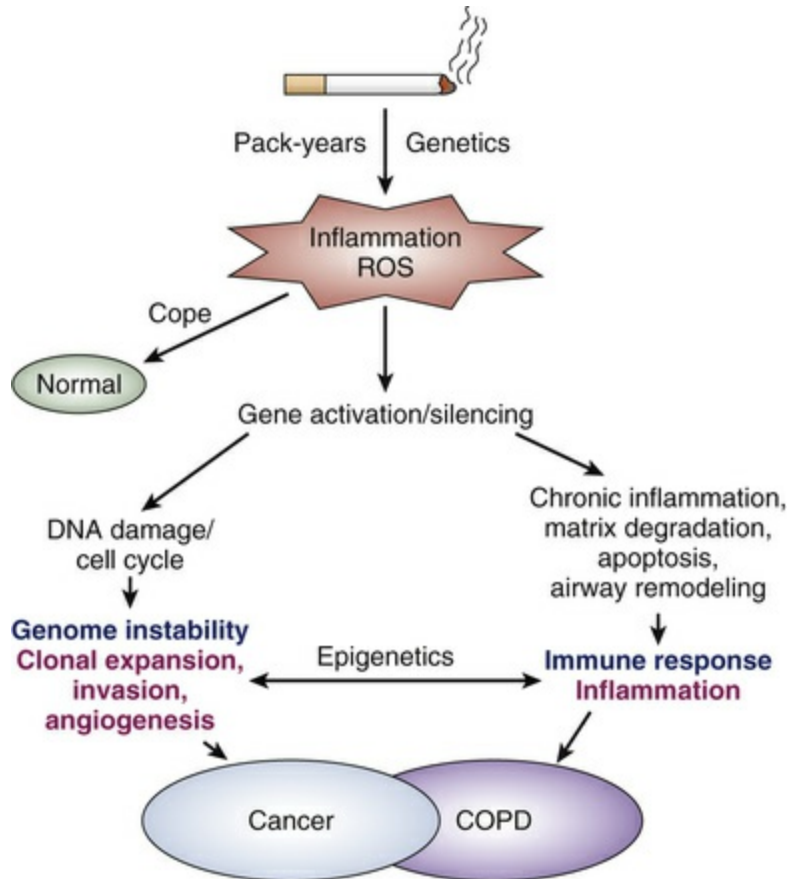

FIGURE 13.5 Working Model of Carcinogenesis by Cigarette Smoke. The major inducer of both lung cancer and chronic obstructive pulmonary disease (COPD) is cigarette smoke. Nonsmokers may develop these diseases caused by other environmental or genetic/epigenetic factors. Cigarette smoke induces an inflammatory response and causes an increase in reactive oxygen species (ROS), causing oxidative stress. Oxidative stress is a risk factor for many diseases because it can alter many cellular proteins. A combination of immune-inflammatory signals and epigenetic events may increase the risk for individuals with COPD developing lung cancer. (From Adcock IM et al: *Respiration* 81[4]:265–284, 2011.)

Diet

Understanding dietary factors that increase the risk for cancer can be difficult. The ways in which diet affects one's likelihood of developing cancer are complicated by the variety of foods consumed, the many constituents of foods, the metabolic consequences of eating, and the temporal changes in the patterns of food use. Cancer risks in older adults may depend as much on diet in early life as on current eating practices. In addition, studies in humans targeting diet and disease

associations face a variety of challenges including measurements of specific nutrients, food types, and dietary patterns.

A summary of convincing and probable judgments related to food (diet and nutrition), physical activity, and weight risk factors and the prevention of cancer is presented in [Fig. 13.6](#). Dietary components can act directly as mutagens or interfere with mutagen elimination. Abundant evidence exists that nutritional factors in many processes are related to cancer development ([Fig. 13.7](#)).

SUMMARY OF STRONG EVIDENCE ON DIET, NUTRITION, PHYSICAL ACTIVITY AND PREVENTION OF CANCER

	MOUTH, PHARYNX, LARYNX (2007)	NASOPHARYNX (2007)	ESOPHAGUS (2016)	LUNG (2007)	STOMACH (2016)	PANCREAS (2012)	GALLBLADDER (2015)	LIVER (2015)	COLORECTUM (2011)	BREAST PREMENOPAUSE (2010)	BREAST POSTMENOPAUSE (2010)	OVARY (2014)	ENDOMETRIUM (2013)	PROSTATE (2014)	KIDNEY (2015)	BLADDER (2015)	SKIN (2007)
Foods containing dietary fibre									Convincing decreased risk								
Aflatoxins								Convincing increased risk									
Non-starchy vegetables¹	Probable decreased risk																
Allium vegetables																	
Garlic									Probable decreased risk								
Fruits²	Probable decreased risk			Probable decreased risk													
Red meat									Convincing increased risk								
Processed meat³						Probable increased risk			Convincing increased risk								
Cantonese-style salted fish		Probable increased risk															
Diets high in calcium⁴									Probable decreased risk								
Foods preserved by salting						Probable increased risk											
Glycaemic load													Probable increased risk				
Arsenic in drinking water				Convincing increased risk										Probable increased risk			Convincing increased risk
Mate⁵			Probable increased risk														
Alcoholic drinks⁶	Convincing increased risk	Convincing increased risk		Convincing increased risk	Probable increased risk			Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk				Probable decreased risk		
Coffee								Probable decreased risk					Probable decreased risk				
Beta-carotene⁷				Convincing increased risk										Substantial effect on risk unlikely			Substantial effect on risk unlikely
Physical activity⁸									Convincing decreased risk		Probable decreased risk		Probable decreased risk				
Body fatness⁹			Convincing increased risk		Probable increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Probable decreased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	
Adult attained height¹⁰						Probable increased risk			Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	
Greater birth weight										Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	Convincing increased risk	
Lactation										Convincing decreased risk	Convincing decreased risk						

1 Includes evidence on foods containing carotenoids for mouth, pharynx, larynx.
 2 Includes evidence on foods containing carotenoids for mouth, pharynx, larynx and lung.
 3 For stomach, probable increased risk of non-cardia cancer only.
 4 For colorectum, evidence is from milk and studies using supplements.
 5 Probable increased risk for oesophageal squamous cell carcinoma only.
 6 For oesophagus, convincing increased risk for oesophageal squamous cell carcinoma only. For liver and stomach, based on evidence for alcohol intakes above around 45 grams per day (about 3 drinks a day). For colorectum, convincing increased risk for men and probable increased risk for women. For kidney, based on evidence for alcohol intakes up to 30 grams per day (about 2 drinks a day).
 7 For lung, evidence is from studies using high-dose supplements in smokers.
 8 Convincing decreased risk for colon and rectum.
 9 For oesophagus, convincing increased risk for adenocarcinoma only. For stomach, probable increased risk of cardia cancer only. For prostate, probable increased risk for advanced prostate cancer only.
 10 Adult attained height is unlikely to directly influence the risk of cancer. It is a marker for genetic, environmental, hormonal and nutritional factors affecting growth during the period from preconception to completion of linear growth.

世界癌症研究基金會

FIGURE 13.6 Summary of Strong Evidence on Diet, Nutrition, Physical Activity, and Prevention of Cancer. Evidence is presented as part of the Continuous Update Project (CUP), an ongoing program to analyze global

research on how diet, nutrition, physical activity, and weight affect cancer risk and survival. Scientific research from around the world is collated and added to a database continuously reviewed by experts at the Imperial College London. The CUP database now contains 9037 publications on breast, colorectal, pancreatic, endometrial, ovarian, prostate, liver, gallbladder, kidney, bladder, and stomach cancers, as well as breast cancer survivors. (From Continuous Update Project [CUP]: London, April 2016, WCRF International.)

FIGURE 13.7 Basis for the Study of Food, Nutrition, Obesity, Physical Activity, and the Cancer Process. The genetic message in the DNA code is translated to RNA, and then into protein synthesis, and so determines metabolic processes. Research methods, called “-omics,” address these different stages. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective*, Washington, DC, 2007, AICR.)

Research is ongoing to understand the complexity of genomics, epigenomics, transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and the way that modifying any one, or more, influences cancer risk. **Nutrigenomics** is the study of the effects of nutrition on the phenotypic variability of individuals based on genomic differences (see [Fig. 13.7](#)).

Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer

What people eat, how much they weigh, and how much they move influence their risks of developing cancer. Mounting evidence is clear—everyday *choices* impact their chances of getting or preventing cancer. Ongoing tedious and comprehensive investigative work is

linking diet, body weight, and exercise to risk of specific cancers.

Nutrition

Data from epidemiologic and clinical research independent of aging are revealing that lifestyle and nutrition are associated with development or progression, or both, of major human cancers.^{56,57} These cancers include some of the most common including breast, prostate, colorectal tumors, and other diet-related cancers.⁵⁶

The Mediterranean diet (MD) has been reported to reduce mortality rates for chronic illnesses, including cardiovascular diseases, neurodegenerative diseases, and cancer.⁵⁶ Two meta-analyses of conformity with the MD were associated with a significant reduction in the risk of overall cancer mortality/incidence, as well as the incidence of several cancer types (colorectal, aerodigestive tract, breast, stomach, pancreas, prostate, liver, and head and neck).^{58,59} Overall risk of cancer mortality was evaluated in 11 cohort studies; 6 of these cohorts did not show a significant correlation between adherence to an MD and cancer risk. Pooling all 11 cohort studies, however, a meta-analysis yielded a 13% risk reduction of overall cancer mortality when comparing the highest to the lowest adherence to the MD.⁵⁹ [Box 13.1](#) presents research outcomes of components of the Mediterranean diet. Recent data of two intervention studies, the MedDiet study and the DiMeSa project, are reviewed assessing the effects of the Mediterranean diet or its components on both plasma and urine biomarkers (see [Box 13.1](#)).

Box 13.1

Research Outcomes for the Mediterranean Diet and Cancer

Fruits and Vegetables

Prospective cohort studies yield inconsistent results regarding

fruit and vegetable intake and cancer risk.

European Prospective Investigation into Cancer and Nutrition (EPIC) cohorts provide evidence of a weak inverse association between high consumers of fruit and vegetable users and lower risk.

Recent meta-analysis from 16 prospective cohort studies reveal a higher consumption of fruit and vegetables correlated with a decrease in all-cause mortality, albeit, not with a significant reduction in cancer-related death.

World Cancer Research Fund/American Institute for Cancer Research from the Continuous Update Project (CUP) reports strong evidence of *probable decrease cancer risk* from nonstarchy vegetables for cancers (mouth, pharynx, larynx, esophagus) and for fruits *probable decreased cancer risk* for cancers (mouth, pharynx, larynx, esophagus, and lung). Data for fruits include evidence on foods containing carotenoids for mouth, pharynx, larynx and lung; foods containing beta-carotene for esophagus; foods containing vitamin C for esophagus.

Biologic Mechanism of Action: Antioxidant, antiinflammatory, antimutagenic, or antiproliferative.

Fish

Recent meta-analyses show inconsistent and inconclusive results.

Biologic Mechanism of Action: Antiinflammatory affects *n*-3 fatty acids.

Whole Grain

Whole grains and dietary fiber were inversely associated with risk of developing colorectal cancer in meta-analyses.

Intervention and observational studies showed dietary fiber is associated with reduced risk of insulin resistance.

Biologic Mechanism of Action: Enlargement of the bulk of stool leading to decreased transit time and decreasing impact of potential carcinogenic substances. Metabolizing of fiber to short-chain fatty acids by intestinal bacteria may prevent dedifferentiation of colonic cells and increase apoptosis.

Olive Oil

Epidemiologic studies on effects of olive oil showed decreased risks or odds ratios for breast cancer and cancers of the digestive system and respiratory tract.

Biologic Mechanism of Action: Extra-virgin olive oil is rich both in monounsaturated fatty acids and in polyphenolic compounds (e.g., tyrosol, hydroxytyrosol, oleuropein). Phenolic content of extra-virgin and virgin olive oil may affect oncogenes. It may exert chemopreventive effects, including direct antioxidant effects, cancer cell signaling, and cell cycle progression.

Alcohol and Red Wine in Moderate Amounts

Some observational studies showed light amounts of alcohol (<30 g of ethanol/day for men; <20 g of ethanol/day for women) with a focus on red wine to be associated with a reduced risk of cardiovascular disease.

Alcoholic beverages, however, ≥ 30 g of ethanol/day, are associated with increased risks of different cancers (e.g., pharynx, larynx, esophagus, colorectal, breast, and liver). The effects of light alcohol drinking on cancer development and progression are controversial.

Biologic Mechanism of Action: Metabolism of alcohol converts ethanol to a highly reactive, toxic chemical called *acetaldehyde*. To prevent excessive increases in acetaldehyde, human cells contain three aldehyde dehydrogenase (ALDH) enzymes

(ALDH1A1, ALDH2, and ALDH1B1) that can metabolize acetaldehyde into acetate. Inherited deficiency of the ALDH2 enzyme is present in approximately 36% of ethnic Japanese, Chinese, and Koreans. The deficiency is linked to facial flushing and, more recently, to squamous cell esophageal cancer. The ALDH enzymes can be overwhelmed by high quantities of alcohol, causing acetaldehyde to increase. This can lead to DNA mutations that can eventually lead to cancer.

Red and Processed Meat

Red and processed meats (sometimes poultry) are regarded to be unfavorable compounds. Meta-analyses link high consumption of meat or processed meat, or both, with an increased risk of cancer mortality.

Meta-analyses of 21 observational studies showed high consumption of red/processed meat is associated with increased risk of colorectal adenomas.

Biologic Mechanism of Action: The exact mechanism is unknown but may be related to chemicals found in meat (heme, N-nitroso, iron?). Cooking meat at high temperatures, such as grilling or barbequing, can create chemical carcinogens.

Dairy Products

Controversial and contradictory results are reported with consumption of milk and dairy products and risk of cancer.

Two Experimental Intervention Studies: The MedDiet Study and the DiMeSa Project for the Mediterranean Diet

From the MedDiet Study Two Important Findings:

1. Both hydroxyl and methoxy estrogen derivatives account for the majority of endogenous estrogens in human urine. Urinary estrogen profiles are considered closer to intratissue estrogen content than respective plasma values (parent estrogens [E2, E1, E3] represent a limited fraction [5% to 8%] of total endogenous estrogens).
2. The traditional Mediterranean diet may reduce the risk of developing breast cancer through its effects on estrogen metabolism, whereby hydroxylation of E2, a process that leads to the formation of genotoxic metabolites, was strongly decreased in the intervention group (e.g., controlled Mediterranean diet) and unchanged in the control group.

From the DiMeSa Project: Primary Prevention

Only preliminary data are currently available.

The randomized intervention is a clinical trial to test the assessment of the health impact of extra-virgin olive oil (EVO) on two cohorts of study subjects: healthy postmenopausal women and those with breast cancer. Two different EVOs were used: one at lower (BL) and one at higher (CS) polyphenols and oleocanthal.

Preliminary data reveal consumption of BL EVO resulted in significant changes of various biomarkers in plasma in both healthy subjects and breast cancer subjects. These biomarkers included reduction of glycemia, insulinemia, and total cholesterol.

Consumption of CS EVO changes included a significant increase of high density lipoprotein (HDL) cholesterol, a reduction of low density lipoprotein (LDL) cholesterol, and a reduction of plasma levels of estradiol.

Under current analysis are results of gene expression, microRNA profiling, and patterns of urinary sex steroids.

Limitations of Research

Mediterranean diet (MD) is a complex food pattern.
Methodologic issues are needed to identify adherence to MD.

Data from Andrici J, Hu SX, Eslick GD: *Cancer Epidemiol* 40:31–38, 2016; Arts IC, Hollman PC: *Am J Clin Nutr* 81(1 Suppl):317S–325S, 2005; Aune D et al: *BMJ* 343:d6617, 2011; Bagnardi V et al: *Ann Oncol* 24(2):301–308, 2013; Benetou V et al: *Cancer Epidemiol Biomarkers Prev* 17(2):387–392, 2008; Boffetta P et al: *J Natl Cancer Inst* 102(8):529–537, 2010; Brooks PJ et al: *PLoS Med* 6(3):e50, 2009; Carruba G, et al: *Immun Ageing* 13:13, 2016; Corona G, Spencer JP, Dessi MA: *Toxicol Ind Health* 25(4–5):285–293, 2009; Haas P et al: *Int J Food Sci Nutr* 60(s6):1–13, 2009; Han YJ et al: *Eur J Clin Nutr* 67(2):147–154, 2013; Jin M et al: *Ann Oncol* 24(3):807–816, 2013; O'Sullivan TA et al: *Am J Public Health* 103(9):e31–e42, 2013; Schwingshackl L, Hoffmann G: *Ann Intern Med* 161(6):455–456, 2014; Schwingshackl L, Hoffmann G: *Lipids Health Dis* 13:154, 2014; Sotirioudis TG, Kyrtopoulos SA: *Eur J Nutr* 47(Suppl 2):69–72, 2008; Williams MT, Hord NG: *Nutr Clin Pract* 20(4):451–459, 2005; World Cancer Research Fund (WCFR)/American Institute for Cancer Research (AICR): *Food, nutrition, physical activity, and the prevention of cancer: a global perspective*, Washington, DC, 2007, AICR; WCRF/AICR Continuous Update Project: *Diet, Nutrition, Physical Activity and Esophageal Cancer*, 2016; Xu X et al: *Int J Cancer* 132(2):437–448, 2013; Zheng J-S et al: *BJM* 346:f3705, 2013.

Many bioactive dietary components have been implicated as promoting or protective factors in cancer development.⁵⁹ Examples of food components reported to have cancer-preventive potential include polyphenols, selenium, methyl group donors, retinoids, isothiocyanates, allyl compounds, and mono- and poly-unsaturated fatty acids.⁵⁷ Although important cellular processes affected by nutrition include the cell cycle, the balance between cell proliferation and cell death (e.g., apoptosis); cell differentiation; oxidative stress and genes, including oncogenes and tumor-suppressor genes; DNA damage and repair; cell signaling; cellular microenvironment that influences gene expression; hormonal regulation; carcinogen metabolism; and inflammation and immunity (Fig. 13.8), the epigenome is being implicated as a major target for nutrition-induced changes of gene expression and function (Fig. 13.9, A).^{56,60} Emerging evidence is revealing epigenetic processes act in synergy with genetic changes during carcinogenesis and tumor progression.^{61–63}

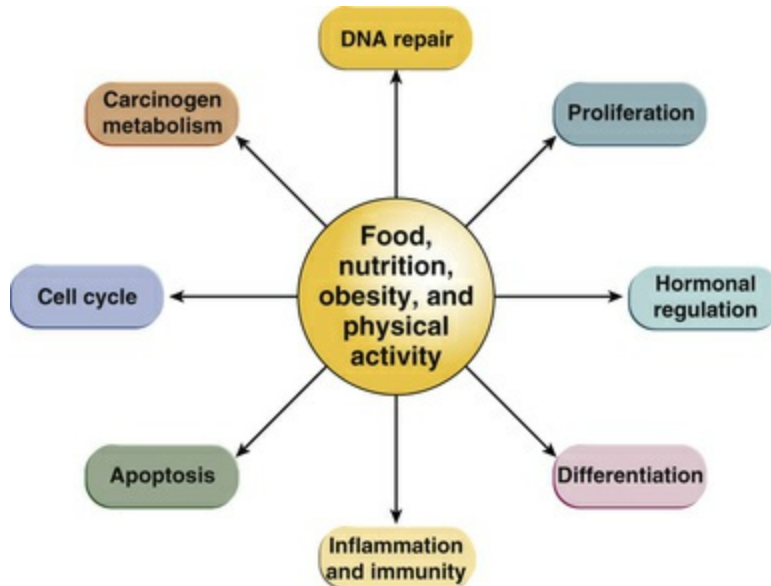

FIGURE 13.8 Food, Nutrition, Obesity, Physical Activity, and Cellular Processes Linked to Cancer. Food, nutrition, and physical activity can influence fundamental processes shown here, which may promote or inhibit cancer development and progression. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective*, Washington, DC, 2007, AICR.)

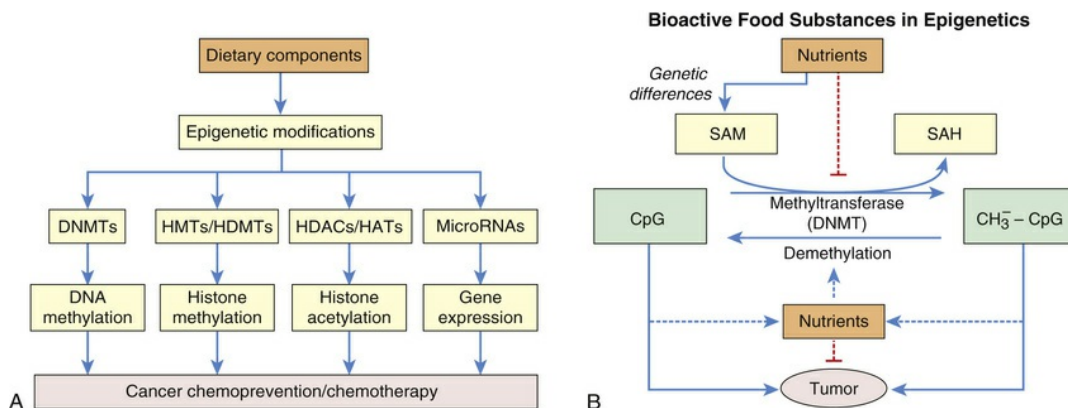

FIGURE 13.9 Dietary Components as Epigenetic-Regulating Agents and DNA Methylation and Cancer. **A**, Epigenetics and gene transcriptional regulation together create a microenvironment for cancer development with alterations in cell proliferation, differentiation, metabolism, DNA repair, and movement. The main epigenetic modifications regulated by dietary components include DNA methylation, histone modifications (acetylation/deacetylation, methylation/demethylation), and microRNAs. DNA methylation and histone modifications can alter chromatin structure and microRNAs can degrade mRNA and affect the translation process. Data are needed on these processes, as well as the potential synergistic effects of dietary components, to revert chemotherapy resistance, side effects from chemotherapy, and increase chemotherapy sensitivity. **B**,

Certain dietary factors (see [Table 13.5](#)) may supply methyl groups (+CH₃) that can be donated through S-adenosylmethionine (SAM) to many acceptors in the cell (DNA, proteins, lipids, and metabolites). Donation and removal (demethylation) are affected by numerous enzymes, including DNA methyltransferase (DNMT). Increased DNMT activity occurs in many tumor cells. Hypermethylation can inhibit or silence tumor-suppressor genes (see [Chapter 12](#)), and DNA methylation inhibitors as anticancer agents can block DNMT activity, thus reactivating tumor-suppressor genes. DNA hypomethylation can reactivate and mutate genes, including cancer-causing oncogenes. CpG, Cytosine guanine nucleotide; HATs, histone acetyltransferases; HDACs, histone deacetylases; HMTs, histone methyltransferases; SAH, S-adenosylhomocysteine. (A adapted from Chang L, Yu Y: *BioMedicine* 6910:9–16, 2016.)

B vitamins, coenzymes in one-carbon metabolism (vitamins B₂, B₆, B₁₂), also are modulators of DNA methylation.⁶⁴ To date there are limited human studies of the effects of methyl donor supply on methylation of specific genomic sequences.⁶⁵ However, a study⁶⁶ found that periconceptional maternal supplementation with 400 micrograms (mcg) of folic acid per day was associated with increased methylation in offspring aged 17 months. Higher methylation levels were observed as being small for gestational age (SGA) compared to appropriate for gestational age (AGA) infants with maternal folic acid supplementation.⁶⁷ In the Waterland study, methylation effects were found to be similar in all tissues examined, suggesting that the mechanism may alter markings in stem cells early in embryogenesis before tissue differentiation, and persist into adult life.²³ Choline deficiency in pregnancy results in hypermethylation of genomic DNA and of the *IGF2* gene.⁶⁸ Several studies have reported that severe folate deficiency (which increases risk of hepatocellular cancer) induces hypomethylation of the *p53* tumor-suppressor gene.⁶⁹ Women with folate deficiency were 3.6 times more likely to display LINE-1 (interspersed genetic elements) hypomethylation than women with no folate deficiency. A dietary pattern characterized by low fruit consumption and folate deficiency is associated with LINE-1 hypomethylation and with cancer risk.⁷⁰ In vitro studies have shown that several bioactive food components, including tea polyphenols and bioflavonoids, inhibit DNA methyltransferase-1 (DNMT-1)-mediated DNA methylation in a dose-dependent manner⁷¹ ([Fig. 13.9, B](#)). Acetylation and deacetylation are mediated by enzyme histones

(see [Fig. 6.1](#)), histone acetyl transferase (HAT), and histone deacetylation (HDAC). There is evidence for the epigenetic effects of organosulfur compounds from garlic and of isothiocyanates from cruciferous vegetables.^{72,73} The chemopreventive effects of garlic may be attributed to the antiinflammatory properties of its sulfur-containing components, for example, diallyl disulfide (DADS).⁷³ Interest in resveratrol, a polyphenolic compound with antiinflammatory, antioxidant, and anticancer activities, is growing because of its demonstrable role from in vitro and animal studies as cardioprotective, neuroprotective, chemopreventive, and antiaging properties.⁷⁴ In an animal model, investigators gave resveratrol immediately after onset of sepsis and found it inhibited endoplasmic stress activated nuclear factor- κ B in the kidney.⁷⁵ Examples of food sources of resveratrol include grapes, peanuts, mulberry, and cocoa. The epigenetic functions of resveratrol include DNA methyltransferase (DNMT) and histone deacetylase (HDAC) inhibition, and mRNA regulation.⁷⁶ Butyrate produced in the colon by bacterial fermentation of nonstarch polysaccharide (fiber), diallyl disulfide from garlic and other allium vegetables, and sulforaphane from cruciferous vegetables can act as histone deacetylase inhibitors to maintain DNA stability or modify transcription.⁷⁷

MicroRNA (miRNA) expression in response to diet may be involved in several cancers.⁷⁷ Several dietary factors, including macronutrients (fat, protein, and alcohol) and micronutrients (folate and vitamin E), alter the expression of many miRNAs in animals and humans⁶⁵ (see [Chapter 12](#)). Investigators indicate for the first time that select dietary agents impact stem cell regulatory networks, somewhat, by modulating steady-state levels of miRNAs.⁷⁸

Bioactive components have a profound effect on differentiation, and a major area of investigation is on the differentiation of cancer stem cells. Cancer stem cells have been isolated and identified in hematopoietic and epithelial cancers, including cancers of the brain, breast, ovary, prostate, colon, and stomach.^{77,79} Although still mysterious biologically, stem cells are found among most adult tissues, where they maintain and regenerate tissues. Stem cells are

capable of both self-renewal and differentiation to generate functional tissue.⁸⁰ The balance between self-renewal and differentiation is critical to understand not only normal development but also disruption of normal development, which can lead to cancer.⁸⁰ Musashi (named after samurai Miyamoto Musashi), a family of RNA-binding proteins discovered originally in *Drosophila*, has arisen as a key signal that allows and protects the stem cell state across organisms.⁸⁰ Emerging evidence shows that RNA-binding proteins (RBPs) play important roles in the regulation of self-renewal by assisting metabolism of coding and non-coding RNAs in normal tissue and cancers.⁸¹ The ways in which all of these processes are influenced by bioactive components need much study. Evidence from both drug and bioactive food constituents shows modifications in cancer stem cell self-renewal capabilities; for example, retinoic acid may promote differentiation of breast cancer stem cells.⁸² Adequate consumption of specific food compounds, including vitamins A and D, genistein, green tea, epigallocatechin gallate (EGCG), sulforaphane, theanine, curcumin, choline, and possibly many others, may suppress cancer stem renewal.^{79,83} Uncontrolled self-renewal process may be initiated by abnormal developmental signals that come from the extracellular microenvironment known as “niches.” The loss of regulation in self-renewal signals, including Wnt, Notch, and hedgehog pathways, is a characteristic of cancer stem cells.⁷⁹ Various food bioactive components can modulate the signaling pathway.

A variety of food constituents may influence DNA repair⁷⁷ (Fig. 13.10). Investigators demonstrate that certain miRNAs have a role in the interplay among the DNA damage response and bioactive compounds, including epigallocatechin-3-gallate, curcumin, resveratrol, and *n*3-polyunsaturated fatty acids.⁸⁴ In vivo studies have demonstrated that healthy adults consuming kiwi fruits, cooked carrots, or supplemental coenzyme Q₁₀ improved their DNA repair.⁷⁷

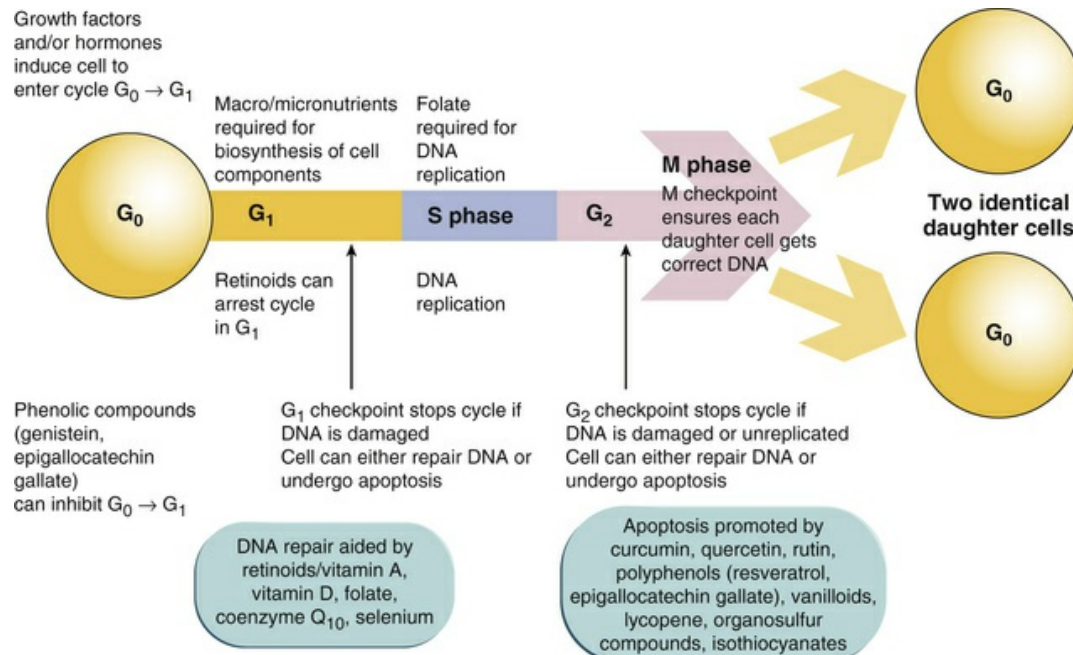

FIGURE 13.10 Cell Cycle and Nutrition Regulation. Nutrition may influence the regulation of the normal cell cycle, which ensures correct DNA replication. G₀ represents the resting phase, G₁ the growth and preparation of the chromosome for replication, S the synthesis of DNA, G₂ the preparation of the cell for division, and M mitosis. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective*, Washington, DC, 2007, AICR.)

Humans are constantly exposed to a variety of compounds termed **xenobiotics** (Greek *xenos*, “foreign”; *bios*, “life”) that include toxic, mutagenic, and carcinogenic chemicals. Many of these chemicals are found in the human diet. Most xenobiotics are transported in the blood by lipoproteins and penetrate lipid membranes. These chemicals can react with cellular macromolecules, such as proteins and DNA, or can react directly with cell structures to cause cell damage.⁸⁵ The body has two main defense systems for counteracting these effects: (1) detoxification enzymes and (2) antioxidant systems (see [Chapter 2](#)). Enzymes that activate xenobiotics are called **phase I activation enzymes** and are represented by the multigene cytochrome P-450 family, aldehyde oxidase, xanthine oxidases, and peroxidases. **Phase II detoxification enzymes** then protect further against a large array of reactive intermediates and nonactivated xenobiotics.⁷⁷ These enzymes are located predominantly in the liver and provide clearance

of compounds through the portal circulation, thereby preventing the potentially carcinogenic agent(s) from entering the body through the gastrointestinal tract and portal circulation. They also occur in the skin epithelia and can be induced in other extrahepatic tissue, such as the lung. They represent a potential target to influence carcinogen metabolism. Isothiocyanates from cruciferous vegetables induce the expression of phase II detoxification enzymes. Food and nutrition modify carcinogen metabolism and may modify carcinogenesis. Some examples include selenium, allyl sulfur, sulforaphane, and isoflavonoids. The enzyme CYP3A4 is involved in the metabolism of many drugs and is sensitive to foods.⁷⁷ For example, interactions have been reported for grapefruit juice, red wine, garlic, and drugs.

Glutathione-S-transferases (GSTs) are enzyme housekeepers involved in the metabolism of environmental carcinogens and reactive oxygen species. Individuals who lack these enzymes may be at higher risk for cancers because of decreased capacity to dispose of activated carcinogens. For example, the fungi that produce aflatoxins can grow on certain crops, such as peanuts and some cereal (e.g., grains). Aflatoxins are carcinogens activated by phase I enzymes in the liver that can produce DNA adducts. Individuals lacking these enzymes are at higher risk of colon cancer. Diets high in isothiocyanates (from cruciferous vegetables) may decrease this risk.⁸⁶

Individuals who consume diets high in red meat and processed meat have an increased risk of developing colorectal cancer.^{77,87,88} Processed meats include those preserved by preservatives or by smoking, curing, or salting. The IARC has classified processed meat as a carcinogen and red meat as a probable carcinogen.⁸⁹ The European Prospective Investigation into Cancer and Nutrition (EPIC) study, which included 478,040 people from 10 countries, reports that the most convincing data are from meats, including sausages, bratwursts, frankfurters, and hot dogs, all of which have nitrites, nitrates, or other preservatives. Potential mechanisms of how processed meat/red meat may increase cancer include the concepts that (1) red meat contains the heme form of iron, which may cause alterations of the lining of the colon; (2) red meat stimulates the production of *N*-nitroso compounds,

which can increase nitrogenous residues in the colon and cause DNA damage; and (3) cooking meat at high temperatures (e.g., grilling) produces two cancer promoters: heterocyclic amines (HCAs) and polycyclic aromatic hydrocarbons (PAHs). Certain single-nucleotide polymorphisms (SNPs) in the *N*-acetyltransferase gene alter the activity of the enzyme involved in the activation of heterocyclic amines from cooking meat at high temperatures and may increase the risk of colon cancer.⁷⁷ Other foods that alter the metabolism of carcinogens and induce GSTs include cruciferous vegetables, especially brussels sprouts and red cabbage. Red cabbage leads to changes in meat-derived mutagens in urine.⁷⁷ Flavonoids found in plants may alter carcinogen metabolism.

Chronic inflammation and immune function may help explain patterns of cancer around the world. Chronic inflammation assists cancer initiation, progression, and dissemination.⁹⁰ People who are undernourished or live in poverty may have impaired immune status, which can be a factor in cancers caused by infectious agents, for example, cancers of the liver and cervix.⁷⁷ Undernutrition can include deficiencies in vitamin A, riboflavin, vitamin B₁₂, folic acid, vitamin C, selenium, and zinc, and these nutrient deficiencies may be related to chronic inflammation and immune alterations.⁷⁷ The cytokine interleukin-6 (IL-6) can act as either a proinflammatory or an antiinflammatory cytokine; consequently, it can enhance both innate and adaptive immunity as well as stimulate or suppress tumor growth (see [Chapter 12](#)).

In summary, epidemiologic and laboratory evidence suggests that diet has important consequences for cancer development and perhaps its rate of progression. Diet affects many pathways to cancer including cell cycle control, differentiation, DNA repair, gene silencing, inflammation, apoptosis, and carcinogen metabolism. Many of these processes are likely influenced, if not regulated, by DNA methylation, an epigenetic mechanism that affects gene function. As illustrated in [Fig. 13.2](#), it is possible that many environmental factors interact with the genome to produce altered epigenetic markers that change the expression of cancer-causing genes, tumor-suppressor genes, and

oncogenes. Future research is needed to define robust biomarkers of cancer risk.

Obesity

Obesity in most developed countries (and in urban areas of many developing countries) has been increasing rapidly over the past 20 years. Obesity in the United States is an epidemic and constitutes a startling setback to major improvements in other areas of health during the past century.⁹¹ Childhood obesity also is increasing and disproportionately affects children from low-income families.⁹² Numerous health conditions are linked to obesity and physical inactivity. The substantial suffering and long-term human and societal costs of obesity underlie the urgency to accelerate progress in obesity prevention.⁹¹ This will require a comprehensive approach including the involvement of knowledgeable healthcare personnel, the provision of appropriate education from schools, the access to healthy food and beverage choices, and the promotion of physical activity.

Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival (see Fig. E 13.1 on Evolve). Being overweight or obese, measured using the body mass index (BMI), is linked to an increased risk of developing 11 cancers: liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal (adenocarcinoma), postmenopausal breast, pancreatic, endometrial, and stomach (cardia) (Fig. 13.11). The IARC identified additional cancers with sufficient evidence that the absence of body fatness lowers cancer risk for thyroid and multiple myeloma.⁹³ Importantly, obesity is recognized as a poor prognostic factor for several cancers.^{94,95}

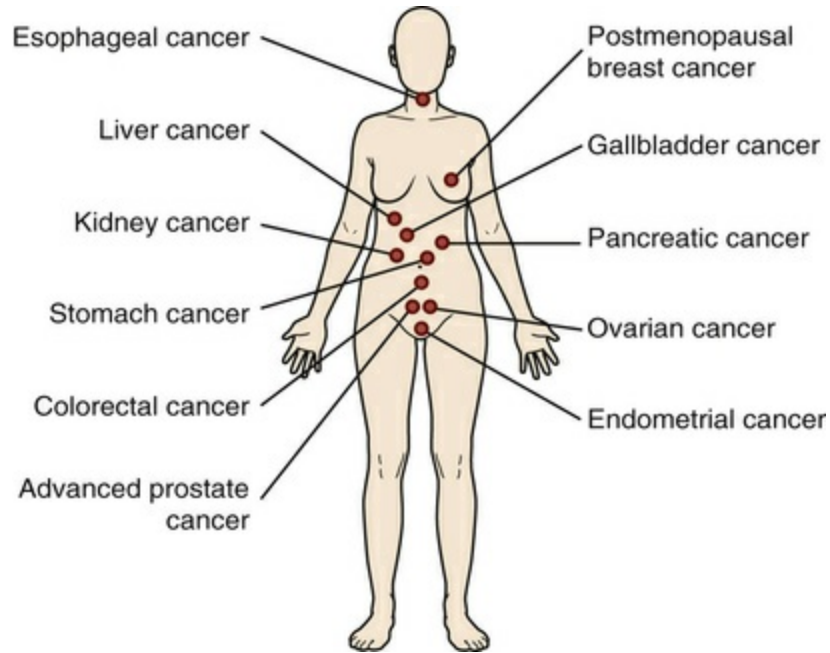

FIGURE 13.11 Overweight and Obesity and Increased Risk for 11 Cancers. (From World Cancer Research Fund [WCRF]: *International weight & cancer continuous update project*, London, 2016, WCRF International.)

The only globally accepted criteria for overweightness and obesity are based on BMI. Widely accepted standards based on BMI criteria for overweightness and obesity are recommended by the WHO^{96,97} and supported by other panels and federal agencies (WHO classifications are shown in [Table 13.4](#)).

TABLE 13.4

WORLD HEALTH ORGANIZATION CLASSIFICATION OF BODY MASS INDEX

BMI (kg/mm ²)*	WHO CLASSIFICATION	OTHER DESCRIPTIONS
<18.5	Underweight	Thin
18.5–24.9	Normal range	“Healthy,” “normal,” or “acceptable” weight
25–29.9	Grade 1 overweight	Overweight
30–39.9	Grade 2 overweight	Obese
≥40	Grade 3 overweight	Morbidly overweight

*The cutoffs are somewhat arbitrary, although they are derived from epidemiologic studies of body mass index (BMI) and overall mortality. It is important to understand that within each category of BMI there can be substantial individual variation in total and visceral adiposity and in related metabolic factors. These

variations are also true for the normal range BMI.

Worldwide estimates suggest that 2 billion adults are overweight (BMI ≥ 25 to 29.9 kg/m^2) and 500 million are obese (BMI $\geq 30 \text{ kg/m}^2$).⁹⁸ The prevalence of overweight and obesity was highest in the WHO regions of the Americas (61% for overweight in both sexes, and 27% for obesity) and lowest in the WHO region for South East Asia (22% overweight in both sexes and 5% for obesity).⁹⁸ More than 50% of women in the WHO region of the Americas and European and Eastern Mediterranean regions were overweight. In all three of these regions, nearly half of overweight women were obese (25% in Europe, 24% in the Eastern Mediterranean, 30% in the Americas). In all WHO regions, women were more likely to be obese than men. In the WHO African, Eastern Mediterranean, and South East Asia regions, women had approximately double the obesity prevalence of men.⁹⁸ In 2014, 41 million children less than 5 years of age in the world were overweight, approximately 10 million more than two decades earlier.⁹⁸ Globally, the prevalence of overweight children has increased between 1990 and 2014 from 4.8% to 6.1%. This disturbing rise is occurring across all income groups and in all regions.⁹⁸

Mechanisms Associated with Energy Balance and Obesity.

The Institute of Medicine (IOM) and National Cancer Policy Forum convened to discuss mechanisms of obesity and cancer, cancer recurrence and mortality, research needs, and future directions.⁹⁹ A simple model based on energy balance and energy expenditure was utilized. **Energy balance** measures intake-absorbable energy against the energy demands of the body. Energy expenditure is comprised of (1) the resting metabolic rate (RMR), the energy required for normal body functions, which constitutes the majority of energy needs; (2) the thermic effect of food, or the amount of energy needed to digest and metabolize food; and (3) physical activity, a moderate and modifiable part of energy expenditure. This model does not include body composition (i.e., lean tissue, adipose tissue) or the dynamic state of body composition. Because lean mass determines resting metabolic rate, it is unknown whether obesity itself drives cancer progression or

whether components of energy balance (i.e., too much consumed or too little expended) have a greater impact, and therefore it is uncertain which factors hold more promise for cancer control and prevention.¹⁰⁰

The mechanisms of obesity-associated cancer risks are unclear and may vary by type of tumor and distribution of body fat. Emerging, however, are three main factors related to obesity and cancer: (1) the insulin–insulin-like growth factor axis (see *What's New: Insulin, Insulin Receptor, Insulin-like Growth Factors, and Cancer*), (2) sex hormones, and (3) adipokines or adipocyte-derived cytokines.¹⁰¹ These three factors are linked to metabolic dysregulation of adipose tissue and endocrine and paracrine altered signaling of adipose tissue in obesity.^{101,102} The factors strongly implicated include insulin, insulin-like growth factor 1 (IGF-1) more than IGF-2, leptin, adiponectin, and IL-6. Metabolic changes in adipose tissue from obesity result in several alterations and include insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation.^{101,103}

What's New?

Insulin, Insulin Receptor, Insulin-Like Growth Factors, and Cancer

Investigators are studying the growth-promoting effect of insulin, the insulin receptor (IR), insulin-related growth factors (**insulin-like growth factor 1 [IGF-1]** and IGF-2), hyperinsulinemia, insulin resistance, hyperglycemia, and diabetes as factors that interfere with the host and the malignant cell responses. These factors are all important for the obese individual and cancer because insulin resistance and hyperinsulinemia are metabolic abnormalities of most obese individuals. Known for years is that cancer cells require insulin for optimal in vitro growth. Recent data indicate that (1) insulin stimulates growth mainly through its own IR and not the IGF-1 receptor and (2) the IR is overexpressed in many cancer cells and the A isoform is more predominant than the B isoform. The IR-A isoform has a major mitogenic effect that can cause proliferation.

Altogether, these factors promote a growth advantage to malignant cells when exposed to insulin. IR overexpression has been found in neoplastic cells but not in stromal adipocytes and inflammatory cells. Increased IR content has been found in breast, colon, lung, ovary, and thyroid carcinomas

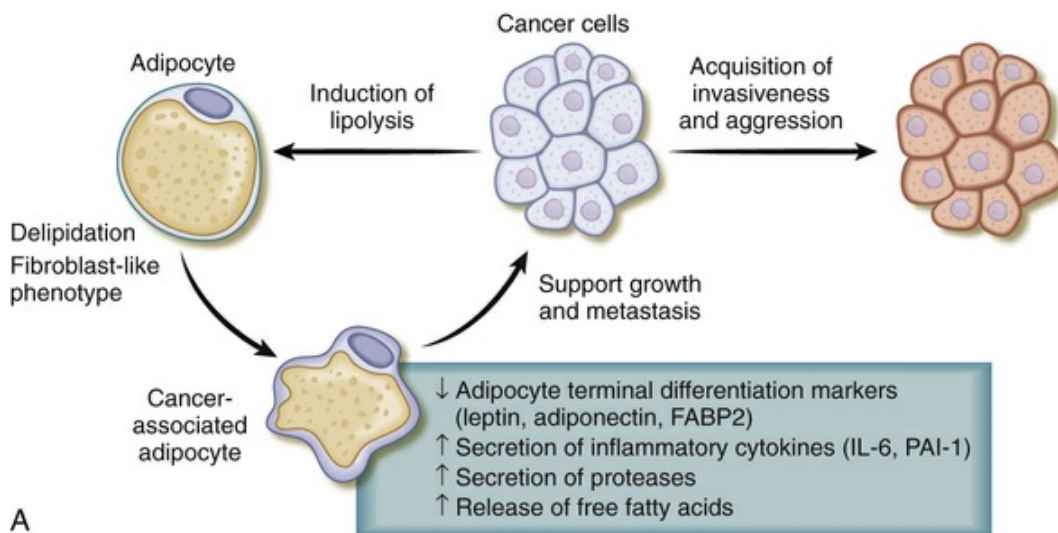

All conditions of hyperinsulinemia, both endogenous (prediabetes, metabolic syndrome, obesity, type 2 diabetes before pancreas exhaustion, and polycystic ovary syndrome) and exogenous (the requirement for exogenous insulin [type 1 diabetes]), will increase the risk of cancer. Cancer-related mortality is increased in individuals exposed to hyperinsulinemia; however, other factors related to different diseases also may contribute. Hyperinsulinemia is often associated with hyperglycemia. Cancer cells have an abnormal metabolism and, compared to normal cells, mainly rely on aerobic glycolysis for energy needed for accelerated growth (Warburg effect). To satisfy this increased energy requirement cancer cells need more sugar (“sugar fuels cancer”).

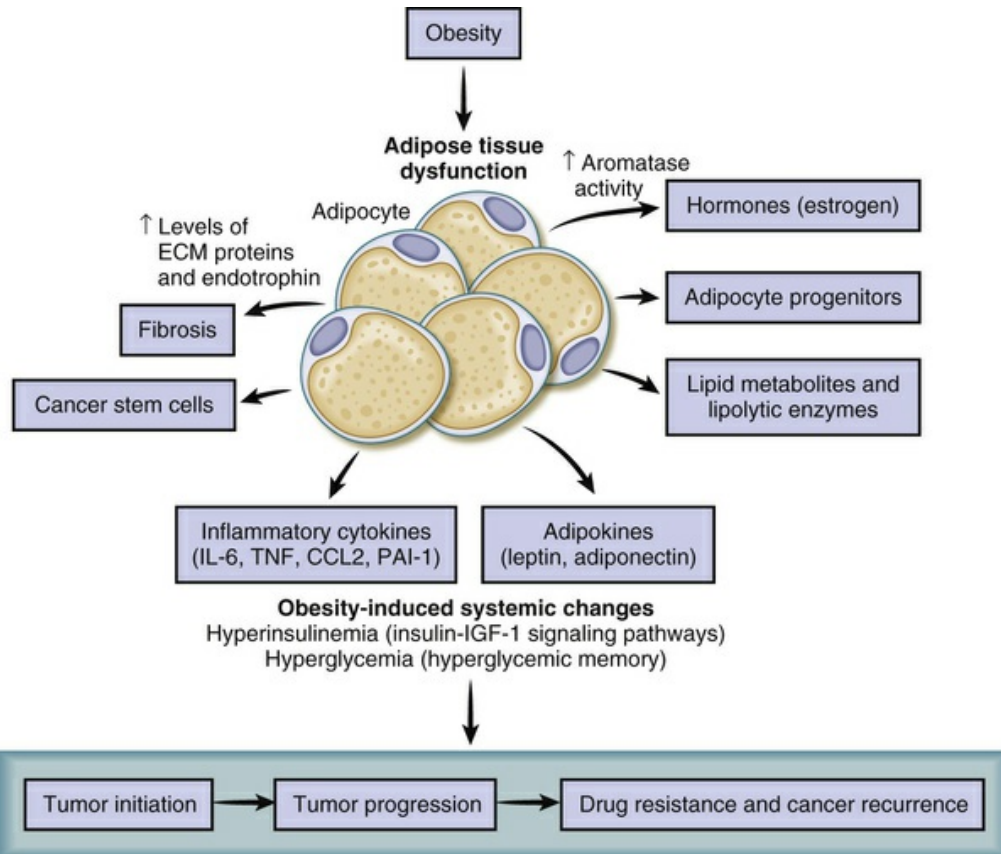

Currently, it is difficult to determine from human data if the diabetic state and which specific mechanism of diabetes may affect fructose absorption in humans. Dietary fructose intake has increased dramatically and recent studies suggest that glucose homeostasis and fructose absorption interact. Using mouse studies, investigators found fructose derived from sucrose facilitated lung metastasis from breast tumors through inflammation. Given the potential importance of fructose metabolism worldwide, more investigation into this subject is needed.

Data from Dotimas JR et al: *eLife* 5:e18313, 2016; Jiang Y et al: *Cancer Res* 76(1):24–29, 2016; Vigneri R, Goldfine ID, Frittitta L: *J Endocrinol Invest* 39(12):1365–1376, 2016.

Emerging is a newer focus also on the consequences of local adipose inflammation.^{104,105} Obesity-associated lipolysis releases saturated fatty acids that induce activation of macrophages and stimulate NF- κ B signaling. This signaling activates transcription of proinflammatory genes, including *cyclooxygenase-2*, IL-6, IL-1 β , and tumor necrosis

factor-alpha (TNF- α); altogether, the elevated levels of proinflammatory mediators cause both local and systemic effects.¹⁰⁴ With breast cancer, for example, the increased transcription of the *CYP19* gene encodes aromatase, an enzyme for estrogen synthesis.¹⁰⁴ Animal studies of pancreatic ductal adenocarcinoma reveal obesity is a *pro-desmoplastic* (insult leading to ECM alterations including dense, fibrosis changes) condition.¹⁰⁵ Obesity leads to adipocyte dysfunction and immune cell recruitment, leading to cytokine production, inflammation, and, ultimately, fibrosis and reduced response to chemotherapy.¹⁰⁵ Because tumor growth is regulated by interactions between tumor cells and their tissue microenvironment or stromal compartments that are rich in adipose tissue, adipocytes function as endocrine cells and critically shape the tumor microenvironment. Dysfunctional adipose tissue can create altered signaling pathways that involve proinflammatory mediators, macrophages, and cancer-associated fibroblasts. All of these cells are tumor-promoting cell types and, with insulin resistance and hypoxia, can trigger compensatory angiogenesis and an energy reservoir for the embedded cancer cells.¹⁰¹ The cancer-associated adipocytes (CAAs) undergo both structural and functional alterations during cancer progression that altogether create an environment toward increased cancer invasiveness and aggression¹⁰¹ (Fig. 13.12).

B

FIGURE 13.12 Structural and Functional Changes in Adipocytes and Interaction with the Microenvironment Contribute to Cancer Progression and Metastases: A Working Model. **A**, Signaling interactions occur between cancer cells and cancer-associated adipocytes. This interaction within the tumor microenvironment creates a place or *niche* permissive for cancer growth. Cancer cells stimulate the breakdown of lipids in adipocytes, leading to *delipidation* and the emergence of a fibroblast-like phenotype in adipocytes. The continuing alterations are associated with functional changes in the cells and include increased secretion of inflammatory mediators (cytokines) and proteases, and increased release of free fatty acids. All of these changes can support tumor growth and invasiveness. **B**, Obesity leads to excessive levels of proinflammatory cytokines, sex hormones, lipid metabolites, and altered adipokines. The altered adipose tissue becomes a source of various extracellular matrix proteins, cancer stem cells, and cancer-associated adipokines. Collectively these alterations contribute to tumor initiation, growth, and recurrence. The systemic metabolic changes of obesity—hyperinsulinemia and hyperglycemia—can further contribute to a tumor-permissive environment. *CCL2*, chemokine ligand 2; *ECM*, extracellular matrix; *FABP2*, fatty acid-binding protein 2; *IGF*, insulin-like growth factor; *IL*, interleukin; *TNF*, tumor necrosis factor. (Adapted from Park J et al: *Nat Rev Endocrinol* 10[8]:455–465, 2014.)

Adipose tissue can have greater effects on the physiology of other tissue (see [Chapter 23](#)). The metabolic function of adipose tissue is derived in part because it can secrete many proteins, collectively

called **adipokines**.¹⁰⁶ The adipokine leptin enhances the production of inflammatory factors and TNF- α .¹⁰⁰ These inflammatory factors also are modulated by sex hormones (e.g., estradiol and testosterone) and growth factors, especially vascular endothelial growth factor (VEGF). Importantly, increased adiposity is correlated with *lower* levels of adiponectin that normally induce apoptosis, thus increasing cell proliferation.¹⁰⁰ Lower levels of adiponectin also give rise to insulin resistance and to compensatory hyperinsulinemia. Adipokines have both proinflammatory and antiinflammatory activities and their balance can contribute to the initiation and progression of obesity-induced metabolic changes that can affect other organs (including the brain, heart, vasculature, liver, and muscle) and increase the risk of cancer, cardiovascular disease, and metabolic disturbances.¹⁰⁶

Studies have linked levels of circulating free hormones (e.g., estradiol) and hormonally driven cancers as an important mechanism (Chapters 22, 25, and 26 contain discussions on hormones and cancer risk). Obesity can increase aromatase expression, resulting in increased estradiol levels, which can promote the growth of estrogen-dependent cancers (e.g., breast and endometrial cancers).

Cancers have altered metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to convert glucose into CO₂ and energy (i.e., ATP). Even with adequate oxygen, cancer cells may not use OXPHOS, but are reprogrammed to glycolysis or the *Warburg effect* (see Chapter 12).

Recent studies reveal a link between glucose availability and protein acetylation, an epigenetic change.¹⁰⁷ Importantly, in the context of constant glucose levels, metabolite levels seem to oscillate in a circadian way within cells and tissues.¹⁰⁷ Food metabolism and circadian cycles are linked, and impairment of clock regulation (e.g., disrupted night sleep and light; shift work) results in dysregulated metabolism.¹⁰⁸ **Circadian rhythms** pervade mammalian biology (Fig. 13.13). They manifest and permeate temporal organization in behavioral, physiologic, cellular, and neuronal processes.^{109,110} This ancient timekeeper interacts with multiple cell systems, including signaling mechanisms, and the cell cycle, thus impacting disease.

Evidence is emerging that circadian mechanisms are linked to cell proliferation and its control at the DNA (epigenetic), RNA, and protein levels. Circadian disruption accelerates malignant growth.^{110,111} In addition to nutrient levels oscillating metabolically, circadian rhythms appear to affect detoxification cycles.^{108,110} Mutations in internal clock genes alter glucose and lipid metabolism and affect the function of the kidney.¹¹²

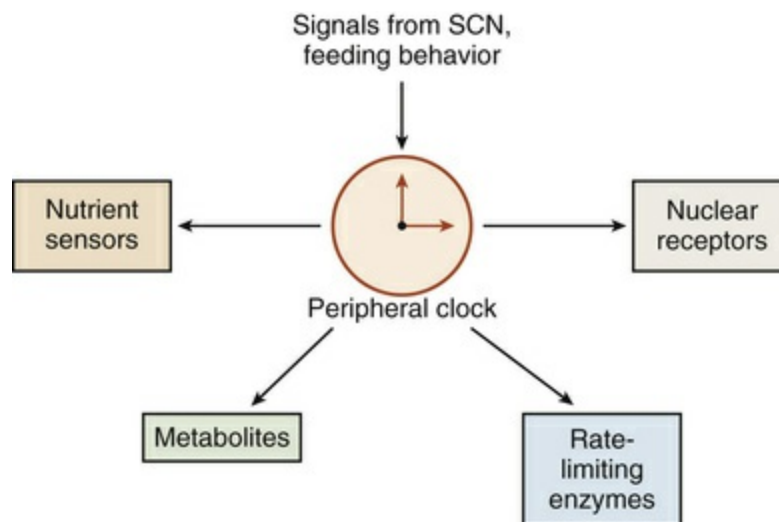

FIGURE 13.13 Regulation of Metabolism by the Circadian Clock. Peripheral clocks, such as that in the liver, are regulated by the master clock present in the suprachiasmatic nucleus (SCN). The liver clock can regulate multiple metabolic pathways by various mechanisms. These mechanisms include regulation of rate-limiting steps, control of metabolite levels, interaction of nutrient sensors, and modulation of nuclear sensors. (Adapted from Sahar S, Sassone-Corsi P: *Trends Endocrinol Metab* 23[1]:1–8, 2011.)

The survivorship literature is growing and data suggest that increasing BMI is related to less favorable outcomes for recurrence, survival, and comorbidities (e.g., cardiovascular disease, diabetes, wound healing).¹⁰⁰ Researchers have documented the development of obesity and diabetes mellitus in aging survivors of childhood cancer, as well as other endocrine disturbances.¹¹³

Alcohol Consumption

Alcohol is classified by the International Agency for Cancer Research

(IACR) as a human carcinogen. Alcohol plays a contributory role in several common cancers. Overall, there are convincing data that alcohol increases the risk of cancer of the mouth, pharynx, larynx, esophagus, liver, and pre- and postmenopausal breast cancer in women and colorectal cancer in men (possibly also in women) (Table 13.5).^{114,115} The evidence does not show any “safe limit” of intake, and the effect is from ethanol regardless of the type of drink.⁷⁷ Modifiable causes of premature death (before the age of 70) in middle-aged persons in Western Europe included smoking, poor diet, overweight and obesity, hypertension, physical inactivity, and excessive alcohol consumption.¹¹⁶

TABLE 13.5

ALCOHOLIC DRINKS AND RISK OF CANCER*

DECREASES RISK		INCREASES RISK		
EXPOSURE	CANCER SITE	EXPOSURE	CANCER SITE	
Convincing		Alcoholic drinks	Mouth, pharynx and larynx, esophagus Colorectum (men) [†] Breast (pre- and postmenopause)	
Probable		Alcoholic drinks	Liver [‡] Colorectum (women) [†]	
Limited – suggestive				
Substantial effect on risk unlikely	Alcoholic drinks (adverse effect): kidney [§]			

*In the judgment of the World Cancer Research Fund/American Institute for Cancer Research Panel, the factors listed modify the risk of cancer. Judgments are graded according to the strength of the evidence.

[†]The judgments for men and women are different because there are fewer data for women. Increased risk is only apparent above a threshold of 30 g/day of ethanol for both genders.

[‡]Cirrhosis is an essential precursor of liver cancer caused by alcohol. The International Agency for Research on Cancer has graded alcohol as a class 1 carcinogen for liver cancer. Alcohol alone only causes cirrhosis in the presence of

other factors.

§The evidence was sufficient to judge that alcoholic drinks are unlikely to have an adverse effect on the risk of kidney cancer; it was inadequate to draw a conclusion regarding the protective effect.

Adapted from World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR): *Second expert report: food, nutrition, physical activity, and the prevention of cancer: a global perspective*, London, 2007, Author.

Several factors contribute to alcohol-induced cancer development, including acetaldehyde, oxidative stress, and nutritional deficiencies, especially folate, a B vitamin (see [Chapter 2](#)). Variations in several genes modulate the risk of alcohol-induced carcinogenesis. New data suggest that the *ADH1B* gene *ARG47His* variant was associated with a decreased risk of esophageal cancer.¹¹⁷ Increasing evidence suggests aberrant patterns of DNA methylation are part of the alcohol-induced mechanisms of carcinogenesis.¹¹⁸ The molecular actions of ethanol are believed to include site-specific changes to histone modifications and alterations of one-carbon metabolism causing methylation changes.¹⁰⁷ MicroRNA expression has been linked to alcohol consumption in a case-controlled study of head and neck cancer (i.e., head and neck squamous cell carcinoma [HNSCC]).¹¹⁹ The risk may be modified by alcohol dehydrogenase genes.¹²⁰ Alcohol interacts with smoke, increasing the risk of malignant tumors including lung cancer, possibly by acting as a solvent for the carcinogenic chemicals in smoke products.

Physical Activity

Studies suggest that regular exercise decreases the risk of breast cancer, colon cancer, and endometrial cancer, independent of weight changes. The World Cancer Research Fund summarized the effects as *convincing* for cancers of the colorectal and *probable* for postmenopausal breast cancer and endometrial cancer^{77,121} ([Table 13.6](#)). Annual deaths attributable to physical inactivity are reported between 3.2 and 5.3 million deaths per year.^{122,123} Investigators confirm irrefutable evidence of the effectiveness of regular physical activity in the primary and secondary prevention of several chronic diseases,

including cardiovascular disease, hypertension, diabetes, cancer, obesity, depression, osteoporosis, and premature death.¹²⁴

TABLE 13.6

PHYSICAL ACTIVITY AND RISK OF CANCER*†

	DECREASES RISK	INCREASES RISK
Convincing	Colon‡	
Probable	Breast (postmenopausal) Endometrium	
Limited—suggestive	Lung Pancreas Breast (premenopausal)	
Substantial effect on risk unlikely	None identified	

*In the judgment of the World Cancer Research Fund/American Institute for Cancer Research Panel, physical activity† modifies the risk of the cancers. Judgments are graded according to the strength of the evidence.

†Physical activity of all types: occupational, household, transport, and recreational.

‡Much of the evidence grouped colon cancer and rectal cancer is together categorized as “colorectal cancer.” The Panel judges that the evidence is stronger for colon cancer than for rectal cancer.

Adapted from World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR): *Second expert report: food, nutrition, physical activity, and the prevention of cancer: a global perspective*, London, 2007, Author.

Several biologic mechanisms suggest physical activity may protect against cancers of the breast and endometrium, by decreasing insulin and IGF levels, decreasing obesity, altering inflammatory mediators, decreasing oncogenes, decreasing levels of circulating sex hormones and metabolic hormones, improving immune function, and enhancing cytochrome P-450 activity, thus modifying carcinogen activation. A new mechanism from exercise is the release of **myokines** or proteins from contracting muscles and their antitumor effects (see [What's New? Exercise and Anticancer Effects of Myokines](#)).

What's New?

Exercise and Anticancer Effects of Myokines

A newer, exercise-induced anticancer mechanism in contracting muscle fibers (from exercise) releases proteins called *myokines* into the bloodstream, which have beneficial effects, such as increasing insulin sensitivity on many systems. Additionally, myokines can induce apoptosis in breast cancer and colon cancer cells. Other investigators found antitumorigenic effects of another myokine, IL-6, from working muscles and epinephrine from the adrenal glands that result in increased mobilization of NK cells that migrate into tumors and destroy tumor cells.

Anticancer Effects of Exercise-Induced Myokines. Exercise and contracting muscle fibers release myokines into the bloodstream, which can induce apoptosis in breast and colon cancer cells. In mouse models, investigators Pedersen and colleagues show antitumor effects from myokine IL-6, which is elevated after exercise. IL-6 and epinephrine released from the adrenal gland move to the bloodstream and result in increased mobilization of natural killer (NK) lymphocytes, which migrate into tumors and destroy tumor cells.

Adapted from Lucia A, Ramirez M: *NEJM* 375(9):892–894, 2016; Pedersen L et al: *Cell Metab* 23:554–562, 2016.

A randomized trial found that, after 12 months of moderate-intensity exercise, postmenopausal women had significantly decreased levels of serum estrogens.¹²⁵ A new study from national and international researchers, including those from the National Cancer Institute (NCI), National Institutes of Health (NIH), and American Cancer Society (ACS), of the relationship between physical activity and cancer has shown that greater levels of leisure-time physical activity were associated with a lower risk of developing 13 different types of cancer. The risk of developing 7 cancer types was 20% (or more) lower among the most active participants (90th percentile of activity) as compared with the least active participants (10th percentile of activity). Leisure-time physical activity was associated with a lower risk of colon, breast, endometrial, esophageal (adenocarcinoma), liver, kidney, and cancer of the gastric cardia and myeloid leukemia.¹²⁶ This study also showed physical activity reduced risks of heart disease and risk of death from all causes.

Many questions are unanswered regarding frequency, intensity, and duration of exercise. The World Health Organization (WHO) recommends at least 600 metabolic equivalent (MET) minutes of total activity per week for benefits; this is about 150 minutes/week of brisk walking or 75 minutes/week of running.¹²⁷ A recent review and dose-response meta-analysis, however, found 3000 to 4000 MET minutes/week is strongly associated with a lower risk of breast cancer, colon cancer, diabetes, ischemic heart disease, and ischemic stroke.¹²⁸ Several reports suggest that physical activity after a cancer diagnosis is associated with better cancer-specific sequelae and improved overall survival time with early-stage breast, prostate, and colorectal cancers.¹⁰⁰ Further research is needed on cancer outcomes and physical activity.

Air Pollution

Research reviews done by the U.S. Environmental Protection Agency, WHO, and others show that long-term exposure to ambient air pollution increases mortality and morbidity and shortens life expectancy from cardiovascular, respiratory disease, and lung cancer¹²⁹ (Table 13.7). The 2015 Global Burden of Diseases, Injuries, and Risk Factors Study identified air pollution as a leading cause of global disease burden, particularly in low-income and middle-income countries.¹²⁹ Long-term exposure to fine particle air pollution (PM_{2.5}) caused 4.2 million deaths and 103.1 million lost years of healthy life in 2015, making it the 5th ranked global risk factor in 2015 or 7.6% of total global mortality¹²⁹ (Fig. 13.14). An additional 254,000 deaths were linked to exposure to ozone.¹²⁹ The risk factor rank for deaths for the top 10 countries attributable to ambient particulate matter pollution include China (1), India (2), Russia (3), Pakistan (4), Bangladesh (5), United States of America (6), Indonesia (7), Japan (8), Brazil (9), and Nigeria (10).¹²⁹ Household air pollution from solid fuel use was responsible for 2.8 million deaths and 85.6 million disability-adjusted life-years, or DALYs, in 2015.¹²⁹

TABLE 13.7

GLOBAL DEATHS, DISABILITY-ADJUSTED LIFE-YEARS, AND AGE-STANDARDIZED RATES ATTRIBUTABLE TO AMBIENT PARTICULATE MATTER POLLUTION IN 2015

FIGURE 13.14 Particle Sizes and Pollution. (From Environmental Protection Agency: *Particulate matter updated March 18, 2013*, Washington, DC, 2013, Author.)

Outdoor air pollution is a complex mixture of many known carcinogens and has been studied for over 50 years on its relationship to lung cancer.¹³⁰ High levels of particulate-based smog can cause dramatic increases in daily mortality.^{131,132} The Harvard Six Cities Study published in 1993 revealed that air pollution was positively associated with death from lung cancer and cardiopulmonary disease.¹³³ **Particulate matter**, also known as *particle pollution*, is a mixture of extremely small particles and liquid droplets. Particle pollution is made up of a complex mix of acids (such as nitrates and sulfates), organic chemicals, metals, and soil or dust particles. The International Agency for Research on Cancer (IARC) concluded that exposure to outdoor air pollution and to particulate matter (PM) in outdoor air is carcinogenic to humans (IARC Group 1) and causes lung cancer.^{134,135} Specifically, focused reviews of lung cancer risk are with prominent components of PM in outdoor air (PM_{2.5} particles with aerodynamic diameter $\leq 2.5 \mu\text{m}$, or fine particles and PM₁₀ [$\leq 10 \mu\text{m}$, or inhalable particles]) (see Fig. 13.14). The major components of PM are transition metals, ions (sulfate, nitrate), radicals of carbonaceous material, organic compound, minerals, reactive gases, and other materials of biologic origin.¹³⁶ The mechanisms of adverse cellular

effects of PM include (1) cytotoxicity through oxidative stress, (2) ROS generation, (3) DNA oxidative damage, (4), mutagenicity, (5) stimulation of proinflammatory factors, and (6) induction of senescence.^{136,137}

Fine or ultrafine particles are easily absorbed by the lungs and phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators. *Acute* exposure to diesel exhaust that contains fine particles is linked to lung, throat, and eye irritations; asthma attacks; and myocardial ischemia.¹³⁸ From three decades of epidemiologic research, diesel exhaust was classified as a carcinogen in humans by the IARC in 2012, based on results from two recent studies of occupational diesel exhaust exposures among nonmetal miners^{139,140} and truck drivers^{141,142} (Fig. 13.15). Importantly, from the WHO, diesel exhaust is carcinogenic and causes lung cancer.¹⁴³ Perhaps similar to cigarette smoking where it took time to understand that it causes cancer of numerous other sites (see Fig. 13.4), diesel exhaust will be studied for its role to other cancer sites including urinary bladder, larynx, and colon.¹⁴⁴ Critical questions are urgent, including how much of the carcinogenicity of air pollution is related to diesel exhaust and its specific role in cardiovascular disease.¹⁴² The central hypothesis, based on rat studies, for the mechanisms related to particle-induced lung carcinogenesis is that insoluble particles cause pulmonary inflammation (e.g., cytokine release, ROS) which leads to oxidative stress and oxidation of DNA, proliferative response, and tissue remodeling progressing toward fibrosis and tumor development.

FIGURE 13.15 Exhaust Particulate Matter. Diesel exhaust is carcinogenic and causes lung cancer. (From Science Photo Laboratory.)

Living close to certain industries is a recognized cancer risk factor.¹⁴⁵ Overall, fine particle pollution also is linked to other health problems and includes (1) premature death in people with heart or lung disease, (2) nonfatal heart attacks, (3) irregular heartbeat, (4) aggravated asthma, (5) decreased lung function, and (6) respiratory symptoms including irritation of the airways, coughing, and shortness of breath. Additionally, other effects of particle pollution include reduced visibility (haze); environmental damage in lakes and streams, coastal waters, and river basins; depletion of nutrients in soil; and damage to forests and food crops.¹⁴⁶

Indoor pollution generally is considered worse than outdoor pollution, partly because of cigarette smoke (Fig. 13.16). Environmental tobacco smoke (ETS; passive smoking) can cause the formation of reactive oxygen free radicals and thus DNA damage. The IARC has classified ETS as a human carcinogen. In China, some regions report very high levels of lung cancer in women who spend much of their time indoors. Exposures from heating and cooking combustion sources (e.g., oil vapors, volatile toxicants) are identified

as risk factors for lung cancer.^{147,148} In addition, domestic coal use and ETS increase the risk of lung cancer in women and men.¹⁴⁹

WHAT'S IN THE AIR INDOORS?

Particulate matter is a mixture of very small solids and liquid droplets that float in the air. Some particles come from a specific source (such as a burning candle), while others form as a result of complicated chemical reactions.

Most Americans spend about **90%** of their time indoors.¹

While much is known about the health effects of exposure to particulate matter outdoors, the effects of indoor exposure are less well-understood. However, indoor exposure to particulate matter is gaining attention as a potential source of adverse health effects.

The National Academies of Sciences, Engineering, and Medicine recently convened a workshop to examine the issues.

WHAT ARE SOME SOURCES OF PARTICULATE MATTER INDOORS?

outdoor sources that enter indoors through heating, ventilation, and air conditioning systems; open doors and windows; and leakage through walls and roofs²

airborne allergens and bacteria in outdoor air and that come from people and their pets and plants indoors²

emissions from food as it's cooking³

candles, incense, wood burning³

cleaning activities like dusting, vacuuming, and ironing³

cigarettes, e-cigarettes, and other smoking materials⁴

desktop laser printers and 3-D printers⁵

gas and electric ranges and stoves⁵

mold that grows on indoor surfaces⁶

chemical reactions between elements in the air and materials inside of buildings⁷

HOW BIG IS PARTICULATE MATTER, AND WHY IS THE SIZE A CONSIDERATION?

PARTICULATE MATTER IS TYPICALLY CLASSIFIED INTO THREE SIZE CATEGORIES:

- Coarse particles are 2.5 to 10 micrometers in diameter (a strand of human hair is 60-120 micrometers wide⁸).
- Fine particles are 2.5 micrometers in diameter or smaller.
- Ultrafine particles are 100 nanometers (0.1 micrometers) or smaller.

Fine and ultrafine particles may be small enough to pass through the throat and nose and enter deeper into the body.⁷

WHAT ARE THE POTENTIAL HEALTH EFFECTS?

A body of epidemiologic research has shown associations between short-term and long-term exposures to particulate matter and a broad array of respiratory and cardiovascular effects.⁹ Results from scientific studies are converging to indicate that exposures both to fine and ultrafine particles may produce such adverse effects.⁸ The size and shape of inhaled particles influence where and how much mass will be deposited in various regions of the respiratory system.⁹

WHAT ARE SOME WAYS OF ALTERING THE LEVELS OF PARTICULATE MATTER INDOORS?

The source of indoor particulate matter may be affected by:

- limiting indoor smoking^{3,10}
- using a correctly installed range hood when cooking^{3,10}
- avoiding burning candles and incense³
- performing regular surface cleaning¹⁰

Ventilation may reduce the levels of particulate matter generated indoors, but it increases the amount of outdoor-generated particulate matter that comes inside.¹⁰

Filtration may lower the concentrations of particulate matter in indoor air.^{3,10}

FIGURE 13.16 What's in the Air Indoors. (From Science Photo Library.)

Another significant indoor air pollutant is radon gas. **Radon** is a natural radioactive gas derived from the radioactive decay of uranium that is ubiquitous in rock and soil; it can become trapped in houses and gives rise to radioactive decay products known to be carcinogenic to humans. The most hazardous houses can be identified by testing and then can be modified to prevent further radon contamination. Exposure levels are greater from underground mines than from houses. Most of the lung cancers associated with radon are bronchogenic; however, small cell carcinoma does occur with greater frequency in underground miners. Radon increases the risk of lung cancer in underground miners whether they smoke or not.

Ionizing Radiation

Much of the knowledge of the effects of ionizing radiation (IR) on human cancer has stemmed from observations of the Hiroshima and Nagasaki atomic bomb (A-bomb) exposures, particularly the Life Span Study. These data provide estimates of human cancer risk over the dose range from 20 to 250 centigray (cGy) for low linear energy transfer (LET) radiation, such as x-rays or γ -rays. Other evidence is derived from groups exposed for medical reasons, underground miners exposed to radon gas, and other occupational exposures (Table 13.8). The atomic bomb exposures in Japan caused acute leukemias in adults and children and increased frequencies of thyroid and breast carcinomas. Lung, stomach, colon, esophageal, and urinary tract cancers and multiple myeloma have been added to the list. At Nagasaki and Hiroshima, leukemia incidence in individuals 15 years or younger reached its peak 6 to 7 years after the explosions and has steadily declined since 1952. People 45 years and older at the time of exposure had a latent period of 20 years before developing acute leukemia.

Data from Jones JA, Casey RC, Karouia F: Ionizing radiation as a carcinogen. In McQueen E, editor: *CA comprehensive toxicology*, ed 2, St Louis, 2010, Elsevier.

Age at the time of radiation exposure is one of the important factors in radiation-induced cancer. Recently, standard models and evaluations of age of exposure to radiation and radiation-induced cancer risks have been questioned.¹⁵⁰⁻¹⁵³ Epidemiologic data from Japanese atomic bomb survivors and from children exposed to radiation for medical intervention suggest that excess relative risks (ERRs) for radiation-induced cancers at a given age are exceptionally higher for individuals exposed during childhood than for those exposed at older ages.¹⁵⁴ These data also are published by the International Commission on Radiological Protection (ICRP) and the National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation (BEIR Committee).¹⁵⁵ What is at question is the ERRs of radiation exposure in adulthood and radiation-induced cancer risk. Recent analyses of Japanese bomb survivors suggest that the ERR for cancer induction decreases with increasing age at exposure only until exposure ages of 30 to 40 years; with radiation exposure at older ages, the ERR does not decrease further and for many individual cancer sites (liver, colon, lung, stomach, and bladder) the ERR may actually increase in all solid cancers combined.^{151,153,154,156}

These new data present a challenge to the conceptual understanding of the mechanisms of cancer induction.¹⁵³ Biologic models of cancer development all predict that ERRs should decrease continuously with increasing age of radiation exposure. Recent models, however, of radiation carcinogenesis show IR acts not only as an initiator of premalignant cell clones but also as a promoter of preexisting premalignant cell alterations.^{151,153,156} Promotion is used here to mean the process by which an initiated cell clonally expands. Therefore promotional processes from radiation can result in increasing excess lifetime cancer risks with increasing age at exposure. From these new data, investigators propose that radiation-induced cancer risks after exposure in middle age may be almost twice as high as previously estimated.¹⁵³

Human exposure to IR includes emissions from the environment (e.g., radon), x-rays, computed tomography (CT) scans, radioisotopes, and other radioactive sources (Fig. 13.17). Health risks involve not only neoplastic diseases but also cardiovascular disease and stroke following high doses in therapeutic medicine and lower doses in A-bomb survivors (BEIR VII).^{155,157} Late effects of radiation in A-bomb survivors show persistent elevations in the levels of inflammatory markers, implying immunologic damage may be the cause of later cardiovascular effects.¹⁵⁸ Investigators for the first time using a model of umbilical vein endothelial cells showed that low doses (0.05 Gy) of x-rays induce DNA damage and apoptosis in endothelial cells. These data will need continued research.¹⁵⁹ Cardiac and blood vessel damage may manifest years after completion of radiation therapy (Box 13.2).¹⁶⁰

Potential Radioprotective Effects of Nanoformulation of Curcumin, Green Tea, and Grape Seed Extracts

Investigators using an irradiated THP-1 macrophage model treated irradiated macrophages with a nanoformulation of curcumin (DNC). The curcumin suppressed IR-induced oxidative damage, inflammation, and foam cell formation in macrophages through multiple mechanisms. Another group of investigators studied the radioprotective effects of green tea extract (GTE) and grape seed

extract (GSE) on radiation-induced immune suppression in rats. The level of proinflammatory cytokines significantly decreased by the GTE and GSE mixture. These results indicate the possible role of these compounds as radioprotectors that may be used as an adjuvant during radiotherapy. These findings need more research.

IR, Ionizing radiation; *THP-1*, is a human monocytic leukemia cell line.

Data from El-Desouky W, Hanafi A, Abbas MM: *Int J Radiat Biol* 94(4):433-439, 2017; Soltani B et al: *Int J Radiat Biol* 93(3):303-314, 2017.

Exposure to ionizing radiation induces apoptosis and senescence. Less is known about senescence. In vitro studies suggest endothelial cell senescence can lead to endothelial dysfunction by altering vasodilation and hemostasis, induction of oxidative stress and inflammation, and inhibition of angiogenesis.¹⁶¹ The underlying biology of radiation-induced cardiovascular disease is poorly described; however, investigators report the role of the 5-lipoxygenase/leukotriene pathway as a possible therapeutic target.¹⁶² Chronic inflammation is increasingly implicated in radiation-induced late tissue injury.¹⁶³ Other risks from IR include somatic mutations and tissue alterations that may contribute to other diseases (e.g., respiratory diseases, birth defects, and eye maladies) and, from animal studies, inherited mutations that may affect the incidence of diseases in future generations. Exposure to relatively low doses of ionizing radiation may be harmful to the lens of the eye and increase risk of cataract formation.¹⁶⁴⁻¹⁶⁶ Conclusions from low dose cohorts suggest an elevated risk of posterior subcapsular cataract (PSC) as well as cortical cataracts.¹⁶⁶ The human embryo and fetus are particularly sensitive to ionizing radiation; the health consequences of exposure even at doses too low to immediately affect the mother can be severe.¹⁶⁷ The consequences include growth retardation, malformations, impaired brain function, and cancer.¹⁶⁷ An important summary point in BEIR VII¹⁵⁵ is the concern from medical exposure, for example, CT. The National Council on Radiation Protection and Measurements reported

in 2006 that Americans were exposed to more than 7 times as much IR from medical procedures compared to their exposure in the 1980s¹⁶⁸ (Fig. 13.18). The increase in imaging is likely driven by several factors, including improvements in the technology, that have led to increased clinical applications, patient demand, physician demand, defensive medical practices, and medical uncertainty.^{169,170} A major concern is the cumulative exposure doses of repetitive tests and the inappropriate utilization of these imaging techniques.

MEDIAN EFFECTIVE RADIATION DOSE FOR EACH TYPE OF CT STUDY			
ANATOMIC AREA, STUDY TYPE	MEDIAN (mSv)	RANGE (mSv)	DOSE EQUIVALENT (NO. OF CHEST X-RAYS)
Head and Neck			
Routine head	2	0.3-6	30
Routine neck	4	0.7-9	55
Suspected stroke	14	4-56	199
Chest			
Chest, no contrast	8	2-24	117
Chest, with contrast	8	2-19	119
Suspected pulmonary embolus	10	2-30	137
Coronary angiogram	22	7-39	309
Abdomen-Pelvis			
Routine abdomen-pelvis, no contrast	15	3-43	220
Routine abdomen-pelvis, with contrast	16	4-45	234
Multiphase abdomen pelvis	31	6-90	442
Suspected aneurysm or dissection	24	4-68	347

FIGURE 13.18 CT Scans in the United States. National Council Radiation Protection estimates that 67 million CT scans (compared to 3 million in 1980), 18 million nuclear medicine procedures, and 17 million interventional fluoroscopy procedures were performed in the United States in 2006. (From NCRP: 2009 *Ionizing radiation exposure of the population of the United States*, NCRP Report No. 160, Bethesda, MD, Author.)

Evidence, usually epidemiologic, shows cancer associated with exposure to IR (see [Table 13.8](#)). Evidence includes animal models and in vitro studies as well as exposed groups including atomic/nuclear survivors, survivors of industrial accidents and the Techa River basin in Siberia, and medical diagnostic/therapeutic data. The studies of exposed groups are large enough to allow epidemiologists to derive detail concerning the dose and quality, age at exposure, and other factors on cancer incidence in a large variety of organs.¹⁷¹ From data collected over several decades, exposed cohorts reveal that IR is a potent carcinogen.¹⁷¹ Additionally, reports of occupational exposures may have increased the incidence of certain types of cancer, for example, underground miners and lung cancer.¹⁷² Certain medical conditions, especially those with a genetic basis, predispose individuals to ionizing radiation–induced injury.¹⁷¹ The most well-known condition is ataxia-telangiectasia (AT), a rare (1 in 300,000 people) condition in which individuals have a strong sensitivity to IR. Individuals with *BRCA1/BRCA2* pathway mutations have increased radiosensitivity caused by insufficient DNA repair and cell cycle control mechanisms.¹⁷³

Investigations conducted jointly by the U.S. Air Force and NASA from 1963 to 1969 studied the relative biologic effectiveness (RBE) of different types of radiation exposures on rhesus monkeys and mice.¹⁷¹ Long-term follow-up studies of the exposed animals showed an induction of solid tumors and leukemia, and the extent of life shortening depended on dose and not on proton energy level.¹⁷⁴ The general characteristics of radiation carcinogenesis were determined from studies done after World War II, mainly from rats and mice.¹⁷¹ However, together with epidemiologic studies of humans, these animal studies elucidated radiation carcinogenesis.¹⁷⁵ The BEIR VII report that focused on low-level radiation determined that the radiation-induced life shortening observed in mice is reflective in

humans of radiation-induced cancer mortality.¹⁷⁶ These studies are important because they show that IR is universally carcinogenic to animals and humans and that there are wide differences in radiation responses according to species, organ, and radiation distribution.¹⁷¹

The universal nature of radiation as a carcinogen relates to its ability to penetrate cells and deposit energy in tissues at random. By the 1980s, using *in vitro* models, the *general* characteristics of IR-induced carcinogenesis were well established.¹⁷⁷ The past two decades have focused on *specific* cellular and molecular mechanisms that relate to the induction of cancer, including dose-response relationships for chromosome aberrations, cell transformation, gene expression (genetic and epigenetic), alternative targets, mutagenesis in somatic cells, and the biologic effects that occur in nonirradiated cells (i.e., **nontargeted effects** [NTEs]) and effects on the microenvironment.¹⁷¹ Through much of the twentieth century, radiobiology was thought to be a relatively simple science and was dominated by physicists. Now, with biologists entering the field, it has become apparent that radiobiology is not so simple and involves much more understanding beyond a DNA-centric model, including alternative targets, such as membranes, repair, and rescue within a biologic system.¹⁷⁸ Because models and underlying assumptions are incomplete, investigators are working hard to understand induced repair, adaptive responses, hormesis, low-dose hypersensitivity, nontargeted effects, microenvironment, immune landscape, signaling, exosomes, and long-term persistence of radiation damage and clonal heterogeneity.^{178,179}

Oncogenes and Tumor-Suppressor Genes

Part of the biologic response of radiation-induced cancer is oncogene activation. Although evidence suggests that interindividual differences in radiation responses may be attributed to certain genes, IR can activate oncogenes, resulting in uncontrolled cell growth¹⁷¹ (see [Chapter 12](#)). Tumor-suppressor genes also are sensitive to IR. Several tumor-suppressor genes have been identified that are deactivated by IR that promotes carcinogenesis.¹⁷¹ Recent research has shown that cells can detect and respond epigenetically, altering gene expression

after low doses of radiation.¹⁷¹ Gene expression can change as a function of radiation dose and radiation type.¹⁷¹

Chromosomal Aberrations

IR is a mutagen and carcinogen; it can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations (e.g., removal of an electron from the target atom). Importantly, arising from IR is the localized release of large amounts of energy that can break a chemical bond (electron volts [eV] is the energy per ionizing event). Damage from IR can occur either *directly* from biologic macromolecules (e.g., DNA) or *indirectly*, in the medium from which organelles are suspended in mostly water, and *irreversibly* from ionizations that can attack by water-based free radicals (e.g., H•, OH•) [radiolysis].¹⁸⁰ Electromagnetic radiations, such as x-rays and γ -rays, damage by reactive species produced by ionizations elsewhere in the cell and thus have indirect action. The biologic effects of indirect action include cell killing (days), mutation (generation), and carcinogenesis (years). IR affects many cell processes, including gene expression, mitochondrial function disruption, cell cycle arrest, and cell death. IR is a potent DNA-damaging agent, causing cross-linking, nucleotide base damage, and single- and double-strand breaks (SSBs and DSBs, respectively) (Fig. 13.19). Damage to DNA and disrupted cellular regulation processes can lead to carcinogenesis.¹⁸¹⁻¹⁸³ The **double-strand break (DSB)** is considered the important lesion in the induction of both chromosomal abnormalities and gene mutations (Fig. 13.20). Persistent disturbance by oxidative metabolism can cause DSBs long after exposure to radiation.¹⁸⁴ The misrepair of DSBs could lead to substantial chromosomal instability.¹⁸⁵ The nonhomologous end-joining (NHEJ) pathway plays a dominant role in repair of DSBs.¹⁸⁶ Another pathway is by homologous recombination (HR); for example, *BRCA1* and *BRCA2* are tumor-suppressor genes and one of their functions is DNA repair by HR.^{187,188} These two mechanisms of DSB repair act at different phases of the cell cycle. Irradiated human cells unable to execute the NHEJ pathway are supersensitive to the introduction of large-scale mutations and chromosomal aberrations.¹⁸⁰

FIGURE 13.19 Free Radicals. Free radicals formed by water nearby and around DNA cause indirect effects. These effects have a short life of single free radicals. Oxygen can modify the reaction, enabling longer lifetimes of oxidative free radicals.

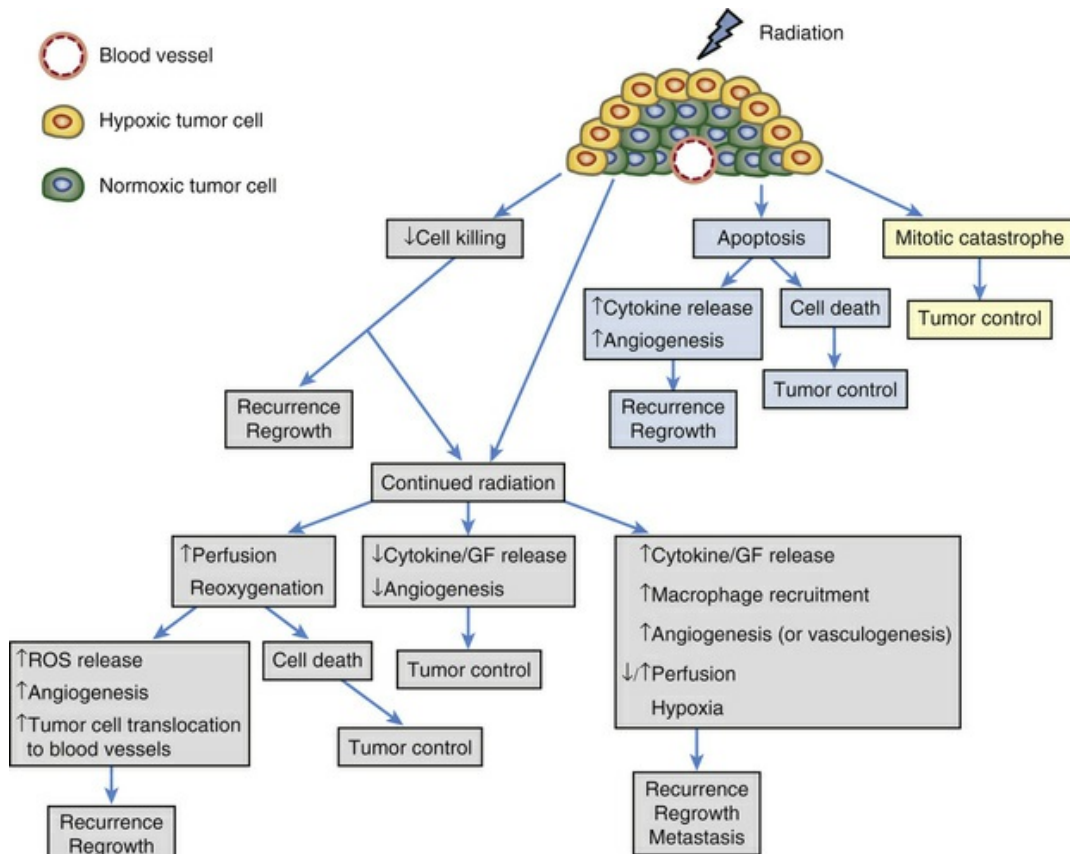

FIGURE 13.20 Simplified Model of the Effects of Radiation on Tumor Microenvironment. Tumor cells that are not hypoxic cells (i.e., called *normoxic*) are more sensitive to radiation and hence more susceptible to

cell death (apoptosis) and mitotic catastrophe or destruction. In some cases, however, proapoptotic mechanisms can cause the release of cytokines that promote tumor regrowth and recurrence. Hypoxic cells are resistant to radiation therapy and more likely lead to tumor recurrence. Continuous radiation (especially fractionated) can lead to reoxygenation, which can improve radiation-induced cell killing or promote release of reactive oxygen species (ROS) and angiogenesis and/or induce tumor cell movement to blood vessels; both mechanisms can result in tumor regrowth and recurrence. Decreased cytokine production and destruction of blood vessels from continued administration of high doses of radiation can increase tumor cell killing. In certain situations, however, irradiation is associated with the production of an aggressive phenotype of the remaining cells that survive radiation therapy. This failure is caused by the release of protective cytokines and/or growth factors (GFs), the recruitment of macrophages, altered perfusion of blood, and hypoxia that increase angiogenesis or blood vessel growth, resulting in tumor regrowth and recurrence and/or metastasis. Importantly, the effects of radiation on tumor microenvironment depend on many factors. (Adapted from Fokas E, McKenna WG, Muschel RJ: *Cancer Metastasis Rev* 31[3–4]:823–842, 2012.)

Cell Transformation

Cell transformation describes the total changes associated with loss of normal homeostatic control.¹⁷¹ The majority of studies on cell transformation in vitro have been quantitative, using rodent-derived models. Few human-derived assays have been conducted. Overall, the exposure to high-LET radiation results in a higher transformation frequency than exposure to low-LET radiation.¹⁷¹ There is no tendency, however, for the response per unit dose to decrease at low doses or low dose rates, and a number of studies have shown an enhanced effect.¹⁷¹

Nontargeted Effects

A long-held assumption is that cellular alterations—mutations and malignant transformation—occur only in cells directly radiated. There is clear evidence indicating that cells not directly traversed by a radiation particle, but in the vicinity of a cell that has been exposed to or received signals from irradiated cells, can participate in the damage response.¹⁸⁹ The **DNA damage response (DDR)** is a coordinated series of events that allows DNA damage detection, signaling that includes cell cycle checkpoint activation, and repair.^{190,191} Emerging and

important data indicate that the DDR should be considered not only at the DNA level but also in the chromatin of cell nuclei where DNA envelopes histone proteins.¹⁹² Additionally, the importance of the plasticity of the microenvironment is becoming integrated into the radiation response.

It is now known that cells not directly exposed to radiation, but instead the progeny of cells that were irradiated many cell divisions previously, may express a high level of gene mutations, cell lethality, and chromosomal aberration. Altogether these effects are called **genomic instability**. Genomic instability can initiate cancer, increase cancer progression, and affect the prognosis.¹⁹³ Therapeutic targeting of genomic instability and antitumor responses includes lifestyle, diet, and nutrition to inhibit proliferative signaling, decrease oncogenic metabolism, and block inflammation.¹⁹³ Multiple, complex genetic pathways, such as DNA damage repair, oxidative stress, and cell cycle control, may contribute to the development of radiation- and chemotherapy-related second primary cancers, supporting a polygenic model for sensitivity to treatment-related cancers.¹⁹⁴ The directly irradiated cells also can lead to genetic effects in so-called *bystander cells* or *innocent cells* (called **bystander effects**) even though they themselves received no direct radiation exposure.¹⁸⁹ The bystander and genomic instability effects also have been termed *nontargeted effects* (NTEs).

The vast majority of bystander effects have been described in cell culture systems. However, investigators, using an in vivo mouse model, found an unexpected enhancement of medulloblastoma in the cerebellum of radiosensitive *Patched-1* (*Ptch*) heterozygous mice after radiation exposure to their bodies.¹⁹⁵ The bystander effect has been demonstrated in three-dimensional human tissues¹⁹⁶ and in other whole animal organisms.^{197,198} Bystander effects can be induced through cellular communication between irradiated cells and nonirradiated cells. The signals that mediate this cellular communication include cytokines, ROS and nitric oxide (oxidative stress), and even microRNAs that can be transferred between cells through gap junctions (gap junctional intercellular communication

[GJIC]) or extracellular medium. A newer process under investigation is *exosome-mediated microRNA transfer*.¹⁹⁹ Numerous intercellular and intracellular signaling pathways are implicated in the bystander response and these effects have been shown to be transmitted to their descendants.

Acute, Latent, and Microenvironmental Effects

IR causes acute and persistent short- and long-term effects.²⁰⁰⁻²⁰² Acute exposure to IR can cause damage to several organ systems, especially those with highly proliferative cells, such as the hematopoietic system, the skin, and the gastrointestinal system²⁰³ (see [Chapter 2](#)). Investigators have postulated that radiation's carcinogenic potential persists because of nontargeted radiation effects that alter cell and tissue signaling and change the microenvironment.^{204,205} [Fig. 13.20](#) provides a simplified model of the effects of radiation on tumor microenvironment. Increasing evidence shows that radiotherapy leads to alterations in the tumor microenvironment, especially for cells of the immune system.²⁰⁶⁻²⁰⁸ Radiotherapy is a treatment for cancer and, with improvement in cancer survival, the long-term risks of a second cancer and other disorders (e.g., atherosclerotic risk factors, stroke) from treatment become more important.^{209,210}

Radiation-induced cancer in humans has latent periods, usually 5 to 10 years, but can be decades.^{171,211} British investigators reported the following results: for solid cancers, radiation-related excess risk starts to appear about 5 years after exposure in therapeutically irradiated groups; and for leukemia, it starts to appear within 5 years of exposure.²¹² Using U.S. Surveillance Epidemiology and End Results (SEER) data, the estimated excess of second cancers that could be related to radiotherapy is about 8%; data from the United Kingdom, which included diagnostic procedures and excluded therapeutic irradiation, yielded an estimation of 15%.^{209,212}

Low Dose and Dose Rate

New studies on low doses of radiation have resulted in three

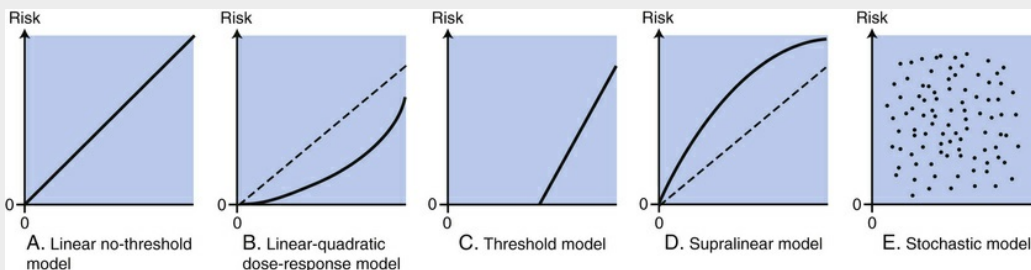

paradigm shifts: (1) bystander effects have been observed in which nonhit cells may respond as well as hit cells; (2) radiation-induced changes in gene expression at very low radiation doses alter response pathways, some of which appear to involve adaptive or protective responses; and (3) early changes in the initiation phase of radiation-induced cancer were thought to be induced by gene mutation and chromosomal aberrations only; however, it is now understood that genomic instability that leads to the loss of genetic control may have a role in the development of cancer.¹⁸⁶ Constant debate involves risk estimates for human exposure at low-dose, low-LET ionizing radiation (0 to 100 mSv or less than 0.1 Gy). Much uncertainty exists about the risks of leukemia and lymphoma after repeated or protracted low-dose radiation typical of exposures from occupational, environmental, and diagnostic settings.²¹³ The first and most striking late effect of radiation exposure from the Life Span Study (Hiroshima and Nagasaki atomic bomb survivors) was a marked increase in leukemia risks. Although the leukemia excess risks generally declined with attained age or time since exposure, the radiation-associated excess leukemia risk, especially for acute myeloid leukemia, persisted through the follow-up period to 55 years after the bombings. There was a weak suggestion of a radiation dose response for nonHodgkin lymphoma among men and no indication of an effect for women. There was no evidence of radiation-associated excess risks for either Hodgkin lymphoma or multiple myeloma.²¹⁴ The INWORKS International Cohort Study provides strong evidence of positive associations between protracted low-dose radiation exposure and leukemia.²¹³ Investigators report an association between the background level of terrestrial γ -radiation in the United Kingdom and the risk of developing acute lymphocytic leukemia (ALL) in children.²¹⁵ Investigators report a linear correlation between estimated bone marrow dose from a head CT scan in children and the risk of developing ALL.²¹⁶ The risks of low doses of radiation are controversial and the uncertainties associated with the best estimates are great.²¹⁷ Theoretical models to understand low-dose radiation are presented in [Box 13.3](#). The risk of neoplastic transformation in

bystander cells remains unclear.

Box 13.3

Theoretic Models to Understand Low-Dose Radiation

Several models include the linear no-threshold (LNT) relationship, in which any dose, including very low doses, has the potential to cause mutations (see **A**). Another model, the linear-quadratic relationship, proposes there is a risk mathematical term that is directly proportional to the dose (linear term) and another term proportional to the square of the dose (quadratic term) (see **B**). The threshold model proposes a threshold dose below which radiation may not cause cancer in humans (see **C**). Proponents of this model argue that such thresholds are derived, for example, from the ability to repair damage caused by lower doses of radiation. There is some evidence that low doses may actually produce a higher level of risk per unit of dose, which is called the *supralinear hypothesis* (see **D**). **E**, Stochastic or random probability is a major model for understanding low-dose radiation. Currently, the shape of the response curve for the low-dose region is really unknown.

Theoretic Models for Estimating Risk of Low-Dose Ionizing Radiation. Collective population dose is expressed as a person-rem (roentgen equivalent, man). Estimating a collective dose then enables an application of a “constant risk factor” to obtain a statistical estimate of the number of additional cancers (above background radiation) from that exposure. These computations apply to low doses—low dose rates only (**A**). Many propose the best fit is the linear no-threshold (LNT) model (**B**). The most common alternative to the LNT model is the linear-quadratic model. The quadratic term is the square of the dose. The linear term is

equal to zero (C). The threshold model is a threshold below which there is *no* increase in cancer risk. Proponents of this model argue that because some toxic chemicals/materials exhibit such thresholds, radiation must also have a threshold. Their arguments are related to repair of the radiation damage caused by lower doses of radiation (D). Some evidence exists that low levels of radiation produce a higher level of risk per unit dose, which is called the *supralinear model*. The stochastic model is where effects are random and the events cannot be predicted (E). (Adapted from Makhijani A, Smith B, Thorne MC: Takoma Park, MD, 2006, Institute for Energy and Environmental Research.)

Ultraviolet Radiation

Ultraviolet radiation (UV radiation) comes from sunlight and is produced in specialized lights, including tanning lamps, black lights, and mercury-vapor lamps. The most preventable cause of skin cancer is exposure to ultraviolet (UV) light either from the sun or from artificial sources, such as tanning beds.²¹⁸ Individuals who tan poorly, whose skin freckles, or who burn easily after sun exposure are most susceptible to developing skin cancer.²¹⁹ UV radiation is divided into three major wavelengths: UVA, UVB, and UVC radiation. Most of the UV radiation received on earth is UVA and some UVB.²²⁰ UVA radiation is weaker than UVB, but UVA penetrates deeper into the skin and is more constant throughout the year despite the weather.²²⁰ UVB affects the outer layer of the skin, and UVC radiation does not increase health risks as much as UVB.²²⁰ UV radiation also can be important to health and produces vitamin D that helps in the absorption of calcium and phosphorus from food, both of which are important for bone development. Food sources of vitamin D include some types of fish, foods with added vitamin D, juices, dairy products, and egg yolks.²²¹ More importantly, continued time in the sun will increase skin cancer risk.²²¹ Prolonged human exposure to solar UV radiation can result in acute and chronic health effects on the skin, eye, and immune system.²²² Organ transplant recipients receiving immunosuppressive drugs have an increased risk of skin

cancer, particularly squamous cell carcinoma (SCC). Arsenic exposure increases the risk of cutaneous SCC.²¹⁹

There are three main types of skin cancer: (1) cancer that forms in melanocytes (pigment cells) derived from the neural crest, called **melanoma**; (2) cancer in the lower part of the epidermis or outer layer of the skin, called **basal cell carcinoma (BCC)**; and (3) cancer in the flat cells that form the surface of the skin, called **squamous cell carcinoma (SCC)** (see [Chapter 47](#)). Solid evidence shows sun and UV radiation exposure are associated with an increased risk of BCC and SCC.²¹⁹ Melanoma, the most lethal form of skin cancer, can occur on any skin surface and also may arise from mucosal surfaces or other sites from which neural crest cells migrate, including the uveal (intraocular) tract; however, in men it is often found on the skin on the head, the neck, between the shoulders, and on the hips. In women it is more commonly found on the skin on the lower legs, between the shoulders, and on the hips. Although rare in people with dark skin, melanoma is usually found under the fingernails, under the toenails, on the palms of the hands, or on the soles of the feet.²²³ Based on fair evidence, *intermittent acute* sun exposure leading to sunburn is associated with an increased risk of melanoma.²¹⁹ Melanomas on sun-exposed skin are heterogeneous tumors and can be classified on the basis of their cumulative levels of exposure to UV radiation. Basal cell carcinoma commonly occurs on the head and neck. Squamous cell carcinoma is found more commonly in men who work outdoors, but can occur in anyone. SCC occurs on sun-exposed areas of the skin including the nose, ears, lower lip, and dorsa of the hand. SCCs are composed of keratinizing cells and are more aggressive than BCC, but the development into invasive SCC is low.²²⁴ The pathogenesis of nonmelanoma skin cancers involves specific gene mutations, DNA methylation and histone modifications, oxidative stress, inflammation, and reduced immune surveillance. For a more complete discussion about these skin cancers, see [Chapter 47](#).

Skin cancer is the most common malignancy diagnosed in the United States. The actual number of nonmelanoma skin cancers is difficult to estimate because they are not reported to cancer registries.

In 2016 an estimated 76,380 cases of melanoma will be diagnosed and 10,100 will die from the disease. Although melanoma accounts for about 1% of all skin cancer cases, it is responsible for substantial morbidity and the vast majority of deaths.²²⁵ Because mortality rates have not risen as rapidly, however, controversy exists as to whether the incidence increase is a true increase in clinically significant melanoma or is a result of overdiagnosis.²²⁶ The U.S. Preventive Services Task Force (USPSTF) concludes that the current evidence is insufficient for early detection of skin cancer and the balance of benefit and harms of visual skin examination by a clinician to screen for skin cancer in asymptomatic adults cannot be determined.²²⁷ A major harm is overdiagnosis and overtreatment (see [Chapter 47](#)).

Death rates varied by race and ethnicity with white men and women more likely to die of melanoma than any other group.²²⁸ Risk factors vary for different types of skin cancer but, in general, the risk factors include a lighter natural skin color; a family history of skin cancer; a personal history of skin cancer; exposure to the sun through work and play; a history of sunburns, especially early in life; a history of indoor tanning; skin that burns, freckles, reddens easily, or becomes painful in the sun; blue or green eyes; blonde or red hair; and certain types of moles and a large number of moles.²²⁸ Higher coffee intake was associated with a modest decrease in risk of melanoma in a large U.S. cohort study.²²⁹

Electromagnetic Radiation

Electromagnetic radiation (EM or EMR) is energy in the form of transverse magnetic and electric waves. Health risks associated with EM are very controversial and have been a concern since at least the 1950s. The early concerns were with radar and other radio and microwave sources.²³⁰ The biologic effects of nonionizing radiation have been difficult to establish, particularly the effects of long-term low-level exposures. A recent emphasis has arisen from the potential effects of low-intensity fields; intermediate radiofrequency (RF); and higher-frequency radiation from devices, such as phones, broadcast antennas, Wi-Fi, security monitors, and others.²³⁰ Exposure to electric

and magnetic fields is widespread. Electric fields are shielded or weakened by walls and other objects; however, magnetic fields are not.²³¹ Electromagnetic fields (EMFs) are, for example, generated by RF sources coupled with the body and result in induced electric and magnetic fields with associated currents inside tissue.²³² The most common sources of **radiofrequency electromagnetic radiation (RF-EMR)** are wireless telecommunication devices and equipment, including cell phones and smart meters, and portable wireless devices, such as laptop computers and tablets.²³¹ Other common sources also include radio and television signals, radar, satellite stations, magnetic resonance imaging (MRI) devices, microwave ovens, cordless phones, television and computer screens, and wireless local area networks (Wi-Fi).²³¹ From household appliances that require electricity, magnetic fields are highest near the source and decrease rapidly with distance.

The major debate for more than five decades has focused on the association of exposure to EMR and resultant health consequences, including cancer. A critical question is how EMR exposure could lead to tumor development or progression, or both. Scientific evidence is accumulating although hampered by the availability of methods to accurately measure exposure, the lack of a clear dose-response relationship, and the difficulty in reproducing effects. In addition, with competing priorities such as convenience, financial interest, and health necessity, a consensus of the risk/benefit ratio of EMR exposure may be difficult to achieve, and safety standards significantly vary, up to 1000 times among countries.^{233,234} In 1998, the National Institute of Environmental Health Sciences Electric and Magnetic Fields Working Group²³⁵ recommended that low-frequency electromagnetic fields (EMFs) be classified as possible carcinogens. The possibility of a causal effect between low levels of low-frequency EMF and cancer led to the classification of EMF by the World Health Organizations International Agency for Research on Cancer (IARC) as a possible cause of cancer.^{236,237}

The National Institute of Environmental Health Sciences is conducting a large-scale study on rodents exposed to radiofrequency

energy (cell phone type). Preliminary results were released in May 2016 and the findings were reviewed by expert peer reviewers selected by the National Toxicology Program (NTP) and the National Institutes of Health (NIH).²³⁸ These studies are the largest and most complex ever conducted by the NTP. For the studies, rats and mice were exposed to frequencies and modulations currently used in cellular communication in the United States. They were exposed for 10-minute on and 10-minute off increments, totaling more than 9 hours a day from birth through 2 years of age. NTP found low incidences of glioma in the brains and schwannomas of the heart of male rats but not in female rats. Studies in mice are continuing. These studies are very important but are limited in that (1) they are done in rats and not humans, (2) the rats were exposed to large amounts of radiation that may not be the same exposures as humans, (3) some of the rats that developed tumors lived longer than control group rats, and (4) the full analysis of the data is ongoing. Replication of these studies is required.

Overall, there is limited evidence that magnetic fields cause childhood leukemia²³¹ (see [Chapter 14](#)). Studies of magnetic field exposure from power lines and electric blankets in adults reveal little evidence of an association with leukemia, brain tumors, or breast cancer.²³¹

Most exposure to EMF from occupational sources comes from near-field sources; the highest exposure to the general population comes from transmitters close to the body, such as hand-held devices like mobile telephones.²³² Epidemiologic evidence for an association between EMF and cancer has been derived from case-control, cohort, and time-trend studies. The most extensively studied exposure is from use of wireless telephones (mobile and cordless); other exposures include occupational settings and sources from the general environment²³² (also see [Chapter 14](#)). The pooled analyses from the INTERPHONE study included 2708 glioma cases and 2972 controls.²³⁹ The odds ratios (ORs) in terms of time spent on the phone showed that the highest time spent on the phone (>1640 hours of use) was related to glioma risk (OR 1.40; 95% confidence interval [CI] 1.03–

1.89). There was a suggestion of increased risk of tumors on the same side of the head as the phone use (ipsilateral exposure) in the temporal lobe, where radiofrequency (RF) EMF exposure is highest.²³² The OR for glioma increased with increasing RF dose for exposure 7 years or more before diagnosis, and there was no association with estimated dose for exposure less than 7 years before diagnosis.²³² A Swedish investigative group performed a pooled analysis of two similar studies between the relationship of glioma, acoustic neuroma, and meningioma manifestation and mobile and cordless phone use.²⁴⁰ Study participants who used a mobile phone for more than 1 year had an OR for glioma of 1.3 (95% CI 1.1–1.6). The OR increased with increasing time since first use and with total call time, 3.2 (2.0–5.1) for more than 2000 hours of use.²³² Ipsilateral use of the phone was associated with higher risk.²³² Similar findings were reported for cordless phones.²³² Although the INTERPHONE and Swedish studies were judged susceptible to bias, the Working Group concluded that the findings could not be dismissed because of bias alone and a causal relationship between phones and glioma is possible.²³² The Working Group also reviewed numerous studies' endpoints relevant to mechanisms of carcinogenicity from RF-EMF.²³² The mechanisms included genotoxicity, effects on immune function, gene and protein expression, cell signaling, oxidative stress, and apoptosis. Studies with large magnetic fields, 1 mT or greater, have shown that magnetic fields can change chemical reaction rates and free radical concentrations.²³⁰ ROS, such as superoxide O_2^- , and nitrogen radicals, such as NO, are both signaling molecules and can attack bacteria and other microorganisms. NO is released by neutrophils and is involved in the activation of macrophages. Additionally, a very large number of molecules are affected by magnetic fields from a free radical mechanism for phosphorylation in many biologic signaling systems and promotion of different biologic processes.²⁴¹ Investigators reported that reductions of the Earth's magnetic field inhibited growth of fibrosarcoma HT1080 cells.²⁴² A working hypothesis is that weak magnetic fields change the rate of recombination for radical pairs that are generated by the metabolic activity in cells and this changes the

concentration of radicals, such as O_2^- and H_2O_2 . The overall effects include generation of antioxidants and activation of the immune system; however, long-term exposure to elevated magnetic fields may lead to increased radical concentrations, which are associated with aging, cancers, and Alzheimer disease.²³⁰ Oxidative stress can activate many transcription factors leading to the expression of genes, including those for growth factors, inflammatory cytokines, chemokines, cell cycle regulators, and antiinflammatory molecules.²⁴³ Although research results are inconsistent, an additional mechanism from exposure to magnetic fields may be decreased production of melatonin.

Concern is for children in whom the effects may be compounded because of increased vulnerability to radiation and their longer use of cell phones into adulthood. In response to the NTP study discussed earlier, the American Academy of Pediatrics issued specific recommendations to reduce wireless cell phone exposure (Box 13.4). Ongoing unbiased research is desperately needed. Chapter 14 discusses cancer in children.

Box 13.4

Cell Phone Radiation and Children's Health: What Parents Need to Know

- Use text messaging when possible and use cell phones in speaker mode or with the use of hands-free kits
- When talking on the cell phone, try holding it an inch or more away from the head
- Make only short or essential calls on cell phones
- Avoid carrying the phone against the body like in a pocket, sock, or bra; cell phone manufacturers cannot guarantee that the amount of radiation absorbed will be at a safe level
- Do not talk on the phone or text while driving; this increases the risk of automobile crashes

Exercise caution when using a phone or texting while walking for performing other activities; “distracted walking” injuries also are on the rise

If planning to watch a movie on the device, download it first, then switch to airplane mode while watching it to avoid unnecessary radiation exposure

Keep an eye on signal strength (i.e., number of bars); the weaker the cell signal, the harder the phone has to work and the more radiation it gives off; it is better to wait until there is a stronger signal before using the device

Avoid making calls in cars, elevators, trains, and buses; the cell phone works harder to get a signal through metal so the power level increases

Remember that cell phones are not toys or teething items

Data from American Academy of Pediatrics June 13, 2016. <http://www.healthychildren.org>.

Infection, Sexual and Reproductive Behavior, Human Papillomaviruses

Infections with certain viruses, bacteria, and parasites are an important contributor to cancer worldwide. Of the 14 million new cancer cases in 2012, 2.2 million (15.4%) were attributable to carcinogenic infections²⁴⁴ (Table 13.9). Infection and cancer rates vary widely between countries and level of socioeconomic development; the higher the development, the lower the attributable fraction (AF) for infection. However, some highly developed countries continue to show a large burden of infection-attributable cancer because of the long interval between infection and cancer development.²⁴⁴ In less-developed countries, infections account for about one in four cancers. The AFs for infection varied from less than 5% in the United States, Canada, Australia, New Zealand, and some countries in western and northern Europe to more than 50% in some countries in sub-Saharan Africa.²⁴⁴ The most significant infections worldwide together accounting for 92% of all infection-attributable cancers were

Helicobacter pylori (*H. pylori* [770,000 cases]), human papillomavirus (640,000), hepatitis B virus (HBV [420,000]), hepatitis C virus (HCV [170,000]), and Epstein-Barr virus (EBV [120,000]). *H. pylori* was the most significant infectious cause of cancer in countries with high and very high development. Liver cancers attributable to HBV and HCV varied greatly with indices of the human development index (HDI). HBV was more significant than HCV as a cause of liver cancer in low-HDI and medium-HDI countries, and the opposite was true in countries with high and very high HDI because of early spread of HCV in some countries with very high HDI and the decreasing prevalence of HBV with increasing HDI.²⁴⁴

TABLE 13.9

NUMBER OF NEW CANCER CASES IN 2012 ATTRIBUTABLE TO INFECTION, BY INFECTIOUS AGENT

	NUMBER OF NEW CASES*	PROPORTION OF NEW CASES ATTRIBUTABLE TO EACH INFECTIOUS AGENT (%)	NUMBER OF NEW CASES ATTRIBUTABLE TO INFECTION BY SEX			NUMBER OF NEW CASES ATTRIBUTABLE TO INFECTION BY AGE GROUP		
			MALES	FEMALES	<50 YEARS	50–69 YEARS	+70 YEARS	
<i>Helicobacter pylori</i>	770,000	35.4	500,000	270,000	91,000	340,000	330,000	
Human papillomavirus	640,000	29.5	66,000	570,000	270,000	280,000	90,000	
Hepatitis B virus	420,000	19.2	300,000	120,000	84,000	190,000	140,000	
Hepatitis C virus	170,000	7.8	110,000	55,000	26,000	76,000	66,000	
Epstein-Barr virus	120,000	5.5	80,000	40,000	61,000	44,000	14,000	
Human herpesvirus type B	44,000	2.0	29,000	15,000	32,000	7,600	4,500	
<i>Schistosoma haematobium</i>	7,000	0.3	4,900	2,200	1,300	3,700	2,100	
Human T-cell lymphotropic virus, type 1	3,000	0.1	1,700	1,200	630	1,200	1,200	
<i>Opisthorchis</i>	1,300	0.1	820	470	130	670	490	

<i>viverrini</i> or <i>Clonorchis</i> <i>sinensis</i>							
All infectious agents	2,200,000	100.0	1,100,000	1,100,000	570,000	950,000	650,

*Numbers are rounded to two significant digits.

Data from Plummer M et al: *Lancet Global Health* 4:e609–e616, 2016.

HPV caused more than half of the total infection-attributable cancers in women worldwide.²⁴⁴ In low-HDI countries, HPV accounted for half of infection-attributable cancers in both sexes combined. Increased rates of cervical cancer resulted from poor screening and treatment of precancerous lesions combined with high prevalence of HPV and HIV infections.²⁴⁵ It has been estimated that *H. pylori* accounts for about 75% of all stomach cancers.²⁴⁶ Epstein-Barr virus (EBV) is associated with a subset of Hodgkin lymphoma, a subset of diffuse large B-cell lymphoma (DLBCL); Burkitt lymphoma; EBV-associated malignant B-cell lymphoma; age-related EBV-positive B-lymphoproliferative diseases (LPDs) that pathologically range from reactive hyperplasia to monomorphous lymphoma; EBV-associated T-/NK-cell LPDs; nasopharyngeal carcinoma; and gastric adenocarcinoma.²⁴⁷ Human herpesvirus type 8 (HHV-8) accounted for about 2% of infection-attributable cancers worldwide and is associated with Kaposi sarcoma, a major public health concern in Africa. Human T-cell lymphotropic virus type 1 (HTLV-1) is associated with adult T-cell leukemia-lymphoma (ATL).

Human papillomavirus (HPV) is the most common sexually transmitted virus in the United States. HPV is extremely common worldwide.²⁴⁸ About 14 million people become infected with HPV each year and about 79 million Americans are currently infected with HPV.²⁴⁹ Most sexually active women and men will be infected at some point in their lives and some are infected repeatedly.²⁴⁸ HPVs are a group of more than 200 related viruses of which at least 13 are cancer causing.²⁴⁸ HPV is mainly transmitted through sexual contact and most people are infected with HPV shortly after the onset of sexual activity. *High-risk*, or oncogenic, HPVs (types 16 and 18) cause about

70% of cervical cancers and precancerous cervical lesions.²⁴⁸ HPV has been linked with cancers of the anus, vulva, vagina, and penis. *Low-risk HPVs* do not cause cancer but can cause skin warts, called *condylomata acuminata*. Most high-risk HPV infections occur without any symptoms, may cause cytologic abnormalities or abnormal cell changes that disappear within 1 to 2 years, and do not cause cancer.²⁵⁰ Persistence of infection with high-risk HPV is a prerequisite for the development of cervical intraepithelial neoplasia (CIN) (see Fig. 25.19), lesions, and invasive cervical cancers.²⁵¹ HPV can cause anal cancer, with about 85% of all cases caused by HPV-16.²⁵⁰ HPV types 16 and 18 also have been found to be responsible for almost half of vaginal, vulvar, and penile cancers.²⁵² Investigators from prospective cohort studies have confirmed that infection with HPV-16 precedes by several years the diagnosis of oropharyngeal cancer (OPC).²⁵³ HPV infections have been found to cause cancer of the oropharynx (most commonly base of the tongue, tonsils, and pharynx).²⁵⁰ More than half of the oropharyngeal cancers diagnosed in the United States are linked to HPV-16.²⁵⁴ The incidence of HPV-associated oropharyngeal cancer has increased during the past 20 years, especially among men, and it has been estimated that by 2020 HPV will cause more oropharyngeal cancers than cervical cancers in the United States.²⁵⁵ Persistent chronic inflammation-related HPV infection might drive oropharyngeal carcinogenesis, and myeloid-derived suppressor cells (MDSCs [e.g., VEGF, GM-CSF, IL-1]) may play a role in this development because they facilitate tumor-induced immune suppression.²⁵⁶ Factors that may increase the risk of developing cancer following a high-risk HPV infection include smoking, decreased immunity, having many children (for increased risk of cervical cancer), long-term oral contraceptive use (for increased risk of cervical cancer), poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.²⁵⁷

HPVs infect epithelial cells that cover the inside and outside surfaces of the body, including the skin, throat, genital tract, and anus. HPV types can easily be spread through direct sexual contact.²⁵⁰ Vertical transmission also is possible in utero and during vaginal birth

(see [Chapter 27](#)). Once an HPV virus enters an epithelial cell, the virus begins to make proteins that can interfere with normal functions in the cell, enabling the cell to grow in an uncontrolled manner, and to avoid apoptosis.²⁵⁰ These infected cells are often recognized by the immune system and eliminated. Sometimes, however, infected cells are not destroyed and a persistent infection results. As the persistently infected cells continue to grow, they may develop mutations that promote even more cell growth, leading to the formation of a high-grade lesion and, ultimately, a tumor.²⁵⁰ Investigators believe that it can take between 10 and 20 years from the time of an initial HPV infection until tumor formation. However, even high-grade lesions do not always lead to cancer²⁵⁰ (see *What's New?* HPV Vaccine in [Chapter 27](#)).

Other Viruses and Microorganisms

A discussion of the relationship between viruses, bacteria, and cancer is contained in [Chapter 12](#) and appropriate chapters in Part Two. Other microorganisms involved in carcinogenesis include parasites such as *Opisthorchis viverrini* and *Schistosoma haematobium*. Their specific roles in carcinogenesis are thought to be related to cofactors or carcinogens, or both. Some viruses, bacteria, and parasites can cause chronic inflammation.

Chemicals and Occupational Hazards as Carcinogens

An estimated 100,000 synthetic chemicals are used in the United States;²⁵⁸ however, a full set of basic toxicity information is available for only about 7% of these chemicals.²⁵⁹ Another 1000 chemicals are added each year.²⁶⁰ The list of chemicals has, therefore, expanded greatly, and other cancer risks related to the workplace now include ergonomic (e.g., sedentary), organizational (e.g., shift work), and biologic factors (e.g., infectious agents, endocrine disruptors). Exposure to chemicals occurs every day—they are present in air, soil,

food, water, household products, toys, personal care products, workplaces, and homes. The number of known carcinogens in experimental animals is large. It is suspected that most of these chemical carcinogens are potentially carcinogenic in humans but documentation is lacking. An extensive list of potential occupational carcinogens is published by NIOSH and is available at <https://www.cdc.gov/niosh/topics/cancer/npotocca.html>. Table 13.1 provides a summary of a limited number of chemicals according to sufficient or limited evidence by IARC in humans by cancer site. A simplified overview of Occupational Safety and Health (OSH)-relevant carcinogenic factors is presented in Table 13.10.

TABLE 13.10

OVERVIEW OF OSH-RELEVANT CARCINOGENIC FACTORS

GROUP	EXAMPLE
Chemicals	
Gases	Vinyl chloride Formaldehyde
Liquids, volatile	Trichloroethylene Tetrachloroethylene Methylchloride Styrene Benzene Xylene
Liquids, nonvolatile	Metalworking fluids Mineral oils Hair dyes
Solids, dust	Silica Wood dust Talc containing asbestiform fibers
Solids, fibers	Asbestos Man-made mineral fibers, for example, ceramic fibers
Solids	Lead Nickel compounds Chromium VI compounds Arsenic Beryllium Cadmium

	Carbon black Bitumen
Fumes, smoke	Welding fumes Diesel emissions Coal tar fumes Bitumen fumes Fire, combustion emissions PAHs Tobacco smoke
Mixtures	Solvents
Pesticides	
Halogenated organic compounds	DDT Ethylene dibromide
Others	Amitrole
Pharmaceuticals	
Antineoplastic drugs	MOPP (Mustargen, oncovin, procarbazine, and prednisone, a combination chemotherapy regimen used to treat Hodgkin disease) and other combined chemotherapy, including alkylating agents
Anesthetics	There is evidence from in vitro experiments that isoflurane increases cancer cells' potential to grow and migrate
Emerging Factors	
Air pollution and fine particulate matter	Emissions from motor vehicles, industrial processes, power generation, and other sources polluting the ambient air
Endocrine-disrupting compounds	Certain pesticides Certain flame retardants
Biologic Factors	
Bacteria	<i>Helicobacter pylori</i>
Viruses	Hepatitis B Hepatitis C
Mycotoxin-producing fungi	Bulk handling of agricultural foodstuffs (nuts, grain, maize, coffee), animal-feed production, brewing/malting, waste management, composting, food production, working with indoor molds, horticulture
<i>Aspergillus flavus</i> , <i>A. parasiticus</i>	Aflatoxin (A1)
<i>Penicillium griseofulvum</i>	Griseofulvin (IARC group 2B)
<i>A. ochraceus</i> , <i>A. carbonarius</i> , <i>P. verrucosum</i>	Ochratoxin A (group 2B)
<i>A. versicolor</i> , <i>Emericella nidulans</i> , <i>Chaetomium</i>	Sterigmatocystin (group 2B)

<i>spp., A. flavus, A. parasiticus</i>	
<i>Fusarium spp.</i>	Fumonisin B1 (group 2B)
Physical Factors	
Ionizing radiation	Radon X-rays
Ultraviolet radiation (UVR)	Solar radiation Artificial UVR
Ergonomics	Sedentary work
Other	
Work organization	Shift work that involves circadian disruption Static work Prolonged sitting and standing
Lifestyle factors	Stress-related obesity, smoking, drinking, drug consumption
Combinations of Various Factors	
Chemicals and radiation	Methoxsalen and UVA radiation Some chemicals, called <i>promoters</i> , can increase the cancer-causing ability of UVR. Conversely, UVR can act as a promoter and increase the cancer-causing ability of some chemicals, particularly coal tar and pitch.
Work organization and chemicals	Shift work and solvents

DDT, Dichlorodiphenyltrichloroethane; *IARC*, International Agency for Research on Cancer; *PAHs*, polycyclic aromatic hydrocarbons; *UVA*, ultraviolet A.

Data from European Agency for Safety and Health at Work: *Exposure to carcinogens and work-related cancer: a review of assessment methods European Risk Observatory Report*, Luxembourg, 2014, European Agency for Safety and Health at Work Eu-OSHA. <http://europa.eu>.

Chemical carcinogenesis involves genotoxic mechanisms and nongenotoxic mechanisms (Fig. 13.21). The nongenotoxic mechanisms include inflammation, immunosuppression, oxidative stress (ROS), receptor activation, and epigenetic silencing.²⁶¹⁻²⁶³ According to the director of the National Institute of Environmental Health Sciences, "...exposure to gene-altering substances, particularly in the womb and shortly after birth, can lead to increased susceptibility to disease. There is a huge potential impact from these exposures, partly because the changes may be inherited across generations."²⁶⁴

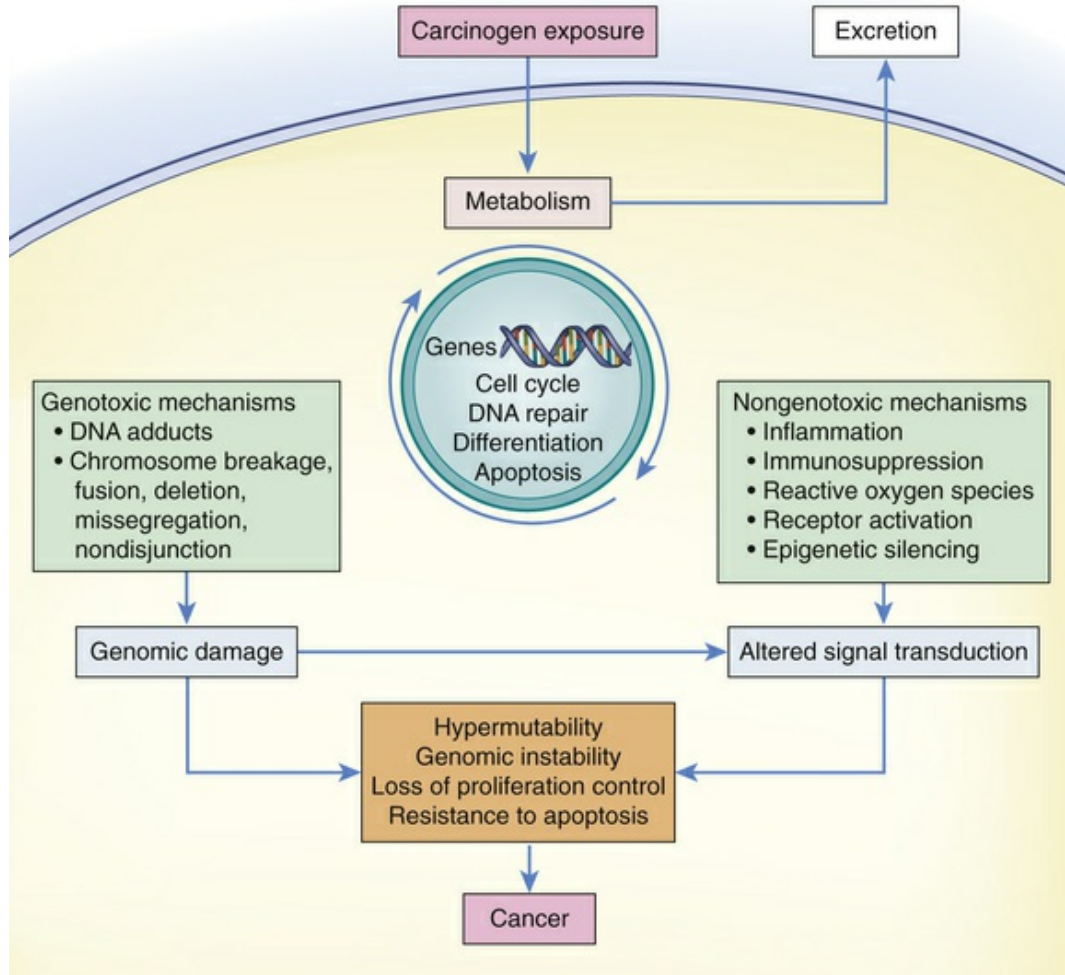

FIGURE 13.21 Mechanisms of Chemical Carcinogenesis. Cellular internalization of chemical carcinogens results in metabolic products that are either excreted or retained by the cell. Within the cell, carcinogens or their metabolic products can directly or indirectly affect the regulation and expression of genes involved in cell cycle control, DNA repair, cell differentiation, or apoptosis. Some chemical carcinogens act by *genotoxic* mechanisms, such as DNA adducts, chromosomal breakage, fusion, deletion, missegregation, and nondisjunction. Other carcinogens act by *nongenotoxic* mechanisms, such as induction of inflammation, immunosuppression, formation of reactive oxygen species (oxidative stress), activation of receptors, and epigenetic mechanisms, such as silencing. Both genotoxic and nongenotoxic mechanisms can alter signal-transduction pathways that result in many features of cancer cells. (Adapted from Luch A: *Nat Rev Cancer* 5:113–125, 2005.)

Millions of U.S. workers are exposed to substances tested as carcinogens in animal studies or possibly found to be carcinogenic in human studies.²⁶⁵ Shift work that involves circadian disruption and sedentary work have recently been identified as possible contributing

factors to the development of work-related cancer.²⁶⁶ Additionally, emerging from animal studies is that specific nonionizing radiation may be linked to human cancer risks.²³⁸ Work-related stress may indirectly lead to cancers because coping strategies can include smoking, alcohol use, drug intake, and excessive and high-risk diets.²⁶⁶ Newer risks identified are from nanomaterials, for example, carbon nanotubes, and from endocrine-disrupting compounds (EDCs).²⁶⁶⁻²⁶⁸ In February 2013, WHO and the United Nations Environment Programme (UNEP) published a report on EDCs.²⁶⁹ The authors reported emerging evidence of a link between exposure to EDCs and an increase in certain cancers, such as breast, endometrial, ovarian, testicular, prostate, and thyroid cancer. These cancers have been increasing over the past 40 to 50 years.²⁶⁹ Occupational exposure to pesticides and to some polychlorinated biphenyls (PCBs) and exposure to arsenic are being studied as causes of prostate cancer. Additionally, concern was for workplace risks to reproduction because many substances also are reprotoxicants.²⁶⁶ Research projects are needed to identify high-risk vulnerable groups (for example, pregnant women, young workers, and those exposed to high levels of carcinogens) for contracting occupational cancer. Model solutions need development to reduce exposure for such groups. In the service sector, awareness is low and workers have little training on how to protect themselves, they may have limited access to preventive services, and they are infrequently consulted on workplace measures.²⁶⁶ It has been estimated that 3% to 6% of all cancers worldwide are caused by workplace exposures to carcinogens.

A substantial percentage of cancers of the upper respiratory passages (lung, bladder, and peritoneum) is attributed to occupational factors; however, fewer studies of nonsmokers exist.^{270,271} Textile industry workers are exposed to a number of chemicals (dyes, solvents, fiber dusts, others) continuously with known carcinogenic properties.²⁷² Exposure to different kinds of chemicals and physical factors in the textile industry induce occupational cancer, including lung, bladder, colorectal, and breast cancer, as a long-term effect among textile industry workers.²⁷² One notable occupational factor is

asbestos, which increases the risk of asbestosis, lung cancer, and mesothelioma. Asbestos was used in homes and buildings built before the 1970s to insulate ceiling tiles, flooring, and pipe covers. Asbestos also has been used for decades in thousands of commercial products, including fireproofing materials, automotive brakes, textile products, cement, and wallboard materials. In Western Europe, the epidemic of mesothelioma in building workers and other workers born after 1940 did not become apparent until the 1990s because of long latency. No exposure to asbestos is without risk and a large number of countries still use, export, and import asbestos-containing products (see [Table 13.1](#)). Many residential and commercial settings still contain asbestos.²⁷³

Carcinoma of the bladder has been linked with the manufacture of dyes, rubber, paint, and aromatic amines, especially β -naphthylamine and benzidine. Benzol inhalation is linked to leukemia in shoemakers and in workers in the rubber cement, explosives, and dyeing industries. Other notable occupational hazards include heavy metals (e.g., high-nickel alloy, chromium VI compounds, inorganic arsenic), silica, polycyclic aromatic hydrocarbons, sulfuric acid, and chloromethyl ether. Occupational exposure to diesel exhaust, especially to underground miners, has been linked to eye and nose irritation, headaches, nausea, and asthma. NIOSH and the EPA have classified diesel exhaust as a possible carcinogen.²⁷⁴ The IARC classifies diesel engine exhaust as carcinogenic to humans and is based on sufficient evidence that it is linked to an increased risk of lung cancer. Disentangling data related to lung cancer, air pollution, and occupational risks is complex, especially in combination with active and passive smoking and the interplay of environmental factors and genetic polymorphisms at multiple loci.

Summary Review

Genes, Epigenetics, and Tissue

1. Cancers are caused by environmental-lifestyle and genetic

factors. Environmental factors and lifestyle behaviors contribute to a very large number of cancer cases. Biologically, cancer is driven by genetic alterations and changes in epigenetic regulation. Different combinations of mutations and epigenetic changes are found in different types of cancer. Avoiding high-risk behaviors and exposures to individual carcinogens, or cancer-causing substances, will prevent many types of cancer.

2. Investigators are connecting the intricate web between genotype, phenotype, high-risk lifestyle behaviors, the environment, and carcinogenesis.
3. Interacting factors that influence cancer risk include detoxifying enzymes, DNA repair genes, immune/inflammation systems, and the cell's immediate environment. The cell's biologic environment is modified by metabolic requirements, physical activity, infections, nutrition, carcinogens, air pollution, and many other environmental factors.
4. Cancer development and progression involve the tissue microenvironment or stroma.
5. The microenvironment participates in a complex signaling process that facilitates tumor promotion and metastases because stromal tissue has immune cells. Chronic inflammation from infiltrating immune cells can be caused by numerous environmental factors, for example, inhaling tobacco smoke.
6. Cancer development in the presence of chronic inflammation involves the continuous presence of cytokines, ROS, COX-2, 5-LOX, MMPs, and essential transcription factors (e.g., NF- κ B).

Incidence and Mortality Trends

1. Cancer is reported to become a major cause of morbidity and mortality in the coming decades in all regions of the world.
2. Data for the United States from 2003 to 2012 showed incidence

of 7 of the 17 more common cancers in men decreased and overall incidence stayed close to the same for women. The decline in lung cancer corresponded to a decrease in tobacco use. Cancer incidence, however, increased among people ages 0 to 19 years. In all racial and ethnic populations, men had about a threefold higher liver cancer incidence than women.

3. Death rates continued to decrease for men, women, and children. Deaths caused by liver cancer, however, increased at the highest rate of all reported cancer sites.

In Utero and Early Life Conditions

1. Accumulating data suggest early life events influence later susceptibility to certain chronic conditions, including cancer.
2. Developmental plasticity is the degree to which an organism's development is contingent on its environment. An emerging hypothesis is that persistent epigenetic adaptations that occur early in development in response to parental nutrition and the environment are associated with increased susceptibility to cancer and other adult-onset chronic diseases.
3. Epidemiologic and animal studies reveal that small changes in the developmental environment can alter phenotypic changes, resulting in individual responses in adulthood.

Environmental-Lifestyle Factors

Tobacco Use

1. Cigarette smoking is carcinogenic and the most important cause of cancer and death from cancer. The risk is greatest in those who begin to smoke when young and continue throughout life.
2. Worldwide, tobacco use is a major preventable cause of premature death and disease where 5.4 million people die each year from tobacco-related illnesses. More than 16 million

Americans live with a smoking-related disease.

3. Smoking affects nearly every organ of the body. Since the first Surgeon's General report on smoking and health in 1964, more than 20 million Americans have died as a result of smoking. Smoking causes even more deaths from vascular, respiratory, and other diseases than from cancer.
4. Smoking tobacco is linked to cancers of the lung, upper aerodigestive tract (oral cavity, pharynx, larynx, nasal cavity, paranasal sinuses, esophagus), stomach, lower urinary tract (renal pelvis, penis, bladder), kidney, pancreas, cervix, and uterus, as well as myeloid leukemia. The new list of disease risks includes liver cancer and colorectal cancer.
5. Secondhand smoke or environmental tobacco smoke (both sidestream smoke [burning end of cigarette, cigar, or pipe] and mainstream smoke exhaled by the smoker) is a cause of stroke; it increases the risk of death in people with cancer and cancer survivors, as well as those with age-related macular degeneration, tuberculosis, ectopic pregnancy, and diabetes mellitus; it increases inflammation and impairs immunity; and it is a cause of rheumatoid arthritis.
6. Nonsmokers who live with smokers are at greatest risk for lung cancer, as well as other noncancerous conditions. Parental smoking is linked to babies who died of sudden infant death syndrome or complications from low birth weight or other conditions. In utero effects from maternal or paternal smoking and subsequent disease are being investigated.
7. Regular cigar smoking is associated with increased risk for cancers of the lung, esophagus, larynx, and oral cavity (lip, tongue, mouth, throat). Heavy cigar smoking increases the risk for lung diseases, including emphysema and chronic bronchitis. Cigar smoking is linked to gum disease and tooth loss. Pipe smokers have an increased risk of dying from cancers of the lung, throat, esophagus, larynx, pancreas, and colorectum. Compared to nonsmokers, bidi smokers have the same risks of cancer and higher risks of heart attacks and

chronic bronchitis. Kreteks are a tobacco product.

8. An e-cigarette delivers a vapor (aerosol) of nicotine, flavorings, and other chemicals when puffed. The vapor is inhaled just like smoke from a regular cigarette and absorbed into the lungs. Colorful “vape pens” or “e-hookahs” are marketed to appeal to youth with flavors like candy and fruit. The electronic nicotine delivery system (ENDS) is designed to deliver nicotine, which is addictive. Many questions have been raised as to the safety of e-cigarettes because ENDS cartridges are *not* labeled with their ingredients.

Nutrition, Obesity, Alcohol Consumption, and Physical Activity

1. Abundant evidence exists that dietary factors are related to cancer development. Emerging is the interaction of dietary factors with genomics, epigenomics, transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and how they influence cancer risk. Nutrigenomics is the study of the effects of nutrition on the phenotypic variability of individuals based on genomic differences.
2. What people eat, how much they weigh, and how much they move influence their risks of developing cancer and other chronic diseases. Everyday choices impact their chances of getting or preventing cancer. Lifestyle and nutrition are associated with development or progression, or both, of major human cancers, including some of the most common (e.g., breast, prostate, colorectal, and others).
3. Researchers are studying types of diet that either prevent or reduce mortality rates for cancer and other chronic diseases. Much attention is the research on the Mediterranean diet.
4. Examples of food components reported to have cancer-preventive potential include polyphenols, selenium, methyl group donors, retinoids, isothiocyanates, allyl compounds,

and mono- and poly-unsaturated fatty acids. Several dietary factors alter the expression of many miRNAs in animals and humans.

5. Various food components can influence DNA repair.
6. Sources of carcinogenic substances include compounds produced in the cooking of fat, meat, or protein, and naturally occurring carcinogens associated with plant food substances, such as alkaloids or mold byproducts.
7. Dietary components can act directly as mutagens or interfere with the elimination of mutagens.
8. Dietary factors may affect the cell cycle, differentiation, DNA damage and repair, stem cell renewal, hormonal axes, the balance of cellular proliferation and cell death, the microenvironment, cell signaling, inflammation, and immunity.
9. Xenobiotics that include toxic, mutagenic, and carcinogenic chemicals are found in the human diet.
10. Food and nutrition modify carcinogen metabolism and include the examples selenium, allyl sulfur, sulforaphane, and isoflavonoids.
11. Diets high in red meat and processed meat are linked to an increased risk of developing colorectal cancer. Several mechanisms are proposed for effects of meat and cancer, for example, *N*-nitroso compounds can increase nitrogenous residues in the colon and cause DNA damage.
12. Undernutrition can be a factor in cancers caused by infectious agents, for example, cancers of the liver and cervix.
13. Future research is needed to define robust biomarkers of cancer risk.
14. Obesity has been increasing in most developed countries and in urban areas of developing countries. Obesity in the United States is an epidemic.
15. Childhood obesity has been increasing. There is considerable concern for children with early onset of obesity.
16. The substantial suffering and long-term human and societal

costs of obesity underlie the urgency to accelerate progress in obesity prevention.

17. Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival.
18. Consensus now exists that obesity is a risk factor for developing the following cancers: liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal (adenocarcinoma), postmenopausal breast, pancreatic, endometrial, and stomach (cardia) (see [Fig. 13.13](#)). The IARC identified additional cancers with sufficient evidence that the absence of body fatness lowers cancer risk for thyroid and multiple myeloma.
19. Obesity is recognized as a poor prognostic factor for several cancers.
20. The mechanisms of obesity-associated cancer risks are unclear and may vary by type of tumor and distribution of body fat. Three main factors related to obesity and cancer are the insulin–insulin-like growth factor axis, sex hormones, and adipokines.
21. Metabolic changes in adipose tissue from obesity result in several alterations and include insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation.
22. Obesity leads to adipocyte dysfunction and immune cell recruitment leading to cytokine production, inflammation, and, ultimately, fibrosis and reduced response to chemotherapy. Adipocytes function as endocrine cells and critically shape the tumor microenvironment.
23. Obesity can increase aromatase expression, resulting in increased estradiol levels, which can promote the growth of estrogen-dependent cancers.
24. Cancers have altered metabolism. Tumors consume large quantities of glucose to make cellular building blocks, called the *Warburg effect*.

25. Food metabolism and circadian cycles are linked, and impairment of inner clock regulation results in dysregulated metabolism.
26. Overall, there are strong data supporting alcohol as a cause of cancers of the mouth, pharynx, larynx, esophagus, and liver; colorectal cancer in men; and postmenopausal breast cancer.
27. Factors contributing to alcohol-induced cancer development include acetaldehyde, oxidative stress, and nutritional deficiencies, especially folate, a B vitamin.
28. Variations in several genes modulate the risk of alcohol-induced carcinogenesis, and increasing evidence suggests aberrant patterns of DNA methylation also contribute.
29. Physical activity reduces the risk for breast cancer, colon cancer, and endometrial cancer, independent of weight changes.
30. Biologic mechanisms for the protective effects of exercise include decreasing insulin and IGF levels, decreasing obesity, increasing free-radical scavenger systems, changing inflammatory mediators, decreasing oncogenes, decreasing the levels of circulating sex hormones and metabolic hormones, improving immune function, and enhancing cytochrome P-450 function, thus modifying carcinogen activation and increasing gut motility.
31. Several reports suggest that implementing a physical activity program after a cancer diagnosis is associated with better cancer-specific outcomes and overall survival with early-stage breast, prostate, and colorectal cancers.
32. Many unanswered questions remain regarding the frequency, intensity, and duration of exercise required for optimal health benefits.

Air Pollution

1. Ambient air pollution increases mortality and morbidity and shortens life expectancy from cardiovascular, respiratory

- disease, and lung cancer.
2. Air pollution is a leading cause of global disease burden. Long-term exposure to fine particle air pollution (PM_{2.5}) caused 4.2 million deaths and 103.1 million lost years of healthy life in 2015. An additional 254,000 deaths were linked to exposure to ozone.
 3. The IARC concluded that exposure to outdoor air pollution and to particulate matter (PM) in outdoor air is carcinogenic to humans and causes lung cancer. Fine or ultrafine particles are easily absorbed by the lungs and phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators.
 4. The mechanisms of adverse cellular effects of PM include (1) cytotoxicity through oxidative stress, (2) ROS generation, (3) DNA oxidative damage, (4) mutagenicity, (5) stimulation of proinflammatory factors, and (6) induction of cell senescence.
 5. The indoor air pollution environmental tobacco smoke (ETS; passive smoking) can cause the formation of reactive oxygen free radicals and thus DNA damage. The IARC has classified ETS as a human carcinogen.
 6. In 2012 diesel exhaust was classified as a carcinogen in humans by the IARC.
 7. The central hypothesis for cancer pathogenesis is that insoluble particles cause pulmonary inflammation (e.g., cytokine release, ROS) which leads to oxidative stress and oxidation of DNA, proliferative response, and tissue remodeling progressing toward fibrosis and tumor development.

Ionizing Radiation, Ultraviolet Radiation, and Electromagnetic Radiation

1. Much of the knowledge of the effects of ionizing radiation (IR) on human cancer has stemmed from observations of the Hiroshima and Nagasaki atomic bomb exposures, particularly the Life Span Study. Other evidence is derived from groups

exposed for medical reasons, underground miners exposed to radon gas, and other occupational exposures.

2. The atomic bomb exposures in Japan caused acute leukemias in adults and children and increased frequencies of thyroid and breast carcinomas. Lung, stomach, colon, esophageal, and urinary tract cancers and multiple myeloma have been added to the list.
3. Recent models of radiation carcinogenesis show ionizing radiation (IR) acts not only as an initiator of premalignant cell clones but also as a promoter of preexisting premalignant cell alterations.
4. Health risks from IR involve cancers, cardiovascular diseases, respiratory diseases, birth defects, and eye maladies.
5. In 2009 the National Council on Radiation Protection and Measurements reported Americans were exposed to more than 7 times as much IR from medical procedures compared to IR exposure in the 1980s.
6. Ionizing radiation is a mutagen and carcinogen and can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations.
7. The past two decades have focused on cellular and molecular mechanisms that relate to the induction of cancer, including dose-response relationships for chromosome aberrations and for cell transformation; gene expression (genetic and epigenetic); alternative targets, such as membranes; mutagenesis in somatic cells; the biologic effects that occur in nonirradiated cells (i.e., nontargeted effects); and effects on the microenvironment.
8. Exposure to ionizing radiation induces apoptosis and senescence. Emerging data are identifying these effects in endothelial cells and the biology of radiation-induced cardiovascular disease.
9. Because models and underlying assumptions of IR and cell damage are incomplete, investigators are working hard to understand induced repair, adaptive responses, hormesis, low-

dose hypersensitivity, nontargeted effects, signaling, exosomes, and long-term persistence of radiation damage and clonal heterogeneity.

10. A long-held assumption is that cellular alterations—mutations and malignant transformation—occur only in cells directly radiated. It is now known that radiation may induce a type of genomic instability to the progeny of the directly irradiated cells over many cell generations and can affect so-called *innocent bystander cells*.
11. Epigenetic events after radiation include alterations in pathways affecting cell adhesion, extracellular matrix interactions, and cell-to-cell communication.
12. The principal source of UV radiation is sunlight. Solid evidence shows sun and ultraviolet (UV) radiation causes basal cell carcinoma and squamous cell carcinoma. Fair evidence showing intermittent acute sun exposure leading to sunburn is associated with an increased risk of melanoma. The most preventable cause of skin cancer is exposure to UV light from the sun or from artificial sources, such as tanning beds.
13. The degree of damage in skin depends on the intensity and wavelength content—ultraviolet A (UVA) or ultraviolet B (UVB).
14. The pathogenesis of nonmelanoma skin cancers involves specific gene mutations, DNA methylation and histone modifications, oxidative stress, inflammation, and reduced immune surveillance. The relationship between sun exposure and the risk of melanoma remains complex.
15. ROS can induce a number of transcription factors (e.g., activator protein 1 [AP-1] and NF- κ B) and increase the levels of regulating genes that induce inflammation. Inflammation is a critical component of tumor progression.
16. The incidence of melanoma in the United States has been increasing annually. Because mortality rates have not risen as rapidly, however, controversy exists as to whether the incidence increase is a true increase in clinically significant

melanoma or is a result of overdiagnosis.

17. Health risks associated with electromagnetic radiation (EMR) are controversial. Exposure to electric and magnetic fields is widespread. EMRs are a type of nonionizing and low-frequency radiation.
18. EMRs generated by radiofrequency sources couple with the body and result in induced electric and magnetic fields with associated currents inside tissue.
19. Microwaves, radar, mobile and cell phones, mobile phone base stations, appliances, power frequency radiation associated with electricity and radio waves, fluorescent lights, computers, and other electric equipment create EMRs of varying strength.
20. Data measuring the relationships between EMR exposure and cancer are limited because of inadequate methods to accurately measure exposure, lack of clear dose-response relationships and reproduction of effects, financial interests, and other priorities such as convenience.
21. Most exposure to EMFs from occupational sources comes from near-field sources; the highest exposure to the general population comes from transmitters close to the body, such as hand-held devices like mobile telephones.
22. The WHO International Agency for Research on Cancer Monograph Working Group reported that the INTERPHONE and Swedish studies were judged susceptible to bias, the findings could not be dismissed because of bias alone, and a causal relationship between phones and glioma is possible. The National Institute of Environmental Health Sciences is doing a large-scale study on rodents exposed to radiofrequency energy (cell phone type). Early preliminary data have been reported.
23. The outcome of the Working Group was to classify RF-EMF as “possibly carcinogenic to humans” (Group 2B). The mechanisms included genotoxicity, effects on immune function, gene and protein expression, cell signaling, oxidative stress, apoptosis, and, possibly, the blood-brain barrier.

24. There are no studies of adults who have used cell phones as children or adolescents. Concern is for children in whom the effects may be compounded because of increased vulnerability to radiation and their longer use of cell phones into adulthood.

Infection

1. Infections with certain viruses, bacteria, and parasites are an important contributor to cancer worldwide. Of the 14 million new cancer cases in 2012, 2.2 million (15.4%) were attributable to carcinogenic infections.
2. Infection and cancer rates vary widely between countries and level of socioeconomic development.
3. The top notable infections and new cancer cases include *Helicobacter pylori* (*H. pylori*), human papillomavirus (HPV), hepatitis B virus (HBV), hepatitis C virus (HCV), and Epstein-Barr virus (EBV).
4. Hepatitis B and hepatitis C can infect the liver and together account for the large majority of liver cancer diagnoses. HPV caused more than half of the total infection-attributable cancers in women worldwide. HPV is the most common viral infection of the reproductive tract. Most sexually active women and men will be infected at some point in their lives and some may be repeatedly infected. *H. pylori* accounts for an estimated 75% of all stomach cancers. EBV is associated with a subset of Hodgkin lymphoma and Burkitt lymphoma, and other types of cancer.
5. HPVs are a group of more than 200 related viruses of which 13 are cancer causing. High-risk or oncogenic HPVs (types 16 and 18) cause about 70% of cervical cancers and precancerous cervical lesions. HPV has been linked with cancers of the anus, vulva, vagina, and penis. Prospective studies have confirmed that infection with HPV-16 precedes by several years the diagnosis of oropharyngeal cancer (OPC).
6. Factors that may increase the risk of developing cancer

following a high-risk HPV infection include smoking, decreased immunity, having many children (for increased risk of cervical cancer), long-term oral contraceptive use (for increased risk of cervical cancer), poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.

Chemicals and Occupational Hazards as Carcinogens

1. An estimated 100,000 synthetic chemicals are used in the United States. Of those, only about 7% have been tested for their health effects and another 1000 are added each year.
2. Chemicals are present in air, soil, food, water, personal care products, toys, household products, medications, workplaces, and homes. The list of chemicals has expanded and added to other cancer risks related to the workplace, including ergonomic, organizational, and biologic factors.
3. An extensive list of potential occupational carcinogens is published by the NIOSH, and known and probable carcinogenic agents are updated by the International Agency for Research on Cancer (IARC).
4. Chemical carcinogenesis involves genotoxic and nongenotoxic mechanisms. The nongenotoxic mechanisms include inflammation, immunosuppression, oxidative stress (ROS), receptor activation, and epigenetic silencing.
5. Work-related stress may indirectly lead to cancer because coping strategies include smoking, alcohol, drug intake, and excessive high-risk diets.
6. A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors; however, fewer studies of nonsmokers exist.
7. Disentangling data related to lung cancer, air pollution, and occupational factors is complex, especially in combination

with active and passive smoking, environmental factors, and multiple interacting genes.

CHAPTER 14

Cancer in Children

Lauri A. Linder

CHAPTER OUTLINE

Incidence and Types of Cancer, 426

Etiology, 427

Genetic Factors, 427

Environmental Factors, 429

Prognosis, 430

Cancer in children and adolescents is rare, but it is still the leading cause of death from disease in this patient population. The 5-year survival rates among children and adolescents with cancer have improved from 59% in the 1970s to nearly 85% today.^{1,2} Factors leading to improved cure rates in children and adolescents with cancer include the use of combination chemotherapy; the development of targeted therapies, including immunotherapy; and the participation in clinical trials.

Incidence and Types of Cancer

More than 15,500 children and adolescents (from birth to 19 years of

age) in the United States will be diagnosed with cancer each year. Just less than 2000 deaths from cancer occur in this age group each year. Deaths from cancer in this age group most commonly result from central nervous tumors, followed by leukemias.^{1,3}

The types of malignancies in children and adolescents are vastly different from those that affect adults. The most common types of cancer among adults include prostate, breast, lung, and colon. Many adult cancers have associated lifestyle factors and many cancers may be prevented (see [Chapter 13](#)).

Among children up to 14 years of age, leukemias and brain tumors account for 61% of childhood cancers; solid tumors, such as neuroblastoma and soft tissue or bone sarcomas, are less common.³ Lymphomas (including Hodgkin and nonHodgkin subtypes) are the most common type of cancer among adolescents (15 to 19 years of age). Leukemia, thyroid carcinoma, brain tumors, and germ cell tumors also are among the most common adolescent cancers.^{1,4} Although very few environmental factors have been linked to pediatric and adolescent malignancies, more data are emerging that the developing child may be affected by parental exposures before conception, exposures in utero, and the contents of breast milk. These exposures may result in epigenetic changes, creating an increased vulnerability to the development of childhood cancer.^{5,6}

Most childhood and adolescent cancers originate from the **mesodermal germ layer** that gives rise to connective tissue, bone, cartilage, muscle, blood, blood vessels, gonads, kidney, and the lymphatic system. Thus the more common childhood cancers are leukemias, sarcomas, and embryonal tumors. **Embryonal tumors** originate during intrauterine life. These tumors contain abnormal cells that appear to be immature embryonic tissue, unable to mature or differentiate into fully developed functional cells. Embryonal tumors are diagnosed early in life (usually before 5 years of age). Embryonal tumors often contain the term **blast cell** in their name, which refers to the immature nature of the cells. Examples of embryonal tumors include retinoblastoma, neuroblastoma, and Wilms tumor (nephroblastoma).

Leukemia is the most common malignancy in children, with most cases occurring in children between 2 and 5 years of age. The most common type of leukemia is acute lymphoblastic leukemia (ALL), which represents approximately 75% of all childhood and 67% of all adolescent leukemia cases.¹ Although the presenting signs of the various types of leukemia may be similar, the treatment and response to treatment of childhood leukemias vary greatly (see [Chapter 31](#)).

Central nervous system (CNS) tumors are the most common types of solid tumors in children and account for 21% of all childhood cancers and 10% of adolescent cancers¹ (see [Chapter 20](#)). Not all brain tumors are diagnosed malignant by histologic studies; however, even a benign tumor can have devastating effects, depending on the anatomic location. The treatment for brain tumors in children often presents difficulties because therapies, such as radiation, may have debilitating effects on the developing brain, particularly in children younger than 3 years of age.

Lymphomas, including Hodgkin and non-Hodgkin subtypes, are malignancies that occur in children, adolescents, and adults. The subtypes of lymphoma and subsequent treatment often differ across the life span.

Many pediatric solid tumors usually develop in children and adolescents, but in very rare instances, may occur in adults. Examples of these tumors include neuroblastoma, Wilms tumor, rhabdomyosarcoma, retinoblastoma, osteosarcoma, and Ewing sarcoma. Likewise, solid tumors that occur more frequently in adults, such as hepatocellular carcinoma, can occur in children and adolescents.

Childhood and adolescent cancers are often associated with specific peak times of physical growth and may occur as a consequence of altered cellular regulatory mechanisms at a given time in the child's or adolescent's development. Embryonal tumors most often develop before the age of 5 years, acute lymphoblastic leukemia occurs most often in younger children, and bone tumors occur most often in adolescents. In general, childhood and adolescent cancers are extremely fast growing, with 80% having distant spread (metastases)

at diagnosis. Overall, cancer is 10% to 25% more common in white than in black children. Boys are more likely to develop cancer than girls.

Etiology

The causes of cancer in children are largely unknown. A few environmental factors are known to predispose a child to cancer, but causal factors have not been established for most childhood cancers. A number of host factors, many of which are genetic risk factors or congenital conditions, have been implicated in the development of childhood cancer (Table 14.1). The interaction of many factors most likely produces cancer, a concept referred to as multiple causation or **multifactorial etiology**. According to this premise, cancer develops because of the predisposing characteristics of the person and the interaction with environmental factors.

TABLE 14.1

CONGENITAL FACTORS ASSOCIATED WITH CHILDHOOD CANCER

SYNDROME	ASSOCIATED CHILDHOOD CANCER
Chromosomal Alterations	
Down syndrome	Acute leukemia
13q syndrome	Retinoblastoma
Chromosomal Instability	
Ataxia-telangiectasia	Lymphoma
Bloom syndrome	Acute leukemia, lymphoma, Wilms tumor
Fanconi anemia	Nonlymphocytic leukemia, myelodysplastic syndrome, hepatic tumors
Hereditary Syndromes	
Beckwith-Wiedemann syndrome	Wilms tumor, sarcoma, brain tumors, neuroblastoma, hepatoblastoma
Neurofibromatosis type 1	Brain tumors, sarcomas, neuroblastomas, Wilms tumor, nonlymphocytic leukemia
Neurofibromatosis type 2	Meningioma (malignant or benign), acoustic neuroma/schwannoma, gliomas, ependymomas

Tuberous sclerosis	Glial tumors
Li-Fraumeni syndrome	Sarcoma, adrenocortical carcinoma
von Hippel-Lindau disease	Cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma, pheochromocytomas
Ataxia-telangiectasia	Leukemia, lymphoma, brain tumors
Gorlin syndrome	Medulloblastoma, skin tumors
Immune Deficiency Disorders	
<i>Congenital</i>	
Agammaglobulinemia	Lymphoma, leukemia, brain tumors
Immunoglobulin A (IgA) deficiency	Lymphoma, leukemia, brain tumors
Wiskott-Aldrich syndrome	Leukemia, lymphoma
<i>Acquired</i>	
Aplastic anemia	Leukemia
Organ transplantation	Leukemia, lymphoma
Congenital Malformation Syndromes	
Aniridia, hemihypertrophy, hamartoma, genitourinary anomalies	Wilms tumor
Cryptorchidism	Testicular tumor
Gonadal dysgenesis	Gonadoblastoma
Family Susceptibility	
Twin or sibling with leukemia	Leukemia

A **multiple causation model** is useful when the results of epidemiologic studies are interpreted. For example, laboratory and epidemiologic studies may indicate that exposure to a certain chemical or ionizing radiation can cause leukemia, but not all children exposed to that chemical will develop leukemia. Additional studies will be needed to determine what other factors must interact with chemical exposure to cause the disease.

Genetic Factors

Oncogenes and tumor-suppressor genes are associated with the development of childhood cancer (Table 14.2; also see Chapter 12). **Proto-oncogenes** code for proteins that help regulate normal cell growth and differentiation. If mutated, proto-oncogenes become

oncogenes that help to turn normal cells into cancer cells. Changes produced by specific oncogenes cause the cell cycle to become dysregulated. An example of an oncogene identified in pediatric cancer is *MYCN*, which is involved in neuroblastoma and glioblastoma. Tumor-suppressor genes are protective genes that normally suppress cancer cell proliferation but have lost their suppressor function. When both copies of a tumor-suppressor gene acquire mutations, normal cell function is lost and cancer can develop. Some childhood and adolescent cancers identified with tumor-suppressor genes include osteosarcoma, leukemia, rhabdomyosarcoma, retinoblastoma, and Wilms tumor.⁷

TABLE 14.2

SELECTED ONCOGENES AND TUMOR-SUPPRESSOR GENES ASSOCIATED WITH CHILDHOOD CANCER

GENE	ASSOCIATED PEDIATRIC TUMOR
Oncogenes	
<i>BCR-ABL</i>	Acute lymphoblastic leukemia
<i>MYCN</i>	Neuroblastoma
<i>MYB</i>	Neural tumors, leukemia, lymphoma, rhabdomyosarcoma, Wilms tumor, neuroblastoma
<i>EGFR/ErbB</i>	Glioblastomas
<i>NRAS</i>	Neuroblastoma, leukemia, rhabdomyosarcoma
<i>KRAS</i>	Leukemia
<i>ATM</i>	Lymphoma, leukemia
Tumor-Suppressor Genes	
<i>RB1</i>	Retinoblastoma, sarcoma
<i>WT1, WT2</i>	Wilms tumor, leukemia
<i>WTC</i>	Wilms tumor
<i>NF-1</i>	Sarcoma, primitive neuroectodermal tumor, juvenile chronic myelocytic leukemia
<i>NF-2</i>	Brain tumors, melanoma, meningiomas
<i>CDKN2A</i>	Melanoma, Ewing sarcoma
<i>PTEN</i>	Glioma, melanoma
<i>INK4A/ARF</i>	Leukemia, glioma
<i>TP53</i>	Sarcoma, leukemia, brain tumors, lymphoma

<i>DCC</i>	Ewing sarcoma, rhabdomyosarcoma, neuroblastoma
<i>ARF</i>	Glioma, T-cell ALL
<i>CDC2L1</i>	Non-Hodgkin lymphoma, neuroblastoma

Data from OMIM Online Mendelian inheritance in man: *An online catalog of human genes and genetic disorders*. Available at <http://www.omim.org>.

Other genetic factors involve chromosomal aberrations, including both germline and acquired abnormalities. These chromosomal abnormalities include aneuploidy, amplifications, deletions, and translocations. Some chromosomal disorders and congenital malformations are associated with the development of pediatric cancer; however, the mechanisms associated with cancer development are not fully understood. Trisomy 21 (Down syndrome) is the most common genetic defect linked to the development of acute leukemia. Children with Down syndrome have a 10- to 20-fold increased risk of developing acute lymphoblastic and myelogenous leukemias and a higher risk for developing acute megakaryocytic leukemia. The risk is highest between 1 and 4 years of age.⁸ The risk of leukemia also is increased for children with congenital malformations involving the circulatory system.⁹

Wilms tumor may occur in combination with other congenital anomalies, including aniridia or congenital absence of the iris of the eye, ambiguous genitalia, and intellectual disability (WAGR syndrome). WAGR syndrome is caused by a mutation on the short arm of chromosome 11. This region includes the Wilms tumor gene (*WT1*) as well as the *PAX6* gene that is associated with ocular development. Wilms tumor also is associated with neurofibromatosis and Beckwith-Wiedemann syndrome.¹⁰ Most cases of Wilms tumor, however, do not occur in children with underlying congenital syndromes.

Population-based studies indicate that children with congenital malformations involving the nervous system are at increased risk for cancer, including cancer in the central nervous system.⁹ Additionally, the siblings of children with congenital malformations involving the central nervous system, eye, ear, face, or neck are at an increased risk for cancer compared with the siblings of unaffected children.¹¹

Retinoblastoma, a malignant embryonal tumor of the eye, results from deletions in the long arm of chromosome 13, which is the locus for the *RB1* gene, a tumor-suppressor gene. Deletions may occur as germline or acquired mutations. Germline deletions are associated with familial retinoblastoma, whereas acquired deletions are associated with sporadic cases (see [Chapter 20](#)).

Translocations, or the exchange of chromosomal material between nonhomologous chromosomes, also are associated with childhood and adolescent cancers. A well-known chromosomal translocation is the Philadelphia chromosome, which involves chromosomes 9 and 22. The Philadelphia chromosome results in the production of the BCR-Abl fusion protein, which accelerates cell division and inhibits DNA repair. It is commonly found in chronic myelogenous leukemia and some cases of acute lymphoblastic leukemias.¹² Chromosomal translocations also are commonly observed in sarcomas.

Several single-gene disorders have been associated with the subsequent development of childhood and adolescent cancers. Fanconi anemia and Bloom syndrome are autosomal recessive conditions that are risk factors for the development of cancer. Fanconi anemia results in altered DNA repair, and the majority of affected individuals develop acute myelogenous leukemia. Bloom syndrome results in chromosomal fragility leading to increased mutations. It is associated with a spectrum of cancers including leukemias, lymphomas, and carcinomas.

Li-Fraumeni syndrome (LFS) is an autosomal dominant disorder involving mutations in the tumor protein p53 (*TP53*) gene, a tumor-suppressor gene on the short arm of chromosome 17. For individuals carrying a TP53 mutation, the risk of developing cancer as a child or adult is significantly higher than that seen in the unaffected population. Children and adults in these families are at risk for soft tissue sarcoma, breast cancer, leukemia, osteosarcoma, melanoma, and cancer of the colon, pancreas, adrenal cortex, and brain. Individuals with LFS also are at increased risk for developing multiple primary cancers.¹³

An increased familial risk has been observed in some pediatric

cancers. Although the majority of pediatric cancers are not genetically transmitted as single-gene disorders, shared genetic and environmental risk factors may contribute to an increased familial risk. A child who has a sibling with leukemia has a risk for the development of leukemia that is 2 to 4 times greater than that for children with healthy siblings. The occurrence of leukemia in monozygous twins is estimated as being as high as 25%. Although susceptibility gene loci have been identified for ALL, they explain only a relatively small portion of the familial risk for recurrence of ALL among siblings. Additional currently unidentified genetic loci are likely to contribute to the additional familial risk.¹⁴ The heritability of adult cancers across the life span also is increased among both monozygotic and dizygotic twins.¹⁵

Cancers in children and adolescents are associated with fewer genetic mutations compared with adult cancers; however, efforts to understand the scope of predisposing mutations in pediatric cancer are ongoing. A recent study identified a greater frequency of germline mutations in cancer predisposition genes among children and adolescents with cancer compared with individuals who do not have cancer. More than one-half of the children and adolescents with germline mutations did not have a family history of cancer¹⁶ (see [What's New? Cancer Predisposition Genes and Pediatric Cancer](#)).

What's New?

Cancer Predisposition Genes and Pediatric Cancer

Genetic technologies are providing insights into the prevalence of genetic mutations that may predispose children and adolescents to cancer. A recent study used genome sequencing techniques to identify the presence of germline mutations in 565 genes associated with cancer development in 1120 children and adolescents with cancer and 966 individuals who did not have cancer. The investigators found that 8.5% of individuals with cancer had a mutation associated with cancer development compared with only

1.1% of the individuals who did not have cancer. Mutations most frequently occurred in the *TP53* gene, a gene involved in regulating cell division and preventing tumor formation. Other frequently affected genes were *APC* and *BRCA2*. The majority of children and adolescents with mutations in cancer predisposition genes did not have a family history of cancer.

The results of this study will guide additional epidemiologic studies, as well as studies investigating mechanisms of cancer development in children and adolescents. Identifying the presence of these predisposition mutations also may help guide treatment, as well as genetic testing and counseling of other family members.

Mutations in individual genes also may result in epigenetic modifications that, in turn, increase an individual's vulnerability to cancer. For example, mutations in genes encoding histone proteins can decrease the expression of other genes without changing the sequence of these genes. This subsequent decreased gene expression can alter cell differentiation, leading to cancer development. Such epigenetic changes are being investigated in relation to the development of diffuse intrinsic pontine glioma (DIPG), an incurable brain tumor, as well as sarcomas.^{17,18}

Environmental Factors

Although many adult cancers are associated with exposure to environmental agents, few childhood tumors share a similar strong association. Because of the lengthy latency period required between exposure and development of cancer, early exposure to carcinogens is presumed not to result in cancer until the child is an adult. To date, exposures to high-dose and high-dose rate ionizing radiation have been established as risk factors for childhood leukemia.¹⁹ Multiple other possible environmental risk factors for childhood cancer have been explored. Results of these studies have been mixed, and no definitive causal pathway for childhood cancer has been determined.

Prenatal Exposure

Prenatal exposure to some drugs, however, has been linked to childhood cancers. The most well-described drug is diethylstilbestrol (DES), which was prescribed by physicians to prevent spontaneous miscarriage (in women with previous miscarriage). In 1971 DES was identified as a transplacental chemical carcinogen because a small percentage of the daughters of the women who took DES developed adenocarcinomas of the vagina and cervix. Since then, other studies have attempted to identify drugs taken by pregnant women that may cause cancer in their offspring, but no other drugs have been found. Prior research suggested an association between antenatal x-ray exposure and childhood cancer, but studies have not been replicated or supported in recent literature. In 2006 the Office of the U.S. Surgeon General suggested evidence of a causal relationship between childhood leukemia, lymphoma, and brain tumors and prenatal or postnatal environmental tobacco smoke exposure.

Results of recent meta-analyses have suggested associations between parental exposure to pesticides and other potential environmental toxins before or during pregnancy and subsequent development of childhood cancer.⁶ Recent studies suggest that the risk of leukemia and lymphoma is increased when the mother was exposed to pesticides in the prenatal period, and the risk of brain tumors is associated with paternal exposure (occupational or household use) either before or after birth.^{20,21} Results of a European population-based study, however, did not suggest an association between parental occupational pesticide exposure and the development of childhood brain tumors.²² In contrast, however, a meta-analysis of 1426 cases of neuroblastoma failed to show an association between paternal occupational exposure to pesticide and development of disease.²³ An Italian case-control study suggested that maternal exposure to hair dyes and occupational chemical exposure was associated with an increased risk of neuroblastoma.²⁴

Childhood Exposure

Childhood exposure to ionizing radiation, drugs, and viruses has been associated with the risk of developing cancer.²⁵ Although high doses of ionizing radiation are established risk factors for the development of childhood cancer, evidence is emerging about the role of lower doses as well as additional variables that may further convey an increased risk. Retrospective studies have demonstrated significant positive correlations between radiation-induced malignancies from radiotherapy (cancer treatment) and from radiation exposure from diagnostic imaging and the development of childhood cancer.²⁶⁻²⁸ A case-control study of more than 1000 children in Finland with leukemia who were less than 15 years of age did not demonstrate an overall association of childhood leukemia with background gamma radiation.²⁹ This study did, however, demonstrate an increased risk of leukemia in relation to increasing radiation dose among children between 2 and 7 years of age. Additionally, this study also identified a positive association between leukemia with high hyperdiploid features and radiation dose. A similar increased risk was not identified for leukemia with other genetic features. Few studies have followed children for a long enough period of time to determine whether the risk of cancer remains increased in adulthood, although current studies with more rigorous methodology are assessing this risk³⁰⁻³² (see [What's New? CT Scans in Childhood Appear to Increase Cancer Risk](#)).

What's New?

CT Scans in Childhood Appear to Increase Cancer Risk

A growing number of international studies are providing evidence of an increased risk of childhood cancer following computed tomography (CT) scans. The findings from a recent study of 176,587 children suggest that those who had 2 or 3 CT scans of the head before age 22 years were 3 times as likely to develop brain cancer as those in the general population, and the risk of developing

leukemia was 3 times as great in those who received 5 to 10 CT scans. A follow-up study involving this same cohort of children addressed underlying unreported conditions that could have introduced bias. Results indicated a lower estimated relative risk for both leukemia and brain tumors than initially reported. The study results did, however, continue to demonstrate an increased risk of childhood cancer following CT exposure and that a significant dose-response risk was present. Although CT scans are important diagnostic imaging studies for children, the results of the study emphasize that children receive scans only when necessary using the lowest dose of radiation possible.

Data from Mathews JD et al: *BMJ* 346:f2360, 2013; Pearce MS et al: *Lancet* 380(9840):499-505, 2012.

In addition to the drug and environmental agents that are known to cause cancer in adults and therefore also are risks for exposure during childhood, a few drugs may particularly increase cancer risk during childhood (Table 14.3). Exposures during childhood to unspecified residential pesticides and insecticides have been associated with childhood leukemia.³³

TABLE 14.3

DRUGS THAT MAY INCREASE RISK OF CHILDHOOD CANCER

DRUG CLASS	USES	CANCER RISK
Anabolic androgenic steroids	Stimulate bone growth and appetite Induce puberty Increase muscle mass and physical strength	Hepatocellular carcinoma Brain tumors
Cytotoxic chemotherapy	Used in cancer treatment	Leukemia
Immunosuppressive agents	Prevent organ rejection following transplantation surgery	Lymphoma

The relationship between childhood cancer and exposure to radon³⁴ and electromagnetic fields has been the focus of many epidemiologic studies, yet no conclusive evidence has been observed.³⁶

In 2007 a task group of scientific experts convened by the World Health Organization (WHO) reported that it could not confirm the existence of any health consequences from exposure to low-level magnetic fields.³⁷ A review of studies from 1997 to 2013 indicated that magnetic field exposure may be associated with an increased incidence of childhood leukemia.³⁸

The strongest association between viruses and the development of cancer in children has been the relationship between exposure to Epstein-Barr virus (EBV) and development of Burkitt lymphoma, nasopharyngeal carcinoma, and Hodgkin disease. Children with acquired immunodeficiency syndrome (AIDS) have an increased risk of developing non-Hodgkin lymphoma and Kaposi sarcoma. However, with the use of highly active antiretroviral therapy (HAART) in the developed world, the incidence of AIDS-related malignancies has declined dramatically³⁹ Current evidence, however, indicates that the rate of non-AIDS-related malignancies is increasing among children and adolescents receiving HAART. Hypothesized mechanisms include oxidative stress and premature aging resulting from shortened telomeres as an adverse effect of HAART.^{39,40}

Prognosis

Nearly 85% of children and adolescents diagnosed with cancer are cured. Mortality rates have declined from 6.5 per 100,000 in 1969 to 2.3 per 100,000 in 2013, largely because of advances in treatment and increased participation in clinical trials.^{1,2}

Some of the factors leading to improved cure rates in pediatric oncology include the use of combination chemotherapy and multimodal treatment for childhood solid tumors. Additionally, development of research centers for comprehensive childhood cancer treatment, cooperation among treatment institutions, and development of cooperative study groups enable the most efficient advancement of treatment regimens. Currently, clinical trials are being conducted by the Children's Oncology Group (COG) at more than 180 hospitals across the United States and are funded by the

National Cancer Institute through CureSearch for Children's Cancer. Clinical trials are continually focusing on more effective, targeted therapies with fewer side effects. Side effects of treatment are better managed as a result of improvements in nursing and supportive care, recognition of the psychologic effects of cancer treatment, and continued follow-up care to track trends in the late effects of cancer treatment. Young children are particularly prone to long-term sequelae of cancer therapy. Supportive care guidelines to manage acute side effects of cancer treatment, as well as long-term follow-up guidelines,⁴¹ are available to guide the care of individuals who are survivors of childhood and adolescent cancers.

Summary Review

Incidence and Types of Cancer

1. Cancer in children and adolescents is rare, but it is still the leading cause of death from disease in this population.
2. Leukemias and brain tumors account for 61% of cancer in children from birth to 14 years of age, with neuroblastoma and soft tissue or bone sarcomas less common.
3. The most common cancers among the adolescent and young adult populations (15 to 39 years of age) are Hodgkin lymphoma, leukemia, germ cell tumors (particularly testicular), central nervous system (CNS) tumors, non-Hodgkin lymphoma, thyroid cancer, melanoma, sarcomas, and breast, cervical, liver, and colorectal cancers.

Etiology

1. The interaction of many factors most likely produces cancer in children and adolescents, a concept referred to as multiple causation or multifactorial etiology.
2. Oncogenes and tumor-suppressor genes have been associated

- with childhood and adolescent malignancies.
3. Chromosomal aberrations or single-gene defects including aneuploidy, amplifications, deletions, translocations, and fragility are associated with the development of childhood cancer.
 4. Wilms tumor and retinoblastoma are pediatric malignancies that are linked in a familial manner.
 5. Childhood exposure to ionizing radiation, drugs, or viruses has been associated with the risk of developing cancer.

Prognosis

1. Nearly 85% of children and adolescents diagnosed with cancer are cured.
2. Mortality rates have declined significantly in the past 45 years largely because of advances in treatment and increased participation in clinical trials.
3. Young children are particularly prone to long-term sequelae of cancer therapy. The development of more effective, targeted therapies with fewer side effects is imperative.

The nervous system is a remarkable structure responsible for the body's ability both to interact with the environment and to regulate and control activities involving internal organs, muscles, and glands. It is a network composed of complex structures that transmit electrical and chemical signals between the brain and the body's many organs and tissues.

Overview and Organization of the Nervous System

Although the components of the nervous system are considered individually to facilitate a better understanding of their function, it is important to recognize that these distinct parts of the nervous system function as a unified whole. Most broadly, the nervous system is divided into the central nervous system and the peripheral nervous system. The central nervous system (CNS) consists of the brain and spinal cord, enclosed within the protective cranial vault and vertebrae, respectively. The peripheral nervous system (PNS) is composed of the cranial nerves, which project from the brain and pass through foramina (openings) in the skull, and the spinal nerves, which project from the spinal cord and pass through intervertebral foramina. PNS pathways can be divided into ascending, **afferent pathways** that carry sensory information toward the CNS, and descending, **efferent pathways** that innervate **effector organs**, such as skeletal, cardiac, and smooth muscle, as well as glands. Most peripheral nerves carry a combination of both afferent and efferent pathways. Cranial nerves are viewed most correctly as modified spinal nerves. Cranial nerves control motor and sensory function similarly to spinal nerves, but also can have specialized sensory tasks, such as smell, taste, sight, and hearing (see [Peripheral Nervous System](#)).

Functionally, the PNS can be divided into the somatic nervous system and the autonomic nervous system. The somatic nervous system consists of motor and sensory pathways regulating voluntary motor control of skeletal muscle. The autonomic nervous system (ANS) also consists of motor and sensory components and is involved with regulation of the body's internal environment (viscera) through involuntary control of organ systems. The ANS is further divided into sympathetic and parasympathetic divisions. Although most aspects of the ANS are involuntary, some aspects can be controlled through mental practice with or without biofeedback techniques.

Cells of the Nervous System

Two basic types of cells comprise nervous tissue: neurons and supporting neuroglia. The **neuron** is an electrically excitable cell and

transmits electrical or chemical information between other neurons or to an effector organ. **Neuroglial cells** provide structural support, protection, and nutrition for the neurons, and facilitate neurotransmission.¹ Neuroglial cells include astrocytes, microglia, and oligodendrocytes in the CNS; and **Schwann (neurilemma)** and **satellite cells** in the PNS.

Neurons

Working alone or in units, neurons detect environmental changes and initiate body responses to maintain a dynamic steady state. Neuronal structure varies markedly so that each neuron is adapted to perform specialized functions. Although they may vary somewhat in function, **neurons** (Fig. 15.1) have three common components: a cell body (soma), dendrites (thin branching fibers of the cell), and the axons. Cell bodies for most neurons, even those extending axons into peripheral nerves, are located within the CNS. Dense collections of cell bodies in the CNS are called **nuclei**. In the PNS, cell bodies can be found in groups called **ganglia**, or plexuses (group of relay nerves). The **dendrites** are extensions that carry nerve impulses *toward* the cell body. The **dendritic zone** is the receptive portion of a neuron that receives a stimulus and either propagates or diminishes conduction. **Axons** are long projections that carry nerve impulses *away* from the cell body. The **axon hillock** is a cone-shaped process where the axon leaves the cell body. The first part of the axon hillock has the lowest threshold for stimulation so action potentials often begin there. The principle of *divergence* refers to the ability of axonal branches to influence many different neurons. *Convergence* applies when branches of various numbers of neurons “converge” on and influence a single neuron.

FIGURE 15.1 Structure of a Typical Neuron. A, Multiple dendrites carry nerve impulses to the cell body, and a single long axon carries nerve impulses away from the cell body. Long axons are encased at intervals by a myelin sheath. B, Photomicrograph of a neuron. C, A segment of myelinated fiber in cross section, showing myelin sheath composed of several layers of myelin, which insulate the axon. D, Axons bundled into fascicles. (A and C from Thibodeau GA, Patton KT: *Structure and function of the human body*, ed 12, St Louis, 2004, Mosby; B copyright Edward Reschke; D from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

The cellular constituents of a typical neuron include **microtubules** (transport substances within the cell), **neurofibrils** (thin supportive fibers that extend throughout the neuron), **microfilaments** (proteins thought to be involved in transport of cellular products), and **Nissl substances/bodies** (endoplasmic reticulum and ribosomes) that are involved in protein synthesis. Although most neurons are nondividing cells, some neurons continue to divide after birth; for example, olfactory neurons in the nose continue to divide throughout life.

A typical neuron has only one axon, which may be tightly wrapped

with a segmented layer of lipid material called **myelin**, an insulating substance. In the brain and spinal cord, myelin is formed by oligodendrocytes. Regions of the brain and spinal cord with a high level of myelination constitute the white matter, whereas regions lacking significant myelination (typically primarily composed of cell bodies) are gray matter. In the PNS, the myelin sheath of motor and sensory axons is formed by Schwann cells. **Myelin sheaths** are interrupted at regular intervals by the **nodes of Ranvier**. Axons can branch at the nodes of Ranvier.

Nutrient exchange is not possible through the myelin sheath, although it can occur at the nodes of Ranvier where the axon is not insulated. Myelin acts as an insulator that allows an action potential to leap between the nodes of Ranvier rather than flow along the entire length of the membrane, yielding increased velocity of conduction. This mechanism is referred to as **saltatory conduction**. Disorders of the myelin sheath (demyelinating diseases), such as multiple sclerosis, Guillain-Barré syndrome, and Charcot-Marie-Tooth disease, demonstrate the important role myelin plays in nerve conduction (see [Chapter 18](#)). Conduction velocities depend not only on the myelin coating but also on the diameter of the axon. Larger axons transmit impulses at a faster rate.

Neurons are structurally classified on the basis of the number of processes (projections) extending from the cell body. There are four basic types of cell configuration: (1) unipolar, (2) pseudounipolar, (3) bipolar, and (4) multipolar ([Fig. 15.2](#)). **Unipolar neurons** have one process that branches shortly after leaving the cell body. One example is found in the retina. **Pseudounipolar neurons** (some authors call them *unipolar*) also have one process. The dendritic portion of each of these neurons extends away from the CNS, and the axon portion projects into the CNS. The configuration is typical of sensory neurons in both cranial and spinal nerves. **Bipolar neurons** have two distinct processes arising from the cell body. This type of neuron connects to rod and cone cells of the retina. **Multipolar neurons** are the most common and have multiple processes capable of extensive branching. A motor neuron is typically multipolar.

FIGURE 15.2 Structural Classification of Neurons. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

Functionally, there are three types of neurons (with their direction of transmission and typical configuration noted in parentheses): (1) sensory (afferent, mostly pseudounipolar), (2) associational (interneurons, multipolar), and (3) motor (efferent, multipolar). **Sensory neurons** carry impulses from peripheral sensory receptors to the CNS ([Box 15.1](#)). **Association neurons (interneurons)** transmit

impulses from neuron to neuron and are located solely within the CNS. **Motor neurons** transmit impulses away from the CNS to an effector organ (i.e., skeletal muscle or organs). In skeletal muscle, the end processes of an axon form a specialized structure called a **neuromuscular junction**.

Box 15.1

Major Types of Sensory Receptors

Nociceptors (pain)

Mechanoreceptors (touch, pressure, and mechanical deformation or encapsulated endings)

Photochemical (light on the retina)

Chemoreceptors (flavors, odors, oxygen levels, osmolarity of body fluids, and carbon dioxide levels in the blood)

Thermoreceptors (heat and cold)

Proprioception (sensing location of body parts)

Audition and balance (sound and positional movement)

Neuroglia and Schwann Cells

Neuroglia (“nerve glue”) are the general classification of non-neuronal cells that support the neurons of the CNS. Conduction velocities depend not only on the myelin coating and nodes of Ranvier, but also on the diameter of the axon. Larger axons transmit impulses at a faster rate. **Oligodendroglia** (oligodendrocytes) form myelin sheaths within the brain and spinal cord. Regions of the brain and spinal cord with a high level of myelination constitute the white matter, whereas regions lacking significant myelination (typically primarily composed of cell bodies) are gray matter. **Schwann cells** form the myelin sheath around axons in the peripheral nervous system and direct axonal regrowth and functional recovery of injured neurons (see [What’s New? Schwann Cells](#)). **Nonmyelinating Schwann**

cells provide metabolic support. Characteristics of neuroglia and Schwann cells are summarized in Fig. 15.3 and Table 15.1.

TABLE 15.1

SUPPORT CELLS (GLIAL CELLS) OF THE NERVOUS SYSTEM

CELL TYPE	PRIMARY FUNCTIONS
Astrocytes	Form specialized contacts between neuronal surfaces and blood vessels Provide rapid transport for nutrients and metabolites Believed to form an essential component of the blood-brain barrier

	<p>Appear to be the scar-forming cells of the CNS, which may be the foci for seizures</p> <p>Participate in CNS immune function</p> <p>Appear to work with neurons in processing information and memory storage</p>
Oligodendroglia (oligodendrocytes)	Formation of myelin sheath and neurilemma in the CNS
Schwann cells	Formation of myelin sheath and neurilemma in the PNS
Microglia	Responsible for clearing cellular debris (phagocytic properties)
Ependymal cells	Serve as a lining for ventricles and choroid plexuses involved in production of CSF

CNS, Central nervous system; *CSF*, cerebrospinal fluid; *PNS*, peripheral nervous system.

What's New?

Schwann Cells

Schwann cells (SCs) are peripheral neuroglial cells derived from the neural crest. They are the most common cell type in the peripheral nervous system. There are several subtypes in addition to the myelin-forming cells. These include non-myelin-forming autonomic nervous system cells, perisynaptic cells, and perineuronal satellite cells of the dorsal root ganglia and of the autonomic ganglia. SCs are important for maintenance of normal nervous system function, repair of neural injury, immune modulation, and upregulation of pain. Myelin-forming SCs form spirals of compact myelin lamellae in both small and large neurons. Increasing layers of lamellae increase the speed of salutatory conduction. These cells also can recognize antigen and be the target of autoimmune responses as occur with Guillain-Barré syndrome. Most neural cells in the peripheral nervous system are unmyelinated, and SCs in these nerves, as well as the dorsal root and sympathetic and parasympathetic ganglia, provide an axonal sheath but do not form myelin. With peripheral nerve injury, perineuronal satellite cells can up-regulate nerve growth factor and

other molecules important to peripheral chronic pain syndromes. At the neuromuscular junction (NMJ), nonmyelinating SCs function to facilitate neurotransmission and repair damage. Transplant of SCs and use of exogenous neurotrophic factors are in the preclinical stage of evaluation.

Data from Armati PJ, Mathey EK: *J Neurol Sci* 333(1–2):68–72, 2013; Armati PJ, Mathey EK: *J Peripher Nerv Syst* 19(1):14–23, 2014; Jones S, Eisenberg HM, Jia X: *Int J Mol Sci* 17(9), 2016; Monk KR, Feltri ML, Taveggia C: *Glia* 63(8):1376–1393, 2015; Namgung U: *Cells Tissues Organs* 200(1):6–12, 2014.

Nerve Injury and Regeneration

Mature neurons do not divide, and injury in the CNS causes permanent loss of damaged neurons. Peripheral nerves can repair themselves through local, anterograde, and retrograde changes. This is known as the **axonal reaction**. *Local changes* occur when the axon is severed. The cut ends retract and the axolemma covers the cut ends, diminishing the escape of axoplasm. Macrophages and Schwann cells begin to phagocytize damaged tissue. The cell body undergoes chromatolysis with swelling, loss of Nissl bodies, and lateral migration of the nucleus. Antegrade (*Wallerian*) *degeneration* occurs in the distal axon: (1) a characteristic swelling appears in the axon terminal, and it degenerates and loses contact with the postsynaptic membrane within 7 days; (2) macrophages and Schwann cells phagocytize the remnants of the axon terminal; and (3) Schwann cells proliferate, forming a column or tube of Schwann cells enclosed by the original basal lamina of the endoneurium. *Retrograde changes* occur at the proximal end of the injured axon and are similar to anterograde changes but only back to the next node of Ranvier. Approximately 7 to 14 days after the injury, new terminal sprouts project from the proximal segment guided by Schwann cells and enter the sustaining substrate of the Schwann cell column or tubes for axonal regrowth. [Fig. 15.4](#) contains a more detailed representation of these events. This process is very slow (about 1 mm per day) and is limited to myelinated fibers in the PNS. The regeneration of axonal constituents

in the CNS is limited by an increased incidence of glial scar formation (gliosis) and the different nature of myelin formed by the oligodendrocyte.

FIGURE 15.4 Peripheral Nerve Regeneration Following Injury. Schwann cells detach from the axons, proliferate, and, with recruited macrophages, help to clear cellular and myelin debris. At the same time, expression of growth factors by Schwann cells creates a favorable environment for nerve regrowth toward the target organ. A damaged motor axon can regrow to its distal connection only if the neurilemma remains intact (to form a guiding

tunnel) and if scar tissue does not block its pathway. (From Gartner LP: *Textbook of histology*, ed 4, Philadelphia, 2017, Elsevier.)

Nerve regeneration depends on many factors, such as the location of the injury, the type of injury, the presence of inflammatory responses, and the process of scarring. The closer the injury is to the cell body of the nerve, the greater the chances that the nerve cell will die and not regenerate. A crushing injury allows recovery more fully than does a cut injury. Crushed nerves sometimes recover fully, whereas cut nerves often form connective tissue scars that block or slow regenerating axonal branches. Peripheral nerves injured close to the spinal cord recover poorly and slowly because of the long distance between the cell body and the peripheral termination of the axon.²

Nerve Impulse

Neurons generate and conduct electrical impulses by selectively changing the conductance across their plasma membrane and influencing other nearby neurons by the release of chemical signals (neurotransmitters). An unexcited neuron maintains a resting membrane potential. When the membrane potential is raised sufficiently, an action potential is generated and propagated to other parts of the neuron (see [Fig. 1.39](#)). The action potential occurs only when the stimulus is strong enough; if it is too weak the membrane remains unexcited. This property is sometimes termed the *all-or-none response*.

Synapses

Neurons are not physically continuous with one another but form points of contact with adjacent neurons with a specialized structure called a **synapse**. The synapse is composed of a small bulbous end of the presynaptic neuron (synaptic knob) that is separated from the postsynaptic neuron by a synaptic cleft. Impulses are transmitted across the synapse by chemical ([Fig. 15.5](#) and see [Fig. 15.16](#)) and electrical conduction; only chemical conduction is discussed here.

Chapter 1 contains information on electrical conduction. The neurons that conduct a nerve impulse are named according to whether they relay impulses *toward* (**presynaptic neurons**) or *away* from the synapse (**postsynaptic neurons**). Four basic types of connections occur in regions of contact between the presynaptic and postsynaptic neurons. These are between axons (axo-axonic), from axon to cell body (axo-somatic), from axon to dendrite (axo-dendritic), and from dendrite to dendrite (dendro-dendritic). In response to the arrival of an action potential at the synaptic knob, vesicles containing neurotransmitters release their contents into the synaptic cleft. Neurotransmitters diffuse across the **synaptic cleft** (the space between the neurons) and bind to specific receptors on postsynaptic neurons, where they trigger an action potential in the postsynaptic neuron (see [Fig. 15.5](#)). Brain synapses can change in strength and number throughout life; this is known as synaptic plasticity or **neuroplasticity**.

FIGURE 15.5 Neuronal Transmission and Synaptic Cleft. Details illustrate the synaptic knob (axon terminal) of a presynaptic neuron, the plasma

membrane of a postsynaptic neuron, and a synaptic cleft. At step (1)—the arrival of an action potential at the synaptic knob—voltage-gated Ca^{++} channels open and allow extracellular Ca^{++} to diffuse into the presynaptic cell. At step (2) the Ca^{++} triggers the rapid exocytosis of neurotransmitter molecules from vesicles in the knob. At step (3) neurotransmitter diffuses into the synaptic cleft and binds to receptor molecules in the plasma membrane of the postsynaptic neuron. The postsynaptic receptors directly or indirectly trigger the opening of stimulus-gated ion channels, initiating a local potential in the postsynaptic neuron. At step (4) the local potential may move toward the axon, where an action potential may begin. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

Neurotransmitters

Neurotransmitters are synthesized in the neuron and localized in the presynaptic terminal (synaptic bouton). Neurotransmitters are released into the synaptic cleft in response to the arrival of an electrical impulse and bind to a receptor site (binding site) on the postsynaptic membrane of an adjacent neuron or other effector. Here, binding of the neurotransmitter to its receptor causes a change in conductance of postsynaptic membrane allowing propagation of the impulse (see Fig. 15.5). Efficient termination of the signal requires rapid degeneration of the neurotransmitter in the cleft or on the postsynaptic cell surface. Neurons can synthesize more than one neurotransmitter, and postsynaptic membranes can contain more than one type of transmitter-specific receptor. Common neurotransmitters include norepinephrine, acetylcholine, dopamine, histamine, and serotonin. These have varied and overlapping functions³ that are summarized in Table 15.2.

TABLE 15.2

SUBSTANCES THAT ARE NEUROTRANSMITTERS OR NEUROMODULATORS

SUBSTANCE	LOCATION	EFFECT	CLINICAL EXAMPLE
Acetylcholine	Many parts of the brain, spinal cord, neuromuscular junction of	Excitatory or inhibitory	Alzheimer disease (a type of dementia) is associated with a decrease in the number of acetylcholine-secreting neurons. Muscle weakness caused by myasthenia gravis results from an autoimmune response to

	skeletal muscle, and many ANS synapses		acetylcholine receptors on the postsynaptic terminal.
Monoamines			
Norepinephrine	Many areas of the brain and spinal cord; also in some ANS synapses	Excitatory or inhibitory	CNS: Sleep-wake cycles and mood. Cocaine and amphetamines* result in overstimulation of postsynaptic neurons. PNS: Sympathetic nerve transmission.
Serotonin	Many areas of the brain and spinal cord	Generally inhibitory	Is involved with mood, anxiety, and sleep induction. Levels of serotonin are elevated in schizophrenia (delusions, hallucinations, withdrawal).
Dopamine	Some areas of the brain and ANS synapses	Generally excitatory	Parkinson disease (depression of voluntary motor control) results from destruction of dopamine-secreting neurons. Drugs used to increase dopamine can induce vomiting and hallucinations.
Histamine	Posterior hypothalamus	Excitatory (H1 and H2 receptors) and inhibitory (H3 receptors)	There is no clear indication of histamine-associated pathologic conditions. Histamine is involved with arousal and attention and links to other brain transmitter systems.
Amino Acids			
Gamma-aminobutyric acid (GABA)	Most neurons of the CNS have GABA receptors	Majority of postsynaptic inhibition in the brain	Drugs that increase GABA function have been used to treat epilepsy by inhibiting excessive discharge of neurons.
Glycine	Spinal cord	Most postsynaptic inhibition in the spinal cord	Glycine receptors are inhibited by strychnine.
Glutamate and aspartate	Widespread in brain and spinal cord	Excitatory	Drugs that block glutamate or aspartate, such as riluzole, are used to treat amyotrophic lateral sclerosis. These drugs might prevent overexcitation from seizures and neural degeneration.
Neuropeptides			
Endorphins and enkephalins	Widely distributed in the CNS and	Generally inhibitory	Morphine and heroin bind to endorphin and enkephalin receptors on presynaptic

	PNS		neurons and reduce pain by blocking the release of neurotransmitter.
Substance P	Spinal cord, brain, and sensory neurons associated with pain, GI tract	Generally excitatory	Substance P is a neurotransmitter involved in pain transmission pathways. Blocking release of substance P by morphine reduces pain.
Vasoactive intestinal peptide	Gastrointestinal tract	Generally excitatory	Stimulates secretion, vasodilation, and smooth muscle relaxation (vasodilation, sphincter relaxation).

*Increase the release and block the reuptake of norepinephrine.

ANS, Autonomic nervous system; *CNS*, central nervous system; *GI*, gastrointestinal; *PNS*, peripheral nervous system.

From Mtui E, Gruener G, Dockery P: *Fitzgerald's clinical neuroanatomy and neuroscience*, ed 7, Philadelphia, 2016, Elsevier.

Because the neurotransmitter is normally stored on the presynaptic side of the synaptic cleft and the receptor sites are on the postsynaptic side, chemical synapses operate in one direction. Therefore action potentials are transmitted along a multineuronal pathway in one direction. The binding of the neurotransmitter at the receptor site changes the permeability of the postsynaptic membrane and, consequently, its membrane potential. Two possible scenarios can follow: (1) the postsynaptic neuron may be excited (depolarized; **excitatory postsynaptic potentials [EPSPs]**), or (2) the postsynaptic membrane may be inhibited (hyperpolarized; **inhibitory postsynaptic potentials [IPSPs]**).⁴ ([Chapter 1](#) contains a review of electrical impulses and membrane potentials.)

Usually, a single postsynaptic potential cannot induce a neuron's action potential and the propagation of the nerve impulse. Whether an action potential occurs depends on the number and frequency of excitatory and inhibitory potentials the postsynaptic neuron receives, a concept known as **summation**. **Temporal summation** refers to the effects of successive, rapid impulses received from a single neuron on the same synapse. **Spatial summation** is the combined effects of impulses from a number of neurons on a single synapse at the same time. **Facilitation** refers to the effect of multiple EPSPs on the plasma

membrane potential. The plasma membrane is facilitated when summation brings the membrane closer to the threshold potential and decreases the stimulus required to induce an action potential. The effect of a neurotransmitter on the membrane potential depends on the balance of these effects. The mechanisms of **convergence** (many neurons firing and converging on one neuron), **divergence** (one neuron firing and diverging on many neurons), summation, and facilitation allow for the integrative processes of the nervous system.

Two points could be helpful in understanding the complexity of brain physiology. First, the aforementioned neuromodulators appear to function to raise or lower the membrane potentials of neurons. These chemicals facilitate or inhibit the effect of neurotransmitters. Second, reciprocal synapses between dendrites—that is, one dendrite being able to depolarize or hyperpolarize the membrane potential of another dendrite through the use of neurotransmitters—demonstrate that the interactions between neurons are far more complicated than postulated by simple on-off models of brain function.

Central Nervous System

The **central nervous system (CNS)** is composed of the brain and the spinal cord. The neuron is the basic structure of the CNS.

Brain

The **brain** is a functionally integrated circuit of millions of neurons with different structures, molecular composition, networks, and connections. It weighs only 3 pounds but receives 15% to 20% of the total cardiac output. The brain enables a person to reason, function intellectually, express personality and mood, and perceive and interact with the environment.

The three major structural divisions of the brain are (1) the forebrain (prosencephalon), which includes the telencephalon and diencephalon; (2) the midbrain (mesencephalon), which connects the pons to the diencephalon and includes the corpora quadrigemina,

tegmentum, and cerebral peduncles; and (3) the hindbrain (rhombencephalon), which includes the cerebellum, pons, and medulla (Table 15.3 and Fig. 15.6). The midbrain, medulla, and pons comprise the **brainstem**, which connects the hemispheres of the brain, cerebellum, and spinal cord. A collection of nuclei within the brainstem collectively constitute the **reticular formation**. The reticular formation is a large network of diffuse nuclei that connect the brainstem to the cortex and control vital reflexes, such as cardiovascular function and respiration. It is essential for maintaining wakefulness and attention and, therefore, is referred to as the **reticular activating system** (Fig. 15.7).

TABLE 15.3

DIVISIONS OF THE CENTRAL NERVOUS SYSTEM

PRIMARY VESICLES	SECONDARY VESICLES	ASSOCIATED STRUCTURES

FIGURE 15.6 Structural Divisions of the Brain. (From Standing S: *Gray's anatomy: the anatomical basis of clinical practice*, ed 40, Philadelphia, 2008, Elsevier.)

FIGURE 15.7 Reticular Activating System. The reticular activating system consists of nuclei in the brainstem reticular formation plus fibers (axons) that conduct to the nuclei from below and fibers that conduct from the

nuclei to widespread areas of the cerebral cortex. Functioning of the reticular activating system is essential for maintaining consciousness.

Divisions of the brain are associated with specific functions, but it is important to recognize that most brain functions require integration of multiple different inputs from different parts of the brain. However, for clinical considerations, functional specificity is useful for localizing pathologic conditions in various nervous system regions. Korbinian Brodmann, a German neuroanatomist, was among the first to define structural and functional aspects of brain anatomy. Brodmann's areas are still used to correlate functional activities to many regions of the cerebral cortex.⁵ Fig. 15.8, C, illustrates these regions and describes some of the areas. The mapping of **brain networks** (interconnected areas of the brain) using functional MRI (fMRI) and other advanced imaging techniques is helping to discover new insights into the function of these complex and interconnected pathways^{6,7} (Box 15.2).

Box 15.2

Brain Networks

The architecture and integrated function of neural nodes, networks, and interconnected pathways within the brain are being mapped with high resolution in the advancing field of human connectomics. Imaging techniques include positron-emission tomography, trace diffusion tensor magnetic resonance imaging, functional MRI, magnetoencephalography, and electroencephalography combined with mathematical and computational models.

The figure at the right provides an illustration of brain connectivity showing interconnecting cortical pathways using diffusion tensor imaging tracking technology. Such mapping of the brain contributes to an understanding of the commonalities and individual differences of the normally functioning brain and changes associated with aging and disease (i.e., degenerative brain disease, epilepsy, schizophrenia, and brain tumors). For example, a recent study was able to identify dysfunctional cholinergic and perfusion networks in Parkinson disease using functional MRI techniques. Such information may be helpful in identifying areas of brain function that improve with treatment.

Forebrain

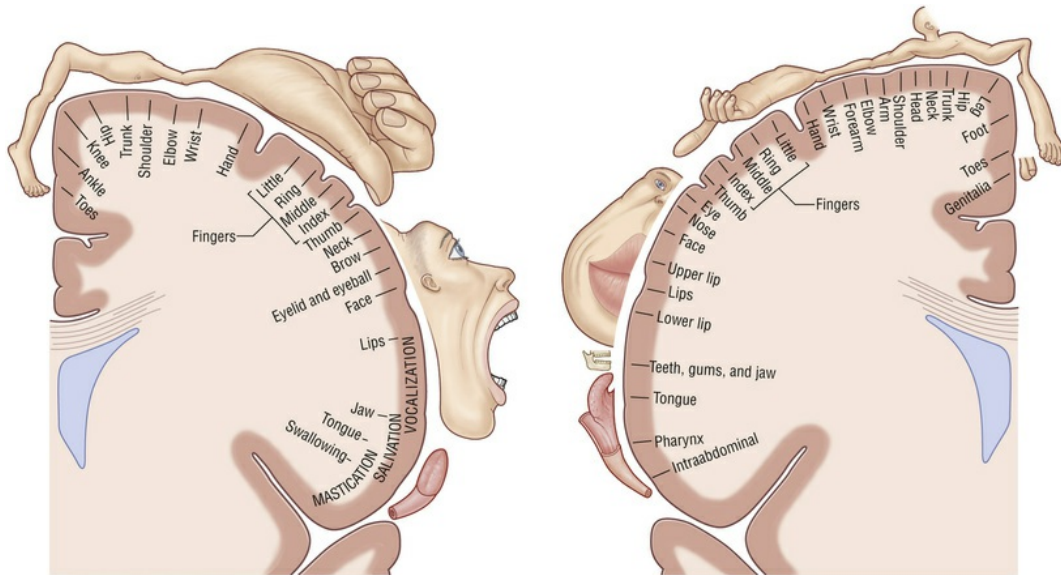

Telencephalon.

The **telencephalon (cerebral hemispheres)** consists of the cerebral cortex (the largest portion of the brain) and the basal ganglia (composed of several *nuclei*). The surface of the cerebral cortex is covered with convolutions called *gyri* (see Fig. 15.8, A) that greatly increase the cortical surface area and the number of neurons. Grooves between adjacent gyri are termed **sulci**; deeper grooves are **fissures**. The **cerebral cortex** contains an outer layer of cell bodies of neurons (**gray matter**). Gray matter is organized into columns perpendicular to the surface that receive, integrate, store, and transmit information. **White matter** lies beneath the cerebral cortex and is composed of myelinated nerve fibers (axons).

The two cerebral hemispheres are separated by a deep groove known as the **longitudinal fissure**. The surface of each hemisphere is divided into lobes named after the region of the skull under which each lobe lies. The posterior margin of the **frontal lobe** is the **central sulcus (fissure of Rolando)** and it borders inferiorly on the **lateral sulcus (sylvian fissure, lateral fissure)** (see Fig. 15.8, A). The **prefrontal area** is responsible for goal-oriented behavior (i.e., ability to concentrate), short-term or recall memory, and the elaboration of thought and inhibition on the limbic (emotional) areas of the CNS. The **premotor area** (Brodmann area 6) (see Fig. 15.8, C) is involved in programming motor movements. This area also contains the cell bodies that form part of the basal ganglia system (extrapyramidal system, efferent pathways outside the pyramids of the medulla oblongata). The frontal eye fields (the lower portion of Brodmann area 8), which are involved in controlling eye movements, are located in the middle frontal gyrus.

The **primary motor area (Brodmann area 4)** is located along the **precentral gyrus** forming the **primary voluntary motor area**, which

has a somatotopic organization that often is referred to as a *homunculus* (little man) (Fig. 15.9). Electrical stimulation of specific areas of this cortex causes specific muscles of the body to move. For example, stimulation of Brodmann area 4 in the medial longitudinal fissure affects the lower limb and foot, whereas stimulation of the superior lateral surface of the precentral gyrus affects the torso and arm, the middle third of the hand, and the lower third of the face and mouth/throat. The axons traveling from the cell bodies in and on either side of this gyrus project fibers (axons) that form the **pyramidal system**. This system includes the **corticobulbar tract** that synapses in the brainstem and provides voluntary control of muscles in the head and neck, and the **corticospinal (pyramidal) tracts** that descend into the spinal cord and provide voluntary control of muscles throughout the body. Cerebral impulses control function on the opposite side of the body, a phenomenon called *contralateral control* (Fig. 15.10, A). **Broca area** in the inferior frontal lobe (Brodmann areas 44, 45) is an important center for speech and language processing. This area, rostral to the inferior edge of the premotor area (Brodmann area 6) on the inferior frontal gyrus, is usually most important in the left hemisphere. Injury to this area results in difficulty forming or inability to form words (expressive aphasia or dysphasia) (see Chapter 17).

A Motor

B Sensory

FIGURE 15.9 Primary Somatic Motor and Sensory Areas of the Cortex. A, The motor homunculus shows proportional somatotopic representation in the main motor area. B, The sensory homunculus shows proportional somatotopic representation in the somaesthetic cortex. (From Standing S et al, editors: *Gray's anatomy*, ed 40, Edinburgh, 2008, Churchill Livingstone.)

FIGURE 15.10 Examples of Somatic Motor and Sensory Pathways. **A**, Motor pathways. The pyramidal pathway through the lateral corticospinal tract and the extrapyramidal pathways through the rubrospinal, reticulospinal, and vestibulospinal tracts. **B**, Sensory pathways. **B1**, The dorsal column-medial lemniscal pathway for transmitting critical types of tactile signals: touch/proprception. Note the later corticospinal tract decussation is in the lower medulla. The corticobulbar tract is not shown. **B2**, Anterior and lateral divisions of the anterolateral sensory pathway: pain/temperature. Note the decussation is in the spinal cord. (A from Compston A et al: *McAlpines's multiple sclerosis*, ed 4, London, 2006, Churchill Livingstone; B from Hall JE: *Guyton and Hall textbook of medical physiology*, ed 13, Philadelphia, 2016, Saunders.)

The **parietal lobe** lies within the borders of the central, parietooccipital, and lateral sulci. This lobe contains the major area for somatic sensory input, located along the **postcentral gyrus** (Brodmann areas 3, 1, 2) (see Fig. 15.8), which is adjacent to the primary motor area in the **precentral gyrus**. Communication between the motor and

sensory areas (and among other regions in the cortex) is provided by **association fibers**. Much of this region is involved in sensory association (storage, analysis, and interpretation of stimuli). [Fig. 15.9](#) shows the distribution of functions associated with both the primary motor area and the primary sensory area of the cerebral cortex (note the somatotopic organization of both primary motor and primary sensory areas).

The **occipital lobe** lies caudal to the parietooccipital sulci and superior to the cerebellum. The primary visual cortex (Brodmann area 17) is located in this region and receives input from the retinas. Much of the remainder of this lobe is involved in visual association (Brodmann areas 18, 19). The **temporal lobe** lies inferior to the lateral fissure and is composed of the superior, middle, and inferior temporal gyri. The primary auditory cortex (Brodmann area 41) and its related association area (Brodmann area 42) lie deep within the lateral sulcus on the superior temporal gyrus. **Wernicke area** (posterior portion of Brodmann area 22), along with adjacent portions of the parietal lobe, constitutes a *sensory speech area*. This area is responsible for reception and interpretation of speech, and dysfunction may result in receptive aphasia or dysphasia. The temporal lobe also is involved in memory consolidation and smell.

The **insula (insular lobe)** lies hidden in the lateral sulci between the temporal and frontal lobes of each hemisphere. The insula processes sensory and emotional information and routes the information to other areas of the brain. Lying directly beneath the longitudinal fissure, the **corpus callosum (transverse commissural fibers)** is a bundle of myelinated fibers that connects the two cerebral hemispheres. The corpus callosum conveys contralateral projection of axons and is essential in coordinating activities between hemispheres (see [Fig. 15.8, B](#)).

Deep inside the cerebrum are numerous white matter tracts and gray matter nuclei and the major **cerebral nuclei** of the basal ganglia (basal nuclei) system. The **basal ganglia system** is a group of nuclei that includes the caudate nucleus, putamen, and globus pallidus. The putamen and globus pallidus together are called the *lentiform nuclei*.

The caudate nucleus and putamen together are called the *striatum*⁵ (Fig. 15.11). Other structures in the basal ganglia include the substantia nigra, the nucleus accumbens (not shown), and the subthalamic nucleus (not shown). The nuclei of the basal ganglia are important for coordination of voluntary movement and cognitive and emotional functions.

FIGURE 15.11 The Basal Ganglia. **A**, The basal ganglia seen through the cortex of the left cerebral hemisphere. **B**, The basal ganglia seen in a frontal (coronal) section of the brain. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

The **internal capsule** is a white matter tract in which afferent (sensory) and efferent (motor) pathways are conveyed to and from the cerebral cortex by passing through the center of the cerebral hemispheres and between the caudate and lentiform nuclei (see Fig. 15.11, *B*). The basal ganglia and their direct and indirect interconnections with the thalamus, premotor cortex, red nucleus, reticular formation, and spinal cord are part of the extrapyramidal

system. The extrapyramidal system is a part of the motor control system that causes involuntary reflexes and has a stabilizing effect on motor control.

The **limbic system** is a group of interconnected structures located between the telencephalon and diencephalon and surrounding the corpus callosum. It is composed of the amygdala, hippocampus, fornix, hypothalamus, and related autonomic nuclei (see [Fig. 15.11](#)). The limbic system mediates emotion and long-term memory through connections in the prefrontal cortex (limbic cortex). Its principal effects are involved in primitive behavioral responses, visceral reaction to emotion, motivation, mood, feeding behaviors, biologic rhythms, and the sense of smell.

Diencephalon.

The **diencephalon (interbrain)**, surrounded by the cerebrum and sitting on top of the brainstem, has four divisions: **epithalamus**, **thalamus**, **hypothalamus**, and **subthalamus** (see [Table 15.3](#) and [Fig. 15.8, B](#)). The epithalamus forms the roof of the third ventricle and composes the most superior portion of the diencephalon. The diencephalon controls vital functions and visceral activities and is closely associated with those of the limbic system.

The largest component of the diencephalon is the thalamus. It borders and surrounds the third ventricle and is a major integrating center for afferent (sensory) impulses to the cerebral cortex. Various sensations are perceived at this level, but cortical processing is required for interpretation. The thalamus also serves as a relay center for information from the basal ganglia and cerebellum to the appropriate motor area.

The hypothalamus forms the ventral part of the diencephalon and functions to maintain a constant internal environment and implement behavioral patterns. Integrative centers control autonomic nervous system (ANS) function, regulate body temperature and endocrine function, and adjust emotional expression. (Temperature regulation is discussed in [Chapter 16](#).) The hypothalamus exerts its influence through the endocrine system, as well as neural pathways ([Box 15.3](#)).

The subthalamus flanks the hypothalamus laterally and serves as an important basal ganglia center for motor activities.

Box 15.3

General Functions of the Hypothalamus

- Visceral and somatic responses
- Affectual responses
- Hormone synthesis
- Sympathetic and parasympathetic activity
- Temperature regulation
- Feeding responses
- Physical expression of emotions
- Sexual behavior
- Pleasure-punishment centers
- Level of arousal or wakefulness

Midbrain (Mesencephalon)

The **midbrain (mesencephalon)** (see [Table 15.3](#)) connects the forebrain with the hindbrain and is composed of the tectum (corpora quadrigemina [forms roof of midbrain]), the tegmentum, and the cerebral peduncles. The **tectum** includes the two pairs of superior colliculi and two pairs of inferior colliculi. The **superior colliculi** are involved with voluntary and involuntary visual motor movements (e.g., the ability of the eyes to *track* moving objects in the visual field). The **inferior colliculi** accomplish similar motor activities but involve movements affecting the auditory system (e.g., positioning the head to improve hearing). The inferior colliculus also is a major relay center along the auditory pathway. The **tegmentum** (floor of the midbrain) is composed of the red nucleus and substantia nigra. The **red nucleus** receives ascending sensory information from the cerebellum and projects a minor motor pathway, the rubrospinal tract, to the cervical

spinal cord. The **substantia nigra** synthesizes **dopamine**. Dysfunction of dopaminergic neurons in the substantia nigra is associated with Parkinson disease and schizophrenia. The **cerebral peduncles** of the anterior midbrain are made up of efferent fibers of the corticospinal, corticobulbar, and corticopontocerebellar tracts (tracts that link the cortex to the brainstem).

Other notable structures of this region are the nuclei of the third and fourth cranial nerves. The **cerebral aqueduct (aqueduct of Sylvius)**, which carries cerebrospinal fluid (CSF) between the third and fourth ventricles, also traverses this structure. Obstruction of this aqueduct is a common cause of hydrocephalus.

Hindbrain

Metencephalon.

The major structures of the **metencephalon** are the cerebellum and the pons. The **cerebellum** (see [Fig. 15.8, A and B](#)) is composed of two lobes of gray and white matter, and its cortical surface is convoluted like the surface of the cerebrum. The lobes are divided by a central fissure and connected by a midline structure, the vermis.

The cerebellum is responsible for reflexive, involuntary fine-tuning of motor control and for maintaining balance and posture through extensive neural connections with the medulla (through the inferior cerebellar peduncle) and with the midbrain (through the superior cerebellar peduncle). The two hemispheres are connected to the pons by the middle cerebellar peduncles. These connections allow extensive sampling of visual, vestibular, and proprioceptive data from other regions of the CNS and periphery. The cerebellum has ipsilateral (same side) control of the body, in contrast to the cerebral cortex, which has contralateral (opposite side) control of the body.

The **pons** (bridge) is easily recognized by its bulging appearance below the midbrain and above the medulla. Primarily it transmits information from the cerebellum to the brainstem between the two cerebellar hemispheres. The nuclei of the fifth through eighth cranial nerves are located in the pons.

Myelencephalon.

The **myelencephalon (medulla oblongata)** forms the lowest portion of the brainstem. Reflex activities, such as heart rate, respiration, blood pressure, coughing, sneezing, swallowing, and vomiting, are controlled in this area. The nuclei of cranial nerves IX through XII are located in this region (see [Table 15.6](#) for details).

A major portion of the descending motor pathways (i.e., corticospinal tracts) cross to the other side, or decussates at the inferior medulla (see [Fig. 15.10, A](#)). These pathways, together with other areas of decussation in the CNS, are the basis for the phenomenon of contralateral control. Sleep-wake rhythms also are processed by neural influences from lower brain centers and are associated with a complex group of diffuse structures and functions including the reticular activating system (see [Fig. 15.7](#)).

Spinal Cord

The **spinal cord** lies within the vertebral canal and is surrounded and protected by the vertebral column. One of the primary functions of the spinal cord is to transmit long motor and sensory tracts that originate in the brain and synapse with cell bodies in gray matter of the spinal cord before exiting to the body. Additional significant functions include somatic and autonomic reflexes, motor pattern control centers, and sensory and motor modulation. The spinal cord originates in the medulla oblongata ([Fig. 15.12](#)) and ends at the **conus medullaris**, a cone shaped structure at the level of the first or second lumbar vertebra in adults ([Fig. 15.13](#)). Spinal nerves extend from the conus medullaris and form a nerve bundle called the **cauda equina**. A thin filament, the **filum terminale**, extends from the conus medullaris and anchors it to the coccyx. The coverings of the spinal cord mirror those of the brain and are illustrated in [Fig. 15.13](#).

FIGURE 15.12 Vertebral Canal, Spinal Cord, and Spinal Nerves. Enlarged segment of the brachial plexus is shown. (From Drake R, et al: *Gray's anatomy for students*, ed 3, London, 2015, Churchill Livingstone. *Inset*, from Chung KC, et al: *Practical management of pediatric and adult brachial plexus palsies*, London, 2012, Saunders.)

FIGURE 15.13 Coverings of the Spinal Cord. The dura mater is shown in purple. Note how it extends to cover the spinal nerve roots and nerves. The arachnoid mater is highlighted in pink and the pia mater in orange. (From Patton KT, Thibodeau GA: *Structure and function of the body*, ed 15, St Louis, 2016, Mosby.)

Grossly, the spinal cord is divided into sections (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that correspond to paired nerves (see [Fig. 15.12](#)). A cross section of the spinal cord (see [Figs. 15.13](#) and [15.14](#)) is characterized by a butterfly-shaped inner core of

gray matter (containing nerve cell bodies) surrounded by white matter tracts. The **central canal** extends through the spinal cord from its origin in the fourth ventricle. The gray matter of the spinal cord is divided into three regions and displays specific functional characteristics. These regions include the **posterior horn (dorsal horn)**, composed primarily of interneurons and axons from sensory neurons whose cell bodies lie in the **dorsal root ganglion**. At the tip of the posterior horn is the **substantia gelatinosa**, a structure involved in pain transmission (see [Chapter 16](#)). The **lateral horn** contains cell bodies involved with the ANS. The **anterior horn (ventral horn)** contains the nerve cell bodies for efferent (motor) pathways that leave the spinal cord by way of spinal nerves. The terms *anterior* and *posterior* are preferred by many authors for describing human spinal cord anatomy, whereas *dorsal* and *ventral* are the common zoologic (veterinary) terms.

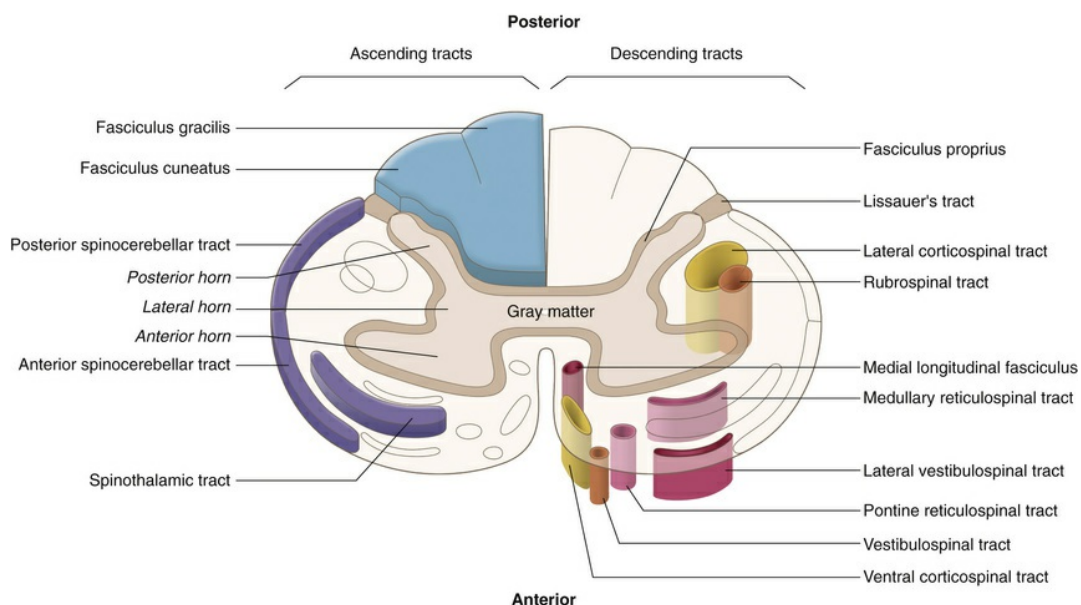

FIGURE 15.14 Ascending and Descending Tracts of the Spinal Cord. Ascending (*sensory*) tracts are emphasized on the left side and descending (*motor*) tracts are emphasized on the right side. The locations of Lissauer's tract and the fasciculus proprius (which contain both ascending and descending fibers) are also shown. (From Crossman AR, Neary D: *Neuroanatomy: an illustrated colour text*, ed 4, London, 2015, Churchill Livingstone.)

Surrounding the gray matter is white matter that forms ascending and descending pathways called **spinal tracts** and short ascending and descending integrative pathways. Spinal tracts are named to denote their beginning and ending points. For example, the **spinothalamic tract** carries nerve impulses from the spinal cord to the thalamus in the diencephalon. Numerous spinal tracts are grouped into columns according to their location within the white matter. These include the **anterior column**, **lateral column**, and **posterior column** (the fasciculus gracilis and fasciculus cuneatus). Ascending tracts are found in all columns. Descending tracts are found only in the lateral and anterior columns. [Fig. 15.14](#) identifies the location and principal activities of the major spinal tracts and the horns of the gray matter.

Neural circuits in the spinal cord, when activated, display specific sets of motor responses. **Reflex arcs** form basic units that respond to stimuli and provide protective circuitry for motor output. Structures mandatory for a reflex arc (monosynaptic reflex) are a receptor, an **afferent (sensory) neuron**, an **efferent (motor) neuron**, and an effector muscle or gland. A simple reflex arc (e.g., knee jerk reflex) contains only two neurons. In most cases, simple reflex arcs are modulated by interneurons that provide a link between sensory and motor neurons ([Fig. 15.15](#) illustrates a reflex arc). The motor effects of reflex arcs generally occur before the event is perceived in the brain's higher centers. Much internal environmental regulation is mediated by reflex activity involving the ANS (e.g., cardiac muscle and smooth muscle contraction/relaxation and glandular responses).

FIGURE 15.15 Cross Section of Spinal Cord Showing Simple Reflex Arc. (From Jarvis C: *Physical examination & health assessment*, ed 7, St Louis, 2016, Mosby.)

Afferent pathways transmit information from peripheral receptors with eventual termination in the cerebral or cerebellar cortex, or both. Efferent pathways primarily relay information from the cerebrum to the brainstem or spinal cord (see Fig. 15.10, A). **Upper motor neurons** (i.e., corticospinal and corticobulbar tracts) are completely contained within the CNS (see Fig. 17.32). Their primary roles are controlling fine motor movement and influencing/modifying spinal reflex arcs and circuits. Generally, upper motor neurons form synapses with interneurons, which then form synapses with lower motor neurons that project into the periphery. **Lower motor neurons** directly influence muscles. Their cell bodies lie in the gray matter of the brainstem and anterior horn of the spinal cord, but their processes extend out of the CNS and into the PNS (see Fig. 15.10, A and Fig. 17.33). Destruction of upper motor neurons usually results in initial paralysis followed within days or weeks by partial recovery, whereas destruction of the lower motor neurons often leads to permanent

paralysis, unless peripheral nerve damage is followed by nerve regeneration and recovery.

Muscle activity (i.e., stimulation and contraction) is regulated by nerve impulses. Motor neurons innervate one or more muscle cells, forming a **motor unit** which consists of a single motor neuron and all of the skeletal muscle fibers it stimulates. The junction between the axon of the motor neuron and the plasma membrane of the muscle cell is called the **neuromuscular (myoneural) junction** (Fig. 15.16). Injury to motor neurons is discussed in [Chapter 18](#).

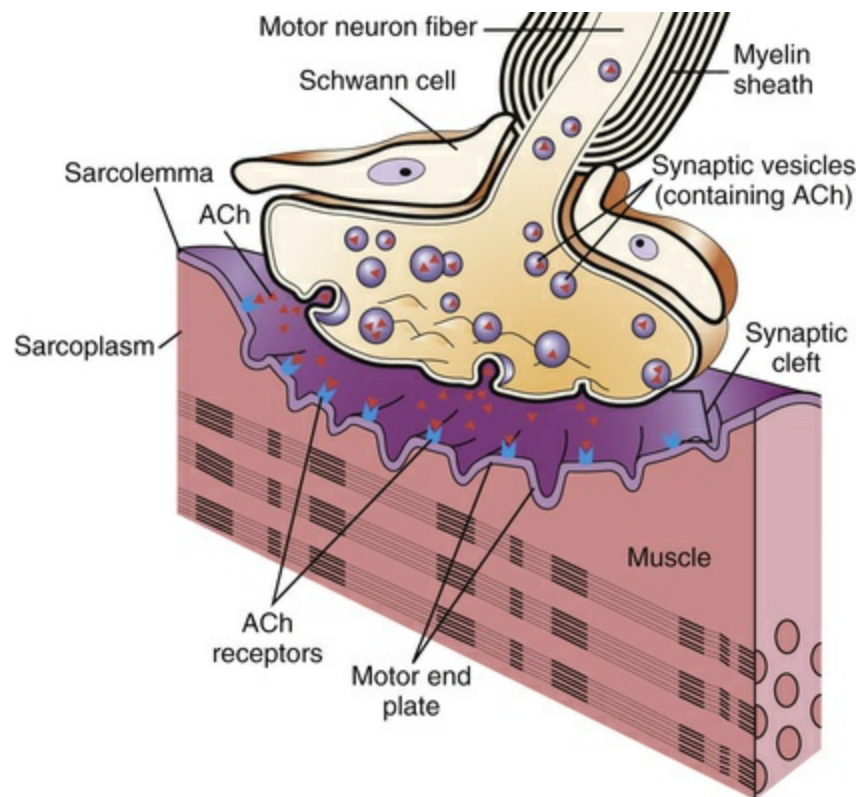

FIGURE 15.16 Normal Neuromuscular Junction. This figure shows how the distal end of a motor neuron fiber forms a synapse with an adjacent muscle fiber. Acetylcholine (ACh) is released from the neuron's synaptic vesicles and diffuses across the synaptic cleft, where it stimulates receptors in the motor end-plate region of the sarcolemma. (From Damjanov I: *Pathology for the health professions*, ed 4, St Louis, 2012, Saunders.)

Motor Pathways (Tracts)

Clinically relevant motor pathways are the corticospinal and corticobulbar (bulbar refers to brainstem) pyramidal tracts; and the extrapyramidal reticulospinal, vestibulospinal, and rubrospinal tracts. The corticospinal (see Fig. 15.10, A) and corticobulbar tracts (cortex to medulla) (see Fig. 17.31) consist of a two-neuron chain. The cell bodies (upper motor neurons) originate in and around the precentral gyrus; pass through the corona radiata of the cerebrum, the internal capsule, and the middle three-fifths of the basis pedunculi, pons, and pyramid; and decussate (cross contralaterally) in the medulla oblongata and form the lateral corticospinal tract of the spinal cord (see Fig. 15.14). The lateral corticospinal tract axons descend in the spinal cord and leave the white matter tract to synapse with specific interneurons or motor neurons in the anterior horn of the spinal cord. The lateral corticospinal tract has the same somatotopic organization as the body. The corticobulbar tract axons synapse on motor cranial nuclei within the brainstem that control muscles of the face, head, and neck. Lower motor neurons project from the anterior horn of the spinal cord through nerves to specific muscles.

The **extrapyramidal tracts** are involved in precise motor movements (see Fig. 15.14). The reticulospinal tract modulates motor movement by inhibiting and exciting spinal activity. The vestibulospinal tract arises from a vestibular nucleus in the pons and causes the extensor muscles of the body to rapidly contract, most dramatically witnessed when a person starts to fall backward. The rubrospinal tract originates in the red nucleus, decussates, and terminates in the cervical spinal cord. It is important for muscle movement and fine muscle control in the upper extremities.

Sensory Pathways

The three clinically important spinal afferent (sensory) pathways are the posterior column, anterior spinothalamic, and lateral spinothalamic (see Fig. 15.14; also see Figs. 16.2 and 16.3). The **posterior column** (fasciculus gracilis and fasciculus cuneatus) carries fine-touch (including two-point discrimination), vibration, and proprioceptive information (epicritic information). The posterior

column is formed by a three-neuron chain. The first neurons of the chain are the primary afferent neuron. They are also the sensory neuron of the reflex arc. After entering the spinal cord, the primary neuron sends its axon ipsilaterally up the spinal cord in a specific part of the posterior column and synapses in one of three posterior column nuclei in the medulla oblongata. The axons of second-order neurons cross contralaterally at the medial lemniscus and ascend and synapse with a specific nucleus of the thalamus. The third-order neurons originate in the thalamus and continue the tract into the internal capsule, corona radiata, and postcentral gyrus (Brodmann areas 3, 1, 2) (see [Fig. 15.8, C](#)).

The **anterior** and **lateral spinothalamic tracts** are responsible for vague touch and for pain and temperature perception, respectively (see [Fig. 15.10, B2](#)). These modalities are referred to as **protopathic**. These tracts also form a three-neuron chain. However, their primary afferent neurons synapse in the posterior horn of the spinal cord, not just at the level they enter the intervertebral foramen but in a number of spinal segments above and below their point of entry. This is an example of divergence. The axons of the second-order neurons in the posterior horn cross to the contralateral side in the spinal cord in the lateral column, and ascend to the same thalamic nucleus as the posterior column pathway and continue on with the posterior column pathway to the postcentral gyrus.

Protective Structures

Cranium

The cranial vault functions to enclose and protect the brain and its associated structures. The bony cranium is composed of eight bones (frontal, two parietal, two temporal, ethmoid, sphenoid, and occipital). The **galea aponeurotica** is a thick, fibrous band of tissue overlying the cranium between the frontal and occipital muscles. This structure affords added protection to the bony structure of the skull. The subgaleal space has venous connections with the dural sinuses, and with increased intracranial pressure, blood can be shunted to this

space, thus reducing pressure in the intracranial cavity. The subgaleal space is also a common site for placement of wound drains after intracranial surgery.

The floor of the cranial vault is irregular and contains many foramina (openings) that act as exit sites for cranial nerves, blood vessels, and the spinal cord. The cranial floor is divided into three fossae (depressions). The frontal lobes lie in the **anterior fossa**; the temporal lobes and base of the diencephalon lie in the **middle fossa (temporal fossa)**; and the cerebellum lies in the **posterior fossa**. These terms are commonly used anatomic landmarks to describe the location of intracranial lesions.

Meninges

Surrounding the brain and spinal cord are three protective membranes: the dura mater, the arachnoid, and the pia mater. Collectively they are called the **meninges** (Fig. 15.17, C). The **dura mater** (meaning literally “hard mother”) is composed of two layers, with the venous sinuses formed between them. The outermost layer forms the **periosteum (endosteal layer)** of the skull. The **inner dura (meningeal layer)** provides rigid membranes that support and separate various brain structures. One of these membranes, the **falx cerebri**, dips between the two cerebral hemispheres along the longitudinal fissure (see Fig. 15.17). The falx cerebri is anchored anteriorly to the base of the brain at the crista galli of the ethmoid bone. The **tentorium cerebelli**, a common landmark, is a membrane that separates the cerebellum from the cerebral structures above. The **arachnoid mater** is a spongy, weblike structure just underneath the dura mater that loosely follows the contours of the cerebral structures.

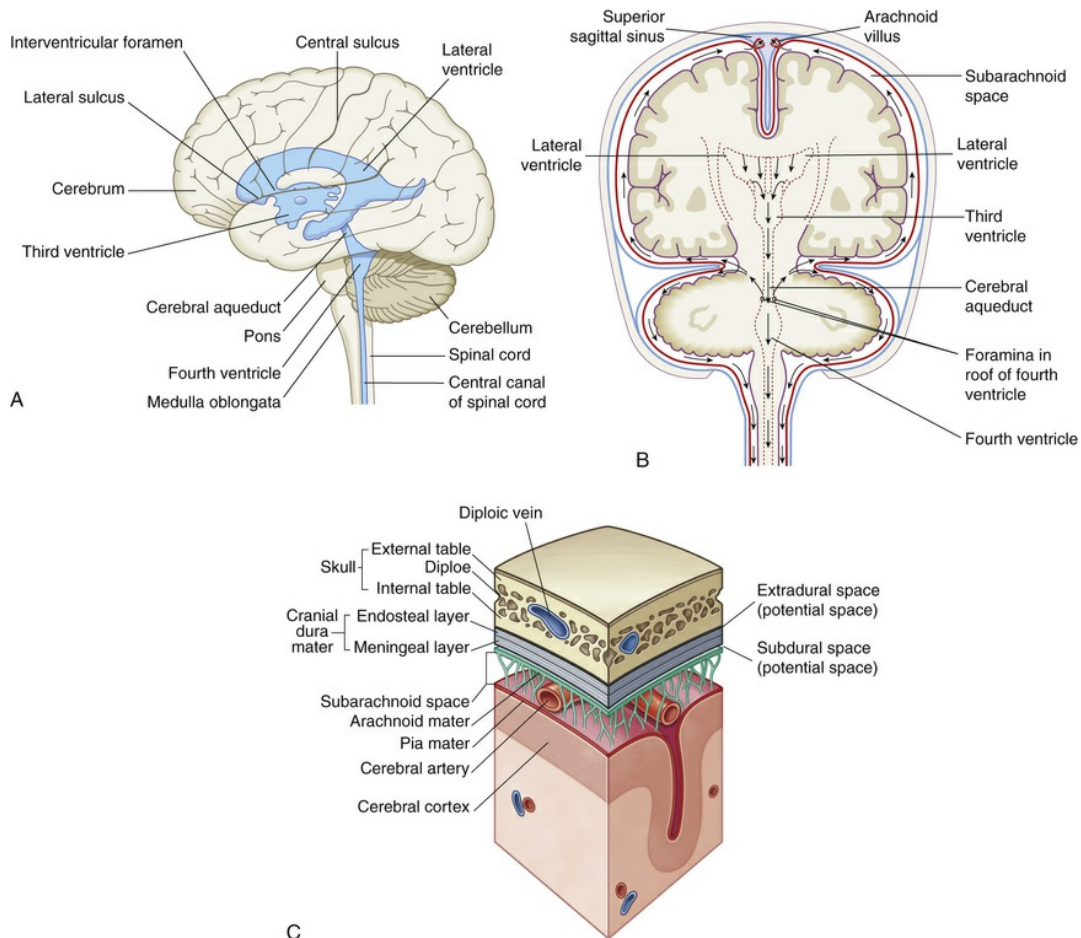

FIGURE 15.17 Flow of Cerebrospinal Fluid and Meninges of the Brain **A**, Ventricles highlighted in blue within a translucent brain in a left lateral view. **B**, Flow of cerebrospinal fluid. The fluid produced by filtration of blood by the choroid plexus of each ventricle flows inferiorly through the lateral ventricles, interventricular foramen, third ventricle, cerebral aqueduct, fourth ventricle, and subarachnoid space to the blood. **C**, Meninges of the brain. (A, B from Waugh A, Grant A: *Ross and Wilson anatomy and physiology in health and illness*, ed 12, London, 2012, Churchill Livingstone; C from Drake R et al: *Gray's anatomy for students*, ed 3, London, 2015, Churchill Livingstone.)

The **subdural space** lies between the dura and arachnoid. Many small bridging veins that have little structural support traverse the subdural space. Their disruption results in a subdural hematoma (see [Chapter 18](#) and [Figs. 18.5](#) and [18.6](#)). The **subarachnoid space** lies between the arachnoid and the pia mater and cerebrospinal fluid (CSF) (see [Fig. 15.17](#)). Unlike the dura mater and arachnoid, the delicate **pia mater** closely adheres to the surface of the brain and spinal cord. It provides support for blood vessels serving brain tissue. The **choroid plexuses** arise from the pia membrane and function to

produce cerebrospinal fluid (CSF). The spinal cord is anchored to the vertebrae by extensions of the meninges called **denticulate ligaments**. The meninges continue beyond the end of the spinal cord (at vertebrae levels L1 and L2) to the lower portion of the sacrum. CSF, contained within the subarachnoid space, also circulates down to the large **lumbar cistern**, which extends from the second lumbar vertebra to the second sacral vertebra. Cisterns are expanded areas of the subarachnoid space. The **cerebellomedullary cistern (cisterna magna)** and the pontine cistern are two other important cisterns.

The meninges form potential and real spaces important to understanding functional and pathologic mechanisms. For example, between the dura mater and skull lies a potential space termed the **epidural space** (see [Fig. 15.17](#)). The arterial supply to the meninges consists of blood vessels that lie within grooves in the skull. A skull fracture can sever one of these vessels and produce an epidural hematoma.

Cerebrospinal Fluid and the Ventricular System

Cerebrospinal fluid (CSF) is a clear, colorless fluid similar to blood plasma and interstitial fluid. The intracranial and spinal cord structures float in CSF and are thereby partially protected from jolts and blows. The buoyant properties of the CSF also prevent the brain from tugging on meninges, nerve roots, and blood vessels. (Constituents of CSF are listed in [Table 15.4](#).) Between 125 and 150 mL of CSF is circulating within the **ventricles** (small cavities) and subarachnoid space at any given time. Approximately 600 mL of CSF is produced daily.

TABLE 15.4

COMPOSITION OF CEREBROSPINAL FLUID

CONSTITUENT	NORMAL VALUE
Na ⁺	148 mM
K ⁺	2.9 mM
Cl ⁻	125 mM

HCO_3^-	22.9 mM
Glucose (fasting)	50–75 mg/dL (60% of serum glucose)
pH	7.3
Protein	15–45 mg/dL
Albumin	80%
Gamma-globulin	6–10%
Cells	
White (lymphocytes)	0–6/mm ³
Red (red blood cell [RBC])	0/mm ³

Cl^- , Chloride; HCO_3^- , bicarbonate; K^+ , potassium; Na^+ , sodium.

The choroid plexuses in the lateral, third, and fourth ventricles produce the major portion of CSF. (Ventricles are illustrated in [Fig. 15.17](#).) These plexuses are characterized by a rich network of blood vessels, supplied by the pia mater, that lie close to the ependymal cells of the ventricles. The tight junctions of the choroid blood vessel provide a limiting barrier between the CSF and blood that functions similarly to the blood-brain barrier (see Blood-Brain Barrier).

The CSF exerts pressure within the brain and spinal cord. When a person is supine, CSF pressure is approximately 80 to 180 mm of water pressure but can double when the person moves to an upright position. CSF flow results from the pressure gradient between the arterial system and the CSF-filled cavities. Beginning in the lateral ventricles, the CSF flows through the interventricular foramen (foramen of Monro) into the third ventricle and then passes through the cerebral aqueduct (aqueduct of Sylvius) into the fourth ventricle. From the fourth ventricle, the CSF may pass through either the paired lateral apertures (foramina of Luschka) or the median aperture (foramen of Magendie) before communicating with the subarachnoid spaces of the brain and spinal cord. CSF is produced continually but does not accumulate. Instead, it is reabsorbed into the venous circulation through a pressure gradient between the arachnoid villi and the cerebral venous sinuses. The arachnoid villi protrude from the arachnoid space, through the dura mater, and lie within the blood flow of the venous sinuses. The villi function as one-way valves

directing CSF outflow into the blood but preventing blood flow into the subarachnoid space. Thus CSF is formed from the blood and, after circulating throughout the CNS, it returns to the blood.

Vertebral Column

The **vertebral column** (Fig. 15.18) is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal. Between each vertebra (except the fused sacral and coccygeal vertebrae) is an **intervertebral disk** (Fig. 15.19). At the center of the intervertebral disk is the **nucleus pulposus**, a pulpy mass of elastic fibers. The intervertebral disk functions to absorb shocks, preventing damage to the vertebrae. The intervertebral disk is also a common source of back problems. If too much stress is applied to the vertebral column, the disk contents may rupture and protrude into the spinal canal, causing compression of the spinal cord or nerve roots. The disks also can degenerate.

FIGURE 15.18 Vertebral Column. A, The normal curves and regions of the vertebral column. The vertebrae in each region are numbered. B, Lateral view of several vertebrae showing how they articulate. (From Solomon E: *Introduction to human anatomy and physiology*, ed 4, St Louis, 2010, Mosby.)

FIGURE 15.19 Intervertebral Disk. A, Sagittal view. B, Superior view. C, Magnified illustration. (A and B from Drake R, Vogl AW, Mitchell AWM: *Gray's anatomy for students*, ed 3, London, 2015, Churchill Livingstone; C from Lawry GV, et al: *Fam's musculoskeletal examination and joint injection techniques*, ed 2, Philadelphia, 2010, Mosby.)

Blood Supply of the Central Nervous System

Blood Supply to the Brain

The brain receives approximately 20% of the cardiac output, or 800 to 1000 mL of blood flow per minute. Carbon dioxide serves as a primary regulator for blood flow within the CNS. It is a potent vasodilator in the CNS, and its effects ensure an adequate blood supply.

The brain derives its arterial supply from two systems: the internal carotid arteries (anterior circulation) and the vertebral arteries (posterior circulation) (Fig. 15.20). The internal carotid arteries supply a proportionately greater amount of blood flow. They originate at the common carotid arteries, enter the cranium through the base of the skull, and pass through the cavernous sinus. After entering the skull, these arteries divide into the anterior and middle cerebral arteries (Fig. 15.21). The vertebral arteries originate at the subclavian arteries and pass through the transverse foramina of the cervical vertebrae, entering the cranium through the foramen magnum. They join at the junction of the pons and medulla oblongata to form the basilar artery. The basilar artery divides at the level of the midbrain to form paired posterior cerebral arteries.

FIGURE 15.20 Major Arteries of the Head and Neck. The internal carotid artery branches are not shown; it branches to the ophthalmic, anterior choroidal, anterior cerebral, middle cerebral, and posterior communicating arteries. (From Moses KP et al: *Atlas of clinical gross anatomy*, ed 2, Philadelphia, 2013, Saunders.)

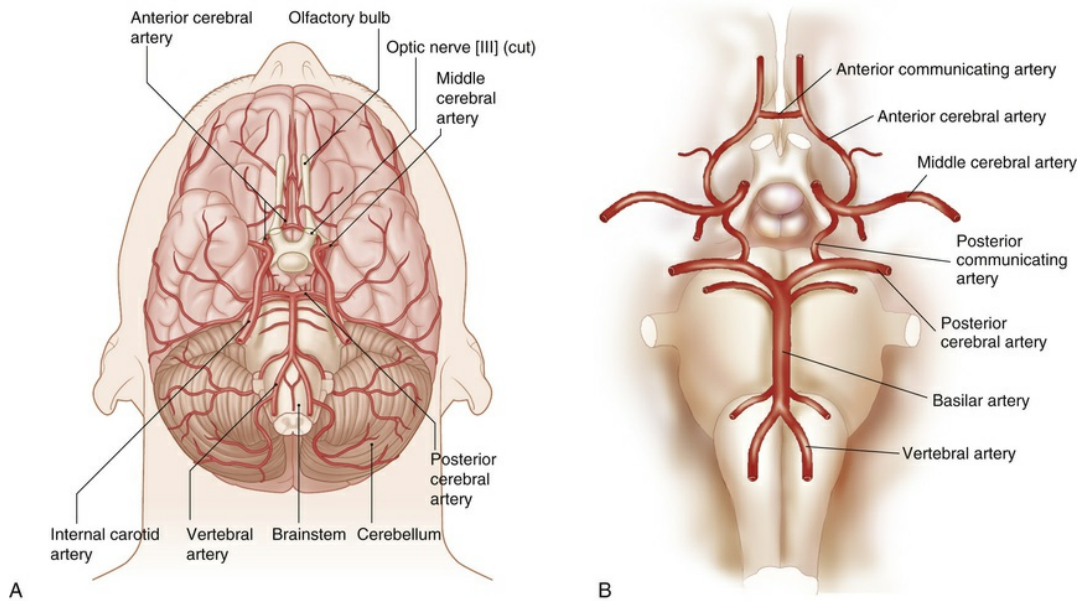

FIGURE 15.21 Arteries at the Base of the Brain. The arteries that compose the circle of Willis are the two anterior cerebral arteries, joined to each other by the anterior communicating artery and two short segments of the internal carotids, off of which the posterior communicating arteries connect to the posterior cerebral arteries. (A from Moses KP et al: *Atlas of clinical gross anatomy*, ed 2, Philadelphia, 2013, Saunders; B from Hagen-Ansert S: *Textbook of diagnostic sonography*, ed 7, St Louis, 2012, Mosby.)

Three major paired arteries perfuse the cerebellum and brainstem: the posterior inferior cerebellar artery, the anterior inferior cerebellar artery, and the superior cerebellar arteries. They originate from the basilar artery. The basilar artery also gives rise to small pontine arteries. The large arteries on the surface of the brain and their branches are called **superficial arteries (conducting arteries)**. Small branches that project into the brain are termed **projecting arteries (nutrient arteries)**.

The **circle of Willis** (see [Fig. 15.21](#)) provides an alternative route for blood flow when one of the contributing arteries is obstructed (collateral blood flow). The circle of Willis is formed by the posterior cerebral arteries, posterior communicating arteries, internal carotid arteries, anterior cerebral arteries, and anterior communicating artery. The anterior cerebral, middle cerebral, and posterior cerebral arteries leave the arterial circle and extend to various brain structures. ([Table 15.5](#) and [Fig. 15.22](#) illustrate structures served, functional relationships, and pathologic considerations related to occlusion of

cerebral arteries.)

TABLE 15.5

ARTERIAL SYSTEMS SUPPLYING THE BRAIN

ARTERIAL ORIGIN	STRUCTURES SERVED	CONDITIONS CAUSED BY OCCLUSION
Anterior cerebral artery	Basal ganglia; corpus callosum; medial surface of cerebral hemispheres; superior surface of frontal and parietal lobes	Hemiplegia on contralateral side of body, greater in lower extremities than in upper extremities
Middle cerebral artery	Frontal lobe; parietal lobe; temporal lobe (primarily cortical surfaces)	Aphasia in dominant hemisphere and contralateral hemiplegia (see Chapter 17)
Posterior cerebral artery	Part of diencephalon and temporal lobe; occipital lobe	Visual loss; sensory loss; contralateral hemiplegia if cerebral peduncle affected

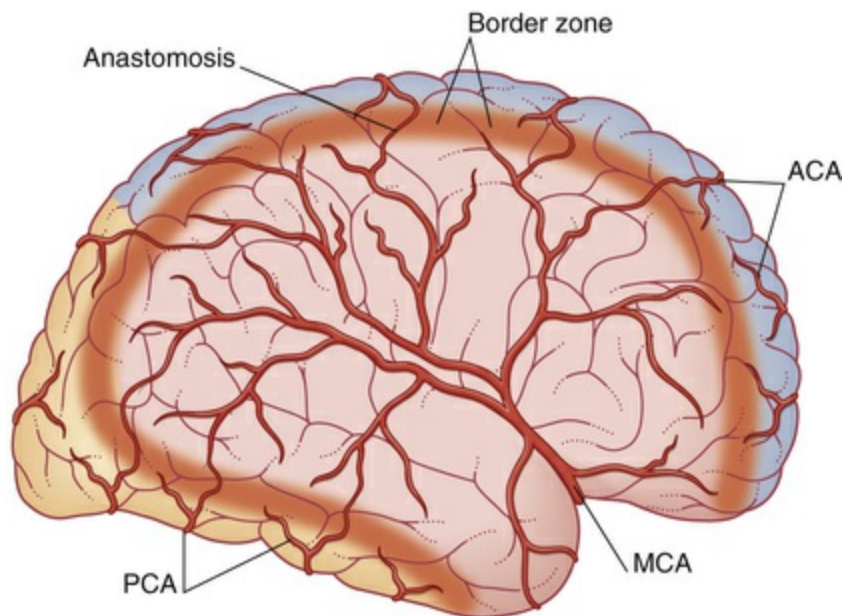

FIGURE 15.22 Areas of the Brain Affected by Occlusion of the Anterior, Middle, and Posterior Cerebral Artery Branches. *ACA*, Gray area affected by occlusion of branches of anterior cerebral artery; *MCA*, pink area affected by occlusion of branches of middle cerebral artery; *PCA*, orange area affected by occlusion of branches of posterior cerebral artery. Occlusions can occur in the cortical or deep areas of the border zone. (From Fitzgerald MJT et al: *Clinical neuroanatomy and neuroscience*, ed 6, Philadelphia, 2012, Saunders.)

Cerebral venous drainage does not parallel its arterial supply, whereas the venous drainage of the brainstem and cerebellum does parallel the arterial supply of the structures. The cerebral veins are classified as superficial veins and deep cerebral veins. The veins drain into venous plexuses and dural sinuses (formed between the dural layers) and eventually join the internal jugular veins at the base of the skull (Fig. 15.23). Adequacy of venous outflow can have a significant effect on intracranial pressure. For example, in individuals with head injury, turning or letting the head fall to the side partially occludes venous return and can increase intracranial pressure because of decreased flow through the jugular veins.

FIGURE 15.23 Veins of the Head and Neck. Deep veins and dural sinuses

are projected on the skull. Note two superficial veins in the face are tributaries that send blood through emissary veins in the skull foramen into deep veins inside the skull terminating in the internal jugular vein. (From Moses KP et al: *Atlas of clinical gross anatomy*, ed 2, Philadelphia, 2012, Saunders.)

Blood-Brain Barrier

The **blood-brain barrier (BBB)** (neurovascular unit) describes cellular structures that selectively inhibit certain potentially harmful substances in the blood from entering the interstitial spaces of the brain or CSF, allowing neurons to function normally. Endothelial cells in brain capillaries with their intracellular tight junctions are the site of the BBB (Fig. 15.24). Supporting cells and their functional interactions include astrocytes, pericytes, and microglia. The exact nature of this mechanism is controversial but permeability is high for water, carbon dioxide, oxygen, and most lipid-soluble substances, including alcohol; moderate for electrolytes, such as sodium, chloride, and potassium; and almost totally impermeable to plasma proteins and most non-lipid-soluble large organic molecules. This has substantial implications for drug therapy because certain types of antibiotics and chemotherapeutic drugs show a greater propensity than others for crossing the blood-brain barrier. Dysfunction or increased permeability of the BBB as occurs in hypoxia can contribute to neuroinflammation, cerebral edema, and neurodegeneration. The epithelium of the choroid plexus and the arachnoid membrane also provide barrier functions.⁸

FIGURE 15.24 Blood-Brain Barrier. A, Cellular structure of brain capillary. Endothelial cell membranes with tight junctions create a physical barrier between capillary blood and the brain, restricting movement of bacteria or neurotoxic substances. The pia mater is present only in larger vessels. B, Cross section. (From Standring S: *Gray's anatomy*, ed 41, London, 2016, Elsevier.)

Blood Supply to the Spinal Cord

The spinal cord derives its blood supply from branches off the vertebral arteries and from branches from various regions of the descending aorta (Fig. 15.25). The **anterior spinal arteries** and the paired **posterior spinal arteries** branch off the vertebral artery at the base of the cranium and descend alongside the spinal cord. Arterial branches from vessels exterior to the spinal cord follow the spinal nerve through the intervertebral foramina, pass through the dura, and

divide into the anterior and posterior radicular arteries.

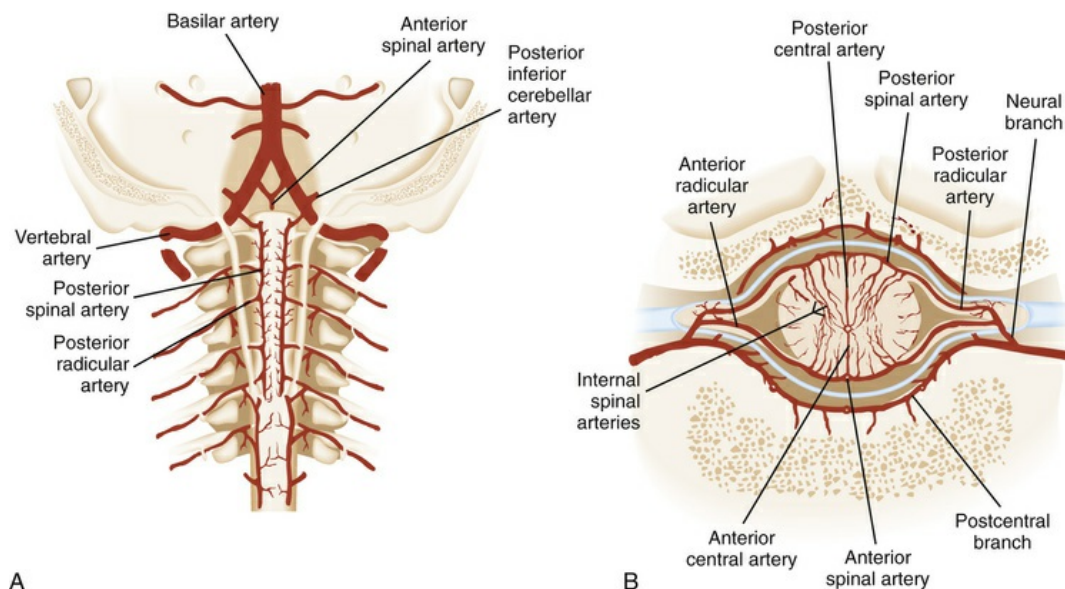

FIGURE 15.25 Arteries of the Spinal Cord. **A**, Arteries of cervical cord exposed (*posterior view*). **B**, Arteries of spinal cord shown in horizontal section. (From Rudy EB, editor: *Advanced neurological and neurosurgical nursing*, St Louis, 1984, Mosby.)

The radicular arteries eventually reconnect to the spinal arteries. Branches from the radicular and spinal arteries form plexuses whose branches penetrate the spinal cord, supplying the deeper tissues. Venous drainage parallels the arterial supply closely and drains into venous sinuses located between the dura and periosteum of the vertebrae.

Peripheral Nervous System

The **peripheral nervous system (PNS)** includes the nerves outside the central nervous system. The **somatic nervous system** is the part of the PNS that controls voluntary muscle movement (efferent nerves) and sensory information (afferent nerves). The cranial and spinal nerves, including their branches and ganglia, constitute the PNS. A peripheral nerve is composed of individual axons/dendrites, with most wrapped in a myelin sheath. These individual fibers are arranged in bundles

called *fascicles* (see Fig. 15.1 and Fig. 15.26, B). The coverings provide structural support, a blood supply, and interstitial compartments necessary for the delivery of essential electrolytes to support nerve impulse conduction.

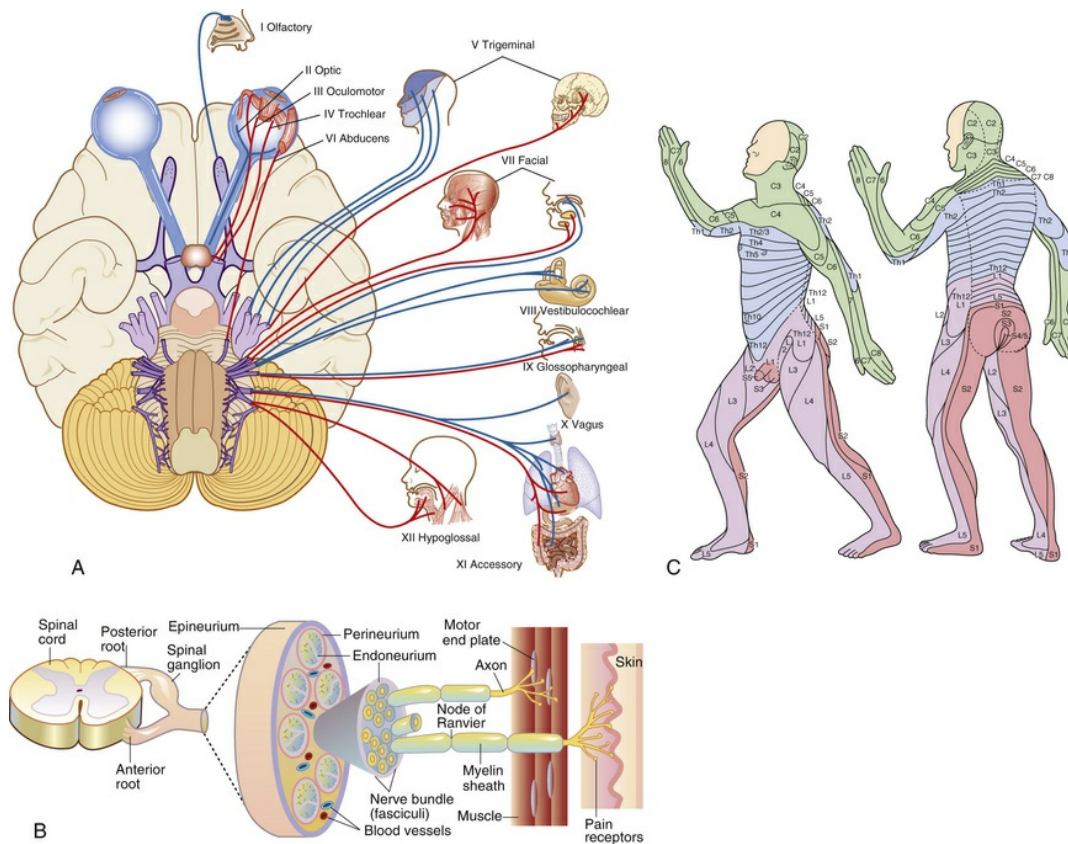

FIGURE 15.26 Cranial and Peripheral Nerves and Skin Dermatomes. **A**, Ventral surface of the brain showing origin of the cranial nerves. The red lines indicate motor function, and the blue lines indicate sensory function. **B**, Peripheral nerve trunk and coverings. **C**, Dermatome map, anterolateral view (left) and posterolateral view (right). (A from Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders; C from Salvo SG: *Mosby's pathology for massage therapists*, ed 3, St Louis, 2014, Mosby.)

The 31 pairs of **spinal nerves** derive their names from the vertebral level from which they exit. There are 8 cervical, 12 thoracic, 5 lumbar, 5 sacral pairs of spinal nerves, and 1 coccygeal. The first cervical nerve exits above the first cervical vertebra, and the rest of the spinal nerves exit below their corresponding vertebrae. From the thoracic region (and inferiorly), nerves correspond to the vertebral level above their

exit (see [Fig. 15.12](#)).

Spinal nerves contain both sensory and motor neurons and are called **mixed nerves**. They arise as rootlets lateral to the anterior and posterior horn cells of the spinal cord. These two spinal nerve roots converge in the region of the intervertebral foramen to form the spinal nerve trunk (see [Fig. 15.13](#)). Shortly after converging, the spinal nerve divides into anterior and posterior rami (branches). The anterior rami (except the thoracic) initially form plexuses (networks of nerve fibers), which then branch into the peripheral nerves. Instead of forming plexuses, the thoracic nerves pass through the intercostal spaces and innervate regions of the thorax.

The main spinal nerve plexuses innervate the skin and the underlying muscles of the limbs. The **brachial plexus**, for example, is formed by the last four cervical nerves (C5–C8) and the first thoracic nerve (T1). The brachial plexus innervates the nerves of the arm, wrist, and hand. The **lumbar plexus** (L2–L4) and **sacral plexus** (L5–S5) contain nerves that innervate the anterior and posterior portions of the lower body, respectively (see [Fig. 15.12](#)).

The posterior rami of each spinal nerve, with their many processes, are distributed to a specific area in the body. Sensory signals thus arise from specific sites associated with a specific spinal cord segment. Specific areas of cutaneous (skin) innervation at these spinal cord segments are called **dermatomes**. The dermatomes of various spinal nerves are distributed in a fairly regular pattern, although adjacent regions between dermatomes can be innervated by more than one spinal nerve (see [Fig. 15.26, C](#)).

Like spinal nerves, **cranial nerves** are categorized as peripheral nerves. Most of these are mixed nerves (like the spinal nerves), although some are purely sensory or purely motor. For example, some cranial nerves carry only special sensory information (e.g., vision, hearing, and taste). Cranial nerves project to nuclei in the brain and brainstem. [Fig. 15.26, A](#), illustrates their location, and [Table 15.6](#) describes structural and functional characteristics.

TABLE 15.6

THE CRANIAL NERVES

NUMBER AND NAME	ORIGIN AND COURSE	FUNCTION	HOW TESTED
I. Olfactory	Fibers arise from nasal olfactory epithelium and form synapses with olfactory bulbs that transmit impulses to temporal lobe	Purely sensory; carries impulses for sense of smell	Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify them
II. Optic	Fibers arise from retina of eye to form optic nerve, which passes through sphenoid bone; two optic nerves then form optic chiasma (with partial crossover of fibers) and eventually end in occipital cortex	Purely sensory; carries impulses for vision	Vision and visual field tested with an eye chart and by testing point at which person first sees an object (finger) moving into visual field; inside of eye is viewed with ophthalmoscope to observe blood vessels of eye interior
III. Oculomotor	Fibers emerge from midbrain and exit from skull and extend to eye	Contains motor fibers to inferior oblique and to superior, inferior, and medial rectus extraocular muscles that direct eyeball; levator muscles of eyelid; smooth muscles of iris and ciliary body; and proprioception (sensory) to brain from extraocular muscles	Pupils examined for size, shape, and equality; pupillary reflex tested with a penlight (pupils should constrict when illuminated); ability to follow moving objects
IV. Trochlear	Fibers emerge from posterior midbrain and exit from skull to run to eye	Proprioceptor and motor fibers for superior oblique muscle of eye (extraocular muscle)	Tested in common with cranial nerve III relative to ability to follow moving objects
V. Trigeminal	Fibers emerge from pons and form three divisions that exit from skull and run to face	Both motor and sensory for face; conducts sensory impulses from mouth, nose, surface of eye, and dura mater; also contains	Sensations of pain, touch, and temperature tested with safety pin and hot and cold objects; corneal reflex tested with a wisp

	and cranial dura mater	motor fibers that stimulate chewing muscles	of cotton; motor branch tested by asking subject to clench teeth, open mouth against resistance, and move jaw from side to side
VI. Abducens	Fibers leave inferior pons and exit from skull and extend to eye	Contains motor fibers to lateral rectus muscle and proprioceptor fibers from same muscle to brain	Tested in common with cranial nerve III relative to ability to move each eye laterally
VII. Facial	Fibers leave pons and travel through temporal bone and extend to face	Mixed: (1) supplies motor fibers to muscles of facial expression and to lacrimal and salivary glands, and (2) carries sensory fibers from taste buds of anterior part of tongue	Anterior two-thirds of tongue tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances; symmetry of face checked; subject asked to close eyes, smile, whistle, and so on; tearing tested with ammonia fumes
VIII. Vestibulocochlear (acoustic)	Fibers run from inner ear (hearing and equilibrium receptors in temporal bone) to enter brainstem just below pons	Purely sensory; vestibular branch transmits impulses for sense of equilibrium; cochlear branch transmits impulses for sense of hearing	Hearing checked by air and bone conduction by use of a tuning fork; vestibular tests: Bárány and caloric tests
IX. Glossopharyngeal	Fibers emerge from midbrain and leave skull and extend to pharynx, salivary glands, and tongue	Mixed: (1) motor fibers serve pharynx (throat) and salivary glands, and (2) sensory fibers carry impulses from pharynx, posterior tongue (taste buds), and pressure receptors of carotid artery	Gag and swallow reflexes checked; subject asked to speak and cough; posterior one-third of tongue may be tested for taste
X. Vagus	Fibers emerge from medulla, pass through skull, and descend through neck region into thorax and abdominal region	Fibers carry sensory and motor impulses for pharynx; a large part of this nerve is parasympathetic motor fibers, which supply smooth muscles of abdominal organs;	Same as for cranial nerve IX (IX and X are tested in common) because they both serve muscles of the throat

		receives sensory impulses from viscera	
XI. Spinal accessory	Fibers arise from medulla and superior spinal cord and extend to muscles of neck and back	Provides sensory and motor fibers for sternocleidomastoid and trapezius muscles and muscles of soft palate, pharynx, and larynx	Sternocleidomastoid and trapezius muscles checked for strength by asking subject to rotate head and shrug shoulders against resistance
XII. Hypoglossal	Fibers arise from medulla and exit from skull and extend to tongue	Carries motor fibers to muscles of tongue and sensory impulses from tongue to brain	Subject asked to stick out tongue, and any position abnormalities are noted

Autonomic Nervous System

The **autonomic nervous system (ANS)** regulates the involuntary function of internal organs. The structure and function of the ANS are complex and still not well understood. Components of the ANS are located in both the CNS and the PNS; however, the ANS is considered part of the efferent division of the PNS, even though visceral afferent neurons are an important part of this system. Many neurons of the ANS travel in spinal nerves and in certain cranial nerves. The widespread activity of this system indicates that its components are distributed over the entire body. The peripheral autonomic nerves carry mainly efferent fibers. The motor component of the ANS is a two-neuron system consisting of **preganglionic (myelinated) neurons** and **postganglionic (unmyelinated) neurons**. This arrangement contrasts with the somatic nervous system, in which a single motor neuron travels from the CNS to the innervated structure. Visceral afferent neurons have their cell bodies in some sensory and cranial ganglia and their fiber processes traveling in peripheral nerves.

The CNS has autonomic areas in the intermediolateral horns of the spinal cord, the cardiovascular and respiratory centers in the reticular formation, and both sympathetic and parasympathetic areas in the hypothalamus. CNS pathways interconnect all these areas.

The ANS coordinates and maintains a steady-state among visceral

(internal) organs, such as regulation of cardiac muscle, smooth muscle, and the glands of the body. This system is considered an involuntary system because one generally cannot *will* these functions to happen. The ANS is separated structurally and functionally into two divisions: (1) the **sympathetic nervous system** and (2) the **parasympathetic nervous system** ([Fig. 15.27](#)).

FIGURE 15.27 Sympathetic and Parasympathetic Divisions of the Autonomic Nervous System. Parasympathetic neuron cell bodies are located in the brainstem and sacral spinal cord (“craniosacral” division). Cell bodies of sympathetic neurons are located in the thoracic and upper

lumbar cord segments (“thoracolumbar” division). The axons of these neurons synapse with postganglionic neurons, which innervate smooth muscle, cardiac muscle, and glands of the body. The postganglionic neuron cell bodies may be located in distinct autonomic ganglia (represented with circles), or in or very near the wall of the innervated visceral organ. Note that sympathetic fibers provide the only innervation to peripheral effectors (sweat glands, arrector pili muscles, adipose tissue, and blood vessels). (From Cramer D et al: *Basic and clinical anatomy of the spine, spinal cord and ANS*, ed 2, St Louis, 2005, Elsevier Mosby.)

Anatomy of the Sympathetic Nervous System

The sympathetic nervous system mobilizes energy stores in times of need (e.g., in the fight-or-flight response) (see [Chapter 11](#) and [Fig. 11.2](#)). The sympathetic division receives its innervation from cell bodies located from the first thoracic (T1) through the second lumbar (L2) regions of the spinal cord and is therefore called the **thoracolumbar division**. The preganglionic axons of the sympathetic division form synapses shortly after leaving the spinal cord in the **sympathetic (paravertebral) ganglia**. Preganglionic axons travel one of several different pathways: (1) directly synapsing with postganglionic neurons in the sympathetic chain ganglion at their level, (2) traveling up or down the sympathetic chain ganglion before forming synapses with a higher or lower postganglionic neuron (divergence), or (3) passing through the sympathetic chain ganglion postganglionic neurons within collateral ganglia (see [Fig. 15.27](#)). Some preganglionic axons form pathways called **splanchnic nerves**, which lead to **collateral ganglia** on the front of the aorta. The collateral ganglia are named according to the branches of the aorta nearest them, namely, the **celiac**, **superior mesenteric**, and **inferior mesenteric**. These postganglionic neurons leave the collateral ganglia and innervate the viscera below the diaphragm.

Preganglionic sympathetic neurons that innervate the adrenal medulla also travel in the splanchnic nerves and do not synapse before reaching the gland. The secretory cells in the adrenal medulla are considered modified postganglionic neurons. Because preganglionic sympathetic fibers are all myelinated, travel to the adrenal medulla is quick and innervation causes the rapid release of

epinephrine and norepinephrine, which mediate the fight-or-flight response (see [Chapter 11](#)).

Anatomy of the Parasympathetic Nervous System

The parasympathetic nervous system functions to conserve and restore energy. The nerve cell bodies of this division are located in the cranial nerve nuclei and in the sacral region of the spinal cord, and therefore constitute the **craniosacral division**. Unlike the sympathetic division, the preganglionic fibers in the parasympathetic division travel to ganglia close to the organs they innervate before forming synapses with the relatively short postganglionic neurons (see [Fig. 15.27](#)). Parasympathetic nerves arising from nuclei in the brainstem travel to the viscera of the head, thorax, and abdomen within cranial nerves—including the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves.

Preganglionic parasympathetic nerves that originate from the sacral region of the spinal cord run either separately or together with spinal nerves. The preganglionic axons join to form the **pelvic nerve**, which innervates the viscera of the pelvic cavity. These preganglionic axons synapse with postganglionic neurons in terminal ganglia located close to the organs they innervate.

Neurotransmitters and Neuroreceptors

Sympathetic preganglionic fibers and parasympathetic preganglionic and postganglionic fibers release **acetylcholine**—the same neurotransmitter released by somatic efferent neurons ([Fig. 15.28](#)). These fibers are characterized by **cholinergic transmission**. Most postganglionic sympathetic fibers release **norepinephrine** (adrenaline) and thus are considered to function by **adrenergic transmission**. A few postganglionic sympathetic fibers, such as those that innervate the sweat glands, release acetylcholine.

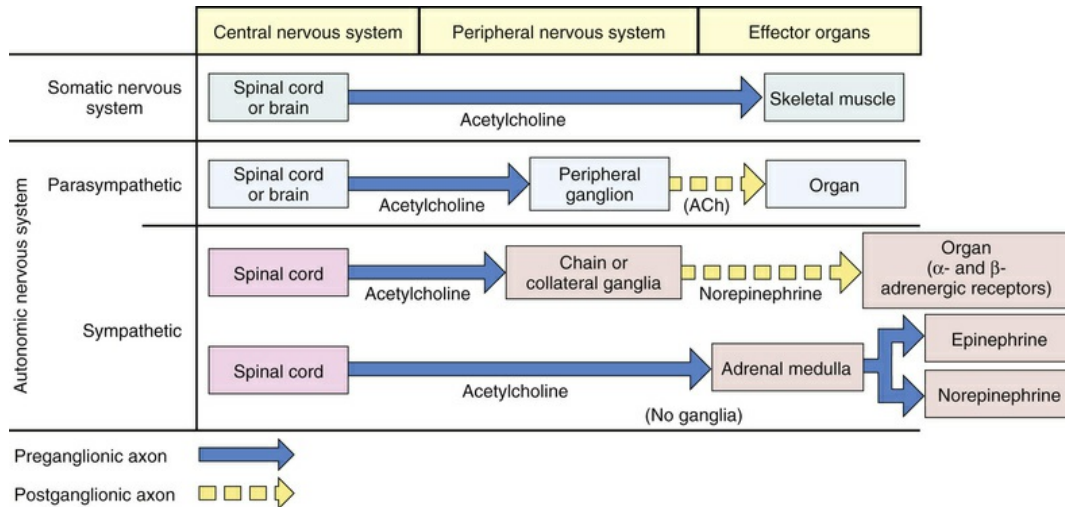

FIGURE 15.28 Autonomic Nervous System and Type of Neurotransmitters Secreted by Preganglionic and Postganglionic Fibers. Note that all preganglionic fibers are cholinergic (acetylcholine [ACh]). A somatic nerve is used for comparison.

The action of catecholamines (epinephrine, norepinephrine, dopamine) varies with the type of neuroreceptor stimulated. It should be remembered that catecholamines also are released by the adrenal medulla that physiologically and biochemically resembles the sympathetic nervous system. Two types of adrenergic receptors exist: α and β . Cells of the effector organs may have only one or both types of adrenergic receptors. The **α -adrenergic receptors** have been further subdivided according to the action produced: α_1 -adrenergic activity is associated mostly with excitation or stimulation; α_2 -adrenergic activity is associated with relaxation or inhibition. Most of the α -adrenergic receptors on effector organs belong to the α_1 -adrenergic class. The **β -adrenergic receptors** are classified as β_1 -adrenergic receptors (which facilitate increased heart rate and contractility and cause the release of renin from the kidney), and β_2 -adrenergic receptors (which facilitate all of the remaining effects attributed to β -adrenergic receptors).

Norepinephrine stimulates all α -adrenergic and β_1 -adrenergic receptors and only certain β_2 -adrenergic receptors. The most significant response from norepinephrine, however, is stimulation of the α_1 -adrenergic receptors that cause vasoconstriction. Epinephrine strongly stimulates all four types of receptors and induces general

vasodilation because of the predominance of β -adrenergic receptors in muscle vasculature. (Table 15.7 summarizes the effects of neuroreceptors on their effector organs.)

TABLE 15.7

ACTIONS OF AUTONOMIC NERVOUS SYSTEM NEURORECEPTORS

EFFECTOR ORGAN OR TISSUE	ADRENERGIC RECEPTORS	ADRENERGIC EFFECTS	CHOLINERGIC EFFECTS (NICOTINE AND MUSCARINIC* RECEPTORS)
Eye			
<i>Iris</i>			
Radial muscle	α_1	Dilation	–
Sphincter muscle	–	–	Constriction
<i>Ciliary muscle</i>	β_2	Relaxation for far vision	Contraction for near vision
Lacrimal glands	α_1	Secretion	Secretion
Nasopharyngeal glands	–	–	Secretion
Salivary glands	α_1	Secretion of potassium and water	Secretion of potassium and water
	β	Secretion of amylase	–
Heart			
Sinoatrial (SA) node	β_1, β_2	Increase heart rate	Decrease heart rate; vagus arrest
Atrial	β_1, β_2	Increase contractility and conduction velocity	Decrease contractility; shorten action potential duration
Atrioventricular (AV) junction	β_1, β_2	Increase automaticity and propagation velocity	Decrease automaticity and propagation velocity
Purkinje system	β_1, β_2	Increase automaticity and propagation velocity	–
Ventricles	β_1, β_2	Increase contractility	Slight decrease in contraction
Arterioles			
Coronary	$\alpha_1, \alpha_2, \beta_2$	Constriction, dilation	Dilation
Skin and mucosa	α_1, α_2	Constriction	Dilation

Skeletal muscle	α, β_2	Dilation, constriction	Dilation
Cerebral	α_1	Constriction (slight)	Dilation
Pulmonary	α_1, β_2	Constriction, dilation	Dilation
Mesenteric	α_1	Constriction	Dilation
Renal	$\alpha_1, \beta_1, \beta_2$	Constriction, dilation	Dilation
Salivary glands	α_1, α_2	Constriction	Dilation
Veins, systemic	$\alpha_1, \alpha_2, \beta_2$	Constriction, dilation	–
Lung			
Bronchial muscle	α_2	Relaxation	Contraction
Bronchial glands	α_1, β_2	Decrease secretion; increase secretion	Stimulation
Stomach			
Motility	$\alpha_1, \alpha_2, \beta_1, \beta_2$	Decrease (usually)	Increase
Sphincters	α_1	Contraction (usually)	Relaxation (usually)
Secretion	α_2	Inhibition	Stimulation
Liver	α_1, β_2	Glycogenolysis and gluconeogenesis	–
Gallbladder and ducts	β_2	Relaxation	Contraction
Pancreas			
Acini	α	Decrease secretion	Secretion
Islet cells	α_2, β_2	Decrease secretion; increase secretion	–
Intestine			
Motility and tone	$\alpha_1, \alpha_2, \beta_1, \beta_2$	Decrease	Increase
Sphincters	α_1	Contraction	Relaxation (usually)
Secretion	α_2	Inhibition	Stimulation
Adrenal medulla	–	Secretion of epinephrine and norepinephrine (nicotinic effect)	
Kidney			
Renin secretion	α_1, β_1	Decrease; increase	–
Ureter			
Motility and tone	β_1	Increase	Increase (?)

Urinary bladder			
Detrusor	β_2	Relaxation	Contraction
Trigone and sphincter	α_1	Contraction	Relaxation
Sex organs, male	α_1	Ejaculation	Erection
Skin			
Pilomotor muscles	α_1	Contraction	–
Sweat glands	α_1	Localized secretion	–
Fat cells	$\alpha_2, \beta_1, \beta_2, \beta_3$	Inhibition of lipolysis; stimulation of lipolysis	–
Pineal gland	β	Melatonin synthesis	–

* Muscarinic receptors respond to circulating muscarinic antagonists.

Modified from Brunton LL et al, editors: *Goodman & Gilman's the pharmacological basis of therapeutics*, ed 12, New York, 2010, McGraw-Hill; Yagiela JA et al: *Pharmacology and therapeutics for dentistry*, ed 6, St Louis, 2011, Mosby.

Dopamine is a precursor of norepinephrine and epinephrine and is a brain neurotransmitter synthesized in the substantia nigra and the ventral tegmental areas of the brain. There are five types of dopamine receptors distributed throughout the brain, D_1 , D_2 , D_3 , D_4 , and D_5 . They have varying functions including pleasure, motivation, cognition, attention, memory, learning, fine motor control, sleep regulation, hormonal regulation, sympathetic regulation, penile erection, and immune function.⁹

Functions of the Autonomic Nervous System

Many body organs are innervated by the sympathetic and parasympathetic nervous systems. The two divisions frequently cause opposite responses; for example, sympathetic stimulation of the gastrointestinal (GI) tract causes decreased peristalsis, whereas parasympathetic stimulation of the GI tract increases peristalsis. In general, sympathetic stimulation promotes responses that are concerned with the protection of the individual. For example, sympathetic activity increases blood glucose levels and temperature

and raises blood pressure. In emergency situations a generalized and widespread discharge of the sympathetic system occurs and is known as the “fight or flight” reflex or acute stress response (see [Chapter 11](#)). This is accomplished by an increased firing frequency of sympathetic fibers and by activation of sympathetic fibers normally silent (fibers to the sweat glands, pilomotor muscles, and the adrenal medulla, as well as vasodilator fibers to muscle). Regulation of vasomotor tone is considered the single most important function of the sympathetic nervous system. ([Fig. 15.29](#) illustrates some of the most important functions of the sympathetic nervous system; also see [Fig. 11.2](#).)

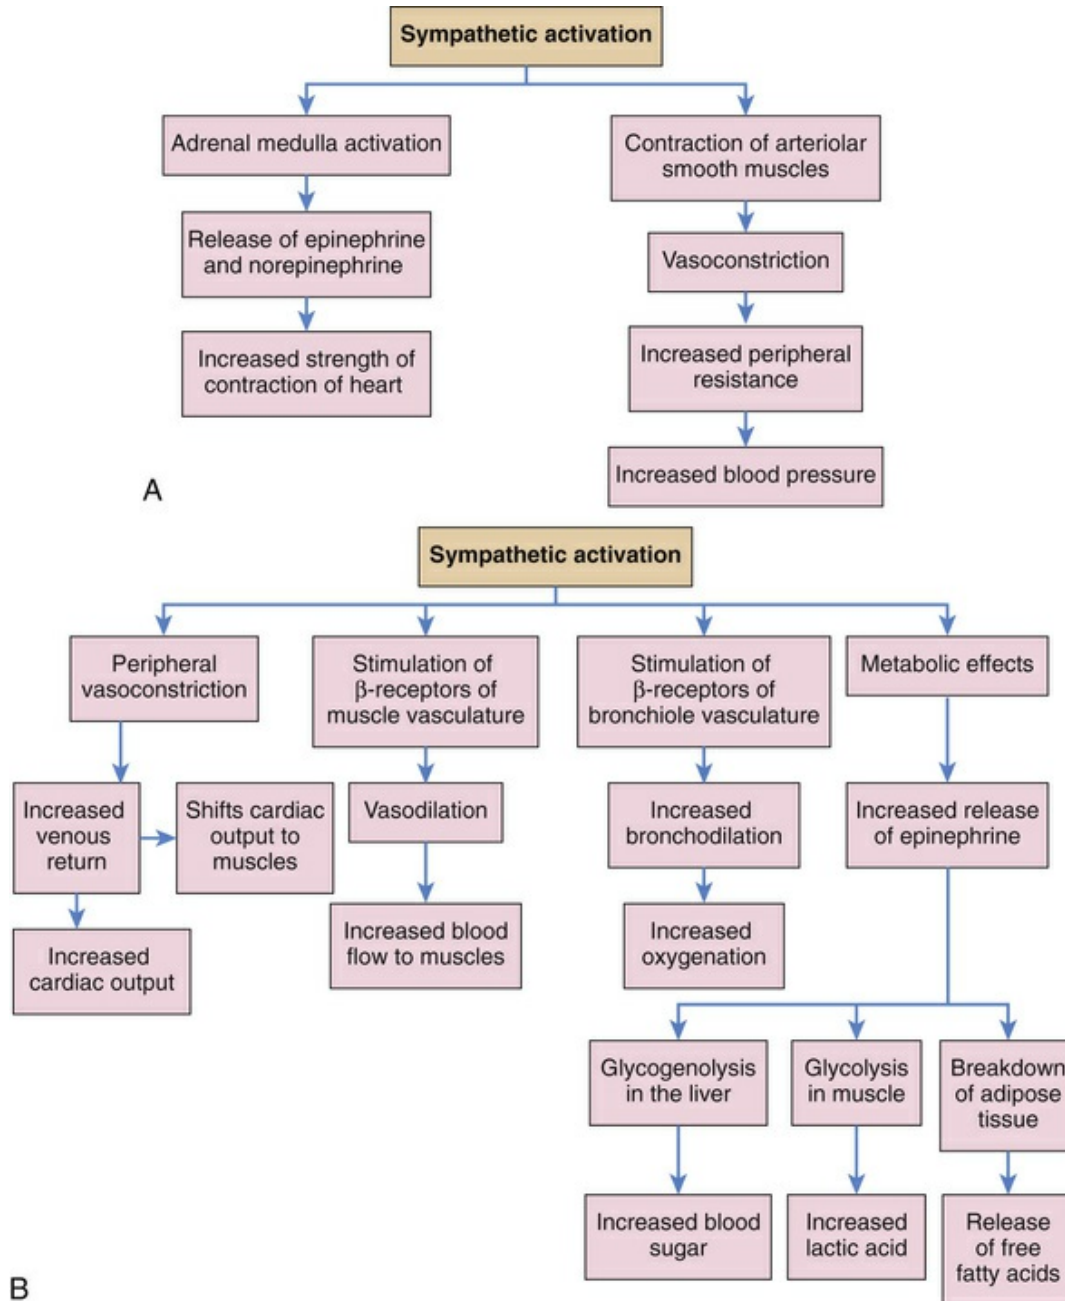

FIGURE 15.29 Important Functions of the Sympathetic Nervous System. **A**, Regulation of vasomotor tone. **B**, Regulation of strenuous muscular exercise (fight-or-flight response). (See also [Chapter 11](#) and [Fig. 11.2](#) for more detail of the stress response.)

Increased parasympathetic activity promotes rest and tranquility and is characterized by reduced heart rate and enhanced visceral functions leading to digestion. Stimulation of the vagus nerve in the GI tract increases peristalsis and secretion, as well as relaxation of sphincters. Activation of parasympathetic fibers traveling with cranial

nerves III, VII, and IX causes pupillary constriction, tear secretion, and increased salivary secretion. Stimulation of the sacral division of the parasympathetic system contracts the urinary bladder and facilitates the process of genital erection.

The parasympathetic system lacks the generalized and widespread response of the sympathetic system. Specific parasympathetic fibers are activated to regulate particular functions. Although the actions of the parasympathetic and sympathetic systems usually are antagonistic, there are exceptions. Changes in the shape of the lens (for near vision) require only oculomotor parasympathetic activity. Most of the blood vessels involved in the control of blood pressure are innervated by sympathetic nerves. Peripheral vascular resistance is increased and decreased by the relative activity of the sympathetic division without a counteracting parasympathetic component. To decrease blood pressure, therefore, it is more important to block the continuous (tonic) discharge of the sympathetic system than to promote parasympathetic activity.

Aging and the Nervous System

The CNS mechanisms involved in the aging process are extremely complex, and many questions concerning the neurologic effects of aging have yet to be answered. Some of the identified mechanisms associated with aging are pathologic, but the distinction between these mechanisms and those that are a part of the normal aging process remains somewhat ambiguous. [Box 15.4](#) contains information on the structural, cellular, cerebrovascular, and functional changes that occur in the nervous system with aging.

Box 15.4

Aging and the Nervous System

Structural Changes with Aging

Decreased brain weight and size, particularly frontal regions
Fibrosis and thickening of the meninges
Narrowing of gyri and widening of sulci
Increase in size of ventricles

Cellular Changes with Aging

Decrease in the number of neurons, not consistently related to changes in mental function
Decreased amount of myelin
Lipofuscin deposition (a pigment resulting from cellular autodigestion)
Decreased number of dendritic processes and synaptic connections
Activation of microglial function, increased neuroinflammation and loss of protective brain mechanisms
Formation of intracellular neurofibrillary tangles; significant accumulation in hippocampus and cortex associated with Alzheimer dementia
Imbalance in the amount and distribution of neurotransmitters
Atrophy of epithelial cells and thickening of the basement membrane in the choroid plexus can increase or decrease CSF production
Declines in melatonin level can alter circadian rhythms and brain energy metabolism

Cerebrovascular Changes with aging

Arterial atherosclerosis (may cause infarcts and scars)
Increased permeability of the blood-brain barrier (escape of toxins into the brain)
Decreased vascular density

Functional Changes with Aging

Decreased tendon reflexes
Skeletal muscle atrophy
Progressive deficit in taste and smell
Decreased vibratory sense
Decrease in accommodation and color vision
Decrease in neuromuscular control with change in gait and posture
Sleep disturbances
Memory impairments
Cognitive alterations associated with chronic disease

Functional changes and nervous system aging have significant individual variation; the plasticity of the brain and variations in genetics, diet, exercise, environment, and chronic disease significantly affect brain changes and sensory-motor and cognitive abilities in older adults.

Tests of Nervous System Structure and Function

Skull and Spine Roentgenograms

Roentgenograms (x-ray films) of the skull or spine from multiple angles (views) are used primarily to localize bony defects, bone density, erosion, or calcified structures. The pineal gland in older people becomes calcified and is useful as an internal brain landmark. Probably the most commonly used radiologic studies are x-ray films.

Computed Tomography

Computed tomography (CT) creates two-dimensional reconstructions from multiple radiologic images (x-rays) using computer-assisted analysis. It is capable of demonstrating fine distinctions in shape, size, and densities of a variety of tissues based on differential absorption of x-rays. CT imaging is a noninvasive procedure used in evaluating cranial and spinal structures, as well as hemorrhages, tumors, and distortions in the brain caused by pressure differences. A variety of contrast media also are commonly used in conjunction with this procedure to aid in enhanced delineation of selected structures. **Spiral or helical CT** uses a multidetector scanner mounted on a rotating gantry to provide several axial images of a large continuous anatomic area in a matter of seconds. **Helical CT angiography** uses contrast media for detection of aneurysms or ruptured aneurysms.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) uses a static magnetic field, instead of x-rays, to orient physiologic atomic particles. Disruption of this orientation by excitation of the particles using serial radiofrequency pulsations provides the image data. The specific tissue reaction is computer-analyzed to give an image with much better spatial resolution than that provided by CT. The MRI also provides reconstruction of images in three views at right angles (i.e., axial, sagittal, coronal). MRI is reported to have none of the adverse effects associated with radiation examinations. **Magnetic resonance spectroscopy (MRS)** can be completed at the same time as a standard MRI by analyzing the chemical composition of proton (hydrogen) or phosphorous-based molecules and is useful for differentiating the chemical composition and function of various regions of the brain. **Functional MRI (fMRI)** detects changes in blood oxygenation and flow and can be used to produce maps showing the parts of the brain that are functioning during a mental process. **Diffusion tensor imaging (DTI)** is an MRI technique that quantifies the size and direction of white matter tracts by measuring asymmetries in the magnitude and direction of the diffusion of water molecules. Color coding and fiber tracking (tractography) add detail.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) uses special imaging techniques to visualize blood vessels in great detail. MRA can be used in conjunction with cerebral angiography to detect and localize pathologic lesions of the circulatory system of the brain, particularly the arterial system. In some cases contrast agents are used.

Positron-Emission Tomography Scan

The **positron-emission tomography (PET) scan** uses CT imaging to detect the emission of positive electrons from trace amounts of radioactive substances injected into the bloodstream or administered as inhaled gases. With radioactive decay, radioactive substances emit a positron. As they are distributed in tissues, they display characteristic patterns that indicate physiologic and metabolic processes, for example, glucose and oxygen uptake, cerebral blood flow, neural and neurotransmitter function, and the effects of drugs. As a research tool, PET is being used to visualize the specific brain sites that are involved in the processing of information in the brain.

Single Photon Emission Computed Tomography

Single photon emission computed tomography (SPECT) uses radiotracers that have longer half-lives than PET. Images are created by CT after radionuclide substances (technetium [^{99m}Tc]) have been introduced into the bloodstream. For example, visualization of tissue uptake of the radioactive agent provides an indication of blood-brain barrier integrity (increased uptake of the agent indicates disruption). This scanning technique also can identify abnormalities in blood flow dynamics and cellular metabolic function. The brain scan is particularly helpful in detecting abnormal vascularity resulting from neoplasms, abscesses, and vascular lesions.

Cerebral Angiography

Cerebral angiography is a radiologic technique that demonstrates

cerebrovascular blood flow. This technique commonly is performed by the introduction of a small catheter into the femoral artery. The catheter is then passed to the level of the cerebral circulation and through the aorta, and a contrast dye is injected. Serial x-ray films are then taken. These films demonstrate flow of the dye through the cerebral vasculature and provide information on patency, location, size, and flow pattern of the vessels. Another technique used in cerebral angiography is the retrograde (reverse flow) injection of the dye through catheterization of a brachial, axillary, subclavian, or femoral vein.

Echoencephalography (Ultrasound)

Echoencephalography, or **ultrasound**, is a safe, noninvasive procedure using sound waves that are deflected at differing rates, depending on the density of the tissue. Information is processed and displayed on an oscilloscope screen. It is useful primarily in the detection of structural characteristics of intracranial space-occupying mass lesions and the determination of ventricular dimensions, especially in newborns where open fontanelles provide good acoustic windows.

Electroencephalography

The **electroencephalograph (EEG)** is a recording of electrical impulses arising from the cortical surface of the brain that are detected by scalp electrodes. The recording of brain wave patterns is analyzed for alterations or localization (or both) of specific electrical activity. This test is especially useful in detecting and localizing foci that initiate seizure activity. It is also an important technique in assessment of encephalopathy (altered mental status). Complete absence of electrical activity is seen in individuals who are legally “brain dead.”

Magnetoencephalography

Magnetoencephalography (MEG) is a specialized imaging technique

used to measure magnetic fields induced by electrical activity in the brain. Electrical activity in the brain, such as that detected by EEG, induces an orthogonally oriented magnetic field. MEG uses multiple sensors that allow vectoring and ultimately localization of the origin of the electrical activity that generated the field. Use of MEG has the advantage over EEG in that the induced magnetic field is not significantly dispersed by passing through the skull and soft tissues of the scalp. Co-registration of MEG and MRI data allow precise localization of the electrical focus for seizure onset.

Evoked Potentials

Evoked potentials (EPs) are a method of detecting electrical brain activity that results from a stimulus—primarily auditory, visual, or peripheral sensory. Electrical activity is computer formatted to display changes in trends. The primary uses of EPs include perioperative detection of sensory pathway integrity and disease- or drug-related sensory dysfunction.

Cerebrospinal Fluid Analysis

CSF generally is obtained from the lumbar or cisternal subarachnoid space by means of a hollow needle that allows passive flow. The lumbar puncture is performed most often at the L3–L4 interspace (below the level of the spinal cord at L1–L2). Cisternal puncture is performed by the insertion of a needle into the cerebellomedullary cistern using an approach from the back of the neck in the region of the foramen magnum. CSF pressure is commonly measured during these procedures. The CSF can be analyzed also for gross characteristics and constituents (color, blood cells, electrolytes, and protein) and cultured for microorganisms ([Table 15.8](#)).

TABLE 15.8

CEREBROSPINAL FLUID ANALYSIS

PARAMETERS	NORMAL	ABNORMAL	POSSIBLE CAUSE

Pressure (initial readings)	12–18 cm H ₂ O (9–14 mmHg)	<6 cm H ₂ O	Faulty needle placement Dehydration Spinal block along subarachnoid space Block of foramen magnum
		>20 cm H ₂ O	Muscle tension Abdominal compression Brain tumor Subdural hematoma Brain abscess Brain cyst Cerebral edema (any cause) Hydrocephalus
Color (turbidity)	Clear, colorless	Cloudy	Increased cell count Increased microorganisms (meningitis)
		Yellow	Xanthochromic (caused by red blood cell [RBC] pigments) High protein content
		Smoky	Presence of RBCs
Red blood cells	None	Blood-tinged Grossly bloody	Traumatic tap Traumatic tap Subarachnoid hemorrhage
White blood cells	0–6/mm ³	>10/mm ³ (cell counts range from <100/mm ³ to many thousands depending on causative factor; all are abnormal findings)	Occurs in many conditions: Bacterial infections of meninges Viral infections of meninges Neurosyphilis Tuberculous meningitis Metastatic neoplastic lesions

			Parasitic infections Acute demyelinating diseases Following introduction of air or blood into subarachnoid space
Protein*	15–45 mg/dL (1% of serum protein)	<10 mg/dL	Little clinical significance
		>60 mg/dL	Occurs in many conditions: Complete spinal block Guillain-Barré syndrome Carcinomatosis of meninges Tumors close to pial or ependymal surfaces or in cerebellopontine angle Acute and chronic meningitis Meningeal hemorrhage Demyelinating disorders Degenerative diseases
Glucose (CSF/serum ratio)	0.6 (approximately 60% of blood glucose level: 50–55 mg/dL)	<0.4: <40 mg/dL >0.6: >60 mg/dL	Acute bacterial meningitis Tuberculous meningitis Meningeal carcinomatosis Acute viral meningitis Glucose transporter deficiency
		>100 mg/dL	Diabetes
Chloride	700–750 mg/dL 116–130 mEq/L	<625 mg/dL <110 mEq/L	Hypochloremia Tuberculous meningitis

		>800 mg/dL	Not of neurologic significance; correlates with blood levels of chloride
--	--	------------	--

* **NOTE:** If CSF contains blood, this will raise the protein level.

Summary Review

Overview and Organization of the Nervous System

1. The divisions of the nervous system have been categorized as either structural (CNS and PNS) or functional (somatic nervous system and ANS).
2. The CNS is contained within the brain and spinal cord.
3. The PNS is composed of cranial and spinal nerves that carry impulses toward the CNS (afferent) and away from the CNS (efferent) to target organs or skeletal muscle.
4. The somatic nervous system consists of motor and sensory pathways regulating voluntary motor control of skeletal muscle.
5. The ANS consists of motor and sensory involuntary control of organ systems.

Cells of the Nervous System

1. The neuron and neuroglial cells make up nervous tissue. The neuron is specialized to transmit and receive electrical and chemical impulses, and the neuroglial cell provides supportive functions.

2. The neuron is composed of a cell body, one or more dendrites, and an axon. A myelin sheath around selected axons forms an insulation that allows quicker nerve impulse conduction, referred to as *saltatory conduction*.
3. Neurons have four basic types of cell configuration: (a) unipolar, (b) pseudounipolar, (c) bipolar, and (d) multipolar. The three function types of neurons are sensory, associational, and motor.
4. Neuroglial cells (“nerve glue”) support the CNS and comprise approximately half of the total brain and spinal cord volume.
5. Nerve injury in peripheral neurons triggers a sequence of events known as the *axonal reaction* and includes local, antegrade, and retrograde changes in the injured neuron that can lead to recovery of function. CNS neuron injury usually leads to permanent loss of function.

Nerve Impulse

1. The region between adjacent neurons is the synapse, and the region between the neuron and muscle is the myoneural junction.
2. Neurotransmitters are responsible for chemical conduction across the synapse and myoneural junction. The nerve impulse is predominantly regulated by a balance of IPSPs and EPSPs, temporal and spatial summation, and convergence and divergence.

Central Nervous System

1. The brain is contained within the cranial vault and is divided into three distinct regions: (a) forebrain, (b) midbrain, and (c) hindbrain.
2. The forebrain comprises the two cerebral hemispheres (telencephalon) and includes the cerebral cortex and basal

ganglia and is associated with conscious perception of internal and external stimuli, cognition and memory processes, and voluntary control of skeletal muscles. The posterior portion of the forebrain is termed the *diencephalon* (thalamus, hypothalamus, epithalamus, and subthalamus), which relays sensory information, controls autonomic functions, and links to the limbic system for memory and emotion. The center for voluntary control of skeletal muscle movements is located along the precentral gyrus in the frontal lobe, whereas the center for sensory perception is along the postcentral gyrus in the parietal lobe. The Broca area (anterior to the postcentral gyrus) and the Wernicke area (superior posterior temporal lobe) are major speech and language centers.

3. The midbrain connects the forebrain and hindbrain and is primarily a relay center for some motor and sensory tracts, as well as a center for auditory and visual reflexes, temperature control, sleep-wake cycles, arousal, and attention.
4. The hindbrain consists of the metencephalon (cerebellum and pons) and the myelencephalon (medulla oblongata). The metencephalon allows sampling and comparison of sensory data from the periphery and motor impulses from the cerebral hemispheres for the purpose of coordination and refinement of skeletal muscle movement. The medulla controls activities such as heart rate, blood pressure, and reflex activities, such as swallowing, coughing, and vomiting. The reticular formation maintains wakefulness and attention.
5. The midbrain, medulla, and pons comprise the brainstem, which connects the hemispheres of the brain, cerebellum, and spinal cord.
6. The spinal cord contains the majority of nerve fibers connecting the brain with the periphery and is divided into cervical, thoracic, lumbar, and sacral regions. The gray matter (cell bodies) of the spinal cord is divided into regions: the anterior (contains the lower motor neurons), posterior (sensory neurons), and lateral horns (autonomic neurons). The white

matter is divided into posterior, lateral, and anterior columns. Ascending (sensory) tracts are found in all columns. Descending (motor) tracts are found only in the lateral and anterior columns. Reflex arcs are completed in the spinal cord and influenced by the higher centers in the brain.

7. The major motor tracts are the corticobulbar, lateral corticospinal, and anterior corticospinal and carry motor neurons of the pyramidal tract. The reticulospinal, vestibulospinal, and rubrospinal tracts are extrapyramidal tracts that modulate fine motor movement.
8. The major sensory pathways are the posterior column, spinothalamic, and spinocerebellar tracts.
9. The CNS is protected by the scalp, bony cranium, meninges, vertebral column, and CSF. The CSF is formed from blood components in the choroid plexuses of the ventricles and is reabsorbed in the arachnoid villi (located in the dural venous sinuses) after circulating through the brain and spinal cord.
10. The paired carotid and vertebral arteries supply blood to the brain and connect to form the circle of Willis. The major branches projecting from the circle of Willis are the anterior, middle, and posterior cerebral arteries. Drainage of blood from the brain is accomplished through the venous sinuses and jugular veins.
11. Blood supply to the spinal cord originates from the vertebral arteries and branches arising from the aorta.
12. The blood-brain barrier is composed of endothelial cells in brain capillaries and associated supporting cells. The barrier prevents harmful substances from entering the brain.

Peripheral Nervous System

1. The PNS functions to relay information from the CNS to muscle and effector organs through cranial and spinal nerve tracts arranged in fascicles (multiple fascicles bound together form the peripheral nerve).

2. The 31 pairs of spinal nerves contain sensory and motor neurons.

Autonomic Nervous System

1. The ANS is responsible for the maintenance of a steady state in the internal environment. Two opposing systems constitute the ANS: (a) the sympathetic nervous system responds to stress by mobilizing energy stores and prepares the body to defend itself, and (b) the parasympathetic nervous system conserves energy and the body's resources.

Aging and the Nervous System

1. Major structural changes with aging include a decrease in number of neurons and a decrease in brain weight and size.
2. Decreased amounts of myelin, deposition of lipofuscin, and the presence of neuritic (amyloid) plaques, multiple neurofibrillary tangles, and Lewy bodies are common cellular changes with aging.
3. Cerebral atherosclerosis, decreased vascular density, and increased permeability of the blood-brain barrier occur with aging.
4. Functional changes with aging include diminished sensory functions, sleep disturbances, and memory impairments.

Tests of Nervous System Structure and Function

1. Tests of nervous system structure and function include x-ray films, CT, MRI and MRA, PET, SPECT, cerebral angiography, echoencephalography, electroencephalography, magnetoencephalography, EPs, and analysis of CSF.

Alterations in sensory function may involve dysfunctions of the general or the special senses. Dysfunctions of the general senses include chronic pain and abnormal temperature regulation. Somatosensory alterations include tactile, proprioceptive, and vestibular dysfunction.

Pain is a unique sensory experience that, although universally described as unpleasant, is nonetheless essential to an individual's survival. Pain provides protection by signaling the presence of disease or injury. Unlike pain, which need not be a part of everyday life, temperature is carefully monitored and regulated within clearly defined normal limits. Like pain, however, variations in temperature can signal disease. Fever is a common manifestation of dysfunction and is often the first symptom observed in an infectious or inflammatory condition.

Sleep is a normal, cyclic process that restores the body's energy and

maintains normal functioning. Sleep is so essential to physiologic and psychologic function that sleep deprivation causes a wide range of clinical manifestations. Prolonged deprivation or disruption of sleep ultimately leads to serious dysfunction.

The special senses of vision, hearing, touch, smell, and taste are the means by which individuals perceive stimuli that are essential for interacting with the environment. Special sensory receptors are connected to specific areas of the brain through the afferent pathways of the peripheral and central nervous system (CNS). Each of the special senses thus involves a connected system of organs and tissues that receives stimuli and sends sensory messages to areas of the CNS, where they are processed and guide behavior. Dysfunctions of the special senses include visual, auditory, olfactory, and gustatory (taste).

Pain

Pain is one of the body's most important adaptive and protective mechanisms. It is a complex experience composed of dynamic interactions among physical, cognitive, spiritual, emotional, and environmental factors and cannot be characterized as only a response to injury. The International Association for the Study of Pain (IASP) and accepted by the American Pain Society and the World Health Organization define pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”¹ McCaffery defined pain as “whatever the experiencing person says it is, existing whenever he says it does.”² Waddell defines pain as “a symptom, not a clinical sign, diagnosis or disease.”³

Theories of Pain

The theories of pain include the specificity theory, pattern theory, gate control theory, and neuromatrix theory.⁴ **Specificity theory** proposes that pain and touch are carried on distinct pathways that project to

distinct brain centers. Injury activates only specific pain receptors and fibers that project to the brain. *Intensity of pain* is directly related to the amount of associated tissue injury (i.e., pricking one's finger with a needle would cause minimal pain, whereas cutting one's hand with a knife would produce more pain). The theory is useful when applied to specific injuries and the acute pain associated with them. It does not account for chronic pain or cognitive and emotional elements that contribute to more complex types of pain.⁵

Pattern theory proposes that any somatic sense organs respond to a dynamic range of stimulus intensities. Different sense organs have different levels of responsiveness to stimuli with different spatial and temporal profiles of firing. The patterns of impulse intensity are encoded in the central nervous system (CNS). The pattern theory is limited because it does not account for all types of pain experiences.⁴

Gate control theory (GCT) integrates and builds upon features of the other theories to explain the complex multidimensional aspects of pain perception and pain modulation. Pain transmission is modulated by a balance of impulses conducted to the spinal cord where cells in the substantia gelatinosa function as a "gate." The spinal gate regulates pain transmission to higher centers in the CNS. Large myelinated A-delta fibers and small unmyelinated C fibers respond to a broad range of painful stimuli (mechanical, thermal, and chemical). These fibers terminate on interneurons in the substantia gelatinosa (laminae in the dorsal horn of the spinal cord) and "open" the spinal gate to transmit the perception of pain. Closure or partial closure of the spinal gates can occur from **nonnociceptive stimulation** (i.e., from touch sensors in the skin) carried on large A-beta fibers decreasing pain perception. This is why rubbing a painful area may alleviate some of the discomfort. Other efferent CNS pathways descend to the spinal cord and may close, partially close, or open the gate modulating the pain experience. The gate control theory, bolstered by progress in understanding neuronal pathways in the peripheral and central nervous systems, has greatly advanced the understanding of pain. As good as the GCT has been, however, there are observations about phantom pain in paraplegics and other pain syndromes that

“do not fit the theory.”⁶

Neuromatrix theory is an advancement of the gate control theory and proposes that the brain produces patterns of nerve impulses drawn from various inputs, including genetic, sensory-discriminative, affective-motivational, and evaluative-cognitive experiences.⁷ The qualities individuals normally feel from the body, including pain, also can be felt in the absence of inputs from the body (as noted with phantom limb pain). In other words, stimuli may trigger the patterns but do not produce them. Neuromatrix patterns are normally activated by sensory inputs from the periphery, but may originate independently in the brain with no external input. The pain experience involves an extensive network of brain regions and networks that may shift and evolve over time.⁸ The neuromatrix theory illustrates the plasticity (adaptable change in structure and function) of the brain.⁹ It does not supplant the understanding of the gate theory and what has been learned about peripheral inflammation, spinal modulation, and midbrain descending control of pain. The neuromatrix theory expands on the gate control theory by explicating a body-self that provides a holistic, integrated, dynamic consideration of pain. However, there are many different kinds of pain, and no single theory is adequate to explain the complex dynamics of the pain experience. Continuing research is advancing the understanding of the neural mechanisms of pain.

Neuroanatomy of Pain

The integrated function of three components of the nervous system mediates the sensation, perception, and response to pain:

1. The afferent pathways, which begin in the peripheral nervous system (PNS), travel to the spinal gate in the dorsal horn and then ascend to higher centers in the CNS
2. The interpretive centers located in the brainstem, midbrain, diencephalon (thalamus, hypothalamus, epithalamus, and subthalamus), and cerebral cortex
3. The efferent pathways that descend from the CNS to the dorsal

horn of the spinal cord

The processing of potentially harmful (noxious) stimuli through a normally functioning nervous system is called **nociception**. **Nociceptors** are free nerve endings in the afferent peripheral nervous system that selectively respond to different chemical, mechanical, and thermal stimuli. When stimulated, they cause **nociceptive pain**. Nociceptors are unevenly distributed throughout the body, so the relative sensitivity to pain differs according to their location ([Table 16.1](#)). For example, fingertips have more nociceptors than the skin of the back, and all skin has many more nociceptors than the internal organs. Unlike sensory neurons of the special senses of vision, gustation, and olfaction (discussed later), which are required to detect only one type of sensory stimulus (e.g., light for the sense of vision), primary nociceptive afferents have the remarkable ability to detect a wide range of stimuli. To do this, nociceptors are equipped with an array of transduction channels that can sense different forms of noxious stimulation and at different intensities. In addition to the previously well-studied voltage-gated potassium, sodium, and calcium channels, there are multiple types of transmembrane receptors (called *transient receptor potential [TRP] channels*), which reside on “naked nerve endings” and respond to a variety of physical, chemical, and thermal stimuli.¹⁰

TABLE 16.1

STIMULI THAT ACTIVATE NOCICEPTORS (PAIN RECEPTORS)

LOCATION OF RECEPTOR	PROVOKING STIMULI
Skin	Pricking, cutting, crushing, burning, freezing, inflammation
Gastrointestinal tract	Engorged or inflamed mucosa, distention or spasm of smooth muscle, traction on mesenteric attachment
Skeletal muscle	Ischemia, injuries of connective tissue sheaths, necrosis, hemorrhage, prolonged contraction, injection of irritating solutions
Bone	Periosteal injury, inflammation, fractures, tumors
Joints	Synovial membrane inflammation

Arteries	Piercing, inflammation
Head	Traction, inflammation, or displacement of arteries, meningeal structures, and sinuses; prolonged muscle contraction
Heart	Ischemia and inflammation

Nociceptors (*primary order neurons*) are categorized according to the stimulus to which they respond and by the properties of the axons associated with them. **A-delta (A δ) fibers** are lightly myelinated, medium-sized fibers that are stimulated by severe mechanical deformation (*mechanonociceptors*) or by mechanical deformation and/or extremes of temperature (*mechanothermal nociceptors*). A δ fibers rapidly transmit sharp, well-localized “fast” pain sensations. These fibers are responsible for causing reflex withdrawal of the affected body part from the stimulus before a pain sensation is perceived. The smaller **unmyelinated C fibers** are polymodal and are stimulated by mechanical, thermal, and chemical nociceptors. The unmyelinated C fibers slowly transmit dull, aching, or burning sensations that are poorly localized and longer lasting. **A-beta (A β) fibers** are large myelinated fibers that transmit touch and vibration sensations. They do not normally transmit pain but play a role in pain modulation.¹¹ Nociception involves four phases: transduction (stimulation of nociceptors in the periphery), transmission (axonal conduction), perception (cortical processing of stimuli), and modulation (descending pathways and neurotransmitters that inhibit or amplify pain).

Pain transduction begins when tissue is damaged by exposure to chemical (acids or chemicals of inflammation, such as bradykinin, histamine, leukotrienes, prostaglandins, interleukin [IL]-1, IL-6, IL-7, IL-17), mechanical (pressure or stretch), or thermal (extreme temperatures) noxious stimuli and is translated into electrophysiological activity. This causes activation of nociceptors.

Pain transmission is the conduction of pain impulses along the A δ and C fibers (primary order neurons) into the dorsal horn of the spinal cord (Fig. 16.1). Here they form synapses with excitatory or inhibitory interneurons (second-order neurons) that may branch into ascending or descending collaterals for one or two cord segments in neuronal

projections called the *dorsolateral tract*. Eventually all of the primary afferents terminate on interneurons in the *marginal layer* (laminae I) or *substantia gelatinosa* (laminae II) of the spinal cord (Fig. 16.2). The impulses then synapse with projection neurons (third order neurons), cross the midline of the spinal cord, and ascend to the brain through two lateral spinothalamic tracts. The neospinothalamic tract (anterior spinal thalamic tract) carries fast impulses for acute sharp pain. The paleospinothalamic tract (lateral spinothalamic tract) carries slow impulses for dull or chronic pain. The fast sharp pain is perceived first, followed by dull, throbbing pain. These tracts connect to the reticular formation, hypothalamus, thalamus (the major relay station of sensory information), and limbic system. The impulses are then projected to the somatosensory cortex for interpretation of location and intensity of pain, and to other areas of the brain for an integrated response to pain (Fig. 16.3).¹²

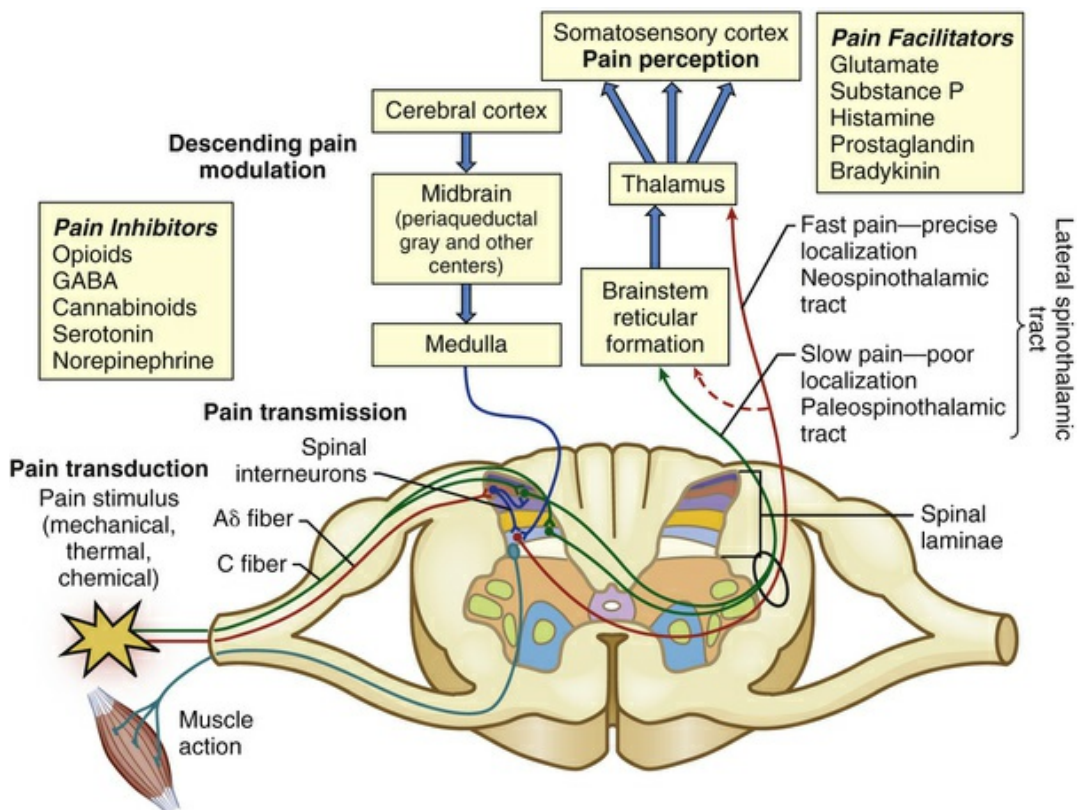

FIGURE 16.1 Transmission of Pain Sensations. The Aδ and C fibers synapse in the laminae of the dorsal horn, cross over to the contralateral

spinothalamic tract, and then ascend to synapse in the midbrain through the neospinothalamic (lateral spinothalamic tract) and paleospinothalamic tracts (anterior spinothalamic tracts). Impulses are then conducted to the sensory cortex. Descending pain inhibition is initiated in the cerebral cortex or from the midbrain and medulla. *GABA*, Gamma-aminobutyric acid.

FIGURE 16.2 Nociception Pathways. A δ and C fibers comprise the primary, first-order sensory afferents coming into the gate at the dorsal horn of the spinal cord. Second-order neurons cross the cord (“decussate”) and ascend to the thalamus as part of the spinothalamic tract. Third-order afferents project to higher brain centers of the limbic system, the frontal cortex, and the primary sensory cortex of the postcentral gyrus of the parietal lobe.

FIGURE 16.3 Central Nervous System Pathways That Mediate the Sensations of Pain and Temperature. *VPL*, Ventral posterior lateral thalamic nuclei; *VPM*, ventral posterior medial thalamic nuclei.

Pain perception is the conscious awareness of pain that occurs primarily in the reticular and limbic systems and the cerebral cortex. Three systems interact to produce the perception of pain and it changes with age (Table 16.2). The **sensory-discriminative system** is mediated by the somatosensory cortex and is responsible for identifying the presence, character, location, and intensity of pain. The **affective-motivational system** determines an individual's conditioned avoidance behaviors and emotional responses to pain. It is mediated

through the reticular formation, limbic system, and brainstem with projections to the prefrontal cortex. The **cognitive-evaluative system** overlies the individual's learned behavior concerning the experience of pain and can modulate perception of pain. It is mediated through the cerebral cortex. Pain threshold and tolerance are subjective phenomena that influence an individual's perception of pain. They can be influenced by genetics, gender, cultural perceptions, expectations, role socialization, physical and mental health, and age.

TABLE 16.2

PAIN PERCEPTION IN INFANTS, CHILDREN, AND OLDER PERSONS

	INFANTS	CHILDREN	OLDER PERSONS
Pain threshold	Painful neonatal experiences increase pain sensitivity (lower threshold); pain may be increased with future procedures	Lower or same as adults	Individual responses may vary but pain threshold may be lower
Physiologic symptoms	Increased heart rate, blood pressure, and respiratory rate; flushing or pallor, sweating, and decreased oxygen saturation	Same as infants; nausea and vomiting	Same as infants and children; nausea and vomiting; may be decreased in individuals with cognitive impairment
Behavioral responses	Changes in facial expression, crying, and body movements, with lowered brows drawn together; vertical bulge and furrows in forehead between brows; broadened nasal root; tightly closed eyes; angular, square-shaped mouth, chin quiver; withdrawal of affected limbs, rigidity, flailing	Individual responses vary	Individual responses vary and may be influenced by presence of painful chronic diseases and decline in renal, intestinal, hepatic, cardiovascular, and neurologic function; individuals with cognitive impairment may demonstrate changes in behavior (e.g., combative or withdrawn, increased confusion)

Pain Modulation

Pain modulation involves many different mechanisms that increase or decrease the transmission of pain signals throughout the nervous system. Depending on the mechanism, modulation can occur before, during, or after pain is perceived.¹³

Pathways of Modulation

Descending inhibitory or facilitatory pathways, nuclei, and neurotransmitters inhibit or facilitate pain. Afferent stimulation of particularly the periaqueductal gray (PAG; gray matter surrounding the cerebral aqueduct) and raphe nucleus in the midbrain stimulates efferent pathways, which inhibit afferent pain signals at the dorsal horn. The rostroventromedial medulla (RVM) stimulates efferent pathways that facilitate or inhibit pain in the dorsal horn through the dorsal lateral funiculus.¹⁴ Inhibitory pathways activate opioid receptors and inhibit release of excitatory neurotransmitters, facilitate release of inhibitory neurotransmitters, or stimulate inhibitory interneurons (Fig. 16.4).

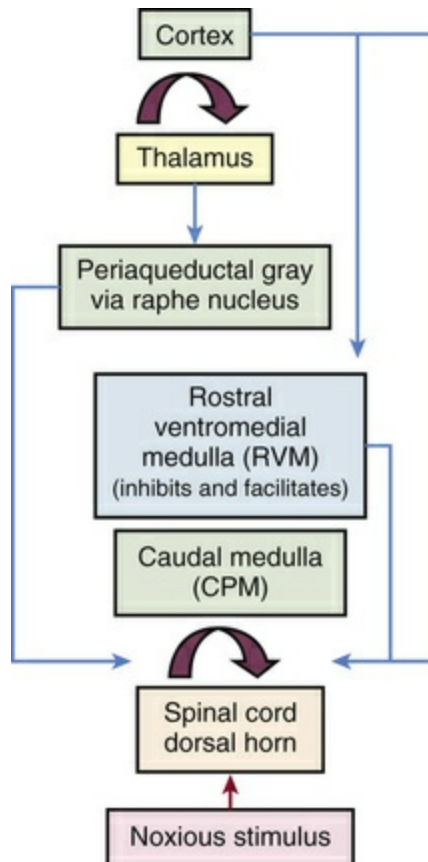

FIGURE 16.4 Diagram Representing the Central Mechanisms of Pain Modulation. A noxious peripheral stimulus activates both segmental and top-down (corticofugal and bulbospinal heterosegmental) modulatory mechanisms, which either accentuate or inhibit afferent pain transmission to the brain. The most important and widespread source of top-down (corticofugal) modulation arises from the cortex. Both thalamic and prethalamic nociceptive relays are under the influence of this top-down control. The dorsal horn of the spine is also under the influence of the caudal medulla through conditioned pain modulation (CPM). (Modified from Villanueva L, Fields HL: *The pain system in normal and pathological states: a primer for clinicians*, Seattle, 2004, IASP Press.)

Segmental inhibition of pain occurs when $A\beta$ fibers (which synapse in the dorsal horn along with their nociceptive $A\delta$ and C fiber counterparts) are stimulated and the impulses arrive at the same spinal level as impulses from $A\delta$ or C fibers. They stimulate an inhibitory interneuron and decrease pain transmission. An example is rubbing an area that has been injured to relieve pain.¹³

Conditioned pain modulation (previously known as *diffuse noxious inhibitory control [DNIC]*) is an inhibitory pain system that involves a spinal-medullary-spinal pathway. Pain is relieved when two noxious stimuli occur at the same time from different sites (pain inhibiting

pain). This also is known as *heterosegmental pain inhibition* (simultaneous pain stimulation and pain inhibition) and is the basis for pain relief with acupuncture, deep massage, or intense cold or heat.¹⁵

Expectancy-related cortical activation (**placebo effect** [positive expectations] or **nocebo effect** [adverse expectations]) can exert control over analgesic systems to attenuate or intensify pain. In other words, cognitive expectations can cause real, measurable physiologic effects that share some of the same descending pain pathways as the pain modulatory systems.¹⁶

Neurotransmitters of Pain Modulation

A wide variety of neurotransmitters act to modulate control over transmission of pain impulses in the periphery, spinal cord, and brain (**Box 16.1**).^{17,18} The peripheral triggering mechanisms that initiate release of **excitatory neurotransmitters** include tissue injury and inflammation (prostaglandins, histamine, bradykinin, tumor necrosis factor-alpha [TNF- α], nitric oxide) and chronic inflammatory lesions (lymphokines). Activity within nociceptors or damage to them causes release of peptides and neurotransmitters, such as tachykinins (e.g., substance P and neurokinins), calcitonin gene-related peptide (CGRP), and adenosine triphosphate (ATP). Glutamate, aspartate, substance P, and calcitonin are common excitatory neurotransmitters in the brain and spinal cord. These substances reduce the activation threshold, leading to increased responsiveness of nociceptors

Box 16.1

Mediators That Activate Nociceptors

**Excitatory Mediators
(Inflammatory)**

Bradykinin
Leukotrienes
Prostaglandins
Serotonin
Substance P
Interleukins 1, 6, 7, 17
Tumor necrosis factor-alpha
Nitric oxide
ATP
Neurokinins
Calcitonin gene-related peptide

Excitatory Transmitters

Glutamate (fast pain)
NMDA
AMPA
Tachykinins
Neurokinin A

Neurokinin B
Substance P
Calcitonin gene-related peptides
Somatostatins
Bombesins
Cholecystokinins

Inhibitory Mediators

Gamma-aminobutyric acid (GABA)
Glycine
Descending pain modulators
Norepinephrine- α_2 -receptors
Serotonin (5-hydroxytryptamine)
Opioids (μ , δ , κ receptors)
Endorphins } Released from PAG
Enkephalins } and NRM and
Dynorphins } other areas of
the brain

AMPA, α -Amino-3-hydroxy-5-methyl-4-isoxazole-propionate; ATP, adenosine triphosphate; NMDA, N-methyl-D-aspartate; NRM, nucleus raphes magnus; PAG, periaqueductal gray.

Inhibitory neurotransmitters in the spinal cord include gamma-aminobutyric acid (GABA) and glycine. Norepinephrine and 5-hydroxytryptamine (serotonin) contribute to pain inhibition in the medulla and pons but can excite peripheral nerves.^{18,19}

Endogenous opioids are a family of morphine-like neuropeptides that inhibit transmission of pain impulses in the spinal cord, brain, and periphery. Their receptors also play a role in various central nervous, gastrointestinal, immune, and other organ system disorders. There are four types of opioid neuropeptides: (1) *enkephalins*, (2) *endorphins*, (3) *dynorphins*, and (4) *endomorphins*. These neurohormones act as neurotransmitters by binding to one or more G-protein-coupled opioid receptors. There are three specific types of neuron opioid receptors: mu (μ), kappa (κ), and delta (δ). A fourth receptor subtype is nociception-opioid peptide (NOP), and its ligand is **nociceptin/orphanin FQ**.

Each receptor type binds differently with the various types of opioids. They inhibit ion channels in the dorsal horn, preventing the release of excitatory neurotransmitters, such as substance P and glutamate, or other areas of the brain such as the PAG or rostral ventromedial nuclei in the brainstem (Fig. 16.5). In the midbrain they influence descending inhibitory pathways.²⁰ In peripheral inflamed tissue, opioids are produced and released from leukocytes and activate opioid receptors on sensory nerve terminals.²¹ Because leukocyte opioids do not cross the blood-brain barrier, they do not have central nervous system side effects, such as respiratory depression, somnolence, or addiction. Opioid receptors are widely distributed throughout the body and are responsible for general sensations of well-being and modulation of many physiologic processes, including control of respiratory and cardiovascular functions, stress and immune responses, gastrointestinal function, reproduction, and neuroendocrine control.^{22,23}

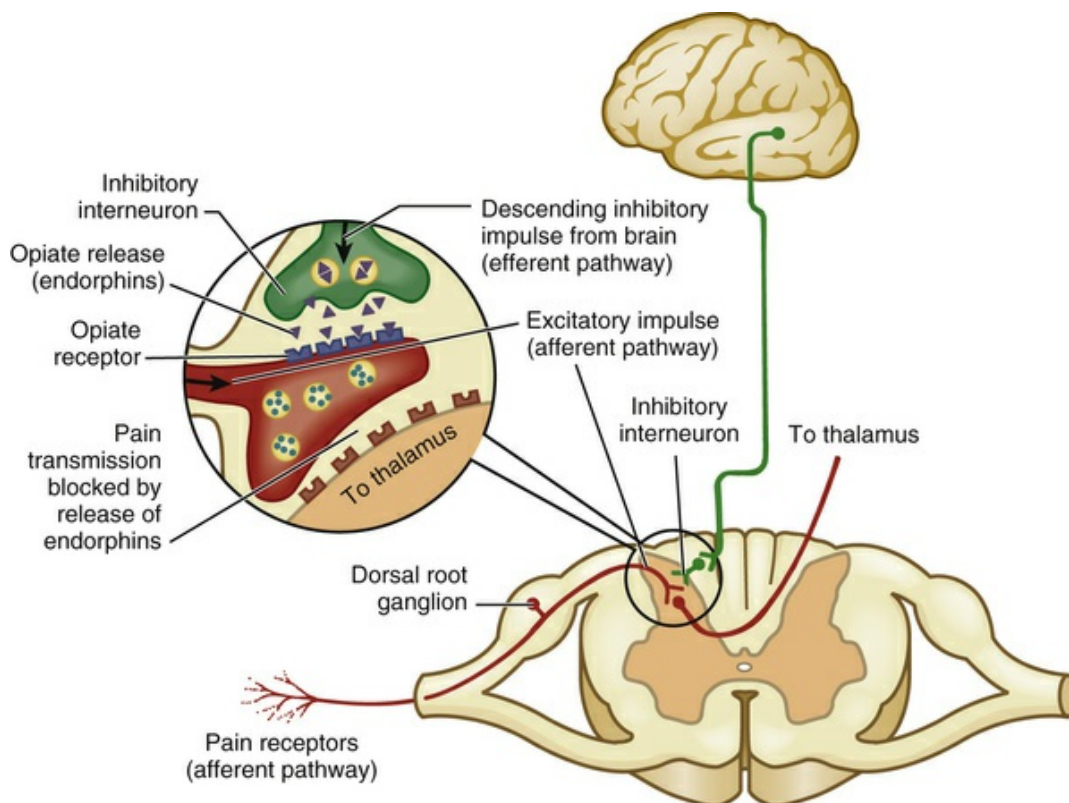

FIGURE 16.5 Descending Pathway and Endorphin Response. In this

figure, a descending inhibitory impulse is transmitted from the brain to an inhibitory interneuron in the dorsal horn, stimulating the release of endorphin. The endorphin activates a mu opioid receptor and results in inhibition of pain transmission to ascending pathways.

Enkephalins are the most prevalent of the natural opioids and bind to δ opioid receptors. They are concentrated in the hypothalamus, the PAG matter, the nucleus raphe magnus of the medulla, and the dorsal horns of the spinal cord.

Endorphins (endogenous morphine) are produced in the brain. The best studied endorphin, β -endorphin, binds to μ receptors in the hypothalamus and pituitary gland and is purported to produce the greatest sense of exhilaration as well as substantial natural pain relief.

Dynorphins are the most potent of the endogenous opioids binding strongly with κ receptors to impede pain signals in the brain. They play a role in mood disorders and drug addiction and paradoxically in stimulating chronic pain.²⁴ **Endomorphins**-1 and -2 bind with μ receptors throughout the brain, brainstem, and gastrointestinal tract and have analgesic and antiinflammatory effects.^{25,26}

Nociceptin/orphanin FQ produces antiopioid hyperalgesic effects in supraspinal pain pathways, while exerting analgesic properties in spinal pain pathways. It does not interact with opioid receptors. The nociceptin receptor (κ -type 3 opioid receptor) is widely distributed throughout the peripheral and central nervous system; is associated with inflammation, immune regulation, feeding behavior, and mood elevation; and blunts addictive behavior.²⁷

In addition to analgesic effects, endogenous opioids are involved in a variety of other functions throughout the body, including modulation of stress and anxiety, feeding behavior, cough suppression, immune and inflammatory responses, and alcohol intake.²⁸ Endogenous opioids of one type or another are found to bind to almost all tissues in the body and thus affect numerous biologic functions.²⁹

Pain Threshold and Pain Tolerance

Pain threshold is the point at which a stimulus is perceived as pain,

and it does not vary significantly among people or in the same person over time. Intense pain at one location, however, may cause an increase in the threshold in another location. For example, a person with severe pain in one knee is more likely to experience chronic back pain that is less intense. This phenomenon is called **perceptual dominance**. Because of perceptual dominance, pain at one site may mask other painful areas.

Pain tolerance is the duration of time or the intensity of pain that an individual will endure before initiating overt pain responses and is generally decreased with repeated exposure to pain. Pain tolerance is influenced by the person's cultural perceptions, expectations, role behaviors, physical and mental health, gender, age, fatigue, anger, boredom, apprehension, and sleep deprivation (see [Table 16.2](#)). Tolerance may be increased by alcohol consumption, persistent use of pain medication, hypnosis, warmth, distracting activities, and strong beliefs or faith.³⁰

Clinical Descriptions of Pain

Pain can be described in a variety of ways. Because of the complex nature of pain, however, many terms overlap and more than one description is often used. The broad categories of pain are summarized in [Box 16.2](#). Some of the most common clinical pain presentations are summarized in the following sections.

Box 16.2

Categories of Pain

Neurophysiologic Pain

A. Nociceptive pain

1. Somatic (e.g., fracture, thermal, or traumatic injury)
2. Visceral (e.g., bowel obstruction, endometriosis, gastritis)

3. Referred (e.g., ureteral distention localizes to testicle, angina localizes to arm, neck, or back)
- B. Neuropathic (nonnociceptive)
1. Central pain (lesion/dysfunction in brain or spinal cord)
 2. Peripheral pain (lesion/dysfunction in peripheral nervous system [PNS])

Neurogenic Pain

- A. Neuralgia (pain in the distribution of a nerve)
- B. Constant
1. Sympathetically independent
 2. Sympathetically dependent

Temporal Pain (Time Related)

- A. Acute pain
- B. Chronic

Regional Pain

- A. Abdominal pain
- B. Chest pain
- C. Headache
- D. Low back pain
- E. Orofacial pain
- F. Pelvic pain
- G. Joint pain

Etiologic Pain

- A. Cancer pain
- B. Dental pain
- C. Inflammatory pain (e.g., infection, trauma)
- D. Ischemic pain
- E. Vascular pain
- F. Postoperative pain

Adapted from Derasari MD: Taxonomy of pain syndromes: classification of chronic pain syndromes. In Raj PP, editor: *Practical management of pain*, ed 3, St Louis, 2000, Mosby.

Acute Pain

Acute pain (nociceptive pain) is a normal protective mechanism that alerts the individual to a condition or experience that is immediately harmful to the body and mobilizes the individual to take prompt action to relieve it. Acute pain is transient, usually lasting seconds to days, and sometimes up to 3 months.³¹ It begins suddenly and is relieved after the chemical mediators that stimulate pain receptors are removed. Stimulation of the autonomic nervous system results in physical manifestations including increased heart rate, hypertension, diaphoresis, and dilated pupils. Anxiety related to the pain experience, including its cause, treatment, and prognosis, is common and there is expectation of limited duration.

Acute pain arises from cutaneous and deep somatic tissue, or from visceral organs, and can be classified as (1) somatic, (2) visceral, or (3) referred. **Somatic pain** arises from muscle, bone, joints, and skin. It is either sharp and well localized (especially fast pain carried by A δ fibers) or dull, aching, throbbing, and poorly localized as seen in polymodal C fiber transmissions.

Visceral pain is transmitted by C fibers and refers to pain in internal organs and the lining of body cavities with an aching, gnawing, throbbing, or intermittent cramping quality. It is transmitted by sympathetic afferents and tends to be poorly localized, because of the lesser number of nociceptors in the visceral structures. Visceral

pain is associated with nausea and vomiting, hypotension, restlessness, and, in some cases, shock. It often radiates (spreads away from the actual site of the pain) or is referred.

Referred pain is pain felt in an area removed or distant from its point of origin. The area of referred pain is supplied by the same spinal segment as the actual site of pain. Impulses from many cutaneous and visceral neurons converge on the same ascending neuron, and the brain cannot distinguish between the two. Because the skin has more receptors, the painful sensation is experienced at the referred site instead of the site of origin.³² For example, an inflamed gallbladder or pancreas may refer pain to the shoulder and scapular regions. Referred pain can be acute or chronic. Fig. 16.6 illustrates common areas of referred pain and their associated sites of origin.

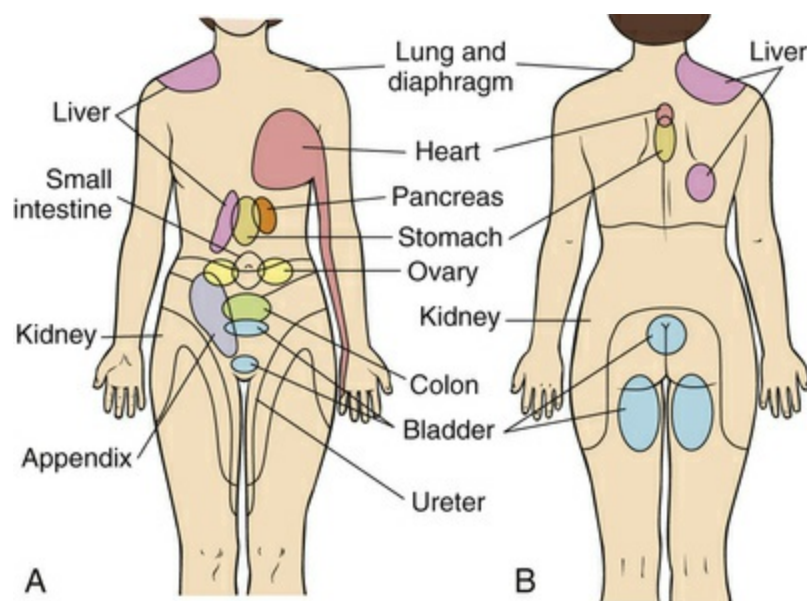

FIGURE 16.6 Sites of Referred Pain. A, Front. B, Back.

Chronic Pain

Chronic or persistent pain is usually defined as lasting for more than 3 to 6 months and is pain lasting well beyond the expected normal healing time. Chronic or persistent pain serves no purpose, is poorly understood, is often accompanied by anxiety and depression, and

causes suffering. It often appears to be out of proportion to any observable tissue injury. It may be ongoing (e.g., low back pain) or intermittent (e.g., migraine headaches). Changes in the peripheral and central nervous systems that cause dysregulation of nociception and pain modulation processes (peripheral and central sensitization) are thought to lead to chronic pain (see Neuropathic Pain, described later in this section).

Neuroimaging studies (functional, structural, and neurochemical imaging) have demonstrated brain changes (neuroplasticity) in individuals with chronic pain which can lead to the maintenance of pain even in the absence of the original nociceptive input. These negative manifestations of chronic pain are thought to be caused by, in part, the stress of coping with continuous pain and may be reversible when pain is controlled.^{33,34} Because it is not yet possible to predict when acute pain will develop into chronic pain, early treatment of acute pain is encouraged.

Neuropathic pain is chronic pain initiated or caused by a primary lesion or dysfunction in the nervous system and leads to long-term changes in pain pathway structures (neuroplasticity) and abnormal processing of sensory information.³⁵ There is amplification of pain without stimulation by injury or inflammation. Neuropathic pain is often described as burning, shooting, shocklike, or tingling. It is characterized by **hyperalgesia**, increased sensitivity to a normally painful stimulus (touch, pressure, pinprick, cold, and heat), or **allodynia**, the induction of pain by normally nonpainful stimuli.³⁶ Neuropathic pain is classified as either peripheral or central and is associated with central and peripheral sensitization.³⁷

Peripheral neuropathic pain is caused by peripheral nerve lesions and an increase in the sensitivity and excitability of primary sensory neurons and cells in the dorsal root ganglion (**peripheral sensitization**). Examples include nerve entrapment, diabetic neuropathy, or chronic pancreatitis. **Central neuropathic pain** is caused by a lesion or neuroplastic changes in the brain or spinal cord. A progressive repeated stimulation of group C neurons (wind-up) in the dorsal horn leads to increased sensitivity of central pain signaling

neurons (**central sensitization**). This results in pathologic changes in the CNS that cause chronic pain. Examples include brain or spinal cord trauma, tumors, vascular lesions, multiple sclerosis, Parkinson disease, postherpetic neuralgia, and phantom limb pain.

The following mechanisms have been implicated in the cause of neuropathic pain.^{35,38}

- Changes in sensitivity of neurons—lower threshold with peripheral and central sensitization
- Spontaneous impulses from regenerating peripheral nerves
- Alterations in the dorsal root ganglion in response to peripheral nerve injury and neurotransmitters—reorganization of nociceptive neurons (deafferentation pain)
- Loss of GABAergic pain inhibition in the spinal cord
- Activation of microglia and upregulation of nociceptive chemokines and their receptors
- Structural and functional alterations in brain processing neural networks

Comparison of acute and chronic pain is summarized in [Table 16.3](#). Common chronic pain conditions are listed in [Table 16.4](#).

TABLE 16.3

COMPARISON OF ACUTE AND CHRONIC PAIN

CHARACTERISTIC	ACUTE PAIN	CHRONIC PAIN
Experience	An event	A situation; state of existence
Source	External agent or internal disease	Unknown; if known, treatment is

	usually known	prolonged or ineffective
Onset	Usually sudden	May be sudden or develop insidiously
Duration	Transient (up to 6 months)	Prolonged and persistent (months to years)
Pain identification	Painful and nonpainful areas generally well identified	Painful and nonpainful areas less easily differentiated; change in sensations becomes more difficult to evaluate
Clinical signs	Increased pulse rate, elevated blood pressure, increased respiratory rate, diaphoresis, dilated pupils	Response patterns vary; fewer overt signs (adaptation)
Significance	Significant (informs person something is wrong)	Person looks for significance
Pattern	Self-limiting or readily corrected	Continuous or intermittent; intensity may vary or remain constant
Course	Suffering usually decreases over time	Suffering usually increases over time
Actions	Leads to actions to relieve pain	Leads to actions to modify pain experience
Prognosis	Likelihood of eventual complete relief	Complete relief usually not possible

Data from Black RG: *Surg Clin North Am* 55(4):999, 1975.

TABLE 16.4

COMMON CHRONIC PAIN CONDITIONS

CONDITION	DESCRIPTION
Persistent low back pain	Most common chronic pain condition Results from poor muscle tone, inactivity, muscle strain, or sudden, vigorous exercise
Myofascial pain syndromes	Second most common chronic pain condition Pain results from muscle spasm, tenderness, and stiffness Examples include myositis, fibrositis, myofibrositis, myalgia, and muscle strain—conditions that involve injury to the muscle and fascia As disorder progresses, pain becomes increasingly generalized
Chronic postoperative pain	Chronic pain that can occur with disruption or cutting of sensory nerves
Cancer pain	Can be pain attributed to advance of disease, associated with treatment, or attributed to coexisting disease entities

Deafferentation pain	Painful condition resulting from damage to a peripheral nerve Common types include severe burning pain triggered by various stimuli, such as cold, light touch, or sound, and reflex sympathetic dystrophies (occur after peripheral nerve injury and are characterized by continuous, severe, burning pain associated with vasomotor changes and muscle wasting)
Hyperesthesias	Increased sensitivity and decreased pain threshold to tactile and painful stimuli Pain is diffuse, modified by fatigue and emotion, and mixed with other sensations May result from chronic irritations of central nervous system areas
Hemiagnosia	Loss of ability to identify source of pain on one side of the body Painful stimuli on that side produce discomfort, anxiety, moaning, agitation, and distress but no attempt to withdraw from the stimulus Associated with stroke
Phantom limb pain	Pain experienced in amputated limb after stump has completely healed; may be immediate or occur months later Influenced by emotions or sympathetic stimulation Trigger points—small hypersensitive regions in muscle or connective tissues that, when stimulated, produce pain in a specific area
Complex regional pain syndrome	Chronic pain usually associated with limb injury, surgery, or fractures Characterized by autonomic and neuroinflammatory features and pain out of proportion to expected pain

An Overview of Chronic Pain Syndromes.

Specific spinal pain (i.e., intervertebral disk degeneration) and **nonspecific spinal pain** (i.e., low back pain not attributable to a specific pathologic source) are global, common, chronic, and disabling pain conditions (see [Chapter 18](#)). The prevalence of nonspecific low back pain is about 23% with 11% to 12% of those affected being disabled.^{39,40} Prevalence estimates and definition of risk factors vary among studies depending on the definition of low back pain used. Acute back pain is relatively rare, and many individuals of all ages have chronic recurrent back pain. Common causes include muscle tension and spasm (i.e., fibromyalgia; degeneration, including disk hernia, lumbar stenosis, and osteoarthritis; and fractures, mostly in those with osteoporosis).⁴¹ Both cortical and spinal alterations in pain processing are associated with low back pain.⁴² Treatment is individualized and often ineffective, and the personal and societal burden is great.^{43,44}

Myofascial pain syndrome (MPS) is a regional pain syndrome

associated with injury to muscle, fascia, and tendons and includes myositis, fibrositis, myofibrositis, myalgia (see [Chapter 45](#) for fibromyalgia), and muscle strain. These conditions involve myofascial trigger points within a taut band of skeletal muscle. The pain may be the result of low-threshold mechanosensitive afferents projecting to sensitized dorsal horn neurons and the development of peripheral and central sensitization.⁴⁵ Neuroaxonal degeneration with alterations in neuromuscular transmission (i.e., extra leakage of acetylcholine at the neuromuscular junction induces persistent contraction) may occur.⁴⁶ Compression of the trigger point causes referred pain, motor dysfunction, and autonomic responses. During the early stages of the disorder the pain is localized, but as the disorder progresses it becomes deep, aching, and more generalized. These, like many other chronic conditions, begin as a result of poor muscle tone, inactivity, muscle or tendon strain, or sudden vigorous exercise and can evolve into a chronic pain state.⁴⁷

Chronic postoperative pain occurs in some individuals and includes nerve injury, complex regional pain syndrome, phantom limb pain, chronic donor site pain, postthoracotomy pain syndrome, postmastectomy pain syndrome, joint arthroplasty pain, and postsurgical abdominal and pelvic pain. Plastic changes in the peripheral nervous system (PNS) and CNS contribute to allodynia and hypersensitivity. Multimodal approaches to analgesia are needed for pain management including adequate management of preoperative pain and postoperative management of acute pain.^{48,49}

Cancer pain is often chronic and the cause is unknown. Cancers generate and secrete mediators that sensitize and activate primary afferent nociceptors in the area of the tumor, resulting in neurochemical reorganization of the spinal cord, which contributes to spontaneous activity and enhanced pain responsiveness. Cancer pain is greater than inflammatory pain and has decreased expression of the μ -opioid receptor on dorsal root ganglia. Tumors also can secrete neurotrophic factors that contribute to enhanced responsiveness to pain.⁵⁰ Increasing pressure of a growing tumor on nerve endings, tissue destruction, distention of visceral surfaces, obstruction of ducts

and intestine, chemotherapy, radiation therapy, and surgical procedures also cause pain.⁵¹ Therapeutic approaches to the management of cancer pain have advanced significantly in recent years, particularly in palliative care and hospice programs. Frequent assessment of pain, management of breakthrough pain, and implementation of individualized interdisciplinary therapeutic strategies (including pharmacotherapeutic, anesthetic, neurosurgical, psychologic, and rehabilitative techniques along with frequent evaluations) are essential to optimal cancer pain management.⁵²⁻⁵⁴

Central poststroke pain is a form of central pain associated with stroke which occurs along the spinothalamocortical pathway and produces hypersensitivity on one-half of the body. There may be hyperexcitation in the damaged sensory pathways, damage to the central inhibitory pathways, or a combination of the two. The pain can be persistent or intermittent; burning or aching (more common); or stabbing, widespread, or focused. Allodynia may occur. The symptoms usually develop weeks or months after the stroke and can be difficult to differentiate from other causes of pain.^{55,56}

Phantom limb pain is pain that an individual feels in an amputated limb, usually distally (hands and feet) after the stump has completely healed (1 to 3 months after amputation). Nonpainful phantom limb sensations occur in almost all amputees, but the sensations usually fade with time. This is distinguished from the syndrome of phantom limb pain, a chronic pain occurring in 60% to 80% of amputees.⁵⁷ It is more likely to appear in individuals who experienced pain in the limb before amputation. Theories about the cause of phantom limb pain include regeneration or hyperactivity of injured or cut peripheral nerves, scar tissue or neuroma formation in the cut peripheral nerves, spinal cord deafferentation (loss of sensory fibers), nerve injury causing sensitization of dorsal horn neurons mediated by release of glutamate and neurokinins, and alterations in the thalamus and cortex. It has been proposed that CNS integration, including reorganization and plastic changes of the somatosensory cortex, results in the perception of pain from receptors associated with the amputated limb even though the limb itself is no longer present. The

absence of inhibitory effects of sensory input from the missing peripheral body part may cause increased autonomous activity of dorsal horn neurons with pain transmission. The cause is likely multifactorial, contributing to the difficulty of prevention or effective treatment.⁵⁸

Complex regional pain syndrome (CRPS) is chronic neuropathic pain usually associated with limb injury. Two forms are described: complex regional pain syndrome-I (CRPS-I) (previously termed *reflex sympathetic dystrophy syndrome*) associated with injury but no apparent nerve injury; and complex regional pain syndrome-II (CRPS-II) (previously termed *causalgia*) with evidence of nerve injury. The symptoms of both forms are similar.⁵⁹ CRPS is distinguished from other chronic pain disorders by signs of autonomic and inflammatory changes in the pain region of the injured nerve. There are *autonomic symptoms*: changes in skin color, temperature, and sweating and alterations in hair and nail growth for the affected limb; *motor symptoms*: tremor or weakness may be present; and *sensory symptoms*: hypersensitivity and allodynia.⁶⁰ CRPS is further distinguished as “warm CRPS,” associated with a warm, red, and edematous extremity; and “cold CRPS,” associated with a cold, dusky, and sweaty extremity. Acute CRPS is more often associated with a warm CRPS presentation, whereas chronic CRPS is more often characterized by a cold CRPS presentation. Peripheral and central sensitization contribute to the pain syndrome, but the mechanisms are unknown. A combination of injury and the presence of inflammatory cytokines and neuropeptides may lead to peripheral nociceptive sensitization and physiologic change in pain transmission and in autonomic and motor systems.⁶¹

Pediatrics and Perception of Pain

Infants and children have the anatomic and functional ability to perceive pain. Pain pathways and cortical and subcortical centers for pain perception, as well as neurochemicals associated with pain transmission and modulation, are functional in preterm and newborn

infants. The nociceptor system is functional in fetuses by 15 to 20 weeks' gestation, and painful fetal procedures require adequate analgesia.^{62,63} Repetitive, painful experiences and prolonged exposure to analgesic drugs in preterm infants may permanently alter developing synaptic and neuronal pain processing networks, causing irreversible hypersensitivity to pain with subsequent injury. Alterations occur in both the excitatory and inhibitory pathways in the spinal cord and descending inhibitory processing from the brainstem. Repeated painful procedures require increased amounts of analgesia.⁶⁴ Preterm infants experiencing the stress of repeated painful procedures also have delayed postnatal growth and poor early neurodevelopment with long-term consequence in both cognitive and motor functions.^{65,66} More research is needed to guide selection of analgesic and anesthetic agents and nonpharmacologic therapies for infant pain management in relation to effects on long-term neurodevelopment.⁶⁷⁻⁶⁹

Facial expression, crying, body movements, and lack of consolability are the most consistent expressions of pain in infants. The painful facial expression includes lowered brows drawn together; presence of a vertical bulge and furrows in the forehead between the brows; broadened nasal root; tightly closed, scoured eye fissures; angular, tongue cupping, squarish mouth; and chin quiver (Fig. 16.7). There may be finger clenching, writhing, back arching, and head banging. Physiologic responses include increases in heart rate, blood pressure, and respiratory rate, although these measures lack sensitivity and specificity. There may be flushing or pallor, sweating, and decreased oxygen saturation. Toddlers also express pain with crying, facial expression, and body language (tensed body, guarding, and hands holding body).⁷⁰ Older children, between ages 5 and 18 years, tend to have a lower pain threshold than do adults. Children, like adults, have highly individual responses to pain. Any behavioral and physiologic indicators of pain must be carefully and accurately assessed^{71,72} and adequately treated for children of all ages.^{73,74}

FIGURE 16.7 Painful Facial Expression of Infants. (From Hockenberry MJ: *Wong's nursing care of infants and children*, ed 7, St Louis, 2003, Mosby.)

Aging and Perception of Pain

Studies on pain perception in the older adult population have yielded conflicting evidence. Some studies show an increase in pain threshold with aging; others show no change.⁷⁵⁻⁷⁷ The varied results are probably a function of independent variation in the sensory-discriminative, motivational-affective, and cognitive-evaluative components of the pain experience. In general, studies confirm that an increase in the pain threshold occurs in some older adults. This change may be caused by peripheral neuropathies and changes in the thickness of the skin or cognitive impairment. (Neuropathies are discussed in [Chapter 18](#).) A decrease in pain tolerance is also evident in some older adults and may be related to decreased descending inhibitory modulation, decreased synthesis of neurotransmitters, or decreased opioid receptor density.⁷⁸ Women appear to be more sensitive to pain than

are men⁷⁹ (see [What's New? Sex Differences and Pain](#)). Pain in the older adult is also influenced by cognitive function and liver and renal function, including alterations in metabolism of drugs and metabolites and age-associated brain changes. Pain must be accurately assessed in relation to its effect on cognitive function, coexisting disease, drug interactions, other reactions to treatment, and an individual's ability to express pain and maintain safety.^{80,81} Poorly managed pain can result in depression, inactivity, and failure to maintain activities of daily living.⁸²

What's New?

Sex Differences and Pain

Sex differences in the experience of pain, modulation of pain, and the response to analgesics have been studied in both animal and human research. Women report higher pain levels or have less tolerance for pain stimuli, such as heat, cold, pressure, and electrical stimulation. The differences may be related to mechanisms of excitatory and inhibitory control. Sex differences also exist in the prevalence of painful chronic diseases; for example, women are more affected by interstitial cystitis, fibromyalgia, and rheumatoid arthritis, and men are more affected by cluster headache. Pain symptoms differ for men and women for diseases such as coronary artery disease, irritable bowel syndrome, appendicitis, and cancer. Sex hormones are known to have an effect on the mechanisms and outcomes of opiate analgesia, and in rodents, morphine analgesia is more effective in males than in females. Pain sensitivities in women also vary across the phases of the menstrual cycle. Recent human and animal studies suggests that κ -opioid receptor analgesia is greater in women than in men and may reflect a difference in endogenous pain circuits mediated by different opiate receptor subtypes and influenced by effects of estrogen and progesterone. Sex differences with respect to pain also are influenced by role socialization, cognitive factors, and culture. Continuing research is

needed to further understand sex differences in the operation of pain mechanisms and the development of more specific pain management strategies.

Temperature Regulation

Human thermoregulation is achieved through precise balancing of heat production, heat conservation, and heat loss. The normal range of body temperature is 36.2° to 37.7°C (97.2° to 99.9°F) overall, but a person's individual body parts will vary in temperature. The extremities are generally cooler than the trunk, and the temperature at the core of the body (as measured by rectal temperature) is generally 0.5°C (0.9°F) higher than the surface temperature (as measured by oral temperature). Internal temperature varies in response to activity, environmental temperature, and daily fluctuations (circadian rhythm). Oral temperatures fluctuate within 0.2° to 0.5°C (0.36° to 0.9°F) during a 24-hour period. Women tend to have wider fluctuations that follow the menstrual cycle, with a sharp rise in temperature just before ovulation. The daily fluctuating temperature is similar in both sexes.⁸³ Maintenance of body temperature within the normal range is necessary for life.

Control of Temperature

Temperature regulation (**thermoregulation**) is mediated primarily by the preoptic anterior area of the hypothalamus. Peripheral thermoreceptors in the skin and abdominal organs (unmyelinated C fibers and thinly myelinated A δ fibers) and central thermoreceptors in the spinal cord and trigeminal ganglia provide the hypothalamus with information about skin and core temperatures. These peripheral thermoreceptors have heat-sensitive ion channels (TRP cation

channels) which are activated at variable temperatures and provide thermotransduction of energy into a neural signal to the hypothalamus.⁸⁴ If these temperatures are low or high, the hypothalamus responds by triggering heat production, heat conservation, or heat loss mechanisms.

Body heat is produced by the chemical reactions of metabolism and skeletal muscle tone and contraction. The heat-producing mechanism (chemical or nonshivering thermogenesis) begins with hypothalamic thyrotropin-stimulating hormone-releasing hormone (TSH-RH); it stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH), which acts on the thyroid gland and stimulates the release of thyroxine. Thyroxine then acts on the adrenal medulla, causing the release of epinephrine into the bloodstream. Epinephrine causes vasoconstriction, stimulates glycolysis, and increases metabolic rate, thus increasing body heat. Norepinephrine and thyroxine activate brown fat thermogenesis, where energy is released as heat instead of as adenosine triphosphate (ATP). Heat is distributed by the circulatory system.

The hypothalamus also triggers heat conservation by stimulating the sympathetic nervous system, which stimulates the adrenal cortex and results in increased skeletal muscle tone, initiating the shivering response, and producing vasoconstriction. By constricting peripheral blood vessels, centrally warmed blood is shunted away from the periphery to the core of the body where heat can be retained. This involuntary mechanism takes advantage of the insulating layers of the skin and subcutaneous fat to protect core temperature. The hypothalamus relays information to the cerebral cortex about cold, and voluntary responses result. Individuals typically bundle up, keep moving, or curl up in a ball. These types of voluntary physical activities respectively provide insulation, increase skeletal muscle activity, and decrease the amount of skin surface available for heat loss through radiation, convection, and conduction.

The hypothalamus responds to warmer core and peripheral temperatures by reversing the same mechanisms. The TSH-RH pathway is shut down. The sympathetic pathway is prompted to

produce cutaneous vasodilation, decreased muscle tone, and increased sweat production. Hypothalamic stimulation of the cerebral cortex provokes voluntary behavior to reduce heat production and promote heat loss. [Table 16.5](#) summarizes further information about heat production and loss.

TABLE 16.5

MECHANISMS OF HEAT PRODUCTION AND HEAT LOSS

CONDITION	DESCRIPTION
Heat Production	
Chemical reactions of metabolism	Occurs during ingestion and metabolism of food and while maintaining body at rest (basal metabolism); occurs in body core (e.g., liver)
Skeletal muscle contraction	Gradual increase in muscle tone or rapid muscle oscillations (shivering); controlled by posterior hypothalamus
Chemical (nonshivering) thermogenesis	Epinephrine and norepinephrine are released and produce rapid, transient increase in heat production by raising basal metabolic rate; quick, brief effect that counters heat lost through conduction and convection; occurs in brown and beige adipose tissue (thermogenic adipocytes), which decreases markedly in older adults; thyroid hormone increases metabolism and heat production
Heat Loss	
Radiation	Heat loss through electromagnetic waves emanating from surfaces with temperature higher than surrounding air
Conduction	Heat loss by direct molecule-to-molecule transfer from one surface to another, so that warmer surface loses heat to cooler surface
Convection	Transfer of heat through currents of gases or liquids; exchanges warmer air at body's surface with cooler air in surrounding space
Vasodilation	Diverts core-warmed blood to surface of body, with heat transferred by conduction to skin surface and from there to surrounding environment; occurs in response to autonomic stimulation under control of hypothalamus
Evaporation	Body water evaporates from surface of skin and linings of mucous membranes; major source of heat reduction connected with increased sweating in warmer surroundings
Decreased muscle tone	Exhausted feeling caused by moderately reduced muscle tone and curtailed voluntary muscle activity
Increased respiration	Air is exchanged with environment through normal process; minimal effect
Voluntary	"Stretching out" and "slowing down" in response to high body temperatures;

mechanisms	increasing body surface area available for heat loss; dressing in light-colored, loose-fitting garments
Adaptation to warmer climates	Gradual process beginning with lassitude, weakness, and faintness; proceeding through increased sweating, lowered sodium content, decreased heart rate, and increased stroke volume and extracellular fluid volume; and terminating in improved warm weather functioning and decreased symptoms of heat intolerance (work output, endurance, and coordination increase; subjective feelings of discomfort decrease)

Mechanisms of Heat Production

Chemical Reactions of Metabolism.

The *chemical reactions* that occur during the ingestion and metabolism of food and those required to maintain the body at rest (basal metabolism) require energy and produce heat. These processes occur in the body core (primarily the liver) and are in part responsible for the maintenance of core temperature.

Skeletal Muscle Contraction.

Skeletal muscles produce heat through two mechanisms: (1) gradual increase in muscle tone and (2) production of rapid muscle oscillations (*shivering*—which does not occur in neonates). Both increasing muscle tone and shivering are controlled by the posterior hypothalamus and occur in response to cold. As peripheral temperature drops, muscle tone increases and shivering begins. Shivering is a fairly effective method for increasing heat production because no work is performed and all the energy produced is retained as heat.⁸⁵

Chemical Thermogenesis.

Chemical thermogenesis, also called *nonshivering thermogenesis* or *adrenergic thermogenesis*, results from the release of epinephrine and norepinephrine. Epinephrine and norepinephrine produce a rapid, transient increase in heat production by raising the body's basal metabolic rate. Chemical thermogenesis seems to be different from hormone-triggered increases in the basal metabolic rate. Chemical thermogenesis produces a quick, brief rise in basal metabolic rate,

whereas the hormone thyroxine triggers a slow, prolonged rise. Chemical thermogenesis occurs in brown and beige adipose tissue (see [Chapter 23](#) for adipose tissue as an endocrine organ). Brown adipose tissue is rich with mitochondria and blood vessels and is essential for nonshivering thermogenesis. Beige (bright) adipocytes are found within subcutaneous white adipose tissue.⁸⁵ White adipocytes store energy, and brown and beige adipocytes produce heat. Beige adipocytes demonstrate transdifferentiation to white adipocytes, and such plasticity allows direct conversion of one cell type into the other. With chronic cold exposure white-to-beige conversion increases thermogenesis.⁸⁶

Mechanisms of Heat Loss

Heat loss is achieved through many mechanisms: (1) radiation, (2) conduction, (3) convection, (4) vasodilation, (5) decreased muscle tone, (6) evaporation, (7) increased pulmonary ventilation, (8) voluntary measures, and (9) adaptation to warmer climates.

Radiation.

Radiation refers to heat loss through electromagnetic waves. These waves emanate from surfaces with temperatures higher than the surrounding air temperature. Thus, if the temperature of the skin is higher than that of the air, the skin and therefore the body lose heat to the air.

Conduction.

Conduction refers to heat loss by direct molecule-to-molecule transfer from one surface to another. Through conduction, the warmer surface loses heat to the cooler surface. Thus the skin loses heat through direct contact with cooler air, water, or another surface. In the same manner, the core of the body loses heat to the cooler body surface.

Convection.

Convection is the transfer of heat through currents of gases or liquids. It greatly aids heat loss through conduction by exchanging warmer air

at the surface of the body with cooler air in the surrounding space. Convection occurs passively as warmer air at the surface of the body rises away from the body and is replaced by cooler air, but the process may be aided by fans or wind. (The combined effect of conduction and convection by wind is conventionally measured as the *windchill factor*.)

Vasodilation.

Peripheral vasodilation increases heat loss by diverting core-warmed blood to the surface of the body. As the core-warmed blood passes through the periphery, heat is transferred by conduction to the skin surface and from the skin to the surrounding environment. Because heat loss through conduction depends on the surrounding temperature, it is minimal to nonexistent if the surrounding air or water is warmer than the body surface.

Vasodilation occurs in response to autonomic stimulation under the control of the hypothalamus. It is useful in instances of moderate temperature elevation. As core temperature increases, vasodilation increases until maximal dilation is achieved. At that point the body must use additional heat loss mechanisms.

Decreased Muscle Tone.

To decrease heat production, muscle tone may be moderately reduced and voluntary muscle activity curtailed. These mechanisms explain in part the “washed-out” feeling associated with high temperatures and warm weather. Decreased muscle tone and reduced activity have a limited effect on decreasing heat production, however, because muscle tone and heat production cannot be reduced below basal body requirements.

Evaporation.

Evaporation of body water from the surface of the skin and the linings of the mucous membranes is a major source of heat reduction. Insensible water loss (in the absence of perceptible sweating) accounts for a loss of about 600 mL of water per day. Heat is lost as surface

fluid is converted to gas, so that heat loss by evaporation is increased if more fluids are available at the body surface. To speed this process, fluids are actively secreted through the sweat glands. As much as 2.2 L of fluid per hour may be lost by sweating. Electrolytes are lost with the water. Therefore loss of large volumes through sweating may result in decreased plasma volume, decreased blood pressure, weakness, and fainting. (Alterations in fluid balance are discussed in [Chapter 3](#).)

Like other heat reduction mechanisms, stimulation of sweating occurs in response to sympathetic neural activity and depends on a favorable temperature difference between the body and the environment. In addition, heat loss through evaporation is affected by the relative humidity of the air. If the humidity is low, sweat evaporates quickly, but if the humidity is high, sweat does not evaporate and instead remains on the skin or drips off it.

Increased Pulmonary Ventilation.

Exchanging air with the environment through the normal pulmonary ventilation provides some heat loss, although it is minimal in humans. As air is inhaled, the air draws heat from the upper respiratory tract. The air is further warmed in the alveoli by blood in the microcirculation. This warmed air then is exhaled into the environment. This normal process occurs faster at higher body temperatures through an increase in ventilatory rates. Thus hyperventilation is associated with hyperthermia. (Normal pulmonary function is discussed in [Chapter 35](#).)

Voluntary Mechanisms.

In response to high body temperatures, people physically “stretch out,” thereby increasing the body surface area available for heat loss. They also “slow down” or “take it easy,” thereby decreasing skeletal muscle work, and they “dress for warm weather” with light-colored, loose-fitting garments to reflect heat and promote convection, conduction, and evaporation.

Heat Adaptation.

The body of an individual who moves from a cooler to a much warmer climate undergoes a period of adjustment, a process that takes several days to weeks. At first the individual experiences feelings of lassitude, weakness, and faintness with even moderate activity. Body temperatures rise with any work. Within several days, however, the individual experiences an earlier onset of sweating, the volume of sweat is increased, the sodium content is lowered, and skin blood flow increases. Heart rate is decreased and stroke volume increased so that cardiac output remains unchanged. Extracellular fluid volume increases, as does plasma volume. These physiologic adaptations result in improved warm weather functioning and decreased symptoms of heat intolerance. People's work output, endurance, and coordination increase, and their subjective feelings of discomfort decrease.^{87,88}

Mechanisms of Heat Conservation

Vasoconstriction.

By constricting peripheral blood vessels, centrally warmed blood is shunted away from the periphery (where radiation, conduction, and convection would allow heat loss) to the core of the body, where heat can be retained. This mechanism takes advantage of the insulating layers of the skin and subcutaneous fat to protect core temperature.

Voluntary Mechanisms.

In response to lower body temperatures, individuals typically “bundle up,” “keep moving,” or “curl up in a ball.” Bundling up involves dressing with several layers of clothes that allow air to be trapped between the skin and the clothing, thus providing an additional layer of insulation. Keeping moving, stamping feet, clapping hands, jogging, and other types of physical activity increase skeletal muscle activity and thus promote heat production. Curling up in a ball decreases the amount of skin surface available for heat loss through radiation, convection, and conduction.

Pediatrics and Temperature Regulation

Infants and older adults require special attention to maintenance of body temperature. Term infants produce body heat primarily through the metabolism of brown fat, but it may not be adequately developed for cold stress.⁸⁹ They also are unable to efficiently conserve heat because of the infant's small body size, greater ratio of body surface area to body weight with heat loss through conduction and convection, and decreased ability to shiver. Infants have a thin layer of subcutaneous fat and thus are not as well insulated as adults.⁹⁰ Therefore it is important to keep infants warm with hats, clothing, and blankets. Children also have a greater ratio of body surface area to body weight, fewer sweat glands, lower sweating rate, higher peripheral blood flow in the heat, and a greater extent of vasoconstriction in the cold than adults. They can acclimatize to changes in environmental temperatures, but do so at a lower rate than that seen in adults.⁹¹

Aging and Temperature Regulation

Older adults have lower body temperatures than younger people. They have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in the skin, an overall decrease in heat-producing activities, and the presence of disease (e.g., congestive heart failure, chronic lung disease, diabetes mellitus, or peripheral vascular disease). Cold stress in older adults also decreases coronary perfusion.⁹² Other factors affecting thermal regulation in the older adult population include decreased shivering response (delayed onset and decreased effectiveness), slowed metabolic rate, sedentary lifestyle, decreased vasoconstrictor and vasodilator responses, diminished or absent sweating, decreased amount of brown fat, desynchronization of circadian rhythm, undernutrition, and decreased perception of heat and cold.^{93,94}

Pathogenesis of Fever

Fever (febrile response or pyrexia) is a temporary resetting of the hypothalamic thermostat to a higher level in response to pyrogenic cytokines (previously known as endogenous pyrogens) and exogenous pyrogens.⁹⁵ The pathophysiologic mechanism of fever begins with the introduction of **exogenous pyrogens** or endotoxins produced by pathogens. The most frequently encountered exogenous pyrogens are the lipopolysaccharide complexes in the cell wall of gram-positive bacteria and viruses released with rupture of the cell wall when the microbe dies. **Pyrogenic cytokines**, including tumor TNF- α , IL-1, IL-6, and interferon- γ , are produced by phagocytic cells as they destroy microorganisms within the host. The final common step for fever generation by pyrogens is the production of prostaglandin E₂ (PGE₂) in both the periphery and the brain. PGE₂ acts on warm sensitive neurons in the preoptic area of the hypothalamus. An integrated behavioral, endocrine, and autonomic nervous system response is then initiated. Centers in the hypothalamus and brainstem signal an increase in heat production and heat conservation to raise the set point for body temperature regulation (Fig. 16.8). Peripheral vasoconstriction occurs with shunting of blood from the skin to the body core. Epinephrine release increases metabolic rate, and muscle tone increases. Decreased release of vasopressin reduces the volume of body fluid to be heated. Shivering also may occur. The individual dresses more warmly, decreases body surface area by curling up, and may go to bed in an effort to get warm. Body temperature is maintained at the new level until the fever “breaks.”

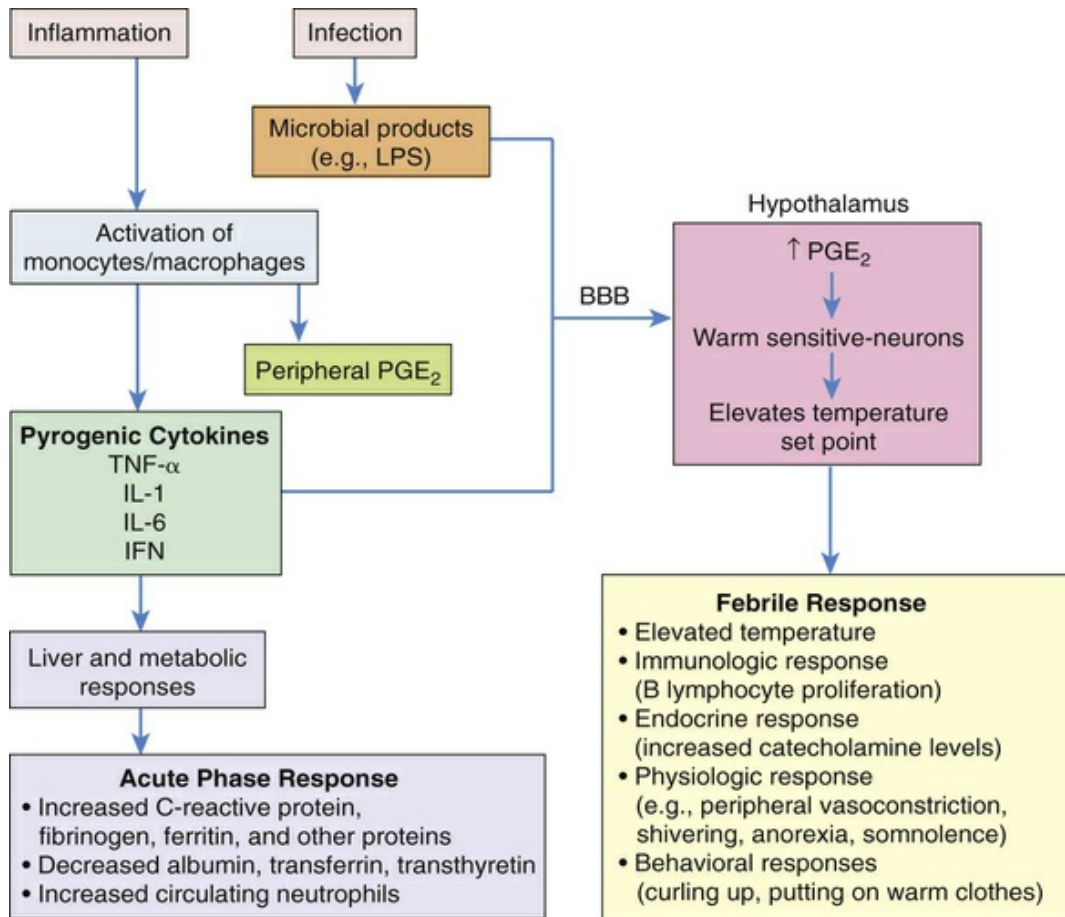

FIGURE 16.8 Pathogenesis of Fever and Acute Phase Response. Inflammation and infection initiate the release of pyrogenic cytokines and exogenous pyrogens. Exogenous pyrogens lead to production of PGE_2 in the periphery and the brain, and pyrogenic cytokines stimulate PGE_2 release in the brain. PGE_2 acts on warm-sensitive neurons in the hypothalamus, setting a higher temperature set point and initiating an integrated febrile response. Concurrently, pyrogenic cytokines initiate the acute phase response. *BBB*, blood-brain barrier; *IFN*, interferon; *IL-1*, *IL-6*, interleukin-1, interleukin-6; *LPS*, lipopolysaccharide; *PGE₂*, prostaglandin E_2 ; *TNF- α* , tumor necrosis factor-alpha. (Adapted from Bennett JE et al: *Mandell, Douglas, and Bennett's principles and practice of infectious disease*, ed 8, Philadelphia, 2015, Saunders.)

The “acute phase response” is a reaction that occurs when pyrogenic and other cytokines are released in response to infection and inflammation. In addition to fever, other symptoms occur including anorexia, fatigue, malaise, somnolence, and loss of concentration. At the cellular level, inflammatory pyrogenic cytokines promote muscle catabolism and hyperglycemia (gluconeogenesis, glycogenolysis, and insulin resistance) by stimulating release of

adrenocorticotrophic hormone and glucocorticoids to support glucose-consuming cells. The hepatic acute phase response involves increasing or decreasing protein synthesis. C-reactive protein, mannose-binding protein, complement factors, ferritin, ceruloplasmin, serum amyloid A, fibrinogen, and haptoglobin are increased. Albumin, transferrin (binds iron), retinol-binding proteins, and transthyretin (transports thyroid hormone) are reduced. The erythrocyte sedimentation rate (ESR) increases as the increase in fibrinogen and other plasma proteins decrease rouleaux formation, allowing the red blood cells to fall faster. Acute phase proteins and the ESR can serve as biomarkers for the inflammatory response.⁹⁶ The general functions of increased acute phase proteins are to opsonize and trap microorganisms and their products, activate complement, neutralize enzymes, and modulate the host's immune response (see [Chapter 7](#)).

During fever, arginine vasopressin (AVP), α -melanocyte-stimulating hormone (α -MSH), and corticotropin-releasing factor are released from the brain, and systemic antiinflammatory cytokines (i.e., IL-1 receptor agonist and IL-10) can act as **endogenous cryogens** or **antipyretics** to help diminish and control the febrile response.^{97,98} This antipyretic effect constitutes a negative-feedback loop. The antipyretic effect may help explain fluctuations in the febrile response. When the fever breaks, the set point is returned to normal. The hypothalamus responds by signaling a decrease in heat production and an increase in heat reduction mechanisms. The result is decreased muscle tone, peripheral vasodilation, flushed skin, and sweating. The individual feels very warm, replaces warm clothing with cooler clothes, throws off the covers, and stretches out. Once the body has returned to a normal temperature, the individual feels more comfortable and the hypothalamus adjusts thermoregulatory mechanisms to maintain the new temperature.

Benefits of Fever

Moderate fever aids responses to infectious processes through several mechanisms.⁹⁹ A raised body temperature kills many microorganisms and has adverse effects on the growth and replication of others.

Higher body temperatures decrease serum levels of iron, zinc, and copper, all of which are needed for bacterial replication. The body switches from burning glucose to a metabolism based on lipolysis and proteolysis, thereby depriving bacteria of a food source. Increased temperature also causes lysosomal breakdown and autodestruction of cells, thus preventing viral replication in infected cells. Acute-phase proteins produced by the liver during inflammation bind cations necessary for bacterial reproduction. Heat increases lymphocytic transformation and motility of polymorphonuclear neutrophils, thus facilitating the immune response. Phagocytosis is enhanced, and production of antiviral interferon may be augmented.¹⁰⁰

Because fever is a beneficial response to infection, suppressing fever with antipyrogenic medications should be reviewed carefully.¹⁰¹ Such treatment should be used only if the fever is high enough to produce serious side effects, such as nerve damage or convulsion, although more studies are needed to guide practice.¹⁰²

Infection and fever responses in older adults and in children may vary from those in the adult. Older individuals may have decreased or no fever response to infection. The absence of fever responses to infection and therefore the beneficial aspects of fever production may explain the increase in morbidity and mortality rates seen in very old individuals.¹⁰³ In contrast, children develop higher temperatures than do adults for relatively minor infections.

Febrile seizures may occur with temperatures greater than 38°C (100.4°F), although most children do not develop febrile seizures until temperatures are much higher. Febrile seizures are more predominant in boys before age 5 years, and genetic factors contribute to susceptibility.¹⁰⁴ Febrile seizures are generally brief and self-limiting, lasting less than 5 minutes in 40% of children and less than 20 minutes in 75% of children (see [Chapter 20](#)). Although in most instances there appear to be no long-term effects on the child, a small percentage of children (1% to 2%) may develop epilepsy.¹⁰⁵ Prolonged febrile seizures are associated with the development of temporal lobe epilepsy in children and are probably associated with functional changes in neurons and neural networks.¹⁰⁶

Fever of unknown origin (FUO) is a fever with a body temperature greater than 38.3°C (101°F) that remains undiagnosed after 3 days of hospital investigation or two or more outpatient visits. The clinical categories of FUO include classic, nosocomial, neutropenic, and HIV associated. The history and clinical examination can assist in differentiating possible causes.^{107,108}

Disorders of Temperature Regulation

Internal body temperature is maintained within a narrow range. Alterations in the regulation of heat production or heat loss can be life-threatening.

Hyperthermia

Hyperthermia is elevation of the body temperature without an increase in the hypothalamic set point. Hyperthermia can produce nerve damage, coagulation of cell proteins, and death. At 41°C (105.8°F), nerve damage produces convulsions in the adult. Death results at 43°C (109.4°F). Hyperthermia may be therapeutic, accidental, or associated with stroke or head trauma. Prevention of hyperthermia in stroke and head trauma assists in limiting brain injury.¹⁰⁹ **Therapeutic hyperthermia** is a form of local, regional, or whole-body induced hyperthermia used to destroy pathologic microorganisms or tumor cells by facilitating the host's natural immune process or tumor blood flow.¹¹⁰

The forms of **accidental hyperthermia** are summarized as follows:¹¹¹

1. **Heat cramps**—severe, spasmodic cramps in the abdomen and extremities that follow prolonged sweating and associated sodium loss. They usually occur in those not accustomed to heat or those performing strenuous work in very warm climates. Fever, rapid pulse rate, and increased blood pressure accompany the cramps. Treatment involves administration of dilute salt solutions through oral or parenteral routes.

2. **Heat exhaustion**—results from prolonged high core or environmental temperatures, which cause profound vasodilation and profuse sweating, leading to dehydration, decreased plasma volumes, hypotension, decreased cardiac output, and tachycardia. Symptoms include weakness, dizziness, confusion, nausea, and fainting. The symptoms of heat exhaustion cause the individual to stop work, lie down, and rest. Ceasing activity decreases muscle work, causing decreased heat production. Lying down redistributes vascular volume. The individual should be encouraged to drink cool fluids to replace fluid lost through sweating.
3. **Heat stroke**—a potentially lethal result of an overstressed thermoregulatory center. Heat stroke can be caused by exertion, by overexposure to environmental heat, or from impaired physiologic mechanisms for heat loss. With very high core temperatures ($>40^{\circ}\text{C}$; 104°F), the regulatory center ceases to function and the body's heat loss mechanisms fail. Symptoms include high core temperature, absence of sweating, rapid pulse rate, confusion, agitation, and coma. Complications include cerebral edema, degeneration of the CNS, swollen dendrites, renal tubular necrosis, and hepatic failure with delirium, coma, and eventually death if treatment is not undertaken.¹¹²
4. **Malignant hyperthermia**—a potentially lethal hypermetabolic complication of a rare inherited muscle disorder that may be triggered by inhaled anesthetics and depolarizing muscle relaxants.^{113,114} The syndrome involves either increased myoplasmic calcium release or decreased calcium uptake. This allows intracellular calcium levels to rise, producing sustained, uncoordinated muscle contractions; muscle cell hypermetabolism; increased muscle work; increased oxygen consumption; and a raised level of lactic acid production. Acidosis develops and body temperature rises (body temperature may rise 1°C [1.8°F] every 5 minutes) with resulting tachycardia and cardiac dysrhythmias, hypotension,

decreased cardiac output, and cardiac arrest. The syndrome is caused by a defect in the ryanodine receptor. Signs resemble those of coma: unconsciousness, absent reflexes, fixed pupils, apnea, and occasionally a flat electroencephalogram. Oliguria and anuria are common. It is most common in children and adolescents. Treatment includes withdrawal of the provoking agents, body cooling therapy, and drugs that antagonize the ryanodine receptor.¹¹⁴

Hypothermia

Hypothermia (core body temperature less than 35°C [95°F]) produces depression of the central nervous and respiratory systems, vasoconstriction, alterations in microcirculation and coagulation, and ischemic tissue damage. In a controlled situation, such as a surgical procedure, most tissues can tolerate temperatures as low as 33°C (91.4°F). In severe hypothermia (less than 28°C [82.4°F]), ice crystals forming on the inside of the cell cause cells to rupture and die. Tissue hypothermia slows the rate of chemical reactions (tissue metabolism), increases the viscosity of the blood, slows blood flow through the microcirculation, impairs platelet function and blood coagulation, stimulates profound vasoconstriction, suppresses myocardial contractility, and induces arrhythmias. Hypothermia may be accidental or therapeutic. In accidental hypothermia, high-energy phosphates (e.g., ATP) are depleted, and in therapeutic hypothermia, ATP storage is preserved.¹¹⁵

Accidental Hypothermia.

Accidental hypothermia is generally the result of sudden immersion in cold water or prolonged exposure to cold environments. At particular risk for accidental hypothermia are infants and older adults, because thermoregulatory mechanisms are immature or altered in these two groups. Also at risk are individuals with conditions that diminish the ability to generate heat. Such conditions include hypothyroidism, hypopituitarism, decreased liver function, malnutrition, Parkinson disease, and rheumatoid arthritis. Other risk

factors include chronic increased vasodilation and decreased thermoregulatory control caused by cerebral injuries, ketoacidosis, uremia, and drug overdoses. In acute hypothermia, peripheral vasoconstriction shunts blood away from the cooler skin to the core in an effort to decrease heat loss, which produces peripheral tissue ischemia. Intermittent reperfusion of the extremities (the Lewis phenomenon) helps preserve peripheral oxygenation. Intermittent peripheral perfusion continues until core temperatures drop dramatically.

The hypothalamic center stimulates **shivering** in an effort to increase heat production. Severe shivering occurs at core temperatures of 35°C (95°F) and continues until core temperature (measure by esophageal probe) drops to about 30° to 32°C (86° to 89.6°F). Prolonged shivering can lead to exhaustion of liver glycogen stores. Thinking becomes sluggish and coordination is decreased at 34°C (93.2°F). As hypothermia deepens, paradoxical undressing may occur as hypothalamic control of vasoconstriction is lost and vasodilation occurs with loss of core heat to the periphery. The hypothermic individual therefore feels suddenly warm and begins to remove clothing.¹¹⁶

At 30°C (86°F), the individual becomes stuporous, heart rate and respiratory rate decline, and cardiac output is diminished. Cerebral blood flow is decreased. Metabolic rate declines, further decreasing core temperature. Sinus node depression occurs with slowing of conduction through the atrioventricular node. In severe hypothermia (core temperature of 26° to 28°C [78.8° to 82.4°F]), pulse and respirations may be undetectable and require resuscitation. Acidosis is moderate to severe. Coagulopathy, ventricular fibrillation, and asystole are common.¹¹⁷ Surface cooling may cause frostbite and fat necrosis.

If hypothermia is mild, passive rewarming may be sufficient. If core temperature is greater than 30°C (86°F), active rewarming also may be required. Active rewarming uses warm-water baths, warm blankets, heating pads, and warm oral fluids when the individual is fully alert. Core rewarming may be accomplished through administration of

warm intravenous (IV) solutions, warm gastric lavage, warm peritoneal lavage, inhalation of warmed gases, and, in extreme cases, exchange transfusions, warming blood in a pump oxygenator circuit, and mediastinal lavage.¹¹⁸

Rewarming generally should proceed no faster than a few degrees per hour. Short-term complications of rewarming include acidosis, rewarming shock, and dysrhythmias. Long-term complications include congestive heart failure, hepatic and renal failure, abnormal erythropoiesis, myocardial infarction, pancreatitis, and neurologic dysfunctions.¹¹⁹

Therapeutic Hypothermia.

Therapeutic hypothermia is used to slow metabolism and preserve ischemic tissue after brain trauma or during brain surgery, after cardiac arrest, and in neonatal hypoxic encephalopathy.¹²⁰ Hypothermia protects the brain by reduction in metabolic rate, ATP consumption, oxidative stress, and the critical threshold for oxygen delivery; modulation of excitotoxic neurotransmitters and calcium antagonism; preservation of protein synthesis and the blood-brain barrier; decreased edema formation; and modulation of the inflammatory response.¹²¹⁻¹²³

Trauma and Temperature Regulation

Major body trauma has varying effects on temperature regulation, depending on the body systems involved. Five types of traumatic injury that usually affect temperature regulation are: (1) CNS trauma (discussed in [Chapter 18](#)), (2) accidental injury, (3) hemorrhagic shock, (4) major surgery, and (5) thermal burns.

Central Nervous System Trauma.

CNS trauma that causes CNS damage, inflammation, increased intracranial pressures, or intracranial bleeding typically produces a temperature greater than 39°C (102.2°F). This temperature, often referred to as *neurogenic or central fever*, appears with or without relative bradycardia and is not caused by infection. The temperature is

sustained, does not induce sweating, and is highly resistant to antipyretic therapy.^{124,125}

Accidental Injuries.

Mild accidental injuries may produce a slight elevation in core temperature. Moderate to severe injuries result in peripheral vasoconstriction with decreased surface and core temperatures. Core temperature is thought to be inversely related to the severity of the injury and may be a result of decreased oxygen transport to the tissues. In severe injuries, shivering is absent and some alteration in thermoregulation is evident.¹²⁶

Hemorrhagic Shock.

Loss of blood volume in hemorrhage triggers peripheral vasoconstriction and hypoxia, contributing to hypothermia. Risk for subsequent decreases in core temperature occurs when hemorrhagic shock is treated with unwarmed, volume-expanding solutions and surgery. Volume expansion with warmed solutions is recommended to prevent the deleterious effects of hypothermia on cardiac output, cardiac rhythm, and the immune system.

Major Surgery.

Major surgery often induces significant hypothermia through exposure of body cavities to the relatively cool operating room environment, irrigation of body cavities with room temperature solutions, infusion of room temperature intravenous solutions, use of drugs that impair thermoregulatory mechanisms, and inhalation of unwarmed anesthetic agents. Anesthesia induces hypothermia, reduces platelet function, and impairs the coagulation cascade, contributing to transfusion requirements and postoperative complications. Use of warmed irrigating and intravenous solutions and perioperative forced air and skin warming procedures reduce intraoperative hypothermia and postoperative complications.¹²⁷

Thermal Burns.

Large burn injuries produce significant hypothermia because of the loss of the skin barrier to fluid evaporation and the loss of control of the microcirculation in the skin. Severe burns also compromise the normal insulation of the skin and subcutaneous tissues. (Burns are discussed in [Chapter 49](#).)

Sleep

Sleep is an active, multiphase process that provides restorative functions and promotes memory consolidation. Complex neural circuits in the hypothalamus, thalamus, brainstem, and cortex interacting with hormones and neurotransmitters control the timing of the sleep-wake cycle and coordinate this cycle with circadian rhythms (24-hour rhythm cycles).¹²⁸ Normal sleep has two independent phases that can be documented by electroencephalogram (EEG): rapid eye movement (REM) sleep and non-REM (NREM) slow wave sleep. NREM and REM sleep alternate, with each cycle lasting for approximately 90 to 100 minutes. NREM sleep is further divided into three stages (N1, N2, N3) from light to deep sleep followed by REM sleep. Four to six cycles of REM and NREM sleep occur each night in an adult. The first cycle of the night begins with stage N1. The individual then progresses through stages N2, N3, and REM sleep. A new cycle, beginning with stage N2, follows each REM sleep. With each successive cycle, the amount of time spent in stage N3 sleep decreases and the amount of time spent in REM sleep increases ([Fig. 16.9](#)). The individual who is awakened begins the next cycle with stage N1.

FIGURE 16.9 Normal Sleep Cycles. Rapid eye movement (*REM*) sleep occurs cyclically throughout the night at intervals of approximately 90 minutes in all age groups. REM sleep shows little variation in the different age groups, whereas stage N3 sleep decreases with age. In addition, older adults awaken frequently and show a marked increase in total time awake.

A complex interaction of neural networks and neurotransmitters promote wakefulness and sleep. The hypothalamus, brainstem, and basal forebrain are involved in promoting wakefulness. The neurotransmitters include brainstem and basal forebrain serotonin, norepinephrine, dopamine acetylcholine (ACh), and glutamine. Hypothalamic wakefulness is associated with orexin and histamine. The production of these neurotransmitters decreases during sleep. Neurons in the preoptic area and basal forebrain induce sleep. The

primary neurotransmitters are GABA and galanin. Other sleep promoters, particularly for NREM sleep, are melanin-concentrating hormone and adenosine, prostaglandin D₂, nitric oxide, and cytokines. ACh, GABA, and glutamate also promote REM sleep.¹²⁹ The phases of sleep are based on changes in the EEG pattern (Fig. 16.10):

FIGURE 16.10 Electroencephalogram (EEG) Stages of Wakefulness and NREM Sleep. *Awake*, Low-voltage fast activity; *stage N1*, falling asleep; *stage N2*, light sleep with sleep spindles; *stage N3*, slow delta waves. Rapid eye movement (REM) sleep looks similar to awake and stage N1 sleep. Sleep spindles are bursts of brain activity associated with onset of sleep.

Awake—Wakefulness with eyes closed and predominated by alpha waves (8 to 25 Hz)

NREM sleep (75% to 80% of sleep time):

N1—Light sleep, with alpha waves (6 to 8 Hz) interspersed with low-frequency theta waves; slow eye movements; cycle lasts 10 to 12 minutes (3% to 8% of sleep time)

N2—Further slowing of the EEG (4 to 7 Hz) with the presence of sleep spindles and slow eye movements; cycle lasts 30 to 60 minutes (45% to 55% of sleep)

time)

N3—Low-frequency (1 to 3 Hz) high-amplitude delta waves with occasional sleep spindles—also known as *slow-wave sleep*; no slow eye movements (13% to 23% of sleep time)

REM sleep—time of most dreaming (20% to 25% of sleep time)

Non–Rapid Eye Movement Sleep

Non-REM (NREM) slow wave sleep is initiated when inhibitory signals are released from the hypothalamus. Sympathetic tone is decreased and parasympathetic activity is increased during NREM sleep, creating a state of reduced activity. The basal metabolic rate falls by 10% to 15%; temperature decreases 0.5° to 1.0°C (0.9° to 1.8°F); heart rate, respiration, blood pressure, and muscle tone decrease; and knee jerk reflexes are absent. Pupils are constricted. During stages N1 and N2, cerebral blood flow to the brainstem and cerebellum is decreased. During stage N3, cerebral blood flow to the cortex is decreased.¹³⁰ Growth hormone is released during stage N3, and levels of corticosteroids and catecholamines are depressed.

Rapid Eye Movement Sleep

Rapid eye movement (REM) sleep is initiated by *REM-on* and *REM-off* neurons in the pons and mesencephalon. *REM-on* cells use the transmitter gamma-aminobutyric acid (GABA), glycine, acetylcholine, and glutamate. *REM-off* cells use the transmitters norepinephrine, epinephrine, serotonin, histamine, and GABA.¹³¹ REM sleep occurs about every 90 minutes beginning 1 to 2 hours after NREM sleep begins. This sleep is known as *paradoxical sleep* because the EEG pattern is similar to that of the normal awake pattern and the brain is very active with dreaming. REM and NREM sleep alternate throughout the night, with lengthening intervals of REM sleep and fewer intervals of deeper stages of NREM sleep toward morning. The changes associated with REM sleep include increased parasympathetic activity and variable sympathetic activity associated

with rapid eye movement; antigravity muscle relaxation or atonia (requires GABA and glycine inhibition of motor neurons); loss of temperature regulation; altered heart rate, blood pressure, and respiration; penile erection in men and clitoral engorgement in women; release of steroids; and many memorable dreams. Respiratory control appears largely independent of metabolic requirements and oxygen variation. Loss of normal voluntary muscle control in the tongue and upper pharynx may produce some respiratory obstruction. Cerebral blood flow and brain oxygen consumption increase.¹³¹

Pediatrics and Sleep Patterns

Sleep patterns of children change as they age. Newborns sleep about 16 to 18 hours per day on an irregular schedule related to culture and parental and family influences. About 53% of that time is spent in active sleep (REM sleep), 23% in quiet sleep (NREM sleep), and the remainder in an indeterminate phase. The infant sleep cycle is approximately 50 to 60 minutes long, with 20 minutes of NREM sleep and 10 to 45 minutes of REM sleep, in contrast to the adult sleep cycle. Newborns enter REM sleep immediately on falling asleep¹³² and have well developed sleep-wake cycling.¹³³ At about 1 year of age, an infant spends approximately 45% of total sleep time in quiet sleep and 41% in REM sleep. Total sleep time decreases slightly from birth to 1 year. In the young child, the sleep cycle length is 45 to 60 minutes, in contrast to 90 to 100 minutes in the adult. The child assumes the adult sleep pattern at some point during the first 3 to 5 years of life and sleeps 9 to 10 hours per night.¹³⁴ Sleep for infants and children is important for growth and neurocognitive development. Sudden infant death syndrome (SIDS) is presented in [Chapter 37](#). Sleep disorders are common in children and include insomnia and dyssomnias.¹³⁵ Obstructive sleep apnea syndrome (OSAS) in children is related to anatomic obstruction, collapse of airways, and adenotonsillar inflammation.¹³⁶ Sleep deprivation in adolescents is associated with obesity, depression, anxiety disorders, poor academic performance,

and safety issues.¹³⁷

Aging and Sleep Patterns

The sleep pattern of the older adult differs from that of the younger adult or child and is variable among individuals. Total sleep time is decreased, and the older individual takes longer to initiate and maintain sleep. Older adults tend to go to sleep earlier in the evening and awaken more frequently during the night and earlier in the morning. REM and NREM sleep decreases and the amount of time awake at night increases. Decreased NREM sleep is more common in men over 70 years of age. Changes in the older adult's sleep pattern may be associated with loss of orexin synthesis or sensitivity, changes in lifestyle, presence of chronic disease, lack of daily routine, desynchronization of circadian rhythm, and use of medications.¹³⁸ Growth hormone and cortisol levels are diminished in the older adult and decrease slow wave sleep.¹³⁹ The alteration in sleep pattern typically appears about 10 years later in women than in men. Older adults are less able than younger individuals to tolerate sleep deprivation, and good sleep quality in middle age promotes better cognitive function and memory in older age.^{140,141}

Sleep Disorders

The classification of sleep disorders is complex. A system has been established by the American Academy of Sleep Medicine and includes four classifications:¹⁴² (1) dyssomnias (disorders of initiating and maintaining sleep and disorders of excessive sleepiness), (2) parasomnias (disorders that primarily do not cause a complaint of insomnia or excessive sleepiness), (3) sleep disorders associated with medical/psychiatric disorders, and (4) proposed sleep disorders. The most common, dyssomnias and parasomnias, are reviewed here.

Common Dyssomnias

The **dyssomnias** are sleep disorders related to difficulty in initiating

or maintaining sleep or the presence of excessive sleepiness. The most common dyssomnias include insomnia, restless legs syndrome, obstructive sleep apnea syndrome, circadian rhythm disorder, and hypersomnia.

Insomnia is the inability to fall or stay asleep; it is accompanied by fatigue during wakefulness and may be mild, moderate, or severe. It may be transient, lasting a few days or months (primary insomnia), and related to travel across time zones or caused by acute stress.¹⁴³ Chronic insomnia can be idiopathic, start at an early age, and be associated with drug or alcohol abuse, chronic pain disorders, chronic depression, the use of certain drugs (amphetamines, steroids, central adrenergic blockers, bronchodilating agents, and caffeine), obesity, aging, genetics, and environmental factors that result in hyperarousal, reduced cortical GABA, increased arousals during REM sleep, and dysregulation of sleep-wake cycles.¹⁴⁴

Restless legs syndrome (RLS) is a sensorimotor disorder associated with unpleasant sensations (prickling, tingling, crawling) and a compelling urge to move the legs for relief that occurs at rest and is worse in the evening or at night. Sensations also may be experienced in the arms. The syndrome can lead to insomnia and affect quality of life. The age of onset is 30 to 40 years and is more common in women and individuals with iron deficiency. RLS has a familial tendency and may be related to diurnal variation in iron transport across the blood-brain barrier and a loss of dopamine in the substantia nigra. Iron is a cofactor in dopamine production. Treatment options include alpha-2-delta drugs, such as gabapentin; dopamine agonists; and iron administration.¹⁴⁵

Obstructive sleep apnea syndrome (OSAS) is a disorder of breathing during sleep related to repetitive upper airway collapse (obstruction) that is associated with reduced blood oxygen saturation and hypercapnia. OSAS is the most commonly diagnosed sleep disorder. An estimated 1% to 5% of children, 9% of women, and 24% of men younger than 65 years of age in the United States have diagnosable sleep-disordered breathing. The incidence increases in those older than 65 years. Major risk factors include obesity, male sex,

older age, and postmenopausal status (not on hormone therapy) in women.¹⁴⁶ The typical classification of the severity of this disease uses the Apnea Hypopnea Index (AHI).¹⁴⁷ This index represents how many apnea (total airway closure) or hypopnea (partial airway closure) episodes occur per night—the number of which is then divided by the night's total sleep time to give an average number of apnea or hypopnea episodes per hour. The AHI severity scale is as follows:

- *Normal*: 0 to 5 abnormal sleep episodes per hour
- *Mild*: 5 to 15 abnormal sleep episodes per hour
- *Moderate*: 15 to 29 abnormal sleep episodes per hour
- *Severe*: more than 30 abnormal sleep episodes per hour

OSAS is increasingly prevalent in the rapidly expanding older adult population.¹⁴⁸ Premenstrual women may be protected from sleep-disordered breathing because the female hormone progesterone is a respiratory stimulant. The longer pharyngeal airway in males also may contribute to increased risk for OSAS. Women have different symptoms than men such as insomnia, restless legs, depression, nightmares, palpitations, and hallucinations. Men are more likely to report snoring and apneic episodes. Obese individuals often have a short, thick neck; pharyngeal airway collapse; impaired respiratory mechanics; and depressed respiratory control, particularly during sleep.¹⁴⁹ **Obesity hypoventilation syndrome** (obesity, daytime hypoventilation, and sleep-disordered breathing not related to other causes) may be related to leptin resistance because leptin is also a respiratory stimulant.¹⁵⁰ It is important to note that the current obesity pandemic has not spared the pediatric population, and there has been an increased prevalence of OSAS among obese children.¹⁵¹

OSAS results from partial or total upper airway collapse related to pharyngeal anatomy or decreased pharyngeal dilator muscle tone.

There is obstruction to airflow recurring during sleep with excessive loud snoring, gasping, and multiple apneic episodes that last 10 seconds or longer. The periodic breathing eventually produces arousal, which interrupts the sleep cycle, reducing total sleep time, and sleep stage fragmentation with REM deprivation. Associated conditions include decreased sensitivity to carbon dioxide and oxygen tensions, upper airway obstruction, a small airway, and decreased pharyngeal dilator muscle activation.¹⁵² The level of negative intrathoracic pressure is the most likely stimulus for arousal, possibly mediated by mechanoreceptors in the upper airway. Sleep apnea produces hypercapnia and low oxygen saturation and eventually leads to polycythemia, pulmonary hypertension, systemic hypertension, stroke, right-sided congestive heart failure, dysrhythmias, liver congestion, cyanosis, and peripheral edema. There also is increasing recognition that OSAS may accelerate the loss of kidney function.¹⁵³ The mechanisms responsible for renal damage from OSAS are not completely clear, but activation of the renin-angiotensin system has been proposed as a contributor.¹⁵⁴

Laboratory polysomnography and home sleep testing are used to diagnose OSAS in addition to history and physical examination. Treatments include use of continuous positive airway pressure (treatment of choice), dental devices, surgery of the upper airway and jaw in selected individuals, and management of obesity.¹⁵⁵ Adenotonsillar hypertrophy is the major cause of obstructive sleep apnea in children, and obesity increases risk. Adenotonsillectomy is the treatment of choice.

Hypersomnia is excessive daytime sleepiness and is commonly associated with voluntary sleep deprivation. There may also be an underlying sleep disorder such as OSAS or narcolepsy. Individuals may fall asleep while driving, working, or even conversing, resulting in significant concerns for safety.¹⁵⁶ Treatment is symptomatic with reinforcement of good sleeping habits.¹⁵⁷

Narcolepsy is hypersomnolence characterized as Type 1, with excessive daytime sleepiness, cataplexy (brief spells of involuntary muscle weakness or paralysis), and hypocretin-1 deficiency; and Type

2, absence of cataplexy and normal levels of hypocretin-1. The disorder is a REM sleep disorder, with hypothalamic hypocretin (orexin) deficiency and immune-mediated T-cell destruction of hypocretin-secreting cells. There is a genetic association with HLA DQB1*06:02 allele, infections, and vaccination (H1N1 Pandemrix vaccine).^{131,158} Older adults with narcolepsy are far more likely to have associated sleep disorders, such as OSAS and RLS.¹⁵⁹

Circadian rhythm sleep disorders are common disorders of the sleep-wake schedule and occur with rapid time-zone changes (jet-lag syndrome) and in about 5% to 10% of shift workers.¹⁶⁰ There is an alteration in sleep schedule with an advance (advanced sleep-wake phase disorder), a delay (delayed sleep-wake phase disorder) of 3 hours or more in sleep time, changes in sleep patterns from day to day (non-24-hour sleep-wake rhythm disorder [N24SWD], a problem occurring in totally blind individuals), and irregular sleep-wake rhythm disorder (ISWRD).¹⁶¹ These changes in the timing of established sleep schedules have been shown to desynchronize circadian rhythm. Affected shift workers exhibit a decrease in vigilance, accuracy, and work performance, as well as increased accident proneness. Individuals may experience short sleep episodes called *microsleeps* without being aware of decreased vigilance. For similar reasons, people suffering from jet-lag syndrome require several days to adapt to a new time zone. Travel across time zones requires 2 days to adjust the sleep-wake schedule, 5 days to adjust the body temperature cycle, and 8 days to adjust cortisol level secretion. There is a need to phase delay sleep when traveling from east to west, and to phase advance sleep when traveling from west to east. Bright light exposure and administration of exogenous melatonin provide some success in retiming or resetting the body clock before or after time-zone shifts.¹⁶²

Sleep deprivation can result in neuropsychologic effects, including:¹⁶³⁻¹⁶⁵

1. A marked impact on performance through decreases in cognitive functions and specific effects on brain regions that support cognitive function (vigilance, attention, learning,

- memory, decision making)
2. Decreased speed of mental processing
 3. Declines in attention and vigilance with distinct intraindividual variability
 4. Abnormal activation in the prefrontal cortex, parietal lobes, thalamus, and temporal lobes as shown by functional neuroimaging
 5. Task performance decreases as sleep debt accumulates in a manner that is “dose dependent”

Sleep disturbance and resultant sleep deprivation also are associated with increased risk for heart disease, stroke, obesity, diabetes, infection, and depression.^{137,166-168} Sleep of poor quality and quantity also is now recognized as an important biomarker for cerebral pathologies other than just sleep disturbance-related large and small vessel stroke. There has been increasing recognition that insidious and progressive neurodegenerative diseases are now associated with sleep disorders.¹⁶⁹

Common Parasomnias

Parasomnias are complex behaviors related to awakening from REM sleep or partial arousal from NREM sleep and disorders of sleep stage transitions. Three types of parasomnias include *arousal disorders* such as confusional arousals, sleepwalking (somnambulism), night terrors (dream anxiety attacks), rearranging furniture, eating food, violent behavior, bruxism (teeth grinding), and sleep enuresis; *sleep-wake transition disorders* such as rhythmic movements (head banging), sleep talking, and nocturnal leg cramps; and *disorders associated with REM sleep* such as sleep paralysis and nightmares, sleep apnea, and SIDS (see [Chapter 37](#)). Parasomnias are more common in children and may be familial.¹⁷⁰

REM sleep behavior disorder is loss of normal skeletal muscle atonia during REM sleep and may cause injury from the acting-out of dreams. It is caused by alterations to the brainstem circuits that mediate REM sleep atonia and is more common in older adult men. It

is an early symptom (i.e., 5 years) associated with Parkinson disease and other neurodegenerative diseases.¹⁷¹

Somatosensory Function and the Special Senses

The somatosensory system includes the peripheral receptors and central nervous system pathways that detect internal and external information, which is then processed and interpreted by the brain. This system includes touch, proprioception and vestibular function, and the special senses—sight, hearing, smell, and taste.

Touch

Touch is not a uniform sensory experience. The sensation of touch involves the fusion of several qualities, including modality, intensity, location, and duration of the sensory stimulus. Receptors sensitive to touch are present in the skin. Meissner and pacinian corpuscles are rapidly adapting receptors, whereas Merkel disks and Ruffini endings are slowly adapting touch receptors. Touch receptors are most numerous in the skin of the fingers and lips and are more scarce in the skin of the trunk. Specific sensory input is carried to the higher levels of the CNS by the dorsal column of the spinal cord and the anterior spinothalamic tract.

Much of the development of the cutaneous senses takes place before birth, but structural growth of the cutaneous senses continues into early adulthood at a reduced rate. Then a gradual decline occurs.¹⁷² Studies have documented loss in tactile sensitivity with advancing age.^{173,174} This occurs simultaneously with an increase in the size of pacinian corpuscles and a decrease in the number of corpuscles.

Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex. Any factor that interrupts or impairs reception, transmission, perception, or interpretation of touch also alters tactile sensation. Trauma, tumor, infection, metabolic changes, vascular changes, and

degenerative diseases thus may cause tactile dysfunction, which may involve heightened or diminished tactile perceptions.

In addition, most tactile sensations evoke affective responses that determine whether the sensation is unpleasant, pleasant, or neutral. Cerebral and hypothalamic centers influence this response. Sedative drugs and prefrontal injury, which interrupt connections between the prefrontal cortex and subcortical centers, diminish the interpretation of tactile sensations.

Proprioception

Perception and awareness of the position and movement of the body and its parts depend on impulses from the inner ear and from receptors in joints and ligaments. The role of muscle, tendon, and cutaneous receptors is indefinite. Sensory data are transmitted to higher centers, primarily through the dorsal columns and the spinocerebellar tracts, with some data passing through the medial lemnisci and thalamic radiations to the cortex. These stimuli are necessary for the coordination of movements, the grading of muscular contraction, and the maintenance of equilibrium and postural control.

A progressive loss of proprioception has been reported in older adults with increased risk for falls and injury.¹⁷⁵ Proprioceptive dysfunction may be caused by alterations at any level of the nervous system. As with tactile dysfunction, any factor that interrupts or impairs the reception, transmission, perception, or interpretation of proprioceptive stimuli also alters proprioception. Two common causes of proprioceptive dysfunction are vestibular dysfunction and neuropathy.

Specific vestibular dysfunctions are vestibular nystagmus and vertigo. **Vestibular nystagmus** is the constant, involuntary movement of the eyeball caused by ear disturbances. This condition occurs when the semicircular canal system is overstimulated. Vestibular **vertigo** (dizziness) is the sensation of spinning that occurs with inflammation of the semicircular canals or displacement of otoliths in the utricle and saccule of the semicircular canal system (benign positional vertigo). The individual may feel either that he or she is moving in space or

that the world is revolving. Vertigo often causes loss of balance and may be accompanied by nausea. Vertigo and nystagmus may occur in a variety of conditions, including labyrinthitis, vestibular neuritis, acute toxic labyrinthitis, benign paroxysmal positional vertigo (displacement of otoliths in the utricle and saccule of the semicircular canal system), migrainous vertigo, and Ménière disease.¹⁷⁶

Ménière disease (endolymphatic hydrops) is an idiopathic episodic vestibular disorder resulting from neuroepithelial damage related to abnormalities in the quantity, composition, and pressure of the endolymph in the middle ear.¹⁷⁷ The individual with Ménière disease experiences vertigo, hearing loss, tinnitus (ringing or buzzing sounds), and aural fullness and may have proprioceptive dysfunction and headache. Standing or walking may be impossible because of loss of balance. **Ménière syndrome**, or secondary endolymphatic hydrops, is secondary to other conditions that alter the production or absorption of endolymph.

Peripheral neuropathies also can cause proprioceptive dysfunctions.¹⁷⁸ Neuropathies may be caused by a variety of conditions and commonly are associated with renal disease and diabetes mellitus. Although the exact sequence of events is unknown, neuropathies are thought to be caused by a metabolic disturbance of the neuron itself. The result is a diminished or absent sense of body position or position of body parts. Gait changes often occur. (Neuropathies are further discussed in [Chapter 18](#).)

Vision

The eyes are complex sense organs responsible for vision. Within a protective casing, each eye has receptors, a lens system for focusing light on the receptors, and a system of nerves for conducting impulses from the receptors to the brain. Visual dysfunction may be caused by abnormal ocular movements or alterations in visual acuity, refraction, color vision, or accommodation. Visual dysfunction also may be the secondary effect of another neurologic disorder.

The External Eye

Protective external eye structures include the eyelids (palpebrae), conjunctivae, and lacrimal apparatus (Fig. 16.11). The eyelids are used to control the amount of light reaching the eyes, and the conjunctivae line the eyelids. Tears released from the lacrimal apparatus bathe the surface of the eye and prevent friction, maintain hydration, and wash out foreign bodies and other irritants.

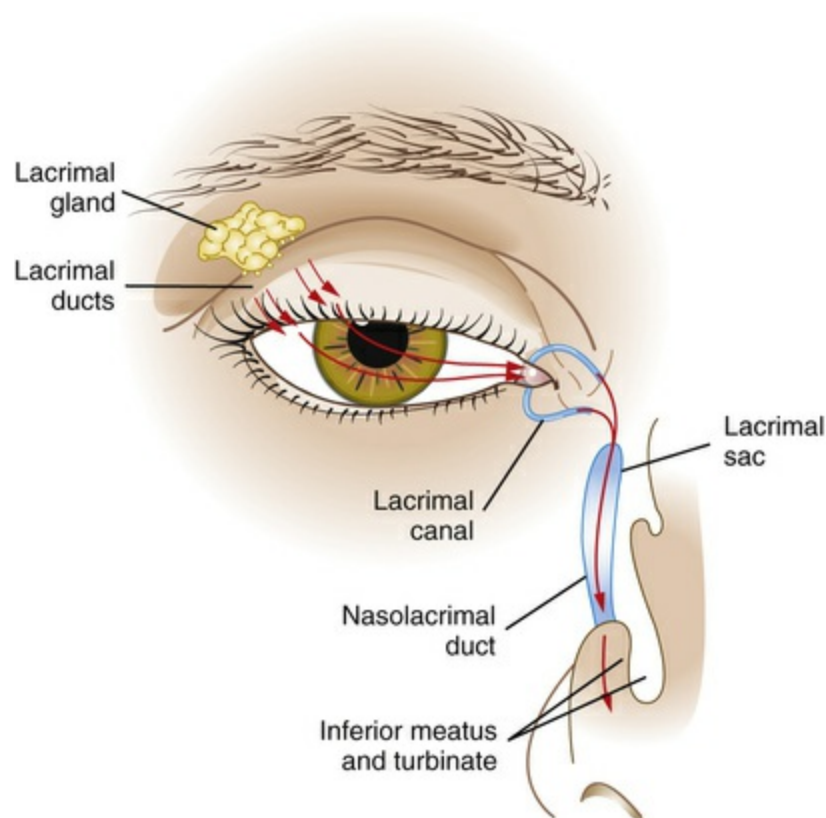

FIGURE 16.11 Lacrimal Apparatus. Fluid produced by lacrimal glands (tears) streams across the eye surface, enters the canals, and then passes through the nasolacrimal duct to enter the nose. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

Infection and inflammatory responses are the most common conditions affecting the supporting structures of the eyes. **Blepharitis** is an inflammation of the eyelids caused by *Staphylococcus* or seborrheic dermatitis. Redness, edema, tearing, and itching are common symptoms. An external **hordeolum** (**anterior blepharitis**

[**stye**]) is an infection of the sebaceous glands of the eyelids, and an internal hordeolum is an infection of the eyelid margin. A **chalazion** (posterior blepharitis) is a noninfectious lipogranuloma of the meibomian (oil-secreting) gland and may be associated with an internal hordeolum. These conditions present with redness, swelling, and tenderness and are treated symptomatically.¹⁷⁹ **Entropion** is a common eyelid malposition in which the lid margin turns inward against the eyeball. In **ectropion**, the eyelid turns outward away from the eye. **Trichiasis** is abnormally positioned eyelashes that grow back toward the eye. There are both surgical and nonsurgical treatments to reposition the lid margin.¹⁸⁰

Conjunctivitis

Conjunctivitis (“red eye”) is an inflammation of the conjunctiva (mucous membrane covering the front part of the eyeball). Conjunctivitis may be caused by bacteria, viruses, allergies, or chemical irritations. The inflammatory response produces photophobia, visual blurring, redness, edema, pain, and lacrimation. Treatment is related to cause.¹⁸¹

Acute bacterial conjunctivitis (pinkeye) is highly contagious and often is caused by gram-positive organisms (*Staphylococcus*, *Haemophilus*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*), although other bacteria may be involved. The onset is acute, characterized by mucopurulent drainage from one or both eyes. In children younger than 6 years, *Haemophilus* infection often leads to otitis media (conjunctivitis-otitis syndrome). Preventing spread of the organism with meticulous handwashing and use of separate towels is important. The disease often is self-limiting and resolves spontaneously in 10 to 14 days. Antibiotic eyedrops usually are effective.

Viral conjunctivitis is caused by an adenovirus. Again, it is contagious with symptoms of watering, redness, and photophobia. Some strains of virus cause conjunctivitis and pharyngitis (pharyngoconjunctival fever), and others cause keratoconjunctivitis. Both diseases are contagious, with watering, redness, and

photophobia. Treatment is symptomatic.

Allergic conjunctivitis is associated with a variety of antigens, including pollens. Ocular itching is associated with photophobia, burning, and gritty sensations in the eye. Treatment is symptomatic and may include antihistamines, low-dose corticosteroids, mast cell stabilizers, and vasoconstrictors.

Chronic conjunctivitis is the result of any persistent conjunctivitis. The cause requires identification for effective treatment.

Trachoma (chlamydial conjunctivitis) is caused by *Chlamydia trachomatis*. It often is associated with poor hygiene and is the leading cause of preventable blindness in the world. The severity of the disease varies, but it can involve inflammation with scarring of the conjunctiva and eyelids causing distorted lashes to abrade the cornea, leading to corneal scarring and blindness. Chlamydial organisms are sensitive to local or systemic antibiotics. The World Health Organization aims to eliminate trachoma as a public health problem by 2020 using the SAFE Strategy: Surgery for intumed lashes, Antibiotics, Facial cleanliness, and Environmental improvement.¹⁸²

Keratitis.

Keratitis is an inflammation of the cornea that can be noninfectious or caused by bacteria, viruses, fungus, or amoebae. Bacterial infections often cause corneal ulceration and require intensive antibiotic treatment. *Staphylococcus aureus* is the most common bacterial infection. Type 1 herpes simplex virus can involve the cornea and conjunctiva. Predisposing factors include contact lens use, trauma, and penetrating keratoplasty (corneal grafting). *Acanthamoeba* is associated with contact lens use and is a severe sight-threatening corneal infection.¹⁸³ Common symptoms include photophobia, pain, and lacrimation. Severe ulcerations with residual scarring require corneal transplantation.

The Eye

The wall of the eye is formed of three layers: sclera, choroid, and retina (Fig. 16.12). The **sclera** is the thick, white, outermost layer. It

becomes transparent at the **cornea**, the portion of the sclera in the central anterior region that allows light to enter the eye. The **choroid** is the deeply pigmented middle layer that prevents light from scattering inside the eye. The **iris**, part of the choroid, has a round opening, the **pupil**, through which light passes. Smooth muscle fibers control the size of the pupil so that in close vision and bright light the pupil constricts and in distant vision and dim light the pupil dilates.

FIGURE 16.12 Structure of the Eyeball and Cell Layers of the Retina. **A**, The right eye is viewed from above (horizontal section). **B**, The various layers and cells of the retina. **AC**, Anterior chamber. (A from Forrester JV et al: *The eye: basic sciences in practice*, ed 4, St Louis 2016, Elsevier; B from Gartner LP: *Textbook of histology*, ed 4, Philadelphia, 2017, Elsevier.)

The **retina** is the innermost layer of the eye and contains millions of rods and cones, special photoreceptors that convert light energy into nerve impulses. **Rods** mediate peripheral and dim light vision and are densest at the periphery. **Cones**, densest in the center of the retina, are color and detail receptors. The photoreceptive rods and cones are distributed over the entire retina, except where the optic nerve leaves the eyeball. Lack of rods and cones in this area form the **optic disc**, or

blind spot. Lateral to each optic disc is the **macula**, a yellow disc that absorbs ultraviolet light. The **fovea centralis** is a tiny central area of the macula that contains only cones and provides the greatest visual acuity (see [Fig. 16.12](#)).

The **optic nerve** (second cranial nerve) is composed of retinal cell axons. As shown in [Fig. 16.13](#), nerve impulses pass through the optic nerves after leaving the retinas. At the optic chiasm the fibers from the inner (nasal) halves of the retinas cross to the opposite side, where they join fibers from the outer (temporal) halves of the retinas to form the optic tracts. The fibers of the optic tracts synapse in the dorsal lateral geniculate nucleus, and from there the geniculocalcarine fibers pass by way of the optic radiation (or geniculocalcarine tract) to the primary visual cortex in the occipital lobe of the brain. Some fibers terminate in the suprachiasmatic nucleus (located above the optic chiasm) and are involved in regulating the sleep-wake cycle.

FIGURE 16.13 Visual Fields and Defects That Accompany Damage to the Right Visual Pathways. 1, Optic nerve: blindness. 2, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopsia. 3, Central optic chiasm: bitemporal hemianopsia. 4, Optic tract: incongruous, incomplete homonymous hemianopsia. 5, Temporal loop of the optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. 6, Parietal (*superior*) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. 7, Complete parietooccipital interruption of the optic radiation: complete congruous homonymous hemianopsia with psychophysical shift of the foveal point, often sparing central vision and resulting in “macular sparing.” 8, Incomplete (subtotal) damage to the visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Goldman C, editor: *Goldman’s Cecil medicine*, ed 24, vol 2, Philadelphia, 2012, Saunders.)

Light entering the eye is focused on the retina by the **lens**—a flexible, biconvex, crystal-like structure. In youth the lens is transparent and has the consistency of hardened jelly. The flexibility of the lens allows a change in curvature with contraction of the ciliary muscles. This is called **accommodation**, and it allows the eye to focus

on objects at different distances. Anterior to the lens are the iris and the aqueous chamber, which is filled with **aqueous humor**. The aqueous humor helps to maintain the pressure inside the eye and provides nutrients to the lens and cornea. Aqueous humor is free-flowing fluid, secreted by the ciliary processes and reabsorbed into the canal of Schlemm. If drainage is blocked, pressure within the eye increases (as it does with glaucoma). Posterior to the lens is the vitreous chamber, which is filled with a gel-like substance called **vitreous humor**. Vitreous humor helps prevent the eyeball from collapsing inward.

The central retinal artery provides blood to the inner retinal surface. Nutrients and oxygen are supplied to the outer surface of the retina by the choroid, a vascular layer that lies between the retina and sclera. Six extrinsic eye muscles, attached to the outer surface of each eye, allow gross eye movements and permit the eyes to follow a moving object (Fig. 16.14).

FIGURE 16.14 Extrinsic Muscles of the Right Eye. A, Superior view. B, Inferior view. (From Dutton JJ: *Atlas of clinical and surgical orbital anatomy*, ed 2, Philadelphia, 2011, Saunders.)

Aging and Vision

Changes in the visual and motor components of the eye caused by aging begin at an early age, particularly in the lens of the eye. Changes caused by aging are summarized in [Table 16.6](#). Structural changes combined with chronic diseases, including dementias and diabetes mellitus, result in a decline in visual acuity and extraocular motor muscle function.¹⁸⁴

TABLE 16.6

CHANGES IN THE EYE CAUSED BY AGING

STRUCTURE CHANGE		CONSEQUENCE
Cornea	Thicker and less curved; decreased sensitivity to touch Formation of a gray ring at the edge of cornea (arcus senilis)	Increase in astigmatism Not detrimental to vision
Anterior chamber	Decrease in size and volume caused by thickening of lens	Occasionally exerts pressure on Schlemm canal and may lead to increased intraocular pressure and glaucoma
Lens	Increase in thickness and opacity (yellowing)	Decrease in refraction with increased light scattering and decreased color vision (green and blue); delayed dark adaptation; cataracts
	Loss of elasticity	Loss of accommodation (presbyopia: loss of focus for near objects)
Ciliary muscles	Reduction in pupil diameter; atrophy of radial dilation muscles	Persistent constriction (senile miosis); decrease in critical flicker frequency*
Retina	Reduction in number of rods at periphery; loss of rods and associated nerve cells	Increase in the minimum amount of light necessary to see an object
Macula	Atrophy (age-related macular degeneration)	Loss of vision
Vitreous	Liquefaction of vitreous and decrease in gel volume	Posterior vitreous detachment causing “floaters;” risk for retinal detachment

*The rate at which consecutive visual stimuli can be presented and still be perceived as separate.

Visual Dysfunction

Alterations in Ocular Movements.

Abnormal ocular movements occur as a result of oculomotor, trochlear, or abducens cranial nerve dysfunction (see [Table 15.6](#)). The three types of eye movement disorders are (1) strabismus, (2) nystagmus, and (3) paralysis of individual extraocular muscles.

Strabismus is the deviation of one eye from the other when a person is looking at an object; it results in failure of the two eyes to simultaneously focus on the same image and therefore loss of binocular vision. The deviation may be upward, downward, inward, or outward, resulting from a weak or hypertonic muscle in one of the eyes. Strabismus may be caused by a neuromuscular disorder of the eye muscle, diseases involving the cerebral hemispheres, or thyroid disease.¹⁸⁵

The primary symptom of strabismus is **diplopia** (double vision). Strabismus in children requires early intervention to prevent the development of amblyopia (reduced vision in the affected eye without ocular pathology and with full optical correction). Surgery may be helpful to both children and adults with strabismus.¹⁸⁶

Nystagmus is an involuntary unilateral or bilateral rhythmic movement of the eyes and can occur in infants (congenital) or adults (acquired). It may be present at rest, or it may occur with eye movement. The two major forms of nystagmus are pendular nystagmus and jerk nystagmus. **Pendular nystagmus** is characterized by a regular alternating forward and backward movement of the eyes in which both phases of the movement are equal in length. In **jerk nystagmus** one phase of the eye movement is faster than the other. Nystagmus may be caused by an imbalance in the normally coordinated reflex activity of the inner ear, vestibular nuclei (connecting the vestibular nerve with vestibulospinal tracts), cerebellum, medial longitudinal fascicle (connecting the

mesencephalon with the upper portion of the spinal cord), or nuclei of the oculomotor, trochlear, and abducens cranial nerves (see [Table 15.6](#)). Drugs, retinal disease, and diseases involving the cervical cord also may produce nystagmus. **Infantile nystagmus syndrome** has an unknown pathogenesis. The syndrome develops in the first 6 months of age and is more prevalent in males. Ocular motor control and anterior visual pathway disturbances are under investigation. One disease-causing gene has been identified, X-linked *FRMD7*. There may be an associated strabismus, amblyopia, torticollis, or visual impairment.¹⁸⁷ Untreated nystagmus can lead to loss of visual acuity.¹⁸⁸

Paralysis of specific extraocular muscles may cause a variety of abnormalities, including limited abduction, abnormal closure of the eyelid, ptosis (drooping of the eyelid), and diplopia. The abnormalities occur as a result of unopposed muscle activity. Trauma or pressure in the area of the cranial nerves may cause paralysis of specific extraocular muscles. Diseases such as diabetes mellitus and myasthenia gravis also may affect specific extraocular muscles.

Alterations in Visual Acuity.

Visual acuity is the ability to see objects in sharp detail. With advancing age the eye's lens becomes less flexible and less adjustable, and visual acuity declines. Visual acuity also may change or diminish for many other reasons. Specific causes of visual acuity changes include: (1) amblyopia, (2) scotoma, (3) cataracts, (4) papilledema, (5) dark adaptation, (6) glaucoma, (7) retinal detachment, and (8) macular degeneration.

Amblyopia (lazy eye) is a reduction or dimness of vision related to altered development of the visual cortex and is the most common cause of childhood monocular blindness. It does not result from a change in refraction (i.e., deviation of light rays) or from any visible changes in the eye. Amblyopia is associated with strabismus, anisometropia (refractive error in one eye differs from that of the other eye), ametropia (severe refractive error in both eyes), stimulus deprivation (congenital cataracts or orbital lesions); with diseases such

as diabetes mellitus, renal failure, and malaria; and with toxic substances, such as alcohol and tobacco. Early detection is required to restore vision. Treatment includes patching the unaffected eye for extended times to ensure a period of use of the affected eye, or administering atropine eyedrops (blurring vision). Research related to brain plasticity with bilateral treatment approaches, including visual perceptual learning and video gaming, is promising for visual restoration in both children and adults.^{189,190} Refractive errors are treated with corrective lenses.

A **scotoma** is a circumscribed defect of the central field of vision. It can be caused by lesions of the central retina or a sequela to demyelinating optic neuritis, an inflammatory lesion of the optic nerve frequently associated with optico-spinal multiple sclerosis (see [Chapter 18](#)). Age-related macular degeneration is associated with scotoma. Less common causes include the compression of one optic nerve by a retroorbital tumor, neuromyelitis optica (autoantibody-related inflammation of the optic nerve and spinal cord), pernicious anemia, and toxic or metabolic causes such as methyl alcohol poisoning and use of tobacco. The precise mechanisms for these conditions causing a scotoma are uncertain, but the result is always a serious impairment in visual acuity.¹⁹¹

A **cataract** is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis. The incidence of cataracts increases with age as the lens enlarges. Cataracts develop because of alterations of metabolism and transport of nutrients within the lens. Although the most common form of cataract is degenerative, cataracts also may occur congenitally or as a result of infection, radiation, trauma, drugs, or diabetes mellitus. Cataracts cause decreased visual acuity, blurred vision, glare, and decreased color perception. Cataracts are treated by removal of the entire lens and replacement with an intraocular artificial lens.¹⁹²

Dark adaptation also affects visual acuity. Low illumination causes impaired visual acuity, particularly in older adults. The average 80-year-old person needs more than twice as much light as a 20-year-old person to see equally well. Changes in the quantity and quality of

rhodopsin, a substance found in the rods and responsible for low-light vision, are thought to be responsible for reduced dark adaptation in older adults.¹⁹³ Vitamin A deficiencies can cause the same phenomenon in individuals of any age.

Glaucomas are the second leading cause of blindness and are characterized by intraocular pressures greater than 12 to 20 mmHg, with death of retinal ganglion cells and optic nerve axons. Family history is a risk factor, and several glaucoma-associated genes have been identified.¹⁹⁴ The types of glaucoma are summarized in [Table 16.7](#) and [Fig. 16.15](#). Most forms of glaucoma are associated with resistance to aqueous humor outflow. Primary open-angle glaucoma is the most common and is associated with alterations in the trabecular meshwork. Chronic increased intraocular pressure causes death of retinal ganglions and optic nerve degeneration with loss of peripheral vision, followed by central vision impairment and blindness. Extremely high pressures can cause blindness within days or hours. Loss of visual acuity results from pressure on the optic nerve, which is believed to block the flow of cytoplasm from neuronal bodies in the retina to peripheral optic nerve fibers entering the brain. Lack of nutrients, ischemia, oxidative stress associated with mitochondrial failure, inflammatory cytokines, excessive apoptosis, and altered immune mechanisms may lead to death of the involved neurons.¹⁹⁵ Initially there are no symptoms. With increasing pressure acute pain may result, and there is loss of peripheral vision and progression to blindness. Early detection and treatment prevent optic neuropathy and visual impairment. Screening programs assist in identifying this silent disease. Glaucoma often is treated with pharmaceutical eyedrops to reduce secretion or increase absorption of aqueous humor. Surgery may be needed to open the spaces of the trabeculae and reduce intraocular pressure. Neuroprotective therapies are being evaluated.¹⁹⁶

TABLE 16.7

TYPES OF GLAUCOMA

--

TYPE	MECHANISM OF INCREASED PRESSURE
Open-angle	Obstruction of outflow of aqueous humor at trabecular meshwork or Schlemm canal; myopia may be a risk factor
Normal or low-tension	Form of open-angle glaucoma with symptomless damage to the optic nerve and gradual vision loss when intraocular pressure is within normal range (12-20 mmHg)
Narrow-angle (angle-closure)	Forward displacement of iris toward cornea with narrowing of iridocorneal angle and obstruction to outflow of aqueous humor from anterior chamber
Acute angle-closure	Acute closure of iridocorneal angle with a sudden rise in intraocular pressure, producing pain, redness, and visual disturbances
Chronic angle-closure	Progressive, permanent closure of anterior chamber angle
Secondary	Open- or closed-angle obstruction caused by, for example, uveitis, hemorrhage, rupture of lens or tumors
Congenital glaucoma	Malformation of trabecular meshwork and excess extracellular matrix in outer meshwork

FIGURE 16.15 Glaucoma. 1, Open-angle glaucoma. The obstruction to aqueous flow lies in the trabecular meshwork. 2, Closed-angle glaucoma.

The iris presses against the lens, blocking aqueous flow into the anterior chamber and raising intraocular pressure.

Retinal detachment is a common cause of visual impairment and blindness. Risk factors include retinal holes and vitreoretinal traction. Fluid (exudate, hemorrhage, or liquid vitreous) separates the photoreceptors from the retinal pigment epithelium. The separation deprives the outer retina of oxygen and nutrients because the diffusion distance is increased. Communication is also disrupted between the pigment epithelium and photoreceptors. **Rhegmatogenous retinal detachment** (full thickness retinal breaks caused by vitreoretinal traction) is the most common form of retinal detachment. Causes include intracapsular cataract extraction, severe myopia, age-related lattice degeneration, vitreoretinal traction, and trauma. Contraction of fibrous membranes can cause tractional separation of the retinal layers as occurs in proliferative diabetic retinopathy. Treatment involves immediate surgical retinal reattachment.¹⁹⁷

Age-related macular degeneration (AMD) is a severe and irreversible loss of vision and a major cause of central blindness in older individuals. Risk factors include older age, hypertension, cigarette smoking, diabetes mellitus, previous cataract surgery, and family history of AMD. The degeneration usually occurs after the age of 60 years.

There are two forms: atrophic (dry, nonexudative–geographic atrophic) and neovascular (wet, exudative). The atrophic form is more common and is slowly progressive with inflammation and accumulation of lipofuscin (a lysosomal pigmented residue) and drusen (waste products from photoreceptors) in the retina. Symptoms include limited night vision and difficulty reading. The neovascular form includes accumulation of drusen and lipofuscin, abnormal choroidal blood vessel growth, leakage of blood or serum, retinal detachment, fibrovascular scarring, loss of photoreceptors, and more severe and rapid loss of central vision. Treatment for wet AMD includes antivascular endothelial growth factor (anti-VEGF) injections; new treatments are under investigation.¹⁹⁸ Two carotenoids, lutein

and zeaxanthin, are antioxidants that selectively accumulate in the macula. Supplements of lutein and zeaxanthin may enhance vision in early dry AMD.¹⁹⁹

Alterations in Accommodation.

Accommodation is the process whereby the thickness of the lens changes with contraction of the ciliary muscles. Accommodation is needed for clear vision and is mediated through the oculomotor nerve (cranial nerve III). Pressure, inflammation, and disease of the oculomotor nerve may alter accommodation. Symptoms include diplopia, blurred vision, and headache. Loss of accommodation in adults beginning at ages 45 to 50 years is termed **presbyopia**, a condition in which the ocular lens becomes larger, firmer, and less elastic in response to ciliary muscle contraction. The major symptom is reduced near vision, causing the individual to hold reading material at arm's length. Correction of presbyopia is accomplished through reading glasses or bifocal lenses, accommodative intraocular lenses, or surgical treatment.²⁰⁰

Alterations in Refraction.

Alterations in refraction are the most common visual problem. Errors in refraction are caused by irregularities of the corneal curvature, the focusing power of the lens, and the length of the eye. The major symptoms of refraction alterations are blurred vision and headache. Three types of refraction alterations are myopia, hyperopia, and astigmatism (Fig. 16.16).

FIGURE 16.16 Alterations in Refraction. A, Myopic eye. Parallel rays of light are brought to a focus in front of the retina. B, Hyperopic eye. Parallel rays of light come to a focus behind the retina in the nonaccommodative eye. C, Simple myopic astigmatism. The vertical bundle of rays is focused on the retina; the horizontal rays are focused in front of the retina and the image is blurred. (From Stein HA, Stein RM, Freeman MI: *The ophthalmic assistant: a text for allied and associated ophthalmic personnel*, ed 9, Philadelphia, 2013, Saunders.)

In **myopia** (nearsightedness), the axis of the eyeball is lengthened and light rays are focused in front of the retina when a person is looking at a distant object, resulting in blurred vision. The cause is unknown. A concave lens is needed for correction. Myopia requires frequent changes of eyeglasses while the eyeball is lengthening in childhood. Myopia is a risk factor for retinal detachment, cataract formation, and glaucoma.

In **hyperopia** (farsightedness), the axis of the eyeball is too short and light rays are focused behind the retina when a person is looking at a near object. **Astigmatism** is caused by an unequal curvature of the cornea. In astigmatism, light rays are bent unevenly and do not come to a single focus on the retina. Astigmatism may coexist with myopia, hyperopia, or presbyopia. Hyperopia is corrected with a convex lens or laser refractive surgery.

Alterations in Color Vision.

Normal sensitivity to color diminishes with age because of the progressive yellowing of the lens that occurs with aging. All colors become less intense, although color discrimination for blue and green is most greatly affected. Color vision deteriorates more rapidly for individuals with diabetes mellitus than for the general population. The deterioration is thought to be an accelerated version of senile color vision deterioration.

Abnormal color vision also may be caused by **color blindness**, an inherited trait. Color blindness is generally an X-linked recessive characteristic affecting 6% to 8% of the male population and 0.5% of the female population. Although many forms of color blindness exist, most commonly the affected individual cannot distinguish red from green.²⁰¹ In the most severe form individuals see only shades of gray, black, and white.

Neurologic Disorders Causing Visual Dysfunction.

Various neurologic disorders may cause visual dysfunction.²⁰² Vision may be disrupted at many points along the visual pathway, causing a variety of defects in fields of vision. Visual changes do not always cause defects or blindness in the entire visual field; **hemianopia** is the term that describes defective vision in half of a visual field. (Fig. 16.13 illustrates the many areas along the visual pathway that may be damaged and the associated visual changes.) Because of the anatomy of the optic nerves, injury to the optic nerve causes ipsilateral (same side) blindness but a normal contralateral (opposite side) visual field. Injury to the **optic chiasm** (the X-shaped crossing of the optic nerves), often caused by atherosclerotic ischemia or external compression from trauma or aneurysm, can cause a variety of defects, depending on the location of injury. These defects vary because at the optic chiasm, nerve fibers from the medial half of each retina separate from the lateral half and enter the opposite optic tract.

Because of the normal structure of the visual pathways, destruction of one optic tract causes **homonymous hemianopsia** (complete loss of vision in the inner half of one eye and the outer half of the other). Thus, if an injury to the left optic tract occurs, the individual is blind

in the right eye's medial (inner) field and the left eye's lateral (outer) field. If the compression of the optic tract is asymmetric, an incongruous (or uneven) homonymous defect results. Injury to one optic radiation (an ocular pathway in the internal capsule, temporal lobe, or occipital lobe) also causes a homonymous (same field) defect. A major injury in the optic radiation causes homonymous hemianopsia. A lesser injury may cause an upper quadrant homonymous defect. Generally the defects are the same size in both eyes. When the homonymous hemianopsia is caused by an occipital lobe lesion, the area of hemianopsia is split. Although visual acuity may remain unimpaired, reading is difficult because of the inability to group words.

Papilledema is edema of the optic nerve at its point of entrance into the eyeball. Papilledema is caused by increased intracranial pressure (e.g., brain tumors, intracranial hemorrhage, hydrocephalus). The subarachnoid space of the brain is continuous with the optic nerve sheath. As cerebrospinal fluid (CSF) pressure increases, the pressure is transmitted to the optic nerve, and the optic nerve sheath compresses the nerve and impedes axoplasmic transport. This leads to accumulation of axoplasmic substances at the level of the lamina cribrosa (a meshlike structure in the sclera where the retinal nerves exit the eye and form the optic nerve), resulting in the characteristic swelling of the optic disc. Obliteration of the physiologic cup (a bright area normally located in the center of the optic disc) follows. Later the optic disc becomes raised above the level of the surrounding retina, and the margins become blurred and indistinct. With severe swelling, hemorrhage and patches of white exudate (caused by nerve infarcts) surround the disc margins. The edematous nerves compress the small retinal veins, causing venous stasis and engorgement. Headache is common, and there may be no visual changes, blurred vision, or constriction of visual fields.

Hearing

The **external auditory canal** is surrounded by the bones of the cranium. The opening (meatus) of the canal is just above the **mastoid**

process (Fig. 16.17). The air-filled sinuses, called **mastoid air cells**, are located in the mastoid process and promote conductivity of sound between the external and the middle ear. Mastoid air cells communicate with the middle ear cavity through the entrance to the mastoid antrum.

FIGURE 16.17 The Ear. External, middle, and inner ear structures. (From Glynn M, Drake WM: *Hutchison's clinical methods: an integrated approach to clinical practice*, ed 23, London, 2012, Elsevier.)

The Ear

The ear is divided into three areas: (1) the external ear, involved only with hearing; (2) the middle ear, involved only with hearing; and (3) the inner ear, involved with both hearing and equilibrium. The external ear is composed of the **pinna** (auricle), which is the visible portion of the ear, and the external auditory canal, a tube that leads to the middle ear (see Fig. 16.17). Sound waves entering the external auditory canal hit the **tympanic membrane** (eardrum) and cause it to vibrate. The tympanic membrane separates the external ear from the middle ear.

The middle ear is composed of the **tympanic cavity**, a small

chamber in the temporal bone. Three ossicles (small bones known as the **malleus [hammer]**, **incus [anvil]**, and **stapes [stirrup]**) transmit the vibration of the tympanic membrane to the inner ear. When the tympanic membrane moves, the malleus moves with it and transfers the vibration to the incus, which passes it on to the stapes. The stapes presses against the **oval window**, a small membrane of the inner ear. The movement of the oval window sets the fluids of the inner ear in motion ([Fig. 16.18](#)).

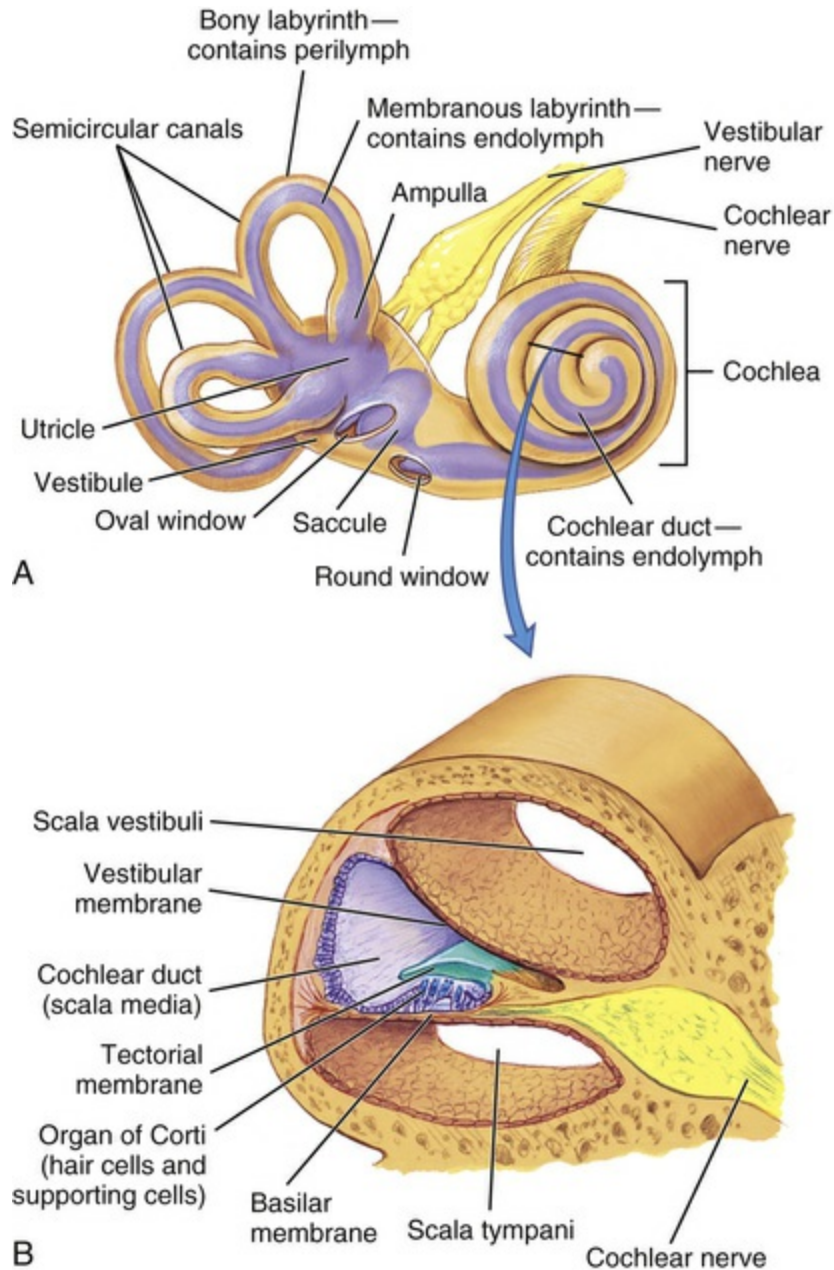

FIGURE 16.18 The Inner Ear. **A**, The bony labyrinth (*tan*) is the hard outer wall of the entire inner ear and includes semicircular canals, vestibule, and cochlea. Within the bony labyrinth is the membranous labyrinth (*purple*), which is surrounded by perilymph and filled with endolymph. Each ampulla in the vestibule contains a crista ampullaris that detects changes in head position and sends sensory impulses through the vestibular nerve to the brain. **B**, Section of the membranous cochlea. Hair cells in the organ of Corti detect sound and send the information through the cochlear nerve. The vestibular and cochlear nerves join to form the eighth cranial nerve. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

The eustachian (pharyngotympanic) tube connects the middle ear

with the thorax. Normally flat and closed, the eustachian tube opens briefly when a person swallows or yawns, and it equalizes the pressure in the middle ear with atmospheric pressure. Equalized pressure permits the tympanic membrane to vibrate freely. Through the eustachian tube the mucosa of the middle ear is contiguous with the mucosal lining of the throat.

The inner ear is a system of osseous labyrinths (bony, mazelike chambers) filled with a fluid called **perilymph**. The bony labyrinth is divided into the **cochlea**, the **vestibule**, and the **semicircular canals** (see [Fig. 16.18](#)). Suspended in the perilymph is the endolymph-filled membranous labyrinth that basically follows the shape of the bony labyrinth.

Within the cochlea is the **organ of Corti**, which contains **hair cells** (hearing receptors). Sound waves that reach the cochlea through vibrations of the tympanic membrane, ossicles, and oval window set the cochlear fluids into motion. Receptor cells on the basilar membrane are stimulated when their hairs are bent or pulled by the movement. Once stimulated, hair cells transmit impulses along the cochlear nerve (a division of the vestibulocochlear nerve) to the auditory cortex of the temporal lobe in the brain (see [Fig. 16.18](#)), where interpretation of the sound occurs. Directional hearing is controlled by the angle of the sound source to both ears and by the axonal delay in conduction in groups of neurons.

The semicircular canals and vestibule of the inner ear contain **equilibrium receptors**. In the semicircular canals the dynamic equilibrium receptors respond to changes in direction of movement. Within each semicircular canal is the **crista ampullaris**, a receptor region composed of a tuft of hair cells covered by a gelatinous cupula. When the head is rotated, the endolymph in the canal lags behind and moves in the direction opposite to the head's movement. The hair cells are stimulated, and impulses are transmitted through the vestibular nerve (a division of the vestibulocochlear nerve) to the cerebellum.

The vestibule in the inner ear contains maculae, receptors essential to the body's sense of static equilibrium. As the head moves, **otoliths** (small pieces of calcium salts) move in a gel-like material in response

to changes in the pull of gravity. The otoliths pull on the gel, which in turn pulls on the hair cells in the maculae. Nerve impulses in the hair cells are triggered and transmitted to the brain (see Fig. 16.18). Thus the ear not only permits the hearing of a large range of sounds but also assists with maintaining balance through the sensitive equilibrium receptors.

Aging and Hearing

Presbycusis is loss of hearing in older age.²⁰³ Auditory changes caused by aging are common, incremental, and with considerable individual variation. Changes in hearing with aging are summarized in Table 16.8. Approximately 30% to 40% of people older than 65 years have hearing loss caused by genetic and environmental factors. Changes may occur in the structural and functional components of the peripheral or central auditory system. Accumulative damage to the middle ear and inner ear, particularly of hair cells (sensory presbycusis) and the cochlea (neural presbycusis), is caused by damaging factors such as noise, inflammation, toxins, oxidative stress, and vascular damage (i.e., atherosclerosis and diabetes mellitus).

TABLE 16.8

CHANGES IN HEARING CAUSED BY AGING

CHANGES IN STRUCTURE	CHANGES IN FUNCTION
Cochlear hair cell degeneration	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Loss of auditory neurons in spiral ganglia of organ of Corti	Inability to hear high-frequency sounds (presbycusis, sensorineural loss); interferes with understanding speech; hearing may be lost in both ears at different times
Degeneration of basilar (cochlear) conductive membrane of cochlea	Inability to hear at all frequencies, but more pronounced at higher frequencies (cochlear conductive loss)
Decreased vascularity of cochlea	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound

Loss of cortical auditory neurons	Equal loss of hearing at all frequencies (strial loss); inability to disseminate localization of sound
-----------------------------------	--

Ototoxic drugs include antibiotics, such as streptomycin, neomycin, gentamicin, and vancomycin; diuretics, such as ethacrynic acid and furosemide; chemicals, such as salicylate, quinine, carbon monoxide, nitrogen mustard, arsenic, mercury, gold, tobacco, and alcohol; and cancer drugs (i.e., cisplatin). Because of increased concentrations of antibiotics in the endolymph, these drugs generally cause damage to the cells of the cochlea or the hair cells of the organ of Corti. Diuretics affect hearing primarily by altering the sodium-potassium balance, causing extracellular fluid accumulation and changes in the microstructure of secretory cells. Quinine, mercury, and lead affect the neural pathways of hearing, including the spinal ganglia, the eighth cranial nerve, and the cochlear nucleus.

Loss of hearing for sounds in the high-frequency range is most common and interferes with understanding speech, particularly high-frequency consonant sounds (e.g., *s*, *sh*, *f*). Hearing may be lost in both ears but not at the same time. The ability to discriminate localization of sound varies with high and low frequencies and diminishes with age. In the low-frequency range, sound localization is a function of the timing of sound arrival between the two ears; localization of high-frequency sounds is a function of sound intensity. Because older adults tend to lose high-frequency hearing first, they may have difficulty localizing high-frequency sounds and understanding speech. Cognitive impairment and poor quality of life are associated with presbycusis.²⁰⁴

Auditory Dysfunction

Between 5% and 10% of the general population have a hearing impairment. The major categories of auditory dysfunction are conductive hearing loss, sensorineural hearing loss, mixed hearing loss, and functional hearing loss.

Conductive Hearing Loss.

Conductive hearing loss occurs when a change in the outer or middle

ear impairs sound from being conducted from the outer to the inner ear. Conductive hearing loss occurs when there is interference in air conduction. Conditions that commonly cause a conductive hearing loss include impacted cerumen, foreign bodies lodged in the ear canal, benign tumors of the middle ear, carcinoma of the external auditory canal or middle ear, eustachian tube dysfunction, otitis media, acute viral otitis media, chronic suppurative otitis media, cholesteatoma, and otosclerosis (impaired mobility of the stapes footplate in the presence of dense sclerotic bone).

Symptoms of conductive hearing loss include diminished hearing and soft speaking voice. The voice is soft because often the individual hears his or her voice, conducted by bone, as loud. In addition, although the cause is unknown, the individual often hears better in a noisy environment than in a quiet one (a condition called *paracusia willisiana*). Treatment of the underlying cause generally improves hearing, and a hearing aid can improve quality of life.²⁰⁵

Sensorineural Hearing Loss.

A **sensorineural hearing loss** is caused by impairment of the organ of Corti or its central connections. The hearing loss may be gradual or sudden. Conditions that commonly cause sensorineural hearing loss include congenital and hereditary factors, noise exposure, aging, Ménière disease, ototoxicity (see drugs associated with presbycusis above), and systemic disease (syphilis, Paget disease, collagen diseases, diabetes mellitus). Congenital and neonatal sensorineural hearing loss may be caused by maternal rubella, cytomegalovirus, ototoxic drugs, prematurity, traumatic delivery, erythroblastosis fetalis, and congenital hereditary malfunction.²⁰⁶ Diagnosis often is made when delayed speech development is noted. Treatment includes hearing aids and cochlear implant. Gene therapy and allotransplantation of stem cells are under investigation.²⁰⁷

Mixed Hearing Loss.

A **mixed hearing loss** is caused by a combination of conductive and sensorineural losses.

Functional Hearing Loss.

A **functional hearing loss** occurs for no organic reason. The individual does not respond to voice and appears not to hear. Functional hearing loss is thought to be caused by emotional or psychologic factors. It occurs only rarely.

Ear Infections

Otitis Externa.

Otitis externa is inflammation of the external ear canal with or without infection and may include parts of the outer ear. It is commonly acute rather than chronic. Regular swimming is a risk factor. Alterations in the normal acidic environment, lack of cerumen, and trauma to skin epithelium can lead to bacterial and, less commonly, fungal infections with inflammation. The most frequently found microorganisms are *Pseudomonas*, *Escherichia coli*, and *Staphylococcus aureus*. Infection usually follows prolonged exposure to moisture (swimmer's ear). The earliest symptoms are inflammation with swelling, tenderness, and itching with clear drainage progressing to purulent drainage and obstruction of the canal. Treatment includes topical antibiotics and steroids.²⁰⁸

Otitis Media.

Otitis media is an infection of the middle ear and is the most common infection of infants and children. Otitis media is the leading cause of healthcare visits and drug prescriptions throughout the world, with 50% occurring in the under 5-year age group.²⁰⁹ Most children have one episode by 3 years of age. The most common pathogens are *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Respiratory viruses also may have an etiologic role.²¹⁰ Predisposing factors include allergy, sinusitis, submucous cleft palate, adenoidal hypertrophy, and immune deficiency. Breast-feeding is a protective factor.

Acute otitis media (AOM) is associated with ear pain, fever, irritability, inflamed tympanic membrane, and fluid in the middle ear.

The tympanic membrane progresses from erythema to opaqueness with bulging as fluid accumulates. An increasing prevalence of AOM is caused by methicillin-resistant microorganisms. Otitis media with effusion (OME) is the presence of fluid in the middle ear without symptoms of acute infection. Treatment includes antimicrobial therapy for AOM, particularly in children 2 years and younger. Reduction in the incidence of AOM has accompanied the widespread use of bacterial and viral vaccines in young children, including pneumococcal conjugate and influenza vaccines.²¹¹

Chronic otitis media (COM) is persistent or recurring infection of the middle ear. Chronic suppurative OM (CSOM) is associated with ear drum perforation and purulent discharge. Conductive hearing loss occurs when the effusion prevents the middle ear ossicles from effectively relaying sound vibrations from the ear drum to the oval window of the inner ear. Sensorineural hearing loss occurs when inflammatory mediators penetrate into the inner ear through the round window with loss of hair cells in the cochlea. Placement of tympanostomy tubes is considered when bilateral effusion persists for 3 months and for significant hearing loss. Mastoidectomy combined with tympanostomy ventilation tubes may be required when there is cholesteatoma (skin growth into the middle ear associated with perforation of the eardrum). Complications include mastoiditis, brain abscess, meningitis, and chronic otitis media with hearing loss. Speech, language, and cognitive disabilities may be affected by persistent middle ear effusions. Eosinophilic COM is associated with bronchial asthma and with sensitization to bacterial or fungal ear infection.²¹²

Olfaction and Taste

Olfaction (smell) dysfunction and taste (gustation) dysfunction may occur separately or jointly. The strong relationship between smell and taste creates the sensation of flavor. If either sensation is impaired, the perception of flavor is altered. (Olfactory structures are illustrated in [Fig. 16.19.](#))

FIGURE 16.19 Olfaction. Midsagittal section of the nasal area shows the locations of major olfactory sensory structures. (From Patton KT, Thibodeau GA, Douglas MM: *Essentials of anatomy & physiology*, St Louis, 2012, Mosby.)

Olfaction is a function of cranial nerve I (olfactory) and part of cranial nerve V (trigeminal). The receptor cells for smell are located in the olfactory epithelium. Seven primary classes of olfactory stimulants have been identified: (1) camphoraceous, (2) musky, (3) floral, (4) peppermint, (5) ethereal, (6) pungent, and (7) putrid. Olfaction is important for detection of hazards in the environment, generating feelings of pleasure, promoting adequate nutrition, influencing sexuality, and maintenance of mood.²¹³

Olfactory dysfunctions include hyposmia, anosmia, hallucinations, and parosmia. **Hyposmia** is the impaired sense of smell, and **anosmia** is the complete loss of smell. Both conditions are associated with aging, neurodegenerative and nasal/sinus disorders, and head trauma. When hyposmia or anosmia occurs bilaterally, it is usually the result of rhinitis (inflammation of nasal mucosa), sinusitis, nasal polyps, or excessive smoking. Unilateral hyposmia or anosmia may indicate compression of one olfactory bulb (a bulblike portion of the olfactory nerves) or nerve tract (olfactory nerve pathway), possibly by tumor or head trauma. **Olfactory hallucinations** arise from hyperactivity in cortical neurons and involve smelling odors that are not really present. They are associated with temporal lobe seizures and rarely

with schizophrenia. **Parosmia**, an abnormal or perverted sense of smell, may occur with severe depression and in Parkinson and Alzheimer disease.²¹⁴

Taste is a function of multiple nerves in the tongue, soft palate, uvula, pharynx, and upper esophagus, including cranial nerves VII (facial) and IX (glossopharyngeal). Taste buds (fungiform, foliate, and circumvallate) sensitive to each of the primary sensations are located in specific areas of the tongue and are continuously renewing.²¹⁵

The primary sensations of taste are sour, salty, sweet, bitter, and umami (savoriness). Taste buds sensitive to each of the primary sensations are located on the circumvallate, fungiform, and foliate papillae in specific areas of the tongue. Taste receptors also are found on airway smooth muscle (bitter) and in the gastrointestinal tract (bitter and sweet). Their function is not for taste. In the lung they stimulate bronchodilation, and in the gastrointestinal tract they may participate in metabolic and digestive regulation.^{216,217}

Alterations in taste can be caused by injury, medications, oral infections, or aging. A change in taste also may be attributable to impairment of smell associated with injury near the hippocampus.

Hypogeusia is a decrease in taste sensation, and **ageusia** is the absence of taste. Ageusia affecting the entire tongue may follow head injury. Hypogeusia and ageusia occur with viral respiratory and oral infections. Autoimmune disease (i.e., systemic lupus erythematosus) and cancer chemotherapy alter taste sensitivity. Damage to the glossopharyngeal nerve (cranial nerve IX, which innervates the posterior one third of the tongue) causes the loss of the ability to detect bitterness. This loss occurs because the receptors for bitter are located on the base of the tongue. Damage to the facial nerve (cranial nerve VII, which innervates the anterior two-thirds of the tongue) causes loss of the ability to detect sour, sweet, and salty tastes. Only bitter tastes can be detected. These losses occur because sour, sweet, and salt receptors are located on the anterior portion of the tongue.²¹⁸

Aging and Olfaction and Taste

Sensitivity to odors declines steadily with aging.²¹⁹ A study of odor identification indicates an increasing ability from childhood to adolescence and then a decline after 60 years of age. The sense of smell begins to degenerate with loss of olfactory sensory neurons and loss of cells from the olfactory bulbs. The mechanism of loss is unknown. Loss of olfactory sensitivity and odor identification may diminish appetite and food selection and thus may lead to malnutrition. Safety also may be compromised by an inability to smell spoiled food or hazardous gases.²²⁰

Parageusia is a perversion of taste in which substances possess an unpleasant flavor. Parageusia occasionally develops for no apparent reason in older adults, leading to anorexia and malnutrition. The decline in taste sensation is more gradual than that of smell and is associated with loss of olfaction. Higher concentrations of flavors are required, and older adults have difficulty differentiating combinations of flavors. Taste changes with aging are associated with decline in the number of fungiform papillae on the tongue, and changes in taste receptor function.²¹⁸ Taste also may be affected by decreased salivary gland secretion. Amylase, contained in saliva, facilitates perception of sweet flavors.

Summary Review

Pain

1. Pain is a protective and a complex phenomenon composed of sensory experiences (time, space, intensity) and emotion, cognition, and motivation.
2. The portions of the nervous system responsible for the sensation and perception of pain may be divided into three areas: (a) the afferent pathways; (b) the interpretive centers in the brainstem, midbrain, and diencephalon; and (c) the descending pathways from the brain to the dorsal horn of the spinal cord.
3. Nociceptors are pain receptors that detect a wide range of

stimuli and respond to chemical, mechanical, and thermal stimulation.

4. The afferent system is composed of nociceptors, A δ and C fibers (first-order neurons); the dorsal horn of the spinal column (second-order neurons); and afferent neurons in the spinothalamic tract (third-order neurons).
5. Myelinated A δ receptor transmission is fast and conveys mechanical and thermal, sharp, localized pain. Unmyelinated polymodal C fiber transmission is slower and conveys diffuse burning and aching sensations. These primary-order neurons terminate on second-order neurons.
6. Three classes of second-order neurons modulate pain transmission: projection cells, excitatory interneurons, and inhibitory interneurons. The second-order neurons are located in the spinal cord laminae and function as a pain gate to regulate pain transmission.
7. Second-order neurons cross over the cord and ascend primarily in the lateral spinothalamic tract to projection centers including the thalamus, reticular formation, and PAG matter.
8. Third-order neurons carry information to the sensory cortex and reticular and limbic systems for pain processing and interpretation.
9. Efferent pathways from the PAG are responsible for modulation or inhibition of afferent pain signals. The thalamus, cortex, and postcentral gyrus perceive, describe, and localize pain. The reticular formation and limbic system control the emotional and affective response to pain.
10. Pain threshold is the point at which pain is perceived. Pain threshold does not vary significantly among people or within the same person over time.
11. Pain tolerance is the duration of time or the intensity of pain that an individual will endure before initiating overt pain response. Tolerance varies widely among individuals and in the same individual over time.
12. Descending inhibitory or facilitatory pathways, nuclei, and

neurotransmitters inhibit or facilitate pain. Segmental inhibition is the peripheral stimulation of nociceptors by touch, vibration, or pressure resulting in closure of the spinal cord pain gate. The higher brain centers also can influence painful stimuli (heterosegmental control of nociception) as well as inhibition from the caudal medulla (diffuse noxious inhibitory controls). Thus pain can be modulated with stimulation from the periphery or by descending impulses from the brain.

13. Cognitive expectation can attenuate or intensify pain, and this is known as the placebo and nocebo effects.
14. Pain neurotransmitters can be classified as inflammatory, excitatory, and inhibitory modulators of pain. Inflammatory neurotransmitters are usually excitatory. Gamma-aminobutyric acid (GABA) and glycine are inhibitors of pain.
15. Endogenous opioids are a family of morphine-like neuropeptides that inhibit transmission of pain by acting on specific opioid receptors (μ [μ], κ [κ], and δ [δ]).
16. Classifications of pain include nociceptive pain (with a known physiologic cause), nonnociceptive pain (neuropathic pain), acute pain (signal to the person of a harmful stimulus), and chronic pain (persistence of pain of unknown cause or unusual response to therapy).
17. Acute pain may be (a) somatic (superficial), (b) visceral (internal), or (c) referred (present in an area distant from its origin).
18. Somatic pain arises from connective tissue, muscle, bone, and skin and is sharp and localized.
19. Visceral pain is from internal organs and is transmitted by sympathetic afferents and is poorly localized.
20. Referred pain usually arises from the viscera and terminates in an area of the spinal cord that is conjoined with fibers originating in the skin and other areas and thereby produces the perception of pain at the referred site.
21. Physiologic responses to acute pain include increased heart

- rate, respiratory rate, and blood pressure; pallor or flushing; dilated pupils; and diaphoresis. Blood glucose level is elevated; gastric secretion and motility are decreased; and blood flow to the viscera and skin is decreased.
22. Chronic pain generally lasts at least 3 months and may be persistent, for example, low back pain, myofascial pain syndromes, chronic postoperative pain, and chronic pain associated with cancer.
 23. Neuropathic pain is usually chronic, results from nerve trauma or disease, and leads to abnormal peripheral and central pain processing. Types of neuropathic pain include deafferentation pain, sympathetically maintained pain, central poststroke pain, phantom limb pain, and complex regional pain syndrome.
 24. Newborns and young children have the anatomic and functional ability to perceive pain. Repeated pain experienced by infants may have prolonged effects on brain neurodevelopment and motor and cognitive function.
 25. Older individuals may or may not have an increased pain threshold. In all age groups, women appear to be more sensitive to pain than are men.
 26. Pain in older adults is influenced by liver and renal function, including alterations in the metabolism of drugs and metabolites.

Temperature Regulation

1. Temperature regulation (thermoregulation) is achieved through precise balancing of heat production, heat conservation, and heat loss. Body temperature is maintained around 37°C (98.6°F).
2. Temperature regulation is mediated by the hypothalamus. Peripheral thermoreceptors in the skin and central thermoreceptors in the hypothalamus, spinal cord, and abdominal organs provide the hypothalamus with information

about skin and core temperatures.

3. Heat is produced through chemical reactions of metabolism, skeletal muscle contraction (shivering), and brown fat (nonshivering) thermogenesis.
4. Heat is lost through radiation, conduction, convection, vasodilation, decreased muscle tone, evaporation of sweat, increased ventilation, and voluntary mechanisms.
5. Heat conservation is accomplished through vasoconstriction and voluntary mechanisms.
6. Infants and older adults require special attention to maintenance of body temperature. Because of their greater body surface area to mass ratio and decreased subcutaneous fat, infants do not conserve heat well. Older individuals have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in skin, and an overall decrease in heat-producing activities.
7. Fever is triggered by the release of pyrogens from leukocytes and other cells involved in the immune response (endogenous pyrogens) and bacteria (exogenous pyrogens). Fever is both a symptom of a disease and a normal immunologic mechanism.
8. Fever involves resetting the hypothalamic thermostat to a higher level. When a fever breaks, the set point is returned to normal.
9. Fever production aids responses to infectious processes. Higher temperatures kill many microorganisms and decrease serum levels of iron, zinc, and copper that are needed for bacterial replication.
10. Endogenous cryogens diminish and control the febrile response.
11. Hyperthermia (marked warming of core temperature) can produce nerve damage, coagulation of cell proteins, and death. Therapeutic hyperthermia is used in the treatment of infection to treat cancer. Forms of accidental hyperthermia include heat cramps, heat exhaustion, heat stroke, and

malignant hyperthermia. Heat stroke and malignant hyperthermia are potentially lethal developments.

12. Hypothermia (marked cooling of core temperature) slows the rate of chemical reaction (tissue metabolism), increases the viscosity of the blood, slows blood flow through the microcirculation, facilitates blood coagulation, and stimulates profound vasoconstriction. Hypothermia may be accidental or therapeutic and used to reduce metabolic needs and for neuroprotection.
13. Temperature regulation can be disrupted by central nervous system trauma, bodily injury, hemorrhagic shock, major surgery, and thermal burns.

Sleep

1. Sleep may be divided into REM and NREM stages, each of which has its own series of stages. While asleep, an individual progresses through the three stages of NREM (slow-wave) sleep and REM sleep in a predictable cycle. Restorative, reparative, and growth processes occur during NREM sleep.
2. NREM sleep is initiated when inhibitory signals are released from the hypothalamus. There is decreased sympathetic tone, temperature, blood pressure, and muscle tone. Parasympathetic activity increases.
3. REM sleep is mediated in the pons and mesencephalon and is associated with increased parasympathetic activity and variable sympathetic activity associated with rapid eye movement, atonia, loss of temperature regulation, and changes in heart rate, blood pressure, and respiration.
4. The sleep patterns of the newborn and young child vary from those of the adult in total sleep time, cycle length, and percentage of time spent in each sleep cycle. Older adults experience a total decrease in sleep time.
5. Sleep deprivation can cause profound changes in personality and functioning.

6. Sleep disorders include: (a) dyssomnias; (b) parasomnias; (c) sleep disorders associated with mental, neurologic, or other medical disorders; and (d) proposed sleep disorders.
7. Common dyssomnias include insomnia, RLS, OSAS, hypersomnia, narcolepsy, and circadian rhythm disorder.
8. Common parasomnias include arousal disorders, sleep-wake transition disorder, and disorders associated with REM sleep.

Somatosensory Function and the Special Senses

1. The sensation of touch involves the fusion of several qualities, including modality, intensity, location, and duration of the sensory stimulus.
2. Receptors sensitive to touch are present in the skin; these include Meissner and pacinian corpuscles and Merkel disks and Ruffini endings. The sensory response is conducted to the brain through the dorsal column and anterior spinothalamic tract.
3. Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex.
4. Proprioception is the perception of the position and location of the body and its parts. Proprioceptors are located in the inner ear, joints, and ligaments. Proprioceptive stimuli are necessary for balance, coordinated movement, and grading of muscular contraction.
5. Disorders of proprioception can be caused by alterations at any level of the nervous system. Two common causes of proprioceptive dysfunction are vestibular dysfunction and peripheral neuropathy.

Vision

1. The eyelids, conjunctivae, and lacrimal apparatus protect the

eye. Infections are the most common disorders; they include blepharitis, conjunctivitis, chalazion, and hordeolum.

2. Conjunctivitis can be acute or chronic, bacterial, viral, or allergic. Redness, edema, pain, and lacrimation are common symptoms. Trachoma (chlamydial conjunctivitis) is the leading cause of blindness in the world and is associated with poor sanitary conditions.
3. Keratitis is a bacterial or viral infection of the cornea that can lead to corneal ulceration. Photophobia, pain, and tearing are common symptoms.
4. The wall of the eye has three layers: sclera, choroid, and retina. The retina contains millions of photoreceptors known as rods and cones that receive light through the lens and then convey signals to the optic nerve and subsequently to the visual cortex of the brain.
5. The eye is filled with vitreous and aqueous humor, which prevent it from collapsing.
6. Structural eye changes caused by aging or chronic disease result in decreased visual acuity.
7. The major alterations in ocular movement include strabismus, nystagmus, and paralysis of the extraocular muscles.
8. Alterations in visual acuity can be caused by amblyopia, scotoma, cataracts, papilledema, macular degeneration, retinal detachment, and glaucoma.
9. Alterations in accommodation develop with increased intraocular pressure, inflammation, and disease of the oculomotor nerve. Presbyopia is loss of accommodation caused by loss of lens elasticity with aging.
10. Alterations in refraction, including myopia, hyperopia, and astigmatism, are the most common visual disorders.
11. Alterations in color vision occur with disorders of the cornea and the inherited trait of color blindness.
12. Trauma or disease of the optic nerve pathways, or optic radiations, can cause blindness in the visual fields. Homonymous hemianopsia is caused by damage of one optic

tract.

Hearing

1. The ear is composed of external, middle, and inner structures. The external structures are the pinna, auditory canal, and tympanic membrane. The tympanic cavity (containing three bones: malleus, incus, and stapes), oval window, eustachian tube, and fluid compose the middle ear and transmit sound vibrations to the inner ear.
2. The inner ear includes the bony and membranous labyrinths that transmit sound waves through the cochlea to the division of the eighth cranial nerve (i.e., vestibulocochlear). The semicircular canals and vestibule help maintain balance through the equilibrium receptors.
3. Approximately one-third of all people older than 65 years have hearing loss.
4. Hearing loss can be classified as conductive, sensorineural, mixed, or functional.
5. Conductive hearing loss occurs when sound waves cannot be conducted through the middle ear.
6. Sensorineural hearing loss develops with impairment of the organ of Corti or its central connections. Presbycusis is age-related hearing loss and is the most common form of sensorineural hearing loss.
7. A combination of conductive and sensorineural loss is a mixed hearing loss.
8. Loss of hearing with no known organic cause is a functional hearing loss.
9. Otitis externa is an infection of the outer ear. Otitis media, an infection of the middle ear, is common in children and can be acute or chronic.
10. Acute otitis media is an infection of the middle ear associated with ear pain, fever, an inflamed tympanic membrane, and fluid in the middle ear.

11. Chronic otitis media is persistent or recurrent middle ear infection.

Olfaction and Taste

1. The perception of flavor is altered if olfaction or taste dysfunctions occur. Sensitivity to odor and taste decreases with aging.
2. Hyposmia is a decrease in the sense of smell, and anosmia is the complete loss of smell. Inflammation of the nasal mucosa and trauma or tumors of the olfactory nerve lead to a diminished sense of smell.
3. Hypogeusia is a decrease in taste sensation, and ageusia is the absence of taste. Loss of taste buds or trauma to the facial or glossopharyngeal nerves decreases taste sensation.
4. Parageusia is a perversion of taste in which substances possess an unpleasant flavor.

CHAPTER 17

Alterations in Cognitive Systems, Cerebral Hemodynamics, and Motor Function

Barbara J. Boss, Sue E. Huether

CHAPTER OUTLINE

Alterations in Cognitive Systems, 504

- Alterations in Arousal, 505
- Alterations in Awareness, 512
- Data Processing Deficits, 514
- Seizure Disorders, 525

Alterations in Cerebral Hemodynamics, 527

- Increased Intracranial Pressure, 528
- Cerebral Edema, 529
- Hydrocephalus, 530

Alterations in Neuromotor Function, 530

- Alterations in Muscle Tone, 531
- Alterations in Muscle Movement, 533
- Alterations in Complex Motor Performance, 543
- Extrapyramidal Motor Syndromes, 544

A person achieves cognitive and behavioral functional adequacy by integrated processes of cognitive systems, sensory systems, and motor systems. Alterations in any or all of these affect functional adequacy. The purpose of this chapter is to present the concepts and processes of these alterations as an approach to understanding the manifestation of neurologic dysfunction. Some specific diseases are also presented (i.e., Parkinson disease, Huntington disease, and amyotrophic lateral sclerosis) because they fit best here. The manifestations for specific central and peripheral nervous system disorders are presented in [Chapter 18](#). Alterations in sensory function are presented in [Chapter 16](#).

The neural systems essential to cognitive function are: (1) attentional systems that provide arousal and maintenance of attention over time; (2) memory and language systems by which information is communicated; and (3) affective or emotive systems that mediate mood, emotion, and intention. These core systems are fundamental to the processes of abstract thinking and reasoning. The products of abstraction and reasoning are organized and made operational through the executive attentional networks. The normal functioning of these systems manifests through the motor system in a behavioral array viewed by others as being appropriate to human activity and successful living.

Alterations in Cognitive Systems

Full **consciousness** is a state of awareness both of oneself and of the environment and a set of responses to that environment. The fully conscious individual responds to external stimuli with a wide array of responses. Any decrease in this state of awareness and varied responses is thus a decrease in consciousness.

Consciousness has two distinct components: arousal (state of awakeness) and awareness (content of thought). **Arousal** is mediated by the reticular activating system, which regulates aspects of attention and information processing and maintains consciousness (see [Fig. 15.7](#)). Cognitive cerebral functions require a functioning reticular

activating system. Awareness encompasses all cognitive functions and is mediated by attentional systems, memory systems, language systems, and executive systems.

Alterations in Arousal

Alterations in level of arousal may be caused by structural, metabolic, or psychogenic (functional) disorders.

◆Pathophysiology.

Structural alterations in arousal are divided according to original location of the pathologic condition: supratentorial (above the tentorium cerebelli); infratentorial (subtentorial, below the tentorium cerebelli); subdural (below the dura mater [see [Figs. 15.17](#) and [17.18](#)]); extracerebral (outside the brain tissue); and intracerebral (within the brain tissue). Causes include infection, vascular alterations, neoplasms, traumatic injury, congenital alterations, degenerative changes, polygenic traits, and metabolic disorders.

Supratentorial disorders (above the tentorium cerebelli) produce changes in arousal by either diffuse or localized dysfunction. Diffuse dysfunction may be caused by disease processes affecting the cerebral cortex or the underlying subcortical white matter (e.g., encephalitis). Disorders outside the brain but within the cranial vault (extracerebral) also can produce diffuse dysfunction, including neoplasms, closed-head trauma with subsequent bleeding, and subdural empyema (accumulation of pus). Disorders within the brain substance (intracerebral)—bleeding, infarcts, emboli, and tumors—function primarily as masses. Such localized destructive processes directly impair function of the thalamic or hypothalamic activating systems.

Infratentorial disorders (below the tentorium cerebelli) produce a decline in arousal by (1) direct destruction of the reticular activating system (RAS) and its pathways (e.g., accumulations of blood or pus, neoplasms, and demyelinating disorders), or (2) the brainstem (midbrain, pons, medulla) may be destroyed either by direct invasion or by indirect impairment of its blood supply. The most common cause of direct destruction is cerebrovascular disease. Demyelinating

diseases, neoplasms, granulomas, abscesses, and head injury also may cause brainstem destruction by tissue compression. This compression may occur because of (1) direct pressure on the pons and midbrain, producing ischemia and edema of the neurons of the RAS; (2) upward herniation of the cerebellum through the tentorial notch, thus compressing the upper midbrain and diencephalon; or (3) downward herniation of the cerebellum through the foramen magnum, compressing and displacing the medulla oblongata.

Metabolic alterations in arousal produce a decline in arousal by alterations in delivery of energy substrates as occurs with hypoxia, electrolyte disturbances, or hypoglycemia. Metabolic disorders caused by liver or renal failure cause alterations in neuronal excitability because of failure to metabolize or eliminate drugs and toxins. All the systemic diseases that eventually produce nervous system dysfunction are part of this metabolic category.

Psychogenic alterations in arousal (unresponsiveness), although uncommon, may signal general psychiatric disorders (see [Chapter 19](#)). Despite apparent unconsciousness, the person actually is physiologically awake and the neurologic examination reflects a normal response.

◆ **Clinical Manifestations and Evaluation.**

Five patterns of neurologic function are critical to the evaluation process: (1) level of consciousness, (2) pattern of breathing, (3) pupillary reaction, (4) oculomotor responses, and (5) motor responses. Patterns of clinical manifestations help determine the extent of brain dysfunction and serve as indices for identifying increasing or decreasing central nervous system (CNS) function. Distinctions are made between metabolic and structurally induced manifestations ([Table 17.1](#)). The types of manifestations suggest the cause of the altered arousal state ([Table 17.2](#)).

TABLE 17.1

CLINICAL MANIFESTATIONS OF METABOLIC AND STRUCTURAL CAUSES OF ALTERED AROUSAL

MANIFESTATION	METABOLICALLY INDUCED	STRUCTURALLY INDUCED
Blink to threat (cranial nerves II, VII)	Equal	Asymmetric
Discs (cranial nerve II)	Flat, good pulsation	Papilledema
Extraocular movement (cranial nerves III, IV, VI)	Roving eye movements; normal doll's eyes and calorics	Gaze paresis, nerve III palsy, medial longitudinal fasciculus (MLF) syndrome (internuclear ophthalmoplegia)
Pupils (cranial nerves II, III)	Equal and reactive; may be large (e.g., atropine), pinpoint (e.g., opiates), or midposition and fixed (e.g., glutethimide [Doriden])	Asymmetric and/or nonreactive; may be midposition (midbrain injury), pinpoint (pons injury), large (tectal injury)
Corneal reflex (cranial nerves V, VII)	Symmetric response	Asymmetric response
Grimace to pain (cranial nerve VII)	Symmetric response	Asymmetric response
Motor function movement	Symmetric	Asymmetric
Tone	Symmetric	Paratonic, spastic, flaccid, especially if asymmetric
Posture	Symmetric	Decorticate, especially if symmetric; decerebrate, especially if asymmetric
Deep tendon reflexes	Symmetric	Asymmetric
Babinski sign	Absent or symmetric response	Present
Sensation	Symmetric	Asymmetric

TABLE 17.2

DIFFERENTIAL CHARACTERISTICS OF DISORDERS CAUSING ALTERED AROUSAL

MECHANISM	MANIFESTATIONS
Supratentorial mass lesions compressing or displacing diencephalons or brainstem	Initiating signs usually of focal cerebral dysfunction Signs of dysfunction progress rostral to caudal Neurologic signs at any given time point to one anatomic area (e.g., diencephalon, mesencephalon, medulla) Motor signs often asymmetric
Infratentorial mass or destruction, causing coma	History of preceding brainstem dysfunction or sudden onset of coma Localizing brainstem signs precede or accompany onset

	<p>of coma and always include oculovestibular abnormality</p> <p>Cranial nerve palsies; usually manifest as “bizarre” respiratory patterns that appear at onset</p>
<p>Metabolic coma</p> <p>Exogenous toxins (drugs)</p> <p>Endogenous toxins (organ system failure)</p>	<p>Confusion and stupor commonly precede motor signs</p> <p>Motor signs usually are symmetric</p> <p>Pupillary reactions usually are preserved</p> <p>Asterixis, myoclonus, tremor, and seizures are common</p> <p>Acid-base imbalance with hyperventilation or hypoventilation is common</p>
<p>Psychiatric unresponsiveness</p>	<p>Lids close actively</p> <p>Pupils reactive or dilated (cycloplegics)</p> <p>Oculocephalic reflexes are unpredictable; oculovestibular reflexes are physiologic (nystagmus is present)</p> <p>Motor tone is inconsistent or normal</p> <p>Eupnea or hyperventilation is usual</p> <p>No pathologic reflexes are present</p> <p>Electroencephalogram (EEG) is normal</p>

Level of Consciousness

Level of consciousness is the most critical clinical index of nervous system function with changes indicating either improvement or deterioration of the individual's condition. A person who is alert and oriented to self, others, place, and time is considered to be functioning at the highest level of consciousness, which implies full use of all the person's cognitive capacities. From this normal alert state, levels of consciousness diminish in stages from confusion and disorientation (can occur simultaneously) to coma, each of which is clinically defined (Table 17.3).

TABLE 17.3

LEVELS OF ALTERED CONSCIOUSNESS

STATE	DEFINITION
Confusion	Loss of ability to think rapidly and clearly; impaired judgment and decision making
Disorientation	Beginning loss of consciousness; disorientation to time followed by disorientation to place and impaired memory; lost last is recognition of self
Lethargy	Limited spontaneous movement or speech; easy arousal with normal speech or touch;

	may not be oriented to time, place, or person
Obtundation	Mild to moderate reduction in arousal (awakeness) with limited response to the environment; falls asleep unless stimulated verbally or tactilely; answers questions with minimum response
Stupor	A condition of deep sleep or unresponsiveness from which the person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often withdrawal or grabbing at stimulus
Light coma	Associated with purposeful movement on stimulation
Coma	No verbal response to the external environment or to any stimuli; noxious stimuli such as deep pain or suctioning yields motor movement
Deep coma	Associated with unresponsiveness or no response to any stimulus

Pattern of Breathing

Respiratory patterns help evaluate the level of brain dysfunction and coma. Rate, rhythm, and pattern should be evaluated. Breathing patterns can be categorized as hemispheric or brainstem (Table 17.4 and Fig. 17.1).

TABLE 17.4

PATTERNS OF BREATHING

BREATHING PATTERN	DESCRIPTION	LOCATION OF INJURY
Hemispheric Breathing Patterns		
Normal	After a period of hyperventilation that lowers the arterial carbon dioxide pressure (PaCO ₂), the individual continues to breathe regularly but with a reduced depth.	Response of the nervous system to an external stressor—not associated with injury to the central nervous system (CNS)
Posthyperventilation apnea	Respirations stop after hyperventilation has lowered the PaCO ₂ level below normal. Rhythmic breathing returns when the PaCO ₂ level returns to normal. (Usually an intact cerebral cortex will trigger breathing within 10 seconds regardless of PaCO ₂ .)	Associated with diffuse bilateral metabolic or structural disease of the cerebrum
Cheyne-Stokes respirations	Breathing pattern has a smooth increase (crescendo) in the rate and depth of breathing (hyperpnea), which peaks and is	Bilateral dysfunction of the deep cerebral or diencephalic structures;

	followed by a gradual smooth decrease (decrecendo) in the rate and depth of breathing to the point of apnea when the cycle repeats itself. The hyperpneic phase lasts longer than the apneic phase (represents an amplitude change).	seen with supratentorial injury and metabolically induced coma states unrelated to neurologic dysfunction; may see also in congestive heart failure (CHF)
Brainstem Breathing Patterns		
Central reflex hyperpnea (central neurogenic hyperventilation)	A sustained deep rapid but regular pattern (hyperpnea) occurs, with a decreased PaCO ₂ and a corresponding increase in pH and increased PO ₂ .	May result from CNS damage or disease that involves the lower midbrain and upper pons; seen after increased intracranial pressure and blunt head trauma
Apneusis	A prolonged inspiratory cramp (a pause at full inspiration) occurs. A common variant of this is a brief end-inspiratory pause of 2 or 3 seconds, often alternating with an end-expiratory pause.	Indicates damage to the respiratory control mechanism located at the pontine level; most commonly associated with pontine infarction but documented with hypoglycemia, anoxia, and meningitis
Cluster breathing	A cluster of breaths has a disordered sequence with irregular pauses between breaths.	Dysfunction in the lower pontine and high medullary areas
Ataxic breathing	Completely irregular breathing occurs, with random shallow and deep breaths and irregular pauses. Often the rate is slow.	Originates from a primary dysfunction of the medulla
Gasping breathing pattern (agonal gasps)	A pattern of deep "all-or-none" breaths is accompanied by a slow respiratory rate.	Indicative of a failing medullary respiratory center

FIGURE 17.1 Abnormal Respiratory Patterns with Corresponding Level of Central Nervous System Injuries. A, Cheyne-Stokes respiration is seen with metabolic injury and lesions in the forebrain and diencephalon. B, Central neurogenic hyperventilation is most commonly seen with metabolic encephalopathies (lesion of midbrain, pons, or medulla). C, Apneustic breathing (inspiratory pauses) is seen in patients with bilateral pontine lesions. D, Cluster breathing and ataxic breathing are seen in lesions at the pontine medullary junction. E, Ataxic breathing occurs when the medullary ventral respiratory nuclei are injured. (From Urden LD et al: *Critical care nursing: diagnosis and management*, ed 6, St Louis, 2010, Mosby.)

With normal breathing, a neural center in the forebrain (cerebrum) produces a rhythmic breathing pattern. When consciousness decreases, lower brainstem centers regulate the breathing pattern by responding only to changes in PaCO_2 levels, called **posthyperventilation apnea (PHVA)**.

Cheyne-Stokes respiration is an abnormal rhythm of ventilation (periodic breathing) with alternating periods of hyperventilation and apnea (crescendo-decrescendo pattern). In the damaged brain, higher levels of PaCO_2 are required to stimulate ventilation, and increases in PaCO_2 lead to tachypnea. The PaCO_2 level then decreases to below normal, and breathing stops (apnea) until the carbon dioxide reaccumulates and again stimulates tachypnea (see Fig. 17.1). In cases of opiate or sedative drug overdose, the respiratory center is depressed and the rate of breathing gradually decreases until respiratory failure occurs.

Central neurogenic hyperventilation is a respiratory pattern of sustained hyperventilation caused by a lesion in the central pons. **Apneustic respirations** have prolonged inspiratory and expiratory phases caused by injury to the pons or upper medulla. **Cluster respirations** are characterized by periods or clusters of rapid respirations of near equal depth resulting from trauma or compression to the medulla or from chronic opioid abuse. **Ataxic respirations** are irregular respirations with prolonged periods of apnea associated with damage to the medulla (see Fig. 17.1).

Pupillary Changes

Brainstem areas that control arousal are adjacent to areas that control the pupils. Pupillary changes thus are a valuable guide to evaluating the presence and level of brainstem dysfunction (Fig. 17.2). For example, severe ischemia and hypoxia usually produce dilated, fixed pupils. Hypothermia may cause fixed pupils.

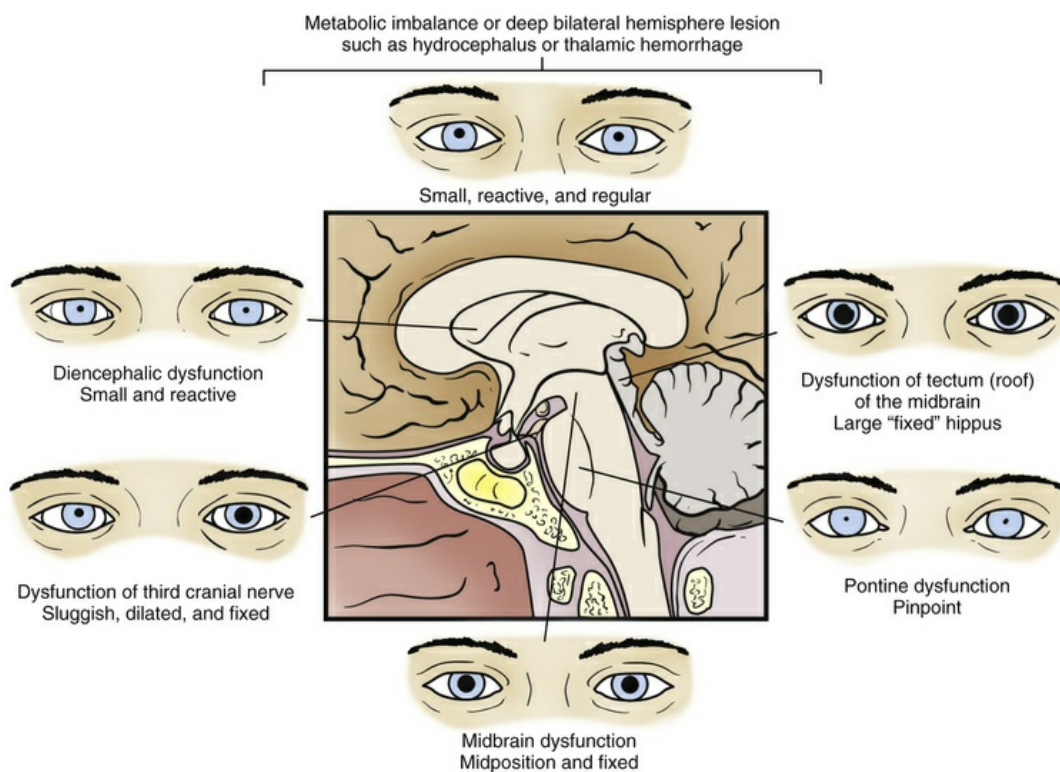

FIGURE 17.2 Appearance of Pupils at Different Levels of Consciousness.

Some drugs affect pupils and must be considered in evaluating individuals in comatose states. Large doses of atropine and scopolamine fully dilate and fix pupils. Doses of sedatives (e.g., glutethimide) in sufficient amounts to produce coma cause the pupils to become midposition or moderately dilated, unequal, and commonly fixed to light. Opiates cause pinpoint pupils. Severe barbiturate intoxication may produce fixed pupils.

Oculomotor Responses

Oculomotor responses (resting, spontaneous, and reflexive eye movements) change at various levels of brain dysfunction in comatose individuals (Table 17.5). Persons with metabolically induced coma, except in cases of barbiturate-hypnotic and phenytoin (Dilantin) poisoning, generally retain ocular reflexes, however, even when other signs of brainstem damage, such as central neurogenic hyperventilation, are present.

TABLE 17.5

CHANGES IN OCULOMOTOR RESPONSES

STATE	RESTING AND SPONTANEOUS EYE MOVEMENTS	REFLEXIVE EYE MOVEMENTS
Full consciousness	Eyes at rest, still (cortical gaze centers inhibit spontaneous roving eye movements)	Eyes move as the head turns Oculocephalic responses not elicited or inconsistently elicited (frontal gaze centers inhibit brainstem reflexes that fix gaze straight ahead) Oculovestibular (caloric) stimulation produces nystagmus
Cortical dysfunction or disruption of efferent pathways	Conjugate, horizontal, roving eye movements may well be present (cortical gaze centers no longer inhibit these brainstem-generated roving eye movements)	Gaze fixed straight ahead regardless of head position—positive doll's eyes reaction (normal oculocephalic reflexes are no longer inhibited by frontal gaze centers)

Diffuse anoxic damage to cortex	“Ocular dipping” – slow, dysrhythmic downward movement followed by faster, upward movement	<p>Nystagmus is no longer induced by caloric stimulation (normally a cold-water stimulus produces deviation of the eyes opposite the irrigated ear; a warm-water stimulus deviates the eyes to the same [ipsilateral] side)</p> <p>With an injury that depresses cortical gaze center function, the eyes (and often the entire head) deviate or appear to look toward the side of the injured hemisphere</p> <p>With an injury that irritates (stimulates) the neurons of the cortical gaze center, the eyes (and often the entire head) deviate away from the injured hemisphere (all fibers from the frontal gaze centers decussate and therefore control the function of the contralateral pontine gaze center, which moves the eyes in the ipsilateral direction)</p>
Mesencephalon dysfunction	<p>Roving eye movements cease, and the eyes become immobile and directed ahead (roving eye movements require an intact brainstem)</p> <p>Eyes may turn down and inward</p>	<p>Oculovestibular reflexes become inconsistent and abnormal</p> <p>Loss of Bell phenomenon (upward deviation of eyes on stimulation) (requires intact eye movement pathways from the mesencephalon to pons)</p>
Pontine dysfunction	<p>Loss of spontaneous blinking (requires an intact pons)</p> <p>“Ocular bobbing” – brisk, conjugate, downward movement of eyes with loss of horizontal eye movements</p>	

The presence of brisk oculocephalic reflexes and roving eye movements, as well as the failure to elicit nystagmus with instillation of cold or warm water into the external ear canal, indicates a decrease in consciousness (loss of cortical influence) but an intact brainstem (Figs. 17.3 and 17.4).

FIGURE 17.3 Test for Oculocephalic Reflex Response (Doll's Eyes Phenomenon). A, Normal response—eyes turn together to side opposite from turn of head. B, Abnormal response—eyes do not turn in conjugate manner. C, Absent response—eyes do not turn as head position changes. (A and C from Rudy EB: *Advanced neurological and neurosurgical nursing*, St Louis, 1984, Mosby.)

FIGURE 17.4 Test for Oculovestibular Reflex (Caloric Ice-Water Test). A, Normal response—conjugate eye movements. B, Abnormal response—dysconjugate or asymmetric eye movements. C, Absent response—no eye movements.

Destructive or compressive injury to the brainstem causes specific abnormalities of the oculocephalic and oculovestibular reflexes. For example, a skewed deviation, in which one eye diverges downward and the other looks upward, indicates brainstem dysfunction. Destructive or compressive disease processes that involve an oculomotor nucleus or nerve cause the involved eye to deviate outward, producing a resting dysconjugate lateral position of the eyes (each eye diverges laterally). Unilateral abducens paralysis (paralysis of cranial nerve VI) results in an upward deviation of the ipsilateral eye. With bilateral abducens paralysis, the eyes come together (converge). Reflexive eye movements may be suppressed by drugs, most commonly phenytoin, tricyclics, and barbiturates. Occasionally alcohol, phenothiazines, and diazepam may alter reflex eye movements.

Motor Responses

Assessment of motor responses helps to evaluate the level of brain dysfunction and determine the side of the brain that is maximally damaged. The pattern of response noted may be (1) purposeful (a defensive or withdrawal movement of limbs to noxious stimuli); (2) inappropriate, or not purposeful (generalized motor movement, posturing, grimacing, or groaning); or (3) not present (unresponsive, no motor response). Purposeful movement requires an intact corticospinal system. Nonpurposeful movement is evidence of severe

dysfunction of the corticospinal system.

Motor signs indicating loss of cortical inhibition are commonly associated with decreased consciousness and include primitive reflexes and rigidity (paratonia) (Fig. 17.5). Primitive reflexes include grasping, reflex sucking, snout reflex, and palmomental reflex, all of which are normal in the newborn but disappear in infancy. Abnormal flexor and extensor responses in the upper and lower extremities are defined in Table 17.6 and illustrated in Fig. 17.6.

FIGURE 17.5 Pathologic Reflexes. A, Grasp reflex. B, Snout reflex. C, Palmomental reflex. D, Suck reflex.

TABLE 17.6

ABNORMAL MOTOR RESPONSES WITH DECREASED RESPONSIVENESS

MOTOR RESPONSE	DESCRIPTION OF MOTOR RESPONSES	LOCATION OF INJURY
Decorticate posturing/rigidity: upper extremity flexion, lower extremity extension (Fig. 17.6)	Slowly developing flexion of the arm, wrist, and fingers with abduction in the upper extremity and extension, internal rotation, and plantar flexion of the lower extremity	Hemispheric damage above midbrain releasing medullary and pontine reticulospinal systems
Decerebrate	Opisthotonos (hyperextension of the vertebral	Associated with severe

posturing/rigidity: upper and lower extremity extensor responses (Fig. 17.6)	column) with clenching of the teeth; extension, abduction, and hyperpronation of the arms; and extension of the lower extremities	damage involving midbrain or upper pons
	In acute brain injury, shivering and hyperpnea may accompany unelicited recurrent decerebrate spasms	Acute brain injury may cause limb extension regardless of location
Extensor responses in the upper extremities accompanied by flexion in the lower extremities		Pons
Flaccid state with little or no motor response to stimuli		Lower pons and upper medulla

FIGURE 17.6 Decorticate and Decerebrate Responses. A, *Decorticate response (flexor posturing)*: bilateral flexion of elbows and wrists with shoulder adduction in upper extremities. Extension, internal rotation of lower extremities (lesions above the midbrain). B, *Decerebrate response (extensor posturing)*: all four extremities in rigid extension, internal rotation of shoulders with hyperpronation of forearms (midbrain lesions). C, *Decorticate response on right side of body and decerebrate response on left side of body*: the most pronounced response differences are in the upper body. (From Rudy EB: *Advanced neurological and neurosurgical nursing*, St Louis, 1984, Mosby.)

Vomiting, yawning, and hiccups are complex reflex-like motor responses that are integrated by neural mechanisms in the lower

brainstem. These responses may be produced by compression or diseases involving tissues of the medulla oblongata (e.g., infection, neoplasm, infarct, or other more benign stimuli to the vagal nerve). Most CNS disorders produce nausea and vomiting. Vomiting without nausea indicates direct involvement of the central neural mechanism (or pyloric obstruction). Vomiting often accompanies CNS injuries that (1) involve the vestibular nuclei or its immediate projections, particularly when double vision (diplopia) also is present; (2) impinge directly on the floor of the fourth ventricle; or (3) produce brainstem compression secondary to increased intracranial pressure.

Outcomes of Alterations in Arousal

Outcomes of alterations in arousal fall into two categories: *extent of disability (morbidity)* and *mortality*. Outcomes depend on the cause and extent of brain damage and the duration of coma. Some individuals may recover consciousness and an original level of function, some may have permanent disability, and some may never regain consciousness and experience neurologic death. Two forms of neurologic death—brain death and cerebral death—result from severe pathologic conditions and are associated with irreversible coma. Other possible outcomes are a vegetative state, a minimally conscious state, or locked-in syndrome. The extent of disability has four subcategories: recovery of consciousness, residual cognitive function, psychologic function, and vocational function.

Brain death (total brain death) occurs when brain damage is so extensive that it can never recover (irreversible) and cannot maintain the body's internal homeostasis. State laws define brain death as irreversible cessation of function of the entire brain, including the brainstem and cerebellum. On postmortem examination, the brain is autolyzing (self-digesting) or already autolyzed. Brain death has occurred when there is no evidence of brain function for an extended period.¹ The abnormality of brain function must result from structural or known metabolic disease and must *not* be caused by a depressant drug, alcohol poisoning, or hypothermia. An isoelectric, or flat, electroencephalogram (EEG) (electrocerebral silence) for 6 to 12 hours

in a person who is not hypothermic and has not ingested depressant drugs indicates brain death. The clinical criteria used to determine brain death are noted in [Box 17.1](#). A task force for determination of brain death in children recommended the same criteria as for adults but with a longer observation period.¹

Box 17.1

Criteria for Brain Death

1. Completion of all appropriate diagnostic and therapeutic procedures with no possibility of brain function recovery
2. Unresponsive coma (no motor or reflex movements)
3. No spontaneous respiration (apnea)
4. No brainstem functions (ocular responses to head turning or caloric stimulation; dilated, fixed pupils; no gag or corneal reflex [see [Figs. 17.3](#) and [17.4](#)])
5. Isoelectric (flat) EEG (electrocerebral silence)
6. Persistence of these signs for an appropriate observation period

EEG, electroencephalogram.

Summarized from Wijdicks EF et al: *Neurology* 74(23):1911-1918, 2010.

Cerebral death or **irreversible coma** is death of the cerebral hemispheres exclusive of the brainstem and cerebellum. Brain damage is permanent, and the individual is unable to ever respond behaviorally in any significant way to the environment. The brainstem may continue to maintain internal homeostasis (i.e., body temperature, cardiovascular functions, respirations, and metabolic functions). The survivor of cerebral death may remain in a coma or emerge into a persistent vegetative state (VS) or a minimally conscious state (MCS). In coma, the eyes are usually closed with no eye opening.

The person does not follow commands, speak, or have voluntary movement (Table 17.7).

TABLE 17.7

COMPARATIVE CLINICAL FEATURES OF ALTERATIONS IN LEVELS OF AROUSAL

DIAGNOSIS	AROUSAL	AWARENESS	COMMUNICATION
Coma	Eyes do not open spontaneously or in response to stimulation	No evidence of perception, communication ability, only reflexes and postural responses	None
Persistent vegetative state	Eyes open spontaneously; no visual tracking; sleep-wake cycle resumes or state of chronic wakefulness; arousal often sluggish	No evidence of cognitive function or purposeful motor activity	None
Akinetic mutism	Eyes open spontaneously; normal sleep-wake cycle; arousal level is normal	Visual tracking present; little or no following of commands	Little or no volitional speech or movement
Minimally conscious state	Eyes open spontaneously; normal to abnormal sleep-wake cycle; arousal level ranges from obtunded to normal	Inconsistent evidence of perception, communication ability, or purposeful motor activity; visual tracking often intact	Inconsistent verbalization and gesturing
Locked-in syndrome	Full arousal; sleep-wake cycle present; quadriplegic	Perceptions and emotions intact	Cannot speak or move muscles except vertical eye movement and blinking

Data from Giacino JT et al: *Neurology* 58(3):349-353, 2002; Owen AM: *Ann N Y Acad Sci* 1125:225–238, 2008.

A **persistent vegetative state (VS)**, or **unresponsive wakefulness syndrome**, is complete unawareness of the self or surrounding environment and complete loss of cognitive function. The individual does not speak any comprehensible words or follow commands.² Sleep-wake cycles are present, eyes open spontaneously, and blood pressure and breathing are maintained without support. Brainstem reflexes (pupillary, oculocephalic, chewing, swallowing) are intact but

cerebral function is lost. There may be random hand, extremity, or head movements. There is bowel and bladder incontinence. Recovery is unlikely if the state persists for 12 months.

In a minimally conscious state (MCS) individuals may follow simple commands; manipulate objects; gesture or give yes/no responses; have intelligible speech; and have movements, such as blinking or smiling, that occur in a meaningful relationship to the eliciting stimulus and are not attributable to reflexive activity.

With **locked-in syndrome (ventral pontine syndrome)** there is complete paralysis of voluntary muscles with the exception of eye movement. Content of thought and level of arousal are intact but the efferent pathways are disrupted (injury at the base of the pons with the reticular formation intact, often caused by basilar artery occlusion).³ The individual cannot communicate either through speech or through body movement but is fully conscious with intact cognitive function. The upper cranial nerves (I through IV) often are preserved, so that the person possesses vertical eye movement and blinking as a means of communication.

Akinetic mutism (AM) is a neurobehavioral state characterized by a severe loss of motivation to move or inability to voluntarily initiate motor responses, or both. It exemplifies an inability to voluntarily execute motor functions including speech, gestures, and facial expression. Generally, these individuals are alert, orient to external stimuli, and can follow the examiner with their eyes but do not initiate other voluntary activity or movement. This is not attributable to decreased wakefulness, motor weakness, or paralysis. The neuropathology is different when compared with the vegetative state and locked-in syndrome and involves damage to the frontal lobe or bilateral cingulate cortex (a component of the limbic system).^{4,5} Combined deficits of vigilance, detection, and working memory accompanied by other deficits of the cognitive systems are common.

Alterations in Awareness

Awareness (content of thought) encompasses all cognitive functions, including awareness of self, environment, and affective states (i.e.,

moods). Awareness is mediated by all of the core networks under the guidance of executive attention networks, including selective attention and memory. Executive attention networks involve abstract reasoning, planning, decision making, judgment, error correction, and self-control. Each attentional function is a network of interconnected brain circuits and not localized to a single brain area.

Selective attention (orienting) refers to the ability to select specific information to be processed from available, competing environmental and internal stimuli and to focus on that stimulus (i.e., to concentrate on a specific task without being distracted).⁶ *Selective visual (spatial) attention* is the ability to select objects/events from multiple visual stimuli (location and movement in visual space) and process them to complete a task. *Selective auditory or hearing attention* is the ability to select or filter specific sounds and process them to complete a task. Multiple areas of the brain are involved in selective attention, including cortical areas, thalamic nuclei, and the limbic system. Frontal and parietal regions of the right hemisphere contribute to selective attention. The engage component (identifying the target of attention) is mediated by the pulvinar nucleus of the thalamus and regulates cortical synchrony⁷ (Fig. 17.7). The disengagement mechanism (shifting attention to a new target and re-engaging on the new target) is mediated by the right parietal lobe. The motor consequences of attention are mediated by the superior colliculi for visual orienting and spatial attention.⁸

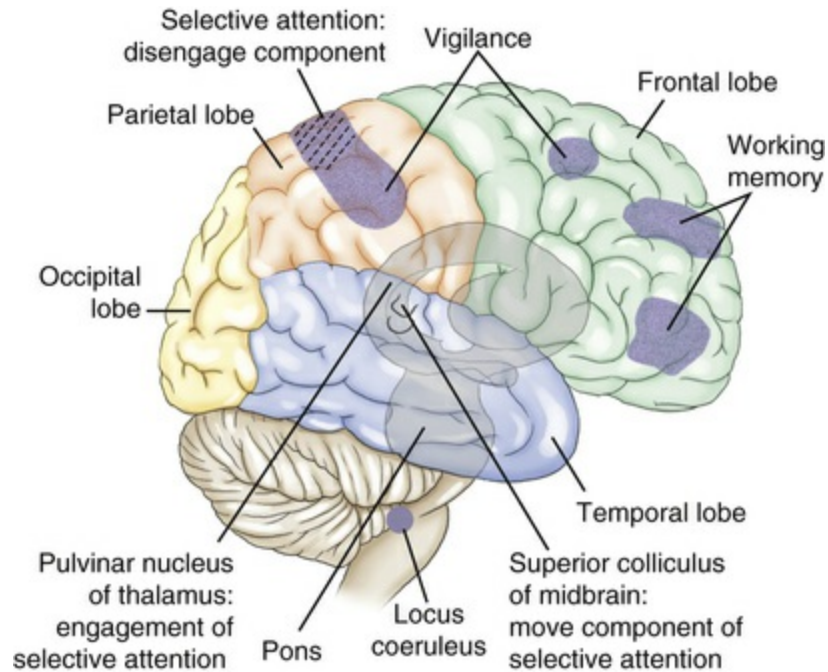

FIGURE 17.7 Right Cortical, Subcortical, and Brainstem Areas of the Brain—Mediating Cognitive Functions. (From Boss BJ, Wilkerson R: Communication: language and pragmatics. In Hoeman SP, editor: *Rehabilitation nursing: prevention, intervention, & outcomes*, ed 4, p 508, St Louis, 2008, Mosby.)

Selective attention deficits can be temporary, permanent, or progressive. Disorders associated with selective attention deficits include seizure activity, parietal lobe contusions, subdural hematomas, stroke, gliomas or metastatic tumor, late Alzheimer dementia, frontotemporal dementia, and psychotic disorders. Disorders of selective attention related to visual orienting behavior are produced by disease that involves portions of the midbrain. Disease affecting the superior colliculi manifests as a slowness in orienting attention. Parietal lobe disease may produce *unilateral neglect syndrome*, which is failure to report, respond, or orient to visual, auditory, or tactile stimuli that are presented contralateral to a brain lesion, provided this failure is not explained by primary sensory or motor disorders. For example, an individual with neglect following a right hemisphere lesion may fail to recognize a left limb, read from the left side of a book, ignore the food on the left side of the plate, remain unaware of numerals on the left side of a clock, or have an abnormal rightward shift in head and eye position. The person is able to

recognize individual sensory input from the ipsilateral side (the side with the hemispheric lesion) when asked, but ignores (i.e., neglects, extinguishes) the sensory input from the contralateral side when stimulated from both sides. This phenomenon is called *extinction*.⁹ The entire complex of sensory inattentiveness, loss of recognition of one's own body parts, and extinction, sometimes referred to as *neglect syndrome*, is common after stroke, generally in the right hemisphere.¹⁰

Memory is the recording, retention, and retrieval of information. Two types of long-term memory exist: declarative and nondeclarative¹¹ (Fig. 17.8). **Declarative memory** involves the learning and remembrance of *episodic memories* (personal history, events, and experiences) and *semantic memories* (facts and information). Declarative memory is mediated by domain-specific cortical areas of the association areas. This includes: (1) areas of the temporal, parietal, and occipital lobes (Fig. 17.9), where long-term memories are thought to be stored; and (2) domain-independent areas of the medial temporal lobe (i.e., hippocampus), the diencephalon (thalamic structures and hypothalamus), and the basal forebrain (located ventral to the striatum and produces acetylcholine) (Fig. 17.10), where it is thought distinct domain-specific features of an experience are related or bound.¹¹

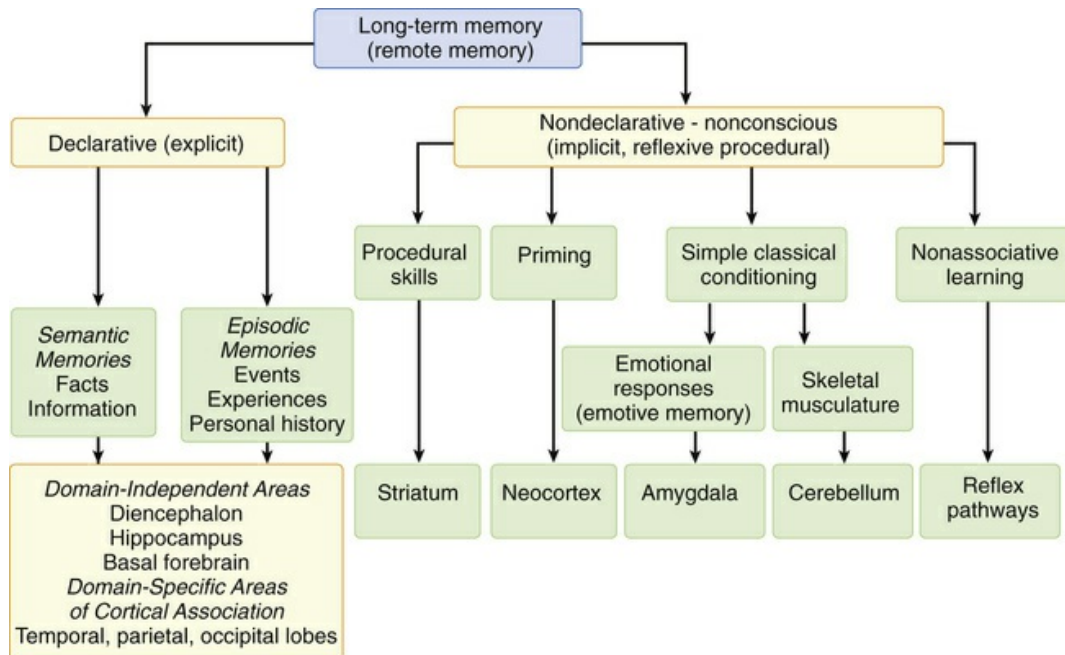

FIGURE 17.8 Types of Memory and Associated Brain Systems. (From Miller RD et al: *Miller's anesthesia*, ed 7, Philadelphia, 2010, Churchill Livingstone.)

FIGURE 17.9 Cortical Areas of the Left (Dominant) Hemisphere. (Adapted from Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

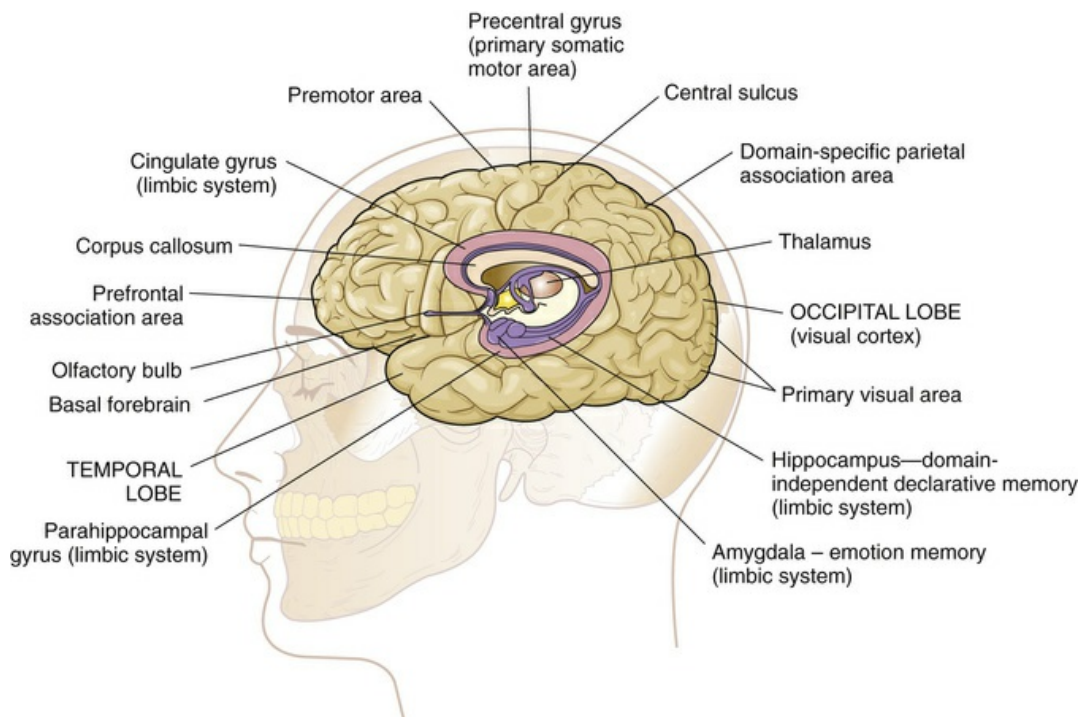

FIGURE 17.10 Midline Cortical and Deep Areas of the Cerebral Hemisphere.

Nondeclarative memory (nonconscious), also called *reflexive, procedural, or implicit memory*, is the memory for actions, behaviors (habits), skills, and outcomes.¹¹ It is not a language memory but a motor memory. Nondeclarative memory involves the construction of the motor pattern so that the action, behavior, or skill becomes increasingly automatic. The striatum of the basal ganglia supports this learning across trials (stimulus-response learning), as well as probabilistic classification learning, which supports outcome prediction. All skills and habits are stored in this memory network.¹² *Cerebellar memory* is involved in working memory (short term memory), in addition to motor coordination and nonmotor functions of cognition, emotion, and learning.¹³ *Emotional memory* is mediated by the amygdala (located on the inner surface of the temporal lobe) (see Fig. 17.10) and other neural networks. The amygdala attaches positive (e.g., pleasure) or negative (e.g., fear) dispositions to stimuli in the

absence of conscious recollection of the circumstances of the emotional experience.¹⁴

Amnesia is the loss of memory and can be mild or severe. Two types of amnesia are retrograde amnesia and anterograde amnesia. The person experiencing retrograde amnesia has difficulty retrieving past personal history memories or past factual memories. In anterograde amnesia, new personal or factual memories cannot be formed, but memories of the distant past are retained and retrieved. These are disorders of domain-independent declarative memory networks, and the hippocampus and other temporal lobe structures often are involved. These memory disorders may be temporary (e.g., after a seizure) or permanent (e.g., after severe head injury or in Alzheimer disease). There may be only the memory disorder, or the memory disorder may be associated with other cognitive disorders. Global amnesia is a combination of anterograde and retrograde amnesia and involves the hippocampus. *Transient global amnesia* has a sudden onset and lasts less than 24 hours. The causal mechanisms are not clear, but it can be associated with migraine headache and cerebrovascular ischemia.¹⁵ *Permanent global amnesia* is rare and associated with damage to the hippocampus.¹⁶ *Domain-specific declarative memory loss* can manifest as agnosias (agnosias are in the section on [Data Processing Deficits](#)).

Image processing is a higher level of memory function and includes the ability to use sensory data and language to form concepts, assign meaning, and make abstractions. Alterations in image processing include an inability to form concepts and generalizations or to reason. Thinking is very concrete. These memory disorders may be temporary (e.g., after a seizure or postconcussive states) or permanent (e.g., after severe head injury, severe stroke, or in Alzheimer disease). There may be only the memory disorder, or the memory disorder may be associated with other cognitive disorders.

The prefrontal areas mediate several cognitive functions, called *executive attention functions* (planning, problem solving, goal setting). The *vigilance system* provides the person with the ability to maintain a sustained state of alertness or concentration for searching and

scanning activities and involves the right frontal areas and the locus ceruleus (LC) (located in the rostral pons) (see Fig. 17.7). Through the neurotransmitter norepinephrine from the LC, the speed of the orienting (selective attention) network is increased and the detection function of the anterior cingulate gyrus (see Fig. 17.10) is decreased.

Detection is the recognition of the object's identity and the realization that the object fulfills a desired goal (i.e., target selection among competing, complex contingencies). There is conscious execution of an instruction, ensuring that the instructions are followed. The anterior cingulate cortex inhibits automatic responses so that a less routine response can be given. The basal ganglia and cingulate, as well as other frontal areas, function in color, motion, and form detection.

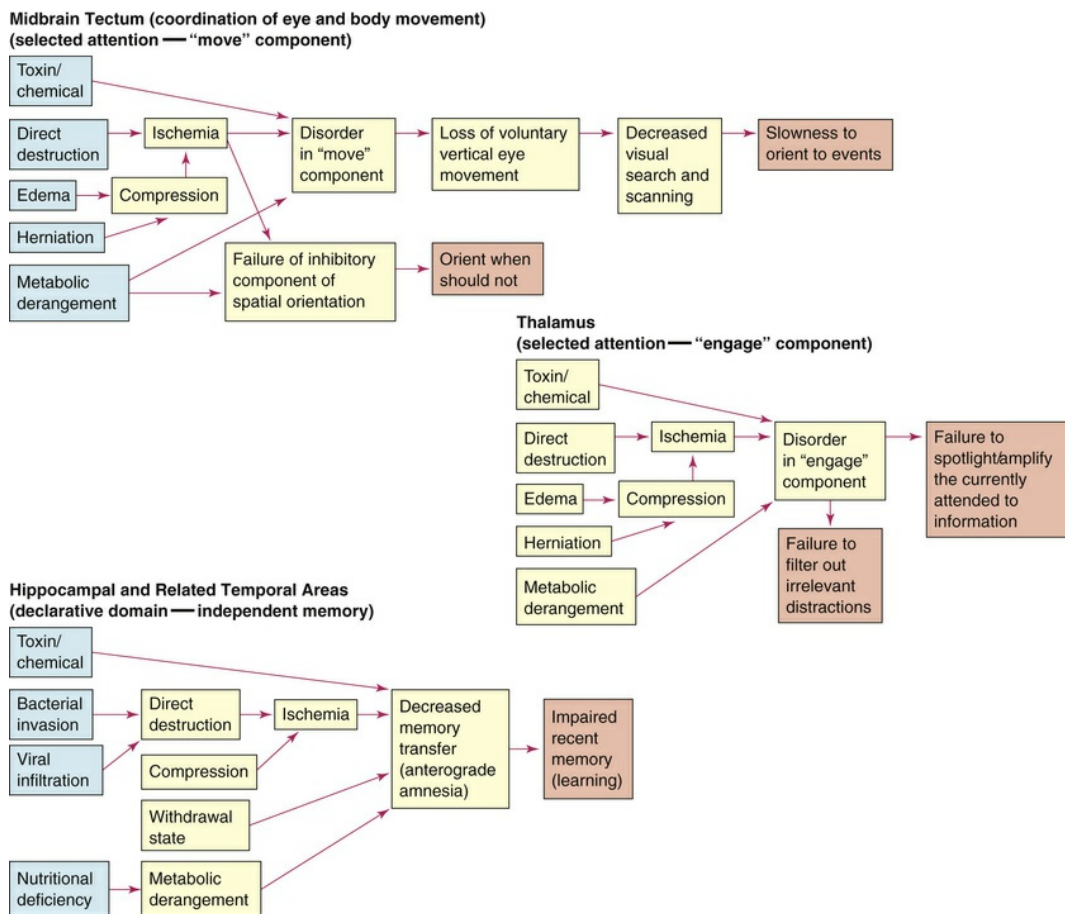

The anterior cingulate plus the ventrolateral and dorsolateral prefrontal cortex (see Fig. 17.10) are involved in the representations of information in the absence of a stimulus, such as spatial position of visual events in memory when the event is removed from view. Working memory (short-term or recent memory) gives the person control over information processing (see Fig. 17.7). These temporary storage areas permit the brain to maintain or discard a limited amount of information (i.e., to retrieve instructions, such as strings or patterns of words or colors) and other information (i.e., strings of digits) needed to maintain a current stream of thought, resist distraction, and perform an immediate task. When attention is diverted, long-term memory is required to complete the task.¹¹ **Isolated (pure) vigilance deficit, detection deficit, and working memory deficits** are uncommon and involve focal lesions of the prefrontal cortex. Whether these losses are temporary or permanent depends on the cause and severity of injury.^{17,18}

Executive attention deficits include the inability to maintain sustained attention and a working memory deficit. Sustained attention deficit is an inability to plan, set goals, and recognize when an object meets a goal. A working memory deficit is an inability to focus and remember instructions and information needed to guide behavior and complete a single task. Executive attention deficits may be temporary,

progressive, or permanent.

◆ Pathophysiology.

Very generally, the primary pathophysiologic mechanisms that operate in disorders of awareness are (1) direct destruction because of direct ischemia and hypoxia or indirect destruction as a result of compression and (2) the effects of toxins and chemicals or metabolic derangement, including processes related to dementia. The pathophysiologic processes are summarized in Fig. 17.11.

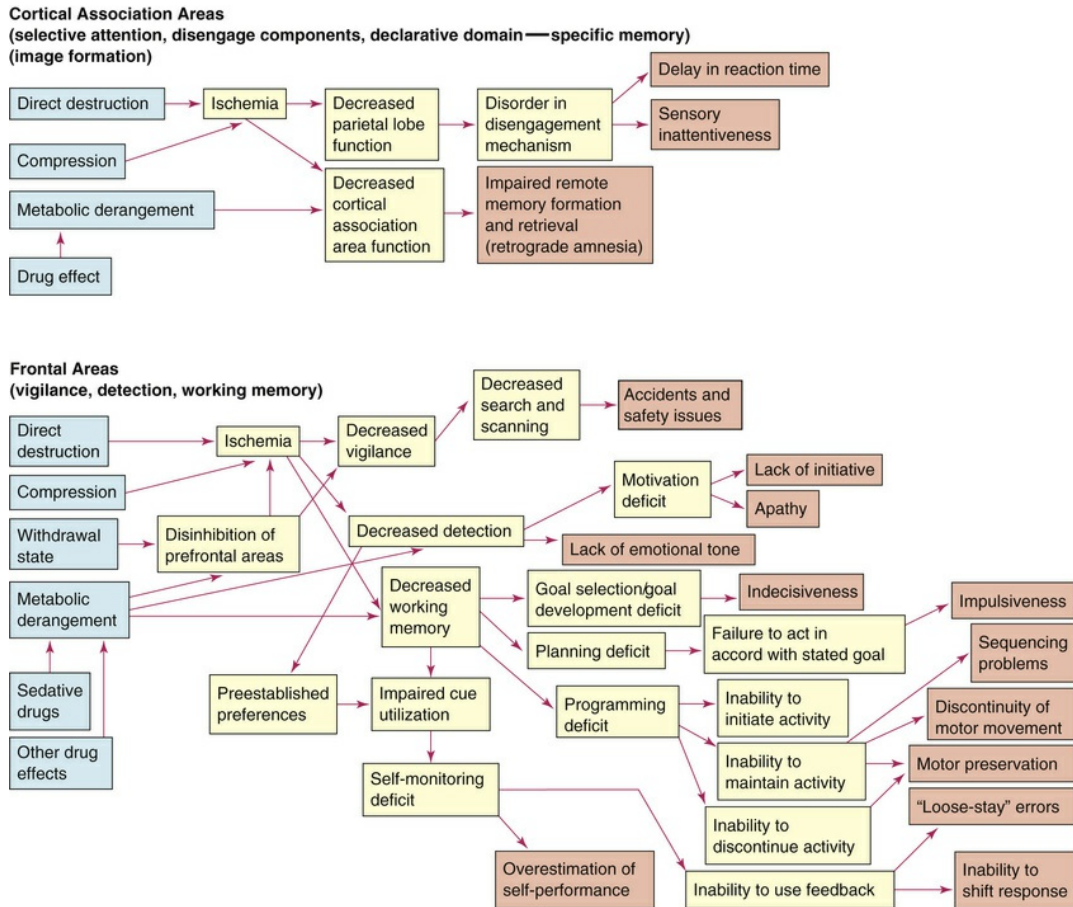

FIGURE 17.11 Cognitive Network Deficits. General pathophysiologic mechanisms underlying cognitive network deficits.

🔗Clinical Manifestations.

Clinical manifestations of selective attention deficits, memory deficits, and executive attention function deficits are presented in [Table 17.8](#).

TABLE 17.8

CLINICAL MANIFESTATIONS OF COGNITIVE NETWORK DEFICITS

DEFICIT	CLINICAL SIGNS	SYMPTOMS
Attention		
Selective attention (orienting)	Inability to focus attention; decreased eye, head, and body movements associated with focusing on the stimuli; decreased search and scanning; faulty orientation to stimuli causing safety problems	Person reports inability to focus attention, failure to perceive objects and other stimuli (history of injuries, falls, and safety problems)

Memory (Long Term, Remote)		
Domain-independent declarative	<p><i>Left hemisphere:</i> disorientation to time, situation, place, name, person (verbal identification); impaired language memory (e.g., names of objects); impaired semantic memory</p> <p><i>Right hemisphere:</i> disorientation to self, person (visual), place (visual); impaired episodic memory (personal history); impaired emotional memory</p>	Person reports disorientation, confusion, "not listening," "not remembering"; reports by others of person being disoriented, not able to remember, not able to learn new information
	<p><i>Either or both hemispheres:</i> confusion; behavioral change</p>	
Domain-specific declarative	<p><i>Left hemisphere:</i> inability to retrieve personal history, past medical history; unaware of recent current events</p> <p><i>Right hemisphere:</i> inability to recognize persons, places, objects, music, etc., from the past</p>	Person reports remote memory problems; others report that person cannot recall formerly known information
Image processing (semantic processing)	Inability to categorize (identify similarities and differences), sort; inability to form concepts; inability to analyze relationships; misinterpretation; inability to interpret proverbs	Reports by others of frequent misinterpretation of data; failure to conceptualize or generalize information
	Inability to perform deductive reasoning (convergent reasoning); inability to perform inductive reasoning (divergent reasoning); inability to abstract; concrete reasoning demonstrated; delusions	Reports by others of predominantly concrete thinking; lack of understanding of everyday situations, healthcare regimens, delusional thinking
Executive Attention Deficits		
Vigilance	Failure to search and scan environment	Person reports accidents, safety issues
Detection	Lack of initiative (anergy); lack of ambition; lack of motivation; flat affect; no awareness of feelings; appears depressed, apathetic, and emotionless; fails to appreciate deficit; disinterested in appearance; lacks concern about childish or crude behavior	Reports by others of laziness or apathy, flat affect or lack of emotional expression, failing to exhibit or be aware of feelings
Mild	Responds to immediate environment but no new ideas; grooming and social graces are lacking	Reports by others of lack of ambition, motivation, or initiative; failure to carry out adult tasks; lack of social graces and new ideas
Severe	Motionless, lack of responding to even internal cues; does not respond to	Reports by others of failure to groom or toilet self, unawareness of

	physical needs; does not interact with surroundings	surroundings and own physical needs
	Inability to use feedback regarding behavior; failure to recognize omissions and errors in self-care, speech, writing, and arithmetic; impaired cue utilization; overestimation of performance	Reports by others of not changing behavior when requested; unawareness of limitations; does not recognize and correct errors in dressing, grooming, toileting, eating; fails to recognize speech and arithmetic errors; careless speech
	Failure to shift response set; failure to change behavior when conditions change; cue utilization may be impaired	Reports by others of failure to use feedback; inability to incorporate feedback (does not correct when feedback is given)
Working memory (recent memory, short-term memory)	Inability to set goals or form goals; indecisiveness	Reports by others of failure to set goals, indecisiveness
	Failure to make plans; inability to produce a complete line of reasoning; inability to make up a story; appears impulsive	Reports by others of failure to plan, impulsiveness, "does not think things through"
	Failure to initiate behavior; failure to maintain behavior; failure to discontinue behavior; slowness to alternate response for the next step; motor perseveration	Reports by others of not knowing where to begin, inability to carry out sequential acts (maintain a behavior), inability to cease a behavior

◆ Evaluation and Treatment.

Immediate medical management is directed at diagnosing the cause and treating reversible factors. Rehabilitative measures for cognitive system deficits generally are either compensatory or restorative in nature and have been greatly facilitated by computer technology and other electronic-assisted devices. Approaches based on behavioral techniques tend to be compensatory, whereas process-oriented approaches, it is hoped, are restorative.

Selective attention and executive attention deficits masquerade as other cognitive deficits. Differential diagnosis of other cognitive deficits is blocked, and learning potential is largely obscured, by the presence of an attention deficit. Therefore diagnosis and treatment of attention deficits are fundamental.

Data Processing Deficits

Data processing deficits are problems associated with recognizing and processing sensory information and include agnosias, aphasias, and acute confusional states.

Agnosia

Agnosia is a defect of pattern recognition—a failure to recognize the form and nature of objects. Agnosia can be tactile, visual, or auditory, but only one sense is generally affected. For example, an individual may be unable to identify a safety pin by touching it with a hand but able to name it when looking at it. Agnosia may be as minimal as a finger agnosia (failure to identify by name the fingers of one's hand) or more extensive, such as a color agnosia.

Agnosia is produced by dysfunction in the primary sensory area or in the interpretive areas of the cerebral cortex (temporo-occipital area) (see Fig. 17.9). The types of agnosia and the associated area that is most commonly involved with each are presented in Table 17.9. Although agnosia most commonly is associated with cerebrovascular accidents, it may arise from any pathologic process that injures these specific areas of the brain.

TABLE 17.9

TYPES OF AGNOSIA (CONCEPT DISORDERS)

TYPE OF AGNOSIA	DEFINITION	LOCATION OF INJURY
Tactile agnosia (astereognosis)	Inability to recognize objects by touch	Parietal lobe
Spatial agnosia	Incapacity to find one's way around familiar places; disturbance of perception of space (disorders of [1] topographic [extrapersonal] orientation or [2] topographic and geographic memory [construction])	Parietal lobe
Gerstmann syndrome	Loss of spatial orientation of fingers, body, sides, and numbers	Left angular gyrus (parietal lobe)
Finger agnosia (digital agnosia)	Inability to identify the names of one's fingers	
Right-left	Inability to distinguish right from left	

confusion		
Agraphia	Inability to write	
Acalculia	Inability to perform mathematic calculations	
Visual agnosia		
Object agnosia	Inability to recognize objects and pictures	Temporo-occipital area
Prosopagnosia	Inability to recognize faces	Temporo-occipital lobe, ventromedial region
Color agnosia	Inability to understand colors as qualities of objects; faulty color concepts and inability to evoke color images in the absence of color blindness; specific types: (1) "hue" problem, (2) color anomia (cannot name color)	Inferior occipital cortex in left hemisphere
Body image agnosias (may be spatial)		
Anosognosia	Ignorance or denial of existence of the disease	Right parietal lobe
Autotopagnosia	Loss of ability to identify the body, in whole or in part, or to recognize relationships among various parts	Right parietal lobe
Word blindness (alexia/dyslexia)	Inability to recognize written symbols	Left parietotemporal region
Auditory agnosia (pure word deafness)	Inability to recognize speech sounds	Superior temporal area
Amusia (music deafness)	Loss of capacity to recognize tones and melodies	Right superior temporal area

Aphasia

Aphasia is impairment of comprehension or production of language with impaired written or verbal communication. The terms aphasia and dysphasia are often used interchangeably; the term aphasia is used here.¹⁹ Aphasia results from dysfunction in the left cerebral hemisphere (i.e., Broca area [inferior frontal gyrus] and Wernicke area [superior temporal gyrus]) and the subcortical and cortical connecting networks (see Fig. 15.8, C). Aphasias are usually associated with a cerebrovascular accident involving the middle cerebral artery or one

of its many branches (see [Fig. 15.22](#)). Language disorders, however, may arise from a variety of injuries and diseases including vascular, neoplastic, traumatic, degenerative, metabolic, or infectious causes. Most language disorders result from acute processes or a chronic residual deficit of the acute process.

Aphasias have been classified anatomically (i.e., Wernicke or Broca area aphasias) or functionally as disorders of fluency (quality and content of speech). Expressive or motor aphasia, also known as *Broca*, *motor*, or *nonfluent aphasia*, involves loss of ability to produce spoken or written language with slow or difficult speech. Verbal comprehension is usually present. Expressive aphasia is differentiated from *dysarthria*, in which words cannot be articulated clearly as a result of cranial nerve damage or muscle impairment. Receptive aphasia, also known as *Wernicke*, *sensory*, or *fluent dysphasia*, involves an inability to understand written or spoken language. Speech is fluent, flowing at a normal rate but words and phrases have no meaning. Anomic aphasia is a sensory aphasia distinguished by difficulty finding words and naming a person or object. Circumlocution, or describing an object as a way of trying to name something, is common in anomic aphasia. Auditory comprehension is present in conductive aphasia but there is impaired verbatim repetition. Naming also can be impaired. The person recognizes the errors and tries to correct them. Speech is fluent but words and sounds may be transposed. Damage is in the left hemisphere to networks that connect Broca and Wernicke areas. Transcortical aphasias are rare and can be motor, sensory, or mixed. They involve areas of the brain that connect into the language centers. Global aphasia is the most severe aphasia and involves both expressive and receptive aphasia. The individual is nonfluent or mute; cannot read or write; and has impaired comprehension, naming, reading, and writing. Global aphasia is usually associated with a cerebrovascular accident involving the middle cerebral artery. [Table 17.10](#) compares types of aphasia, and [Table 17.11](#) illustrates some of the language disturbances. Pure aphasias are rare and are often mixed, making diagnosis difficult. All types of aphasia usually improve with speech

rehabilitation.

TABLE 17.10

MAJOR TYPES OF APHASIA

TYPE	EXPRESSION	VERBAL COMPREHENSION	REPETITION	READING COMPREHENSION
Expressive				
Broca, nonfluent or motor aphasia	Cannot find words, difficulty writing	Relatively intact	Impaired	Variable
Transcortical motor, nonfluent aphasia	Halting speech	Intact	Intact	Impaired
Receptive				
Wernicke, receptive fluent or sensory aphasia	Meaningless verbal language, inappropriate words or unable to monitor language for correctness so errors are not recognized Intonation, accent, cadence, rhythm, and articulation normal	Impaired; disturbance in understanding all language	Impaired	Impaired
Conductive aphasia	Difficulty repeating words, phrases	Intact	Severely impaired	Variable

	spoken to them; naming is impaired			
Anomic aphasia	Hesitancy, difficulty recalling names, objects, or numbers	Intact	Impaired	Variable
Transcortical sensory, fluent aphasia	Repeats words and phrases spoken to them	Poor	Intact	Impaired
Other				
Transcortical mixed motor and sensory, nonfluent	Repeats words and phrases spoken to them	Impaired	Intact	Impaired
Global or nonfluent; summation of motor and sensory aphasia	Mute	Impaired	Impaired	Impaired

TABLE 17.11

EXAMPLES OF APHASIA

DISORDER	EXAMPLE
Wernicke/Fluent/Sensory Aphasia	
Verbal paraphasia	<i>Question:</i> What did the car do?
	<i>Patient:</i> The car would spit sweetly down the road. (The car sped swiftly down the road.)
Literal paraphasia	<i>Request:</i> Say "persistence is essential to success."
	<i>Patient:</i> Mesastence is instans to success.
Neologism	<i>Question:</i> What do you call this? (Pointing to a plant.)
	<i>Patient:</i> It's a logper.
Anomic aphasia (circumlocution example)	<i>Question:</i> What do you call this? (Pointing to a plant.) <i>Patient:</i> Something that grows. <i>Patient:</i> It's ...
	Or
	<i>Question:</i> What did you do this morning?
	<i>Patient:</i> Reading.
	<i>Question:</i> Were you reading a book or newspaper?
	<i>Patient:</i> One of those.
Broca or Motor Aphasia	
Telegraphic style	<i>Question:</i> Where is your daughter?
	<i>Patient:</i> New Orleans ... home ... Monday.

From Boss BJ: *J Neurosurg Nurs* 16(3):151-160, 1984.

Acute Confusional States and Delirium

Acute confusional states (ACSs) (also may be known as *acute organic brain syndromes*) are transient disorders of awareness and may have either a sudden or a gradual onset. Delirium can be considered as a type of acute confusional state, but for this discussion acute confusional states and delirium are considered to be synonymous. The many medical conditions associated with delirium are summarized in [Box 17.2](#). It most commonly occurs in critical care units, following surgery, or during withdrawal from central nervous system depressants (i.e., alcohol or narcotic agents). Hospitalized older individuals are at greatest risk for delirium.²⁰

Box 17.2

Conditions Causing Acute Confusional States or Delirium

- Drug intoxication
- Alcohol or drug withdrawal
- Metabolic disorders (i.e., hypoglycemia, thyroid storm)
- Brain trauma or surgery
- Postanesthesia
- Febrile illnesses or heat stroke
- Electrolyte imbalance, dehydration
- Heart, kidney, or liver failure

◆Pathophysiology.

Acute confusional states arise from disruption of a widely distributed neural network involving the reticular activating system of the upper brainstem and its projections into the thalamus, basal ganglion, and specific association areas of the cortex and limbic areas (see [Figs. 17.7, B](#) and [17.10](#)). **Delirium** is associated with autonomic nervous system hyperactivity and typically develops over 2 to 3 days. Hyperactive delirium (hyperactive confusional state) is associated with right-upper middle-temporal gyrus or left-temporal-occipital junction disruption. Several neurotransmitters are involved, including decreased acetylcholine and/or melatonin; excess in dopamine, norepinephrine, and/or glutamate release; and variable alterations (e.g., either a decreased or increased activity, depending on delirium presentation and cause) in serotonin, histamine, and/or γ -aminobutyric acid.²¹ Inflammatory cytokines, including C-reactive protein, interleukins, interferon, and tumor necrosis factor-alpha (TNF- α), may contribute to delirium by altering blood-brain barrier permeability causing oxidative stress, altering cerebral blood flow, and activating microglia, all affecting neurotransmission and subsequent neurobehavioral and

cognitive symptoms.²² Most metabolic disturbances (i.e., hypoglycemia, thyroid disorders, liver or kidney disease) that produce delirium interfere with neuronal metabolism or synaptic transmission. Many drugs and toxins also interfere with neurotransmission function at the synapse. Hypoactive delirium (hypoactive confusional state) is more likely to be associated with right-sided frontal-basal ganglion disruption.

◆Clinical Manifestations.

Delirium initially manifests as difficulty in concentrating and focusing attention, restlessness, irritability, insomnia, tremulousness, and poor appetite. Some persons experience seizures. Unpleasant, even terrifying dreams, hallucinations or delusions may occur. In a fully developed delirium state, the individual is completely inattentive and perceptions are grossly altered, with extensive misperception and misinterpretation. The person appears distressed and often perplexed; conversation is incoherent. Frank tremor and high levels of restless movement are common. Violent behavior may be present. The individual cannot sleep, is flushed, and has dilated pupils, a rapid pulse rate (tachycardia), elevated temperature, and profuse sweating (diaphoresis).

Excited delirium syndrome (ExDS), also known as *agitated delirium*, is a type of hyperkinetic delirium that can lead to sudden death. Its symptoms include altered mental status, combativeness, aggressiveness, tolerance to significant pain, rapid breathing, sweating, severe agitation, elevated temperature, noncompliance or poor awareness to direction from police or medical personnel, inability to become fatigued, unusual or superhuman strength, and inappropriate clothing for the current environment. Hypoglycemia, thyroid storm, certain kinds of seizures, cocaine or methamphetamine intoxication, and/or catecholamine-induced fatal arrhythmias are associated with ExDS.²³

Hypoactive delirium is associated with underactivity and may occur in individuals who have fevers or metabolic disorders (i.e., chronic liver or kidney failure) or who are under the influence of

central nervous system depressants or are postoperative. The individual exhibits decreases in mental function, specifically alertness, attention span, accurate perception, interpretation of the environment, and reaction to the environment. Forgetfulness, confusion, and apathy are prominent, speech may be slow, and the individual dozes frequently. Hypoactive delirium can be mistaken for depression or dementia.²⁴

Mixed delirium is a combination of both types of delirium fluctuating from one to the other. Delirium resolves suddenly or gradually in 2 to 3 days, although delirium states occasionally persist for weeks.

◆Evaluation and Treatment.

An ACS is an acute medical problem. The initial goal is to establish that the individual is confused, and to identify the cause and contributing factors. Hypokinetic delirium will need to be differentiated from depression or an underlying dementia^{25,26} (Table 17.12). A complete history and physical examination, as well as laboratory tests including an electrocardiogram and blood, urine, cerebral spinal fluid (CSF), and imaging studies are needed. Several assessment scales are available to guide evaluation.²⁷⁻²⁹

TABLE 17.12

COMPARISON OF DELIRIUM AND DEMENTIA

FEATURE	DELIRIUM	DEMENTIA
Age	Usually older	Usually older
Onset	Acute—common during hospitalization	Usually insidious; acute in some cases of strokes/trauma
Associated conditions	Urinary tract infection, thyroid disorders, hypoxia, hypoglycemia, toxicity, fluid-electrolyte imbalance, renal insufficiency, trauma, multiple medications	May have no other conditions Brain trauma
Course	Fluctuating; remits with treatment	Chronic slow decline, usually starts with memory loss
Duration	Hours to weeks	Months to years

Attention	Impaired	Intact early; often impaired late
Sleep-wake cycle	Disrupted	Usually normal or fragmented
Alertness	Impaired	Normal
Orientation	Impaired	Intact early; impaired late
Behavior	Agitated, withdrawn/depressed	Intact early
Speech	Incoherent, rapid/slowed	Word-finding problems
Thoughts	Disorganized, delusions	Impoverished
Perceptions	Hallucinations/illusions	Usually intact early

Adapted from Caplan JP, Rabinowitz T: *Med Clin North Am* 94(6):1103-1116, ix, 2010.

Once the cause is established, treatment is directed at controlling the primary disorder. Drugs that may be contributing to or causing the condition are discontinued unless the problem is the result of drug withdrawal. Both nonpharmacologic (i.e., orientation to surroundings, pain management, hydration, nutrition, early mobilization, sleep maintenance) and pharmacologic (i.e., antipsychotics) interventions may be implemented.^{30,31} Delirium is preventable in some individuals with management of risk factors and early intervention.

Dementia

Dementia is an acquired deterioration and a progressive failure of many cerebral functions that includes impairment of intellectual processes with a decrease in orienting, memory, language, judgment, and decision making. Because of declining intellectual ability, the individual may exhibit alterations in behavior, for example, agitation, wandering, and aggression.

Dementias can be classified according to etiologic factors (e.g., trauma, tumors, vascular disorders, infections) and to associated clinical and laboratory signs. Dementing processes also have been grouped as cortical, subcortical, or both. [Box 17.3](#) lists the potentially reversible and irreversible causes of dementia. Alzheimer disease

(AD) is the most common cause followed by vascular dementia, then dementia associated with Lewy bodies (i.e., Parkinson disease [see section on [Parkinson Disease](#)]), and frontotemporal dementia.^{32,33} In people younger than 60 years, frontotemporal dementia (FTD) rivals AD in terms of frequency.³⁴

Box 17.3

Causes of Dementia

Potentially Reversible Causes of Dementia

Infection

- Encephalitis
- Meningitis
- Neurosyphilis

Normal Pressure Hydrocephalus

- Chronic Subdural Hematoma
- Nutritional Deficiencies

- Vitamin B₁ (thiamine) deficiency
- Vitamin B₁₂ (cobalamin) deficiency
- Nicotinic acid deficiency (pellagra)

Chronic Drug Intoxication

- Alcohol*
- Sedatives

Metabolic Disorders

- Thyroid abnormalities

Chronic hepatic encephalopathy
Cerebral vasculitis
Sarcoidosis

Some Types of Tumors

Frontal and temporal lobe
Pseudodementia of depression

Medical Side Effects

Anticholinergics
Antihypertensives
Antihistamines

Irreversible Causes of Dementia

Neurodegenerative Disorders

Alzheimer disease*
Dementia with Lewy bodies
Frontotemporal dementia
Pick disease
Huntington disease
Parkinson disease

Vascular Disease

Vascular dementia*
Multi-infarct
Strategic single infarct
Binswanger disease* (diffuse white matter disease)
Amyloid angiopathy

Infection

Creutzfeldt-Jakob disease (CJD)
 Postencephalitic dementia
 Dementia associated with HIV

—————
 *Most common.

◆Pathophysiology.

Mechanisms leading to dementia include neuron degeneration, compression of brain tissue, atherosclerosis of cerebral vessels, and brain trauma. Genetic predisposition (Table 17.13) is associated with the neurodegenerative diseases, including Alzheimer, Huntington (see section on Huntington Disease), and Parkinson diseases (see section on Parkinson Disease). CNS infections, including the human immunodeficiency virus (HIV) and prions in Creutzfeldt-Jakob disease (Table 17.13 and Box 17.4), also lead to nerve cell degeneration and brain atrophy.

TABLE 17.13

THE MOLECULAR BASIS FOR DEGENERATIVE DEMENTIA

DEMENTIA	MOLECULAR MECHANISM	CAUSAL GENES (CHROMOSOME)	SUSCEPTIBILITY GENES (CHROMOSOME)	PATHOLOGY
Alzheimer disease (familial)	Amyloid beta protein	<i>Early onset: autosomal dominant:</i> <2% carry these mutations <i>APP</i> (21), <i>PSEN1</i> (14), <i>PSEN2</i> (1) (most mutations are in <i>PSEN1</i>)	<i>Late onset: risk gene apoE4</i> (19) <i>CUGBP2</i> (10p)	Amyloid plaque neurofibrillar tangles; neuronal and synaptic loss in the brain
Creutzfeldt-Jakob	PrP ^{SC} proteins type	Prion (20) (up to 15%)	<i>PRNP</i> codon 129	Tau inclusions,

disease (hereditary form)	1 and 2	of cases carry these dominant mutations)	homozygosity for methionine or valine	spongiform changes, gliosis
Dementia with Lewy bodies	Alpha-synuclein	Very rare alpha-synuclein (4) (dominant)	Unknown	Alpha-synuclein inclusions (Lewy bodies)
Behavioral variant frontotemporal dementia	Microtubule-associated protein tau (MAPT) Progranulin (PGRN)	Tau exon and intron mutation (17) (about 10% of familial cases) <i>PGRN</i> (17) (10% of familial cases)	Tau haplotypes (<i>H1</i> and <i>H2</i>)	Tau inclusions, Pick bodies, neurofibrillar tangles
Huntington disease (autosomal dominant)	Huntingtin protein (polyglutamine)	<i>Autosomal dominant:</i> <i>HD-IT15</i> (4) (trinucleotide repeat expansion)	None known	Neuronal degeneration astrogliosis
Parkinson disease Dementia	<i>Autosomal dominant:</i> Alpha-synuclein Leucine-rich repeat kinase 2 <i>Autosomal recessive:</i> Parkin (juvenile onset) DJ-1 protein PTEN-induced putative kinase 1	<i>Autosomal dominant:</i> <i>SNCA-PARK1</i> (4) <i>LRRK2-PARK8</i> (12) <i>Autosomal recessive:</i> <i>PARK2</i> (4) oncogene DJ-1 (<i>PARK7</i>) <i>PINK1 (PARK6)</i>	<i>GBA</i> (glucosidase beta acid) <i>SNCAIP</i> (alpha-synuclein interacting protein) <i>NR4A2</i> (orphan nuclear receptor) <i>UCH-L1 (PARK5)</i> ubiquitin C-terminal hydrolase Other low-risk genes	Neuronal degeneration alpha-synuclein inclusions (Lewy bodies) gliosis; neuronal degeneration

APP, Amyloid precursor protein; *PRNP*, prion protein; *PrP^{Sc}*, prion protein scrapie form; *PSEN*, presenilin; *PTEN*, phosphatase and tensin homolog.

Box 17.4

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease is a progressive, fatal, dementing

neurologic illness caused by an infectious protein known as a *prion*. Prions are composed of misfolded prion proteins and are able to self-replicate and cause spongiform encephalopathy (numerous small vacuoles within the grey matter). The incidence is about 1 in 1.5 million population per year, and 10% of cases are genetic. Most cases are sporadic. Diagnosis is made by clinical evaluation, magnetic resonance imaging, and electroencephalography. Spinal fluid analysis shows the presence of 14-3-3 protein or human prion protein (PrP^{Sc}), and it also may be detected in olfactory epithelium, blood, and/or urine samples. There is progressive dementia and at least two of the four following features: myoclonus, visual or cerebellar disturbance, pyramidal or extrapyramidal signs, and akinetic mutism. The disease is fatal in an average of 8 months, and there is no treatment. Tissue from persons with prion disease must not be transplanted. Animal forms of prion disease include scrapie in sheep; chronic wasting disease in deer, elk, and moose; and bovine spongiform encephalopathy (BSE) in cows. BSE can be transmitted to humans by consumption of infected meat and is known as *new variant Creutzfeldt-Jakob disease*.

Data from Iwasaki Y: Creutzfeldt-Jakob disease, *Neuropathology* 37(2):174-188, 2017; Kim MO, Geschwind MD: *Curr Opin Neurol* 28(3):302-310, 2015; Lee J et al: *J Med Virol* 87(1):175-186, 2015.

◆Clinical Manifestations.

Clinical manifestations of the major dementias are presented in [Table 17.14](#).

TABLE 17.14

CLINICAL DIFFERENTIATION OF THE MAJOR DEGENERATIVE DEMENTIAS

DISEASE	MENTAL STATUS	NEUROBEHAVIOR	NEUROLOGIC EXAMINATION
Alzheimer disease	Memory loss, disorientation to place and time, loss of facial recognition	Initially normal; progressive cognitive, language, abstraction, and judgment impairment	Initially normal

Creutzfeldt-Jakob disease	Variable, frontal/executive, focal cortical, memory	Depression, anxiety, decreased cognitive function, and memory loss	Myoclonus, rigidity, parkinsonism
Dementia with Lewy body (Lewy body dementia)	Initially affects concentration and attention, then memory or cognition loss but unpredictable levels of ability, attention, or alertness; delirium prone	Visual hallucinations, depression, sleep disorder, delusions, transient loss of consciousness	Parkinsonism Changes in walking or movement may present first
Frontotemporal disorders/degeneration/dementia	PPA variant Language loss with talking less and speech becoming hesitant, or loss of understanding of language, which may precede memory loss; spares drawing	Behavioral variant FTD Loss of empathy (emotional blunting), apathy, increased inappropriate or decline in personal or social conduct, loss of judgment and reasoning, hyperorality, euphoria, depression	Caused by CBD and PSP variants
Huntington disease		Apathy, loss of interest early; impaired cognition, judgment, and memory occur later	Chorea, bradykinesia, dystonia
Vascular dementia	Frontal/executive, cognitive slowing; memory can be intact	Often but not always sudden, usually within 3 months of a stroke; variable; apathy, falls, focal weakness, delusions, anxiety	Usually motor slowing, spasticity; can be normal or may have symptom improvement with stroke recovery

FTD, frontotemporal dementia; *CBD*, corticobasal degeneration; *PPA*, primary progressive aphasia; *PSP*, progressive supranuclear palsy.

Data from Bott NT et al: *Neurodegener Dis Manag* 4(6):439-454, 2014; Darrow MD: *Prim Care* 42(2):195-204, 2015; Hugo J, Ganguli M: *Clin Geriatr Med* 30(3):421-442, 2014; Nordberg A: *Nat Rev Neurol* 11(2):69-70, 2015.

◆ Evaluation and Treatment.

Establishing the cause for a dementia may be complicated, but individuals with clinical manifestations of dementia should be evaluated with laboratory and neuropsychologic testing to identify underlying conditions that may be treatable. Unfortunately, no specific cure exists for most progressive dementias. Therapy is directed at maintaining and maximizing use of the remaining capacities, restoring functions if possible, and accommodating to lost abilities. Helping the family to understand the process and to learn ways to assist the individual is essential.

Alzheimer Disease.

Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex) is the leading cause of severe cognitive dysfunction in older adults. The three forms of AD are nonhereditary sporadic or late-onset AD (70% to 90%), early-onset familial AD (FAD), and early-onset AD (very rare). An estimated 5.3 million Americans have AD, and two-thirds of these individuals are women.³⁵ The greatest risk factors are age and family history. Other proposed risk factors include diabetes, midlife hypertension, hyperlipidemia, midlife obesity, smoking, depression, cognitive inactivity or low educational attainment, female gender, estrogen deficit at the time of menopause, physical inactivity, head trauma, elevated serum homocysteine and cholesterol levels, oxidative stress, and neuroinflammation (Fig. 17.12). Proposed protective factors include lifelong activity, the presence of *apoE2* and antioxidant substances, omega-3 fatty acids, estrogen replacement at the time of surgical menopause, low-calorie diet, and use of nonsteroidal anti-inflammatory agents.³⁶⁻³⁹ Statins are being investigated for their role in preventing AD; recent reviews do not support their use.⁴⁰

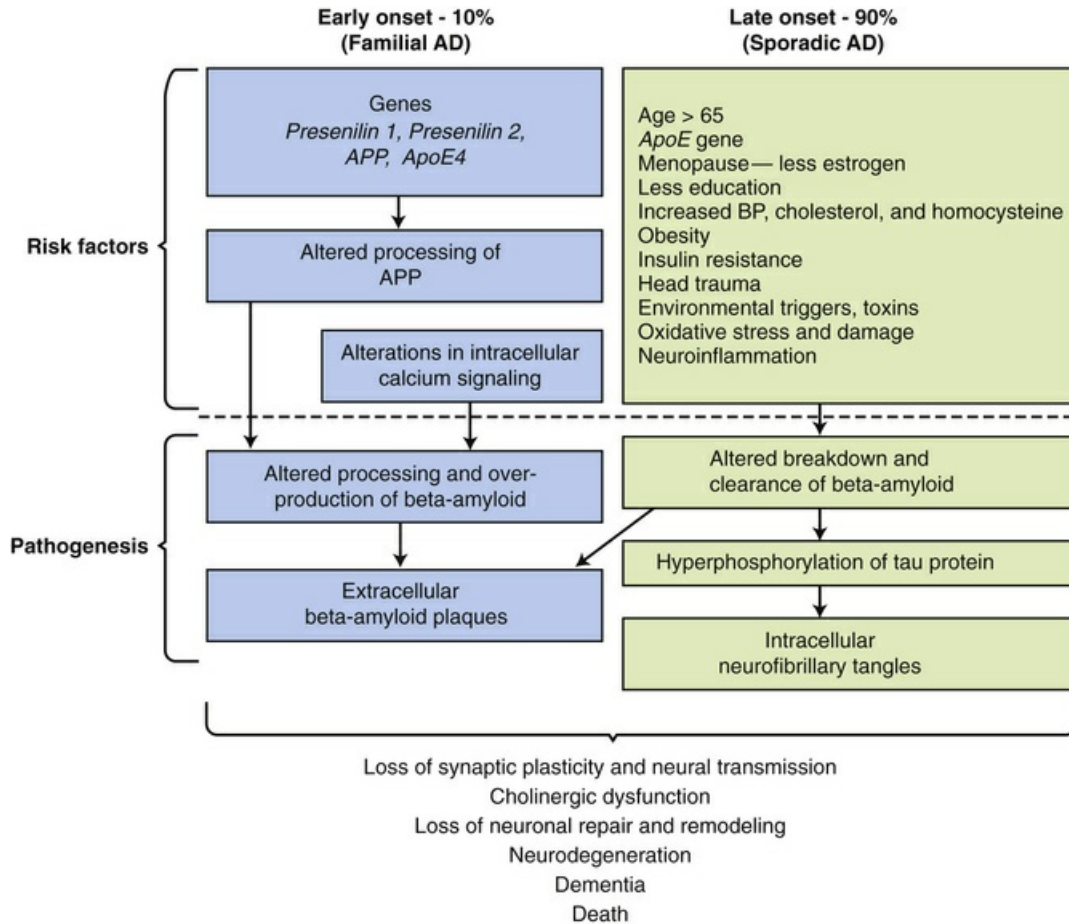

FIGURE 17.12 Proposed Risk Factors and Pathogenesis of Alzheimer Disease (AD). *ApoE*, Apolipoprotein E; *APP*, amyloid precursor protein; *BP*, blood pressure. (Data from Barnes DE, Yaffe K: *Lancet Neurol* 10[9]:819-828, 2011; de la Monte SM: *Drugs* 72[1]:49-66, 2012; Daviglus ML et al: *Arch Neurol* 68[9]:1185-1190, 2011; Hasan MK, Mooney RP: *W V Med J* 107[3]:26-29, 2011.)

◆Pathophysiology.

The exact cause of AD is unknown. Early-onset FAD is autosomal dominant and has been linked to three genes with mutations on chromosome 21 (abnormal amyloid precursor protein 14 [*APP14*], abnormal presenilin 1 [*PSEN1*], and abnormal presenilin 2 [*PSEN2*]). The major genetic risk for late-onset AD is related to apolipoprotein E gene-allele 4 (*apoE4*) on chromosome 19, which interferes with amyloid beta clearance from the brain and also is processed into neurotoxic fragments found in the plaques and tangles in the brain of people with AD.⁴¹ Studies are ongoing to classify the genetic

variations of AD; genome-wide association studies have identified numerous single nucleotide variations for late-onset Alzheimer disease.⁴² Epigenetic mechanisms are associated with the pathology of Alzheimer disease, but the mechanisms are yet to be determined.⁴³

Sporadic late-onset AD is the most common and does not have a specific genetic association; however, the cellular pathology is the same as that for gene-associated early- and late-onset AD.⁴⁴ Pathologic alterations in the brain include accumulation of extracellular neuritic plaques containing a core of abnormally folded amyloid beta and tau proteins, intraneuronal neurofibrillary tangles, and degeneration of basal forebrain cholinergic neurons with loss of acetylcholine. Failure to process and clear amyloid precursor protein results in the accumulation of toxic fragments of amyloid beta protein that leads to formation of diffuse neuritic plaques, disruption of nerve impulse transmission, and death of neurons. Aging and injury may result in changes that contribute to the development and progression of this disease. Misfolded and aggregated proteins trigger immune responses with activation of glial cells and release of cytokines leading to neuroinflammation and oxidative stress; decreased oxygen and glucose transport; molecular changes in vascular smooth muscle and in the blood-brain barrier; and mitochondrial defects that alter cell metabolism and processing of proteins, including amyloid (apolipoprotein-4) (*apoE4*), that lead to cell death.⁴⁵⁻⁴⁸

Amyloid also is deposited in the smooth muscle of cerebral arteries, causing an amyloid angiopathy and disturbance in blood flow⁴⁹ (Fig. 17.13). The tau protein, a microtubule-binding protein, in neurons detaches and forms an insoluble filament called a **neurofibrillary tangle**, contributing to neuronal death. Tangles are flame-shaped (Fig. 17.14). Neuritic plaques and neurofibrillary tangles are more concentrated in the cerebral cortex and hippocampus (important for memory). The loss of neurons results in brain atrophy with decreases in weight and volume. The sulci widen and the gyri thin, especially in the frontal and temporal lobes, and the ventricles enlarge to fill the space (Fig. 17.15). Loss of synapses, acetylcholine, and other neurotransmitters contributes to the decline of memory and attention

and the loss of other cognitive functions associated with AD.

FIGURE 17.13 Altered Cerebral Blood Flow in Alzheimer Disease. Single photon emission computerized tomography scan showing reduction of temporoparietal blood flow (*right*) compared with normal blood flow (*left*). (From Perkin GD et al: *Atlas of clinical neurology*, ed 3, Philadelphia, 2011, Saunders.)

FIGURE 17.15 Comparison of Normal and Alzheimer Brain. The brain decreases in volume and weight, the sulci widen, and the gyri thin, especially in the temporal and frontal lobes. The ventricles enlarge to fill the space. (From National Institute on Aging Scientific Images, *Brain images*. Available at <https://www.nia.nih.gov/alzheimers/scientific-images>.)

◆Clinical Manifestations.

AD has a long preclinical and prodromal course, and pathophysiologic changes can occur decades before the appearance of the clinical dementia syndrome. The disease progresses from mild short-term memory deficits to total loss of cognition and executive functions. Initial clinical manifestations are insidious and often attributed to forgetfulness, emotional causes, or other illness. The individual becomes progressively more forgetful over time, particularly in relation to recent events. Memory loss increases as the disorder advances, and the person becomes disoriented, confused, and loses the ability to concentrate. Abstraction, problem solving, and judgment gradually deteriorate with failure in mathematic calculation ability, language, and visuospatial orientation. Dyspraxia may appear. The mental status changes induce behavioral changes, including

irritability, agitation, and restlessness. Mood changes also result from the deterioration in cognition. The person may become anxious, depressed, hostile, emotionally labile, and prone to mood swings. Motor changes may occur if the posterior frontal lobes are involved, causing rigidity and flexion posturing. Weight loss can be significant (see *Nutrition & Disease: Diet and Alzheimer Disease*). Great variability in age of onset, intensity and sequence of symptoms, and location and extent of brain abnormalities is common. Stages for the progression of Alzheimer disease are summarized in [Table 17.15](#).

TABLE 17.15

PROGRESSION OF ALZHEIMER DISEASE

STAGE	MILD COGNITIVE IMPAIRMENT	EARLY STAGE	MIDDLE STAGE	LATE STAGE	END STAGE
Cognitive	Mild memory loss, particularly for recent event (episodic memory) and new information (semantic memory)	Measurable short-term memory loss; difficulty planning; disorientation to location	Significant forgetfulness; easy to get lost; may dress inappropriately; may have hallucinations	Little cognitive ability; language not clear; personality change; does not recognize family members; wandering; repetitive behavior	No significant cognitive function; loss of speech
Functional	Possibly depression (vs. apathy); mild anxiety	Mild IADL problems	IADL-dependent; some ADL problems	ADL-dependent; incontinent; difficulty eating	Nonambulatory/unable to eat

ADL, Activities of daily living; *IADL*, instrumental activities of daily living.

Adapted from National Conference of Gerontological Nurse Practitioners and the National Gerontological Nursing Association, *Counseling Points* 1(1):6, 2008.

Nutrition & Disease

Nutrition and Alzheimer Disease (AD)

Research is in progress to evaluate the effects of nutrition on delaying the onset and preventing the progression of AD. Nutrition has a role in arresting the pathogenesis of dementia, particularly processes related to oxidative stress, inflammation, and vascular disease. Dietary patterns that include a diet high in fruits, vegetables, other plant-derived products, fish and lower intakes of meat, saturated fats, and added refined sugar have been associated with reduced cognitive decline. Diets and supplements that include docosahexaenoic acid (DHA-an omega-3 fatty acid), the vitamin B family, antioxidant vitamins E and C, and vitamin D have shown some evidence in sustaining healthy neurons. Adherence to a Mediterranean diet also has shown reduced risk for AD. Weight loss is a major concern for older adults with AD and it may precede onset of the classic motor symptoms. Weight loss may be a result of (1) increased incidence of infection, (2) increased energy output because of constant pacing, (3) olfactory and taste changes making food less appealing, (4) inadequate food intake, (5) decreased independence and difficulty in self-feeding, and (6) loss of neural regulation of appetite. Dementia may lead to memory loss, social isolation, depression, and poor food intake with resultant weight loss. Individuals may forget or refuse to eat, fail to communicate the need to eat, throw away or hide food, eat spoiled food or nonfood substances, eat favorite foods to the exclusion of other foods, take a long time to eat, have difficulty in preparing foods, and be unable to feed themselves. Reduced lean body mass has been associated with brain atrophy and declining cognitive performance. Nutritional intervention is an important component of care for individuals with Alzheimer disease.

Data from Barnard ND et al: *Neurobiol Aging* 35(Suppl 2):S74-S78, 2014; Droogsman E, van Asselt D, De Deyn PP: *Z Gerontol Geriatr* 48(4):318-324, 2015; Mohajeri MH, Troesch B, Weber P: *Nutrition* 31(2):261-275, 2015; Singh B et al: *J Alzheimers Dis* 39(2):271-282, 2014; Swaminathan A, Jicha GA: *Front Aging Neurosci* 6:282, 2014; eCollection 2014; van de Rest O

◆ Evaluation and Treatment.

The clinical diagnosis of AD is made by ruling out other causes, and criteria have been developed to assist diagnosis.⁵⁰⁻⁵² The definitive diagnosis can only be made at autopsy.

The clinical history, including mental status examinations (mini-mental status examination, clock drawing, and geriatric depression scale), cerebrospinal fluid analysis, brain imaging of structure, blood flow and metabolism, and the course of the illness (which may span 5 years or more) is used to assess progression of the disease. Genetic susceptibility tests for *PSEN1*, *PSEN2*, and *APP* are used to screen for early-onset AD.⁵³ Efforts are underway to identify imaging and biochemical markers to assist with risk assessment, early diagnosis, and evaluation of progression of Alzheimer-type and other neurodegenerative causes of dementia.^{54,55}

Treatment is directed at using devices to compensate for the impaired cognitive function, such as memory aids; maintaining unimpaired cognitive functions; and maintaining or improving the general state of hygiene, nutrition, and health. There are no disease-modifying therapies. Cholinesterase inhibitors (ChE-Is) are used in mild cases to moderate AD. An *N*-methyl-D-aspartate (NMDA) receptor antagonist blocks glutamate activity and may slow progression of disease in moderate to severe AD.^{56,57} Anti-amyloid drugs are in clinical trials.

Vascular Dementia.

Vascular dementia is a progressive disease caused by reduced brain blood flow and accounts for 10% to 15% of cases. The pathology can be variable, including multiple infarcts and hemorrhages that occur in different parts of the brain, and can be related to stroke and small vessel disease. The disease can be difficult to clinically differentiate from AD, and the symptoms can be much more variable. The diseases often coexist. Loss of executive functions, attention deficit, and loss of

information processing often occur first. Brain imaging provides the most definitive diagnosis. There is no specific treatment.^{32,58}

Frontotemporal Dementia.

Frontotemporal dementia (FTD), previously known as *Pick disease*, is a form of dementia and a degenerative disease of the frontal lobes. There is a familial association with an age of onset less than 60 years and an estimated incidence of 15 per 100,000. The majority of cases involve mutations of genes encoding tau protein or progranulin. Three distinct clinical syndromes have been described depending on the site of atrophy: behavioral variant of frontotemporal dementia, progressive nonfluent aphasia, and semantic dementia. Neuroimaging identifies atrophy of the frontal and temporal lobes. The specific mechanism of pathogenesis is unknown, and there is no specific treatment.^{59,60}

Seizure Disorders

Seizure disorders represent a manifestation of disease and not a specific disease entity. A **seizure** is a sudden, transient disruption in brain electrical function caused by abnormal excessive discharges of cortical neurons.⁶¹ **Epilepsy** is “a disease of the brain with: (1) at least two unprovoked (or reflex) seizures occurring more than 24 hours apart; (2) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; (3) diagnosis of an epilepsy syndrome.”⁶² The term **convulsion** is sometimes applied to seizures and refers to the tonic-clonic (jerky, contract-relax) movement associated with some seizures. Epilepsy was estimated to have affected about 4.3 million adults and 750,000 children in the United States in 2013.⁶³ Seizures in children are presented in [Chapter 20](#).

Conditions Associated with Seizure Disorders

Any disorder that alters the neuronal environment may cause seizure activity. Conditions that may produce a seizure are metabolic disorders, congenital malformations, genetic predisposition, perinatal injury, postnatal trauma, myoclonic syndromes, infection, brain tumor, vascular disease, and drug or alcohol abuse. The onset of seizures also may indicate the presence of an ongoing primary neurologic disease. Metabolic and structural causes of recurrent seizures in adults are summarized in [Table 17.16](#). The cause of seizures is often unknown.

TABLE 17.16

STRUCTURAL/METABOLIC CAUSES OF RECURRENT SEIZURES IN ADULTS

AGE AT ONSET	PROBABLE CAUSE
Young adults (18-35 yr)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Idiopathic

	Illicit drug use (e.g., cocaine, amphetamines) Posttraumatic brain injury Perinatal insults
Older adults (>35 yr)	Alcohol or drug withdrawal (e.g., barbiturates, benzodiazepines) Brain tumor Cerebrovascular disease (e.g., stroke, aneurysm, arteriovenous malformations) CNS degenerative diseases (e.g., Alzheimer disease, multiple sclerosis) Major depression Idiopathic Metabolic disorders (e.g., uremia, hepatic failure, electrolyte abnormalities, hypoglycemia) Posttraumatic brain injury

CNS, Central nervous system.

Data from Daroff RB et al: *Bradley's neurology in clinical practice*, ed 7, Philadelphia, 2016, Elsevier.

The threshold for seizures may be lowered by hypoglycemia; fatigue or lack of sleep; emotional or physical stress; fever; large amounts of water ingestion (hyponatremia); constipation; use of antipsychotic drugs (i.e., chlorpromazine and clozapine), especially when combined with alcohol; or hyperventilation (respiratory alkalosis). Some environmental stimuli, such as blinking lights, a poorly adjusted television screen, loud noises, certain music, certain odors, or merely being startled, have been known to initiate a seizure. Women may have increased seizure activity immediately before or during menses.^{64,65}

Types of Seizure

Seizures are classified in different ways: clinical manifestations, site of origin and pattern of spread, EEG correlates, or response to therapy. Types of seizures and clinical manifestation are presented in [Table 17.17](#).

TABLE 17.17

TYPES OF SEIZURES AND DESCRIPTION OF SEIZURE EVENT

TYPE	DESCRIPTION OF SEIZURE EVENT
Focal seizures	Seizures originating in one area of the brain; an aura is common

(previously partial seizures)	<p><u>Motor</u></p> <p>Tonic: stiffening of body muscles with falling; loss of consciousness; can occur in sleep; more common in infants and children</p> <p>Atonic: sudden, brief loss of muscle tone with falling (drop attacks); usually no loss of consciousness</p> <p>Myoclonic: sudden brief shocklike jerks or twitches of the arms and/or legs; may drop things; no impairment of consciousness; frequently occurs shortly after awakening</p> <p>Tonic-clonic: Abrupt loss of consciousness, body stiffening (tonic) and then shaking (clonic); may begin with sudden cry, sometimes loss of bladder control or biting of tongue; usually lasts about two minutes, followed by a period of confusion, agitation, and fatigue; headaches and soreness are common afterwards</p> <p>Hypermotor: bimanual or bipedal motor activity such as kicking and thrashing, clapping and rubbing of both hands, hugging, sometimes with sexual automatisms and autonomic changes with or without preserved awareness</p> <p><u>Nonmotor</u></p> <p>Sensory: numbness, tingling or burning sensation, flashing lights, auditory experiences</p> <p>Cognitive: aphasia, hallucination, memory or attention impairment</p> <p>Emotional or affective: fear, agitation, anger, crying, laughing, paranoia</p> <p>Autonomic: blushing, pallor, increased or decreased heart rate, hyper- or hypoventilation nausea</p>
Without loss of awareness	Recall, responsiveness, and consciousness are intact
Impaired awareness (also known as <i>complex focal seizure</i>)	Loss of consciousness or awareness; vague or dreamlike state
Awareness unknown	Unable to determine awareness
Focal to bilateral tonic-clonic seizure	Begins in one part of brain (focal seizure) and spreads to both sides of brain followed by generalized tonic-clonic seizure; loss of consciousness
Generalized seizures	Seizures originating in both sides of the brain simultaneously; can include tonic, atonic, clonic, myoclonic, myoclonic-atonic, clonic-tonic-clonic activity (see above descriptions)
Epileptic spasms (formerly known as <i>infantile spasms</i>)	Episodes of sudden flexion or extension involving neck, trunk, and extremities; clinical manifestations range from subtle head nods to violent body contractions (jackknife seizures); onset between 3 and 12 months of age; may occur after infancy, may be idiopathic, genetic, result of metabolic disease, or in response to CNS insult; spasms occur in clusters of 5 to 150 times per day; EEG shows large-amplitude, chaotic, and disorganized pattern called "hypsarrhythmia"
Epilepsy	Seizure disorder that displays a group of signs and symptoms that occur collectively and

syndromes (examples)	characterize or indicate a particular condition; usually associated with genetic or developmental cause
Neonatal seizures	Wide variety of abnormal clinical activity, including rhythmic eye movements, chewing, and swimming movements; common in neonatal seizures; there are five main types of neonatal seizures: (1) subtle seizures (50%), (2) tonic seizures (5%), (3) clonic seizures (25%), (4) myoclonic seizures (20%), (5) nonparoxysmal repetitive behaviors
Lennox-Gastaut syndrome	Epileptic syndrome with onset in early childhood, 1 to 5 years of age; includes various generalized seizures (tonic-clonic, atonic [drop attacks], akinetic, absence, and myoclonic); EEG has characteristic “slow spike and wave” pattern; results in intellectual disability and delayed psychomotor developments
Juvenile myoclonic epilepsy	Generalized epilepsy syndrome with onset in adolescence; multifocal myoclonus; seizures often occur early in morning, aggravated by lack of sleep or after excessive alcohol intake; occasional generalized convulsions; requires long-term medication treatment
Unclassified epileptic seizures	Etiology remains unknown; seizures do not have distinct clinical and EEG features
Simple febrile seizures	Common in children younger than 5 to 6 years of age; brief (less than a few minutes) generalized convulsions associated with high fever; important to exclude meningitis as cause of seizures; usually do not develop epilepsy
Pseudoseizures	Nonepileptic phenomena that look like epileptic seizures; diagnosis often requires video-EEG monitoring to capture spells, and determine that EEG is normal during clinical events; frequently occurs in setting of child abuse
Status Epilepticus	Continuing or recurring seizure activity in which recovery from seizure activity is incomplete; unrelenting seizure activity can last 30 min or more; other forms can evolve into status epilepticus; medical emergency that requires immediate intervention

CNS, Central nervous system; *EEG*, electroencephalogram.

Data from: Fisher RS, et al: Operational classification of seizure types by the International League Against Epilepsy, 2016, available at:

<http://www.ilae.org/Visitors/Centre/documents/ClassificationSeizureILAE-2016.pdf>, accessed June 2, 2017; Scheffer IE, et al: *Epilepsia Open* 1(1-2):37-44, 2016.

◆Pathophysiology.

Epilepsy is considered to be the result of the interaction of complex genetic mutations with environmental effects that cause abnormalities in synaptic transmission, an imbalance in the brain's neurotransmitters, or the development of abnormal nerve connections or loss of nerves after injury.^{66,67} The International League Against

Epilepsy has proposed six groups for categorizing causes of epilepsy: genetic, structural, metabolic, immune, infectious, and unknown. These categories may be interrelated and continue to be revised⁶⁸ (Fig. 17.16).

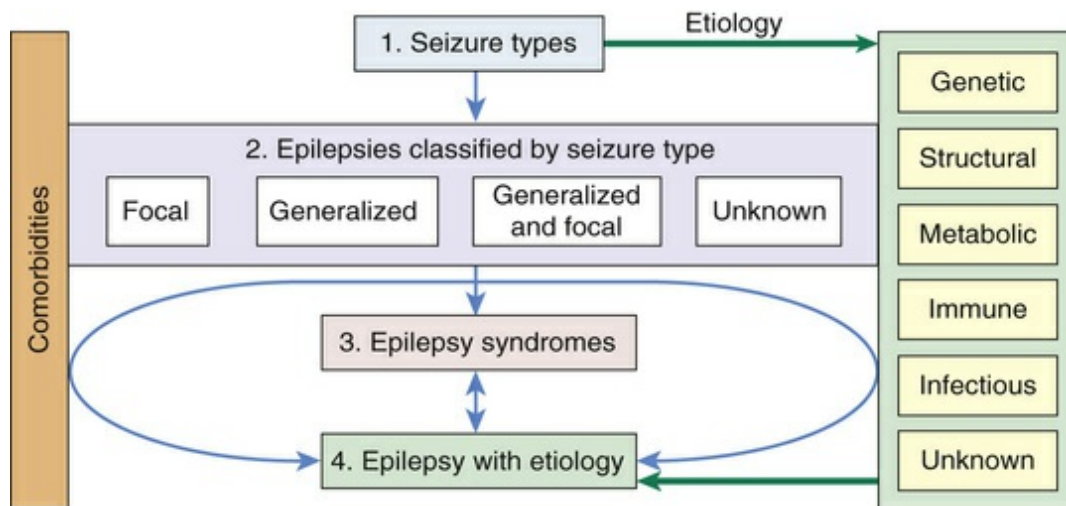

FIGURE 17.16 Framework for Classification of Epilepsy. (From Scheffer IE, et al: *Epilepsia Open* 1(1-2):37-44, 2016.)

A group of neurons may exhibit a paroxysmal depolarization shift and function as an **epileptogenic focus**. These neurons are hyperexcitable and are more easily activated by hyperthermia, hypoxia, hypoglycemia, hyponatremia, repeated sensory stimulation, and certain sleep phases. Epileptogenic neurons fire more frequently and with greater amplitude. When the intensity reaches a threshold point, cortical excitation spreads. Excitation of the subcortical, thalamic, and brainstem areas corresponds to the **tonic phase** (muscle contraction with increased muscle tone) and is associated with loss of consciousness. The **clonic phase** (alternating contraction and relaxation of muscles) begins when inhibitory neurons in the cortex, anterior thalamus, and basal ganglia react to the cortical excitation. The seizure discharge is interrupted, producing intermittent muscle contractions that gradually decrease and finally cease. The epileptogenic neurons are exhausted.

During seizure activity, oxygen is consumed at a high rate—about

60% greater than normal. Although cerebral blood flow also increases, oxygen is rapidly depleted along with glucose, and lactate accumulates in brain tissue. Continued, severe seizure activity has the potential for progressive brain injury and irreversible damage. In addition, if a seizure focus in the brain is active for a prolonged period, a **mirror focus** may develop in contralateral normal tissue and cause seizure activity, particularly with focal (i.e., temporal or frontal lobe) epilepsy.⁶⁹

The person is still in a postictal state (a state that follows an epileptic seizure and returns to baseline) when the next seizure begins. Status epilepticus most often results from abrupt discontinuation of antiseizure medications but also may occur in untreated or inadequately treated persons with seizure disorders. The situation is a medical emergency because of the resulting cerebral hypoxia. Intellectual disability, dementia, other brain damage, and even death are serious threats. Aspiration also is a great risk.

◆Clinical Manifestations.

The phases associated with a seizure are summarized in [Table 17.18](#). Two types of symptoms signal the **preictal phase** of a generalized tonic-clonic seizure: prodroma, early manifestations occurring hours to days before a seizure and may include anxiety, depression, or inability to think clearly; and a focal seizure or **aura** that immediately precedes the onset of a generalized tonic-clonic seizure. Both may become familiar to the person experiencing recurrent generalized seizures and may enable the person to prevent injuries during the seizure. The **ictus** is the episode of the epileptic seizure with tonic-clonic activity. Relaxation of urinary and bowel sphincters may occur, leading to bladder and bowel incontinence. Airway maintenance needs to be ensured. **Status epilepticus** in adults is a state of continuous tonic-clonic seizures lasting more than 5 minutes, or rapidly recurring seizures before the person has fully regained consciousness from the preceding seizure, or a single seizure lasting more than 30 minutes. It is a condition requiring prompt diagnosis and treatment because of the resulting cerebral hypoxia. Long-term

consequences can include neuronal death, neuronal injury, and alteration of neuronal networks.⁷⁰ The **postictal state** follows an epileptic seizure and can include signs of headache, confusion, aphasia, memory loss, and paralysis that may last hours or a day or two. Deep sleep also is common.

TABLE 17.18

TERMINOLOGY USED TO DESCRIBE PHASES OF A SEIZURE

TERM	DEFINITION
Prodroma	Early clinical manifestations, such as malaise, headache, or a sense of depression, that may occur hours to a few days before the onset of a seizure
Aura	A focal seizure experienced as a peculiar sensation preceding the onset of a generalized seizure or complex partial seizure that may take the form of gustatory, visual, or auditory experience; a feeling of dizziness or numbness; or just “a funny feeling”
Ictus	The episode of the seizure
Tonic phase	A state of muscle contraction in which there is excessive muscle tone
Clonic phase	A state of alternating contraction and relaxation of muscles
Postictal state	The period immediately following the cessation of seizure activity

◆ **Evaluation and Treatment.**

Health history is the most critical aspect in diagnosing a seizure disorder and establishing the cause and onset. The health history is supplemented by the physical examination and laboratory tests of blood and urine (blood glucose, serum calcium, blood urea nitrogen, urine sodium, and creatinine clearance measurements) to identify any systemic diseases known to have seizures as a clinical manifestation. Brain imaging and CSF examination are useful for identifying any neurologic diseases associated with seizures. The EEG is useful in assessing the type of seizure and may help determine its focus. Combined EEG and functional magnetic resonance imaging (fMRI) are useful in identifying neural networks involved in epileptic activity. Differentiating a generalized epilepsy from a focal epilepsy is

vital to treatment and prognosis.^{71,72}

Treatment for a seizure disorder is first to correct or control its cause, if possible. If this is not possible, the major means of management is the judicious administration of antiseizure medications. The therapeutic goal is complete suppression of seizure activity without intolerable side effects of the drug or drug resistance. Dietary treatments (e.g., ketogenic and modified Adkins diet) are effective for some individuals.⁷³ Surgical interventions can improve seizure control and quality of life in people with drug-resistant epilepsy.⁷⁴ Vagus nerve stimulation can reduce seizure frequency in persons with drug-resistant focal seizures.⁷⁵

Alterations in Cerebral Hemodynamics

An injured brain reacts with structural, chemical, and pathophysiologic changes. Primary brain injury is the original trauma, and secondary brain injury (see [Chapter 18](#)) is a consequence of alterations in cerebral blood flow, intracranial pressure, and oxygen delivery. Several relevant features of cerebral hemodynamics relate to cerebral oxygenation ([Box 17.5](#)).

Box 17.5

Cerebral Hemodynamics

Cerebral blood flow (CBF) to the brain is normally maintained at a rate that matches local metabolic needs of the brain. CBF to gray matter is about 3 to 4 times greater than that to white matter because of the increased metabolic activity.

Cerebral perfusion pressure (CPP) (70-90 mmHg) is the pressure required to perfuse the cells of the brain.

Cerebral blood volume (CBV) is the amount of blood in the intracranial vault at a given time.

Cerebral blood oxygenation is measured by oxygen saturation

in the internal jugular vein.

Intracranial pressure (ICP) is normally 1 to 15 mmHg, or 60 to 180 cm H₂O.

Alterations in cerebral blood flow may be related to three injury states: inadequate cerebral perfusion, normal cerebral perfusion but with an elevated intracranial pressure, and excessive **cerebral blood volume (CBV)**. Treatments for these injury states are directed at improving or maintaining **cerebral perfusion pressure (CPP)**, as well as controlling intracranial pressure. Target values for relevant clinical parameters are presented in [Table 17.19](#).

TABLE 17.19

THERAPEUTIC MANAGEMENT GOALS FOR INDIVIDUALS WITH ALTERED CEREBRAL HEMODYNAMICS

CLINICAL PARAMETER	TARGET VALUE
Central perfusion pressure	>70 mmHg
Intracranial pressure	<20 mmHg
Arterial CO ₂ pressure (PaCO ₂)	35 mmHg
Mean arterial pressure	90 mmHg
Temperature	34-36°C (93.2-96.8°F)
Pulmonary capillary wedge pressure	10-15 mmHg

Increased Intracranial Pressure

Intracranial pressure (ICP) normally is 5 to 15 mmHg, or 60 to 180 mm H₂O. **Increased intracranial pressure (IICP)** may result from an increase in intracranial content (as occurs with tumor growth), edema, excess CSF, or hemorrhage. It necessitates an equal reduction in volume of the other cranial contents. The most readily displaced content is CSF. If ICP remains high after CSF displacement out of the cranial vault, cerebral blood volume and blood flow are altered.

In *stage 1 of intracranial hypertension*, vasoconstriction and external compression of the venous system occur in an attempt to further decrease the ICP. Thus, during the first stage of IICP, ICP may not change because of the effective compensatory mechanisms, and there may be few symptoms (Fig. 17.17). Small increases in volume, however, cause an increase in pressure, and the pressure may take longer to return to baseline. This can be detected with ICP monitoring.

FIGURE 17.17 Clinical Correlates of Compensated and Uncompensated Phases of Intracranial Hypertension. (From Beare PG, Myers JL: *Principles and practice of adult health nursing*, ed 3, St Louis, 1998, Mosby.)

In *stage 2 of intracranial hypertension*, there is continued expansion of intracranial contents. The resulting increase in ICP may exceed the brain's compensatory capacity to adjust. The pressure begins to compromise neuronal oxygenation, and systemic arterial vasoconstriction occurs in an attempt to elevate the systemic blood pressure sufficiently to overcome the IICP. Clinical manifestations at this stage are usually subtle and transient, including episodes of confusion, restlessness, drowsiness, and slight pupillary and breathing changes (see Fig. 17.17).

In *stage 3 of intracranial hypertension*, the ICP begins to approach

arterial pressure, the brain tissues begin to experience hypoxia and hypercapnia, and the individual's condition rapidly deteriorates. Clinical manifestations include decreasing levels of arousal or central neurogenic hyperventilation, widened pulse pressure, bradycardia, and pupils that become small and sluggish (see [Fig. 17.17](#)).

Dramatic sustained rises in ICP are not seen until all compensatory mechanisms have been exhausted. Then dramatic rises in ICP occur over a very short period. **Autoregulation**, the compensatory alteration in the diameter of the intracranial blood vessels designed to maintain a constant blood flow during changes in cerebral perfusion pressure, is lost with progressively increased ICP. Accumulating carbon dioxide may still cause vasodilation locally, but without autoregulation this vasodilation causes the hydrostatic (blood) pressure in the vessels to drop and blood volume to increase. The increasing pressure may obstruct venous outflow. The brain volume is thus further enhanced, and ICP continues to rise. Small increases in volume cause dramatic increases in ICP, and the pressure takes much longer to return to baseline. As the ICP begins to approach systemic blood pressure, cerebral perfusion pressure falls and cerebral perfusion slows dramatically. The brain tissues experience severe hypoxia, hypercapnia, and acidosis, all of which cause cerebrovascular vasodilation.

In *stage 4 of intracranial hypertension*, brain tissue shifts (herniates) from the compartment of greater pressure to a compartment of lesser pressure, and ICP in one compartment of the cranial vault is not evenly distributed throughout the other vault compartments (see [Figs. 17.17](#) and [17.18](#)). With this shift in brain tissue, the herniating brain tissue's blood supply is compromised, causing further ischemia and hypoxia in the herniating tissues. The volume of content within the lower pressure compartment increases, exerting pressure on the brain tissue that normally occupies that compartment and impairing its blood supply. Small hemorrhages often develop in the involved brain tissue. Obstructive hydrocephalus may develop. The herniation process markedly and rapidly increases ICP. Mean systolic arterial pressure soon equals ICP, and cerebral blood flow ceases at this point.

The types of **herniation syndromes** are outlined in [Box 17.6](#).

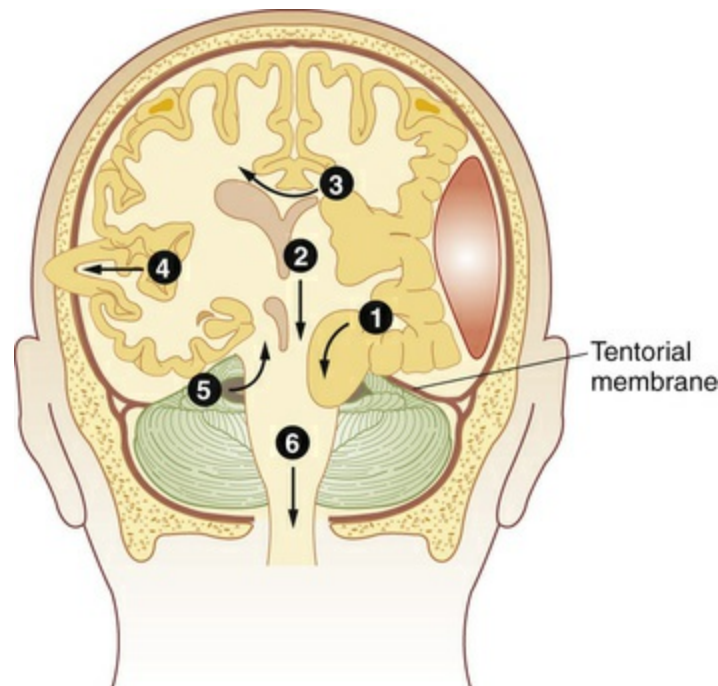

FIGURE 17.18 Brain Herniation. Herniations can occur both above and below the tentorial membrane. *Supratentorial*: 1, uncal (transtentorial); 2, central; 3, cingulate; 4, transcalvarial (external herniation through an opening in the skull). *Infratentorial*: 5, upward herniation of cerebellum; 6, cerebellar tonsil moves down through foramen magnum.

Box 17.6

Brain Herniation Syndromes

Supratentorial Herniation

1. *Uncal herniation*. This occurs when the uncus or hippocampal gyrus, or both, shifts from the middle fossa through the tentorial notch into the posterior fossa, compressing the ipsilateral third cranial nerve, the contralateral third cranial nerve, and the mesencephalon. Uncal herniation generally is caused by an expanding mass in the lateral region of the

middle fossa. The classic manifestations of uncal herniation are a decreasing level of consciousness, pupils that become sluggish before fixing and dilating (first the ipsilateral, then the contralateral pupil), Cheyne-Stokes respirations (which later shift to central neurogenic hyperventilation), and the appearance of decorticate and then decerebrate posturing.

2. *Central herniation*. This is the straight downward shift of the diencephalon through the tentorial notch. It may be caused by injuries or masses located around the outer perimeter of the frontal, parietal, or occipital lobes; extracerebral injuries around the central apex (top) of the cranium; bilaterally positioned injuries or masses; and unilateral cingulate gyrus herniation. The individual rapidly becomes unconscious; moves from Cheyne-Stokes respirations to apnea; develops small, reactive pupils and then dilated, fixed pupils; and passes from decortication to decerebration.
3. *Cingulate gyrus herniation*. This occurs when the cingulate gyrus shifts under the falx cerebri. Little is known about its clinical manifestations.
4. *Transcalvarial herniation*. The brain shifts through a skull fracture or a surgical opening in the skull. This type of external herniation may occur during a craniectomy—surgery in which a flap of skull is removed, preventing the piece of skull from being replaced.

Infratentorial Herniation

The most common syndrome is *cerebellar tonsillar*. The cerebellar tonsil shifts through the foramen magnum because of increased pressure within the posterior fossa. The clinical manifestations are an arched stiff neck, paresthesias in the shoulder area, decreased consciousness, respiratory abnormalities, and pulse rate variations. Occasionally the force produces an *upward transtentorial* herniation of a cerebellar tonsil or the lower brainstem. There is increased intracranial pressure but no specific set of clinical manifestations associated with infratentorial herniation (see [Fig. 17.18](#)).

Cerebral Edema

Cerebral edema is an increase in the fluid content of brain tissue (Figs. 17.19 and 17.20). The result is increased extracellular or intracellular tissue volume. It occurs after brain insult from trauma, infection, toxicity, hemorrhage, tumor, ischemia, infarction, or hypoxia. The harmful effects of cerebral edema are caused by the distortion of blood vessels, the displacement of brain tissues, increase in ICP, and the eventual herniation of brain tissue from one brain compartment to another.

FIGURE 17.19 Brain Edema. This coronal section of cerebrum demonstrates marked compression in the lateral ventricles (*long arrows*) and flattening of gyri (*short arrows*) from extensive bilateral cerebral edema. Edema increases intracranial pressure, leading to herniation. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 2, Philadelphia, 2010, Saunders.)

FIGURE 17.20 Cerebral Edema, Gross. The surface of the meninges of the brain with cerebral edema shows widened, flattened gyri (*) with narrowed sulci (◊). (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 2, Philadelphia, 2010, Saunders.)

Three types of cerebral edema are (1) vasogenic edema, (2) cytotoxic (metabolic) edema, and (3) interstitial edema. **Vasogenic edema** is clinically the most common form. It is caused by the increased permeability of the capillaries that form the blood-brain barrier. Plasma proteins leak into the extracellular spaces, drawing water to them, and increasing the water content of brain parenchyma, particularly the white matter. Vasogenic edema begins in the area of injury and spreads with fluid accumulating in the white matter of the ipsilateral side because the parallel myelinated fibers separate more easily. Edema promotes more edema because of ischemia from the increasing ICP.

Clinical manifestations of vasogenic edema include focal neurologic deficits, disturbances of consciousness, and a severe increase in ICP. Vasogenic edema resolves by slow diffusion.

In **cytotoxic (metabolic) edema**, toxic factors directly affect the cellular elements of the brain parenchyma (neuronal, glial, and endothelial cells), causing failure of the active transport systems. The most common cause is ischemia/hypoxia. The blood-brain barrier is not disrupted. The cells lose their potassium and gain larger amounts of sodium because of failure of cell membrane ion pumps. Water follows by osmosis into the cell so that the cells swell (intracellular

edema). Cytotoxic edema occurs principally in the gray matter and may increase vasogenic edema because of the loss of endothelial tight junctions.⁷⁶

Interstitial edema is seen most often with noncommunicating hydrocephalus (see following section and [Chapter 20](#)). The edema is caused by transependymal movement of CSF from the ventricles into the extracellular spaces of the brain tissues. The brain fluid volume thus is increased predominantly around the ventricles. The hydrostatic pressure within the white matter increases, and the size of the white matter is reduced because of the rapid disappearance of myelin lipids.

Hydrocephalus

The term **hydrocephalus** refers to various conditions characterized by an excess of fluid within the cerebral ventricles, subarachnoid space, or both (see [Figs. 15.17](#) and [20.11](#)). Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production, obstruction within the ventricular system, or defective reabsorption of the fluid. A tumor of the choroid plexus may, in rare instances, cause overproduction of CSF ([Fig. 17.21](#)). Hydrocephalus may develop from infancy through adulthood.

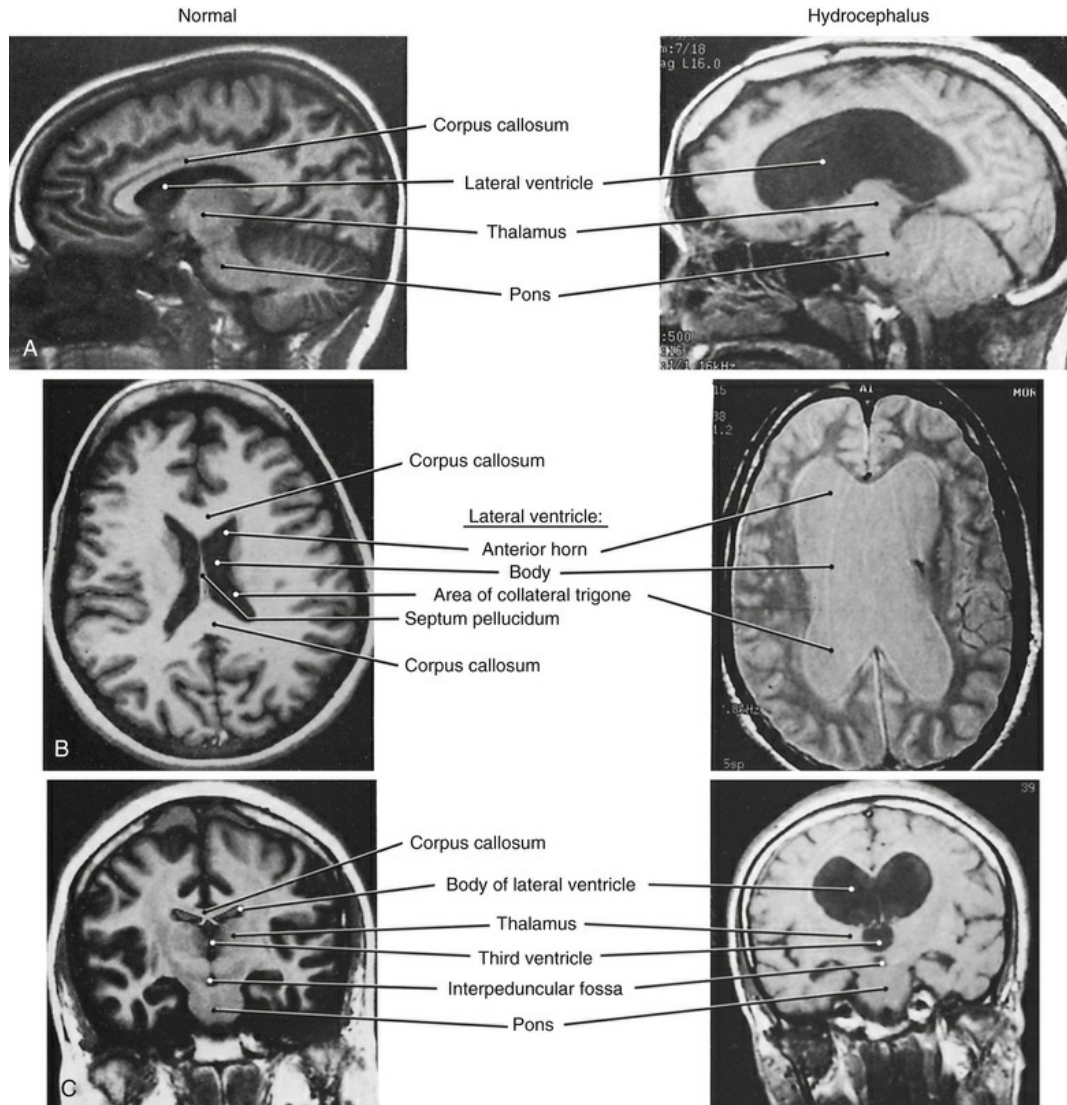

FIGURE 17.21 Comparison of Normal and Hydrocephalic Brains. A, Sagittal; B, axial; and C, coronal planes as seen in magnetic resonance imaging (MRI). (From Haines DE, editor: *Fundamental neuroscience for basic and clinical applications*, ed 4, Philadelphia, 2013, Saunders.)

Types of Hydrocephalus

Noncommunicating hydrocephalus (obstructive) (*internal or intraventricular hydrocephalus*) is caused by obstruction within the ventricular system and occurs more often in children. Impaired absorption of CSF from the subarachnoid space occurs when an obstructive process disrupts the flow of CSF through the subarachnoid space. The fluid is prevented from reaching the convex

portion of the cerebrum, where the arachnoid granulations are located.

Communicating hydrocephalus (nonobstructive) (*extraventricular*) results from impaired reabsorption of CSF in the absence of obstruction between the ventricles and subarachnoid space. The most common causes of communicating hydrocephalus are subarachnoid hemorrhage, developmental malformation, head injury, neoplasm, inflammation (i.e., meningitis), high venous pressure in the sagittal sinus, and increased CSF secretion by the choroid plexus. It occurs more commonly in adults.

Normal-pressure hydrocephalus (dilation of the ventricles without increased pressure) is a slowly developing form of communicating hydrocephalus that occurs mostly in late middle age. The ventricles are enlarged and the cerebrospinal fluid pressure is minimally elevated. This form of hydrocephalus is idiopathic, occurs secondarily as a complication of head injury or subarachnoid hemorrhage, or is associated with a benign external hydrocephalus (enlarged frontal subarachnoid spaces) in infancy.⁷⁷

Acute hydrocephalus may develop in several hours in persons who have sustained head injuries. Acute hydrocephalus contributes significantly to increased ICP.

◆Pathophysiology.

The obstruction of CSF flow associated with hydrocephalus produces increased pressure and dilation of the ventricles proximal to the obstruction. The increased pressure and dilation cause atrophy of the cerebral cortex and degeneration of the white matter tracts. Selective preservation of gray matter occurs. When excess CSF fills a defect caused by atrophy, a degenerative disorder, or a surgical excision, this fluid is not under pressure; therefore atrophy and degenerative changes are not induced. This is known as **hydrocephalus ex vacuo**.

◆Clinical Manifestations.

Most cases of hydrocephalus develop gradually and insidiously over time. Acute hydrocephalus presents with signs of rapidly developing

increased ICP. The person rapidly deteriorates into a deep coma if not promptly treated. Normal-pressure hydrocephalus has a long-term presentation and develops slowly over time. A triad of symptoms, including declining memory with loss of cognitive function; unsteady, broad-based gait; and urinary urgency and incontinence from detrusor overactivity, are common and make diagnosis difficult to differentiate from other causes of dementia. Additional clinical manifestations are apathy, inattentiveness, and indifference to self, family, and the environment.^{78,79}

◆Evaluation and Treatment.

The diagnosis is made on the basis of clinical history, physical examination, computed tomography (CT) scan, and magnetic resonance imaging (MRI). A radioisotopic cisternogram may be performed to diagnose normal-pressure hydrocephalus. Hydrocephalus can be treated by surgery to resect cysts, neoplasms, or hematomas or by ventricular bypass into the normal intracranial channel or into an extracranial compartment using a shunting procedure, one of the three most common neurosurgical procedures. Excision or coagulation of the choroid plexus is occasionally needed when a papilloma is present. In normal-pressure hydrocephalus, reduction in CSF is achieved through diuresis or placement of a ventriculoperitoneal shunt.⁸⁰

Alterations in Neuromotor Function

Movements are complex patterns of activity controlled by the cerebral cortex, the pyramidal system, the extrapyramidal system, and the muscle motor units. Dysfunction in any of these areas can cause motor dysfunction. General motor dysfunctions are associated with changes in muscle tone, movement, and complex motor performance.^{81,82}

Alterations in Muscle Tone

Normal muscle tone involves a slight resistance to passive movement.

The resistance is smooth, constant, and even throughout the range of motion. The alterations of muscle tone and their characteristics and causes are presented in [Table 17.20](#).

TABLE 17.20

ALTERATIONS IN MUSCLE TONE

ALTERATIONS CAUSE		CHARACTERISTICS
Hypotonia	Thought to be caused by decreased muscle spindle activity as a result of decreased excitability of neurons	Passive movement of a muscle mass with little or no resistance Difficult to detect; extremity is floppy and allows excessive movement when displaced
	Occurs typically when nerve impulses necessary for muscle tone are lost	Muscles may be rapidly moved without resistance
Flaccidity		Associated with limp, atrophied muscles and paralysis
Hypertonia	Results when the lower motor unit reflex arc continues to function but is not mediated or regulated by higher centers	Increased muscle resistance to passive movement May be associated with paralysis May be accompanied by muscle hypertrophy (see Fig. 17.25)
Spasticity	Exact mechanism unclear; appears to arise from an increased excitability of the alpha motor neurons to any input because of absence of the descending inhibition of the pyramidal systems	A gradual increase in tone causing increased resistance until tone suddenly is reduced, which results in clasp-knife phenomenon Velocity dependent (may be absent with slow speed of displacement) Selective distribution (predominates in flexors of upper extremities and extensors of lower extremities and in pronators compared with supinators)
Paratonia (gegenhalten)	Exact mechanism unclear; associated with frontal lobe injury	Resistance to passive movement, which varies in direct proportion to force applied
Dystonia	Loss of central nervous system (CNS) inhibitory function with sustained	Sustained involuntary twisting and repetitive movements or

	muscular contraction	abnormal posture
Rigidity	Occurs as a result of constant, involuntary contraction of muscle	Muscle resistance to passive movement of a rigid limb that is uniform in both flexion and extension throughout the motion Not velocity dependent Activated by contraction of muscles in contralateral extremities Uniform through range in displacement
Plastic or lead-pipe	Associated with basal ganglion damage	Increased muscular tone relatively independent of degree of force used in passive movement; does not vary throughout the passive movement
Cogwheel	Associated with basal ganglion damage	The uniform resistance may be interrupted by a series of brief jerks resulting in movements much like a ratchet, "cogwheel" phenomenon
Gamma	Loss of excitation of extensor inhibitory areas by the cerebral cortex, decreasing the inhibition of alpha and gamma motor neurons	Characterized by extensor posturing (decerebrate rigidity)
Alpha	Loss of cerebellum input to lateral vestibular nuclei	Impaired relaxation characterized by extensor rigidity of skeletal muscle after the contraction
Myotonia		Impaired relaxation of skeletal muscle after the contraction

Hypotonia

In **hypotonia (decreased muscle tone)**, passive movement of a muscle occurs with little or no resistance. Hypotonia is a symptom of cerebellar and pure pyramidal tract damage (a rare occurrence). It is thought to be caused by decreased muscle spindle activity secondary to decreased excitability of neurons. Hypotonia contributes to the ataxia and intention tremor in cerebellar damage and manifests with minimal weakness and normal or slightly exaggerated reflexes. A

pure pyramidal tract injury produces hypotonia and weakness. Hypotonia, often described as flaccidity (a state in which the muscle may be moved rapidly without resistance), occurs when nerve impulses necessary for muscle tone are lost, such as in spinal cord injury or cerebrovascular accident.

Individuals with hypotonia report that they tire easily (asthenia) or are weak. They may have difficulty rising from a sitting position, sitting down without using arm support, or walking up and down stairs, as well as an inability to stand on their toes. Because of their weakness, accident proneness during locomotion and self-care activities is common. The joints become hyperflexible, so people with hypotonia may be able to assume positions that require extreme joint mobility. The joints may appear loose. The muscle mass atrophies because of decreased input entering the motor unit. Muscle cells gradually are replaced by connective tissue and fat. The muscles are flabby on palpation and are flat in appearance. Fasciculations may be present in some cases.

Hypertonia

In **hypertonia (increased muscle tone)**, passive movement of a muscle occurs with resistance to stretch and is caused by upper motor neuron damage. The four types of hypertonia are spasticity, paratonia (gegenhalten), dystonia, and rigidity.

Spasticity results from hyperexcitability of the stretch reflexes (overactivation of the alpha motor neurons) and is associated with damage to the motor, premotor, and supplementary motor areas, as well as lateral corticospinal tract damage (Fig. 17.22). Spasticity is accompanied by increased deep tendon reflexes (hyperreflexia) and the spread of reflexes (clonus).

FIGURE 17.22 Left-Sided Hemifacial Spasm. (From Perkin GD: *Mosby's color atlas and text of neurology*, London, 1998, Mosby-Wolfe.)

Paratonia (gegenhalten) is resistance to passive movement that increases with velocity of movement. **Dystonia** is increased involuntary muscle contraction, manifested as sustained, involuntary twisting movements. It is caused by slow muscle contraction and may be caused by a failure in appropriate reciprocal inhibition of the muscles (Figs. 17.23 and 17.24). Injury to the putamen or its outflow tracts also is associated with hemidystonia.

FIGURE 17.23 Dystonic Posturing of the Hand and Foot. (From Perkin GD: *Mosby's color atlas and text of neurology*, London, 1998, Mosby-Wolfe.)

FIGURE 17.24 Spasmodic Torticollis. A characteristic head posture related to spasticity. (From Perkin GD et al: *Atlas of clinical neurology*, ed

Rigidity produced by tonic reflex activity mediated by gamma motor neurons may be continuous or intermittent. The involved muscles are firm and tense; the increase in muscle movement is even and uniform throughout the range of passive movement. Four types of rigidity are described: plastic, or lead-pipe; cogwheel; gamma; and alpha (see [Table 17.20](#)).

Individuals with hypertonia may tire easily (asthenia) or be weak. Passive movement and active movement are equally affected, except in paratonia, in which more active than passive movement is possible. As a result of hypertonia and weakness, accident proneness during locomotion and self-care activities is common.

The muscles may atrophy because of decreased use. However, hypertrophy occasionally occurs from overstimulation of muscle fibers. Overstimulation occurs when the motor unit reflex arc remains intact and functioning but is not inhibited by higher centers. The loss of inhibition and the constant state of excitation cause continual muscle contraction, resulting in enlargement of the muscle mass. The muscles are firm on palpation ([Fig. 17.25](#)).

FIGURE 17.25 Pseudohypertrophy of the Calf Muscles. (From Perkin GD et al: *Atlas of clinical neurology*, ed 3, Philadelphia, 2011, Saunders.)

Alterations in Muscle Movement

Movement requires a change in the contractile state of muscles. Abnormal movements may occur when a variety of CNS dysfunctions alter muscular innervation. *Dopamine*, a neurotransmitter, has a role in several movement disorders. Some movement disorders (e.g., the akinesias) result from too little dopaminergic activity, whereas others (e.g., chorea, ballism, tardive dyskinesia) result from too much dopaminergic activity. Still others are not related primarily to dopamine function. Movement disorders are not associated necessarily with mass, strength, or tone but are neurologic dysfunctions with either an excess of movement or a lack of voluntary movement. Muscle strength is quantitatively evaluated on a scale of 0 to 4+ or 0 to 5, in which 4+ or 5 is normal and 0 indicates an inability to move against gravity (Table 17.21).

TABLE 17.21

UNITED KINGDOM MEDICAL RESEARCH COUNCIL CLASSIFICATION OF MUSCLE POWER

GRADE	DEFINITION
0	Total paralysis—no muscle contraction
1	Flicker of contraction—no joint movement
2	Movement with gravity eliminated
3	Movement against gravity but not resistance
4	Movement against resistance but incomplete
5	Normal power against resistance

Data from Vanhoutte EK et al: *Brain* 135(Pt 5):1639-1649, 2012.

Hyperkinesia

Hyperkinesia is excessive, purposeless movement. Within this category are a number of specific dysfunctions including tremors (Table 17.22). Also included under the general category of hyperkinesias are *dyskinesias* and abnormal involuntary movements.

Huntington disease symptoms are the hallmark of hyperkinesia.

TABLE 17.22

TYPES OF HYPERKINESIA SYNDROMES

TYPE	CHARACTERISTICS	CAUSES
Chorea*	Nonrepetitive muscular contractions, usually of the extremities of the face; random pattern of irregular, involuntary rapid contractions of groups of muscles; disappears with sleep, decreases with resting; increases with emotional stress and attempted voluntary movement	Associated with excess concentration of or a supersensitivity to dopamine within basal ganglia
Athetosis*	Disorder of distal-muscle postural fixation; slow, twisting, sinuous, irregular movements most obvious in the distal extremities, more rhythmic than choreiform movements and always much slower; movements accompany characteristic hand posture; slowly fluctuating grimaces	Occurs most commonly as a result of injury to the putamen of the basal ganglion; exact pathophysiologic mechanism is not known
Ballism	Disorder of proximal-muscle postural fixation with wild flinging movement of the limbs; movement is severe and stereotyped, usually lateral; does not lessen with sleep; ballism is most common on one side of the body, a condition termed <i>hemiballism</i>	Results from injury to the subthalamic nucleus (one of the nuclei that comprise the basal ganglia); thought to be caused by reduced inhibitory influence in the nucleus, a release phenomenon; hemiballism results from injury to the contralateral subthalamic nucleus
Hyperactivity	State of prolonged, generalized, increased activity that is largely involuntary but may be subject to some voluntary control; not highly stereotyped but rather manifests as continual changes in total body posture or in excessive performance of some simple activity, such as pacing under inappropriate circumstances	May be caused by frontal and reticular activating system injury
Wandering	Tendency to wander without regard for environment	“Release” phenomenon; associated with bilateral injury to globus pallidus or putamen

Akathisia	Special type of hyperactivity; mild compulsion to move (usually more localized to legs); severe frenzied motion possible; movements are partly voluntary and may be transiently suppressed; carrying out the movement brings a sense of relief; a frequent complication of antipsychotic drugs	Dopaminergic transmission may be involved
Tremor at rest	Rhythmic, oscillating movement affecting one or more body parts	Caused by regular contraction of opposing groups of muscles
Parkinsonian tremor	Regular, rhythmic, slow flexion-extension contraction; involves principally the metacarpophalangeal and wrist joints; alternating movements between thumb and index finger described as "pill rolling"; disappears during voluntary movement	Loss of inhibitory influence of dopamine in the basal ganglia, causing instability of basal ganglia feedback circuit within the cerebral cortex
Postural Tremor		
Asterixis (tremor of hepatic encephalopathy)	Irregular flapping movement of the hands accentuated by outstretching arms	Caused by transient inhibition of muscles that maintain posture; thought to be related to accumulation of products normally detoxified by the liver
Metabolic	Rapid, rhythmic tremor affecting fingers, lips, and tongue; accentuated by extending the body part; enhanced physiologic tremor	Occurs in conditions associated with disturbed metabolism or toxicity, as in thyrotoxicosis (hyperthyroidism), alcoholism, and chronic use of barbiturates, amphetamines, lithium, amitriptyline (Elavil); exact mechanism responsible unknown
Essential (familial)	Tremor of fingers, hands, and feet; absent at rest but accentuated by extension of body part, prolonged muscular activity, and stress	Not associated with any other neurologic abnormalities; cause unknown
Intentional Tremor		
Cerebellar	Tremor initiated by movement, maximal toward end of movement	Occurs in disease of the dentate nucleus (one of the deep cerebellar nuclei responsible for efferent output) and the superior cerebellar peduncle (a stalklike structure connected to the pons); caused by errors in feedback from the periphery and errors in preprogramming goal-directed

		movement
Rubral	Rhythmic tremor of limbs that originates proximally by movement	Results from lesions involving the dentatorubrothalamic tract (a spinothalamic tract connecting the red nucleus in the reticular formation and the dentate nucleus in the cerebellum)
Myoclonus	Series of shocklike, nonpatterned contractions of a portion of a muscle, entire muscle, or group of muscles that cause throwing movements of a limb; usually appear at random but frequently triggered by sudden startle; do not disappear during sleep	Associated with an irritable nervous system and spontaneous discharge of neurons; structures associated with myoclonus include the cerebral cortex, cerebellum, reticular formation, and spinal cord

*Choreoathetosis involves chorea and athetosis; precise pathophysiology unknown.

Paroxysmal dyskinesias are abnormal, involuntary movements that occur as spasms. The type of dyskinesia varies depending on the specific disorder.

Tardive dyskinesia (slow onset dyskinesia) is the involuntary movement of the face, trunk, and extremities. Although the condition occurs occasionally in individuals with Parkinson disease, it usually occurs as a side effect of prolonged antipsychotic drug therapy.⁸³ The antipsychotic drugs cause denervation hypersensitivity, thereby mimicking the effect of excessive dopamine. The most common symptom of tardive dyskinesia is rapid, repetitive, stereotypic movements, such as continual chewing with intermittent protrusions of the tongue, lip smacking, and facial grimacing. The symptoms also are called *extrapyramidal symptoms* because the extrapyramidal system controls involuntary reflexes and coordination of movement and posture (see section on [Extrapyramidal Motor Syndromes](#)).

Other movement disorders in this category are (1) complex repetitive movements, including automatism (unconscious behavior), stereotypy (ritualistic behavior such as rocking), complex tics such as Tourette syndrome [see [What's New? Tourette Syndrome](#)], compulsions, perseverations, and mannerisms; (2) excessive reactions to certain stimuli; and (3) paroxysmal excessive activity, including cataplexy and excessive startle reaction.

What's New?

Tourette Syndrome

There is growing evidence that Tourette syndrome (TS) occurs worldwide and has common features across all races and cultures. The hallmark of TS is the presence of motor tics (sudden, rapid, repetitive nonrhythmic movements) and vocal tics. The tics may be either simple, involving only an individual muscle group (e.g., eye blinking or grunting), or complex, requiring coordinated movement of muscle groups (e.g., head banging or repeating of another person's words). Sensory tics involve unpleasant sensations in the face, head, and neck areas. Probably underdiagnosed, the onset of TS is typically between the ages of 2 and 15 years, with the tics lessening in adulthood. The syndrome has a complex multifactorial etiology with undetermined genetic, environmental, immune, and hormonal factors. The pathophysiology of TS is unclear and currently under study. There is evidence of cortico-striato-thalamocortical dysfunction and, in some cases, altered dopaminergic neurotransmission and abnormalities in brain GABA (loss of inhibition). TS is often diagnosed in association with anxiety, depression, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder. Habit reversal therapy of the urge to move is the most common behavioral therapy, and all behavioral therapy needs further investigation. Pharmacologic treatments target symptoms and can have significant side effects. New drugs are being evaluated to identify the best outcomes. Deep brain stimulation is under investigation.

GABA, gama-aminobutyric acid.

Data from Hallett M: *Brain Dev* 37(7):651-655, 2015; Hirschtritt ME et al: *J Am Med Assoc Psychiatry* 72(4):325-333, 2015; Schrock LE et al: *Mov Disord* 30(4):448-471, 2015; Serajee FJ, Mahbubul Huq AH: *Pediatr Clin North Am* 62(3):687-701, 2015.

Hypokinesia is decreased amplitude of movement, **bradykinesia** is

decreased speed of movement, and **akinesia** is absence of voluntary movement. These are all terms that represent a deficit of voluntary movement. Parkinson disease symptoms are the hallmark of a lack of voluntary movement.

Huntington Disease

Huntington disease (HD), also known as *chorea*, is a relatively rare, hereditary, degenerative hyperkinetic movement disorder diffusely involving the basal ganglia and cerebral cortex. The onset of HD is usually between 25 and 45 years of age, when the trait may already have been passed to the person's children. The disorder has a prevalence rate of approximately 5 to 10 per 100,000 persons, occurs in all races, and rates vary in different regions across the world.⁸⁴

◆Pathophysiology.

HD is inherited from one or both parents who have the autosomal dominant trait with high penetrance. The genetic defect of HD is on the short arm of chromosome 4. There is an abnormally long polyglutamine tract in the huntingtin (*htt*) protein with abnormal folding that is toxic to neurons caused by a cytosine-adenine-guanine (CAG) trinucleotide repeat expansion (40 to 70 repeats instead of 9 to 34). Age of symptom onset is related to the length of the repeat sequences and mechanisms of toxicity. Repeat lengths greater than 60 cause the juvenile form of the disease.⁸⁵ Fathers, but not mothers, with high normal alleles do not develop HD but are at risk of transmitting potentially penetrant HD alleles (≥ 36) to their offspring, who can develop HD.⁸⁶

The principal pathologic feature of HD is severe degeneration of the striatum. The degeneration of the basal ganglia leaves enlarged lateral ventricles (Fig. 17.26) and there is widespread degeneration in late stages of the disease. Expression of the *huntingtin* gene produces tangles of protein that collect in brain cells and chains of glutamine on the abnormal molecules that adhere to each other. The mechanism of neuronal death is unknown. The excitotoxic theory of striatal and cortical degeneration proposes that the mutated huntingtin protein

produces excitotoxic pathways mediated by glutamate function that also induce concomitant dysregulation of dopaminergic function. Lysosomal autophagy is disrupted, resulting in accumulation of misfolded proteins. The huntingtin protein also alters cellular organelles, including mitochondrial function, axon transport, and synapses. Apoptotic pathways may be activated and cause neuronal death. Neurotrophic factors also may be depleted, contributing to loss of neurons.^{87,88}

FIGURE 17.26 Huntington Disease. On the right is a normal brain with a normal caudate (C); on the left is a brain from an individual with Huntington disease showing severe atrophy of the caudate (A) and an enlarged lateral ventricle. (From Stevens A, Lowe J, Scott I: *Core pathology*, ed 3, London, 2009, Mosby.)

◆Clinical Manifestations.

Symptoms of Huntington disease progress slowly and include involuntary fragmentary movements, such as chorea, athetosis, and ballism (see [Table 17.22](#)). Chorea, the most common type of abnormal movement, begins in the face and arms, eventually affecting the entire body. There is emotional lability and progressive dysfunction of intellectual and thought processes (dementia) that may precede motor symptoms. Cognitive deficits include loss of working memory and

reduced capacity to plan, organize, and sequence. Thinking is slow and apathy is present. Any one of these features may mark the onset of the disease. Restlessness, disinhibition, and irritability are common. Euphoria or depression may be present.

◆Evaluation and Treatment.

The diagnosis of HD is based on family history, clinical presentation of the disorder, and genetic testing. Neuroradiologic abnormalities can be demonstrated up to 15 years before clinical symptoms. No known treatment is effective in halting the degeneration or progression of symptoms, and the disease is fatal. Efforts are underway to identify biomarkers for early diagnosis and to monitor disease progression.⁸⁹ Symptomatic drug therapies are available.⁹⁰

Hypokinesia

Hypokinesia (decreased movement) is loss of voluntary movement despite preserved consciousness and normal peripheral nerve and muscle function. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movement.

Akinesia and Bradykinesia.

Akinesia is a decrease in voluntary and associated movements. It is related to dysfunction of the extrapyramidal system and caused by either a deficiency of dopamine or a defect of the postsynaptic dopamine receptors, which occurs in parkinsonism. **Bradykinesia** is slowness of voluntary movements. All voluntary movements become slow, labored, and deliberate with difficulty in (1) initiating movements, (2) continuing movements smoothly, and (3) performing synchronous (at the same time) and consecutive tasks. Both akinesia and bradykinesia involve a delay in the time it takes to start to perform a movement.

Loss of Associated Movement.

In hypokinesia, the normal, habitually associated movements that provide skill, grace, and balance to voluntary movements are lost.

Decreased associated movements accompanying emotional expression cause an expressionless face, a statue-like posture, absence of speech inflection, and absence of spontaneous gestures. Decreased associated movements accompanying locomotion cause reduction in arm and shoulder movements, hip swinging, and rotary motion of the cervical spine.

Parkinson Disease

Parkinson disease (PD) is a complex motor disorder accompanied by systemic nonmotor and neurologic symptoms. Etiologic classification of parkinsonism includes primary parkinsonism and secondary parkinsonism. The onset of primary PD begins after 40 years of age, with the incidence increasing after 60 years. Approximately 60,000 new cases are diagnosed in the United States each year, and an estimated 10 million people worldwide are living with PD. Men are 150% more likely to have PD than women.⁹¹ The familial form represents about 10% of PD; however, the majority of cases are sporadic or idiopathic. Secondary parkinsonism is parkinsonism caused by other neurodegenerative diseases and acquired disorders. Drug-induced parkinsonism is the most common secondary form and is usually reversible ([Box 17.7](#)).

Box 17.7

Primary and Secondary Causes of Parkinsonism

Primary Parkinsonism

Sporadic (idiopathic); most common form
Genetic: autosomal dominant; autosomal recessive
Phenotype may be influenced by gene-environment interactions

Secondary Parkinsonism

- Neurodegenerative disorders (sporadic or genetic)
 - Disorders associated with alpha-synuclein pathology
 - Multiple system atrophies (glial and neuronal inclusions)
 - Nigrostriatal degeneration
 - Olivopontocerebellar atrophy
 - Shy-Drager syndrome
 - Motor neuron disease with Parkinson disease (PD) features
 - Dementia with Lewy bodies (cortical and brainstem neuronal inclusions)
 - Disorders associated with primary tau pathology (“tauopathies”)
 - Progressive supranuclear palsy
 - Corticobasal degeneration
 - Frontotemporal dementia
 - Disorders associated with primary amyloid pathology (“amyloidopathies”)
 - Alzheimer disease with parkinsonism
- Genetically mediated disorders with occasional parkinsonian features
 - Wilson disease
 - Hallervorden-Spatz disease
 - Chédiak-Higashi syndrome
 - SCA-3 spinocerebellar ataxia
 - X-linked dystonia-parkinsonism (*DYT3*)
 - Fragile X permutation associated with ataxia-tremor-parkinsonism syndrome
 - Huntington disease (Westphal variant)
 - Prion disease
 - Rett syndrome
- Miscellaneous acquired conditions

Vascular parkinsonism: atherosclerosis, amyloid angiopathy
Normal pressure hydrocephalus
Catatonia
Cerebral palsy
Repeated head trauma (“dementia pugilistica” with parkinsonian features)
Infectious and postinfectious diseases
 Postencephalitic PD
 Creutzfeldt-Jakob disease
 Neurosyphilis
Metabolic conditions
 Hypoparathyroidism or pseudohypoparathyroidism with basal ganglia calcifications
 Nonwilsonian hepatolenticular degeneration
Multiple sclerosis
Neoplastic disease
Drugs
 Neuroleptics (typical antipsychotics)
 Selected atypical antipsychotics
 Antiemetics (e.g., prochlorperazine, metoclopramide)
 Dopamine-depleting agents (reserpine, tetrabenazine)
 α -Methyldopa
 Lithium carbonate
 Valproic acid
 Fluoxetine
Toxins
 1-Methyl-1,2,4,6-tetrahydropyridine (MPTP)
 Manganese
 Cyanide
 Methanol
 Carbon monoxide
 Carbon disulfide
 Hexane
 Pesticides (i.e., paraquat, rotenone)

Data from Checkoway H, Nielsen SS, Racette BA: Chapter 12: Environmental exposures and risks for Parkinson's disease. In Aschner M, editor: *Environmental factors in neurodevelopmental and neurodegenerative disorders*, Amsterdam, 2015, Academic Press, pp 253-265; Fahn S, Jankovic J, Hallett M: Atypical parkinsonism, parkinsonism-plus syndromes, and secondary parkinsonian disorders. In Fahn S, Jankovic J, Hallett M, editors: *Principles and practice of movement disorders*, ed 2, Philadelphia, 2011, Saunders, pp 197-240; Singer HS et al, editors: *Movement disorders in childhood*, ed 2, Amsterdam, 2016, Academic Press, pp 301-316.

◆Pathophysiology.

The pathogenesis of primary PD is unknown. Several gene mutations have been identified, the most significant of which are listed in [Table 17.13](#). The hallmark pathologic features of PD are loss of dopaminergic pigmented neurons in the substantia nigra (SN) pars compacta with dopaminergic deficiency in the putamen portion of the striatum (the striatum includes the putamen and caudate nucleus) ([Fig. 17.27](#)). Dopamine loss in other brain areas, including the brainstem, thalamus, and cortex, also occurs.⁹² The primary pathology is degeneration of the basal ganglia (corpus striatum, globus pallidus, subthalamic nucleus, and substantia nigra) ([Fig. 17.28](#)) with formation of Lewy bodies (fibrillar intracellular eosinophilic inclusions with high concentrations of alpha-synuclein, ubiquitin, tau protein, tuberculin, and other proteins) in the substantia nigra and dorsal striatum. There is loss of dopaminergic pigmented neurons in the substantia nigra (SN) pars compacta (see [Fig. 17.27](#)) with dopaminergic deficiency in the putamen portion of the striatum (the striatum includes the putamen and caudate nucleus). Dopamine loss occurs in other brain areas, including the brainstem, thalamus, and cortex. Degeneration of the locus coeruleus (LC), which contains noradrenergic neurons, also occurs in PD. Norepinephrine is thought to be neuroprotective, and loss of LC neurons may be associated with a worsening of disease progression and the behavioral symptoms of PD.⁹³ Molecular events thought to be associated with the neurodegeneration of PD include mitochondrial dysfunction, oxidative stress, abnormal folding and accumulation of alpha-synuclein, abnormal phosphorylation, and dysfunction of the ubiquitin proteasome system (which regulates

intracellular protein processing).^{94,95} The resulting depletion of dopamine, an inhibitory neurotransmitter, and relative excess of cholinergic (excitatory) activity in the feedback circuit are manifested by hypertonia (tremor and rigidity) and akinesia, producing a syndrome of abnormal movement called **parkinsonism (Parkinson syndrome, parkinsonian syndrome, paralysis agitans)** (Fig. 17.29). Neuroimaging shows degeneration of dopaminergic neurons preceding the onset of motor symptoms by as long as 3 to 6 years.⁹¹ Dementia may develop over decades with infiltration of Lewy bodies and plaque formation similar to Alzheimer disease.⁹⁶ Loss of cholinergic subcortical input into the cortex is associated with nonmotor symptoms of PD.⁹⁷

Positron-emission tomography scan showing reduced fluorodopa uptake in the basal ganglia consistent with neurodegeneration (*right*) compared with a normal control (*left*). (From Perkin GD et al: *Atlas of clinical neurology*, ed 3, Philadelphia, 2011, Saunders.)

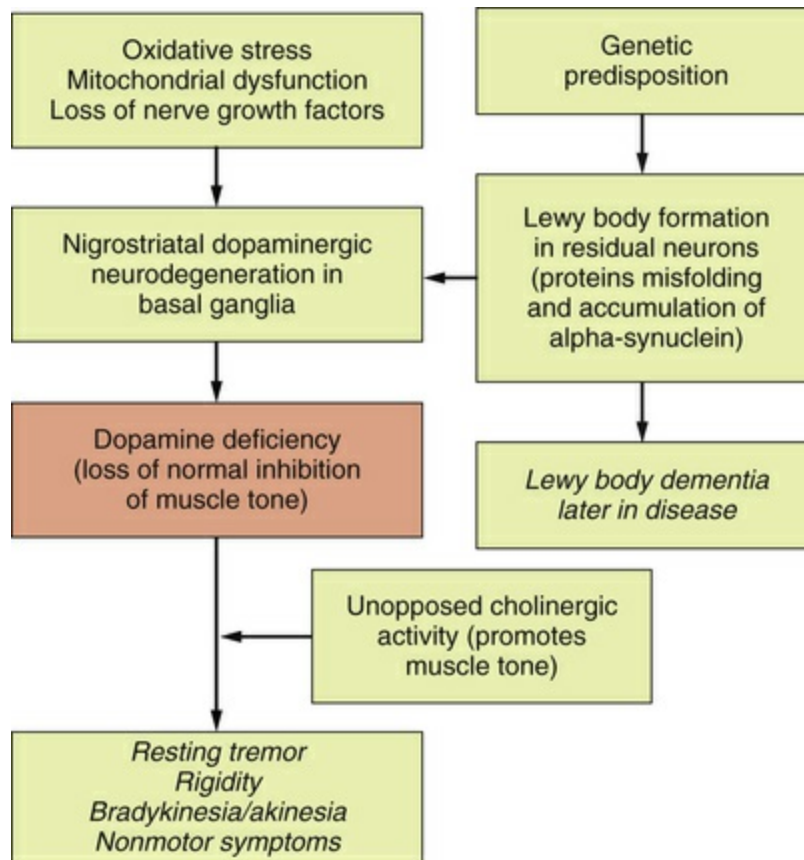

FIGURE 17.29 Pathophysiology of Parkinson Disease.

◆Clinical Manifestations.

The classic manifestations of Parkinson disease are resting tremor, rigidity, bradykinesia/akinesia, postural disturbance, dysarthria, and dysphagia. They may develop alone or in combination but, as the disease progresses, all are usually present. There is no true paralysis. Onset of symptoms is insidious, and symptoms appear after a 70% to 80% loss of pigmented nigral neurons and a 60% to 70% loss of striatal dopamine.⁹⁸ The symptoms are always bilateral but usually involve one side early in the illness. Because the onset is insidious, the beginning of symptoms is difficult to document. Reflex status, sensory status, and mental status usually are normal early in the disease.

Postural abnormalities (flexed, forward leaning), difficulty walking, and weakness develop as neurodegeneration progresses (Fig. 17.30). Disorders of equilibrium result from postural abnormalities. The person with PD is unable to make the appropriate postural adjustment to tilting or falling and falls like a post when starting to tilt. The short, accelerating steps of the person with PD are an attempt to maintain an upright position while walking. Individuals also are unable to right themselves when changing from a reclining or crouching position to a standing position. Speech may be slurred.

FIGURE 17.30 Stooped Posture of Parkinson Disease. (From Perkin DG et al: *Mosby's color atlas and text of neurology*, ed 2, London, 2002, Mosby.)

Nonmotor symptoms are common. Sleep disorders and excessive daytime sleepiness are commonly experienced. Sensory disturbances (pain and impaired smell and vision), urinary urgency, difficulty concentrating, depression, apathy, and hallucinations are some of the nonmotor symptoms of Parkinson disease. Loss of smell can be an early nonmotor symptom.⁹⁹ Autonomic-neuroendocrine changes also contribute to nonmotor symptoms and include inappropriate diaphoresis, orthostatic hypotension, drooling, gastric retention, constipation, and urinary retention.¹⁰⁰

Progressive dementia is more common in persons older than 70 years with alterations in executive function (concept formation, planning, abstraction, calculations, and judgment) and memory and

visuospatial (complex perceptual discrimination and spatial orientation) deficits.¹⁰¹ Lewy bodies are distributed diffusely in many neurons causing a Lewy body dementia.³³ Mental status may be further compromised by the side effects of the medication taken to control symptoms.

◆Evaluation and Treatment.

There is no diagnostic marker for PD.¹⁰² The diagnosis of PD is based on the history and clinical features of the disease. Causes of secondary parkinsonism are first excluded. Specific gene panels and imaging studies are evolving for early diagnosis.¹⁰³ Early nonmotor symptoms of PD can precede motor symptoms, and their identification may assist early diagnosis and guide disease-modifying strategies.¹⁰⁴ Treatment of PD is symptomatic, with drug therapy to protect or restore striatal dopamine levels and decrease akinesia and manage nonmotor symptoms.¹⁰⁵ However, because of troublesome side effects and loss of effectiveness, drug therapy may not be started until the symptoms become incapacitating.^{106,107} Recent studies of the gut microbiome in mice indicate that gut dysbiosis is a cause of synucleinopathies and neuroinflammation, with early manifestations of subtle motor and gastrointestinal symptoms, such as constipation. More research is needed to assist with early diagnosis and preventive strategies.¹⁰⁸ Deep brain stimulation (i.e., subthalamic neurostimulation) is replacing surgery to treat persons unresponsive to drug therapy. Implants of stem cells and fetal cells, as well as gene therapy, are strategies for future treatments.¹⁰⁹ Nonmotor symptoms and general immobility are special problems requiring interdisciplinary efforts to improve functional status.¹¹⁰

Upper and Lower Motor Neuron Syndromes

Paresis and paralysis are symptoms of upper and lower motor neuron syndromes (Table 17.23). **Paresis (weakness)** is impairment of motor function, that is, partial paralysis with incomplete loss of muscle power. **Paralysis** is loss of motor function so that a muscle group is unable to overcome gravity.

TABLE 17.23**UPPER AND LOWER MOTOR NEURON SIGNS AND SYMPTOMS**

UPPER MOTOR NEURON (PYRAMIDAL CELLS [MOTOR CORTEX])	LOWER MOTOR NEURON (VENTRAL HORN [SPINAL CORD], MOTOR NUCLEI [BRAINSTEM])
Muscle groups are affected	Individual muscles may be affected
Mild weakness	Mild weakness
Minimal disuse muscle atrophy	Marked muscle atrophy
No fasciculations	Fasciculations
Increased muscle stretch reflexes (clasp-knife spasticity; resistance to passive flexion that releases abruptly to allow easy flexion)	Decreased muscle stretch reflexes
Clonus may be present	Clonus not present
Hypertonia, spasticity	Hypotonia, flaccidity Hyporeflexia
Pathologic reflexes (Babinski and Hoffmann signs, loss of abdominal reflexes)	No Babinski sign
Often initial impairment of only skilled movements	Asymmetric and may involve one limb only in beginning to become generalized as disease progresses

Upper Motor Neuron Syndromes.

Upper motor neuron syndromes are the result of damage to descending motor pathways at cortical, brainstem, or spinal cord levels. Upper motor neurons direct the lower motor neurons to produce movements, such as walking or chewing. Upper motor neuron paresis/paralysis also is known as *spastic paresis/paralysis*, and different terms are used to describe the specific disorders ([Box 17.8](#)).

Box 17.8**Upper Motor Neuron Paralysis**

Hemiparesis/hemiplegia is paresis/paralysis of the upper and

lower extremities on one side.

Diplegia is paralysis of corresponding parts of both sides of the body as a result of cerebral hemisphere injuries.

Paraparesis/paraplegia is weakness/paralysis of the lower extremities as a result of lower spinal cord injury.

Quadriparesis/quadriplegia is paresis/paralysis of all four extremities as a result of upper spinal cord injury (spinal cord injury is discussed in [Chapter 18](#)).

Upper motor neuron paresis/paralysis is associated with a pyramidal motor syndrome. The **pyramidal motor syndrome** involves a series of motor dysfunctions resulting from interruption of the pyramidal system ([Figs. 17.31](#) and [17.32](#)). The injury may be in the cerebral cortex, the subcortical white matter, the internal capsule, the brainstem, or the spinal cord. The clinical manifestations reflect overactivity and include excessive movements, such as clonus and spasms, occurring regularly as a result of loss of higher motor control. The clinical manifestations can vary depending on the location of the lesion, suddenness of onset, and age of the individual.

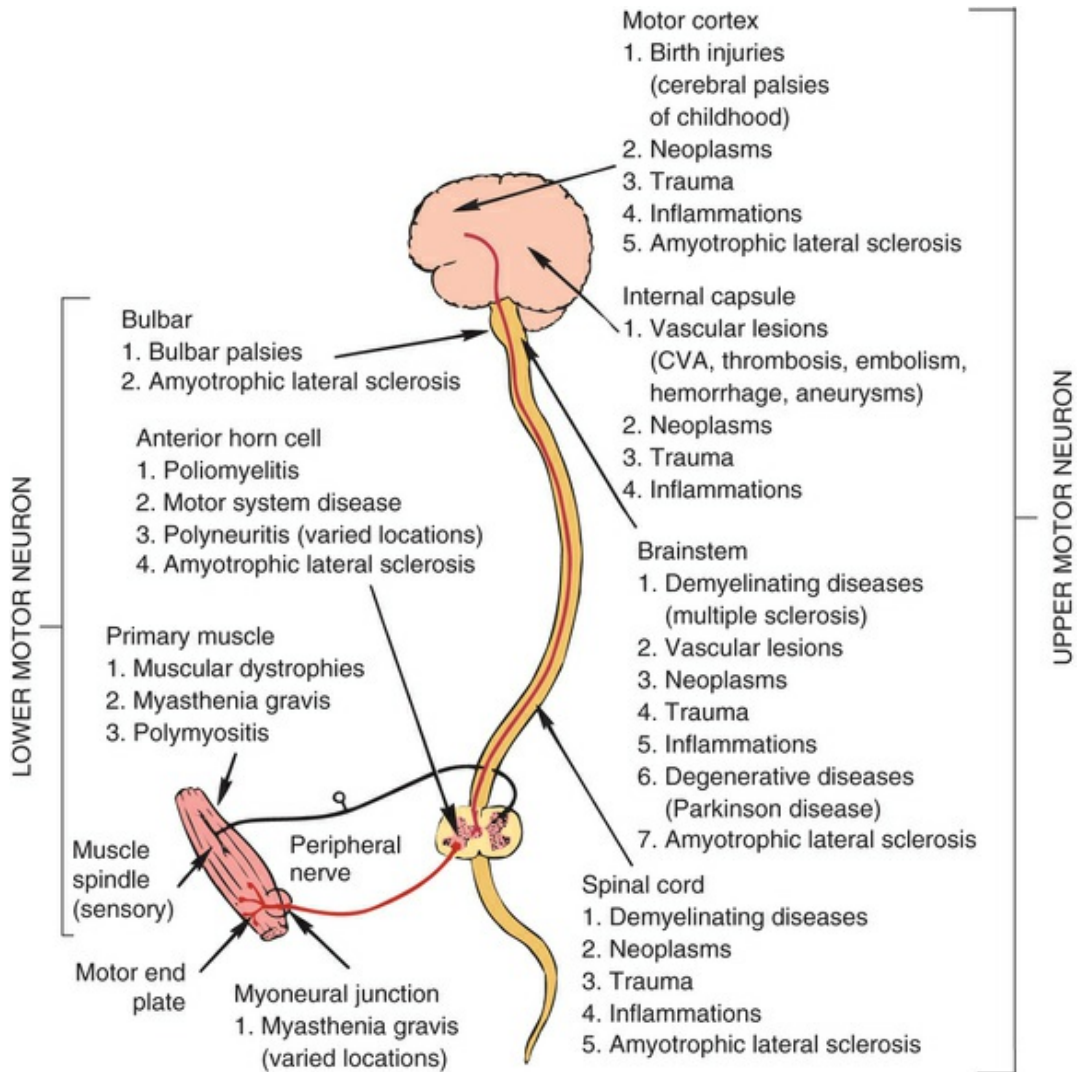

FIGURE 17.31 Disturbances in Motor Function. Disturbances in motor function are classified pathologically along upper and lower motor neuron structures. It should be noted that neoplasms occur at more than one site in an upper motor neuron (*above right*). A few pathologic conditions, such as amyotrophic lateral sclerosis, involve upper and lower motor neuron structures. Other lesion sites include myoneural junctions and primary muscles, making it possible to classify conditions as neuromuscular and muscular, respectively. CVA, Cerebrovascular accident.

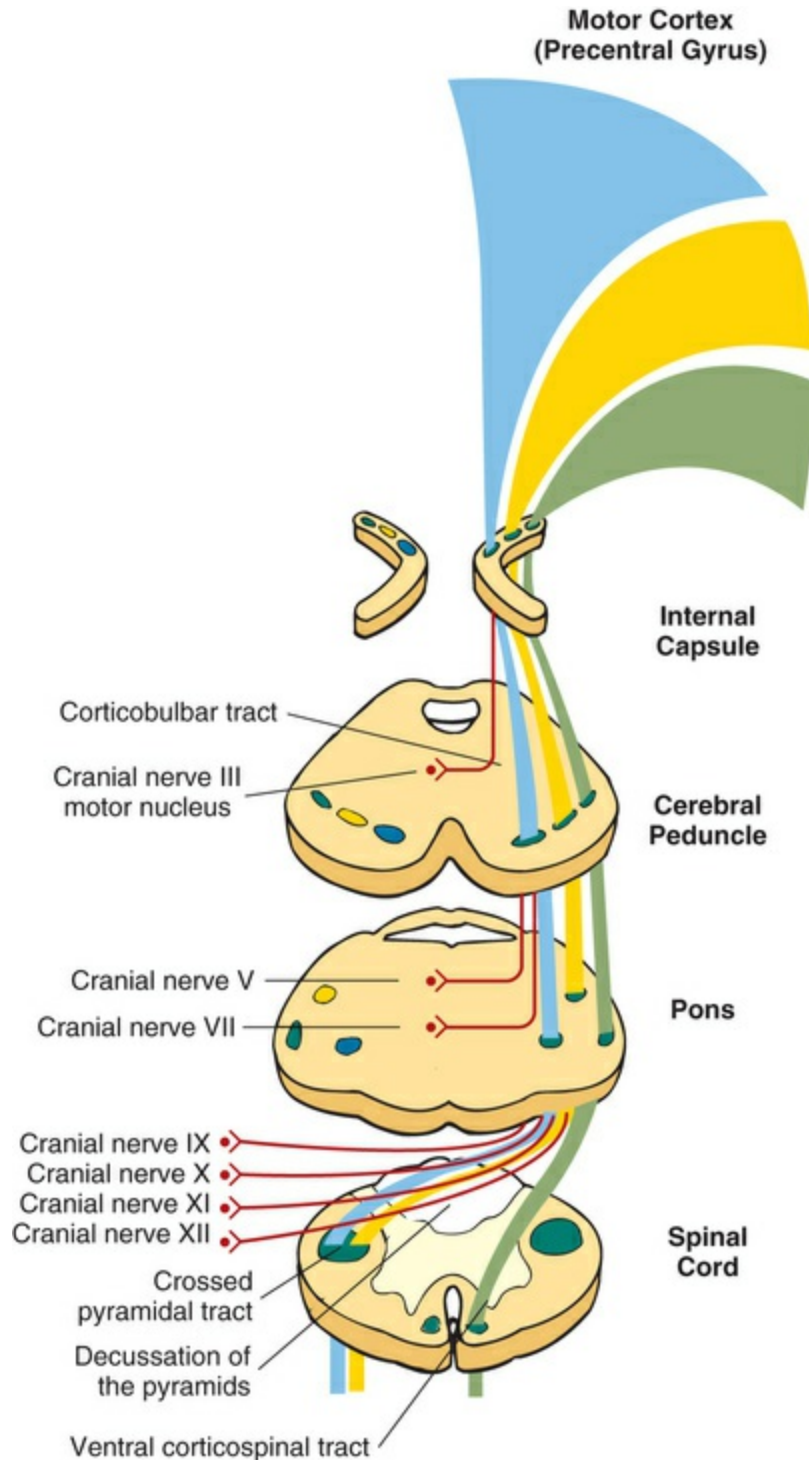

FIGURE 17.32 Structures of the Upper Motor Neuron, or Pyramidal, System. Pyramidal system fibers are shown to originate primarily in the cells in the precentral gyrus of the motor cortex; to converge at the internal capsule; to descend to form the central third of the cerebral peduncle; to descend further through the pons, where small fibers supply cranial nerve motor nuclei along the way; to form pyramids at the medulla, where most of the fibers decussate; and then to continue to descend in the lateral column of the white matter of the spinal cord. A few fibers descend without

crossing at the medulla level.

Spinal shock is the temporary loss of all spinal cord functions below the lesion (below the level of the pons). It is characterized by complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function. Hypotension can occur from loss of sympathetic tone at higher levels of spinal cord injury. A major factor in spinal shock is the sudden destruction of the efferent pathways from the motor cortex and brainstem. If destruction occurs more slowly, spinal shock may not develop (see [Chapter 18](#)).

If the pyramidal system is interrupted above the level of the pons, the hand and arm muscles are greatly affected. Paralysis rarely involves all the muscles on one side of the body, even when the hemiplegia results from complete damage to the internal capsule. Bilateral movements, such as those of the eye, jaw, and larynx, are affected only slightly, if at all. Predominantly the limbs are influenced. Because of their bilateral control, trunk muscles are much less affected.

Paralysis associated with a pyramidal motor syndrome rarely remains flaccid for a prolonged time. After a few days or weeks, a gradual return of spinal reflexes marks the end of spinal shock. Reflexes then become hyperactive, and muscle tone is increased significantly, particularly in antigravity muscles. Spasticity is common, although rigidity occasionally occurs. Most often, passive range of motion causes the “clasp-knife” phenomenon, probably by activating stretch receptors in the muscle spindles and Golgi tendon organ. (Muscle function is discussed in [Chapter 44](#).) With pyramidal motor syndrome, predominantly the flexors of the arms and the extensors of the legs are affected. The Babinski sign is present (stroking the sole of the foot causes extension of the big toe rather than flexion, and fanning of the other toes).

Lower Motor Neuron Syndromes.

Lower (primary, alpha) motor neurons are the large motor neurons in the anterior (ventral) horn of the spinal cord and the motor nuclei of the brainstem. The axons from these nerve cell bodies bring nerve

impulses from upper motor neurons to the skeletal muscles through the anterior spinal roots or cranial nerves (Fig. 17.33). **Lower motor neuron syndromes** impair voluntary and involuntary movement. The degree of paralysis or paresis is proportional to the number of lower motor neurons affected. If only some of the motor units that supply a muscle are affected, only partial paralysis or paresis results. If all the motor units are affected, a complete paralysis results. Other clinical manifestations also are proportional to the degree of dysfunction, but the precise manifestations depend on the location of the dysfunction in the motor unit and in the CNS.

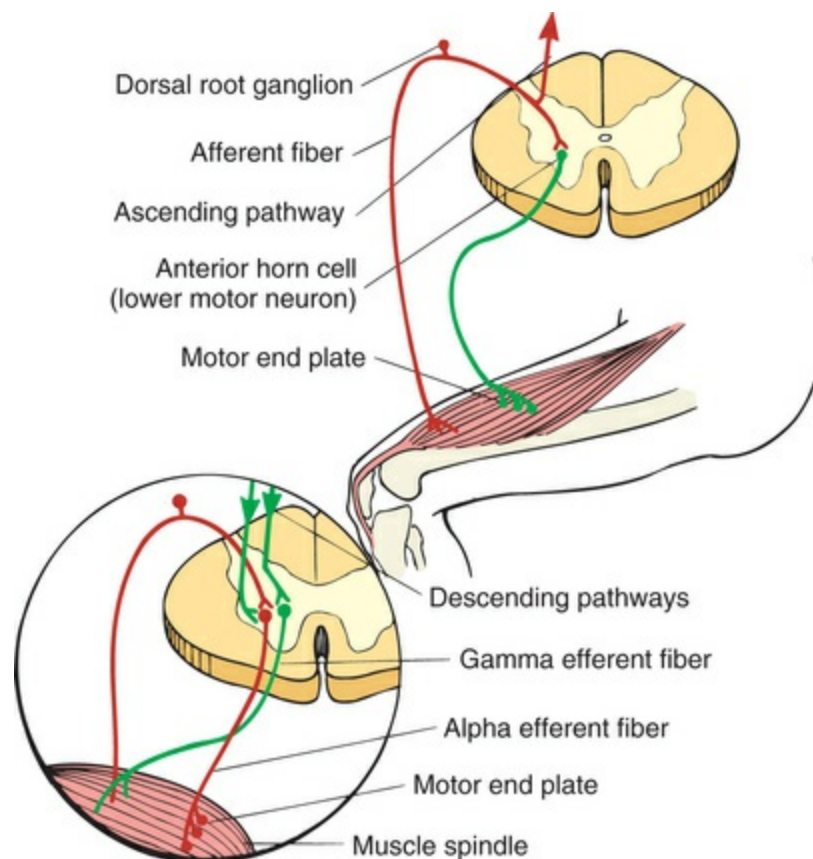

FIGURE 17.33 Component Structure of a Lower Motor Neuron, Including Motor (Efferent) and Sensory (Afferent) Elements. *Top*, Anterior horn cell (in anterior gray column of spinal cord and its axon), terminating in motor end plate as it innervates extrafusal muscle fibers in the quadriceps muscle. *Detailed enlargement*: Sensory and motor elements of the gamma loop system. The gamma efferent fiber is shown innervating the polar, or end, region of the muscle spindle (sensory receptor of skeletal muscle). Contraction of muscle spindle fibers stretches the central portion of the spindle and causes the afferent spindle fiber to transmit the impulse

centrally to the cord. Muscle spindle afferent fibers in turn synapse on the anterior horn cell and are transmitted by way of gamma efferent fibers to skeletal (extrafusal) muscle, causing it to contract. Muscle spindle discharge is interrupted by active contraction of extrafusal muscle fibers.

Small motor (gamma) neurons, which function to maintain muscle tone and protect the muscle from injury, also are necessary for normal motor movement. They depend on input from the muscle spindle (arriving through an afferent limb rising to the cord). Dysfunction in this motor system (the gamma loop) impairs tone and reduces the tendon reflexes, causing hyporeflexia. The muscles become susceptible to damage from hyperextensibility because the normal protective mechanisms that prevent muscle fiber injury are impaired. The degree of tone loss and the loss of tendon reflexes are proportional to the dysfunction in these reflex motor units.

Generally, the large and small motor neuron systems are equally affected. Therefore the muscle has reduced or absent tone and is accompanied by hyporeflexia or areflexia (loss of tendon reflexes) and flaccid paresis/paralysis.

Denervated muscles (i.e., muscles that have lost their nervous system input) atrophy over weeks to months, mostly from disuse, and demonstrate fasciculations (muscle rippling or quivering under the skin). Occasionally denervated muscles cramp. Fibrillation is isolated contraction of a single muscle fiber because of metabolic changes in denervated muscle and is not clinically visible.

Motor Neuron Diseases

Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the spinal cord, brainstem, or cortex. Amyotrophic lateral sclerosis (see section on [Amyotrophic Lateral Sclerosis](#)) and paralytic poliomyelitis (see [Chapter 10](#)) are examples of these diseases.

Several pathologic processes may generate motor neuron diseases that can be sporadic or inherited. A virally induced or postinfectious or postvaccination inflammatory process may injure or destroy anterior horn cells or cranial nerve cell bodies. Most of these

inflammatory processes are mild and are followed by rapid cellular recovery (Box 17.9).

Box 17.9

Bell Palsy

The etiology of Bell palsy (facial nerve palsy) remains unknown. There is usually an inflammatory reaction compressing the facial nerve in the fallopian (facial) canal of the middle ear, particularly in the narrowest labyrinthine segment, followed by demyelinating neural change. The most distressing symptoms are unilateral facial weakness and inability to smile or whistle. Bell palsy may be caused by reactivation of herpesviruses in cranial nerve VII (facial) geniculate ganglia or an autoimmune response. The signs usually have an acute onset (within 72 hours). Herpes simplex type 1 has been detected in up to 78% of cases and herpes zoster in 30% of cases. Severe pain with facial palsy and a vesicular rash in the ear or mouth suggest herpes zoster infection. Ramsay Hunt syndrome (herpes zoster oticus) is rare, but complete recovery is less than 50%. Recovery from Bell palsy is usually complete and may not require treatment. Both disorders may be treated with antivirals, corticosteroids, or both, and physiotherapy. Treatment should be individualized according to severity of symptoms.

Data Vakharia K, Vakharia K. *Facial Plast Surg Clin North Am* 24(1):1-10, 2016; Glass GE, Tzafetta K: *Fam Pract* 31(6):631-642, 2014; Eviston TJ et al: *J Neurol Neurosurg Psychiatry* 86(12):1356-1361, 2015.

In motor neuron disease, muscle strength, muscle tone, and muscle bulk are affected in the muscles innervated by the involved motor neurons. The paresis and paralysis associated with anterior horn cell injury are segmental, but because each muscle is supplied by two or more roots, the segmental character of the weakness may be difficult to recognize. When cranial nerve motor nuclei are affected (these lack nerve roots and have only small rootlets near the point of exit from

the brainstem), the distribution of the motor weakness follows that of the peripheral nerve. The weakness may involve distal muscles, proximal muscles, and the muscles of midline structures. Hypotonia and hyporeflexia or areflexia are present.

The atrophy associated with motor neuron disease is segmental when the anterior horn cells of the spinal cord are involved and follows the distribution of the peripheral nerve when the motor nuclei of the cranial nerves are affected. The atrophy may be in distal, proximal, or midline muscles. Fasciculations are particularly associated with primary motor neuron injury, and muscle cramps are common. Mild fatigue is a common complaint. If the pathologic process is limited to the primary motor neuron, no sensory changes are evident.

Because degenerative disorders can cause loss of nerve cells in the anterior horn or motor nuclei, the surviving cells are small and shrunken and filled with lipofuscin. Lost neurons are replaced by astrocytes. The roots or rootlets are thin, and the muscles show denervation and atrophy.

Several brainstem syndromes involve damage to one or more of the cranial nerve nuclei. These are called *cranial nerve palsy* (Table 17.24) and may be caused by vascular occlusion, tumor, aneurysm, tuberculosis, or hemorrhage.

TABLE 17.24

EXAMPLES OF CRANIAL NERVE PALSIES

TYPE OF NUCLEAR PALSY	CAUSES	ASSOCIATED CLINICAL MANIFESTATIONS
Ocular	Upper brainstem tumor	Other cranial nerve signs
	Cerebrovascular disease in the vertebrobasilar system Aneurysm Intramedullary bleeding	Contralateral spastic hemiparesis/hemiplegia Contralateral hyperreflexia Contralateral extensor plantar reflex

Facial	Pontine tumor Cerebrovascular disease in the vertebrobasilar system	Paresis/paralysis of both upper and lower facial muscles for both voluntary movement and emotionally induced movement
Vagal	Intramedullary tumor	Ipsilateral loss of pain and temperature sensations of the face
	Cerebrovascular disease in the vertebrobasilar system	Contralateral spastic arm and leg paresis/hemiplegia Ipsilateral cerebellar signs
Hypoglossal	Intramedullary tumor	Contralateral loss of position sense and vibration in the arm and leg
	Cerebrovascular disease in the vertebrobasilar system	Contralateral spastic hemiparesis/hemiplegia

The anterior horn cells and the motor nuclei of the cranial nerves may be affected secondarily in many severe pathologic processes that primarily involve the peripheral nerves. The condition may extend proximally to affect the nerve roots or rootlets and the motor neurons themselves, a process commonly seen, for example, in Guillain-Barré syndrome (see [Chapter 18](#)). If sufficient numbers of motor neurons are destroyed, permanent loss of motor function results because regeneration of the damaged axons requires a living neuronal cell body.

A group of degenerative disorders principally cause progressive motor cell atrophy. One of these is **progressive spinal muscular atrophy**, in which the degenerated anterior horn cells of the spinal cord are the affected motor neurons. This disorder occurs in adults and closely resembles the familial progressive muscular atrophies that occur in infants and children and that are considered inherited metabolic disorders (see [Chapter 46](#)). If the motor nuclei of the cranial nerves are affected instead of the anterior horn cells, the disorder is labeled **progressive bulbar palsy**, so named because the myelencephalon (medulla and upper cranial nerves) originally was called the *bulb* and a degenerative process causes a progressively more serious condition. When any lower motor neuron syndrome involves the cranial nerves that arise from the bulb (i.e., cranial nerves IX, X,

and XII), the dysfunction is called a **bulbar palsy**.

The clinical manifestations of bulbar palsy include paresis or paralysis of the jaw, face, pharynx, and tongue musculature. Articulation is affected, especially articulation of the lingual (*r, n, l*), labial (*b, m, p, f*), dental (*d, t*), and palatal (*k, g*) consonants. Modulation is impaired, making the voice rasping or nasal. Pharyngeal reflexes are diminished or lost. Palate and vocal cord movement during phonation is impaired, and chewing and swallowing are affected. The facial muscles are weak, and the face appears to droop. The jaw jerk reflex is decreased. Atrophy eventually becomes apparent, as do fasciculations. All these manifestations become progressively worse, leading to aspiration, malnutrition, possible dehydration, and an inability to communicate verbally.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease) is a worldwide degenerative disorder with loss of lower and upper motor neurons resulting in progressive muscle weakness. *Amyotrophic* (without muscle nutrition or progressive muscle wasting) refers to the predominant lower motor neuron component of the syndrome. *Lateral sclerosis*, scarring of the corticospinal tract in the lateral column of the spinal cord, refers to the upper motor neuron component of the syndrome.

ALS may begin at any time from the fourth decade of life; its peak occurrence is between 60 and 69 years of age with about 3.9 cases per 100,000 population in the United States. The prevalence is higher in males.¹¹¹ Most cases of ALS are sporadic. A subset (about 10% to 20%) have a familial form with genetic mutations in C9ORF72 (chromosome 9 open reading frame 72), superoxide dismutase (*SOD1*), and fused in sarcoma (*FUS*) that contribute to the neurotoxicity affecting motor neurons. Mutated TAR RNA-binding protein 43 (*TDP-43*) is a major constituent of the toxic ubiquitinated protein inclusions found in motor neurons and glial cells. More than 40 ALS-associated genes have been identified.^{112,113} Gene and environmental interactions

are being evaluated as a cause of ALS.¹¹⁴ Genetic testing is available.

◆Pathophysiology.

The cause of ALS is unknown. Apoptotic factors, abnormal synthesis of filament units, defects in axonal transport, glutamate excitotoxicity, oxidative stress, growth factors, mitochondrial dysfunction, and neuroinflammation are under investigation.¹¹⁵

The principal pathologic feature of ALS is degeneration and death of upper and lower motor neurons, including the neuromuscular junction. There is a decrease in large motor neurons in the spinal cord, brainstem, and cerebral cortex (premotor and motor areas) with ongoing degeneration in the remaining motor neurons. The nuclei of cranial nerves III, IV, and VI usually are not involved. Death of the motor neuron results in axonal degeneration and secondary demyelination with glial proliferation and sclerosis (scarring) along the corticospinal tract. Inclusion bodies containing the protein *ubiquitin* are found in surviving neurons. However, there also is widespread neural degeneration of nonmotor neurons in the spinal cord and motor cortices, as well as in the premotor, sensory, and temporal cortices.¹¹⁶ Altered astrocytes and microglial functions are suspected to exist.

Lower motor neuron degeneration denervates motor units. Adjacent, still-viable lower motor neurons attempt to compensate by distal intramuscular sprouting, reinnervation, and enlargement of motor units.

◆Clinical Manifestations.

Presentation of symptoms can be variable among individuals because of the numerous genes and multiple systems involved. The initial onset of ALS can be subtle with cramping or weakness that affects a limb, incoordination, slurring of speech, and difficulty swallowing. About 60% of individuals have a spinal form of the disease with focal muscle weakness beginning in the arms and legs and progressing to muscle atrophy, spasticity, and loss of manual dexterity and gait. No associated mental, sensory, or autonomic symptoms are present.¹¹⁷

Muscle weakness in ALS exhibits the following characteristics:

1. Paresis usually begins in a single muscle group.
2. Corresponding muscle groups are asymmetrically affected in a mottled distribution.
3. Gradual involvement occurs in all striated muscles, except extraocular and heart muscles, and progresses to paralysis with no remissions.
4. Flaccid and spastic paresis may coexist in a single muscle group; flaccid paresis may mask spasticity, which is usually mild.
5. Urethral and anal sphincter weakness is uncommon.

The lower motor neuron syndrome of flaccid paresis consists of weakness of individual muscles, progressing to paralysis, associated with hypotonia and primary muscle atrophy (i.e., atrophy caused by denervation). Hypotonia is manifested by (1) decreased resistance to passive movement, (2) hypoactive or absent deep tendon reflexes, (3) absent abdominal and cremasteric reflexes, and (4) absent Babinski sign. Primary atrophy is manifested by (1) severe, irreversible muscular wasting; (2) fasciculations and fibrillation; (3) metabolically related changes in the skin and appendages; and (4) specific electromyographic (EMG) findings. Metabolic changes include: (1) thinning of the skin, (2) thickening of the nails, (3) loss of body hair, and (4) decreased perspiration.

The upper motor neuron syndrome of spastic paresis consists of weakness of movement patterns, progressing to paralysis, associated with spasticity and, in some cases, atrophy secondary to disuse. Spasticity is manifested by (1) clasp-knife phenomenon, evident with passive movement; (2) hyperactive deep tendon reflexes and clonus with severe spasticity; (3) absent abdominal and cremasteric reflexes; and (4) presence of Babinski sign. The coexistence of frontal dementia and ALS has been demonstrated and may be related to common gene mutations.¹¹⁸

◆Evaluation and Treatment.

The diagnosis of ALS is based predominantly on medical history and physical examination with no evidence of other neuromuscular disorders. Electromyography and muscle biopsy results verify lower motor neuron degeneration and denervation. Imaging studies and cerebrospinal fluid biomarkers can assist in making the diagnosis. Riluzole (Rilutek), an antiglutamate, is the only drug approved by the Food and Drug Administration for treatment of ALS and prolongs life for months. Supportive and rehabilitation management is directed at relief of symptoms, prevention of complications, maintenance of maximal function, and maintenance of optimal quality of life. Special problems requiring preventive and symptomatic management are communication difficulties caused by dysarthria and dysphonia, salivation problems with either thick saliva or excessively thin saliva (sialorrhea), and dyspnea caused by diaphragmatic and intercostal weakness. Ventilatory issues become prominent. Psychologic support of the affected individual and the family is extremely important in this disorder. ALS is fatal from respiratory failure usually within 3 years of diagnosis. A small percentage of individuals live 5 to 10 years or longer.¹¹⁷

Alterations in Complex Motor Performance

The alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.

Disorders of Posture (Stance)

An inequality of tone in muscle groups because of a loss of normal postural reflexes results in a posturing of limbs. Many reflex systems govern tone and posture, but the most important factor in posture control is the stretch reflex, in which extensor (antigravity) muscles stretching causes increased extensor tone and inhibited flexor tone. Four types of disorders of posture are described: (1) dystonic posture, (2) decerebrate posture, (3) basal ganglion posture, and (4) senile posture. Equilibrium and balance are disrupted when postural

disorders are present.

Dystonia is the maintenance of an abnormal posture through muscular contractions. When muscular contractions are sustained for several seconds, they are called **dystonic movements**; when contractions last for longer periods, they are called **dystonic postures**, such as in torticollis. Dystonic postures may last for weeks, causing permanent fixed contractures. Dystonia has been associated with basal ganglia abnormality, but the exact pathophysiologic mechanisms are unknown (Box 17.10). One dystonic posture discussed earlier in this chapter is decorticate posture (striatal posture or upper motor neuron dysfunction posture), which may be unilateral or bilateral in occurrence.

Box 17.10

Botulinum Toxin Therapeutic Effectiveness in Dystonia

Botulinum toxin, both A and B, is effective in relieving cervical dystonia (spasmodic torticollis) symptoms in adults and is the mainstay of modern treatment for focal dystonia and pain. The effectiveness of other drugs (benzodiazepines, gamma-aminobutyric acid [GABA] inhibitors, atypical anticonvulsants, dopaminergic agonists and antagonists), as well as the effect of surgical interventions or physical therapies, is not empirically known. Deep brain stimulation also is an option when other procedures are ineffective.

Data from Fox MD, Alterman RL: *JAMA Neurol* 72(6):713-719, 2015; Jinnah HA, Factor SA: *Neurol Clin* 33(1):77-100, 2015; Skogseid IM: *Acta Neurol Scand Suppl* 198:13-19, 2014.

Decorticate posture (antigravity posture or hemiplegic posture) is characterized by upper extremities that are flexed at the elbows and held close to the body and by lower extremities that are externally rotated and extended (see Fig. 17.6). Decorticate posture/response is

believed to occur when the brainstem is not inhibited by the motor function of the cerebral cortex. Upper motor neuron posture is more commonly described as the arm flexed at the elbow with a wristdrop; the leg inadequately bent at the knee, the hip excessively circumducted, and the presence of a footdrop.

Decerebrate posture refers to increased tone in extensor muscles and trunk muscles, with active tonic neck reflexes. When the head is in a neutral position, all four limbs are rigidly extended (see Fig. 17.6). The decerebrate posture is caused by severe injury to the brain and brainstem, resulting in overstimulation of the postural righting and vestibular reflexes.

Basal ganglion posture refers to a stooped, hyperflexed posture with a narrow-based, short-stepped gait. This posture abnormality results from the loss of normal postural reflexes and not from defects in proprioceptive, labyrinthine, or visual function. Dysfunctional equilibrium results when the individual loses stability and cannot make the appropriate postural adjustment to tilting or loss of balance, falling instead. Dysfunctional righting is the inability to right oneself when changing from a lying or crouching to a standing position or when rolling from the supine to the lateral or prone position. Dysfunctional postural fixation is the involuntary flexion of the head and neck, causing the person difficulty in maintaining an upright trunk position while standing or walking. Basal ganglion dysfunction, with loss of dopaminergic and cholinergic neurons, accounts for this posture.

Disorders of Gait

Four predominant types of gait associated with neurologic disorders are (1) upper motor neuron dysfunction gait, (2) cerebellar (ataxic) gait, (3) basal ganglion gait, and (4) frontal lobe ataxic gait. As with posture, equilibrium and balance are affected with gait disturbances.¹¹⁹

Several upper motor neuron gaits exist. With mild forms, the individual may have footdrop with fatigue and hip and leg pain. A **spastic gait**, which is associated with unilateral injury, is manifested

by a shuffling gait with the leg extended and held stiff, causing a scraping over the floor surface. The leg swings improperly around the body rather than being appropriately lifted and placed. The foot may drag on the ground, and the person tends to fall to the affected side. A **scissors gait** is associated with bilateral injury and spasticity. The legs are adducted, causing them to touch each other. As the person walks, the legs are still swung around the body but then cross in front of each other because of adduction. Injury to the pyramidal system accounts for these gaits (e.g., stroke, cerebral palsy, multiple sclerosis, spinal cord tumor).

A **cerebellar gait** is wide-based with the feet apart and often turned outward or inward for greater stability. The pelvis is held stiff and the individual staggers when walking. Cerebellar dysfunction with loss of coordination accounts for this particular gait.

A **basal ganglion gait** is a wide-based gait in which the person walks with small steps and a decreased arm swing. The head and body are flexed and the arms are semiflexed and abducted, whereas the legs are flexed and rigid in more advanced states. Basal ganglion dysfunction accounts for this gait and is associated with PD.

A **frontal lobe ataxic gait** also is wide-based with increased body sway and falls, loss of control of truncal motion, gait ignition failure, start hesitation, shuffling, and freezing. The gait is associated with frontal lobe damage or degeneration. The pattern may change as the frontal disease progresses. The slowness of walking, lack of heel-shin or upper limb ataxia, dysarthria, or nystagmus distinguishes the wide stance from cerebellar gait ataxia.¹²⁰

Gait disorders are often accompanied by balance, coordination, and sensory dysfunction that further alter mobility and increase risk for falls. Assessment and intervention strategies are important for prevention of injury.

Disorders of Expression

Disorders of expression involve the motor aspects of communication and include (1) hypermimesis, (2) hypomimesis, and (3) dyspraxias and apraxias. **Hypermimesis** is a disinhibition phenomenon that most

commonly manifests as pathologic laughter or crying. Pathologic laughter is associated with right hemisphere injury, and pathologic crying is associated with left hemisphere injury. The exact pathophysiology is not known. **Hypomimesis** manifests as aprosody, or the loss of voice modulation (pitch, speed, emphasis, emotion). Receptive aprosody involves an inability to *understand* emotion in speech and facial expression, whereas expressive aprosody involves the inability to *express* emotion in speech and facial expression. Aprosody is associated with right hemisphere damage.

Dyspraxia is the partial inability and **apraxia** is the complete inability to perform purposeful or skilled motor acts in the absence of paralysis, sensory loss, abnormal posture and tone, abnormal involuntary movement, incoordination, or inattentiveness. These are disorders of learned skilled movements (i.e., arm and hand movement [eating], standing and turning around, blowing out a candle).¹²¹ Dyspraxia and apraxia are associated with left hemisphere vascular disorders, particularly stroke, trauma, tumor, degenerative disorders, infections, and metabolic disorders. Both motor and sensory neural networks play a role in skilled movements¹²¹ (Table 17.25).

TABLE 17.25

DYSPRAXIAS AND APRAXIAS

TYPES	DESCRIPTION	LOCATION
Ideomotor apraxia	Impairment in selecting, sequencing, and spatial orientation of movements involved in gestures (spatial and temporal production errors)	Left parietal cortex (angular gyrus) or supramarginal gyrus
Posterior form	Difficulty performing in response to command and imitation; cannot discriminate well between poorly performed and well-performed acts	Left parietal cortex (angular gyrus or supramarginal gyrus) lesion
Anterior form	Performs poorly to command and imitation but comprehends and discriminates pantomime	Lesions anterior to the supramarginal gyrus, which disconnects visual kinesthetic motor engrams from premotor and motor areas
Conduction apraxia	Greater impairment in performance when imitating movements than when pantomiming to command;	Location unknown at this time

	comprehends pantomime and gesture but cannot perform the movements	
Disassociation apraxia	Inability to gesture normally to command and required verbal mediation; has good performance with imitation and actual tools and objects	Callosal abnormalities, but not all locations known
Ideational apraxia	Inability to carry out an ideational plan or a series of acts in the proper sequence	Location unclear at this time
Conceptual apraxia	Cannot recall type of action associated with specific tools, utensils, or objects (content and tool selection errors; may be unable to recall which tool is associated with a specific object or may have impaired mechanical knowledge)	Bilateral frontal and parietal dysfunction

True dyspraxias occur when the connecting pathways between the left and right cortical areas are interrupted, causing language-motor and motor representation disconnections between the hemispheres. Dyspraxias may result from any pathologic process that disrupts the cortical areas necessary for the conceptualization and execution of a complex motor act or the communication pathways within the left hemisphere or between the hemispheres.

Extrapyramidal Motor Syndromes

Because the extrapyramidal system encompasses all the motor pathways except the pyramidal system, two types of motor dysfunction comprise the **extrapyramidal motor syndromes**: (1) the basal ganglia motor syndromes and (2) the cerebellar motor syndromes. Unlike pyramidal motor syndromes, both extrapyramidal motor syndromes result in movement or posture disturbance without significant paralysis, along with other distinctive symptoms ([Table 17.26](#)).

TABLE 17.26

PYRAMIDAL VS. EXTRAPYRAMIDAL MOTOR SYNDROMES

	PYRAMIDAL MOTOR SYNDROME	EXTRAPYRAMIDAL MOTOR SYNDROME
MANIFESTATIONS	Unilateral movement	Paralysis of
		Little or no paralysis of voluntary movement

	voluntary movement	
Tendon reflexes	Increased tendon reflexes	Normal or slightly increased tendon reflexes
Babinski sign	Present	Absent
Involuntary movements	Absence of involuntary movements	Presence of tremor, chorea, athetosis, or dystonia
Muscle tone	Spasticity in muscles (e.g., clasp-knife phenomenon)	Plastic (equal throughout movement) rigidity or intermittent (generalized but predominantly in flexors of limbs and trunk) rigidity (cogwheel rigidity)
	Hypertonia present in flexors of arms and extensors of legs	Hypotonia, weakness, and gait disturbance in cerebellar disease

Basal ganglia motor syndromes are movement disorders that involve either a paucity or an excess of movements. Stress and nervous tension typically worsen the symptoms, whereas relaxation improves motor performance. Akinesia may occur despite normal strength. Involuntary movements, such as tremor, chorea, ballism, athetosis, and dystonia, also may occur and probably are caused by the loss of the normal modulating effects of the corpus striatum and other parts of the basal ganglia. They can be associated with brain trauma, stroke tumors, infection, metabolic disorders, multiple sclerosis, progressive supranuclear palsy, PD, and medication side effects.

Basal ganglia motor syndromes also are characterized by alterations in muscle tone and posture. Rigidity, together with the cogwheel phenomenon, is present in all muscle groups but is most prominent in those that maintain flexed position. Postural abnormalities result from the loss of normal postural reflexes. Dysfunctional equilibrium results from the loss of postural stability.

Cerebellar motor syndromes involve the cerebellum and may result in (1) acute loss of muscle tone; (2) difficulty with coordination of voluntary movements (ataxia); (3) minor degrees of muscle weakness, tendency toward fatigue, and impairment of associated

movements; and (4) disorders of equilibrium, posture, and gait. They are associated with hereditary ataxias and stroke, brain trauma, multiple sclerosis or tumors; or with systemic disorders (toxin exposure, celiac disease, heat stroke); or they are idiopathic. Cerebellar effects can be ipsilateral (primarily affecting the same side of the body), so damage to the right cerebellum generally causes symptoms on the right side of the body. Predominant symptoms depend on the area and extent of damage within the cerebellum. The four cerebellar syndromes are the rostral vermis, caudal vermis, cerebellar hemisphere, and pancerebellum¹²² (Table 17.27).

TABLE 17.27

CEREBELLAR MOTOR SYNDROMES

ANATOMIC LOCATION OF DYSFUNCTION	CHARACTERISTICS
Rostral vermis (so-called <i>anterior lobe</i>)	Ataxia of stance and gait with varying degrees of instability of the trunk and ataxia of legs; anteroposterior body sway; presence of Romberg sign
Caudal vermis (including flocculonodular lobe)	Truncal, postural, and gait ataxia; omnidirectional body sway; Romberg negative; tendency to fall; saccadic slow pursuit, nystagmus; inability to suppress vestibulo-ocular reflex (doll's eyes)
Cerebellar hemisphere (neocerebellar syndrome)	Severe disturbance in ipsilateral limb movements; hypotonia in acute situation; dysmetria (extremity overshooting its target); decomposition of movement; kinetic tremor, past-pointing; deviation of gait; dysarthria
Pancerebellum (combines all other syndromes)	Ataxia of trunk and bilateral limbs; ataxia of gait and stance; dysarthria; oculomotor disturbance

Data from McGee S: *Evidence-based physical diagnosis*, ed 4, St Louis, 2018, Elsevier; Timmann D, Diener HC: Coordination and ataxia. In Goetz GC, editor: *Textbook of clinical neurology*, St Louis, 2007, Saunders.

Diagnosis of a cerebellar motor syndrome is based on the symptoms, but these may vary because of the individual's attempts at compensation. Further, the nervous system often can operate well despite destruction of parts of the cerebellum, although the

mechanisms responsible for this retained function are not fully understood.

Summary Review

Alterations in Cognitive Systems

1. Three systems support cognitive function: attentional systems, memory and language systems, and affective or emotive systems.
2. Full consciousness is an awareness of oneself and the environment and includes an ability to respond to external stimuli with a wide variety of responses.
3. Consciousness has two components: arousal (state of awakesness) and awareness (content of thought).
4. Alterations in level of arousal may be caused by structural, metabolic, or psychogenic disorders.
5. Levels of consciousness can diminish in stages from alert and oriented to confusion and coma.
6. An alteration in breathing pattern and level of coma reflects the level of hemispheric and brainstem dysfunction.
7. Pupillary changes reflect changes in level of brainstem function, drug action, and response to hypoxia and ischemia.
8. Abnormal eye movements, including nystagmus and divergent gaze, reflect alterations in brainstem function.
9. Level of brain function manifests by changes in generalized motor responses or the presence of no responses.
10. Loss of cortical inhibition associated with decreased consciousness includes abnormal flexor and extensor movements.
11. Brain death represents irreversible total brain damage including an inability to maintain cardiac, respiratory, and other vital functions. Cerebral death or irreversible coma is death of the cerebral hemispheres exclusive of the brainstem and cerebellum.

12. Arousal returns in the vegetative state and minimally conscious state, but content of thought is absent or markedly reduced, respectively.
13. With locked-in syndrome (ventral pontine syndrome) content of thought and level of arousal are intact but the efferent pathways are disrupted with complete paralysis.
14. Akinetic mutism is a neurobehavioral state characterized by a severe loss of motivation to move or inability to voluntarily initiate motor responses, or both.
15. Alterations in awareness encompass all cognitive functions including awareness, selective attention, and memory.
16. With a deficit in selective attention, mediated by the brainstem, the parietal lobe structures, and the pulvinar nucleus of the thalamus, the individual cannot focus on selective stimuli and thus neglects those stimuli, causing a neglect syndrome.
17. Amnesia can be retrograde (loss of past memories) or anterograde (retention of old memories but an inability to form new ones). Global amnesia is a combination of both.
18. Frontal areas mediate vigilance, detection, and working memory (temporary storage of information). With a vigilance deficit, the person cannot maintain search and scanning activities. With a detection deficit, the person is unmotivated and unable to use feedback.
19. Data processing deficits are problems associated with recognizing and processing sensory information and include agnosias, aphasia, and acute confusional states.
20. Agnosias are a defect of recognition and may be tactile, visual, or auditory. They are caused by dysfunction in the primary sensory area or the interpretive areas of the cerebral cortex.
21. Aphasia is an impairment of comprehension (sensory) or production of language (expressive or motor).
22. Expressive aphasia involves loss of ability to produce spoken or written language with slow or difficult speech.
23. Receptive aphasia is a disturbance in understanding all

- language—verbal and reading comprehension.
24. Anomic aphasia is an inability to name objects, people, or qualities.
 25. Transcortical aphasias can be motor, sensory, or mixed.
 26. Global aphasia involves anterior and posterior speech areas, with expressive and receptive aphasia.
 27. Acute confusional states are characterized chiefly by defects in attention and coherence of thoughts and actions and, in the case of hyperactive delirium, an intense, autonomic nervous system hyperactivity.
 28. Dementia is an acquired impairment of intellectual function, memory, and language with alteration in behavior and can be caused by trauma, vascular disease, infection, and progressive neurodegeneration.
 29. AD is the most common chronic, irreversible dementia with accumulations of amyloid and tau protein neurofibrillary tangles in the brain. Less common forms include vascular and frontotemporal dementia.
 30. Seizures represent abnormal, excessive hypersynchronous discharges of cerebral neurons with transient alterations in brain function. Seizures may be focal or generalized. The categories of seizures include genetic, structural, metabolic, immune, infectious, and unknown.

Alterations in Cerebral Hemodynamics

1. Cerebral oxygenation is a critical management issue.
2. Cerebral perfusion pressure determines cerebral blood flow.
3. An injured brain may experience cerebral oligemia, normal cerebral blood flow but with increased intracranial pressure, or cerebral hyperemia.
4. Increased intracranial pressure may result from edema, excess CSF, hemorrhage, or tumor growth. When intracranial pressure approaches arterial pressure, hypoxia and hypercapnia produce brain damage.

5. Cerebral edema is an increase in the fluid content of the brain resulting from infection, hemorrhage, tumor, ischemia, infarct, or hypoxia.
6. The shifting or herniation of brain tissue from one compartment to another disrupts the blood flow of both compartments and damages brain tissue.
7. Supratentorial herniation involves temporal lobe and hippocampal gyrus shifting from the middle fossa to the posterior fossa; transtentorial herniation with a downward shift of the diencephalon through the tentorial notch; and shifting of the cingulate gyrus herniation under the falx.
8. The most common infratentorial herniation is a shift of the cerebellar tonsils through the foramen magnum.
9. Hydrocephalus comprises a variety of disorders characterized by an excess of fluid within the cranial vault, subarachnoid space, or both. Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production or obstruction within the ventricular system or by defective reabsorption of the fluid.

Alterations in Neuromotor Function

1. Motor dysfunction may be characterized as alterations of motor tone, movement, and complex motor performance.
2. Hypotonia and hypertonia are the main categories of altered muscle tone.
3. Four types of hypertonia exist: spasticity, paratonia (gegenhalten), dystonia, and rigidity.
4. Alteration in muscle movement includes hyperkinesia (excessive movement), hypokinesia (slow movement), and dyskinesias (abnormal voluntary movement).
5. Included in the category of hyperkinesia are chorea, athetosis, ballism, akathisia, tremor, and myoclonus.
6. HD (chorea) is a rare hereditary irreversible disease involving the basal ganglia and frontal cerebral cortex with a depletion

of neurons that secrete GABA (an inhibitory neurotransmitter) that causes involuntary, fragmentary movements accompanied by emotional lability and progressive dementia.

7. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movements.
8. PD is a common degenerative disorder of the basal ganglia (corpus striatum) involving degeneration of the dopamine-secreting nigrostriatal pathway resulting in overactivity by the subthalamic nucleus, causing tremor, rigidity, and bradykinesia. Involvement of the limbic system causes emotional lability. Progressive dementia may be associated with an advanced stage of the disease.
9. Two subtypes of paresis and paralysis are described: upper motor neuron and lower motor neuron.
10. An upper motor neuron syndrome is characterized by spastic paresis or paralysis, hypertonia, and hyperreflexia from interruption of the pyramidal system.
11. Interruption of the pyramidal tract below the pons results in spinal shock with complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function.
12. Lower motor neuron syndromes manifest with impaired voluntary and involuntary movements and flaccid paralysis.
13. Partial paralysis occurs with only partial loss of alpha motor neurons, and total paralysis is complete loss of alpha motor neurons. Loss of gamma motor neurons impairs muscle tone and decreases deep tendon reflexes.
14. Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the spinal cord, brainstem, or cortex.
15. Nuclear palsies involve damage to the cranial nerve nuclei.
16. Bulbar palsies involve cranial nerves IX, X, and XII.
17. ALS is a motor neuron disease. The pathogenesis of ALS is not fully known; however, lower and upper motor neuron degeneration occurs as well as degeneration of the nonmotor

neurons in the cortices and spinal cord. Clinical manifestations of ALS may include weakness in all muscles that may begin in a single muscle group, slurring of speech, and difficulty swallowing. Flaccid paresis progressing to paralysis is characteristic of the lower motor neuron syndrome.

18. Alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.
19. Disorders of posture include dystonic posture, decerebrate posture, basal ganglion posture, and senile posture.
20. Disorders of gait include upper motor neuron gaits, cerebellar gait, basal ganglion gait, and senile gait.
21. Disorders of expression include hypermimesis, hypomimesis, and dyspraxia or apraxia.
22. Dyspraxia is the partial inability and apraxia is the complete inability to perform purposeful or skilled motor acts.
23. Extrapyrarnidal motor syndromes include basal ganglia and cerebellar motor syndromes.
24. Basal ganglia disorders manifest with alterations in muscle tone and posture, including rigidity, involuntary movements, and loss of postural reflexes.
25. Cerebellar motor syndromes result in loss of muscle tone, difficulty with coordination, and disorders of equilibrium and gait.

Peripheral Nervous System and Neuromuscular Junction Disorders, 583

- Peripheral Nervous System Disorders, 583
- Neuromuscular Junction Disorders, 585

Tumors of the Central Nervous System, 587

- Brain Tumors, 587
- Spinal Cord Tumors, 592

Alterations in central nervous system (CNS) structure and function are caused by traumatic injury, vascular disorders, tumor growth, infectious and inflammatory processes, metabolic derangements (including those arising from nutritional deficiencies and drugs/chemicals), and degenerative processes. Alterations in peripheral nervous system function involve the nerve roots (radiculopathies), a nerve plexus, the nerves themselves (neuropathies), or the neuromuscular junction.

Central Nervous System Disorders

Traumatic Brain and Spinal Cord Injury

Traumatic Brain Injury

Traumatic brain injury (TBI) is an alteration in brain function or other evidence of brain pathology caused by an external force. The most common causes are falls for children and older adults followed by unintentional blunt trauma and motor vehicle accidents. Males have the highest incidence in every age group.¹ The incidence of TBI is highest among American Indian/Alaska Natives and blacks and in lower- and median-income families. In recent years, individuals with TBI have shown improved survival outcomes. Advancements have been made in enhanced safety measures (e.g., passive seat restraints, air bags, protective head gear), reduced transport time to hospitals or trauma centers, improved on-scene medical management, imaging of brain injury, prevention and management of secondary brain injury, and a better understanding of long-term consequences of all degrees of brain injury severity.

TBI can be classified as primary and secondary. Primary brain injury is caused by the direct impact or injury and can be focal, affecting one area of the brain, or diffuse (diffuse axonal injury [DAI]), involving more than one area of the brain.² Both types of injury can be associated with the same initiating event. Focal brain injury and diffuse axonal injury each account for half of all injuries. Focal brain injury accounts for more than two-thirds of head injury deaths and

DAI accounts for less than one-third of deaths. Secondary injury is an indirect consequence of the primary injury and includes systemic responses and a cascade of molecular and chemical events that affect the brain (Fig. 18.1). TBI can be mild, moderate, or severe. The Glasgow Coma Scale (GCS) is commonly used to grade severity of injury (Table 18.1). Other scales also may be used, including the Abbreviated Injury Scale, Injury Severity Score, and the length of posttraumatic amnesia.³ Most TBIs are mild.

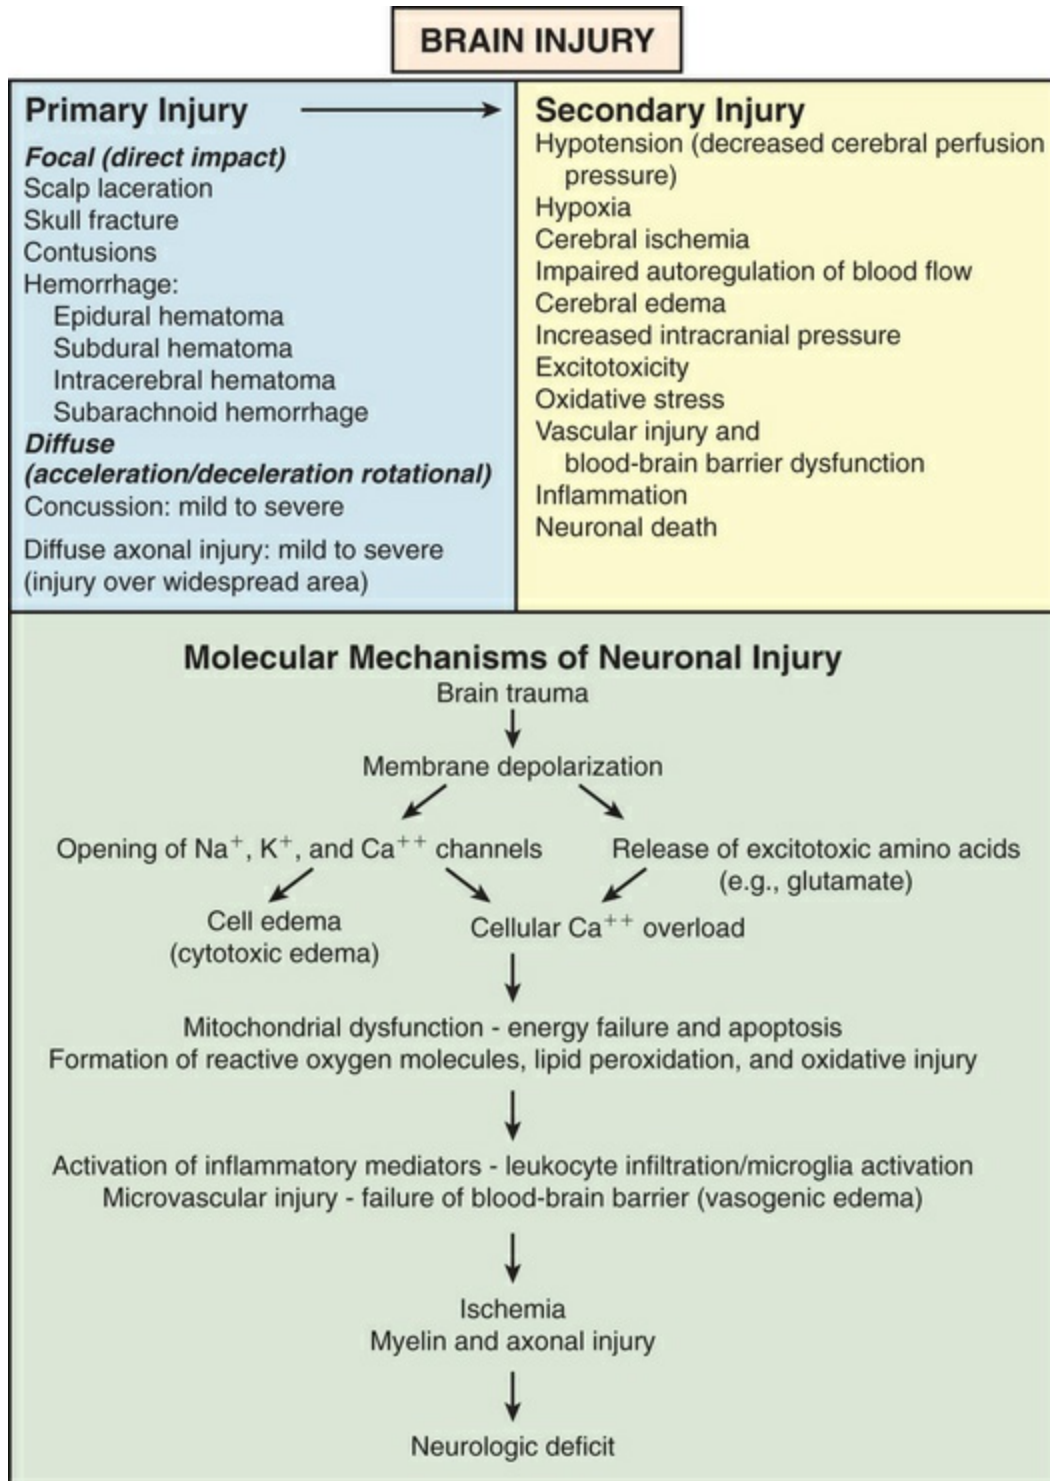

FIGURE 18.1 Pathophysiology of Brain Injury.

TABLE 18.1

GLASSOW/COMA SCORE*

GLASGOW COMA SCORE**

SCORE [†]	BEST EYE RESPONSE SCORE (4)	BEST VERBAL RESPONSE SCORE (5)	BEST MOTOR RESPONSE SCORE (6)
1	No eye opening	No verbal response	No motor response
2	Eye opening to pain	Incomprehensible sounds	Extension to pain
3	Eye opening to verbal command	Inappropriate words	Flexion to pain
4	Eyes open spontaneously	Confused	Withdrawal from pain
5	NA	Oriented	Localizing pain
6	NA	NA	Obeys commands

*The Glasgow Coma Score (GCS) is scored between 3 and 15, with 3 being the worst and 15 the best. It is composed of the sum of three parameters: Best Eye Response, Best Verbal Response, and Best Motor Response. Mild Brain Injury, 13 or higher; Moderate Brain Injury, 9 to 12; Severe Brain Injury, 8 or less.

†It is important to break the scoring report into its components, for example, E3V3M5 = GCS 11. A total score is meaningless without this information. Age affects the GCS. Elderly individuals with traumatic brain injury (TBI) have better GCS scores than younger individuals with TBI with similar TBI severity (i.e., elderly individuals have higher GCS scores than younger individuals with TBI with similar anatomic TBI severity).

Data from Teasdale G, Jennett B: *Lancet* 2:81-84, 1974; Salottolo K et al: *J Am Med Assoc Surg* 149(7):727-734, 2014.

Primary Brain Injury

Focal Brain Injury.

Focal brain injury can be caused by **closed (blunt) trauma** or **open (penetrating) trauma**. Closed injury is more common and involves the head striking a hard surface, a rapidly moving object striking the head, or blast waves. The dura mater remains intact, and brain tissues are not exposed to the environment. Blunt trauma can result in both focal brain injuries and diffuse axonal injuries, and they can occur at the same time. **Open head injury** involves a skull fracture, and a break in the dura results in exposure of the cranial contents to the environment. Skull fractures include compound fracture or perforated fracture and linear, comminuted, and basilar skull fracture (in the

cranial vault or at the base of the skull).

Closed head injuries are specific, grossly observable skull and brain lesions that occur in a precise location. Of blunt trauma injuries, 75% to 90% are mild. Injury to the cranial vault, vessels, and supporting structures can produce more severe damage, including contusions and epidural, subdural, subarachnoid, and intracerebral hematomas. The dura mater remains intact, and brain tissues are not exposed to the environment. Compression of the skull at the point of impact produces **contusions** or brain bruising from blood leaking from an injured vessel (Fig. 18.2). The injury may be **coup** (injury at site of impact) or **contrecoup** (injury from the brain rebounding and hitting the opposite side of skull) or both (Fig. 18.3). The severity of contusion varies with the amount of energy transmitted by the skull to underlying brain tissue. The smaller the area of impact, the more severe the injury because of the concentration of force. Brain edema forms around and in damaged neural tissues, contributing to increasing intracranial pressure (ICP) (see Chapter 17). Multiple hemorrhages, edema, infarction, and necrosis can occur within the contused areas. The tissue has a pulpy quality. The maximal effects of these injuries peak 18 to 36 hours after severe head injury.

FIGURE 18.2 Cerebral Contusion. Close-up view of a contused brain region with characteristic streaklike, densely arranged hemorrhages in the cortex (cut surface here). Such lesions represent “bruises” on the surface

of the brain caused by violent contact between the delicate brain parenchyma and the hard inner surface of the skull. (From Pollak S, Saukko P: Blunt injury, forensic medicine/causes of death, *Encyclopedia of forensic sciences*, London, 2013, Academic Press.)

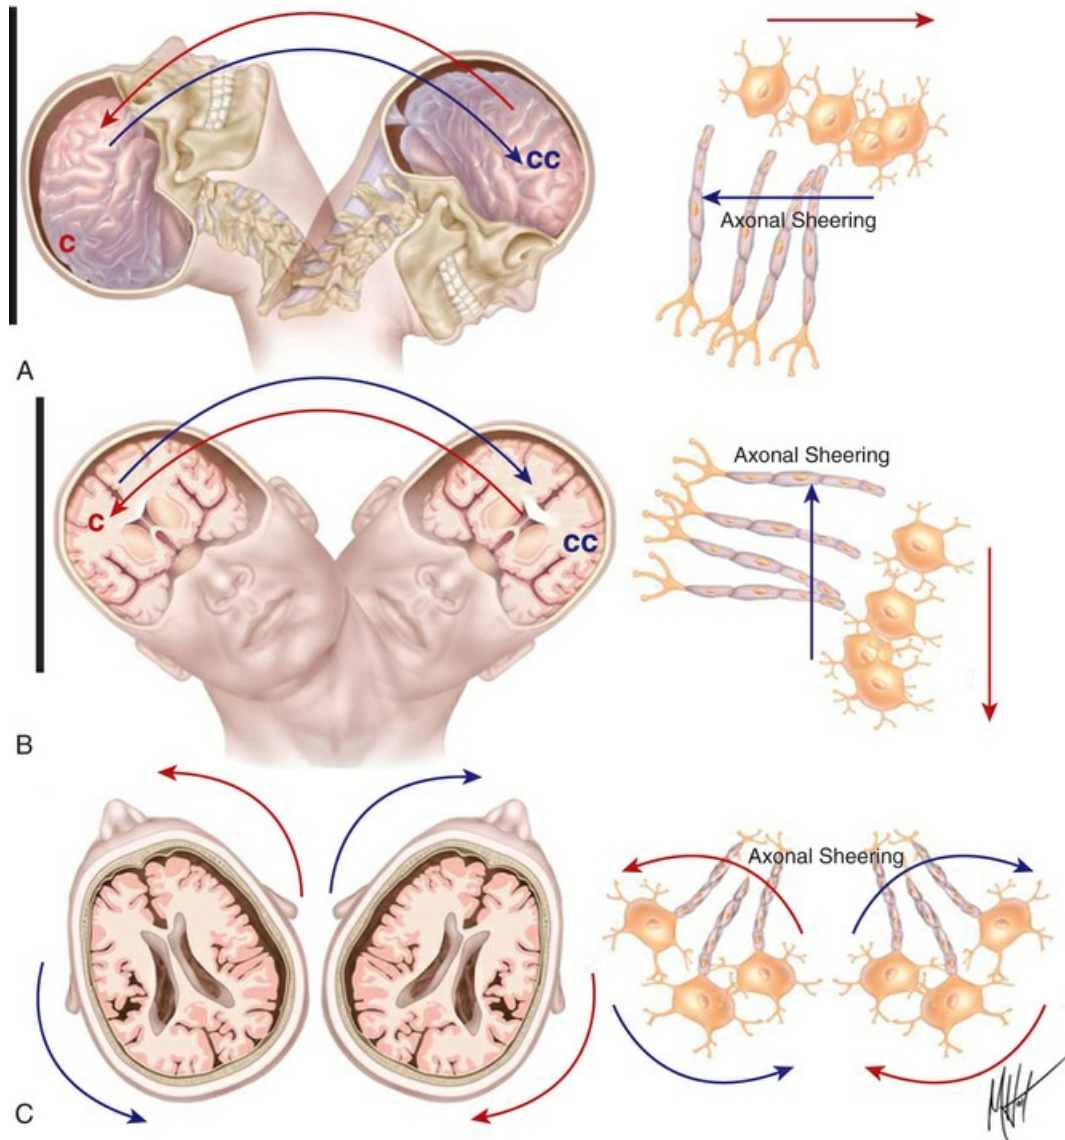

FIGURE 18.3 Coup and Contrecoup Brain Injury Following Blunt Trauma. A, Sagittal force causing coup (c) and contrecoup injury (cc). B, Lateral force causing coup (c) and contrecoup (cc) injury. C, Axial or rotational injury with shearing of axons, particularly at base of brain. Acceleration/deceleration axonal shearing injury occurs throughout the brain (red and blue directional arrows in all three images). (Borrowed from Pascual JM, Preito R: Surgical management of severe closed head injury in adults. In Quinones-Hinojosa A, editor: *Schmidek and Sweet operative neurosurgical techniques*, ed 6, vol 2, Philadelphia, 2012, Saunders, pp 1513-1538. Originally redrawn from Adams JH: *Brain damage in fatal non-*

missile head injury in man. In Braakman R, editor: *Handbook of clinical neurology, head injury*, vol 13, Amsterdam, 1990, Elsevier Science Publishers BV, pp 43-63; Gennarelli TA et al: *Ann Neurol* 12:564-574, 1982.)

Contusions are found most commonly in the frontal lobes, particularly at the poles and along the inferior orbital surfaces; in the temporal lobes, especially at the anterior poles and along the inferior surface; and at the frontotemporal junction. They cause changes in attention, memory, executive functions (see [Chapter 17](#)), affect, emotion, and behavior. Less commonly, contusions occur in the parietal and occipital lobes. Focal cerebral contusions are usually superficial, involving just the gyri. Hemorrhagic contusions may coalesce into a large confluent intracranial hematoma.

A closed brain injury may be evidenced by immediate (generally accepted to last no longer than 5 minutes) loss of consciousness, loss of reflexes (individual falls to the ground), transient cessation of respiration, brief period of bradycardia, and decrease in blood pressure (lasting 30 seconds to a few minutes). Increased cerebrospinal fluid (CSF) pressure and electrocardiogram (ECG) and electroencephalogram (EEG) changes occur on impact. Vital signs may stabilize to normal values in a few seconds; reflexes then return and the person regains consciousness over minutes to days. Residual deficits may persist, and some persons never regain a full level of consciousness.

Evaluation is based on results of the health history, level of consciousness according to the Glasgow Coma Scale (see [Table 18.1](#)), outcomes of imaging studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and positron emission tomography [PET] scans), and assessment of vital parameters (e.g., ICP and EEG). Large contusions and lacerations with hemorrhage may be surgically excised. Treatment is otherwise directed at controlling ICP, neuroprotection, and managing symptoms.

Epidural (extradural) hematomas (bleeding between the dura mater and the skull) represent 1% to 2% of major head injuries and occur in all age groups, but most commonly in those 20 to 40 years of age. Extradural hematomas are caused most commonly by motor vehicle accidents (MVAs) and occasionally by falls and sporting

accidents.

An artery is the source of bleeding in 85% of epidural hematomas, usually accompanied by a skull fracture; 15% of these injuries result from injury to the meningeal vein or dural sinus (Fig. 18.4). The temporal fossa is the most common site of epidural hematoma caused by injury to the middle meningeal artery or vein. The temporal lobe shifts medially, precipitating uncal and hippocampal gyrus herniation through the tentorial notch. Epidural hemorrhages are found occasionally in the subfrontal area, especially in the young and elderly populations, caused by injury to the anterior meningeal artery or a venous sinus; and in the occipital-suboccipital area, resulting in herniation of the posterior fossa contents through the foramen magnum (see Fig. 17.18).

FIGURE 18.4 Epidural Hematoma, CT Image. Note the large right epidural hematoma with a lens-shaped outline as the smooth dura becomes indented against the underlying cortex on the right lateral aspect of the cerebrum. The epidural hematoma is confined within an area bounded by cranial sutures where the dura is firmly adherent to the skull. Note the mass effect with effacement of the lateral ventricles and the shift of midline to the left (*arrows*). In this case the individual fell from a height and struck the right side of the head, severing the middle meningeal artery. This epidural hematoma collected within hours. CT, Computed tomography.

(From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

Individuals with temporal epidural hematomas (i.e., over the temporal lobe) lose consciousness at injury; one-third of those affected then become lucid within a few minutes to a few days (if a vein is causing slow bleeding). As the hematoma accumulates, a headache of increasing severity, vomiting, drowsiness, confusion, seizure, and hemiparesis may develop. Because temporal lobe herniation occurs, the level of consciousness is rapidly lost with ipsilateral pupillary dilation and contralateral hemiparesis. A CT scan or MRI is usually needed to diagnose epidural hematoma. The prognosis is good if intervention is initiated before bilateral dilation of the pupils occurs. Epidural hematomas are almost always medical emergencies requiring monitoring and evaluation and surgical evacuation of the hematoma.⁴

Subdural hematomas (bleeding between the dura mater and the brain) arise in 10% to 20% of TBIs. *Acute subdural hematomas* develop rapidly, usually within hours, and are commonly located at the top of the skull (the cerebral convexities). Bilateral hematomas occur in 15% to 20% of persons. The expanding clots directly compress the brain. As the ICP rises the bleeding veins are compressed. Thus bleeding is self-limiting, although cerebral compression and displacement of brain tissue can cause temporal lobe herniation. Symptoms classically begin with headache, drowsiness, restlessness or agitation, slowed cognition, and confusion. These symptoms worsen over time and progress to loss of consciousness, respiratory pattern changes, and pupillary dilation (i.e., the symptoms of temporal lobe herniation). Homonymous hemianopia (defective vision in either the right or the left field [see [Fig. 16.13](#)]), dysconjugate gaze, and gaze palsies also may occur.

Subacute subdural hematomas develop more slowly, often over 48 hours to 2 weeks. Bridging veins (extending from the dura into the surface of the brain) tear, causing both rapidly and subacutely developing subdural hematomas, although torn cortical veins or venous sinuses and contused tissue also may be the source ([Fig. 18.5](#)).

They occur more commonly in older adults and those who abuse alcohol because they have some degree of brain atrophy with a subsequent increase in the size of the extradural space. These subdural hematomas act like expanding masses, increasing ICP that eventually compresses the bleeding vessels. Brain herniation can result.

FIGURE 18.5 Subdural Hematoma, Gross, and Bridging Veins, Gross. A large subdural hematoma (A) is seen in the frontoparietal region. A subdural hematoma forms after head trauma that severs the bridging veins from dura to brain, shown in the right panel (B), where the dura has been folded back to reveal the normal appearance of the bridging veins that extend across to the superior aspect of the cerebral hemispheres. Older adults and the very young are at greater risk because their cerebral veins are more vulnerable to injury. Because the bleeding is venous, blood collects over hours to weeks, with variable onset of symptoms. Because the blood collects beneath the dura, a subdural hematoma can be seen to cross the region of cranial sutures. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

Chronic subdural hematomas develop over weeks to months. The existing subdural space contains the liquefied clot from the acute bleed and/or accumulation of blood from a leaking vein. A vascular membrane forms around the hematoma in approximately 2 weeks (Fig. 18.6). Of those individuals affected by chronic subdural hematomas, 80% have chronic headaches and tenderness over the hematoma on palpation. They may have confusion, memory loss, or coma, difficulty speaking or swallowing, and weakness with difficulty

walking, loss of sensation, or seizures. Chronic subdural hematomas require a craniotomy to evacuate the gelatinous blood and to prevent brain herniation. Percutaneous drainage for chronic subdural hematomas has proven successful; however, reaccumulation often occurs. Subarachnoid hemorrhage is presented in the section on [Subarachnoid Hemorrhage](#).

FIGURE 18.6 Chronic Subdural Hematoma. Compression of underlying brain and lateral ventricle. Note the capsule around the hematoma. (From Kissane JM, editor: *Anderson's pathology*, ed 9, St Louis, 1993, Mosby.)

Intracerebral hematomas (bleeding within the brain) occur in 2% to 3% of head injuries, may be single or multiple, and are associated with contusions. Although most are commonly located in the frontal and temporal lobes, intracerebral hematomas may occur in the hemispheric deep white matter. Penetrating injury or shearing forces traumatize small blood vessels. The intracerebral hematoma then acts as an expanding mass, increasing ICP, compressing brain tissues, and causing edema and ischemia ([Fig. 18.7](#)). Delayed intracerebral hematomas may appear 3 to 10 days after the head injury. Intracerebral hematomas also can occur with nontraumatic brain injury, such as hemorrhagic stroke (see the section on [Hemorrhagic](#)

Stroke).

FIGURE 18.7 Acute Intracerebral Hemorrhage. A fresh hematoma has disrupted and expanded the left cerebral hemisphere, causing the midline structures to shift to the right. Uncontrolled hypertension is an important cause of this catastrophic lesion. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

Intracerebral hematomas cause a decreasing level of consciousness. Coma or a confusional state from other injuries, however, can make the cause of this increasing unresponsiveness difficult to detect. Contralateral hemiplegia also may occur and, as ICP rises, temporal lobe herniation may appear. In delayed intracerebral hematoma, the presentation is similar to that of hypertensive brain hemorrhage with sudden, rapidly progressive decreased level of consciousness with pupillary dilation; breathing pattern changes; hemiplegia; and bilateral positive Babinski reflexes.

History and physical examination help to establish the diagnosis, and CT scan, MRI, and cerebral angiography confirm it. Evacuation of a singular intracerebral hematoma has only occasionally been helpful, mostly for subcortical white matter hematomas. Otherwise, treatment is directed at reducing ICP to maintain cerebral perfusion pressure and allowing the hematoma to reabsorb slowly. Secondary brain

injury is common (see the section on [Secondary Brain Injury](#)).

Open brain trauma (trauma that penetrates the dura mater) produces both focal and diffuse injuries and includes compound skull fractures and missile injuries (e.g., bullets, rocks, shell fragments, knives, and blunt instruments). The mechanisms of open brain trauma are crush injury (laceration and crushing of tissue touched by the missile) and stretch injury (damage of blood vessels and nerves not directly contacted, occurring as a result of stretching).

A compound skull fracture opens a communication between the cranial contents and the environment and should be investigated whenever there are lacerations of the scalp, tympanic membrane, a sinus, an eye, or mucous membranes. Such fractures may involve the cranial vault or the base of the skull (basilar skull fracture). A basilar skull fracture can involve the temporal, sphenoid, and occipital bones. Severity of brain damage is related to the severity of skull fracture. Infection is a significant complication. Bone fragments or debris from projectiles may contuse brain tissues or lacerate blood vessels.

Most victims lose consciousness with open-head injury. The depth and duration of the coma are related to the location of injury, extent of damage, and amount of bleeding. Open brain injury often requires débridement of the traumatized tissues to prevent infection and to remove blood clots and debris, thereby reducing ICP. ICP also is managed with dehydrating agents, osmotic diuretics, or a combination of these drugs.

A compound fracture may be diagnosed through physical examination, skull radiographs, or both. Basilar skull fracture is determined on the basis of clinical findings (i.e., involvement of cranial nerves, ecchymosis around the eyes, ears and nose or spinal fluid leaking from the ear or nose.). Skull radiographs often do not demonstrate the fracture, although intracranial air or air in the sinuses on radiograph, CT, or MRI is indirect evidence of a basilar skull fracture. A compound fracture is débrided and bone grafts may be required. Antibiotics are administered after surgery. Bed rest and close observation for meningitis and other complications are prescribed for a basilar skull fracture.

Diffuse Axonal Injury.

Diffuse axonal injury (DAI) involves neurons in widespread areas of the brain and occurs with all severities of brain injury. Mechanical effects from high levels of acceleration and deceleration, such as whiplash, and rotational forces, cause stretching and shearing of delicate axonal fibers and white matter tracts that project to the cerebral cortex (see [Fig. 18.3](#)). The most severe axonal injuries are located more peripheral to the brainstem, causing extensive cognitive and affective impairments. Axonal damage reduces the speed of information processing and responding and disrupts cognitive function.⁵

Pathophysiologically, axonal damage can be seen only with an electron microscope and involves numerous axons, either alone or in conjunction with actual tissue tears. Advanced imaging techniques using MRI are assisting to define areas and extent of injury. Areas where axons and small blood vessels are torn appear as small hemorrhages ([Fig. 18.8](#)), located particularly in the parasagittal white matter near the cerebral cortex, corpus callosum, and brainstem and at the superior cerebellar peduncle.⁶ More damaged axons are visible 12 hours to several days after the initial injury. The severity of DAI correlates with the amount of shearing force. DAI is not associated with intracranial hypertension immediately after injury. However, acute brain swelling from increased intravascular blood flow within the brain, loss of cerebrovascular autoregulation, vasodilation, and increased cerebral blood volume is often seen and can result in death. DAI may induce long-term neurodegenerative processes, with progressive axonal pathology that may continue for years after injury and may play a role in the development of chronic traumatic encephalopathy and Alzheimer disease-like pathologic changes.⁷

FIGURE 18.8 Diffuse Axonal Injury. Gross photograph demonstrating characteristic hemorrhage lesions within the corpus callosum. (Courtesy Walter Kemp, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas. From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

There is currently a lack of consensus regarding the terminology to grade or define the clinical syndromes associated with TBI, and several categories exist: mild concussion and classic concussion, and mild, moderate, and severe TBI.⁸⁻¹³ The symptoms associated with grades of concussion or TBI are often the same. Concussion has been described as a set of symptoms with or without neuropathologic damage that may or may not involve loss of consciousness following TBI.^{14,15} However with new imaging techniques and discovery of molecular markers associated with mild and moderate TBI, it is likely that DAI occurs in mild, moderate, and severe TBI¹⁶ (see [What's New? Biomarkers and Concussion](#)). Methods of grading severity of TBI are arbitrary, with the GCS most commonly used along with clinical evaluation of neurologic function. Recommendations are available to direct imaging of TBI.¹⁷ The discussion presented here considers the severity of grades of concussion and TBI as the same.

What's New?

Biomarkers and Concussion

Biomarker research has focused on proteins abundant in cells impacted by TBI. Glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase L1 (UCH-L1) have been studied in both animals and humans and show promise for diagnosis of suspected TBI and mild to moderate concussion. Both markers cross the blood-brain barrier after TBI and are detectable in the blood. Subjects were assessed for blunt head trauma with loss of consciousness, amnesia, or disorientation and a Glasgow Coma Scale score of 9 to 15. Both GFAP and UCH-L1 were detectable within 1 hour of injury. GFAP peaks in 20 hours and declines slowly over 72 hours. UCH-L1 rises rapidly and peaks in 8 hours. The markers distinguished mild to moderate concussion with and without a neurosurgical intervention and provided values consistent with CT findings with 97% accuracy. The ultimate goal is to use the biomarkers for diagnosis, for monitoring progression of injury and recovery, and avoid radiation exposing CT scans, particularly in children with TBI.

Data from Kulbe JR, Geddes JW: *Exp Neurol* 275 Pt 3:334-352, 2016; Papa L et al: *JAMA Neurol* 73(5):551-560, 2016; Mannix R et al: *J Neurotrauma* 31(11):1072-1075, 2014.

Mild traumatic brain injury (mild concussion) is characterized by immediate but transitory clinical manifestations without loss of consciousness, or loss of consciousness that is momentary or less than 30 minutes. Most blunt trauma injuries cause mild TBI.¹⁸ The GCS is 13 to 15.¹⁹ Posttraumatic anterograde amnesia also may exist transiently to less than 24 hours.²⁰ There may be no findings with diagnostic imaging. Persons may experience headaches, nausea and vomiting, confusion, disorientation, attention deficit, dizziness, and impaired ability to concentrate for days after the injury. Diffuse axonal injury, metabolic impairment, alterations in neural activation, and cerebral blood flow perturbations can occur and may contribute to acute symptomatology. Lesions may be detected with advanced MRI imaging. Biomarkers are under investigation to assist with diagnosis of mild TBI.¹⁸

Moderate traumatic brain injury (moderate cerebral concussion) is any loss of consciousness lasting more than 30 minutes, accompanied by posttraumatic anterograde amnesia lasting 24 hours or more. A GCS between 8 and 13 is classified as moderate TBI. A basal skull fracture may be present with moderate TBI, but there is no brainstem injury. There is transitory decerebration or decortication (see Fig. 17.6) with unconsciousness lasting days or weeks. The person is confused and experiences a long period of posttraumatic amnesia. There often are permanent deficits in selective attention, vigilance, detection, working memory, data processing, vision or perception, and language, as well as mood and affect changes ranging from mild to severe.

Severe traumatic brain injury (severe concussion) is a GCS less than 8 associated with brainstem signs (pupillary reaction, cardiac and respiratory symptoms, posturing) and intracranial contusions, hematomas, or lacerations. Loss of consciousness lasts more than 24 hours. The person experiences immediate autonomic dysfunction that resolves in a few weeks. Increased ICP appears 4 to 6 days after injury. Pulmonary complications occur frequently, with profound sensorimotor and cognitive system deficits. Severely compromised coordinated movements and verbal and written communication, inability to learn and reason, and inability to modulate behavior also are evident. Severe injury causes permanent neurologic deficits (20% of adults) and it has been shown that up to 14% remain in a vegetative state, and 20% to 40% of patients end up dying as a result of brain injury or secondary complications.²¹

The goal of treatment is to maintain cerebral perfusion and oxygenation, promote neuroprotection, and mitigate long-term neurologic deficits. The Corticosteroid Randomisation After Significant Head Injury (CRASH) trial showed corticosteroids increase mortality with acute TBI; consequently these drugs are no longer used. Guidelines are available to direct evaluation and treatment.^{18,22}

Secondary Brain Injury.

Secondary brain injury is an indirect result of primary brain injury

(see Fig. 18.1), including trauma and stroke syndromes. Systemic and cerebral processes are contributing factors. Systemic processes include hypotension, hypoxia, anemia, hypoglycemia, hyperglycemia, and hypercapnia or hypocapnia. Cerebral contributions include inflammation, oxidative stress, alterations in the blood-brain barrier, excitotoxicity, cerebral edema, increased intracranial pressure (IICP), decreased cerebral perfusion pressure, cerebral ischemia, and brain herniation. Cellular and molecular brain damage from the effects of primary injury develops hours to days later. Cerebrovascular autoregulation (vasoconstriction or vasodilation in response to increases or decreases in cerebral perfusion pressure) is impaired after brain injury and may be transient or persistent with alterations in CO₂ reactivity (i.e., CO₂ vasodilation). Vasospasm commonly occurs, contributing to brain hypoperfusion, and is caused by chronic depolarization of vascular smooth muscle, release of endothelin (vasoconstrictor), and decreased availability of nitric oxide (vasodilator).

Ischemia contributes to excitotoxicity with release of excitatory neurotransmitters, such as glutamate that escapes from stretched and injured neurons. They cause cellular influx of calcium and stimulate neuronal hyperexcitability by depolarizing the membrane potential (excitotoxicity). A hypermetabolic state, poor perfusion, influx of inflammatory mediators, fluctuations in cellular sodium and potassium ion channels, and mitochondrial failure all contribute to cytotoxic edema, axonal swelling, and neuronal death.²³

Mitochondrial failure, anaerobic metabolism, lactic acid production, and increased levels of reactive oxygen species (ROS), phospholipases, and other enzymes damage proteins and the phospholipid components of cell and organelle membranes. Cell swelling, vacuolization, and, ultimately, necrotic or programmed cell death (apoptosis) occur.²⁴ These events lead to failure of the capillary blood-brain barrier and *vasogenic edema*. The influx of sodium and water results in intracellular cytotoxic edema in neurons, astrocytes, and microglia irrespective of the integrity of the vascular endothelial wall. Edema increases ICP, contributing to tissue hypoxia and cerebral

ischemia. Inflammation occurs immediately and persists for weeks. Inflammation is critical for wound healing; immune cells, including neutrophils, macrophages, and T-cell lymphocytes, need to infiltrate injured tissue and clear debris, thus promoting formation of scar tissue. However, an overactive response leads to occlusion of the microvasculature with leukocytes and platelets. The release of inflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF- α], interleukins, and interferons), proteases, free radicals, prostaglandins, and complement proteins alters the blood-brain barrier and causes vasoconstriction, brain edema, IICP, reduced cerebral perfusion, and ischemia, aggravating secondary brain injury.²⁵ Activation of astrocytes and microglia contributes to persistent neuroinflammation, alters the blood-brain barrier, and can cause progressive neurodegeneration that occurs over weeks after traumatic injury.²⁶

Intracranial hemorrhage, whether traumatic or related to a stroke syndrome, may contribute to secondary brain injury. The bleeding is often accompanied by IICP, ischemia, oxidative damage, and vasogenic and cytotoxic edema as previously described. In addition, the vascular injury can cause activation of platelets, which contribute to vasoconstriction in large arteries and vasodilation in small arteries with spreading cortical ischemia. Activated platelets also trigger the release of free radicals from granulocytes, enhancing oxidative stress. Vascular injury causes coagulation disorders from release of increased amounts of tissue factor from endothelial cells, which initiates the coagulation cascade and overwhelms the normal factors that control coagulation. Free heme and free iron are released from red blood cells, and both cause the induction of free radicals, lipid peroxidation, and further nerve damage.²⁷

The management of secondary brain trauma includes removal of hematomas and management of hypotension, hypoxemia, anemia, ICP, fluid and electrolyte balance, body temperature, ventilation, and nutrition. Numerous agents are under investigation and may be neuroprotective by decreasing excitotoxicity, neuroinflammation, apoptosis, mitochondrial failure, blood-brain barrier disruption, edema, and other mechanisms of secondary injury.^{28,29} Progress is

difficult because of lack of predictive biomarkers and drugs that can cross the blood-brain barrier. Fluid and nutrition management have emerged as critically important in the care of individuals with severe brain injury.³⁰ Long-term recovery can be influenced by systemic complications, such as pneumonia, fever, infections, and immobility.

Complications of Traumatic Brain Injury.

Many complications are associated with TBI and are related to the severity of injury and the parts of the brain that are affected. Altered states of consciousness can range from confusion to deep coma (see [Table 17.3](#)). Cognitive deficits, hydrocephalus, and sensory-motor disorders, including pain, paresis, and loss of coordination, may be present. Three of the most common posttraumatic brain syndromes are summarized next.

Postconcussion syndrome occurs with mild TBI including sports concussion.³¹ Symptoms are nonspecific and include headache, dizziness, fatigue, nervousness or anxiety, irritability, insomnia, photophobia, depression, inability to concentrate, and forgetfulness, and may last for weeks to months. Treatment entails reassurance and symptomatic relief in addition to 24 hours of close observation after the concussion in the event bleeding or swelling in the brain occurs. Symptoms requiring further evaluation and treatment include drowsiness or confusion, nausea or vomiting, severe headache, memory deficit, seizures, drainage of CSF from the ear or nose, weakness or loss of feeling in the extremities, asymmetry of the pupils, and double vision. Guidelines for the management of pediatric and adult mild TBI are available.³²⁻³⁴ Guidelines also have been published for the management of sports-related concussion.^{35,36}

Posttraumatic seizures (epilepsy) occur in about 10% of TBIs, with the highest risk among open brain injuries.³⁷ Seizures can occur early, within days, and up to 2 to 5 years or longer after the trauma. Causal mechanisms are poorly understood, and cellular and molecular changes in the brain associated with injury and repair, such as sprouting of new neurons with hyperexcitability and decreases in GABAergic inhibition, may cause the hyperexcitable state that leads to

epileptogenesis. Seizure prevention using drugs, such as phenytoin, is initiated for moderate to severe TBI at the time of injury. Neuromodulation with implantable devices is under evaluation. Clinical trials are ongoing to test drugs that prevent the development of posttraumatic seizures.³⁸

Chronic traumatic encephalopathy (CTE) (previously called *dementia pugilistica*) is a progressive dementing disease that develops with repeated brain injury associated with sporting events, blast injuries in soldiers, or work-related head trauma. Tau neurofibrillary tangles are present in the brain. CTE is associated with violent behaviors, loss of control, depression, suicide, memory loss, and cognitive change. Research is in progress to discover the mechanistic link between neurotrauma and CTE. It is diagnosed from history and clinical evaluation, and at autopsy.³⁹

Spinal Cord and Vertebral Injury

Approximately 282,000 people were living with spinal cord injury (SCI) in the United States, with approximately 17,000 new cases in 2016. About 80% are males, and the average age is 42 years. Since 2010, the causes include vehicular crashes (38%), falls (30%), violence (14%), and sports (9%). The extent of injury has been 45% incomplete quadriplegia, 14% complete quadriplegia, 21% incomplete paraplegia, and 20% complete paraplegia.⁴⁰

◆Pathophysiology.

Primary spinal cord injury occurs with the initial mechanical trauma and immediate tissue destruction from shearing, compression, or penetration. Injuries to the cord are summarized in [Table 18.2](#). Primary spinal cord injury also can occur if an injured spine is not adequately immobilized immediately following injury. Primary spinal cord injury may occur in the absence of vertebral fracture or dislocation from longitudinal stretching of the cord with or without flexion or extension of the vertebral column, or both. The stretching causes altered axon transport, edema, myelin degeneration, and retrograde or wallerian degeneration (see [Chapter 15](#)).

TABLE 18.2**SPINAL CORD INJURIES**

INJURY	DESCRIPTION
Cord concussion	Results in a temporary disruption of cord-mediated functions
Cord contusion	Bruising of the neural tissue causing swelling and temporary loss of cord-mediated functions
Cord compression	Pressure on the cord causing ischemia to tissues; must be relieved (decompressed) to prevent permanent damage to the spinal cord
Laceration	Tearing of the neural tissues of the spinal cord; may be reversible if only slight damage is sustained by the neural tissues; may result in permanent loss of cord-mediated functions if spinal tracts are disrupted
Transection	Severing of the spinal cord, causing permanent loss of function
Complete	All tracts in the spinal cord are completely disrupted; all cord-mediated functions below the transection are completely and permanently lost
Incomplete	Some tracts in the spinal cord remain intact, together with functions mediated by these tracts; has the potential for recovery although function is temporarily lost
Preserved sensation only	Some demonstrable sensation below the level of injury
Preserved motor nonfunctional	Preserved motor function without useful purpose; sensory function may or may not be preserved
Preserved motor functional	Preserved voluntary motor function that is functionally useful
Hemorrhage	Bleeding into the neural tissue because of blood vessel damage; usually no major loss of function
Damage or obstruction of spinal blood supply	Causes local ischemia

Secondary spinal cord injury is a pathophysiologic cascade of vascular, cellular, and biochemical events that begins within a few minutes after injury and continues for weeks. Edema, ischemia, excitotoxicity (excessive stimulation by excitatory neurotransmitters such as glutamate), inflammation, oxidative damage, and activation of necrotic and apoptotic cell death signal events similar to those previously described for TBI^{41,42} (see the [Secondary Brain Injury](#) section).

With secondary spinal cord injury, microscopic hemorrhages appear in the central gray matter and pia-arachnoid, increasing in size until the entire gray matter is hemorrhagic and necrotic. Edema in the white matter occurs, impairing the microcirculation of the cord. Hemorrhages and edema are followed by loss of autoregulation and reduced vascular perfusion and development of ischemic areas, which are maximal at the level of injury and two cord segments above and below it. Cellular and subcellular alterations with myelin disruption, axonal degeneration, and tissue necrosis occur. Impaired perfusion is aggravated by systemic responses, including neurogenic or hemorrhagic shock, and dysrhythmias. Cord swelling increases the individual's degree of dysfunction, making it difficult to distinguish functions permanently lost from those temporarily impaired. In the cervical region, cord swelling may be life-threatening. Diaphragm function may be impaired because phrenic nerves exit at C3 to C5. Cardiovascular and respiratory functions mediated by the medulla oblongata can be lost. Efforts are in progress to identify biomarkers that reflect severity of injury and guide treatment.⁴³

Circulation in the white matter tracts of the spinal cord returns to normal in about 24 hours, but gray matter circulation remains altered. Phagocytes appear 36 to 48 hours after injury, and microglia proliferate with altered astrocytes promoting inflammation.⁴⁴ Red blood cells then begin to disintegrate, and resorption of hemorrhages and edema begins. Degenerating axons are engulfed by macrophages in the first 10 days after injury. The traumatized cord is replaced by acellular collagenous tissue, usually in 3 to 4 weeks. Meninges thicken as part of the scarring process.

Vertebral injuries result from acceleration, deceleration, rotation, or deformation forces at impact. These forces cause vertebral fractures, dislocations, and bone fragments that can cause compression or exert traction (tension) on the tissues, or shear tissues so they slide into one another (Figs. 18.9 through 18.12). Vertebral injuries can be classified as (1) simple fracture—a single break usually affecting transverse or spinous processes; (2) compressed (wedged) vertebral fracture, that is, a vertebral body compressed anteriorly; (3) comminuted (burst)

fracture—vertebral body shattered into several fragments; and (4) dislocation.

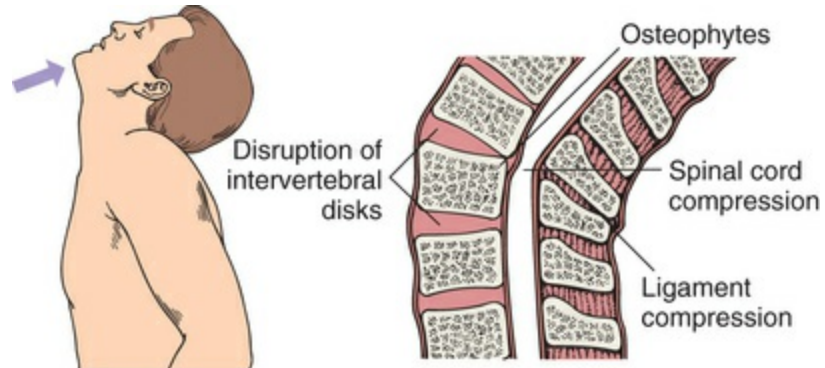

FIGURE 18.9 Hyperextension Injuries of the Spine. Hyperextension injuries of the spine can result in fracture or nonfracture injuries with spinal cord damage.

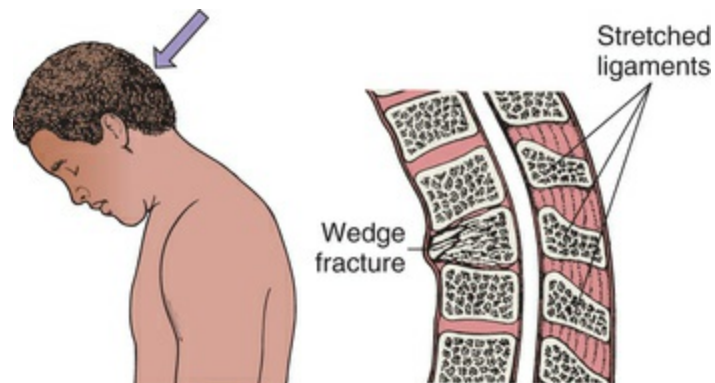

FIGURE 18.10 Flexion Injury of the Spine. Hyperflexion produces translation (subluxation) of vertebrae that compromises the central canal and compresses spinal cord parenchyma or vascular structures.

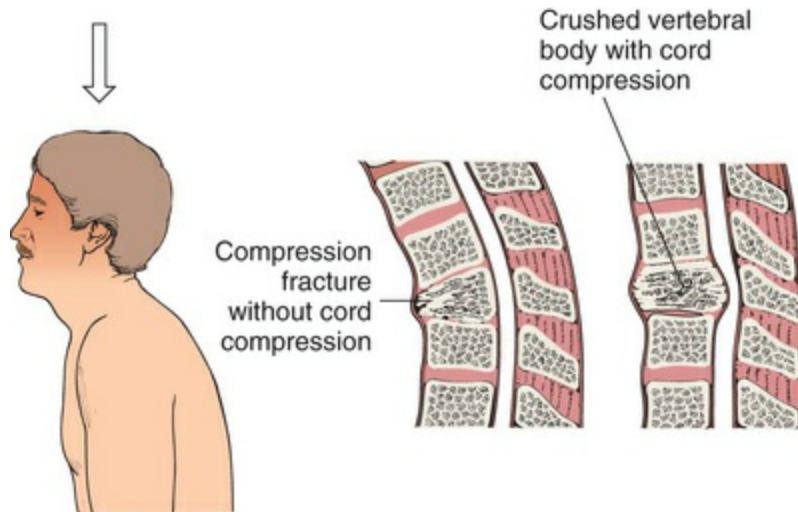

FIGURE 18.11 Axial Compression Injuries of the Spine. In axial compression injuries of spine, the spinal cord is contused directly by retropulsion of bone or disk material into the spinal canal.

FIGURE 18.12 Flexion-Rotation Injuries of the Spine.

The vertebrae fracture readily with direct and indirect trauma. When the supporting ligaments are torn, the vertebrae move out of alignment, and dislocations occur. A horizontal force moves the vertebrae straight forward; if the individual is in a flexed position at the time of injury, the vertebrae are then in an angulated position. Flexion and extension injuries may result in dislocations. (Mechanisms of vertebral injury are presented in [Table 18.3](#).) Vertebral injuries in adults occur most often at vertebrae C1-C2 (cervical), C4-C7, and T10 to L2 (thoracic-lumbar) (see [Fig. 15.18](#)), the most mobile

portions of the vertebral column. The spinal cord occupies most of the vertebral canal in the cervical and lumbar regions, so it also can be easily injured in these locations.

TABLE 18.3

MECHANISMS OF VERTEBRAL INJURY

MECHANISMS OF INJURY	VERTEBRAL INJURY	FORCES OF INJURY	LOCATION OF INJURY
Hyperextension	Fracture and dislocation of posterior elements such as spinous processes, transverse processes, laminae, pedicles, or posterior ligaments	Results from forces of acceleration-deceleration and the sudden reduction in the anteroposterior diameter of the spinal cord	Cervical area
Hyperflexion	Fracture or dislocation of the vertebral bodies, disks, or ligaments	Results from sudden and excessive force that propels the neck forward or causes an exaggerated lateral movement of the neck to one side	Cervical area
Vertical compression (axonal loading)	Shattering fractures	Results from a force applied along an axis from the top of the cranium through the vertebral bodies	T12-L2
Rotational forces (flexion-rotation)	Ruptures support ligaments in addition to producing fractures	Adds shearing force to acceleration-deceleration forces	Cervical area

◆Clinical Manifestations.

Spinal shock develops immediately after injury because of loss of continuous tonic discharge from the brain or brainstem and inhibition of suprasegmental impulses caused by cord hemorrhage, edema, or anatomic transection. All motor, sensory, reflex, and autonomic functions cease below any transected area and may cease below concussive, contused, compressed, or ischemic areas. There is flaccid paralysis, absence of sensation, loss of bladder and rectal control, transient drop in blood pressure, and poor venous circulation. The condition also results in disturbed thermal control because the sympathetic nervous system is damaged. The hypothalamus cannot

regulate body heat through vasoconstriction and increased metabolism; therefore the individual assumes the temperature of the air (poikilothermia).⁴⁵ Spinal shock generally lasts 7 to 20 days, with a range of a few days to 3 months. It terminates with the reappearance of reflex activity, hyperreflexia, spasticity, and reflex emptying of the bladder. [Table 18.4](#) summarizes the clinical manifestations of spinal cord injury.

TABLE 18.4

CLINICAL MANIFESTATIONS OF SPINAL CORD INJURY

STAGE	MANIFESTATIONS
Spinal Shock Stage	
Complete spinal cord transection	Loss of motor function 1. Quadriplegia with injuries of cervical spinal cord 2. Paraplegia with injuries of thoracic spinal cord
	Muscle flaccidity
	Loss of all reflexes below level of injury
	Loss of pain, temperature, touch, pressure, and proprioception below level of injury
	Pain at site of injury caused by a zone of hyperesthesia above the injury
	Atonic bladder and bowel
	Paralytic ileus with distention
	Loss of vasomotor tone in lower body parts; low and unstable blood pressure
	Loss of perspiration below level of injury
	Loss or extreme depression of genital reflexes such as penile erection and bulbocavernosus reflex
	Dry and pale skin, possible ulceration over bony prominences
	Respiratory impairment
Partial spinal cord transection	Asymmetric flaccid motor paralysis below level of injury
	Asymmetric reflex loss
	Preservation of some sensation below level of injury
	Vasomotor instability less severe than with complete cord transection
	Bowel and bladder impairment less severe than that seen with complete cord transection
	Preservation of ability to perspire in some portions of the body below level of injury
	<i>Brown-Séquard syndrome</i> (associated with penetrating injuries, hyperextension and flexion, locked facets, and compression fractures)

	<ol style="list-style-type: none"> 1. Ipsilateral paralysis or paresis below level of injury 2. Ipsilateral loss of touch, pressure, vibration, and position senses below level of injury 3. Contralateral loss of pain and temperature sensations below level of injury
	<p><i>Central cervical cord syndrome</i> (acute cord compression between bony bars or spurs anteriorly and thickened ligamentum flavum posteriorly associated with hyperextension)</p> <ol style="list-style-type: none"> 1. Motor deficits in upper extremities, especially hands; more dense than in lower extremities 2. Varying degrees of bladder dysfunction
	<p><i>Burning hand syndrome</i> (variant of central cord syndrome; half of cases have an underlying spine fracture/dislocation present)</p> <ol style="list-style-type: none"> 1. Severe burning paresthesias and dysesthesias in the hands and/or feet
	<p><i>Anterior cord syndrome</i> (compromise of anterior spinal artery by occlusion or pressure effect of disk)</p> <ol style="list-style-type: none"> 1. Loss of motor function below level of injury 2. Loss of pain and temperature sensations below level of injury 3. Touch, pressure, position, and vibration senses intact
	<p><i>Posterior cord syndrome</i> (associated with hyperextension injuries with fractures of vertebral arch)</p> <ol style="list-style-type: none"> 1. Impaired light touch and proprioception
	<p><i>Conus medullaris syndrome</i> (compression injury at T12 from disk herniation or burst fracture of body of T12)</p> <ol style="list-style-type: none"> 1. Flaccid paralysis of legs 2. Flaccid paralysis of anal sphincter 3. Variable sensory deficits
	<p><i>Cauda equina syndrome</i> (compression of nerve roots below L1 caused by fracture and dislocation of spine or large posterocentral intervertebral disk herniation)</p> <ol style="list-style-type: none"> 1. Lower extremity motor deficits 2. Variable sensorimotor dysfunction 3. Variable reflex dysfunction 4. Variable bladder, bowel, and sexual dysfunction
	<p><i>Syndrome of neuropraxia</i> (seen as post-athletic injury, associated with congenital spinal stenosis)</p> <ol style="list-style-type: none"> 1. Dramatic but transient neurologic deficits including quadriplegia
	<p><i>Horner syndrome</i> (injury to preganglionic sympathetic trunk or postganglionic sympathetic neurons of superior cervical ganglion)</p> <ol style="list-style-type: none"> 1. Ipsilateral pupil smaller than contralateral pupil 2. Sunken ipsilateral eyeball 3. Ptosis of affected eyeball 4. Lack of perspiration on ipsilateral side of face
Heightened Reflex Activity Stage	
	Emergence of Babinski reflexes, possibly progressing to a triple reflex; possible development of still later flexor spasms

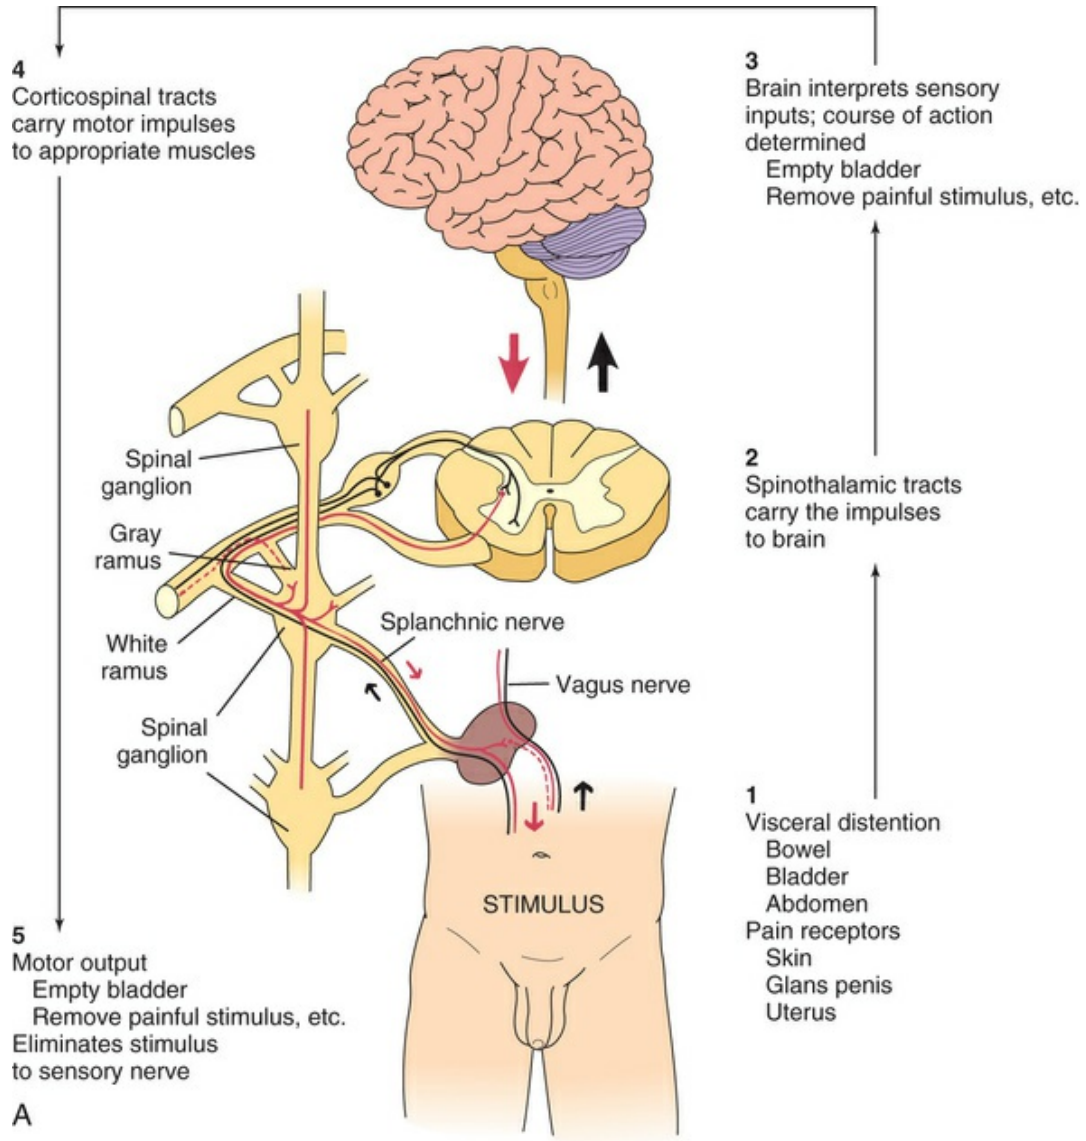

Reappearance of ankle and knee reflexes, which become hyperactive
Contraction of reflex detrusor muscle, leading to urinary incontinence
Appearance of reflex defecation
Mass reflex with flexion spasms, profuse sweating, piloerection, and bladder and occasional bowel emptying may be evoked by an autonomic stimulation of skin or from a full bladder
Episodes of hypertension
Defective heat-induced sweating
Eventual development of extensor reflexes, first in muscles of hip and thigh, later in leg
Possible paresthesias below level of transaction: dull, burning pain in lower back, abdomen, buttocks, and perineum

Neurogenic shock, also called vasogenic shock, occurs with cervical or upper thoracic cord injury above T6 and may be seen in addition to spinal shock. Neurogenic shock is caused by the absence of sympathetic activity through loss of supraspinal control and unopposed parasympathetic tone mediated by the intact vagus nerve and may last up to 5 weeks after injury. Symptoms include vasodilation, hypotension, bradycardia, and hypothermia (failure of body temperature regulation). Neurogenic shock may be complicated by hypovolemic or cardiogenic shock if there is concurrent heart failure or blood loss⁴⁶ (see [Chapter 33](#)).

Continued loss of motor and sensory function depends on the extent and level of injury. Paralysis of the lower half of the body with both legs involved is termed *paraplegia*. Paralysis involving all four extremities is termed *quadriplegia* (tetraplegia). In complete quadriplegia the level of injury is above C6, and all upper extremity function is lost. In incomplete quadriplegia, function at or above C6 is preserved, leaving the shoulder, upper arm, and some forearm muscle control intact. With acceleration injuries the greatest stress point is C4-C5. With a deceleration force the greatest stress point is at C5-C6. The initial clinical manifestations associated with acute spinal cord injury are (1) rapid loss of voluntary movements in body parts below the level of injury, (2) loss of sensations in the lower extremities and possibly lower trunk (depending on the level of injury), and (3) loss of spinal and autonomic reflexes below the level of injury. The duration

of this areflexic state is highly variable. In most persons, reflex activity returns in 1 to 2 weeks. Return of spinal neuron excitability occurs slowly. Depending on the degree of damage, either of the following can occur: (1) motor, sensory, reflex, and autonomic functions return to normal; or (2) autonomic neural activity in the isolated segment develops. Spasticity is common with hyperreflexia, clonus, and painful muscle spasms. Sometimes after several months, episodes of autonomic hyperreflexia occur.

Autonomic hyperreflexia (dysreflexia) is a syndrome of sudden, life-threatening massive reflex sympathetic discharge associated with spinal cord injury at level T6 or above where descending inhibition is blocked (Fig. 18.13). It may occur after spinal shock resolves and can be a recurrent complication. Characteristics include paroxysmal hypertension (up to 300 mmHg, systolic), a pounding headache, blurred vision, sweating above the level of the lesion with flushing of the skin, nasal congestion, nausea, piloerection caused by pilomotor spasm, and bradycardia (30 to 40 beats/min). The symptoms may develop singly or in combination. The condition can cause serious complications (stroke, seizures, myocardial ischemia, and death) and requires immediate treatment.⁴⁷

FIGURE 18.13 Autonomic Hyperreflexia. A, Normal response pathway. B, Autonomic dysreflexia pathway. SA, Sinoatrial. (Modified from Rudy EB: *Advanced neurological and neurosurgical nursing*, St Louis, 1984, Mosby.)

In autonomic hyperreflexia, sensory receptors below the level of the cord lesion are stimulated. The intact autonomic nervous system reflexively responds with an arteriolar spasm that increases blood pressure. Baroreceptors in the cerebral vessels, the carotid sinus, and the aorta sense the hypertension and stimulate the parasympathetic

system. The heart rate decreases, but the visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the cord.

The most common cause is a distended bladder or rectum; however, any sensory stimulation (i.e., skin or pain receptors) can elicit autonomic hyperreflexia. Emptying of the bladder or bowel usually relieves the syndrome, and the head of the bed should be elevated. Drug therapy, including nifedipine (a calcium channel blocker) and nitrates (e.g., nitroglycerine paste or sublingual nitroglycerine), may be required to lower blood pressure and reduce complications. Bladder, bowel, and skin care management are important preventive strategies. Education of the individual and family regarding triggers and acute management is important, as is wearing a medic alert tag.⁴⁸

◆Evaluation and Treatment.

Diagnosis of spinal cord injury is made on the basis of physical examination and imaging studies (e.g., MRI). Neurogenic shock must be differentiated from other kinds of shock (i.e., hypovolemic shock). For a suspected or confirmed vertebral fracture or dislocation, regardless of the presence or absence of spinal cord injury, the immediate intervention is immobilization of the spine to prevent further injury. Decompression and surgical fixation should be performed early. High-dose methylprednisolone steroid therapy has been given within 8 hours of the time of injury to decrease secondary cord injury. There are no clinical trials indicating this treatment is effective, and more research is needed.⁴⁹ Therapeutic hypothermia (32°C to 34°C; 89.6° to 93.2°F) has shown some encouraging evidence for improved outcomes, particularly for cervical cord injuries, but more research is needed.⁵⁰ Clinical trials are in progress to treat acute spinal cord injury, including cell-based therapies, immune modulators, vasculature selective treatments, functional electrical stimulation, and tissue engineering (hydrogels, nanofibers, and gene therapy).^{51,52}

Nutrition; lung function; skin integrity, particularly prevention of pressure ulcers; and bladder and bowel management must be

addressed. Plans for rehabilitation require early consideration. Impairments are permanent because endogenous repair events fail to restore the damaged axonal circuits.

Degenerative Disorders of the Spine

Low Back Pain

Low back pain (LBP) affects the area between the lower rib cage and gluteal muscles and often radiates into the thighs. The percentage of the population affected with recent LBP is about 29%, with a higher percentage among older individuals, particularly women older than age 60.⁵³ Most people will experience back pain at some time in their lives. LBP is the primary cause of disability worldwide.⁵⁴ The burdens of disability include psychologic, financial, occupational, and social effects on the person and family members.

Risk factors include occupations that require repetitious lifting in the forward bent-and-twisted position, exposure to vibrations caused by vehicles or industrial machinery, obesity, and cigarette smoking.

◆Pathophysiology.

Most cases of LBP are idiopathic or nonspecific, and no precise diagnosis is possible.⁵⁵ Acute LBP is often associated with muscle or ligament strain and is more common in individuals younger than 50 years of age without a history of cancer. Common causes of chronic LBP include degenerative disk disease and lumbar disk herniation. Genetic causes include isthmic spondylolisthesis (vertebra slides forward or slips in relation to a vertebra below), spinal osteochondrosis, and spinal stenosis associated with achondroplasia.⁵⁶ Other causes include tension caused by tumors or disk prolapse, bursitis, synovitis, rising venous and tissue pressures (found in degenerative joint disease), abnormal bone pressures, spinal immobility, inflammation caused by infection (as in osteomyelitis), and pain referred from viscera or the posterior peritoneum. Systemic causes of LBP include bone diseases, such as osteoporosis or osteomalacia, and hyperparathyroidism. Anatomically, low back pain

must originate from innervated structures, but deep pain is widely referred and varies. The nucleus pulposus has no intrinsic innervation but, when extruded or herniated through a prolapsed disk, it irritates the spinal nerve dural membranes and causes pain referred to the segmental area.⁵⁷ Diskogenic pain also may be related to nerve sprouting and inflammation within the disk.⁵⁸

The interspinous bursae can be a source of pain between L3, L4, L5, and S1, but also may affect L1, L2, and L3 spinous processes. The anterior and posterior longitudinal ligaments of the spine and the interspinous and supraspinous ligaments are abundantly supplied with pain receptors, as is the ligamentum flavum. All of these ligaments are vulnerable to traumatic tears (sprains) and fracture.

◆Clinical Manifestations.

About 1% of individuals with acute LBP have sciatica or pain along the distribution of a lumbar nerve root (radicular pain), most commonly involving the sciatic nerve (sciatica). Sciatica is often accompanied by neurosensory and motor deficits, such as tingling, numbness, and weakness in various parts of the leg and foot. Major or progressive motor or sensory deficit, cauda equina syndrome (new-onset bowel or bladder incontinence or urinary retention, loss of anal sphincter tone, saddle anesthesia), history of cancer metastasis to bone, and suspected spinal infection can be associated with chronic LBP.

◆Evaluation and Treatment.

Diagnosis of LBP is based on the history and physical examination. Imaging and nerve conduction studies are obtained with severe neurologic deficit or serious underlying disease. Diagnosis and treatment guidelines are available to plan therapy.^{59,60} Most individuals with acute LBP benefit from nonspecific short-term treatment, including nonsteroidal antiinflammatory medications, exercises, physical therapy, and education. Individuals with chronic LBP (pain for more than 3 months) can be treated with antiinflammatory and muscle relaxant medications, exercise

programs, massage, topical heat, spinal manipulation, acupuncture, cognitive-behavioral therapy, and interdisciplinary care.⁶¹ There is scant evidence for efficacy of opioids for chronic LBP, and there is high risk for addiction.⁶² Surgical treatments for identified pathologic conditions include discectomy and spinal fusions. Radiotherapy is used for treatment of facet-related pain after diagnostic nerve block. Evaluation of treatment outcomes should include pain, function, and quality of life.⁶³

Spondylolysis.

Spondylolysis is a structural defect (degeneration, fracture, or developmental defect) in the pars interarticularis of the vertebral arch (the joining of the vertebral body to the posterior structures). The lumbar spine at L5 is affected most often. Mechanical pressure may cause an anterior displacement of the deficient vertebra (spondylolisthesis). This defect occurs in the portion of the lamina between the superior and inferior articular facets called the *pars interarticularis*. Heredity plays a significant role, and spondylolysis is associated with an increased incidence of other congenital spinal defects. As a result of torsional and rotational stress, “microfractures” occur at the affected site and eventually cause dissolution of the pars interarticularis. Symptoms include lower back and lower limb pain.

Cervical spondylolysis is facet hypertrophy and disk degeneration with narrowing in the cervical spine predominantly at C5-C6 and C6-C7.⁶⁴ It may present as a cervical radiculopathy or a cervical myelopathy. Clinical manifestations of cervical radiculopathy include neck or occipital pain as well as pain in the medial aspects of the scapula, shoulder, or arm. Sensory symptoms, such as tingling or numbness, follow a dermatomal pattern; weakness follows the pattern of innervation of the affected nerve root. Occipital or suboccipital headache is another symptom. Cervical myelopathy can also cause difficulty walking, altered sensation in the feet, and sphincter disturbances (occurs late).

Spondylolisthesis.

Spondylolisthesis is an osseous defect of the pars interarticularis allowing a vertebra to slide forward in relation to the vertebra below, commonly occurring at L5-S1. It is more prevalent in adolescent athletes.⁶⁵ Grades 1 and 2 have symptoms of pain in the lower back and buttocks, muscle spasms in the lower back and legs, and tightened hamstrings. Conservative management includes exercise, rest, and back bracing. Vertebral slippage in grades 3 and 4 usually requires surgical decompression, stabilization, or both.

Spinal Stenosis.

Spinal stenosis is a narrowing of the spinal canal that causes pressure on the spinal nerves or cord and can be congenital or acquired (more common) and associated with trauma or arthritis. It is categorized by the area of the spine affected: cervical, thoracic, or lumbar. Acquired conditions include a bulging disk, facet hypertrophy, or a thick ossified posterior longitudinal ligament. Symptoms are related to the area of the spine affected and can produce pain; numbness; and tingling in the neck, hands, arms, or legs with weakness and difficulty walking. Surgical decompression is recommended for those with chronic symptoms and those who do not respond to medical management.

Degenerative Disk Disease

Degenerative disk disease (DDD) is common in individuals 30 years of age and older. It is, in part, a process of normal aging as a response to continuous vertical compression of the spine (axial loading). DDD includes a genetic component involving over expression of genes that code the cartilage intermediate layer protein (CILP). The combination of environmental interactions and genetic predisposition increases susceptibility to nontraumatic lumbar disk disease by disrupting normal building and maintenance of cartilage.⁵⁸ Causes include biochemical (e.g., inflammatory mediators) and biomechanical alterations (e.g., mechanical loading and compression) of the intervertebral disk tissue. For example, loss of disk proteoglycans and collagen with disk dehydration and loss of hydrostatic pressure alters

disk structure and function. The annulus can tear and the disk can herniate, pinching nerves or placing strain on the spine. Fibrocartilage replaces the gelatinous mucoid material of the nucleus pulposus as the disk changes with age. There may be shrinkage of the nucleus pulposus that produces prolapse or folding of the annulus with secondary osteophyte formation at the margins of the adjacent vertebral body. The pathologic findings in DDD include disk protrusion, spondylolysis and/or spondylolisthesis, degeneration of vertebrae, and spinal stenosis. Lumbar disk disease causes one-third of all back pain that affects 70% to 90% of adults at some point in their lives. However, only a small percentage of people with **DDD** have any functional incapacity because of pain.⁶⁶

Symptoms result from either (1) protrusion of the disk or annulus or (2) narrowing of the spinal canal or intervertebral foramen by osteophytes. A congenital narrow canal or congenitally short pedicles may be present. Posterior disk protrusion in the cervical, thoracic, and lumbar regions leads to spinal cord compression causing *myelopathy* (pathology in the spinal cord). Posterolateral disk protrusions, with or without a contribution from the vertebral body or apophyseal joint osteophytes, lead to nerve root compression causing *radiculopathy* (nerve root damage).

Thoracic disk disease is rarely symptomatic. Lumbosacral disk disease (*lumbar spondylosis*) involves degeneration of the lower two lumbar disks in 90% of persons. There may be (1) lateral disk protrusion (10% of cases), manifesting as pain referred to the anterior thigh and leg; (2) posterolateral disk protrusion; or (3) central disk protrusion, manifesting with pain, lower extremity weakness, impaired sphincter function, and saddle anesthesia. Clinical manifestations of posterolateral protrusions (Fig. 18.14) include pain in the back, the sacroiliac joint, and the medial aspect of the buttock and upper thigh; radicular pain exacerbated by movement and straining (medial calf suggests L5, lateral calf suggests S1 root compression); sensory symptoms that are common and segmental in distribution; focal tenderness on palpation of the back; limited range of motion in the back and scoliosis secondary to paravertebral spasms;

restricted straight-leg raising (root at or below L5); positive femoral stretch test (roots of L2, L3, or L4); and focal signs that are determined by the root affected.

FIGURE 18.14 Motor, Sensory, and Reflex Changes in Lumbosacral Root Disorders. (From Perkin DG et al: *Atlas of clinical neurology*, ed 3, Philadelphia, 2011, Saunders.)

Herniated Intervertebral Disk

Herniation of an intervertebral disk is a displacement of the nucleus pulposus or annulus fibrosus beyond the intervertebral disk space⁶⁷

(Figs. 18.15 and 18.16). Rupture of an intervertebral disk is usually caused by trauma, degenerative disk disease, or both. Risk factors are weight-bearing sports; light weight lifting; and certain work activities, such as repeated lifting. Men are more affected than women, with the highest incidence in the 30- to 50-year age group. The lumbosacral disks L4-L5 and L5-S1 are most commonly affected. Herniation is typically at higher vertebrae in older persons. Disk herniation occasionally occurs in the cervical area, usually at C5-C6 and C6-C7. Herniations at the thoracic level are extremely rare. The herniation may occur immediately, within a few hours, or months to years after injury.

FIGURE 18.15 Disk Bulge, Protrusion, and Herniation. Sagittal T2-weighted image demonstrates examples for all stages of disk pathology. Viewing from rostral to caudal, a disk bulge (*arrow*), a small and more prominent protrusion (*arrowheads*), and a herniation (*double arrowhead*) are seen. (From Daroff RB et al: *Bradley's neurology in clinical practice*, Philadelphia, 2012, Saunders.)

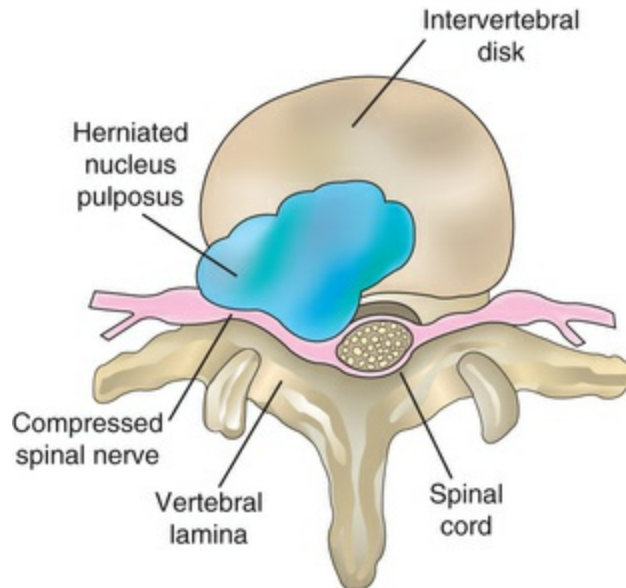

FIGURE 18.16 Herniated Nucleus Pulposus.

◆Pathophysiology.

In a herniated disk, the ligament and posterior capsule of the disk usually are torn, allowing the gelatinous material (the nucleus pulposus) to extrude and compress the nerve root. The vascular supply may be compromised and cause inflammatory changes in the nerve root (radiculitis). Occasionally, the injury tears the entire disk loose, causing the disk capsule and nucleus pulposus to protrude onto the nerve root or compress the spinal cord. Multiple nerve root compression may be found at the L5-S1 level, where the cauda equina may be compressed, causing cauda equina syndrome.

◆Clinical Manifestations.

The location and size of the herniation into the spinal canal, together with the amount of space in the canal, determine the clinical manifestations associated with the injury (see [Fig. 18.14](#)). Compression or inflammation, or both, of a spinal nerve resulting from disk herniation follows a dermatomal distribution called **radiculopathy** ([Fig. 18.17](#)). A herniated disk in the lumbosacral area is associated with pain that radiates along the sciatic nerve course over the buttock and into the calf or ankle. The pain occurs with straining, including

coughing and sneezing, and usually on straight-leg raising. Other clinical manifestations include limited range of motion of the lumbar spine; tenderness on palpation in the sciatic notch and along the sciatic nerve; impaired pain, temperature, and touch sensation in the L5-S1 or L4-L5 dermatomes of the leg and foot; decreased or absent ankle jerk reflex; and mild weakness of the foot. More rarely, there is development of cauda equina syndrome (saddle anesthesia, decreased or absent reflexes in the lower extremities, and neurogenic bowel or bladder dysfunction).

FIGURE 18.17 Sensory Nerve Distribution of Skin Dermatomes. (Redrawn from Patton HD, et al, editors: *Introduction to basic neurology*, Philadelphia, 1976, WB Saunders. Borrowed from Canale ST, Beaty JH: *Campbell's operative orthopaedics*, ed 12, St Louis, 2013, Mosby.)

With the herniation of a lower cervical disk, paresthesias and pain are present in the upper arm, forearm, and hand in the affected nerve root distribution. Neck motion and straining, including coughing and sneezing, may increase neck and nerve root pain. Neck range of motion is diminished. Slight weakness and atrophy of biceps or triceps may occur; the biceps or triceps reflex may decrease. Occasionally signs of corticospinal and sensory tract impairments appear. These include motor weakness of the lower extremities, sensory disturbances in the lower extremities, and presence of a Babinski reflex.

◆Evaluation and Treatment.

Diagnosis of a herniated intervertebral disk is made through the history and physical examination, spinal x-ray films, electromyography, CT scan, MRI, myelography, diskography, and nerve conduction studies. Evidence-based practice guidelines have been published to guide treatment options.⁶⁸ Most herniated disks heal spontaneously over time and do not require surgery. A surgical approach is indicated if there is evidence of severe compression (weakness or decreased deep tendon, bladder, or bowel reflexes) or if a conservative approach is unsuccessful.⁶⁹ Cauda equina syndrome requires emergency surgical evaluation⁷⁰ (see [Table 18.4](#)).

Cerebrovascular Disorders

Cerebrovascular disease is the most frequently occurring neurologic disorder, accounting for more than 50% of persons admitted to general hospitals with neurologic problems. Any abnormality of the brain caused by a pathologic process in the blood vessels is referred to as a *cerebrovascular disease*. Included in this category are lesions of the vessel wall (e.g., aneurysm or malformations); occlusion of the vessel lumen by thrombus or embolus; rupture of the vessel; and alteration in blood quality, such as increased blood viscosity or clotting.

The brain abnormalities induced by cerebrovascular disease are either (1) ischemia with or without infarction (death of brain tissues) or (2) hemorrhage. The common clinical manifestation of

cerebrovascular disease is a cerebrovascular accident or stroke. The symptoms occur suddenly and are usually focal (i.e., slurred speech, difficulty swallowing, limb weakness, or paralysis). In its mildest form, a cerebrovascular accident is so minimal that it is almost unnoticed. In its most severe form, hemiplegia, coma, and death result.

Cerebrovascular Accidents (Stroke Syndromes)

Cerebrovascular accidents (CVAs) are the leading cause of disability, the third cause of death in women, and the fifth leading cause of death in men in the United States. About 75% of CVAs occur among those older than 65 years. There has been a decline in ischemic strokes among whites but not blacks. The yearly incidence of new and recurrent stroke is 795,000; approximately 185,000 of these are recurrent and there are about 128,932 deaths each year, a decline of 18.2% from 2003 to 2013. The incidence of stroke is about 150% greater in blacks than whites. Stroke tends to run in families. Of all strokes, 87% are ischemic (thrombotic or embolic), 10% are intracerebral hemorrhagic, and 3% are subarachnoid hemorrhagic.⁷¹ Strokes in children are presented in [Chapter 20](#).

Cerebrovascular accidents (stroke syndromes) are classified pathophysiologically as ischemic, hemorrhagic, or cryptogenic. If no identifiable cause can be established by conventional diagnostic tests in ischemic strokes, they are classified as “undetermined” or “cryptogenic.” Risk factors for stroke include the following:⁷²

- Poorly or uncontrolled arterial hypertension
- Smoking, which increases the risk of stroke by 50%
- Insulin resistance and diabetes mellitus
- Polycythemia and thrombocythemia
- High total cholesterol or low high-density lipoprotein (HDL) cholesterol, elevated

lipoprotein-a

- Congestive heart disease and peripheral vascular disease
- Hyperhomocysteinemia
- Atrial fibrillation
- Physical inactivity
- Family history and genetics
- Sleep apnea
- *Chlamydia pneumoniae* infection⁷³
- Sickle cell disease
- Postmenopausal hormone therapy
- High sodium intake, >2300 mg; low potassium intake, <4700 mg
- Obesity
- Depression

Ischemic Stroke.

Ischemic stroke occurs when there is obstruction to arterial blood flow to the brain from thrombus formation, an embolus associated with atherosclerosis, or hypoperfusion related to decreased blood volume or heart failure. The inadequate blood supply results in ischemia (inadequate cellular oxygen) and can progress to infarction (death of tissue).

Transient ischemic attacks (TIAs) are episodes of neurologic dysfunction lasting no more than 1 hour and resulting from focal cerebral ischemia. The clinical manifestations of a TIA may include weakness, numbness, sudden confusion, loss of balance, loss of vision, or sudden severe headache resulting from focal cerebral ischemia. The use of brain imaging modalities often reveals a brain infarction. About 3% to 17% of individuals experiencing a TIA will have a stroke within 90 days.⁷⁴ Risk stratification for early stroke is enhanced when

imaging is combined with a risk stratification score (e.g., the ABCD[3] and ABCD[3]-I) which considers age, blood pressure, neurologic symptoms, symptom duration, and diabetes.⁷⁵ Guidelines are available for the prevention of future strokes.⁷⁶

Thrombotic strokes (cerebral thrombosis) arise from arterial occlusions caused by thrombus formation in large or small arteries supplying the brain or intracranial vessels. Conditions causing increased coagulation or inadequate cerebral perfusion (e.g., dehydration, hypotension, prolonged vasoconstriction from malignant hypertension) increase the risk of thrombosis. Cerebral thrombosis develops most often from atherosclerosis and inflammatory disease processes that damage arterial walls. It may take as long as 20 to 30 years for obstruction (stenosis) to develop at the branches and curvatures found in the cerebral circulation (see [Chapter 33](#) for a discussion of atherogenesis). The smooth stenotic area can degenerate, forming an ulcerated area of vessel wall. Platelets and fibrin adhere to the damaged wall, and clots form, gradually occluding the artery. The thrombus may enlarge both distally and proximally in the vessel. Thrombotic strokes occur when portions of the clot detach, travel upstream, and obstruct blood flow, causing acute ischemia.

Embolic stroke involves fragments that break from a thrombus formed outside the brain usually in the heart, aorta, or common carotid artery. Other sources of embolism include fat, air, tumor, bacterial clumps, and foreign bodies. The embolus usually involves small brain vessels and obstructs at a bifurcation or other point of narrowing, thus causing ischemia. An embolus may obstruct the lumen entirely and remain in place or shatter into fragments and become part of the vessel's blood flow. Risk factors for an embolic stroke are atrial fibrillation (15% to 25% of strokes), left ventricular aneurysm or thrombus, left atrial thrombus, recent myocardial infarction, rheumatic valvular disease, mechanical prosthetic valve, nonbacterial thrombotic endocarditis, bacterial endocarditis, patent foramen ovale, and primary intracardiac tumors.⁷⁷ In persons who experience an embolic stroke, a second stroke usually follows at some

point because the source of emboli continues to exist. Embolization is usually in the distribution of the middle cerebral artery (the largest cerebral artery). Ischemic strokes in children are associated with congenital heart disease, cerebral arteriovenous malformations, and sickle cell disease.

Lacunar strokes (lacunar infarcts or small vessel disease) are usually caused by perivascular edema, thickening and inflammation of the arteriolar wall in a deep perforating artery that supplies small penetrating subcortical vessels (small vessel disease). The ischemic lesions (0.5 to 15 mm) or lacunes are predominantly in the basal ganglia, internal capsules, and pons. They are associated with hyperlipidemia, smoking,⁷⁸ hypertension, and diabetes mellitus. These strokes represent about 25% of ischemic strokes and, because of the location and small area of infarction, may have pure motor or sensory deficits.⁷⁹

Hemodynamic stroke (brain hypoperfusion) is associated with *systemic hypoperfusion* caused by cardiac failure, pulmonary embolism, or bleeding that results in inadequate blood supply to the brain. Stroke may occur more readily if there is carotid artery occlusion. Symptoms usually are bilateral and diffuse.⁸⁰

◆Pathophysiology.

Cerebral infarction results when an area of the brain loses its blood supply because of vascular occlusion. Causes include (1) abrupt vascular occlusion (e.g., embolus or thrombi), (2) gradual vessel occlusion (e.g., atheroma), and (3) vessels that are stenosed but not completely occluded. Cerebral thrombi and cerebral emboli most commonly produce occlusion, but atherosclerosis and hypotension are the dominant underlying processes.

There is a central core of irreversible ischemia and necrosis or cerebral infarction. The central core is surrounded by a zone of borderline ischemic tissue, the **ischemic penumbra**. Ischemia in the penumbra is not severe enough to result in structural damage. Prompt restoration of perfusion in the penumbra by injection of thrombolytic agents promotes perfusion and may prevent necrosis and loss of

neurologic function. The window of opportunity for protecting the penumbra is about 3 hours.

Cerebral infarctions are ischemic or hemorrhagic. In *ischemic infarcts*, the affected area becomes pale and softens 6 to 12 hours after the occlusion (white infarct). Necrosis, swelling around the insult, and mushy disintegration appear by 48 to 72 hours after infarction. There is infiltration of macrophages and phagocytosis of necrotic tissue. The necrosis resolves by about the second week, ultimately leaving a cavity surrounded by glial scarring.

After occlusion of a cerebral artery, anastomoses connecting the distal segments of the middle cerebral artery with distal branches of the anterior and posterior cerebral arteries (known as *leptomeningeal* or *pial collaterals*) can partially maintain blood flow in the ischemic penumbra and delay or prevent cell death in some individuals. Vascular remodeling (angiogenesis) can occur with new arterioles sprouting from penumbra vessels that penetrate the ischemic core to reestablish collateral circulation. Efforts are in progress to enhance and promote collateral circulation following acute ischemic stroke (i.e., inhaled nitric oxide, transient suprarenal aortic occlusion, and electrical stimulation of the parasympathetic sphenopalatine ganglion).⁸¹

In *hemorrhagic infarcts*, bleeding occurs into the infarcted area through leaking vessels when the embolic fragments resolve and reperfusion begins to occur. Hemorrhagic transformation of ischemic infarct (red infarct) may be exacerbated by thrombolytic therapy.⁸² Unfortunately, reperfusion can compromise recovery by accelerating the sequence of metabolically damaging events, including oxidative stress (reperfusion injury) (see [Chapter 2](#)).

◆Clinical Manifestations.

Clinical manifestations of thrombotic or embolic ischemic stroke vary, depending on the distribution of the artery obstructed. Different sites of vessel obstruction create different occlusion syndromes. [Table 18.5](#) summarizes the various stroke syndromes. Contralateral sensory and motor manifestations occur on the opposite side of the body from the

location of the brain lesion because motor tracts originate in the cortex and most cross over in the medulla. Sensory tracts originate in the periphery and cross over in the spinal cord. Ipsilateral manifestations occur on the same side as the brain lesion for tracts that do not cross over.

TABLE 18.5

STROKE SYNDROMES SECONDARY TO OCCLUSION OR STENOSIS

LOCATION/VESSEL	AREA OF BRAIN INFARCTED	SIGNS AND SYMPTOMS NOTED
Anterior and Central Circulation		
<p>Note: The internal carotid artery enters the circle of Willis and supplies the lateral anterior and central portions of the cerebral hemispheres through the middle cerebral artery and the paramedial frontal lobe superior to the corpus callosum through the anterior cerebral artery; penetrating branches serve the deeper layers of the hemispheres.</p>		
Internal carotid	If collateral circulation is intact, there is commonly no infarction; if infarcted, it is in the same area of the middle cerebral artery	<ul style="list-style-type: none"> • Arterial pressure may be low in the retina • Bruits over the internal carotid artery • Possible retinal emboli • History of transient ischemic attacks (TIAs) • Positive noninvasive studies
Middle cerebral artery (MCA) (most common area); either stem or branches of MCA	Cortical motor area (face, arm, leg) and/or posterior limb, internal capsule, corona radiata	<ul style="list-style-type: none"> • Motor: contralateral hemiparesis or hemiplegia, greater in face and arm than leg
	Cortical sensory area (face, arm, leg) and/or posterior limb of internal capsule	<ul style="list-style-type: none"> • Sensation: contralateral loss in same distribution as motor loss
	Broca area and deep fibers in the dominant hemisphere	<ul style="list-style-type: none"> • Speech: expressive (motor) disorder with anomia (left hemisphere most commonly affected) with nonfluent aphasia and some comprehension defects
	Broca area and deep fibers in the nondominant hemisphere	<ul style="list-style-type: none"> • Speech: dysarthria
	Optic radiations deep in the temporal lobe	<ul style="list-style-type: none"> • Vision: contralateral homonymous hemianopsia or quadranopsia

	Location not known	<ul style="list-style-type: none"> • Motor: mirror movements • Respirations: Cheyne-Stokes respirations, contralateral hyperhidrosis, occasional mydriasis
	Posterior limb or internal capsule and adjacent corona radiata	<ul style="list-style-type: none"> • Motor: pure motor hemiplegia
	Penetrating branches of MCA (lenticulostriate branches) into the basal nuclei	<ul style="list-style-type: none"> • Motor: varying degrees of contralateral weakness of face, arm, or leg
		<ul style="list-style-type: none"> • Sensory: little or no loss; if present, contralateral following the motor distribution
		<ul style="list-style-type: none"> • Speech: transcortical sensory aphasia (communicating pathways are interrupted)
		<ul style="list-style-type: none"> • Perception: transient visual and sensory neglect on the left if a right lesion
Anterior cerebral artery (ACA) (least common)	Proximal segment: corona radiata (rarely)	<ul style="list-style-type: none"> • Motor: when present, a mild contralateral hemiparesis, greater in leg; with bilateral occlusion of ACA, cerebral paraplegia in both legs can occur
	Main stem (complete occlusion is uncommon, thus areas affected differ and collateral circulation may alleviate signs or symptoms); medial aspect of frontal lobes, caudate nucleus, and corpus callosum are supplied by the ACA	<ul style="list-style-type: none"> • Motor: contralateral paralysis or paresis (greater in foot and thigh); mild upper extremity weakness • Sensory: mild contralateral lower extremity deficiency with loss of vibratory and/or position sense, loss of two-point discrimination • Speech: may have transcortical motor and sensory aphasia if left hemisphere • Frontal lobe releasing signs (grasp, snout, root, and suck reflexes) • Apraxia
Posterior Circulation		
<p>Note: The posterior circulation includes the posterior cerebral artery, the vertebral arteries, and the basilar artery; the anatomic territory covered includes the posterior aspects of the hemispheres, the central areas of the thalamus and midbrain, and the brainstem; occlusion of the vessels is most commonly by emboli; effects of infarct in these vessels and their penetrating vessels can be specific or devastatingly global; many complex syndromes have been identified.</p>		
Vertebral arteries	Medulla and spinal cord tracts, anterior spinal artery and penetrating branches (medial medullary	<ul style="list-style-type: none"> • Motor: contralateral hemiparesis (face spared) and/or impaired contralateral proprioception; flaccid weakness or paralysis of the tongue and/or dysarthria

	syndrome)	
Basilar artery (three sets of branches)	Midline structures of pons (paramedian branches); three general areas of infarction are common: (1) medial inferior pontine syndrome, (2) medial midpontine syndrome, and (3) medial superior pontine syndrome	<ul style="list-style-type: none"> • Motor: contralateral hemiparesis or hemiplegia, ipsilateral lower motor neuron facial palsy, “locked-in syndrome” • Sensory: contralateral loss of vibratory sense, sense of position with dysmetria, loss of two-point discrimination, impaired rapid alternating movements • Visual: inferior pontine: diplopia; impaired abduction of ipsilateral eye: internuclear ophthalmoplegia; medial superior; diplopia, internuclear ophthalmoplegia, skewed deviation
	Corticospinal and corticobulbar tracts in pons, sensory tracts of medial and lateral lemnisci, vestibular nuclei, inferior and middle cerebellar peduncles, cranial nerve nuclei and/or fibers, cerebellar connections in tectum, descending sympathetic pathways, central brainstem, pontine tegmentum (vertebrobasilar syndrome)	<ul style="list-style-type: none"> • Motor: upper motor neuron type of weakness: paralysis in combinations involving face, tongue, throat, and extremities; dysphagia, facial weakness, dysmetria, ataxia (either trunk or extremities), weak mastication muscles • Sensation: combinations of impaired sensation (vibratory, two-point, position sense, pain, temperature), facial hypesthesia, anesthesia of cranial nerve V
Posterior cerebral artery (PCA)	Central territory (thalamic area, dentothalamic tract, cerebral peduncle, red nucleus, subthalamic nucleus, and cranial nerve III)	<ul style="list-style-type: none"> • Motor: contralateral hemiplegia with possible dysmetria, dyskinesia, hemiballism or choreoathetosis, dystaxia, cerebellar ataxia, and tremor; contralateral upper motor neuron palsy; several syndromes are associated: (1) Weber: cranial nerve III palsy and contralateral hemiplegia; (2) thalamoperforate syndrome: superior crossed cerebellar ataxia or inferior crossed cerebellar ataxia with cranial nerve III palsy (Claude syndrome); (3) decerebrate attacks • Sensory: contralateral sensory loss of all modalities without agraphia • Function: prosopagnosia (inability to recognize familiar faces), topographic disorientation, memory deficits, alexia,

		inability to read, color anomia • Level of consciousness: in bilateral PCA syndromes, coma with absent doll's eyes reflex or loss of alertness may occur; if tegmentum of midbrain near hypothalamus and third ventricle is damaged, akinetic mutism may occur
--	--	--

Small Vessel Disease

Note: Small penetrating vessels in brain parenchyma that supply areas near the basal ganglia are most vulnerable to infarction, although any small vessels can occlude deep in the brain and cause injury, producing neurologic signs or symptoms; such infarcts are commonly called *lacunes* (small pit or hollow), a term that is changing in meaning; they can be caused by emboli but are most commonly associated with microatheromas; although they can be found in otherwise healthy people, those with concurrent atherosclerosis, arterial hypertension, and/or diabetes have a higher incidence of this type of infarct.

	Internal capsule, most commonly	• Motor: contralateral hemiparesis on a single side, with equal deficit in face, arm, and leg; often unaccompanied by detectable signs of sensory, visual, and speech loss, depending on location; old term is <i>pure motor stroke</i> , although evidence suggests that other neurologic signs are present but overlooked because of low intensity
	Thalamus, most commonly	• Sensory: complete or partial loss in face, arm, trunk, and leg that appears exactly midline; may be accompanied by pain, hyperesthesias, and uncomfortable sensations (hemisensory stroke)
	Pons	• Dysarthria, clumsy hand
	Pons, midbrain, capsule or parietal white matter	• Hemiparesis, ataxia on same side

Modified from Barker E: *Neuroscience nursing*, St Louis, 1994, Mosby.

◆ **Evaluation and Treatment.**

Imaging is used to diagnose the different subtypes of ischemic stroke (i.e., MRI and CT imaging). Treatment of ischemic stroke is focused on (1) restoring brain perfusion in a timeframe that does not contribute to reperfusion injury, (2) counteracting the ischemic cascade pathways, (3) lowering cerebral metabolic demand so that the susceptible brain

tissue is protected against impaired perfusion, (4) preventing recurrent ischemic events, and (5) promoting tissue restoration. Intravenous thrombolysis (i.e., recombinant tissue plasminogen activator [rtPA]) given within 3 and up to 4.5 hours of onset of symptoms increases independent ambulation at 6 months when the diagnosis of ischemic stroke has been confirmed and contraindications are eliminated. Endovascular intraarterial thrombectomy can be used in combination with rtPA or alone as an approach to endovascular reperfusion.⁸³ Intracranial hemorrhage can be a complication of rTPA administration.⁸⁴ The American Heart Association and American Stroke Association provide guidelines for the early management of acute ischemic stroke.⁸⁵

Acute ischemic stroke frequently presents with hypertension, but the systemic blood pressure should not be treated unless the systolic pressure is 150 to 220 mmHg or mean arterial pressure exceeds 150 mmHg. Overly aggressive treatment of hypertension can compromise collateral perfusion of the ischemic penumbra. When the pathophysiology of stroke is stabilized, all individuals should receive blood pressure (BP)-lowering therapy to maintain BP lower than 140/90 mmHg or 130/90 mmHg if there are comorbidities, such as diabetes or chronic kidney disease.⁸⁶ Hypothermia has been used for neuroprotection in ischemic stroke with some promising results, but additional studies are needed to determine best methods and clinical practice guidelines.⁸⁷

Neuroprotective agents have not been shown to significantly reduce the risk of poor outcome including death with ischemic stroke. New neuroprotective agents are continuing to be evaluated for neuroprotection and to improve neuroplasticity and remodeling, including cell transplantation and neurostimulation.⁸⁸ Arresting the disease process by control of risk factors is critical to prevention of stroke and to reduce associated morbidity and costs.

Hemorrhagic Stroke.

Hemorrhagic stroke (spontaneous intracranial hemorrhage [ICH]) is the third most common cause of CVA. Hemorrhagic stroke can occur

within the brain tissue (intraparenchymal) or in the subarachnoid or subdural spaces. The primary cause of intraparenchymal hemorrhagic stroke is hypertension with other causes including tumors; coagulation disorders; trauma; or illicit drug use, particularly cocaine. Hypertensive causes of hemorrhagic stroke evolve over several years. They involve primarily smaller arteries and arterioles, resulting in thickening of the vessel walls and increased cellularity of the vessels. Necrosis may be present with vessel rupture. Microaneurysms in these smaller vessels or arteriolar necrosis may precipitate bleeding. Prevention or control of hypertension reduces the incidence of hemorrhagic stroke. Subarachnoid hemorrhage is associated with ruptured aneurysms, arteriovenous malformations or cavernous angioma or brain trauma. Subdural hemorrhage (hematoma) is usually associated with brain trauma.

◆Pathophysiology.

A mass of blood is formed as bleeding occurs into the brain tissue (Fig. 18.18). Adjacent brain tissue is deformed, compressed, and displaced producing ischemia, edema, IICP, and necrosis. Rupture or seepage of blood into the ventricular system often occurs and is associated with higher mortality. Hemorrhages are described as massive, small, slit, or petechial. Massive hemorrhages are several centimeters in diameter, small hemorrhages are 1 to 2 cm in diameter, a slit hemorrhage occurs in small penetrating vessels in the subcortical area leaving a slitlike cavity, and a petechial hemorrhage is the size of a pinhead. The most common sites for hypertensive hemorrhages are in the putamen of the basal ganglia, the thalamus, the cortex and subcortex, the pons, the caudate nucleus, and the cerebellar hemispheres.

FIGURE 18.18 Hypertensive Intracerebral Hemorrhage. Cross section of the pons showing a hypertensive intracerebral hemorrhage. (From Damjanov I: *Pathology for the health professions*, Philadelphia, 2012, Saunders.)

Because neurons surrounding the ischemic or infarcted areas undergo changes that disrupt plasma membranes, cellular edema results, causing further compression of capillaries. In massive intracerebral hemorrhage (volume greater than 150 mL), cerebral perfusion falls to zero and cerebral blood flow stops, resulting in death. In strokes with less than massive hemorrhage, adjacent brain tissue is displaced and compressed. Maximal cerebral edema develops in approximately 72 hours and takes about 2 weeks to subside. An inflammatory reaction in surrounding brain tissue appears rapidly and peaks in several days. [Fig. 18.19](#) illustrates additional detail. Most persons survive an initial hemispheric ischemic stroke unless there is massive cerebral edema, which is nearly always fatal. The cerebral hemorrhage resolves through reabsorption; macrophages and astrocytes clear blood from the area; and a cavity forms surrounded by a dense gliosis (glial scar) after removal of the blood.

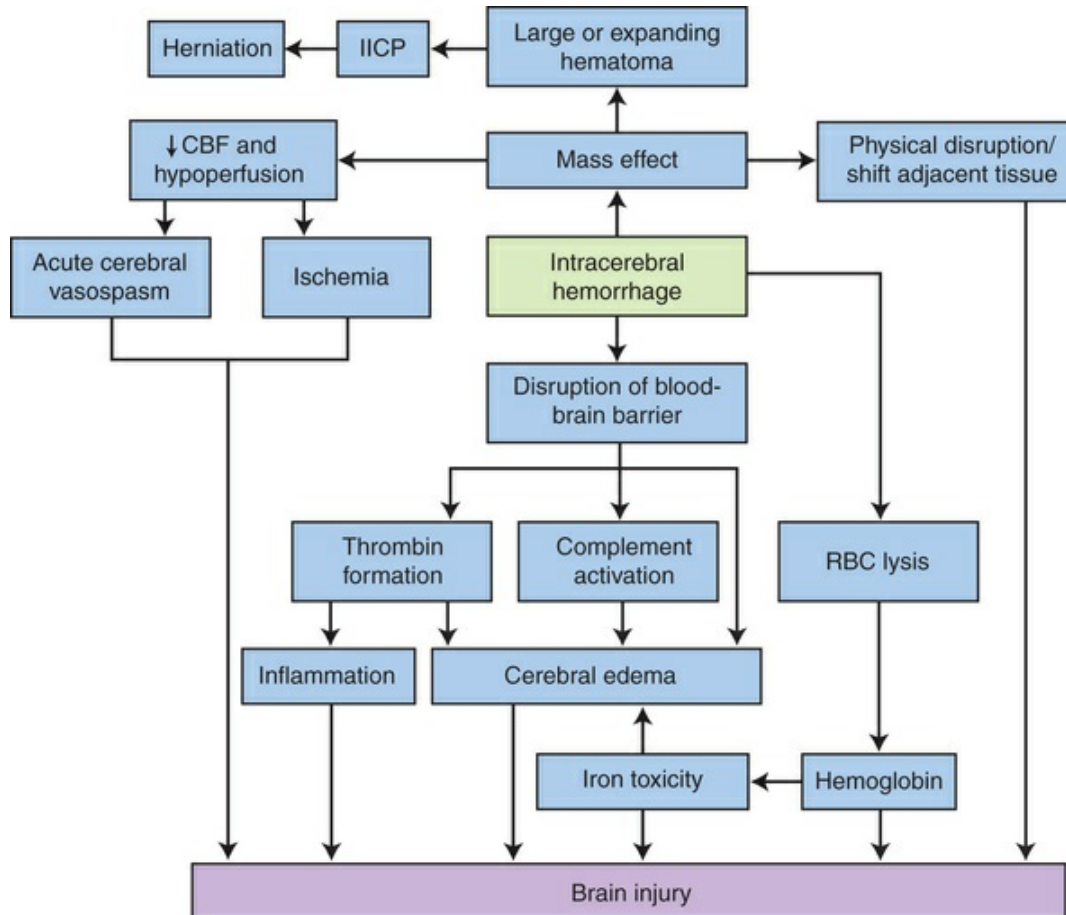

FIGURE 18.19 Injury Mechanisms Promoted by Intracerebral Hemorrhage. Hemorrhages can induce neuronal injury through mass effect, particularly in large hematomas that can cause increased intracranial pressure and herniation. Hemorrhages may also cause tissue damage through cerebral edema and secondary “neurotoxic” mechanisms caused by activation of the coagulation cascade and inflammation. Not all potential interactions are shown (e.g., thrombin may potentiate iron-induced injury; the complement and inflammatory systems overlap; and several factors contribute to cerebral edema). *CBF*, Cerebral blood flow; *IICP*, increased intracranial pressure; *RBC*, red blood cell. (Data from Mocco J, et al: *Neurosurg Focus* 15:22[5]:E7, 2007; Schubert GA, Thome C: *Front Biosci* 13:1594–1603, 2008; Xi G, Keep RF, Hoff JT: *Lancet Neurol* 5[1]:53–63, 2006.)

🔗Clinical Manifestations.

The clinical manifestations of hemorrhagic stroke are similar to those for embolic and thrombotic stroke and depend on the location and size of the bleed. Once a deep unresponsive state occurs, the immediate prognosis is grave, and the individual rarely survives. If the person survives, however, recovery of function frequently is possible.

Individuals experiencing intracranial hemorrhage from a ruptured or leaking aneurysm have one of three sets of symptoms: (1) onset of an excruciating generalized headache with an almost immediate lapse into an unresponsive state; (2) headache, but with consciousness maintained; and (3) sudden lapse into unconsciousness. If the hemorrhage is confined to the subarachnoid space, there may be no local signs. If bleeding spreads into the brain tissue, hemiparesis/paralysis, dysphasia, or homonymous hemianopsia may be present. Warning signs of an impending aneurysm rupture include headache, transient unilateral weakness, transient numbness and tingling, and transient speech disturbance. Such warning signs are often absent.

◆ Evaluation and Treatment.

Clinical guidelines for the management of spontaneous intracerebral hemorrhage have been published by the American Heart Association/American Stroke Association.⁸⁹

Diagnosis of hemorrhagic stroke considers the health history, clinical presentation, laboratory tests, and neuroimaging procedures (CT and MRI). Treatment needs to be initiated within 3 to 4 hours of symptom onset for reversibility of brain ischemia. Care in multidisciplinary stroke rehabilitation units appears to be most effective at reducing disability, dependency, and length of hospital stay for all stroke syndromes.⁹⁰

Treatment of a hemorrhagic stroke, regardless of cause, is focused on (1) stopping or reducing the bleeding, (2) controlling cerebral edema and IICP, (3) preventing a rebleed, (4) preventing vasospasm, and (5) promoting tissue restoration and preventing or controlling seizures. Known coagulopathies should be corrected and oral anticoagulation reversed.⁹¹

Hypertension management is individualized. Elevated blood pressure can expand the hematoma, and low blood pressure can contribute to ischemia. Lowering systolic blood pressure to no lower than 130 mmHg is probably beneficial but requires more evaluative studies.^{86,92} Intracranial hemorrhage and hemorrhagic transformation

of ischemic stroke are risk factors for early seizures, and cortical involvement is associated with late seizures. Routine prophylactic treatment of seizures that may be associated with stroke is controversial and requires more investigation.⁹³

Disruption of the blood-brain barrier results in cerebral edema and IICP. Osmotic therapies (e.g., mannitol) are used for the treatment of IICP and cerebral edema in hemorrhagic stroke.⁹⁴ Medical therapies to control clot expansion have not shown significant effects on improving mortality. There are some attempts to drain blood in a cerebral bleed, but the benefit is not documented in studies. Microsurgical interventions are under investigation. Surgical treatments are options for ruptured aneurysms, vascular malformations, and subarachnoid hemorrhage.^{95,96} Supportive care is provided for airway management; respiratory function; blood pressure control; avoidance of fever; and maintenance of fluids, glucose, electrolytes, and nutrition.

Intracranial Aneurysm.

Intracranial aneurysms (weak bulging areas of an arterial vessel wall) may result from arteriosclerosis, congenital abnormality, cocaine use, trauma, inflammation, and vascular shear wall stress. The size of the aneurysm may vary from 2 mm to 3 cm. Aneurysms may be single; however, more than one is present in 20% to 25% of cases. The aneurysms may be unilateral or bilateral in these instances. Peak incidence of rupture occurs in persons 50 to 59 years of age, with the incidence in postmenopausal women slightly higher than that in men.

◆Pathophysiology.

No single pathologic mechanism exists. A combination of genetic, congenital, and acquired factors (hypertension) is usually present. Abnormalities in multiple layers of the blood vessel are found. The endothelial layer is thin, the internal elastic lamina is not present or fragmented, and the muscularis layer of the media ends at the aneurysm. Inflammatory cells are recruited, inducing apoptosis and remodeling of the vascular wall. Atherosclerotic changes are found.

Aneurysm development is attributed to hemodynamic and wall shear stress and flow turbulence, particularly at bifurcations, such as in or near the circle of Willis, in the vertebrobasilar arteries, or within the carotid artery system (see Figs. 15.20 and 15.21). They are symptoms of underlying vascular disease. Hypertension and certain connective tissue disorders in which there are abnormalities in the extracellular matrix exacerbate aneurysm formation.⁹⁸ Aneurysms may be classified on the basis of shape and form (Fig. 18.20).

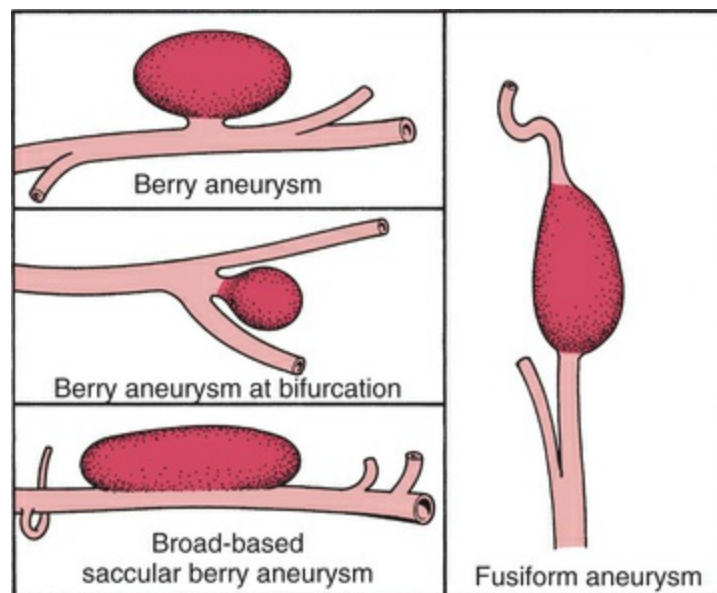

FIGURE 18.20 Types of Aneurysms.

Saccular aneurysms (berry aneurysms) occur frequently (in approximately 2% of the population) and are the result of a combination of a congenital abnormality in the media of the arterial wall with loss of smooth muscle cells, inflammation, thrombus formation, and degenerative changes. The sac expands over time.⁹⁹ A saccular aneurysm may be (1) round with a narrow stalk connecting it to the parent artery (Fig. 18.21), (2) broad based without a stalk, or (3) cylindrical. Saccular aneurysms are rare in childhood; their highest incidence of rupturing or bleeding is among people 20 to 50 years of age.

FIGURE 18.21 Berry Aneurysm, Angiogram. This lateral view, with contrast filling a portion of the cerebral arterial circulation, shows a berry aneurysm (*arrow*) involving the middle cerebral artery of the circle of Willis at the base of the brain. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

Fusiform aneurysms (giant aneurysms), by definition greater than 25 mm in diameter, make up 5% of all intracranial aneurysms. They occur as a result of diffuse arteriosclerotic changes and are found most commonly in the basilar arteries or terminal portions of the internal carotid arteries. They act as space-occupying lesions and often present as an ischemic stroke. **Mycotic aneurysms** are rare and result from arteritis caused by bacterial emboli (e.g., associated with bacterial endocarditis); these aneurysms are uncommon. **Traumatic (dissecting) aneurysms** are a weakening of the arterial wall caused by a fracture line, a penetrating missile, or after neurosurgical or imaging (e.g., angiographic) procedures.

What causes an aneurysm to rupture is not known.¹⁰⁰ Aneurysms rupture through thin areas, often at bifurcation sites, and cause hemorrhage into the subarachnoid space (subarachnoid hemorrhage) (see the [Subarachnoid Hemorrhage](#) section) with rapid spread, producing localized changes in the cerebral cortex and focal irritation of nerves and arteries. Because of compression, bleeding ceases with the formation of a fibrin-platelet plug at the point of rupture. Blood undergoes reabsorption through arachnoid villi within 3 weeks.

◆Clinical Manifestations.

Aneurysms are often asymptomatic. Of all persons undergoing routine autopsy, 5% are found to have one or more intracranial aneurysms. Clinical manifestations may arise from cranial nerve compression, but the signs vary, depending on the location and size of the aneurysm. Most often, cranial nerves III, IV, V, and VI are affected (see [Table 15.6](#)). Unfortunately the most common first indication is a ruptured aneurysm causing acute subarachnoid hemorrhage, intracerebral hemorrhage, or combined subarachnoid-intracerebral hemorrhage.

◆Evaluation and Treatment.

Diagnosis before a bleeding episode is made using arteriography. Intracranial aneurysms may be found incidentally during CT or MRI imaging for other conditions. After a subarachnoid or an intracerebral hemorrhage, a tentative diagnosis of an aneurysm that has bled is based on clinical manifestations, history, and imaging. Modifiable risk factors include smoking, alcohol use, and hypertension. Treatments for intracranial aneurysm are both medical (i.e., control of hypertension) and surgical (i.e., microvascular clipping or placement of endovascular coils). The mortality rate following rupture is 50%, and 50% of survivors are disabled, often severely.¹⁰¹

Vascular Malformations

Vascular malformations are rare, congenital vascular lesions that usually occur sporadically. An **arteriovenous malformation (AVM)** is a mass of dilated vessels between the arterial and venous systems (arteriovenous fistula) that lack a muscularis layer and have the absence of an intervening capillary bed. They can cause hemorrhagic stroke, epilepsy, chronic headache, or focal neurologic deficits.¹⁰²

Four types of vascular malformation exist: arteriovenous malformation, cavernous angioma, capillary telangiectasis, and venous angioma.¹⁰³ They usually rupture in the second and third decades of life. **Cavernous angiomas (malformations)** are rare sinusoidal collections of blood vessels without interspersed normal

brain tissue. They rarely hemorrhage and comprise 2% to 4% of hemorrhagic strokes. A **capillary telangiectasis** is dilated capillaries with interspersed normal brain tissue found deep in the brain, particularly in the brainstem; hemorrhage is rare. These vascular malformations are associated with Rendu-Osler-Weber disease (AVM in various areas of the body). **Venous angioma**, the most common vascular malformation found at autopsy (3% of cases), is considered a subset of developmental venous anomalies that occur secondary to arrested development. The result is primitive embryologic veins in a radial pattern feeding a central vein. These rarely hemorrhage.¹⁰⁴

◆Pathophysiology.

AVMs are developmental abnormalities that represent persistence of embryonic patterns of blood vessels. The vessels are abnormally thin and have complex growth and remodeling patterns¹⁰⁵ (Fig. 18.22). Their size is variable. The direct shunting of arterial blood into the venous vasculature without the dissipation of the arterial blood pressure increases risk for rupture. One or several arteries may feed the AVM, and over time, they become tortuous and dilated. With moderate to large AVMs, sufficient blood is shunted into the malformation to deprive surrounding tissue of adequate blood perfusion.

FIGURE 18.22 Vascular Malformation, Gross. A vascular malformation represented by a mass of irregular tortuous vessels over the left posterior parietal region of the brain. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

◀Clinical Manifestations.

Twenty percent of persons with an AVM have a characteristic chronic, nondescript headache, although some experience migraine. Fifty percent of persons experience seizures. The other 50% experience an intracerebral, subarachnoid, or subdural hemorrhage with progressive neurologic deficits.¹⁰⁶ Bleeding from an AVM into the subarachnoid space causes clinical manifestations identical to those associated with a ruptured aneurysm. If bleeding is into the brain tissue, focal signs progress over a short period of time. Ten percent of persons experience hemiparesis or other focal signs. Hemiparesis usually is caused by compression or rupture. At times, noncommunicating hydrocephalus (see [Chapters 17](#) and [20](#)) develops with a large AVM that extends into the ventricle lining. AVMs account for up to 1% of all sudden deaths.

◀Evaluation and Treatment.

A systolic bruit over the carotid in the neck, the mastoid process, or (in a young person) the eyeball is almost diagnostic of an AVM.

Confirming diagnosis is made by CT and MRI followed by magnetic resonance angiography (MRA). Treatment options include direct surgical excision, endovascular embolization, or radiotherapy.¹⁰⁷

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) is the escape of blood from a defective or injured vasculature into the subarachnoid space (Fig. 18.23). Individuals at risk for SAH are those with intracranial aneurysm, intracranial arteriovenous malformation, hypertension, a family history of SAH, and those who have sustained head injuries. Subarachnoid hemorrhages often recur, especially from a ruptured intracranial aneurysm. Other risk factors include heavy alcohol use, smoking, anticoagulation use, and oral contraceptive use. Mortality is approximately 50%, and about one-third of survivors require dependent care. SAHs often recur, especially from a ruptured intracranial aneurysm.¹⁰⁸

FIGURE 18.23 Subarachnoid Hemorrhage, Gross. Subarachnoid hemorrhage resulting from rupture of a berry aneurysm. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

When a vessel is leaking, blood oozes into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. The blood increases the intracranial volume, is extremely irritating to the meningeal and other neural tissues, and produces an inflammatory reaction. Additionally, the blood coats nerve roots, clogs arachnoid granulations (impairing CSF reabsorption), and clogs foramina within the ventricular system (impairing CSF circulation). ICP immediately increases to almost diastolic levels. ICP returns to near baseline in about 10 minutes. Autoregulation of blood flow is impaired and there is a compensatory increase in systolic blood pressure.¹⁰⁹ The expanding hematoma acts like a space-occupying lesion, compressing and displacing brain tissue with ICP, decreased cerebral perfusion pressure, decreased cerebral blood flow, blood-brain barrier breakdown, brain edema, inflammation, and cell death. Secondary brain injury can occur as described for TBI.

Delayed cerebral ischemia (DCI), a syndrome of progressive neurologic deterioration, is associated with *cerebral artery vasospasm*. From 40% to 60% of persons with a subarachnoid hemorrhage experience vasospasms in adjacent and, occasionally, in nonadjacent vessels. Vasospasm may occur because of leukocyte–endothelial cell interactions or the effects of inflammatory vasoactive substances (e.g., calcium, prostaglandins, serotonin, catecholamines, endothelin-1) on the arteries of the subarachnoid space. Edema, medial necrosis, and proliferation of the tunica intima have been found. Vasospasm causes decreased cerebral blood flow, ischemia, and possibly infarct and can lead to delayed ischemic injury and death 3 to 14 days after the initial hemorrhage.¹¹⁰

◆Clinical Manifestations.

Early manifestations associated with leaking vessels are episodic and include headache; changes in mental status or level of consciousness; nausea or vomiting; and focal neurologic defects, such as visual or speech disturbances, cranial nerve palsies, or stiff neck. A ruptured vessel causes a sudden throbbing, “explosive” headache accompanied

by nausea and vomiting, visual disturbances, motor deficits, and loss of consciousness related to a dramatic rise in ICP. Meningeal irritation and inflammation often occur, causing neck stiffness (nuchal rigidity), photophobia, blurred vision, irritability, restlessness, and low-grade fever. A positive Kernig sign (straightening the knee with the hip and knee in a flexed position produces pain in the back and neck regions) and a positive Brudzinski sign (passive flexion of the neck produces neck pain and increased rigidity) may appear. No localizing signs are present if the bleed is confined completely to the subarachnoid space. Hyponatremia is common and related to cerebral salt wasting or syndrome of inappropriate antidiuretic hormone. Several scales have been developed for grading SAH.¹¹¹ One of the commonly used is the Hunt and Hess grading system combined with the Glasgow Coma Score (see [Table 18.1](#)). The Hunt and Hess SAH grading system is based on description of the clinical manifestations ([Table 18.6](#)). Rebleeding is a significant risk with a high mortality (up to 70%). The period of greatest risk is the first 6 hours after an SAH in association with high systolic blood pressure and higher Hunt and Hess grade (III-IV), larger-sized aneurysm (>10 mm), and large posterior hematomas.¹¹² Rebleeding is manifested by a sudden increase in blood pressure and ICP, along with a deteriorating neurologic status.

TABLE 18.6

SUBARACHNOID HEMORRHAGE CLASSIFICATION SCALE

CATEGORY	DESCRIPTION
Grade I	Neurologic status intact; mild headache, slight nuchal rigidity
Grade II	Neurologic deficit evidenced by cranial nerve involvement; moderate to severe headache with more pronounced meningeal signs (e.g., photophobia, nuchal rigidity)
Grade III	Drowsiness and confusion with or without focal neurologic deficits; pronounced meningeal signs
Grade IV	Stuporous with pronounced neurologic deficits (e.g., hemiparesis, dysphasia); nuchal rigidity
Grade V	Deep coma state with decerebrate posturing and other brainstem dysfunction

From Hunt WE, Hess RM: *J Neurosurg* 28(1):14-20, 1968.

Seizures occur in 25% of persons with an SAH. Granulation tissue is formed and scarring of the meninges, with resulting impairment of CSF reabsorption leads to secondary hydrocephalus in about 20% of cases. Hypothalamic dysfunction, manifested by salt wasting, hyponatremia, and ECG changes, is common.

◆Evaluation and Treatment.

The diagnosis of an SAH is based on the clinical presentation, imaging, and CSF evaluation. Treatment is directed at controlling ICP, improving cerebral perfusion pressure, preventing ischemia and hypoxia of neural tissues, and avoiding rebleeding episodes. Surgical intervention is common, including surgical clipping of the aneurysm and endovascular placement of coils to occlude the aneurysm. Nimodipine (a calcium channel blocker) is used to prevent vasospasm, and magnesium, phosphodiesterase 3 inhibitors, and therapeutic hypothermia are being evaluated.¹¹³ Treatment guidelines are available to direct therapy.¹¹⁴

Primary Headache Syndromes

Headache is a common neurologic disorder and is usually a benign symptom. However, it can be associated with serious disease, such as brain tumor, meningitis, giant cell arteritis, and cerebrovascular disease (secondary headaches). The primary headache syndromes discussed here are the chronic, recurring type not associated with structural abnormalities or systemic disease and include migraine, cluster, paroxysmal hemicrania, and tension headaches. Characteristics of the major types of headache syndromes are summarized in [Table 18.7](#).

TABLE 18.7

CHARACTERISTICS OF COMMON HEADACHES

MIGRAINE		CLUSTER	TENSION
WITHOUT AURA	WITH AURA (25%-30%)	HEADACHE/PROXIMAL HEMICRANIA	TYPE OF HEADACHE

Age of onset	Childhood, adolescence, or young adulthood	Childhood, adolescence, or young adulthood	Young adulthood, middle age	Young adulthood, middle age
Sex	Higher in females	Higher in females	Male	Not sex specific
Family history of headaches	Yes	Yes	No	Yes
Onset and evolution	Slow to rapid	Slow to rapid	Rapid	Slow to rapid
Time course	Episodic	Episodic	Clusters in time	Episodic, may become constant
Quality	Usually throbbing	Usually throbbing	Steady	Steady
Location	Variable, unilateral to bilateral	Variable, unilateral to bilateral	Orbit, temple, cheek	Variable
Associated features	Prodrome, vomiting	Aura: visual, sensory, language, and motor disturbance Prodrome, vomiting	Lacrimation, rhinorrhea, Horner syndrome	None

Migraine

Migraine is an episodic neurologic disorder whose marker is headache lasting 4 to 72 hours. It is diagnosed when any two of the following features occur: unilateral head pain, throbbing pain, pain worsens with activity, moderate or severe pain intensity; *and* at least one of the following: nausea and/or vomiting, or photophobia and phonophobia.¹¹⁵ Migraine is broadly classified as (1) *migraine with aura* with visual, sensory, or motor symptoms; and, more commonly, (2) *migraine without aura* (most common) and (3) *chronic migraine*.¹¹⁶

Migraine occurs in about 18% of women, 6% of men, and about 10% of children in the United States. It is more common in those 25 to 55 years of age. There often is a family history of migraine. In susceptible

women, migraine occurs most frequently before and during menstruation and is decreased during pregnancy and menopause. The cyclic withdrawal of estrogen and progesterone may trigger attacks of migraine.¹¹⁷

Migraine is caused by a combination of multiple genetic and environmental factors. Persons with migraine have an increased risk for epilepsy, depression, anxiety disorders, cardiovascular disease, and ischemic stroke.¹¹⁹ Migraine may be precipitated by triggers. Individuals with migraine are likely to have a genetically determined reduced threshold for triggers. Triggers can include endogenous factors (e.g., altered sleep patterns [becoming tired or too much sleep], missed meals, overexertion, weather change, stress or relaxation from stress, hormonal changes [such as menstrual periods], excess afferent stimulation [bright lights, strong smells], and chemicals [alcohol or nitrates]).¹²⁰

The pathophysiologic basis for migraine is complex and not clearly established. There is no identifiable pathology, but there are associated changes in brain metabolism and blood flow. Current theories include neurologic, vascular, hormonal, and neurotransmitter components. Migraine aura is associated with cortical spreading depression (CSD). CSD is a spontaneous, self-propagating wave of glial and neuronal depolarization resulting in hyperactivity that starts in the occipital region and spreads across the cortex.¹²¹ CSD initiates the headache phase with release of neurotransmitters that activate the trigeminal vascular system (afferent projections from cranial nerve V), stimulating vasodilation of dural blood vessels, activation of inflammation, peripheral and central sensitization of pain receptors (hypersensitivity to pain), and activation of areas of the brainstem and forebrain that modulate pain. Release of inflammatory mediators with sterile meningeal inflammation and edema of blood vessels may be an important component of migraine pain. Vasodilation of blood vessels is not sufficient to account for the pain of migraine. Calcitonin gene-related peptide (CGRP) release by the trigeminal vascular system is related to migraine pain. The mechanism is not clear, but CGRP antagonists prevent the headache. Glutamate (an excitatory

neurotransmitter) concentration is increased and 5-hydroxytryptamine (5-HT, serotonin) concentration is decreased. 5-HT causes vasoconstriction and antagonizes CGRP. Consequently, 5-HT(1B/1D) receptor agonists (i.e., triptans) and CGRP receptor and glutamate receptor antagonists have been used for the acute treatment of severe migraine.¹²²

The clinical phases of a migraine attack are as follows:

1. *Premonitory phase*: Up to one-third of persons have premonitory symptoms hours to days before onset of aura or headache. These symptoms may include tiredness, irritability, loss of concentration, stiff neck, and food cravings.
2. *Migraine aura*: Up to one-third of persons have aura symptoms at least some of the time that may last up to 1 hour. Symptoms can be visual, sensory, or motor. There are no associated focal neurologic symptoms in migraine without aura.
3. *Headache phase*: Throbbing pain usually begins on one side and spreads to include the entire head. Headache may be accompanied by fatigue, nausea, and vomiting or dizziness. There may be hypersensitivity to anything touching the head. Symptoms may last from 4 to 72 hours (usually about a day).
4. *Recovery phase*: Irritability, fatigue, or depression may take hours or days to resolve.

The diagnosis of migraine is made from medical history and physical examination. Differential diagnosis is confirmed by imaging and EEG. Functional neuroimaging and genetic studies are advancing the understanding of the mechanisms involved in migraine attacks and individual variants involved with disease susceptibility.¹²³ The management of migraine includes avoidance of triggers (e.g., darkening the room, applying ice). Sleeping can provide some relief with the onset of acute migraine. Pharmacologic management for the treatment and prevention of migraine is available and individualized.¹²⁴ A transcutaneous electrical stimulation device providing trigeminal neurostimulation has been approved by the

Food and Drug Administration for the prevention of migraine.¹²⁵

Chronic migraines usually begin as episodic migraines that increase in frequency over time. Chronic migraine occurs at least 15 days in a month (can occur daily or on a near-daily basis) for more than 3 months. Chronic migraines are associated with overuse of analgesic migraine medications (sometimes called rebound headaches), obesity, and caffeine overuse. Treatment is similar to that for episodic migraine. Injections with botulinum toxin A are approved for preventing chronic migraine.¹²⁶ Individuals with chronic migraine unresponsive to medical treatment should be evaluated for intracranial hypertension without papilledema and the possibility of sinus venous stenosis.¹²⁷

Cluster Headache

Cluster headaches are one of a group of rare disorders referred to as trigeminal autonomic cephalgia.¹²⁸ They occur in one side of the head primarily in men between 20 and 50 years of age. The pain may alternate sides with each headache episode and is severe, stabbing, and throbbing. These uncommon headaches occur in clusters (up to eight attacks per day) and last for minutes to hours for a period of days, followed by a long period of spontaneous remission. Cluster headache has an episodic and a chronic form with extreme pain intensity and short duration. If the cluster of attacks occurs more frequently without sustained spontaneous remission, they are classified as *chronic cluster headaches* (10% to 20% of cases) (see [Table 18.7](#)). Triggers are similar to those that cause migraine headache.

Trigeminal activation occurs, but the mechanism is unclear. Functional imaging indicates a role for concomitant posterior hypothalamic and pain neuromatrix activation with opioid system involvement.¹²⁹ The pathogenic mechanism for pain is related to the release of vasoactive peptides and the formation of neurogenic inflammation. Autonomic dysfunction is characterized by sympathetic underactivity and parasympathetic activation. The headache attack usually begins without warning. There is unilateral trigeminal distribution of severe pain with ipsilateral autonomic

manifestations, including tearing on the affected side, ptosis of the ipsilateral eye, and congestion of the nasal mucosa. Pain often is referred to the midface and teeth. Prophylactic drugs and avoidance of triggers are used to treat cluster headache. Acute attacks are managed with oxygen inhalation, sumatriptan or inhaled ergotamine administration, and nerve stimulation. New drugs are under investigation.¹³¹

Chronic paroxysmal hemicrania (CPH) is a cluster-type headache with unilateral head pain associated with autonomic features (lacrimation or rhinorrhea) that occurs with more daily frequency (4 to 12 times per day) but with shorter duration (20 to 120 minutes). The remission phases are often shorter. The attacks occur in both men and women beginning at 30 to 40 years of age. The symptoms are similar to cluster headache. As with cluster headache, there is an episodic and a chronic form. The pathophysiology involves a disorder of sympathetic hyperactivity, but the mechanism is different from that of cluster headache because there is effective relief of symptoms with indomethacin.¹³²

Tension-Type Headache

Tension-type headache (TTH) is the most prevalent type of recurrent headache. It is not a vascular or migrainous headache. The average age of onset is during the second decade of life. It is usually a mild to moderate bilateral headache with a sensation of a tight band or pressure around the head. The onset of pain is usually gradual. *Episodic tension-type headache* occurs less than 15 days per month and may last for several hours or several days. It is not aggravated by physical activity and may be triggered by sleep disorders (insomnia). *Chronic tension-type headache* evolves from episodic TTH and occurs at least 15 days per month for at least 3 months. Many individuals have both tension-type and migraine headaches.

Both central and peripheral mechanisms operate in causing tension headache. The central mechanism probably involves hypersensitivity of pain fibers from the trigeminal nerve that leads to central sensitization with deficits in the descending inhibitory pain pathways

within the brainstem. The peripheral sensitization of myofascial sensory afferents may contribute to muscular hypersensitivity and the development of chronic TTH. Headache sufferers have more localized pain and tenderness of pericranial muscles.¹³³

Mild headaches are treated with ice, and more severe forms are treated with aspirin or other nonsteroidal antiinflammatory drugs. Chronic TTHs are best managed with a tricyclic antidepressant and behavioral and relaxation therapy. Some individuals benefit from injection of botulinum toxin A. Long-term use of analgesics or other drugs, such as muscle relaxants, antihistamines, tranquilizers, caffeine, and ergot alkaloids, should be avoided.¹³⁴

Infection and Inflammation of the Central Nervous System

The CNS may be infected by bacteria, viruses, fungi, parasites, and mycobacteria. The infecting microorganisms gain entry to the nervous system by (1) spreading through arterial blood vessels or (2) direct extension from another site of infection. Neurologic infections produce disease by several mechanisms: direct neuronal or glial infection, mass lesion formation, inflammation with subsequent edema, interruption of CSF pathways, neuronal or vascular damage, and secretion of neurotoxins. An immune process initiates an inflammatory reaction.

Syndromes are acute and subacute bacterial meningitis, epidural and brain abscess, encephalitis, peripheral neuropathy, or neurosyphilis, depending on the infecting microorganism. Signs and symptoms are produced because of (1) interference with the function of the nervous system tissue being invaded or compressed or (2) the inflammatory response produced by the body in response to infection. The cardinal signs of CNS infection are fever, head or spine pain, and generalized or focal neurologic dysfunction.¹³⁵

Meningitis

Meningitis is inflammation of the brain or spinal cord. Infectious meningitis may be caused by bacteria, viruses, fungi, parasites, or toxins. (The pathophysiology of infection is discussed in [Chapter 10](#).) The infection may be acute, subacute, or chronic with the pathophysiology, clinical manifestations, and treatment differing for each type of microorganism.

Bacterial Meningitis.

Bacterial meningitis is primarily an infection of the pia mater and arachnoid villi, the subarachnoid space, the ventricular system, and the CSF. About 5 to 10 per 100,000 persons are affected annually.¹³⁶ Meningococcus (*Neisseria meningitidis*) and pneumococcus

(*Streptococcus pneumoniae*) are the most common pathogens. An increase of drug-resistant strains of *S. pneumoniae* is an emerging problem worldwide. Meningococcus has been identified worldwide, and there are six serogroups: A, B, C, W-135, X, and Y. Most cases are sporadic and occur predominantly in children younger than 1 year of age and adolescents. Local outbreaks may occur in dormitories, military bases, or sub-Saharan Africa. Young persons and those more than 40 years of age are mostly affected with pneumococcal meningitis. Predisposing conditions are otitis or sinusitis (25%), immunocompromised status (16%), and pneumonia (12%).¹³⁶ The disease is spread by respiratory droplets and contact with contaminated saliva or respiratory tract secretions (kissing, coughing, and sneezing or sharing utensils, food, and drink).¹³⁸ Carriers of the meningococcal bacteria do not develop meningitis but may pass it on to others.

Bacterial meningococci and pneumococci are inhaled and attach to epithelial cells in the nasopharynx where they evade immune defenses, cross the mucosal barrier, enter the bloodstream, travel to cerebral blood vessels, cross the blood-brain barrier, and infect the meninges (Fig. 18.24). Bacteria multiply in the subarachnoid space and attract large numbers of neutrophils. Release of cytotoxic inflammatory agents and bacterial endotoxin alter the blood-brain barrier, cause cerebral edema, and damage brain tissue. The inflammatory exudate thickens the CSF and interferes with normal CSF flow around the brain and spinal cord, possibly obstructing arachnoid villi and producing hydrocephalus. Meningeal cells become edematous, and the combined exudate and edematous cells increase ICP. Engorged blood vessels and thrombi can disrupt blood flow, causing further injury¹³⁹ (Fig. 18.25). The cortical neurons also show some changes, including an increase in the number of microglia and astrocytes. Acute infectious **purpura fulminans** is a rare, rapidly progressive syndrome of hemorrhagic infarction of the skin and disseminated intravascular coagulation that can lead to multiple organ failure, ischemic necrosis of digits and limbs with amputation required, and death. It is caused by bacterial endotoxin and

inflammatory cytokines associated with meningitis.

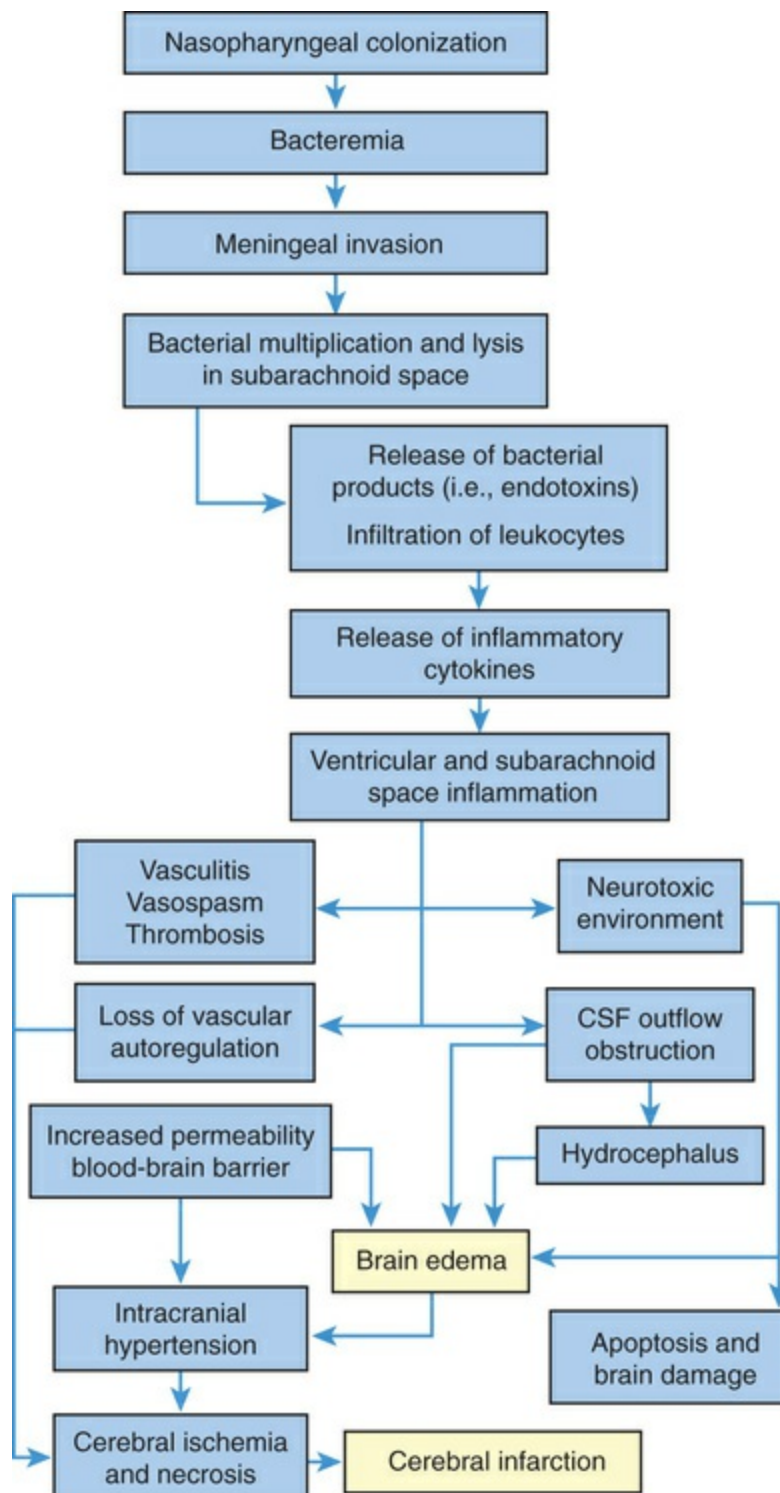

FIGURE 18.24 Pathogenesis of Meningitis. (Adapted from Cohen J, Powderly WG: *Infectious diseases*, ed 2, Mosby, 2004, Edinburgh.)

FIGURE 18.25 Acute Bacterial Leptomeningitis. The leptomeninges contain abundant creamy, purulent exudate, most prominently over the superior surface of the cerebrum. The underlying brain is swollen, and the vessels are congested. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

The clinical manifestations of bacterial meningitis can be grouped into infectious signs, meningeal inflammatory signs, and neurologic signs. The clinical manifestations of systemic infection include fever, tachycardia, and chills. The clinical manifestations of meningeal irritation are a severe throbbing headache, severe photophobia, nuchal rigidity, and positive Kernig and Brudzinski signs. The neurologic signs include a decrease in consciousness, focal neurologic deficits (such as hemiparesis/hemiplegia and ataxia), and seizures. The irritation and damage to the cranial nerves produced by the inflamed sheaths manifest as follows:

Cranial nerve II: papilledema, blindness

Cranial nerves III, IV, and VI: ptosis, visual field deficits, diplopia

Cranial nerve V: photophobia

Cranial nerve VII: facial paresis

Cranial nerve VIII: deafness, tinnitus, vertigo

Neck stiffness and pain, and possibly head retraction, reflect the irritability of spinal accessory and cervical spinal nerves. Often the vomiting center is irritated, causing projectile vomiting. Confusion and decreasing responsiveness are evidence of cortical involvement. In meningococcal meningitis, petechial or purpuric rash involving the skin and mucous membranes occurs. As ICP increases, papilledema may develop with declining levels of consciousness.

Rapid diagnosis, antibiotic administration, and supportive treatment are important to prevent morbidity and mortality from bacterial meningitis. Dexamethasone therapy has been implemented as adjunctive treatment of adults with pneumococcal meningitis.¹³⁹ Diagnosis is based on physical examination, blood cultures, and the results of nasopharyngeal smear and antigen tests. CSF analysis and cultures are required to diagnose fungal meningitis. Other supportive measures may be needed. Serious complications, including septic shock, disseminated intravascular coagulation, purpura fulminans, and multiple organ failure, require intensive multidisciplinary care.¹⁴⁰ Vaccinations are available to prevent meningococcal, pneumococcal, and *Haemophilus influenzae* meningitis.

Viral Meningitis.

Viral meningitis (aseptic meningitis) is believed to be limited to the meninges and an identifiable bacterium or specific pathogen cannot be found in the CSF. The most at-risk populations and the time of year when occurrences are seen depend on the virus and on the immune status of the individual. Viral meningitis produces a variety of symptoms and is caused by a variety of viruses. Viruses infecting specific cell types are presented in [Fig. 18.26](#). Viruses causing acute and chronic CNS infections are listed in [Table 18.8](#).

FIGURE 18.26 Viral Infection of Specific Cells in the Central Nervous System (CNS). Viruses infect specific cell types within the CNS depending on the specific properties of the virus together with individual cell-membrane proteins expressed on permissive cell types. Normally the brain is protected from circulating pathogens and toxins by the blood-brain barrier. *CMV*, Cytomegalovirus; *HIV*, human immunodeficiency virus; *HSV*, herpes simplex virus; *HTLV-1*, human T-cell lymphotropic virus type 1 (causes T-cell leukemia); *JCV*, John Cunningham virus (a polyomavirus causing progressive multifocal leukoencephalopathy); *SSPE*, subacute sclerosing panencephalitis; *VZV*, varicella-zoster virus. (Adapted from Power C, Noorbakhsh G: Central nervous system viral infections: clinical aspects and pathogenic mechanisms. In Gilman S, editor: *Neurobiology of disease*, Burlington, MA, 2007, Elsevier, p 488.)

Nipah virus	Paramyxoviridae	RNA	Encephalitis	Neuron, endothelia
Rubella virus	Togaviridae	RNA	Meningitis, encephalitis	Not specified
Equine encephalitis viruses	Togaviridae	RNA	Meningitis, encephalitis	Neuron, astrocytes
Coxsackievirus, echovirus	Picornaviridae	RNA	Meningitis, meningoencephalitis, myelitis	Neuron
Poliovirus	Picornaviridae	RNA	Meningitis, myelitis	Neuron
California encephalitis virus	Bunyaviridae	RNA	Meningitis, encephalitis	Neuron
Viruses Causing Chronic CNS Disease				
Human immunodeficiency virus	Retroviridae	RNA	Encephalitis, meningitis, myelitis	Microglia, macrophage, astrocytes
Human T-cell leukemia viruses 1 and 2	Retroviridae	RNA	Myelitis	Astrocyte, leukocyte
JC virus	Polyomaviridae	DNA	Progressive multifocal leukoencephalopathy	Oligodendrocyte, astrocyte
Measles virus	Paramyxoviridae	RNA	Encephalitis; SSPE	Neuron
Varicella-zoster virus	Herpesviridae	DNA	Leukoencephalitis, cerebellitis, meningitis, myelitis	Neurons, satellite cell
Cytomegalovirus	Herpesviridae	DNA	Encephalitis	Neuron, ependymal cell, oligodendrocyte, monocytoid cell,

				endothelia
Epstein-Barr virus	Herpesviridae	DNA	Encephalitis, meningitis, myelitis	Infiltrating mononuclear cells

CNS, Central nervous system; *DNA*, deoxyribonucleic acid; *HAART*, highly active antiretroviral therapy; *IVIg*, intravenous immunoglobulin; *JC*, John Cunningham; *ND*, not determined; *RIG*, rabies immune globulin; *RNA*, ribonucleic acid; *SSPE*, subacute sclerosing panencephalitis.

From Lindquist L, Vapalahti O: *Lancet* 371(9627):1861-1871, 2008; Power C, Noorbakhsh F: Central nervous system viral infections: clinical aspects and pathogenic mechanism. In Gilman S, editor: *Neurobiology of disease*, Burlington, MA, 2007, Elsevier, pp 487-488.

In viral meningitis, the virus reaches the CNS by hematogenous spread (Fig. 18.27). The virus enters the brain either directly or indirectly, through infected migrating leukocytes, and then infects vascular endothelial cells. The virus then enters the subarachnoid space, leading to meningitis. The immune response leads to release of inflammatory cytokines with increased permeability of the blood-brain barrier and entry of circulating immunoglobulins that combat the virus.

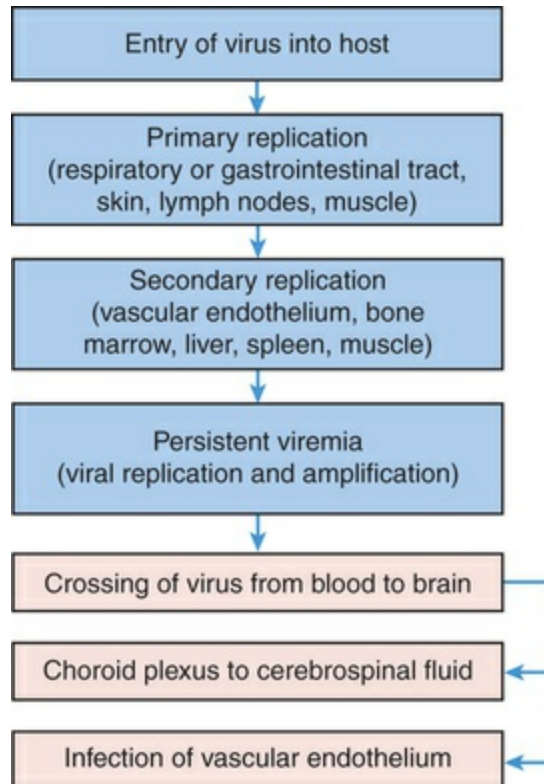

FIGURE 18.27 Hematogenous Spread of Viral Pathogens to the Central Nervous System. (Adapted from Cohen J, Powderly WG: *Infectious diseases*, Mosby, 2007, Edinburgh.)

The clinical manifestations of viral meningitis are mild compared with those associated with bacterial meningitis. Mild generalized throbbing headache, mild photophobia, mild neck pain, stiffness, fever, and malaise are manifestations of viral meningitis. Treatment is primarily supportive and the disease usually resolves within 7 to 10 days.

Fungal Meningitis.

Fungal meningitis is a chronic condition that is much less common than bacterial or viral meningitis. The most common fungal infections of the nervous system are histoplasmosis, cryptococcosis, coccidioidomycosis, mucormycosis, candidiasis, and aspergillosis. It develops insidiously, usually over days or weeks.

Fungi in the nervous system usually produce a granulomatous reaction with formations of granulomas or gelatinous masses. These usually develop in the meninges at the base of the brain. Fungi also

may extend along the perivascular sites in the subarachnoid space and into the brain tissue, producing arteritis with thrombosis, infarction, and communicating hydrocephalus. Meningeal fibrosis develops later in the inflammatory process. Cranial nerve dysfunction, caused by compression, often results from the granulomas and fibrosis.

The first manifestations are often those of dementia or communicating hydrocephalus (see [Chapter 17](#)). The individual is characteristically afebrile. Cryptococcal meningitis occurs in immunosuppressed hosts, including organ transplant recipients and individuals with HIV/AIDS.¹⁴² *Candida* and *Aspergillus* are less common infections. Antifungal treatments are organism-specific and effective.¹⁴³

Tubercular Meningitis.

Tubercular meningitis is a common and serious form of CNS tuberculosis, especially in immunosuppressed persons or those with acquired immunodeficiency syndrome (AIDS). Mycobacteria are acquired through inhalation of aerosolized droplet nuclei. The miliary tubercles form in the brain and meninges. At some point the tuberculomas erode the pia mater, and the mycobacteria enter the CSF, producing a hypersensitivity reaction that results in a purulent exudate involving the basal meninges, cerebrum, and spinal nerves. Cerebral ischemia and infarction occur from vasculitis. Symptoms are nonspecific, making early diagnosis difficult. Symptoms include headache, low-grade fever, nausea and vomiting, irritability, difficulty sleeping, and fatigue.¹⁴⁴ These signs and symptoms increase to confusion, stiff neck, significant behavioral changes, and seizures. Hydrocephalus and cranial nerve palsies or cerebral infarcts may occur. Recovery rate is 90% with early diagnosis and treatment with appropriate antituberculosis therapy. Treatment is difficult in resource-poor countries.¹⁴⁵

Brain or Spinal Cord Abscess

Abscesses are localized collections of pus within the parenchyma of the brain or spinal cord and are rare. Immunosuppressed persons are

particularly at risk.

Brain abscesses are classified as extradural, subdural, or intracerebral. **Extradural brain abscesses (empyemas)** are associated with osteomyelitis in a cranial bone. **Subdural brain abscesses (empyemas)** arise from a sinus infection or a vascular source. **Intracerebral brain abscesses** arise from a vascular source. Brain abscesses progress from localized inflammation to a necrotic core with the formation of a connective tissue capsule, usually within 14 days or longer.¹⁴⁶ Existing abscesses also tend to spread and form daughter abscesses. **Spinal cord abscesses** are rare and classified as epidural or intramedullary. Epidural spinal abscesses usually originate as osteomyelitis in a vertebra or as a bacterial meningitis; the infection then spreads into the epidural space.¹⁴⁷

◆Pathophysiology.

Microorganisms gain entrance to the CNS from adjacent sites by direct extension from trauma, mastoiditis, sinusitis, or dental infection. Blood vessels carry infective emboli from distant sites, such as the heart, lungs, pelvic organs, skin, tonsils, abscessed teeth, osteomyelitis (with the exception of cranial bones), and dirty needles (especially in immune-compromised hosts). *Streptococci*, *Staphylococci*, and *Bacteroides*, often in combination with anaerobes, are the most common bacteria that cause abscesses; however, yeast and fungi also have been found in CNS abscesses. *Toxoplasma gondii* is producing an ever-increasing number of CNS abscesses in persons with AIDS. Most CNS abscesses are located in the frontal and temporal lobes (Fig. 18.28).

FIGURE 18.28 Brain Abscess. The abscess is sharply demarcated, indicating that it has been present for some time. Purulent exudate is visible in the center of the abscess. Because antibiotics penetrate very poorly into abscesses, surgical drainage is often necessary to treat such lesions. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

Brain abscesses evolve through four stages regardless of infecting microorganism, except in the immunosuppressed host where the process may be incomplete. The stages are as follows:

1. *Early cerebritis* (days 1 to 3): A localized inflammatory process develops in which perivascular infiltration and inflammatory cells, composed of neutrophils, plasma cells, and mononuclear cells, surround a central core of coagulative necrosis; marked cerebral edema surrounds the area.
2. *Late cerebritis* (days 4 to 9): The necrotic center is surrounded by an inflammatory infiltrate of macrophages and fibroblasts; rapid new blood vessels form around the abscess; a thin capsule of fibroblasts and reticular fibers gradually develops; the area is still surrounded by cerebral edema.
3. *Early capsule formation* (days 10 to 13): The necrotic center decreases in size; the inflammatory infiltrate changes in character and contains an increasing number of fibroblasts and macrophages; mature collagen evolves, forming a capsule.
4. *Late capsule formation* (days 14 and longer): A well-formed

necrotic center surrounded by a dense collagenous capsule develops.¹⁴⁸

◆Clinical Manifestations.

Early manifestations include low-grade fever, headache (most common symptom), nausea and vomiting, neck pain and stiffness, confusion, drowsiness, sensory deficits, and communication deficits. Later manifestations are associated with an expanding mass and include decreased attention span, memory deficits, decreased visual acuity and narrowed visual fields, papilledema, ocular palsy, ataxia, cognitive deficits, and seizures. The development of symptoms may be very insidious, often making an abscess difficult to diagnose.

Extradural brain abscesses are associated with localized pain, purulent drainage from the nasal passages or auditory canal, fever, localized tenderness, and neck stiffness; occasionally the individual experiences a focal seizure. Clinical manifestations of spinal cord abscesses have four stages: (1) spinal aching; (2) root pain, which is usually severe, accompanied by spasms of the back muscles and limited vertebral movement because of pain and spasm; (3) weakness caused by progressive cord compression; and (4) paralysis.¹⁵⁰

◆Evaluation and Treatment.

The diagnosis is suggested on the basis of clinical features and confirmed with MRI or contrast-enhanced CT. Stereotactic surgical aspiration is usually indicated for identification of the pathogen and for decompression of the abscess. Antibiotics are initiated when there is clinical suspicion of an abscess. Multiple or surgically inaccessible abscesses are treated with antibiotics, often in conjunction with corticosteroid therapy to treat the cerebral edema. In addition, ICP or hydrocephalus, or both, require management.¹⁴⁸ Because decompression is necessary, spinal cord abscesses are treated with surgical excision or aspiration. Antibiotic administration and supportive therapy are instituted.

Encephalitis

Encephalitis is an acute febrile illness, usually of viral origin, with nervous system involvement. The most common forms are caused by bites of mosquitos, ticks, or flies. Herpes simplex type 1 is the most common sporadic cause of encephalitis. Etiologic agents for viral encephalitis are presented in [Table 18.8](#). Referred to as *infectious viral encephalitides*, encephalitis also may occur as a complication of systemic viral diseases such as poliomyelitis, rabies, mononucleosis, rubella, or rubeola. Encephalitis also may follow vaccination with a live attenuated virus vaccine if the vaccine has an encephalitis component. Such vaccines include measles, mumps, rubella; varicella; rotavirus; and yellow fever. Typhus, trichinosis, malaria, and schistosomiasis also are associated with encephalitis. Toxoplasmosis may acutely reactivate in immunosuppressed hosts when the once-dormant parasite in cyst form disseminates in brain tissues.¹⁵¹

With the exception of the California viral encephalitis, which is endemic, the arthropod-borne encephalitides occur in epidemics, varying in geographic and seasonal incidence ([Table 18.9](#)). Eastern equine encephalitis is the most serious but least common of the encephalitides.¹⁵² West Nile virus is presented in [Box 18.1](#).

TABLE 18.9

CLASSIFICATION AND CHARACTERISTICS OF ARTHROPOD-BORNE VIRUSES (ARBOV) CAUSING ENCEPHALITIS

VIRUSES	INCUBATION PERIOD (DAYS)	VIRUS	LOCATION	VECTOR	SEASON	AI PC
Eastern equine encephalitis	5-10	Togaviridae <i>Alphavirus</i> (formerly group A arbovirus)	Swampy areas of eastern United States and Michigan	Mosquito	June to October	Inf
Western equine encephalitis	5-10	Same as above	All parts of United States: eastern, central, and western	Mosquito	July to October	AI

Venezuelan equine encephalitis	2-5	Same as above	Texas, Florida, Mexico; Central and South America	Mosquito	All year	Inf

La Cross encephalitis including California	5-15	Bunyaviridae <i>Bunyavirus</i> (California virus serogroup)	Midwestern United States, eastern seaboard, and Canada	Woodland mosquito	July to September	Ch
West Nile encephalitis	3-14	Flaviviridae <i>Flavivirus</i>	Lower 48 states of United States	Mosquito	Summer and fall	Ol

Box 18.1

West Nile Virus

West Nile virus (WNV), a *Flavivirus* transmitted predominantly by the *Culex* mosquito, emerged in New York state in 1999. By the end of 2004, human cases had been found in the 48 contiguous states. Humans and horses, as well as other mammals, are incidental hosts. Birds and mosquitoes are life cycle hosts. Summer and fall are peak times of infection incidence. The highest amount of virus carried by mosquitoes is in early fall. Besides mosquito transmission, WNV can be transmitted through blood transfusions and organ transplants. Health experts believe transmission from mother to unborn child and through breast milk is possible.

The human incubation period is 2 to 14 days; however, most individuals develop no symptoms. About 20% of those infected have mild symptoms that last 4 to 6 days and generally include fever, headache, skin rash, and lymphadenopathy. Less than 1% of

affected persons develop severe illness, including *WNV encephalitis* marked by headache, disorientation, stupor, coma, seizures, and movement disorders, including tremor, ataxia, extrapyramidal signs, and paralysis. *WNV meningitis* is characterized by meningeal signs of severe headache, high fever, and nuchal rigidity. Myelitis and polyradiculitis also may be present. Abnormalities in the thalamus, basal ganglia, and cerebellum are often seen on MRI in people with severe infection. Identifiable risk factors are very young children or those with advanced age, immunocompromised individuals, and pregnant women.

A preliminary diagnosis is made if WNV-specific IgM for the virus is found in serum or CSF. A rapid test became available in 2007. Plaque reduction neutralization assay (PRNA) is the confirmatory test. MRI may show abnormalities in the basal ganglia, thalamus, and brainstem in those with encephalitis. Treatment is supportive care. No WNV vaccine has been developed for humans. Environmental control and prevention of mosquito bites are the best protection. Since 2003, all blood banks use blood-screening tests for West Nile virus.

CSF, Cerebrospinal fluid; *IgM*, immunoglobulin M; *MRI*, magnetic resonance imaging.

Data from Brandler S, Tangy F: *Viruses* 5(10):2384-2409, 2013; Centers for Disease Control and Prevention: *West Nile virus*, updated February 12, 2015, Available at: www.cdc.gov/westnile/index.html; Petersen LR et al: *J Am Med Assoc* 310(3):308-315, 2013; Pierce KK et al: *J Infect Dis* 215(1):52-55, 2017.

◆Pathophysiology.

Viruses gain access to the CNS through the bloodstream, olfactory bulb, or choroid plexus or through an intraneuronal route from peripheral nerves. Meningeal involvement is present in all encephalitides. The arthropod-borne viral encephalitides cause widespread nerve cell degeneration. Edema and areas of necrosis with or without hemorrhage develop. IICP develops and may progress to herniation. Large degenerative injuries are found in eastern equine

encephalitis, whereas the other arthropod-borne viral encephalitides have microscopic areas of injury and degeneration. Infectious encephalitis may result from a postinfectious autoimmune response to the virus or from direct invasion of the CNS by the virus. Herpes simplex type 1 has a tendency to infect the inferomedial surfaces of the temporal and frontal lobes and causes hemorrhagic necrosis.

◆Clinical Manifestations.

Encephalitis may range from a mild infectious disease to a life-threatening disorder. The dramatic clinical manifestations of encephalitis are fever (minor criterion), altered mental status, delirium, or confusion progressing to unconsciousness, seizure activity, cranial nerve palsies, paresis and paralysis, involuntary movement, and abnormal reflexes. Signs of marked ICP may be present.

◆Evaluation and Treatment.

Diagnosis is based on health history and clinical presentation aided by CSF examination and culture, serologic examination, white blood cell (WBC) count, CT scan, or MRI. (Treatment available for the viral encephalitides is listed in [Table 18.8](#).) Antiviral or immune therapy is initiated as well as supportive therapy for cerebral edema, status epilepticus, and thrombocytopenia.¹⁵³

Neurologic Complications of Acquired Immunodeficiency Syndrome

Approximately 40% to 60% of all persons with AIDS have neurologic complications (see [Chapter 10](#) for the pathophysiology of AIDS). On postmortem examination, 75% have nervous system pathologic findings. The CNS pathologic findings result from (1) the primary human immunodeficiency virus (HIV) infection, which seeds the CNS soon after primary infection when CD4⁺ T cells are depressed; (2) the immune dysregulation of early HIV infection and progressive immunosuppression in late HIV infections resulting in opportunistic

infections, neoplasms, and systemic illness; and (3) the complications of therapy.¹⁵⁴

Human Immunodeficiency Virus–Associated Neurocognitive Disorders (HANDs).

A variety of names have been used for **human immunodeficiency virus–associated neurocognitive disorders (HANDs)**, including HIV-associated dementia (HAD), HIV-associated cognitive dysfunction, HIV encephalopathy, subacute encephalitis, HIV-associated dementia complex, HIV cognitive motor complex, AIDS encephalopathy, AIDS dementia complex, or AIDS-related dementia. Both adults and children may be affected with progressive cognitive dysfunction in conjunction with motor and behavioral alterations. The syndrome typically develops later in the disease but may be an early or a singular manifestation. The syndrome is more prevalent in drug users with HIV and among those with reduced highly active antiretroviral therapy adherence (HAART).¹⁵⁶ HAART with more efficient CNS drug penetration has reduced the prevalence and improved survival for severe HAND, but milder forms of the disease persist because of longer life.¹⁵⁷

The neurologic syndromes develop from properties of the virus, genetic characteristics of the host, and interactions with the environment (including treatment). At the time of primary HIV infection, HIV infects the perivascular macrophages, microglial cells, and astrocytes, particularly in the basal ganglia and deep white matter. Affected macrophages, macrophage-derived multinucleated cells, and microglia cause an immune-mediated demyelination process in white matter. Focal and diffuse demyelination of white matter and spongy changes of the spinal cord are present.

HAND is insidious in onset and unpredictable in its course. Most individuals experience a steady progression of mental decline characterized by abrupt accelerations of signs over several months to more than 1 year, although some experience an abrupt onset or an accelerated course. The triad of clinical manifestations are neurocognitive impairment, behavioral disturbance, and motor

abnormalities. Clinical manifestations are summarized in [Box 18.2](#).

Box 18.2

Clinical Manifestations of HIV-Related Dementia

Early Stages	
<ul style="list-style-type: none"> • <i>Cognitive impairments</i> Short-term memory deficit Decreased concentration/attention Confusion and disorientation Visuospatial perception deficits • <i>Changes in personality or behavior</i> Apathy, depression Impaired judgment, erratic behavior Social withdrawal Rigidity of thought Speech impairment 	<ul style="list-style-type: none"> • <i>Psychotic symptoms</i> Hallucinations and delusions Suspiciousness and delusions Agitation and inappropriate behavior • <i>Motor symptoms</i> Ataxia, loss of coordination, weakness Tremors • <i>Generalized systemic symptoms</i> Fatigue, sleep changes (hypersomnia) Anorexia, weight loss Enuresis Hypersensitivity to drugs and alcohol
Advanced Stages	
<ul style="list-style-type: none"> • <i>Cognitive symptoms</i> Global cognitive impairment Impaired social relationship Disorientation Psychomotor retardation, decreased spontaneity Agitation (e.g., nighttime delusions) Coma, vegetative state 	<ul style="list-style-type: none"> • <i>Motor symptoms</i> Ataxia Spastic weakness Paraplegia, quadriparesis Hyperreflexia, myoclonus, seizures Bladder and bowel incontinence

Data from Clark C: Psychiatric aspects of AIDS. In Jacobson JL, Jacobson AM, editors: *Psychiatric secrets*, ed 2, Philadelphia, 2001, Hanley & Belfus; Stern TA et al: *Massachusetts General Hospital comprehensive clinical psychiatry*, St Louis, 2008, Mosby.

Diagnosis is difficult, especially in early stages. The individual's health history, along with physical examination findings and supporting CSF analysis, CT, and MRI data, helps establish the diagnosis, although the brain may appear normal until there is advanced disease. Research is continuing to evaluate the best

treatment protocols and the possible neurotoxicity of HAART.¹⁵⁹

HIV Myelopathy.

HIV myelopathy involving diffuse degeneration of the spinal cord may occur with HIV. **Vacuolar myelopathy** is believed to be a direct consequence of HIV. The lateral and posterior columns of the lumbar spinal cord are affected. A progressive spastic paraparesis with ataxia is the predominant clinical manifestation. Leg weakness, upper motor neuron signs, incontinence, and posterior column sensory loss may be present. Diagnosis is made on the basis of history, physical findings, and supporting data from diagnostic procedures. Vacuolar myelopathy is treated supportively and does not respond to antiretrovirals.¹⁶⁰

HIV-Associated Peripheral Neuropathy.

Some **HIV-associated peripheral neuropathies** occur early, may coincide with seroconversion, are immune-mediated, and respond to standard immunotherapies. Other peripheral neuropathies primarily develop with advanced HIV infection and immunocompromised states and are facilitated by HIV replication, neurotoxicity from antiretroviral therapies, and coinfection with opportunistic pathogens.

HIV neuropathy may have one or a combination of several presentations: a predominantly sensory neuropathy, an autonomic neuropathy, a mononeuritis multiplex, an inflammatory demyelinating polyneuropathy (e.g., a Guillain-Barré–like syndrome), and a myopathy. The peripheral nervous system may sustain injury in HIV, manifesting as a peripheral neuropathy or radiculopathy. A progressive radiculopathy of predominantly the dorsal roots of the lumbar and sacral nerves may occur, involving severe myelin and axonal loss.

HIV-associated distal symmetric polyneuropathy, a sensory neuropathy occurring late in the disease, is the most commonly occurring neuropathy, with slowly progressive numbness and paresthesias and burning sensations in the extremities and feet. Weakness may be present, and distal reflexes may be decreased or

absent.¹⁶¹ The most common myopathy is polymyositis; it may be present initially or develop later. Inflammation leads to muscle cell degeneration and necrosis resulting in weakness of extremities with myalgia and fatigue.

HIV Meningitis.

Some people develop an acute viral meningitis at approximately the time of seroconversion. This may well represent the initial infection of the nervous system by HIV. Symptoms include headache, fever, and meningismus.

Opportunistic Infections and HIV.

Opportunistic infections may be bacterial, fungal, protozoal, or viral in origin and produce nervous system disease.¹⁶² Cytomegalovirus encephalitis and tuberculosis meningitis have high incidence rates in African countries.¹⁶³ Typically bacterial infections are caused by unusual microorganisms. Cryptococcal infection is the most common fungal disorder and the most common cause of meningitis in HIV. In *Cryptococcus neoformans*, small granulomas and cysts are found in the cerebral cortex and later may be present in deep cerebral tissues. The symptoms are vague, such as fever, headache, malaise, and meningismus. Herpes encephalitis and herpes varicella-zoster radiculitis may develop. Polyomavirus (especially John Cunningham virus [JCV]) in the immunocompromised person with HIV may produce a demyelinating disorder called *progressive multifocal leukoencephalopathy (PML)*. This virus is found in 90% of healthy persons but is dormant. The virus reactivates to cause PML in 15% of persons with HIV. Sensory and motor deficits, aphasia, and apraxia are common clinical manifestations. The condition is progressive, and there is no effective treatment.

Toxoplasmosis (a protozoan infection) is the most common opportunistic infection and occurs in one-third of persons with HIV. CNS toxoplasmosis typically manifests as focal encephalitis. *Toxoplasma gondii*, a protozoan, is thought to reactivate from latent lesions to produce a well-demarcated necrotizing process. Lesions

may be multiple and exist throughout the cerebral hemispheres. Clinical manifestations of CNS toxoplasmosis are focal but highly variable and include clumsiness to hemiplegia, aphasia, seizures, ataxia, cognitive changes, and constitutional symptoms. Fever, headache, and confusion are common initial symptoms. Toxoplasmosis is difficult to diagnose but is treated effectively with pyrimethamine, sulfadiazine plus leucovorin (folinic acid) for 6 to 8 weeks.¹⁶⁴

HIV-Associated Central Nervous System Neoplasms.

HIV-associated CNS neoplasms have declined significantly with HAART, particularly primary CNS lymphoma. Other neoplasms associated with HIV include systemic non-Hodgkin lymphoma and metastatic Kaposi sarcoma. Metastasis of a Kaposi sarcoma to the CNS is uncommon.¹⁶⁵

Demyelinating Disorders

Demyelinating disorders are the result of damage to the myelin nerve sheath and affect neural transmission. They can occur in either the central (e.g., multiple sclerosis) or the peripheral (e.g., Guillain-Barré syndrome) nervous system. Contributing factors include genetics, infections, autoimmune reactions, environmental toxins, and unknown factors.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic inflammatory disease involving degeneration of CNS myelin, scarring (sclerosis or plaque formation), and loss of axons. MS is caused by an autoimmune response to self or microbial antigens in genetically susceptible individuals. The onset of MS is usually between 20 and 40 years of age and is more common in women. Men may have a more severe progressive course. The prevalence rate is higher in northern latitudes. Risk factors that may be involved include smoking, vitamin D deficiency, and Epstein-Barr virus infection.¹⁶⁶ An estimated 2.3 million people worldwide live with

MS. Life expectancy is not greatly altered by MS, and the disease course often extends over 30 years. The etiology of MS is unknown.¹⁶⁷

The first demyelinating event, or “clinically isolated syndrome” (CIS), is a single episode of neurologic dysfunction lasting greater than 24 hours that can be a prelude to MS. Characteristic episodes include optic neuritis, solitary brainstem lesions, and transverse myelitis.¹⁶⁸

◆Pathophysiology.

MS is a diffuse and progressive CNS inflammatory autoimmune disease that affects white and gray matter. Autoreactive T and B cells and macrophages breach the blood-brain barrier of the brain and spinal cord in association with upregulation of adhesion molecules and inflammatory cytokines. These cells recognize myelin autoantigens and produce myelin-specific antibodies triggering inflammatory demyelination. There is subsequent loss of oligodendrocytes, and the hallmark plaque of MS is characterized by loss of myelin sheaths, relative preservation of axons, and glial (astrocytic) scar formation (Fig. 18.29). Activated macrophages and microglial cells (brain macrophages) are found in active MS lesions. Loss of myelin disrupts nerve conduction leading to symptom presentation. There is at least partial myelin repair during relapse of symptoms. There is, ultimately, death of neurons and brain atrophy in the most progressive forms of the disease.¹⁷⁰

FIGURE 18.29 Pathogenesis of Multiple Sclerosis.

MS is characterized not only by focal inflammatory changes but also by diffuse injury throughout the CNS (MS lesions) (Fig. 18.30). MS lesions may occur anywhere in white or gray matter.¹⁷² A paucity of immune cells and iron deposits are found, particularly in gray matter,

and the pathologic significance may be associated with mitochondrial and oxidative injury.¹⁷³ Research is in progress to determine if cerebral hypoperfusion is a pathogenic factor in MS.¹⁷⁴

FIGURE 18.30 Multiple Sclerosis, Gross. Seen here in periventricular white matter is a large “plaque” (*P*) of demyelination that has a sharp border with adjacent normal white matter. Such plaques have a gray-tan appearance and are typically associated with the clinical appearance of transient or progressive loss of neurologic function in multiple sclerosis (MS). Because MS is often multifocal, and the lesions appear in various white matter locations in the central nervous system over time, the clinical course and findings can be quite varied. *V*, ventricle. (From Stevens A, et al: *Core pathology*, ed 3, London, 2009, Mosby.)

◆Clinical Manifestations.

Clinically isolated syndrome, an acute neurologic episode, is the first manifestation of the disease. There is no evidence of previous episodes of demyelination. Symptoms last more than 24 hours; occur in the absence of fever, infection, or encephalopathy; and are caused by inflammation and demyelination in the CNS. Symptoms can be multifocal, including paresthesias of the face, trunk, or limbs; weakness; impaired gait; visual disturbances; or urinary incontinence,

indicating diffuse CNS involvement. Monofocal symptoms are caused by a single lesion and include optic neuritis, spinal cord syndrome, and brainstem and cerebellar syndromes. *Optic neuritis* is a common presentation in one eye with progressive blurring of vision and pain with eye movement. *Spinal cord syndrome* can involve both sensory and motor tracks starting on one side and progressing to the other. *Brainstem syndromes* can involve facial sensory loss or weakness, vertigo, or double vision. *Cerebellar syndromes* demonstrate lack of coordination, tremor, gait instability, and ataxia. Lesions in the cerebrum present as hemifacial weakness, pain, and motor impairments. Cognitive deficits, including memory and attention problems, are common later in the disease as well as psychiatric disorders, depression, and dementia. Individuals with CIS may or may not progress to MS. MS is diagnosed by MRI-detected brain or spinal cord lesions. The initial syndrome depends on the portion of the CNS that is most involved. After years of disease, 50% of individuals appear to have established syndromes of multifocal involvement.¹⁷⁵

The four symptom subtypes of MS are:¹⁷⁶

Relapsing/remitting: This subtype is the most common type of MS and is characterized by relapses or exacerbations (flares) of previous symptoms or worsening of neurologic symptoms. After a relapse, a period of full or partial recovery lasts for days, weeks, or months. It is more common in women.

Primary progressive MS: This subtype is the least common and characterized by a gradual progression of the disease without periods of remission. Men and women seem to be equally affected, with the most common age of onset between late 30s and early 40s. Disease activity is more prevalent in the spinal cord and is less likely than other forms to affect cognitive function. There is gradual loss of power in the lower limbs that can be asymmetric, and bowel and bladder symptoms. Symptom acuity has the potential to level off.

Secondary progressive MS: This subtype follows an initial period

of relapsing/remitting MS followed by a gradual worsening of the symptoms between relapses. Although there may be short intervals of symptom remission, these periods decrease over time and are often accompanied by more severe symptoms.

Progressive relapsing multiple sclerosis (PRMS): This subtype is also characterized by steadily worsening symptoms from the onset with clear acute relapses but often with more severe symptoms.

◆ Evaluation and Treatment.

There is no single test available to diagnose or rule out MS, and many conditions can mimic MS clinically and radiologically, particularly early in the disease process. The diagnostic criteria for MS were revised in 2010 and are known as the *McDonald criteria*. The criteria include the clinical examination in combination with MRI to demonstrate MS lesions in time and space. MRI is the most sensitive and available method of detecting demyelinated plaques and monitoring disease (Table 18.10) and quantifying macrophage infiltration and abnormal iron deposition.¹⁷⁷ Evoked potential (EP) testing aids diagnosis by detecting decreased conduction velocity in visual, auditory, and somatosensory pathways. Further studies are needed to confirm the diagnostic value of CSF findings.¹⁷⁸

TABLE 18.10

DIAGNOSTIC EVALUATION FOR MULTIPLE SCLEROSIS

FINDINGS IN MULTIPLE SCLEROSIS	
Clinical Signs and Symptoms	Signs and symptoms indicating disease of the brain or spinal cord not attributable to another diagnosis with two or more episodes lasting at least 24 hours and occurring at least 1 month apart
Tests	
Dissemination in space	
Magnetic resonance imaging (MRI), T2 weighted	Demyelinated plaques, both active and inactive; two of the following: Periventricular: three or more lesions Cortical-juxtacortical: one or more lesions Infratentorial: one or more lesions

	Spinal cord: one or more lesions Optic nerve: one or more lesions
Dissemination in time	
Gadolinium-enhanced MRI	A new lesion when compared to a previous scan (irrespective of timing)
MRI, T2 weighted	Presence of enhancing lesion and a nonenhancing T2 bright lesion on any one scan
Cerebrospinal fluid analysis	Oligoclonal bands of immunoglobulin G Elevated immunoglobulin G index
Evoked potentials	Slowed nerve impulse conduction

Data from Filippi M, Rocca MA, Ciccarelli O: *Lancet Neurol* 15(3):292–303, 2016; Polman CH et al: *Ann Neurol* 69(2):292-302, 2011.

The treatment goal in MS is to prevent exacerbations, decrease MRI lesion burden, and control symptoms. Disease-modifying drugs are initiated with diagnosis and include corticosteroids, immunosuppressants, and immune system modulators. They suppress circulating immune cells, inhibit passing the blood brain barrier (BBB), and decrease the inflammatory responses.¹⁷⁹ Continuous monitoring is important because of the increased risk for infection when taking these drugs. Acute relapses are treated with corticosteroids to speed recovery. Both oral and injectable immunosuppressant and immune system modulators (i.e., monoclonal antibodies) are used to decrease the number of relapses, promote remyelination and repair, prevent demyelination, suppress selective B-cell and T-cell function, and prevent disability. New agents are under investigation.¹⁸⁰ Vitamin D supplementation may reduce the risk of MS and promote a more favorable progression.¹⁸¹ Stem cell therapy is under investigation.¹⁸²

Symptom management for fatigue, weakness, vertigo, ataxia, tremor, heat intolerance, spasticity, bladder dysfunction, bowel dysfunction, sexual dysfunction, sensory sensations, pain, cognitive difficulties, depression, and psychosocial issues is essential to improve quality of life. Many treatments are only partially effective, particularly for fatigue and spasticity. Supportive and rehabilitative management is directed toward preventing the complications of immobility, especially pressure sores and infections of the pulmonary and genitourinary systems. Interdisciplinary inpatient rehabilitation

may improve function in the short term.¹⁸³ Supportive care includes participation in a regular exercise program, cessation of smoking, and avoidance of overwork, extreme fatigue, and heat exposure.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory demyelinating polyradiculopathy, acute autoimmune neuropathy) is a rare demyelinating disorder caused by a humoral (antibody) and cell-mediated immunologic reaction directed at the peripheral nerves. The subtypes and their features are presented in [Table 18.11](#). GBS usually occurs after a respiratory tract or gastrointestinal infection, and has been associated with surgery, immunization, and viral infections including the Zika virus.¹⁸⁴ In axonal forms of GBS, it is proposed that molecular mimicry of pathogen-borne antigens (i.e., *Campylobacter jejuni*) leads to generation of cross-reactive antibodies that target axonal gangliosides at nodes of Ranvier, activate complement, and disrupt nerve conduction in peripheral motor nerves.

TABLE 18.11

EXPANDED CLASSIFICATION OF GUILLAIN-BARRÉ SYNDROME (GBS)

SUBTYPES	CLINICAL FEATURES	PATHOLOGY	PATHOGENESIS
Acute inflammatory demyelinating polyneuropathy (AIDP; accounts for most cases of GBS)	Ascending paralysis with typically distant start	Macrophages invade myelin sheaths and denude axons Lymphocytic inflammation Demyelination	T-cell-mediated lymphocytic infiltration into nerves is common
	Early sensory symptoms Loss of deep tendon reflexes	Endoneurial edema Some degree of axon loss (all findings most prominent in the spinal roots and nerve terminals)	Antibody-mediated pathogenesis not yet demonstrated
		CD4 and CD8 lymphocytes and macrophages are present	
		Complement is deposited on the outermost Schwann cell	

		plasmalemma	
Acute motor axonal neuropathy (AMAN)	Acute progressive weakness with no sensory impairment	Autoantibodies invade nodes of Ranvier; activate complement and disrupt sodium-channel clusters and axoglial junctions; leads to nerve conduction failure and muscle weakness; leaves the myelin sheath intact (absence of demyelination) Axonal degeneration in ventral root in severe cases	Immunoglobulin G (IgG)-mediated attack on nodes of Ranvier Associated with <i>Campylobacter jejuni</i> enteritis
		Lymphocyte infiltration sparse	GM1 autoantibodies play a direct pathogenic role through molecular mimicry
Acute motor and sensory axonal neuropathy (AMSAN)	Ascending paralysis Early sensory symptoms	Similar to AMAN Absence of demyelination Evidence of axonal loss in dorsal and ventral roots	Undetermined
		Lymphocytic infiltration sparse	
		Extensive sensory nerve fiber degeneration	
Miller Fisher syndrome (MFS) (5% of cases of GBS)	In purist form have ophthalmoparesis, areflexia, and ataxia	Pathologic features similar to those in AIDP, but are atypical MFS	Antibodies to ganglioside GQ1b measured in serum in 90% of cases
	In atypical MFS also have features of AIDP	Deposition of antiganglioside antibodies initially causes reversible conduction block followed by axonal degeneration	Anti-GQ1b antibodies cross-react with other gangliosides (typically GT1a, but in many cases with GD3, GD1b, and GT1b)
	Infections are common triggers for MFS (<i>Campylobacter jejuni</i> enteritis)		

Data from Hosokawa T et al: *J Neurol* 261(10):1986-1993, 2014; Arcila-Londono X, Lewis RA: *Semin Neurol* 32(3):179-186, 2012.

The clinical manifestations can vary from ascending flaccid paresis

starting in the legs to complete quadriplegia, respiratory insufficiency, and autonomic nervous system instability. Diagnostic criteria include progressive weakness of more than two limbs, areflexia, and progression for no more than 4 weeks. Intravenous immunoglobulin or plasmapheresis is used during the acute phase and followed by aggressive rehabilitation. A monoclonal antibody to human complement is under investigation.¹⁸⁵ Recovery occurs within weeks to months or up to 2 years. About 30% of individuals have residual weakness.¹⁸⁶

Peripheral Nervous System and Neuromuscular Junction Disorders

Peripheral Nervous System Disorders

Neuropathies

Neuropathies are disease processes that may injure axons traveling to and from the brainstem and spinal cord neuronal cell bodies.¹⁸⁷ The injury may affect distinct anatomic areas of the axon, or the spinal nerves may be injured at the roots, at the plexus before peripheral nerve formation, or at the peripheral nerves themselves. The cranial nerves do not have roots or plexuses so are affected only within themselves. Autonomic nerve fibers may be injured as they travel in certain cranial nerves or emerge through the ventral root and plexuses to pass through the peripheral nerves of the body.

Neuropathies can be classified as (1) generalized symmetric polyneuropathies, (2) generalized neuropathies, and (3) focal or multifocal neuropathies. **Generalized symmetric polyneuropathies** are characterized by symmetric involvement of sensory, motor, or autonomic fibers, although, with clinical signs, one type of fiber may predominate. Generalized symmetric polyneuropathies further subdivide into **distal axonal polyneuropathy** and **demyelinating polyneuropathy**. Distal axonal polyneuropathy affects peripheral axons and is the generalized peripheral neuropathy commonly seen.

The clinical feature of distal axonal polyneuropathy is initial involvement of the longest nerves of the body, those going to the feet. Sensory impairment is greater than motor impairment. Symptoms are burning pain, tingling, and numbness of the feet. Small nerve fiber damage produces decreased pain and temperature sensation, as well as burning, numbness, and tingling. Large nerve fiber injury causes decreased light touch, vibration, and position sense. The two most common causes are diabetes mellitus and alcohol abuse; occasionally, neurotoxic therapeutic agents also are the cause. Within the classification of distal axonal neuropathies is another group of neuropathies called *autonomic neuropathy*. This neuropathy can involve virtually any sympathetic or parasympathetic nerve fiber with impairment of cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor, and pupillomotor autonomic function. Autonomic neuropathies have a progressive course and are usually reversible. The myelin or Schwann cells are affected in demyelinating polyneuropathy, which occurs far less frequently. Weakness is the predominant sign with far less sensory impairment. Acute and chronic inflammatory demyelinating neuropathies make up this group, of which Guillain-Barré syndrome is the most widely recognized disorder (see previous discussion).

Generalized neuropathies affect the cell body of only one type of peripheral neuron. The dorsal root ganglion cell is affected in sensory neuropathies, producing numbness that may begin in a focal or asymmetric distribution or in a distal symmetric pattern. **Sensory neuropathies** are seen in leprosy, some industrial solvent poisonings, some hereditary disorders, and chloramphenicol toxicity. **Motor neuropathies** are caused by anterior horn cell disease, such as amyotrophic lateral sclerosis or paralytic poliomyelitis. There is weakness or paralysis that may be symmetric or asymmetric.

Focal neuropathy (mononeuropathies) or **multifocal neuropathies** affect sensory and motor fibers (i.e., asymmetric limb weakness) in one or more nerves, as is seen in common compression neuropathies such as carpal tunnel syndrome (median nerve compression), ulnar nerve compression (at the elbow), peroneal nerve compression, or

sciatic nerve compression. Focal neuropathies can involve one or more cranial nerves. Plexus injuries and radiculopathies also fall into this category.

◆Pathophysiology.

Although distinct pathophysiologic processes are recognized in a neuropathy, these are not disease specific and may exist simultaneously in any one neuropathy. Pathologic processes that may be present include *wallerian degeneration*, in which the axon and myelin distal to the site of axonal interruption degenerate (see [Chapter 15](#)). This type of degeneration is characteristic of a traumatic nerve injury in which the nerve is severed. *Axonal degeneration* is caused by metabolic failure within an axon or vascular ischemia. In axonal degeneration, distal degeneration of the axon occurs first and is followed by degeneration of the myelin and the axis cylinder. This results in “stocking and glove” sensory or motor symptoms. In *demyelinating neuropathies*, the axon may be spared and only the myelin degenerates. Electromyography and ultrasound can assist in differentiating axonal from demyelination neuropathies.¹⁸⁸ Many pathologic processes may give rise to neuropathy, and one or more nerves may be involved.

◆Clinical Manifestations.

When the axons are affected, muscle strength, muscle tone, and muscle mass also are affected. Whole muscles or groups of muscles are paretic or paralyzed, and the muscles of the feet and legs often are affected first and more severely. These long, large axons are thought to (1) be more vulnerable to injury because of their size and length, (2) have more Schwann cells available to be injured, and (3) exhibit a “dying back” phenomenon caused by difficulty of the nerve cell body in maintaining the terminal portion of the axon. If unchecked, the pathologic process tends to involve the hands and arms because these have the next longest and largest axons.

Tone and the deep tendon reflexes in the affected muscles generally are decreased in a neuropathy. Atrophy is distributed according to the

peripheral nerves involved. The degree and distribution of the atrophy probably depend on the extent of the injury. Fasciculation may be present, especially with associated ventral root or motor neuron changes, or both, as in Guillain-Barré syndrome, diabetic neuropathy, and porphyric neuropathy. Mild fatigue may be experienced. A few disorders, notably Guillain-Barré syndrome, produce a pattern of paresis and paralysis that involves all limbs, the trunk, and the neck. Peripheral bifacial and other cranial nerve palsies may be seen with a variety of disorders. Tenderness of the nerve trunks and associated sensory alterations help to distinguish neuropathy from amyotrophy. These include paresthesias and dysesthesias as well as decreased or absent primary sensations (e.g., of temperature, touch, light pain, position, or vibration). Ataxia of gait or limb may arise from the loss of position and vibratory sensations (i.e., proprioceptive sensory loss) and may be enhanced by motor weakness.

Reflexes may be altered. Reflex-mediated autonomic nervous system functions, such as sweating, pupillary size, bladder, gastric, intestinal, and cardiovascular function, may be affected. Neuropathies associated with autonomic disturbances include diabetes mellitus, alcoholism and related nutritional neuropathies, amyloidosis, porphyria, Guillain-Barré syndrome, Riley-Day syndrome, and familial sensory neuropathy. In many chronic polyneuropathies, the feet, hands, and spine become deformed. Metabolic changes may arise secondary to nerve dysfunction.

◆Evaluation and Treatment.

The diagnostic workup to determine the cause of a neuropathy is often extensive. Early diagnosis and treatment before irreversible neuronal cell damage ensues are of paramount importance. Although axonal regrowth and recovery of function may take months, many neuropathies can be reversed. The therapeutic management is directed first at elimination of the cause, if possible. At least the primary disorder, such as diabetes mellitus, should be controlled. Further damage to the axon must be prevented by avoiding (1)

trauma from premature demand for reuse of the nerve, (2) accidents that cause tissue damage, and (3) hypoxia and ischemia or other deprivation of essential substrates.

Radiculopathies

Radiculopathies are disorders of spinal nerve roots. As the spinal roots emerge from or enter the vertebral canal, they may be injured or damaged by compression, infection, inflammation, ischemia, or direct trauma whereby the roots are stretched or torn. Cervical and lumbar nerve roots are more commonly affected. **Radiculitis (radiculoneuritis)** refers to an inflammatory disorder of the spinal nerve roots. One or more roots may be affected.

◆**Pathophysiology.**

Many different pathologic conditions may cause tearing, compression, or inflammation of nerve roots.¹⁸⁹ Roots may be traumatized by a forceful tearing of a nerve, termed *avulsion*, often associated with injuries to the head and shoulders. An acute intervertebral disk prolapse (herniated disk), degenerative spondyloarthropathies, or a benign tumor may compress nerve roots. Metastatic tumors of the lung, breast, and gastrointestinal tract may produce a carcinomatous meningitis, causing compression and inflammatory changes in nerve roots. Other causes of inflammatory changes in nerve roots are chronic meningitis, neurosyphilis, sarcoidosis, and inflammatory arachnoiditis produced by myelography and lumbar punctures.¹⁹⁰

◆**Clinical Manifestations.**

The strength, tone, and bulk of the muscles innervated by the involved roots are affected. The pattern and distribution of weakness and atrophy are similar to those of the amyotrophies. Tone and deep tendon reflexes are decreased, but rarely absent, because the involved muscles are usually innervated by two or more spinal roots. Fasciculations often are present, and mild fatigue may be experienced. Because pathologic processes usually affect the ventral as well as the dorsal roots, sensory alterations are common.

Diseases that involve spinal roots typically produce local pain; pain on local percussion; pain and paresthesias in the sensory root distribution (called **radicular pain** and **radicular paresthesia**); increased pain with movement, stretching of the root, and maneuvers that transiently increase CSF pressure; sensory loss in a radicular pattern; and spasms of the muscles surrounding the vertebral column (i.e., paravertebral muscle spasms).

◆Evaluation and Treatment.

Diagnostic measures may include physical examination, spinal films, nerve conduction studies, electromyogram (EMG), lumbar puncture with CSF examination, myelography, and biopsy of tumor masses.¹⁹¹

Treatment is directed at the cause of the injury and may take the form of surgical intervention, antibiotic administration, removal of the injurious agent, corticosteroid use, and radiation therapy and chemotherapy. Supportive management may include control of the discomfort, protection from further injury, prevention of complications, and rehabilitation when appropriate.

Nerve Plexus Injuries

Plexus injuries involve the nerve plexus distal to the spinal roots but proximal to the formation of the peripheral nerves. Such injuries may be caused by trauma, compression (entrapment), or infiltration, or they may be iatrogenic, caused by positioning during surgery or by an intramuscular injection. Clinical manifestations include motor weakness, muscle atrophy, and sensory loss in affected areas. Paralysis can occur with complete plexus lesions.¹⁹²

The diagnosis is made on the basis of history and clinical manifestations. Therapeutic treatment is directed at removal of the cause, surgical repair and approximation of nervous tissue, nerve transfers, growth factors, prevention of further injury, control of discomfort, prevention of complications, and rehabilitation when appropriate.

Neuromuscular Junction Disorders

Transmission of the nerve impulse at the neuromuscular junction requires the release of adequate amounts of neurotransmitter from the presynaptic terminals of the axon and effective binding of the released transmitter to the receptors on the membranes of muscle cells (see [Fig. 15.16](#)).

Botulism is a food poisoning resulting from the botulinum neurotoxins being released from *Clostridium botulinum*. The toxins are the most potent known and act at the myoneural junction, inhibiting release of acetylcholine (ACh) and causing severe flaccid paralysis including respiratory paralysis and death. Other forms include *C. botulinum*-contaminated wounds, infant and adult intestinal botulism released from spores that grow in the intestine after eating contaminated food, and iatrogenic botulism from accidental overdose of botulinum toxin. The endospores are resilient and resistant to heat. All forms are life-threatening and require emergency treatment. Treatments include supportive care with mechanical ventilation and antitoxin.¹⁹³

Neuromuscular junction disorders (NMJDs), whose pathogenesis is caused by autoantibodies, include myasthenia gravis and Lambert-Eaton myasthenic syndrome. In addition, there are rare **inherited (congenital) myasthenic syndromes** that result from mutations in different key proteins for the postsynaptic nicotinic acetylcholine receptor, ion channels, and motor end plates at the neuromuscular junction.

Myasthenia Gravis

Myasthenia gravis is a chronic autoimmune disease mediated by acetylcholine receptor (AChR) antibodies that act at the neuromuscular junction ([Fig. 18.31](#) and [Table 18.12](#)). About 20,000 to 70,000 people in the United States have the disease. Myasthenia gravis is associated with an increased incidence of other autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, polymyositis, and thyrotoxicosis. (Autoimmune mechanisms

are discussed in [Chapter 9](#).) The etiology of myasthenia gravis is unknown. Some persons have genetic susceptibility related to variants in AChR genes, as well as the major histocompatibility genes, and they can present with varying clinical phenotypes.¹⁹⁴ Presynaptic autoimmune diseases are rare and include **Lambert-Eaton myasthenic syndrome** with autoantibodies to calcium channels on presynaptic nerve terminals, which presents with muscle weakness and is commonly associated with small-cell lung carcinoma (see [Fig. 18.31](#)).¹⁹⁵

FIGURE 18.31 Antibodies and Myasthenia Gravis. Schematic diagrams of (A) a normal neuromuscular junction illustrating locations of the presynaptic vesicles, acetylcholine within the synapse, and the postsynaptic acetylcholine receptors, as well as (B) a neuromuscular junction affected by myasthenia gravis, with antibodies that interfere with the binding or structure, or both, of the acetylcholine receptors and muscle-specific kinase (MuSK). (Note that antibodies to both proteins are not typically present in the same individual, though this phenomenon has been reported on occasion.) Presynaptic calcium channel antibodies occur with Lambert-Eaton myasthenic syndrome. (From Darras BT et al: *Neuromuscular disorders of infancy, childhood, and adolescence*, ed 2, London, 2015, Academic Press.)

TABLE 18.12

ANTIBODIES AND MECHANISMS OF ACTION AT NEUROMUSCULAR JUNCTION

MYASTHENIA	MUSCLE-	LAMBERT-EATON
------------	---------	---------------

FEATURES	GRAVIS (MG)	SPECIFIC KINASE MG	MYASTHENIC SYNDROME	NEUROMYOTON
Target	AChR	MuSK	α 1A VGCC	VGKC
Principal subclass of antibody	IgG1, IgG3 (autoantibodies against AChR) Autoantibodies against LRP4, an agrin receptor critical for NMJ formation found in AChR and MuSK-negative MG	IgG4 (autoantibody against MuSK)	Autoantibodies to voltage-gated calcium channel	IgG4 (autoantibody against voltage-gated K ⁺ channels)
Principal mechanisms of action at NMJ	Postsynaptic antibody destruction of nicotinic AChR	Not clear yet; complement not activated; may involve mutations in end-plate protein Dok-7	Presynaptic antibody destruction of voltage-gated calcium channels inhibit fusion of ACh at presynaptic membrane	Increased turnover
Compensatory mechanisms identified	Increased presynaptic ACh release, increased postsynaptic AChR synthesis	Not clear yet	Involvement of other VGCCs in release process	Probable up-regulation of other VGKCs

ACh, acetylcholine; *AChR*, Acetylcholine receptor; *Ig*, immunoglobulin; *LRP4*, low-density lipoprotein receptor-related protein 4; *MuSK*, muscle-specific kinase; *NMJ*, neuromuscular junction; *VGCC*, voltage-gated calcium channel; *VGKC*, voltage-gated potassium channel.

Data from Oger J, Frykman H: *Clin Chim Acta* 449:43-48, 2015.

The subtypes of autoimmune myasthenia gravis are generalized AChR, ocular, and neonatal. Generalized AChR myasthenia gravis is further subdivided based on age and thymic pathology into the following categories:

1. Early onset: young persons, mostly female, with thymomas;

generally begins with ocular weakness followed by generalized weakness

2. Late onset: males over 60 years without thymomas
3. Persons of both sexes with thymomas

Generalized AChR myasthenia involves the proximal musculature throughout the body and has several courses: (1) a course with periodic remissions, (2) a slowly progressive course, (3) a rapidly progressive course, or (4) a fulminating course. Classification by disease severity is as follows:¹⁹⁶

Class I: Any eye muscle weakness, possible ptosis, no other evidence of muscle weakness elsewhere

Class II: Eye muscle weakness of any severity, mild weakness of other muscles

Class II a: Predominantly limb or axial muscles

Class II b: Predominantly bulbar or respiratory muscles, or both

Class III: Eye muscle weakness of any severity, moderate weakness of other muscles

Class III a: Predominantly limb or axial muscles

Class III b: Predominantly bulbar and/or respiratory muscles

Class IV: Eye muscle weakness of any severity, severe weakness of other muscles

Class IV a: Predominantly limb or axial muscles

Class IV b: Predominantly bulbar or respiratory muscles, or both (can also include feeding tube without intubation)

Class V: Intubation needed to maintain airway

In **neonatal myasthenia**, transitory signs of myasthenia gravis are present in 10% to 15% of infants born to mothers with myasthenia gravis. The signs appear 1 to 3 days after birth and persist for a few days to a few weeks. Myasthenia immunoglobulin is transferred from the mother to the neonate through the placenta. **Ocular myasthenia**, which is more common in males, involves weakness of the eye muscles and eyelids and may include swallowing difficulties and

slurred speech as well.

◆Pathophysiology.

Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction. The main defect is T-cell–dependent formation of autoantibodies (an IgG antibody) against nicotinic AChR (90% of cases), muscle-specific kinase (MuSK), lipoprotein-related protein 4 (LRP4), or agrin in the postsynaptic membrane at the neuromuscular junction. Agrin is a component of MuSK receptor function. The autoantibodies destroy the AChR through antibody-mediated complement activation (see [Fig. 18.31](#)).¹⁹⁷ The cause of this autosensitization is unknown. Destruction of receptor sites occurs, decreasing the number of receptors on the plasma membrane and causing diminished transmission of nerve impulses across the neuromuscular junction. Muscle depolarization is incomplete or unsuccessful. About 10% to 15% of individuals with myasthenia gravis do not have AChR antibodies on testing but have MuSK antibodies (an IgG4). This is now subtyped as MuSK antibody–associated myasthenia gravis.

◆Clinical Manifestations.

Myasthenia gravis has an insidious onset. The variable distribution of ACh receptor sites or the number of and different isoforms of antibodies may determine when and which muscle groups are affected first—usually the muscles of the eyes, face, mouth, throat, and neck. The extraocular (eye) muscles and the levator muscles are most affected. Manifestations include diplopia, ptosis, and ocular palsies. The muscles of facial expression, mastication, swallowing, and speech are the next most involved. The results are facial droop and an expressionless face; difficulty chewing and swallowing associated with dietary changes and weight loss; drooling; episodes of choking and aspiration; and a nasal, low-volume but high-pitched monotonous speech pattern.

The muscles of the neck, shoulder girdle, and hip flexors are less frequently affected, but muscle fatigue is common after exercise and

there can be progressive weakness. The respiratory muscles of the diaphragm and chest wall become weak, with impaired ventilation. Impairment in deep breathing and coughing predisposes the individual to atelectasis and congestion. MuSK antibody type MG often involves severe swallowing and breathing (bulbar) problems

Clinical manifestations may first appear during pregnancy, during the postpartum period, or in conjunction with the administration of certain anesthetic agents. The progression of myasthenia gravis varies, appearing first as a mild case that spontaneously remits with a series of relapses and symptom-free intervals ranging from weeks to months. Over time, the disease can progress, and all muscles are weak.

Myasthenic crisis occurs when severe muscle weakness causes extreme quadriparesis or quadriplegia, respiratory insufficiency with shortness of breath and a markedly decreased tidal volume and vital capacity, and extreme difficulty in swallowing. The individual in myasthenic crisis is in danger of respiratory arrest.

Cholinergic crisis may arise from anticholinesterase drug toxicity with increased intestinal motility, episodes of diarrhea and complaints of intestinal cramping, bradycardia, pupillary constriction, increased salivation, and diaphoresis. The clinical picture resembles that of myasthenic crisis but the weakness occurs 30 to 60 minutes after taking anticholinergic medication. The clinical manifestations are caused by the smooth muscle hyperactivity secondary to excessive accumulation of acetylcholine at the neuromuscular junctions and excessive parasympathetic-like activity. As in myasthenic crisis, the individual is in danger of respiratory arrest.

◆Evaluation and Treatment.

The diagnosis of myasthenia gravis is made on the basis of a response to edrophonium chloride (Tensilon), results of results of EMG studies, and detection of AChR and MuSK antibodies. With the intravenous administration of the drug, immediate demonstrable improvement in muscle strength usually persists for several minutes. Mediastinal tomography and MRI help determine whether a thymoma is present.

Treatment of myasthenia gravis is individualized. Anticholinesterase drugs, corticosteroids, immunosuppressant drugs (e.g., rituximab, chimeric monoclonal antibody against the protein CD20 primarily found on the surface of B cells, azathioprine, cyclosporine, and mycophenolate mofetil) are used to treat myasthenia gravis and myasthenic crisis. Plasmapheresis may be lifesaving during myasthenic crisis, before and after thymectomy, and at the start of immunosuppressant therapy. For individuals with cholinergic crisis, treatment is to withhold anticholinergic drugs until blood levels fall out of the toxic range while providing ventilatory support and preventing respiratory complications. Thymectomy is the treatment of choice for a thymoma.¹⁹⁸ Complement inhibitors are being evaluated. Current treatments for myasthenia gravis have improved prognosis, including in those individuals who have ocular myasthenia.

Tumors of the Central Nervous System

Central nervous system (CNS) tumors include brain and spinal cord tumors. The incidence of CNS tumors increases to age 70 years and then decreases. CNS tumors are the second most common group of tumors occurring in children. Approximately 70% to 75% of all intracranial tumors in children are located infratentorially (see [Chapter 20](#)), and 70% are located supratentorially in adults. Peripheral nerve tumors are rare in children and common in adults. Carcinogenesis is discussed in [Chapter 12](#), pituitary tumors are discussed in [Chapter 22](#), and cerebral tumors in children are discussed in [Chapter 20](#).

Brain Tumors

Primary brain tumors (both malignant [32%] and nonmalignant) had an estimated incidence rate of 80,000, with about 17,000 deaths in the United States in 2017.¹⁹⁹ Tumors within the cranium can be either primary or metastatic. *Primary (intracerebral) brain tumors* originate

from brain substance (neuroepithelium), including neuroglia, neurons, cells of blood vessels, and connective tissue. *Extracerebral tumors* originate outside substances of the brain and include meningiomas, acoustic nerve tumors, and tumors of pituitary and pineal glands. *Metastatic (secondary) brain tumors* arise in organ systems outside the brain and spread to the brain. Sites of intracranial tumors are illustrated in [Fig. 18.32](#).

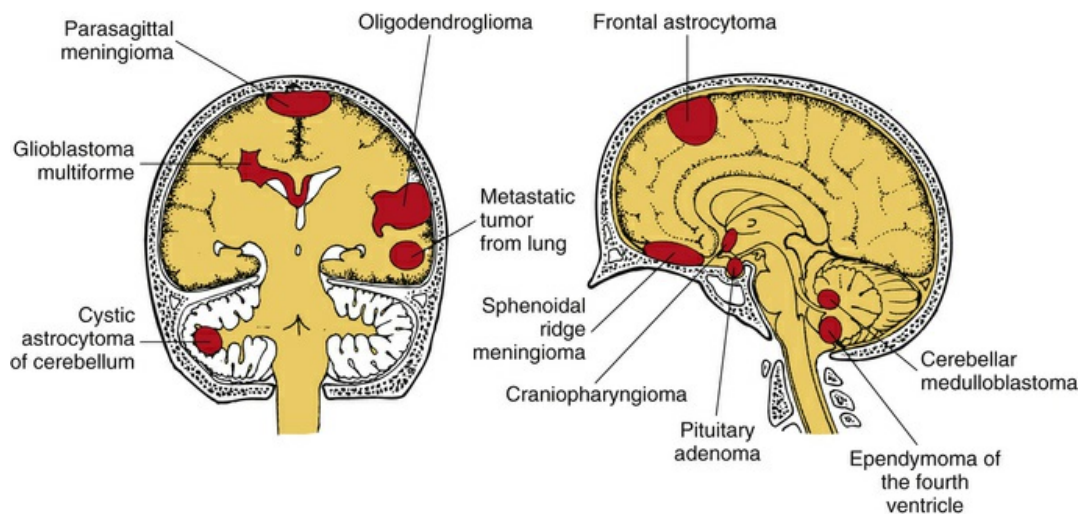

FIGURE 18.32 Common Sites of Intracranial Tumors.

Intracranial brain tumors do not metastasize as readily as tumors in other organs because there are no lymphatic channels within the brain substance. If metastasis does occur, it is usually through seeding of cerebral blood, through CSF, during cranial surgery, or through artificial shunts.

Cranial tumors cause local and generalized clinical manifestations. The local effects are caused by the destructive action of the tumor itself on a particular site in the brain and compression causing decreased cerebral blood flow. The effects are varied and include seizures, visual disturbances, unstable gait, and cranial nerve dysfunction. The generalized effects result from IICP ([Fig. 18.33](#)). IICP may occur because of obstruction of the ventricular system, hemorrhages occurring in and around the tumor, cerebral edema caused by tumors, or expansion of the tumor mass.

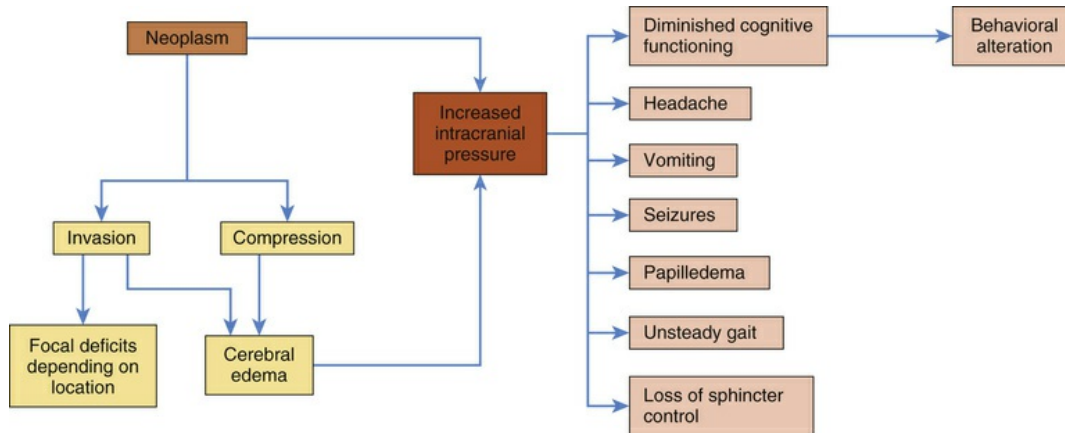

FIGURE 18.33 Origin of Clinical Manifestations Associated with an Intracranial Neoplasm.

Primary Brain (Intracerebral) Tumors

Primary brain tumors constitute about 2% of all cancers in the United States. **Gliomas** comprise about 25% of all adult primary brain tumors and 74.6% of malignant brain tumors. Gliomas include astrocytomas, oligodendrogliomas, mixed oligoastrocytomas, and glioblastoma multiforme. The World Health Organization (WHO) divides gliomas into four grades based on histopathologic features, cellular density, atypia, mitotic activity, microvascular proliferation, and necrosis (Table 18.13). Grades I and II are generally benign or slow growing, and well to moderately differentiated. Grades III and IV are malignant tumors and poorly differentiated. Other CNS tumors include meningiomas, ependymomas, nerve sheath tumors (schwannomas), and neurofibromas. Etiology for primary brain tumors is not clearly known. Ionizing radiation is the only known environmental risk factor. The association between mobile phone use and gliomas and acoustic neuromas is controversial.²⁰¹

TABLE 18.13

BRAIN AND SPINAL CORD TUMORS

NEOPLASM	LOCATION	CHARACTERISTICS	CELL OF ORIGIN
Gliomas			

<i>Astrocytomas</i>			
Pilocytic astrocytoma (grade I)	Anywhere in brain or spinal cord	Slow growing, well circumscribed Common in children and young adults and people with neurofibromatosis type 1; common in cerebellum	Astrocytes
Diffuse astrocytoma (grade II)	Anywhere in brain	Slow growing; marked cellular differentiation; infiltrative; undergoing malignant progression over time	Astrocytes
Anaplastic astrocytoma (grade III)	Anywhere in brain or spinal cord, but predominantly in cerebral hemispheres	Malignant; many cells undergoing mitosis; infiltrates adjacent tissue; frequently recurs at higher grade	Astrocytes
Glioblastoma multiforme (grade IV astrocytoma)	Predominantly in cerebral hemispheres	Poorly differentiated neoplastic cells; extensive cellular heterogeneity; well-developed microvascular proliferation; necrosis	Astrocytes
Oligodendroglioma; anaplastic oligodendroglioma (grades II and III)	Most commonly in frontal lobes deep in white matter; may arise in brainstem, cerebellum, and spinal cord	Well differentiated; diffusely infiltrative; well-demarcated borders; increased mitotic activity, often associated with microvascular proliferation and necrosis	Oligodendrocytes
Oligoastrocytoma (grades II and III)	Same as with diffuse astrocytoma and oligodendroglioma	Most common mixed glioma	At least two distinct populations of neoplastic cell types— astrocytes and oligodendrocytes
Anaplastic oligoastrocytoma	Same as with anaplastic astrocytoma	Same as anaplastic astrocytoma or	Astrocytes and oligodendrocytes

(grade III)		anaplastic oligodendroglioma	
Ependymoma (grade II)	Intramedullary: wall of ventricles, may arise in caudal tail of spinal cord	More common in children, variable growth rates; more malignant, invasive form is called <i>ependymoblastoma</i> ; may extend into ventricle or invade brain tissue	Ependymal cells
Neuronal Cell			
Medulloblastoma	Posterior cerebellar vermis, roof of fourth ventricle	Well demarcated, rapid growing, fills fourth ventricle	Embryonic cells
Mesodermal Tissue			
Meningioma	Intradural, extramedullary: sylvian fissure region, superior parasagittal surface of frontal and parietal lobes, olfactory groove, wing of sphenoid bone, superior surface of cerebellum, cerebellopontine angle, spinal cord	Slow growing, circumscribed, encapsulated, sharply demarcated from normal tissues, compressive in nature	Arachnoid cells, may be from fibroblast
Choroid Plexus			
Papillomas	Choroid plexus of ventricular system, lateral ventricle in children, fourth ventricle in adults	Usually benign, slow expansion inducing hemorrhage and hydrocephalus; malignant tumor is rare	Epithelial cells
Cranial Nerves and Spinal Nerve Roots			
Schwannoma (neuroma, neurolemma)	Cranial nerves (most commonly vestibular division of cranial nerve VIII)	Slow growing	Sheath of Schwann cells
Neurofibroma (NF1 and NF2)	NF1 primarily PNS, occasionally CNS NF2 primarily CNS	Both types slow growing	Nerve sheath
Pituitary Tumors	Pituitary gland; may extend to or invade floor of third	Age linked, several types, slow growing,	Pituitary cells, pituitary

	ventricle	macroadenomas and microadenomas	chromophobes, basophils, eosinophils
Germ Cell Tumors	Neurohypophysis, hypothalamus, pineal region	Rare, 0.5% of all primary brain tumors; primarily in adolescents; male more common than female; variable prognosis	Several types: germinoma, embryonal carcinoma, yolk sac tumor, choriocarcinoma, teratoma, mixed germ cell tumor, with different cell origins
Blood Vessel Tumors			
Angioma	Predominantly in posterior cerebral hemispheres	Slow growing	Arising from congenitally malformed arteriovenous connections
Hemangioblastomas	Predominantly in cerebellum	Slow growing	Embryonic vascular tissue

CNS, Central nervous system; PNS, peripheral nervous system.

Molecular characteristics of gliomas include mutation of the isocitrate dehydrogenase 1 (*IDH1*) gene, or, less commonly, mutation of the related *IDH2* gene identified in the vast majority of World Health Organization (WHO) grades II and III astrocytic, oligodendroglial, and oligoastrocytic gliomas. Silencing of the *MGMT* gene (methylated-DNA-protein-cysteine methyltransferase, a DNA repair enzyme) is found in astrocytomas. Mutant epidermal growth factor vIII (EGFRvIII) amplification is found in most subtype gliomas. Chromosome 1p and 19q deletions are associated with oligodendrogliomas,²⁰² and gliomas may arise from cancer-initiating resident stem cells.²⁰⁴

The principal treatment for cerebral tumors is surgical or radiosurgical excision or surgical decompression if total excision is not possible. Chemotherapy, radiation therapy, or their combination may be used. The blood-brain barrier is an obstacle to the delivery of chemotherapeutic agents. New methods are in progress for

penetration of this barrier, including nanoparticle drug carriers and focused ultrasound combined with microbubbles.^{205,206}

Specificity of treatment is advancing with the development of vaccines (i.e., tumor-specific peptides), cell therapy (T cells and antibodies), reshaping of the tumor microenvironment (i.e., transforming growth factor β [TGF β] inhibition), immune checkpoint inhibitors,²⁰⁷ and modified polio virus.²⁰⁹ (Cancer treatment is discussed in [Chapter 12](#).)

Astrocytoma.

Astrocytomas are the most common glioma (about 75% of all tumors of the brain and spinal cord)²¹⁰ (see [Table 18.13](#)). These tumor cells develop from astrocytes and are believed to have lost normal growth restraint and thus proliferate uncontrollably. Astrocytomas are graded I through IV. They may occur anywhere in the brain or spinal cord and are generally located in the cerebrum, hypothalamus, or pons. Low-grade astrocytomas tend to be located laterally or supratentorially in adults and in the posterior fossa in children.

Headache and subtle neurobehavioral changes may be early signs, with other neurologic symptoms evolving slowly and IICP occurring late in the tumor's course. Onset of a focal seizure disorder between the second and sixth decade of life suggests an astrocytoma. Low-grade astrocytomas are treated with surgery or by external radiation, and at least 50% of persons survive 5 years when surgery is followed by radiation therapy (RT).^{210,211}

Grades III and IV astrocytomas are found predominantly in the frontal lobes and cerebral hemispheres, although they may occur in the brainstem, cerebellum, and spinal cord ([Figs. 18.34](#) and [18.35](#)). Men are twice as likely to have astrocytomas as women; in the 15- to 34-year-old age group they are the third most common brain cancer, whereas in the 35- to 54-year-old age group they are the fourth most common.

FIGURE 18.34 Well-Differentiated Infiltrating Astrocytoma. The right temporal lobe contains an infiltrative, homogeneous lesion that has expanded the lobe and obscured the normal boundaries between gray and white matter (compare to left temporal lobe). Because of the ill-defined borders, surgical resection rarely removes all of the tumor in such cases. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

FIGURE 18.35 Glioblastoma Multiforme. In contrast to the well-differentiated infiltrating astrocytoma in Fig. 18.34, this glioblastoma contains irregular areas of discoloration and cystic change, reflecting the presence of necrosis and hemorrhage. These lesions are widely infiltrative and associated with considerable mass effect. Note the shift of midline structures to the right. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

Grade IV astrocytoma, **glioblastoma multiforme (GBM)**, is the most lethal and common type of primary brain tumor. GBM is highly vascular and extensively irregular and infiltrative, making them difficult to remove surgically. Fifty percent of glioblastomas are bilateral or at least occupy more than one lobe at the time of death. The typical clinical presentation for a glioblastoma multiforme is that of diffuse, nonspecific clinical signs, such as headache, irritability, and “personality changes” that progress to more clear-cut manifestations of IICP, including headache on position change, papilledema, vomiting, or seizure activity. Symptoms may progress to include definite focal signs, such as hemiparesis, dysphasia, dyspraxia, cranial nerve palsies, and visual field deficits. Treatment for newly diagnosed GBM is radiotherapy with temozolomide (alkylating agent) following maximal surgical resection. Adjuvant immunotherapy may be beneficial.²¹² Survival at 5 years for grades III and IV astrocytomas is about 5% to 10%.

Oligodendroglioma.

Oligodendrogliomas constitute about 2% of all primary brain tumors and 10% to 15% of all gliomas. They are typically slow-growing tumors; most oligodendrogliomas are macroscopically indistinguishable from other gliomas and may be a mixed type of oligodendroglioma and astrocytoma (oligoastrocytoma). The majority are found in the frontal and temporal lobes, often in the deep white matter, but they are also found in other parts of the brain and spinal cord. Many are found in young adults with a history of temporal lobe epilepsy. Malignant degeneration occurs in approximately one-third of persons with oligodendrogliomas (a grade II tumor), and the tumors are then referred to as anaplastic oligodendroglioma (a grade III tumor).

More than 50% of individuals experience a focal or generalized seizure as the first clinical manifestation. Only half of those with an oligodendroglioma have IICP at the time of diagnosis or surgery, and only one-third develop focal manifestations. Those with 1p19q codeletion experience a benefit from adding chemotherapy to

radiation.²¹³

Ependymoma.

Ependymomas are nonencapsulated gliomas that arise from ependymal cells that form the walls of the ventricles or the spinal canal (Fig. 18.36, and see Table 18.13). They are rare in adults, usually occurring in the spinal cord. They comprise about 6% of all primary brain tumors in adults and 10% in children and adolescents, usually occurring in intracranial locations. Approximately 70% of these tumors occur in the fourth ventricle, with others found in the third and lateral ventricles and caudal portion of the spinal cord. Approximately 40% of infratentorial ependymomas occur in children younger than 10 years of age. Cerebral (supratentorial) ependymomas occur at all ages.

FIGURE 18.36 Ependymoma. These tumors may arise in both the intracranial compartment and the spine. Intracranial tumors typically originate from a ventricular surface, as in the case of this large lesion arising in the fourth ventricle (*arrow*). (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders.)

Fourth ventricle ependymomas present with difficulty in balance, unsteady gait, uncoordinated muscle movement, and difficulty with fine motor movement. The clinical manifestations of a lateral and third ventricle ependymoma that involves the cerebral hemispheres

are seizures, visual changes, and hemiparesis. Blockage of the CSF pathway produces hydrocephalus and presents with headache, nausea, and vomiting.

Ependymomas are treated with surgical resection and adjuvant radiotherapy and chemotherapy.²¹⁴ About 20% to 50% of persons survive 5 years. Some persons benefit from a shunting procedure when the ependymoma has caused a noncommunicating hydrocephalus.

Primary Extracerebral Tumors

Meningioma.

Meningioma constitutes about 36% of all primary brain tumors and is more common in women. Predisposing factors include neurofibromatosis (NF) type 2 (NF2; see [Nerve Sheath Tumors](#)) and undergoing ionizing radiation after a several-decade latency period. Formation of benign meningiomas has been linked to *NF2* gene mutation and chromosome 22q12-2 loss along with *DAL-1* loss on chromosome 18. Atypical and anaplastic meningiomas have been linked to additional gene alterations involving other multiple chromosomes. They are resistant to treatment.²¹⁵

A meningioma is sharply circumscribed and adapts to the shape it occupies. It may extend to the dural surface and erode the cranial bones or produce an osteoblastic reaction. A few meningiomas exhibit malignant, invasive qualities ([Fig. 18.37](#)).

FIGURE 18.37 Meningioma, Gross. Meningioma beneath the dura with compression of underlying cerebral hemisphere. (From Klatt EC: *Robbins and Cotran atlas of pathology*, ed 3, Philadelphia, 2015, Saunders.)

Meningiomas are slow growing, and clinical manifestations occur when they reach a certain size and begin to indent the brain parenchyma. Focal seizures are often the first manifestation, and IICP is less common than with gliomas. Other symptoms are related to the site of tumor location:

1. *Sphenoidal wing*: ophthalmoplegia, mild proptosis, and involvement of the ophthalmic division of the trigeminal nerve
2. *Olfactory groove*: anosmia, personality change, and visual failure
3. *Parasagittal*: focal seizures of a focal motor or sensory deficit
4. *Parasellar*: evidence of chiasmatic compression; urinary incontinence; dementia; gradual paraparesis, hormonal failure; optic atrophy; bitemporal hemianopia
5. *Lateral convexity*: variable depending on structures compressed, including slow hemiparesis, speech abnormalities

Because of the extremely slow-growing nature of most meningiomas, IICP is less common than with gliomas. Diagnosis is made using contrast-enhanced CT, MRI, or both. The primary treatment is surgical resection. Stereotactic radiotherapy is used with incomplete resection or recurrence (20% rate).²¹⁶

Nerve Sheath Tumors.

Nerve sheath tumors are either neurofibromas or schwannomas (neuroma, neurolemma). **Neurofibromas (benign nerve sheath tumors)** are a group of autosomal dominant disorders of the nervous system. They include neurofibromatosis type 1 (NF1, previously known as *von Recklinghausen disease*) and neurofibromatosis type 2 (NF2); NF1 and NF2 are also known as *peripheral* and *central neurofibromatosis*, respectively.

Neurofibromatosis type 1 is the most prevalent with an incidence of about 1 in 3500 people and causes multiple cutaneous neurofibromas; cutaneous macular lesions (café-au-lait spots and freckles); and, less commonly, bone and soft tissue tumors. Inactivation of the *NF1* gene (chromosome 17q11.2) results in loss of function of neurofibromin in Schwann cells and promotes tumorigenesis (neurofibromas). Learning disabilities are present in about 50% of affected individuals.²¹⁷

Neurofibromatosis type 2 is rare and occurs in about 1 in 60,000 people. The *NF2* gene (chromosome 22 q12–2) product is neurofibromin 2 (merlin), a tumor-suppressor protein. Mutations promote development of central nervous system tumors, particularly schwannomas, although other tumor types can occur (meningiomas, ependymomas, astrocytomas, and neurofibromas). Benign bilateral schwannomas of the vestibular nerves present with hearing loss progressing to deafness, dizziness and balance problems, tinnitus, and facial nerve paralysis. Other symptoms may include loss of balance and dizziness. Schwannomas also may develop in other cranial, spinal, and peripheral nerves, and cutaneous signs are less prominent. Intracranial meningiomas can involve the optic nerve with loss of visual acuity and cataracts or can be intraspinal with formation of ependymomas.²¹⁸

Genetic testing is available for the management of families susceptible to NF, and prenatal diagnosis is possible. Diagnosis is based on clinical manifestations and neuroimaging studies. Criteria for the diagnosis of neurofibromatosis types 1 and 2 are presented in [Box 18.3](#).^{219,220}

Box 18.3

Nih Diagnostic Criteria for Neurofibromatosis

Criteria for the Diagnosis of NF1

Two of the following seven criteria:

- Six or more café-au-lait macules greater than 5 mm in greatest diameter in prepubertal individuals and greater than 15 mm in greatest diameter in postpubertal individuals (adults)
- Multiple axillary or inguinal freckles
- One plexiform neurofibroma or two or more neurofibromas of any type
- Optic glioma
- Two or more Lisch nodules (iris hamartomas)
- A distinctive osseous lesion such as sphenoid dysplasia or thinning of the cortex of long bones with or without pseudarthrosis
- A first-degree relative with NF1 by the above criteria

Criteria for the Diagnosis of NF2

Either one of the following criteria:

- Bilateral masses of the eighth cranial nerve seen with appropriate imaging techniques (e.g., CT or MRI)
- A first-degree relative with NF2 and either:
 - a. Unilateral mass of the eighth cranial nerve or
 - b. Two of the following:
 1. Neurofibroma
 2. Meningioma
 3. Glioma

4. Schwannoma
5. Juvenile posterior subcapsular lenticular opacity

CT, Computed tomography; *MRI*, magnetic resonance imaging; *NF*, neurofibromatosis; *NIH*, National Institutes of Health.

Surgery is the major treatment. Individuals with NF2 have extensive morbidity and reduced life expectancy, particularly with early age of onset. Molecular targeted therapies (i.e., angiogenesis and epidermal growth factor inhibitors) are likely to provide personalized treatment for both of these devastating conditions.²²¹

Metastatic Brain Tumors.

Metastatic brain tumors from systemic cancers are approximately 10 times more common than primary brain tumors. Ten percent to 20% of persons with cancer have metastasis to the brain. Lung (40% to 50%) and breast cancer (15% to 20%) are the most common tumors to have brain metastases within 1 to 3 years, followed by malignant melanoma, renal cell carcinoma, and, less commonly, gastrointestinal and reproductive tract cancers. Metastasis to the brain is believed to be through vascular channels.

The brain metastatic process requires a series of sequential events called the metastatic cascade²²² (see [Chapter 12](#) and [Fig. 12.19](#)). Peripheral cancer cells degrade the extracellular matrix, invade blood vessels and lymph nodes, migrate, extravasate, and colonize at their new locations forming a metastatic niche. Tumor cells reach the brain vasculature by attaching themselves to endothelial cells of brain microvessels in the blood-brain barrier. Using enzymes, they disrupt the epithelial basement membrane and extravasate into the brain parenchyma. They can attach platelets that protect them from immune defenses. Local brain invasion requires cell motility, adhesion, survival, and proliferation. They induce blood vessel development (angiogenesis) and proliferate in response to growth factors, cytokines, and chemokines.²²³ The cerebrum is the most common site

of seeding.²²⁴

Metastatic brain tumors produce signs resembling those of glioblastomas, although several unusual syndromes do exist. Carcinomatous (metastatic cancer) encephalopathy causes headache, nervousness, depression, trembling, confusion, forgetfulness, and gait disorder. In carcinomatosis of the cerebellum, headache, dizziness, and ataxia are found. Carcinomatosis of the craniospinal meninges (also called carcinomatous meningitis) manifests with headache, confusion, and symptoms of cranial or spinal nerve root dysfunction.

Contrast-enhanced CT and MRI imaging techniques are the most sensitive imaging procedures for metastatic brain tumors. Treatment is guided by the pathology of the original tumor; number, size, and location of the brain metastasis; and prior cancer treatments. Corticosteroids and antiepileptic drugs can help relieve symptoms. One to four lesions are treated with stereotactic radiosurgery. Chemotherapy is considered when surgery or radiation therapy is not possible. With the development of new drugs that cross the blood-brain barrier, chemotherapy is increasingly recommended.²²⁶ Survival with treatment is about a year.

Spinal Cord Tumors

Primary spinal cord tumors are rare and represent about 2% of CNS tumors. They are histologically classified as extradural, intradural extramedullary, or intradural intramedullary. **Extramedullary tumors** originate from tissues outside the spinal cord. Extramedullary tumors are either peripheral nerve sheath tumors (neurofibromas or schwannomas) or meningiomas. Neurofibromas are generally found in the thoracic and lumbar region, whereas meningiomas are more evenly distributed through the spine. Complete resection of these tumors can be curative. Other extramedullary tumors are sarcomas, vascular tumors, chordomas, and epidermoid tumors.

Intramedullary tumors are least common (5% to 10% of all spinal tumors) and originate within the neural tissues of the spinal cord. Intramedullary tumors are primarily gliomas (astrocytomas, ependymomas, hemangioblastomas). Gliomas are difficult to resect

completely, and radiotherapy is required. Spinal ependymomas may be completely resected and are more common in adults.²²⁷

Metastatic spinal cord tumors are usually carcinomas (i.e., from breast, lung, or prostate cancer), lymphomas, or myelomas. Their location is often extradural, having proliferated to the spine through direct extension from tumors of the vertebral structures or from extraspinal sources extending through the intervertebral foramen or bloodstream. They are three to four times more common than primary spinal cord tumors.

◆Pathophysiology.

Extramedullary spinal cord tumors produce dysfunction by compression of adjacent tissue, not by direct invasion. The spinal cord is compressed by the tumor from without, and destruction of the white matter tracts occurs. The spinal canal around the cord becomes filled by tumor.

Intramedullary spinal cord tumors produce dysfunction by invasion and compression. The cord enlarges as a result of the tumor that is enlarging inside the cord. In addition, distortion of adjacent white matter tracts occurs. Metastases from spinal cord tumors occur from seeding through the CSF; medulloblastomas and ependymomas establish distant implants in this manner.

◆Clinical Manifestations.

Clinical manifestations depend on growth rate, location, and longitudinal extent of the tumor. An acute onset suggests a vascular occlusion of vessels supplying the spinal cord, whereas gradual and progressive symptoms suggest compression with dural distention and irritation. Pain is usually a presenting symptom. The **compressive syndrome (sensorimotor syndrome)** involves both the anterior and the posterior spinal tracts and nerve roots, and motor function and sensory function are affected as the tumor grows, with weakness, spasticity, and clumsiness and a decrease in pain and temperature sensation.

The **irritative syndrome (radicular syndrome)** combines the clinical

manifestations of cord compression with radicular pain that occurs in the sensory root distribution and indicates root irritation. The segmental manifestations include segmental sensory changes, such as paresthesias and impaired pain and touch perception; motor disturbances, including cramps, atrophy, fasciculations, and decreased or absent deep tendon reflexes; and continuous spinal pain.

◆Evaluation and Treatment.

The diagnosis of a spinal cord tumor is made using MRI techniques, bone scan, PET, CT-guided needle biopsy, or open biopsy. Involvement of specific cord segments is established. Any metastases also are identified. Spinal tumors are not staged but can be classified as slow growing (low-grade) or rapidly growing (high-grade). Treatment varies depending on the nature of the tumor and the person's clinical status, but surgery is essential for all spinal cord tumors.²²⁸ Radiotherapy, chemotherapy, hormonal therapy, and pain management protocols may be appropriate.²²⁹

Summary Review

Central Nervous System Disorders

1. Traumatic brain injury (TBI) is an alteration in brain function or other evidence of brain pathology caused by an external force.
2. Primary brain injury is caused by an impact and can be focal or diffuse with open- or closed-head injury.
3. Severity of TBI is graded using the Glasgow Coma Score.
4. Focal brain injury includes coup and contrecoup, contusion (bruising of the brain), laceration (tearing of brain tissue), extradural hematoma (accumulation of blood above the dura mater), subdural hematoma (blood between the dura mater and arachnoid membrane), intracerebral hematoma (bleeding into the brain), and open-head trauma.
5. Open-head injury involves a skull fracture with exposure of the

cranial vault to the environment. The types of skull fracture include compound fracture or perforated fracture and linear, comminuted, and basilar skull fracture.

6. Closed-head injuries occur in a precise location, and most are mild. More severe damage includes contusions and epidural, subdural, subarachnoid, and intracerebral hemorrhage.
7. Diffuse axonal injury (DAI) results from mechanical forces of acceleration, deceleration, and rotation that cause stretching and shearing of axons and can only be seen microscopically. The injury can be mild, moderate, or severe.
8. Secondary neuronal injury occurs as an indirect result of primary brain injury. Systemic processes include hypotension, hypoxia, anemia, hypoglycemia, hyperglycemia, and hypercapnia or hypocapnia. Cerebral contributions include inflammation, oxidative stress, alterations in the blood-brain barrier, excitotoxicity, cerebral edema, increased intracranial pressure (IICP), decreased cerebral perfusion pressure, cerebral ischemia, and brain herniation.
9. Complications of TBI include postconcussion syndrome, posttraumatic seizures, and chronic and traumatic encephalopathy.
10. Spinal cord and vertebral injuries occur most often in young men who sustain various kinds of injuries (recreational or travel-related) and older adults because of preexisting degenerative vertebral disorders.
11. Vertebral injuries include fractures, dislocations, compressions, and penetrating bone fragments from shearing and compression force. Fractures can be simple, compressed, or comminuted.
12. Primary spinal cord injury involves damage to vertebral or neural tissues from shearing, compression, or traction forces.
13. Secondary spinal cord injury is related to edema, ischemia, excitotoxicity, inflammation, oxidative damage, and activation of necrotic and apoptotic cell death and begins within minutes after injury and continues for weeks.

14. Spinal cord injury often causes spinal shock with cessation of all motor, sensory, reflex, and autonomic functions below any transected area. Loss of motor and sensory function depends on the level of injury.
15. Neurogenic shock (vasogenic shock) occurs with cervical or upper thoracic cord injury above T5 and may be seen in addition to spinal shock. There is loss of sympathetic activity and unopposed vagal parasympathetic activity with symptoms of hypotension, bradycardia, and hypothermia.
16. Paralysis of the lower half of the body with both legs involved is called *paraplegia*. Paralysis involving all four extremities is called *quadriplegia*.
17. Return of spinal neuron excitability occurs slowly. Reflex activity can return in 1 to 2 weeks in most people with acute spinal cord injury. A pattern of flexion reflexes emerges, involving first the toes and then the feet and legs. Eventually reflex voiding and bowel elimination appear, and mass reflex (flexor spasms accompanied by profuse sweating, piloerection, and automatic bladder emptying) may develop.
18. Autonomic hyperreflexia (dysreflexia) is a syndrome of sudden massive reflex sympathetic discharge associated with spinal cord injury at level T5-T6 or above and can cause life-threatening hypertension.
19. The pathologic findings in degenerative disk disease (DDD) include disk protrusion, spondylosis and/or spondylolisthesis, degeneration of the vertebrae (spondylolisthesis), and spinal stenosis.
20. Low back pain is pain between the lower rib cage and gluteal muscles and often radiates into the thigh.
21. Most causes of low back pain are unknown; however, some secondary causes are disk prolapse, tumor, bursitis, synovitis, degenerative disk disease, osteoporosis, hyperparathyroidism, fracture, inflammation, and sprain.
22. Degenerative disk disease is part of normal aging as a response to continuous vertical compression of the spine,

usually in the lumbar region. Both genetic and environmental factors contribute to loss of disk connective tissue. Disks can tear and herniate, pinching nerves and straining the spine. In addition there may be changes in the vertebral body with spondylolysis or spondylolisthesis, or both, degeneration of vertebrae, and spinal stenosis.

23. Spondylolysis is a structural defect in the pars interarticularis of the vertebral arch with anterior displacement (sliding) of the deficient vertebra (spondylolisthesis) and is a cause of low back pain.
24. Cervical spondylolysis is facet hypertrophy and disk degeneration with narrowing in the cervical spine predominantly at C5-C6 and C6-C7 and can cause radiculopathy and myelopathy with numbness and tingling in the arms, occipital headache, difficulty walking, altered sensation in the feet, and sphincter disturbances.
25. Spinal stenosis is narrowing of the spinal canal that causes pressure on the spinal cord and is associated with trauma or arthritis. Symptoms include pain, numbness, and weakness in the areas of affected spinal nerves.
26. Herniation of an intervertebral disk is a protrusion of part of the nucleus pulposus, most commonly at L5-S1 and L4-L5. The extruded pulposus compresses the nerve root, causing pain that radiates along the sciatic nerve.
27. Cerebrovascular disease is the most frequently occurring neurologic disorder. Any abnormality of the blood vessels of the brain is referred to as *cerebrovascular disease* and includes vessel wall abnormalities and vascular malformations, thrombotic or embolic occlusion, and increased blood viscosity or clotting.
28. Cerebrovascular disease causes (a) ischemia with or without infarction and (b) hemorrhage. The common clinical manifestation is a cerebrovascular accident (CVA) or stroke syndrome. Hypertension is the greatest risk factor followed by other preventable risks.

29. CVAs are classified according to pathophysiology and include ischemic (thrombotic, embolic, and hypoperfusion), lacunar (small vessel disease), and hemorrhagic strokes.
30. A transient ischemic attack is a transient episode of neurologic dysfunction resulting from focal cerebral ischemia with risk for progressing to stroke.
31. Ischemic strokes result from interruption in brain blood flow with a core of irreversible ischemia and necrosis or infarction that appears pale (white infarct). The zone around the infarction has reversible ischemia, is called the *ischemic penumbra*, and can regain neurologic function, particularly with thrombolytic treatment. Leaking blood vessels can develop in the infarcted area, resulting in a hemorrhagic transformation (a red infarct) that can be exacerbated by thrombolytic therapy.
32. Reperfusion injury can occur with ischemic stroke.
33. Intracerebral hemorrhagic stroke is primarily associated with vessel disease related to hypertension. Subarachnoid hemorrhage is associated with ruptured aneurysms, arteriovenous malformations (AVMs), or cavernous angioma.
34. Intracranial aneurysms result from defects and weakness in the vascular wall and are classified on the basis of form and shape. They are commonly asymptomatic, but the signs vary according to the location and size of the aneurysm.
35. An AVM is a tangled mass of dilated blood vessels. Although sometimes present at birth, AVM exhibits a delayed age of onset with symptoms ranging from headache and dementia to seizures and ICH or SAH. Vasospasm and delayed cerebral ischemia are serious complications.
36. Subarachnoid hemorrhage is bleeding into the subarachnoid space commonly associated with intracranial aneurysms, AVM, and hypertension. The expanding hematoma increases ICP, compresses brain tissue, reduces cerebral perfusion, disrupts the blood-brain barrier, and causes inflammation and neuronal death. Secondary brain injury follows. Seizures and

hydrocephalus can accompany neurologic deficits.

37. Migraine is an episodic disorder whose marker is headache lasting 4 to 72 hours. Migraine is classified as a headache with and without aura and chronic migraine (migraines 15 days in a month for more than 3 months). Migraine may be precipitated by a triggering event. The aura is associated with cortical spreading depression, which initiates the release of neurotransmitters, particularly CGRP, that stimulate vasodilation in the trigeminal vascular system, inflammation, and sensitization of pain receptors. Glutamate is increased and serotonin is decreased.
38. Cluster headaches (trigeminal autonomic cephalgia) occur in episodes several times during a day for a period of days at different times of the year, primarily in men. The pain is unilateral, intense, tearing, and burning and associated with ptosis, lacrimation, reddening of the eye, and nausea. The cause of trigeminal activation is unknown. There is sympathetic nervous system underactivity and parasympathetic overactivity with trigger events similar to migraine. The two forms are acute and chronic.
39. Chronic paroxysmal hemicranias are a cluster-type headache that occurs 4 to 12 times per day for 20 to 120 minutes in both men and women. There is sympathetic activity different from that in cluster headache, as it is relieved with indomethacin.
40. Tension-type headache (TTH) is the most common type of headache. Both central and peripheral pain mechanisms are associated with the etiology. The headache is bilateral, with the sensation of a tight band around the head. The pain may last for hours or days. There are acute and chronic forms.
41. Infection and inflammation of the CNS can occur by bacteria, viruses, fungi, parasites, and mycobacteria (i.e., tuberculosis). The resulting infection by bacteria is pus-producing, or pyogenic.
42. Meningitis is inflammation of the brain or spinal cord. Bacterial meningitis is primarily an infection of the pia mater

and arachnoid villi and of the fluid of the subarachnoid space. Viral meningitis is believed to be limited to the meninges. Fungal and tubercular meningitis are less common, and immunosuppressed individuals are at greatest risk.

43. The meningeal vessels become hyperemic, and neutrophils migrate into the subarachnoid space with bacterial meningitis. An inflammatory reaction occurs, and exudation ensues and increases, rapidly producing edema and brain injury.
44. Brain abscesses can be extradural, subdural, or intracerebral and often originate from infections outside the CNS. Microorganisms gain access to the CNS from adjacent sites or spread along the wall of a vein. A localized inflammatory process develops with exudate formation, vessel thrombosis, and leukocyte degeneration. After a few days the infection becomes delimited, with a center of pus and a wall of granular tissue that forms a capsule.
45. Encephalitis is an acute febrile illness of viral origin with nervous system involvement. The most common encephalitides are caused by arthropod-borne viruses and herpes simplex virus. The infection causes widespread brain edema and necrosis. Meningeal involvement appears in all encephalitides.
46. The common neurologic complications of AIDS are HIV-associated neurocognitive disorder (HAND), HIV neuropathy, HIV myelopathy, opportunistic infections, cytomegalovirus infection, parasitic infection, and neoplasms. Pathologically, there may be diffuse CNS involvement, focal pathologic findings, and obstructive hydrocephalus. Neurologic involvement associated with HIV has declined with HARRT.
47. MS is a chronic inflammatory disease involving degeneration of CNS myelin in genetically susceptible individuals. The cause is unknown and autoreactive T and B cells recognize myelin autoantigens and produce myelin-specific antibodies triggering inflammatory demyelination with loss of oligodendrocytes and plaque formation leading to disruption

of nerve conduction.

48. The clinical manifestations of MS involve different types: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing.
49. Guillain-Barré syndrome is a rare demyelinating disorder caused by an antibody and cell-mediated immunologic reaction directed against peripheral nerves that causes weakness or paralysis and can have irreversible effects. Different subtypes have been identified, and clinical manifestations depend on the subtype.

Peripheral Nervous System and Neuromuscular Junction Disorders

1. Neuropathies result when there is injury to peripheral nerves and can involve sensory, motor, and autonomic pathways. Axon and myelin degeneration may be present. Neuropathies are classified as generalized symmetric polyneuropathies, generalized neuropathy, and focal or multifocal neuropathies.
2. Radiculopathies are disorders of spinal cord nerve roots. The roots may be compressed, inflamed, or torn. Cervical and lumbar nerve roots are more commonly affected.
3. Plexus injuries involve the nerve plexus distal to the spinal roots but proximal to the formation of the peripheral nerves and are caused by trauma, compression, or infiltration with motor and/or sensory loss, weakness, and muscle atrophy.
4. Botulism is poisoning by botulinum toxin released by *Clostridium botulinum* that acts by inhibiting release of ACh at the myoneural junction causing life-threatening flaccid paralysis.
5. Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction with generalized, ocular, or neonatal subtypes. Autoantibodies, complement deposits, and membrane attack complex destroy the acetylcholine receptor (AChR) sites, causing decreased

transmission of nerve impulses, leading to muscle weakness, including ocular and systemic muscles. There can be childhood and adult onset.

Tumors of the Central Nervous System

1. Tumors that occur within the cranium are either primary or metastatic (secondary). Primary tumors arise from brain tissue and are classified as intracerebral or extracerebral. Metastatic tumors to the brain arise in organs outside the brain and are much more common than primary brain tumors.
2. Primary brain tumors include astrocytomas, oligodendrogliomas, mixed oligoastrocytomas, glioblastoma multiforme (grade IV astrocytoma), and ependymomas. Other CNS tumors include meningiomas, nerve sheath tumors (schwannomas), and neurofibromas.
3. Metastatic brain tumors invade brain tissue by attaching to endothelial cells of microvessels and use enzymes to cross the blood-brain barrier and extravasate into the brain parenchyma.
4. Spinal cord tumors are classified as intramedullary (within the neural tissues) or extramedullary (outside the spinal cord). Metastatic spinal cord tumors are usually carcinomas, lymphomas, or myelomas.
5. Extramedullary spinal cord tumors produce dysfunction by compression of adjacent tissue, not by direct invasion. Intramedullary spinal cord tumors produce dysfunction by invasion and compression.

Key Terms

[Arteriovenous malformation \(AVM\), 571](#)

[Astrocytoma, 590](#)

CHAPTER 19

Neurobiology of Schizophrenia, Mood Disorders, Anxiety Disorders, and Obsessive-Compulsive Disorder

Lorey K. Takahashi

CHAPTER OUTLINE

Schizophrenia, 600

Mood Disorders: Depression and Bipolar Disorder, 605

Anxiety Disorders, 611

Panic Disorder, 611

Social Anxiety Disorder, 612

Generalized Anxiety Disorder, 613

Posttraumatic Stress Disorder, 613

Obsessive-Compulsive Disorder, 614

Mental illnesses are common and found in different cultures and across the socioeconomic spectrum. When left untreated, the consequences can be devastating. This chapter provides an introduction to the neurobiology of schizophrenia, mood disorders,

and some anxiety disorders. The etiology and pathophysiology of mental illnesses are diverse and complex. Diagnostic criteria are constantly being updated to more precisely diagnose and effectively treat the disorders. Every mental disorder manifests a range of symptoms that vary in intensity. Symptom variations likely reflect individual differences in pathologic brain structures and functions which affect treatment. Risk factors, such as exposure to uncontrollable psychosocial stress, may precipitate the onset of mental disorders and point to the challenge in understanding how diseased genes and environmental factors interact.

The development of visual and quantitative structural and functional neuroimaging techniques provides insight into the pathophysiologic basis of mental disorders. In schizophrenia, neuroanatomic, functional, and neurochemical alterations associated with this debilitating illness have uncovered abnormal brain regions along with a host of candidate genes that confer risk. Similarly, in mood and anxiety disorders, brain scans are revealing structural and functional abnormalities. Notably, many brain regions implicated in normal cognitive and emotional processing are found in schizophrenia, mood, and anxiety disorders. The future lies in unraveling how the highly interconnected brain structures modulated by neurotransmitters, neuropeptides, and hormones operate in normal to abnormal mental states.

Knowledge of the pathophysiology associated with a specific mental illness has guided the development of new psychopharmacologic medications with fewer side effects. However, some individuals with mental disorders do not respond to current medications or may relapse after a period of treatment. The use of psychotherapies alone or as an adjunct to pharmacotherapy also may be effective in treating some disorders by making the person aware of potential environmental factors that trigger stress and the onset of the illness. Learning to cope with these triggers offers hope for alleviating psychiatric symptoms or attenuates pathophysiologic functions.

Schizophrenia

Schizophrenia is a serious psychiatric illness that strikes 1% of the world's population. The illness is equally prevalent in males and females and emerges in young adults during the late teens and early twenties, with a slightly earlier onset in males than in females. **Schizophrenia** is the term coined originally by Eugen Bleuler in 1911 to describe a collection of illnesses characterized by **thought disorders**, which reflect a break in reality or splitting of the cognitive from the emotional side of one's personality. A schizophrenic individual may exhibit a feeling of happiness when recollecting a terrible event or emotional indifference when describing a joyful occasion. Today, disorganized thought in schizophrenia is characterized by positive and negative symptoms including auditory hallucinations, paranoid delusions, and cognitive deficits that have devastating effects on the individual and the individual's family.

♦ Etiology and Pathophysiology

Genetic Predisposition

Schizophrenia is a heritable disorder. In monozygotic twins, the concordance rate varies from 30% to 50%. This variability may stem from different diagnostic criteria and methodologic or sampling differences across studies. In dizygotic twins and siblings the concordance rate decreases to 12%, which is still considerably higher than the 1% figure found in the general population.

Nonetheless, schizophrenia is not a simple genetic disorder in which inherited disease alleles will always lead to illness. Schizophrenia likely involves several genes located on different chromosomes and differs from mendelian disorders, in which genes are fully penetrant and recognized as the primary cause of disease (e.g., genes for Huntington disease). As indicated by the 50% concordance rate in monozygotic twins, the genes for schizophrenia show reduced penetrance, resulting in individuals who carry the disease genes without manifesting the illness. Further complicating

the search for the specific genes that confer risk of schizophrenia is the variability in biologic and phenotypic traits among individuals who manifest the illness. Ongoing studies based on protein interactions may be valuable in identifying novel gene associations.¹

Prenatal and Perinatal Vulnerability Factors.

Because the concordance rate of schizophrenia in monozygotic twins is never 100% as in mendelian disorders, environmental factors likely play an important role in increasing the risk of developing the disorder. A leading hypothesis suggests that early environmental factors interfere with genetically programmed neural developmental alterations that eventually compromise normal brain structures and functions.² An early brain defect may remain silent and not dramatically affect the individual until subsequent development requires adaptive use of brain structures.³ Several hypothesized early environmental factors that may alter brain development and increase the risk of developing schizophrenia include exposure to prenatal infection, prenatal nutritional deficiencies, perinatal complications (such as birth defects and neonatal hypoxia), and upbringing in an urban environment.⁴

Neuroanatomic and Functional Abnormalities

Neuroanatomic Alterations.

Advanced neuroimaging techniques have revealed structural brain abnormalities in schizophrenia.^{5,6} A consistent finding is the enlargement of the lateral and third ventricles and the widening of frontocortical fissures and sulci (Fig. 19.1). Schizophrenics with cerebral ventricular enlargement often exhibit cognitive impairments and negative symptoms and respond poorly to treatment. Other studies reported a reduction in the thalamus and temporal lobe areas (e.g., amygdala, hippocampus, and parahippocampal gyrus).⁷ A reduction in thalamus size may disrupt neurotransmission between the frontal cortex and primary sensory and motor areas. Hippocampal volume loss in the first years of the illness is another consistent

finding, and hippocampal volume reduction accelerates in schizophrenics more than 50 years of age.⁸ This hippocampal atrophy is strongly associated with global cognitive and socio-occupational functional impairments, which also may reflect a fronto-hippocampal disconnection in socio-cognitive processing.

FIGURE 19.1 Magnetic Resonance Imaging (MRI) Comparison of Normal Brain and Brain with Schizophrenia. Three-dimensional MRI reconstructions showing A, the cerebral ventricles (*gray regions*) and hippocampus (*yellow regions*) of a schizophrenic patient, and B, those of a healthy individual. Note the enlarged cerebral ventricles and reduced hippocampal volume of the brain of the schizophrenic individual. (From Gershon ES, Rieder RO: *Sci Am* 267:128, 1992. Original illustrations by Nancy C. Andreason, University of Iowa.)

The amygdala plays a central role in the **social brain emotional processing network**.⁹ Abnormal amygdala connectivity is widely reported in schizophrenia and hypothesized to represent the basis underlying pronounced difficulties for schizophrenics to make appropriate social judgments as found in tests of facial identity, affect recognition, and in emotional processing.¹⁰ Reported amygdala abnormalities in schizophrenia include reduced volume⁷ and abnormal functional activation patterns for social and emotion processing.¹¹ The induction of abnormal amygdala projections to brain regions such as the hippocampus during late adolescence and young adulthood may be linked to the onset of schizophrenia.

Brain imaging studies in adolescents with early-onset schizophrenia reveal progressive loss of cortical gray matter in temporal lobes, somatosensory and motor cortices, and the dorsolateral cortex (Fig. 19.2). Of clinical concern is the loss of cortical tissue, which is evident by the time the individual seeks treatment and continues throughout the course of the illness despite the use of antipsychotic medication.¹² The progressive loss in frontal lobe volume is accompanied by increased severity of negative symptoms and further reductions in cognitive functioning. These results highlight the ineffectiveness of current medications for schizophrenia to attenuate or reverse the loss of frontal brain tissue.

FIGURE 19.2 Accelerated Gray Matter Loss in Brains of Early-Onset Schizophrenic Adolescents. Annual gray matter loss ranging from 2% to 5% was found in 13- to 18-year-old schizophrenics—compared with age-matched healthy adolescents. (From Thompson PM et al: *Proc Natl Acad Sci U S A* 98:11650, 2001.)

Brain abnormalities in schizophrenia are believed to originate in the prenatal period of cell proliferation and migration. Reelin, an extracellular matrix protein involved in neuronal migration during development and in synaptic function during adulthood, is reduced in the prefrontal cortex and hippocampus of schizophrenic individuals.^{13,14} Reelin is concentrated in interneurons that contain **gamma-aminobutyric acid (GABA)**, the most widespread inhibitory neurotransmitter. Furthermore, in the dorsal prefrontal cortex of schizophrenic brains, the level of glutamic acid decarboxylase, the major enzyme in GABA biosynthesis, is reduced, which likely impairs normal cognitive/emotional functions.

Pathophysiologic changes in the dorsal prefrontal cortex are believed to contribute to the production of negative symptoms in schizophrenia (Fig. 19.3). In particular, the **dorsolateral prefrontal cortex (DLPFC)** (Brodmann areas 9, 10, 46, 47) is intricately involved in the initiation and maintenance of goal-directed activities and in

solving cognitive problems related to working memory. **Working memory** involves the brief storage and use of information to complete cognitive tasks such as language comprehension, learning, and reasoning. Blood flow and metabolism normally increase in the DLPFC during working memory processing but not in schizophrenics, who also perform poorly in tests of working memory. Thus the dorsolateral prefrontal cortex appears to be hypoactive in schizophrenia.

FIGURE 19.3 The Prefrontal Cortex. The prefrontal cortex consists of a dorsolateral (*blue*) and an orbitofrontal (*green*) region.

Neurotransmitter Alterations.

The onset of schizophrenia was initially hypothesized to stem from abnormally high concentrations of the brain neurotransmitter dopamine. This **dopamine hypothesis** of schizophrenia was proposed on the basis of pharmacologic studies showing that antipsychotic drugs were potent blockers of brain dopamine receptors. A strong positive correlation was found between the clinical potencies of first-generation antipsychotic drugs (e.g., chlorpromazine, fluphenazine, and haloperidol) and their affinity for the dopamine D₂ receptor. In addition, drugs at high doses that dramatically increased dopaminergic transmission—such as levodopa (L-dopa), cocaine, and amphetamine—produced schizophrenic-like psychosis, which was reversed by dopamine blockers.

A current view of the dopamine hypothesis of schizophrenia is that brain dopamine pathways are altered in different ways (Fig. 19.4). For example, the negative symptoms and cognitive alterations in schizophrenia are proposed to result from reduced dopaminergic neurotransmission in the mesocortical dopamine pathway.¹⁵ This hypodopaminergic transmission in the prefrontal cortex contrasts with the hypothesized hyperdopaminergic secretion in mesolimbic brain regions that may contribute to the production of positive schizophrenic symptoms. The mesolimbic dopamine pathway innervates temporal lobe structures including the hippocampal formation and amygdala, as well as the nucleus accumbens and anterior cingulate cortex.

FIGURE 19.4 The Dopamine System. Dopamine cell bodies are located in the substantia nigra, where they project to the striatum (nigrostriatal pathway); and in the ventral tegmental area, where they project to the frontal and cingulate cortex (mesocortical pathway), the striatum, the hippocampus, and other limbic structures (mesolimbic pathway). Dopamine nuclei are also located in the hypothalamus and project to the pituitary.

Another neurotransmitter system that may underlie the pathogenesis of schizophrenia is the excitatory neurotransmitter glutamate and its actions on the *N*-methyl-D-aspartate (NMDA) receptor subtype. The **glutamate hypothesis** of schizophrenia proposes that underactivation of glutamate receptors contributes to schizophrenia.¹⁶ In schizophrenia, glutamate concentrations in the cerebrospinal fluid (CSF) are reduced along with a decrease in cortical glutamate synthesis. Furthermore, in unaffected individuals, blocking the glutamate NMDA receptor with antagonists, such as phencyclidine (PCP) and ketamine, facilitates the positive and negative symptoms of schizophrenia. PCP users report auditory hallucinations and disorientation and may become violent from their delusions. In monkeys, chronic PCP treatment impairs cognitive performance in a test associated with prefrontal cortical damage.¹⁷

◀ Clinical Manifestations

The symptoms of schizophrenia are currently divided into three broad categories of positive, negative, and cognitive symptoms (Box 19.1). *Positive symptoms* frequently occur during a **psychotic episode**, when an individual loses touch with reality and experiences something that should be absent (e.g., hallucinations). *Negative symptoms* are characterized by disruptions in normal emotional states and expressions. Cognitive symptoms are fairly common and involve problems with thought processes that severely impair the ability to perform routine daily tasks that involve attention, planning, and social skills. According to the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)*,¹⁸ the diagnosis of schizophrenia begins by eliminating other mental disorders and symptoms not caused by substance abuse, medication, or medical condition. The individual will then be diagnosed with schizophrenia when at least two of the following symptoms (1) delusions, (2) hallucinations, (3) disorganized speech, (4) disorganized or catatonic behavior, and (5) negative symptoms are experienced most of the time during a 1-month period with some disturbance present over 6 months. In addition, one of the symptoms must be delusions, hallucinations, or disorganized speech.

Box 19.1

Major Symptoms of Schizophrenia

Positive Symptoms

Hallucinations

- Auditory
- Olfactory
- Somatic-tactile
- Visual
- Voices commenting
- Voices conversing

Delusions

Delusions of being controlled
Delusions of mind reading
Delusions of reference
Grandiosity
Guilt
Persecutory
Religious
Somatic
Thought broadcasting
Thought insertion
Thought withdrawal

Positive Formal Thought Disorder

Circumstantiality
Derailment
Distractible speech
Illogicality
Incoherence
Pressure of speech
Tangentiality

Bizarre Behavior

Aggressive, agitated
Clothing, appearance
Repetitive, stereotyped
Social, sexual behavior

Negative Symptoms

Affective Flattening

Affective nonresponsivity
Decreased spontaneous movements
Inappropriate affect
Lack of vocal inflections
Paucity of expressive gestures
Poor eye contact
Unchanging facial expression

Alogia

Blocking
Increase in response latency
Poverty of speech
Poverty of speech content

Anhedonia-Asociality

Few recreational interests
Few social relationships
Impaired intimacy
Little sexual interest

Attention

Social inattentiveness
Inattentiveness during testing

Avolition-Apathy

Impaired personal hygiene
Lack of persistence
Physical anergia

Cognitive Symptoms

Inability to understand information and make proper decision to complete a task

Difficulty paying attention

Problems with working memory or the inability to use recently learned information

Lack of insight

Psychotic Dimension

Psychotic dimension refers to hallucinations and delusions and reflects a person's confusion or loss of touch with the external world. Hallucinations and delusions are classified as positive symptoms and are the most common in schizophrenia.

Hallucinations.

A **hallucination** is a perception experienced without external stimulation of the sense organs. Sensory hallucinations can be auditory, tactile, visual, gustatory, and olfactory. For example, the schizophrenic individual may hear voices, experience touch or electrical sensations, report images of animate and inanimate objects, or complain of unpleasant tastes and odors. These hallucinations may occur alone or together.

Delusions.

A **delusion** is a persistent belief contrary to the educational and cultural background of the individual. Delusions may involve grandiose, nihilistic, persecutory, somatic, sexual, and religious themes. Paranoid beliefs are common and may involve spying, conspiracy, persecution, and ridicule. Delusions also may be referential in that particular stimuli or events become highly personalized, such as believing a television talk show host is directing information specifically at them.

Disorganized Behavior

Disorganized behavior includes disorganized speech and disorganized or bizarre behavior. Incongruity of affect is another dimension of disorganized behavior.

Disorganized Speech.

A common form of disorganized speech is **formal thought disorder**, which involves fluent speech that is difficult to comprehend. The speech often moves from one topic to another unexpectedly (loose associations) and illogically, and the person becomes easily distracted when talking.

Another form of disorganized speech is called **poverty of content**. Here, the use of vocabularies to convey information is severely retarded despite a fair amount of spoken words. For instance, the same phrases are used repeatedly throughout a conversation.

Disorganized Behavior.

Disorganized (or bizarre) behavior is the conceptual equivalent of disorganized speech. The individual has difficulty engaging in goal-directed activities. Repetitive (e.g., stereotyped rocking) or aimless behavior and poor personal hygiene are exhibited. Another feature is the incongruity of affect or the manifestation of inappropriate situational affect as exemplified by hostility without provocation or child-like silliness in sober situations.

Negative Dimensions

Negative dimensions reflect a deficit in normal functioning and are characterized by affective flattening, anhedonia, alogia (poverty of speech), and avolition. **Affective flattening** is the near absence of emotional or facial expressions throughout a conversation or in different situations. In **anhedonia**, individuals are unable to experience emotions such as pleasure or pain and report a sense of detachment from the environment. **Alogia** is the absence of spontaneous speech production for the purpose of answering

questions or expressing oneself. **Avolition** is a deficit in spontaneous or goal-directed behavior, such as completing simple daily tasks.

◀Treatment

The use of chlorpromazine in the mid-1950s dramatically altered the treatment of schizophrenia, which previously required extensive institutional hospitalization. The drug was especially effective in reducing positive symptoms such as hallucinations and delusions as well as thought disorders and hyperactivity. The beneficial effects of chlorpromazine and similar first-generation antipsychotic drugs such as haloperidol on positive symptoms were believed to stem from their ability to block the dopamine D₂-receptor subtype, especially in the overly active mesolimbic dopamine pathways.

However, D₂-receptor blockade, such as in the striatum, produces a notable neurologic side effect resembling Parkinson disease—a disorder associated with degeneration of dopamine cell bodies in the substantia nigra that project to the striatum. A related side effect of conventional antipsychotics that develops in 15% to 20% of schizophrenics after several years of treatment is a condition called **tardive dyskinesia**. This condition is characterized by tic-like jerky movements, such as smacking the lips or flicking the tongue, unsteady gait, or rocking back and forth when seated. Other side effects may include sedation, hypotension, akathisia (motor restlessness), constipation, weight gain, amenorrhea, and, less frequently, hepatotoxicity and electrocardiographic changes.

Although the majority of schizophrenic individuals obtained some positive symptom relief from the first-generation or conventional antipsychotics, approximately 20% failed to respond to D₂-blocking drugs (Table 19.1), especially those with pronounced symptoms of apathy, disorientation, and social withdrawal. However, some of these treatment-resistant individuals responded to a second generation of drugs that became known as *atypical antipsychotic drugs*.¹⁹ Atypical antipsychotics also were shown to have superior efficacy in reducing not only the positive but also the negative

symptoms in comparison with conventional antipsychotics. For example, clozapine improves some cognitive functions (such as verbal fluency, verbal learning, and memory) and some physical functions (such as psychomotor speed). In addition, the notable neurologic side effects that accompany the use of the conventional antipsychotics were diminished.

TABLE 19.1

MEDICATIONS USED IN THE TREATMENT OF SCHIZOPHRENIA

GENERIC NAME	BRAND NAME
Conventional Antipsychotics	
Chlorpromazine	Thorazine
Fluphenazine	Prolixin
Haloperidol	Haldol
Perphenazine	Trilafon
Pimozide	Orap
Prochlorperazine	Compazine
Thioridazine	Mellaril
Thiothixene	Navane
Trifluoperazine	Stelazine
Second-Generation Atypical Antipsychotics	
Aripiprazole	Abilify
Clozapine	Clozaril
Loxapine	Loxitane
Lurasidone	Latuda
Molindone	Moban
Olanzapine	Zyprexa
Paliperidone	Invega
Quetiapine	Seroquel
Risperidone	Risperdal
Ziprasidone	Geodon

Unlike conventional antipsychotics, atypical drugs appear to work by blocking a range of neurotransmitter receptors. For example,

clozapine blocks not only D₂ receptors but also D₁, D₃, D₄, and D₅ receptors and serotonin (5-hydroxytryptamine, i.e., 5-HT₂, 5-HT₆, 5-HT₇); norepinephrine; and cholinergic and histamine receptors. Risperidone and ziprasidone have higher affinity for blocking 5-HT₂ than D₂ receptors. The higher 5-HT₂/D₂-receptor-binding ratio of atypical antipsychotics in comparison with conventional drugs may reflect a normalization of serotonin-dopamine interactions leading to clinical efficacy not observed with D₂-receptor blockade alone.

Atypical antipsychotics are not without adverse effects, most notably metabolic abnormalities including regulation of glucose and lipid levels and weight gain. For example, long-term clozapine or olanzapine treatment increases body weight gain, which becomes a risk factor for diabetes and cardiovascular disease. Schizophrenics treated with clozapine also are at risk of developing **agranulocytosis**, a potentially lethal blood disorder involving the loss of white blood cells and a compromised immune system.

In conjunction with antipsychotic medication, psychosocial therapy can facilitate the management of schizophrenia. Psychosocial relationships assist the individual in developing coping strategies and in identifying stressors and relapse symptoms. Cognitive-behavioral therapy (CBT), a talking therapy that initiates cognitive and behavioral change based on an individualized reappraisal of the person's faulty beliefs, is effective in treating schizophrenics with stabilized antipsychotic medications.²⁰ An important benefit of psychosocial and family support is the encouragement of compliance with antipsychotic medication that requires a period before the emergence of clinical efficacy.

Mood Disorders: Depression and Bipolar Disorder

Mood refers to a sustained emotional state as opposed to brief emotional feelings, which are termed *affective states*. Healthy individuals are normally capable of experiencing a variety of affective

states including euphoria, joy, surprise, fear, sadness, anxiety, and depression. When emotional states, such as sadness, become chronic and uncontrollable, individuals may be diagnosed with a mood disorder called *depression*. The two major classifications of mood disorder are (1) **unipolar or major depressive disorder**, also known as *major depression* or *clinical depression*; and (2) **bipolar disorder**, which is further classified into bipolar I and bipolar II disorders. **Major (unipolar) depressive disorder** consists of depressed mood, loss of interest/pleasure, changes in activity, guilt/worthlessness, death/suicide, fatigue/loss of energy, decreased concentration, and changes in sleep, appetite, or weight. In addition, two new specifiers were added in *DSM-5*. One specifier with mixed symptoms allows for the occurrence of manic symptoms as part of the diagnosis in depressed people who do not meet the criteria for a manic episode. Another specifier with anxious distress was added because anxiety may affect treatment choices for major depressive disorder. A manic episode consists of elevated, expansive, and irritable mood, as well as changes in energy and activity levels. In bipolar I disorder, the person experienced at least one manic episode that may be preceded or followed by hypomanic or major depressive episodes. Mania symptoms may significantly impair the individual, trigger psychosis, and require hospitalization. In bipolar II disorder, the individual experiences one major depressive episode for at least 2 weeks and at least one hypomanic episode for at least 4 days. [Box 19.2](#) presents the major criteria of major depression and bipolar disorder according to the American Psychiatric Association's *DSM-5*.¹⁸

Box 19.2

Major Symptoms of Depression and Mania

Symptoms of Depression*

Depressed or irritable mood
Loss of interests and pleasure

Significant (>5%) weight gain or loss in a month
Insomnia or hypersomnia
Psychomotor agitation or retardation
Fatigue or loss of energy
Feelings of worthlessness or excessive guilt
Poor concentration or indecisiveness
Recent thoughts of death or suicide

Symptoms of Manic Episode[†]

Elevated mood
Irritable mood
Inflated self-esteem
Decreased need for sleep
Excessive talking
Racing/crowded thoughts
Distractibility
Increase in goal-directed activity
Excessive risky activities

*Five or more of the symptoms are present in a 2-week period and at least one of the symptoms is either depressed mood or loss of interests or pleasure.

[†]Three or more symptoms (four if the mood is only irritable) during a distinct period of abnormally and persistently elevated, expansive, or irritable mood occurring for at least 1 week.

Major (unipolar) depressive disorder is the most common mood disorder and the leading cause of disability in the United States and throughout the world.²¹ Unipolar depression appears in all age groups including young children. In the United States, the lifetime prevalence rate is 16.2% of the population with a twofold greater risk in women than men after adolescence. In children and adolescents, 2% to 6% suffer from depression. The prevalence of bipolar disorder ranges from 3% to 5% in the general population. Bipolar I disorder occurs

equally in men and women in comparison with bipolar II disorder, which afflicts more women than men. When left untreated, a number of depressed and bipolar individuals are at risk of developing a host of medical illnesses, including cardiovascular disease, obesity, diabetes, and thyroid disease.

◀ Etiology and Pathophysiology

Genetic Predisposition and Environmental Influences

Family and twin studies indicate a strong basis for mood disorders. Concordance rates for bipolar disorder ranged up to 62% and 42% for monozygotic and dizygotic twins, respectively.²² Concordance rates of 62% and 28% for unipolar disorder were reported in monozygotic and dizygotic twins, respectively. Even among adoptees with a biologic family history of mood disorders, the incidence of developing major depression or manic-depressive illness is higher than among control adoptees. The strong tendency for mood disorders to run in families has encouraged a search for the abnormal gene or genes. Interestingly, loci on chromosomes 18 and 22 have been linked to both bipolar disorder and schizophrenia. Bipolar individuals, who may exhibit psychotic behavior, have deficits in reelin expression linked to genetic loci, located on chromosome 22, which confers susceptibility to schizophrenia (see preceding section on [Schizophrenia](#)). However, the large variation in clinical symptoms suggests that developmental and environmental factors are as important as genetic factors in contributing to the etiology of mood disorders.

Neurochemical Dysregulation

Modern theories of mood disorders began with the important observations that drugs such as imipramine that elevated norepinephrine levels within the synapse reduced depression whereas drugs that depleted monoamine levels (e.g., reserpine) increased depression. These studies led to the dominant **monoamine**

hypothesis of depression, in which a deficit in the concentration of brain norepinephrine, dopamine, and/or serotonin is the underlying cause of depression, in contrast to mania, which results from elevated concentrations of monoamines. Three major classes of antidepressant drugs were initially developed and included monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs). These antidepressants shared the common property, albeit through different mechanisms, that increasing monoamine neurotransmitter levels within the synapse is the basis for their antidepressant effects (Fig. 19.5).

FIGURE 19.5 Schematic Diagrams Showing the Sites of Actions of Antidepressants and Their Effects on Neurotransmitter Levels. A, MAO inhibitors (MAOIs) act by blocking the enzyme that normally degrades neurotransmitters, such as norepinephrine and serotonin increasing their

presynaptic concentration. B, The tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin-norepinephrine reuptake inhibitors (SNRIs) act by reducing the uptake of neurotransmitters from the synapse, which leads to increased neurotransmitter levels.

Additional support for the monoamine hypothesis of depression came from studies showing a reduction of monoamine metabolites in the cerebral spinal fluid (CSF) of depressed people. Other work demonstrated that dietary depletion of tryptophan, the precursor of serotonin synthesis, or alpha-methylparatyrosine (AMPT), a drug that inhibits dopamine and norepinephrine synthesis, produced a rapid return to depression in individuals successfully treated with antidepressants.²³

Neuroendocrine Dysregulation

Stress and Hypothalamic-Pituitary-Adrenal System Dysregulation.

The hypothalamic-pituitary-adrenal (HPA) system plays an essential role in an individual's ability to cope with stress (see [Chapter 11](#)). However, chronic stress-induced activation of the HPA system and elevated glucocorticoid secretion are found in a large percentage (30% to 70%) of people with major depression, suggesting that mechanisms responsible for increased HPA hormone secretion contribute to the pathophysiology of depression.²⁴ Notably, antidepressant drugs effective in normalizing the HPA system are associated with a good clinical response, whereas persistent dysregulation of the HPA system is related to continued depression or relapse. Psychosocial stress-induced activation of the immune system increases secretion of proinflammatory cytokines, such as interleukin-1 α (IL-1 α) and IL- β , tumor necrosis factor-alpha (TNF- α), and IL-6, which modulates signaling pathways throughout the periphery and brain and augments further secretion of HPA hormones and monoamine metabolism. Evidence suggests that **inflammation** is another risk factor that triggers the onset of depression. For example, a study involving 73,131 Danish individuals from the general population

reported elevated levels of C-reactive protein, a commonly used marker of inflammatory disease, was associated with increased risk of psychologic distress and depression.²⁵ Another study reported that depressed people treated with antidepressants, a combination of antidepressants and psychotherapy, or psychotherapy alone initially exhibited elevated cytokine levels that returned to normal levels after recovery from depression.²⁶ These studies suggest that cytokines are involved in the pathophysiology of depression (see [What's New? Inflammatory Cytokines Are Linked to Diverse Mental Illnesses](#)).

What's New?

Inflammatory Cytokines Are Linked to Diverse Mental Illnesses

Inflammation plays a major role in the pathophysiology of many chronic diseases, such as cardiovascular disease, diabetes, rheumatoid arthritis, asthma, multiple sclerosis, and chronic pain. A growing body of evidence now suggests that psychologic and social stressors increase inflammatory cytokine production that contribute to the pathophysiology of mental illnesses including schizophrenia, depression, bipolar disorder, and anxiety disorders, such as posttraumatic stress disorder. Although normal brain function requires low levels of inflammatory cytokines, derived from the brain's resident innate immune cells called microglia, elevated cytokine levels in the brain appear to facilitate neuronal damage, atrophy, and loss of spine synapses. In addition, peripheral cytokines may contribute to microglia functional alterations by entering the brain through the circumventricular organs and also compromise the protective role of the blood-brain barrier resulting in direct trafficking of cells and inflammatory molecules between the periphery and brain to enhance brain inflammation. The peripheral cytokines, such as interleukin 6 (IL-6) may also bind to vagus nerve receptors to activate a pathway that reaches hypothalamic brain nuclei to further stimulate microglia

secretion of proinflammatory cytokines, chemokines, and proteases.

In schizophrenia, studies found increased blood concentrations of inflammatory cytokines in subjects with first-episode, drug-naive psychosis suggesting an association independent of the effects of antipsychotic medications. People diagnosed with schizophrenia also have higher cytokine levels, especially during periods of symptomatic exacerbation, than controls, but not during periods of clinical stability. Studies further suggest that inflammatory cytokines may predict subsequent relapse.

Similarly, high levels of inflammation appear to increase the risk of developing depression. For example, elevations in IL-6 and C-reactive protein predict the eventual onset of depressive symptoms. Of particular interest is that selective serotonin reuptake inhibitor treatment is shown to decrease the production of the proinflammatory cytokines, tumor necrosis factor-alpha (TNF- α), and interleukin-1 (IL-1). However, depressed people with heightened plasma inflammatory markers respond poorly when treated with antidepressant medications. Studies further found significant elevations of proinflammatory cytokines in symptom severity and manic episodes in medication-free bipolar disorder.

The role of inflammation in depression also extends to posttraumatic stress disorder (PTSD). A strong comorbidity exists between depression and PTSD and people with this comorbidity show higher inflammatory responses than those with PTSD or depression alone. As in depression, the inflammatory marker C-reactive protein was found to be a predictor of PTSD onset in a study of war zone-deployed soldiers. Recent evidence further showed inflammation in PTSD is associated with reduced volume of the hippocampus, a structure that processes memory. The severity of stress and trauma and the association between PTSD and smoking, obesity/metabolic syndrome, and sleep disorders may further exacerbate the activation of immuno-inflammatory pathways in PTSD or comorbid PTSD and depression.

Future research will likely yield insights into the basis of inflammation that promotes the pathophysiology of diverse mental

illnesses. New treatments that reduce inflammation and attenuate the adverse effects of proinflammatory cytokines could have a major impact on alleviating serious psychiatric disorders.

Data from Khandaker GM et al: *Lancet Psychiatry* 2:258-270, 2015; Kiecolt-Glaser JK et al: *Am J Psychiat* 172:1075-1091, 2015; Kirkpatrick B, Miller BJ: *Schizophrenia Bull* 39:1174-1179, 2013; Miller AH, Raison CL: *Nat Rev Immunol* 16:22-34, 2016; Modabbernia A et al: *Biol Psychiatry* 74:15-25, 2013; O'Donovan A et al: *Psychoneuroendocrinology* 51:557-566, 2015.

Increasing evidence from animal models of stress-induced depression shows that depression-like behavior is accompanied by atrophy of neurons in the hippocampus, a reduction in the development of new hippocampal neurons (i.e., **neurogenesis**), and a deficit in hippocampal **brain-derived neurotrophic factor (BDNF)** levels.^{27,28} Consistent with animal studies, human postmortem work indicates low hippocampal BDNF levels in depression. Because the growth factor BDNF supports the survival of neurons and facilitates neurogenesis from hippocampal stem cells, a neurotrophic hypothesis of depression has been proposed as an extension of the monoamine hypothesis of depression to broadly account for the pathophysiologic basis of depression. That is, stress-induced depression and the accompanying reduction in levels of monoamines are caused by deficits in neurogenesis and BDNF levels. Of clinical relevance, administration of antidepressants to animals reverses the depression-like state and increases the development of neurogenesis and BDNF levels.

Hypothalamic-Pituitary-Thyroid System Dysregulation.

Alterations in thyroid function and mental illnesses, particularly major depression and anxiety disorders, have long been recognized. People with hyperthyroidism often manifest symptoms of dysphoria, anxiety, irritability, emotional lability, and cognitive impairments. On the other hand, individuals with severe hypothyroid exhibit features of major depression, apathy, psychomotor slowing, and dementia.²⁹ Notably, although thyroid dysfunction may be linked to symptoms of depression and anxiety, people diagnosed with primary depression

generally have normal thyroid function.³⁰ The causal mechanisms or basis underlying altered thyroid secretion and depression remain to be determined.

Neuroanatomic and Functional Abnormalities

The dorsal and median raphe nuclei, located in the central gray matter of the caudal mesencephalon and rostral pons, contain a large group of serotonin-synthesizing neurons that project extensively to all regions of the cortex, basal ganglia, limbic system, hypothalamus, cerebellum, and brainstem (Fig. 19.6). Postmortem and/or brain imaging studies of depressed individuals revealed a widespread decrease in serotonin 5-HT_{1A} receptor subtype binding in the frontal, temporal, and limbic cortex as well as serotonin transporter binding in the cerebral cortex and hippocampus. Mood disorders in some people may reflect a dysfunctional raphe-serotonin system, which normally modulates homeostasis, emotionality, and tolerance to aversive experiences.

FIGURE 19.6 The Serotonin System. Serotonin neurons are located in the brainstem raphe nuclei. They project diffusely to all regions of the cortex, temporo limbic regions, hypothalamus, basal ganglia, cerebellum, the brainstem, and spinal cord.

A group of norepinephrine-containing cells located in the locus ceruleus of the rostral pons project to vast areas of the forebrain, brainstem, and spinal cord (Fig. 19.7). The locus ceruleus–norepinephrine system is implicated in global psychologic processes including attention, vigilance, and orientation to novel, aversive, or threatening stimuli. Activation of the locus ceruleus–norepinephrine system is also capable of inhibiting the raphe-serotonin system, suggesting an indirect role in modulating serotonin functions. Norepinephrine receptor alterations (e.g., α - and β -adrenergic receptor subtypes) are found in the frontal cortex of some suicide victims with major depression. Alterations in norepinephrine systems may be linked to attention or concentration difficulties as well as sleep and arousal disturbances in depression.

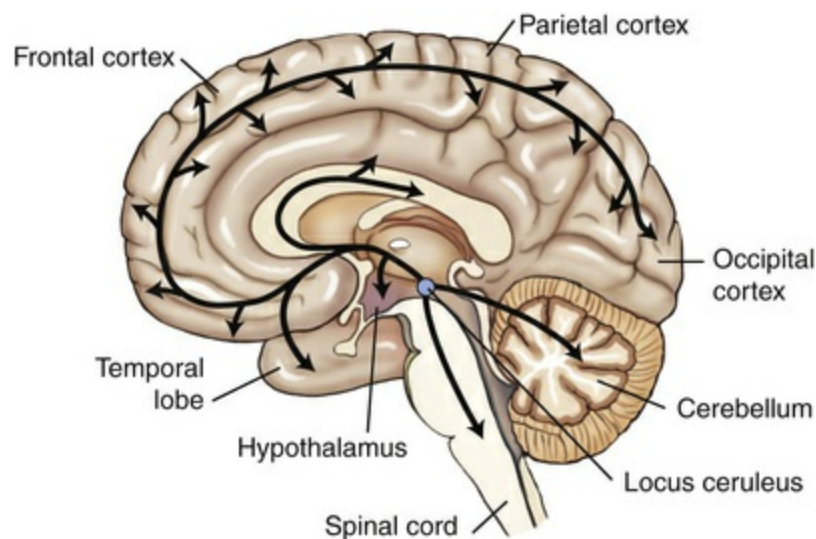

FIGURE 19.7 The Norepinephrine System. The norepinephrine cell bodies originate in the locus ceruleus and project throughout the brain, including the hypothalamus, the temporal lobe, the entire cortex, the cerebellum, and spinal cord.

Functional abnormalities associated with mood disorders are found in frontal and limbic regions such as the amygdala.^{31,32} Postmortem studies report a reduction in glial cell numbers in people with unipolar and bipolar disorders. There are also reports of reduced frontal lobe volume in depressed individuals and decreased or

asymmetric temporal lobe volume in individuals with bipolar illness and depression.

Functional neuroimaging studies indicate decreased cerebral blood flow and glucose metabolism in the dorsolateral and dorsomedial prefrontal cortex of individuals affected by major depression or bipolar disorder. Dorsolateral prefrontal abnormalities in depression may be responsible for the retardation in cognitive processing and speech deficits similar to those found in schizophrenia. Dorsomedial frontal dysfunction may be associated with mnemonic and attentional impairments that accompany mood disorders. Other frontocortical regions, including the ventrolateral, ventromedial, and orbital areas, exhibit increased blood flow and metabolism in unipolar depression (Fig. 19.8). These frontal brain areas have extensive interconnections with the amygdala, and increased blood flow and metabolism, especially in the right amygdala, are positively related to negative affect in depressed individuals. These functional changes in brain activity begin to normalize with successful antidepressant treatments, suggesting they are state rather than trait related.

FIGURE 19.8 Positron-Emission Tomography (PET) Comparison of Brain Activity in Depression and in Remittance. PET scan showing increased activity in the left prefrontal cortex in a depressed person but not in the remitted person. *VLPFC*, Ventrolateral prefrontal cortex. (From Drevets WC et al: *J Neurosci* 12:3628, 1992. Copyright ©1992 by the Society for Neuroscience.)

Hippocampal volume reduction in major depression is a widely reported finding, especially in people with a history of recurrent major depression.³³ Similar to the hippocampus, the amygdala is reduced in volume after experiencing a number of major depression episodes and a family history of depression, albeit enlarged in first episode depression.³⁴ The cumulative effects of stress may be responsible of a reduction in hippocampal and amygdala volume.

MRI studies showed increased volume of the amygdala in bipolar illness and larger lateral ventricles in people suffering multiple bipolar episodes compared to those with only a single episode or healthy controls.³⁵ Ventricular enlargement suggests progressive brain tissue loss resulting from multiple bipolar episodes.

The Glutamate System.

Because of the delayed onset of action of current antidepressants and poor remission rates, investigators are constantly searching for new drugs with novel mechanisms of actions. An emerging body of evidence suggests that elevated cortical levels of glutamate, the major excitatory neurotransmitter in the central nervous system, may be involved in the pathophysiology of major depression. A potential promising target is the glutamate *N*-methyl-D-aspartate (NMDA) receptor. At nontoxic doses, the glutamate receptor antagonist ketamine was found in animal models to rapidly increase synaptic density and signaling in cortical neurons. Of clinical relevance, a few studies reported ketamine was effective in inducing rapid but transient antidepressant effects in treatment-resistant depressed people.^{36,37} Further research on unraveling the mechanism of action of ketamine and on the long-term safety and efficacy of ketamine will be required before this drug can be recommended as an alternative innovative treatment for depression.

◀Clinical Manifestations

Depression

Major **depression** is characterized by unremitting feelings of sadness and despair (see [Box 19.2](#)). The **dysphoric mood** or intensely painful mood is accompanied frequently by insomnia, loss of appetite and body weight, and reduced interest in pleasurable activities and interpersonal relationships. Sleep disturbances may include difficulty in initially falling asleep and awakening in the middle of the night, lying awake for several hours with an inability to subsequently fall asleep. Individuals may have reduced motor activity and suffer

marked fatigue. Others complain of restlessness and agitation. Feelings of worthlessness and guilt are common, and pessimistic or negative outcomes are often perceived even in routine situations. The ability to function (e.g., work) and concentrate is greatly diminished. Depressive episodes may occur or recur suddenly or gradually and continue from a few weeks to months, and 20% may exhibit a chronic form of depression.

Suicidal risk increases in depression. Factors such as living alone or being divorced, having a prior history of drug abuse or suicide attempt, or having depression at midlife or older ages contribute to suicide in 10% to 15% of depressed individuals.

Bipolar Disorder: Mania

Manic individuals experience elevated levels of euphoria and self-esteem and feelings of grandiosity. Energy levels are greatly enhanced even after only a few hours of sleep each night. The increased energy, however, does not lead to organized plans and thoughts. The individual may show poor judgment in spending money, may become hypersexual, or may make poor business commitments. Other hallmarks of mania are excessive, rapid, loud, and pressured speech. The manic person frequently skips from one topic of conversation to another and is easily distracted both when speaking and when performing tasks. Approximately 50% of manic individuals develop psychotic symptoms, such as delusions or hallucinations, which require hospitalization. The onset and termination of manic symptoms (see [Box 19.2](#)) are usually abrupt and may last for a few days or months followed by depression. The risk of recurrence of bipolar disorder is high, especially without immediate treatment.

◀Treatment

Depression

Approximately 80% of depressed persons will respond to antidepressant drugs such as MAOIs, TCAs, and SSRIs ([Table 19.2](#)); psychotherapy; or a combination of both treatment modalities.

Although SSRIs have become the standard first-line treatment for major depression, initial selection of an antidepressant often includes an assessment of the person's symptoms and age as well as the side effects, safety, cost, and convenience of the prescribed medication. For example, medications that produce sedation may be helpful for the treatment of sleep disturbances. Approximately 50% of depressed individuals may not show a favorable response during initial treatment to an antidepressant drug, and 10% to 20% may continue to exhibit symptoms after 2 years. Individuals who are nonresponsive to a specific antidepressant during a 2-month period may be given another antidepressant medication. Atypical antidepressants, such as nefazodone, trazodone, and mirtazapine, presumably produce their clinical effects by blocking specific receptors (e.g., 5-HT_{2A}). A new generation of antidepressants that selectively block serotonin and norepinephrine reuptake is available in the United States (e.g., venlafaxine) and Europe (i.e., milnacipran, reboxetine). At present, there are no criteria to determine whether selection of the next antidepressant will be efficacious. Among children and adolescents, only fluoxetine is currently approved for use in children by the U.S. Food and Drug Administration (FDA)³⁸ (Box 19.2).

TABLE 19.2

FDA-APPROVED MEDICATIONS USED IN THE TREATMENT OF DEPRESSION AND ANXIETY DISORDERS

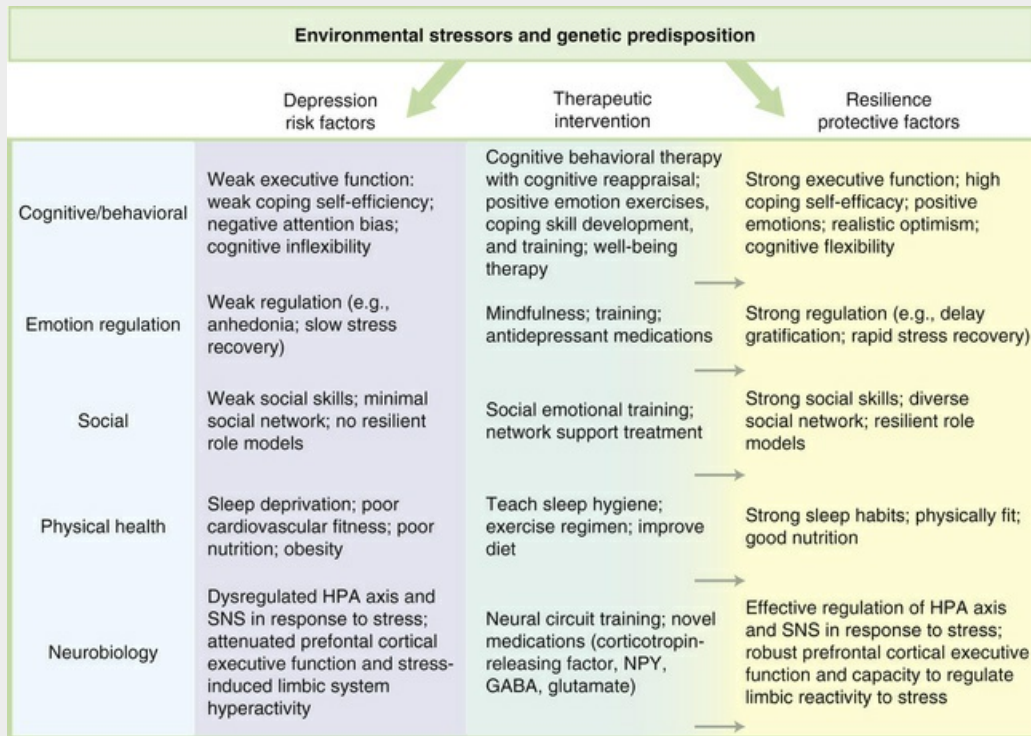

GENERIC NAME	BRAND NAME
Monoamine Oxidase Inhibitors	
Isocarboxazid	Marplan
Phenelzine	Nardil
Tranlycypromine	Parnate
Selegiline	Emsam
Tricyclics	
Amitriptyline	Elavil, Endep, Levate
Amoxapine	Asendin
Clomipramine	Anafranil

Desipramine	Norpramin, Pertofrane
Doxepin	Adapin, Sinequan
Imipramine	Tofranil
Maprotiline	Ludimil
Nortriptyline	Aventyl, Pamelor
Protriptyline	Vivactil
Trimipramine	Surmontil
Selective Serotonin Reuptake Inhibitors	
Citalopram	Celexa
Escitalopram	Lexapro
Fluoxetine	Prozac
Fluvoxamine	Luvox
Paroxetine	Paxil
Sertraline	Zoloft
Serotonin and Norepinephrine Reuptake Inhibitors	
Desvenlafaxine	Pristiq
Duloxetine	Cymbalta
Levomilnacipran	Fetzima
Venlafaxine	Effexor, Effexor XR
Serotonin Reuptake Inhibitor and 5-HT_{1A} Receptor Partial Agonist	
Vilazodone	Viibryd
Norepinephrine and Specific Serotonergic Modulator	
Mirtazapine	Remeron
Norepinephrine–Dopamine Reuptake Inhibitor	
Bupropion	Wellbutrin, Zyban
Serotonin Modulator	
Nefazodone	Serzone
Trazodone	Desyrel, Oleptro
Vortioxetine	Trintellix

Box 19.3

Comprehensive Treatment of Risk Factors

May Promote Resilience and Rapid Recovery From Depression

From Southwick SM, Charney DS: *Science* 338(6103):79-82, 2012.

Genetic and environmental factors, such as uncontrollable stress, interact to increase the risk of developing major depression. These factors interact in complex ways that are not fully understood to dysregulate neurobiologic systems that compromise adaptive cognitive, emotional, social, and physiologic/health functions. For example, exaggerated stress-induced arousal of sympathetic and neuroendocrine systems may be due, in part, to genetic polymorphisms in serotonin, endocrine, and neuropeptide systems. However, the extent to which a genetic predisposition contributes to severe depression also may arise from the individual's inability to cope with stressors, inexperience in exhibiting flexible psychosocial and emotional skills, and lack of physical health, among others. Identifying and addressing these varied genetic and

cognitive/behavioral/socioemotional/health risk factors of depression may open new doors to effective treatment. In particular, combined treatments or behavioral programs that promote resilience, the ability to recover from adversity—such as cognitive-behavioral therapy; social support; and improved diet, sleep, and exercise used in conjunction with current or novel drug medications that lessen or reverse the neuropathophysiology associated with heightened activation of stress systems—may quickly lead to remission. Although in its early stages, the development of comprehensive resilience programs holds promise not only for treating depressed individuals but also for proactively serving to diminish or prevent the risk of acquiring stress-related disorders.

GABA, Gamma-aminobutyric acid; *HPA*, hypothalamic pituitary adrenal axis; *NPY*, neuropeptide Y; *SNS*, sympathetic nervous system.

Data from Karatsoreos IN, McEwen BS: *Trends Cogn Neurosci* 15(12):576-584, 2011; Southwick SM, Charney DS: *Science* 338(6103):79-82, 2012.

In bipolar depression, antidepressant medications may lead to cycle acceleration or induction of mania. However, SSRIs and bupropion may be less likely to induce these effects than MAOIs or TCAs.

A number of side effects are reported with MAOIs, TCAs, and SSRIs. Commonly reported side effects of MAOIs include sedation or agitation, insomnia, dry mouth, impotence, and weight gain. MAOIs also may induce acute and heightened elevations in blood pressure (e.g., hypertensive crisis) after intake of tyramine-rich foods, such as aged cheeses, sour cream, pods of broad beans, pickled herring, liver, canned figs, raisins, and avocados. In addition, MAOI interactions with TCAs, SSRIs, stimulants, and over-the-counter flu medications are dangerous and should be avoided. Because of these adverse side effect issues, MAOIs are used less often than other antidepressants.

TCAs may produce sedation, insomnia, orthostatic hypotension, seizures, and weight gain. Some TCAs have moderate anticholinergic

side effects, including constipation, urinary hesitancy or retention, dry mouth, blurred vision, and memory impairment. These side effects may be an issue when considering TCA treatment of older adults, in which case the TCAs desipramine and nortriptyline may be preferred because of their reduced anticholinergic, cardiovascular, and sedating effects.

Common side effects of SSRIs include sleep disturbances (e.g., insomnia) and nausea. However, agitation, allergic skin reactions, dry mouth, anxiety, altered appetite, and sexual dysfunction have been reported. Unlike MAOIs and TCAs, SSRIs do not have pronounced effects on the cardiovascular or cholinergic systems. SSRIs are potent inhibitors of cytochrome P-450 isoenzymes, which are involved in drug metabolism. Therefore SSRIs may lead to dangerous elevations in blood concentrations of other psychiatric medications when taken together. SSRIs should not be taken with MAOIs or immediately after discontinuing MAOI treatment. A serotonin syndrome characterized by excitement or autonomic hyperactivity, abdominal pain, rigidity, and hyperthermia may develop, leading to coma or death.

Side effects of atypical antidepressants may include sedation, dry mouth, weight gain, and constipation. Nefazodone and trazodone have been associated with hepatic toxicity. Venlafaxine and reboxetine lack many of the serious side effects associated with TCAs; however, sweating, dry mouth, and some sedation may occur. Electroconvulsive therapy (ECT) may be used when individuals fail to respond to antidepressants or when they are severely depressed, pregnant, suicidal, or psychotic. ECT effectively alleviates depressive symptoms in about 50% to 80% of people, who may then begin to respond to antidepressant medications. Recent work suggests that ECT increases the volume of the hippocampus and amygdala, brain structures linked to emotion, mood, and cognitive functions.³⁹ Depressed people with relatively small hippocampal volumes were most likely to show hippocampal volume increases and improved clinical response after ECT. Neurotrophic processes activated by ECT, including neurogenesis, may underlie these structural changes and clinical benefits.

Deep brain stimulation (DBS) is another treatment showing promise to alleviate major depression in people resistant to current antidepressant medications, ECT, and psychotherapy.^{40,41} The treatment involves implanting electrodes during neurosurgery into brain regions such as the subcallosal cingulate gyrus (SCG [Brodmann area 25 and parts of 24 and 32]) and the nucleus accumbens.⁴² This SCG region was targeted because abnormal SCG brain activity, a suggested pathophysiologic cause of major depression, is reversed by effective antidepressant treatment. A 3- to 6-year follow-up study of 20 treatment-resistant depressed individuals who received DBS in the SCG found that more than half eventually returned to work and improved their quality of life.⁴³ Preliminary work with DBS in the nucleus accumbens, a region involved in rewarding experiences, was shown to reverse treatment-resistant depression in people unresponsive to pharmacotherapy, psychotherapy, and ECT.⁴² Pathophysiology in the nucleus accumbens may be linked to impairments in reward processing and underlie the anhedonic symptom of depression. Preclinical studies suggest that the mechanism responsible for reversing the anhedonic state of depression is caused by the rapid increase in monoamine release in the prefrontal cortical areas following DBS stimulation in the nucleus accumbens.⁴⁴

Another therapy for treatment-resistant depression is transcranial magnetic stimulation (TMS). This FDA-approved treatment involves noninvasive focal brain stimulation—unlike DBS, which requires neurosurgery, or ECT seizure induction. The procedure uses an electromagnetic coil to create a magnetic field that passes from the scalp to the brain, where the electrical current flow stimulates neurons. Daily repeated left prefrontal TMS was shown to induce acute antidepressant effects with few side effects and remission in 30% to 40% of depressed people.⁴⁵

A weakness of many antidepressant treatments is that, even among individuals who receive the gold standard of antidepressant pharmacotherapy with psychotherapy, at least 50% of people who recover from a first episode of depression will, nonetheless,

experience another one or more depression episodes in their lifetime (see [What's New? Are Nutraceuticals Effective in the Treatment of Depression?](#)). The recurrence rate of depression increases to approximately 80% in those with a history of two episodes.⁴⁶ One contributing factor for relapse is the failure of people to continue with their treatment plan by stopping their therapy sessions or drug medications. Another related factor is low social support and perceived loneliness. Studies reported low social support predicts poor response to depression treatment, early drop-out, and heightened risk of relapse.^{47,48} Interventions aimed at increasing social interactions may prove to be valuable in reducing depression symptoms and relapse.⁴⁹

What's New?

Are Nutraceuticals Effective in the Treatment of Depression?

Although many pharmacologic medications were developed to treat depression, effective therapeutic drugs remain a challenge. Recent interest has begun to focus on alternative treatments, such as nutraceuticals or pharmaceutical-grade nutrients, which have the potential to modulate neurochemical systems involved in depression without adverse side effects. For instance, some studies reported beneficial effects of zinc supplementation as an adjunct to antidepressant treatment. Zinc is an essential trace element and serves diverse functions, such as growth, development, immune response, neurotransmission, and hormone storage and release. In the brain, zinc is found in glutamatergic neurons that modulate the circuitry involving the cortex, amygdala, and hippocampus to affect mood and cognitive functions. Serum zinc is reduced in major depression, which may contribute to the symptomatology and pathophysiology (e.g., monoamine deficiency, inflammation, stress hormone hypersecretion) of the disorder. Zinc deficiency also may serve as a state marker and risk factor of treatment-resistant

depression. Another nutraceutical of considerable interest in the treatment of major depression is the omega-3 polyunsaturated fatty acid (n-3 PUFA) eicosapentaenoic acid (EPA). Omega-3 fatty acids are well known to be derived through consumption of fatty cold-water fish. Studies reported that omega-3 fatty acid deficiency is associated with depression and omega-3 fatty acid supplementation alone or as an adjunct to antidepressant medications may be more effective in the treatment of depression than placebo or antidepressant medication. Of interest, a subset of depressed people with high inflammation biomarkers (e.g., IL-6, high-sensitivity C-reactive protein) are more likely to benefit from EPA than placebo. Omega-3 fatty acids are known to suppress cytokine production, and their antiinflammatory effects may contribute to the efficacy of EPA treatment in depressed people with high inflammatory biomarkers. Zinc and omega-3 fatty acids are two from a growing list of potential nutraceuticals, including S-adenosylmethionine, tryptophan, and vitamin D₃, which are generally well tolerated with low dropout rates. Data from large-scale studies that reliably replicate the antidepressant effects of nutraceuticals for depression are needed.

Data from Hegarty B, Parker G: *Curr Opin Psychiatry* 26:33-40, 2013; Rapaport MH et al: *Mol Psychiatry* 21:71-79, 2016; Sarris J et al: *Am J Psychiatry* 173:575-587, 2016; Swardfager W et al: *Neurosci Biobehav Rev*, 37:911-929, 2013.

Bipolar Disorder

FDA-approved treatments are available for bipolar disorders.⁵⁰ Individuals with bipolar I disorder are usually treated with lithium, the first choice of treatment to control mania and rapid cycling and to reduce the risk of suicide. In some cases, lithium in combination with SSRIs is used to treat bipolar disorder. In addition to lithium, several medications are used, including anticonvulsants (e.g., carbamazepine, valproate, gabapentin, lamotrigine, or topiramate) or atypical antipsychotics (e.g., clozapine, risperidone, ziprasidone, quetiapine, or a combination of olanzapine with the SSRI fluoxetine). Some bipolar

individuals benefit from thyroid augmentation (levothyroxine). As in depression, ECT is administered when manic individuals fail to respond to medication, are pregnant, or have cardiovascular disease.

Frequently reported side effects of lithium treatment include increased thirst, tremors, diarrhea, and weight gain, which diminish over time. A potentially serious side effect is lithium toxicity. Lithium is normally removed from the kidneys; however, when the body is sodium depleted, the kidneys will reabsorb sodium along with lithium. Individuals receiving lithium treatment are advised to avoid physically demanding activities that may dehydrate the body and to seek medical attention during fever or other conditions that may increase sweating. Anticonvulsant treatment may produce unsteadiness, dizziness, tremors, nausea, and blurry vision.

In addition to pharmacotherapy, psychotherapy can be beneficial for those who have difficulty with psychosocial stressors, such as low self-esteem, legal problems, fear of recurrence, and interpersonal conflicts. Treatment is effective when the individual becomes aware of the bipolar disorder, copes with psychosocial stressors, engages in drug compliance, and monitors symptom recurrences.

Unlike treatment of mania in bipolar I disorder, a major focus in the treatment of bipolar II disorder, the less severe form of mania, is on the recurrent depressive symptoms. Here, antidepressants alone (e.g., escitalopram, fluoxetine, venlafaxine) are reported to be effective in treating bipolar II disorder.

The treatment of bipolar II in children has raised concerns because of complications with its diagnosis. For example, bipolar II and attention-deficit/hyperactivity disorder (ADHD) share the common features of elevated behavioral activity levels, excessive talking, restlessness, and distractibility. Misdiagnosing bipolar II as ADHD has negative consequences for treatment because the stimulant drugs Ritalin and Adderall, which are frequently used to treat ADHD, will potentially exacerbate the symptoms of a child with bipolar II disorder. On the other hand, when ADHD is misdiagnosed as bipolar disorder, the child may begin an ineffective treatment regimen. To reduce misdiagnosis of children with bipolar and other similar

symptomatic characteristics, such as ADHD as well as conduct disorder and oppositional defiant disorder, the *DSM-5*¹⁸ now includes a category called *disruptive mood dysregulation disorder*. This diagnosis will be used to describe a young child (6 to 10 years of age) who exhibits only some of the symptoms of bipolar II, such as frequent temper outbursts, irritability, and bad moods. This category is hoped to exclude children from being diagnosed with bipolar disorder and reduce possible unwarranted treatment with strong medications.⁵¹

Anxiety Disorders

Fear and anxiety are normal feelings expressed in threatening or harmful situations. The symptoms may include arousal, tenseness, and increased autonomic activity such as heart rate, blood pressure, and respiration. In addition, individuals often engage in protective behavioral responses such as flight or avoidance. These physiologic and behavioral responses allowed humans to adapt and cope under a variety of situational challenges. However, when fear and anxiety become too intense and undermine the ability to function on a daily basis, the individual may develop an anxiety disorder. **Anxiety disorders** are the most prevalent psychiatric illness, occurring in approximately 10% to 30% of the general population. Notably, many individuals with anxiety disorders develop major depression, and the high comorbidity of anxiety disorders and depression suggests a common neural pathophysiologic basis linking these two mental illnesses. This section presents an overview of several anxiety disorders, including panic disorder, social anxiety disorder, generalized anxiety disorder, and posttraumatic stress disorder, which in *DSM-5* is listed in the chapter on Trauma- and Stressor-Related Disorders.¹⁸

Panic Disorder

Panic disorder consists of multiple disabling panic attacks and is characterized by intense autonomic arousal involving a wide variety

of symptoms, including lightheadedness, a rapid heart rate (tachycardia), difficulty breathing, chest discomfort, generalized sweating, general weakness, trembling, abdominal distress, and chills or hot flashes. Between panic attacks the individual often worries about future panic attacks and fear of losing control and dying. Symptoms originally occur spontaneously and vary in length from several minutes to an hour.

A notable complication of panic disorder is the development of **agoraphobia** or phobic avoidance of places or situations where escape or help is not readily available. The agoraphobic individual will avoid being away from home, standing in line or in a crowd, or traveling in a train, plane, or automobile. Severely agoraphobic individuals become housebound.

◆ Etiology and Pathophysiology

Genetic factors play a major role in panic disorder. The risk is nearly 20% among first-degree relatives, and the prevalence of panic disorder is about 1.5% in men and up to 3.0% in women with no family history of the illness. Some studies suggest that the cholecystokinin (CCK) receptor gene on chromosome 11p may be linked to panic disorder.⁵²

The etiology of panic disorder is not known, but the ability to elicit physical symptoms of panic attacks by chemicals, called *panicogens*, provides insight into its pathophysiology. Panic-prone individuals respond to panicogens that include carbon dioxide, caffeine, cholecystokinin, sodium lactate, and adrenergic receptor agonists, such as yohimbine. Carbon dioxide and sodium lactate, two well-studied panicogens, alter brain pH balance that panic-prone people are sensitive in detecting. Brain pH chemosensors are located in the brainstem medulla and pons, the midbrain serotonergic raphe neurons, the hypothalamus, and the amygdala. Heightened pH sensitivity in the amygdala may play a key role in generating fearful perceptions and activating the cerebral cortex and neural circuits in the temporal lobe and brainstem, which further facilitates the production of panic symptoms (see Figs. 19.7 and 19.9).⁵³ Exaggerated activation of physiologic and behavioral arousal stemming from the

noradrenergic locus ceruleus neurons also may enhance the symptoms of panic. Thus panic-prone people appear especially sensitive in detecting pH alterations in brain sites that modulate fear and arousal.

FIGURE 19.9 The Limbic System. Structures of the limbic system play important roles in emotion, learning, and memory. Pathophysiology in limbic structures is frequently found in mental disorders.

Panic disorder also may involve the GABA-benzodiazepine (BZ) receptor system. BZ increases the GABA_A ion channel response to GABA, thereby elevating chloride ion influx and producing a neuronal inhibitory effect. Brain imaging work reveals a reduction in BZ receptor binding in brain regions including the hippocampus, insular, and prefrontal cortex.⁵⁴ Drugs that block the benzodiazepine receptor are reported to increase panic attacks and feelings of anxiety, suggesting that an alteration in inhibitory neuromodulation contributes to panic disorder.

◆ Treatment

Up to 80% of individuals affected by panic disorder respond to CBT and antidepressant drugs, either separately or in combination. In CBT, the individual learns that the physical symptoms are not fatal and attempts to exert control over the anxiety and panic. For example, breathing exercises to control hyperventilation serve to lessen the intense physiologic symptoms of panic, such as elevated heart and respiration rates. Another benefit of CBT is awareness of compliance with drug medications. However, for individuals with mild agoraphobia, CBT alone may be effective.

Antidepressants such as SSRIs are considered first-line medications for panic disorder. Among the SSRIs, paroxetine and sertraline have received FDA approval specifically for panic disorder. Venlafaxine, a serotonin-norepinephrine reuptake blocker, also is effective.

BZs, such as alprazolam and clonazepam, are other medications for treating panic disorder. These drugs also serve as an adjunct or augmentation therapy for individuals who do not fully respond to SSRIs. Short-term effects of BZs include sedation, ataxia, and cognitive impairments. Long-term BZ treatment may lead to potential physiologic and psychologic dependence. Abrupt BZ withdrawal induces a withdrawal syndrome of heightened reemergence of anxiety, insomnia, photophobia, and diarrhea. A gradual reduction in BZ medication or adjunct CBT may reduce the reliance and withdrawal symptoms of BZs.

Social Anxiety Disorder

Social anxiety disorder (SAD), also known as *social phobia*, is characterized by fear and avoidance of social situations. For example, the anxious person may feel very uncomfortable having a conversation or interacting with others and very conscious of being scrutinized and humiliated or rejected by others. A person diagnosed with SAD suffers significant distress or impairment that interferes with ordinary routines in everyday social settings, at work or at school.¹⁸ Epidemiologic surveys indicate that SAD is one of the most common psychiatric disorders with 12-month and lifetime prevalence rates of 6.8% and 12.1%, respectively.⁵⁵ The onset of SAD often occurs

during adolescence.⁵⁶ As with adults, children with SAD exhibit fear of speaking, reading, and eating in public; going to parties; speaking to authority figures; and engaging in informal social interactions.

• Etiology and Pathophysiology

A prominent finding from brain imaging work with SAD people is the increased activity found in limbic and frontal cortical areas. Exposure to facial expressions of threat, which hypersensitive SAD people are likely to perceive as extreme dislike, rejection, or criticism, often implicates the amygdala and its connections to other brain regions. Heightened anxiety in SAD may arise from deficits in an inhibitory tone from prefrontal cortical areas to the amygdala resulting in increased amygdala activation and a fear bias in threat-related processing.⁵⁷ Support of abnormal signaling comes from work showing decreased white matter connectivity between amygdala and orbitofrontal cortex.⁵⁸

Neuroimaging studies have also implicated neurotransmitter systems. One study in SAD people noted altered serotonergic neurotransmission,⁵⁹ which may be caused by a reduction in the serotonin 5-HT_{1A}-binding protein in the amygdala, anterior cingulate, and insula. Another study found a reduction in GABA in the thalamus of SAD people.⁶⁰ Impaired GABAergic function may contribute to amygdala hyperactivity observed in SAD.

The neuropeptide oxytocin (OXT) has attracted considerable research attention. OXT is produced in the hypothalamic paraventricular and supraoptic nuclei and secreted by the posterior pituitary gland. OXT is well known to be secreted during childbirth and lactation. In addition, an increasing body of work indicates that OXT secretion has antianxiety effects by reducing HPA activation; promoting social, attachment, and maternal behavior; and increasing empathy and trust.

Of relevance to SAD, OXT plasma levels are reduced in SAD people before and after playing a trust game, which normally increases OXT levels and promotes cooperation and reciprocation in control groups.⁶¹ The reduction on OXT may account for the amygdala hyperactivity

accompanied by excessive social avoidance and fear in SAD.⁶² Indeed, intranasal OXT administration is reported to attenuate amygdala reactivity to threatening facial expressions,⁶³ perhaps by promoting GABAergic inhibition in the amygdala.⁶⁴ Intranasal OXT also improves self-reported speech performance compared with placebo.⁶⁵ The oxytocin system is further implicated in SAD on a genetic level. An OXT receptor single nucleotide polymorphism was found to be associated with negative emotionality⁶⁶ and moral judgments.⁶⁷ On the basis of these studies, the oxytocin system is a promising target to potentially develop treatments for SAD and disorders related to social dysfunctioning, such as autism.⁶⁸

◀ Treatment

The antidepressant SSRIs that include fluoxetine, paroxetine, sertraline, and fluvoxamine along with the serotonin norepinephrine reuptake inhibitor (SNRI) venlafaxine are considered first-line pharmacotherapies for SAD. These drugs shared similar efficacy profiles and are approved by the FDA for treatment of SAD. However, drug-related side effects, such as agitation and sexual dysfunction, can be distressing for some SAD people. Also, discontinuation of medication increases the risk for relapse. One study reported that 60% of people with SAD relapsed after discontinuation of sertraline treatment.⁶⁹

Alternatives to SSRI and SNRI treatments may include psychologic or cognitive and group behavioral therapies.^{70,71} People with SAD are reported to respond well to CBT compared to placebo. The choice between pharmacotherapy and CBT may depend on the person's preference and access to treatment. Of note, psychologic interventions at the end of acute drug treatment appear beneficial in continuing to alleviate the symptoms of SAD and may lower the side effects of long-term drug treatment.

Generalized Anxiety Disorder

Excessive and persistent worries are the hallmarks of **generalized**

anxiety disorder (GAD). The individual worries about life events such as marital relationships, job performance, health, money, or social status. The lifetime prevalence rates of GAD range from 4.1% to 6.6%, with somewhat higher rates in women than in men. GAD usually emerges in the early twenties, but can occur in childhood. Six major symptoms of GAD have been identified and include restlessness, muscle tension, irritability, being easily fatigued, difficulty concentrating, and difficulty sleeping. The individual startles easily and frequently suffers from depression and panic attacks. The severity of symptoms fluctuates over time and may be linked to the changing nature of stress. Although GAD tends to be chronic, the symptoms may lessen with age. A frequent complication of GAD is substance abuse, which may result from self-medication with alcohol or drugs to relieve anxiety symptoms.

◆ Etiology and Pathophysiology

Female twin studies suggest a concordance rate of 30%, but disease genes linked to specific chromosomes have yet to be identified. Abnormalities in the norepinephrine and serotonin systems were reported in GAD.⁷² For example, there is a reduction in α_2 -adrenergic receptor binding, a decrease in serotonin levels in CSF, and reduced platelet binding of paroxetine, an SSRI. Another reported alteration in GAD is a reduction of BZ binding in the left temporal hemisphere.⁷³

Two functional magnetic resonance imaging (fMRI) studies have revealed alterations in specific brain regions in adults and adolescents with GAD. One study in GAD adults showed that increased anticipatory anxiety was associated with elevated cingulate cortex activity, and both the heightened anxiety and cingulate cortex activation were reduced after 8 weeks of treatment with venlafaxine, a serotonin and norepinephrine reuptake inhibitor.⁷⁴ This study suggests that a decrease in pathophysiologic cingulate cortex activity is a predictor of GAD treatment efficacy. In children and adolescents with GAD, brief exposure to masked angry faces induced heightened right amygdala activation, which correlated positively with severity of anxiety.⁷⁵ This study underscores the role of abnormal amygdala

activity in attentional bias or vigilance to threats in GAD.

◀Treatment

GAD is diagnosed when a person spends at least 6 months worrying excessively and engages in at least three of the six major symptoms.¹⁷ 5-HT/norepinephrine (NE) reuptake inhibitors, such as venlafaxine or the SSRIs paroxetine and escitalopram, have become first-line therapeutics for managing GAD. These medications may produce relief of GAD symptoms within 1 week and are effective in treating comorbid symptoms of depression. Buspirone, which has an affinity for serotonin receptors (5-HT_{1A}), is another treatment option, although the onset of clinical efficacy may take 2 weeks. The primary side effects of buspirone, which lessen over time, include dizziness, headaches, nausea, and mild nervousness. GAD nonresponders to 5-HT/NE reuptake inhibitors or buspirone may be treated with BZs. However, because GAD tends to be chronic, and comorbid with depression or other anxiety disorders,⁷⁶ BZs are usually limited to uncomplicated cases of GAD. In addition to drug therapy, behavioral therapy is used to acquire relaxation techniques that control anxiety.

Posttraumatic Stress Disorder

Exposure to a terrifying or life-threatening event may produce **posttraumatic stress disorder (PTSD)**.^{77,78} Although the disorder was initially described in combat situations and called “shell shock,” “war neurosis,” or “traumatic neurosis,” PTSD does not develop only from exposure to traumatic experiences in the battlefield. PTSD may develop after exposure to threat of death, serious injury, or sexual violation. The disorder may develop within hours of the traumatic experience or after several months or years. The *DMS-5* criteria for PTSD list four diagnostic clusters described as re-experiencing, avoidance, negative cognitions and mood, and arousal. *Re-experiencing* refers to spontaneous recollection of the traumatic event, recurrent nightmares, flashbacks, or other intense or chronic psychological distress. *Avoidance* refers to distressing memories, feelings, or external

reminders of the traumatic event. *Negative cognitions and mood* may occur from a persistent and distorted sense of blame of self or others, from estrangement from others or diminished interest in activities, or from an inability to remember key aspects of the event. *Arousal* is marked by aggressive, reckless, or self-destructive behavior, sleep disturbances, hypervigilance, or related problems. The “flight” or “fight” behavioral aspects also are associated with the arousing nature of PTSD.

The lifetime prevalence rate of PTSD is 7% to 8%. In men, PTSD is usually found among combat veterans, whereas PTSD in women is often related to rape or assault. Abused children also may develop PTSD. Individuals with a history of psychiatric illness (major depression, panic disorder) or those lacking strong social support appear more sensitive to the effects of traumatic stress.

◆ Etiology and Pathophysiology

The primary etiology of PTSD is exposure to a terrifying life-threatening event and likely involves stress-induced alterations in several neural structures and neurotransmitter systems. The amygdala and prefrontal cortex are highly involved in the pathophysiology of PTSD because these brain structures normally play important roles in how fearful memories are stored, retrieved, and extinguished. Individuals with PTSD who are exposed to trauma-related stimuli generally exhibit increased activity in the amygdala and diminished activity in prefrontal cortical areas. Persistent dysregulation of this fear-based memory system may underlie chronic PTSD—that is, the failure of prefrontal cortical inhibition to control amygdala-induced activation of fear compromises the extinction of fear memory.⁷⁹ Structural brain imaging studies show that combat-exposed PTSD victims also have a smaller hippocampus, a brain structure involved in endocrine functions and memory formation. Pediatric PTSD studies reveal a more generalized effect of trauma on reducing total brain volume. Other brain sites exhibiting increased activity in PTSD are the dorsal anterior cingulate cortex and insula, albeit similar findings were reported in other anxiety disorders (e.g., GAD, obsessive-

compulsive disorder)⁸⁰ (see [What's New? A Stress-Related Protein Kinase in the Prefrontal Cortex Is Downregulated in Posttraumatic Stress Disorder](#)).

What's New?

A Stress-Related Protein Kinase in the Prefrontal Cortex Is Downregulated in Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) develops after exposure to traumatic experiences, such as combat-related trauma, domestic violence, rape, or natural disasters. Although the pathophysiology of PTSD is not fully understood, preclinical and clinical research have identified at least two brain structures, the amygdala and prefrontal cortex (PFC), that are reciprocally connected and suggested to play major roles underlying the debilitating effects of the disorder. The amygdala is necessary in detecting threat and in modulating associative emotional or conditioned fear. Animal and human laboratory studies demonstrate that under normal circumstances one important function of the PFC is to exert an inhibitory influence on amygdala activation of conditioned fear and allow fear extinction to occur. Lessening amygdala activation of the fear experience enables the individual to acquire coping skills. Clinical studies, however, revealed that many PTSD subjects exhibit impairments in prefrontal cortical inhibitory control of amygdala. Thus increased activity in the amygdala is accompanied by uncontrolled recollection of the traumatic experience with heightened fear expression and deficits in fear extinction. The potential mechanism contributing to this pathophysiologic PFC-amygdala connection was not clear until a recent study using whole genome microarray analysis examined the expression of genes in the postmortem PFC of people diagnosed with PTSD. The investigators in this study reported that serum and glucocorticoid regulated kinase 1 (SGK1), a protein kinase involved in cellular

responses to stress, was dramatically down-regulated in the PFC. To support an important function of SGK1 in PTSD, the investigators further demonstrated in an animal model that inhibition of SGK1 in the PFC induced a behavioral phenotype that mimics that effects of traumatic stress. The authors concluded that down-regulation of PFC SGK1 in people may be a major factor responsible for the eventual development of PTSD. Further characterization of SGK1 could lead to a clearer understanding of the molecular pathophysiology of PTSD and development of novel medications for the disorder.

Data from Licznarski P et al: *PLoS Biol* 13(10):e1002282, 2015; Mahan AL, Ressler KJ: *Trends Neurosci* 35:24-35, 2012; Pitman RK et al: *Nat Rev Neurosci* 13:769-787, 2012.

As in panic disorder, BZ binding is altered in PTSD as indicated by a reduced distribution of BZ receptor binding in the prefrontal cortex compared with healthy controls.⁸¹ This reduction in prefrontal BZ receptor distribution was not found in other brain regions.

◀ Treatment

Chronic PTSD lasting for years may occur in 30% of diagnosed individuals. Paroxetine and sertraline are considered first-line SSRI medications for chronic PTSD because of their tendency to lessen the recurrent nightmares and flashbacks and to treat the high accompanying prevalence of depression and substance abuse. Other antidepressants, such as the TCAs (amitriptyline and imipramine), have moderate effects and are second-line drugs; drugs such as nefazodone and bupropion may provide benefits. BZs may be used in the aftermath of a traumatic event to control hyperarousal symptoms such as irritability, insomnia, and muscle tension. However, there is no clear evidence that BZs have clinical efficacy or provide prophylaxis against the development of chronic PTSD, and BZs should be carefully monitored among individuals with a history of drug abuse.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is a chronic, disabling illness characterized by the two core symptoms of obsessions and compulsions. Obsessions are recurrent, intrusive thoughts or impulses that provoke an intense anxiety that leads the individual to perform compulsive repetitive behavioral acts to alleviate the anxiety activated by the obsessions. Although *DSM-5* no longer classifies OCD as an anxiety disorder,¹⁸ obsessions are associated with significant distress and compulsions that are consciously performed to reduce the obsession-related anxiety. OCD is a time-consuming illness that significantly impairs a range of everyday functions, such as social relationships, job performance, and academic success.

Examples of obsessions may include preoccupation with contamination, doubting, religious or sexual themes, or the belief that a negative outcome will occur if a specific act is not performed. Compulsions are ritualized acts such as washing, cleaning, checking, counting, organizing, and repeating specific thoughts or prayers. Performing the compulsions may provide temporary relief of the anxiety but also reinforces the dysfunctional thoughts and neural circuits that underlie the negative obsessions that generate the compulsive anxiety.

The lifetime prevalence rates of OCD range from 2% to 3% with a slightly higher onset in males during childhood or adolescence. In many cases, the OCD individual also is diagnosed with major depression, panic disorder, or GAD.⁸² Among children with OCD, common comorbid disorders include Tourette syndrome, oppositional defiant disorder, attention-deficit/hyperactivity disorder, and depression⁸³; 30% to 50% of adults report experiencing OCD in childhood.⁸⁴

◆ Etiology and Pathophysiology

Family and twin studies demonstrate that OCD involves polygenetic and environmental risk factors.⁸⁵ First-degree relatives of affected adults also are at increased risk (4.6%) of Tourette syndrome and tics

in comparison with control relatives (1%). Thus OCD and Tourette syndrome may share common genes and pathophysiology.

Functional brain imaging studies have identified a pathologic brain circuit consisting of increased metabolism in the anterior thalamus, orbitofrontal cortex, dorsal anterior cingulate cortex, and especially in the basal ganglia (Fig. 19.10) subregions of the caudate and putamen.^{86,87} Abnormalities in caudate volume in OCD also are found using structural neuroimaging techniques. This neural circuit is activated in OCD people by symptom provocation and reduced by effective pharmacotherapy or psychotherapy. Genetic studies further indicate that genes affecting the serotonergic, dopaminergic, and glutamate systems play a major role in the pathophysiologic basis of this OCD neural circuit.⁸⁵

FIGURE 19.10 Basal Ganglion. Structures of the basal ganglion, which include the caudate nucleus, putamen, globus pallidus, and substantia nigra, are important in movement.

One particular abnormality in the neural circuit of OCD is the dorsal anterior cingulate cortex (dACC). Several functional neuroimaging studies reported hyperactivity of the dACC in OCD

people compared to controls. Furthermore, electrophysiologic studies showed altered biomarkers of cognitive control in the dACC. The dACC is hypothesized to be a key center that receives negative emotional and reinforcing information and integrates that information to direct motivated behavior.^{88,89}

◀Treatment

SSRIs, including citalopram, fluvoxamine, paroxetine, and sertraline, are the first drugs of choice for OCD.⁹⁰ Approximately 70% to 80% of OCD individuals show a partial positive response that may be further improved by other medications. For example, clonazepam, a BZ, is found to improve the effects of fluoxetine and clomipramine therapy. The tricyclic antidepressant clomipramine is also used if SSRIs are not effective or are not tolerated by the OCD person. The therapeutic effects of SSRIs and clomipramine may be the result of blocking serotonin reuptake and increasing serotonin availability to postsynaptic receptors to stimulate serotonergic neurotransmission in dysfunctional serotonin neurons in the brain of OCD people.

Antipsychotic drugs (e.g., haloperidol, risperidone, olanzapine, or quetiapine) in combination with SSRIs also are effective, especially in comorbid OCD and tic disorders. Here, the normalization of dysfunctional serotonin and dopamine brain systems in OCD may underlie the therapeutic effects of SSRIs and dopamine receptor-related drugs.

Psychotherapy involves verbal interactions between a therapist and the individual to overcome the mental disorder. Several types of psychotherapy are available, but CBT and response preventive therapy are effective in treating OCD. CBT is a problem-focused, goal-directed, and time-limited treatment of the abnormal learned obsessions and compulsive actions. Response prevention therapy involves exposure to cues that elicit distress followed by preventing the individual from engaging in compulsive rituals for at least an hour or until the anxiety subsides. CBT employing response prevention therapy is found to produce long-term symptom remission.⁹¹

Because of the chronic nature of OCD, treatment in adults may

involve pharmacotherapy, psychotherapy, a combination of pharmacotherapy and psychotherapy, brain modulation, or invasive brain methods.⁹² In children, the American Academy of Child and Adolescent Psychiatry (AACAP)⁹³ recommends a combination of SSRI and CBT for those with moderate or severe OCD. However, recent meta-analysis studies find no strong evidence for the superiority of SSRI and CBT combination treatment in comparison to CBT alone for children with OCD.^{94,95}

In people with severe OCD who are resistant to pharmaco- or psychotherapy, electroconvulsive therapy⁹⁶ and transcranial magnetic stimulation⁹⁷ may be used to provide some relief of OCD symptoms. An alternative, promising treatment for OCD is deep brain stimulation, which also is used for intractable depression.⁹⁷ Deep brain stimulation in the anterior limb of internal capsule, striatum/ventral capsule, nucleus accumbens, subthalamic nucleus, and inferior thalamic peduncle is effective in alleviating some OCD symptoms.^{98,99} Stimulating these brain regions may be reducing abnormal neuronal firing in the neuroanatomic circuitry linked to OCD. The long-term treatment effects of deep brain stimulation are still under investigation.

Another invasive treatment for people with severe treatment-resistant OCD is neurosurgery. One focus of neurosurgery is to disconnect the basal ganglia from the frontal cortex.¹⁰⁰ Dorsal anterior cingulotomy also is used in the treatment of refractory OCD.¹⁰¹ Neurosurgery offers significant relief of obsessions and compulsions in nearly 50% of treatment-resistant OCD individuals.

Summary Review

Schizophrenia

1. Schizophrenia is characterized by thought disorders that reflect a break between the cognitive and the emotional sides of one's personality.
2. Schizophrenic symptoms are classified into positive, negative,

and cognitive categories. Positive symptoms include hallucinations, delusions, formal thought disorder, and bizarre behavior. Negative symptoms include flattened affect, alogia, anhedonia, attention deficits, and apathy. Cognitive symptoms are the inability to perform daily tasks requiring attention and planning.

3. Schizophrenia has a strong genetic predisposition, and environmental factors (e.g., viral infection, nutritional deficiencies, prenatal birth complications, urban upbringing) may interfere with genetically programmed neural development to alter brain structure and function.
4. Brain imaging studies reveal structural brain abnormalities including an enlargement of the cerebral ventricles and widening of the fissures and sulci in the frontal cortex. In addition, there is a reduction in the volumes of both the thalamus, which may disrupt communication among cortical brain regions, and the temporal lobe, which may be responsible for the manifestations of positive symptoms.
5. In schizophrenia the frontal lobe shows a progressive loss in volume and a worsening of negative symptoms despite the use of antipsychotic medications. Blood flow and metabolism are reduced in the dorsolateral prefrontal cortex, which compromises the ability to engage in goal-directed and cognitive problem-solving behavior.
6. Neurochemical abnormalities in dopamine and glutamate systems are found in schizophrenia.
7. The first generation of antipsychotic drugs blocks the dopamine D_2 receptor. The second generation, called atypical antipsychotics, blocks not only D_2 receptors but also dopamine, serotonin, and other neurotransmitter receptors. Antipsychotic medications, however, are not always effective in treating schizophrenic individuals with severe negative symptoms. Talk therapies are used to increase drug compliance and to encourage coping strategies.

Mood Disorders: Depression and Bipolar Disorder

1. Major depression and bipolar disorder are two common mood disorders. Major depression is characterized by an intense and sustained unpleasant state of sadness and hopelessness. In bipolar disorder, individuals show recurrent patterns of depression and mania, the latter characterized by extreme levels of energy and euphoria.
2. Environmental triggers such as psychosocial stress appear to facilitate the onset of depression in individuals with a genetic vulnerability.
3. A reduction in brain monoamine neurotransmission is linked to depression, whereas an elevated monoamine level is associated with mania.
4. Exposure to uncontrollable stress elevates secretion of the stress hormone cortisol, which increases both the secretion of proinflammatory cytokines and the risk of developing depression. Abnormalities involving thyroid hormones also are found in depression.
5. Stress-induced depression is accompanied by deficits in brain-derived neurotrophic factor (BDNF) and neurogenesis in the hippocampus. In animal models, stress-induced depression-like behavior and the accompanying deficits in hippocampal BDNF and neurogenesis are reversed by antidepressant treatment.
6. The frontal lobe and limbic system volumes are reduced in major depression and bipolar illness. In addition, blood flow is altered in prefrontal and limbic brain regions that include the amygdala, a structure implicated in emotional behavior.
7. Pharmacotherapy involves the use of MAOIs, TCAs, SSRIs, and atypical antidepressants. Manic and bipolar individuals are treated with lithium or mood stabilizers. Severely depressed and manic people may be administered ECT. Deep brain stimulation is another promising treatment for intractable depression.

Anxiety Disorders

1. When normal fear and anxiety mental states persist and become uncontrollable, an individual may develop an anxiety disorder. PD, SAD, GAD, and PTSD are examples of uncontrollable fear and anxiety states that require medical attention.
2. Panic disorder consists of panic attacks characterized by intense autonomic arousal that occurs spontaneously and is accompanied by symptoms including lightheadedness, tachycardia, and difficulty breathing. In addition, the intense occurrence of autonomic responses is accompanied by heightened fear and anxiety that often continue between panic attacks.
3. Panic-prone people are sensitive in detecting pH alterations in the amygdala, a brain structure that modulates fear. An activated amygdala recruits the cerebral cortex and neural circuits in the temporal lobe and brainstem, which may further exacerbate symptoms of panic.
4. A reduction in BZ receptor binding in brain regions, including the hippocampus, insula, and prefrontal cortex, also may contribute to the pathophysiology of panic disorder.
5. Panic disorder is generally treatable with CBT and antidepressants such as TCAs and SSRIs. BZs are used as an adjunct or augmentation therapy for individuals who are nonresponsive to SSRIs or TCAs.
6. Social anxiety disorder is a common anxiety disorder that often emerges in adolescence and is characterized by fear and avoidance of social situations. SAD people are very sensitive in being evaluated and embarrassed or rejected by others.
7. Neuroimaging studies in SAD people are revealing abnormal connections between the prefrontal cortex and the amygdala.
8. The neuropeptide oxytocin promotes social behavior, empathy, and trust. Secretion of OXT is reduced in SAD people, and a single nucleotide polymorphism of an OXT receptor gene is

found to be altered in SAD, both of which suggest that OXT plays a major role in the pathophysiology of SAD.

9. SAD treatment may involve SSRI or SNRI drug or cognitive therapies.
10. GAD is characterized by excessive and persistent worries about life events. Individuals exhibit varying levels of motor disturbances, irritability, and fatigue that may be linked to fluctuations in psychosocial stress. Many GAD individuals manifest symptoms of depression.
11. Pathophysiologic changes in the cingulate cortex and amygdala may have prominent roles in stimulating anticipatory anxiety and attentional bias to threats in people with GAD.
12. Treatment of GAD usually involves a combination of behavioral therapy and drug medications, especially 5-HT/NE reuptake inhibitors.
13. PTSD develops after exposure to a life-threatening or traumatic experience. Individuals experience recurring thoughts and flashbacks and nightmares of the terrifying event.
14. In PTSD structural and/or functional alterations exist in the amygdala, prefrontal cortex, and hippocampus, which likely contribute to dysfunction in an emotional fear memory system.
15. Treatment of chronic PTSD is difficult and involves psychotherapy and SSRI pharmacotherapy.

Obsessive-Compulsive Disorder

1. OCD is a chronic illness characterized by irrational obsessions and ritualized acts that impair normal functioning and cause severe distress. It is a chronic disabling illness.
2. OCD is a time-consuming illness, which significantly impairs everyday functions, such as social relationships, job performance, and academic success. Examples of obsessions

- include preoccupation with doubting, religious or sexual themes, or the belief that a negative outcome will occur if a specific act is not performed.
3. A pathophysiologic brain circuit consisting of the anterior thalamus, orbitofrontal cortex, dorsal anterior cingulate cortex, and especially in the basal ganglia subregions of the caudate and putamen is involved in OCD.
 4. OCD requires long-term treatment that may include psychotherapy and pharmacotherapy. However, people with severe OCD who are resistant to these treatments may require neurosurgery to disconnect regions of pathophysiologic brain circuit to provide relief of OCD symptoms. Deep brain stimulation may be another option for uncontrollable OCD.

Brain Tumors, 635

Retinoblastoma, 639

Neurologic disorders in children can arise any time before birth through adolescence and include congenital malformations, genetic defects in metabolism, brain injuries, infection, tumors, and other disorders that affect neurologic structure and function. The symptoms, diagnosis, and management of neurologic disorders in children are often different from those of adults, even with similar disorders.

Development of the Nervous System in Children

Both genetics and environment shape development of the nervous system. Because brain development starts in the first days of embryonic development, maternal factors, including lifestyle, nutrition, exposure to toxins or infection, and state of health, have crucial effects on the developing nervous system.

The nervous system develops from embryonic ectoderm through a complex and sequential process, including (1) formation of the neural tube (3 to 4 weeks' gestation), (2) development of the forebrain from the neural tube (2 to 3 months' gestation), (3) neuronal proliferation and migration (3 to 5 months' gestation), (4) formation of network connections and synapses (5 months' gestation to many years postnatally), and (5) myelination (birth to many years postnatally). Formation of the neural tube begins between 3 and 4 weeks' gestation as the neural plate folds to form a neural groove and neural folds. The neural groove deepens and closes dorsally to form the **neural tube**, which gives rise to the entire central nervous system (CNS). The neural tube closes first in the cervical region and then “zippers” in two directions—cranially and caudally (Fig. 20.1).

FIGURE 20.1 Neural Tube at 3 Weeks' Gestation. Neural folds have begun to fuse at the cervical level of the future spinal cord. *Right*, Cross sections of the neural tube at four different levels; at any given level the embryonic central nervous system (CNS) goes through a series of stages resembling these four cross sections. Total length of neural tube at this time is about 2.5 mm.

The caudal end of the neural tube forms the brain, and the remainder develops into the spinal cord. The lumen of the neural tube becomes the ventricles of the brain and the central canal of the spinal cord (Fig. 20.2). Some neuroectodermal cells separate from the neural tube but remain between the tube and the surface ectoderm, creating the **neural crest**. This cellular band develops into the *peripheral nervous system*. On either side of the neural tube's inner surface is a longitudinal groove (**sulcus limitans**). Anterior to this region (**basal plate**) the gray matter differentiates into the nuclei of the lower motor neurons. The region posterior to the sulcus (**alar plate**) differentiates into the sensory nuclei of the spinal cord.

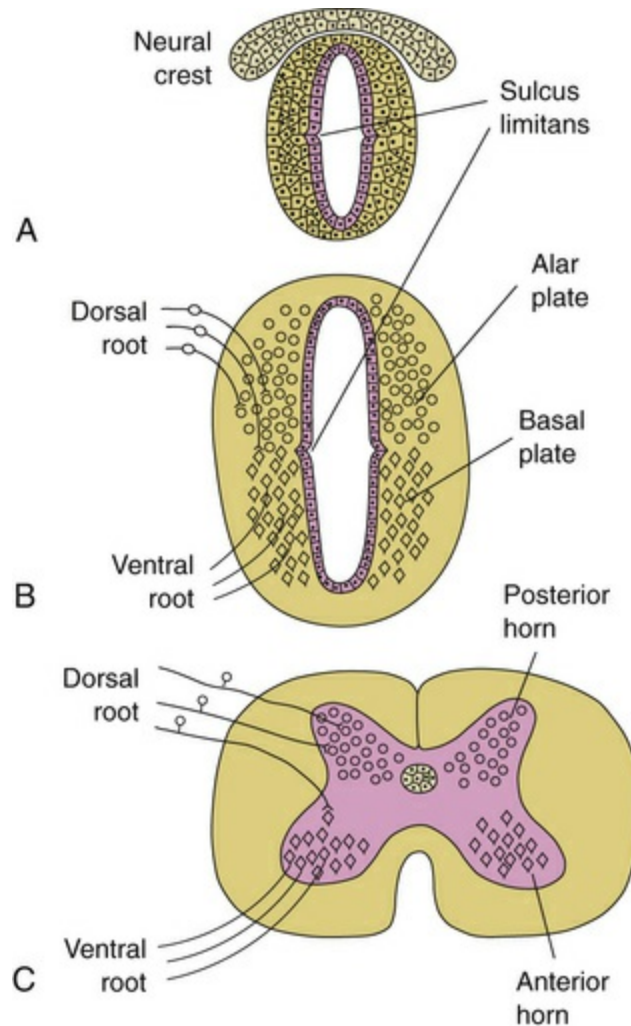

FIGURE 20.2 Sulcus Limitans and Alar and Basal Plates. A, Neural tube during the fourth week of gestation. B, Embryonic spinal cord during the sixth week of gestation; dorsal root ganglion cells, derived from the neural crest, send their central processes into the spinal cord to terminate mainly in alar plate cells; basal plate cells become motor neurons, whose axons exit in the ventral roots. C, Adult spinal cord.

The growth and development of the brain occurs rapidly during the third and fourth months of gestation and again from the fifth month of gestation through the first year of life, reflecting the proliferation of neurons and glial cells. Although most of the neurons that an individual will have are present at birth, development of skills, such as walking, talking, and thinking, depends on these neurons making correct connections with other neurons and on myelination of the axons making those connections. The head is the fastest-growing body part during infancy. One half of postnatal brain growth is achieved by

the first year and is 90% complete by age 6 years. The cortex thickens with maturation and the sulci deepen as a result of rapid expansion of the surface area of the brain. Cerebral blood flow and oxygen consumption during these years are about twice those of the adult brain. Structures arising from mesoderm (**somite**) include blood vessels, microglial cells, dural and arachnoid layers of the meninges, the capsule of some peripheral sensory nerve endings, and peripheral nerve coverings.

The bones of the infant's skull are separated at the suture lines, forming two **fontanels** or “soft spots”: one diamond-shaped anterior fontanel and one triangular-shaped posterior fontanel. The unclosed sutures allow for expansion of the rapidly growing brain. The posterior fontanel may be open until 2 to 3 months of age; the anterior fontanel normally does not fully close until 18 months of age ([Fig. 20.3](#)). Head growth almost always reflects brain growth. Monitoring the fontanels and careful measurement of the head circumference on standardized growth charts are essential elements of the pediatric examination.

FIGURE 20.3 Cranial Sutures and Fontanelles in Infancy. Fibrous union of suture lines and interlocking of serrated edges (occurs by 6 months; solid union requires approximately 12 years).

Because of the immaturity of much of the human forebrain at birth, neurologic examination of the infant detects mostly reflex responses that require an intact spinal cord and brainstem. Some of these reflex patterns are inhibited as cerebral cortical function matures; these patterns disappear at predictable times during infancy ([Table 20.1](#)).

TABLE 20.1

REFLEXES OF INFANCY

REFLEX	AGE AT APPEARANCE OF REFLEX	AGE AT WHICH REFLEX SHOULD NO LONGER BE OBTAINABLE
Stepping	Birth	6 weeks
Moro	Birth	3 months
Sucking	Birth	4 months awake
		7 months asleep
Rooting	Birth	4 months awake
		7 months asleep
Palmar grasp	Birth	6 months
Plantar grasp	Birth	10 months
Tonic neck	2 months	5 months
Neck righting	4-6 months	24 months
Landau	3 months	24 months
Parachute reaction	9 months	Persists for life

Absence of expected reflex responses at the appropriate age indicates general depression of central or peripheral motor function. Asymmetric responses may indicate lesions in the motor cortex on the contralateral side of the brain or may occur with fractures of bones after traumatic delivery or postnatal injury. As the infant matures, the primitive reflexes disappear in a predictable order as voluntary motor functions supersede them. Abnormal persistence of these reflexes is

seen in infants with developmental delays or with central nervous system lesions.

Structural Malformations

CNS malformations are a common cause of significant morbidity and mortality in the first year of life. Malformations include defects of neural tube closure (anencephaly, spina bifida, myelomeningocele), formation of the skull and surrounding structures (craniosynostosis), neuronal migration (lissencephaly, microcephaly), and flow of CSF (hydrocephalus).

Defects of Neural Tube Closure

Neural tube defects (NTDs) are the most common anomaly of the CNS. They occur in about 3000 pregnancies in the United States each year, although there are significant regional differences in prevalence.¹ Maternal folate deficiency had been associated with significant risk for NTD. These defects originate during the first month of embryonic development when the neural tube fails to close completely. Fetal death often occurs in the more severe cases, thereby reducing the actual prevalence of neural defects at birth.^{2,3} In 1996 the United States mandated folate fortification in many foods, and since that time neural tube defects have decreased by 20% to 30%.⁴ Guidelines are available for folic acid supplementation for women at high risk for neural tube defects.⁵

Defects of neural tube closure are divided into two categories: anterior midline defects (ventral induction) and posterior defects (dorsal induction). Anterior midline defects may cause brain and face abnormalities in the holoprosencephaly spectrum, with the most extreme form being **cyclopia**, in which the child has a single midline orbit and eye with a protruding noselike proboscis above the orbit. Posterior defects result from failure of closure of the neural tube and result in a variety of myelodysplasias depending on the level of the failure. Although **myelodysplasia** is defined as a defect in formation

of the spinal cord, the term is used to refer to anomalies of both the vertebral column and the spinal cord. **Spina bifida (split spine)** is the most common neural tube defect and includes anencephaly, encephalocele, meningocele, and myelomeningocele. Disorders of embryonic neural development are summarized in [Fig. 20.4](#).

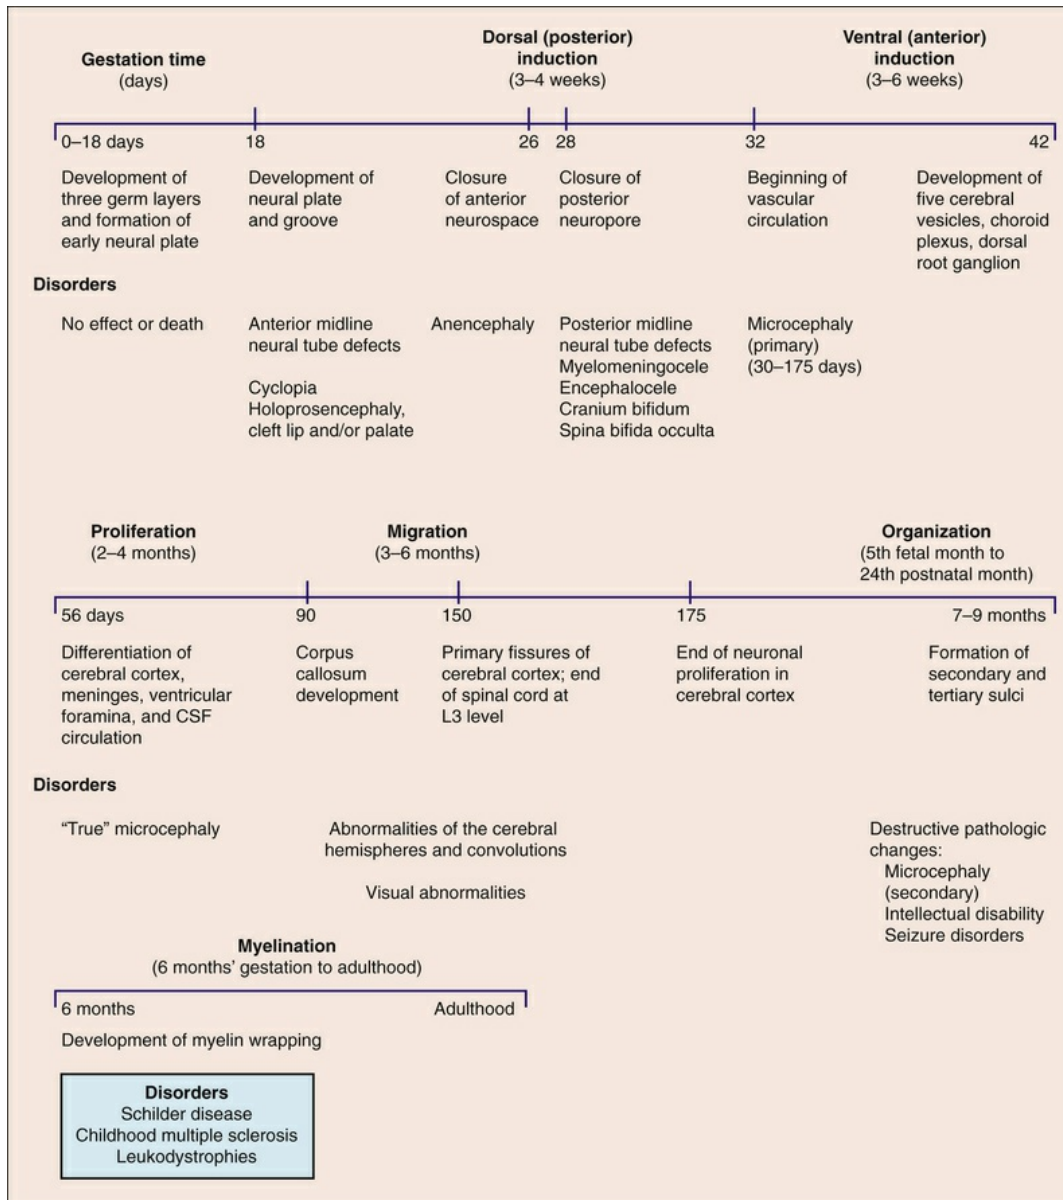

FIGURE 20.4 Disorders Associated with Specific Stages of Embryonic Development. CSF, Cerebrospinal fluid.

Anencephaly (*an*, "without"; *enkephalos*, "brain") is an anomaly in

which the soft, bony component of the skull and part of the brain are missing. This is a relatively common disorder, with an incidence of approximately 1 per 4859 live births in the United States each year.² These infants are stillborn or die within a few days after birth. The pathologic mechanism is unknown. Diagnosis is often made prenatally using ultrasound or evaluating maternal serum α_1 -fetoprotein (AFP).⁶

Encephalocele refers to a herniation or protrusion of various amounts of brain and meninges through a defect in the skull, resulting in a saclike structure (Fig. 20.5). The incidence is approximately 1 in 10,000 live births in the United States each year.⁷ Encephalocele occurs during the first weeks of pregnancy. When the defect contains only meninges, it is referred to as a **cranial meningocele**. Most encephaloceles, which contain neural tissue as well as meninges, occur in the occipital area, with the remainder found in the frontal, parietal, or nasopharyngeal regions. If the defect is located in the nasopharynx, no external anomaly is visible but the child may experience nasal airway obstruction. On examination with a nasal speculum, a smooth, round mass will be visible in the nasal passages. A frontal encephalocele may extend into the orbit of the eye and produce proptosis on the affected side. An occipital encephalocele may be associated with other findings, such as blindness and cognitive impairment. The size, location, and involvement of the encephalocele help determine a child's development and intellectual outcome.

FIGURE 20.5 Meningoencephalocele of the Occipital Region. (From Gilbert-Barness: *Potter's pathology of the fetus, infant and child*, ed 2, Philadelphia, 2007, Mosby.)

Meningocele is a saclike cyst of meninges filled with spinal fluid and is a mild form of spina bifida. It develops during the first 4 weeks of pregnancy when the neural tube fails to close completely. The cystic dilation of meninges protrudes through a defect in the posterior arch of the vertebra. The vertebral defect does not involve the spinal cord or nerve roots and may produce no neurologic deficit or symptoms. Meningoceles occur with equal frequency in the cervical, thoracic, and lumbar spine. With cranial meningocele, surgical repair of the cranial defect affords a good prognosis for most affected infants whose intellectual and motor functioning is usually normal.

Myelomeningocele (meningomyelocele; spina bifida cystica) is a hernial protrusion of a saclike cyst (containing meninges, spinal fluid, and a portion of the spinal cord with its nerves) through a defect in the posterior arch of a vertebra (Fig. 20.6). Myelomeningocele is one of the most common developmental anomalies of the nervous system, with an incidence ranging from 0.5 to 1.0 per 1000 pregnancies.⁸ Eighty percent of myelomeningoceles are located in the lumbar and lumbosacral regions, the last regions of the neural tube to close.

Myelomeningocele with an intact sac

FIGURE 20.6 Normal Spine, Spina Bifida, Meningocele, and Myelomeningocele. (From Nockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

Meningocele and myelomeningoceles are evident at birth as a pronounced skin defect on the infant's back. The bony prominences of the unfused neural arches can be palpated at the lateral border of the defect. The defect is usually covered by a transparent membrane that may have neural tissue attached to its inner surface. This membrane may be intact at birth or may leak cerebrospinal fluid (CSF), thereby increasing the risks of infection and neuronal damage.

The spinal cord and nerve roots are malformed below the level of the lesion, resulting in loss of motor, sensory, reflex, and autonomic functions. A brief neurologic examination concentrating on motor function in the legs, reflexes, and sphincter tone is usually sufficient to determine the level above which spinal cord and nerve root function is preserved (Table 20.2). This is useful to predict if the child will ambulate, require bladder catheterization, or be at high risk for developing scoliosis (see Chapter 46).

TABLE 20.2

FUNCTIONAL ALTERATIONS IN MYELODYSPLASIA (NEURAL TUBE DEFECTS) RELATED TO LEVEL OF LESION

LEVEL OF LESION	FUNCTIONAL IMPLICATIONS
Thoracic	Flaccid paralysis of lower extremities; variable weakness in abdominal trunk musculature; high thoracic level may mean respiratory compromise; absence of bowel and bladder control
High lumbar	Voluntary hip flexion and adduction; flaccid paralysis of knees, ankles, and feet; may walk with extensive braces and crutches; absence of bowel and bladder control
Midlumbar	Strong hip flexion and adduction; fair knee extension; flaccid paralysis of ankles and feet; absence of bowel and bladder control
Low lumbar	Strong hip flexion, extension, and adduction and knee extension; weak ankle and toe mobility; may have limited bowel and bladder function

Data from Martin RJ, Fanaroff AA, Walsh MC: *Fanaroff and Martin's neonatal-perinatal medicine*, Philadelphia, 2015, Saunders.

Hydrocephalus occurs in 85% of infants with myelomeningocele.⁹ Seizures also occur in 30% of those with myelodysplasia. Visual and perceptual problems, including ocular palsies, astigmatism, and visuoperceptual deficits, are common. Motor and sensory functions below the level of the lesions are altered. Often these problems worsen as the child grows and the cord ascends within the vertebral canal, pulling primary scar tissue and tethering the cord.

Myelomeningoceles are almost always associated with a brain malformation known as type II **Arnold-Chiari malformation**.⁹ This is a complex malformation of the brainstem and cerebellum in which the cerebellar tonsils are displaced downward into the cervical spinal canal, the upper medulla and lower pons are elongated and thin, and the medulla also is displaced downward and sometimes has a “kink” (Fig. 20.7). The Chiari II malformation is associated with hydrocephalus from pressure that blocks the flow of cerebrospinal fluid and syringomyelia, an abnormality causing cysts at multiple levels within the spinal canal. Cognitive and motor deficits are common.¹⁰ Symptomatic Chiari II malformations require surgical decompression or placement of cerebrospinal fluid shunts, or both. The type I Chiari malformation does not involve the brainstem and may be asymptomatic. In type III, the brainstem or cerebellum extends into a high cervical myelomeningocele. Type IV is characterized by lack of cerebellar development.

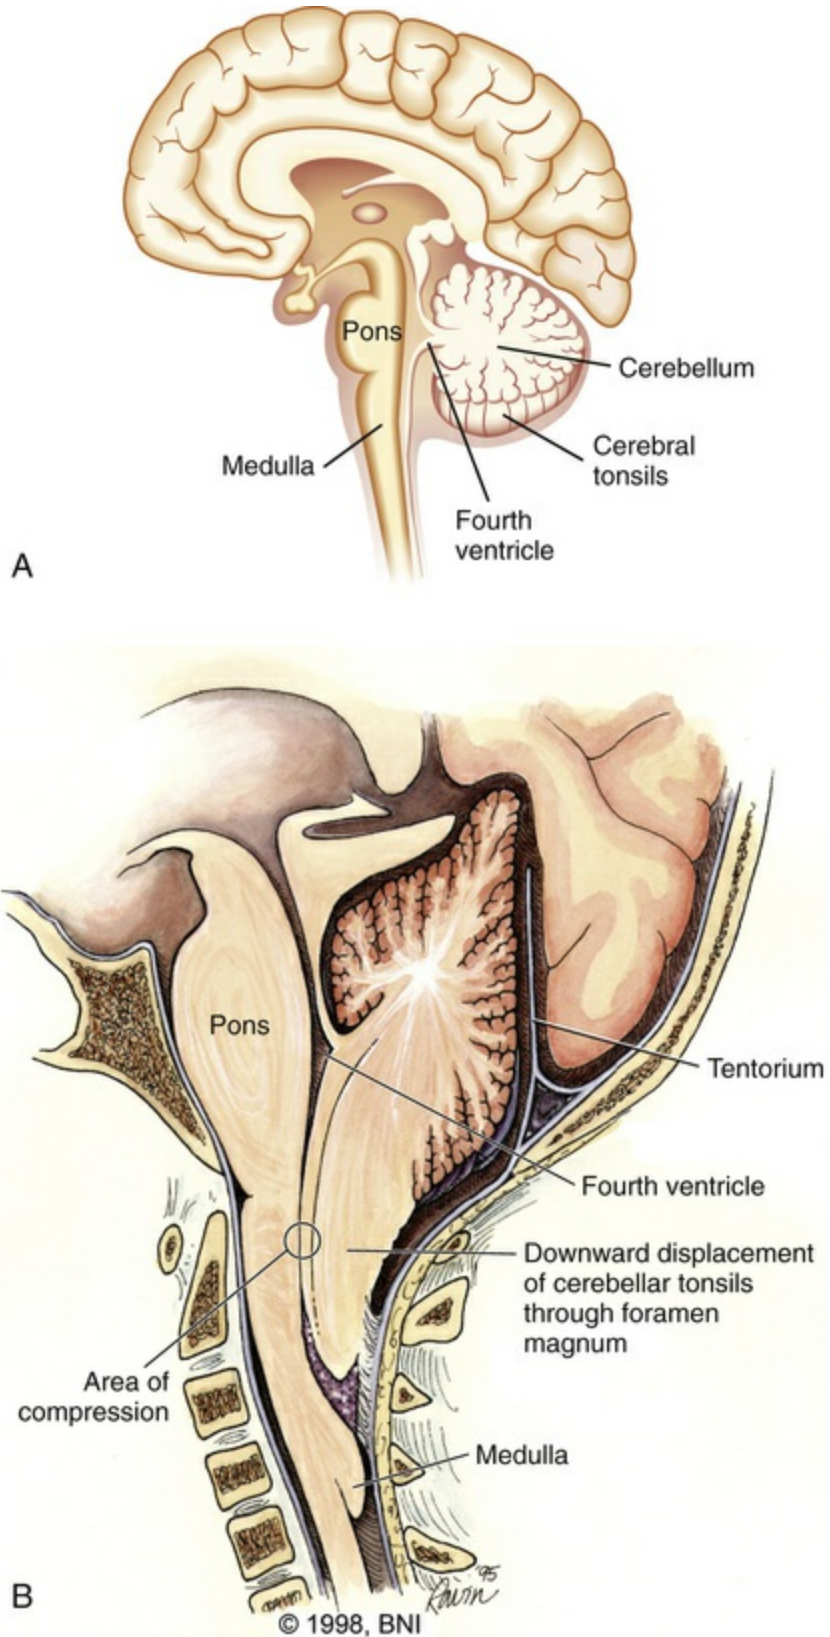

FIGURE 20.7 Normal Brain and Chiari Type II Malformation. A, Normal brain. B, Chiari II malformation with downward displacement of cerebellar

tonsils and medulla through foramen magnum causing compression and obstruction to flow of CSF. (B modified from Barrow Neurological Institute of St. Joseph's Hospital and Medical Center, Phoenix, Arizona. Reprinted with permission.)

Most cases of meningocele and myelomeningocele are diagnosed prenatally by a combination of maternal serologic testing (α -fetoprotein) and prenatal ultrasound. In these cases, the fetus is usually delivered by elective cesarean section to minimize trauma during labor. Surgical repair is critical and can be performed by in utero fetal surgery or during the first 72 hours of life.¹¹

It is possible for a defect to occur without any visible exposure of meninges or neural tissue. This defect, termed **spina bifida occulta**, is common and occurs to some degree in 10% to 25% of infants. Spina bifida occulta usually causes no neurologic dysfunction because the spinal cord and spinal nerves are normal. Surgical treatment is usually directed at associated intraspinal abnormalities that occur with growth of the child (tethered cord, sacral lipoma, or dermoid cyst). **Tethered cord syndrome** may develop after surgical correction for myelomeningocele.¹² In these cases, the cord becomes abnormally attached or tethered as a result of scar tissue as the cord transcends the vertebral canal with growth. Traction decreases blood flow and impairs oxidative metabolism. The cord can be untethered surgically.¹²

Craniosynostosis

Skull malformations range from minor, insignificant defects to major defects that are incompatible with life. **Craniosynostosis (craniostenosis)** is the premature closure of one or more of the cranial sutures (sagittal, coronal, lambdoid, metopic) during the first 18 to 20 months of an infant's life. The incidence of craniosynostosis is 1 in 2000 to 2500 live births.¹³ Males are affected twice as often as females. Fusion of a cranial suture prevents growth of the skull perpendicular to the suture line, resulting in an asymmetric shape of the skull. The general term *plagiocephaly*, meaning "misshapen skull," is used to describe deformities that result from craniosynostosis or from

asymmetric head posture (positional). When a single coronal suture fuses prematurely, the head is flattened on that side in front. When the sagittal suture fuses prematurely, the head is elongated in the anteroposterior direction and is termed *scaphocephaly*¹⁴ (Fig. 20.8). Diagnosis of craniosynostosis is made on the basis of physical examination, head circumference, and radiologic examination. Single-suture craniosynostosis is usually only a cosmetic issue. Rarely, when multiple sutures fuse prematurely, brain growth may be restricted and surgical repair may prevent neurologic dysfunction (Fig. 20.9). **Syndromic craniosynostosis** involves deformities in other systems (i.e., the heart, limbs, and central nervous system).

FIGURE 20.8 Types and Frequency of Craniosynostosis. Abnormal head configuration resulting from premature closing of cranial sutures. *Normal skull*: Bones separated by membranous seams until sutures gradually close. *Microcephaly and craniosynostosis*: Microcephaly is head

circumference more than two standard deviations below the mean for age, sex, race, and gestation and reflects a small brain; craniosynostosis is premature closure or fusion of sutures. *Scaphocephaly or dolichocephaly* (frequency 56%): Premature closure of sagittal suture, resulting in restricted lateral growth. *Brachycephaly*: Premature closure of coronal suture, resulting in excessive lateral growth. *Oxycephaly or acrocephaly* (frequency 5.8% to 12%): Premature closure of all coronal and sagittal sutures, resulting in accelerated upward growth and small head circumference. *Anterior plagiocephaly* (frequency 13%): Unilateral premature closure of coronal suture, resulting in asymmetric growth. (From Hockenberry JH, Wilson D: *Wong's nursing care of infants and children*, ed 10, St Louis, 2015, Mosby.)

FIGURE 20.9 Lateral View of a Child with Scaphocephaly Resulting from Sagittal Synostosis. Note the frontal bossing, elongation along the anteroposterior (AP) axis, and prominent occiput, all of which are characteristic of this condition. (From Coran A et al: *Pediatric surgery*, ed 7, St Louis, 2012, Mosby.)

Malformations of Brain Development

Structural malformations of the brain are a diverse group of disorders caused by abnormal neuronal migration, abnormal neuronal, or glial proliferation. Reduced proliferation or accelerated apoptosis causes congenital microcephaly (small brain) and increased proliferation

causes megalencephaly (abnormally large brain). Malformations can occur any time during fetal development or after birth. There are specific genetic defects for some of these disorders; others are multifactorial or acquired (i.e., intrauterine trauma or infection). Most brain malformations increase the risk for seizures, developmental delay, and motor dysfunction. Diagnosis is made by clinical history, family history, and magnetic resonance imaging (MRI) of the brain. Genetic testing is done for diagnosis to assess risk in other family members and to guide prospective therapy.¹⁵

Microcephaly is a defect in brain growth as a whole (see Fig. 20.8). Cranial size is significantly below average for the infant's age, sex, race, and gestation. The small size of the skull reflects a small brain (microencephaly, head circumference two standard deviations below the mean for age and sex). *Primary microcephaly* is caused by an autosomal recessive genetic defect in 1 of as many as 16 or more different genes. *Secondary (acquired) microcephaly* is associated with various causes, including infection, trauma, metabolic disorders, toxin or radiation exposure, maternal anorexia experienced during the third trimester of pregnancy, and the presence of other genetic syndromes (Box 20.1). Maternal infection with Zika virus causes microcephaly and other congenital malformations known as *congenital Zika syndrome*. The current theory is that the virus crosses the placental barrier and blood-brain barrier inducing neural cell death and inhibiting brain tissue development.¹⁶

Box 20.1

Causes of Microencephaly

Defects in Brain Development

- Hereditary (recessive) microcephaly
- Down syndrome and other trisomy syndromes
- Fetal ionizing radiation exposure
- Maternal phenylketonuria

Seckel syndrome
Cornelia de Lange syndrome
Rubinstein-Taybi syndrome
Smith-Lemli-Opitz syndrome
Fetal alcohol syndrome

Intrauterine Infections

Congenital rubella
Cytomegalovirus infection
Congenital toxoplasmosis
Congenital syphilis
Congenital Zika virus

Perinatal and Postnatal Disorders

Intrauterine or neonatal anoxia
Severe malnutrition in early infancy
Neonatal herpesvirus infection

Cortical dysplasias are a heterogeneous group of disorders caused by defects in brain development. These disorders may range from a small area of abnormal tissue (e.g., heterotopia, which are areas of gray matter that did not migrate to their normal position in the cortex) to an entire brain that is smooth without the normal gyri and sulci of a developed brain (lissencephaly) (Fig. 20.10). Specific genetic defects are known for some of these disorders; others are multifactorial or acquired (e.g., intrauterine trauma or infection). Cortical dysplasias increase the risk for seizures that are difficult to control and cause developmental delay and motor dysfunction.¹⁷ Genetic testing assists diagnosis, assesses risk in other family members, and guides therapy.

FIGURE 20.10 Lissencephaly. The absence of cortical gyri defines this abnormality, seen here in the brain from a full-term infant. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Saunders, 2010, Philadelphia.)

Congenital hydrocephalus is present at birth and characterized by increased CSF pressure. It may be caused by obstruction within the ventricular system, an imbalance in the production, or reabsorption of CSF. *Obstructive hydrocephalus* is most commonly caused by congenital aqueductal stenosis. The cerebral aqueduct, which connects the third ventricle to the fourth ventricle, is narrowed or replaced by multiple channels that end blindly. In a small number of children the stenosis is transmitted as an X-linked recessive trait that affects brain growth and development or as nonsyndromic autosomal recessive hydrocephalus.¹⁸ The increased pressure within the ventricular system dilates the ventricles and compresses the brain tissue against the skull (Fig. 20.11). When hydrocephalus develops before fusion of the cranial sutures, the skull has the capacity to increase its size to accommodate this additional space-occupying volume (progressive macrocephaly) (Fig. 20.12) and to preserve neuronal function. The overall incidence of hydrocephalus is approximately 1 to 3 per 1000 live births.¹⁹ The incidence of hydrocephalus that is not associated with myelomeningocele is approximately 0.5 to 1 per 1000 live births, with

aqueductal stenosis as the cause for approximately one-third of these cases.²⁰ (Types of hydrocephalus are discussed in [Chapter 17](#).)

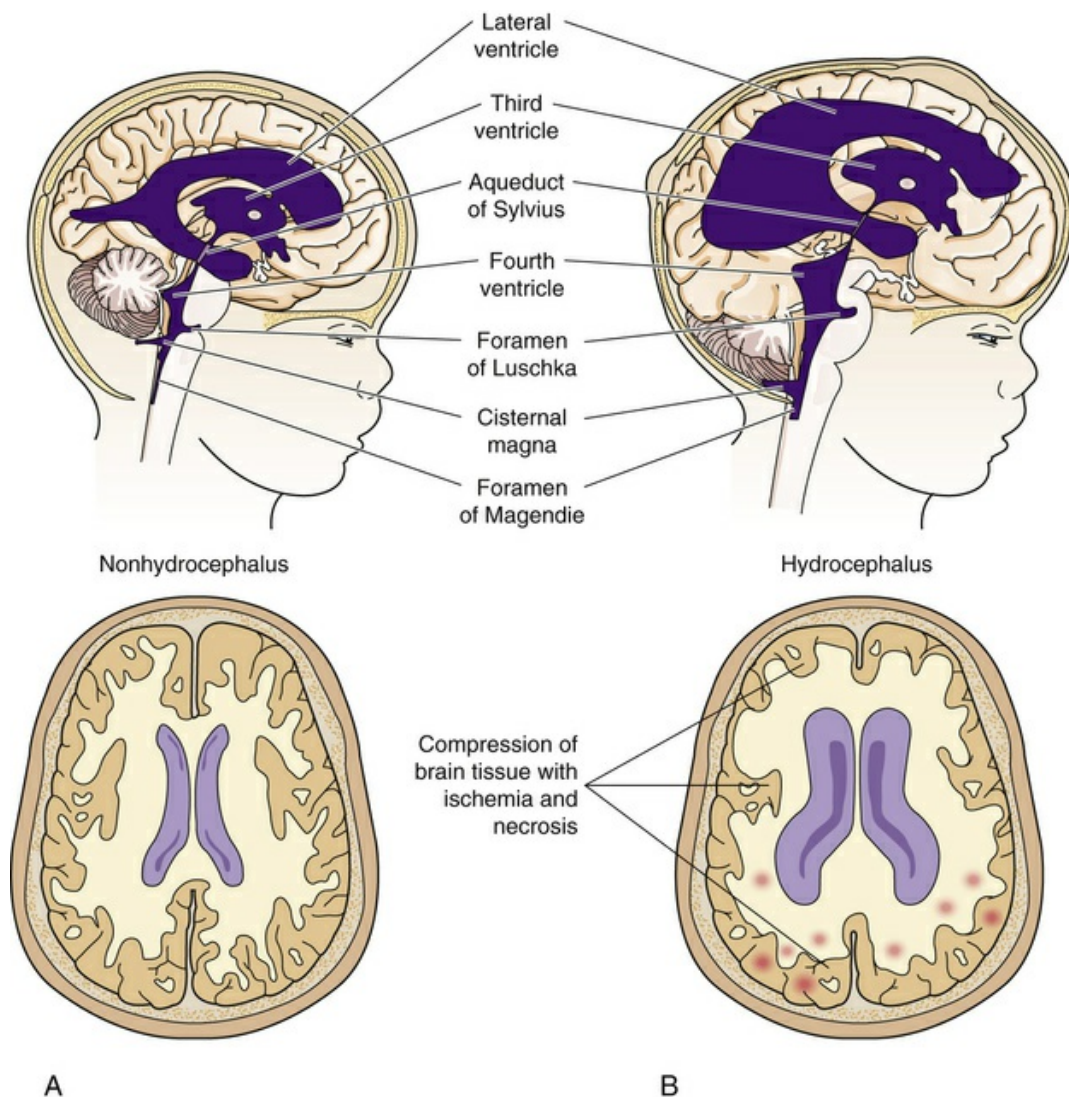

FIGURE 20.11 Hydrocephalus. Fluid accumulation in the brain because of blockage in the flow of cerebrospinal fluid (CSF). **A**, Patent cerebrospinal fluid circulation. **B**, Enlarged lateral and third ventricles caused by obstruction of circulation of CSF—stenosis of aqueduct of Sylvius.

FIGURE 20.12 Child with Enlarged Head Caused by Hydrocephalus. (From McLaurin DC: *Pediatric neurosurgery*, ed 2, Philadelphia, 1989, Saunders.)

Congenital hydrocephalus may cause fetal death in utero, or the increased head circumference may require cesarean delivery of the infant. Symptoms depend directly on the cause and rate of progression. When there is separation of the cranial sutures, a resonant note sounds when the skull is tapped, a manifestation termed Macewen sign or “cracked pot” sign. Typically, the fontanelles enlarge and become full and bulging. The eyes may assume a staring expression, with sclera visible above the cornea, called *sunsetting*. Cognitive impairment in children with hydrocephalus is often related to associated brain malformations, episodes of shunt failure, or infection. Approximately 30% to 40% of children with uncomplicated congenital hydrocephalus complete schooling and are employed when treated successfully with shunting or endoscopic third ventriculostomy and choroid plexus cauterization.¹⁸

Hydrocephalus caused by CSF obstructions within the ventricular system can result from **Dandy-Walker malformation (DWM)** brain tumors, cysts, trauma, arteriovenous malformations, blood clots,

infections, and the Chiari malformations (see the [Defects of Neural Tube Closure](#) section). DWM is a congenital defect of the cerebellum characterized by a large posterior fossa cyst that communicates with the fourth ventricle and an atrophic, upwardly rotated, cerebellar vermis.²¹ DWM is commonly associated with hydrocephalus caused by compression of the aqueduct of Sylvius.

Alterations in Function: Encephalopathies

Encephalopathy, meaning dysfunction of overall brain function, is a general category that includes a large number of syndromes and diseases. These disorders may be acute or chronic, as well as static or progressive. Some common neurologic disorders with a genetic basis are summarized in [Table 20.3](#).

TABLE 20.3

SELECTED NEUROLOGIC DISORDERS WITH A GENETIC BASIS

SYNDROME/DISORDERS	CURRENTLY KNOWN GENETIC COMPONENTS	PATHOPHYSIOLOGY	MAJOR NEUROLOGIC FEATURE
Angelman syndrome	Microdeletion on chromosome 15 leading to loss of function of the <i>UBE3A</i> gene (ubiquitin protein ligase); can be acquired from mother	Protein, important in degradation of proteins in the brain	Little to no verbal language disability disorder, movement disorder
Batten disease	Autosomal recessive; mutation of the <i>CLN3</i> gene (ceroid-lipofuscinosis, neuronal 3) (chromosome 16)	Lysosomal storage defect resulting in abnormal storage of cerebral lipofuscins	Develops normal months to years after age when brain disability apparent intellectual blindness
Branched-chain ketoaciduria (maple syrup urine disease)	Autosomal recessive; most common type is classic	All types result in inability to metabolize three	Intellectual disability seizures,

	caused by mutation of the <i>BCKDHA</i> gene (2-oxoisovalerate dehydrogenase subunit alpha, a mitochondrial enzyme) (chromosome 19)	amino acids; these acids accumulate and are toxic at high levels	treatable diagnosis
Cri du chat syndrome	Autosomal dominant; deletion on the short arm of chromosome 5 (also called <i>5p minus syndrome</i>)	Deletion of multiple genes responsible for phenotype; evidence that deletion of telomerase reverse transcriptase gene contributes to phenotype	High-pitched intellectual microcephaly birth weight; weak eyes (ocular hypertelorism) unusually small (micrognathia)
Lesch-Nyhan syndrome	X-linked recessive; mutation of the <i>HPRT</i> gene (hypoxanthine phosphoribosyltransferase 1)	Metabolism disturbance of purines; excessive production of uric acid	Intellectual disability, progressive disorder, compulsive self-mutilations
Neurofibromatosis (NF)	Autosomal dominant	Variable expressivity	Multiple café-au-lait spots, neurofibromas, learning disabilities, seizures
NF1 (von Recklinghausen disease)	Mutation of the <i>NF1</i> gene (neurofibromin) (chromosome 17)	A large, complex protein; this protein may act as a switch to regulate cell growth; mutation may lessen or inhibit the normal output of this protein and allow irregular cell growth that may lead to tumor development	Increased risk of neurofibrosarcoma, optic glioma, brain tumors
NF2 (bilateral acoustic NF)	Autosomal dominant: mutation of either the <i>NF2</i> gene (merlin; moesin-ezrin-radixin-like protein or schwannomin) (chromosome 22)	A tumor-suppressor protein (merlin or schwannomin)	Multiple tumors (schwannomas, meningiomas, cranial nerves, acoustic neuroma, meningioma, glioma, neurofibrosarcoma)
Progressive myoclonic epilepsy (Unverricht-Lundborg disease)	Autosomal recessive; mutation <i>CSTB</i> gene (cystatin B, a cysteine protease inhibitor)	This protein regulates enzymes that break down other proteins	Onset at age 1-2 years; severe intellectual disability; stimulus-induced myoclonic seizures; progressive

	(chromosome 21)		myoclonic epileptic seizures, characteristic abnormal electroencephalogram also may have other neurological symptoms such as ataxia, incontinence, and dyspraxia
Lafora disease	Autosomal recessive; mutation of the <i>EMP2A</i> gene (epilepsy, progressive myoclonus type 2A or laforin) and <i>EMP2B</i> gene (malin) (chromosome 6)	Concentric amyloid (Lafora) bodies found in neurons, liver, skin, bone, and muscle; defects in protein degradation and clearance	Grand mal seizures and/or myoclonus about age 10 and severe coordination impairment; mental development often with autistic features; short, less than 10 years after onset
Rett syndrome	X-linked dominant; appears to occur only in girls; defective <i>MECP2</i> gene (methyl CpG binding protein 2) (X-chromosome)	Protein involved in regulation of gene expression; defects in this gene allow other genes to be expressed at inappropriate times in development	Progressive neurodevelopmental disorder; normally high IQ, then mental and motor skills loss of purposeful hand movements; stereotypical hand wringing
Tay-Sachs disease	Autosomal recessive; mutation of the <i>HEXA</i> gene (chromosome 15)	Caused by a deficiency of hexosaminidase, an enzyme, which results in accumulation of a material that damages the brain	Failure to see or blindness; progressive neurodegeneration; usually childhood onset
Tuberous sclerosis	Autosomal dominant; mutation of either the <i>TSC1</i> gene (hamartin) (chromosome 9) or the <i>TSC2</i> gene (tuberin) (chromosome 16)	These proteins act as tumor growth suppressors	Develops in childhood; intellectual disability; skin and multiple benign tumors in various organs; other vitreous opacities

Static Encephalopathies

Static or nonprogressive encephalopathy describes a neurologic condition caused by a fixed lesion without active and ongoing disease. Causes include brain malformations or brain injury that may occur during gestation or birth, or at any time during childhood. The degree of neurologic impairment is directly related to the extent of the injury or malformation. Anoxia, trauma, and infections are the most common factors that cause injury to the nervous system in the perinatal period. Infections, metabolic disturbances (acquired or genetic), trauma, toxins, and vascular disease may injure the nervous system in the postnatal period. The clinical manifestations of a static encephalopathy depend on the site and extent of the injury, as well as the age of the child and stage of development at the time of injury.

Cerebral palsy (CP) is a disorder of movement, muscle tone, or posture that is caused by injury or abnormal development in the immature brain, before, during, or after birth up to 1 year of age. CP is one of the most common disorders of childhood, affecting nearly 500,000 children in the United States alone. Although the exact incidence is unknown, studies suggest that the prevalence is approximately 1 in 323 children in the United States.²² Risk factors include prenatal or perinatal cerebral hypoxia, hemorrhage, infection, genetic abnormalities, or low birth weight (Table 20.4). Severity of CP depends on the gestational age at the time of the injury and the type and degree of injury sustained. CP can be classified on the basis of neurologic signs and motor symptoms, with the major types involving spasticity (increased tone), dystonia, ataxia, or a combination of these symptoms (mixed). Diplegia, hemiplegia, or tetraplegia may be present.

TABLE 20.4

CEREBRAL PALSY: PREDISPOSING FACTORS AND KNOWN CAUSES

RISK FACTORS	ASSOCIATED CAUSES
Prenatal	
Maternal	Metabolic diseases

	Nutritional deficiencies (e.g., anemia)
	Twin or multiple births
	Bleeding
	Toxemia
	Blood incompatibilities
	Exposure to radiation
	Infection (e.g., rubella, toxoplasmosis, cytomegalic inclusion disease)
	Premature labor
Prematurity	Asphyxia leading to cerebral hemorrhage
Genetic factors	Absence of corpus callosum, aqueductal stenosis, cerebellar hypoplasia
Congenital anomalies of the brain	Unknown causes not evident on clinical examination
Perinatal	Anesthesia or analgesia during labor and delivery
	Mechanical trauma or hypoxia during delivery
	Immaturity at birth
	Metabolic disorders (e.g., hyperbilirubinemia, hypoglycemia, amino acid disorders, hyperosmolality)
	Electrolyte disturbances (e.g., hyponatremia, hypoglycemia)
Postnatal	Head trauma
	Infections (e.g., meningitis, encephalitis)
	Cerebrovascular accidents
	Toxicosis
	Environmental toxins (e.g., lead ingestion, methyl mercury ingestion from contaminated fish)

Pyramidal/spastic cerebral palsy results from damage to corticospinal pathways (upper motor neurons) and is associated with increased muscle tone, persistent primitive reflexes, hyperactive deep tendon reflexes, clonus, rigidity of the extremities, scoliosis, and contractures. This accounts for 70% to 80% of cerebral palsy cases.²³

Extrapyramidal/nospastic cerebral palsy is caused by damage to cells in the basal ganglia, thalamus, or cerebellum and includes two subtypes: dyskinetic and ataxic. **Dyskinetic (dystonic and athetoid) cerebral palsy** results in movements that are stiff, uncontrolled, abrupt, and can be repetitive resulting in extreme difficulty in fine motor coordination and purposeful movements. Dyskinetic CP

accounts for 10% to 20% of cases. **Ataxic cerebral palsy** manifests with gait disturbances and reflects cerebellar involvement. The infant with this form of CP may have hypotonia at birth, but stiffness of the trunk muscles develops by late infancy. Persistence of increased tone in truncal muscles affects the child's gait and ability to maintain balance. Ataxic CP accounts for 5% to 10% of cases. A child may have symptoms of each of these cerebral palsy types, which leads to a mixed disorder accounting for approximately 13% of cases.²⁴

Children with CP often have associated neurologic disorders, such as seizures (about 50%) and intellectual impairment ranging from mild to severe (about 67%). Other complications include visual impairment, communication disorders, difficulty swallowing, respiratory problems, bowel and bladder problems, malnutrition, and orthopedic disabilities.²⁵ The management of children with CP varies with age, type, severity of involvement, and associated disorders. Thus the scope of care required by the child and family includes ongoing medical, social, and educational intervention and a family-focused multidisciplinary team approach.^{26,27}

Inherited Metabolic Disorders of the Central Nervous System

A large number of inherited metabolic disorders have been identified leading to diffuse brain dysfunction. Inborn errors of metabolism are present at birth, including defects in amino acid and lipid and, more rarely, carbohydrate metabolism. Most cause disturbances of the nervous system, although they may not manifest until childhood or even adulthood. Early diagnosis and treatment is vital if these infants are to survive without severe neurologic problems. Newborn screening is recommended for 35 different genetic and metabolic conditions and has led to many of these children being identified before symptoms develop. The following website contains a list of the newborn metabolic screening tests: www.marchofdimes.com/professionals/bringinghome_screening.html.

Table E 20.1 (on Evolve) lists some of these inherited metabolic

disorders

Defects in Amino Acid Metabolism.

Biochemical defects in amino acid metabolism include (1) those in which the transport of an amino acid is impaired; (2) those involving an enzyme or cofactor deficiency; and (3) those encompassing certain chemical components, such as branched chain or sulfur-containing amino acids.²⁸ Most of the disorders are caused by genetic defects resulting in a lack of a normal protein and absence of enzymatic activity.

Phenylketonuria (PKU), an inborn error in the metabolism of amino acids, is characterized by phenylalanine hydroxylase deficiency and results in the inability of the body to convert the essential amino acid phenylalanine to tyrosine. PKU is an autosomal recessive disorder characterized by mutations of the phenylalanine hydroxylase (*PAH*) gene. PKU has an incidence of about 1 per 10,000 to 15,000 live births in the United States.²⁹ Statistical prevalence varies widely on the basis of geographic and ethnic differences.³⁰

Most natural food proteins contain about 15% phenylalanine, an essential amino acid. Phenylalanine hydroxylase controls the conversion of this essential amino acid to tyrosine in the liver. Tyrosine is essential for the biosynthesis of proteins, melanin, thyroxine, and the catecholamine neurotransmitters in the brain and adrenal medulla. Phenylalanine hydroxylase deficiency causes an accumulation of phenylalanine in the serum. Elevated serum phenylalanine levels result in developmental abnormalities of the cerebral cortical layers, defective myelination, and cystic degeneration of the gray and white matter ([Fig. 20.13](#)). Unfortunately, brain damage occurs before the metabolites can be detected in the urine and damage continues as long as phenylalanine levels remain high. Nonselective newborn screening is used to detect PKU in the United States and in more than 30 other countries. Treatment, consisting of reduction of dietary phenylalanine (PKU diet), is effective and allows for normal development. Treatment must be continued for life, and strict adherence to the diet is especially important for pregnant women with

PKU so that damage does not occur prenatally to the fetus.

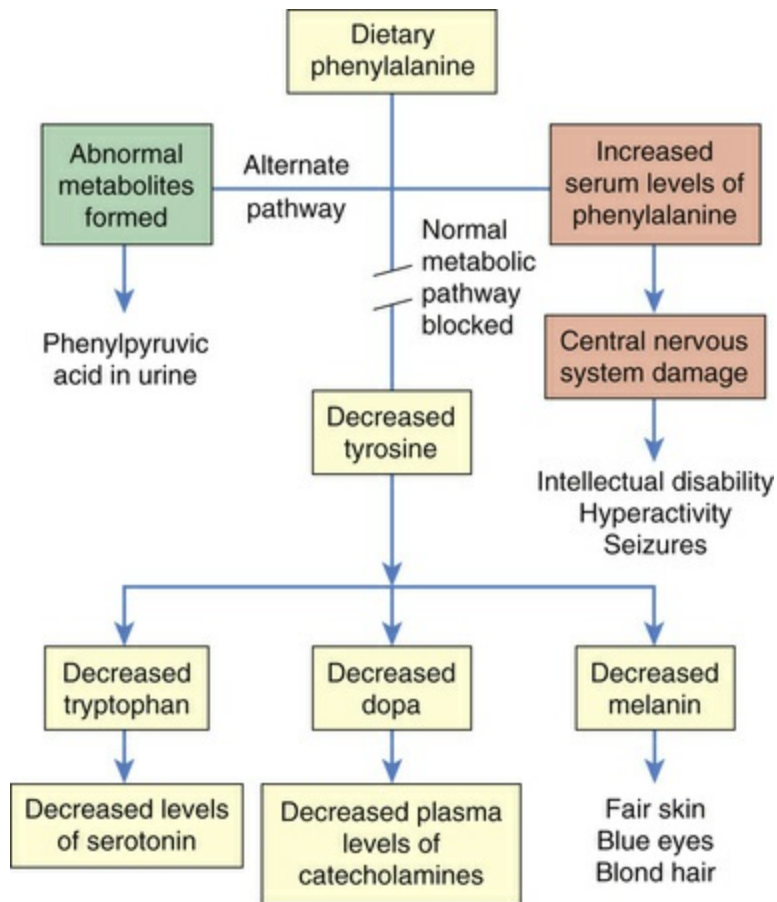

FIGURE 20.13 Metabolic Errors and Consequences in Phenylketonuria. (Redrawn from Hockenberry MJ et al: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.)

Mutations in the *PAH* gene are the most common cause of PKU.³¹ In one such variation, there is impaired synthesis of cofactors (e.g., tetrahydrobiopterin [BH_4]) which contributes to elevated levels of phenylalanine. Individuals with impaired synthesis of BH_4 have a positive response when sapropterin, a synthetic form of tetrahydrobiopterin, is included in their treatment.³² Because of the lack of tyrosine and its relationship to the biosynthesis of melanin, untreated children with PKU have a characteristic phenotype that includes blond hair, blue eyes, and fair skin. Children with genetically darker complexions may be red haired or brunette in contrast to their

parents.

Storage Diseases.

Disorders of lipid metabolism are termed **lysosomal storage diseases** because each disorder in this group can be traced to a missing lysosomal enzyme. Lysosomal storage disorders include more than 50 known genetic disorders, including sphingolipidoses (i.e., Gaucher disease, Fabry disease, Tay-Sachs disease), mucopolysaccharidoses (lack of enzymes to break down glycosaminoglycans), and oligosaccharidoses (lack of enzymes to break down glycoproteins). They occur in 7.7 to 23.5 per 100,000 live births.³³

Lipids include oils, fatty acids, waxes, steroids (such as cholesterol and estrogen), and other related compounds. Although these compounds accumulate to some extent in cells, excess amounts are broken down in lysosomes (vesicles within the cell whose primary function is to degrade the breakdown products of cellular metabolism as discussed in [Chapter 1](#)). A genetic defect resulting in a missing or defective enzyme, such as lysosomal hydrolase, causes an excessive accumulation of the enzyme's substrate, which alters cell function. These disorders cause an excessive accumulation of a particular cell product, occurring in the brain, liver, spleen, bone, and lung, thus involving several organ systems. Generally, these disorders have not been included in newborn screening, but support for screening is growing. Some of these disorders may be treated with enzyme replacement therapy, which is effective in peripheral organs but cannot cross the blood-brain barrier to prevent neurodegeneration.³⁴

Perhaps the best known of the lysosomal storage disorders is **Tay-Sachs disease (GM₂ gangliosidosis)**, an autosomal recessive disorder (*HexA* gene on chromosome 15) caused by a deficiency of the lysosomal enzyme hexosaminidase A (HexA), an enzyme that degrades GM₂ gangliosides (fatty acids) within nerve cell lysosomes. Accumulation of gangliosides (**gangliosidosis**) causes toxicity to nerve cells, particularly in the CNS. Because of a founder effect, approximately 80% of individuals diagnosed are of Jewish ancestry, although sporadic cases appear in the non-Jewish population. Onset

of this disease usually occurs when the infant is 4 to 6 months old. Symptoms of Tay-Sachs include an exaggerated startle response, seizures, developmental regression, dementia, and blindness. Death from this disease is almost universal and occurs by 5 years of age. Screening for carriers of the gene defect concomitant with genetic counseling has been a successful approach to prevent disease transmission.³⁵

Acute Encephalopathies

Intoxications of the Central Nervous System

Drug-induced encephalopathies must always be considered a possibility in the child with unexplained neurologic changes. Such encephalopathies may result from accidental ingestion, therapeutic overdose, intentional overdose, or ingestion of environmental toxins (the most commonly ingested poisons are listed in [Box 20.2](#)). Approximately 42.6 children younger than 6 years/1000 persons were exposed to poisons, and approximately 1.1% of these children died in the United States in 2014.³⁶

Box 20.2

Common Poisons

PHARMACOLOGIC AGENTS	HEAVY METALS	MISCELLANEOUS AGENTS
Acetaminophen	Lead	Botulinum toxin
Amphetamines	Acute	Alcohols
Anticonvulsants	Chronic	Ethyl, isopropyl, methyl
Antidepressants	Mercury	Pesticides
Antihistamines	Thallium	Organophosphates
Atropine	Arsenic	Chlorinated hydrocarbons
Barbiturates	Cadmium	Mushrooms
Methadone		Venoms
Phencyclidine		Snake bite

Salicylates		Tick paralysis
Tranquilizers		Ethylene glycol Aliphatic hydrocarbons (e.g., gasoline, kerosene, lamp oil)

Data from Swaiman KF et al: *Swaiman's pediatric neurology: principles and practice*, vol 2, ed 5, St Louis, 2012, Mosby.

Lead poisoning results in high blood lead levels. No level of lead in the blood is safe. If lead poisoning is untreated, lead encephalopathy results and is responsible for serious and irreversible neurologic damage^{37,38} Those at greatest risk are children less than 72 months of age, those with pica, or those living in lead-contaminated environments. It is a global health concern in children. **Pica** is the habitual, purposeful, and compulsive ingestion of nonfood substances such as clay, dirt, or paint chips. Lead intoxication also may occur from long-term exposure to smelters, sniffing of lead-containing solvents, exposure to lead-based paint, and ingestion of airborne lead or contaminated food and water.³⁹

An estimated 535,000 U.S. children (2.6%) had excessive amounts of lead in their blood (>5 µg/dL) based on 2010 census data.⁴⁰ Excessive amounts cause varying degrees of intellectual disability depending on level and length of exposure. Young children are more likely to be exposed to lead-containing materials than older children because of mouthing behavior, and they absorb lead more easily than older children and adults. Levels continue to be highest among non-Hispanic black children, Mexican American, and non-Hispanic white children, with the greatest risk being in the non-Hispanic black population.⁴¹ The toxic effects of lead are summarized in [Fig. 20.14](#) (also see [Table 2.6](#), [Table 2.7](#), and [Fig. 2.20](#)). The neurologic effects include developmental delays and encephalopathy with ataxia, stupor, coma, seizures, and death.⁴² Guidelines are available for the treatment of lead exposure in children and include decontamination and chelation therapy.⁴³

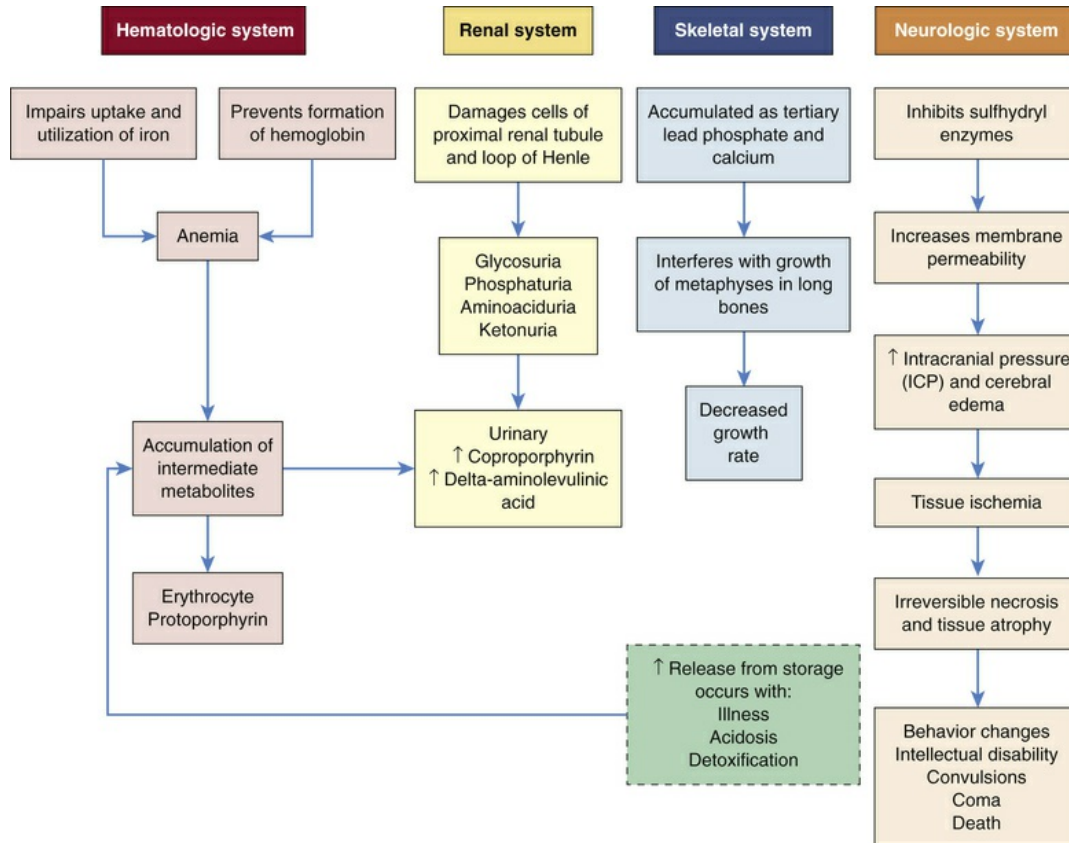

FIGURE 20.14 Systemic Effects of Increased Lead Absorption in Children.

Infections of the Central Nervous System

Meningitis is infection of the meninges and subarachnoid space of the brain and spinal cord, whereas the word **encephalitis** reflects inflammation within the brain. In many infections of the meninges, encephalitis also is present and the term *meningoencephalitis* is used. Such inflammation and acute encephalopathy can be caused by bacteria, viruses, or other microorganisms. **Aseptic meningitis** has no evidence of bacterial infection but may be associated with viral infection, systemic disease, or drugs.

Bacterial Meningitis.

Acute bacterial meningitis is one of the most serious infections to which infants and children are susceptible. In the United States approximately 4100 cases of bacterial meningitis occurred each year

between 2003 and 2007, including 500 deaths.⁴⁴ About half of these cases occurred in children younger than 18 years of age. The most common microorganisms accountable for bacterial meningitis in children are summarized in [Table 20.5](#).

TABLE 20.5

CAUSES OF BACTERIAL MENINGITIS

AGE GROUP	COMMON BACTERIAL PATHOGENS
Newborns	Group B <i>Streptococcus</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i>
Infants and children	<i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> type b
Adolescents and young adults	<i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i>

The introduction of conjugate vaccines against *Haemophilus influenzae* type B, *Streptococcus pneumoniae*, and *Neisseria meningitidis* (meningococcus) has greatly decreased the incidence of bacterial meningitis. Vaccines for *H. influenzae* and *S. pneumoniae* are available for young children, and a vaccine for serogroup B *N. meningitidis* is available for individuals 10 to 25 years of age.⁴⁵ Meningitis is still prevalent in countries without access to these vaccines.⁴⁴ (Note that although many families are worried about potential side effects from giving their infants vaccines, the introduction of these vaccines has resulted in a drastic reduction of these serious illnesses; bacterial meningitis is just one example.)

Group B *Streptococcus* causes lethal meningitis and sepsis in neonates and is transmitted to the child from the mother's birth canal. *S. pneumoniae* is the most common cause for meningitis in children 1 to 23 months of age. Staphylococcal or streptococcal meningitis can occur in children of any age but shows a predilection for children who have had neurosurgical procedures, skull fracture, or systemic bacterial infection. Infections that originate in the middle ear, sinuses, or mastoid cells also may lead to *S. pneumoniae* infection in children. Children who have sickle cell disease or have undergone a splenectomy are particularly at risk for pneumococcal infection.⁴⁶

Escherichia coli and group B streptococcus are the most common causes of meningitis in the newborn period. The second most common microorganism causing bacterial meningitis, particularly in children younger than 4 years, is *Neisseria meningitidis* (meningococcus), and it has the potential to occur in epidemics, especially among teens and young adults who are more likely to be carriers of *N. meningitidis*.⁴⁷

◆Pathophysiology.

Pathogens enter the nervous system by direct extension from a contiguous source (i.e., paranasal sinuses or mastoid cells) or, more commonly, by hematogenous spread (e.g., infective endocarditis, pneumonia, neurosurgical procedures, severe burns) (see [Figs. 18.24](#) and [18.27](#)). Many of these microorganisms have developed successful mechanisms to evade the normal defenses (see [Chapter 10](#)). Pathogens cross the blood-brain barrier, enter the cerebrospinal fluid, and multiply.⁴⁸ Bacterial toxins increase cerebrovascular permeability, causing alterations in blood flow and edema. Increased intracranial pressure (ICP) may be increased further by obstruction to the CSF circulation. Herniation of the brainstem causes death.

◆Clinical Manifestations.

Acute bacterial meningitis often is preceded by an upper respiratory tract or a gastrointestinal tract infection. Inflammation leads to the general symptoms of fever, headache, vomiting, and irritability. Specific symptoms of concern for meningitis include photophobia, nuchal and spinal rigidity, decreased level of consciousness, and seizures. Irritation of the meninges and spinal roots causes pain and resistance to neck flexion (nuchal rigidity), a positive Kernig sign (resistance to knee extension in the supine position with the hips and knees flexed against the body), and a positive Brudzinski sign (flexion of the knees and hips when the neck is flexed forward rapidly). With severe meningeal irritation the child may demonstrate opisthotonic posturing (rigid arching of the back with the head extended). Infants may have bulging fontanelles. Meningococcal meningitis can produce a characteristic purpuric rash, particularly when there is sepsis.

◆ Evaluation and Treatment.

A definitive diagnosis is made by examination of CSF obtained from a lumbar puncture and by CSF and blood cultures. The principles of treatment are similar to those followed for adults (see [Chapter 18](#)) and are based on the culture results in which the causative microorganism is identified. Empirical antibiotic therapy should be initiated and continued until CSF cultures are negative or changed if the empirical therapy is not correct for the bacteria cultured from the CSF.⁴⁹ Bacterial lysis induced by antibiotics can cause subarachnoid inflammation; the severity may be reduced with corticosteroid treatment.⁵⁰ The factors that influence outcomes are the age of the child (mortality is highest in infants younger than 1 year), the infective microorganisms (the lowest mortality is in meningococcal meningitis and the highest in meningitis caused by gram-negative enteric microorganisms), and the duration and extent of inflammation before treatment. Approximately 8% of children with *H. influenzae* meningitis die; 35% of the survivors have serious and permanent sensory or motor dysfunction caused by pressure on the peripheral nerves during the early phases of the illness. Approximately 5% of the children who survive meningitis have hearing deficits; 15% to 30% have cerebral damage, hydrocephalus, motor deficits, or sensory impairments.^{51,52}

Viral Meningitis.

Viral meningitis may result from direct infection by a virus, or it may be secondary to disease, such as measles, mumps, herpes, or leukemia. The hallmark of viral meningitis is a mononuclear pleocytosis in the CSF and the presence of normal blood glucose level.

The clinical manifestations are similar to those in bacterial meningitis, although usually milder. Isolation of the specific virus is difficult. An exception is when the virus responsible is the herpes simplex virus, which can occur in infants after exposure to herpesvirus type 2 in the birth canal, or sporadic cases caused by herpesvirus type 1, which is the type that causes cold sores. It is possible to test for herpesvirus and, unlike most of the other viruses,

there is a specific antiviral medication, acyclovir. When a child has symptoms of bacterial or viral meningoencephalitis, antibiotic and antiviral treatments are administered until the cause is determined.⁵³

Human Immunodeficiency Virus Encephalopathy.

Human immunodeficiency virus type 1 (HIV-1) causes a syndrome called *HIV-1 encephalopathy* (see [Chapter 10](#) for details of HIV infection, which results in developmental delays and impaired brain growth in children not directly related to opportunistic infections in the brain).

◆Pathophysiology.

The CNS is a distinct reservoir for HIV-1, but the pathogenesis of HIV encephalopathy in children is not clearly understood. HIV-1 invades the CNS early in infection, primarily through infected monocytes/macrophages and CD4+ T lymphocytes. The presence of viral products and inflammatory mediators induce neurotoxicity that leads to neuronal injury and death, particularly in the immature brain.⁵⁴

◆Clinical Manifestations.

The 1994 revised classification from the Centers for Disease Control and Prevention (CDC) requires one of the following progressing findings to be present for at least 2 months,⁵⁵ in the absence of a concurrent illness other than HIV that could explain the findings:

1. Failure to attain or loss of developmental milestones, or loss of intellectual ability, verified by standard developmental scale or neuropsychologic tests
2. Impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy established by CT or MRI, with serial imaging required in children younger than 2 years
3. Acquired symmetric motor deficits manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait

disturbances

The onset of progressive encephalopathy may be a prognostic indicator of a poor outcome, and it may be difficult to completely differentiate the effects of HIV infection on the CNS from the effects of prenatal and perinatal exposures. In addition, other insults, such as drug exposure, prematurity, and chronic illness, may accompany HIV in a young child and affect growth and development.

◆Evaluation and Treatment.

A definite diagnosis of HIV is made by patient history, viral culture, and clinical manifestations. Monitoring CD8+ T lymphocytes and monocytes, in addition to CD4+ T lymphocytes, has been suggested for predicting risk for progressive encephalopathy. Decreases in CD8+ T lymphocytes diminish defenses against viral infection and facilitate infected monocytes to cross the blood-brain barrier. In general, treatment is focused on preservation and maintenance of the immune system, aggressive response to opportunistic infections, and support and relief of symptomatic occurrences by administration of highly active antiretroviral therapy (HAART). (HIV treatment is discussed in [Chapter 10](#).) Progressive HIV encephalopathy is an infrequent and reversible complication of HIV infection because the disease responds to HAART.⁵⁶

Cerebrovascular Disease in Children

Perinatal Stroke

Perinatal stroke is estimated to occur in about 1 to 2 in 5000 live births. Strokes can be either ischemic or hemorrhagic. Neonatal ischemic strokes occur between 20 weeks of fetal life and the 28th postnatal day and are confirmed by neuroimaging or neuropathologic studies. The cause is usually secondary to arterial or cerebral venous thrombosis or embolization.⁵⁷ Intraventricular hemorrhage (IVH) is a common complication of prematurity and is related to the fragility of an

immature vasculature and the hemodynamic and respiratory instability associated with prematurity. Prenatal glucocorticoids are the most effective means of preventing IVH. Fifty percent to 75% of premature infants with IVH develop hydrocephalus, cerebral palsy, and/or intellectual disability.⁵⁸

Children with perinatal stroke may not be diagnosed until later in infancy or childhood when it becomes apparent that the child is not moving one side of the body as much as the other. Early signs may consist of the family noticing that one hand is preferred over the other at an early age—typical “handedness” does not usually occur until 16 to 18 months of age—or one foot is dragging. An MRI is often performed at this point and is most likely to show evidence of a previous middle cerebral artery stroke. The clinical pattern that usually results from this type of stroke is contralateral hemiplegia, with the arm more affected than the leg. Children with hemiplegia caused by perinatal stroke (hemiplegic CP) are prone to seizures, although they generally do well cognitively. Testing for abnormalities in blood-clotting mechanisms, such as antithrombin enzyme activity, protein C and protein S deficiencies, or abnormal factor V Leiden, is often performed in children with prenatal stroke. Although often normal, abnormalities in these clotting mechanisms should be assessed because they may make the child prone to further vascular events.

Childhood Stroke

Childhood stroke occurs in about 1 to 13 per 100,000 live births (Box 20.3).⁵⁹

Box 20.3

Stroke in Children

- Risk factors different from those for adult (i.e., hypertension, atherosclerosis, diabetes, smoking, obesity)

- Important risk factors (causes) include:
 - Ischemic stroke*—heart disease or congenital cardiac disorders (most common), blood disorders, clotting or coagulation disorders, sickle cell anemia, infections (chickenpox, meningitis, encephalitis, Moyamoya disease), and arterial dissection
 - Hemorrhagic stroke*—vascular malformations, including arteriovenous malformations (AVMs) and aneurysms; blood disorders, including thrombocytopenia and leukemia; and malignancy, including intracranial tumors; head and neck trauma
- Vascular occlusion occurs more often in intracranial vessels (cerebral arteriopathy), including internal carotid, middle cerebral, and basilar arteries; infarcts more often limited to deep regions of the cerebral hemispheres, mostly basal ganglion and internal capsule areas.
- Intracerebral hemorrhage and subarachnoid hemorrhage account for a much higher percentage of strokes in children.
- Risk for recurrence and mortality appear to be low for neonatal and childhood stroke.

From Kirton A, deVeber G: *Lancet Neurol* 14(1):92-102, 2015; Lo WD, Kumar R: *Continuum (Minneapolis)* 23(1, Cerebrovascular Disease):158-180, 2017; Numis AL, Fox CK: *Curr Neurol Neurosci Rep* 14(1):422, 2014; Moraitis E, Ganesan V: *Curr Cardiol Rep* 16(9):527, 2014.

Ischemic Stroke

Ischemic stroke is rare in children and may result from embolism, arteriopathy, or, rarely, sinovenous thrombosis leading to a decreased flow of blood and oxygen to areas of the brain. Children with arterial ischemic stroke do not have the typical adult risk factors, such as atherosclerosis and hypertension. Approximately 40% of children with ischemic stroke have no identifiable underlying risk factors. Sickle cell disease, cerebral arteriopathies, cardiac anomalies, and brain infections are the most common disorders that lead to **arterial**

ischemic stroke.⁶⁰

Hemorrhagic Stroke

Congenital cerebral arteriovenous malformations are the most common cause of intracranial bleeding and hemorrhagic stroke in children.⁶¹ **Hemorrhagic stroke** may result from vascular anomalies that lead to rupture, such as aneurysm, or from congenital arteriovenous malformations (pial arteriovenous malformations, vein of Galen malformations, and arteriovenous fistulae). The rupture of a cerebral aneurysm is rare in children younger than 19 years. Intraventricular hemorrhage associated with premature birth is related to immature blood vessels and unstable blood pressure. There is a high risk of developing posthemorrhagic hydrocephalus.⁶²

Moyamoya Disease

Moyamoya disease is a rare, chronic, progressive stenosis of the anterior circulation, such as the internal carotid arteries and middle cerebral arteries. *Moyamoya* is a Japanese term that means “puff of smoke,” which describes the vascular appearance on cerebral angiogram. The disease is more common among the east Asian population. *Moyamoya* results from fibrocellular thickening of the intima of the arterial wall of large cerebral vessels. Obstruction of arterial flow to the brain occurs slowly, and neovascularization and increased collateral blood flow to ischemic areas develop. Moyamoya vasculopathy may be idiopathic, associated with certain genetic or metabolic syndromes, or develop as a result of cranial radiation therapy. Complications are developmental delay/intellectual disability, recurrent ischemic strokes, and cerebral hemorrhage. Treatment is surgical bypass of the ischemic region.⁶³ Symptoms of ischemic or hemorrhagic stroke may include degrees of hemiplegia (flaccid, spastic), weakness, seizures, headache, high fever, nuchal rigidity, hemianopia, sensory changes, facial palsy, and temporary aphasia.

Diagnosis of cerebrovascular disease is made through a series of

tests, including imaging studies, particularly MRI. The most important factor in diagnosis is the recognition that children can have strokes, but this possibility is often not recognized. History of evolving neurologic symptoms (seizures, altered mental status, weakness, numbness on one side of body or face, expressive or sensory aphasia) for less than 12 hours and medical history are of vital importance in attaining an accurate diagnosis of stroke etiology, although causative factors often cannot be determined.⁶⁴ There is no evidence-based treatment for pediatric stroke. Prophylactic medications may be prescribed in those children who have suffered an ischemic stroke (e.g., aspirin, but Reye syndrome must be considered).⁶⁰ Arteriovenous malformations that may leak and cause hemorrhagic stroke vary in size, location, and symptoms, and these factors determine treatment. If a malformation is present, treatment options include endovascular, surgical, and radiosurgical techniques for embolic occlusion or resection of the malformation.⁶⁵ Excellent collateral circulation in the child's brain allows for more rapid recovery of motor function than in adults. The developing brain, however, may suffer more global, long-term effects leading to intellectual disability, behavior disorders, and seizures.

Epilepsy and Seizure Disorders in Children

Epilepsy is defined as the occurrence of at least two unprovoked seizures more than 24 hours apart.⁶⁶ The incidence of epilepsy varies greatly with age, geographic location, and study design. The highest incidence is in children younger than 2 years of age and adults older than 65 years. Approximately 150,000 persons in the United States are newly diagnosed each year.⁶⁷ The focus of content in this section is related to children. [Chapter 17](#) contains a general discussion of seizures and epilepsy and content related to adults.

Seizures are the abnormal autonomous discharge of electrical activity within the brain (an **epileptogenic focus**). When a sufficient

number of neurons become overexcited, they discharge abnormally, which sometimes results in clinical manifestations (seizures) with alterations in motor function, sensation, autonomic function, behavior, and consciousness. Dysregulation of inhibitory GABA_A neurotransmission with imbalance of glutamatergic excitatory mechanisms is speculated to be a cause of early childhood seizures. Dysregulation of other types of voltage- and ligand-gated ion channels (i.e., sodium, calcium, potassium, and chloride) is associated with genetically determined epileptic syndromes.⁶⁸ If seizures develop, the specific physical activity that occurs depends on the origin of the electrical activity and its extent within the brain. If a child has more than one unprovoked seizure, that child is said to have epilepsy, although there are a few exceptions—one example being febrile seizures. Seizures can be the result of an underlying disorder (e.g., meningitis or a brain tumor), or seizures themselves may be the primary disorder; the latter may have a genetic or a familial predisposition (for instance, childhood absence epilepsy and juvenile myoclonic epilepsy) (see later and [Table 17.16](#) and [Table 17.17](#)). Nearly half of childhood epilepsy is of unknown etiology.⁶⁹

Seizures and seizure patterns may change as a child grows and develops. The differences between the immature and mature nervous systems may help explain the changing patterns of clinical seizures with age. For example, febrile seizures manifest in children 6 months to 3 years of age, and juvenile myoclonic epilepsy is first noted in adolescence. The immature nervous system has a reduced capacity for sustaining well-organized seizures and, therefore, infants are prone to have seizures that occur only in small parts of the body compared to generalized tonic-clonic seizures in older children. This is because intracortical connections are poorly developed in children and the sending of impulses throughout the cortex is limited. At the cellular level, neurons are less capable of firing in repetitive high-frequency bursts. The excitatory output of a seizure focus is further diminished because the affected neurons do not act synchronously. In addition, changing neurotransmitters, immaturity of cells, and ongoing postnatal factors affect seizure expression in children.

During the newborn period, asphyxia, intracranial hemorrhage, CNS infection, injury, electrolyte imbalances, and inborn errors of metabolism may cause seizures. Despite an extensive search for a cause, the etiology often remains unknown. Infants and children may have seizures based on earlier brain damage (e.g., cerebral palsy) or may manifest specific epilepsy syndromes (childhood absence epilepsy, Lennox-Gastaut syndrome). Adolescents may have seizures caused by juvenile myoclonic epilepsy or because of other underlying conditions. There is an association between autism spectrum disorder and seizures; however, the mechanisms are unclear.⁷⁰

The clinical manifestations at the time of the seizures vary depending on the primary cause and the extent and involvement of abnormal electrical discharges within the neuronal tissue. Because of the diversity and complexity that seizure activity invariably displays, an international classification system was adopted. This classification system groups seizures with similar clinical manifestations (see [Table 17.17](#)). Its general purpose is to assist the clinician with the type of evaluation needed, the identification of the most appropriate treatment, and the evaluation of the individual's response to treatment.⁷¹

Focal seizures are characterized by seizure activity that begins in and usually is limited to one part of either the left or the right hemisphere, and may occur with or without loss of consciousness. The clinical activity displayed is contingent on the particular part of the cortex from which the seizure is generated. For example, focal seizures may result in abnormal motor activity, such as twitching or loss of tone, or sensory changes, such as tingling or numbness (see [Table 17.17](#)).

Focal seizures may evolve into a generalized tonic, clonic, or atonic seizures. Focal seizures are more likely to be caused by an abnormality in a specific part of the brain, and thus brain imaging is usually performed in children whose seizures have started in a localized manner, even if they generalize later. Possibilities include brain tumors, small areas of localized brain damage, and other causes.

Generalized seizures are those in which the first clinical

manifestations indicate that the seizure activity starts in or involves both cerebral hemispheres. Because both hemispheres are involved, the clinical manifestations are almost always bilateral. Consciousness may be impaired in this grouping of seizures. The clinical manifestations may include convulsive activity (tonic-clonic, tonic, clonic, myoclonic, myoclonic-atonic, or epileptic spasms) or absence seizures (nonconvulsive activity). Generalized seizures are more likely than focal seizures to have a genetic component; although the genetics of some of the epilepsy syndromes have been identified, many appear to have a multifactorial genetic etiology.⁷²

Childhood absence epilepsy (also called *petit mal seizures* or *nonconvulsive epilepsy*) is a type of generalized epilepsy. The age of onset is 4 to 10 years. The genetic causes are unknown and probably multifactorial; it also can be sporadic. Mutations in inhibitory gamma-aminobutyric acid A (GABA_A) receptor subunit genes and ion channel genes are associated with absence seizures. The seizures are initiated at a cortical site and spread to other cortical areas and to the thalamus. The electroencephalogram (EEG) shows a characteristic bilateral 3-Hz spike-wave discharge. The characteristic absence seizure is of sudden onset and sudden termination, with impairment of consciousness and unresponsiveness usually lasting less than 10 seconds with no residual deficits. There is interruption of ongoing voluntary activity accompanied by staring, mild eyelid fluttering, or myoclonic jerks. There is no aura. Pallor is common. Seizures may be provoked by about 3 minutes of hyperventilation. Hundreds of seizures can occur per day, disrupting schoolwork and socialization. Behavioral, cognitive, and linguistic impairment is common. Antiepileptic drugs provide beneficial treatment.⁷³

Epilepsy Syndromes

Epilepsy syndromes are seizure disorders that display a common group of signs and symptoms that occur in a recognizable pattern. Several syndromes associated with epilepsy occur in infants and children: neonatal seizure, febrile seizures, infantile spasms, Lennox-Gastaut syndrome, and juvenile myoclonic epilepsy.

Neonatal seizures have activity that includes rhythmic eye movements, chewing, and swimming movements. These seizures are more often associated with hypoxic-ischemic encephalopathy, transient metabolic disturbance, infection, stroke, or intracranial hemorrhage rather than neonatal-onset epilepsies, which may stem from malformation, prior injury, or genetic causes. The immature brain is hyperexcitable and vulnerable to seizure activity. Meticulous efforts are required for diagnosis, and there are no standardized treatment guidelines. Some seizures are self-limiting.^{74,75}

Febrile seizures are defined as seizures associated with fever in the absence of central nervous system infection. They are divided into two types: simple febrile seizures and complex febrile seizures. Simple febrile seizures occur in 2% to 5% of children. They are benign and the most common childhood seizure.

The pathogenesis of simple febrile seizures is unknown. A familial incidence of simple febrile seizures indicates a genetic predisposition. Factors that contribute to susceptibility include age, degree and rate of temperature elevation, and nature of the particular fever-inducing illness. Any disorder producing a high fever may provoke benign febrile seizures in susceptible children.

The following characteristic features distinguish simple febrile seizures from complex seizures precipitated by fever:

1. Simple febrile seizures usually occur between 3 months and 5 years of age.
2. The convulsion occurs with a rise in temperature to greater than 39°C (102.2°F).
3. An acute respiratory tract or ear infection usually is present, with no evidence of CNS infection or inflammation.
4. Most seizures occur during the first 24 hours of the illness.
5. The convulsion is short (15 minutes or less), generalized, and predominantly tonic.
6. Interictal (period between seizures) EEG is normal.
7. The seizure usually does not recur during the same infection.
8. No acute systemic metabolic disorder is present.

Complex febrile seizures have characteristic features similar to those of simple febrile seizures except that (1) they have a longer duration than do benign febrile seizures, usually longer than 15 minutes; (2) they have focal characteristics, confined to one side of the child's body; and (3) they usually occur more than once in a 24-hour period. The link between complex febrile seizures and the development of epilepsy continues to be evaluated.⁷⁶

For febrile seizures, the cause of the child's fever should be determined, and meningitis should be considered in the differential diagnosis. Medications for preventing recurrence of simple febrile seizures are rarely used because side effects outweigh benefits.⁷⁷

Infantile spasms (also known as **West syndrome**) are a severe form of epilepsy characterized by a variety of clinical manifestations. Children with infantile spasms have episodes consisting of sudden flexion or extension involving the neck, trunk, and extremities. Infantile spasms in some children are caused by underlying brain abnormalities such as intrauterine stroke or tuberous sclerosis, whereas others may be caused by mutations in one of several genes. Clinical manifestations of the resulting spasms may range from subtle head nods to violent body contractions, commonly referred to as *jackknife seizures*. Onset of infantile spasms usually is between 4 and 8 months of age and may be idiopathic or may occur in response to a CNS insult. An EEG will display the classic hypsarrhythmic pattern on a slow, disorganized background. After infantile spasms begin, there is usually a typical clinical course. The "spasms" usually occur in clusters and happen 5 to 150 times per day. They are usually worse when the infant is waking up or falling asleep. Once begun, the seizure activity increases in intensity and severity over time. Invariably, a loss of developmental milestones and disability is associated with this syndrome. A short-term course of adrenocorticotrophic hormone or prednisolone is effective in many cases of infantile spasms.⁷⁸

Infantile spasms are present in about 30% of children with **tuberous sclerosis complex (TSC)**. TSC develops from autosomal dominant mutations in hamartin (*TSC1*) found on chromosome 9q34 or tuberin

(*TSC2*) genes found on chromosome 16p13. *Tubers* are cortical developmental malformations in the brain; they also form in other organs (i.e., skin, heart, lung, kidneys). Epilepsy associated with TSC is often difficult to treat. Steroids or vigabatrin, which may cause vision defects, are the medications of choice for children with infantile spasms attributable to tuberous sclerosis because they seem to be particularly effective in these children.⁷⁹ Epilepsy surgery (resection of the epileptogenic zone of brain tissue or severing of the corpus callosum for intractable generalized epilepsy) also may be effective.⁸⁰

Lennox-Gastaut syndrome is an epileptic syndrome characterized by an onset of seizures early in childhood; it occurs in males more often than females and begins between 1 and 8 years of age. This syndrome includes a variety of generalized seizures—predominantly tonic-clonic, atonic (drop attacks), akinetic, absence, and myoclonic activity and a specific pattern on EEG (slow spike and wave). Seizures associated with this syndrome are usually very difficult to treat. Children may be prescribed multiple medications and alternative therapies, such as a ketogenic diet (see [Nutrition & Disease: Ketogenic Diet in Children with Epilepsy](#)), vagal nerve stimulation, or epilepsy surgery. Although children may be developmentally on track when the seizures begin, development is usually affected and the future manifestation of intellectual disability is common.⁸¹

Nutrition & Disease

Ketogenic Diet in Children with Epilepsy

The goal of the ketogenic diet is to maintain a state of ketosis, which appears to facilitate reduced seizure frequency and severity for difficult-to-control (medically refractory, nonsurgical) seizures in children. The diet may be helpful to children who do not respond to conventional therapy or have intolerable side effects from antiepileptic medications. Seizure reduction can occur within 5 to 14 days of initiating the diet and usually within 6 months with beneficial effects after discontinuation. Two basic approaches to the

ketogenic diet are: (1) a traditional approach with four parts fat to one part carbohydrate/protein in the diet, and (2) the medium-chain triglyceride (MCT) approach, in which MCTs make up about 50% to 70% of the diet. Either diet may be unpalatable and difficult to follow, particularly if the child has free access to food. Carbohydrates can be added by 5-g increments after 3 to 6 months if there has been no seizure activity, provided ketosis is maintained. Both dietary approaches include adequate protein for growth. A medium-chain triglyceride diet, modified Atkins diet, or low glycemic index treatment can also induce ketosis and does not restrict protein, fluid, or calories. The mechanisms are not clearly understood, but enhanced mitochondrial respiration, adenosine triphosphate (ATP) production, and reduced reactive oxygen species formation may influence the dynamics of excitatory and inhibitory neurotransmitter systems in the brain and may be neuroprotective. Side effects can include acidosis, kidney stones, hypoglycemia, gastrointestinal distress, dehydration, lethargy, and poor growth. Most side effects are treatable.

Data from Agarwal et al: *SAGE Open Med* 5:2050312117712887, 2017; Lin A et al: *Pediatr Neurol* 68:35-39, 2017; Sampaio LPB, Takakura G, Manreza MLG: *Arg Neuropsiquiatr* 75(4):234-237, 2017.

Juvenile myoclonic epilepsy (JME) is a primary, generalized epilepsy that usually affects adolescents and young adults. Genetic factors are complex and are still being clarified. JME is a relatively benign form of epilepsy involving myoclonic jerks of the neck, shoulders, and arms as well as generalized tonic-clonic seizures. Myoclonic jerks typically occur after awakening. The seizures may occur singularly or repetitively. This form of epilepsy is commonly associated with a normal neurologic examination, normal intelligence, and a family history of seizures. Cognitive impairment and psychiatric disorders have been reported. Because clinical features can be subtle, JME is likely to be underdiagnosed. Children with this syndrome will usually need to take medications for life, but with

appropriate treatment, seizures are well controlled.⁸²

Childhood Tumors

Brain Tumors

Brain tumors are the most common solid tumor and cause of cancer death in children⁸³ (see *What's New? Childhood Brain Cancer Deaths*). Approximately 45% of primary brain tumors in children are nonmalignant.⁸⁴ Overall, primary brain tumors account for nearly 26% of all childhood cancers, with an annual incidence of 5.37 per 100,000 for primary malignant and nonmalignant tumors in the United States; approximately 4,630 new cases will be diagnosed in 2016. Many nonmalignant brain and CNS tumors are not histologically confirmed, and reporting varies across cancer registries. Survival at 5 years for primary malignant brain tumor for ages 0 to 19 years of age is 73.9%, varying significantly by tumor type, and there is often significant morbidity.⁸⁵

What's New?

Childhood Brain Cancer Deaths

From 1999 to 2014, brain cancer replaced leukemia as the most common cancer cause of death among children and adolescents. In 2014 brain cancer accounted for 29.9% of total cancer deaths or 3 of 10 deaths in children with cancer ages 10 to 19 years. Efforts are in progress for the molecular identification of subgroups of pediatric brain tumors, particularly medulloblastoma, ependymoma, and high-grade glioma, including diffuse intrinsic pontine glioma. Such identification will direct individualized, tumor-specific treatment.

Data from Centers for Disease Control and Prevention (CDC): *National Center for Health Statistics: Declines in Cancer Death Rates among Children and Adolescents in the United States, 1999–2014*, NCHS Data Brief N. 257, September 2016. Available at

Primary brain tumors arise from brain tissue and do not metastasize outside the brain. The cause of brain tumors is largely unknown, although genetic, environmental, and immune factors have been investigated. Exposure to ionizing radiation has been the only environmental factor consistently related to the development of brain tumors.⁸⁶

◆Pathophysiology.

Brain tumors can arise from any CNS cell and are classified by cell type. Medulloblastoma, ependymoma, astrocytoma, brainstem glioma, craniopharyngioma, and optic nerve glioma constitute approximately 75% to 80% of all pediatric brain tumors.⁸⁵ Germ cell tumors are rare. Two-thirds of all pediatric brain tumors in children are located in the posterior fossa (Fig. 20.15). Brain tumors spread by direct invasion or dissemination of cells through CSF. Specific characteristics, treatment strategies, and prognoses are listed in Table 20.6.

FIGURE 20.15 Location and Approximate Percentage of Brain Tumors in Children.

TABLE 20.6

BRAIN TUMORS IN CHILDREN

TYPE	CHARACTERISTICS	TREATMENT	PROGNOSIS
Astrocytoma	<p>Arises from astrocytes, often in cerebellum or lateral cerebral hemisphere</p> <p>Slow growing, solid or cystic</p> <p>Often very large before diagnosed</p> <p>Varies in degree of malignancy</p>	<p><i>Cerebellar astrocytoma</i></p> <p>Surgery; possibly curative</p> <p>Radiation and chemotherapy not proved successful but may delay recurrence</p> <p><i>Cerebral astrocytoma</i></p> <p>Surgery used if resection is possible</p> <p>Radiation useful for all grades of astrocytoma</p> <p>Chemotherapy beneficial in higher grade tumors but further study required</p>	<p><i>Cerebellar astrocytoma</i></p> <p>90%–100% 5-year survival rate if pilocytic type (most common); if tumor recurs, it does so very slowly</p> <p><i>Cerebral astrocytoma</i></p> <p>75% 5-year survival rate with lower grade tumors</p> <p>20% 5-year survival rate if high-grade tumor</p>

<p>Optic pathway glioma</p>	<p>Arises from optic chiasm or optic nerve (association with neurofibromatosis type 1) Slow-growing, low-grade astrocytoma</p>	<p>In setting of visual impairment or progression (increase in size), chemotherapy is usual initial treatment Radiation therapy for tumors that progress or recur in spite of chemotherapy Surgery for large tumors, or hydrocephalus, or other complications; rarely for diagnosis</p>	<p>100% 5-year survival when confined to optic nerve 70% 5-year survival for tumor progression beyond optic chiasm</p>
<p>Medulloblastoma (infiltrating glioma)</p>	<p>Often located in cerebellum, extending into fourth ventricle and spinal fluid pathway Can extend outside central nervous system Rapidly growing malignant tumor</p>	<p>Type of treatment is age and tumor type dependent Surgery, primarily as partial resection to relieve increased intracranial pressure and “debulk” tumor Radiation as primary treatment; may include spinal radiation Chemotherapy showing some promise in conjunction with craniospinal radiation</p>	<p>65%–85% 5-year survival rate depending on stage/type</p>
<p>Brainstem glioma</p>	<p>Arises from pons Numerous cell types Compresses cranial nerves V through X</p>	<p>Surgery, resection occasionally possible Radiation, primarily palliative treatment Chemotherapy not yet proven beneficial, but new protocols being studied</p>	<p>20%–40% 5-year survival rate</p>
<p>Ependymoma</p>	<p>Arises from ependymal cells lining ventricles Circumscribed, solid, nodular tumors</p>	<p>Tumor possibly indolent for many years Surgery rarely curative; risk of resecting an infratentorial tumor</p>	<p>20%–80% 5-year survival rate dependent on total resection</p>

		<p>too great</p> <p>Radiation for palliation (current controversy over whether local or craniospinal radiation is best)</p> <p>Chemotherapy used for recurrent disease but with disappointing results</p>	
Craniopharyngioma	<p>Arises near pituitary gland, optic chiasm, and hypothalamus</p> <p>Cystic and solid tumors that affect vision, pituitary, and hypothalamic functions</p>	<p>Surgery possibly successful when complete resection is performed (partial resection usually requires further treatment)</p> <p>Radiation after partial surgical resection</p> <p>Chemotherapy not commonly used</p>	80%–95% 5-year survival rate

Brain tumors, by virtue of their location, have unique characteristics that distinguish them from tumors found elsewhere in the body. A number of brain tumors in children may be considered histologically benign yet clinically malignant and life threatening because of their location. For example, a tumor located in the brainstem may appear benign under the microscope, but the clinical presentation threatens and all too often overrides the vital functions of the brainstem.

◆Clinical Manifestations.

The location of the brain tumor, cell type, and rate of growth dictate the presenting signs and symptoms (discussed in greater detail with each particular brain tumor type). The ability of the brain and intracranial cavity to compensate for tumor growth is directly related to the rate of its growth. This compensatory mechanism allows the components of the intracranial space (blood, brain, and CSF) to adapt temporarily to slow changes in increased intracranial pressure. Therefore slow-growing tumors can grow to enormous size before signs and symptoms are apparent. Conversely, fast-growing tumors allow little time for compensation of the space-occupying lesion, and

clinical symptoms occur quickly. Clinical symptoms may range from changes in personality to paralysis, depending on the location of the tumor.

Signs and symptoms of brain tumors in children vary from generalized and vague to those that are localized and related specifically to the area of the brain involved. If the tumor is located in the posterior fossa, the fourth ventricle may become blocked, which leads to obstructive hydrocephalus and signs of increased ICP. The symptoms of increased ICP include headache, vomiting, lethargy, and irritability. If a young child complains of repeated and worsening headache, a thorough investigation should take place because headache is an uncommon complaint in young children. Headache caused by increased ICP usually is worse in the morning and gradually improves during the day when the child is upright and venous drainage is enhanced. The frequency of headache and other symptoms increases as the tumor grows. Irritability or possible apathy and increased somnolence also may result from increased ICP. Like headache, vomiting occurs more commonly in the morning. It is often *not* preceded by nausea and may become projectile, differing from a gastrointestinal disturbance in that the child may be ready to eat immediately after vomiting. Other signs and symptoms that can accompany increased ICP include increased head circumference with bulging fontanelles in children younger than 2 years, cranial nerve palsies, and papilledema.

Localized findings relate to the degree of disturbance in physiologic functioning in the area where the tumor is located. Children with infratentorial tumors exhibit localized signs of impaired coordination and balance, including ataxia, gait difficulties, truncal ataxia, and loss of balance. Medulloblastoma and ependymoma are embryonal tumors. **Medulloblastoma** is the most common, develops in the vermis of the cerebellum, and may extend into the fourth ventricle. Angiogenesis is the hallmark of progressive medulloblastomas. Subclassifications based on histopathology and genomics are contributing to targeted therapy.⁸⁷ **Ependymoma** develops in the fourth ventricle and arises from the ependymal cells that line the

ventricular system. Because both tumors are located in the posterior fossa region along the midline, presenting signs and symptoms are similar, and they are more likely to spread throughout the neuraxis. In contrast, **cerebellar astrocytomas** are located on the surface of the right or left cerebellar hemisphere and cause unilateral symptoms (occurring on the same side as the tumor), such as head tilt, limb ataxia, and nystagmus when the eyes are turned toward the side with the tumor.

Brainstem gliomas often cause a combination of cranial nerve involvement (facial weakness, limitation of horizontal eye movement), ataxia, and corticospinal tract dysfunction. A common clinical pattern includes unilateral paralysis of cranial nerves with contralateral paralysis of the arm and leg, hyperreflexia, and extensor plantar responses. Increased ICP can occur if there is expansion of the pons.⁸⁸

The area of the sella turcica, the structure containing the pituitary gland, is the site of several childhood brain tumors. Most common in this group is **craniopharyngioma**. This tumor originates from the pituitary gland or hypothalamus. Usually slow growing, it may be quite large at the time of diagnosis with compression of the pituitary gland and hypothalamus and increased intracranial pressure. Symptoms include headache, seizures, diabetes insipidus, early onset of puberty, and growth delay. Other tumors located in this region of the brain include **optic gliomas**. Optic nerve gliomas are associated with neurofibromatosis type 1, a neurocutaneous condition characterized by café-au-lait macules on the skin and benign tumors of the skin. Tumors that involve the optic tract may cause complete unilateral blindness and hemianopia of the other eye. Optic atrophy is another common finding.

Supratentorial tumors of the cerebral hemispheres are more common in neonates and adolescents.⁸⁹ **Pilocytic astrocytomas** are the most common supratentorial tumors. These are localized (grade I) slow-growing, cyst-filled gliomas that are often completely removed surgically with very high survival rates. Tumors located in the cortex may cause focal cerebral dysfunction, weakness, hemiparesis, seizures, and visual changes. Involvement of particular lobes may

result in more specific localized symptoms. For example, a tumor located in the frontal lobe may cause changes in affect and behavior, and a tumor in the occipital lobe may cause cortical blindness or blindness in half of the visual field.

◆Evaluation and Treatment.

A child with signs and symptoms of a brain tumor requires a complete workup, including a neurologic, developmental, and ophthalmic examination. CT with contrast enhancement allows direct visualization of the tumor mass. MRI provides advanced, high-resolution examination of the brain and neoplasms. Small low-grade tumors not seen on CT may be detected by MRI. Magnetic resonance angiography (MRA) is very helpful in assessing the vascularity of the tumor and its relationship to major blood vessels. Spine MRI examination may be used to evaluate tumor dissemination along the spinal column. Lumbar puncture to examine CSF for tumor cells also may be performed. Histochemical and molecular genetic analysis of tumor tissue assists with tumor classification.

The most useful treatment for brain tumors is surgical resection. Surgery is important to establish the diagnosis, reduce tumor size, and relieve tumor compression and obstructive hydrocephalus when present. Some brain tumors, such as low-grade cerebellar astrocytomas, may be cured with complete resection alone. Contraindications to such interventions are tumors in which surgical resection and biopsy carry a high risk of mortality or serious morbidity (brainstem gliomas). In these instances, diagnosis is made on the basis of radiologic evidence and clinical manifestations.

Most brain tumors require additional radiation and chemotherapy. Although these treatments are essential for potential eradication of the brain tumor, radiation to a young child's brain is associated with significant morbidity, including acute- and long-term sequelae. Prognosis varies according to the type, classification, location of the brain tumor, and age of the child (see [Table 20.6](#)). Historically, survival rates have been low; however, advances have been made with the combination of surgery, radiation therapy, and

chemotherapy. High-dose chemotherapy with autologous stem cell rescue has been used for treatment of resistant tumors.⁹⁰ Advances are being made in areas of immunotherapy and targeted molecular therapy.⁹¹ Comprehensive care and management of these children and their families are vital. Multidisciplinary teams enhance the continuity and consistency needed to care for these children and their families.⁹²

Neuroblastoma

Neuroblastoma is an embryonal tumor derived from neural crest cells that form the adrenal medulla and the sympathetic nervous system. Neuroblastoma involves a defect of embryonic tissue and is the most common extra-cranial solid tumor in infants less than 1 year of age. Seventy-five percent of neuroblastomas are found before the child is 5 years old, and onset after 10 years of age is rare. Occasionally, these tumors have been diagnosed at birth, with metastasis apparent in the placenta. The incidence is about 10.54 per million per year in children younger than 15 years. Black children are more likely to have high-risk disease and fatal outcomes. Approximately 70% of children with neuroblastoma have metastatic disease at diagnosis.⁹³ Neuroblastomas are heterogeneous and can spontaneously regress or become highly metastatic with low, intermediate, or high risk for recurrence. Prognosis is worse for children older than 2 years of age with disseminated disease. Neuroblastoma is sporadic in most children. Familial cases of neuroblastoma (1% to 2% of cases) are considered to have an autosomal dominant pattern of inheritance (mechanisms of inheritance are discussed in [Chapter 4](#)).

Ganglioneuroblastomas are localized tumors of an intermediate level of cellular differentiation composed of mature ganglion and myelin sheath. The most differentiated tumor is a **ganglioneuroma**, which is considered benign and does not metastasize. They are usually surgically removed.

◆Pathophysiology.

Neuroblastomas arise from neural crest tissue, and the mechanisms are not clearly understood. Both genetic and epigenetic events are

involved. The most common location of neuroblastoma is in the retroperitoneal region (65% of cases), most often the adrenal medulla. The tumor is evident as an abdominal mass and may cause anorexia, bowel and bladder alteration, and sometimes spinal cord compression. The second most common location of neuroblastoma is the mediastinum (15% of cases), where the tumor may cause dyspnea or infection related to airway obstruction. Less commonly, neuroblastoma may arise from the cervical sympathetic ganglion (3% to 4% of cases). Cervical neuroblastoma often causes Horner syndrome, which consists of miosis (pupil contraction), ptosis (drooping eyelid), enophthalmos (backward displacement of the eyeball), and anhidrosis (sweat deficiency). Neuroblastoma presents with a neurologic syndrome called *opsoclonus-myoclonus syndrome* (jerky movements of the limbs, ataxia, and chaotic eye movements in all directions).⁹⁴

◆Clinical Manifestations.

A number of systemic signs and symptoms are characteristic of neuroblastoma, including weight loss, irritability, fatigue, and fever. Intractable diarrhea occurs in 7% to 9% of children and is caused by tumor secretion of a hormone called *vasoactive intestinal polypeptide (VIP)*. More than 90% of children with neuroblastoma have increased amounts of catecholamines and associated metabolites in their urine. High levels of urinary catecholamines and serum ferritin are associated with a poor prognosis.

◆Evaluation and Treatment.

Initial diagnostic studies are dictated by the location of the primary tumor. Diagnosis begins with a complete physical and neurologic examination. Laboratory analyses include measurement of levels of urinary catecholamines; plasma ferritin; serum neuron-specific enolase (NSE), an enzyme produced by neuronal tissues; and gangliosides, lipid molecules that may be shed from the surface of tumor cells; and bone marrow biopsy. Imaging studies assist with localization. The diagnosis of neuroblastoma is confirmed by surgical

biopsy and histopathologic results. Antenatal ultrasound may detect the tumor in the antenatal period.⁹⁵

Treatment is based on the extent of the disease and prognostic markers, such as age, *MYCN* copy numbers (a proto-oncogene), chromosome 11q status, DNA ploidy, and high serum ferritin or NSE levels. Low-risk disease is treated surgically. Chemotherapy is used if there is recurrence. Intermediate-risk tumors are treated with surgery and chemotherapy. High-risk neuroblastomas are treated with high-dose chemotherapy and radiotherapy followed by transplantation of purged autologous bone marrow. Monoclonal antibody-based immunotherapy has been shown to be effective for high-risk tumors.⁹⁶ Approximately 50% of children with high-risk disease will die despite intensive therapy, although this percentage is improving.⁹⁷

Retinoblastoma

Retinoblastoma is a rare congenital eye tumor of young children that originates in the retina of one or both eyes. Retinoblastoma can be either inherited and acquired. The inherited form of the disease generally is diagnosed during the first year of life. The acquired disease is most commonly diagnosed in children 2 to 3 years of age and involves unilateral disease.⁹⁸ Approximately 40% of retinoblastomas are inherited as an autosomal dominant trait with incomplete penetrance. The remaining 60% are acquired. About 200 to 300 children are diagnosed in the United States each year and 1 in 4 cases involves both eyes.⁹⁹

◆Pathophysiology.

In the early 1970s, Knudson proposed the “two-hit” hypothesis to explain the occurrence of both hereditary and acquired forms of the disease.¹⁰⁰ This hypothesis predicts that two separate transforming events, or “hits,” must occur in a normal retinoblast cell to cause the cancer. Further, it proposes that in the inherited form, the first hit or mutation occurs in the germ cell (inherited from either parent), and the mutation is contained in every cell of the child's body. Only a second, random mutation in a retinoblast cell is needed to transform

that cell into cancer. Multiple tumors are observed in the inherited form because these second mutations are likely to occur in several of the approximately 1 to 2 million retinoblast cells. In contrast, the acquired form of retinoblastoma requires two independent hits or mutations to occur in the same somatic cell (after the egg is fertilized) for the transformation to cancer. This is much less likely to happen. [Fig. 20.16](#) illustrates the two-mutation model for these two patterns of mutation.

FIGURE 20.16 The Two-Mutation Model of Retinoblastoma Development.

In inherited (familial) retinoblastoma, mutations of the *RB1* gene on chromosome 13q14 lead to neoplastic proliferation of retinal cells. The first mutation is transmitted through the germline of an affected parent. The second mutation occurs somatically in a retinal cell, leading to development of the tumor. In sporadic retinoblastoma, development of a tumor requires two somatic mutations. (From Kumar V, Cotran RS, Robbins SL: *Robbins basic pathology*, ed 8, Philadelphia, 2010, Saunders.)

Tumor formation usually begins with mutation in both alleles of the retinoblastoma tumor suppressor gene *RB1*, which codes for retinoblastoma protein. Retinoblastoma grows as one or more tumors in the retina and extends into the vitreous humor. Free-floating, small tumors in the vitreous humor may attach to the surface of the retina in multiple areas and proliferate and detach the retina (Fig. 20.17). The tumor also can invade the optic nerve by infiltrating the cribriform plate of the ethmoid bone or can spread through the sheath around the nerve. In either case the tumor can gain access to the subarachnoid space and the CNS. The tumor spreads into the choroid in 25% of children with retinoblastoma. Because the choroid is highly vascular, metastasis by means of hematogenous spread is possible. When hematogenous spread occurs, metastatic sites include the bone marrow, long bones, lymph nodes, and liver. If the tumor invades the orbit, lymphatic spread is possible. Spontaneous regression occurs, although infrequently, and may be caused by the tumor outgrowing its blood supply.¹⁰¹

FIGURE 20.17 Retinoblastoma. Presence of white mass surrounding the detached retina (*r*). (From Roberts F: *Semin Diagn Pathol* 33(3):114-121, 2016.)

◆Clinical Manifestations.

The primary sign of retinoblastoma is leukocoria, a white pupillary reflex (white reflex) also called *cat's eye reflex*, which is caused by the mass behind the lens (see Fig. 20.18). This easy-to-identify sign can be missed. Other signs and symptoms include strabismus; a red, painful eye; and limited vision.

FIGURE 20.18 Retinoblastoma. The tumor occupies a large portion of the inside of the globe. (From Damjanov I: *Pathology for the health professions*, ed 3, St Louis, 2006, Saunders. Courtesy Dr. Walter Richardson and Dr. Jamsheed Khan, Kansas City, Kansas.)

◆Evaluation and Treatment.

Because retinoblastoma is a treatable tumor, the priorities are saving the child's life, preservation of the eye, and restoring useful vision. Diagnostic evaluation for retinoblastoma includes documentation of family history; complete ophthalmologic examination; and metastatic studies that include bone marrow aspiration, lumbar puncture for spinal fluid examination, bone scan, and MRI scanning. Because of the potential hereditary risk to a child's siblings, all siblings younger than 4 years also should receive ophthalmologic evaluations. Treatment is related to tumor stage, number of tumor foci and unilateral (75% of cases, 10% carry *RB1* gene) or bilateral (carries the *RB1* gene) disease, vitreous seeding, and age of the child. The need for enucleation has been significantly reduced with the use of intra-arterial chemotherapy. The prognosis for most children with retinoblastoma is excellent, with

greater than 90% long-term survival, although children with bilateral or metastatic disease at diagnosis have a poor prognosis. Approximately 75% of children have useful vision in the treated eye. Children with bilateral disease need to be monitored for the development of other cancers.^{102,103}

Summary Review

Development of the Nervous System in Children

1. The central nervous system develops in a sequential process from the ectodermal neural tube. The cranial end of the tube forms the brain, and the spinal cord is formed from the remainder of the tube.
2. The cranial and spinal ganglia (peripheral nervous system) develop from the neural crest.
3. The nervous system develops in stages, and disruption of any of the stages can lead to malfunction of the nervous system.
4. The bones of the skull are joined by sutures; the wide, membranous junctions of the sutures, known as *fontanelles*, close by 20 months of age.
5. Myelin is a sheath that develops around axons to facilitate speed of nerve impulse conduction. Progressive development of reflexes corresponds to normal maturation of nerve tissue and development of voluntary movement.
6. Neurologic functioning at birth is at the subcortical level with reflex patterns mediated by the brainstem and spinal cord. With maturation, neonatal reflexes disappear and voluntary motor functions develop.
7. The fontanelles of the skull allow for cranial expansion because the head is the fastest-growing body part during infancy. Sutures close by 5 to 8 years after birth.

Structural Malformations

1. Defects of neural tube closure include anencephaly (absence of part of the brain and soft, bony part of skull), encephalocele (protrusion of brain and meninges through a skull defect), and myelodysplasias: meningocele (cystlike defect with protrusion of spinal fluid-filled meninges through a vertebral defect), myelomeningocele (a defect like meningocele only also containing the spinal cord), and spina bifida (failure of the vertebrae to close with protrusion of neural tube contents with intact skin).
2. Craniosynostosis (craniostenosis) is premature closure of one or more of the cranial sutures and prevents normal skull expansion, causing compression of growing brain tissue.
3. Microcephaly is lack of brain growth and retarded mental and motor development.
4. Cortical dysplasias are a heterogeneous group of disorders caused by defects in neuronal cell migration and subsequent abnormalities in connections between cells.
5. Congenital hydrocephalus results from an imbalance between the production and reabsorption of cerebrospinal fluid.

Alterations in Function: Encephalopathies

1. Static encephalopathies (i.e., cerebral palsy and epilepsy) are nonprogressive disorders of the brain that can occur during gestation, birth, or childhood and can be caused by trauma or genetic factors.
2. Cerebral palsy (CP) is a group of nonprogressive syndromes that can be caused by prenatal cerebral hypoxia or perinatal or postnatal trauma with symptoms of intellectual disability, seizure disorders, or developmental disabilities. CP can be extrapyramidal/nospastic or pyramidal/spastic.
3. Inherited disorders that damage the nervous system include metabolic defects in amino acid metabolism (phenylketonuria)

and storage diseases.

4. Storage diseases, including lysosomal storage disease, are linked to a missing lysosomal enzyme, such as Tay-Sachs disease (GM₂ gangliosidosis). Both inherited disorders and storage diseases result in abnormal behavior, seizures, and deficient psychomotor development.
5. Poisonings from a variety of toxins can cause serious neurologic damage, including drugs and lead poisoning.
6. Infections of the nervous system include bacterial and viral infections, or aseptic meningitis.
7. Bacterial meningitis is commonly caused by *Haemophilus influenzae* type B, *S. pneumoniae*, or *N. meningitidis* and may result from respiratory tract or gastrointestinal tract infections with symptoms of fever, headache, photophobia, seizure, rigidity, and stupor.
8. Viral meningitis presents similar to bacterial meningitis, and the specific virus is often unknown.
9. HIV-1 encephalopathy is a CNS infection that can occur in infants and children.

Cerebrovascular Disease in Children

1. Perinatal strokes can be either ischemic or hemorrhagic and occur between the 20th week of fetal life and 28th postnatal day, usually secondary to arterial or cerebral venous thrombosis, embolization, or intraventricular hemorrhage.
2. Ischemic stroke is rare in children and may result from embolism, arteriopathy, or, rarely, sinovenous thrombosis.
3. Hemorrhagic stroke results from congenital arteriovenous malformations that rupture and cause intracranial bleeding.

Epilepsy and Seizure Disorders in Children

1. Epilepsy is the occurrence of seizures. Seizures are the

abnormal discharge of electrical activity within the brain. Seizure disorders are associated with numerous nervous system disorders and more often are a generalized rather than a focal type of seizure.

2. Generalized forms of seizures involve both brain hemispheres and include tonic-clonic, myoclonic, atonic, akinetic, and infantile spasms.
3. Focal seizures suggest more localized brain dysfunction.
4. Childhood absence epilepsy (petit mal seizures or nonconvulsive epilepsy) is a type of generalized epilepsy.
5. Epilepsy syndromes include febrile seizures, infantile spasms, Lennox-Gastaut syndrome, and juvenile myoclonic epilepsy.
6. Unclassified epileptic seizure that do not fit neatly into a classified grouping include neonatal seizures and febrile seizures.

Childhood Tumors

1. Brain tumors are the most common primary neoplasm and cause of cancer death in children. They are classified by cell type as medulloblastoma, ependymoma, gliomas (astrocytoma, brainstem glioma, and optic nerve glioma), and craniopharyngioma.
2. Tumors in children are most often located below the tentorial membrane in the posterior fossa.
3. Fast-growing tumors produce symptoms early in the disease, whereas slow-growing tumors may become very large before symptoms appear.
4. Symptoms of brain tumors may be generalized or localized. The most common general symptom is increased ICP (headache, irritability, vomiting, somnolence, and bulging of fontanelles).
5. Localized signs of infratentorial tumors in the cerebellum include impaired coordination and balance. Cranial nerve signs occur with tumors near the brainstem.

6. Supratentorial tumors may be located near the cortex or deep in the brain. Symptoms depend on the specific location of the tumor.
7. Neuroblastoma is an embryonal tumor of the sympathetic nervous system and can be located anywhere there is sympathetic nervous tissue. It is the most common type of solid tumor occurring in the first year.
8. Symptoms are related to tumor location and size and site of metastasis.
9. Retinoblastoma is a rare, congenital eye tumor of young children that originates in the retina of one or both eyes and may be inherited or acquired.

The endocrine system is composed of various glands located throughout the body (Fig. 21.1). These glands synthesize and release special chemical messengers called **hormones**. In addition, numerous hormones are synthesized and released from endocrine cells within the upper and lower gastrointestinal tract (i.e., incretins). The endocrine system has five general functions:

FIGURE 21.1 Major Endocrine Glands. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

1. Differentiation of the reproductive and central nervous systems in the developing fetus
2. Stimulation of sequential growth and development during childhood and adolescence
3. Coordination of the male and female reproductive systems, which makes sexual reproduction possible
4. Maintenance of an optimal internal environment throughout the life span
5. Initiation of corrective and adaptive responses when emergency demands occur

The endocrine, nervous, and immune systems work together to regulate responses to the internal and external environments. Hormones convey specific regulatory information among cells and organs and are integrated with the nervous system to maintain communication and control. The mechanisms of communication and control occur within a cell (*autocrine*), between local cells (*paracrine*), and between cells located remotely from each other (*endocrine*).

Mechanisms of Hormonal Regulation

Endocrine glands respond to specific signals by synthesizing and releasing hormones into the circulation, which then trigger intracellular responses. Although a wide variety of hormones function within the body, they share certain general characteristics:

1. Hormones have specific rates and rhythms of secretion. Three basic secretion patterns are: (1) circadian or diurnal patterns, (2) pulsatile and cyclic patterns, and (3) patterns that depend on levels of circulating substrates (e.g., calcium, sodium, potassium, or the hormones themselves).
2. Hormones operate within feedback systems, either positive or negative, to maintain an optimal internal environment.

3. Hormones affect only cells with appropriate receptors and then act on those cells to initiate specific cell functions or activities.
4. Steroid hormones are either excreted directly by the kidneys or metabolized (conjugated) by the liver, which inactivates them and renders the hormone more water soluble for renal excretion. Peptide hormones are catabolized by circulating enzymes and eliminated in the feces or urine.

Hormones may be classified according to their structure, gland of origin, effects, or chemical composition. (Table 21.1 categorizes hormones based on structure.) The secretion and mechanisms of action of hormones represent an extremely complex system of integrated responses.

TABLE 21.1

STRUCTURAL CATEGORIES OF HORMONES

STRUCTURAL CATEGORY	EXAMPLES
Water Soluble	
Peptides	Growth hormone
	Insulin
	Leptin
	Parathyroid hormone
	Prolactin
Glycoproteins	Follicle-stimulating hormone
	Luteinizing hormone
	Thyroid-stimulating hormone
Polypeptides	Adrenocorticotrophic hormone
	Antidiuretic hormone
	Calcitonin
	Endorphins
	Glucagon
	Hypothalamic hormones
	Lipotropins
	Melanocyte-stimulating hormone

	Oxytocin
	Somatostatin
	Thymosin
	Thyrotropin-releasing hormone
Amines	Epinephrine
	Norepinephrine
Lipid Soluble	
Thyroxine (an amine but lipid soluble)	Thyroxine (both thyroxine [T ₄] and triiodothyronine [T ₃])
Steroids (cholesterol is a precursor for all steroids)	Estrogens Glucocorticoids (cortisol)
	Mineralocorticoids (aldosterone)
	Progestins (progesterone)
	Testosterone
Derivatives of arachidonic acid (autocrine or paracrine action)	Leukotrienes Prostacyclins Prostaglandins Thromboxanes

Regulation of Hormone Release

Hormone release occurs either in response to an alteration in the cellular environment or in the process of maintaining a regulated level of certain hormones or certain substances. Hormone release is regulated by one or more of the following mechanisms: (1) chemical factors (i.e., blood glucose or calcium levels); (2) endocrine factors (a hormone from one endocrine gland controlling another endocrine gland); and (3) neural control. An example of chemical regulation is seen when insulin is secreted following chemical stimulation by increased plasma glucose levels. Cortisol from the adrenal cortex is an endocrine factor that regulates and stimulates insulin secretion from beta cells within the pancreas. Neural control occurs when the autonomic nervous system directly stimulates the insulin-secreting cells of the pancreas.

Feedback systems provide precise monitoring and control of the cellular environment. Both negative and positive feedback systems are

important for maintaining hormone levels within physiologic ranges. **Negative feedback** is the most common and occurs when a changing chemical, neural, or endocrine response decreases the subsequent synthesis and secretion of a hormone. Positive feedback occurs when a neural, chemical, or endocrine response increases the synthesis and secretion of a hormone. [Fig. 21.2](#) illustrates both positive and negative feedback within the hypothalamus-pituitary-target organ axis. Positive feedback also occurs when an increased hormone level further increases the synthesis and secretion of that same hormone. An example of this kind of positive feedback is found in the female reproductive system. The cyclic rise of estradiol levels provides positive feedback on the anterior pituitary and hypothalamus, causing a subsequent increase in gonadotropin-releasing hormone and follicle-stimulating hormone (see [Fig. 24.3](#)).

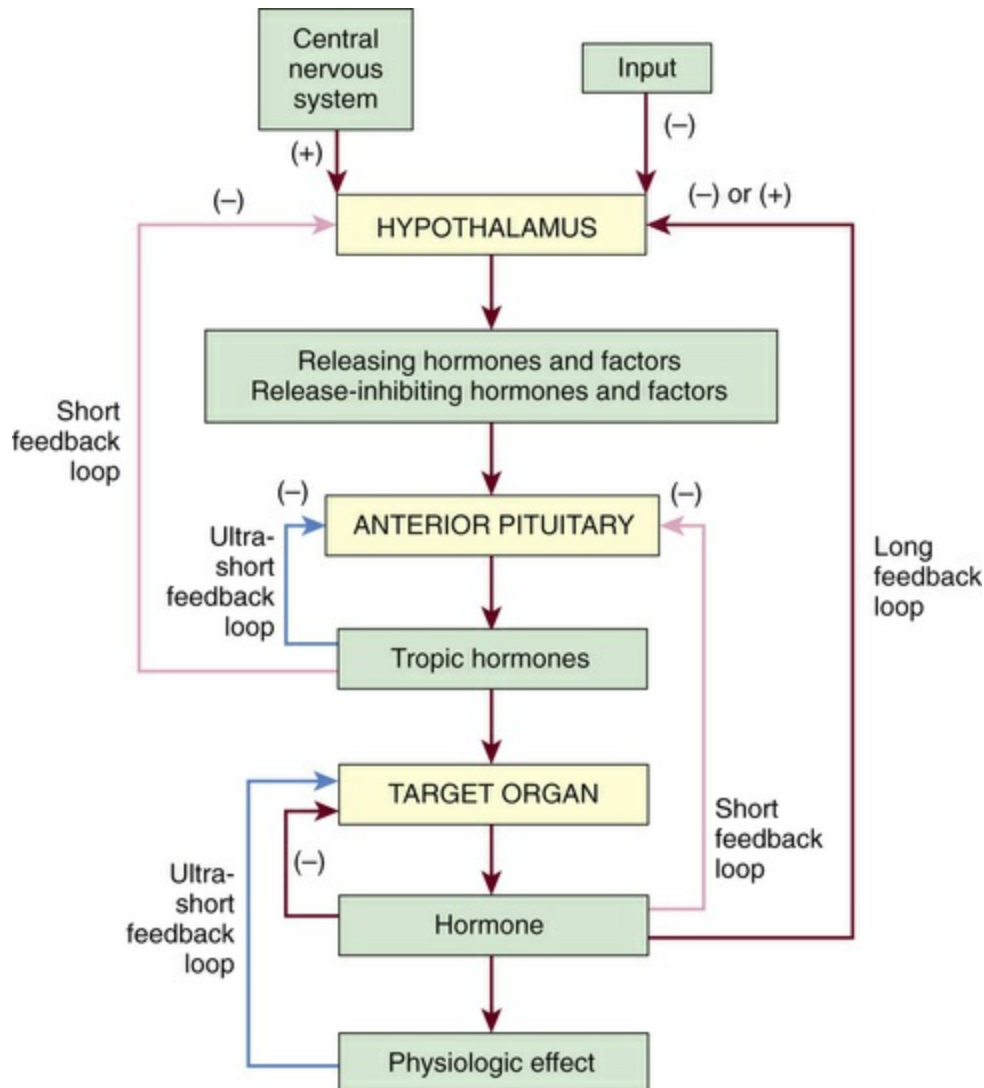

FIGURE 21.2 Feedback Loops. General model for control and negative feedback to hypothalamic-pituitary target organ systems. Negative-feedback regulation is possible at three levels: target organ (ultra-short feedback), anterior pituitary (short feedback), and hypothalamus (long feedback).

Hormone Transport

Once hormones are released into the circulatory system, they are distributed throughout the body. The protein (peptide) hormones (Table 21.2) are water soluble and generally circulate in free (unbound) forms. Water-soluble hormones generally have a short half-life of seconds to minutes because they are catabolized by circulating enzymes. For example, insulin has a half-life of 3 to 5

minutes and is catabolized by insulinases. Lipid-soluble hormones (see [Table 21.2](#)), such as cortisol and adrenal androgens, are transported bound to a carrier protein and can remain in the blood for hours to days. Only free hormones (those not bound to the carrier protein) can initiate changes within a target cell. At the cell membrane, lipid-soluble hormones dissociate from their carrier protein and diffuse into the cell. Because there is equilibrium between the concentrations of free hormones and hormones bound to plasma proteins, a significant change in the concentration of binding proteins can affect the concentration of free hormones in the plasma (see [Table 21.2](#)). (Mechanisms of hormone binding are discussed in [Chapter 1](#).)

TABLE 21.2

BINDING PROTEINS, THEIR HORMONES, AND VARIABLES THAT AFFECT THEIR CIRCULATING LEVELS

BINDING PROTEIN	HORMONE	FACTORS THAT INCREASE BINDING PROTEIN LEVELS	FACTORS THAT DECREASE BINDING PROTEIN LEVELS
Corticosteroid-binding globulin	Cortisol	Estrogen	Liver disease
	Progesterone		
Sex hormone-binding globulin	Dihydrotestosterone	—	Androgens
	Testosterone		Hypothyroidism
	Estradiol		Liver disease
Thyroid-binding globulin	Thyroxine (T ₄)	Estrogen	Testosterone
	Triiodothyronine (T ₃)	Hyperthyroidism	Glucocorticoids
			Liver disease
Albumin	All lipid-soluble hormones	Estrogen	Liver disease
			Malnutrition
			Renal disease

Hormone Receptors

Although a hormone is distributed throughout the body, only target

cells with specific receptors for that hormone are affected. Target cell response depends on blood levels of the hormone, the concentration of target cell receptors, and affinity of the receptor for the hormone. *Hormone receptors* of the target cell have two main functions: (1) to recognize and bind with high affinity to their particular hormones and (2) to initiate a signal to appropriate intracellular effectors. See [Chapter 1](#) for cell signaling pathways, particularly [Figs. 1.20](#) and [1.21](#).

The sensitivity or affinity of the target cell to a particular hormone is related to the concentration of receptors per cell: the more receptors, the higher the affinity or the more sensitive the cell is to the stimulating effects of the hormone. Low concentrations of hormone increase the number of receptors per cell, called **upregulation** ([Fig. 21.3, A](#)). High concentrations of hormone decrease the number or affinity of receptors, called **downregulation** (see [Fig. 21.3, B](#)). Thus the cell can adjust its sensitivity to the concentration of the signaling hormone. The receptors on the plasma membrane are continuously synthesized and degraded, so that changes in receptor concentration may occur within hours. Various physiochemical conditions also can affect both the receptor number and the affinity of the hormone for its receptor. Some of these physiochemical conditions are the fluidity and structure of the plasma membrane, pH, temperature, ion concentration, diet, and the presence of other chemicals (e.g., drugs). Finally, mutations in receptor structure can affect target cell activation such that normal cellular responses are increased or decreased. For example, mutations in thyroid-stimulating hormone receptors can lead to resistance to thyroid hormone and can contribute to defective thyroid hormone production.¹

FIGURE 21.3 Regulation of Target Cell Sensitivity. **A**, Low hormone level and upregulation, or an increase in the number of receptors. **B**, High hormone level and downregulation, or a decrease in the number of receptors.

Hormone receptors may be located in or on the plasma membrane or in the intracellular compartment of the target cell (Fig. 21.4). **Water-soluble hormones** (see Table 21.1) are proteins that are polarized with a high molecular weight and cannot diffuse across the lipid layer of the cell (plasma) membrane. They interact or bind with receptors in or on the cell membrane and activate a second messenger to mediate short-acting responses. Most **lipid-soluble steroids** diffuse freely across the plasma and nuclear membranes and bind the cytosolic or nuclear receptors (see Fig. 21.4), although receptors for some lipid-soluble hormones are also located in or on the plasma membrane.

FIGURE 21.4 Hormone Binding at Target Cell.

Water Soluble Hormone Receptors

Water-soluble hormone binding with the plasma membrane receptor initiates a complex cascade of intracellular effects. In this cascade, the hormone is termed the **first messenger**. The hormone-receptor interaction initiates a signal that generates a small molecule inside the cell, called the **second messenger**. The second messenger conveys the signal from the receptor to the cytoplasm and nucleus of the cell and mediates the effect of the hormone on the target cell (e.g., membrane permeability alterations, protein synthesis, inhibition of specific metabolic pathways, enzyme activation, or cellular growth) (Table 21.3 and Fig. 21.5). Second messengers include (1) cyclic adenosine monophosphate (cAMP), (2) cyclic guanosine monophosphate (cGMP), calcium, (3) inositol triphosphate (IP₃) and membrane-associated diacylglycerol (DAG), and (4) the tyrosine kinase system (see Table 21.3).

TABLE 21.3**SECOND MESSENGERS IDENTIFIED FOR SPECIFIC HORMONES**

SECOND MESSENGER	ASSOCIATED HORMONES
Cyclic AMP	Adrenocorticotrophic hormone (ACTH)
	Luteinizing hormone (LH)
	Human chorionic gonadotropin (hCG)
	Follicle-stimulating hormone (FSH)
	Thyroid-stimulating hormone (TSH)
	Antidiuretic hormone (ADH)
	Thyrotropin-releasing hormone (TRH)
	Parathyroid hormone (PTH)
	Glucagon
Cyclic GMP	Atrial natriuretic peptide
Calcium	Angiotensin II
	Gonadotropin-releasing hormone (GnRH)
	Antidiuretic hormone (ADH)
IP ₃ and DAG	Angiotensin II
	Antidiuretic hormone (ADH)
	Luteinizing hormone–releasing hormone (LHRH)
Tyrosine phosphorylation	
Tyrosine kinase	Insulin
JAK-STAT	Growth hormone
	Leptin
	Prolactin

AMP, Adenosine monophosphate; *DAG*, diacylglycerol; *GMP*, guanosine monophosphate; *IP₃*, inositol triphosphate; *JAK*, Janus family of tyrosine kinases; *STAT*, signal transducers and activators of transcription.

FIGURE 21.5 Examples of First- and Second-Messenger Signaling. A nonsteroid hormone (first messenger) binds to a fixed receptor of the target cell (1). The hormone-receptor complex activates the G protein (2). The activated G protein (*G*) reacts with guanosine triphosphate (*GTP*), which in turn activates the membrane-bound enzyme adenylyl cyclase (3). Adenylyl cyclase catalyzes the conversion of adenosine triphosphate (*ATP*) to cyclic adenosine monophosphate (*cAMP*; second messenger) (4). *cAMP* activates protein kinase (5). Protein kinases activate specific intracellular enzymes (6). These activated enzymes then influence specific cellular reactions and metabolic pathways, thus producing the target cell's response to the hormone (7). *ACTH*, Adrenocorticotrophic hormone. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

When first messengers (i.e., adrenocorticotrophic hormone and thyroid-stimulating hormone) from the anterior pituitary gland bind to a cell membrane receptor, intracellular levels of cAMP increase. Second-messenger cAMP activates protein kinases, leading to phosphorylation of cellular proteins. This either activates or deactivates intracellular enzymes, thus directing the actions or products of specific cells. For example, binding of epinephrine to a β -adrenergic receptor subtype activates (through a stimulatory G protein [G_s]) the enzyme adenylyl cyclase. Adenylyl cyclase catalyzes the conversion of adenosine triphosphate (ATP) to the second messenger 3',5'-cAMP. Elevation of cAMP activates the enzyme

cAMP-dependent protein kinase A (PKA). PKA phosphorylates and activates nuclear transcription factors (cAMP response element-binding [CREB] proteins) that influence numerous cellular functions.² Alterations in CREB activity have been implicated in many disease states including diabetes and cancer.^{3,4} The actions of cAMP are terminated by the enzyme phosphodiesterase (PDE) III, which hydrolyzes cAMP into inactive adenosine monophosphate (AMP).

cGMP also functions as a second messenger following receptor binding of first messengers (e.g., atrial natriuretic peptide and nitric oxide). These hormones and signaling molecules play crucial roles in cardiovascular and pulmonary health and disease; thus drugs, such as phosphodiesterase inhibitors that sustain the action of cGMP, are being explored for the treatment of vascular and pulmonary hypertension and cognitive dysfunction (i.e., phosphodiesterase inhibitors).^{5,6}

Hormone receptor binding of first-messenger angiotensin II and antidiuretic hormone (ADH) results in generation of second messengers DAG or IP₃ and triggers a release of intracellular calcium, as another second messenger. Increased intracellular calcium levels can lead to the formation of the calcium-calmodulin complex, which mediates the effects of calcium on intracellular activities that are crucial for cell metabolism and growth. For example, calmodulin-dependent protein kinases control intracellular contractile components (myosin and actin, which cause muscle contraction), alter plasma membrane permeability to calcium, and regulate the intracellular enzyme activity that promotes hormone secretion.

Some hormone first messengers, such as insulin, growth hormone, and prolactin, bind to surface receptors in the cell membrane that have a transmembrane domain and directly activate second messengers of the tyrosine kinase family (a subgroup of protein kinases). These tyrosine kinases transfer a phosphate group from ATP to a protein in a cell, including the Janus family of tyrosine kinases (JAK) and signal transducers and activators of transcription (STAT)—the JAK/STAT pathway. They regulate a wide range of intracellular processes that contribute to cellular metabolism, immunity, growth,

apoptosis, and oncogenesis and are targeted for inhibition in treatments for tuning down immune-mediated responses, as in rheumatoid arthritis and cancer.

Steroid (Lipid-Soluble) Hormone Receptors

With the exception of thyroid hormones, the lipid-soluble hormones are synthesized from cholesterol (giving rise to the term “steroid”). These include glucocorticoids, androgens, estrogens, progestins, mineralocorticoids, vitamin D, and retinoid. Because they are relatively small, nonpolar, lipophilic, hydrophobic molecules, steroid hormones can cross the plasma and nuclear membranes by simple diffusion (see [Chapter 1](#)). They bind with cytosolic or nuclear receptors ([Fig. 21.6](#)), which keeps them from diffusing back out of the cell. Examples of cytosolic steroid hormone receptors include those for glucocorticoids and androgens, whereas progesterone has nuclear receptors.⁷ The hormone-receptor complex then binds to a specific region in the deoxyribonucleic acid (DNA) which initiates transcription of specific genes to form messenger ribonucleic acid (mRNA) with translation at the ribosome for protein synthesis.⁸ Modulation of gene expression can take hours to days.

FIGURE 21.6 Steroid Hormone Signaling Mechanism. Lipid-soluble steroid hormone molecules detach from the carrier protein (1) and pass through the plasma membrane (2). Hormone molecules then diffuse into the nucleus, where they bind to a receptor to form a hormone-receptor complex (3). This complex then binds to a specific site on a DNA molecule (4), triggering transcription of the genetic information encoded there (5). The resulting messenger ribonucleic acid (*mRNA*) molecule moves to the cytosol, where it associates with a ribosome, initiating synthesis of a new protein (6). This new protein—usually an enzyme or channel protein—produces specific effects on the target cell (7). The classic genomic action is typically slow (red arrows). Steroids also may exact rapid effects by binding to receptors on the plasma membrane (A) and activating an intercellular second messenger (B). (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

In addition, lipid hormone receptors for estrogen, thyroid hormone, and aldosterone are also located in the plasma membrane and are associated with rapid responses (seconds or minutes). These receptors, when activated, have primarily intracellular nongenomic (membrane initiated steroid signaling) effects. Through crosstalk, nongenomic (membrane-initiated steroid signaling) responses and gene transcription modulate each other, allowing cells to adapt rapidly to environmental changes.^{9,10}

Hormone Effects

The binding of hormones with their receptors stimulates three general types of effects by:

1. Acting on preexisting channel-forming proteins to alter membrane channel permeability
2. Activating preexisting proteins through a second-messenger system
3. Activating genes to cause protein synthesis

Hormones affect target cells directly or permissively. **Direct effects** are the obvious changes in cell function that specifically result from stimulation by a particular hormone. **Permissive effects** are less obvious hormone-induced changes that facilitate the maximal response or functioning of a cell. For example, insulin has a direct effect on skeletal muscle cells, causing increased glucose transport into these cells and a permissive effect on mammary cells, facilitating their response to the direct effects of prolactin.

Some hormones have biphasic effects that are dependent on the concentration or secretion pattern of the hormone. For example, low or physiologic levels of antidiuretic hormone (ADH; or arginine-vasopressin) stimulate renal tubular reabsorption of sodium and water. However, at supraphysiologic levels (i.e., those that can be achieved by exogenous administration), ADH acts as a vasoconstrictor.

Structure and Function of the Endocrine Glands

Hypothalamic-Pituitary Axis

The hypothalamic-pituitary axis (HPA) forms the structural and functional basis for central integration of the neurologic and endocrine systems, creating what is called the **neuroendocrine system**. The HPA

produces a number of releasing/inhibitory hormones and tropic hormones that affect a number of diverse body functions (Fig. 21.7), including thyroid, adrenal, and reproductive functions.

FIGURE 21.7 Pituitary Hormones and Their Target Organs. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

Hypothalamus

The hypothalamus is located at the base of the brain. It is connected to the pituitary gland by the infundibulum (pituitary stalk) (Fig. 21.8), to the anterior pituitary through hypophysial portal blood vessels (Fig. 21.9), and to the posterior pituitary through a nerve tract referred to as the *hypothalamohypophysial tract* (Fig. 21.10). These connections are vital to the functioning of the hypothalamic-pituitary system.¹¹ The hypothalamus contains special neurosecretory cells that are like other neurons in that they have similar electrical properties, organelles, membranes, and synapses. Hypothalamic neurosecretory cells, however, can synthesize and secrete the hypothalamic-releasing hormones that regulate the release of hormones from the anterior

pituitary. In addition, these cells synthesize the hormones ADH and oxytocin that are then stored and released from the posterior pituitary gland.

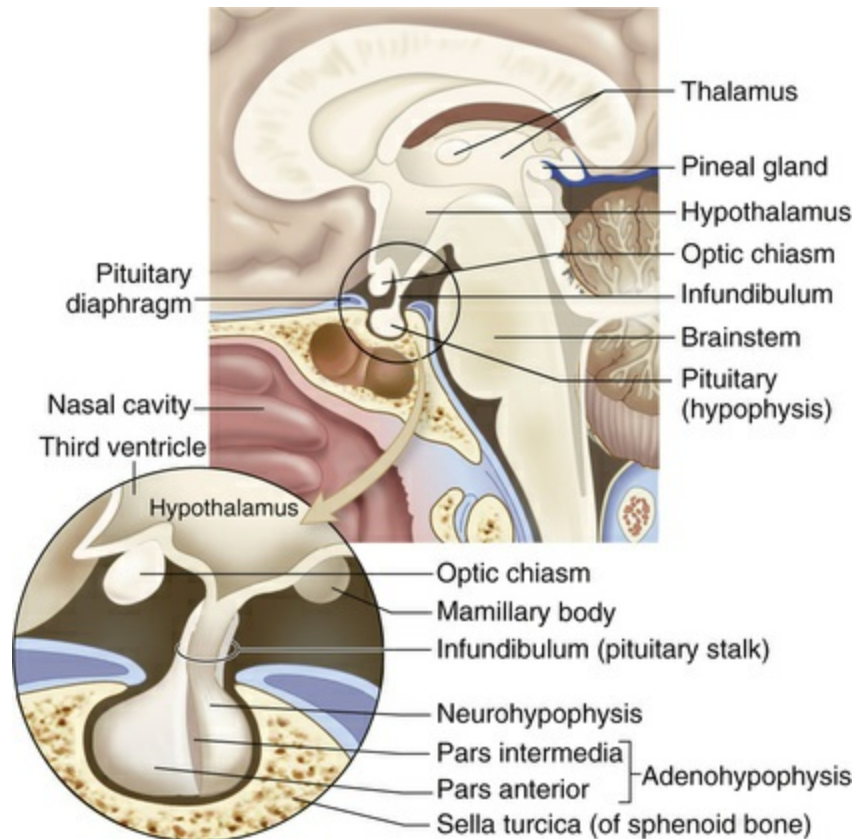

FIGURE 21.8 Location and Structure of the Pituitary Gland (Hypophysis). The pituitary gland is located within the sella turcica of the skull's sphenoid bone and is connected to the hypothalamus by a stalklike infundibulum. The infundibulum passes through a gap in the portion of the dura mater that covers the pituitary (the pituitary diaphragm). The inset shows that the pituitary is divided into an anterior portion, the adenohypophysis, and a posterior portion, the neurohypophysis. The adenohypophysis is further subdivided into the pars anterior and pars intermedia. The pars intermedia is almost absent in the adult pituitary. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

FIGURE 21.9 Hypophysial Portal System. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 13, Philadelphia, 2016, Saunders.)

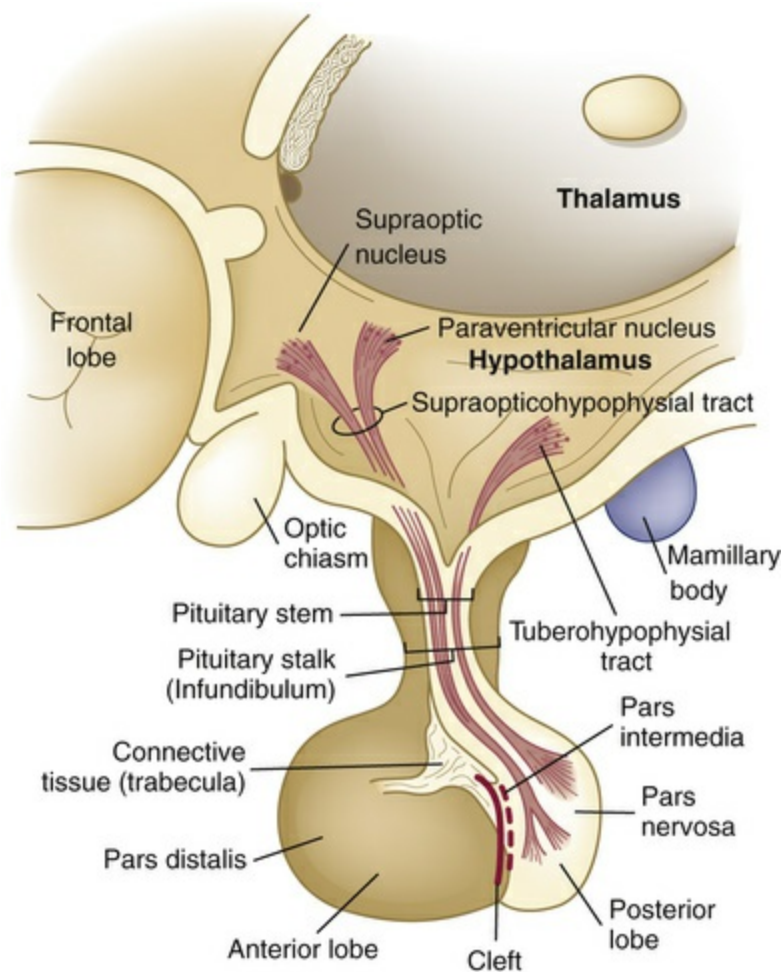

FIGURE 21.10 Nerve Tracts from Hypothalamus to Posterior Lobe of Pituitary Gland.

ADH and oxytocin travel to the posterior pituitary by way of the hypothalamohypophysial nerve tract. Releasing and inhibitory hormones also are synthesized in the hypothalamus and are secreted into the portal blood vessels, through which they travel to their target tissues within the anterior pituitary and control the release of tropic hormones. These releasing/inhibitory hormones from the hypothalamus include **prolactin-inhibiting hormone (PIH)**, **prolactin-releasing hormone (PRH)**, **thyrotropin-releasing hormone (TRH)**, **gonadotropin-releasing hormone (GnRH)**, **hypothalamic somatostatin**, **growth hormone-releasing hormone (GHRH)**, **corticotropin-releasing hormone (CRH)**, and **substance P**. These hormones are summarized in [Table 21.4](#).

TABLE 21.4**HYPOTHALAMIC HORMONES (HYPOPHYSIOTROPIC HORMONES)**

HORMONE	TARGET TISSUE	ACTION
Thyrotropin-releasing hormone (TRH)	Anterior pituitary	Stimulates release of thyroid-stimulating hormone (TSH) Modulates prolactin secretion
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH)
Somatostatin	Anterior pituitary	Inhibits release of growth hormone (GH) and TSH
Growth hormone-releasing hormone (GHRH)	Anterior pituitary	Stimulates release of GH
Corticotropin-releasing hormone (CRH)	Anterior pituitary	Stimulates release of adrenocorticotrophic hormone (ACTH) and β -endorphin
Substance P	Anterior pituitary	Inhibits synthesis and release of ACTH Stimulates secretion of GH, FSH, LH, and prolactin
Dopamine	Anterior pituitary	Inhibits synthesis and secretion of prolactin
Prolactin-releasing hormone (PRH)	Anterior pituitary	Stimulates secretion of prolactin
Prolactin-inhibiting hormone (PIH)	Anterior pituitary	Inhibits secretion of prolactin

The Anterior Pituitary

The **anterior pituitary** (adenohypophysis) accounts for 75% of the total weight of the pituitary gland. It is composed of three regions: (1) the pars distalis, (2) the pars tuberalis, and (3) the pars intermedia. The **pars distalis** is the major component of the anterior pituitary and the source of the anterior pituitary hormones. The **pars tuberalis** is a thin layer of cells on the anterior and lateral portions of the pituitary stalk. The **pars intermedia** lies between the two. In the adult the distinct intermediate lobe disappears, and the individual cells are distributed diffusely throughout the pars distalis and **pars nervosa (neural lobe)**, which are part of the posterior pituitary. The anterior

pituitary is composed of two main cell types: (1) the **chromophobes**, which appear to be nonsecretory; and (2) the **chromophils**, which are considered the secretory cells of the adenohypophysis. The chromophils are subdivided into seven secretory cell types, each type secreting one or more specific tropic hormones (Table 21.5).

TABLE 21.5

TROPIC HORMONES OF THE ANTERIOR PITUITARY AND THEIR FUNCTIONS

HORMONE	SECRETORY CELL TYPE	TARGET ORGANS	FUNCTIONS
Adrenocorticotrophic hormone (ACTH)	Corticotropic	Adrenal gland (cortex)	Increased steroidogenesis (cortisol and androgenic hormones) Synthesis of adrenal proteins contributing to maintenance of the adrenal gland
Melanocyte-stimulating hormone (MSH)	Melanotropic	Anterior pituitary	Promotes secretion of melanin and lipotropin by anterior pituitary; makes skin darker
Somatotropic Hormones			
Growth hormone (GH)	Somatotropic	Muscle, bone, liver	Regulates metabolic processes related to growth and adaptation to physical and emotional stressors, muscle growth, increased protein synthesis, increased liver glycogenolysis, increased fat mobilization
		Liver	Induces formation of somatomedins, or insulin-like growth factors (IGFs) that have actions similar to insulin
Prolactin	Lactotropic	Breast	Milk production
Glycoprotein Hormones			
Thyroid-stimulating hormone (TSH)	Thyrotropic	Thyroid gland	Increased production and secretion of thyroid hormone Increased iodide uptake Promotes hypertrophy and hyperplasia of thymocytes
Luteinizing hormone (LH)	Gonadotropic	In women: granulosa cells In men:	Ovulation, progesterone production Testicular growth, testosterone production

		Leydig cells	
Follicle-stimulating hormone (FSH)	Gonadotropic	In women: granulosa cells In men: Sertoli cells	Follicle maturation, estrogen production Spermatogenesis
β -Lipotropin	Corticotropic	Adipose cells	Fat breakdown and release of fatty acids
β -Endorphins	Corticotropic	Adipose cells Brain opioid receptors	Analgesia; may regulate body temperature, food and water intake

The **tropic hormones secreted by the chromophils** affect the physiologic function of specific target organs (see [Fig. 21.7](#)). These hormones can be grouped into three categories: corticotropin-related hormones (adrenocorticotropin hormone [ACTH] and melanocyte-stimulating hormone [MSH]), glycoproteins (luteinizing hormone [LH], follicle-stimulating hormone [FSH], and thyroid-stimulating hormone [TSH]), and somatotropins (growth hormone [GH] and prolactin). The corticotropin-related hormones are all derived from the precursor pro-opiomelanocortin (POMC). **Melanocyte-stimulating hormone (MSH)** promotes the pituitary secretion of melanin, which darkens skin color. β -Lipotropin and β -endorphins are corticotropic hormones also released from the anterior pituitary. β -Lipotropin plays a role in fat catabolism, and β -endorphins impact pain perception, body temperature, and food and water intake. The glycoprotein hormones **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** influence reproductive function and are discussed in [Chapter 24](#). **Adrenocorticotropin hormone (ACTH)** regulates the release of cortisol from the adrenal cortex. Thyroid-stimulating hormone (TSH) regulates the activity of the thyroid gland. The roles of ACTH and TSH are discussed later in this chapter.

Growth hormone (GH) and prolactin are called the *somatotropic hormones* and have diverse effects on body tissues. GH secretion is controlled by two hormones from the hypothalamus: growth hormone–releasing hormone (GHRH), which increases GH secretion; and somatostatin, which inhibits GH secretion. GH is essential to

normal tissue growth and maturation and peaks during adolescence. GH also impacts aging, sleep, nutritional status, stress, and reproductive hormones. In the bone, GH stimulates epiphyseal growth and increases osteoclast and osteoblast activity, resulting in increased bone mass. GH also increases amino acid transport in muscles. Other functions of GH include lipolysis and enhancement of hepatic protein synthesis. Many of the anabolic functions of GH are mediated, at least in part, by the insulin-like growth factors (IGFs), which are also known as the *somatomedins* (promote cell growth and division).

There are two primary forms of IGF: IGF-1 and IGF-2, of which IGF-1 is the most biologically active. They both circulate bound to a group of IGF-binding proteins (IGFBPs) modulating their availability. IGF-1 binds to IGF-1 receptors, mediating the anabolic effects of GH. IGF-1 also binds to insulin receptors, providing an insulin-like effect on skeletal muscle. IGF-2 has important effects on fetal growth, but suppresses GH in the adult. Because of the anabolic effects of GH and IGF-1, they can be used to treat growth disorders, increase muscle mass, and potentially slow the aging process; however, their use also has been linked to increased rates of cancer.^{12,13}

Prolactin primarily functions to induce milk production during pregnancy and lactation. It has immune stimulatory effects and modulates immune and inflammatory responses with both physiologic and pathologic reactions.¹⁴ Its synthesis and release are increased by stimulation of the nipples and mammary gland during nursing. Vasoactive intestinal polypeptide, serotonin, and growth factors also stimulate the synthesis of prolactin, while its release is inhibited by dopamine.

The Posterior Pituitary

The embryonic **posterior pituitary (neurohypophysis)** is derived from the hypothalamus and is composed of three parts: (1) the median eminence located at the base of the hypothalamus; (2) the pituitary stalk; and (3) the infundibular process, also known as the *pars nervosa* or *neural lobe*. The **median eminence** is composed largely of the nerve

endings of axons that arise primarily in the ventral hypothalamus. It often is designated as part of the posterior pituitary but contains at least 10 biologically active hypothalamic-releasing hormones, as well as the neurotransmitters dopamine, norepinephrine, serotonin, acetylcholine, and histamine. The **pituitary stalk** contains the axons of neurons that originate in the supraoptic and paraventricular nuclei of the hypothalamus. Axons originating in the hypothalamus terminate in the pars nervosa, which secretes the hormones of the posterior pituitary (see [Fig. 21.10](#)).

The posterior pituitary secretes two polypeptide hormones: (1) ADH, also called *arginine-vasopressin*; and (2) oxytocin. These hormones differ by only two amino acids. They are synthesized along with their binding proteins, the neurophysins, in the supraoptic and paraventricular nuclei of the hypothalamus (see [Fig. 21.10](#)). They are packaged in secretory vesicles and are moved down the axons of the pituitary stalk to the pars nervosa for storage. The posterior pituitary thus can be seen as a site for both storing and releasing hormones synthesized in the hypothalamus. The release of ADH and oxytocin is mediated by cholinergic and adrenergic neurotransmitters. The major stimulus to both ADH and oxytocin release is glutamate, whereas the major inhibitory input is through gamma-aminobutyric acid (GABA). Before release into the circulatory system, ADH and oxytocin are split from the neurophysins and are secreted in unbound form.

Antidiuretic Hormone.

The major homeostatic function of the posterior pituitary is the control of plasma osmolality, as regulated by ADH (see [Chapter 3](#)). At physiologic levels, ADH acts on the vasopressin 2 (V2) receptors of the renal tubular cells to increase their permeability (see [Chapter 38](#)). This increased permeability leads to increased water reabsorption into the blood, thus concentrating the urine and reducing serum osmolality. These effects may be inhibited by hypercalcemia, prostaglandin E, and hypokalemia.

The secretion of ADH is regulated primarily by the osmoreceptors of the hypothalamus, located near or in the supraoptic nuclei. As

plasma osmolality increases, these osmoreceptors are stimulated, the rate of ADH secretion increases, more water is reabsorbed from the kidney, and the plasma is diluted to its set-point osmolality (approximately 280 mOsm/kg). ADH has no direct effect on electrolyte levels, but with increasing water reabsorption, serum electrolyte concentrations may decrease because of a dilutional effect.

ADH secretion also is increased by changes in intravascular volume, which are monitored by baroreceptors in the left atrium and in the carotid arteries and aortic arch. A volume loss of 7% to 25% acts through these receptors to stimulate ADH secretion. Stress, trauma, pain, exercise, nausea, nicotine, exposure to heat, and drugs such as morphine also increase ADH secretion. ADH secretion decreases with a decrease in plasma osmolality; an increase in intravascular volume; hypertension; an increase in estrogen, progesterone, and angiotensin II levels; and alcohol ingestion.

Physiologic levels of ADH do not significantly affect vessel tone. However, at pathophysiologically high serum levels, ADH acts on vasopressin 1 (V1) receptors causing vasoconstriction resulting in an increase in arterial blood pressure. For example, high doses of ADH (given as the drug vasopressin) may be administered to achieve hemostasis during hemorrhage and to raise blood pressure in shock states.¹⁵

Oxytocin.

Oxytocin is responsible for contraction of the uterus and milk ejection in lactating women and may affect sperm motility in men. In both sexes, oxytocin has an antidiuretic effect similar to that of ADH. In women, oxytocin is secreted in response to suckling and mechanical distention of the female reproductive tract. Oxytocin binds to its receptors on myoepithelial cells in the mammary tissues and causes contraction of those cells which increases intramammary pressure and milk expression (“let down” reflex). Oxytocin also acts on the uterus to stimulate contractions. Uterine contractions act in a positive feedback loop to further increase oxytocin secretion. Oxytocin functions near the end of labor to enhance the effectiveness of

contractions, promote delivery of the placenta, and stimulate postpartum uterine contractions, thereby preventing excessive bleeding. The function of this hormone is discussed in more detail in [Chapter 24](#).

Pineal Gland

The pineal gland is located near the center of the brain (see [Fig. 21.1](#)) and is composed of melatonin-secreting photoreceptive cells. It is innervated by noradrenergic sympathetic nerve terminals controlled by pathways within the hypothalamus. **Melatonin** release is stimulated by exposure to dark and inhibited by light exposure. It is synthesized from tryptophan, which is first converted to serotonin and then to melatonin. Melatonin regulates circadian rhythms and reproductive systems, including the secretion of gonadotropin-releasing hormones and the onset of puberty. It also plays an important role in immune regulation and is postulated to affect the aging process. Further effects of melatonin include increasing nitric oxide release from blood vessels, removing toxic oxygen free radicals, and decreasing insulin secretion. Melatonin has been used therapeutically in humans to help with sleep disturbances, jet lag, and inflammatory and psychologic disorders. Its utility for numerous other disorders including anti-cancer therapy is being explored.¹⁶

Thyroid and Parathyroid Glands

The thyroid gland, located in the neck just below the larynx, produces hormones that control the rates of metabolic processes throughout the body. The four parathyroid glands are located near the posterior side of the thyroid and function to control serum calcium levels ([Fig. 21.11](#)).

FIGURE 21.11 Thyroid and Parathyroid Glands. Note the relationship of the thyroid and parathyroid glands to each other, to the larynx (voice box), and to the trachea. (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

Thyroid Gland

The two lobes of the **thyroid gland** lie on either side of the trachea, inferior to the thyroid cartilage, and are joined by a small band of tissue termed the **isthmus** which crosses the anterior surface of the trachea and larynx at the cricoid cartilage (see [Fig. 21.11](#)). The **pyramidal lobe** is superior to the isthmus. The normal thyroid gland is not visible on inspection, but it may be palpated on swallowing, which causes it to be displaced upward. The thyroid gland consists of **follicles** that contain follicular cells surrounding a viscous substance called *colloid* ([Fig. 21.12](#)). The follicular cells synthesize and secrete thyroid hormones. Neurons of the autonomic nervous system terminate on blood vessels within the thyroid gland and on the follicular cells themselves. Acetylcholine, catecholamines, and other peptides directly affect secretory activity of the follicular cells and thyroid blood flow. Approximately a 2-month supply of thyroid hormone is stored in the gland.

FIGURE 21.12 Thyroid Follicle Cells.

Also found in the tissue of the thyroid are parafollicular cells, or **C cells** (see [Fig. 21.12](#)). C cells secrete various regulatory peptides, including **calcitonin**, and, in much smaller quantities, the neuropeptides ghrelin, serotonin, and somatostatin. At high levels, calcitonin, also called *thyrocalcitonin*, lowers serum calcium levels by inhibiting bone-resorbing osteoclasts. However, in humans the metabolic consequences of calcitonin deficiency or excess do not appear to be significant (bone resorption is described in [Chapter 44](#)). Calcitonin is used therapeutically to treat a number of bone disorders, including osteoporosis, osteoarthritis, Paget bone disease, hypercalcemia, osteogenesis imperfecta, and metastatic cancer of the bone. The precursor molecule to calcitonin, called *procalcitonin*, is a stress hormone that is elevated in infectious and inflammatory disorders, and its measurement can aid in the diagnosis of these serious diseases.^{17,18}

Regulation of Thyroid Hormone Secretion.

Thyroid hormone (TH) is regulated through a negative-feedback loop involving the hypothalamus, the anterior pituitary, and the thyroid gland ([Fig. 21.13](#)). This loop is initiated by TRH, which is synthesized and stored within the hypothalamus. TRH is released into the hypothalamic-pituitary portal system and circulates to the anterior pituitary, where it stimulates the release of TSH. TRH levels increase with exposure to cold or stress and from decreased levels of T_4 .

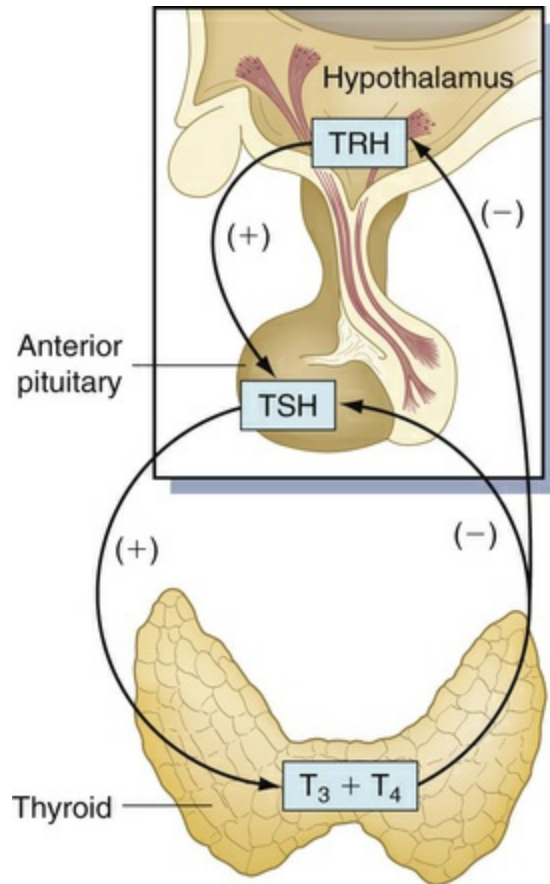

FIGURE 21.13 Feedback Loops for the Thyroid Gland. *TRH*, Thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone; *T₃*, triiodothyronine; *T₄*, tetraiodothyronine (thyroxine).

Thyroid-stimulating hormone (TSH) is a glycoprotein hormone synthesized and stored within the anterior pituitary. It circulates to bind with TSH receptor sites located on the plasma membrane of the thyroid follicular cells. The primary effects of TSH on the thyroid gland include: (1) an immediate increase in the release of stored thyroid hormones, (2) an increase in iodide uptake and oxidation, (3) an increase in thyroid hormone synthesis, and (4) an increase in the synthesis and secretion of prostaglandins by the thyroid. TSH also increases growth of the thyroid gland by stimulating thymocyte hyperplasia and hypertrophy and decreasing apoptosis.¹⁹ As TH levels rise, there is a negative-feedback effect on the HPA to inhibit TRH and TSH release, which then results in decreased TH synthesis and secretion. TH synthesis also is controlled by serum iodide levels and by circulating selenium-dependent enzymes, called *deiodinases*,

which inactivate the precursor molecule thyroxine.²⁰ Thyroid gland hormones and their regulation and function are summarized in [Table 21.6](#).

TABLE 21.6

Synthesis of Thyroid Hormone.

Thyroid hormone synthesis is summarized in the following steps:

1. Uniodinated thyroglobulin (a large glycoprotein) is produced by the endoplasmic reticulum of the follicular cells.
2. Tyrosine is incorporated into the thyroglobulin as it is synthesized.
3. Iodide (the inorganic form of iodine) is actively transferred (pumped) from the blood into the colloid by carrier proteins located in the outer membrane of the follicular cells. This active transport system is called the *iodide trap* and is very efficient at accumulating the trace amounts of iodide from the blood.
4. Iodide is oxidized and quickly attaches to tyrosine within the thyroglobulin molecule.
5. Coupling of iodinated tyrosine forms thyroid hormones. Triiodothyronine (T_3) is formed from coupling of monoiodotyrosine (one iodine atom and tyrosine) and diiodotyrosine (two iodine atoms and tyrosine). Tetraiodothyronine (T_4), commonly known as *thyroxine*, is formed from coupling of two diiodotyrosines.
6. Thyroid hormones are stored attached to thyroglobulin within the colloid until they are released into the circulation.

The thyroid gland normally produces 90% T_4 and 10% T_3 . Once released into the circulation, T_3 and T_4 are primarily transported bound to one of three carrier proteins: thyroxine-binding globulin (though some TH is transported by thyroxine-binding prealbumin

[transthyretin]), albumin, or lipoproteins. The bound form serves as a reservoir, whereas the unbound form is active. In the body tissues, most of the T_4 is converted to T_3 , which acts on the target cell. T_3 binds with three different receptors ($TR\alpha 1$, $TR\beta 1$, and $TR\beta 2$).

Actions of Thyroid Hormone.

TH has a significant effect on the growth, maturation, and function of cells and tissues throughout the body. TH is essential for normal growth and neurologic development in the fetus and infant and affects metabolic, neurologic, cardiovascular, and respiratory functioning across the life span. In addition, TH is required for the metabolism and function of blood cells, as well as normal muscle functioning and the integrity of skin, nails, and hair. Similar to some steroid hormones, thyroid hormones bind to intracellular receptor complexes and then influence the genetic expression of specific proteins. They also may bind to receptors in the plasma membrane, mitochondria, or cytoplasm and mediate nongenomic (membrane-initiated signaling) effects.²¹ Thyroid hormones affect cell metabolism by altering protein, fat, and glucose metabolism and, as a result, heat production and oxygen consumption are increased.

TH has permissive effects throughout the body, optimizing the actions of other hormones and neurotransmitters. These effects can become very pronounced when there are either high or low levels of circulating thyroid hormones. For example, in the heart, T_3 stimulates the synthesis of specific contractile proteins (e.g., α -myosin heavy chain), sarcolemmal ion pumps (Na^+ - K^+ ATPase pump, Ca^{++} ATPase pump), and membrane receptors (β -adrenergic receptors). Therefore in hyperthyroidism, which is associated with elevated levels of thyroid hormones, cardiac effects include increased heart rate and cardiac output, as well as the development of cardiomyopathy. Thyroid hormones also affect the respiratory center, contributing to the normal hypoxic and hypercapnic drives. In severe hypothyroidism, ventilation can become very depressed. Thyroid hormone also stimulates bone resorption, and hyperthyroidism is associated with osteopenia, hypercalcemia, and hypercalciuria.

Parathyroid Glands

Normally, two pairs of parathyroid glands are present behind the upper and lower poles of the thyroid gland (see [Fig. 21.11](#)), but the number may range from two to six. The parathyroid glands produce **parathyroid hormone (PTH)**, which is the single most important factor in the regulation of serum calcium concentration.²² The overall effect of PTH secretion is to increase serum calcium concentration and decrease the concentration of serum phosphate. A decrease in serum-ionized calcium level stimulates PTH secretion. On release, PTH enters the circulation in unbound form. The hormone attaches to plasma membrane receptors in target tissues, where the biologic effects of PTH are mediated primarily by activation of the adenylyl cyclase system (see [Chapter 1](#)). To achieve regulation of serum calcium concentration, PTH acts directly on bone with at least two effects. In acute hypocalcemia, PTH secretion stimulates osteoblasts to release receptor activator for nuclear factor κ B (NF- κ B), receptor activator of nuclear factor κ B ligand (RANKL), and macrophage-colony stimulating factor (M-CSF), which results in osteoclast proliferation, maturation, and release of acidic enzymes, such as cathepsin. These enzymes mobilize calcium release from bone (bone resorption), which increases the serum calcium level ([Fig. 21.14](#)). There is bone remodeling with chronic stimulation by PTH, a process in which bone is broken down and re-formed. Paradoxically, when PTH is administered intermittently and at a low dose, it stimulates bone formation. This observation led to the use of PTH for treatment of osteoporosis.²³

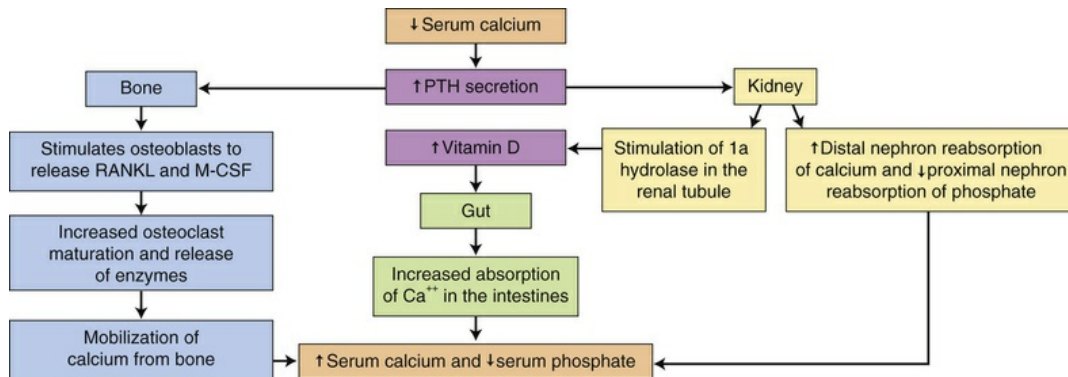

FIGURE 21.14 Normal Calcium Metabolism Regulated by PTH and Vitamin D. *M-CSF*, Macrophage-colony stimulating factor; *PTH*, parathyroid hormone; *RANKL*, receptor activator of NF- κ B ligand.

PTH also acts on the kidney to increase calcium reabsorption while phosphate reabsorption is decreased. PTH acts on its plasma membrane receptor in the distal tubules of the nephron to increase reabsorption of calcium. It acts on the proximal tubules to decrease reabsorption of phosphorus and bicarbonate. The resultant increase in serum calcium concentration inhibits PTH secretion. In renal cells, PTH also stimulates the activity of 1α -hydroxylase, which mediates a step in the formation of the biologically active form of vitamin D, or **1,25-dihydroxy-vitamin D₃**. Vitamin D works as a cofactor with PTH to promote calcium and phosphate absorption in the gut and enhance bone mineralization. Vitamin D also plays an important role in metabolic processes and controlling inflammation. It has been found to be deficient in the majority of individuals in the United States and many other countries.²⁴

Magnesium and phosphate concentrations also affect PTH secretion. Hypomagnesemia in persons with normal calcium levels acts as a mild stimulant to PTH secretion, whereas in hypocalcemic individuals, hypomagnesemia decreases PTH secretion. Hyperphosphatemia leads to hypocalcemia because of calcium phosphate precipitation in soft tissue and bone. Alterations in serum phosphate levels therefore may indirectly influence PTH secretion by affecting serum calcium levels.

Another hormone that plays an important role in calcium and bone physiology is parathyroid hormone–related protein (PTHrP). This hormone is synthesized in many adult and fetal tissues and affects

tissues around it in a paracrine fashion. It has similar biologic properties to PTH and uses the same receptors but has other actions mediated by different regions within the molecule. It is important for endochondral bone formation and bone remodeling. It was discovered as the primary hormone involved in malignancy-related hypercalcemia.²⁵

Endocrine Pancreas

The **pancreas** is both an endocrine gland that produces hormones and an exocrine gland that produces digestive enzymes. (The exocrine pancreas is discussed in [Chapter 41](#).) The pancreas is located behind the stomach, between the spleen and the duodenum and houses the **islets of Langerhans**. The islets of Langerhans have four types of hormone-secreting cells: **alpha cells**, which secrete glucagon; **beta cells**, which secrete insulin and amylin; **delta cells**, which secrete gastrin and somatostatin; and **F (or PP) cells**, which secrete pancreatic polypeptide that stimulates gastric secretion and antagonizes cholecystokinin. These hormones regulate carbohydrate, fat, and protein metabolism. (The pancreas is illustrated in [Fig. 21.15](#).) Nerves from both the sympathetic and the parasympathetic divisions of the autonomic nervous system innervate the pancreatic islets.

FIGURE 21.15 The Pancreas. **A**, Pancreas dissected to show main and accessory ducts. The main duct may join the common bile duct, as shown here, to enter the duodenum by a single opening at the major duodenal papilla, or the two ducts may have separate openings. The accessory pancreatic duct is usually present and has a separate opening into the duodenum. **B**, Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic juice, alpha endocrine cells secrete glucagon, and beta cells secrete insulin. (Adapted from Patton KT, Thibodeau GA: *The human body in health & disease*, ed 7, St Louis, 2018, Elsevier.)

The perfusion of the anterior lobe of the pancreas, where alpha, beta, and delta cells are most numerous, comes from branches of the superior mesenteric artery. The posterior lobe is perfused by branches of the celiac artery. The pancreatic islets receive 10% of the pancreatic blood flow but represent only 1% of pancreatic mass. This is necessary for oxygenation and delivery of islet hormones to target cells.

Insulin

The beta cells of the pancreas synthesize **insulin** from the precursor proinsulin, which is formed from a larger and earlier precursor molecule, preproinsulin. Proinsulin is composed of an A peptide and a B peptide connected by a C peptide and two disulfide bonds. C

peptide is cleaved by proteolytic enzymes, leaving the bonded A and B peptide chains that become insulin. Insulin circulates freely in the plasma and is not bound to a carrier. C peptide can be measured in the blood as an indirect measure of serum insulin synthesis.

Secretion of insulin is regulated by chemical, hormonal, and neural control. Insulin secretion is pulsatile, increasing when the beta cells are stimulated by the parasympathetic nervous system, usually before eating a meal. Other factors stimulating insulin secretion include increased blood levels of glucose, amino acids (leucine, arginine, and lysine), and gastrointestinal hormones (glucagon, gastrin, cholecystokinin, secretin). Insulin secretion diminishes in response to low blood levels of glucose (hypoglycemia), high levels of insulin (through negative feedback to the beta cells), and sympathetic stimulation of the beta cells in the islets. Prostaglandins also inhibit insulin secretion.

At the target cell, insulin binds with an enzyme-linked plasma membrane receptor that contains tyrosine kinase on the cytosolic surface found on cells throughout the body. Insulin receptor binding sends a cascade of signals to activate glucose transporters (GLUT) for entry of glucose into the cell. The primary GLUT is called GLUT4. It is stored in cellular vesicles until activated by the insulin receptor and is then translocated to the cell surface where it facilitates the diffusion of glucose into the cell. Translocation of GLUT4 to the cell surface is associated with a 10- to 21-fold increase in glucose diffusion into the cell, particularly in skeletal and cardiac muscle, liver, and adipose cells (Fig. 21.16). Insulin sensitivity, denoting the biological responsiveness to insulin, is affected by age, weight, abdominal fat, and physical activity. Insulin resistance, a subnormal biological response to normal insulin concentrations, has been implicated in numerous diseases, including hypertension, heart disease, and type 2 diabetes mellitus. Adipocytes release a number of hormones that are altered in obesity and have an important adverse effect on insulin sensitivity. The most effective measures shown to improve insulin sensitivity in humans are weight loss and exercise.²⁶

FIGURE 21.16 Insulin Action on Cells. Binding of insulin to its receptor causes autophosphorylation of the receptor, which then itself acts as a tyrosine kinase that phosphorylates insulin receptor substrate 1. Numerous target enzymes, such as protein kinase B and MAP kinase, are activated, and these enzymes have a multitude of effects on cell function. The glucose transporter, GLUT4, is recruited to the plasma membrane, where it facilitates glucose entry into the cell. The transport of amino acids, potassium, magnesium, and phosphate into the cell is also facilitated. The synthesis of various enzymes is induced or suppressed, and cell growth is regulated by signal molecules that modulate gene expression. *MAP*, Mitogen-activated protein. (Redrawn from Levy MN, Koeppen BM, Stanton BA: *Principles of physiology*, ed 4, St Louis, 2006, Mosby.)

Insulin is an anabolic hormone that promotes glucose uptake primarily in liver, muscle, and adipose tissue. It also increases the synthesis of proteins, carbohydrates, lipids, and nucleic acids. [Table 21.7](#) summarizes the actions of insulin. The net effect of insulin in these tissues is to stimulate protein and fat synthesis and decrease blood glucose level. The brain, red blood cells, kidney, and lens of the eye do not require insulin for glucose transport. Insulin also facilitates the intracellular transport of potassium (K⁺), phosphate, and magnesium. Insulin is metabolized in the liver and kidney by enzymes that split disulfide bonds. Very little insulin is excreted unchanged in the urine.

TABLE 21.7

INSULIN ACTIONS

ACTIONS	SITES OF INSULIN-PROMOTED SYNTHESIS		
	LIVER CELLS	MUSCLE CELLS	ADIPOSE CELLS
Glucose uptake	Increased	Increased	Increased
Glucose use	—	—	Increased glycerol phosphate
Glycogenesis	Increased	Increased	—
Glycogenolysis	Decreased	Decreased	—
Glycolysis	Increased	Increased	Increased
Gluconeogenesis	Increased	—	—
Other	Increased fatty acid synthesis	Increased amino acid uptake	Increased fat esterification
	Decreased ketogenesis	Increased protein synthesis	Decreased lipolysis
	Decreased urea cycle activity	Decreased proteolysis	Increased fat storage

Amylin

Amylin (islet amyloid polypeptide) is a peptide hormone cosecreted with insulin by beta cells in response to nutrient stimuli. It regulates blood glucose concentration by delaying gastric emptying and suppressing glucagon secretion after meals. Amylin also has a satiety effect which reduces food intake. Through these mechanisms, amylin has an antihyperglycemic effect.²⁷

Glucagon

Glucagon is produced by the alpha cells of the pancreas and by cells lining the gastrointestinal tract. Glucagon is an antagonist to insulin and acts to increase blood glucose during fasting, exercise, and hypoglycemia. It acts primarily in the liver to increase blood glucose concentration by stimulating glycogenolysis. Glucagon also stimulates gluconeogenesis in the kidneys and lipolysis in adipose tissue. Muscle glucagon is used only by muscle and not systemically. High glucose levels cause glucagon release to be inhibited; low glucose levels and sympathetic stimulation promote glucagon release. Amino acids, such

as alanine, glycine, and asparagine, also stimulate glucagon secretion. A protein-rich meal has the same effect. Glucagon also stimulates lipolysis, which has a ketogenic effect caused by the metabolism of free fatty acids in the liver. These effects have led to the hypothesis that impaired glucagon secretion is as important as insulin insufficiency in the pathogenesis of diabetes.²⁸

Pancreatic Somatostatin

Pancreatic somatostatin is produced by delta cells of the pancreas in response to food intake and is a hormone essential in carbohydrate, fat, and protein metabolism. It differs from hypothalamic somatostatin, which inhibits release of growth hormone and TSH. Pancreatic somatostatin is involved in regulating alpha-cell and beta-cell function within the islets by inhibiting secretion of insulin, glucagon, and pancreatic polypeptide.

Incretins

The incretin hormones are secreted from endocrine cells in the gastrointestinal tract in the presence of carbohydrates, proteins, and fats. The major incretin hormones are glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). They control postprandial glucose levels by promoting glucose-dependent insulin secretion, inhibiting glucagon synthesis, promoting hepatic glucose secretion, and delaying gastric emptying. Incretins also enhance beta-cell mass and replenish intracellular stores of insulin. Incretins are broken down by an enzyme called *dipeptidyl peptidase 4 (DPP-4)*, and drugs that inhibit this enzyme (called *gliptins*) increase incretin levels. The gliptins are incretin agonists used for the treatment of type 2 diabetes.²⁹

Gastrin, Ghrelin, and Pancreatic Polypeptide

Gastrin is released by G cells in the stomach and stimulates the secretion of gastric acid. **Ghrelin** is an intestinal hormone and

stimulates GH secretion, controls appetite, and plays a role in obesity and the regulation of insulin sensitivity and glucose tolerance.³⁰ **Pancreatic polypeptide** is released by PP cells (gamma cells) in response to hypoglycemia and protein-rich meals. It promotes gastric secretion, antagonizes cholecystokinin, and is frequently increased in pancreatic tumors and in diabetes.³¹

Adrenal Glands

The **adrenal glands** are paired pyramid-shaped organs located behind the peritoneum and close to the upper pole of each kidney. Each gland is surrounded by a capsule embedded in fat and well supplied with blood from the phrenic and renal arteries and the aorta. Venous return from the left adrenal gland is to the renal vein and from the right is to the inferior vena cava.

Each adrenal gland consists of two separate portions: an outer cortex and an inner medulla. These two portions have different embryonic origins, different structures, and different hormonal functions. The adrenal cortex and medulla function like two separate but interrelated glands (Fig. 21.17).

FIGURE 21.17 Structure of the Adrenal Gland Showing Cell Layers (Zones) of the Cortex. A, Adrenal glands. Each gland consists of cortex and medulla. The cortex has three layers: zona glomerulosa, zona fasciculata, and zona reticularis. B, A portion of the medulla is visible at the lower right in the photomicrograph ($\times 35$) and at the bottom of the drawing. ACTH, Adrenocorticotropic hormone. (A from Damjanov I: *Pathophysiology*, Philadelphia, 2008, Saunders; B from Kierszenbaum A: *Histology and cell biology*, St Louis, 2002, Mosby.)

Adrenal Cortex

The **adrenal cortex** accounts for 80% of the weight of the adult gland. The cortex is histologically subdivided into the following three zones:

1. The **zona glomerulosa**, the outer layer, constitutes about 15% of the cortex and primarily produces the mineralocorticoid aldosterone.
2. The **zona fasciculata**, the middle layer, constitutes 78% of the cortex and secretes the glucocorticoids cortisol, cortisone, and

corticosterone.

3. The **zona reticularis**, the inner layer, constitutes 7% of the cortex and secretes mineralocorticoids (aldosterone), adrenal androgens and estrogens, and glucocorticoids.

The cells of the adrenal cortex are stimulated by the anterior pituitary hormone ACTH. All hormones of the adrenal cortex are synthesized from low-density lipoprotein cholesterol. The best-known pathway of steroidogenesis involves the conversion of cholesterol to pregnenolone, which is then converted to the major corticosteroids.³²

Glucocorticoids.

The **glucocorticoids** are steroid hormones and have metabolic, neurologic, antiinflammatory, immunosuppressive, and growth-suppressing effects (Fig. 21.18). They are released under stress conditions.³³ They act through nuclear (genomic) and nongenomic (membrane-initiated steroid signaling) pathways in the cell. The term *glucocorticoid* refers to those steroid hormones that have direct effects on carbohydrate metabolism. These hormones increase blood glucose concentration by promoting gluconeogenesis in the liver and conserving glucose by decreasing uptake of glucose into muscle cells, adipose cells, and lymphatic cells by antagonizing insulin. This results in increased glucose for the brain during stress.³⁴ In extrahepatic tissues, the glucocorticoids stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. The ultimate effect on the body is protein catabolism and muscle wasting.

FIGURE 21.18 Effects of Glucocorticoids on the Body. *CNS*, Central nervous system; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GI*, gastrointestinal; *LH*, luteinizing hormone; *TSH*, thyroid-stimulating hormone. (From Steward PM, Newell-Price JDC: The adrenal cortex. In Melmed S et al, editors: *Williams textbook of endocrinology*, ed 13, Philadelphia, 2016, Saunders.)

The glucocorticoids act at several sites to suppress immune and inflammatory reactions (described in [Chapters 7 and 9](#)).³⁵ They affect innate immunity through several pathways, including inhibition of antigen presentation by dendritic cells and decreased activity of pattern recognition receptors on the surface of macrophages (see [Chapter 7](#)). They decrease the proliferation of T lymphocytes, primarily T-helper lymphocytes. There is a greater adverse effect on T-helper 1 cell cytokine production (including antiviral interferons) than there is on T-helper 2 cell cytokine production and therefore

greater depression of cellular immunity than humoral immunity (see [Chapter 8](#)). Glucocorticoids also decrease immune and inflammatory responses by decreasing natural killer cell activity; by blocking phospholipase A and the synthesis of prostaglandins, thromboxanes, and leukotrienes; and by inhibiting inflammatory gene expression. In addition, glucocorticoids suppress the synthesis, secretion, and actions of chemical mediators involved in inflammatory and immune responses, including histamine, adhesion molecules, inducible cyclooxygenase, and inducible nitric oxide synthase.³⁶

Glucocorticoids increase resistance to the severe inflammatory response to lipopolysaccharide (LPS, a bacterial endotoxin) through the inhibition of cytokines, chemokines, certain hormones, and neurotransmitters. In addition, glucocorticoids stimulate antiinflammatory cytokines (e.g., interleukin-10 [IL-10] and transforming growth factor-beta). Lysosomal membranes are also stabilized, decreasing the release of proteolytic enzymes. This suppression of innate and adaptive immunity by glucocorticoids means that infection and poor wound healing are some of the most problematic complications of the use of glucocorticoids in the treatment of disease. Similarly, psychologic and physiologic stress increases glucocorticoid production, which provides a pathway for the well-described decrease in immunity seen in both acute and chronic stress conditions (see [Chapter 11](#)).^{37,38}

Other effects of glucocorticoids include inhibition of bone formation, inhibition of ADH secretion, and stimulation of gastric acid secretion. Glucocorticoids appear to potentiate the effects of catecholamines, including sensitizing the arterioles to the vasoconstrictive effects of norepinephrine. Thyroid hormone and growth hormone effects on adipose tissue also are potentiated by glucocorticoids. A metabolite of cortisol may act like a barbiturate and depress nerve cell function in the brain, accounting for the noted effects on mood associated with steroid level fluctuation in disease or stress.

Pathologically high levels of glucocorticoids increase the number of circulating erythrocytes (leading to polycythemia), increase the

appetite, promote fat deposition in the face and cervical areas, increase uric acid excretion, decrease serum calcium levels (possibly by inhibiting gastrointestinal absorption of calcium), suppress the secretion and synthesis of ACTH, and interfere with the action of growth hormone so that somatic growth is inhibited.³⁹

The most potent of the naturally occurring glucocorticoids is **cortisol**. It is the main secretory product of the adrenal cortex and is needed to maintain life and regulate the body during both positive and negative stress (see [Chapter 11](#), particularly [Fig. 11.2](#)). Cortisol has a biologic half-life of approximately 90 minutes, with the liver primarily responsible for its deactivation.

Cortisol secretion is regulated primarily by the hypothalamus and the anterior pituitary gland ([Fig. 21.19](#)). Corticotropin-releasing hormone is produced in several nuclei in the hypothalamus and stored in the median eminence. Once released, CRH travels through the portal vessels to stimulate the production of ACTH, β -lipotropin, γ -lipotropin, endorphins, and enkephalins by the anterior pituitary. ACTH is the main regulator of cortisol secretion and adrenocortical growth.

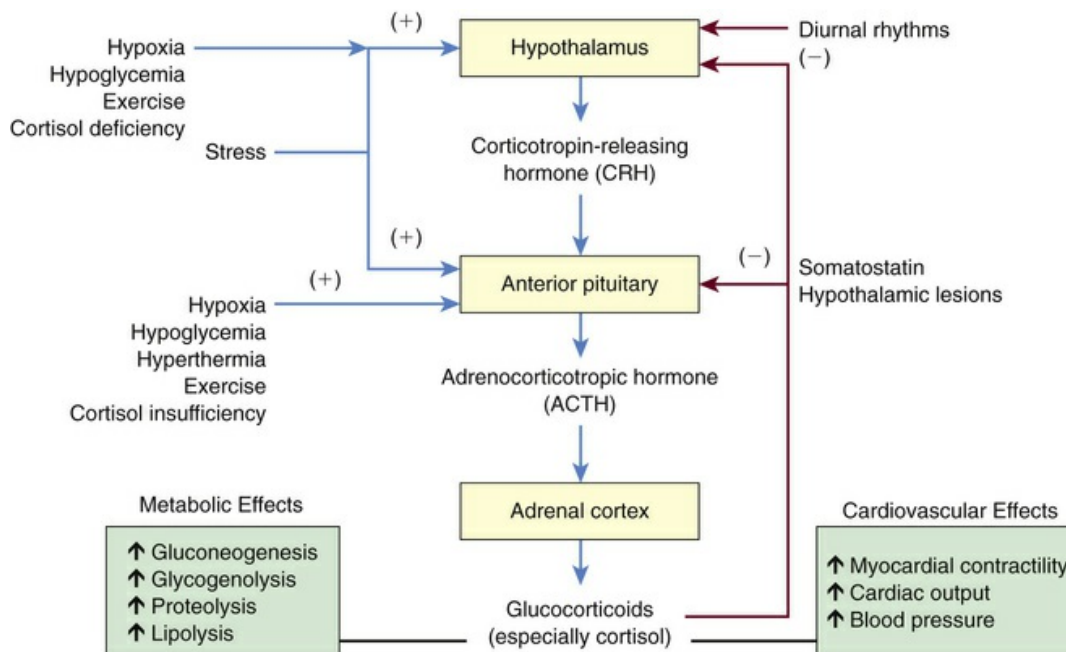

FIGURE 21.19 Feedback Control of Glucocorticoid Synthesis and

Secretion.

The precursor from which ACTH is synthesized is proopiomelanocortin (POMC). Three factors appear to be primarily involved in regulating the secretion of ACTH: (1) negative feedback effects of high circulating levels of cortisol and synthetic glucocorticoids suppress both CRH and ACTH, whereas low cortisol levels stimulate their secretion; (2) diurnal rhythms affect ACTH and cortisol levels (in persons with regular sleep-wake patterns, ACTH peaks 3 to 5 hours after sleep begins and declines throughout the day; and cortisol levels follow a similar pattern, peaking just before awakening); and (3) psychologic and physiologic (e.g., hypoxia, hypoglycemia, hyperthermia, exercise) stress increases ACTH secretion, leading to increased cortisol levels.⁴⁰ (Neurologic mechanisms regulating sleep are discussed in [Chapter 16](#).)

There also is evidence that there is synthesis and secretion of glucocorticoids from extra-adrenal tissue including the thymus, lung, intestine, skin, brain, and possibly heart in response to immune stimulation. This is thought to provide autocrine and paracrine immune regulation and control of inflammation.^{41,42}

When ACTH is secreted, it binds to specific plasma membrane receptors on the cells of the adrenal cortex and on other extra-adrenal tissues. Because both adrenal and extra-adrenal tissues have ACTH receptors, a number of effects result from stimulation by ACTH (these effects are summarized in [Box 21.1](#)).⁴³

Box 21.1

Effects of Adrenocorticotrophic Hormone

Adrenal

- Maintenance of gland size
- Depletion of ascorbic acid
- Activation of adenylyl cyclase

Conversion of cholesterol to pregnenolone
Maintenance of enzymes active in converting pregnenolone to other steroids
Accumulation of cholesterol for steroid hormone synthesis
Secretion of cortisol and adrenal androgens

Extra-Adrenal

Stimulation of melanocytes
Activation of tissue lipase

Once ACTH stimulates the cells of the adrenal cortex, cortisol synthesis and secretion immediately occur. In the healthy person, the secretory patterns of ACTH and cortisol are nearly identical. After secretion, most cortisol circulates in bound form: 15% to 30% is bound to albumin, 55% to 75% is tightly but reversibly bound to a plasma glycoprotein called *transcortin*, and 10% to 15% is unbound. The levels of transcortin play a role in the HPA feedback system controlling cortisol secretion. Transcortin levels are significantly elevated by increased estrogen levels that occur with pregnancy and hormone therapy. The unbound portion is free to diffuse into cells, but only those cells with specific intracellular glucocorticoid receptors respond to cortisol stimulation. ACTH is rapidly inactivated in the circulation, and the liver and kidneys remove the deactivated hormone.

Mineralocorticoids: Aldosterone.

Mineralocorticoid steroids directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss. **Aldosterone** is the most potent of the naturally occurring mineralocorticoids and acts to conserve sodium by increasing the activity of the sodium pump of the epithelial cells in the nephron. (The sodium pump is described in [Chapter 1](#).)

The initial stages of aldosterone synthesis occur in the adrenal zona

fasciculata and zona reticularis. The final conversion of corticosterone to aldosterone occurs in the zona glomerulosa. Aldosterone synthesis and secretion are regulated primarily by the renin-angiotensin-aldosterone system (described in [Chapter 3](#) and [Chapter 38](#); see [Figs. 3.4](#) and [38.10](#)), although other factors also may be involved. The renin-angiotensin system is activated by sodium and water depletion, increased potassium levels, and a diminished effective blood volume ([Fig. 21.20](#)). Angiotensin II is the primary stimulant of aldosterone synthesis and secretion; however, increases in serum potassium concentration also directly stimulate aldosterone secretion. ACTH acutely stimulates aldosterone secretion but is secondary to angiotensin II and potassium.⁴⁴

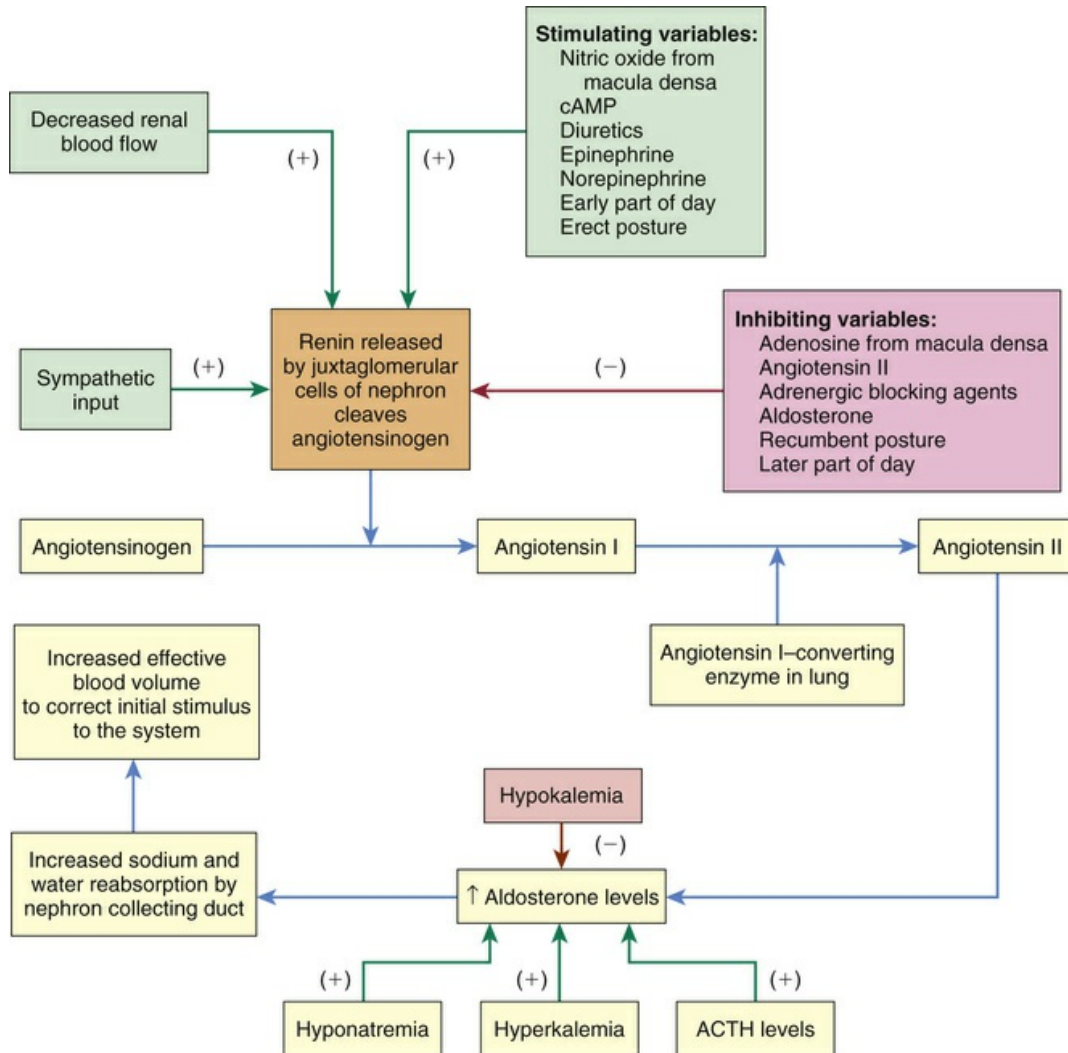

FIGURE 21.20 Feedback Mechanisms Regulating Aldosterone Secretion. *ACTH*, Adrenocorticotropic hormone; *cAMP*, cyclic adenosine monophosphate.

When sodium and potassium levels are within normal limits, approximately 50 to 250 mg of aldosterone is secreted daily. Of the secreted aldosterone, 50% to 75% binds to plasma proteins. The proportion of unbound aldosterone contributes to its rapid metabolic turnover in the liver, its low plasma concentration, and its short half-life (about 15 minutes). Aldosterone is degraded in the liver and is excreted by the kidney.

Aldosterone maintains extracellular volume and blood pressure by acting on distal nephron epithelial cells to increase sodium reabsorption and potassium and hydrogen excretion.⁴⁵ The renal effect takes from 90 minutes to 6 hours. Other effects of aldosterone include

enhancement of cardiac muscle contraction, stimulation of ectopic ventricular activity through secondary cardiac pacemakers in the ventricles, stiffening of blood vessels with increased vascular resistance, and decreased fibrinolysis. Pathologically elevated levels of aldosterone have been implicated in the myocardial changes associated with heart failure.⁴⁶

Adrenal Estrogens and Androgens.

The healthy adrenal cortex secretes small amounts of estrogen and androgens. ACTH appears to be the major regulator. Some of the weak androgenic substances secreted by the cortex (dehydroepiandrosterone [DHEA], androstenedione) are converted by peripheral tissues to stronger androgens, such as testosterone, thus accounting for some androgenic effects initiated by the adrenal cortex. Peripheral conversion of adrenal androgens to estrogens is enhanced in aging or obese persons, as well as in those with liver disease or hyperthyroidism. The biologic effects and metabolism of the adrenal sex steroids do not vary from those produced by the gonads (see [Chapter 24](#)).

Adrenal Medulla

The **adrenal medulla**, together with the sympathetic division of the autonomic nervous system, is embryonically derived from neural crest cells. **Chromaffin cells (pheochromocytes)** are the cells of the adrenal gland that store and secrete the catecholamines epinephrine (adrenaline) and norepinephrine. Both are synthesized from the amino acid phenylalanine ([Fig. 21.21](#)). Only 30% of circulating epinephrine comes from the adrenal medulla; the other 70% is released from nerve terminals. The medulla is only a minor source of norepinephrine.⁴⁷ The adrenal medulla functions as a sympathetic ganglion without postganglionic processes. Sympathetic cholinergic preganglion fibers terminate on the chromaffin cells and secrete catecholamines directly into the bloodstream. The catecholamines are, therefore, hormones and not neurotransmitters.

FIGURE 21.21 Synthesis of Catecholamines.

Physiologic stress to the body (e.g., traumatic injury, hypoxia, hypoglycemia, and many others) triggers release of adrenal catecholamines through acetylcholine (from the preganglionic sympathetic fibers), which depolarizes the chromaffin cells. Depolarization causes exocytosis of storage granules from the chromaffin cells with release of epinephrine and norepinephrine into the bloodstream. Secretion of adrenal catecholamines is also increased by ACTH and the glucocorticoids.

Once released, the catecholamines remain in the plasma for only seconds to minutes. The catecholamines exert rapid biologic effects

after binding to a plasma membrane receptor (α_1 , α_2 , β_1 , β_2 , β_3) in target cells and activating the adenylyl cyclase system (see [Table 15.7](#)). Catecholamines are rapidly removed from the plasma by neurons for storage in new cytoplasmic granules, or they may be metabolically inactivated and excreted in the urine.

Catecholamines have diverse effects on the entire body. Their release and the body's response have been characterized as the “fight or flight” response (see [Chapter 11](#) and [Table 11.1](#)). In general, the effects of catecholamines activate adrenergic receptors on cell membranes of all visceral organs and smooth muscles and promote hyperglycemia.⁴⁸

Tests of Endocrine Function

Evaluation of the endocrine system is challenging because of (1) the complexity of the clinical presentation as a result of multiple organ system involvement, (2) the nonspecific nature of complaints frequently associated with endocrine dysfunction, and (3) the inappropriate use of laboratory test interpretations.

Tests of the endocrine system involve several general types of clinical evaluation. Measurement of hormone level is accomplished by radioimmunoassay, by enzyme-linked immunosorbent assay, and less commonly by bioassay. **Radioimmunoassay (RIA)**, a technique for measuring the minute quantities of hormones in the blood, uses antibodies and radiolabeled hormones to determine the quantity of hormone in the plasma. **Enzyme-linked immunosorbent assay (ELISA)** also is used to determine circulating hormone levels. This method is similar to that of RIA but is less expensive and easier to conduct. Instead of radiolabeled hormones, an enzyme-labeled hormone is used. A **bioassay** involves the use of graded doses of hormone in a reference preparation and then comparison of the results with an unknown sample. Bioassays are used more commonly in investigative endocrinology than in clinical laboratories. If the serum level is greater or less than the reference values, more definitive tests are required to determine the source of the problem.

Measurement of individual hormones does not always permit

differentiation between normal and abnormal values when hormone levels are changing over time. For an accurate interpretation, the broad normal range of some hormones requires knowledge of previous hormonal levels and timed sampling. Stimulation and suppression tests that determine the response to exogenous stimulants or inhibitors can help to decipher some of these complexities.

Indirect assessment of hormonal function often includes measurement of concentrations of serum glucose and electrolytes that are affected by the endocrine process. Evaluation of hormonal function also may include radiographic imaging of specific glands.

Aging and the Endocrine System

The precise relationship between aging and the endocrine system is not clear. Perhaps most important, the question of whether changes in endocrine function are a consequence or a cause of aging has yet to be resolved. These relationships have been difficult to identify, in part because of a number of age-related variables that may coexist, such as acute and chronic nonendocrine disease; use of medications; alterations in diet, body composition, and weight; and changes in sleep-wake cycles. However, the endocrine system is so integral to health that changes in endocrine function have been used as “biomarkers” for unhealthy aging.

Investigation into the role of the endocrine glands and their interactions in the aging process has generated much data, although the evidence is contradictory. There are complex changes within the HPA; altered biologic activity of hormones, altered circulating levels of hormones, altered secretory response of the endocrine glands, altered metabolism of hormones, loss of circadian control of hormone secretion, and effects of oxidative stress and inflammation are among the findings. Changes in secretion of hypothalamic regulatory factors and hormones or changes in hypothalamic feedback sensitivity may contribute to alterations in control of an optimal internal environment.⁴⁹

The dynamic equilibrium of the endocrine system also may be

affected by altered secretion of neurotransmitters within certain areas of the brain, affecting hypothalamic and pituitary function. Such alterations may include an excess or deficit in secretion of pituitary hormones and loss of appropriate secretory pattern of those hormones. Loss of endocrine steady states may be associated with or contribute to aging.⁵⁰

The most studied changes in hormone function with aging affect the levels of reproductive hormones and gonadotropins (menopause and andropause) (discussed in [Chapter 24](#)). Two of the most important endocrine changes associated with aging affect the thyroid gland and the pancreas. Other important hormone changes associated with aging include a decline in serum levels of growth hormone and IGF-1, parathyroid hormone, dehydroepiandrosterone, and ADH.

Thyroid Gland

Changes in thyroid structure and function occur with aging.⁵¹ Structurally, some glandular atrophy and fibrosis occur with nodularity and increasing inflammatory infiltrates. These infiltrative changes may reflect age-related autoimmune damage. Clinical signs of thyroid disease are more difficult to detect in older adults. Overall, it is estimated that there is some evidence of thyroid dysfunction in 5% to 10% of older adult women. The presence of thyroid nodules increases after the age of 70 years. Changes relative to thyroid hormone and its function are more difficult to assess and much of the available data are contradictory. Overall, TSH secretion is thought to increase slightly, but there is controversy regarding whether this is normal aging or the presence of hypothyroidism with risk for adverse consequences.⁵²

Treatment for thyroid deficiency is also affected by aging. The appropriate dose for TH replacement is often lower in older adults because the peripheral metabolism of TH decreases with age. In addition, TH must be replaced slowly in older adults with coronary artery disease to prevent angina and myocardial infarction.⁵¹

The Endocrine Pancreas

It is estimated that 40% to 50% of individuals older than age 65 have impaired glucose tolerance or diabetes and there is an age-dependent decline in beta-cell function.⁵³ With aging, pancreatic cell regeneration declines and there is increased distribution of fat tissue.⁵⁴

Dysfunction of the pancreas with decreased insulin secretion of beta cells and insulin receptors and increased insulin resistance have all been documented and may be related to changes in adipokine physiology.⁵⁵ These changes have significant implications for many target organs, particularly the cardiovascular system, which is increasingly at risk for both vascular (hypertension, atherosclerosis, glomerulosclerosis) and cardiac (infarction, failure) disorders.

Growth Hormone and Insulin-Like Growth Factors

The amounts of GH and IGF decline with aging, a process that has been called the *somatopause*.⁵⁶ This decline in anabolic stimuli is linked to decreases in muscle size and function, decreased amounts of fat and bone mass, and changes in reproductive and cognitive function.⁵⁷ Some studies have shown that growth hormone resistance and declines in GH are associated with longevity in animals, but this has not been confirmed in humans.⁵⁸

Parathyroid Glands

An age-related alteration in PTH secretion has been proposed to explain alterations in calcium homeostasis that have been noted in older adults.⁵⁹ Calcium intake, especially in women, tends to decrease with aging and may contribute to osteoporosis (see [Chapter 45](#)). The average daily intake of 450 to 500 mg/day causes a negative calcium balance greater than 40 mg/day and may be related to the absolute bone loss of approximately 1.5% per year. Older adults show decreased intestinal adaptation to variations in calcium intake. Hyperparathyroidism may occur secondary to calcium malabsorption and hypocalcemia with increased bone remodeling that results in cortical bone thinning and porosity. Elevated levels of parathyroid

hormone have been linked with an increase in mortality in older adults, many of whom also have a mild, persistent hypercalciuria, which indicates a defective renal mechanism for responding to decreased calcium intake. Decreased circulating levels of vitamin D are common in older adults, especially those in long-term care institutions. Vitamin D deficiency has been linked to not only osteoporosis but also cancer, autoimmune diseases, diabetes, cardiovascular disease, and mental health disorders. The parathyroid gland, kidney, and choroid plexus secrete the **Klotho protein**, which, when overexpressed, has antiaging effects (see [What's New? Klotho Protein and Aging](#)).

What's New?

Klotho Protein and Aging

Klotho is a protein known to have antiaging effects and is expressed in parathyroid glands, kidney distal tubules, and choroid plexus of the brain. The transmembrane form of Klotho protein functions as an obligatory co-receptor for FGF23, which is important for the regulation of vitamin D metabolism and subsequently blood phosphate levels. In addition, the extracellular domain of the protein is secreted into the blood, cerebrospinal fluid, and urine. This suggests that Klotho may function as an endocrine or paracrine hormone, but the mechanisms are not clearly known. Decreased plasma, urinary, and renal Klotho levels are associated with normal aging, chronic kidney disease, salt-sensitive hypertension, cancers, osteoporosis, atherosclerosis, coronary artery disease, and increased mortality. Klotho also is known to have a tumor suppressor function. In contrast, overexpression of the Klotho gene results in longevity and reversal of the aging process in animals. It is postulated that Klotho extends life by attenuating generation of reactive oxygen species, cytokines, and growth factors, including insulin, insulin-like growth factor-1 (IGF-1), transforming growth factor- β (TGF- β), and interferon- γ (IFN- γ). Finally, the Klotho

protein is a powerful regulator of a wide variety of cellular transport systems, including ion channels, transport proteins, and the Na⁺-K⁺-ATPase pump. These functions can be stimulatory or inhibitory, and more research is needed to determine how these processes have antiaging effects and how their disruption contributes to disease. Recombinant human Klotho protein has been developed, and efforts are in progress to target its function in both health and disease.

Data from Kim JH et al: *J Lifestyle Med* 5(1):1-6, 2016; Sopjani M, Dërmaku-Sopjani M: *Vitam Horm* 101:59-84, 2016; Sopjani M et al: *Curr Mol Med* 15(1):27-37, 2015; Tang X et al: *Klotho: Lab Invest* 96(2):197-205, 2016.

Adrenal Glands

The adrenal cortex loses some weight and has more fibrous tissue after the age of 50 years. Age does not appear to affect the feedback mechanisms involved in maintaining glucocorticoid levels, but there is an age-related decrease in the metabolic clearance rate of the glucocorticoids.

The metabolic clearance of cortisol decreases with an age-related decline in liver and kidney function. Further, less cortisol appears to be used by the body when aging is accompanied by a loss of lean body mass. Decreased clearance and reduced use of cortisol contribute to higher circulating cortisol levels, but diurnal variation is maintained. Because feedback mechanisms are intact, the higher cortisol levels cause a decrease in cortisol secretion. Circadian patterns of ACTH and cortisol secretion may change with aging.

Plasma levels of the adrenal androgens, as well as urinary excretion of the metabolic end products, decrease gradually but dramatically with age, to as much as 50% to 70% of the young adult level. This change in adrenal function has been called the *adrenopause* and is correlated with decreased synthesis activity of DHEA.⁶⁰

This change appears to reflect a decline in the function of the zona reticularis. In postmenopausal women, this decline in adrenal androgen secretion is especially important because nearly all sex

steroids after menopause come from adrenal and ovarian production of androgen precursors converted to estrogens in the periphery. In older adult men, adrenal androgen production accounts for more than half of circulating testosterone levels.

Antidiuretic Hormone

Although hyponatremia is a common finding in older adults, it appears related to changes in renal function or sensitivity rather than to ADH-related mechanisms. Morphologic studies have not shown significant age-related degenerative changes in the neuroendocrine pathways that regulate the synthesis and secretion of ADH. However, it appears that ADH secretion is augmented when stimulated by changes in osmotic concentration, whereas baroreceptor-mediated ADH secretion is reduced producing the syndrome of inappropriate ADH secretion (SIADH), common in older adults.⁶¹

Summary Review

Mechanisms of Hormonal Regulation

1. The endocrine system has diverse functions, including reproductive and CNS differentiation, sequential growth and development, coordination of reproductive systems, continuous maintenance of the body's internal environment, and adaptive responses to stress.
2. Hormones are chemical messengers synthesized by endocrine glands and released into the circulation; they work with the nervous and immune systems to maintain communication and control.
3. Hormones have specific negative- and positive-feedback mechanisms. Most hormone levels are regulated by negative feedback, in which tropic hormone secretion raises the level of a specific hormone. The elevated level of the specific hormone then causes negative feedback, decreasing secretion of the

tropic hormone. Positive feedback systems, in which elevated hormone levels increase a response which then further increases hormone secretion, is seen most often in reproductive hormones.

4. In addition to negative and positive feedback systems, endocrine feedback is described in terms of the levels of feedback (long and short feedback loops).
5. Endocrine communications occur within cells (autocrine), between cells (paracrine), and between remote cells (endocrine).
6. Water-soluble hormones circulate throughout the body in unbound form, whereas lipid-soluble hormones (i.e., steroid and thyroid hormones) circulate throughout the body bound to carrier proteins.
7. Hormones affect only cells with appropriate receptors (target cells) and then act on those cells to initiate specific cell functions or activities.
8. Hormones have two general types of effects on cells: direct effects, or obvious changes in cell function; and permissive effects, or less obvious changes that facilitate cell function.
9. Receptors for hormones are large proteins and may be located either on or in the plasma membrane, in the cytosol, or in the nucleus of the target cell. Receptors include those that are G-protein linked, enzyme linked, or ion gated channels.
10. Water-soluble hormones act as first messengers, binding to specific receptors on the cell's plasma membrane. The signals initiated by hormone-receptor binding are then transmitted into the cell by the action of second messengers.
11. Second messengers that have been identified include cAMP, cGMP, and calcium. Calcium associates with IP_3 and DAG to produce physiologic effects.
12. For cells that have cAMP as their second messenger, a series of interactions within the plasma membrane take place, activating adenylyl cyclase.
13. Cells that have cGMP as their second messenger are activated

by the enzyme guanylyl cyclase.

14. For cells that have calcium as their second messenger, an increase in intracellular calcium concentration causes calcium to bind with calmodulin, a regulatory protein. This step then initiates other intracellular processes.
15. Lipid-soluble hormones (including steroid and thyroid hormones) may have rapid (nongenomic) effects by binding to a plasma membrane or receptor or crossing the plasma membrane through diffusion. These hormones then either bind to cytoplasmic proteins or diffuse directly into the cell nucleus and bind to nuclear receptors.

Structure and Function of the Endocrine Glands

1. The hypothalamic-pituitary axis (HPA) forms the structural and functional basis for central integration of the neurologic and endocrine systems
2. The pituitary gland, consisting of anterior and posterior portions, is connected to the central nervous system through the hypothalamus.
3. The hypothalamus regulates anterior pituitary function by secreting releasing hormones into the portal circulation.
4. Hypothalamic hormones include dopamine, which inhibits prolactin secretion; TRH, which affects release of thyroid hormones; CRH, which facilitates release of ACTH and endorphins; and substance P, which inhibits ACTH release and stimulates release of a variety of other hormones. ADH and oxytocin are synthesized in the hypothalamus and stored and secreted by the posterior pituitary.
5. The posterior pituitary stores and secretes oxytocin and ADH, also called arginine-vasopressin.
6. ADH controls serum osmolality, increases the permeability of the renal tubules to water, and causes vasoconstriction when administered pharmacologically in high doses. ADH also may regulate some central nervous system functions.

7. Oxytocin causes uterine contraction and lactation in women and may have a role in sperm motility in men. In men and women, oxytocin has an antidiuretic effect similar to that of ADH.
8. The majority of the hormones of the anterior pituitary are regulated by (1) secretion of hypothalamic-releasing hormones or factors, (2) negative feedback from hormones secreted by target organs, and (3) mediating effects of neurotransmitters. Prolactin is regulated by a positive feedback system.
9. Hormones of the anterior pituitary include ACTH, MSH, somatotrophic hormones (GH and prolactin), and glycoprotein hormones (FSH, LH, and TSH).
10. Growth hormone stimulates bone growth, increased protein metabolism in muscles, and lipolysis. Its anabolic effects are mediated in part by IGFs, of which IGF-1 is the most biologically active.
11. Prolactin functions to produce milk during pregnancy and lactation.
12. The pineal gland produces melatonin, which affects sleep, circadian rhythms, secretion of GHRH onset of puberty, immune function, and aging.
13. The two-lobed thyroid gland contains follicles, which secrete the thyroid hormones, and parafollicular cells (C cells), which secrete calcitonin and, in smaller quantities, the neuropeptides ghrelin, serotonin, and somatostatin.
14. Regulation of TH levels is complex and involves the hypothalamus (TRH), anterior pituitary (TSH), thyroid gland, and numerous biochemical variables.
15. TH secretion is regulated by TRH through a negative-feedback loop that involves the anterior pituitary and hypothalamus.
16. TSH, which is synthesized and stored in the anterior pituitary, stimulates secretion of TH by activating intracellular processes, including uptake of iodine necessary for the synthesis of TH.
17. Synthesis of TH depends on the glycoprotein thyroglobulin,

which contains a precursor of TH, tyrosine. Tyrosine then combines with iodide to form precursor molecules of the thyroid hormones T_4 and T_3 .

18. When released into the circulation, T_3 and T_4 are bound by carrier proteins in the plasma that store these hormones and provide a buffer for rapid changes in hormone levels.
19. Thyroid hormones alter protein synthesis and have a wide range of metabolic effects on proteins, carbohydrates, lipids, and vitamins. TH is responsible for growth, maturation, and function of cells and body systems throughout the body and across the life span.
20. The paired parathyroid glands normally are located behind the upper and lower poles of the thyroid gland. These glands secrete PTH, the single most important regulator of serum calcium and phosphate levels.
21. PTH secretion is regulated by levels of ionized calcium in the plasma and by cAMP within the cell. Some other substances—hormones, neurotransmitters, and ions— affect PTH secretion by inhibiting cAMP or by changing calcium levels.
22. In bone, PTH causes bone breakdown and resorption. In the kidney, PTH increases reabsorption of calcium, decreases reabsorption of phosphorus and bicarbonate, and stimulates synthesis of the active form of vitamin D. Paradoxically, low-dose PTH, administered intermittently, stimulates bone formation.
23. Parathyroid hormone–related peptide (PTHrP) has properties similar to those of PTH and plays a role in placental calcium transport, lactation, and fetal tooth development.
24. The endocrine pancreas contains the islets of Langerhans, which secrete hormones responsible for much of the carbohydrate metabolism in the body.
25. The islets of Langerhans consist of alpha cells, beta cells, delta cells, and F cells.
26. Alpha cells produce glucagon, which is secreted inversely to blood glucose concentrations and stimulates glycogenolysis,

- gluconeogenesis, and lipolysis.
27. Beta cells synthesize insulin, a hormone that regulates blood glucose concentrations and overall body metabolism of fat, protein, and carbohydrates. Secretion of insulin is regulated by chemical, hormonal, and neural control. Biological responsiveness to insulin is affected by age, weight, abdominal fat, and physical activity.
 28. Beta cells also secrete amylin, which promotes glucose-dependent insulin secretion, inhibits glucagon synthesis, and delays gastric emptying, producing an antihyperglycemic effect.
 29. Delta cells secrete pancreatic somatostatin, which inhibits secretion of glucagon, insulin, and polypeptide.
 30. F cells secrete pancreatic polypeptide, which stimulates Y receptors, promotes gastric secretion, and antagonizes cholecystokinin.
 31. Incretin hormones are produced by endocrine cells of the gastrointestinal tract and promote glucose-dependent insulin secretion, inhibit glucagon synthesis, and delay gastric emptying.
 32. The paired adrenal glands are situated on the kidneys. Each gland consists of an adrenal medulla, which secretes catecholamines, and an adrenal cortex, which secretes steroid hormones.
 33. The steroid hormones secreted by the adrenal cortex are all synthesized from cholesterol. These hormones include glucocorticoids, mineralocorticoids, and adrenal androgens and estrogens.
 34. Glucocorticoids directly affect carbohydrate metabolism by increasing blood glucose concentration through gluconeogenesis in the liver and by decreasing use of glucose. Glucocorticoids also inhibit immune and inflammatory responses, inhibit bone formation and ADH secretion, and stimulate gastric secretion.
 35. Cortisol secretion is related to secretion of ACTH, which is

stimulated by CRH. ACTH binds with receptors of the adrenal cortex, which activates intracellular mechanisms (specifically cAMP) and leads to cortisol release.

36. Mineralocorticoids, especially aldosterone, are steroid hormones that directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss.
37. Aldosterone secretion is controlled by the renin-angiotensin-aldosterone system and acts by binding to a site on the cell nucleus and altering protein production within the cell. Its principal site of action is the kidney, where it causes sodium reabsorption and potassium and hydrogen excretion.
38. Androgens and estrogens secreted by the adrenal cortex act in the same way as those secreted by the gonads.
39. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Catecholamines are synthesized from the amino acid phenylalanine. Their release is stimulated by sympathetic nervous system stimulation, ACTH, and glucocorticoids.
40. Catecholamines bind with various target cells and are taken up by neurons or excreted in the urine. They cause a range of metabolic effects that generally are characterized as the “fight or flight” response.
41. The endocrine system acts together with the nervous and immune systems to respond to stressors, providing an integrated and protective response.
42. Several assay methods are used to measure levels of hormones in the plasma. RIA compares the proportion of radiolabeled and nonradiolabeled hormone against standard reference curves.
43. ELISA is a method similar to RIA, but uses a radiolabeled enzyme rather than a radiolabeled hormone.
44. Bioassays use graded doses of hormone in a reference preparation and then compare the results with an unknown sample to determine the hormone level.

Aging and the Endocrine System

1. Endocrine changes that may be associated with aging include altered biologic activity of hormones, altered circulating levels of hormones, altered secretory responses of endocrine glands, altered metabolism of hormones, loss of circadian control of hormone release, and changes in secretion of hypothalamic regulatory hormones.
2. Cellular damage associated with aging, genetically programmed cell change, and chronic wear and tear may contribute to endocrine gland dysfunction or alterations in the responsiveness of target organs.
3. Aging apparently causes atrophy of the thyroid gland and is associated with infiltrative glandular changes. Secretion of thyroid hormones may diminish with age.
4. Aging causes pancreatic fat deposition and is associated with a decrease both in insulin secretion and in insulin sensitivity. In addition, there is an age-dependent decline in beta-cell function.
5. Growth hormone levels decrease with aging, leading to decreased bone and muscle mass.
6. Aging is associated with alterations in calcium steady states, which may be related to alterations in PTH secretion from the parathyroid glands.
7. Age-related changes in adrenal function include decreased clearance of glucocorticoids and a decrease in levels of adrenal androgens. The effects of these changes, however, are offset by feedback mechanisms that maintain glucocorticoid levels and by gonadal secretion of androgens.
8. The kidney, choroid plexus, and parathyroid gland secrete the Klotho protein, which has antiaging effects.

Types of Diabetes Mellitus, 685

Acute Complications of Diabetes Mellitus, 692

Chronic Complications of Diabetes Mellitus, 694

Alterations of Adrenal Function, 699

The function of the endocrine system involves complex interrelationships and interactions that maintain dynamic steady-states, provide growth and reproductive capabilities, and allow for adaptive changes in times of stress. Alterations in function are caused by either hypersecretion or hyposecretion of the various hormones, leading to abnormal hormone concentrations in the blood and abnormal receptor function or from altered intracellular response to the hormone-receptor complex.

Mechanisms of Hormonal Alterations

Significantly elevated or depressed hormone levels may result from a variety of causes (Box 22.1). Dysfunction of an endocrine gland may involve the gland's failure to produce adequate amounts of biologically free or active hormone forms (hyposecretion). This failure may occur when the secretory cells are unable to produce or obtain an adequate quantity of required hormone precursors or when they are unable to convert the precursors to the active hormone. Once hormones are released into the circulation, they may be degraded at an altered rate or inactivated by antibodies before reaching the target cell. Other causes of decreased hormone delivery to the target cell include an inadequate blood supply to the gland or target tissues or an abnormal amount of the appropriate carrier proteins in the serum. A gland also may synthesize or release excessive amounts of hormone (hypersecretion). For example, feedback systems that recognize the need for a particular hormone may fail to function properly or may respond to inappropriate signals. Ectopic sources of hormones (hormones produced by nonendocrine tissues) may result also in abnormally elevated hormone levels without benefit of the normal feedback system for hormone control. In these cases the ectopic

hormone production is said to be *autonomous*. There also may be alterations in the expression/function of hormone receptors, thus affecting hormone action.

Box 22.1

Mechanisms of Hormone Alterations

INAPPROPRIATE AMOUNTS OF HORMONE DELIVERED TO TARGET CELL	INAPPROPRIATE RESPONSE BY TARGET CELL
<p>Inadequate Hormone Synthesis Inadequate quantity of hormone precursors Secretory cell unable to convert precursors to active hormone</p> <p>Failure of Feedback Systems Do not recognize positive feedback leading to inadequate hormone synthesis Do not recognize negative feedback leading to excessive hormone synthesis</p> <p>Inactive Hormones Inadequate biologically free hormone Hormone degraded at an altered rate Circulating inhibitors</p> <p>Dysfunctional Delivery System Inadequate blood supply Inadequate carrier proteins Ectopic production of hormones</p>	<p>Cell Surface Receptor–Associated Disorders Decrease in the number of receptors Impaired receptor function (altered affinity for hormones) Presence of antibodies against specific receptors Unusual expression of receptor function</p> <p>Intracellular Disorders Acquired defects in postreceptor signaling cascades Inadequate synthesis of a second messenger Intracellular enzymes or proteins are altered Alterations in nuclear co-regulators Altered protein synthesis</p>

Target cells may fail to appropriately respond to hormonal stimulation (*hormone insensitivity*) (see [Box 22.1](#)). Two general types of target cell insensitivity to hormones are cell surface receptor–associated disorders and intracellular disorders:

1. *Cell surface receptor–associated disorders*. These disorders have been identified primarily in water-soluble hormones, such as insulin. They may involve (1) a decrease in the number of receptors, leading to decreased or defective hormone-receptor

binding; (2) impairment of receptor function, resulting in insensitivity to the hormone; (3) presence of antibodies against specific receptors that either reduce available binding sites or mimic hormone action suppressing or exaggerating, respectively, the target cell response; or (4) unusual expression of receptor function, as occurs in some tumor cells.

2. *Intracellular disorders.* These disorders involve acquired defects in postreceptor signaling cascades or inadequate synthesis of a second messenger, such as cyclic adenosine monophosphate (cAMP), needed to transduce the hormonal signal into intracellular events. The target cell for water-soluble hormones may have a faulty response to hormone-receptor binding and thus fail to generate the required second messenger, or the cell also may have an abnormal response to the second messenger if levels of intracellular enzymes or proteins are altered. (Second messengers for various hormones are listed in [Table 21.3](#).) As a result, the target cell fails to express the usual hormonal effect (e.g., see pseudohypoparathyroidism under Hypoparathyroidism).

Pathogenic mechanisms affecting target cell response for lipid-soluble hormones, such as thyroid hormone or glucocorticoids, are recognized less often than those affecting the water-soluble hormones. When they do occur, the mechanisms are similar to those for water-soluble hormones, including changes in the number and binding affinity of intracellular receptors or altered generation of new messenger ribonucleic acid (mRNA) and substrates for new protein synthesis. In other cases, hormone responsiveness may be linked to alterations in nuclear co-regulators, or transcription factors, which are proteins (such as cAMP response element-binding protein [CREB]; see [Chapter 21](#)) that facilitate or inhibit the transcription of the target gene.^{1,2}

Alterations of the Hypothalamic-

Pituitary System

Perhaps the most common cause of apparent hypothalamic dysfunction is interruption of the pituitary stalk, which can be caused by destructive lesions, rupture after head injury, surgical transection, or tumor. In these cases, the absence of hypothalamic releasing or inhibiting hormones (Fig. 22.1) causes a variety of manifestations that present clinically as pituitary disease. For example, if there is an absence of gonadotropin-releasing hormone (GnRH) from the hypothalamus, then there is a lack of stimulation of gonadotropin follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary; thus menses cease in women and spermatogenesis is impaired in men. Adrenocorticotrophic hormone (ACTH) response to low serum cortisol levels is decreased because of the absence of corticotropin-releasing hormone (CRH). Hypothalamic hypothyroidism is caused by the absence of thyrotropin-releasing hormone (TRH). Low levels of growth hormone-releasing hormone (GHRH) result in growth hormone (GH) deficiency and growth failure in children. Hyperprolactinemia is caused by an absence of the usual inhibitory control of prolactin secretion by dopamine.

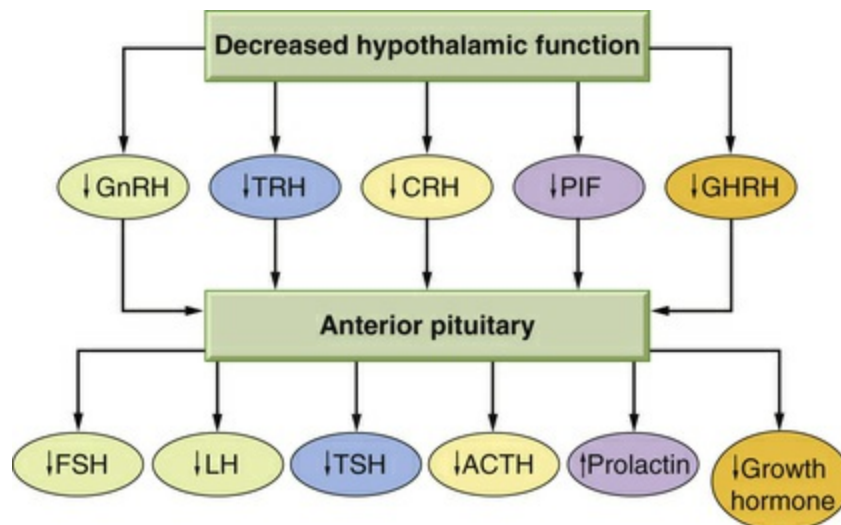

FIGURE 22.1 Loss of Hypothalamic Hormones. *ACTH*, Adrenocorticotrophic hormone; *CRH*, corticotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *GHRH*, growth hormone-releasing hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *PIF*,

prolactin inhibitor factor; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

Diseases of the Posterior Pituitary

Diseases of the posterior pituitary usually cause abnormal secretion of antidiuretic hormone (ADH, arginine vasopressin). An excess amount of this hormone results in water retention and a hyposmolar state, whereas deficiency in the amount or response to ADH results in serum hyperosmolarity (see [Chapters 1](#) and [3](#)). Changes in both ADH and oxytocin release and function are increasingly linked to changes in social behavior, particularly during stress.³ Thus these complex pathophysiologic states not only have significant clinical effects on the modulation of body fluids and electrolytes, but also affect cognitive, emotional, and behavioral responses to stress.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate antidiuretic hormone (SIADH) secretion is characterized by high levels of ADH in the absence of normal physiologic stimuli for its release. A common cause of SIADH is the ectopic production of ADH by tumors, such as small cell carcinoma of the duodenum, stomach, and pancreas; cancers of the bladder, prostate, and endometrium; lymphomas; and sarcomas. Pulmonary disorders associated with SIADH include pneumonia (e.g., tuberculosis), small cell carcinoma, asthma, cystic fibrosis, and respiratory failure requiring mechanical ventilation. Central nervous system disorders that may cause SIADH include encephalitis, meningitis, intracranial hemorrhage, tumors, and trauma including neurosurgery. A nephrogenic form of SIADH involves an X-linked mutation in arginine vasopressin (AVP) genes leading to chronic activation of tubular V2 receptor and resulting in excessive free water reabsorption and concentrated urine.⁴ Any surgery can result in an increased ADH secretion for as long as 5 to 7 days. The precise mechanism is uncertain but is likely related to fluid and volume

changes following surgery, the amount and type of intravenous fluids given, and the use of narcotic analgesics. Transient SIADH is especially common after pituitary surgery because stored ADH is released in an unregulated fashion.⁵

Medications are an important cause of SIADH, especially in the elderly. These include hypoglycemic medications (e.g., chlorpropamide), antidepressants, antipsychotics, narcotics, general anesthetics, chemotherapeutic agents, nonsteroidal antiinflammatory drugs, and synthetic ADH. These drugs either stimulate ADH release, enhance the physiologic effects of ADH, or have a biologic action similar to that of ADH.⁶

◆Pathophysiology.

The pathophysiologic features of SIADH are the result of enhanced renal water retention. ADH increases renal collecting duct permeability to water by inducing the insertion of aquaporin-2, a water channel protein, into the tubular luminal membrane, which increases water reabsorption by the kidneys.⁷ This results in an expansion of extracellular fluid volume that leads to dilutional hyponatremia (low serum sodium concentration), hypoosmolarity, and urine that is inappropriately concentrated with respect to serum osmolarity, because water is reabsorbed that normally would be excreted.

◆Clinical Manifestations.

The symptoms of SIADH result from hypotonic (dilutional) hyponatremia and are associated with hypervolemia and weight gain. The severity and rapidity of onset determine the extent of the symptoms. Thirst, impaired taste, anorexia, dyspnea on exertion, fatigue, and dulled sensorium occur when the serum sodium level decreases rapidly from 140 to 130 mEq/L. Peripheral edema is usually absent. Gastrointestinal symptoms, including vomiting and abdominal cramps, occur with a drop in sodium concentration from 130 to 120 mEq/L. There is weight gain from water retention, even with nausea and vomiting. Even if hyponatremia develops slowly,

serum sodium levels less than 110 to 115 mEq/L cause confusion, lethargy, muscle twitching, and seizures; severe and sometimes irreversible neurologic damage may occur. Symptoms resolve with correction of hyponatremia (see [Chapter 3](#)).

◆ Evaluation and Treatment.

A diagnosis of SIADH includes the following manifestations: (1) serum hypoosmolality (<280 mOsm/kg) and hyponatremia (serum sodium level <135 mEq/L); (2) urine hyperosmolality (i.e., the osmolality of the urine is always higher than the concurrent serum osmolality); (3) urine sodium excretion that matches sodium intake; (4) normal renal, adrenal, and thyroid function; and (5) absence of conditions that can alter volume status (e.g., recent diuretic use, heart or liver failure, hypervolemia from any cause, or renal insufficiency). ADH is difficult to measure in the serum. Copeptin, an ADH precursor molecule, may be used as a surrogate marker.⁸ Individuals with neurologic injury also may develop hyponatremia caused by cerebral salt wasting syndrome. This can be differentiated from SIADH because cerebral salt wasting is characterized by hyponatremia, hypovolemia, and weight loss. In addition, urine sodium levels are elevated.⁹

The treatment of SIADH involves the correction of any underlying causal problems and fluid restriction (when feasible) with careful monitoring of sodium level status and neurologic symptoms. In severe SIADH, emergency correction of severe hyponatremia involves careful administration of hypertonic saline and, most importantly, fluid restriction to 800 to 1000 mL/day. Resolution usually occurs within 3 days, with a 2- to 3-kg weight loss resulting from enhanced free water clearance and correction of hyponatremia and salt wasting. If hyponatremia is corrected too rapidly, a severe neurologic syndrome called *central pontine myelinolysis* can ensue. Demeclocycline, which causes the renal tubules to develop resistance to ADH, may be used to treat resistant or chronic SIADH. Vasopressin receptor antagonists, known as *vaptans*, are effective in treating SIADH.¹⁰

Diabetes Insipidus

Diabetes insipidus (DI) is an insufficiency of ADH, leading to polyuria (frequent urination) and polydipsia (frequent drinking). There are two forms: neurogenic or central (hypothalamic) and nephrogenic (renal).¹¹

Neurogenic or central DI is caused by insufficient secretion of ADH. It occurs when any organic lesion of the hypothalamus, pituitary stalk, or posterior pituitary interferes with ADH synthesis, transport, or release. Causative lesions include primary or metastatic brain tumors, hypophysectomy, aneurysms, thrombosis, infections, and immunologic disorders. Neurogenic DI is a well-recognized complication of traumatic brain injury or pituitary surgery in which DI can be transient or permanent. Neurogenic DI can be a complication of pregnancy. In rare cases, it also can be caused by hereditary disorders that affect ADH genes or result in structural changes in the pituitary gland.

Nephrogenic DI is caused by inadequate response of the renal tubules to ADH and is usually acquired or may be genetic, including genes that code for vasopressin V2 receptor (*AVPR2*) and aquaporin 2 (*AQP2*) proteins. Acquired nephrogenic DI is generally related to disorders and drugs that damage the renal tubules or inhibit the generation of cAMP in the tubules. These disorders include pyelonephritis, amyloidosis, destructive uropathies, polycystic disease, and intrinsic renal disease, all of which lead to irreversible DI. Drugs that may induce a reversible form of nephrogenic DI include lithium carbonate, colchicines, amphotericin B, loop diuretics, general anesthetics (such as methoxyflurane), and demeclocycline.¹²

Gestational DI is a rare form associated with pregnancy in which the level of the vasopressin-degrading enzyme vasopressinase is increased. Clinical manifestations are usually mild and do not require treatment.¹³

Dipsogenic or primary polydipsia may be confused with DI. It occurs when excessive fluid intake lowers the plasma osmolarity to the point that it falls below the threshold for ADH secretion. This condition may be associated with psychiatric disorders but also has

been found in individuals who have a low osmotic threshold for inducing thirst. It is caused by chronic ingestion of extremely large quantities of fluid that wash out the renal medullary concentration gradient, which results in a partial resistance to ADH. This condition resolves with decreased fluid ingestion. Psychogenic causes of polydipsia must be differentiated from true DI because administering an ADH analog to an individual with psychogenic DI will result in severe hyposmolality.

◆Pathophysiology.

Individuals with diabetes insipidus have a partial to total inability to concentrate urine. Insufficient ADH activity causes excretion of large volumes of dilute urine, leading to increased plasma osmolality. In conscious individuals, the thirst mechanism is stimulated and induces polydipsia—usually a craving for cold drinks. Dehydration develops rapidly without ongoing fluid replacement. If the individual with DI cannot conserve as much water as is lost in the urine, serum hypernatremia and hyperosmolality occur. Concentrations of other serum electrolytes generally are not affected.

◆Clinical Manifestations.

The clinical manifestations of DI include polyuria, nocturia, continuous thirst, and polydipsia. Urine output is varied but can increase from the normal output of 1 to 2 L/day to as much as 8 to 12 L/day, and can be higher than daily fluid intake. Individuals with long-standing DI may develop a large bladder capacity and hydronephrosis (see [Chapter 39](#)). Neurogenic DI usually has an abrupt onset, and many individuals can specifically recall the date of onset of their symptoms. Nephrogenic DI usually has a more gradual onset. [Table 22.1](#) compares the signs and symptoms of DI and SIADH.

TABLE 22.1

Signs and Symptoms of Diabetes Insipidus (DI) and Syndrome of Inappropriate Antidiuretic Hormone (SIADH) Secretion

--

SIGNS AND SYMPTOMS	DI	SIADH
Urine output	High	Low (no hypovolemia)
Urine osmolality	Low (<100–200 mOsm/L)	High (>800 mOsm/L)
Urine specific gravity	Low (<1.010)	High (>1.020)
Serum sodium	Hypernatremia (>145 mEq/L)	Hyponatremia (<135 mEq/L)
Serum osmolality	Hyperosmolar (>300 mOsm/L)	Hypoosmolar (<285 mOsm/L)
Symptoms	Polyuria, thirst, high urine output, signs of dehydration	Water retention, low urine output, nausea, vomiting, mental changes

◆Evaluation and Treatment.

DI must be distinguished from other polyuric states, including diabetes mellitus, osmotically induced diuresis, and psychogenic polydipsia. The criteria for the diagnosis of DI include polyuria, polydipsia, low urine specific gravity (<1.010), low urine osmolality (<200 mOsm/kg), hypernatremia, high serum osmolality (300 mOsm or more depending on adequate water intake), and continued diuresis despite a serum sodium level of 145 mEq/L or greater.

The first step in the diagnosis of DI uses water deprivation with measurement of serum osmolarity and plasma ADH levels. Water deprivation is a useful test because individuals without DI respond with a rapid decrease in urine volume and an increase in urine osmolality, whereas those with DI have no decrease in urine volume or increase in urine osmolality. In individuals with severe DI, water deprivation testing can be hazardous. If the individual loses more than 3% of the pretest body weight, circulatory collapse and shock can ensue. Neurogenic DI can be differentiated from nephrogenic DI by measuring the response to administered desmopressin. Neurogenic DI will respond with an increased ability to concentrate the urine, whereas nephrogenic DI will not respond. The diagnosis of dipsogenic polyuria can be extremely difficult, and differentiation from nephrogenic DI is based on plasma ADH levels. Copeptin, an ADH precursor molecule, is a reliable surrogate measurement for ADH secretion and can be used for the diagnosis of dipsogenic polyuria.¹⁴

Treatment for nephrogenic DI is based on the extent of the ADH deficiency and on the individual's age, endocrine and cardiovascular status, and lifestyle. Some individuals require ADH replacement, but fluid replacement using oral or intravenous routes is usually adequate. ADH replacement therapy for symptomatic central or neurogenic diabetes insipidus includes intravascular or, more commonly, oral or intranasal administration of the synthetic vasopressin analog DDAVP (desmopressin).¹⁵ Management of nephrogenic DI requires treatment of any reversible underlying disorders, discontinuation of etiologic medications, and correction of associated electrolyte disorders. Surprisingly, thiazide diuretics may improve renal tubular salt and water retention in individuals with moderate nephrogenic DI. Drugs that potentiate the action of otherwise insufficient amounts of endogenous ADH, such as chlorpropamide, carbamazepine, and clofibrate, may be used in individuals with incomplete ADH deficiency. New treatments aimed at reversing aquaporin-2 dysfunction are being developed.¹⁶

Diseases of the Anterior Pituitary

Disorders of the anterior pituitary may involve either hypofunction or hyperfunction of the gland.

Hypopituitarism

Hypopituitarism is the absence or deficiency of one or more anterior pituitary hormones or the complete failure of all anterior pituitary hormone functions. Hypopituitarism results from an inadequate supply of hypothalamic-releasing hormones, damage to the pituitary stalk, or an inability of the gland to produce hormones. The most common causes of hypopituitarism are pituitary adenoma, pituitary surgery or radiotherapy, pituitary infarction resulting from severe shock; pituitary apoplexy; aneurysms; or sickle cell disease. Pituitary infarction may occur in women during the postpartum period (Sheehan syndrome) because of blood loss (hemorrhage, not common in developed countries) and hypovolemic shock.¹⁷ Traumatic brain

injury is increasingly recognized as an important cause of hypopituitarism and can have a significant impact on acute and long-term recovery in children and adults.¹⁸ Other causes of hypopituitarism include infections (e.g., meningitis, syphilis, tuberculosis), sarcoidosis, autoimmune hypophysitis, or certain drugs (e.g., bexarotene, carbamazepine).¹⁹ Immune checkpoint inhibitors, such as ipilimumab, have been associated with hypophysitis in up to 11% of individuals treated for melanoma.²⁰ A rare form of hypopituitarism is characterized by combined hormonal deficiencies and is related to mutations of the thyroid-stimulating hormone (TSH) biosynthetic pathway or early or late transcription factors involved in early embryonic pituitary development.²¹

◆Pathophysiology.

The pituitary gland is highly vascular and relies heavily upon portal blood flow from the hypothalamus. Therefore it is extremely vulnerable to ischemia and infarction. Infarction results in tissue necrosis and edema with swelling of the gland. Expansion of the pituitary within the fixed compartment of the sella turcica further impedes blood supply to the pituitary. Over time, fibrosis of pituitary tissue occurs and the symptoms of hypopituitarism develop. Adenomas and aneurysms may compress otherwise normal secreting pituitary cells and lead to compromised hormonal output.

◆Clinical Manifestations.

The signs and symptoms of hypofunction of the anterior pituitary are variable and depend on which hormones are affected. In **panhypopituitarism**, all hormones are deficient and the individual suffers from multiple complications including cortisol deficiency from lack of ACTH, thyroid deficiency from lack of TSH, and loss of secondary sex characteristics from lack of FSH and LH. Low levels of GH and insulin-like growth factor-1 (IGF-1) affect growth in children and can cause physiologic and psychologic symptoms in adults. Postpartum women cannot lactate because of decreased or absent prolactin.

ACTH deficiency, with associated loss of cortisol, is a potentially life-threatening disorder. ACTH deficiency is usually encountered with generalized pituitary hypofunction. It rarely occurs as an isolated event.²² Within 2 weeks of the complete absence of ACTH, symptoms of cortisol insufficiency develop, including nausea, vomiting, anorexia, fatigue, and weakness. Hypoglycemia results from increased insulin sensitivity, decreased glycogen reserves, and decreased gluconeogenesis associated with hypocortisolism. ACTH deficiency also limits maximum aldosterone secretion, although the renin-angiotensin system can stimulate some aldosterone secretion. The glomerular filtration rate decreases, causing decreased urine output.

TSH deficiency is rarely seen in isolation but occurs in conjunction with other pituitary hormone deficiencies. Symptoms develop 4 to 8 weeks after hypothropinemia occurs and includes cold intolerance, skin dryness, mild myxedema, lethargy, and decreased metabolic rate. The symptoms are usually less severe than those associated with primary hypothyroidism.

The onset of **FSH and LH deficiencies** in women of reproductive age is associated with amenorrhea and with atrophy in the vagina, uterus, and breasts. In postpubertal males, the testicles atrophy and facial hair growth is diminished. Both men and women experience a decrease in body hair and diminished libido.

GH deficiency occurs in children and adults. As described previously, GH deficiency may result from any of the causes of hypopituitarism. Several genetic defects have been identified in the GH axis in children, including a recessive mutation in the *GH* gene, resulting in a failure of growth hormone secretion. These include a recessive mutation in the *GHRH* gene, resulting in a failure of GH secretion, and mutations that cause GH insensitivity by affecting the GH receptor, IGF-1 biosynthesis, IGF-1 receptors, or defects in GH signal transduction.²¹

GH deficiency in children is manifested by growth failure and a condition known as *hypopituitary dwarfism* (Fig. 22.2); however, not all children with short stature have growth hormone deficiency because there is wide variation in normal growth patterns. Another feature of

GH deficiency in children is fasting hypoglycemia, likely attributable to impaired substrate mobilization for gluconeogenesis and enhanced insulin sensitivity.²³ Symptoms of chronic adult GH deficiency syndrome include increased body fat; decreased muscle bulk and lean body mass; osteoporosis; reduced sweating; dry skin; and psychologic problems, including depression, social withdrawal, fatigue, loss of motivation, and a diminished feeling of well-being. Without adequate GH replacement, increased mortality can occur as a result of myocardial infarction and stroke associated with dyslipidemias and atherosclerosis.²⁴

FIGURE 22.2 Hypopituitary Dwarfism. A 4-year-old boy whose height is 25 inches. The girl is also 4 years old and has a normal height of 39 inches. Dwarf has a normal face, as well as head, trunk, and limbs of approximately normal proportions. (From Brashear HR, Raney RB: *Shands' handbook of orthopaedic surgery*, ed 10, St Louis, 1986, Mosby.)

◆ Evaluation and Treatment.

The diagnostic evaluation of suspected pituitary disease is often challenging and must be carefully interpreted together with the individual's signs and symptoms. Simultaneous measurements of the tropic hormones from the pituitary and target endocrine glands are crucial and, in some cases, dynamic testing of the various axes is indicated, particularly GH and ACTH.²⁵

Radiographic assessment of the pituitary (magnetic resonance imaging [MRI] or computed tomography [CT] scans) may demonstrate enlargement of the pituitary, abnormal areas of enhancement suggestive of an adenoma, deviation of the pituitary stalk, or evidence of a locally aggressive tumor.

Management of hypopituitarism is individualized and requires correction of the underlying disorder as quickly as possible. Replacement of target gland hormones that are deficient because of lack of tropic anterior pituitary hormones is essential (such as cortisol, thyroid hormone, growth hormone, and sex-specific steroid hormones). In cases of circulatory collapse, immediate therapy with glucocorticoids and intravenous fluids is critical. Treatment adaptations are made during pregnancy and in transition from childhood to adulthood. Treatment of adult GH deficiency improves quality of life, metabolism, body composition, and physical performance in some individuals.¹⁹

Hyperpituitarism: Primary Adenoma

Pituitary adenomas are usually benign slow-growing tumors that arise from cells of the anterior pituitary. The cause of pituitary adenomas is not known and most occur sporadically. Altered gene expression is commonly detected and familial pituitary adenomas occur as part of syndromes affecting other organs, such as multiple endocrine neoplasia type 1.²⁶ Microadenomas (≤ 10 mm) are found only on postmortem examinations or incidentally discovered on MRI examinations. The majority of pituitary microadenomas are hormonally silent and do not pose significant hazards to the individual. Macroadenomas (≥ 10 mm) and giant adenomas (≥ 40 mm) are associated with morbidity and mortality attributable to alterations

in hormone secretion or to invasion or impingement of structures surrounding the pituitary.²⁷ The pathogenesis of pituitary adenomas includes hypothalamic and intrapituitary factors, including altered expression of pituitary cell cycle genes, activation of pituitary selective oncoproteins, or loss of pituitary suppressor factors.²⁶ Several associated gene mutations have been identified, including isolated growth hormone deficiency and those associated with multiple endocrine neoplasia (MEN) syndromes.²⁸ Primary pituitary carcinomas are rare, representing about 0.2% of all pituitary tumors.

◆Pathophysiology.

Local expansion of pituitary adenomas may impinge on the optic chiasm and cause various visual disturbances, depending on the area of the optic nerve that is compressed. If the tumor is locally aggressive, invasion of the cavernous sinuses may occur, resulting in compromise of the oculomotor, trochlear, abducens, and trigeminal nerves with attending symptoms. Extension to the hypothalamus disturbs control of wakefulness, thirst, appetite, and temperature. Benign, slow-growing adenomas can transform to aggressive adenomas or carcinomas.²⁶

Hormonal effects of adenomas include hypersecretion from the adenoma itself, and hyposecretion from surrounding pituitary cells. The adenomatous tissue secretes the hormone of the cell type from which it arose, without regard to physiologic needs and without benefit of regulatory feedback mechanisms. Because of the pressure exerted by the tumor in the unexpandable bony sella turcica, hyposecretion from those cells is most sensitive to common pressure (GH-, FSH-, and LH-secreting cells).²⁹

◆Clinical Manifestations.

The clinical manifestations of pituitary adenomas are related to tumor growth and hormone hypersecretion or hyposecretion. Increased tumor size causes headache and fatigue, neck pain or stiffness, and seizures. Visual changes include visual field impairments (often beginning in one eye and progressing to the other) and temporary

blindness. If the tumor infiltrates other cranial nerves, neurologic function is affected.

Pituitary adenomas are most often associated with increased secretion of GH and prolactin (see [Hypersecretion of Growth Hormone: Acromegaly](#) and [Hypersecretion of Prolactin: Prolactinoma](#) in this chapter). Gonadotropic hyposecretion results in menstrual irregularity in women, decreased libido, and receding secondary sex characteristics in both men and women. If the tumor exerts sufficient pressure, thyroid and adrenal hypofunction may occur because of lack of TSH and ACTH resulting in the symptoms of hypothyroidism and hypocortisolism, respectively.

◆ **Evaluation and Treatment.**

Diagnosis of pituitary adenoma involves physical and laboratory evaluations, including pertinent hormone assays and radiographic examination of the skull (MRI [preferred] or contrast-enhanced CT). The goal of treatment is to protect the individual from the effects of tumor growth and manage hormone hypersecretion or hyposecretion while minimizing damage to appropriately secreting portions of the pituitary. Depending on the tumor size and type, individuals may be treated by administration of specific medications to suppress tumor growth, transsphenoidal tumor resection, or radiation therapy including stereotactic treatments. Observation and close follow-up are commonly employed for individuals who have no evidence of hormonal alterations and no suggestion of anatomic aggressiveness. Chemotherapy with temozolomide is considered for those individuals who are still uncontrolled.

Hypersecretion of Growth Hormone: Acromegaly

Acromegaly results from continuous exposure to high levels of GH and IGF-1. It almost always is caused by a GH-secreting pituitary adenoma and rarely results from the ectopic production of GHRH.³⁰ Acromegaly usually occurs in adults in the 40–59-year-old age group, although it is often present for years before diagnosis because of the insidious nature of the disease. Consequently, there are systemic

complications at diagnosis leading to increased mortality and premature death. Deaths from acromegaly are caused by heart disease secondary to hypertension and coronary artery disease, stroke, diabetes mellitus, or malignancy (colon or lung cancers).

◆Pathophysiology.

With a GH-secreting adenoma, the usual GH baseline secretion pattern and sleep-related GH peaks are lost, and an unpredictable secretory pattern ensues. However, GH levels in acromegalics are never completely suppressed. Only slight elevations of GH and IGF-1 levels can stimulate growth. In children and adolescents whose epiphyseal plates have not yet closed, the effect of increased GH levels causes excessive skeletal growth, with some individuals becoming 8- or 9-feet tall, termed **giantism** (Fig. 22.3). In the adult, epiphyseal closure has occurred and increased amounts of GH and IGF-1 cause connective tissue proliferation and increased cytoplasmic matrix, as well as bony proliferation that results in the characteristic appearance of acromegaly (Figs. 22.4 and 22.5).

FIGURE 22.3 Giantism. A pituitary giant and dwarf contrasted with normal-size men. Excessive secretion of growth hormone by the anterior lobe of the pituitary gland during the early years of life produces giants of this type, whereas deficient secretion of this hormone produces well-formed dwarfs. (From Patton K, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

FIGURE 22.4 Acromegaly in a Male. Chronologic sequence of photographs showing slow development of acromegaly. (From Chanson P et al: *Best Pract Res Clin Endocrinol Metab* 23[5]:555–574, 2009.)

FIGURE 22.5 Acromegaly. (From Talley NJ, O'Connor S: *Clinical examination*, ed 7, Australia, 2014, Churchill Livingstone.)

GH also has significant effects on glucose, lipid, and protein metabolism. Hyperglycemia results from inhibition of peripheral glucose uptake, and increased hepatic glucose production followed by compensatory hyperinsulinism. Adipose tissue inflammation and impaired adipogenesis contribute to insulin resistance.³¹ Diabetes mellitus occurs when the pancreas cannot secrete enough insulin to offset the effects of GH. Excessive levels of GH and IGF-1 also affect the cardiovascular system. Although the associated pathophysiology is not clearly understood, hypertension and left heart failure are seen in one-third to one-half of individuals with acromegaly.

Cardiomyopathy associated with progressive and unrestrained myocardial growth is a significant factor. Valvular heart disease and arrhythmias can occur.³² GH also acts on the renal tubules to increase phosphate reabsorption, leading to mild hyperphosphatemia. Because the adenoma increasingly becomes a space-occupying lesion, hypopituitarism may occur because of compression of surrounding hormone-secreting cells.

◆Clinical Manifestations.

With connective tissue proliferation, individuals with acromegaly have enlarged tongues, interstitial edema, enlarged and overactive sebaceous and sweat glands (leading to increased body odor), and coarse skin and body hair. Bony proliferation involves large joint arthropathy, periosteal vertebral growth, and enlargement of the bones of the face, hands, and feet. As a result, decreased joint range of motion, kyphosis, and lower jaw and forehead protrusion are common (see [Figs. 22.4](#) and [22.5](#)). Increased IGF-1 levels stimulate cartilaginous growth and cause ribs to elongate at the bone-cartilage junction, leading to a barrel-chest appearance, and increased proliferation of cartilage in the spine and joints, which causes backache and arthralgias. With continued bony and soft tissue overgrowth, entrapment of nerves may occur, leading to peripheral nerve damage as manifested by weakness, muscular atrophy, footdrop, and sensory changes in the hands (carpal tunnel syndrome). Sleep-disordered breathing is common and may exacerbate cardiovascular dysfunction.

Symptoms of diabetes mellitus, such as polyuria and polydipsia, may occur because of decreased insulin sensitivity in an individual who cannot mount adequate compensatory hyperinsulinemia. Acromegaly-associated hypertension is usually asymptomatic until heart failure symptoms develop. Increased tumor size results in central nervous system symptoms of headache, seizure activity, visual field disturbances, and papilledema. If compression hypopituitarism occurs, gonadotropin secretion may be affected, causing amenorrhea in women and sexual dysfunction in men. Hyperprolactinemia can

occur in 30% to 40% of individuals with acromegaly.³³ Recent reports have documented mutations in the aryl hydrocarbon–interacting protein gene (*AIP*) in sporadic cases of familial acromegaly, polymorphisms in the somatostatin receptor type 5 gene, and GTP-binding (G) protein receptor mutations.³⁴

◆Evaluation and Treatment.

Diagnosis is confirmed by the appearance of clinical features of the disease, visual field testing, MRI scans, and elevated levels of IGF-1.³⁵ GH level is typically elevated and not suppressed with oral glucose tolerance testing. The goals of treatment are to normalize GH and IGF-1 serum levels to age range, restoring normal pituitary function and relieving or preventing complications related to tumor expansion. The treatment of choice for acromegaly is transsphenoidal surgery for removal of the GH-secreting adenoma. Treatment by stereotactic radiation therapy may be effective when rapid control of GH levels is not essential, when the individual is not a good surgical candidate, or when hyperfunction persists after subtotal resection. Somatostatin analogs, such as octreotide, octreotide acetate, and lanreotide, normalize IGF-1 levels and lower growth hormone levels. Pegvisomant can be used to supplement somatostatin analogs and is an effective drug that induces tissue insensitivity to GH by blocking the GH receptor.³³ Dopaminergic agonists, such as cabergoline, also may be helpful, especially if the tumor also secretes prolactin. Diagnostic and therapeutic clinical practice guidelines are available to support management during pregnancy and long-term management.³⁶ Cardiovascular, metabolic, and symptoms of tumor compression often improve with treatment. Skeletal abnormalities are irreversible.

Hypersecretion of Prolactin: Prolactinoma

Pituitary tumors that secrete prolactin, **prolactinomas**, are the most common of the hormonally active pituitary adenomas.

Other conditions or medications can elevate prolactin level in the absence of a pituitary pathologic condition. For example, renal failure, polycystic ovarian disease, breast stimulation, or even the stress of

venipuncture can increase prolactin levels. Prolactin is under tonic inhibitory hypothalamic control through the secretion of dopamine (prolactin inhibitor factor [PIF]). Thus medications that block the effects of dopamine can increase prolactin production and stimulate proliferation of prolactin-secreting cells (lactotropes). These include antipsychotics (risperidone, chlorpromazine), metoclopramide, tricyclic antidepressants, and methyldopa. Any process that interferes with the delivery of dopamine from the hypothalamus to the lactotropes (pituitary stalk tumor, pituitary stalk transection, or compressive pituitary tumor) also results in hyperprolactinemia. Because TRH stimulates prolactin secretion, in addition to enhancing TSH release, prolactin concentration may be elevated in individuals with primary hypothyroidism.

◆Pathophysiology.

The hallmark of a prolactinoma is sustained increases in serum prolactin concentration. These tumors can be classified as microprolactinomas (<1 cm in size) or macroprolactinomas (>1 cm in size). Microprolactinomas are usually encapsulated and noninvasive, whereas macroprolactinomas commonly expand into the optic chiasm, invade local structures, and are more difficult to treat.³⁷ Because the adenoma can become an increasingly space-occupying lesion, hypopituitarism may occur because of compression of surrounding hormone-secreting cells. Central nervous system symptoms may develop because of growth and pressure of the adenoma within the sella turcica.

◆Clinical Manifestations.

The physiologic actions of prolactin include breast development during pregnancy, postpartum milk production, and suppression of ovarian function in nursing women. Pathologic elevation of prolactin levels inhibits the pulsatile secretion of gonadotropin-releasing hormone, alters the pattern of release of luteinizing hormone and follicle-stimulating hormone, and suppresses gonadal steroidogenesis, thereby resulting in hypogonadotropic hypogonadism in both sexes.

This causes amenorrhea, infertility, nonpuerperal milk production (galactorrhea), and hirsutism in women. If not detected until after many years, estrogen deficiency may result in osteopenia or osteoporosis. Hyperprolactinemia in men causes erectile dysfunction, infertility, and osteopenia. Symptoms related to the increasing size of the adenoma include headache or visual impairment.³⁸

◆Evaluation and Treatment.

The diagnostic evaluation of hyperprolactinemia includes a careful history to exclude medications or other diseases that may cause elevations in prolactin level. Symptoms of hypothyroidism should be elicited, and screening with a serum TSH measurement is mandatory. MRI scanning of the pituitary is indicated to determine the size and location of an adenoma. If prolactin concentration is less than 50 ng/mL, a careful search for a nonpituitary cause should be pursued.

The goals of treatment are to restore normal gonadal function and fertility and reduce tumor size. Dopaminergic agonists (cabergoline) are the treatment of choice for prolactinomas, and their use is often associated with both a rapid reduction in the size of the tumor and a reversal of the gonadal effects of hyperprolactinemia. Restoration of fertility in previously anovulatory women is common. In individuals resistant or intolerant to these medications, transsphenoidal surgery and radiotherapy are options. New chemotherapeutic and targeted molecular therapies are being explored.³⁸

Alterations of Thyroid Function

Disorders of thyroid function develop as a result of primary dysfunction or disease of the thyroid gland or, secondarily, as a result of pituitary or hypothalamic alterations. **Primary thyroid disorders** result in alterations of thyroid hormone (TH) levels with secondary feedback effects on pituitary TSH levels. For example, when there are primary elevations in TH level, TSH level will secondarily decrease because of negative feedback. When TH level is decreased because of a condition affecting the thyroid gland, TSH level will be elevated.

Thyroid disease also can present with no or minimal symptoms but with abnormal laboratory values. This is known as *subclinical thyroid disease*. Central (secondary) thyroid disorders are related to disorders of pituitary gland TSH production. When there is excessive TSH production, TH level is elevated secondary to the primary elevation of TSH level. The reverse is true with inadequate TSH production. Exposure to iodinated contrast media has been shown to be associated with development of both hyperthyroidism and hypothyroidism

Thyrotoxicosis/Hyperthyroidism

◆Pathophysiology.

Thyrotoxicosis is a condition that results from any cause of increased amounts of TH levels. **Hyperthyroidism** is a form of thyrotoxicosis in which excess amounts of TH are secreted from the thyroid gland. The terms *thyrotoxicosis* and *hyperthyroidism* are often used interchangeably. The prevalence of hyperthyroidism is estimated to be 0.7% to 2.1% in the United States, of which 0.7% is subclinical and is more prevalent in women and in iodine-deficient geographical areas.³⁹ Thyroid hormones are regulated by a negative feedback loop involving the hypothalamus, pituitary gland, and thyroid gland (see Fig. 21.13). Common diseases that cause **primary hyperthyroidism** include Graves disease, toxic multinodular goiter, a solitary toxic adenoma (Fig. 22.6), and, very rarely, follicular thyroid carcinoma. **Central (secondary) hyperthyroidism** is less common and is caused by TSH-secreting pituitary adenomas. Thyrotoxicosis not associated with hyperthyroidism includes ectopic thyroid tissue or ingestion of excessive TH, and low thyroid radioactive iodine uptake. Each condition is associated with specific pathophysiology, manifestations, and treatments. However, all forms of thyrotoxicosis share some common characteristics.⁴⁰

FIGURE 22.6 Causes of Hyperthyroidism. Hyperthyroidism may have several causes, among them: 1, Graves disease; 2, toxic multinodular goiter; 3, follicular adenoma; 4, thyroid medication. *IgG*, Immunoglobulin G; *T₃*, triiodothyronine; *T₄*, tetraiodothyronine; *TSH*, thyroid-stimulating hormone; *TSI*, thyroid-stimulating immunoglobulin. (Adapted from Damjanov I: *Pathology for the health professions*, ed 4, St Louis, 2012, Saunders.)

◆Clinical Manifestations.

The clinical features of thyrotoxicosis are attributable to the metabolic effects of increased circulating levels of TH (Fig. 22.7). This usually results in an increased metabolic rate with heat intolerance and increased tissue sensitivity to stimulation by the sympathetic division of the autonomic nervous system. The major manifestations are summarized in Table 22.2. Enlargement of the thyroid gland (goiter) is

common in hyperthyroid conditions caused by stimulation of TSH receptors.

FIGURE 22.7 Clinical Manifestations of Hyperthyroidism and Hypothyroidism. (From Damjanov I: *Pathology for the health professions*, ed 4, St Louis, 2012, Saunders.)

TABLE 22.2**SYSTEMIC MANIFESTATIONS OF HYPERTHYROIDISM**

SYSTEM	CLINICAL MANIFESTATIONS	MECHANISMS UNDERLYING CLINICAL MANIFESTATIONS
Endocrine	Enlarged thyroid gland (goiter) (97%–99% of cases); systolic or continuous bruit over thyroid; increased cortisol degradation; hypercalcemia and decreased parathyroid hormone (PTH) secretion; diminished sensitivity to exogenous insulin	Hyperactivity of the thyroid gland; excess bone resorption leading to hypercalcemia and a disruption of PTH-regulating mechanisms; increased insulin degradation
Reproductive	Oligomenorrhea or amenorrhea; erectile dysfunction and decreased libido; increased serum estradiol and estrone levels but lower than normal levels of free estradiol and estrone	Menstrual cycle alterations that may be related to hypothalamic or pituitary disturbances; increase in sex hormone-binding globulin
Gastrointestinal	Weight loss; increased peristalsis leading to less formed and more frequent stools; nausea, vomiting, anorexia, abdominal pain; increased use of hepatic glycogen stores and of adipose and protein stores; decrease in serum lipid levels (including triglycerides, phospholipids, and cholesterol); changes in vitamin metabolism leading to decrease in tissue stores of vitamins	Increased catabolism leading to the body's inability to meet its metabolic needs; increased glucose absorption; increase in cholesterol excretion in feces and cholesterol conversion to bile salts; impaired conversion of B vitamins to their coenzymes, causing increased need for water-soluble and fat-soluble vitamins
Integumentary	Excessive sweating, flushing, and warm skin; heat intolerance; hair fine, soft, and straight; temporary hair loss; nails that grow away from nail beds, palmar erythema	Hyperdynamic circulatory state
Sensory (eyes)	Ocular manifestations including elevated upper eyelid leading to decreased blinking and a staring quality; fine tremor of lid; infiltrative ocular changes associated with Graves disease	Overactivity of Müller muscle; inflammation of retroorbital contents
Cardiovascular	Increased cardiac output and decreased peripheral resistance; tachycardia at rest; loud heart sounds; supraventricular dysrhythmias, left ventricular dilation and hypertrophy	Hypermetabolism and need to dissipate heat
Nervous	Restlessness; short attention span; compulsive movement; fatigue; tremor; insomnia;	Not clearly defined; alterations in cerebral metabolism resulting from

	increased appetite; emotional lability	excess thyroid hormone
Pulmonary	Dyspnea; reduced vital capacity	Weakness of respiratory muscles

◆ Evaluation and Treatment.

Elevated serum tetraiodothyronine (thyroxine) (T_4) and triiodothyronine (T_3) levels and decreased serum TSH levels are diagnostic for primary hyperthyroidism. By contrast, central (secondary) hyperthyroidism caused by TSH-secreting pituitary tumors is characterized by normal to increased TSH levels despite elevated thyroid hormone concentrations. Radioactive iodine is used to test for increased uptake in primary hyperthyroidism (Fig. 22.8).

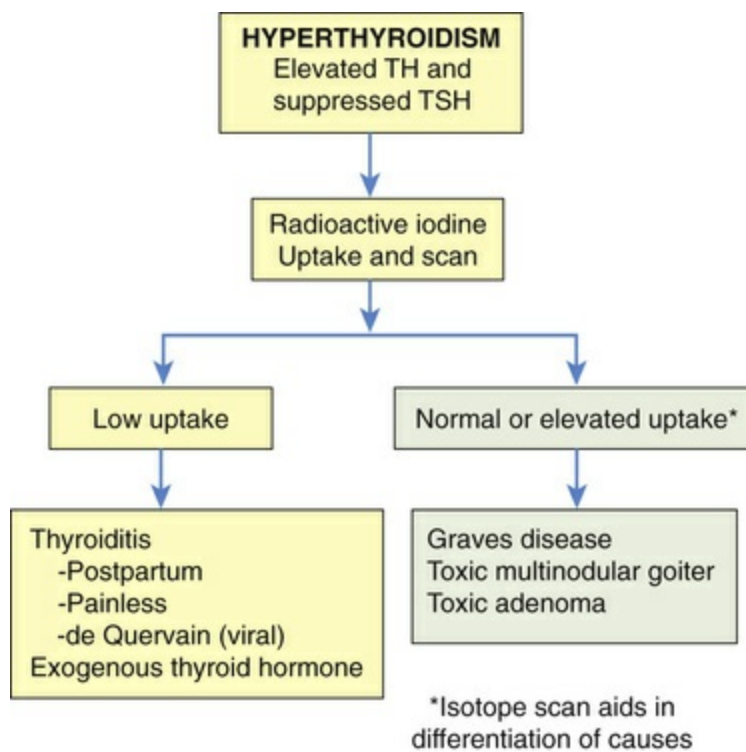

FIGURE 22.8 Evaluation of Hyperthyroidism. Radioactive iodine is used in the differential diagnosis of hyperthyroidism. *TH*, Thyroid hormone; *TSH*, thyroid-stimulating hormone.

Treatment is directed at controlling excessive TH production, secretion, or action and includes antithyroid drug therapy (methimazole or propylthiouracil), radioactive iodine therapy

(absorbed only by thyroid tissue, causing death of cells), and surgery. Guidelines for the treatment of hyperthyroidism and thyrotoxicosis have been published.⁴¹ Treatment of **subclinical hyperthyroidism** is based on lower levels of TSH with free T_4 and T_3 concentrations within the reference range and clinical symptoms.⁴² A major complication of all forms of treatment for hyperthyroidism is hypothyroidism.

Hyperthyroid Conditions

Graves Disease.

Graves disease is the underlying cause of 50% to 80% of cases of hyperthyroidism and has a prevalence of approximately 3.0% of women and 0.5% of men in the United States.⁴³ Although the cause of Graves disease is not known, genetic factors interacting with environmental triggers play an important role in the pathogenesis. Graves disease is classified as an autoimmune disease and results from a form of type II hypersensitivity (see [Chapter 9](#)) in which there is infiltration of lymphocytes and stimulation of the thyroid by autoantibodies directed against the TSH receptor. These autoantibodies, called *thyroid-stimulating immunoglobulins* (TSIs; also called *thyroid-stimulating antibodies* [TSAbs] or *thyroid receptor antibodies* [TRAbs]), override normal negative feedback mechanisms. The TSI stimulation of TSH receptors in the gland results in hyperplasia of the gland (goiter) and increased synthesis of TH, especially of T_3 . Increased levels of TH affect every physiologic system and result in the classic signs and symptoms of hyperthyroidism illustrated in [Fig. 22.8](#). TSH production by the pituitary is inhibited through the usual negative feedback loop.

TSIs also contribute to two major distinguishing clinical manifestations of Graves disease: ophthalmopathy and dermopathy (pretibial myxedema and acropachy). Two categories of ophthalmopathy associated with Graves disease are (1) functional abnormalities resulting from hyperactivity of the sympathetic division of the autonomic nervous system (lag of the globe on upward gaze or

a lag of the upper lid on downward gaze) and (2) infiltrative changes involving the orbital contents with enlargement of the ocular muscles. The infiltrative changes possibly result from TSH receptor autoantibodies reacting with receptors on orbital fibroblasts (Fig. 22.9, A). These changes affect more than half of individuals with Graves disease. Increased secretion of hyaluronic acid, adipogenesis, inflammation, and edema of the orbital contents result in **exophthalmos** (protrusion of the eyeball), periorbital edema, and extraocular muscle weakness leading to strabismus and diplopia (double vision). The individual may experience irritation, pain, lacrimation, photophobia, blurred vision, decreased visual acuity, papilledema, visual field impairment, exposure keratosis, and corneal ulceration.⁴⁴ Smoking exacerbates the disease.

FIGURE 22.9 Thyrotoxicosis (Graves Disease). A, Exophthalmos (large and protruding eyeballs often in association with a large goiter). B, Pretibial myxedema associated with Graves disease; note lumpy and swollen appearance from accumulation of connective tissue and pinkish-purple discoloration. (A from Belchetz P, Hammond P: *Mosby's color atlas and text of diabetes and endocrinology*, Edinburgh, 2003, Mosby; B from Habif T: *Clinical dermatology*, ed 5, St Louis, 2009, Mosby.)

A small number of individuals with Graves disease and very high levels of TSI experience **pretibial myxedema (Graves dermatopathy)**, characterized by subcutaneous swelling on the anterior portions of the legs and by indurated and erythematous skin (see Fig. 22.9, B). Graves

dermopathy is associated with thyrotropin receptor antigens on fibroblasts and recruited T lymphocytes that stimulate excess amounts of hyaluronic acid production in the dermis and subcutaneous tissue. The manifestations occasionally appear on the hands, giving the appearance of clubbing of the fingers (thyroid acropachy).⁴⁵

Therapy for Graves disease includes antithyroid drugs, radioactive iodine ablation (used with caution in Graves ophthalmopathy because it may worsen the condition), or surgery. Smoking cessation is necessary. Unfortunately, current treatment for Graves disease does not reverse the infiltrative ophthalmopathy or the pretibial myxedema. Surgical orbital decompression and glucocorticoids can help many individuals with progressive ophthalmopathy. Immunosuppressive drugs, such as rituximab, are being evaluated.⁴³ Skin lesions rarely require treatment, but if they are symptomatic they may respond to topical glucocorticoids.⁴⁵

Hyperthyroidism Resulting from Nodular Thyroid Disease.

The thyroid gland normally enlarges in response to an increased secretion of TSH that occurs in puberty, pregnancy, or iodine deficiency, and from immunologic, viral, or genetic disorders. The increased number of follicles is a compensatory mechanism in response to increased TSH levels. When the condition requiring increased TH resolves, TSH secretion normally subsides and the thyroid gland returns to its original size.

Irreversible changes may occur in some follicular cells; thus these cells function autonomously and produce excessive amounts of TH. On the other hand, some follicular cells may cease to function. The balance between the amount of TH produced by hyperfunctioning nodules and that produced by the remainder of the gland determines whether an individual becomes euthyroid (nontoxic nodular goiter) or hyperthyroid. **Nontoxic nodular goiter** is more common in iodine-deficient regions and may require decompression when associated with airway, esophageal, or venous obstruction.⁴⁶ **Toxic multinodular goiter** occurs when there are several hyperfunctioning nodules leading to hyperthyroidism. If only one nodule becomes

hyperfunctioning it is termed **solitary toxic adenoma**. Unlike Graves disease, there is absence of an autoimmune stimulus. The classic clinical manifestations of hyperthyroidism (see Fig. 22.7) usually develop slowly, and exophthalmos and pretibial myxedema do not occur. Nodules may be palpable on physical examination and there is increased uptake of radioactive iodine. The incidence of malignancy in toxic multinodular goiter is more likely in single nodules so most individuals should undergo a fine-needle aspiration biopsy of suspicious nodules before treatment.⁴⁷ Treatment consists of a combination of radioactive iodine, surgery, or antithyroid drugs.

Thyrotoxic Crisis (Thyroid Storm).

Thyrotoxic crisis (thyroid storm) is a rare but dangerous worsening of the thyrotoxic state, in which death can occur within 48 hours without treatment. The condition may develop spontaneously, but it usually occurs in individuals who have undiagnosed or partially treated severe hyperthyroidism and who are subjected to excessive stress from other causes. These causes may include infection, pulmonary or cardiovascular disorders, trauma, burns, seizures, surgery (especially thyroid surgery), obstetric complications, emotional distress, or dialysis. The symptoms of thyroid crisis are caused by the sudden release and increased action of thyroxine (T_4) and triiodothyronine (T_3) exceeding metabolic demands.⁴⁸

The systemic symptoms of thyrotoxic crisis include hyperthermia; tachycardia, especially atrial tachydysrhythmias; high-output heart failure; agitation or delirium; and nausea, vomiting, or diarrhea, contributing to fluid volume depletion. Treatment includes (1) the use of drugs that block TH synthesis (i.e., propylthiouracil or methimazole), (2) the use of beta-blockers for control of cardiovascular symptoms, (3) administration of corticosteroids or (4) iodine (e.g., saturated solution of potassium iodide [SSKI]), and (5) supportive care. Plasma exchange or thyroidectomy may be used when medical treatment fails.⁴⁹

Hypothyroidism

Hypothyroidism results from deficient production of TH by the thyroid gland. Hypothyroidism is the most common disorder of thyroid function; it affects between 0.1% and 2% of the U.S. population and is more common in women and the elderly. It may be primary or secondary. Primary hypothyroidism accounts for 99% of all cases. Central (secondary) hypothyroidism, which is much less common, is related to either pituitary or hypothalamic failure.

◆Pathophysiology.

Loss of thyroid function in *primary hypothyroidism* leads to a decreased production of TH and increased secretion of TSH and TRH. The most common causes in adults include autoimmune thyroiditis (Hashimoto disease), iatrogenic loss of thyroid tissue after surgical or radioactive treatment for hyperthyroidism, head and neck radiation therapy, medications, and endemic iodine deficiency. Infants and children may present with hypothyroidism because of congenital defects in the pituitary or thyroid glands. *Central (secondary) hypothyroidism* is caused by the pituitary's failure to synthesize adequate amounts of TSH or a lack of TRH. Pituitary tumors that compress surrounding pituitary cells or the consequences of their treatment are the most common causes of **secondary hypothyroidism**. Other causes include traumatic brain injury, subarachnoid hemorrhage, or pituitary infarction. Hypothalamic dysfunction results in low levels of TRH, TSH, and TH (Fig. 22.10). **Subclinical hypothyroidism** is mild thyroid failure and is estimated to occur in 4% to 8% of U.S. adults. It is defined as an elevation in TSH level with normal levels of circulating TH.⁵⁰

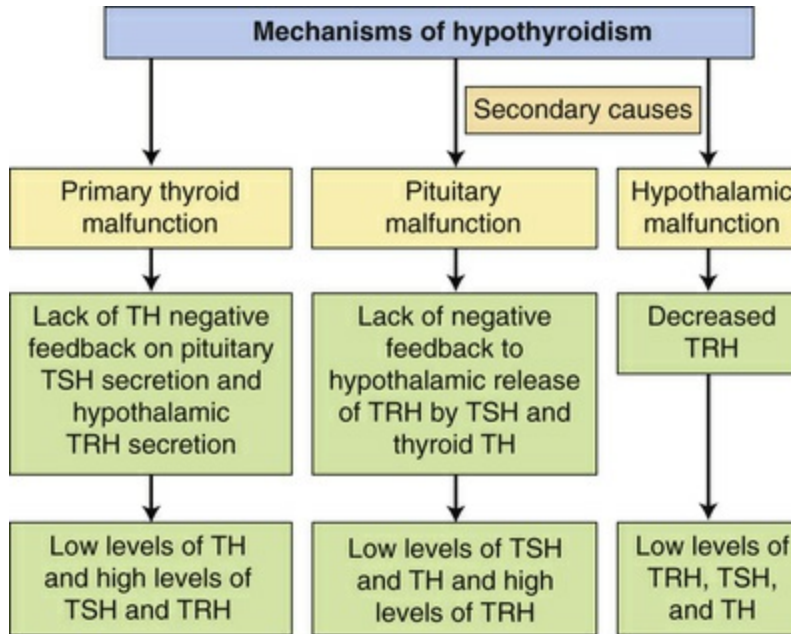

FIGURE 22.10 Mechanisms of Primary and Central (Secondary) Hypothyroidism. *TH*, Thyroid hormone; *TRH*, thyroid-releasing hormone; *TSH*, thyroid-stimulating hormone.

◀Clinical Manifestations.

Hypothyroidism generally affects all body systems and occurs insidiously over months or years. The extent of the symptoms is closely related to the degree of TH deficiency (see Fig. 22.7). The decrease in TH level lowers energy metabolism and heat production. The individual develops a low basal metabolic rate, cold intolerance, lethargy, tiredness, and slightly lowered basal body temperature and also may have diastolic hypertension. Many organ systems are affected (Table 22.3). The decrease in the level of TH can lead to excessive TSH production, which stimulates thyroid tissue and causes goiter.

TABLE 22.3

SYSTEMIC MANIFESTATIONS OF HYPOTHYROIDISM

SYSTEM	CLINICAL MANIFESTATIONS	MECHANISMS UNDERLYING CLINICAL MANIFESTATIONS
Neurologic	Confusion, syncope, slowed speech and thinking,	Decreased cerebral blood flow

	memory loss; lethargy, headaches, hearing loss, night blindness; slow, clumsy movements; cerebellar ataxia; slow alpha-wave activity and loss of amplitude in EEG; reduced cAMP response to epinephrine, glucagons, and PTH stimulation; decreased appetite	leading to cerebral hypoxia; reduced intracellular processes caused by decreased β -adrenergic activity that may be related to a decrease in the number of β -adrenergic receptor sites
Endocrine	Increased TSH production in primary hypothyroidism; enlarged pituitary thyrotropes, increase in serum prolactin levels with galactorrhea; decreased rate of cortisol turnover but with normal serum cortisol levels	Impaired TH synthesis or defects in iodide trapping leading to compensatory TSH production; chronic overstimulation of thyrotropes of TRH and by TSH synthesis; stimulation of lactotropes by TRH related to increased prolactin levels; decreased deactivation of cortisol
Reproductive	Decreased androgen secretion in men, increased estriol formation in women; low total hormone values but with increased amounts of unbound hormone; anovulation, decreased libido, menorrhagia, and a high incidence of spontaneous abortion in women; erectile dysfunction, decreased libido, and oligospermia in men	Altered metabolism of estrogens and androgens; decreased levels of sex hormone-binding globulin
Hematologic	Decrease in red cell mass leading to normocytic, normochromic anemia; macrocytic anemia associated with vitamin B ₁₂ deficiency and inadequate folate or iron absorption in the gastrointestinal tract	Decreased basal metabolic rate and reduced oxygen requirements; decreased production of erythropoietin; possible relationship between TH and optimal hematologic response to vitamin B ₁₂
Cardiovascular	Reduction in stroke volume and heart rate causing lowered cardiac output; increased peripheral vascular resistance to maintain systolic blood pressure can cause hypertension; normal response to exercise but with alterations in circulatory system at rest (prolonged circulation time and decreased blood flow to tissues); cool skin and cold tolerance; enlarged heart; decreased intensity of heart sounds and variety of ECG changes (sinus bradycardia, prolonged PR interval, depressed P waves, flattened or inverted T waves, and low-amplitude QRS complexes); cardiac tamponade (although rare) (see Chapter 33)	Decreased metabolic demands and loss of regulatory and rate-setting effects of TH; protein-mucopolysaccharide-rich fluid in the pericardial sac associated with enlarged heart; pericardial effusions associated with heart sounds and ECG changes Increases in peripheral vascular resistance and increased blood volume can cause hypertension

Pulmonary	Dyspnea; myxedematous changes in respiratory muscles leading to hypoventilation and carbon dioxide retention, which contribute to myxedema coma	Pleural effusions associated with dyspnea, although effusions may be asymptomatic
Renal	Reduced renal blood flow and glomerular filtration rate leading to decreased renal excretion of water; increase in total body water and dilutional hyponatremia; reduced production of erythropoietin	Hemodynamic alterations associated with reduced blood flow and filtration; increased total body water related to decreased excretion and mucinous deposits in tissue
Gastrointestinal	Constipation, weight gain, and fluid retention; decreased absorption of most nutrients; decreased protein metabolism leading to retarded skeletal and soft tissue growth and slightly positive nitrogen balance; edema; decreased glucose absorption and delayed glucose uptake; elevated serum lipid values	Reduced intake and reduced peristaltic activity that may progress to fecal impaction; water absorption related to prolonged transit time; fluid retention associated with myxedematous changes; edema associated with high concentrations of exchangeable albumin in the extravascular space caused by increased capillary permeability to proteins; depressed insulin degradation; depressed lipid synthesis and degradation
Musculoskeletal	Muscle aching and stiffness; slow movement and slow tendon jerk reflexes; decreased bone formation and resorption, increased bone density; aching and stiffness in joints	Decreased rate of muscle contraction and relaxation contributing to slow movement and reflexes
Integumentary	Dry, flaky skin; dry, brittle head and body hair; reduced growth of nails and hair; slow wound healing	Reduced sweat and sebaceous gland secretion
	Myxedema	Accumulation of hyaluronic acid, which binds water and causes a puffy appearance
	Cool skin	Decreased circulation to skin

cAMP, Cyclic adenosine monophosphate; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *PTH*, parathyroid hormone; *TH*, thyroid hormone; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

The characteristic sign of severe or long-standing hypothyroidism is **myxedema**, which results from altered composition of the dermis and other tissues. The connective fibers are separated by an increased

amount of protein and mucopolysaccharides. This protein-mucopolysaccharide complex binds water, producing nonpitting, boggy edema, especially around the eyes, hands, and feet and in the supraclavicular fossae. The tongue and laryngeal and pharyngeal mucous membranes thicken, producing thick, slurred speech and hoarseness.

Myxedema coma, a medical emergency, is a diminished level of consciousness associated with severe hypothyroidism. Most individuals are not unconscious. Precipitating events include infections, discontinuation of thyroid supplements, overuse of narcotics or sedatives, or a consequence of an acute illness in individuals who have hypothyroidism. Older individuals with comorbid conditions, such as pulmonary or urinary tract infections, congestive heart failure, or cerebrovascular accident, and with moderate or untreated hypothyroidism are particularly at risk. Signs and symptoms include hypothermia without shivering, hypoventilation, hypotension, hypoglycemia, lactic acidosis, and coma. Symptoms of hypothyroidism in older adults should not be attributed to normal aging changes.⁵¹

◆Evaluation and Treatment.

The diagnosis of primary hypothyroidism is made by documentation of the clinical symptoms of hypothyroidism and by measurement of increased levels of TSH and decreased levels of TH (total T_3 and both total and free T_4). When hypothyroidism is caused by pituitary deficiencies, serum TSH levels are decreased or are inappropriately normal in the face of low levels of TH. Hormone replacement therapy with the hormone levothyroxine is the treatment of choice for hypothyroidism. Treatment of subclinical hypothyroidism is related to elevated levels of TSH and clinical symptoms. The restoration of normal TH levels should be timed appropriately; a regimen of hormonal therapy depends on the individual's age, the duration and severity of the hypothyroidism, and the presence of other disorders, particularly cardiovascular disorders. Pregnant women need to be evaluated for thyroid function.⁵² Treatment of myxedema coma with

TH, combined with circulatory and ventilatory support and management of hyponatremia and hypothermia, is usually effective. Mortality can be as high as 25%.⁴⁸

Hypothyroid Conditions

Primary Hypothyroidism.

Primary hypothyroidism has several causes. **Iodine deficiency (endemic goiter)** is the most common cause worldwide, but is relatively rare in the United States because of the use of iodized table salt and fortified foods.⁵³

The most common cause of hypothyroidism in the United States is **autoimmune thyroiditis (Hashimoto disease, chronic lymphocytic thyroiditis)**, which results in gradual inflammatory destruction of thyroid tissue. Hashimoto disease occurs in genetically predisposed individuals and epigenetic mechanisms are probably involved.⁵⁴ Variants in major histocompatibility complex (MHC) antigens have been associated with autoimmune thyroiditis that are different from those found in Graves disease. Infiltration of thyroid autoantibodies (antithyroid peroxidase and antithyroglobulin antibodies), autoreactive T lymphocytes, natural killer cells, and inflammatory cytokines, and induction of apoptosis are involved in the tissue destruction seen in Hashimoto thyroiditis. Goiter formation is commonly observed. Hashimoto disease is commonly associated with other autoimmune conditions. Autoimmune thyroiditis is diagnosed by the presence of thyroperoxidase and thyroglobulin antibodies. Treatment is symptomatic and requires thyroid hormone replacement.⁵⁵

Subacute thyroiditis (subacute granulomatous thyroiditis, or de Quervain thyroiditis) is an uncommon nonbacterial inflammation of the thyroid often preceded by a viral infection. It is accompanied by fever, tenderness, and enlargement of the thyroid. The inflammatory process initially results in elevated levels of TH caused by release of stored thyroglobulin, which is then followed by transient hypothyroidism before the gland recovers normal activity. Thyroid

antibodies are not present in the blood. Symptoms may last 2 to 4 months and nonsteroidal antiinflammatory drugs or corticosteroids usually resolve symptoms. **Painless (silent) thyroiditis (silent or subacute lymphocytic thyroiditis)** has a course similar to that of subacute thyroiditis but is pathologically identical to Hashimoto disease. **Iatrogenic hypothyroidism** results from radioiodine thyroid ablation, thyroidectomy, and medications (lithium and amiodarone). **Postpartum thyroiditis** is pathologically related to Hashimoto disease and generally occurs within 6 to 12 months of delivery with a course similar to that of painless thyroiditis. A hyperthyroid phase (with a low thyroid radioiodine uptake) precedes the hypothyroid phase in typical cases of subacute, painless, or postpartum thyroiditis. Spontaneous recovery occurs in 95% of these conditions.⁵⁶

Congenital Hypothyroidism.

Congenital hypothyroidism in infants occurs when thyroid tissue is absent (thyroid dysgenesis) or with hereditary defects in TH synthesis.⁵⁷ Thyroid dysgenesis occurs more often in female infants, with permanent abnormalities in 1 of every 4000 live births. Congenital central hypothyroidism in children is caused by defects in thyroid-stimulating hormone (TSH) synthesis.⁵⁸ Because TH is essential for embryonic growth, particularly of brain tissue, the infant will be cognitively disabled if there is no thyroxine during fetal life. The fetus is dependent on maternal thyroxine for the first 20 weeks of gestation. Hypothyroidism may not be evident at birth since there is transplacental passage of some maternal thyroid hormone. Symptoms may include high birth weight, hypothermia, delay in passing meconium, and neonatal jaundice. Cord blood can be examined in the first days of life for measurement of T_4 and TSH levels. The probability of normal growth and intellectual function is high if treatment with levothyroxine is started before the child is 3 or 4 months old. The earlier thyroid hormone replacement therapy is initiated, the better the child's outcome.⁵⁹

Without early screening, hypothyroidism may not be evident until after 4 months of age. Symptoms include difficulty eating, hoarse cry,

and protruding tongue caused by myxedema of oral tissues and vocal cords; hypotonic muscles of the abdomen with constipation, abdominal protrusion, and umbilical herniation; subnormal temperature; lethargy; excessive sleeping; slow pulse rate; and cold, mottled skin. Skeletal growth is stunted because of impaired protein synthesis, poor absorption of nutrients, and lack of bone mineralization. The individual will become dwarfed, with short limbs, if not treated (cretinism) (Fig. 22.11). Dentition is often delayed. Cognitive disability varies with the severity of hypothyroidism and the length of delay before initiation of treatment. Treatment is required for life.

FIGURE 22.11 Adult Cretin. Note characteristic facial features, dwarfism (44 inches), absent axillary and scant pubic hair, poorly developed breasts, potbelly, and small umbilical hernia. (From Schneeberg NG: *Essentials of clinical endocrinology*, St Louis, 1970, Mosby.)

Thyroid Carcinoma.

Thyroid carcinoma accounts for 56,870 estimated new cases and 2010 estimated cancer deaths in 2017 in the United States.⁶⁰ Although it is the most common endocrine malignancy, it constitutes less than 4% of all neoplasms. Exposure to ionizing radiation, especially during childhood, is the most consistent causal factor.⁶¹ Papillary and follicular thyroid carcinomas are the most frequent (80% to 85%) and are usually well differentiated. Medullary (occurs in C cells and secretes calcitonin and carcinoembryonic antigen) and anaplastic thyroid carcinomas are less common.

Most individuals with thyroid carcinoma have normal T_3 and T_4 levels and are therefore euthyroid. Thyroid cancer typically is discovered as a small thyroid nodule or as a metastatic tumor most commonly occurring in the regional lymph nodes, lungs, brain, or bone. Changes in voice and swallowing and difficulty in breathing are related to tumor growth impinging on the trachea or esophagus. Ultrasonographic characteristics may be suggestive of malignancy, but are neither sensitive nor specific. The diagnosis of thyroid carcinoma is generally made by fine-needle aspiration of a thyroid nodule.⁶²

Treatment for well-differentiated thyroid carcinoma remains somewhat controversial mainly because of its protracted nature and the relatively low mortality regardless of the method of treatment. Treatment of well-differentiated tumors includes surgical dissection (e.g., a near-total or total thyroidectomy), postoperative radioactive iodine therapy to treat any microscopic residual tumor, and suppression of TSH with levothyroxine to replace TH and suppress TSH on any tumor cells.⁶³ Anaplastic thyroid carcinoma carries a grave prognosis, and palliation with surgical debulking, external beam radiotherapy, and chemotherapy may be offered. New insights into the molecular pathogenesis of thyroid carcinoma are leading to new therapies, including immunotherapy and oncolytic virotherapy.⁶⁴

Alterations of Parathyroid Function

Hyperparathyroidism

Hyperparathyroidism is characterized by greater than normal secretion of parathyroid hormone (PTH) and hypercalcemia. Hyperparathyroidism is classified as primary, secondary, or tertiary.

◀Pathophysiology.

Primary hyperparathyroidism is characterized by inappropriate excess secretion of PTH by one or more of the parathyroid glands. It is one of the most common endocrine disorders: 80% to 85% of cases are caused by parathyroid adenomas, another 10% to 15% result from parathyroid hyperplasia, and approximately 1% of cases are caused by parathyroid carcinoma.⁶⁵ In addition, primary hyperparathyroidism may be caused by a variety of genetic causes (about 5% of cases), especially the genes that cause multiple endocrine neoplasia (*MEN-1* and *MEN-2a*).⁶⁵

In primary hyperparathyroidism, PTH secretion is increased and is not under the usual feedback control mechanisms. The calcium level in the blood increases because of increased bone resorption and gastrointestinal absorption of calcium, but fails to inhibit PTH secretion at normal levels of calcium because the feedback threshold for calcium is set at a higher level in the abnormal parathyroid tissue. Hypercalcemia and hypophosphatemia are the hallmarks of primary hyperparathyroidism. The effects of excessive PTH secretion and primary hyperparathyroidism on various organ systems are summarized in [Table 22.4](#).

TABLE 22.4

MANIFESTATIONS OF PRIMARY HYPERPARATHYROIDISM

SYMPTOMS	RESPONSIBLE DERANGEMENTS	MECHANISMS
Renal colic, nephrolithiasis, recurrent urinary tract	Hypercalciuria, hyperphosphaturia,	Calcium phosphate salts precipitate in alkaline urine, renal pelvis, and

infections, renal failure	proximal renal tubular bicarbonate leak, urine pH >6	collecting ducts; calcium oxalate stones also formed
Abdominal pain, peptic ulcer disease	Hypercalcemia-stimulated hypergastrinemia	Elevated hydrochloric acid secretion
Pancreatitis	Hypercalcemia	Etiology of relationship unknown
Bone disease, osteitis fibrosa and osteitis cystica, osteoporosis	Parathyroid hormone (PTH)-stimulated bone resorption, metabolic acidosis	Osteoporosis now more commonly encountered, but other disorders are more specific for hyperparathyroidism
Muscle weakness, myalgia	PTH excess, possible direct effect on striated muscle and on nerves	Characteristic myopathic changes in muscle histology (neuropathy of type I and type II muscle fibers)
Neurologic and psychiatric problems (impaired memory, confusion, depression, anxiety, psychosis)	Hypercalcemia	Neuropathy; electroencephalographic changes present
Polyuria, polydipsia	Hypercalcemia	Direct effect on renal tubule to decrease responsiveness to antidiuretic hormone
Constipation	Hypercalcemia	Decreased peristalsis of gastrointestinal tract
Anorexia, nausea, and vomiting	Hypercalcemia	Central stimulation of vomiting center
Hypertension	Renal disease, direct effect of calcium on arterial smooth muscle, pheochromocytoma	Plasma renin activity elevated or normal
Arthralgia and arthritis	Gout, pseudogout, periarticular classification	Hyperuricemia, chronic renal failure with high calcium phosphate product

Data from Flint PW et al: *Cummings otolaryngology: head & neck surgery*, ed 5, St Louis, 2010, Mosby.

Normocalcemic hyperparathyroidism is a phenotype of primary hyperparathyroidism characterized by increased levels of PTH, normal total and ionized serum calcium concentrations, normal activated vitamin D levels, and no underlying etiology. Increased PTH screening for osteoporosis has led to the development of this diagnosis. There may be tissue resistance to PTH or the elevated level of PTH may represent an early phase of primary hyperparathyroidism

as, ultimately, there is development of hypercalcemia.⁶⁶

Secondary hyperparathyroidism is a compensatory response of the parathyroid glands to chronic hypocalcemia, which is a common complication of chronic kidney disease (see [Chapter 39](#)) or vitamin D deficiency. Secretion of PTH is elevated, but PTH cannot achieve normal calcium levels because of insufficient levels of activated vitamin D.⁶⁷ Other causes of secondary hyperparathyroidism include chronic vitamin D or calcium deficiency; decreased intestinal absorption of vitamin D or calcium; and ingestion of drugs, such as phenytoin, phenobarbital, and laxatives, which either accelerate the metabolism of vitamin D or decrease the intestinal absorption of calcium.

Tertiary hyperparathyroidism can develop after any long-standing period of hypocalcemia, such as those seen with chronic dialysis or gastrointestinal malabsorption. In these individuals, prolonged hypocalcemia causes parathyroid chief cell hyperplasia and excess PTH production. It is most commonly seen after renal transplantation. After correction of the renal failure by renal transplant, the hypertrophied parathyroid tissue continues to over-secrete PTH. Consequently, serum calcium levels are normal or even elevated in these individuals because the hyperplastic glands function autonomously despite withdrawal of calcium and calcitriol. New drugs are being used to inhibit the synthesis of PTH. Surgical removal of one or more of the parathyroid glands is completed when there is no response to medical treatment.⁶⁸

Familial hypocalciuric hypercalcemia (FHH) is a benign autosomal dominant condition that can mimic hyperparathyroidism and is characterized by a high serum calcium level, low serum phosphate level, and low urine calcium excretion. It is caused by a mutation in the calcium-sensing receptor in the parathyroid gland. It can be differentiated from primary hyperparathyroidism by measurement of 24-hour urine calcium excretion, which is very low in FHH.⁶⁹

◆Clinical Manifestations.

Hypercalcemia and hypophosphatemia are the hallmarks of primary

hyperparathyroidism and may be discovered incidentally. Hypercalcemia and hypophosphatemia may be asymptomatic or affected individuals may present with symptoms related to the muscular, nervous, and gastrointestinal systems, including fatigue, headache, depression, anorexia, and nausea and vomiting. Excessive osteoclastic and osteocytic activity resulting in bone resorption may cause pathologic fractures, kyphosis of the dorsal spine, and compression fractures of the vertebral bodies. (Bone resorption is discussed in [Chapter 44](#).)

The increased renal filtration load of calcium leads to hypercalciuria. Hypercalcemia also affects proximal renal tubular function, causing metabolic acidosis and production of an abnormally alkaline urine. PTH hypersecretion enhances renal phosphate excretion and results in hypophosphatemia and hyperphosphaturia. The combination of these three variables—hypercalciuria, alkaline urine, and hyperphosphaturia—predisposes the individual to the formation of calcium stones, particularly in the renal pelvis or in the renal collecting ducts. These may be associated with infections.⁷⁰ Hypercalcemia also impairs the concentrating ability of the renal tubule by decreasing its response to ADH. Chronic hypercalcemia of hyperparathyroidism is associated with mild insulin resistance, necessitating increased insulin secretion to maintain normal glucose levels.⁷¹

Secondary hyperparathyroidism caused by renal disease presents clinically not only with bone resorption but also with the symptoms of hypocalcemia and hyperphosphatemia. Hypocalcemia can cause many significant clinical problems (see [Chapter 3](#)). Hyperphosphatemia can cause deleterious effects on the cardiovascular system (i.e., increased calcification).

◆**Evaluation and Treatment.**

The concurrent findings of increased ionized calcium concentration in the face of elevated PTH concentration are suggestive of primary hyperparathyroidism. PTH levels also may be inappropriately within the normal range because hypercalcemia should completely suppress

PTH production. Observation of asymptomatic individuals with mild hypercalcemia is recommended; these individuals are advised to avoid dehydration and limit dietary calcium intake. Definitive treatment of severe primary hyperparathyroidism involves surgical removal of a solitary adenoma or, in the case of hyperplasia, complete removal of three and partial removal of the fourth hyperplastic parathyroid glands. Imaging procedures are used to localize adenomas before surgery. In those individuals who fail surgery, other treatments, such as bisphosphonates and calcimimetics (e.g., cinacalcet), may be considered. Calcimimetics increase the parathyroid calcium receptor sensitivity, thus lowering PTH levels.

If hypercalcemia is documented but PTH levels are low, the differential diagnosis shifts to hypercalcemia of malignancy, granulomatous diseases (sarcoidosis), excessive calcium ingestion, or hypervitaminosis A or D. Treatment of these conditions depends on the underlying cause.

If serum calcium level is low but PTH level is elevated, secondary hyperparathyroidism is likely. Evaluation for renal function frequently documents chronic renal disease. Treatment for secondary hyperparathyroidism in chronic kidney disease requires calcium replacement, dietary phosphate restriction and phosphate binders, and vitamin D replacement. Treatment also may include calcimimetics but adverse effects must be considered.⁷²

Hypoparathyroidism

Hypoparathyroidism (abnormally low PTH levels) most commonly is caused by damage to or removal of the parathyroid glands during thyroid surgery and occurs because of the anatomic proximity of the parathyroid glands to the thyroid (see [Fig. 21.11](#)).⁷⁰ Hypoparathyroidism also is associated with genetic syndromes, including familial hypoparathyroidism and DiGeorge syndrome (velocardiofacial syndrome), and an idiopathic or autoimmune form of the disease.⁷³ Hypomagnesemia also can cause a decrease in PTH secretion and function. There is an inherited condition associated with hypocalcemia with normal to elevated levels of PTH called

pseudohypoparathyroidism. Individuals with this condition are resistant to PTH in the proximal renal tubule and cannot produce cAMP in response to PTH (a postreceptor defect in PTH action).⁷⁴

◆Pathophysiology.

A lack of circulating PTH causes depressed serum calcium levels and increased serum phosphate levels. In the absence of PTH, resorption of calcium from bone and regulation of calcium reabsorption from the renal tubules are impaired. Therefore phosphate reabsorption by the renal tubules is increased, causing decreased renal phosphate excretion and hyperphosphatemia.

Hypomagnesemia inhibits PTH secretion. When serum magnesium levels return to normal, however, PTH secretion returns to normal, as does the responsiveness of peripheral tissues to PTH. Hypomagnesemia may be related to chronic alcoholism, malnutrition, malabsorption, increased renal clearance of magnesium caused by the use of aminoglycoside antibiotics or certain chemotherapeutic agents, or prolonged magnesium-deficient parenteral nutritional therapy.

◆Clinical Manifestations.

Symptoms associated with hypoparathyroidism are primarily those of hypocalcemia. Hypocalcemia causes a lowered threshold for nerve and muscle excitation so that a nerve impulse may be initiated by a slight stimulus anywhere along the length of a nerve or muscle fiber. This creates perioral numbness, paresthesias, tingling, and tetany caused by muscle spasms, hyperreflexia, tonic-clonic convulsions, laryngeal spasms, and, in severe cases, death from asphyxiation. Chvostek and Trousseau signs may be used to evaluate for neuromuscular irritability. Chvostek sign is elicited by tapping the cheek, resulting in twitching of the upper lip. Trousseau sign is elicited by sustained inflation of a sphygmomanometer placed on the upper arm to a level above the systolic blood pressure with resultant painful carpal spasm. Other symptoms of hypocalcemia include dry skin, loss of body and scalp hair, hypoplasia of developing teeth, horizontal ridges on the nails, cataracts, basal ganglia calcifications

(which may be associated with a parkinsonian syndrome), and bone deformities, including brachydactyly and bowing of the long bones.

Phosphate retention caused by increased renal reabsorption of phosphate is associated also with hypoparathyroidism. Hyperphosphatemia results from PTH deficiency and, in turn, hyperphosphatemia further lowers calcium concentration by inhibiting the activation of vitamin D, thereby lowering the gastrointestinal absorption of calcium.

◆Evaluation and Treatment.

A low serum calcium level and a high phosphorous level in the absence of renal failure, intestinal disorders, nutritional deficiencies, or in individuals who have had thyroidectomy suggest hypoparathyroidism. PTH levels are low in hypoparathyroidism, and measurement of serum magnesium and urinary calcium excretion can help in diagnosis. Treatment is directed toward the alleviation of hypocalcemia. In acute states this involves parenteral administration of calcium, which corrects serum calcium concentration within minutes. Maintenance of serum calcium level is achieved with pharmacologic doses of an active form of vitamin D and oral calcium. Hypoplastic dentition, cataracts, bone deformities, and basal ganglia calcifications do not respond to the correction of hypocalcemia, but the other symptoms of hypocalcemia are reversible. PTH hormone replacement therapy with recombinant human parathyroid hormone (rhPTH[1–84]) is safe and effective with reduced requirements for supplemental calcium and vitamin D.⁷⁵

As serum calcium levels return to normal, phosphaturia usually is stimulated with a return to normal serum phosphate levels. In some individuals, however, the absence of the phosphaturic effect of PTH causes a persistent hyperphosphatemia, which should be treated with drugs that inhibit gastrointestinal absorption of phosphate (i.e., non-calcium-containing phosphate binders).

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

Diabetes mellitus (DM) is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. In 2015 in the United States, an estimated 30.3 million people (9.4%) had diabetes and 7.2 million were estimated to be undiagnosed. DM was the seventh leading cause of death in 2015.⁷⁶

The American Diabetes Association (ADA)⁷⁷ classifies four categories of diabetes mellitus (see details in [Table 22.5](#)) as follows:

TABLE 22.5

CLASSIFICATION AND CHARACTERISTICS OF DIABETES MELLITUS

NAME	CHARACTERISTICS
Type 1 Beta-cell destruction leading to absolute insulin deficiency; immune-mediated diabetes is most common form (≈90%)	Cellular-mediated autoimmune destruction of pancreatic beta cells Individual prone to ketoacidosis Little or no insulin secretion Insulin dependent 75% of individuals develop before 30 years of age; can occur up to the tenth decade Usually not obese
Idiopathic (≈10%)	No defined etiologies; absolute requirement for insulin replacement therapy in affected individuals may be sporadic
Type 2 Progressive loss of b-cell insulin secretion frequency on the background of insulin resistance	Usually not insulin dependent but may be insulin requiring Individual not ketosis prone (but may form ketones under stress) Obesity common in the abdominal region Generally occurs in those older than 40 years, but the frequency is rapidly increasing in children Strong genetic predisposition Often associated with hypertension and dyslipidemia
Other Specific Types	
Genetic defects of beta-cell function	Genetic abnormalities that decrease the ability of the beta cell to secrete insulin: 1. Maturity-onset diabetes of youth (MODY) includes six specific autosomal dominant mutations including genes for hepatocyte

	<p>nuclear factor-1α (HNF-1α; <i>MODY 3</i>), glucokinase (<i>MODY 2</i>), HNF-4α (<i>MODY 1</i>), insulin-promoter factor-1 (IPF-1; <i>MODY 4</i>), HNF-1β (<i>MODY 5</i>), and NeuroD1 (<i>MODY 6</i>)</p> <p>2. Defects in mitochondrial deoxyribonucleic acid (DNA)</p> <p>3. Other (including an inability to convert proinsulin to insulin)</p>
Genetic defects in insulin action	Mutations in the insulin receptor with hyperinsulinism or hyperglycemia or severe diabetes
Diseases of the exocrine pancreas	Any process that diffusely injures the pancreas, including pancreatitis, neoplasia, and cystic fibrosis
Endocrinopathies	Endocrine disorders including acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, and aldosteronoma
Drug- or chemical-induced beta-cell dysfunction	Commonly associated drugs include glucocorticoids, treatment of HIV/AIDS, and after organ transplantation although many others may be implicated
Infections	Beta-cell destruction by viruses including cytomegalovirus, congenital rubella
Uncommon forms of immune-mediated diabetes mellitus	Anti-insulin receptor antibodies Reported with "stiff man syndrome" and individuals receiving interferon- α
Other genetic syndromes sometimes associated with diabetes mellitus	Down, Klinefelter, Turner, and Wolfram syndromes
Gestational Diabetes Mellitus (GDM)	
Any degree of glucose intolerance with onset or first recognition during pregnancy	<p>Insulin resistance combined with inadequate insulin secretion in relation to hyperglycemia</p> <p>Women who are obese, older than 25 years of age, have a family history of diabetes, have a history of previous GDM, or are of certain ethnic groups (Hispanic, Native American, Asian, or black) are at increased risk of developing GDM</p> <p>The metabolic stress of pregnancy may uncover a genetic tendency for type 2 diabetes mellitus</p>

Data from American Diabetes Association: *Diabetes Care* 40(Suppl 1): S11–S24, 2017.

1. Type 1 beta-cell destruction, usually leading to absolute insulin deficiency
2. Type 2: ranging from predominantly insulin resistance with relative insulin deficiency to predominantly an insulin secretory defect with insulin resistance

3. Other specific types
4. Gestational diabetes

The diagnosis of diabetes mellitus is based on glycosylated hemoglobin (HbA_{1c}) levels, fasting plasma glucose (FPG) levels, 2-hour plasma glucose level during oral glucose tolerance testing (OGTT) using a 75-g oral glucose load, or random glucose levels in an individual with symptoms (Box 22.2). Glycosylated hemoglobin refers to the permanent attachment of glucose to hemoglobin molecules and reflects the average plasma glucose exposure over the life of a red blood cell (approximately 120 days). It provides a more accurate measure for monitoring long-term control of blood glucose levels. This test is critically dependent upon the method of measurement and must be related to established standards.

Box 22.2

Diagnostic Criteria for Diabetes Mellitus

1. HbA_{1c} (as measured in a DCCT-referenced assay) $\geq 6.5\%$
OR
2. FPG ≥ 126 mg/dL (7.0 mmol/L); fasting is defined as no caloric intake for at least 8 hr
OR
3. 2-hr plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during an OGTT
OR
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose ≥ 200 mg/dL (11.1 mmol/L)

Categories of Increased Risk for Diabetes (Prediabetes)

1. FPG 100 to 125 mg/dL
2. 2-hr PG in the range of 140 to 199 mg/dL during an OGTT
3. HbA_{1c} 5.7% to 6.4%

DCCT, Diabetes Control and Complications Trial; *FPG*, fasting plasma glucose; *HbA_{1c}*, hemoglobin A_{1c}; *hr*, hour(s); *OGTT*, oral glucose tolerance test; *PG*, plasma glucose.

From American Diabetes Association (ADA): 2016 *guidelines*. Available at <http://www.ndei.org/ADA-diabetes-management-guidelines-diagnosis-A1C-testing.aspx>.

The ADA classification categories of increased risk for diabetes (or prediabetes)⁷⁷ describe nondiabetic elevations of HbA_{1c}, FPG, or the 2-hour plasma glucose value during OGTT (see [Box 22.2](#)). The Centers for Disease Control and Prevention (CDC) estimates that 37% of U.S. adults aged 20 years or older have prediabetes (86 million people) including 51% of those aged 65 years or older.⁷⁶ This classification includes impaired glucose tolerance (IGT), which results from diminished insulin secretion, and impaired fasting glucose (IFG), which is caused by enhanced hepatic glucose output secondary to hepatic insulin resistance. Individuals with IGT and IFG are at increased risk of cardiovascular disease and premature death and carry a 15% to 50% 5-year risk of developing diabetes, particularly type 2 diabetes.⁷⁸ Thus prevention of diabetes with lifestyle interventions is essential.⁷⁷

Types of Diabetes Mellitus

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (DM) is the most common pediatric chronic disease and affects 0.17% of U.S. children, and the incidence is increasing.⁷⁶ Between 10% and 13% of individuals with newly diagnosed type 1 DM have a first-degree relative (parent or sibling) with type 1 DM. There is a 50% concordance rate in twins.⁷⁹ Diagnosis is rare during the first 9 months of life and peaks at 12 years of age.

Two distinct types of type 1 DM have been identified: autoimmune (type 1A) and idiopathic or nonimmune (type 1B). Type 3c DM is associated with chronic pancreatitis and is discussed in [Chapter 42](#). [Table 22.6](#) summarizes the epidemiology of type 1 and type 2 DM.

TABLE 22.6

EPIDEMIOLOGY AND ETIOLOGY OF DIABETES MELLITUS IN THE UNITED STATES

TYPE 1 DIABETES: PRIMARY BETA-CELL DEFECT OR FAILURE		TYPE 2 DIABETES: INSULIN RESISTANCE WITH INADEQUATE INSULIN SECRETION
Incidence		
Frequency	One of the most common childhood diseases ($\approx 5\%$ of all cases of diabetes mellitus) Prevalence rate is $\approx 0.17\%$	Accounts for most cases ($\approx 90\text{--}95\%$) <i>Incident rates for all diabetes (e.g., type 1 and type 2):</i> women, 11.7%; men, 12.7%. For women and men ages 18–44 yr, 4%; ages 45–64, 17%; ages >65 yr, 25.2%.
Change in incidences	No documented increase in incidence in the United States	Incidence in all age groups increased 382% from 1988 to 2014
Characteristics		
Age at onset	Peak onset at age 11–13 yr (slightly earlier for girls than for boys) Rare in children younger than 1 yr and adults older than 30 yr	Risk of developing diabetes increases after age 40 yr; in general, incidence increases with age into the 70s; among Pima Indians, incidence peaks between ages 40 and 50 yr, then falls
Sex	Similar in males and females	Similar in males and females overall, although black females have the highest incidence and prevalence of all groups
Racial distribution	Rates for whites 1.5–2 times higher than those for nonwhites Higher rates for those of Scandinavian descent than for those of central or southern European descent	<i>For all diabetes (e.g., type 1 and type 2):</i> American Indians/Alaska Natives 15.1%; black, non-Hispanic 12.7%; Hispanic 12.1%; Asian, non-Hispanic 8.0%; white, non-Hispanic 7.4%
Obesity	Generally normal or underweight	Frequent contributing factor to precipitate type 2 diabetes among those susceptible; a major factor in populations recently

		exposed to westernized environment Increased risk related to duration, degree, and distribution of obesity
Etiology		
Common theory	<i>Autoimmune:</i> Genetic and environmental factors, resulting in gradual process of autoimmune destruction in genetically susceptible individuals <i>Nonautoimmune:</i> Unknown Strong association with <i>HLA-DQA</i> and <i>HLA-DQB</i> genes	Disease results from genetic susceptibility (polygenic) combined with environmental determinants and other risk factors; inherited defects in beta-cell mass and function combined with peripheral tissue insulin resistance Associated with long-duration obesity
Heredity	Risk to sibling: 5%–10% Risk to offspring: 2%–5%	Risk to first-degree relative (child or sibling): 10%–15%
Presence of antibody	Islet cell autoantibodies (ICAs) and/or autoantibodies to insulin, and autoantibodies to glutamic acid decarboxylase (GAD ₆₅) and tyrosine phosphatases IA-2 and IA-2 β are present in 85%–90% of individuals when fasting; hyperglycemia is initially detected	Islet cell antibodies not prevalent
Insulin resistance	Insulin resistance at diagnosis is unusual, but insulin resistance may occur as the individual ages and gains weight	Insulin resistance is generally caused by altered cellular metabolism and an intracellular postreceptor defect
Insulin secretion	Severe insulin deficiency or no insulin secretion at all	Typically increased at time of diagnosis, but progressively declines over the course of the illness

Data from Centers for Disease Control and Prevention (CDC): *Diabetes public health resource, diagnosed diabetes*, last updated Dec 1, 2015. Satterfield D et al: *MMWR Suppl* 65(1):4–10, 2016.

◆ Pathophysiology.

In autoimmune-mediated DM, environmental-genetic factors are thought to trigger cell-mediated destruction of pancreatic beta cells. A

specific cause is still unknown. Idiopathic or nonimmune type 1 DM is far less common than autoimmune and does not have an autoimmune basis for beta-cell destruction. It occurs secondary to other diseases, such as pancreatitis, and mostly in people of Asian or African descent. Affected individuals have varying degrees of insulin deficiency, lack islet autoantibodies and HLA association, and have intermittent proneness to ketosis. It also is described as ketosis prone type 2 DM.⁸⁰

Gene/Environmental Factors.

Interactions between environmental factors and susceptibility genes are thought to have a significant contribution to the development of type 1 DM but the mechanisms are still poorly defined. The strongest genetic association is with major histocompatibility complex, or MHC (histocompatibility leukocyte antigen [HLA] class II alleles HLA-DR3-DQ2 or HLA-DR4-DQ8 haplotypes, or both). Numerous other mutations involving single genes both within and outside of the MHC complex have been associated with an increased risk of type 1 DM.⁸¹ Various epigenetic modifications of gene expression also have been postulated. Environmental factors, including viral infections, particularly enteroviruses, coxsackievirus, other infectious microorganisms (such as *Helicobacter pylori*); exposure to cow's milk proteins; a relative lack of vitamin D; air pollution; vaccinations; stress; gut microbial flora; and family density also have been implicated but more research is needed.⁸²

Immunologically Mediated Destruction of Beta Cells.

Autoimmune type 1 DM is a slowly progressive autoimmune T-cell-mediated disease that destroys beta cells of the pancreas and occurs in genetically susceptible individuals (Fig. 22.12 and see Chapter 9). There is a deficient immune tolerance linked to abnormalities in immune cells and changes in beta-cell antigens.⁸³ Gene-environment interactions result in the loss of tolerance to self-antigens with formation of autoantigens that are expressed on the surface of pancreatic beta cells and circulate in the bloodstream and lymphatics. Cellular immunity (T-cytotoxic cells and macrophages) and humoral

immunity (autoantibodies) are stimulated, resulting in beta-cell destruction and apoptosis.

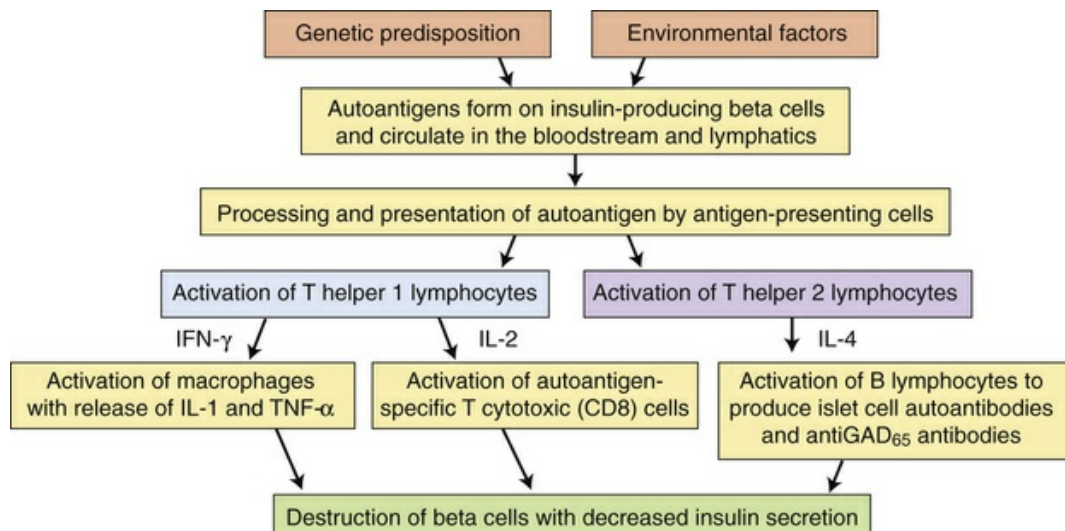

FIGURE 22.12 Pathophysiology of Type 1 Diabetes Mellitus. *GAD*₆₅, Glutamic acid decarboxylase; *IFN-γ*, interferon-gamma; *IL*, interleukin; *TNF-α*, tumor necrosis factor-alpha.

The destruction of beta cells progresses through the following stages:

1. *Lymphocyte and macrophage infiltration of the islets resulting in inflammation (insulinitis) and islet beta-cell death.* Autoantigens are expressed on the surface of pancreatic islet cells and circulate in the bloodstream and lymphatics (see Fig. 22.12). Circulating autoantigens are ingested by antigen-presenting cells that activate CD4⁺ T helper 1 (Th1) lymphocytes. The activated T helper lymphocytes secrete interleukin-2 (IL-2) that activates beta-cell autoantigen-specific T cytotoxic lymphocytes, causing them to proliferate and attack islet cells through secretion of toxic perforins and granzymes.⁸⁴ T helper lymphocytes also secrete interferon that activates macrophages and stimulates the release of inflammatory cytokines (including IL-1, and tumor necrosis factor [TNF]), which cause further beta-cell destruction and apoptosis.⁸⁵

2. *Production of autoantibodies against islet cells, insulin, glutamic acid decarboxylase (GAD), and other cytoplasmic proteins.* Activated T helper 2 (Th2) lymphocytes produce IL-4, which stimulates B lymphocytes to proliferate and produce antibodies (see Fig. 22.12). Islet cell autoantibodies (ICAs) precede evidence of beta-cell deficiency and can be found in the serum years before symptoms occur.⁸⁶ Beta-cell destruction also is mediated by the production of autoantibodies against insulin, glutamic acid decarboxylase (GAD), and tyrosine phosphatase.⁸⁵ Finally, another islet antigen against which antibodies are produced in type 1 and type 2 DM is the zinc transporter 8 (Znt8) protein. It can be measured in the serum and is associated with variation in disease progression.⁸⁷
3. *Relative inactivity of T regulatory cells that contribute to a decrease in beta-cell mass and insulin production.* Normally these T lymphocytes serve to inhibit the immune response and maintain self-tolerance.⁸⁸

For insulin synthesis to decline enough such that hyperglycemia occurs, 80% to 90% of the insulin-secreting beta cells of the islet of Langerhans must be destroyed. Insulin normally suppresses secretion of glucagon and, thus, hypoinsulinemia leads to a marked increase in glucagon secretion. **Glucagon**, a hormone produced by the alpha cells of the islets, acts in the liver to increase blood glucose level by stimulating glycogenolysis and gluconeogenesis. In addition to the decline in insulin secretion, there is decreased secretion of **amylin**, another beta-cell hormone. One of the critical actions of amylin is to suppress glucagon release from the alpha cells. Thus both alpha-cell and beta-cell functions are abnormal and both a lack of insulin and a relative excess of glucagon contribute to hyperglycemia in type 1 DM.⁸⁹

◆Clinical Manifestations.

The onset of type 1 DM involves a long preclinical period with gradual destruction of beta cells, eventually leading to insulin

deficiency and hyperglycemia. Generally, this latent period is longer in older individuals with type 1 DM and often results in misclassification of those affected as having type 2 DM. This is sometimes called *latent autoimmune diabetes of adults (LADA)*.

Type 1 DM affects the metabolism of fat, protein, and carbohydrates. Glucose accumulates in the blood and appears in the urine as the renal threshold for glucose is exceeded, producing an osmotic diuresis manifested as polyuria and thirst. Wide fluctuations in blood glucose levels occur. In addition, protein and fat breakdown occurs because of the lack of insulin, resulting in weight loss. Increased hepatic metabolism of fat leads to high levels of circulating ketones, causing diabetic ketoacidosis (DKA) (Table 22.7, and see [Diabetic Ketoacidosis](#)).

TABLE 22.7

CLINICAL MANIFESTATIONS AND RATIONALE FOR TYPE 1 DIABETES MELLITUS

MANIFESTATIONS RATIONALE	
Polydipsia	Because of elevated blood glucose levels, water is osmotically attracted from body cells, resulting in intracellular dehydration and hypothalamic stimulation of thirst
Polyuria	Hyperglycemia acts as an osmotic diuretic; the amount of glucose filtered by the glomeruli of the kidneys exceeds the amount that can be reabsorbed by the renal tubules; glycosuria results, accompanied by large amounts of water lost in the urine
Polyphagia	Depletion of cellular stores of carbohydrates, fats, and protein results in cellular starvation and a corresponding increase in hunger
Weight loss	Weight loss occurs because of fluid loss in osmotic diuresis and the loss of body tissue as fat and proteins are used for energy as a result of the effects of insulin deficiency
Fatigue	Metabolic changes result in poor use of food products, contributing to lethargy and fatigue; sleep loss from severe nocturia also contributes to fatigue

Currently half of individuals with type 1 DM are obese and there is an increasing number of individuals who have both type 1 DM and the clinical manifestations of metabolic syndrome, including dyslipidemia and hypertension. This is because, in part, of successful intensive insulin therapy that promotes weight gain and also, in part,

because of lifestyle factors, including lack of exercise and poor nutrition. This creates a high risk of synergistic effects for chronic complications of DM, including heart disease and stroke,^{90,91} and adjunctive noninsulin antihyperglycemic therapies are under investigation.⁹²

◆Evaluation and Treatment.

The criteria for diagnosis of type 1 DM are the same as those for type 2 DM (see [Box 22.2](#)). The diagnosis of DM is not difficult when the symptoms of polydipsia, polyuria, polyphagia, weight loss, and hyperglycemia are present in fasting and postprandial states. Many children are first diagnosed when they present with the signs and symptoms of DKA. It reflects lack of awareness by parents and primary care providers of the evolving symptoms of type 1 DM. In DKA, acetone (a volatile form of ketones) is exhaled by hyperventilation and gives the breath a sweet or “fruity” odor. Occasionally, diabetic coma is the initial symptom of the disease.⁹³ C-peptide, a component of proinsulin released during insulin production, can be measured in the serum as a surrogate for insulin levels and is indicative of residual beta-cell mass and function. The zinc transporter 8 autoantibody (ZnT8Ab) test has been approved to help differentiate type 1 from type 2 DM.⁹⁴ Currently, measurement of autoantibodies remains the best way to identify diabetes and to distinguish type 1 DM from other forms of diabetes. Having two or more islet autoantibodies confers a 100% risk of diabetes development.⁹⁵ Other important aspects of evaluation include assessing for evidence of the chronic complications of diabetes (see [Chronic Complications of Diabetes Mellitus](#)).

There are no approved therapies for preserving beta-cell mass. Many different kinds of approaches are being tested to prevent the autoimmune destruction of beta cells that is characteristic of type 1 DM. Avoidance of cow's milk, utilization of a gluten-free diet, and increased intake of omega-3 fatty acids and vitamin D are all being explored.⁹⁵ Pharmacologic prevention trials include immunosuppression and immunomodulation therapies (antigen-

specific therapies, monoclonal antibodies, fusion proteins, alternate Treg effectors, and oral or intranasal insulin)⁹⁶ (see *What's New? Immunomodulation in the Prevention and Treatment of Type 1 Diabetes on Evolve*).

Treatment regimens are designed to achieve optimal glucose control (as measured by the HbA_{1c} value) without causing episodes of significant hypoglycemia. Management requires individual planning according to type of disease, age, and activity level. All individuals with type 1 DM require some combination of insulin therapy, meal planning, exercise program, and self-monitoring of blood glucose level. Several different types of insulin preparations and new technologies for more physiologic insulin delivery systems are available (closed loop systems).⁹⁷ The use of pramlintide, a synthetic analog of amylin, can replace this hormone in individuals with type 1 and type 2 DM.⁹⁸ Blood glucose monitoring is an essential part of management and there are numerous types of monitoring devices for both self and “real-time” blood glucose monitoring.⁹⁹ Individuals also should be screened at least yearly for complications of diabetes. Finally, islet cell, stem cell, and whole pancreas transplantation have been successful in selected individuals.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus (DM) affects 9.3% of adults in the United States.⁷⁶ Prevalence is highest among American Indians and Alaska Natives (16%) and lowest among non-Hispanic whites (7.6%). There also is an increased prevalence of type 2 DM in children, especially in obese children⁷⁶ (see [Table 22.6](#)).

A genetic-environmental interaction appears to be responsible for type 2 DM.^{100,101} The most well-recognized risk factors are age, obesity, hypertension, physical inactivity, and family history. There is increasing evidence that diet, including diet during pregnancy, influences the long-term risk of type 2 DM in children and adults.¹⁰² More than 65 genes have been identified that are associated with type 2 DM, including those that code for beta-cell mass, beta-cell function (ability to sense blood glucose levels, insulin synthesis, and insulin

secretion), proinsulin and insulin molecular structures, insulin receptors, hepatic synthesis of glucose, glucagon synthesis, and cellular responsiveness to insulin stimulation.¹⁰³ **Metabolic syndrome** is a constellation of disorders (central obesity, dyslipidemia, prehypertension, and an elevated fasting blood glucose level) that together confer a high risk of developing type 2 DM and associated cardiovascular complications (**Box 22.3**). The metabolic syndrome develops during childhood, is highly prevalent among overweight children and adolescents, and affects millions of adults. Metabolic syndrome is characterized by many of the same genetic and environmental risks as type 2 DM and individuals should be screened on a regular basis. Early recognition and treatment, including vigorous lifestyle changes, are critical to reducing cardiovascular events and improving clinical outcomes.¹⁰⁴

Box 22.3

Criteria for the Diagnosis of Metabolic Syndrome

Three of the following five traits:

- Increased waist circumference (>40 inches in men; >35 inches in women)
- Plasma triglycerides ≥ 150 mg/dL
- Plasma high-density lipoprotein (HDL) cholesterol <40 mg/dL (men) or <50 mg/dL (women)
- Blood pressure $\geq 130/85$ mmHg
- Fasting plasma glucose ≥ 100 mg/dL

◆ Pathophysiology.

Many organs contribute to insulin resistance, chronic hyperglycemia, and the consequences of type 2 DM (**Fig. 22.13**). The combination of

genetic, and environmental influences results in the basic pathophysiologic mechanisms of type 2 DM (Fig. 22.14).

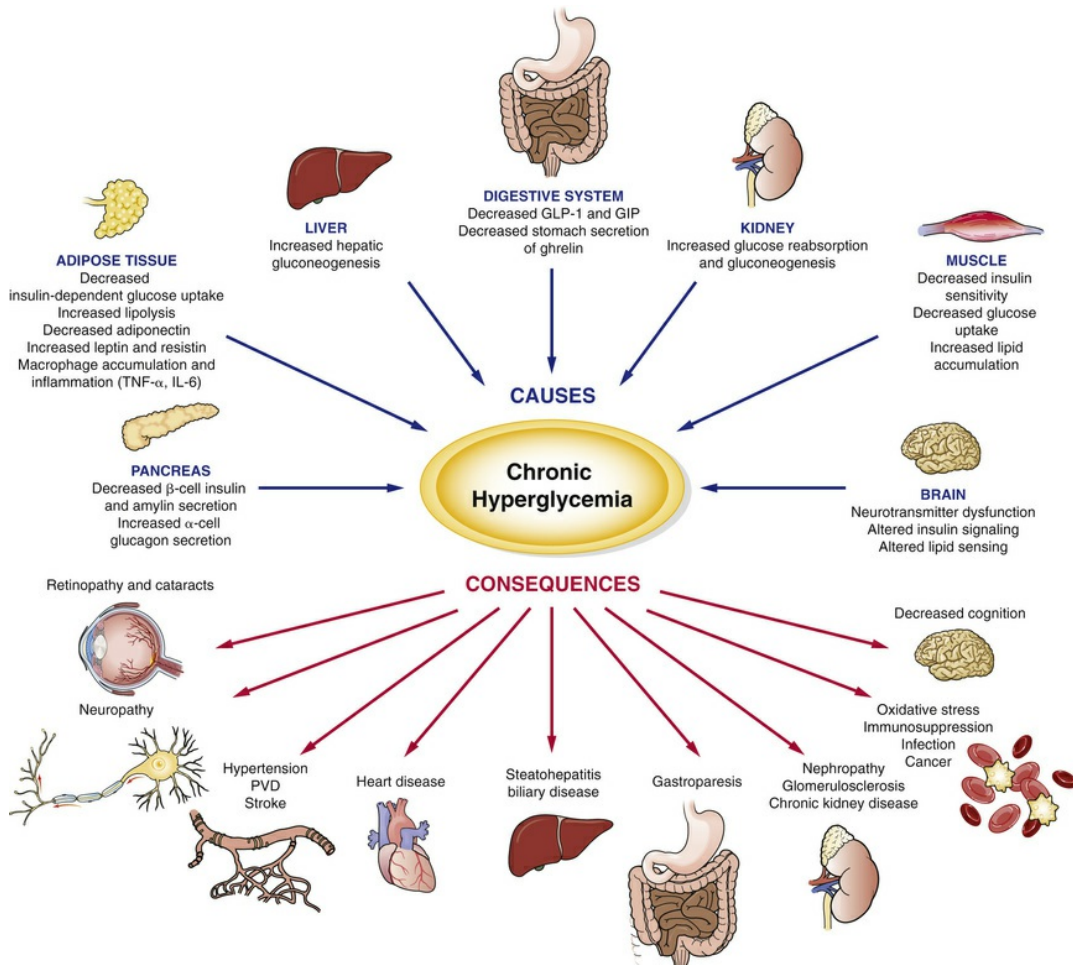

FIGURE 22.13 Multiorgan Causes and Common Consequences of Chronic Hyperglycemia in Type 2 Diabetes Mellitus. *GIP*, Gastric inhibitory peptide; *GLP-1*, glucagon-like peptide-1; *IL*, interleukin; *PVD*, peripheral vascular disease; *TNF*, tumor necrosis factor.

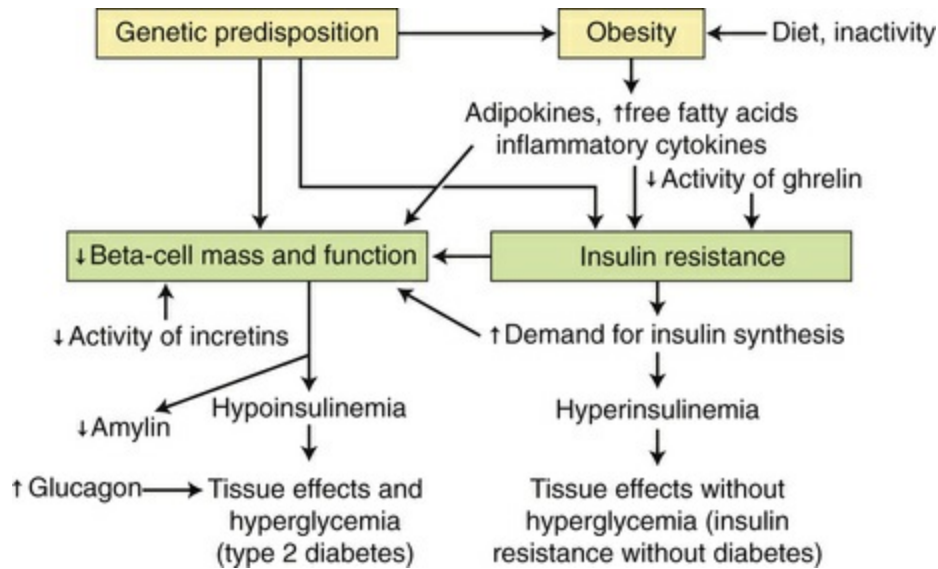

FIGURE 22.14 Pathophysiology of Type 2 Diabetes Mellitus.

Insulin resistance is defined as a suboptimal response of insulin-sensitive tissues (especially liver, muscle, and adipose tissue) to insulin and is associated with obesity. Several mechanisms are involved in abnormalities of the insulin signaling pathway and contribute to insulin resistance. These include an abnormality of the insulin molecule, high amounts of insulin antagonists, downregulation of the insulin receptor, decreased or abnormal activation of postreceptor kinases, and alteration of glucose transporter (GLUT) proteins.

Obesity is one of the most important contributors to insulin resistance and diabetes and acts through several important mechanisms:

1. Adipokines (leptin and adiponectin) are hormones produced in white adipose tissue. Obesity results in increased serum levels of leptin, decreased levels of adiponectin, and inflammation. These changes are associated with decreased insulin synthesis and insulin resistance.¹⁰⁵
2. Elevated levels of serum free fatty acids (FFAs) and intracellular deposits of triglycerides and cholesterol are found in obese individuals. These changes interfere with intracellular insulin signaling, decrease tissue responses to insulin, alter

- incretin action, promote inflammation, and cause apoptotic beta-cell death. This is known as *lipotoxicity*.¹⁰⁶
3. Obesity causes release of inflammatory cytokines (TNF- α , IL-6) from intraabdominal adipocytes or adipocyte-associated mononuclear cells and from activated macrophages that release inflammatory cytokines. These cytokines induce insulin resistance through a postreceptor mechanism and play an important role in the genesis of fatty liver, atherosclerosis, and dyslipidemia.¹⁰⁷
 4. Alterations in oxidative phosphorylation in cellular mitochondria have been documented, resulting in reduced insulin-stimulated mitochondrial activity and insulin resistance, especially in skeletal muscle and hepatocytes. However, the mechanisms are not clearly defined.¹⁰⁸
 5. Obesity is correlated with hyperinsulinemia and impaired insulin receptor signaling.¹⁰⁹

Compensatory hyperinsulinemia prevents the clinical appearance of diabetes for many years. Eventually, however, beta-cell dysfunction develops and leads to a relative deficiency of insulin activity. The islet dysfunction is caused by a combination of a decrease in beta-cell mass and a reduction in beta-cell function. A progressive decrease in the weight and number of beta cells occurs and many of the remaining cells develop “exhaustion” from increased demand for insulin biosynthesis.

Glucagon concentration is increased in type 2 DM because pancreatic alpha cells become less responsive to glucose inhibition, resulting in an increase in glucagon secretion. These abnormally high levels of glucagon increase blood glucose level by stimulating glycogenolysis and gluconeogenesis. As was discussed under type 1 DM, type 2 DM also is associated with a deficiency in amylin, further increasing glucagon levels.

Amylin (islet amyloid polypeptide) is another beta-cell hormone that is decreased in both type 1 and type 2 DM. Amylin increases satiety and suppresses glucagon release from the alpha cells. Amylin

contributes to islet cell destruction through the deposition of abnormal (misfolded) amyloid polypeptide within the pancreas.¹¹⁰ As in type 1 DM, pramlintide, a synthetic analog of amylin, is used for treatment in type 2 DM.

Hormones released from the gastrointestinal (GI) tract play a role in insulin resistance, beta-cell function, and diabetes.⁹⁸ **Ghrelin** is a peptide produced in the stomach and pancreatic islets that regulates food intake, energy balance, and hormonal secretion. Decreased levels of circulating ghrelin have been associated with insulin resistance and increased fasting insulin levels. Its use as a potential treatment for type 2 DM is being investigated.¹¹¹ The **incretins** are a class of peptides that are released from the GI tract in response to food intake and function to increase synthesis and secretion of insulin and beta-cell proliferation and regeneration, and protection against beta-cell damage. The most studied incretin is glucagon-like peptide 1 (GLP-1), and studies have demonstrated that beta-cell responsiveness to GLP-1 is reduced both in prediabetes and in type 2 diabetes.¹¹²

◆Clinical Manifestations.

Clinical manifestations of type 2 DM are nonspecific. The affected individual often is overweight, dyslipidemic, hyperinsulinemic, and hypertensive. Classic symptoms of polyuria and polydipsia may present, but more often individuals will have nonspecific symptoms such as fatigue, pruritus, recurrent infections, visual changes, or symptoms of neuropathy (paresthesias or weakness) (Table 22.8). In those whose diabetes has progressed without treatment, symptoms related to coronary artery, peripheral artery, and cerebrovascular disease may develop.

TABLE 22.8

CLINICAL MANIFESTATIONS AND RATIONALE FOR TYPE 2 DIABETES MELLITUS*

MANIFESTATION	RATIONALE
Recurrent infections (e.g., boils and carbuncles; skin infections) and prolonged wound healing	Growth of microorganisms is stimulated by increased glucose levels; impaired blood supply hinders healing; decline in immune protection

Genital pruritus	Hyperglycemia and glycosuria favor fungal growth; candidal infections, resulting in pruritus, are a common presenting symptom in women
Visual changes	Blurred vision occurs as water balance in the eye fluctuates because of elevated blood glucose levels; diabetic retinopathy is another cause of visual loss
Paresthesias	Paresthesias are common manifestations of diabetic neuropathies
Fatigue	Metabolic changes result in poor use of food products, contributing to lethargy and fatigue
Acanthosis nigricans	Brown to black pigmentation in body folds associated with insulin resistance

*Type 2 diabetes mellitus also can have symptoms of polyuria, polydipsia, polyphagia, and weight loss as in type 1 diabetes mellitus.

◆ Evaluation and Treatment.

The diagnostic criteria for type 2 DM are the same as those for type 1. The diagnostic criteria for prediabetes also have been defined (see [Box 22.2](#)). Prevention of type 2 DM, especially in those individuals with prediabetes, hinges on diet and exercise although there is increasing support for the use of some diabetes medications in high-risk individuals.¹¹³

As with type 1 DM, the goal of treatment for individuals with type 2 DM is the restoration of near-euglycemia (a normal blood glucose level) and correction of related metabolic disorders. Weight loss results in improved insulin sensitivity and glucose tolerance, preserves beta-cell function, and has an inhibitory effect on progression to type 2 DM. Diet should match activity levels and include more complex carbohydrates (rather than simple sugars), foods low in fats, adequate protein, and fiber. Bariatric surgery may be indicated for individuals with morbid obesity who are unresponsive to diet and exercise interventions, although long-term studies are needed to evaluate sustained effectiveness¹¹⁴ (see [What's New? Metabolic Surgery for the Treatment of Type 2 Diabetes](#)).

What's New?

Metabolic Surgery for the Treatment of Type 2 Diabetes

After over 20 years of study, international recommendations were issued in 2016 for the use of metabolic surgery for the treatment of type 2 diabetes. These recommendations state that surgery is indicated in those with either class III obesity (BMI ≥ 40 kg/m²) or class II obesity (BMI 35.0–39.9 kg/m²) when hyperglycemia is inadequately controlled by lifestyle and optimal medical therapy. Surgery can be considered for persons with diabetes who have a BMI of 30.0–34.9 kg/m² if hyperglycemia is inadequately controlled despite optimal treatment with either oral or injectable medications. Postoperatively, caloric restriction along with anatomic rearrangement of the intestinal tract and rapid gastric emptying initiate a series of complex changes in gut hormone physiology, neural inputs, and alterations in the gut microbiome. Changes have been documented in bile acid metabolism and GI tract nutrient sensing and absorption. Peptides associated with these changes include peptide YY, GIP, GLP-1 and -2, FGF-19, and oxyntomodulin. Systemic changes following surgery include decreased hepatic glucose production, enhanced insulin sensitivity, and improved beta-cell function. Long disease duration, insulin use, and low C-peptide levels are associated with higher rates of diabetes nonremission following surgery.

Data from Argyropoulos G: *Curr Diab Rep* 15(4):15, 2015; Batterham R, Cummings D: *Diabetes Care* 39(6):893–901, 2016; Corcelles R, Daigle CR, Schauer PR: *Eur J Endocrinol* 174(1):R19–R28, 2016; de Heide LJ, de Vries F, Lalmohamed A: *JAMA Surgery* 150(12):1126–1133, 2015; Esposito K et al: *Endocrine* 48(2):417–421, 2015; Holst J et al: *Diabetes Care* 39(6):884–892, 2016; Malkani S: *Curr Opinion Endocrinol Diabetes Obes* 22(2):98–105, 2015; Rubino F et al: *Diabetes Care* 39(6):861–877, 2016; Yska JP et al: *JAMA Surgery* 150(10):940, 2015.

Exercise reduces postprandial blood glucose levels, diminishes insulin requirements, lowers triglyceride and cholesterol levels, and increases the level of high-density lipoprotein (HDL) cholesterol.¹¹⁵

Hypoglycemia may result, however, when the exercising individual receives sulfonylurea or insulin therapy. Exercise also can be associated with a decreasing response of counter-regulatory hormones to hypoglycemia.¹¹⁶

For individuals who require further intervention, oral hypoglycemic agents are indicated. Currently, there are nine classes of oral agents available (Table 22.9). Metformin is considered the primary pharmacologic choice for the treatment of type 2 DM and a second oral agent, a GLP-1 receptor agonist, or basal insulin is added if the HbA_{1c} target is not maintained over 3 months.¹¹⁷ A combination of drugs may be required. Insulin therapy may be needed in the later stage of type 2 DM because of the loss of beta-cell function, which is progressive over time. Renal reabsorption of glucose through the sodium-glucose co-transporter 2 (SGLT2) is an important controller of serum glucose levels, and new medications aimed at blocking it have resulted in decreased measurements of blood glucose level, weight, blood pressure, and uric acid level. However, there is increased risk for ketoacidosis and the safety profile continues to be evaluated¹¹⁸ (see [What's New? Selective Sodium-Glucose Cotransporter 2 \[SGLT2\] Inhibitors for Type 2 Diabetes Mellitus Therapy](#)). There are standards of care to guide the management of type 2 DM.¹¹⁹

TABLE 22.9

TYPES OF ORAL HYPOGLYCEMIC DRUGS

DRUG TYPE	MECHANISMS OF METABOLIC CONTROL
α-Glycosidase inhibitor (miglitol and voglibose)	Delays carbohydrate absorption in gut by inhibiting disaccharidases
Biguanide (metformin)	Decreases hepatic glucose production and increases insulin sensitivity and peripheral glucose uptake
Meglitinides (glinides; repaglinide and nateglinide)	Stimulate insulin release from pancreatic beta cells
Sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)	Stimulate insulin release from pancreatic beta cells
Peroxisome proliferator-activated receptor-γ agonists (thiazolidinediones, pioglitazone, and rosiglitazone)	Increase insulin sensitivity, particularly in adipose tissue

Bile acid sequestrant (colesevelam)	Unknown; theories include decreased hepatic glucose production, increased insulin secretion, and increased incretin release
GLP-1 receptor agonists (exenatide and liraglutide)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite, weight loss
DPP-IV inhibitors (sitagliptin, saxagliptin, vildagliptin, and linagliptin)	Increase insulin secretion, decrease glucagon secretion, decrease rate of gastric emptying, decrease appetite
Amylin mimetics (pramlintide)	Decrease glucagon secretion, decrease rate of gastric emptying, and decrease appetite
SGLT2 inhibitor (sodium-glucose cotransporter 2); In clinical trials: canagliflozin, dapagliflozin, empagliflozin	Inhibits proximal tubular renal transport of glucose, decreasing glucose reabsorption and increasing renal excretion of glucose independent of insulin
Bromocriptine mesylate	Increases CNS dopamine, reducing sympathetic nervous activity, hepatic glucose production, and lipolysis

CNS, Central nervous system; *DPP-IV*, dipeptidyl peptidase-IV; *GLP-1*, glucagon-like peptide-1; *SGLT2*, sodium-glucose cotransporter 2.

Data from Brietzke SA: *Med Clin North Am* 99(1):87–106, 2015; Tran L et al: *Ann Pharmacother* 49(5):540–556, 2015.

What's New?

Selective Sodium-Glucose Cotransporter 2 (SGLT2) Inhibitors for Type 2 Diabetes Mellitus Therapy

Under normal conditions, the kidneys act to filter, reabsorb, and return to the circulation almost all of the glucose in the blood. Filtered glucose is actively reabsorbed by specific transporters located on the apical membrane of proximal tubular cells. These transporters are termed sodium-glucose cotransporters 1 and 2 (SGLT1 and -2). Approximately 90% of glucose is reabsorbed in the proximal renal tubule by SGLT2. The remaining 10% is reabsorbed lower in the tubule by SGLT1. Glucose reabsorption by SGLT2 continues even when plasma glucose levels are abnormally

elevated, and glucose begins to be excreted in the urine only once the renal threshold is exceeded (at about 180 to 200 mg/dL). Inhibition of SGLT2 prevents renal reabsorption of glucose and facilitates its excretion in the urine. With an increase in glucose excretion, individuals with type 2 diabetes experience weight loss and serum glucose levels fall independently of insulin levels or beta-cell function. SGLT2 inhibitors currently approved for use in the United States for type 2 diabetes include canagliflozin, empagliflozin, and dapagliflozin, either as monotherapy or as adjunctive therapy. Reduced drug effectiveness occurs in older individuals as well as individuals with impaired renal function, since the mode of action depends upon normal renal glomerular-tubular function. FDA warnings have been issued regarding adverse effects including ketoacidosis, serious urinary tract infections, increased rates of toe amputation, and increased risk of lowered bone density and fractures.

Other Specific Types of Diabetes Mellitus and Gestational Diabetes Mellitus

As listed in [Table 22.5](#), the American Diabetes Association (ADA) classification of DM mellitus encompasses not only the most common forms of diabetes (type 1 and type 2) but also “other specific types of DM” and “gestational DM.” Other specific types of diabetes include genetic defects in beta-cell function, genetic defects in insulin action, diseases of the exocrine pancreas (i.e., cystic fibrosis),

endocrinopathies, drug- or chemical-induced beta-cell dysfunction, infections, and other uncommon autoimmune and inherited disorders that are associated with diabetes. The best-described of these other specific types of diabetes is termed **maturity-onset diabetes of youth (MODY)**.¹²⁰ MODY classically presents as non-insulin-requiring diabetes in lean individuals typically younger than 25 with evidence of autosomal dominant inheritance.

MODY is a monogenic form of diabetes and accounts for 1% to 2% of diabetes and should be considered in children who lack beta-cell antibodies. It also may account for up to 5% of individuals diagnosed with gestational diabetes.¹²¹ MODY includes six specific autosomal dominant mutations, including genes for hepatocyte nuclear factor-1 α /4a (HNF-1 α /4a; *MODY 3* and *MODY 1*), glucokinase (*MODY 2*), and less commonly insulin promoter factor-1 (IPF-1; *MODY 4*), HNF-1 β (*MODY 5*), and NeuroD1 (*MODY 6*) important for the development or function of beta cells.¹²² The clinical diagnosis of MODY is based on the following criteria: family history of diabetes with an autosomal dominant mode of inheritance, insulin independence (nonketotic diabetes mellitus), and age at onset younger than 25 years. Genetic testing confirms the diagnosis. Management is similar to those techniques used for type 2 DM.

Gestational diabetes mellitus (GDM) has been defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, this definition meant that many women with previously undiagnosed type 1 or type 2 DM were diagnosed with GDM, and many of them had progressive disease after diagnosis. Therefore the American Diabetes Association (ADA) recommends that high-risk women found to have diabetes at their initial prenatal visit receive a diagnosis of type 1 or type 2 DM (FPG level >126 mg/dL [7.0 mmol/L] or a casual plasma glucose >200 mg/dL [11.1 mmol/L]) and not GDM.¹²³ GDM complicates approximately 7% of all pregnancies. The exact mechanism of GDM is unknown, but insulin resistance and inadequate insulin secretion are contributing factors both before and during pregnancy. Insulin sensitivity declines with advancing gestation in normal pregnancy, but euglycemia is

maintained by increased insulin secretion.¹²⁴ The ADA recommends that pregnant women with risk factors be screened for type 2 DM at their first prenatal visit. Those without a history of DM also should be screened with an oral glucose tolerance test at 24 to 28 weeks' gestation. Often there are no symptoms and careful glucose level control prenatally, during pregnancy, and after delivery is essential. Women who had a pregnancy affected by GDM and normal results on postpartum screening should be screened at 6 to 12 weeks after delivery with repeat testing every 1 to 3 years depending on risk factors.¹²³ GDM results in increased risk for type 2 DM and long-term metabolic and cardiovascular complications later in life for both mother and baby.¹²⁴

Acute Complications of Diabetes Mellitus

The major acute complications of DM are hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome. [Table 22.10](#) contains a comparison of complications of DM. Morning hyperglycemia in diabetic subjects may be caused by the Somogyi effect, the dawn phenomenon, or poor glycemic control. The **Somogyi effect** is the occurrence of hypoglycemia at about 3:00 AM caused by too much intermediate-acting insulin (i.e., NPH insulin) given at dinner time followed by rebound hyperglycemia caused by normal early morning secretion of counter-regulatory hormones (epinephrine, GH, corticosteroids), which are stimulated by hypoglycemia and cause gluconeogenesis. Excessive carbohydrate intake may contribute to the rebound hyperglycemia. The treatment is to decrease evening insulin level. The Somogyi effect is becoming much less common because of the increasing use of long-acting bioengineered insulins. The **dawn phenomenon** is an early morning rise in blood glucose concentration caused by nocturnal elevations of GH, which decreases metabolism of glucose by muscle and fat. Increasing the dose of evening insulin manages the problem.

TABLE 22.10

COMMON ACUTE COMPLICATIONS OF DIABETES MELLITUS (DM)

COMMON ACUTE COMPLICATIONS OF DIABETES MELLITUS (DM)

HYPOGLYCEMIA IN PERSONS WITH DM	DIABETIC KETOACIDOSIS	HYPERGLYCEMIC NONKETOTIC SYNDROMES
Synonyms		
Insulin shock, insulin reaction	Diabetic coma syndrome	Hyperosmolar hyperglycemia nonketotic coma
Persons at Risk		
Individuals taking insulin Individuals with rapidly fluctuating blood glucose levels Individuals with type 2 diabetes taking sulfonylurea agents	Individuals with type 1 diabetes Individuals with nondiagnosed diabetes	Older adults or very young individuals with type 2 diabetes, nondiabetic individuals with predisposing factors, such as pancreatitis; individuals with undiagnosed diabetes
Predisposing Factors		
Excessive insulin or sulfonylurea agent intake, lack of sufficient food intake, excessive physical exercise, abrupt decline in insulin needs (e.g., renal failure, immediately postpartum), simultaneous use of insulin-potentiating agents or beta-blocking agents that mask symptoms	Stressful situation such as infection, accident, trauma, emotional stress; omission of insulin; medications that antagonize insulin	Infection, medications that antagonize insulin, comorbid condition
Typical Onset		
Rapid	Slow	Slowest
Presenting Symptoms		
Adrenergic reaction: pallor, sweating, tachycardia, palpitations, hunger, restlessness, anxiety, tremors Neurogenic reaction: fatigue, irritability, headache, loss of concentration, visual disturbances, dizziness, hunger, confusion, transient sensory or motor defects, convulsions, coma, death	Malaise, dry mouth, headache, polyuria, polydipsia, weight loss, nausea, vomiting, pruritus, abdominal pain, lethargy, shortness of breath, Kussmaul respirations, fruity or acetone odor to breath	Polyuria, polydipsia, hypovolemia, dehydration (parched lips, poor skin turgor), hypotension, tachycardia, hypoperfusion, weight loss, weakness, nausea, vomiting, abdominal pain, hypothermia, stupor, coma, seizures
Laboratory Analysis		
Serum glucose <30 mg/dL in newborn (first 2–3 days) and <55–60 mg/dL in adults	Glucose levels >250 mg/dL, reduction in bicarbonate concentration; increased	Glucose levels >600 mg/dL, lack of ketosis, serum osmolarity >320 mOsm/L, elevated

	anion gap; increased plasma levels of β -hydroxybutyrate, acetoacetate, and acetone	blood urea nitrogen and creatinine
--	---	------------------------------------

Hypoglycemia

Hypoglycemia occurs when blood glucose levels are less than 47 mg/dL in newborns for the first 48 hours of life (clinical signs should also be considered)¹²⁵ and less than 70 mg/dL in children and adults. Its causes may be exogenous (medications, alcohol, or exercise), endogenous (tumors of the pancreas or inherited disorders), or functional (hyperalimentation, spontaneous, or liver disease). Hypoglycemia in diabetes is sometimes called *insulin shock* or *insulin reaction*. Individuals with type 2 diabetes are at less risk for hypoglycemia than those with type 1 diabetes because they retain relatively intact glucose counter-regulatory mechanisms. However, hypoglycemia does occur in type 2 DM when treatment involves SGLT2 inhibitors, GLP-1 receptor agonists, sulfonylureas, thiazolidinediones, and exogenous insulin, particularly when used in combination (see [Table 22.9](#)).

Symptoms of hypoglycemia result either from activation of the sympathetic nervous system (neurogenic adrenergic symptoms) or from an abrupt cessation of glucose delivery to the brain (neuroglycopenic symptoms), or both.^{126,127} Neurogenic reactions occur when the decrease in blood glucose level is rapid and presents with tachycardia, palpitations, diaphoresis, tremors, pallor, and arousal anxiety. Other symptoms include headache, dizziness, blurred vision, irritability, fatigue, poor judgment, confusion, hunger, seizures, and coma. Hypoglycemia unawareness is a phenomenon that occurs in individuals without appropriate autonomic warning symptoms, and recovery from hypoglycemia may be delayed because of impaired glycogenolysis and hampered delivery of gluconeogenic substrates to the liver.

Treatment requires immediate replacement of glucose either orally or intravenously. Glucagon for home use can be prescribed for

individuals who are at high risk.¹²⁸ Prevention is achieved with individualized management of medications and diet, monitoring of blood glucose levels, and education.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is a serious complication related to a deficiency of insulin and an increase in the levels of insulin counter-regulatory hormones (catecholamines, cortisol, glucagon, growth hormone). DKA occurs in approximately 30% of children with type 1 DM and 5% of children with type 2 DM.¹²⁹ DKA is most common in individuals with type 1 DM because insulin is more deficient. It rarely occurs in those with type 2 DM (called *ketosis-prone type 2 diabetes [KPD]*) and occurs most frequently in obese non-Hispanic blacks.¹³⁰ The most common precipitating factor for DKA is intercurrent illness, such as infection, trauma, surgery, or myocardial infarction. Poor adherence to insulin treatment or interruption of insulin administration also may result in DKA. Factors associated with increased risk are type 1 DM, poor glycemic control, younger or older age, diagnostic error, ethnic minority, lack of health insurance in the United States, lower body mass index, preceding infection, and delayed treatment.¹³¹

◆Pathophysiology.

The most important pathophysiologic mechanisms for DKA are insulin deficiency and an increase in counter-regulatory hormones, including catecholamines, cortisol, glucagon, and GH. The counter-regulatory hormones normally antagonize insulin by increasing glucose production and decreasing tissue use of glucose. Profound insulin deficiency results in decreased glucose uptake, increased fat mobilization with release of fatty acids, and accelerated gluconeogenesis, glycogenesis, and ketogenesis¹³² (Fig. 22.15). In the absence of insulin, the release of free fatty acids from adipocytes increases production of ketone bodies (acetoacetate, hydroxybutyrate, and acetone) by the mitochondria of the liver at a rate that exceeds peripheral use. Accumulation of ketone bodies causes a drop in pH

and triggers the buffering system associated with metabolic acidosis. DKA caused by increased levels of circulating ketones in the absence of the antilipolytic effect of insulin occurs. Relatively increased glucagon levels also contribute to activation of the gluconeogenic (glucose-forming) and ketogenic (ketone-forming) pathways in the liver. Ordinarily ketones are used by tissues as an energy source to regenerate bicarbonate. This balances the loss of bicarbonate, which occurs when the ketone is formed. Hyperketonemia (increased blood ketone levels) may result from impaired use of ketones by peripheral tissue, which permits strong organic acids to circulate freely. Bicarbonate buffering then does not occur, and the individual develops a metabolic acidosis.

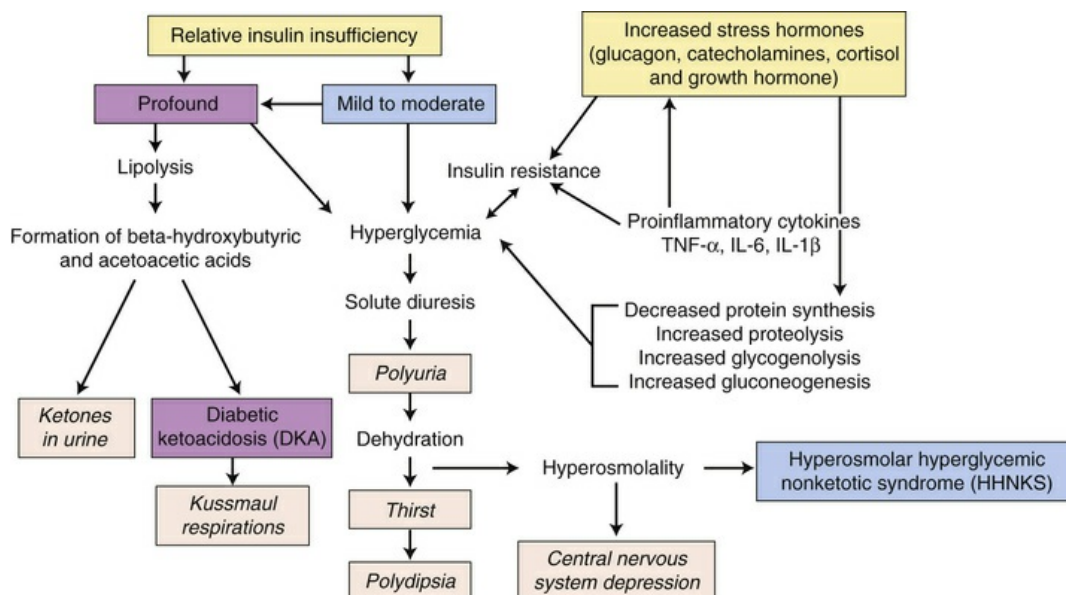

FIGURE 22.15 Pathophysiology of DKA and HHNKS in Diabetes Mellitus. See text for details. *DKA*, Diabetic keto-acidosis; *HHNKS*, hyperosmolar hyperglycemic non-ketotic syndrome; *IL-6*, interleukin-6; *IL-1β*; interleukin-1β; *TNF-α*, tumor necrosis factor-α.

◆ Clinical Manifestations.

The signs and symptoms of DKA include Kussmaul respirations (hyperventilation in an attempt to compensate for the acidosis), postural dizziness, central nervous system depression, ketonuria,

anorexia, nausea, vomiting, abdominal pain, an acetone odor on the breath, dehydration, thirst, and polyuria (see [Table 22.10](#)). Polyuria and dehydration result from the osmotic diuresis associated with hyperglycemia. In this case, the plasma glucose level is higher than the individual's renal threshold, allowing significant amounts of glucose to be lost in the urine. Deficits of sodium, phosphorus, and magnesium are common. The most important electrolyte disturbance is a marked deficiency in the level of total body potassium. Although the serum potassium concentration may appear normal or elevated because of volume contraction and a shift of potassium out of the cell and into the blood caused by metabolic acidosis, the total body deficiency of potassium may reach 3 to 5 mEq/kg.

◆ **Evaluation and Treatment.**

The diagnosis of DKA is suggested when individuals have symptoms described earlier. The American Diabetes Association criteria for the diagnosis of DKA are (1) a serum glucose level >250 mg/dL, (2) a serum bicarbonate level <18, (3) a serum pH <7.30, (4) the presence of an anion gap, and (5) the presence of urine and serum ketones.¹³³

Treatment of DKA involves administration of insulin to decrease glucose levels. Fluids are administered to replace lost fluid volume. Electrolyte deficits become apparent as fluid volume is replaced, and intravenous sodium, potassium, and phosphorus are administered as needed. Potassium moves with insulin into the cell and can contribute to hypokalemia. Volume status and serum electrolytes, particularly potassium, should be monitored closely. After the administration of insulin, the concentration of β -hydroxybutyrate promptly begins to decrease and, after a slight increase, acetoacetate concentration also begins to decrease. A persistent ketonuria may be observed for several days after treatment. Continuous monitoring of the individual is essential to ensure an uncomplicated recovery from DKA. Health teaching emphasizes predisposing factors and strategies for avoiding DKA.

Hyperosmolar Hyperglycemic Nonketotic

Syndrome

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS), or hyperglycemic hyperosmolar state (HHS), is an uncommon but significant complication of type 2 DM with a high overall mortality. It occurs more often in elderly individuals who have other comorbidities, including infections or cardiovascular or renal disease.

◆Pathophysiology.

HHNKS differs from DKA in the degree of insulin deficiency (which is more profound in DKA) and the elevation of glucose levels and degree of fluid deficiency (which are more marked in HHNKS) (see Fig. 22.15). HHNKS has synergistic factors, including insulin deficiency and increased levels of counter-regulatory or stress hormones (glucagon, catecholamines, cortisol, and growth hormone), with increased gluconeogenesis and glycogenolysis and inadequate use of glucose by peripheral tissues, primarily muscle, characterized by a lack of ketosis. Proinflammatory mediators (TNF- α , IL-6, IL-1 β) also promote insulin resistance and release of counter-regulatory hormones contributing to insulin resistance and hyperglycemia. Because the amount of insulin required to inhibit fat breakdown is less than that needed for effective glucose transport, insulin levels are sufficient to prevent excessive lipolysis but not to use glucose properly.¹³⁴

◆Clinical Manifestations.

Glycosuria and polyuria in HHNKS result from the extreme serum glucose level elevation. As much as 19 g of glucose per hour may be lost in diuresis, which causes severe volume depletion, increased serum osmolarity, intracellular dehydration, and loss of electrolytes including potassium. Neurologic changes, such as stupor, correlate with the degree of hyperosmolarity and are common in HHNKS; thus this syndrome is sometimes called *hyperosmolar hyperglycemic coma*.

◆Evaluation and Treatment.

The diagnostic features of HHNKS include a very high serum glucose

concentration (often more than 600 mg/dL), a near-normal serum bicarbonate level and pH, a serum osmolarity that is usually greater than 320 mOsm/L, and either absent or low levels of ketones in the urine and in the serum (lack of ketoacidosis). DKA and HHNKS show considerable overlap in symptoms and treatment. Insulin infusion should be combined with fluid repletion over 24 hours. An important distinction, however, is that the dehydration in HHNKS is far more severe than that in DKA. Thus fluid replacement, with both crystalloids and colloids, is more rapid. Potassium deficits may be extreme and require several days of treatment. Phosphorus and sodium also may be needed. HHNKS is a significant risk factor for infection, sepsis, and venous thrombosis. Mortality is between 10% and 20% and is related to the age of the individual and comorbid conditions, including the severity of the precipitating illness¹³⁴ (see [Table 22.10](#) for a comparison of the three acute complications described thus far).

Chronic Complications of Diabetes Mellitus

A number of serious complications are associated with any type of poorly controlled DM. Insulin resistance or deficit, chronic hyperglycemia (also known as *glucose toxicity*), accumulation of advanced glycation end products and activation of metabolic pathways that cause tissue damage result in the chronic complications of diabetes mellitus (see [Fig. 22.13](#)). These complications include microvascular (damage to capillaries including retinopathies, nephropathies, and neuropathies) and macrovascular disease (damage to larger vessels, including coronary artery disease, and peripheral vascular and cerebral vascular disease). Strict control of blood glucose level significantly reduces some complications, particularly nonfatal myocardial infarction. Strict control is not recommended for high-risk individuals with type 2 DM because it is associated with increased all-cause mortality, cardiovascular mortality, and severe hypoglycemia. However, the individual risk/benefit profile should be considered.¹³⁵

Oxidative stress (overproduction of reactive oxygen species),

activation of several complex metabolic pathways and inflammation have been associated with persistent hyperglycemia, insulin resistance, hyperinsulinemia, dyslipidemia, and the chronic complications of DM. They include shunting of glucose into the polyol pathway, activation of protein kinase C isoforms, increased formation of advanced glycation end products (AGEs), increased expression of the receptor for AGEs (RAGE), and increased activation of the hexosamine pathway.¹³⁶ It has been proposed that hyperglycemia induces mitochondrial overproduction of oxygen free radicals and this is a key pathologic mechanism for the activation of the metabolic pathways associated with atherogenesis and damage to large and small vessels.¹³⁶ Genetic and epigenetic factors also contribute to complications of DM.¹³⁷

Tissues that do not require insulin for glucose transport, such as the kidney, red blood cells (RBCs), blood vessels, eye lens, and nerves, cannot down-regulate the cellular uptake of glucose. Consequently, with hyperglycemia, intracellular glucose is shunted into an alternate metabolic pathway for glucose metabolism known as the **polyol pathway**. Overactivation of the polyol pathway results in two processes that may contribute to the complications of diabetes. One is the excessive accumulation of sorbitol (a polyol-sugar alcohol) through the action of the enzyme **aldose reductase**. The accumulated sorbitol increases intracellular osmotic pressure and attracts water in tissue. Swelling occurs along with visual changes and predisposition to cataracts in the lens of the eye. Sorbitol interferes with ion pumps in the nerves, damages Schwann cells, and disrupts nerve conduction. RBCs become swollen and stiff and interfere with perfusion. Second, activation of the polyol pathway reduces glutathione, an important antioxidant, contributing to oxidative injury in cells and tissues, particularly blood vessels. Aldose reductase inhibitors are being evaluated for treatment of these complications.¹³⁸

Protein kinase C (PKC) is a family of intracellular signaling proteins that can become inappropriately activated in different tissues by hyperglycemia. Intracellular hyperglycemia increases the second-messenger diacylglycerol (DAG)-PKC pathway, which in turn

activates protein kinase C. Various consequences have been observed, including insulin resistance, extracellular matrix and cytokine production, vascular cell proliferation, enhanced contractility, angiogenesis, and increased permeability. These effects may contribute to the microvascular complications of diabetes.¹³⁹

Glycation is a normal nonenzymatic process that involves the *reversible* attachment of glucose to proteins, lipids, and nucleic acids. With recurrent or persistent hyperglycemia, glucose becomes *irreversibly* bound to collagen and other proteins in red blood cells (e.g., glycated hemoglobin [HbA_{1c}] is used as a biomarker for diabetes), blood vessel walls, interstitial tissue, and within cells. The products of this binding are known as **advanced glycation end products (AGEs)**, and their receptor (RAGE). A number of properties may cause tissue injury or pathologic conditions associated with diabetes, such as:

1. Cross-linking and trapping of proteins, including albumin, low-density lipoprotein (LDL), immunoglobulin, and complement, with thickening of the basement membrane or increased permeability in small blood vessels and nerves
2. Binding to cell receptors, such as macrophages and glomerular mesangial cells, inducing release of inflammatory cytokines and growth factors that stimulate cellular proliferation in the glomeruli, smooth muscle of blood vessels, and collagen synthesis with fibrosis
3. Induction of lipid oxidation, oxidative stress, and inflammation
4. Inactivation of nitric oxide with loss of vasodilation and diminished endothelial function
5. Procoagulant changes on endothelial cells with promotion of platelet adhesion and reduced fibrinolysis, and/or
6. Promotion of beta-cell apoptosis and insulin resistance

Pharmacologic agents that inhibit AGE formation or block their receptor (RAGE) are used to treat type 2 DM.^{140,141}

Chronic intracellular hyperglycemia causes shunting of excess

intracellular glucose into the **hexosamine pathway** and leads to O-linked glycosylation (an enzymatic process) of several proteins with alteration in signal transduction pathways and oxidative stress. The O-linked attachment of *N*-acetylglucosamine (O-GlcNAc) on serine and threonine residues of nuclear and cytoplasmic proteins is associated with insulin resistance, oxidative stress, and vascular complications of DM.¹⁴²

Microvascular Disease

Diabetic microvascular complications (disease in capillaries) are a leading cause of blindness, end-stage kidney failure, and various neuropathies. Characteristics of diabetic microangiopathy include occlusion of capillaries with thickening of the capillary basement membrane, endothelial cell hyperplasia, thrombosis, and pericyte degeneration. Hypoxia and ischemia accompany microvascular disease, especially in the eye, kidney, and nerves. The frequency and severity of lesions appear to be proportional to the duration of the disease (more than 10 years) and the status of glycemic control. Many individuals with type 2 DM present with microvascular complications because of the long duration of asymptomatic hyperglycemia that generally precedes diagnosis. This underscores the need to screen for diabetes.

Diabetic Retinopathy.

Diabetic retinopathy is a leading cause of blindness worldwide. The retina is the most metabolically active structure per weight of tissue in the body. Thus the retina is a vulnerable target for neurovascular disease in DM.¹⁴³ In comparison to type 1 DM, retinopathy seems to develop more rapidly in individuals with type 2 DM because of the likelihood of long-standing hyperglycemia before diagnosis. Most individuals with diabetes will eventually develop retinopathy and they also are more likely to develop cataracts and glaucoma (see [Chapter 16](#)).

Diabetic retinopathy results from damage to retinal blood vessels and red blood cells (RBCs), platelet aggregation, relative hypoxemia

and hypertension. Three stages of retinopathy lead to loss of vision: *nonproliferative* (stage I), characterized by thickening of the retinal capillary basement membrane and an increase in retinal capillary permeability, vein dilation, microaneurysm formation, and superficial (flame-shaped) and deep (blot) hemorrhages; *preproliferative* (stage II), a progression of retinal ischemia with areas of poor perfusion that culminate in infarcts; and *proliferative* (stage III), the result of neovascularization (angiogenesis) and fibrous tissue formation within the retina or optic disc (see [Figs. 22.16](#) and [22.17](#), and [Table 22.11](#) for details). Traction of the new vessels on the vitreous humor may cause retinal detachment or hemorrhage into the vitreous humor with severe blurring or loss of vision. **Macular edema** (fluid accumulation and retinal thickening near the center of the macula) is the leading cause of visual impairment (blurring) among persons with diabetes. Blurring of vision also can be a consequence of hyperglycemia and sorbitol accumulation in the lens. Dehydration of the lens, aqueous humor, and vitreous humor also reduces visual acuity.¹⁴⁴ In addition to the ocular vasculopathy associated with hyperglycemia, activation of inflammatory cells (i.e., retinal glial and immune cells) and release of inflammatory mediators contribute to chronic neuroinflammation with injury to retinal sensory cells and loss of vision (optic neuropathy).¹⁴⁵ Cataracts and defects in eye muscle function also are associated with the chronic complications of hyperglycemia and diabetes mellitus.

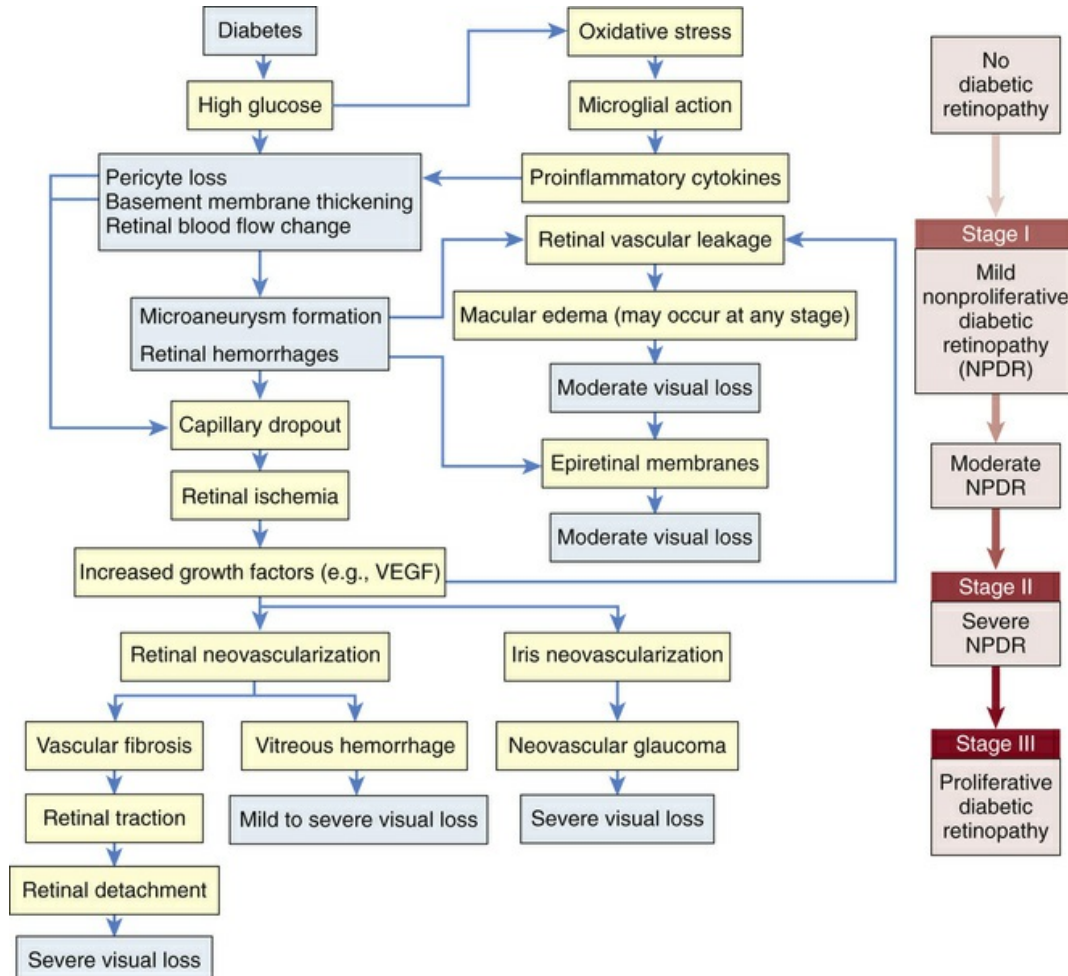

FIGURE 22.16 Pathophysiology of Diabetic Retinopathy. VEGF, Vascular endothelial growth factor. (Adapted from Mehmed S et al: *Williams textbook of endocrinology*, ed 12, Philadelphia, 2012, Saunders.)

FIGURE 22.17 Proliferative Diabetic Retinopathy. Neovascularization is present at the optic nerve (1) and along the vascular arcades (2). Retinal veins are engorged (3), and a preretinal hemorrhage (4) is present inferior to the fovea. This boat-shaped hemorrhage blocks the view of the retinal vessels. A more diffuse hemorrhage (5) is present in an arcuate pattern just inferior to the preretinal hemorrhage that represents a mild vitreous hemorrhage. A few small, hard exudates are visible in the fovea (6). (From Palay D, Krachmer J: *Ophthalmology*, ed 2, St Louis 2005, Mosby.)

TABLE 22.11

FINDINGS IN DIABETIC RETINOPATHY

STAGES OF RETINOPATHY	PATHOLOGIC FINDINGS
Nonproliferative Retinopathy (Stage I)	
Venous abnormalities	Increased tortuosity, dilation with irregular constriction; frequency increases with increased severity of retinopathy
Microaneurysms	Mostly thin walled; 15–50 mcg in diameter; pathogenesis controversial
Interretinal hemorrhage	Circular and small; may take several months to resorb
Macular edema	Caused by serum leakage through incompetent vessel walls; may resorb in several weeks
Hard exudates	Characteristically “hard” exudates with pattern of exudation irregular in shape and

	sharply defined may appear and disappear over months to years; common with hypertension; “soft” exudates may appear and disappear more often; related to increased retinal capillary permeability
Preproliferative Diabetic Retinopathy (Stage II)	
Cotton-wool patches	Infarcts of the nerve fiber layer caused by retinal ischemia
Intraretinal microvascular shunts	Tortuous shunts between patent and occluded retinal vessels
Proliferative Diabetic Retinopathy (Stage III)	
Neovascularization	New vessels surrounded by connective tissue; five distinct groups representing different hazards to the eye
Glial proliferation	Often produced to reinforce neovascularization; may occur on optic disc and along vascular arcades
Vitreoretinal traction hemorrhage; retinal detachment	Traction occurring from the vitreous jelly; eventually causes small blood vessels to hemorrhage and retinal detachment to occur

Diabetic Kidney Disease.

Diabetic kidney disease is the most common cause of chronic kidney disease and end-stage kidney disease. Approximately 50% of individuals with DM develop diabetic kidney disease.¹⁴⁶ Hyperglycemia leads to activation of the polyol pathway, the hexosamine pathway, protein kinase C, and inflammation, and the production of advanced glycation end products (AGEs). All contribute to kidney tissue injury; yet the exact process responsible for destruction of kidneys in diabetes is not clear.

The glomeruli are injured by protein denaturation, hyperglycemia with high renal blood flow (hyperfiltration), activation of the renin-angiotensin system, and production of angiotensin II resulting in intraglomerular hypertension exacerbated by systemic hypertension. Renal glomerular changes can occur early in diabetes mellitus and occasionally may precede the overt manifestations of the disease (Fig. 22.18). Progressive changes include glomerular enlargement, glomerular basement membrane thickening with proliferation of mesangial cells, and proliferation of the mesangial matrix. Later in the

disease, this results in diffuse and nodular glomerulosclerosis (Kimmelstiel-Wilson nodule), loss of podocytes, resistance to glomerular capillary blood flow, and decreased glomerular filtration rates (GFRs). Alterations in glomerular membrane permeability occur with loss of negative charge and albuminuria. Tubular and interstitial fibrosis contributes to loss of function.¹⁴⁷ The proximal tubule is particularly vulnerable because of its aerobic metabolism and high energy requirements.¹⁴⁸

FIGURE 22.18 Diabetic Kidney Disease. *GFR*, Glomerular filtration rate; *RBF*, renal blood flow.

Microalbuminuria (30 to 300 mg/day) is the first manifestation of

diabetic kidney dysfunction and develops within 5 to 10 years of disease. Before proteinuria, no clinical signs or symptoms of progressive glomerulosclerosis are likely to be evident. Later, hypoproteinemia, reduction in plasma oncotic pressure, fluid overload, anasarca (generalized body edema), and hypertension may occur. As renal function continues to deteriorate, individuals with type 1 DM may experience hypoglycemia (because of loss of renal insulin metabolism), which necessitates a decrease in insulin therapy. As the glomerular filtration rate drops below 10 mL/minute, uremic signs, such as nausea, lethargy, acidosis, anemia, and uncontrolled hypertension, occur (see [Chapter 39](#) for a discussion of renal failure). Glomerular filtration rate can decline independently of albuminuria, particularly in type 1 DM.¹⁴⁹ Macroalbuminuria (greater than 300 mg per day) is strongly correlated with morbidity and mortality from cardiovascular disease, particularly in type 2 DM. Early diagnosis and control of hypertension and hyperglycemia decrease the severity of nephropathy and delay the onset of end-stage kidney disease.¹⁵⁰

The development of more sensitive tests has permitted the detection of microalbuminuria. Earlier intervention with tight glucose control and angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers can reduce proteinuria and slow the progression of nephropathy. Newer agents are being evaluated, including renin inhibitors or aldosterone blockers and antiinflammatory agents.¹⁵¹ Aggressive treatment of hypertension is another therapeutic intervention definitively shown to decrease albuminuria of established renal disease, but it has not reduced progression to end-stage renal disease and the need for renal replacement therapy.¹⁵²

Diabetic Neuropathies.

Diabetic neuropathy is the most common cause of neuropathy in the Western world and is probably the most common complication of diabetes. Nerves do not require insulin for glucose transport and are particularly vulnerable to the pathologic effects of chronic hyperglycemia. Peripheral neuropathy affects up to 50% of individuals with diabetes and is more common in type 2 DM.¹⁵³ The

American Diabetes Association has published a guideline to assist clinicians with the prevention, diagnosis, and management of diabetic neuropathy.¹⁵⁴

The underlying pathologic mechanism includes both metabolic and vascular factors related to chronic hyperglycemia with inflammation, ischemia, oxidative stress, advanced glycation end products, and increased formation of polyols contributing to demyelination, nerve degeneration, and delayed conduction¹⁵⁵ (Fig. 22.19). The earliest morphologic change is axonal degeneration that preferentially involves sensory nerve fibers, particularly the smaller polymodal unmyelinated peripheral C fibers and the larger myelinated A δ fibers. The metabolic activity of Schwann cells is disturbed, causing segmental loss of myelin and a characteristic pattern of demyelination and remyelination observed in long-term diabetic neuropathy. Nerve degeneration begins in the periphery, but the pathologic condition also can include the spinal cord and the posterior root ganglia. These changes may occur alone or in combination. Both somatic and peripheral nerve cells show diffuse or focal damage resulting in polyneuropathy. Sensory deficits generally precede motor involvement. The extremities are involved first in a “stocking and glove” pattern.

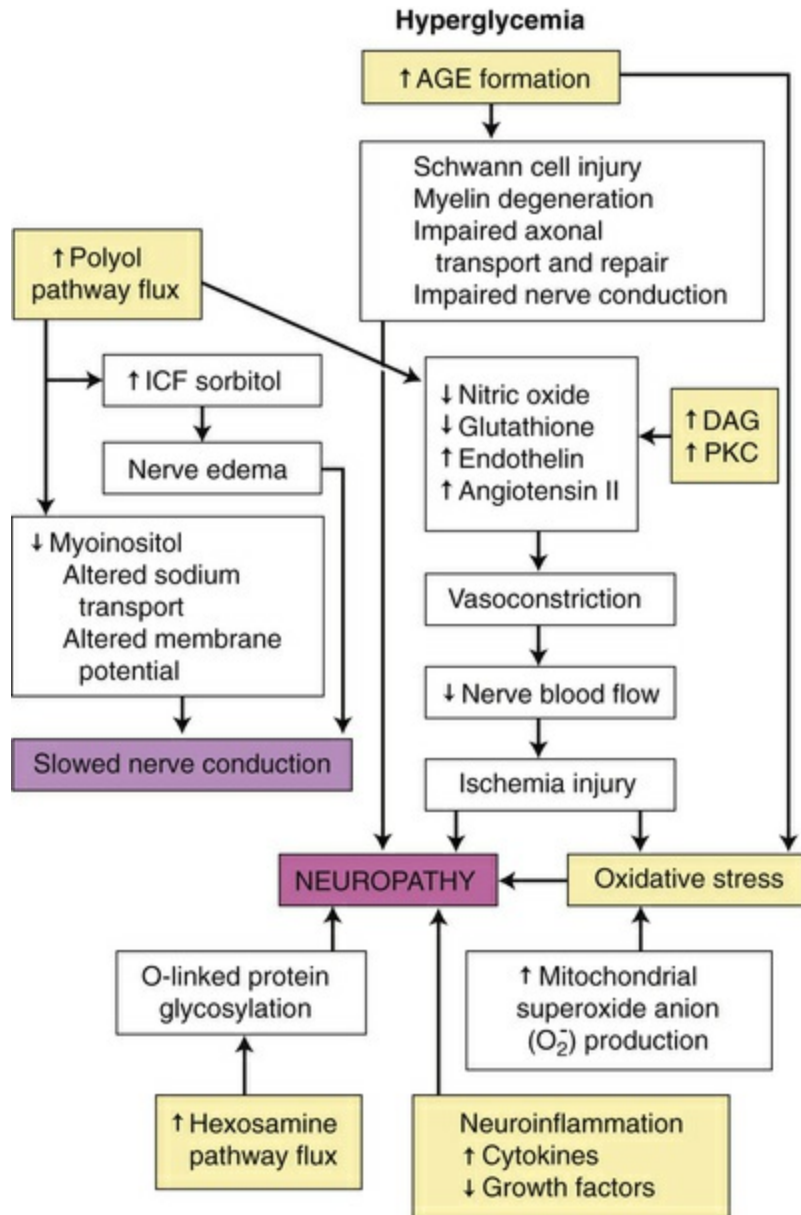

FIGURE 22.19 Multifactorial Pathogenesis of Diabetic Neuropathy. The yellow boxes represent the consequences of chronic hyperglycemia in the development of neuropathy. AGE, Advanced glycation end product; DAG, diacylglycerol; ICF, intracellular fluid; PKC, protein kinase C.

Distal symmetric polyneuropathy (sensory, autonomic, and motor nerve involvement) is the most common neuropathy with involvement of both large and small nerve fibers (Table 22.12). Loss of small nerve fiber function includes neuropathic pain and loss of sensation, and carries high risk for development of foot ulceration with subsequent gangrene and amputation. Large nerve fiber involvement results in sensory loss of proprioception and vibration

with ataxia, loss of coordination, and risk for falls and fractures. Motor involvement is less common and occurs later in the disease with weakness and muscle atrophy, particularly in the lower legs and feet.¹⁵⁶

TABLE 22.12

CLASSIFICATION OF DIABETIC NEUROPATHIES

TYPE OF NEUROPATHY	CHARACTERISTICS
Hyperglycemic neuropathy	Hyperesthesia, tingling and pain associated with hyperglycemia that resolves with glycemic control
Distal symmetric polyneuropathy (sensorimotor neuropathy)	Symmetric loss of large and small myelinated and unmyelinated nerve fibers Longest nerves affected first with numbness, tingling, and pain (sharp, burning, aching) in toes and feet and then ascending to hands (stocking and glove pattern); loss of vibration and proprioception (large nerve fiber); loss of sensory light touch and temperature and pain (small nerve fiber) Motor nerves affected later with weakness, depressed reflexes, and gait disturbances
Autonomic neuropathy	Cardiovascular: postural hypotension; exercise intolerance; silent myocardial infarction Gastrointestinal: decreased esophageal motility, gastroparesis and delayed gastric emptying, diabetic constipation or diarrhea Genitourinary tract: neurogenic bladder, urine retention, erectile dysfunction and retrograde ejaculation in men Sudomotor: anhidrosis, gustatory sweating Cranial nerve III: pain and ptosis and may spare the pupil
Mononeuropathies (focal neuropathies)	Compression and entrapment syndromes: carpal tunnel syndrome, radial nerve (wristdrop), peroneal nerve (footdrop), femoral nerve Cranial neuropathies: cranial nerve III, pain and ptosis and may spare the pupil Truncal mononeuropathy: abdominal or lower chest pain or hyperesthesia, abdominal muscle weakness Asymmetric lower limb neuropathy (diabetic amyotrophy; diabetic polyradiculopathy): involvement of lower thoracic and lumbar nerve roots (upper leg weakness, upper leg muscle atrophy, diminished knee and ankle tendon reflexes); may have paresthesia, hyperesthesia, pain
Prediabetic neuropathy	Same presentation as distal symmetric polyneuropathy primarily involving the feet and ankles and occurring in individuals with prediabetes; may predate the onset of clinical diabetes by several years

Autonomic neuropathies can occur early, affecting gastrointestinal

enteric nerves (nausea, bloating, gastroparesis, diarrhea, or constipation), bladder and sexual function (loss of bladder sensation, urine retention, recurrent infection, erectile dysfunction), sweating, and body temperature regulation. Cardiovascular autonomic neuropathy is a serious complication with heart rate variability, changes in baroreceptor reflexes, postural hypotension, dysrhythmias, exercise intolerance, painless myocardial infarction, and sudden death.¹⁵⁷

Alterations in cognitive function and increased risk for dementia may accompany long-term complications in the brain, particularly in persons with type 2 diabetes. The specific neurodegenerative mechanisms are not clear.¹⁵⁸

Charcot neuroarthropathy (Charcot joint) is the progressive degeneration and structural disorganization of a joint, particularly in the foot and ankle of individuals affected by long-term diabetes. The pathogenesis may be related to inflammation, loss of sensation, and neurally mediated vascular alterations with osteoclastic bone resorption.¹⁵⁹

Macrovascular Disease

Diabetic macrovascular disease (lesions in large and medium-sized arteries) increases morbidity and mortality and increases risk for hypertension, accelerated atherosclerosis, cardiovascular disease, stroke, and peripheral vascular disease, particularly among individuals with type 2 DM. Children with poorly controlled diabetes, particularly type 2 DM, have high risk for macrovascular disease within one or two decades.¹⁶⁰ Unlike microangiopathy, atherosclerotic disease is unrelated to the severity of diabetes and is often present in those with insulin resistance and impaired glucose tolerance.¹⁶¹ The premature atherosclerosis of diabetes has many contributing factors, including hyperinsulinemia (insulin resistance), hyperglycemia, hypertriglyceridemia, low levels of high-density lipoprotein (HDL), high levels of low-density lipoprotein (LDL), lipoprotein oxidation, and platelet abnormalities. Advanced glycosylated end products attach to their receptor (RAGE) in the walls of blood vessels,

promoting oxidative stress, inflammation, endothelial and vascular smooth muscle dysfunction, and thrombosis (Fig. 22.20). The process tends to be more severe and accelerated with the presence of other risk factors, including hyperlipidemia, hypertension, and smoking.¹⁶²

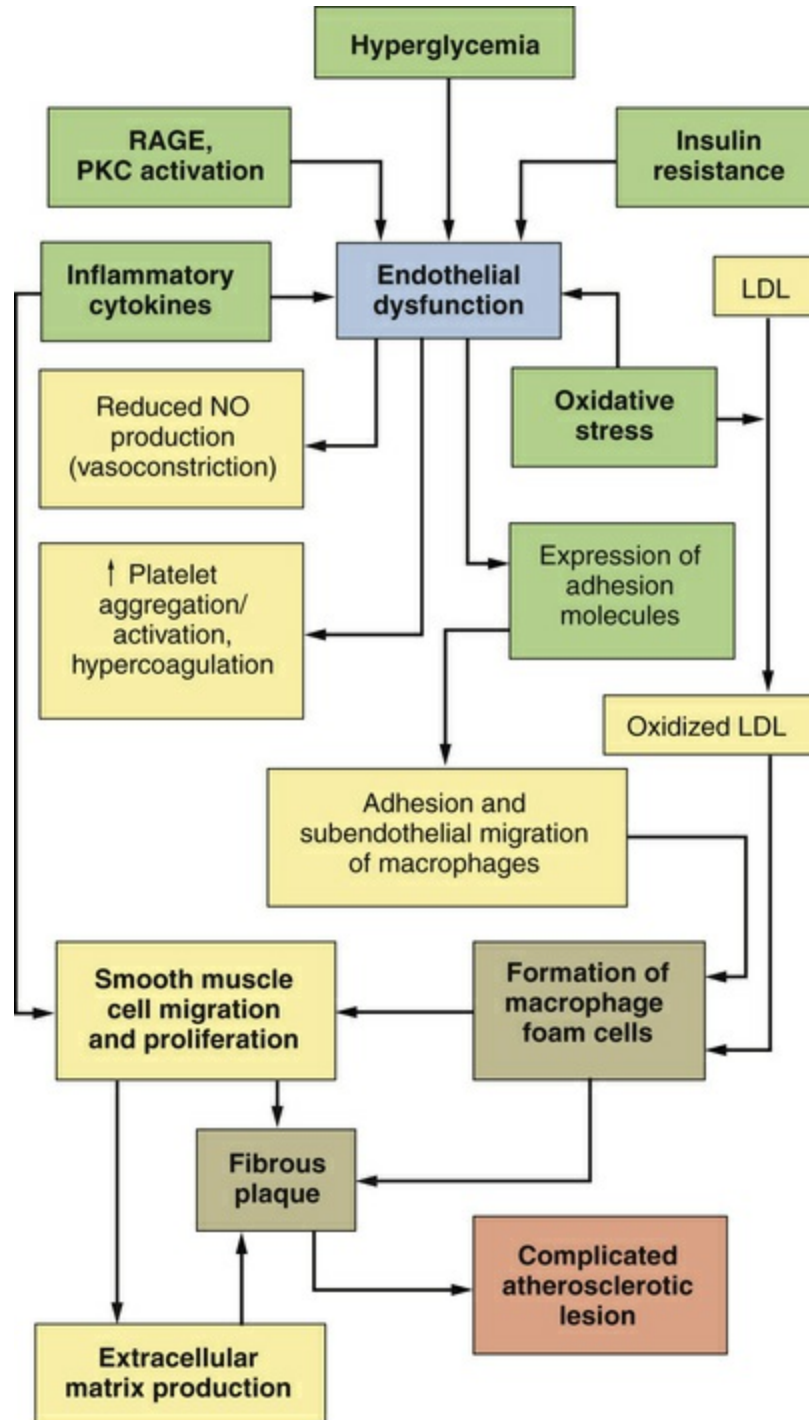

FIGURE 22.20 Diabetes Mellitus and Atherosclerosis. Diabetes with its associated hyperglycemia, relative hypoinsulinemia, oxidative stress, and proinflammatory state contributes to atherogenesis by causing arterial endothelial dysfunction (impaired vasodilation and adhesion of inflammatory cells), dyslipidemia, and smooth muscle proliferation. *LDL*, Low-density lipoprotein; *NO*, nitric oxide; *PKC*, protein kinase; *RAGE*, receptor for advanced glycation end product. (Data from D'Souza A et al: *Mol Cell Biochem* 331[1-2]:89-116, 2009; Stratmann B, Tschoepe D: *Best Pract Res Clin Endocrinol Metab* 23[3]:291-303, 2009.)

Cardiovascular Disease.

Cardiovascular disease is the ultimate cause of death in up to 68% of people with diabetes, with higher risk for women.¹⁶³ Hypertension often coexists with DM, is more prevalent than in the nondiabetic population, and can have many causes. In type 1 DM, hypertension is associated with the development of microalbuminuria. In type 2 DM, hypertension is associated with metabolic syndrome (see [Box 22.3](#)). Hypertension increases the risk for coronary artery disease and stroke. Coronary artery disease (CAD) is the most common cause of morbidity and mortality in individuals with DM (heart disease is described in [Chapter 33](#)). In general, the prevalence of CAD increases with the duration but not the severity of diabetes and the onset can be silent. Myocardial infarction (death of heart muscle as a result of coronary artery occlusion) is the cause of death in up to 75% of those with diabetes. Individuals with diabetes mellitus have a higher mortality during the acute phase of myocardial infarctions than do nondiabetic individuals because they are often asymptomatic as a result of sensory and autonomic neuropathy.¹⁶⁴ Guidelines have been developed to reduce the risk and improve treatment of cardiovascular and coronary artery disease in individuals with diabetes.¹⁶⁵

The incidence of *congestive heart failure* is higher in individuals with diabetes, even without myocardial infarction. This may be related to oxidative stress, proinflammatory factors that result in myocardial remodeling and cardiomyopathy with increased amounts of collagen in the ventricular wall, and ventricular hypertrophy. There is reduced mechanical compliance of the heart during filling with diastolic and, eventually, systolic failure.¹⁶⁶

Stroke.

Stroke is twice as common in those with diabetes (particularly type 2 DM) as in the nondiabetic population and more common in diabetic women.¹⁶⁷ Ischemic and lacunar stroke are more common than hemorrhagic stroke and may be related to autonomic nervous system (ANS) neuropathy-associated atrial fibrillation and platelet

coagulopathy, in addition to other risk factors.¹⁶⁸ The survival rate for an individual with diabetes after a massive stroke is typically shorter than that for nondiabetic individuals. Hypertension, hyperglycemia, hyperlipidemia, thrombosis, and sleep apnea are risk factors (see [Chapters 16](#) and [33](#)), and aggressive management of blood pressure, hyperglycemia, and lipidemia in individuals with diabetes has been shown to reduce the incidence of stroke.¹⁶⁹

Peripheral Artery Disease.

Peripheral vascular disease is an atherosclerotic occlusive disease of the lower extremity. DM increases the incidence of peripheral artery disease (PAD) with claudication (pain from reduced blood flow during exercise), ulcers, gangrene, and amputation¹⁷⁰ (see [Chapter 33](#)). Age, duration of diabetes, glycemic control, genetics, and additional risk factors (smoking, hyperlipidemia, hypertension) influence the development and management of PAD.¹⁷¹ Occlusions of the small arteries and arterioles, particularly below the knee, cause most of the gangrenous changes of the lower extremities and occur in patchy areas of the feet and toes. The lesions begin as ulcers and progress to osteomyelitis or gangrene requiring amputation. Peripheral neuropathies and increased risk for infection advance the disease. [Fig. 22.21](#) illustrates how foot lesions of diabetes can lead to amputation. Significant morbidity and mortality are associated with major amputation.¹⁷²

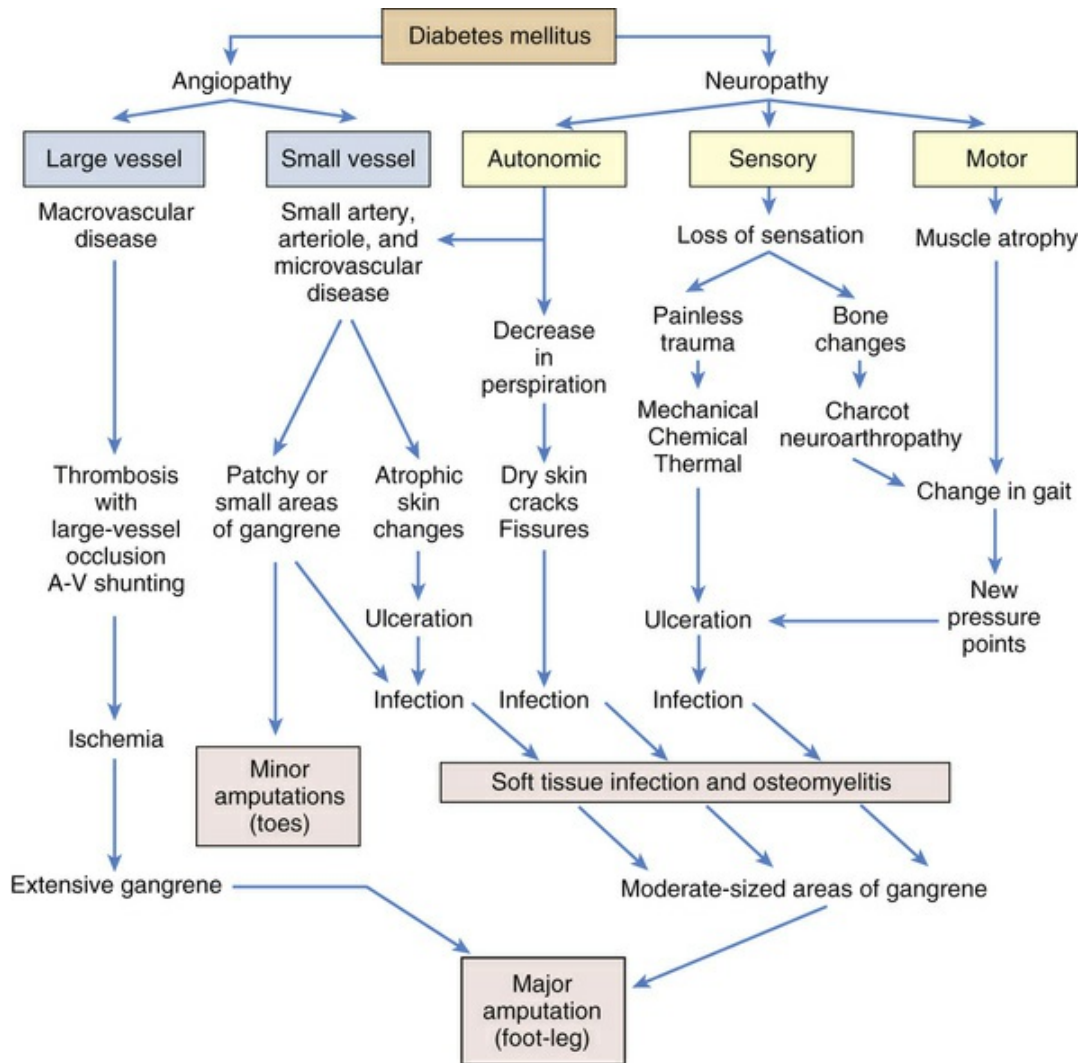

FIGURE 22.21 How Foot Lesions of Diabetes Can Lead to Amputation. A-V, Arteriovenous. (From Levin ME, O'Neal LW, Bowker JH: *The diabetic foot*, ed 5, St Louis, 1993, Mosby.)

Infection

Increased morbidity and mortality from infectious agents have been documented in those with diabetes.¹⁷³ The individual with diabetes is at increased risk for infection for several reasons:

1. *The senses.* Impaired vision caused by retinal changes and impaired touch caused by sensory neuropathy lead to loss of protection with injury.
2. *Hypoxia.* Once skin integrity is compromised, tissues'

susceptibility to infection increases as a result of vascular disease and hypoxia. In addition, the glycosylated hemoglobin in the RBCs impedes the release of oxygen to tissues.

3. *Pathogens*. Some pathogens proliferate rapidly because of increased levels of glucose in body fluids, which provides an excellent source of energy.
4. *Blood supply*. Decreased blood supply results from vascular changes and autonomic dysfunction, which decreases the supply of white blood cells to the affected area.
5. *Suppressed immune response*. Chronic hyperglycemia impairs both the innate and the adaptive immune responses, including abnormal chemotaxis, vasoactive responses, and defective phagocytosis. Clinical signs of infection may be absent.
6. *Delayed wound healing*. Slower collagen synthesis and decreased angiogenesis increase the opportunity for infection.

The risk of infection is especially high for individuals who take immunosuppressant medications, who have comorbidities, or who are undergoing surgery.¹⁷⁴⁻¹⁷⁶

Alterations of Adrenal Function

Disorders of the Adrenal Cortex

Disorders of the adrenal cortex are related to either hyperfunction or hypofunction. Hyperfunction that causes increased secretion of cortisol (**hypercortisolism**) leads to Cushing disease or Cushing syndrome. Hyperfunction that causes increased secretion of adrenal androgens and estrogens leads to virilization or feminization. Hyperfunction that causes increased levels of aldosterone leads to hyperaldosteronism, which may be primary or secondary. These syndromes often have overlapping features. Hypofunction of the adrenal cortex leads to Addison disease.

Hypercortical Function: Cushing Disease,

Cushing Syndrome

Cushing syndrome refers to the clinical manifestations resulting from chronic exposure to excess endogenous cortisol and is more common in women. **Cushing disease** refers to excess endogenous secretion of ACTH (corticotropin).¹⁷⁷ *ACTH-dependent hypercortisolism* (about 80%) results from overproduction of pituitary ACTH by a pituitary adenoma (most common and can occur at any age) or by an ectopic secreting nonpituitary tumor, such as a small cell carcinoma of the lung (more common in older adults). *ACTH-independent hypercortisolism* (about 20%) is caused by cortisol secretion from a rare benign or malignant tumor of one or both adrenal glands (more common in children). A **Cushing-like syndrome** may develop as a side effect of long-term pharmacologic administration of glucocorticoids.

◆Pathophysiology.

With ACTH-dependent hypercortisolism, the excess ACTH stimulates excess production of cortisol and there is loss of feedback control of ACTH secretion. Whatever the cause, two observations consistently apply to individuals with Cushing syndrome: (1) they do not have diurnal or circadian secretion patterns of ACTH and cortisol, and (2) they do not increase ACTH and cortisol secretion in response to a stressor.¹⁷⁸ In individuals with ACTH-dependent hypercortisolism, secretion of both cortisol and adrenal androgens is increased, and corticotropin-releasing hormone (CRH) secretion is inhibited.

ACTH-independent secreting tumors of the adrenal cortex, however, generally secrete only cortisol. Elevated cortisol levels suppress CRH and ACTH secretion from the hypothalamus and anterior pituitary, respectively, which leads to low levels of ACTH. Low levels of ACTH cause atrophy of the remaining normal portions of the adrenal cortex, which over time will alter the cortisol-secreting activity of normal cells. When the secretion of cortisol by the tumor exceeds normal cortisol levels, symptoms of hypercortisolism develop.¹⁷⁹

◀Clinical Manifestations.

Weight gain is the most common feature and results from the accumulation of adipose tissue in the trunk, facial, and cervical areas. These characteristic patterns of fat deposition have been described as “truncal [central] obesity,” “moon face,” and “buffalo hump” (Figs. 22.22 and 22.23). Transient weight gain from sodium and water retention may be present because of the mineralocorticoid effects of cortisol, exhibited when cortisol is present in high levels.

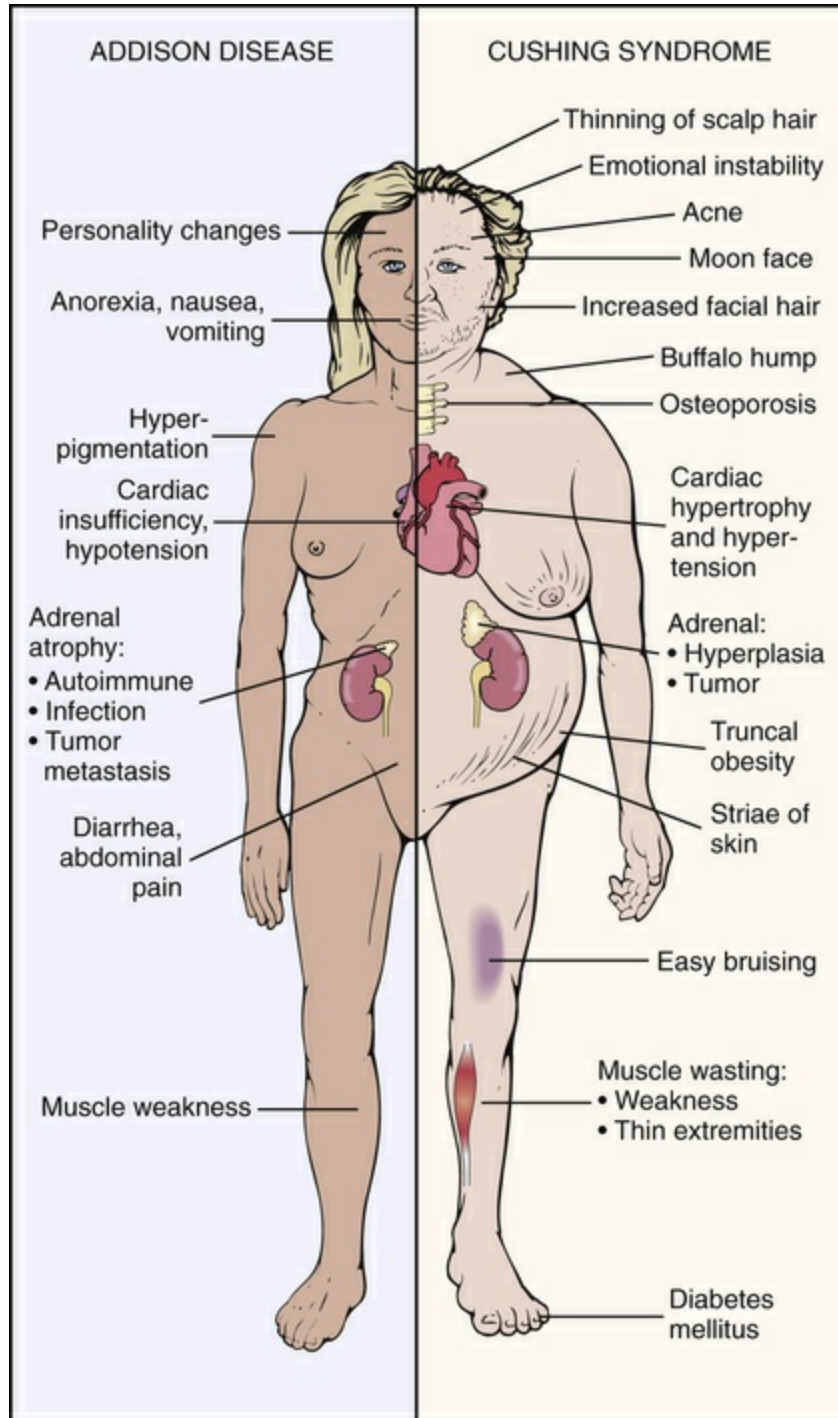

FIGURE 22.22 Symptoms of Addison and Cushing Diseases. (From Goodman CC, Kelly Snyder TE: *Differential diagnosis for physical therapists*, ed 5, Philadelphia, 2013, Saunders.)

FIGURE 22.23 Cushing Syndrome. A, Patient before onset of Cushing syndrome. B, Patient 4 months later. Moon facies is clearly demonstrated. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis*, ed 6, London, 2012, Saunders.)

Glucose intolerance occurs because of cortisol-induced insulin resistance and increased gluconeogenesis and glycogen storage by the liver. Overt diabetes mellitus develops in approximately 20% of individuals with hypercortisolism. Polyuria is a manifestation of hyperglycemia and resultant glycosuria.

Protein wasting is caused by the catabolic effects of cortisol on peripheral tissues. Muscle wasting leads to muscle weakness and is especially obvious in the muscles of the extremities, with thinning of the limbs. In bone, loss of the protein matrix and increases in bone resorption lead to osteoporosis and can result in pathologic fractures, vertebral compression fractures, bone and back pain, kyphosis, and reduced height. Hypercalciuria may result in renal stones, which are experienced by approximately 20% of individuals with this disease. Loss of collagen also leads to thin, weakened integumentary tissues through which capillaries are more visible; the tissues are easily stretched by adipose deposits. Together these changes account for the characteristic purple striae most often observed in the truncal area. Loss of collagenous support around small vessels makes them susceptible to rupture, leading to easy bruising, even with minor trauma. Thin, atrophied skin is also easily damaged, leading to skin breaks and ulcerations. Bronze or brownish hyperpigmentation of the skin, mucous membranes, and hair occurs when there are very high levels of ACTH. This is caused by increased levels of melanocyte-stimulating hormones resulting from excess conversion of pro-opiomelanocortin when ACTH concentration is elevated.¹⁸⁰

With elevated cortisol levels, vascular sensitivity to catecholamines is increased significantly, leading to vasoconstriction and hypertension. Metabolic syndrome with abdominal obesity, hypertension, glucose intolerance, and dyslipidemias is a common complication (see [Box 22.3](#)). Individuals with hypercortisolism are at increased risk for cardiovascular complications (CAD, heart failure, and stroke).^{181,182} Chronically elevated cortisol levels also cause suppression of the immune system, increased susceptibility to infections, and poor wound healing.

Approximately 50% of individuals with hypercortisolism experience alterations in their mental status, caused by the effects of cortisol on hippocampal neurons and the subsequent implications on learning, memory, and other neurologic functions when cortisol levels are elevated. These may range from irritability and depression to severe psychiatric disturbances, such as schizophrenia, which

improve with treatment.^{183,184}

Females may experience symptoms of increased adrenal androgen levels, increased hair growth (especially facial hair), acne, and oligomenorrhea. Rarely do androgen levels become high enough to cause changes of the voice, recession of the hairline, and hypertrophy of the clitoris unless an adrenal carcinoma is involved. Infertility is more common among women.¹⁸⁵

◆Evaluation and Treatment.

A variety of laboratory tests must be used to diagnose hypercortisolism to determine the underlying disorder and differentiate ACTH-dependent (ACTH measurable) from ACTH-independent (ACTH not measurable) Cushing disease. These tests include urinary and serum cortisol and serum ACTH concentration. Other tests include the dexamethasone suppression test and bilateral inferior petrosal sinus sampling. Late night salivary cortisol levels are used as a screening test and to document alterations in the diurnal variation of cortisol level. Routine laboratory examinations may reveal hyperglycemia, glycosuria, hypokalemia, and metabolic alkalosis. Tumors are diagnosed using imaging procedures.¹⁸⁶

Treatment is specific for the cause of hypercorticoadrenalism and includes medication, radiation, and surgery. Differentiation among pituitary, ectopic, and adrenal causes is essential for effective treatment. Without treatment, approximately 50% of individuals with Cushing syndrome die within 5 years of onset as a result of overwhelming infection, suicide, complications from generalized arteriosclerosis, and hypertensive disease. Guidelines are available for the treatment of Cushing syndrome.¹⁸⁷

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is an autosomal recessive disorder that causes the deficiency of an enzyme that is critical in cortisol biosynthesis. Because cortisol production is low, ACTH concentration increases and causes trophic adrenal hyperplasia. The most common form is a 21-hydroxylase deficiency (90%) that results in both

mineralocorticoid and glucocorticoid deficiency and adrenal androgen synthesis. Affected female infants are virilized and infants of both sexes exhibit salt wasting. Neonatal screening includes measurement of 17-hydroxyprogesterone. Treatment includes avoidance of glucocorticoid overtreatment and management of sex steroid excess.¹⁸⁸

Hyperaldosteronism

Hyperaldosteronism is characterized by excessive aldosterone secretion by the adrenal cortex. There are both primary and secondary forms of hyperaldosteronism. Primary hyperaldosteronism (Conn syndrome, primary aldosteronism) is caused by excessive secretion of aldosterone from an abnormality of the adrenal cortex. Secondary hyperaldosteronism (secondary aldosteronism) involves excessive aldosterone secretion from an extra-adrenal stimulus.

◆Pathophysiology.

Primary hyperaldosteronism (Conn syndrome, primary aldosteronism) is usually the result of a unilateral benign aldosterone-producing adrenal adenoma (Fig. 22.24). Bilateral adrenal nodular hyperplasia and adrenal carcinomas account for the remainder of cases. The incidence is estimated to be about 10% of all hypertensive individuals; however, approximately 33% of people with resistant hypertension will have evidence of primary hyperaldosteronism.¹⁸⁹ Excessive autonomous secretion of aldosterone without its principal regulator, angiotensin II, causes hypokalemia and induces insulin resistance; promotes inflammation, endothelial dysfunction, and cardiovascular remodeling (increased left ventricular wall and carotid intima thickness); and affects adipose tissue differentiation and function.¹⁹⁰ Thus primary hyperaldosteronism can influence the features of the metabolic syndrome, including hypertension (most common cause of secondary hypertension), obesity, dyslipidemia, insulin resistance, and hyperglycemia.

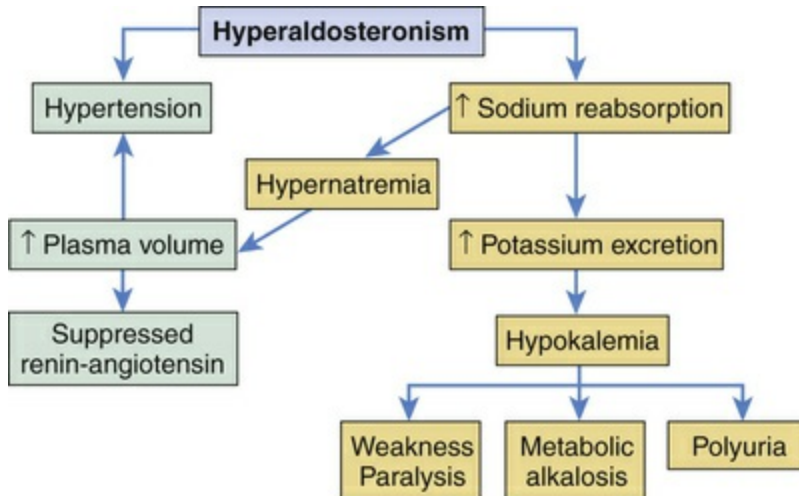

FIGURE 22.24 Pathophysiology of Primary Hyperaldosteronism. (From Bonow RO et al: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 9, Philadelphia, 2012, Saunders.)

Secondary hyperaldosteronism (secondary aldosteronism) involves excessive aldosterone secretion from the action of angiotensin II through a renin-dependent mechanism. (Factors that affect normal renin and aldosterone secretion are summarized in [Table 22.13](#).) Examples include decreased circulating blood volume (e.g., in dehydration, shock, or hypoalbuminemia) and decreased delivery of blood to the kidneys (e.g., renal artery stenosis, heart failure, or hepatic cirrhosis). Here, the activation of the renin-angiotensin system and subsequent aldosterone secretion may be seen as compensatory, although in some instances (e.g., congestive heart failure) the increased circulating volume further worsens the condition. Other causes of secondary hyperaldosteronism are Bartter syndrome, a renal tubular defect causing hypokalemia, and renin-secreting tumors of the kidney.

TABLE 22.13

PHYSIOLOGIC FACTORS AFFECTING RENIN AND ALDOSTERONE SECRETION

FACTORS	RENIN SECRETION
Age	Highest in infants; lowest in older adults
Menstrual cycle	Highest in luteal phase (see Chapter 24)
Sodium intake	Increased by salt restriction

	Decreased by salt loading
Potassium status	Increased by K ⁺ excess
Posture	Increased with erect posture
Sympathetic nervous system	Renin increased by catecholamine stimulation
Time of sampling	Highest before noon; lowest in evening

◀Clinical Manifestations.

Hypertension, hypokalemia, and hypervolemia, because of increased sodium reabsorption (without peripheral edema) and metabolic alkalosis, are the hallmarks of hyperaldosteronism.¹⁸⁹ Hypertension is resistant to treatment and may result from increased intravascular volume from a state of aldosterone-mediated vasoconstriction, although the latter mechanism requires very high levels of aldosterone. If hypertension is sustained, the long-term effects of elevated arterial pressure become evident, which include the development of left ventricular dilation and hypertrophy, vascular disease, and renal disease. In primary hyperaldosteronism, renin secretion is typically suppressed because of the autonomous production of aldosterone, although it is elevated in secondary hyperaldosteronism, which provides a means to clearly differentiate between these conditions.

Edema usually does not occur with primary aldosteronism. Sodium loss and water loss are maintained by hypervolemia-induced atrial natriuretic factor release, pressure natriuresis, and aldosterone escape (spontaneous diuresis). The escape phenomenon changes or resets the rate of sodium excretion in the proximal tubules and prevents more severe sodium retention. Although this mechanism provides protection from excessive sodium reabsorption and edema, it can increase urinary losses of potassium and cause hypokalemia.

Aldosterone-stimulated potassium loss can be variable. Serum potassium levels less than 3.0 mEq/L result in the typical manifestations of hypokalemia (see [Chapter 3](#)). Hypokalemic metabolic alkalosis is caused by the movement of potassium from the intercellular to extracellular space in exchange for hydrogen ions as well as renal loss of hydrogen ions to facilitate sodium reabsorption.

◆ Evaluation and Treatment.

Various clinical and laboratory measurements are useful in the assessment of hyperaldosteronism and include the following:

1. Measurement of blood pressure: hypertension is usually present.
2. Serum and urinary electrolyte levels: serum sodium level is normal or slightly elevated, serum potassium level is normal or depressed, and urinary potassium level is elevated; metabolic alkalosis may be present.
3. Plasma aldosterone-to-renin ratio increases.
4. Aldosterone suppression testing is performed using either salt loading or fludrocortisone acetate (Florinef) if the aldosterone-to-renin ratio is increased.
5. Imaging techniques may be used to localize an aldosterone-secreting adenoma.

Serum aldosterone and plasma renin activity both must be measured under controlled situations and after careful dietary regulation of sodium and potassium intake and withdrawal of hypertensive agents, if feasible. [Table 22.13](#) summarizes normal physiologic factors that affect renin and aldosterone secretion.

Imaging techniques, such as CT and nuclear magnetic resonance (NMR), may be used to localize an autonomous aldosterone-secreting adenoma. Sampling from both adrenal veins also is useful. Renography can be used to diagnose secondary hyperaldosteronism.

Treatment includes management of hypertension and hypokalemia, as well as correction of any underlying causal abnormalities. If an aldosterone-secreting adenoma is present, it is generally approached surgically. Medical management with aldosterone receptor antagonists, such as spironolactone or eplerenone (a drug without the side effects of spironolactone), is a viable option in selected cases. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs),¹⁹¹ and revascularization procedures for renal artery stenosis are used to treat secondary hyperaldosteronism.

Hypersecretion of Adrenal Androgens and Estrogens

Hypersecretion of adrenal androgens and estrogens may be caused by adrenal tumors, either adenomas or carcinomas; endogenous hypercortisolism; or defects in steroid synthesis. The clinical syndrome that is manifested depends on the hormone secreted, the sex of the individual, and the ages at which the hypersecretion is initiated. Hypersecretion of estrogens causes **feminization**, the development of female sex characteristics. Hypersecretion of androgens causes **virilization**, the development of male sex characteristics ([Fig. 22.25](#)).

FIGURE 22.25 Virilization. Virilization of a young girl by an androgen-secreting tumor of the adrenal cortex. Masculine features include lack of breast development, increased muscle bulk, and hirsutism. (From Thibodeau GA, Patton KT: *The human body in health & disease*, ed 4, St Louis, 2010, Mosby.)

The effects of an estrogen-secreting tumor are most evident in males and result in gynecomastia (98% of cases), testicular atrophy, and decreased libido. In female children, such tumors may lead to early development of secondary sex characteristics. The effects of an androgen-secreting tumor are more easily observed in females and include excessive face and body hair growth (hirsutism), clitoral enlargement, deepening of the voice, amenorrhea, acne, and breast atrophy. In children, virilizing tumors promote precocious sexual

development and bone aging. Treatment of androgen-secreting tumors usually involves surgical excision.

Adrenocortical Hypofunction

Hypocortisolism (low levels of cortisol secretion) can be primary, secondary, or tertiary. Primary hypocortisolism (Addison disease) develops because of a primary inability of the adrenals to produce and secrete the adrenocortical hormones. Secondary hypocortisolism develops because of inadequate stimulation of the adrenal glands by ACTH. Sometimes there is partial dysfunction of the adrenal cortex, so only synthesis of cortisol or aldosterone or the adrenal androgens is affected because the adrenal cortex has three distinct zones, which secrete the various hormones. Tertiary hypocortisolism is commonly caused by abrupt withdrawal of exogenous glucocorticoids or as a complication of treatment for Cushing syndrome. High levels of glucocorticoids (endogenous or exogenous) decrease hypothalamic corticotropin-releasing hormone (CRH) synthesis and secretion and also block the trophic and ACTH-secretagogue actions of CRH on anterior pituitary cells, resulting in loss of ACTH and its actions on the adrenal gland. Symptoms and management are similar to those for secondary hypocortisolism.¹⁹²

Primary Adrenal Insufficiency.

Primary adrenal insufficiency (hypocortisolism and hypoaldosteronism) is often termed Addison disease. Addison disease is relatively rare, occurring most often in adults 30 to 60 years of age, although it may appear at any time. The most common cause of Addison disease in the United States is autoimmune destruction of the adrenal cortex and it is more common in women. Other causes include infections (tuberculosis, fungal infections, human immunodeficiency virus [HIV]), infiltrative diseases (amyloidosis, metastatic carcinoma), or bilateral adrenal hemorrhage. Adrenoleukodystrophy and adrenomyeloneuropathy are two rare types of X-linked adrenal deficiency that lead to symptoms of hypocortisolism and progressive neurologic symptoms.

◆Pathophysiology.

Addison disease is characterized by inadequate corticosteroid and mineralocorticoid synthesis and elevated serum ACTH levels (loss of negative feedback). Before clinical manifestations of hypocortisolism are evident, more than 90% of total adrenocortical tissue must be destroyed.

Idiopathic Addison disease (organ-specific autoimmune adrenalitis) causes adrenal atrophy and hypofunction and is an organ-specific autoimmune disease. (Autoimmunity is discussed in [Chapter 9](#).) It may occur in childhood (type 1) or adulthood (type 2). 21-Hydroxylase autoantibodies and autoreactive T cells specific to adrenal cortical cells are present in 50% to 70% of individuals with idiopathic Addison disease; this percentage increases in younger persons and in those with other autoimmune diseases. This deficiency allows the proliferation of immunocytes directed against specific antigens within the adrenocortical cells.

The adrenal glands in idiopathic Addison disease are smaller than normal and may be misshapen. Several genes have been identified. Idiopathic Addison disease often is associated with other autoimmune diseases and in such cases is known as *autoimmune polyendocrine syndrome (APS)*. APSI (APS type I) is inherited as autosomal recessive with childhood onset and includes Addison disease, hypoparathyroidism, mucocutaneous candidiasis, and other less common symptoms. APSII (APS type II) is more common and involves Addison disease, immune thyroid disease, diabetes mellitus, celiac disease, and hypogonadism.¹⁹³ (Mechanisms of inheritance are described in [Chapter 4](#).)

◆Clinical Manifestations.

The symptoms of Addison disease are primarily a result of hypocortisolism and hypoaldosteronism and are often vague and not well-defined (see [Fig. 22.22](#)). With mild to moderate hypocortisolism, symptoms usually begin with weakness and easy fatigability. Skin changes, including hyperpigmentation and vitiligo, may occur. As the condition progresses, anorexia, nausea, vomiting, and diarrhea may

develop. Symptoms of mineralocorticoid deficiency include hypovolemia, postural hypotension and dizziness, dehydration, hyperkalemia, and salt craving. Of greatest concern is the development of hypotension that can progress to complete vascular collapse and shock. This is known as *adrenal crisis* or *addisonian crisis*, and develops with undiagnosed disease, acute withdrawal of glucocorticoid therapy, or the occurrence of infection or other comorbid stressful events.¹⁹⁴

Decreased adrenal androgen secretion is usually not clinically obvious in men because the adrenals are not a major source of male androgens; however, hypogonadism can occur. Women may experience a loss of some secondary sexual characteristics, such as pubic and axillary hair, normally maintained by the adrenal androgens.¹⁹⁵ Some studies also have reported an associated low functional ovarian reserve.¹⁹⁶ Disturbances in mood and motivation are common. The symptoms of Addison disease are summarized in [Table 22.14](#).

TABLE 22.14

CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGIC MECHANISMS OF ADDISON DISEASE

CLINICAL MANIFESTATIONS	PATHOPHYSIOLOGIC MECHANISM
Weakness and easy fatigability that worsen as the day progresses, seen especially after exposure to stressors	Not known; may be related to hypoglycemia, hypotension, decreased metabolism of proteins
Gastrointestinal disturbances: anorexia, nausea, vomiting, diarrhea, abdominal pain, weight loss	May be associated with celiac disease or electrolyte abnormalities
Hypoglycemia, manifested by fatigue, mental confusion, apathy, psychosis	Absence of cortisol leads to decreased gluconeogenesis, decreased glycogen storage by liver, decreased metabolism of proteins, increased insulin sensitivity
Hyperpigmentation	Elevations of ACTH that lead to stimulation of melanocytes
Vitiligo (white patchy areas of depigmented skin)	Autoimmune destruction of melanocytes

Addisonian crisis: severe hypotension and vascular collapse	Combined effects of hypocortisolism, hypoaldosteronism, extracellular volume depletion, and some precipitating stressor (e.g., infection, vomiting, diarrhea); decreased vasomotor tone caused by cortisol deficiency
---	---

ACTH, Adrenocorticotrophic hormone.

◆ Evaluation and Treatment.

Serum and urine levels of cortisol are depressed with primary hypocortisolism, and ACTH levels are increased. Because of dehydration, blood urea nitrogen levels may increase. Serum glucose concentration is low. Eosinophil and lymphocyte counts are often elevated. Hyperkalemia is seen in Addison disease and may cause mild metabolic alkalosis (see [Chapter 3](#)). The ACTH stimulation short test (250 µg) may be used to evaluate serum cortisol levels or, if not possible, the measurement of morning plasma ACTH and cortisol levels. Measurement of serum 21-hydroxylase (anti-adrenal) autoantibodies and a baseline serum 17-hydroxyprogesterone level also may be diagnostic.¹⁹⁷

The treatment of Addison disease involves lifetime glucocorticoid and mineralocorticoid replacement therapy, together with dietary modifications and correction of any underlying disorders. Efforts are in progress to replace cortisol in a physiologic manner using modified-release formulations of hydrocortisone.¹⁹⁸ With acute stressors (e.g., infection, surgery, or trauma), additional cortisol must be administered to approximate the amount of cortisol that might be expected to be secreted if normal adrenal function were present (approximately 100 to 300 mg/day);¹⁹⁹ and this is called *stress dosing*. The individual's diet should include at least 150 mEq of sodium per day, with sodium intake increased in the event of excessive sweating or diarrhea.

Secondary Hypocortisolism.

Secondary hypocortisolism commonly results from prolonged administration of exogenous glucocorticoids and effective treatment of endogenous hypercortisolism. The consequence is suppression of ACTH secretion that causes adrenal atrophy and results in inadequate

corticosteroidogenesis once the exogenous glucocorticoids are withdrawn. Decreased ACTH secretion also can result from pituitary infarction, pituitary tumors that compress ACTH-secreting cells, or hypophysectomy. In all instances of low ACTH levels, adrenal atrophy occurs and endogenous adrenal steroidogenesis is depressed. Clinical manifestations of secondary hypocortisolism are similar to those of Addison disease, although hyperpigmentation usually does not occur because melanocyte-stimulating hormone is also deficient. The renin-angiotensin system usually is normal, so aldosterone and potassium levels also tend to be normal and hypotension is less prominent. Recovery of adrenal function is possible with correction of the primary problem.

Tumors of the Adrenal Medulla

Hyperfunction of the adrenal medulla is caused by **pheochromocytomas** (chromaffin cell tumors) or **sympathetic paragangliomas** of the adrenal medulla that continuously secrete catecholamines (norepinephrine and epinephrine) (Fig. 22.26). These are rare neuroendocrine tumors and are usually sporadic, although up to 40% of them can be inherited. Familial forms are associated with mutations in the neurofibromatosis type 1 gene (*NF1*), von Hippel-Lindau (*VHL*) gene, and multiple endocrine neoplasia type 2 (*RET*). Any of the succinate dehydrogenase complex (*SDHA*) subunit genes can lead to pheochromocytoma and paragangliomas.²⁰⁰ About 10% to 20% of pheochromocytomas are malignant. Those that are malignant metastasize to the lungs, liver, bones, or paraaortic lymph nodes.

FIGURE 22.26 Pheochromocytoma. Gross appearance of adrenal pheochromocytoma. (From Rosai J: *Rosai and Ackerman's surgical pathology*, ed 10, Philadelphia, 2011, Mosby.)

◆Pathophysiology.

Pheochromocytomas and sympathetic paragangliomas cause uncontrolled production of norepinephrine, although large tumors also secrete epinephrine. Approximately 5% of people with pheochromocytomas have no symptoms because the tumor appears to be nonfunctioning. Such tumors can, however, release catecholamines in response to stressors, such as surgery.

◆Clinical Manifestations.

The clinical manifestations of a pheochromocytoma and sympathetic paragangliomas are related to the chronic effects of catecholamine secretion and include persistent hypertension, headache, sweating, palpitations, tachycardia, and pallor. Hypertension results from increased peripheral vascular resistance and may be sustained or paroxysmal. An acute episode of hypertension related to

hypersecretion of catecholamines may follow specific events, such as exercise, excessive ingestion of tyrosine-containing foods (aged cheese, red wine, beer, yogurt), ingestion of caffeine-containing foods, external pressure on the tumor, and induction of anesthesia. Hypertension unresponsive to drug therapy is often the first indication of a pheochromocytoma. Headaches appear because of sudden changes in catecholamine levels in the blood, affecting cerebral blood flow. Hypermetabolism and sweating are related to chronic activation of sympathetic receptors in adipocytes, hepatocytes, and other tissues. Glucose intolerance may occur because of catecholamine-induced inhibition of insulin release by the pancreas. Complaints of warmth, heat intolerance, weight loss, and constipation are common despite a normal or an increased appetite. These tumors tend to be extremely vascular and can rupture, causing massive and potentially fatal hemorrhage.

◆Evaluation and Treatment.

Symptoms of pheochromocytoma can be insidious or intermittent and difficult to diagnose. A diagnosis of pheochromocytoma is made when increased catecholamines are found in the blood or urine. Plasma-free metanephrines and urinary fractionated metanephrine levels are highly sensitive diagnostic indicators when these laboratory techniques are available. The site of the tumor is determined using abdominal imaging techniques. Because of the possibility of metastasis, whole-body scanning may be done. Genetic testing is commonly completed and can guide therapy.²⁰¹

Management of catecholamine excess is essential to prevent hypertensive emergencies and requires the use of α - and β -adrenergic blockers and calcium channel blockers that are typically initiated several weeks before surgery. The usual treatment of pheochromocytoma is laparoscopic surgical excision of the tumor, although open resection is still completed for large tumors or when metastasis is suspected. Medical therapy is continued to stabilize blood pressure before, during, and after surgery. Malignant pheochromocytoma is rarely curable and is usually managed by a

combination of surgical debulking of the tumor combined with chemotherapy.²⁰²

Summary Review

Mechanisms of Hormonal Alterations

1. Abnormalities in endocrine function may be caused by hypersecretion or hyposecretion of hormones or alterations in transport molecules.
2. Endocrine abnormalities also may be caused by alterations in receptor function through a variety of mechanisms: (a) a decrease in the number of receptors, (b) receptor insensitivity to the hormone, (c) the presence of antibodies against specific receptors, and (d) defects in second-messenger generation or postreceptor defects.
3. Abnormally high levels of circulating hormones sometimes are caused by hormone release from tissues outside the endocrine system (ectopic foci) that may not respond to normal feedback mechanisms, in which case they are said to function autonomously.

Alterations of the Hypothalamic-Pituitary System

1. Dysfunction in the release of hypothalamic hormones probably is related to interruption of the connection between the hypothalamus and pituitary — namely, the pituitary stalk.
2. Disorders of the posterior pituitary include SIADH secretion and DI. SIADH secretion is characterized by abnormally high ADH secretion; DI is characterized by abnormally low ADH secretion.
3. In SIADH, high ADH levels interfere with renal free water clearance, leading to hyponatremia and hypoosmolality. SIADH secretion is associated with certain forms of cancer,

- apparently because of ectopic secretion of ADH by tumor cells.
4. DI may be neurogenic, caused by insufficient amounts of ADH, or nephrogenic, caused by an inadequate response to ADH. Its principal clinical features are failure to concentrate urine with polyuria and polydipsia. Dipsogenic polyuria occurs when excessive fluid intake lowers the plasma osmolarity to the point that it falls below the threshold for ADH secretion.
 5. Hypopituitarism is dysfunction of the anterior pituitary that causes failure of hormonal functions. Symptoms may be mild to severe.
 6. Causes of hypopituitarism include pituitary infarction, space-occupying lesions such as tumor or aneurysm, surgical removal, or infections. Symptoms are variable depending on which hormones are deficient (e.g., TSH, ACTH, or GH).
 7. Hyperpituitarism is caused by pituitary adenomas. These are usually benign slow-growing tumors that arise from cells of the anterior pituitary.
 8. Expansion of a pituitary adenoma causes neurologic and secretory effects. Pressure from the expanding tumor causes hyposecretion of cells, dysfunction of the optic chiasm (leading to visual disturbances), and dysfunction of the hypothalamus and some cranial nerves.
 9. Hypersecretion of GH causes acromegaly in adults and gigantism in children. Pituitary adenoma is the most common cause of acromegaly.
 10. Prolonged, abnormally high levels of GH lead to proliferation of body and connective tissues. Renal, thyroid, cardiovascular, and reproductive dysfunctions develop slowly, together with a change in bony proportions and insulin resistance.
 11. GH deficiency in children results in growth failure and fasting hypoglycemia. Adult GH deficiency results in fatigue, osteoporosis, and increased mortality.
 12. Pituitary prolactinomas, renal failure, and medications can result in increased levels of prolactin and affect reproductive organs and function in both men and women.

Alterations of Thyroid Function

1. Thyrotoxicosis is a general condition in which TH levels are elevated and produce an exaggerated physiologic response in tissues. The condition can be primary, secondary, or subclinical.
2. Hyperthyroidism has a range of endocrine, reproductive, gastrointestinal, integumentary, and ocular manifestations. These are caused by increased circulating levels of TH and by stimulation of the sympathetic division of the autonomic nervous system.
3. Graves disease, the most common form of hyperthyroidism, is caused by thyroid-stimulating immunoglobulins that stimulate thyroid TSH receptors, resulting in thyroid hyperplasia and increased synthesis of TH.
4. Manifestations of Graves disease can include symptoms of hyperthyroidism, diffuse thyroid enlargement, and disorders of the skin and eyes.
5. The cutaneous manifestation of Graves disease is pretibial myxedema, a condition characterized by subcutaneous swelling of the legs and, occasionally, the hands.
6. Ocular manifestations of Graves disease are caused by hyperactivity of the sympathetic division of the autonomic nervous system and by immune-induced infiltration of extraocular muscles, orbital fat accumulation, and edema (exophthalmos).
7. Toxic multinodular goiter and solitary toxic adenoma occur when some hyperplastic, hyperfunctioning thyroid nodules autonomously secrete TH, causing hyperthyroidism and producing symptoms similar to those of Graves disease.
8. Toxic multinodular goiters result from multiple functioning adenomas.
9. Thyrotoxic crisis (thyroid storm) is a severe form of hyperthyroidism that often is associated with physiologic stress. Without treatment, death occurs quickly.

10. Hypothyroidism is caused by deficient production of TH by the thyroid gland. The condition may be primary, secondary, or subclinical.
11. Causes of primary hypothyroidism include iodine deficiency, autoimmune thyroiditis, subacute or painless thyroiditis, silent or subacute lymphocytic thyroiditis, iatrogenic hypothyroidism, and postpartum thyroiditis.
12. Autoimmune thyroiditis (Hashimoto disease) is associated with lymphocyte infiltration, antibody activation of natural killer cells, induction of apoptosis with gradual loss of thyroid function, and hypothyroidism.
13. Subacute thyroiditis, a form of hypothyroidism, is a self-limited nonbacterial inflammation of the thyroid gland. The inflammatory process damages follicular cells, causing leakage of triiodothyronine (T_3) and tetraiodothyronine (thyroxine) (T_4). Hyperthyroidism then is followed by transient hypothyroidism, which is corrected by cellular repair and a return to normal levels in the thyroid.
14. Secondary hypothyroidism is caused by hypothalamic-pituitary dysfunction in which TRH and TSH are not produced in sufficient amounts.
15. Thyroid carcinoma is a relatively rare cancer. The most consistent causal risk factor associated with thyroid carcinoma is exposure to ionizing radiation, especially in childhood.
16. Hypothyroidism affects all body systems. Symptoms depend on the degree of TH deficiency. Common manifestations include decreased energy metabolism and loss of heat production.
17. Myxedema is the characteristic sign of hypothyroidism. Myxedema is caused by alterations in connective tissue with water-binding proteins. The excess water leads to thickened mucous membranes and edema, particularly around the eyes and in the hands and feet.
18. Myxedema coma is a severe form of hypothyroidism, which may be life-threatening without emergency medical treatment.

19. Congenital hypothyroidism is TH deficiency at birth; it occurs with thyroid agenesis and results in hypothyroidism, growth failure, and intellectual disability from absence of thyroxine.
20. Papillary and follicular thyroid carcinomas are the most common thyroid malignancies probably caused by exposure to ionizing radiation, particularly during childhood. Thyroid nodules are present with normal thyroxine levels.

Alterations of Parathyroid Function

1. Hyperparathyroidism may be primary, secondary, or tertiary and is characterized by greater than normal secretion of PTH.
2. Primary hyperparathyroidism is usually caused by a parathyroid adenoma with interruption of the normal mechanisms that regulate calcium and PTH levels. Manifestations include chronic hypercalcemia, increased bone resorption, and hypercalciuria.
3. Secondary hyperparathyroidism is a compensatory response to hypocalcemia and often occurs with chronic renal failure or chronic vitamin D deficiency.
4. Tertiary hyperparathyroidism is excessive secretion of PTH and hypercalcemia that occurs after long-standing hypocalcemia.
5. Pseudohypoparathyroidism and familial hypocalciuric hypercalcemia are inherited conditions. In pseudohypoparathyroidism there is resistance to PTH.
6. Hypoparathyroidism, defined by abnormally low PTH levels, is caused by thyroid surgery, autoimmunity, or genetic mechanisms.
7. The lack of circulating PTH in hypoparathyroidism causes depressed serum calcium levels, increased serum phosphate levels, decreased bone resorption, and eventual hypocalciuria.

Dysfunction of the Endocrine Pancreas: Diabetes

Mellitus

1. Diabetes mellitus is a group of diseases characterized by hyperglycemia resulting from defects in insulin secretion or insulin action, or both. The two most common types of diabetes mellitus are type 1 and type 2.
2. A diagnosis of diabetes mellitus is based on glycosylated hemoglobin (HbA_{1c}) levels, fasting plasma glucose (FPG) levels, and 2-hour plasma glucose levels during oral glucose tolerance testing (OGTT).
3. Type 1 diabetes mellitus includes an autoimmune (most common) and a nonimmune type. The immune type (type 1A) is associated with genetic susceptibility, environmental factors, and autoantibody, T-cell, and macrophage destruction of pancreatic beta cells with loss of insulin production and a relative excess of glucagon. Antibodies also can be formed against glutamic acid decarboxylase and insulin.
4. Nonimmune type diabetes (type 1B) occurs secondary to other disease.
5. Type 2 diabetes mellitus is caused by genetic susceptibility that is triggered by environmental factors. The most compelling environmental risk factor is obesity. Insulin production continues but the weight and number of beta cells decrease.
6. Several mechanisms of insulin resistance (hyperinsulinemia) cause reduced glucose uptake and metabolism in type 2 diabetes. These mechanisms include alteration in the production of adipokines by adipose tissue (i.e., leptin resistance), elevated levels of serum free fatty acids and intracellular lipid deposits, release of inflammatory cytokines from adipose tissue, reduced insulin-stimulated mitochondrial activity, and obesity-associated insulin resistance.
7. In type 2 diabetes, amylin deficiency results in increased glucagon secretion and hyperglycemia.
8. Decreased ghrelin and amylin levels and decreased beta-cell response to glucagon-like peptide have been associated with

insulin resistance and type 2 diabetes.

9. Other specific types of diabetes mellitus include MODY associated with autosomal dominant gene mutations and gestational diabetes associated with onset of glucose intolerance during pregnancy.
10. Acute complications of diabetes mellitus include hypoglycemia, DKA, HHNKS, the Somogyi effect, and the dawn phenomenon.
11. Hypoglycemia is a lowered blood glucose level that may be related to exogenous (i.e., insulin shock or insulin reaction), endogenous, or functional causes.
12. Symptoms of hypoglycemia are divided into adrenergic, caused by activation of the sympathetic nervous system; and neuroglycopenic, reflecting defective central nervous system metabolism resulting from impaired energy generation.
13. DKA develops when there is an absolute or relative deficiency of insulin and an increase in the amounts of insulin counter-regulatory hormones of catecholamines, cortisol, glucagon, and GH; increased lipolysis; and accelerated gluconeogenesis and ketogenesis. It is most common in type 1 diabetes, but also occurs in type 2.
14. HHNKS is pathophysiologically similar to DKA, although levels of FFAs are lower in HHNKS and lack of ketosis indicates that some level of insulin is present. The hyperosmolar state can cause osmotic diuresis and profound dehydration, causing coma.
15. The Somogyi effect is a combination of hypoglycemia with rebound hyperglycemia caused by effects of counter-regulatory hormones. It is most common in persons with type 1 diabetes mellitus and in children.
16. The dawn phenomenon is an early morning rise in glucose levels caused by nocturnal elevations of GH concentration.
17. Chronic complications of diabetes mellitus are related to chronic hyperglycemia and include microvascular disease (e.g., retinopathy, nephropathy, and neuropathy),

macrovascular disease (e.g., CAD, stroke, and peripheral vascular disease), and infection. Metabolic changes contributing to complications include oxidative stress, shunting of glucose to the polyol pathway, activation of protein kinase C, formation of AGEs, and accumulation of hexosamines.

18. Microvascular complications are associated with vascular alterations in the endothelium and the basement membrane as well as thrombosis.
19. Diabetic retinopathy is caused by several mechanisms including microvascular changes and thrombosis that lead to microvascular occlusion, retinal ischemia, increased vascular permeability, microaneurysm formation, hemorrhages, and neovascularization with loss of vision.
20. Diabetic nephropathy is related to hyperglycemia, hyperperfusion, oxidative stress, and inflammation with glomerular enlargement and glomerular basement membrane thickening, diffuse intercapillary glomerulosclerosis, expansion of the mesangial matrix, and progressive renal failure.
21. Diabetic neuropathies may be caused by vascular and metabolic mechanisms, or by a combination of both, with axonal and Schwann cell degeneration and abnormalities in sensory and motor nerve conduction velocity, and involvement of the autonomic nervous system.
22. Macrovascular disease associated with diabetes mellitus is associated with hyperglycemia, hyperlipidemia, inflammation, and altered endothelial function.
23. The incidence of coronary heart disease, peripheral vascular disease, and stroke is greater in persons with diabetes than in nondiabetic individuals.
24. CAD and stroke in diabetes are a consequence of accelerated atherosclerosis, hypertension, and increased risk for thrombus formation.
25. Peripheral artery disease is a consequence of neuropathy and

occlusion of large and small arteries with an increased risk of ischemia, necrosis, and amputation.

26. Individuals with diabetes are at risk for a variety of infections related to sensory impairment, vascular complications, impaired white blood cells and suppressed immunity, rapid proliferation of pathogens, and delayed wound healing.

Alterations of Adrenal Function

1. Disorders of the adrenal cortex are related to hyperfunction or hypofunction. No known disorders are associated with hypofunction of the adrenal medulla, but medullary hyperfunction causes clinically defined syndromes.
2. Hypercortisolism is divided into ACTH-dependent (Cushing disease or ectopic ACTH syndrome) and ACTH-independent (adrenal adenoma or adenocarcinoma) mechanisms.
3. Cushing disease is excessive anterior pituitary ACTH production most commonly by an ACTH-secreting pituitary microadenoma.
4. Cushing syndrome occurs whenever there is an excessive level of cortisol regardless of cause. Exogenous forms result from exogenous administration of glucocorticoids. Endogenous forms are either corticotropin dependent (most common and caused by an ACTH-secreting pituitary tumor) or corticotropin independent (usually caused by an adrenal cortical tumor).
5. Individuals with Cushing disease lose diurnal and circadian patterns of ACTH and cortisol secretion, and they lack the ability to increase secretion of these hormones in response to a stressor. Individuals experience weight gain, glucose intolerance, protein wasting, bone disease, hyperpigmentation, and immunosuppression.
6. Congenital adrenal hyperplasia is an autosomal recessive disorder with inadequate synthesis of cortisol and increased levels of ACTH that cause adrenal hyperplasia and overproduction of mineralocorticoids or androgens.

7. Primary hyperaldosteronism is a disorder of excessive aldosterone secretion usually caused by an adrenal cortical adenoma or bilateral nodular hyperplasia. The condition is characterized by hypertension, hypokalemia, renal potassium wasting, and neuromuscular manifestations.
8. Secondary hyperaldosterone secretion is related to a variety of conditions associated with elevated renin release and activation of angiotensin II. These include decreased circulating blood volume, decreased renal blood supply, elevated estrogen levels, Bartter syndrome, and renin-secreting tumors.
9. Adrenal tumors, either adenomas or carcinomas, can autonomously secrete androgens or estrogens.
10. Hypofunction of the adrenal cortex can affect glucocorticoid or mineralocorticoid secretion or both. Hypofunction can be caused by a deficiency of ACTH or by a primary deficiency in the gland itself.
11. Hypocortisolism (low levels of cortisol) is caused by inadequate adrenal stimulation by ACTH or by primary cortisol hyposecretion. Primary adrenal insufficiency is termed Addison disease.
12. Addison disease is characterized by elevated ACTH levels with inadequate corticosteroid synthesis and output. Causes include idiopathic autoimmune disease, tuberculosis of the adrenal gland, familial adrenal insufficiency, amyloidosis, metastatic destruction of the adrenal glands, and adrenal hemorrhage.
13. Manifestations of Addison disease are related to hypocortisolism and hypoaldosteronism. Symptoms include weakness, fatigability, hypoglycemia and related metabolic problems, lowered response to stressors, vitiligo, hyperpigmentation, and manifestations of hypovolemia and hyperkalemia.
14. Secondary hypercortisolism is characterized by low to absent ACTH levels, leading to inadequate adrenal stimulation,

adrenal atrophy, and decreased corticosteroidogenesis. The most common cause is withdrawal of exogenous administration of glucocorticoids. Manifestations are similar to those of Addison disease only without hyperpigmentation.

15. Hyperfunction of the adrenal medulla is caused by a pheochromocytoma, which is a catecholamine-producing tumor. Symptoms of catecholamine excess are related to their sympathetic nervous system effects and include hypertension, palpitations, tachycardia, glucose intolerance, excessive sweating, and constipation.

Key Terms

Acromegaly, 674

ACTH deficiency, 672

Advanced glycation end product (AGE), 695

Aldose reductase, 695

Amylin, 686

Autoimmune thyroiditis (Hashimoto disease, chronic lymphocytic thyroiditis), 679

Autonomic neuropathy, 698

Central (secondary) hyperthyroidism, 676

Charcot neuroarthropathy (Charcot joint), 698

Congenital adrenal hyperplasia, 701

Congenital hypothyroidism, 681

Cushing disease, 699

Cushing-like syndrome, 699

Cushing syndrome, 699

Dawn phenomenon, 693

Diabetes insipidus (DI), 671

Diabetes mellitus (DM), 684

Diabetic ketoacidosis (DKA), 693

Diabetic kidney disease, 695

Diabetic macrovascular disease, 698

Diabetic microvascular complication, 695
Diabetic neuropathy, 697
Diabetic retinopathy, 695
Distal symmetric polyneuropathy, 697
Exophthalmos, 677
Familial hypocalciuric hypercalcemia (FHH), 682
Feminization, 703
FSH deficiency, 673
Gestational diabetes mellitus (GDM), 692
GH deficiency, 673
Ghrelin, 688
Giantism, 674
Glucagon, 686
Glycation, 695
Graves disease, 677
Hexosamine pathway, 695
Hyperaldosteronism, 701
Hypercortisolism, 699
Hyperglycemic hyperosmolar state (HHS), 694
Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS),
694
Hyperparathyroidism, 682
Hyperthyroidism, 676
Hypocortisolism, 704
Hypoglycemia, 693
Hypoparathyroidism, 683
Hypopituitarism, 672
Hypothyroidism, 679
Iatrogenic hypothyroidism, 681
Idiopathic Addison disease (organ-specific autoimmune
adrenalitis), 704
Incretin, 688
Insulin resistance, 688
Iodine deficiency (endemic goiter), 679
LH deficiency, 673

Macular edema, 695
Maturity-onset diabetes of youth (MODY), 691
Metabolic syndrome, 688
Myxedema, 679
Myxedema coma, 679
Nephrogenic diabetes insipidus (DI), 671
Neurogenic (central) diabetes insipidus (DI), 671
Nontoxic nodular goiter, 678
Painless (silent) thyroiditis (silent or subacute lymphocytic thyroiditis), 681
Panhypopituitarism, 672
Pheochromocytoma, 705
Pituitary adenoma, 673
Polyol pathway, 695
Postpartum thyroiditis, 681
Pretibial myxedema (Graves dermopathy), 677
Primary adrenal insufficiency (hypocortisolism and hypoaldosteronism), 704
Primary hyperaldosteronism (Conn syndrome, primary aldosteronism), 701
Primary hyperthyroidism, 676
Primary hypothyroidism, 679
Primary thyroid disorder, 676
Prolactinoma, 675
Protein kinase C (PKC), 695
Pseudohypoparathyroidism, 683
Secondary hyperaldosteronism (secondary aldosteronism), 701
Secondary hypocortisolism, 705
Secondary hypothyroidism, 679
Solitary toxic adenoma, 678
Somogyi effect, 692
Subacute thyroiditis (subacute granulomatous thyroiditis, de Quervain thyroiditis), 681
Subclinical hyperthyroidism, 677
Subclinical hypothyroidism, 679

Sympathetic paraganglioma, 705
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion, 670
Thyroid carcinoma, 681
Thyrotoxic crisis (thyroid storm), 679
Thyrotoxicosis, 676
Toxic multinodular goiter, 678
TSH deficiency, 673
Type 1 diabetes mellitus (DM), 685
Type 2 diabetes mellitus (DM), 688
Virilization, 703

CHAPTER 23

Obesity and Disorders of Nutrition

Sue E. Huether

CHAPTER OUTLINE

Adipose Tissue, 713

Obesity, 715

Food Intake and Energy Balance, 716

Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder, 719

Starvation, 720

Anorexia of Aging, 721

Adipose Tissue

Adipose tissue provides insulation and mechanical support and is the body's major energy reserve to fuel other tissues. As an endocrine organ, **white adipose tissue (WAT)** contributes to the regulation of energy homeostasis by secretion of adipokines that function like hormones with autocrine, paracrine, and endocrine actions necessary for metabolic function and immune responses.¹ Adipocytes are fat-

storing cells and store excess energy in the form of triglycerides (triglycerol), synthesize triglycerides from glucose, and mobilize energy in the form of free fatty acids (FFAs) and glycerol. Adipokines include all of the biologically active substances synthesized by WAT, which function in the control of food intake and energy expenditure, lipid storage, insulin sensitivity, immune and inflammatory responses, coagulation, fibrinolysis, angiogenesis, fertility vascular homeostasis, blood pressure regulation, and bone metabolism. Excess WAT causes dysregulation of the adipokines, contributing to the comorbidities of obesity. The most common adipokines are summarized in [Box 23.1](#).

Box 23.1

Major Adipokines Secreted by Adipose Tissue

Adipokines

Increased in Obesity

Acylation-Stimulating Protein (Also Known as Complement 3a desArg)

- Stimulates triacylglycerol synthesis in adipocytes
- Inhibits action of hormone-sensitive lipase (triglycerol lipase)
- Promotes glucose transport
- Inhibited by insulin

Angiopietin-Related Protein 2 (A Vascular Endothelial Growth Factor)

- Promotes insulin resistance
- Promotes inflammation

Angiotensinogen, Angiotensin Type 1 and Type 1 Receptors, Renin, and Angiotensin Converting Enzyme

- Promotes vasoconstriction
- Promotes inflammation
- Promotes lipogenesis
- Increases insulin resistance

Leptin (Primarily from Subcutaneous White Adipose Tissue [WAT] [Leptin Resistance])

- Inhibits appetite and stimulates energy expenditure
- Promotes satiety (hunger/appetite suppression) and regulation of eating behavior by hypothalamus
- Promotes sympathoactivation
- Is insulin sensitizing in liver and skeletal muscle
- Plays a modulating role in reproduction, angiogenesis, immune response, blood pressure control, and osteogenesis
- Promotes inflammation (a harmful effect)

Resistin (Increased in Obesity; Action Still Being Clarified)

- Expressed by macrophages in adipose tissue
- Promotes insulin resistance and increased blood glucose levels
- Inhibits adipocyte differentiation and may function as a feedback regulator of adipogenesis
- Promotes inflammation

Retinol-Binding Protein 4 (RBP4) (From Visceral WAT, Role Not Clear)

- Promotes insulin resistance in muscle
- Promotes angiogenesis

Serum Amyloid A (An Acute Phase Protein)

Promotes systemic inflammation
Promotes atherosclerosis

Vaspin (From Visceral WAT, Role Not Clear)

Suppresses appetite
Is insulin sensitizing
Is antiinflammatory

Visfatin (From Visceral WAT)

Mimics insulin and binds to insulin receptors and promotes insulin sensitivity
Promotes adhesion of monocytes to endothelial cells and promotes plaque instability (harmful in cardiac disease)

Decreased in Obesity

Adiponectin (Primarily from Subcutaneous WAT)

Is insulin sensitizing
Is antiinflammatory
Is antiatherogenic

Apelin (Role Not Clear)

Improves insulin sensitivity in muscle
Promotes vasodilation by blocking angiotensin
Promotes cardiac contractility

Regulators of Lipoprotein Metabolism

Adipocyte apolipoprotein E (increases adipocyte triglyceride content)
Hormone-sensitive lipase (promotes lipolysis)

Lipoprotein lipase (promotes hypertriglyceridemia)
Lipoprotein lipase (transfers hormone-sensitive lipase to lipid droplet)

Proinflammatory Cytokines: *Increased in Obesity*

Interleukin-6

Promotes insulin resistance
Inhibits adipogenesis
Decreases adiponectin secretion
Promotes inflammation

Monocyte Chemoattractant Protein 1

Attracts macrophages
Promotes insulin resistance
Promotes atherogenesis

Macrophage Products

Plasminogen activator inhibitor 1 (from visceral WAT)
Promotes clot formation (inhibits fibrinolysis) by
inhibiting tissue plasminogen activator and
urokinase (also released by endothelial cells)
Promotes insulin resistance
Prostaglandin E2 and leukotriene B4
Promote inflammation
Tumor necrosis factor-alpha
Promotes insulin resistance
Promotes inflammation

Data from Fasshauer M, Blüher M: *Trends Pharmacol Sci* 36(7):461–470, 2015; Jung UJ, Choi MS: *Int J Mol Sci* 15(4):6184–6223, 2014; Leal Vde O, Mafra D: *Clin Chim Acta* 419:87–94, 2013.

Adipose tissue is classified according to color as WAT, brown adipose tissue (BAT), and beige adipose tissue (bAT). These tissue types are found in different locations, have different gene expression patterns, different rates of lipogenesis and lipolysis, and different origins.^{2,3} The origins of different adipose tissue depots are complex and unclear and likely associated with the heterogeneous function of their different locations.⁴

Most adipose tissue in the body is WAT. WAT is located in visceral (central) and subcutaneous (peripheral) stores. WAT also is found in muscle groups providing mechanical protection and sliding of muscle bundles, and bone marrow. WAT has a stromal structure that contains macrophages, mast cells, neutrophils, fibroblasts, endothelial cells, blood vessels, nerves, and precursor adipocytes. White adipocytes contain a single triglyceride fat droplet or vacuole (unilocular). Visceral adipocytes store fat as triglycerides primarily in the form of very-low-density lipoprotein (VLDL), derived from hepatic and dietary sources. A low nutritional state, stimulation of the β -adrenergic sympathetic nervous system, and release of catecholamines (epinephrine and norepinephrine) activate hormone-sensitive lipase, triggering lipolysis in WAT to release FFAs and glycerol into the circulation.² Pancreatic insulin can inhibit lipolysis by activation of insulin receptors in adipocytes. With obesity adipocytes are resistant to insulin lipolysis.

When energy balance is positive, excess fat is stored in mature white adipocytes, which undergo hypertrophy and adipogenesis (hyperplasia, formation of new fat cells from preadipocytes). Chronic positive energy balance can overwhelm adipogenesis, and fat storage then depends only on hypertrophy. Visceral WAT is more likely to store fat by adipose tissue hypertrophy; produce more adiponectin, less leptin, and more inflammatory cytokines; and result in central (visceral) obesity. Visceral WAT hypertrophy is associated with release of numerous adipokines, greater macrophage infiltration, increased vascularity, insulin resistance, a chronic proinflammatory state, and altered lipid metabolism, all characteristics of the metabolic syndrome associated with obesity.^{5,6} Insulin resistance results in type 2

diabetes mellitus, and excess lipolysis leads to increased release of FFAs into the circulation. With chronic increased energy intake, the increase in adipocyte size in visceral WAT exceeds the supporting vascular supply, resulting in hypoxia and inflamed and fibrotic adipose tissues. Excess FFAs are distributed to nonadipose cells, and when their utilization capacity is exceeded cellular dysfunction or death occurs (lipotoxicity). The increase in FFAs and inflammation contributes to cardiovascular disease, nonalcoholic steatohepatitis (NASH), and other disorders associated with obesity, including carcinogenesis.

Subcutaneous fat is more likely to store fat by adipogenesis (hyperplasia), with smaller adipocytes and greater fat storage capacity. Subcutaneous fat has higher leptin production, lower adiponectin production, lower production of inflammatory cytokines, lower association with insulin resistance, and is a healthier expansion of fat tissue. Thus the complications of obesity are related to where fat is stored, not just the accumulation of fat stores.

Estrogen and estrogen receptors have a role in fat metabolism and enhance the deposition of fat in the subcutaneous tissue and inhibit it in visceral tissue. Estradiol increases α_2 -adrenergic receptors in subcutaneous adipose tissue but not in visceral adipose tissue. The ratio of α_2 -adrenergic receptors to β -adrenergic receptors in the subcutaneous adipose tissue in premenopausal women is increased and accounts for the lower lipolytic response to epinephrine and norepinephrine as compared to adipocytes from men. This ratio is reversed in visceral adipose tissue in women. This may explain the higher incidence of peripheral obesity among premenopausal women and the increase in central obesity with menopause and in men.⁷

Brown adipocytes have multiple lipid droplets or vacuoles (multilocular) and are rich in mitochondria that contain iron, giving them a brown color. Exposure to cold, activation of the sympathetic nervous system and catecholamines, and activation of triiodothyronine (T_3) stimulate BAT to rapidly generate heat through the activation of uncoupling protein 1 (UCP1) (nonshivering thermogenesis). UCP1 promotes mitochondrial respiration and

dissipates chemical energy as heat from increased glucose and free fatty acid (FFA) oxidation. This occurs at a rate 50-fold greater than that in WAT and protects against obesity and metabolic syndrome.⁸ Estrogen-related receptors also participate in the induction of UCP1 in response to cold adrenergic stimulation in BAT.⁹

Neonates generate body heat from BAT primarily located in the interscapular and perirenal regions. It was traditionally thought that brown adipose tissue did not persist into adult life. However, using positron emission tomography (PET) scanning methods it is now known that adults also have UCP1-positive BAT. It is most common in lean individuals, usually located in the neck, supraclavicular, axillary, paravertebral, and perirenal regions.¹⁰ Muscle myokines, irisin and fibroblast growth factor-21, also promote thermogenesis and protect against obesity.

Leptin and adiponectin are minimally produced by BAT so there is little effect on appetite and satiety. There also is an inverse relationship between the amount of BAT, body mass index, and age. Interindividual differences in BAT-mediated thermogenesis may explain some of the variability in obesity susceptibility and the increased prevalence of obesity with aging. Variation in BAT and “brite” adipocytes (bATs) also may participate in natural regulation of weight reduction.

Located within WAT, particularly in subcutaneous fat depots, are beige or bAT (from “brown in white”), a subpopulation of white adipocytes that also contains multiple mitochondria and UCP1 but not in amounts associated with BAT. **Beige adipocytes** are thermogenic and emerge within WAT with chronic exposure to cold, with exercise, and with exposure to the synthetic ligand of peroxisome proliferator-activated receptor- γ (PPAR γ), such as thiazolidinedione (TZD).¹¹ This is known as the “*beiging*” of WAT. They disappear with elevated ambient temperatures.¹² Chronic exposure to cold also stimulates WAT transdifferentiation to bAT, which is thermogenic. With warm adaptation, bAT reverts to WAT. Exercise also promotes browning of white adipose tissue, and several myokines are involved in the crosstalk between adipose and muscle tissue.¹³ Leptin and insulin

together promote bAT, increasing energy expenditure and weight loss. bAT is diminished in obesity. Since “beiging” or “browning” of adipose tissue protects against obesity and metabolic syndrome, efforts are in progress to discover if there is a way to stimulate synthesis and activity of BAT and bAT as an approach to preventing or treating obesity and diabetes mellitus.^{8,14}

Bone marrow adipose tissue (MAT) is found in all bones, but in greater numbers in long bones. MAT releases adipokines with autocrine, paracrine, and endocrine effects. MAT has paracrine effects associated with both osteoblast function and endocrine actions that affect distant organs, including the cardiovascular system. In general, excessive MAT is associated with osteoporosis.¹⁵ Obesity and alterations in adipokines, activation of macrophages, and release of inflammatory mediators are associated with rheumatoid arthritis.¹⁶ Loss of visceral and subcutaneous adipose tissue as occurs in anorexia nervosa results in the accumulation of MAT and osteoporosis. The mechanism is associated with a decrease in myokine, delta homolog 1 protein (DLK1) (inhibits adipogenesis), and hypoleptinemia, resulting in increased adipocyte and osteoblast differentiation.¹⁷

Obesity

Obesity is an increase in body adipose tissue and an endocrine and metabolic disorder that has become epidemic worldwide. Obesity develops when caloric intake exceeds caloric expenditure in genetically susceptible individuals.¹⁸ The incidence among U.S. adults was 36.5% between 2011 and 2014 (women 38.3% and men 34.3%) and 17% among children and adolescents between ages 2 and 19 years. Children tend to become obese adults. There are ethnic differences in rates of obesity: non-Hispanic blacks have the highest age-adjusted rate at 48.1% followed by Hispanics (42.5%), non-Hispanic whites (34.5%), and non-Hispanic Asians (11.7%).¹⁹ It is projected that 42% of people in the United States will be obese by 2030.²⁰ Obesity is defined as a body mass index (BMI) that exceeds 30 kg/m² in adults and a BMI greater than or equal to the age- and sex-specific 95th percentile of the

2000 Centers for Disease Control and Prevention growth charts in children.¹⁹

Obesity is the fifth leading cause of death in the United States and accounts for high healthcare costs worldwide.²¹ Three leading causes of death in the United States are associated with obesity: cardiovascular disease, type 2 diabetes mellitus, and cancer (liver, advanced prostate, ovarian, gallbladder, kidney, colorectal, esophageal [adenocarcinoma], postmenopausal breast, pancreatic, endometrial, and stomach [cardia])²² Obesity also is a risk factor for hypertension, stroke, hyperlipidemia, gallstones, nonalcoholic steatohepatitis, gastroesophageal reflux, hiatal hernia, osteoarthritis, infectious disease, asthma, obstructive sleep apnea, and chronic kidney disease. However, some studies have shown that mild obesity in older individuals is associated with lower mortality (the obesity paradox) but the mechanisms are not clear.²³ The causes and consequences of obesity are multiple and complex and there is rapidly advancing research regarding causal mechanisms, complications, and treatment. Genotype and gene-environment interactions are important predisposing factors²⁴ (see [What's New? Obesogens](#)). Single-gene defects (monogenic) are rare, and obesity is usually polygenic and associated with other phenotypes such as endocrine disorders (i.e., diabetes and hypothyroidism) and intellectual disability (i.e., Down and Prader-Willi syndromes). Single-gene defects include the melanocortin-4 receptor gene, leptin gene (also known as the *obesity gene*), and leptin-receptor gene. All single-gene defects are directly or indirectly related to leptin and melanocortin pathways (decrease appetite and regulate energy homeostasis).^{25,26} Metabolic abnormalities contributing to obesity include Cushing syndrome, Cushing disease, polycystic ovary syndrome, growth hormone deficiency, hypothyroidism, and hypothalamic injury. Contributing environmental factors include socioeconomic status (both high and low incomes), food intake (low-nutrient, energy-dense foods), and physical inactivity. Obesity also is associated with adverse social and psychologic consequences, including depression and mood disorders.²⁷

What's New?

Obesogens

Obesogens are exogenous chemicals that contribute to the development of obesity. These are molecules that stimulate adipogenesis and fat storage and interfere with neuroendocrine control of appetite and satiety. Developmental exposure to environmental obesogens is proposed to contribute to the epidemic of obesity in addition to high caloric intake, a sedentary lifestyle, and genetic predisposition. In early life, these substances are included in the maternal diet (i.e., phytoestrogens) or are associated with exposure to pesticides (i.e., organophosphates), plastics (phthalates, bisphenol-A), personal care products, and household and other consumer products that can cross the placental barrier or be transmitted, or both, through breast milk. Epigenetic changes in gene regulation and expression affect adipocyte differentiation, adipogenesis, and lipid metabolism, resulting in obesity in later life. Animal studies indicate these genetic changes can be transmitted through generations of families.

Data from Janesick AS, Blumberg B: *Am J Obstet Gynecol* 214(5):559–565; 2016; Nappi F et al: *Int J Environ Res Public Health* 13(8):765, 2016; Stel J, Legler J: *Endocrinology* 156(10):3466–3472, 2015.

◆ Pathophysiology.

The pathophysiology of obesity is complex and involves the interaction of peripheral and central pathways, numerous adipokines, hormones, and neurotransmitters (Fig. 23.1). The adipocyte is the cellular basis of obesity and most of the adipocytes are white.²⁸ In the periphery, white adipocytes increase in size and number, store triglyceride, and secrete adipokines. Adipokines and other hormones participate in regulation of food intake, energy metabolism, and other functions as previously described. Adipokines circulate in the blood at concentrations that increase or decrease in relation to body fat mass

(see Box 23.1) and provide signals to the hypothalamus, brainstem, autonomic nervous system, and other centers to regulate hunger, satiety, and energy balance.²⁹ Visceral WAT accumulation causes dysfunction in the regulation and interaction of this signaling system and contributes to the complications and consequences of obesity.³⁰ The following section summarizes the mechanisms controlling food intake and energy balance.

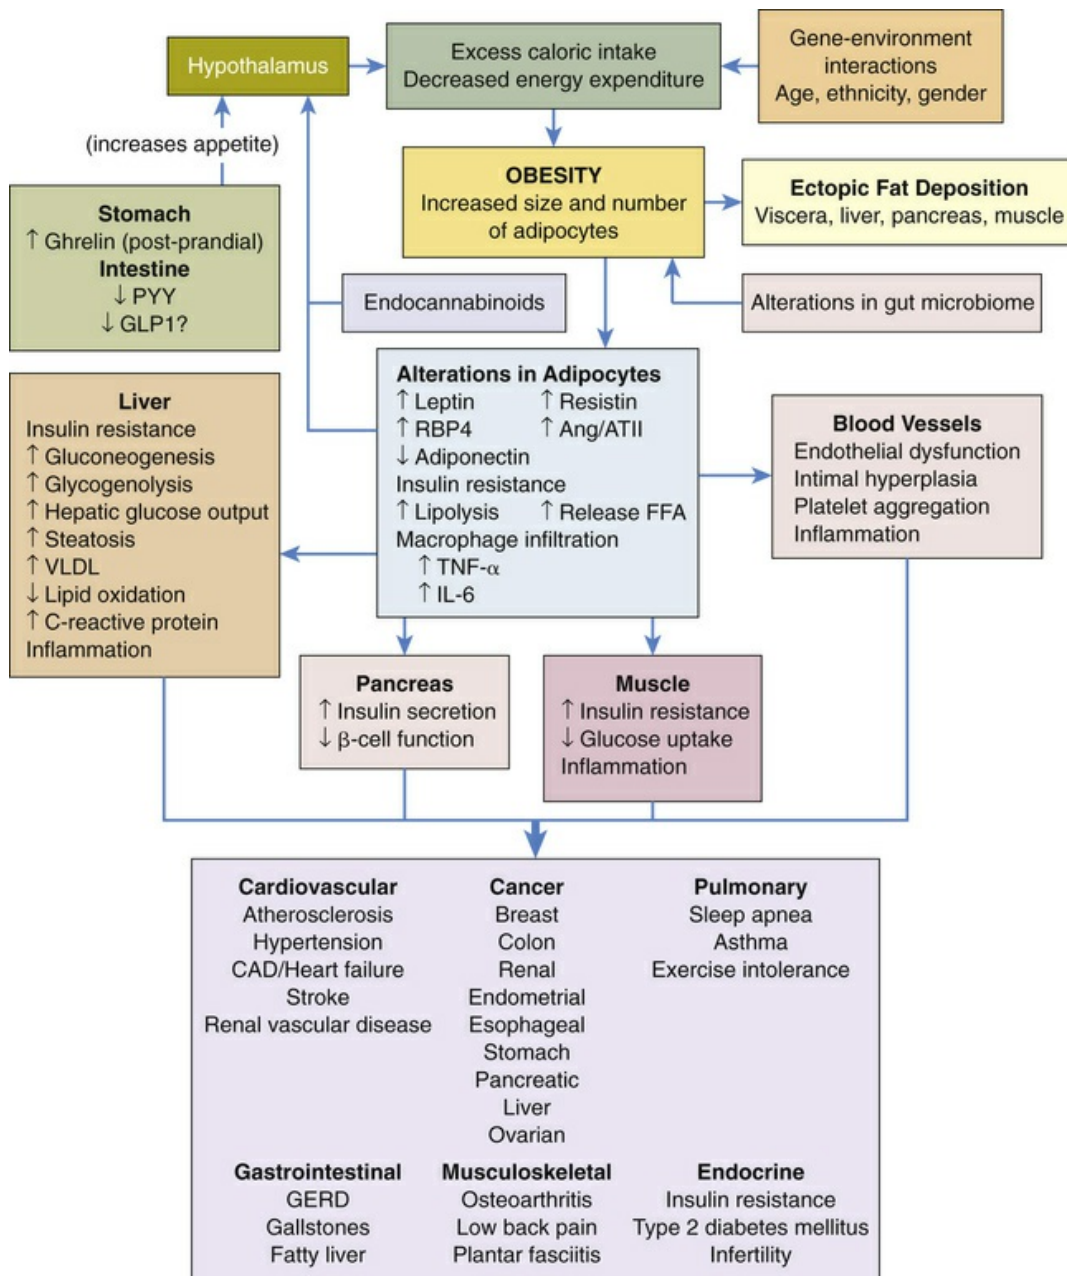

FIGURE 23.1 Pathophysiology and Common Complications of Obesity. See text for details. *Ang/ATII*, Angiotensinogen/angiotensin II; *CAD*, coronary artery disease; *FFA*, free fatty acids; *GERD*, gastroesophageal reflux disease; *GLP1*, glucagon-like peptide 1; *IL-6*, interleukin-6; *PYY*, intestinal peptide YY; *RBP4*, retinol-binding protein 4; *TNF- α* , tumor necrosis factor-alpha; *VLDL*, very-low-density lipoprotein.

Food Intake and Energy Balance

Centrally, the **arcuate nucleus (ARC)** in the hypothalamus regulates food intake and energy metabolism by balancing the opposing effects of two sets of neurons. One set of neurons produces agouti-related protein (AgRP) and neuropeptide Y (NPY), collectively known as *AgRP/NPY neurons*. These neurons promote appetite, stimulate eating, and decrease metabolism (anabolic). They are known as *orexigenic neurons* and are stimulated by molecules called *orexins*. Another set of neurons synthesize pro-opiomelanocortin-producing (POMC-producing) peptide and cocaine-and-amphetamine-regulated transcript (CART), collectively known as *POMC/CART neurons*. These neurons suppress appetite, inhibit eating, and increase metabolism. They are known as *anorexigenic neurons* and are stimulated by molecules called *anorexins* (Box 23.2). The orexin and anorexin signaling pathways are transmitted through the autonomic nervous and endocrine systems to regulate appetite, food intake, energy metabolism, and body temperature.³¹ The hypothalamus also communicates with higher brain centers related to reward, pleasure, memory, and addictive behavior. These centers can override hypothalamic control of food intake and satiety, increasing consumption of highly palatable foods, resulting in increased fat stores.³²⁻³⁴

Box 23.2

Examples of Hormones and Neuropeptides That Influence Eating Behavior

Orexins (Appetite Stimulants)

Neuropeptide Y (NPY)
Melanin-concentrating hormone (MCH)
Agouti-related protein (AgRP)
Ghrelin
Galanin
Orexins A and B
Endocannabinoids
Cortisol

Anorexins (Appetite Suppressants)

Leptin
Insulin
Cholecystokinin (CCK)
Glucagon-like peptide 1 (GLP-1)
Peptide YY (PYY)
Corticotropin-releasing factor (CRF)
Urocortin (a CRF satiety signaling hormone)
Cocaine- and amphetamine-regulated transcript (CART)
Alpha-melanocyte-stimulating hormone (α -MSH)
Bombesin
Serotonin
Calcitonin

Adipokines and hormones released from the gastrointestinal tract and pancreas interact with brain centers (adipose tissue-gut-brain axis), and play a significant role in the pathophysiology of obesity. The major adipokines and hormones are reviewed next.

Leptin is a product of the obesity gene (*Ob* gene) and expressed primarily by adipocytes.³⁵ High leptin levels in the normally fed state act on the hypothalamus to inhibit orexigenic AgRP/NPY neurons and

stimulate anorexigenic POMC/CART neurons to suppress appetite and increase energy expenditure. At low leptin levels (i.e., during fasting), leptin stimulates food intake and reduces energy expenditure. This balance regulates body weight and energy expenditure within a fairly narrow range. Leptin levels increase as the number of adipocytes increases. However, high leptin levels are ineffective at decreasing appetite and energy expenditure, a condition known as central *leptin resistance*.

Leptin resistance fails to inhibit orexigenic hypothalamic satiety signaling and promotes overeating and excessive weight gain. Leptin also regulates hepatic gluconeogenesis, insulin sensitivity, and glucose and lipid metabolism in liver, muscle, and adipose tissue. Peripheral leptin resistance results in hyperglycemia, hyperinsulinemia, and hyperlipidemia, and stimulates macrophages and endothelial cells to produce proinflammatory mediators. The cause of leptin resistance is unknown. It may be related to a defect in leptin transport, an inability of leptin to cross the blood-brain barrier, an alteration in the permissive effect of leptin, or a defect in or suppression of the leptin receptor. The low-grade inflammation accompanying obesity also is thought to contribute to leptin resistance.³⁶ Chronic hyperleptinemia also stimulates the sympathetic nervous system, oxidative stress, chronic low-grade inflammation, and ventricular hypertrophy and contributes to the pathogenesis of hypertension, atherosclerosis, cardiovascular disease, and cancer associated with obesity.³⁷⁻³⁹

Decreased beta-cell function and insulin resistance are associated with obesity. The mechanisms are not clear, but there is an association between hyperlipidemia and fat storage, macrophages and inflammation, and alterations in adipokines. Leptin resistance and decreased adiponectin contribute to insulin resistance.⁴⁰ Insulin resistance results in hyperinsulinemia, hyperglycemia, and a predisposition to type 2 diabetes mellitus. **Retinol-binding protein 4** (binds vitamin A) is an adipocytokine produced both in the liver and by adipocytes. It is increased in visceral adiposity and contributes to inflammation and insulin resistance in liver and muscle and is

associated with hepatic steatosis and cardiovascular disease.^{41,42}

Adiponectin is produced primarily by visceral adipose tissue but is also produced by cardiomyocytes and skeletal muscle. It has insulin-sensitizing and antiinflammatory properties, and plasma levels decrease with visceral obesity, contributing to insulin resistance and type 2 diabetes mellitus.⁴³ Decreased adiponectin levels are associated with increased hepatic gluconeogenesis, decreased skeletal muscle glucose uptake, and increased levels of inflammatory mediators, such as interleukin-6 (IL-6) and tumor necrosis factor-alpha (TNF- α). Adiponectin may serve as an antiinflammatory and antiatherogenic plasma protein; it has an important role in vascular remodeling and is cardioprotective.⁴⁴ Decreased levels of adiponectin are associated with increased risk for coronary artery disease resulting from hyperlipidemia, hypertension, and factors that promote thrombosis and inflammation.^{45,46}

Endocannabinoids (i.e., anandamide) are arachidonic acid derivatives expressed in both the brain and the peripheral nerve tissues, and have effects on endocannabinoid (CB) receptors in orexigenic pathways. They increase appetite, enhance nutrient absorption, stimulate lipogenesis, and increase white adipose tissue accumulation by acting at both central (CB1 receptor) and peripheral sites (CB2 receptor). They also inhibit energy expenditure and thermogenesis. An increase in endocannabinoids is proposed to be associated with obesity.^{47,48}

Angiotensinogen (AGT) is produced in the liver and adipocytes and is increased in obesity. AGT is the precursor to angiotensin I (ATI), which is then converted to angiotensin II (ATII). The effects of ATII include vasoconstriction, renal retention of sodium and water, and release of aldosterone. Increased ATII from adipose tissue also promotes inflammation, lipogenesis, oxidative stress, and insulin resistance, all of which contribute to the hypertension, atherosclerosis, type 2 diabetes mellitus, and cancer associated with obesity.⁴⁹ Paracrine effects of the renin-angiotensin system in the brain also may participate in the control of energy balance and may be involved in the pathogenesis of obesity and obesity-related hypertension.⁵⁰

Gastrointestinal hormones also play a role in the complex pathophysiology of obesity (Box 23.3). The most significant ones are reviewed next.

Box 23.3

Gastrointestinal Hormones and Obesity

Ghrelin: Stomach (role in obesity not clear)

Stimulates hunger and controls gastric motility and acid secretion; stimulates growth hormone

Glucagon-like peptide 1 (GLP-1): Large intestine (decreased in obesity)

Stimulates insulin secretion; inhibits glucagon release; slows gastric emptying to reduce postprandial hyperglycemia; increases satiety

Peptide YY: Small intestine (decreased in obesity)

Reduces appetite; inhibits gastric motility; increases energy expenditure

Amylin: Pancreatic beta cells (increased in obesity; amylin resistance)

Suppresses appetite; delays gastric emptying and postprandial glucagon secretion; promotes glycemic control

Pancreatic polypeptide: Pancreatic F cells (probably decreased in obesity)

Increases satiation; increases energy expenditure

Cholecystikinin: Small intestine (probably increased in obesity)

Increases satiation; reduces food intake; stimulates gallbladder contraction, release of pancreatic enzymes and insulin; slows gastric emptying

Ghrelin is produced by the stomach gastric mucosa in response to hunger and stimulates food intake through activation of the ghrelin receptor (GHS-R) located on neuropeptide Y (NPY)/agouti-related peptide (AgRP) neurons in the hypothalamus. Ghrelin induces metabolic changes leading to an increase in body weight and body fat mass. Ghrelin also stimulates release of growth hormone (GH) from anterior pituitary cells, release of gastric acid, gastrointestinal motility, and pancreatic secretion of insulin. An elevation in the levels of free fatty acids and growth hormone after eating decreases release of ghrelin. It also has satiety, vasodilatory, cardioprotective, and antiproliferative effects.^{51,52} In lean individuals, ghrelin levels increase with hunger and fall during the postprandial interval. In people with diet-induced obesity, circulating ghrelin levels tend to be lower with blunted meal-related fluctuations. An obesity-induced central ghrelin resistance has been observed in neural circuits. However, the causative mechanisms relating ghrelin with obesity have yet to be clearly defined.⁵³

Signals from leptin and ghrelin are complementary yet antagonistic signals reflecting acute and chronic changes in energy balance, the effects of which are mediated by hypothalamic neuropeptides, such as NPY and AgRP. In obesity, plasma ghrelin level does not decrease after eating. Endocrine and vagal afferent pathways also are involved in the actions of ghrelin and leptin, adding to the complexity of mechanisms that can affect obesity.⁵⁴ Ghrelin is thought to have antilipolytic effects and stimulates lipogenesis in visceral WAT.⁵⁵ However, with obesity there is thought to be ghrelin resistance in the hypothalamus. Thus although ghrelin is increased with obesity, its role in contributing to obesity is yet to be clearly defined.⁵³

Glucagon-like peptide 1 is an incretin secreted from intestinal endocrine cells when nutrients enter the small intestine. GLP-1 stimulates pancreatic glucose-dependent insulin secretion, delays gastric emptying, suppresses appetite, and increases energy expenditure. GLP-1 levels may be decreased in obese individuals, and a GLP-1 receptor analog has been approved to treat both obesity and type 2 diabetes mellitus.^{56,57}

Peptide YY (PYY) is released from intestinal endocrine cells in response to nutrients entering the intestine and inhibits gastric motility and decreases appetite. The level of PYY decreases with increases in adiposity, and decreased PYY level is associated with obesity.^{29,58}

Cholecystokinin (CCK) is secreted by proximal small intestinal cells following food intake. Its actions include gallbladder contraction, release of pancreatic enzymes and insulin, satiation, and reduced food intake. CCK secretion is reduced in obesity.⁵⁹

Obesity produces a state of chronic, low-grade inflammation (metabolic triggered inflammation) in WAT. Macrophages, lymphocytes (proinflammatory CD8+ T cells), neutrophils, and mast cells infiltrate enlarged adipocytes and release inflammatory cytokines (e.g., TNF- α , and IL-6)⁶⁰ (see [Box 23.1](#)). Macrophages change their phenotype from antiinflammatory expression of cytokines (M2 macrophages) to expression of proinflammatory cytokines (M1 macrophages). The mechanisms of macrophage infiltration are thought to be related to adipocyte senescence, necrosis, and death. The inflammatory state is supported by increased levels of leptin and resistin and decreased levels of adiponectin, and escalation of eicosanoid-generating prostaglandins and leukotriene B4. The inflammatory state and accelerated lipolysis contribute to the development of insulin resistance and metabolic syndrome, and to the complications of obesity, particularly type 2 diabetes mellitus, cardiovascular disease, and cancer.⁶¹⁻⁶⁴

Changes in the intestinal microbiome also are associated with obesity, although the mechanisms are not clear. Microbes (mostly bacteria) are found in high concentration in the lower gastrointestinal tract, and bacterial composition is affected by genetics, diet, use of antibiotics and other medications, and energy balance. These bacteria have considerable variability among individuals and participate in complex carbohydrate breakdown and nutrient absorption, inflammatory responses, gut permeability, and bile acid metabolism.⁶⁵ Gut microbial fermentation of dietary fiber produces short-chain fatty acids (acetate, butyrate, and propionate) that function as energy

sources and signaling molecules that affect host energy metabolism and inflammation. Gut microbiota transplanted from obese mice into germ-free mice or from an obese human twin have shown that the gut microbiota may have a causal role in the development of obesity and insulin resistance.⁶⁶ More studies are needed to determine how changes in the microbiota contribute to body weight regulation, metabolism, low-grade inflammation and increased adiposity, and how manipulation of the gut microbiota can assist in preventing or treating obesity.^{67,68}

◆Clinical Manifestations.

Obesity usually presents with two different forms or phenotypes of adipose tissue distribution: visceral and peripheral.^{69,70} Visceral obesity (also known as *intraabdominal*, *central*, or *masculine obesity*) occurs when the distribution of body fat is localized around the abdomen and upper body, resulting in an apple shape. Visceral obesity is associated with accelerated lipolysis and has an increased risk for chronic systemic inflammation, metabolic syndrome, obstructive sleep apnea syndrome, type 2 diabetes mellitus, cardiovascular complications, osteoarthritis, and cancer. Visceral venous blood drains into the portal vein, contributing to higher liver synthesis of plasma lipids. Lipids also are located in intracellular liposomes. In the liver, liposomes can increase in size (steatosis). Increased fat in the liver increases the risk for nonalcoholic fatty liver disease, steatohepatitis, and cirrhosis.^{28,71}

Peripheral obesity (also known as *subcutaneous*, *gluteal-femoral*, or *feminine obesity*) occurs when the distribution of body fat is extraperitoneal and distributed around the thighs and buttocks and through the muscle, resulting in a pear shape; it is more common in premenopausal women. Peripheral and subcutaneous fat is less metabolically active and lipolytic and releases fewer adipocytokines (particularly adiponectin) than visceral fat. Risk factors are still present for the complications of obesity, but they are less severe than those for visceral obesity.²

Normal weight obesity (NWO) describes a phenotype of

individuals with normal body weight and BMI with percent of body fat greater than 30%. These individuals are at risk for metabolic dysregulation, increases in inflammatory cytokines, insulin resistance, increased risk for cardiovascular disease, and other complications of obesity, and higher mortality.⁷² NWO is estimated to occur in 2% to 28% of women and 3% of men.⁷³ Another phenotype associated with obesity is metabolically healthy obesity (Box 23.4).

Box 23.4

Metabolically Healthy Obesity

Metabolically healthy obesity (MHO, also known as the *obesity paradox*) describes a phenotype of about 10% to 30% of individuals who are obese but have no metabolic-obesity-associated complications (i.e., high insulin sensitivity, absence of metabolic syndrome, high level of cardiorespiratory fitness, adequate inflammatory profile [high adiponectin level, low C-reactive protein, tumor necrosis factor-alpha, and IL-6 levels]) and decreased risk for morbidity and mortality. However, there is no standard definition for this phenotype, and complications related to pulmonary function and to orthopedic and other disorders are often not described. MHO is more prevalent among those with absence of visceral fat accumulation, among women, and among those who are more physically active. Research is in progress to better understand the genetics, body fat distribution patterns, metabolic pathways, adipocyte differentiation, lifestyle practices, age-related adverse outcomes and patterns of morbidity and mortality, and therapeutic options for these individuals.

Data from Gonçalves CG, Glade MJ, Meguid MM: *Nutrition* 32(1):14–20, 2016; Muñoz-Garach A, Cornejo-Pareja I, Tinahones FJ: *Nutrients* 8(6), 2016; Phillips CM: *Ann N Y Acad Sci* 1391(1):85-100, 2016.

◆ Evaluation and Treatment.

All children and adults should be screened for obesity.⁷⁴ There are several methods for estimating or measuring the amount of adipose tissue: anthropometric measurements including weight, height, and circumferences of various body diameters (i.e., waist-to-hip ratios and waist circumference); skinfold thickness (measured via skinfold calipers); ultrasound to measure peripheral body fat; and bioelectric impedance and underwater hydrostatic weighing to calculate total body fat. The only method for directly measuring total body fat is via the DEXA scans (dual energy x-ray absorptiometry).⁷⁵

In clinical practice, anthropometric and body diameter measures are most commonly used to calculate the body mass index because they are the easiest to measure and most cost-effective. Body mass indices have been established based on height, weight, age, gender, and ethnicity. Overweight is defined as a BMI greater than 25 kg/m² and obesity is a BMI greater than 30 kg/m². BMI charts are available for children ages 2 to 20 years; these can be used for comparison during adulthood because obese children generally become obese adults.

However, BMI does not measure the amount and distribution of body fat. Waist circumference (more than 40 inches [102 cm] for men and more than 35 inches [88 cm] for women) adds information to assist with disease risk assessment in general practice. Obesity risk assessment is available from the American Association of Clinical Endocrinologists and the American College of Endocrinology.⁷⁶ No specific diagnostic criteria for obesity have been established.

Obesity is a chronic disease for which various treatment approaches have been used, including correction of metabolic abnormalities and implementation of individually tailored lifestyle interventions, such as weight-reduction diets and exercise programs. Additional treatments include psychotherapy, behavioral modification, self-motivation, and support systems.⁷⁷

Several drugs have been approved for the pharmacologic management of obesity.⁷⁸ Currently, bariatric surgical procedures (i.e., the Roux-en-Y gastric bypass, adjustable gastric banding, and sleeve gastrectomy) offer the most significant reduction in weight, reduction in comorbidities, and decrease in insulin resistance for treatment of

obesity^{78,79} (see [What's New? Outcomes of Bariatric Surgery](#)). Efforts are continuing to identify the molecular and neuroendocrine causes of obesity. This will lead to more specific and personalized prevention and treatment strategies.^{80,81}

What's New?

Outcomes of Bariatric Surgery

Bariatric surgery (BS) includes malabsorptive procedures, such as Roux-en-Y gastric bypass, biliary pancreatic diversion (BPD), intra-gastric balloon (to restrict the gastric volume), and duodenal-jejunal bypass liner; and restrictive procedures, such as vertical sleeve gastrectomy or adjustable gastric banding. BS results in caloric restriction, sustained weight loss (reduction in BMI), glycemic control, reduced inflammation and complex changes in neuroendocrine and immune signals emanating from the gut. BS is performed for individuals with severe obesity, including extremely obese children and adolescents, and improves quality of life compared to other treatments. Improvements in cognitive function, including attention, executive function, and memory, have been documented and may be related to improved cardiovascular function, correction of sleep apnea, reduced insulin resistance, and improved glycemic control. Depression and anxiety also have improved. Physical functioning improves but may be related to efficiency and not absolute improvement in cardiorespiratory or muscle function. Bariatric surgery-induced weight loss improves secretion of glucagon-like peptide 1 (GLP-1) and insulin sensitivity, and it can result in remission of type 2 diabetes, hypertension, hyperlipidemia, obstructive sleep apnea, gastroesophageal reflux, and degenerative joint disease. More data are needed to understand long-term complications, long-term survival, microvascular and macrovascular events, remission of type 2 diabetes, and psychologic responses. There also are changes in hypothalamic signaling with increases in anorexigenic signals and decreases in orexigenic

signals; however, more research is needed to understand these mechanisms of change in energy homeostasis. Changes in the intestinal microbiota also have been observed after BS, but the specific changes that may promote or inhibit weight loss are to be determined.

Data from Anhê FF et al: *Can J Diabetes* 2017 May 25 [Epub ahead of print]; Inge et al: *Lancet Diabetes Endocrinol* 5(3):165-173, 2017; Jumbe S, Hamlet C, Meyrick J: *Curr Obes Rep* 6(12):71-78, 2017; Labrecque J et al: *Can J Diabetes* 2017 Mar 29 [Epub ahead of print]; Nguyen NT, Varela JE: *Nat Rev Gastroenterol Hepatol* 14(3):160-169, 2017; Thiara G et al: *Psychosomatics* 58(3):217-227, 2017.

Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder

Anorexia nervosa, bulimia nervosa, and binge eating disorder are psychiatric disorders related to a distorted body image with a desire for thinness and a fear of fatness that result in extreme restrictions in eating habits. These psychiatric disorders are included in the Diagnostic and Statistical Manual of Mental Disorders-5 (DSM-5) classification of eating disorders by the American Psychiatric Association (Box 23.5). They occur in as many as 1% of young women and adolescent girls in the United States and rarely occur in black women. Only 5% to 10% of cases are men.^{82,83} However, eating disorders also may occur in children and women ages 45 to 50 years.⁸⁴ Risk factors include genetic, epigenetic, familial, biologic, psychologic, and social factors.⁸⁵⁻⁹⁰

Box 23.5

Diagnostic Criteria for Eating Disorders

Anorexia Nervosa

Persistent restriction of energy intake leading to significantly low body weight (in context of what is minimally expected for age, sex, developmental trajectory, and physical health). Either an intense fear of gaining weight or of becoming fat, or persistent behavior that interferes with weight gain (even though significantly low weight).

Disturbance in the way one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Subtypes:

Restricting type

Binge-eating/purging type

Bulimia Nervosa

Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:

Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.

A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise.

The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.

Self-evaluation is unduly influenced by body shape and weight.

The disturbance does not occur exclusively during episodes of anorexia nervosa.

Binge Eating Disorder*

Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:

Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.

A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

The binge eating episodes are associated with three or more of the following:

Eating much more rapidly than normal.

Eating until feeling uncomfortably full.

Eating large amounts of food when not feeling physically hungry.

Eating alone because of feeling embarrassed by how much one is eating.

Feeling disgusted with oneself, depressed, or very guilty afterward.

Marked distress regarding binge eating is present.

Binge eating occurs, on average, at least once a week for 3 months.

Binge eating is not associated with the recurrent use of inappropriate compensatory behaviors as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa methods to compensate for overeating, such as self-induced vomiting.

* **note:** Binge eating disorder is less common but much more severe than overeating. Binge eating disorder is associated with more subjective distress regarding the eating behavior, and commonly other co-occurring psychologic

problems.

Data from American Psychiatric Association (APA): *DSM-5: diagnostic and statistical manual of mental disorders*, ed 5, Arlington, VA, 2013, Author, pp. 338-345.

Complications of chronic and severe eating disorders are related to malnutrition, and weight changes involve all organ systems and can be life-threatening. Most complications are reversible with treatment (Box 23.6). However, refeeding syndrome can increase morbidity (Box 23.7). The death rate is highest among women with anorexia nervosa, particularly those with a psychiatric comorbidity.^{83,91}

Box 23.6

Complications of Severe Anorexia Nervosa/Bulimia

Anorexia Nervosa

Gastrointestinal

Dysphagia related to weakened pharyngeal muscles
Slowed gastric emptying, early satiety, nausea and bloating;
gastric dilation is a serious complication
Constipation related to slowed peristalsis
Apoptosis of liver cells related to malnutrition; elevated
transaminases

Cardiac

Dysrhythmias: prolonged QT interval, ventricular arrhythmias,
and cardiac syncope
Left ventricular atrophy and mitral valve prolapse
Sudden cardiac death

Pulmonary

Complications are rare, but can include aspiration pneumonitis

Hematologic

Anemia, leukopenia, and thrombocytopenia
Delayed response to infection

Musculoskeletal

Osteoporosis: decreased bone formation and increased bone resorption
Increased risk for stress fractures

Endocrine

Hypogonadal: related to reduced pulsed hypothalamic gonadotropin-releasing hormone secretion
Females: low estrogen, loss of menses
Males: low testosterone, low libido, loss of potency and muscle strength
Hypothyroidism: euthyroid sick syndrome, low blood pressure, cold intolerance
Hypercortisolism
Hypoglycemia: depleted liver glycogen stores
Impaired temperature regulation

Neurologic

Brain atrophy and impaired cognitive function

Dermatologic

Xerosis, hair thinning, acrocyanosis

Bulimia

Self-Induced Vomiting

Persistent gastric acid reflux, dysphagia, and dyspepsia:
chronic induced vomiting

Electrolyte and acid-base disorders: metabolic alkalosis,
hypokalemia

Tooth erosion

Inflammation of vocal cords and hoarse voice

Parotid gland enlargement

Laxative Abuse

Hypokalemic metabolic alkalosis

Diarrhea, hemorrhoids, rectal prolapse

Hyperphosphatemia: use of laxatives containing sodium
phosphate

Data from Donaldson AA, Gordon CM: *Metabolism* 64(9):943–951, 2015; Sangvai D: *Prim Care* 43(2):301-312, 2016; Sato Y, Fukudo S: *Clin J Gastroenterol* 8(5):255–263, 2015; Westmoreland P, Krantz MJ, Mehler PS: *Am J Med* 129(1):30–37, 2016.

Box 23.7

Refeeding Syndrome

Refeeding syndrome occurs in severely malnourished individuals when parenteral or enteral nutritional therapy is initiated. During starvation, loss of body minerals causes the movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma. When refeeding starts, an increase in insulin levels stimulates the movement of glucose and these ions back into the

cells, and the plasma concentrations can decrease to dangerously low levels, causing hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency. Rapid expansion of the extracellular fluid volume also can occur with carbohydrate refeeding and may cause fluid overload. Hypophosphatemia contributes to alterations in red blood cell shape and function, contributing to tissue hypoxia and increased respiratory drive. The consequences of these alterations include life-threatening dysrhythmias, congestive heart failure, muscle weakness (including respiratory muscles), and death. Individuals at greatest risk are those with starvation from any cause including anorexia nervosa, chronic alcoholism, morbid obesity with massive weight loss, and prolonged fasting. Refeeding syndrome is prevented by slowly reinstating feeding (about 20 kcal/kg/day for the first few days) and monitoring plasma levels of phosphate, potassium, magnesium, and calcium during the change from catabolic to anabolic metabolism. Some studies have recommended higher caloric feedings (≥ 1400 kcal/d).

Data from Crook MA: *Nutrition* 30(11–12):1448–1455, 2014; Garber et al: *Int J Eat Disord* 49(3):293–310, 2016; Sachs K et al: *Eat Disord* 2015;23(5):411–421, 2015.

Starvation

Malnutrition is lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals and is caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors. **Starvation** is a reduction in energy intake leading to weight loss. Short-term starvation and long-term starvation have different effects. Therapeutic short-term starvation is part of many weight-reduction programs because it causes an initial rapid weight loss that reinforces the individual's motivation to diet. Therapeutic long-term starvation is used in medically controlled environments to facilitate rapid weight loss in morbidly obese individuals. Pathologic long-term starvation can be caused by

poverty; chronic diseases of the cardiovascular, pulmonary, hepatic, and digestive systems; malabsorption syndromes; human immunodeficiency virus (HIV) infection; and cancer.⁹²

Short-term starvation, or extended fasting, consists of several days of total dietary abstinence or deprivation. The body responds with mechanisms to protect protein mass. For 4 to 6 hours after the last meal, the body is in a well-fed state and its energy requirements are supplied by glucose from recently ingested carbohydrates. Once all available energy has been absorbed from the intestine, glycogen in the liver is converted to glucose through glycogenolysis, the splitting of glycogen into glucose. This process peaks within 4 to 8 hours, and gluconeogenesis begins. Gluconeogenesis is the formation of glucose from noncarbohydrate molecules: lactate, pyruvate, amino acids, and the glycerol portion of fats from lipolysis. Like glycogenolysis, gluconeogenesis takes place within the liver. Both of these processes deplete stored nutrients and thus cannot meet the body's energy needs indefinitely. Proteins continue to be catabolized to a minimal degree, providing carbon for the synthesis of glucose.⁹³

Long-term starvation begins after several days of dietary abstinence and eventually causes death. Absolute deprivation of food causes marasmus or protein-energy malnutrition (loss of muscle mass and body fat depletion). Protein deprivation in the presence of carbohydrate intake is called *kwashiorkor* (loss of muscle mass with sustained body fat). Marasmic kwashiorkor (edematous, severe childhood malnutrition) is a combination of chronic energy deficiency and chronic or acute protein deficiency and inadequate micronutrients.⁹⁴ These conditions are described in [Chapter 43](#). Anorexia nervosa is a psychologic cause of long-term starvation (see [Box 23.5](#)). Cachexia (also known as *cytokine-induced malnutrition*) is physical wasting with loss of weight and muscle atrophy, fatigue, and weakness. Inflammatory mediators (i.e., TNF- α , interferon- γ , IL-1, IL-6) and an increased catabolic response are associated with the cachexia of advanced cancer.⁹⁵⁻⁹⁷ Cancer, AIDS, tuberculosis, and other major chronic progressive diseases contribute to cachexia. Anorexia and cachexia often occur together. Cachexia is not the same as food

deprivation starvation. A healthy person's body can adjust to starvation by slowing the metabolic rate; however, in cachexia, the body does not make this adjustment.

The major characteristic of long-term starvation is a decreased dependence on gluconeogenesis and an increased use of ketone bodies (products of lipid and pyruvate metabolism) as a cellular energy source. During long-term starvation, depressed insulin levels and increased levels of glucagon, cortisone, epinephrine, and growth hormones promote lipolysis in adipose tissue. Lipolysis liberates fatty acids, which supply energy to cardiac and skeletal muscle cells, and ketone bodies, which sustain brain tissue. Fatty acid, or ketone body, oxidation meets most of the energy needs of the cells. (Some glucose is still needed as fuel for brain tissue.) Once the supply of adipose tissue is depleted, proteolysis begins. The breakdown of muscle and visceral protein is the last process the body engages to supply energy for life. Death results from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.⁹⁸

Adequate ingestion of appropriate nutrients is the obvious treatment for starvation. In medically induced starvation the body is maintained in a ketotic state until the desired amount of adipose tissue has been lysed. Starvation imposed by chronic disease, long-term illness, malabsorption syndromes, and chronic eating disorders is treated with enteral or parenteral nutrition. Perioperative or critical care management of nutrition is necessary to prevent unnecessary starvation.⁹⁹ Care must be taken to prevent refeeding syndrome (see [Box 23.7](#)) during the treatment of long-term starvation.

Anorexia of Aging

Anorexia of aging is defined as a decrease in appetite or food intake in older adults, and can occur in illness-free individuals and in the presence of an adequate food supply. The resulting undernutrition leads to adverse outcomes and may affect up to 20% to 30% of elders.¹⁰⁰ The anorexia of aging results from multiple age-related changes, including reduced energy needs, waning hunger, diminished

senses of smell and taste, decreased production of saliva, altered gastrointestinal satiety control mechanisms, and the presence of comorbidities. Centrally, aging is associated with decreased orexigenic signals (e.g., levels of ghrelin or ghrelin resistance and reduced NPY or NPY receptors, or both) and increased anorexigenic signals (e.g., decreased levels of leptin, insulin, PPY, and CCK), which lead to loss of appetite and diminished food intake. Chronic low-grade inflammation with elevated cytokines also can contribute to delayed gastric emptying and decreased motility of the small intestine. Risk factors for anorexia of aging include functional impairments and deficiencies (e.g., loss of vision, poor dentition, inability to prepare foods); medical and psychiatric conditions (such as malabsorption syndromes and depression); loneliness and grief; medications, including polypharmacy; social isolation; and abuse or neglect.¹⁰¹ The consequences of anorexia of aging include malnutrition, physical frailty, mitochondrial dysfunction, reduced regenerative capacity, increased oxidative stress, and imbalanced hormonal levels. There are no currently used specific treatments for the anorexia of aging, though numerous supportive strategies are used (e.g., improved food access and appearance, dental and eye care, social stimulation). Death rates have been shown to be higher in those with anorexia of aging and unintentional weight loss.¹⁰²

Summary Review

Adipose Tissue

1. Adipose tissue provides insulation and tissue support and is the body's major energy reserve, storing triglycerides and glycerol.
2. Adipose tissue is an endocrine organ that secretes hormones called adipokines with autocrine, paracrine, and endocrine actions necessary for metabolic function and immune responses.
3. WAT has a stromal structure that contains macrophages, mast

cells, neutrophils, fibroblasts, endothelial cells, blood vessels, nerves, and precursor adipocytes.

4. WAT is the largest fat depot and is located in visceral (central) and subcutaneous (peripheral) sites. It also is located in muscle and bone marrow.
5. White adipocytes store fat as a single lipid droplet or vacuole.
6. With positive energy balance, WAT storage increases by adipocyte hypertrophy (more common in visceral fat) and adipogenesis (more common in subcutaneous fat).
7. Estrogen enhances the deposition of subcutaneous fat compared to visceral fat.
8. BAT has multiple lipid droplets and is rich in mitochondria containing iron, giving BAT a brown color. Exposure to cold, sympathetic activation and release of catecholamines, and activation of T_3 generate heat through activation of UCP1 and free fatty acid oxidation (nonshivering thermogenesis).
9. Both neonates and adults have BAT, but not in the amounts of WAT.
10. bAT emerges within WAT with exposure to cold, exercise, and synthetic ligands of PPAR γ . This is known as the “*beiging*” of WAT.
11. BAT and bAT both protect against obesity and metabolic syndrome.
12. In muscle, the myokines irisin and fibroblast growth factor-21, respectively, activate BAT and bAT for thermogenesis and protect against obesity.
13. Bone marrow adipose tissue also releases adipokine, and there is crosstalk with osteoclasts to maintain bone structure.

Obesity

1. Obesity is an epidemic that has occurred worldwide in both adults and children and is the fifth leading cause of death in the United States. Three leading causes of death in the United States are associated with obesity: cardiovascular disease, type

- 2 diabetes mellitus, and certain cancers. Obesity also increases the risk for numerous other systemic disorders.
2. Obesity is defined as a BMI greater than 30 kg/m² in adults and a BMI greater than or equal to the age- and sex-specific 95th percentile of the 2000 Centers for Disease Control and Prevention growth charts in children and usually results from energy intake exceeding expenditure.
 3. Single-gene (rare) and polygenetic disorders and metabolic disorders are associated with obesity, as well gene-environment interactions.
 4. Regulation of food intake and energy expenditure is coordinated centrally by the hypothalamus and higher brain centers. Two opposing sets of neurons in the arcuate nucleus of the hypothalamus regulate appetite and energy metabolism: orexigenic neurons, which promote appetite, stimulate eating, and decrease metabolism; and anorexigenic neurons, which suppress appetite, inhibit eating, and increase metabolism.
 5. Brain centers related to reward, pleasure, and memory can override hypothalamic control of food intake and satiety, causing increased fat stores by increasing consumption of highly palatable foods.
 6. Adipokines and gastrointestinal hormones are altered with obesity and contribute to associated complications.
 7. Leptin levels increase with obesity (leptin resistance), promoting overeating, insulin resistance and hyperinsulinemia, and hyperlipidemia, and stimulating adipocyte endothelial cells and macrophages to release inflammatory mediators contributing to the complications of obesity.
 8. RBP4 levels are increased in visceral adiposity and promote insulin resistance and hepatic steatosis.
 9. Adiponectin levels decrease with obesity, contributing to insulin resistance, inflammation, and hyperlipidemia.
 10. Endocannabinoids are increased in obesity and promote food intake and lipogenesis and inhibit energy expenditure.

11. Angiotensin I and angiotensin II increase in obesity, promoting vasoconstriction, inflammation, lipogenesis, oxidative stress, and insulin resistance.
12. Ghrelin increases with obesity and stimulates food intake, promotes release of growth hormone, and stimulates lipogenesis. It also has satiety, vasodilatory, cardioprotective, and antiproliferative effects; its role in obesity is not clear.
13. Glucagon-like peptide 1 promotes insulin secretion, delays gastric emptying, suppresses appetite, and increases energy expenditure, and is decreased with obesity.
14. Peptide YY inhibits gastric motility, decreases appetite, and is decreased with obesity.
15. Obesity is a state of chronic low-grade inflammation caused by expansion of adipocyte macrophages, neutrophils, and lymphocytes that release inflammatory mediators.
16. The chronic inflammation, alterations in adipokine action, and accelerated lipolysis related to excessive fat contribute to the complications of obesity, particularly insulin resistance, type 2 diabetes mellitus, cardiovascular disease, and cancer.
17. Changes in the intestinal microbiome also contribute to obesity, but the mechanisms need to be defined.
18. Obesity has two major phenotypes: visceral, or central obesity; and peripheral, or subcutaneous obesity. Visceral obesity has the greatest risk for accelerated lipolysis, chronic inflammation, insulin resistance, and associated complications.
19. Treatment of obesity may include correction of metabolic abnormalities, and individually tailored lifestyle interventions (diets, exercise, behavioral modifications, self-motivation) and psychotherapy. The current most effective treatment for extreme obesity is bariatric surgery.
20. New drugs are being developed that target specific molecules and will provide a personalized approach to treatment.

Anorexia Nervosa, Bulimia Nervosa, and Binge

Eating Disorder

1. Eating disorders include anorexia nervosa, bulimia nervosa, and binge eating disorder. They are psychogenic disorders that can lead to malnutrition.
2. Complications of chronic and severe eating disorders lead to malnutrition and weight changes, involve all organ systems, and can be life-threatening. Most complications are reversible with treatment.

Starvation

1. The body responds to short-term starvation with mechanisms to protect protein mass, using the processes of glycogenolysis and gluconeogenesis. Neither of these processes can meet the body's energy needs indefinitely since they deplete stored nutrients.
2. Long-term starvation results in an initial decreased dependence on gluconeogenesis and an increased use of ketone bodies as a cellular energy source, followed by lipolysis in adipose tissue. In the absence of adequate nutrition, long-term starvation results in proteolysis with death resulting from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.

Anorexia of Aging

1. Anorexia of aging is a decrease in appetite or food intake in older adults leading to undernutrition and resulting in a decline in function and increased risk for morbidity and mortality.
2. Contributing factors related to aging include diminished sensory functions, poor dentition, decreased gastric emptying, decreased hunger and satiety, effects of medications, social

isolation, and neglect.

Aging and the Male Reproductive System, 751

The male and female reproductive systems have several anatomic and physiologic features in common. Most obvious is their major function, reproduction, through which a 23-chromosome female gamete, the **ovum**, and a 23-chromosome male gamete, the **spermatozoon (sperm cell)**, unite to form a 46-chromosome zygote that is capable of developing into a new individual. The male reproductive system produces sperm and delivers them to the female reproductive tract. The female reproductive system produces the ovum and, if it is fertilized, can nurture and protect it (at that point called the **embryo** and **developing fetus**) and expel it at birth. These functions are determined not only by anatomic structures but also by complex hormonal, neurologic, and psychogenic factors.

Development of the Reproductive Systems

The structure and function of the male and female reproductive systems depend on steroid hormones called **sex hormones** and their precursors. Cholesterol is the precursor for steroid hormones, including the sex hormones. Other hormones support reproduction. The actions of both sex and reproductive hormones are summarized in [Table 24.1](#). Sex hormones, like all hormones, act on target tissues by binding with cellular receptors (see [Chapter 21](#)). Hormonal effects on the reproductive systems begin well before birth and continue for life.

TABLE 24.1

SUMMARY OF FEMALE AND MALE SEX AND REPRODUCTIVE HORMONES

SUMMARY OF FEMALE AND MALE SEX AND REPRODUCTIVE HORMONES

HORMONE (SOURCE)	ACTION IN FEMALES	ACTION IN MALES
<i>Dehydroepiandrosterone (DHEA)</i> (adrenal gland, ovary, other tissues)	Converted to androstenedione and then to estrogens, testosterone, or both	Converted to androstenedione and then to estrogens, testosterone, or both
<i>Estrogens</i> (estrone, estradiol, estriol) function through estrogen receptors alpha and beta (ovary and placenta, small amounts in other tissues)	Stimulates development of female sexual characteristics: maturation of breast, uterus, and vagina; promotes proliferative development of endometrium during menstrual cycle; during pregnancy promotes mammary gland development, fetal adrenal gland function, and uteroplacental blood flow	Growth at puberty, growth plate fusion in bone, prevention of apoptosis of germ cells
<i>Testosterone</i> (adrenal glands from DHEA, ovaries)	Libido, learning, sleep, protein anabolism, growth of muscle and bone; growth of pubic and axillary hair; activation of sebaceous glands, accounting for some cases of acne during puberty	Stimulates spermatogenesis, stimulates development of primary and secondary sexual characteristics, promotes growth of muscle and bone (anabolic effect); growth of pubic and axillary hair; activates sebaceous glands, accounting for some cases of acne during puberty; maintains libido
<i>Gonadotropin-releasing hormone (GnRH)</i> (hypothalamus-neuroendocrine cells)	Stimulates secretion of gonadotropins (FSH and LH) from anterior pituitary	Stimulates secretion of gonadotropins (FSH and LH) from anterior pituitary
<i>Follicle-stimulating hormone (FSH)</i> (anterior pituitary, gonadotroph cells)	Gonadotropin; promotes development of ovarian follicle; stimulates estrogen secretion	Gonadotropin; promotes development of testes and stimulates spermatogenesis by Sertoli cells
<i>Luteinizing hormone (LH)</i> (anterior pituitary, gonadotroph cells)	Gonadotropin; triggers ovulation; promotes development of corpus luteum	Gonadotropin; stimulates testosterone production by Leydig cells of testis
<i>Inhibin</i> (ovary and testes)	Inhibits FSH production in anterior pituitary (perhaps by limiting GnRH)	Inhibits FSH production in anterior pituitary
<i>Human chorionic gonadotropin (hCG)</i> (placenta)	Supports corpus luteum, which secretes estrogen and progesterone during first 7 weeks of pregnancy	

<i>Activin</i> (ovary)	Stimulates secretion of FSH and pituitary response to GnRH and FSH binding in dominant granulosa cells	
<i>Progesterone</i> (ovary and placenta)	Promotes secretory changes in endometrium during luteal phase of menstrual cycle; quiets uterine myometrium (muscle) activity and prevents lactogenesis during pregnancy	
<i>Relaxin</i> (corpus luteum, myometrium, and placenta)	Inhibits uterine contractions during pregnancy and softens pelvic joints and cervix to facilitate childbirth	

Sexual Differentiation and Hormone Production In Utero

Initially in embryonic development, the reproductive structures of male and female embryos are homologous (the same) or undifferentiated. They consist of one pair of primary sex organs, or **gonads**, and two pairs of ducts: the mesonephric ducts (wolffian ducts) and the paramesonephric ducts (müllerian ducts). The müllerian ducts are the precursor of the internal female sex organs (oviducts, uterus, cervix, and upper vagina). Müllerian ducts are initially formed regardless of genotypic sex and require no sex-determining region on the Y chromosome (*SRY*) signaling for development. *SRY* signaling is required in males to cause regression of the müllerian ducts, which in turn prevents the development of the female reproductive tract. The wolffian ducts are the precursors of male internal sex organs (secrete testosterone and promote development of the male sex organs) (Fig. 24.1). Both pairs of ducts empty into an opening called the *urogenital sinus*.

FIGURE 24.1 Internal Genitalia Development. Embryonic and fetal development of the internal genitalia. *MIH*, Müllerian inhibitory hormone; *TDF*, testes-determining factor.

The first sign of development of reproductive organs (male or female) occurs during the fifth week of gestation. Between 6 and 7 weeks' gestation, the male embryo will differentiate under the influence of testes-determining factor (TDF), a protein expressed by a gene in the *SRY*. When the *SRY* gene is expressed, male gonadal development prevails. TDF stimulates the male gonads to develop into the two testes and by 8 weeks of gestation testosterone secretion begins. Müllerian inhibitory hormone (MIH), secreted by Sertoli cells in the testes, promotes degeneration of the müllerian ducts. Without MIH, the müllerian ducts would develop and the wolffian ducts would degenerate with loss of male sex organ development. By 9 months' gestation, the male gonads (testes) have descended into the

scrotum. The testes produce sperm after puberty.

Female gonadal development occurs in the absence of *SRY* expression and with the expression of other genes.¹ The presence of *estrogen* and the absence of *testosterone* and *MIH* cause a loss of the wolffian system and, at 6 to 8 weeks' gestation, the two female gonads develop into ovaries, which will produce ova. By the tenth week, the mesonephric ducts deteriorate and the upper ends of the paramesonephric ducts become the fallopian tubules whereas the lower ends join to become the uterus, cervix, and upper two-thirds of the vagina (see [Fig. 24.1](#)). The fallopian tubes carry ova from the ovaries to the uterus during a woman's reproductive years. Lack of testosterone and the presence of estrogen promote the development of external genitalia (lower end of vagina, labia, and clitoris).

Like the internal reproductive structures, the external structures develop from homologous embryonic tissues. During the first 7 to 8 weeks of gestation, both male and female embryos develop an elevated structure called the *genital tubercle* ([Fig. 24.2](#)). Testosterone is necessary for the genital tubercle to differentiate into male genitalia; otherwise, female genitalia develop, which may occur even in the absence of ovaries, possibly because of the presence of placental estrogens.

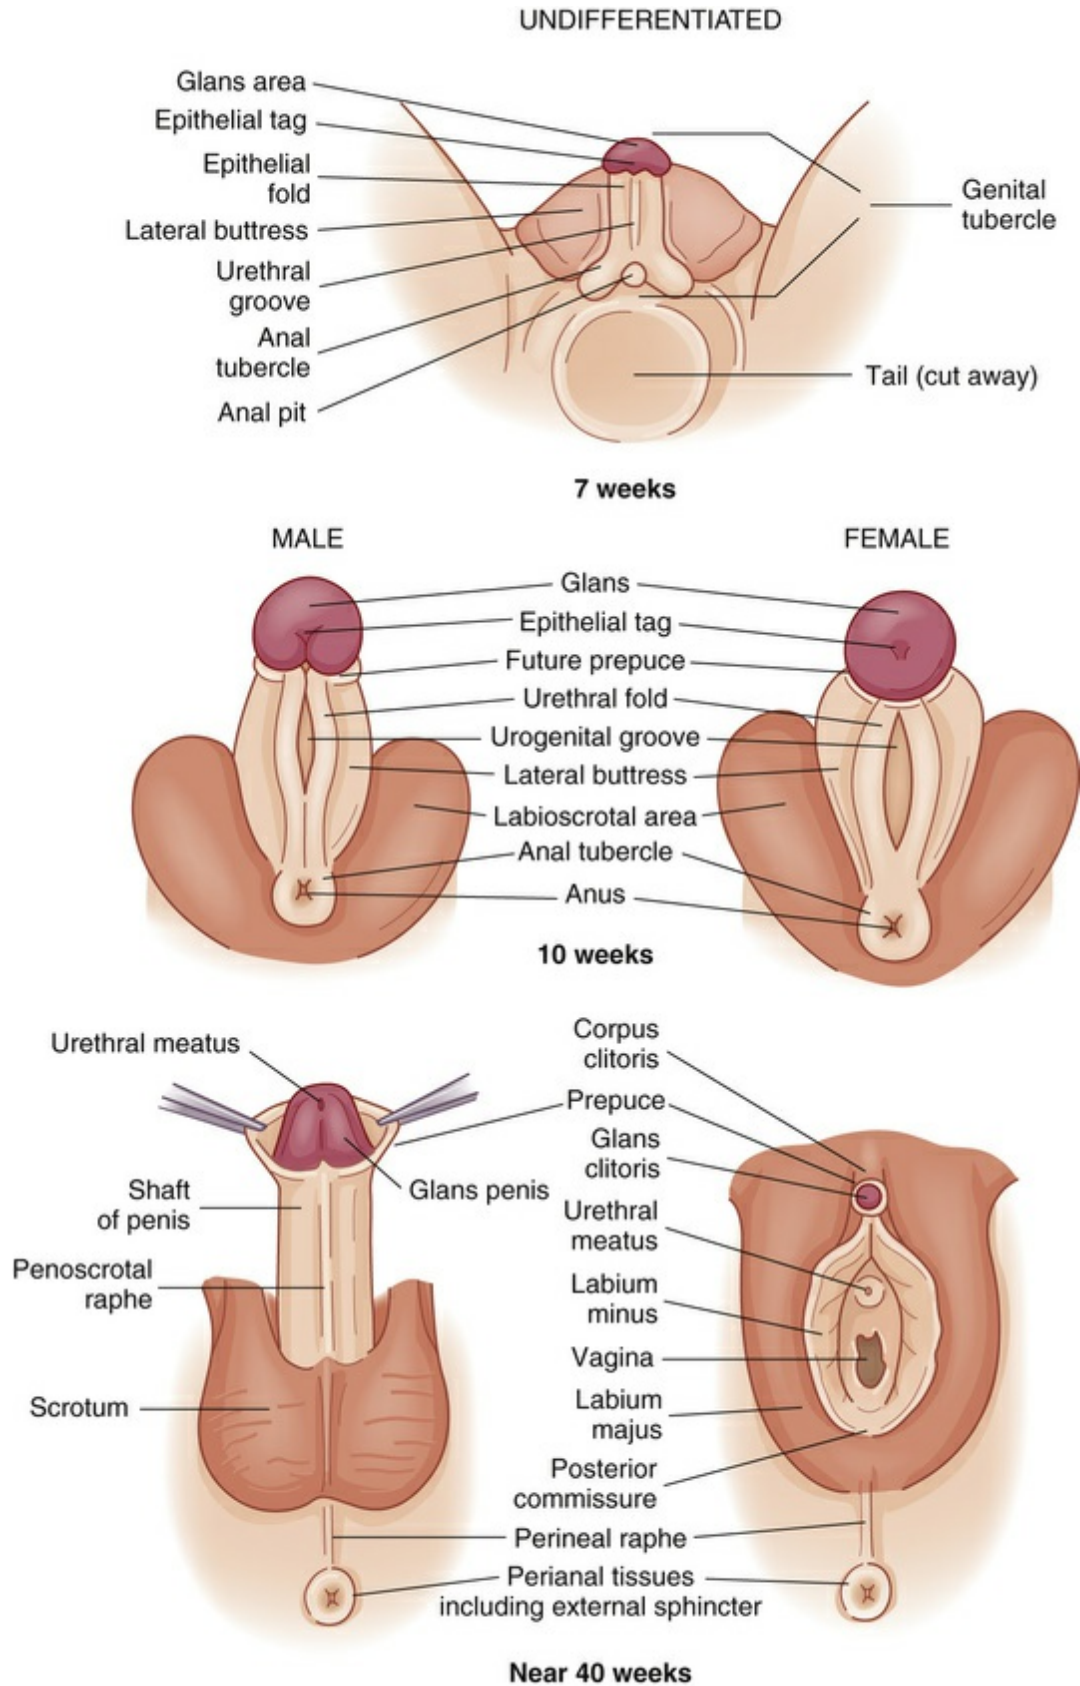

FIGURE 24.2 External Genitalia Development. Embryonic and fetal

development of the external genitalia.

Anterior pituitary gland development begins between the fourth and fifth weeks of fetal life, and the vascular connection between the hypothalamus and the pituitary is established by the 12th week. **Gonadotropin-releasing hormone (GnRH)** is produced in the hypothalamus by 10 weeks' gestation and controls the production of two gonadotropins by the anterior pituitary gland: luteinizing hormone (LH), and **follicle-stimulating hormone (FSH)**. In the female fetus, high levels of FSH and LH are excreted. FSH and LH stimulate the production of estrogen and progesterone by the ovary. The production of FSH and LH rises until about 28 weeks' gestation, when the production of estrogen and progesterone by the ovaries and placenta is high enough to result in the decline of gonadotropin production. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that millions are produced daily, usually for life.

By the end of pregnancy a sensitive negative-feedback system, which includes the **gonadostat** (also known as the **gonadotropin-releasing hormone pulse generator**), is operative in the human fetus. The gonadostat responds to high placental estrogen levels by releasing low levels of GnRH. Soon after birth steroid hormones levels drop because of withdrawal of maternal placental hormones. Hypothalamic pulsatile GnRH is secreted and gonadotropins LH and FSH are released. Their levels peak at 3 to 6 months for boys and at 12 to 18 months for girls, and then fall steadily. The gonadotropins will be suppressed until the onset of puberty.

Puberty and Reproductive Maturation

Puberty is the onset of sexual maturation and differs from adolescence. Adolescence is the stage of human development between childhood and adulthood and includes social, psychologic, and biologic changes. In girls, puberty begins at about ages 8 to 9 years

with thelarche (breast development). In boys, it begins later—at about age 11 years—but occurs earlier with increased weight and body mass index.² Genetics, environment, ethnicity, general health, and nutrition can influence the timing of puberty. There is an association between obesity and earlier puberty in girls, perhaps from higher estrogen levels related to gonadotropin and estrogen secretion.³ Girls who have low body fat and reduced body weight and perform intense exercise may experience delayed maturation.⁵ Although leptin is not the trigger for puberty onset, it plays an important permissive role.

Reproductive maturation involves the hypothalamic-pituitary-gonadal (HPG) axis, the central nervous system, and the endocrine system (Fig. 24.3). There is a sequential series of hormonal events that promote sexual maturation as puberty approaches. About 1 year before puberty in girls, nocturnal pulses of gonadotropin secretion (i.e., LH and FSH) and an increased response in the pituitary to GnRH occur. This, in turn, stimulates gonadal maturation (**gonadarche**) with estradiol secretion in girls and testosterone secretion in boys. Estradiol causes development of the breasts (thelarche), maturation of the reproductive organs (vagina, uterus, ovaries), and deposition of fat deposits in the hips of girls. Estrogen and increased production of growth factors cause rapid skeletal growth in both boys and girls. Testosterone causes growth of the testes, scrotum, and penis. A positive-feedback loop is created with gonadotropins stimulating the gonads to produce more sex hormones. The most important hormonal effects occur in the gonads. In males the testes begin to produce mature sperm that are capable of fertilizing an ovum. Male puberty is complete with the first ejaculation that contains mature sperm. In females, the ovaries begin to release mature ova. Female puberty is complete with the first ovulatory menstrual period; however, this can take up to 1 to 2 years after menarche. **Adrenarche** is the increased production of adrenal androgens (dehydroepiandrosterone and androstenedione, which is converted to testosterone and estrogen) before puberty, which occurs in both sexes, and is manifested by growth of axillary and pubic hair and activation of sweat and sebaceous glands. Puberty is complete when an individual is capable

of reproduction.

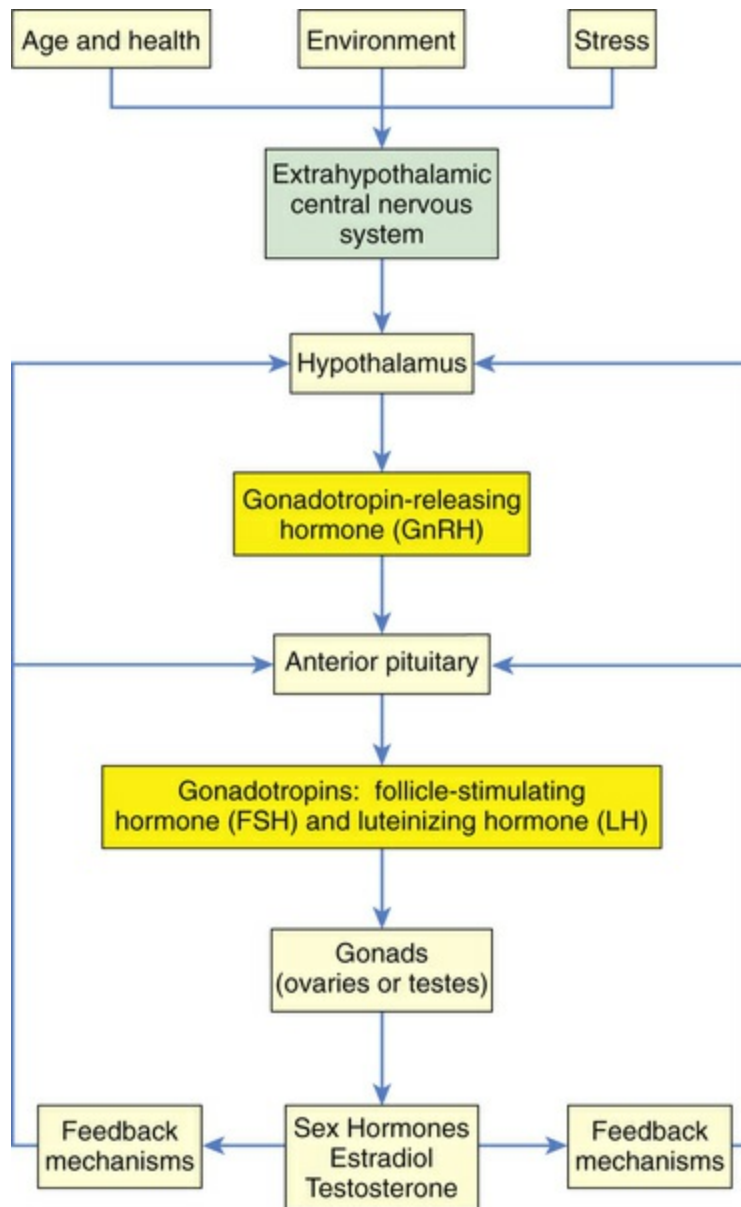

FIGURE 24.3 Hormonal Stimulation of the Gonads. The hypothalamic-pituitary-gonadal axis.

The Female Reproductive System

The function of the reproductive system is to produce mature ova; if

fertilization occurs, the female reproductive system provides protection and nourishment of the fetus until it is expelled at birth. The most important internal reproductive organs in females are the ovaries, fallopian tubes, uterus, and vagina. The external genitalia protect body openings and play an important role in sexual functioning.

External Genitalia

Fig. 24.4 shows the external female genitalia, which are known collectively as the **vulva**, or pudendum. The major structures are as follows:

FIGURE 24.4 External Female Genitalia.

- **Mons pubis** (*mons veneris*)—a fatty layer of tissue over the pubic symphysis (joint formed by

union of the pubic bones). During puberty it becomes covered with pubic hair and sebaceous and sweat glands become more active. Estrogen causes fat to be deposited under the skin, giving the mons pubis a moundlike shape. This cushion of tissue protects the pubic symphysis during sexual intercourse.

- **Labia majora** (*singular, labium majus*)—two folds of skin arising at the mons pubis and extending back to the fourchette, forming a cleft. During puberty the amount of fatty tissue increases, pubic hair grows on lateral surfaces, and sebaceous glands on hairless medial surfaces secrete lubricants. This structure is highly sensitive to temperature, touch, pressure, and pain; it is homologous to the male scrotum and it protects the inner structures of the vulva (see [Figs. 24.1](#) and [24.2](#)).

- **Labia minora** (*singular, labium minus*)—two smaller, thinner, asymmetric folds of skin within the labia majora that form the clitoral hood (prepuce) and frenulum, and then split to enclose the vestibule and converge near the anus to form the fourchette. The labia minora are hairless, pink, and moist and are well supplied with nerves, blood vessels, and sebaceous glands that secrete a bactericidal fluid that has a distinctive odor and

lubricates and waterproofs the vulvar skin. The labia swell with blood during sexual arousal.

- **Clitoris**—richly innervated, erectile organ between the labia minora. It is a small, cylindrical structure having a visible glans and a shaft that lie beneath the skin. The clitoris is homologous to the male penis. It secretes smegma, which has a unique odor that may be sexually arousing to the male. Like the penis the clitoris is a major site of sexual stimulation and orgasm. With sexual arousal, erectile tissues in the clitoris fill with blood, causing it to enlarge slightly.

- **Vestibule**—an area protected by the labia minora and contains the external opening of the vagina, called the **introitus**, or vaginal orifice. A thin, perforated membrane called the **hymen** may cover the introitus. The vestibule also contains the opening of the urethra, or **urinary meatus** (orifice). These structures are lubricated by two pairs of glands: Skene glands and Bartholin glands. The ducts of **Skene glands** (also called the **lesser vestibular** or **paraurethral glands**) open on both sides of the urinary meatus. The ducts of **Bartholin glands** (**greater vestibular** or **vulvovaginal glands**) open on either side of the introitus. In response to sexual stimulation, Bartholin glands secrete mucus that lubricates the

inner labial surfaces, as well as enhances the viability and motility of sperm. Skene glands help lubricate the urinary meatus and the vestibule. Secretions from both sets of glands facilitate coitus. In response to sexual excitement, the highly vascular tissue just beneath the vestibule fills with blood and becomes engorged.

- **Perineum**—an area with less hair, skin, and subcutaneous tissue lying between the vaginal orifice and anus. Unlike the rest of the vulva, this area has little subcutaneous fat so that the skin is close to the underlying muscles. The perineum covers the muscular **perineal body**, a fibrous structure that consists of elastic fibers and connective tissue, and serves as the common attachment for the **bulbocavernosus**, the external anal sphincter, and the levator ani muscles (see [Fig. 24.4](#)). The perineum varies in length from 2 to 5 cm or more and stretches remarkably. The length of the perineum and the elasticity of the perineal body influence tissue resistance and injury during childbirth.

Internal Genitalia

Vagina

The **vagina** is an elastic fibromuscular canal, 9 to 10 cm long in a reproductive-aged female. It extends up and back from the introitus to the lower portion of the uterus. As [Fig. 24.5](#) shows, the vagina lies

between the urethra (and part of the bladder) and the rectum. Mucosal secretions from the upper genital organs, menstrual fluids, and products of conception leave the body through the vagina, which also receives the penis during coitus. During sexual excitement the vagina lengthens and widens and the lower third becomes congested with blood.

FIGURE 24.5 Internal Female Genitalia and Other Pelvic Organs. Midsagittal view. (Modified from Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby.)

The vaginal wall is composed of four layers:

1. Mucous membrane lining of squamous epithelial cells that thickens and thins in response to hormones, particularly

estrogen. The squamous epithelial membrane is continuous with the membrane that covers the lower part of the uterus. In women of reproductive age, the mucosal layer is arranged in transverse wrinkles, or folds, called **rugae** (*singular, ruga*) that permit stretching during coitus and childbirth.

2. Fibrous connective tissue containing numerous blood and lymphatic vessels
3. Smooth muscle
4. Connective tissue and a rich network of blood vessels

The upper part of the vagina surrounds the cervix, the lower end of the uterus (see [Fig. 24.5](#)). The recessed space around the cervix is called the **fornix** of the vagina. The posterior fornix is “deeper” than the anterior fornix because of the angle at which the cervix meets the vaginal canal. In most women this angle is about 90 degrees. A pouch called the **cul-de-sac** separates the posterior fornix and the rectum.

Its elasticity and relatively sparse nerve supply enhance the vagina's function as the birth canal. During sexual arousal the vaginal wall becomes engorged with blood, like the labia minora and clitoris. Engorgement pushes some fluid to the surface of the mucosa, enhancing lubrication. The vaginal wall does not contain mucous-secreting glands; rather, secretions drain into the vagina from the endocervical glands or enter from the vestibule, from the Bartholin and Skene glands.

Two factors help maintain the self-cleansing action of the vagina and defend it from infection, particularly during the reproductive years. They are (1) an acid-base balance that discourages the proliferation of most pathogenic bacteria and (2) the thickness of the vaginal epithelium. Before puberty, the vaginal pH is about 7 (neutral) and the vaginal epithelium is thin. At puberty the pH becomes more acidic (4 to 5) and the squamous epithelial lining thickens. These changes are maintained until menopause (cessation of menstruation), at which time the pH rises again to more alkaline levels and the epithelium thins. Therefore protection from infection is greatest during the years when a woman is most likely to be sexually active.

Between puberty and menopause, vulnerability to infection varies somewhat with cyclic changes in pH and epithelial thickness. Both defenses are greatest when estrogen levels are high and the vagina contains a normal population of *Lactobacillus acidophilus*, a harmless resident bacterium that helps maintain the pH at acidic levels. Any condition that causes the vaginal pH to rise; such as douching or use of vaginal sprays or deodorants, the presence of low estrogen levels, or destruction of *L. acidophilus* by antibiotics; lowers vaginal defenses against infection.

Uterus

The **uterus** is a hollow pear-shaped organ whose lower end opens into the vagina. It anchors and protects a fertilized ovum, provides an optimal environment while the ovum develops, and expels the fetus at birth. In addition, the uterus plays an important role in sexual response and conception. During sexual excitement the opening of the uterus (the cervix) dilates slightly. At the same time, the uterus increases in size and moves upward and backward, creating a tenting effect in the midvagina that results in the cervix “sitting” in a pool of semen. During orgasm, rhythmic contractions facilitate movement of sperm through the cervical os while also enhancing physical pleasure.

At puberty the uterus attains its adult size and proportions and descends from the abdomen to the lower pelvis, between the bladder and the rectum (see [Fig. 24.5](#)). The uterus of a mature, nonpregnant female is approximately 7 to 9 cm long and 6.5 cm wide, with muscular walls 3.5 cm thick. It is held loosely in position by ligaments, peritoneal tissue folds, and the pressure of adjacent organs, especially the urinary bladder, sigmoid colon, and rectum. In most women the uterus is anteverted; that is, it is tipped forward so that it rests on the urinary bladder. However, it may be retroverted, or tipped backward. Various degrees of flexion are normal ([Fig. 24.6](#)).

FIGURE 24.6 Variations in Uterine Position.

The uterus has two major parts (Fig. 24.7): the body, or **corpus**, and the cervix. The top of the corpus, above the insertion of the fallopian tubes, is called the **fundus**. The diameter of the uterine cavity is widest at the fundus and narrowest at the **isthmus**, just above the cervix. The **cervix**, or “neck of the uterus,” extends from the isthmus to the vagina. The passageway between the cervix's upper opening

(the internal os) and its lower opening (the external os) is called the **endocervical canal**. The entire uterus, like the upper vagina, is innervated exclusively by motor and sensory fibers of the autonomic nervous system.

FIGURE 24.7 Cross Section of Uterus, Fallopian Tube, and Ovary. (From Seidel HM et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.)

The uterine wall is composed of three layers (see [Fig. 24.7](#)). The **perimetrium (parietal peritoneum)** is the outer serous membrane that covers the uterus. The **myometrium** is the thick muscular middle layer. It is thickest at the fundus, apparently to facilitate birth. The **endometrium**, or uterine lining, is composed of a functional layer (superficial compact layer and spongy middle layer) and a basal layer. The functional layer of the endometrium is responsive to the sex hormones estrogen and progesterone. This layer proliferates and sloughs off monthly between puberty and menopause. The basal layer, which is attached to the myometrium, regenerates the functional layer after shedding (menstruation).

The endocervical canal does not have an endometrial layer but is lined with columnar epithelial cells. It is continuous with the lining of

the outer cervix and vagina, which are lined with squamous epithelial cells. The point at which the two types of cells meet is called the *transformation zone*, or the **squamous-columnar junction**. The transformation zone is vulnerable to human papillomavirus (HPV), especially HPV types 16 and 18, which can lead to cervical dysplasia or carcinoma in situ. Cells of the transformation zone are removed for examination during a Papanicolaou (Pap test) smear, which may be combined with an HPV DNA test.⁶

The cervix acts as a mechanical barrier to infectious microorganisms from the vagina. The external cervical os is a very small opening that contains thick, sticky mucus (the *mucous plug*) during the luteal phase of the menstrual cycle and all of pregnancy. During ovulation the mucus changes under the influence of estrogen and forms watery strands, or *spinnbarkeit* mucus, to facilitate the transport of sperm into the uterus. In addition, the downward flow of cervical secretions moves microorganisms away from the cervix and uterus. In women of reproductive age, the pH of these secretions is inhospitable to most bacteria. Furthermore, mucosal secretions contain enzymes and antibodies (mostly immunoglobulin A [IgA]) of the secretory (humoral) immune system (see [Chapter 8](#)). Uterine pathophysiologic disorders include infection, displacement of the uterus within the pelvis, benign growths (fibroids) of the uterine wall, hyperplasia of the endometrium, endometriosis, and cancer (see [Chapter 25](#)).

Fallopian Tubes

The two **fallopian tubes (oviducts, uterine tubes)** enter the uterus bilaterally just beneath the fundus (see [Fig. 24.7](#)). Their function is to conduct the ova from the spaces around the ovaries to the uterus. From the uterus the fallopian tubes curve up and over the two ovaries. Each tube is 8 to 12 cm long and about 1 cm in diameter, except at its ovarian end, which flares out like the bell of a trumpet. This widened end, called the **infundibulum**, is fringed or fimbriated. The **fimbriae** (*singular, fimbria*) (fringes) move, creating a current that draws the ovum into the infundibulum. Once the ovum has entered the fallopian tube, cilia and peristalsis (muscle contractions) keep it moving toward

the uterus.

The ampulla, or distal third, of the fallopian tube is the usual site of fertilization (see [Fig. 24.7](#)). Sperm released into the vagina travel upward through the endocervical canal and uterine cavity and enter the fallopian tubes. If an ovum is present in either tube, fertilization can occur. Whether or not the ovum encounters sperm, it continues to travel through the fallopian tube to the uterus. If fertilized, the ovum (then called a *blastocyst*) implants itself in the endometrial layer of the uterine wall. If not fertilized, the ovum breaks down within 12 to 24 hours. Disorders that affect the fallopian tubes (e.g., congenital malformations, infection, and inflammation) can block the path of sperm and ovum and cause infertility or ectopic (tubal) pregnancy.

Ovaries

The **ovaries**, the female gonads, are the primary female reproductive organs. Their two main functions are secretion of female sex hormones and development and release of female gametes, or ova.

The almond-shaped ovaries are located on both sides of the uterus and are suspended and supported by the mesovarian portions of the broad ligament, ovarian ligaments, and suspensory ligaments (see [Fig. 24.7](#)). The ovaries are smaller than their male homologs, the testes. In women of reproductive age, each ovary is 3 to 5 cm long, 2.5 cm wide, and 2 cm thick and weighs 4 to 8 g. Size and weight vary somewhat from phase to phase of the menstrual cycle (see the section titled [The Menstrual \[Ovarian\] Cycle](#)).

[Fig. 24.8, A](#), shows a cross section of an ovary. The central part, or medulla, is composed of connective tissue and contains many small arteries, veins, and lymphatics that enter at the hilum. Surrounding the medulla is the cortex. At birth the cortex of each ovary contains approximately 2 million ova within primordial (immature) **ovarian follicles**. Follicles grow and undergo atresia continuously and irrevocably throughout a woman's life. By puberty the number ranges between 300,000 and 500,000 ova. Between puberty and menopause the ovarian cortex always contains follicles and ova in various stages of development, including the primary and secondary follicles (see

Fig. 24.8, A). Once every menstrual cycle (about every 28 days), usually only one of the follicles reaches maturation (see Fig. 24.8, B and C) and discharges its ovum through the ovary's outer covering, the germinal epithelium. During the reproductive years, 400 to 500 ovarian follicles mature completely and release an ovum (ovulation). The remaining follicles either fail to develop at all or degenerate without maturing completely and are known as *atretic follicles* (Fig. 24.8).

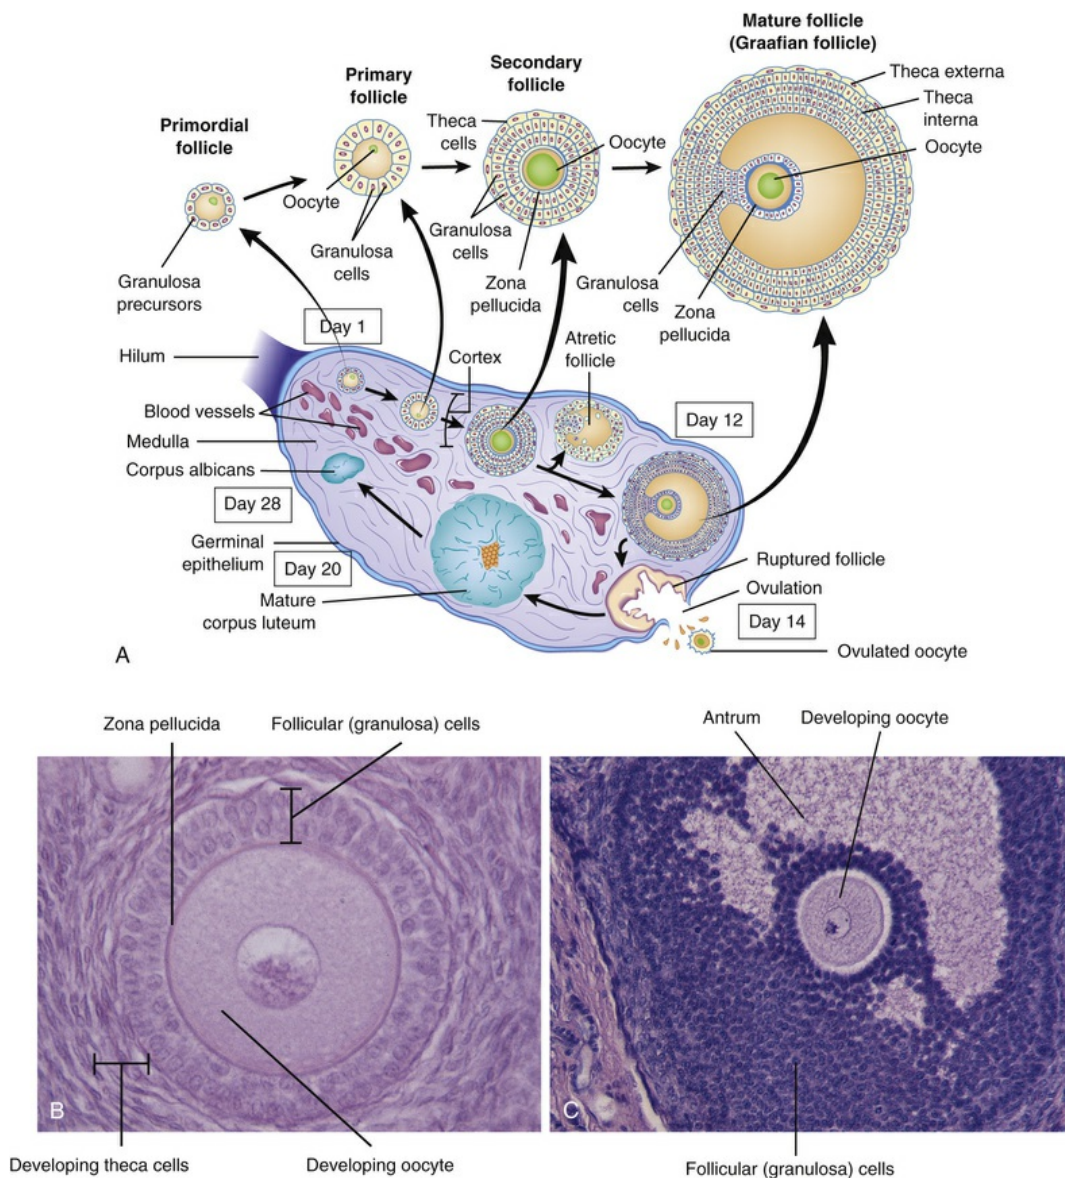

FIGURE 24.8 Cross Section of Ovary and Development of an Ovarian Follicle. A, Schematic representation (not to scale) of the structure of the

ovary, showing the various stages in the development of the follicle and its successor structure, the corpus luteum. B, A developing oocyte surrounded by hormone-secreting follicular (granulosa) cells. C, A more mature ovarian follicle has a fluid-filled cavity called the *antrum*. (A Adapted from Berne RM, Levy MN, editors: *Physiology*, ed 5, St Louis, 2003, Mosby. B and C From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 9, St Louis, 2016, Mosby.)

After release of the mature ovum (ovulation), the follicle develops into another structure, the **corpus luteum** (see [Fig. 24.8](#)). The immediate fate of the corpus luteum depends on whether the ejected ovum is fertilized. If fertilization occurs, the corpus luteum enlarges and begins to secrete hormones that maintain and support pregnancy. If fertilization does not occur, the corpus luteum secretes these hormones for approximately 14 days and then degenerates, which triggers the maturation of another follicle. The **ovarian cycle**—the process of follicular maturation, ovulation, corpus luteum development, and corpus luteum degeneration—is continuous from puberty to menopause, except during pregnancy or hormonal contraceptive use. At menopause this process ceases and the ovaries atrophy to the point that they cannot be felt during pelvic examination.

Sex hormones are secreted by cells present within the ovarian cortex including two types of cells in the ovarian follicle (**theca cells** [produce androgens that migrate to granulosa cells] and **granulosa cells** [convert androgens to estradiol]) and cells of the corpus luteum that primarily secrete progesterone, estrogen, and inhibin (see [Fig. 24.8](#)). These cells all contain receptors for the gonadotropins (LH, FSH) or for the sex hormones, which are discussed in the next section.

Female Sex Hormones

The sex hormones are all steroid hormones and are synthesized from cholesterol (see [Chapter 21](#)). Male and female sex hormones are present in all adults. However, the female body contains low levels of testosterone and other androgens, and the male body contains low levels of estrogen. Individual effects of sex hormones depend on their amount and concentration in the blood.

The dominant female sex hormones, estrogen and progesterone, are produced primarily by the ovaries (see [Table 24.1](#)). During fetal development, infancy, and childhood, sex hormone production is low. At puberty, hormone production surges, triggering sexual maturation and development of secondary sex characteristics. From puberty to menopause, the sex hormones control the menstrual cycle and are produced cyclically; that is, production surges and diminishes monthly, creating the ovarian and uterine changes associated with the menstrual cycle. These hormones also are produced in higher levels during pregnancy by the placenta, inhibiting ovulation. Androgens are produced in small amounts by the ovaries and the adrenals and have important functions in women.

Estrogens and Androgens

Estrogen is a generic term for three similar hormones: estradiol, estrone, and estriol. **Estradiol (E₂)** is the most potent and plentiful of the three and is principally produced (95%) by the ovaries (ovarian follicle and corpus luteum). Limited amounts are secreted by the cortices of the adrenal glands and the placenta during pregnancy. Androgens are converted to estrone in ovarian and peripheral adipose tissue. Estriol is the peripheral metabolite of estrone and estradiol.

Estrogen has numerous biologic effects, many of which involve interactions with other hormones, and is needed for maturation of reproductive organs, development of secondary sex characteristics (differentiating male and female physical characteristics that are not directly related to reproduction), growth, and maintenance of pregnancy. Nonreproductive effects of estrogen include closure of long bones after the pubertal growth spurt (in both males and females), maintenance of bone and skin, and systemic organ function ([Box 24.1](#)). After menopause, the ovaries dramatically reduce production of estradiol and secretion of estrone (see Menopause, under [Aging and the Female Reproductive System](#)). At this time the majority of estradiol is derived from intracellular synthesis in peripheral tissues. Estradiol acts locally to meet physiologic needs according to cell type and is then inactivated without systemic effects.⁷

Box 24.1

Summary of Nonreproductive Effects of Estrogen

- Estrogens (including estrone, estradiol, estriol) function through estrogen receptors alpha and beta, have different roles in different cells and tissues, and have paracrine or intracrine function.
- Maintains bone density.
- Acts in liver to decrease cholesterol level, increase high-density lipoprotein (HDL) level, and decrease low-density lipoprotein (LDL) level (antiatherosclerotic); promotes fat deposition.
- Maintains nervous system (neurotrophic and neuroprotective); facilitates memory and cognition.
- Increases collagen content, dermal thickness, elasticity, water content, and healing ability of skin.
- Protects against chronic kidney disease in individuals without diabetes.
- Prevents vascular injury and early atheroma formation through endothelial mechanisms.
- Inhibits platelet adhesiveness.
- Can promote inflammation and have variable effects on immunity.
- Estrogen associated with pregnancy or use in contraceptive pills promotes clotting and increased risk of thromboembolism.

Like other steroid hormones, estrogens are derived from cholesterol in a complex, enzyme-mediated series of reactions. (Mechanisms of hormone synthesis and action are described in [Chapter 21](#).) The hypothalamus secretes GnRH in a pulsatile manner that stimulates

gonadotropin (LH and FSH) release from the anterior pituitary. Gonadotropins trigger ovarian production of estrogen. The primary function of LH is to stimulate theca cells of the ovarian follicle to produce androgens, mainly androstenedione. (Androgens are discussed further under the section titled [Male Sex and Reproductive Hormones](#).) Some of these androgens are converted to estrogen by the theca cells themselves, and others diffuse into the granulosa cells. Within the granulosa layer, FSH induces conversion (aromatization) of androgens to estrogens. Estrogens are then released into the bloodstream. Estrogen and FSH together increase FSH receptors in the follicle, stimulating additional granulosa cells until a dominant follicle is determined.

Although **androgens** are primarily male sex hormones produced by the testes, small amounts are produced in the adrenal cortex in both men and women and in the ovaries in women. Some androgens (dehydroepiandrosterone and its metabolite androstenedione) are precursors of estrogens (estrone, estradiol). At puberty, androgens contribute to the skeletal growth spurt and cause growth of pubic and axillary hair. The androgens also activate sebaceous glands, accounting for some cases of acne during puberty, and play a role in libido.

Progesterone

Luteinizing hormone (LH) from the anterior pituitary stimulates the corpus luteum to secrete **progesterone**, the second major female sex hormone. With estrogen, progesterone controls the ovarian menstrual cycle. LH surge occurs when there is a peak level of estrogen, about 24 to 36 hours before ovulation. LH promotes luteinization of the granulosa in the dominant follicle and results in progesterone production and the development of blood vessels and connective tissue. During the follicular phase, the ovary and adrenal glands each contribute approximately 50% of the progesterone production. Conversely, large amounts are secreted from the ovary while the corpus luteum is active for about 9 to 13 days after ovulation. The opposing and complementary effects of progesterone and estrogen are

listed in [Table 24.2](#). Progesterone secreted by the corpus luteum stimulates the thickened endometrium to become more complex in preparation for implantation of a blastocyst. If conception and implantation do occur, the corpus luteum persists and secretes progesterone (and estrogen) until the placenta is well established at approximately 8 to 10 weeks' gestation and undertakes progesterone production.

TABLE 24.2

COMPLEMENTARY AND OPPOSING EFFECTS OF ESTROGEN AND PROGESTERONE

STRUCTURE	EFFECT OF ESTROGEN	EFFECT OF PROGESTERONE
Vaginal mucosa	Proliferation of squamous epithelium; increase in glycogen content of cells; layering (cornification) of cells	Thinning of squamous epithelium; decornification
Cervical mucosa	Production of abundant fluid secretions that favor survival and enhance motility of sperm	Production of thick, sticky secretions that tend to “plug” the cervical os
Fallopian tube	Increase of motility and ciliary action	Decrease of motility and ciliary action
Uterine muscle	Increase of blood flow; increase of contractile proteins and uterine muscle and myometrial excitability and action potential; increase of sensitization to oxytocin	Relaxation of myometrium; decrease of sensitization to oxytocin
Endometrium	Stimulation of growth; increase in number of progesterone receptors	Activation of glands and blood vessels; accumulation of glycogen and enzymes; decrease in number of estrogen receptors
Breasts	Growth of ducts; promotion of prolactin effects	Growth of lobules and alveoli; inhibition of prolactin effects

Progesterone is sometimes called the *hormone of pregnancy*. Progesterone's effects in pregnancy include (1) maintaining the thickened endometrium; (2) relaxing smooth muscle in the myometrium, which prevents premature contractions and helps the uterus expand; (3) thickening (hypertrophy) the myometrium, which prepares it for the muscular work of labor; (4) promoting growth of lobules and alveoli in the breast in preparation for lactation but preventing lactation until the fetus is born and then promoting

lactation in collaboration with prolactin after birth; (5) preventing additional maturation of ova by way of suppressing FSH and LH, thereby stopping the menstrual cycle; (6) providing immune modulation, allowing tolerance against fetal antigens (the mother's immune system does not attack the fetus); and (7) preventing preterm birth.⁸

The Menstrual (Ovarian) Cycle

In addition to pregnancy the obvious manifestation of female reproductive functioning is menstrual bleeding (the menses), which starts with **menarche** (first menstruation) and ends with **menopause** (cessation of menstrual flow for 1 year). In the United States, the median age of first menstruation is about 12.14 years in black females, 12.25 years in Latina or Hispanic females, and 12.6 years in white females, with a range from 9 to 13.5 years.⁹ Menarche appears to be related to body weight, especially percentage of body fat (ratio of fat to lean tissue), which may trigger a change in the metabolic rate and lead to hormonal changes associated with early menarche. There is increased circulating **leptin** (a regulatory hormone of appetite and energy metabolism), which promotes the secretion of kisspeptin from the hypothalamus and leads to the release of GnRH, which in turn enhances release of FSH and LH and estradiol, triggering ovulation and the onset of puberty.

Cycles are anovulatory at first and may vary in length from 10 to 60 days or more. As adolescence proceeds into adulthood, regular patterns of menstruation and ovulation are established at intervals ranging from 21 to 45 days.¹¹ Menstruation continues to recur in a recognizable and characteristic pattern during adulthood, with the length of the menstrual cycle varying considerably among women. The commonly accepted cycle average is 28 (27 to 30) days, with rhythmic intervals of 21 to 35 days considered normal. Approximately 2 to 8 years before menopause, cycles begin to lengthen again with variation related to changing hormone levels.¹²

Phases of the Menstrual Cycle

The menstrual (ovarian) cycle ([Fig. 24.9](#)) consists of two phases: the follicular/proliferative phase (postmenstrual) followed by the luteal/secretory phase (premenstrual). During **menstruation (menses)**, the functional layer of the endometrium disintegrates and is discharged through the vagina. Menstruation is followed by the **follicular/proliferative phase**. During the follicular/proliferative phase, GnRH and a balance between activin and inhibin from the granulosa cells contribute to the rise of FSH levels, which stimulates a number of follicles. The pulsatile secretion of FSH from the anterior pituitary gland rescues a dominant ovarian follicle from apoptosis by days 5 to 7 of the cycle. Together estrogen and FSH increase FSH receptors in the granulosa cells of the primary follicle, making them more sensitive to FSH. FSH and estrogen combine to induce production of LH receptors on the granulosa cells, thus promoting LH stimulation to combine with FSH stimulation, causing a more rapid secretion of follicular estrogen. As estrogen levels increase, FSH levels drop because of an increase in inhibin-B secreted by the granulosa cells in the dominant follicle. This drop in FSH level decreases the growth of less-developed follicles (see [Fig. 24.9](#)). Estrogen causes cells of the endometrium to proliferate and stimulates production of LH. A surge in both FSH and LH levels is required for final follicular growth and ovulation. An increase in stromal tissue in the late follicular phase is associated with a rise in androgen levels. Androgen production enhances the process of follicle atresia although there may be a dose-dependent support of follicle maturation.¹³

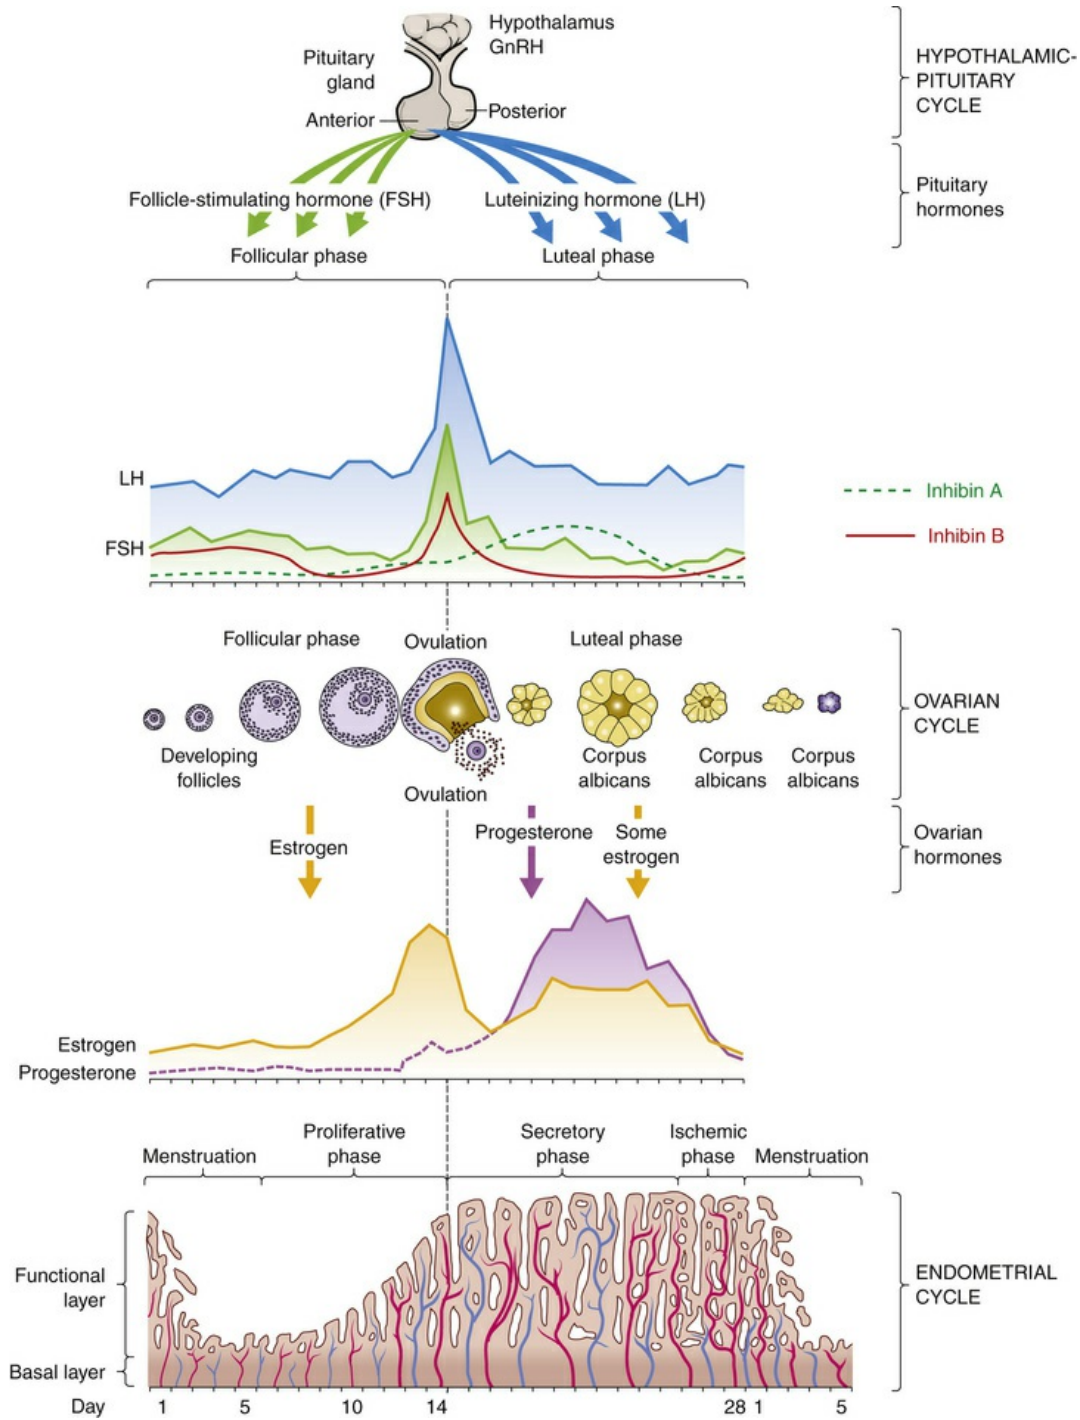

FIGURE 24.9 The Menstrual Cycle. *GnRH*, Gonadotropin-releasing hormone. (Adapted from Lowdermilk DL et al: *Maternity and women's health care*, ed 10, St Louis, 2012, Mosby.)

Ovulation is the release of an ovum from a mature follicle and marks the beginning of the **luteal/secretory phase** of the menstrual cycle. The ovarian follicle begins its transformation into a corpus

luteum (see Fig. 24.8, A), hence the name *luteal phase*. Pulsatile secretion of LH from the anterior pituitary stimulates the corpus luteum to secrete progesterone, which in turn initiates the secretory phase of endometrial development. Glands and blood vessels in the endometrium branch and curl throughout the functional layer, and the glands begin to secrete a thin glycogen-containing fluid, the *secretory phase*. If conception occurs, the nutrient-laden endometrium is ready for implantation. Human chorionic gonadotropin (HCG) is secreted 3 days after fertilization by the blastocytes and maintains the corpus luteum once implantation occurs at about day 6 or 7. HCG can be detected in maternal blood and urine 8 to 10 days after ovulation. The production of estrogen and progesterone continues until the placenta can adequately maintain hormonal production. If conception and implantation do not occur, the corpus luteum degenerates and ceases production of progesterone and estrogen. Without progesterone or estrogen to maintain it, the endometrium becomes ischemic (“blood-starved”) and disintegrates, hence the name **ischemic/menstrual phase**. Menstruation then occurs, marking the beginning of another cycle.

Ovulatory cycles appear to have a minimum length of 24 to 26.5 days: the primary ovarian follicle requires 10 to 12.5 days to develop, and the luteal phase appears relatively fixed at 14 days (± 3 days). Menstrual blood flow usually lasts 3 to 7 days, but it may last as long as 8 days or stop after 1 to 2 days and still be considered within normal limits. Bleeding is consistently scant to heavy and varies from 30 to 80 mL, with most blood loss occurring during the first 3 days of menses. Menstrual discharge consists of blood, mucus, and desquamated endometrial tissue and does not clot under normal circumstances. It is usually dark and produces a characteristic musty odor on oxidation. Environmental factors such as severe emotional stress, illness, malnutrition, obesity, and seasonal variation may affect the length of the menstrual cycle.^{14,15}

Hormonal Control

Hormonal control of the menstrual cycle depends on complex

interactions among the hypothalamus, the anterior pituitary, and the ovaries (or hypothalamic-pituitary-ovarian [HPO] axis) (Table 24.3). Hormonal control is dependent on negative and positive ovarian feedback mechanisms. In the hypothalamus, kisspeptin (also known as *metastin*) activates the release of GnRH to stimulate the gonadotropin production of FSH and LH. The constant and pulsatile release of GnRH is critical to the timing of the menstrual cycle. GnRH is secreted into the hypophyseal portal system and travels to the anterior pituitary, where it stimulates the secretion of LH and FSH. FSH and LH are released from the anterior pituitary in pulses that correspond to the pulsatile secretion of GnRH.

TABLE 24.3

HORMONAL FEEDBACK MECHANISM IN THE MENSTRUAL CYCLE

PHASE OF CYCLE AND OVARIAN HORMONE LEVELS	FEEDBACK TO HYPOTHALAMUS AND ANTERIOR PITUITARY	RESULTANT GNRH, FSH, AND LH LEVELS	OVARIAN AND MENSTRUAL EVENTS
<i>Early follicular phase</i> : estrogen levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	Ovarian follicle develops; endometrium proliferates
<i>Late follicular (preovulatory) phase</i> : estrogen levels high; progesterone increases with small surge before ovulation	Positive and stimulatory	All surge; LH dominates	Process of ovulation begins; endometrial proliferation complete
<i>Ovulatory phase</i> : estrogen levels dip; progesterone levels begin to rise	Negative and inhibitory	All fall sharply	Corpus luteum begins to develop; endometrium enters secretory phase
<i>Early luteal phase</i> : estrogen and progesterone levels high; progesterone dominates	Negative and inhibitory	All continue to decline, but gradually	Corpus luteum fully developed; endometrium ready for implantation
<i>Late luteal phase</i> : estrogen and progesterone levels fall sharply	Negative and inhibitory; feedback lessens slightly	All rise slightly	Corpus luteum regresses; endometrium breaks down; menstruation begins

<i>Menstrual phase:</i> estrogens levels low; minute amount of progesterone secreted	Negative and inhibitory	All low	More ovarian follicles begin to develop; functional layer of endometrium is shed
--	-------------------------	---------	--

FSH, Follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone.

During the early follicular phase, estrogen levels rise steadily and, through negative feedback, suppress FSH and positively increase the production of LH. During the late follicular phase, the preovulatory rise in progesterone concentration facilitates the positive feedback of estrogen; estrogen levels begin to increase, stimulating a surge of LH secretion from the anterior pituitary. The midcycle surge of LH and FSH induces ovulation. A nonsteroidal ovarian factor, gonadotropin surge–attenuating factor (GnSAF), may antagonize the effect of estrogen on the pituitary and regulate the surge of LH at midcycle.¹⁷ Rising estrogen and progesterone levels during the luteal phase may inhibit the anterior pituitary, and thus reduce LH and FSH secretion. Just before the onset of menstruation, FSH and LH levels begin to increase slightly, probably because of declining estrogen and progesterone levels (see [Fig. 24.9](#)).

A variety of growth factors and autocrine/paracrine peptides influence hormonal control and follicular response. During the early follicular stage, FSH stimulates FSH receptors and LH receptors and the release of insulin-like growth factor 1, as well as the production of inhibin and activin in the ovary. **Activin** from granulosa cells stimulates the secretion of FSH and increases the pituitary response to GnRH, and increases FSH binding in the granulosa cells in the dominant follicle. FSH stimulates **inhibin** secretion from granulosa cells and it in turn suppresses FSH synthesis. Inhibin B is primarily secreted in the follicular phase of the cycle but sharply spikes when ovulation occurs. Inhibin A is secreted in the luteal phase and further suppresses FSH. Inhibin also restrains prolactin and growth hormone release, interferes with GnRH receptors, and promotes breakdown of intracellular gonadotropins. In summary, the balance between activin and inhibin regulates FSH secretion. **Follistatin** inhibits activin and boosts inhibin activity. Inhibin and activin also regulate LH

stimulation of androgen synthesis (required for ovarian estrogen biosynthesis) in theca cells.¹⁹ Fig. 24.9 depicts fluctuating estrogen, progesterone, gonadotropin, and inhibin levels. Research continues to advance understanding of the function and structural complexity of these polypeptides and their interaction with GnRH, gonadotropins, and sex hormones.²⁰

Ovarian Cycle

By stimulating follicles, gonadotropins initiate their growth and maturation. The most important hormonal event is a rise in FSH levels. The decline in the late luteal phase of estrogen, progesterone, and inhibin secretion allows FSH levels to rise; concurrently there is a slight increase in LH levels (see Fig. 24.9). FSH stimulates granulosa cell growth and initiates estrogen production in these cells in the next cycle. At this time a group of ovarian follicles is recruited and begins to mature; the exact number depends on the remaining pool of inactive follicles. As the follicles mature, granulosa cells multiply, increasing estradiol secretion. Within a few days of the cycle, one follicle becomes dominant and the others atrophy. The mechanism for follicular recruitment or dominance is unknown.²¹ The dominant follicle begins to secrete progressively larger amounts of estrogen (estradiol), which exerts an increase in GnRH receptor concentration and an increase in pituitary sensitivity to GnRH, creating a positive-feedback effect causing an FSH and LH surge. Ovulation generally occurs 1 to 2 hours before the final progesterone surge, or about 12 to 36 hours after the onset of the FSH and LH surge. Progesterone, proteolytic enzymes, and prostaglandins (E and F series) trigger mechanisms controlling follicular rupture and release of the ovum into the fallopian tube.²² The FSH and LH surge also transforms the granulosa cells of the ovulatory follicle into the corpus luteum. The corpus luteum secretes estrogen and progesterone in amounts that depend in part on adequate development of the follicle before ovulation. Progesterone acts centrally and locally within the ovary to suppress new follicular growth during the early and midluteal phases. If pregnancy does not occur, the corpus luteum persists for 11 to 14

days, and then regresses and eventually disappears. An increase in pulse frequency of GnRH from a low level of estrogen and progesterone reactivates hormonal control of the menstrual cycle and FSH secretion increases.

Uterine Phases

Uterine phases of the menstrual cycle—the follicular/proliferative phase, the luteal/secretory phase, and menstruation—involve cyclic changes that occur in the endometrium controlled by estrogen and progesterone. Hormonal effects are influenced by the presence of receptors and numerous growth factors, peptides, and enzymes that act as intermediaries between the sex steroids and the endometrium. During the midfollicular phase, increasing levels of estrogen contribute to endometrial repair and proliferation, thus increasing endometrial thickness (luteal phase). Once ovulation occurs and serum progesterone levels increase, the endometrial tissue develops secretory characteristics (secretory phase). If implantation of a fertilized ovum does not take place, endometrial tissue begins to break down approximately 11 days after ovulation (ischemic phase of menstruation) (see [Fig. 24.9](#)). Sloughing of tissue (menstrual bleeding) begins about 14 days after ovulation.

Cervical mucus also undergoes cyclic changes. During the proliferative phase the cervical mucus is thin and watery. Peak estrogen levels occur just before ovulation and maximally stimulate the cervical glands to produce mucus. Cervical mucus becomes abundant and more elastic (*spinnbarkeit*). In the presence of estrogen, tiny channels develop in the mucus, which allows sperm access to the interior of the uterus. Changes in the consistency of cervical mucus can be used to identify fertile intervals. After ovulation, the ovary begins to secrete progesterone under the influence of the corpus luteum. The amount of cervical mucus is reduced, becomes thicker and stickier, and blocks sperm migration.

Vaginal Response

The vaginal endothelium also responds to cyclic hormonal changes of the menstrual cycle. Under the influence of estrogen, cells of the vagina epithelium grow maximally during the follicular/proliferative phase. After ovulation, layers of keratinized cells overgrow the basal epithelium, a process known as **cornification**. Near the end of the luteal phase, leukocytes invade vaginal epithelium, removing the outer layers in a process termed **decornification**.

Body Temperature

Basal body temperature (BBT) undergoes characteristic biphasic changes during menstrual cycles in which ovulation occurs. During the follicular phase the BBT fluctuates around 37°C (98°F). After the LH surge, the average temperature increases by 0.2°C to 0.5°C (0.4°F to 1°F). At the end of the luteal phase, 1 to 3 days before the onset of menstruation, BBT declines to follicular-phase levels. The shift in temperature is related to ovulation, corpus luteum formation, and increased serum progesterone levels. Progesterone probably acts on the thermoregulatory center of the hypothalamus to increase body temperature. Changes in BBT are used to document ovulatory cycles, but when used alone are not the best method to predict the exact timing of ovulation.²⁴

Structure and Function of the Breast

The adult **breast** lies on the ventral surface of the thorax, within the superficial fascia of the chest wall, extending vertically from the second rib to the sixth or seventh intercostal space and laterally from the side of the sternum to the midaxillary line. Breast tissue also may extend into the axilla; this tissue is known as the *tail of Spence*.

The Female Breast

The female breast is composed of 15 to 20 pyramid-shaped lobes that are separated and supported by suspensory (Cooper) ligaments (Fig. 24.10). Each lobe contains 20 to 40 lobules. The lobules subdivide

further into many functional units called acini (*singular, acinus*). Each acinus is lined with a layer of epithelial cells capable of secreting milk and an underlying layer of myoepithelial cells capable of contracting to squeeze milk from the acinus. Biochemical signaling and density within the extracellular matrix are essential for differentiation and function of the acini glandular epithelium. The acini empty into a network of lobular collecting ducts, which empty into interlobular collecting and ejecting ducts. Collagen fiber alignment is required for ductal elongation and organized branching.²⁵ The ducts reach the skin through openings (pores) in the nipple. The lobes and lobules are surrounded and separated by muscle strands and fatty connective tissue. The amount of fatty connective tissue varies among individuals, depending on weight and genetic and endocrine factors, and contributes to the diversity of breast size and shape and to the function of the mammary epithelium. Fat increases in the breast after menopause.²⁶

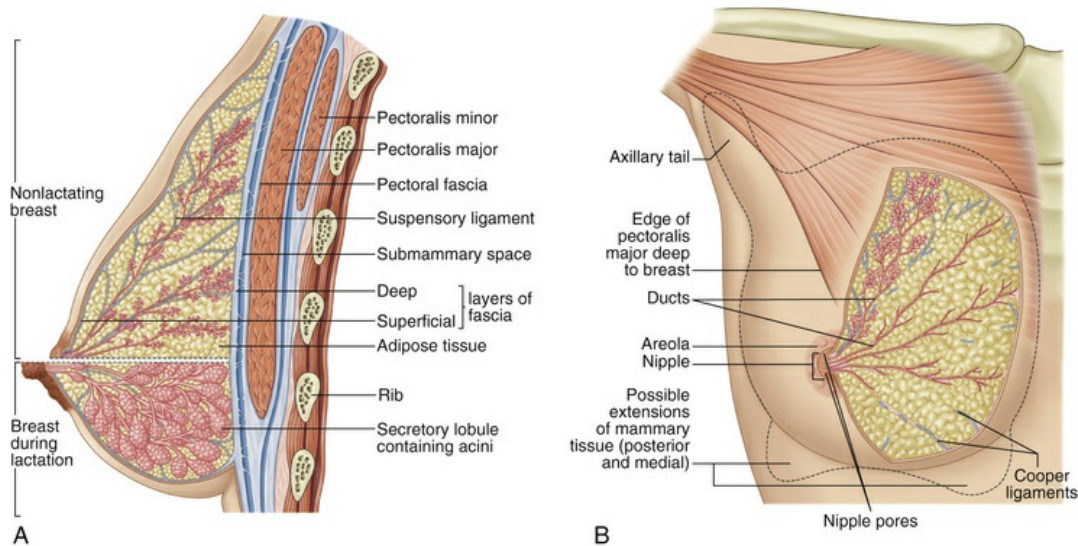

FIGURE 24.10 Schematic Diagram of Breast. A, Lactating breast. B, Structures of the breast. (From Shah P: Breast. In Standing S, editor: *Gray's anatomy*, ed 40, London, 2009, Elsevier Churchill Livingstone.)

Fetal and early postnatal breast tissue development does not depend on hormones, although fetal breast tissue becomes progressively responsive to hormonal stimulation. The neonatal

breasts are rudimentary, containing 10 to 12 branching ducts. During childhood, breast growth is latent and growth of the nipple and areola keep pace with other body tissues. (Male breast development normally does not progress any further.) At the onset of puberty in the female, growth hormone, insulin-like growth factor-1 (IGF-1), and estrogen stimulate mammary growth. Breast development, or **thelarche**, is usually the first sign of puberty in the female. Full differentiation and maturation of breast tissue occur over approximately 4 years and are mediated by the levels of a variety of hormones, including estrogen, progesterone, prolactin, growth hormone, thyroid and parathyroid hormones, insulin, and cortisol. Estrogen promotes the increase in size of the breast by the formation of a mass of tissue under the areola, increases the size and pigmentation of the areola, and promotes development of the lobular ducts. The breast cells of parous women are different than those of women who never become pregnant as expansion of acini only occurs with pregnancy when the mammary gland prepares for lactation. During menopause the lobules of the parous breast involute to prepregnancy composition and become identical to the nulliparous breast.²⁷ Variations in breast development are listed in Box E 24-1 found on Evolve.

During the reproductive years the breast undergoes cyclic changes in response to changes in the levels of estrogen and progesterone associated with the menstrual cycle. Estrogen promotes development of the lobular ducts; progesterone stimulates development of cells lining the acini. Lactation (milk production) occurs after childbirth in response to increased levels of prolactin. Prolactin secretion, in turn, increases by continued breast-feeding. **Oxytocin**, another hormone released from the hypothalamus after delivery, controls milk ejection (let-down) from acini cells. During the follicular/proliferative phase of the menstrual cycle, high estradiol levels increase the vascularity of breast tissue and stimulate proliferation of ductal and acinar tissue. This effect is sustained into the luteal/secretory phase of the cycle. During this phase, progesterone levels increase and contribute to the breast changes induced by estradiol. Specific effects of progesterone

include dilation of the ducts and conversion of the acinar cells into secretory cells. Most women experience some degree of premenstrual breast fullness, tenderness, and increased nodularity. Breast volume may increase as much as 10 to 30 mL. Because the length of the menstrual cycle does not allow for complete regression of new cell growth, breast growth continues at a slow rate until approximately 35 years of age. Because of the cyclic changes that occur in breast tissue, clinical breast examination is recommended at the conclusion of or a few days after the menstrual cycle when hormonal effects are minimal and breasts are at their smallest and least tender.

During pregnancy the breast remodels into a milk-secreting organ and reaches its ultimate mature developmental stage. With increased levels of estrogen, the lobules further differentiate. Progesterone stimulates development of cells lining the alveoli to produce milk. Lactation (milk production) occurs after childbirth in response to increased levels of prolactin. Prolactin secretion, in turn, increases by continued breast-feeding. Milk is continuously secreted into the alveolar lumen and is stored there until the myoepithelial cells are stimulated by suckling stimulation of oxytocin, which triggers the let-down reflex. The alveoli empty into a network of lactiferous ducts. These ducts reach the skin through 9 or 10 openings (pores) in the nipple. After pregnancy, the milk is continuously secreted into the alveolar lumen and is stored there until the myoepithelial cells are stimulated by oxytocin to contract, which triggers the let-down reflex. The alveoli empty into a network of lactiferous ducts. These ducts reach the skin through 9 or 10 openings (pores) in the nipple.

The breast has the capacity to regress to a resting state after cessation of lactation and then undergo the same cycle of expansion and regression in subsequent pregnancies, a process possibly maintained by stem cells.³⁰ This remarkable plasticity of the breast suggests tight hormonal control and dramatic tissue-stromal and lobular restructuring.³¹

An extensive capillary network surrounds the acini and is supplied by perforating branches of the internal mammary, the thoracoacromial, the internal and lateral thoracic, and the intercostal

arteries. Venous return follows arterial supply, with relatively rapid emptying into the superior vena cava. The breasts receive sensory innervation from branches of the second through sixth intercostal nerves and the cervical plexus. This accounts for the fact that breast pain may be referred to the chest, back, scapula, medial arm, and neck. Lymphatic drainage from the subareolar plexus occurs largely through axillary nodes but there may be a predominance of superficial mammary routes with resultant asymmetry between a person's breasts (Fig. 24.11).²⁶

FIGURE 24.11 Lymphatic Drainage of the Female Breast. Arrows indicate the direction of lymphatic drainage. (From Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby.)

The **nipple** is a pigmented, cylindrical structure usually located at the fourth or fifth intercostal space. On its surface lie multiple openings, one from each lobe. It measures 0.5 to 1.3 cm in diameter and is approximately 10 to 12 mm in height when erect. The **areola** is the pigmented circular area in the center of the breast surrounding the nipple. It may be 15 to 60 mm in diameter. A number of sebaceous

glands, the **glands of Montgomery**, are located within the areola and aid in lubrication of the nipple during lactation. The nipple and areola contain smooth muscles that receive motor innervation from the sympathetic nervous system. Breast-feeding, sexual stimulation, and exposure to cold cause the nipple to become erect.

The function of the female breast is primarily to provide a source of nourishment for the newborn. Physiologically, breast milk is the most appropriate nourishment for newborns. Colostrum, produced in low quantities in the first few days postpartum, is rich in immunologic components, including secretory IgA, lactoferrin, leukocytes, and developmental factors, such as epidermal growth factor. The nutrient composition changes over time to meet the changing digestive capabilities and nutritional requirements of the infant. Secretory IgA and nonspecific antimicrobial factors, such as lysosomes and lactoferrin, protect the infant against infection.³² During lactation, high prolactin levels interfere with hypothalamic-pituitary hormones that stimulate ovulation. This mechanism suppresses the menstrual cycle and can prevent ovulation.³³ In some parts of the world, breast-feeding is the major means of contraception (lactational amenorrhea method).³⁵ However, it is not absolute that ovulation will not occur and this method will not ensure that pregnancy will not occur. Breasts also are a source of pleasurable sexual sensation and in Western cultures have become a sexual symbol.

The Male Breast

Until puberty, development of the male breast is similar to that of the female breast. In the absence of sufficiently high levels of estrogen and progesterone, the male breast does not develop any further. The normal male breast consists of a small underdeveloped nipple, some fatty and fibrous tissue, and a few ductlike structures in the subareolar area. The male breast may appear enlarged in obese men because of accumulation of fatty tissue. During puberty, some males experience benign gynecomastia (benign proliferation of male breast glandular tissue), a condition in which the breasts enlarge temporarily as a result of hormonal fluctuations, and should be differentiated from

any underlying systemic disorders.³⁶

The Male Reproductive System

The external genitalia in men perform the major functions of reproduction. Sperm are produced in the male gonads, the testes, and delivered by the penis to the female vagina. The internal male genitalia consist of conducting tubes and fluid-producing glands, all of which aid in the transport of sperm from the testes to the urethral opening of the penis. The male reproductive and urinary structures are shown in [Fig. 24.12](#).

FIGURE 24.12 Structure of the Male Reproductive Organs. (From Ball JW et al: *Seidel's guide to physical examination*, ed 8, St Louis, 2015, Mosby.)

External Genitalia

Testes

In men the **testes** (*singular, testis*) are the essential organs of reproduction. Like the ovaries, the testes have two functions: (1) production of gametes (i.e., sperm) and (2) production of sex hormones (i.e., androgens and testosterone).

During embryonic and fetal life, the testes develop within the abdomen (see [Fig. 24.1](#)). About 3 months before birth, the testes start to descend toward the developing scrotum. About 1 month before birth they enter twin passageways called **inguinal canals**. The inguinal canals are vaginal processes created by outpouchings of the peritoneum (lining of the abdominal cavity). The descent of a testis is shown in [Fig. 24.13](#). Each testis moves down outside the peritoneum until it is suspended in the scrotal sac by its supply lines: the ducts, blood vessels, lymphatic vessels, and nerves of the **spermatic cord**. When descent is complete, the abdominal end of each vaginal process closes and the inguinal canal disappears. If peritoneal closure at the site of the inguinal canal is incomplete or weak, an inguinal hernia may occur later in life. The scrotal end of each vaginal process becomes the outer covering of the testis, the **tunica vaginalis**. Failure of the testes to descend through the inguinal canal is known as *cryptorchidism*.

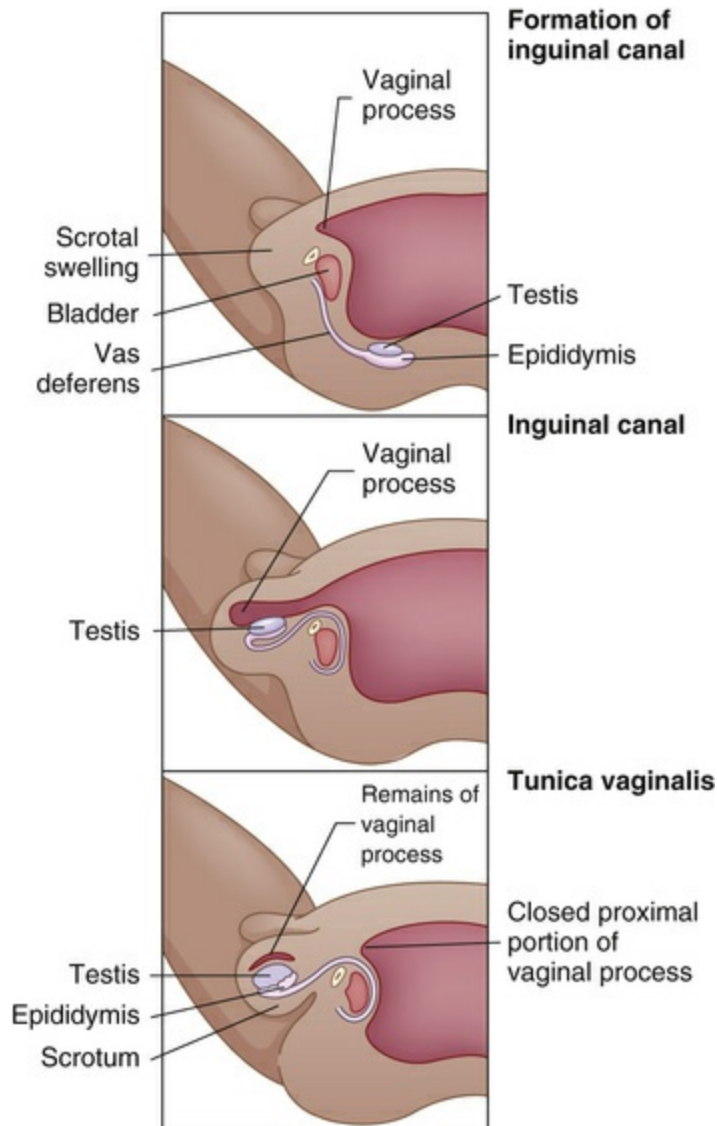

FIGURE 24.13 Descent of a Testis. The testes descend from the abdominal cavity to the scrotum during the last 3 months of fetal development.

Fig. 24.14 shows a sagittal section of a mature testis. The adult testis is ovoid and varies considerably in length (3 to 6 cm), width (2 to 3.5 cm), depth (3 to 4 cm), and weight (10 to 40 g). The testis is almost entirely surrounded by an outer covering, the tunica vaginalis, which separates the testis from the scrotal wall, and an inner covering, the **tunica albuginea**. Inward extensions of the tunica albuginea form septa that separate the testis into about 250 compartments, or lobules, each of which contains several tortuously coiled ducts called **seminiferous tubules**. The seminiferous tubules constitute the bulk

(80%) of testicular volume and are the site of sperm production. Spermatogenesis is described under the section titled [Spermatogenesis](#). Tissue surrounding these ducts contains blood and lymphatic vessels, fibroblastic support cells, macrophages, mast cells, and Leydig cells. **Leydig cells** occur in clusters and produce androgens, chiefly testosterone.

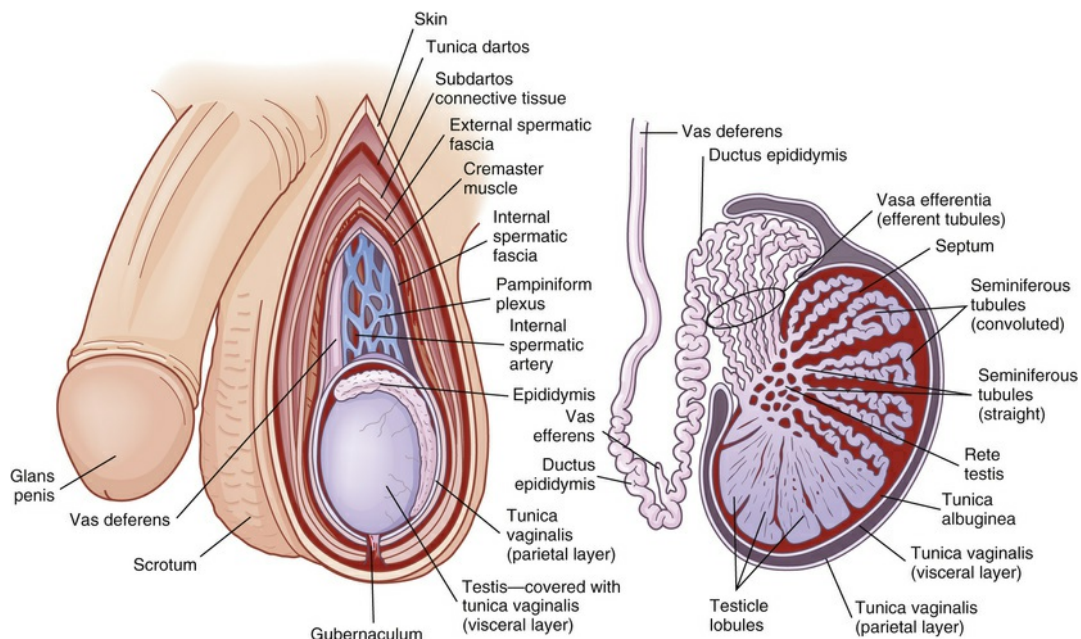

FIGURE 24.14 The Testes. External and sagittal views showing interior anatomy. (From Seidel HM et al: *Mosby's guide to physical examination*, ed 6, St Louis, 2006, Mosby.)

The two ends of each seminiferous tubule join and leave the lobule through a short, straight section called the **tubulus rectus**. Sperm travel from the seminiferous tubules into these straight sections, which lead to the central portion of the testis, the **rete testis**. From the rete testis, sperm move through the **efferent tubules**, or vasa efferentia, to the epididymis, where they mature.

The testes are innervated by adrenergic fibers, whose sole function is to regulate blood flow to the Leydig cells. Arterial blood from the internal spermatic and differential arteries flows over the surface of the testes before entering the parenchyma (functional tissues). Surface flow cools the blood to temperatures that promote spermatogenesis,

approximately 2°C to 7°C (3.6°F to 12.6°F) below body core temperature.³⁷

Additionally, the testes are suspended outside the pelvic cavity to facilitate cooling.

Epididymis

The **epididymis** (*plural, epididymides*) is a comma-shaped structure that curves over the posterior portion of each testis (see [Fig. 24.14](#)). It consists of a single highly packed and markedly coiled duct measuring 5 to 7 cm in length (about 6 meters in length when uncoiled). The epididymis has structural and physiologic functions. Its structural function is to conduct sperm from the efferent tubules to the vas deferens, whereas physiologic functions include sperm maturation, mobility, and fertility. When sperm enter the head of the epididymis, they are not fully mature or motile, nor are they capable of fertilizing an ovum. During the 12 days (or more) sperm take to travel the length of the epididymis, they receive nutrients and testosterone from the epididymal epithelium, and their capacity for fertilization is enhanced.³⁸ After traveling the length of the epididymis, sperm are stored in the epididymal tail, which is continuous with the vas deferens. The **vas deferens (ductus deferens)** is a duct with muscular layers capable of powerful peristalsis that transports sperm toward the urethra. The vas deferens enters the pelvic cavity through the spermatic cord (see [Fig. 24.14](#)).

Scrotum

The testes, epididymides, and spermatic cord are enclosed and protected by the **scrotum**—a skin-covered fibromuscular sac that is homologous to the female labia majora (see [Fig. 24.2](#)). The skin of the scrotum is thin and has rugae (wrinkles or folds) that enable it to enlarge or relax away from the body. At puberty the scrotal skin darkens, develops active sebaceous glands, and becomes sparsely covered with hair. Just under the skin lies a layer of connective tissue (fascia) and smooth muscle, the tunica dartos (see [Fig. 24.14](#)). The

tunica dartos also forms a septum that separates the two testes. Exposure to cold temperatures causes the tunica dartos to contract, pulling the testes close to the warm body. In warm temperatures the tunica dartos relaxes, suspending the testes away from body heat. These mechanisms promote optimal temperatures for spermatogenesis. In addition, scrotal sensitivity to touch, pressure, temperature, and pain protects the testes against potential harm. During sexual excitement the scrotal skin and tunica thicken, the scrotum tightens and lifts, and the spermatic cords shorten, partially elevating the testes toward the body. As excitement plateaus, the engorged testes increase 50% in size, rotate anteriorly, and flatten against the body, signaling impending ejaculation.

Penis

The **penis** has two main functions: delivery of sperm to the female vagina and elimination of urine. (Urine formation and excretion are the subjects of [Chapter 38](#).) Embryonically, the penis is homologous to the female clitoris (see [Fig. 24.2](#)).

[Fig. 24.12](#) shows a sagittal section of the adult penis and its anatomic relation to other urogenital structures. Externally the penis consists of a shaft with a tip, the **glans**, that contains the opening of the urethra (see [Figs. 24.14](#) and [24.15](#)). The skin of the glans folds over the tip of the penis, forming the prepuce, or **foreskin (prepuce)**. At birth, the foreskin is adhered to the glans. Penile erections, which commonly occur, cause the adhesions to break so that by age 3 years the foreskin becomes completely retractable. The skin of the penis is continuous with that of the groin, scrotum, and inner thighs. It is hairless, movable, and darker than the surrounding skin.

FIGURE 24.15 The Penis. A, Cross section of the penis. B, Cross section of the shaft of the penis showing three columns of erectile, or cavernous, tissue. (A From Netter illustration from www.netterimages.com. Copyright Elsevier Inc. All rights reserved. B From Vidic B, Suarez RF: *Photographic atlas of the human body*, St Louis, 1984, Mosby.)

Internally the penis consists of the urethra and three compartments: two **corpora cavernosa** (*singular, corpus cavernosum*) and the **corpus spongiosum** (see Fig. 24.15) separated by Buck fascia. Like the testes, these compartments are enclosed by the fibrous tunica albuginea. The **urethra** passes through the corpus spongiosum and ends at a sagittal slit in the glans.

Penetration of the female vagina is made possible by the **erectile reflex**, a process in which erectile tissues within the corpora cavernosa and corpus spongiosum become engorged with blood, generally 20 to 50 mL. The erectile tissues consist of vascular spaces, or chambers, that are supplied with blood by arterioles (small arteries). Typically, the arterioles are constricted through tonic noradrenaline release from sympathetic nerves so that small amounts of blood flow through the erectile tissues. Sexual stimulation, however, causes the arterioles to dilate through release of nitric oxide and fill with blood, expanding the erectile tissues and causing an erection. Other central transmitters, such as dopamine and acetylcholine, are facilitators of erectile control, as well. Erection apparently is maintained by compression or constriction of veins that drain the corpora cavernosa and corpus spongiosum. When sexual stimulation ceases or orgasm and ejaculation occur, these veins open, blood flows out of the arterioles, and the penis becomes flaccid (soft and pendulous).

Erection is under the control of the autonomic nervous system but can be stimulated or inhibited by central nervous system input. Stimulation of mechanoreceptors of the penis, particularly of the

glans, causes parasympathetic nerves of the autonomic nervous system to relax smooth muscle in the walls of penile arterioles. At the same time, the effects of sympathetic nerves, which normally cause arteriolar smooth muscle to constrict, are inhibited.

Erections begin in utero and continue throughout life, but ejaculation does not occur until sperm production begins at puberty. Growth of the penis and scrotal contents continues well past puberty, however, and may not be complete until the late teens or early twenties. Penis size, when flaccid, varies considerably; with an erection, differences in penis size diminish. Sexual excitement causes the corpora cavernosa to increase in length and width and become rigid; the penis becomes erect. Stimulation of the glans, which is endowed with copious sensitive nerve endings, provides maximum erotic sensation. With sexual arousal, skin color deepens, the glans doubles in size, and the urethral meatus dilates. Ejaculation occurs with frequent, strong contractions of the vas deferens, epididymis, seminal vesicles, prostate, urethra, and penis. Erection and ejaculation can occur independently of each other, but it is not common.³⁹

Internal Genitalia

Fig. 24.13 shows the anatomy of the internal genitalia and their relation to other pelvic organs. The internal genitalia consist of ducts and glands as follows:

Ducts—consist of two vasa deferentia, the ejaculatory duct, and the urethra—conduct sperm and glandular secretions from the testes to the urethral opening of the penis

Glands—consist of the prostate gland, two seminal vesicles, and two Cowper (or bulbourethral) glands—secrete fluids that serve as a vehicle for sperm transport and create an alkaline, nutritious medium that promotes sperm motility and survival

Together the sperm and the glandular fluids comprise **semen**.

Sperm leave the epididymides and travel rapidly through the internal ducts in a process called **emission**. Emission occurs just

seconds before ejaculation, at the moment when sexual arousal peaks. It always leads to ejaculation.

Emission occurs as smooth muscle in the walls of the epididymides and vasa deferentia begins to contract rhythmically, pushing sperm and epididymal secretions through the vasa deferentia. Each vas deferens is a firm, elastic fibromuscular tube that begins at the tail of the epididymis, enters the pelvic cavity within the spermatic cord, loops up and over the bladder, and ends in the prostate gland (Fig. 24.16; see also Fig. 24.12). Sperm are moved along by peristaltic contractions of smooth muscle in the walls of the vas deferens.

FIGURE 24.16 Zones of the Prostate Gland and Seminal Vesicles. **A**, Zones of the prostate. The peripheral zone, accounting for 70% of the prostate gland, is the site of origin of $\leq 70\%$ of prostate cancers; the central zone, approximately 25% of the prostate gland, gives rise to only 1% to 5%

of prostate cancers; and the transition zone, approximately 5% to 10% of the prostate gland, gives rise to 20% of prostate cancers and is the site of origin of benign prostatic hyperplasia (BPH). B, Prostate gland within the male reproductive system. (A Copyright Baylor College of Medicine, Houston, TX. B From Drake et al: *Gray's atlas of anatomy*, Philadelphia, 2008, Churchill Livingstone.)

As sperm leave the ampulla (wide portion) of the vas deferens, the seminal vesicles secrete a nutritive glucose-rich fluid into the ejaculate (semen). The **seminal vesicles** are a pair of glands, each about 4 to 6 cm long, that lie behind the urinary bladder and in front of the rectum. The seminal vesicles provide fructose as a source of energy for ejaculated sperm, and secrete prostaglandins that promote smooth muscle contraction, assisting with sperm transport. The ducts of the seminal vesicles join the ampulla of the vas deferens to become the **ejaculatory duct**, which contracts rhythmically during emission and ejaculation. As can be seen in [Figs. 24.12](#) and [24.16](#), the ejaculatory duct joins the urethra, where both pass through the prostate gland. During emission and ejaculation a sphincter (muscle surrounding a duct) closes, preventing urine from entering the prostatic urethra.

The **prostate gland** is about the size of a walnut, has three zones, and surrounds the urethra (see [Fig. 24.16](#)). It is composed of glandular alveoli and ducts embedded in fibromuscular tissue. Prostate growth, development, and function are regulated by androgens and the androgen receptor. Nerves required for penile erection travel along the posterolateral surface of the prostate. Included in prostate epithelial secretions are prostate-specific antigen (PSA), cytokeratins, prostate-specific membrane antigen (PSMA), and prostate-specific acid phosphatase. Prostate secretions contribute to the ejaculate. While semen moves through the prostatic portion of the urethra, the prostate gland contracts rhythmically and secretes prostatic fluid into the mixture. Prostatic fluid is a thin, milky substance with an alkaline pH that helps sperm survive in the acid environment of the female reproductive tract. In addition, clotting enzymes and fibrinolysin in prostatic fluids help mobilize sperm after ejaculation.

Cowper glands (bulbourethral glands) are the last pair of glands to add fluid to the ejaculate; their ducts secrete mucus into the urethra near the base of the penis. Ejaculation occurs as semen reaches the

base of the penis and muscles there begin the rhythmic contractions that expel semen. A man normally ejaculates between 2 and 6 mL of semen, containing 75 million to 400 million sperm. About 98% of the ejaculate consists of glandular fluids; 60% to 70% of volume originates from the seminal vesicles and 20% from the prostate. Therefore the ejaculate of a man who has undergone a vasectomy (a surgical procedure that prevents sperm from entering the vas deferens) is reduced by about 2%.

Spermatogenesis

Spermatogenesis begins at puberty and continues for life. In this respect, spermatogenesis differs markedly from oogenesis (production of primordial ova), which occurs during fetal life only.

Spermatogenesis (the production of sperm) takes place within the seminiferous tubules of the testes (see [Fig. 24.14](#)). The basement membrane of each seminiferous tubule is lined with diploid (46-chromosome) germ cells called **spermatogonia** (*singular, spermatogonium*). These cells undergo continuous mitotic division (division into two identical cells, see [Chapter 1](#)). Some spermatogonia move away from the basement membrane and mature, becoming **primary spermatocytes** ([Fig. 24.17](#)). These undergo meiosis, cell division that results in two haploid (23-chromosome) cells called **secondary spermatocytes**. (Meiosis is described and illustrated in [Chapter 4](#).) The secondary spermatocytes also undergo meiosis, resulting in four **spermatids**. The spermatids differentiate into spermatozoa, or sperm, each of which contains 23 chromosomes ([Fig. 24.18](#)).

FIGURE 24.17 Seminiferous Tubule and Spermatogenesis. Cross section

of a seminiferous tubule showing the different cell types. Interstitial cells that produce testosterone are between the seminiferous tubules. Spermatids in the lumen become sperm by a process called spermatogenesis. The numbers in white represent the number of chromosomes. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

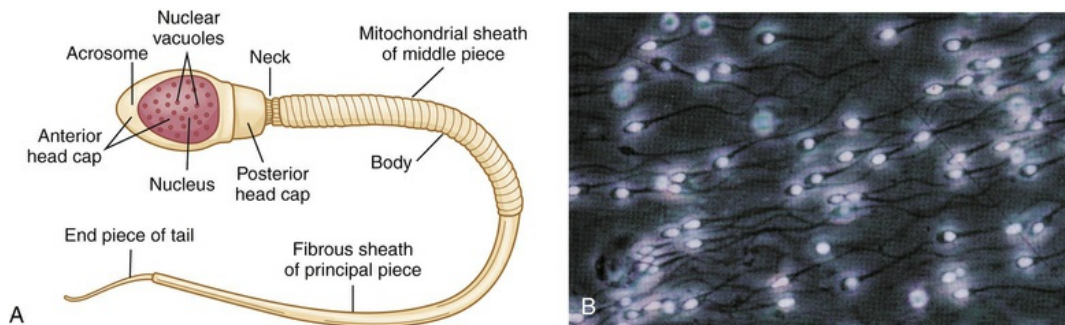

FIGURE 24.18 Mature Sperm Cell (Spermatozoon). A, Anatomy of mature sperm cell. B, Human sperm with nuclear material glowing with a fluorescent dye. (B From Lennart Nilsson.)

The development of spermatids into sperm depends on the presence of **Sertoli cells (nondividing support cells)** within the seminiferous tubules. Spermatids attach themselves to the Sertoli cells, from which they receive nutrients and hormonal signals (i.e., testosterone) needed to develop into sperm.⁴¹ The process of spermatogenesis, from mitotic division of a spermatogonium to maturation of the spermatids, takes about 70 to 80 days. Mature sperm migrate from the seminiferous tubules to the epididymis, where their capacity for fertilization continues to develop. Although they are completely mature by the time they are ejaculated, the sperm do not become motile (capable of movement) until they are activated by biochemicals in semen and in the female reproductive tract.

Male Sex and Reproductive Hormones

The male sex hormones are androgens. **Testosterone**, the primary male sex hormone, and other androgens are produced mainly by Leydig cells of the testes. The adrenal glands produce testosterone and other androgens in lesser amounts. In men, sex hormone production is

relatively constant and does not occur in a cyclic pattern, as it does in women. The physiologic actions of androgen are related to growth and development of male tissues and organs. Androgens are responsible for the fetal differentiation and development of the male urogenital system and have some effects on the fetal brain. After birth, the Leydig cells become quiescent until activated by the gonadotropins during puberty. Then androgens cause the sex organs to grow and secondary sex characteristics to develop.

Testosterone affects nervous and skeletal tissues, bone marrow, skin and hair, and sex organs. It has an anabolic effect on skeletal muscle tissue, thereby contributing to the difference in body weight and composition between men and women. Testosterone also stimulates growth of the musculature and cartilage of the larynx, causing a permanent deepening of the voice. Testosterone directly stimulates the bone marrow and indirectly stimulates renal erythropoietin production to achieve increased hemoglobin and hematocrit levels. Because sebaceous gland activity is stimulated by testosterone, acne may develop. In the presence of testosterone, hair becomes coarser in texture, and facial hair, axillary hair, and pubic hair grow in male patterns. Testosterone is required for spermatogenesis and for secretion of fluid by the prostate gland, seminal vesicles, and Cowper glands. Testosterone is also associated with an increase in **libido** (sex drive). Other, less-understood, effects of testosterone include regulatory proteins involved in glycolysis, glycogen synthesis, insulin action, and lipid and cholesterol metabolism.⁴³

The regulation of androgen production and spermatogenesis is achieved by a complex feedback system involving the extrahypothalamic central nervous system, the hypothalamus, the anterior pituitary, the testes, and the androgen-sensitive end organs. These relationships, which are essentially the same in women, are summarized in [Fig. 24.3](#). Extrahypothalamic influences include such variables as physiologic and psychologic stress, which may inhibit or augment hypothalamic activity. In the hypothalamus, neurotransmitters regulate GnRH synthesis and pulsatile release (about every 3 hours) into the hypophyseal portal veins.

Norepinephrine stimulates GnRH secretion, and serotonin and dopamine inhibit GnRH secretion. GnRH is transported by portal flow to the median eminence of the pituitary gland, where it binds to receptors and stimulates the synthesis and secretion of the gonadotropins LH and FSH. These gonadotropins are named for their effects in the female reproductive system, but have important effects on the male system as well. LH acts on the Leydig cells to regulate testosterone secretion. FSH acts on the seminiferous tubule Sertoli cells to promote spermatogenesis. FSH secretion is inhibited by inhibin secreted by the Sertoli cells. Similar to their action in the female gonad, inhibin functions as an autocrine/paracrine regulator in the male gonad. Inhibin inhibits proliferation of spermatogonia by regulating pituitary FSH levels. In addition, inhibin facilitates LH stimulation of androgen biosynthesis in Leydig cells.⁴⁴

Ninety-eight percent of testosterone, the major steroid hormone produced by the testes, binds to either **sex hormone-binding globulin (SHBG)** (40%) or albumin (48%). The remaining 2% remains unbound in the plasma and is free to enter cells and wield its metabolic effects. Changes in the amount of available SHBG affect the amount of testosterone within tissues. The testes secrete only 25% of circulating estrogen (estradiol). The majority is produced by peripheral conversion of testosterone and androstenedione. Estrogens help regulate GnRH and LH secretion. Peripheral conversion of testosterone by 5-alpha-reductase also produces **dihydrotestosterone (DHT)**, another potent androgen. DHT is necessary for external virilization during embryogenesis and androgen activity beginning at puberty and continuing throughout adulthood. **Prolactin**, a polypeptide synthesized and secreted from the pituitary, helps maintain biosynthesis of testosterone. However, elevated prolactin levels may suppress biosynthesis.⁴⁵

In summary, hormones secreted at each level of the hypothalamic-pituitary-testicular (HPT) axis control and coordinate testicular function (Fig. 24.19). This control is exerted through positive and negative feedback signals by (1) sex steroids that inhibit hypothalamic GnRH secretion and pituitary LH responsiveness to GnRH; and (2)

testicular inhibin that inhibits pituitary FSH and, possibly, circulating estrogens (E_2). Any disruption along the HPT axis may lead to hypogonadism or infertility.

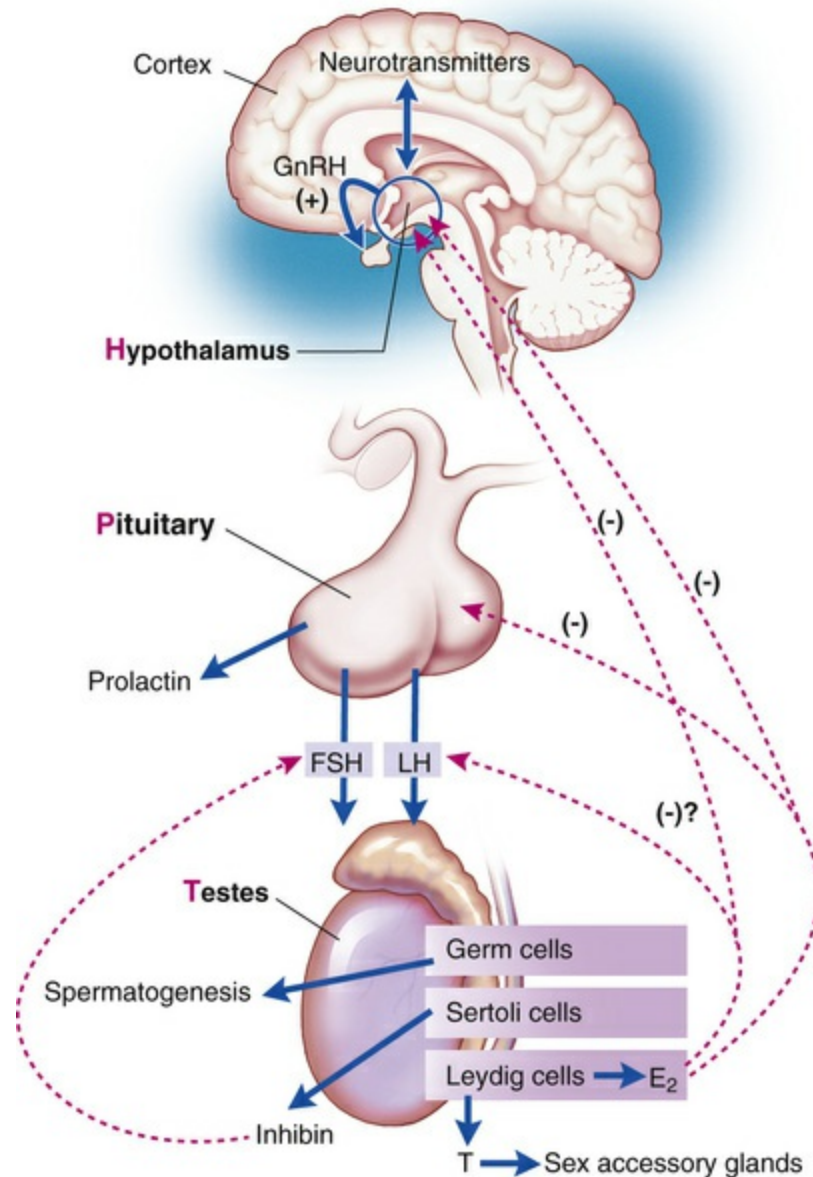

FIGURE 24.19 Schematic Representation of Activity Along the Hypothalamus-Pituitary-Testicular (HPT) Axis. E_2 , Estrogen; FSH , follicle-stimulating hormone; $GnRH$, gonadotropin-releasing hormone; LH , luteinizing hormone; T , testosterone.

Tests of Reproductive Function

Diagnostic tests of the male and female reproductive systems are performed to determine the cause of infertility, detect the presence of endometriosis or cancerous lesions, or identify the presence of sexually transmitted infections.⁴⁶ (Alterations of the female reproductive system including carcinoma are discussed in [Chapter 25](#). Alterations of the male reproductive system including carcinoma are discussed in [Chapter 26](#). Sexually transmitted infections are discussed in [Chapter 27](#).)

Tests of reproductive function are performed most commonly when infertility exists. Both partners are examined, and several diagnostic evaluations may be completed. The types of tests and their normal values are summarized in [Tables 24.4](#) and [24.5](#). The man is evaluated for number, amount, structure, and motility of sperm and obstruction along the reproductive tract. Tests for women determine whether (1) the reproductive tract (cervix, uterus, fallopian tubes) is adequately patent to allow for passage of ovum and sperm, (2) ovulation occurs normally, (3) the endometrium is responding normally to hormones, and (4) reproductive tissues are free of tumors or infections. Hormonal assays evaluate the adequacy of pituitary function and target organ response. The position and size of organs or the presence of tumors can be detected by direct observation procedures using a laparoscope or by ultrasound, radiographic studies, such as plain films, computerized scans, or tomography.⁴⁷

TABLE 24.4

TESTS AND NORMAL VALUES OF REPRODUCTIVE FUNCTION/FERTILITY

TEST	DESCRIPTION	NORMAL VALUE
Basic Assessment		
Semen analysis (two samples at least 2 weeks apart)	Determines number, motility, and structure of sperm cells	Volume = 2–6 mL Number = >20 million/mL Motility = >50% with forward progression
Sperm DNA	Determines the percentage of sperm DNA	Less than 15%–25%

fragmentation	strand breaks and likelihood of infertility	
White blood cells	Determines presence of bacteria/leukocytes	Morphology = >50% normal shape
Immunologic tests	Detects antibody to sperm	Immunobead test = <20% with adherent particles
		Sperm MAR test (mixed antiglobulin reaction) = <10% with adherent particles
		<10 ⁶ WBC/mL
		No sperm agglutinins present
Other Assessments		
Basal body temperature	Determines whether ovulation has occurred	Decrease in basal body temperature before ovulation followed by a rise in temperature at the time of ovulation
FSH level	Day 2–3 of cycle to measure ovarian reserve	Lab specific results
Estradiol	Day 2–3 of cycle to measure ovarian reserve	Low FSH in conjunction with low estradiol—lab specific results
Progesterone	Midluteal phase—1 week before menses	Lab specific results—low level associated with decreased or absent ovulation.
Prolactin	Day 3 of cycle	Lab specific results—high levels can interfere with ovulation
TSH level	Day 3 of cycle	Lab specific results—elevated value associated with hypothyroidism
Urinary LH	Day 11 of cycle	Identifies LH surge and indirect evidence of ovulation: if positive should ovulate in 24–36 hours; high false negative and positive rates
Cervical mucus	Evaluates presence of ovulation from estrogenic effects at ovulation; mucus also may be examined for pH, glucose, or proteins or cultured for presence of infection	Fern pattern appears when cervical mucus dries on a clean slide; mucus is clear, watery, and elastic (spinnbarkeit ≥8–10 cm) with no inflammatory cells
Postcoital cervical mucus (Sims-Huhner test)	Tests ability of sperm to penetrate and maintain motility in cervical mucus 2–4 hours after coitus approximately 1 day before ovulation	≥10 motile sperm in each high-power field; motility in one direction; previous sperm analysis normal

Zona binding test or hamster penetration test	Nonliving oocytes are surgically removed and bisected; sperm added to the hemi-oocyte to test fertilizing capability	Bonding <30% predicted failed fertilization 70% of the time Bonding >30% predicted successful fertilization 85% of the time
		Results may vary with lab
Ultrasound vaginal scanning	Provides superior quality resolution of the uterine, fallopian, and ovarian structures; also can be used to study folliculogenesis, ovulation, and luteogenesis to detect abnormalities	Normal structures visualized
More Specialized Tests		
Endometrial biopsy	Determines whether ovulation has occurred by obtaining endometrial tissue on day 26 of 28-day menstrual cycle (or postovulatory day 12)	Finding is “secretory-type” endometrium if ovulation has occurred; read in conjunction with day of cycle and serum progesterone levels
Hysterosalpingogram	Assessment of uterus and fallopian tubes for obstructions using transuterine injection of contrast material and radiography; performed 1–2 days after cessation of menses	No obstruction evident
Laparoscopy (pelvic endoscopy)	Visualization of reproductive organs using a laparoscope inserted within the pelvic cavity through the abdomen to assess structure or determine presence of adhesions, endometriosis, tumors, or infection	Normal structure and position of organs
Hysteroscopy	Visualization of uterine cavity using modified cystoscope inserted through cervical os; best done during first 14 days of cycle	Absence of intrauterine lesions
Transvaginal ultrasound	Identifies endometrial development	Shows size and numbers of developing follicles and evidence of ovulation – low counts associated with infertility

FSH, Follicle-stimulating hormone; *TSH*, thyroid-stimulating hormone; *WBC*, white blood cell.

TABLE 24.5

SERUM HORMONE VALUES

HORMONE	VALUE
Serum progesterone	Normal = >10 ng/dL, presumptive evidence of ovulation; draw level between days 20 and 25 of 28-day cycle or 6–10 days postovulation
	<10 ng/mL = inadequate luteal function
	<3 ng/mL suggests anovulation
Serum testosterone	Normal = 300–1200 ng/dL; must be interpreted with serum LH and FSH levels
Resulting from diurnal and pulsatile pattern, need serial blood draws	Low values in male hypogonadism
Serum FSH and LH	FSH = <22 international units/L
Resulting from diurnal and pulsatile pattern, need serial blood draws	LH = 4–24 international units/L High levels in males indicate primary testicular disease; low levels in males indicate hypogonadism caused by hypothalamic-pituitary dysfunction

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone.

Aging and Reproductive Function

Aging and the Female Reproductive System

Natural menopause is the cessation of ovulation and menses caused by ovarian failure. It is a normal developmental event marking the end of reproduction. Menopause is universally experienced by midlife women at the average age of 50.5 to 51.4 years in North America with variability between 40 and 60 years.^{48,49} Premature menopause is cessation of ovulation before 40 years of age. A number of factors are thought to influence the age of menopause, including genetics, socioeconomic status, race, parity, oral contraceptive use, and lifestyle, such as smoking or weight.⁵⁰ It can occur 2 years sooner on average for smokers; thinner women also tend to experience menopause at a slightly younger age. Genetics accounts for about 50% of the variation in age at menopause.⁵¹ The term “climacteric” refers to gradual changes of ovarian function that start before menopause and result in the symptoms associated with loss of ovarian function.⁵² For clarity,

the term *menopause* will be used here. The primary changes of menopause are as follows:

- *Perimenopause*: This is the transitional period between reproductive and nonreproductive years, a transition lasting 2 to 8 years. About 5 to 10 years before menopause, approximately 90% of women note mild to extreme variability in frequency and quality of menstrual flow. Changes in hormones occur during this time including erratically higher estradiol levels, decreased progesterone levels (in normal ovulatory, short luteal phase, or anovulatory cycles), and a disturbed ovarian-pituitary-hypothalamic feedback relationship with higher LH levels. A decrease in the sensitivity of the target tissue receptors and the development of perimenopausal symptoms commonly are experienced. Symptoms usually begin with a lengthening of the menstrual cycle, which correlates with anovulatory cycles. Unpredictable or irregular ovulation uniformly precedes menopause. The perimenopause experience varies among women and from cycle to cycle in the same woman. Estradiol levels remain in the normal to slightly elevated range until about 1 year before menopause.
- *Menopause*: Menopause is defined by the point that marks 12 consecutive months of amenorrhea

and is determined retrospectively after a woman has not had a menstrual period for 1 year. It is characterized by loss of ovarian function, low estrogen and progesterone levels, and high FSH and LH levels (Fig. 24.20). Early menopause is the 5 years after menopause onset. Late menopause follows and continues until death.⁵⁴

FIGURE 24.20 The Perimenopausal Hormone Transition. Mean circulating hormone levels. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone.

- *Ovarian changes*: Beginning in utero, the number of follicles steadily decreases through activation, maturation, and atresia. Around 37 to 38 years of age, women experience accelerated follicular loss, which ends when the supply of follicles is

depleted at menopause. This accelerated loss is correlated with increased FSH stimulation, slightly elevated estradiol levels, declining inhibin B production (normally maintain folliculogenesis and estradiol secretion), and decreasing amounts of anti-müllerian hormone (normally decreases FSH effects). Attenuated LH surges are associated with impaired hypothalamic responses to estradiol positive feedback (see [Fig. 24.20](#) and [Box 24.2](#)). The ovarian response to high FSH recruits increasing numbers of follicles; these follicles only partially develop, with a net effect of irregular ovulation, lower progesterone levels, depleted follicle reserve, and infertility. The ovaries begin to decrease in size around age 30; this decrease accelerates after age 60. Of the 500,000 follicles present at the onset of puberty, the number dwindles to between 100 and 1000 with menopause.⁵⁵ [Table 24.6](#) summarizes endocrine events occurring during the perimenopause. [Table 24.7](#) provides a template to visualize the complex physiology of the perimenopause and the dynamic changes that occur during this time.

Box 24.2

Changes in Ovarian Folliculogenesis During the Perimenopause Leading to

Endogenous Overstimulation

- ↑ FSH → ovarian hyperstimulation → ↑ number of follicles recruited (net effect of follicular depletion) → ↑ estradiol
- ↓ Follicular reserve → ↓ inhibin and ↑ activin in FP and LP → ↑ FSH → ↑ number of follicles recruited, partial development, infrequent ovulation → ↑ estrogen (E₂) and ↓ progesterone

FP, Follicular phase; *FSH*, follicle-stimulating hormone; *LP*, luteal phase.

TABLE 24.6

ENDOCRINE EVENTS ASSOCIATED WITH PERIMENOPAUSE

HORMONE CHANGES	EFFECTS
Estradiol (E ₂) levels	Erratic and intermittent increase
Mean FP level 1 greater than mean FP level in younger women	First in FP (inverse relationship between length of FP and estradiol level)
FP level may be greater than midcycle peak level in fertile women	Later during premenstrual phase
Ovulatory cycles	Short or insufficient LP (decreased fertility)
Progesterone levels	Decreased in ovulatory cycle; minimal during anovulatory cycles
Anovulatory cycles	Increased to about 50%; perhaps more in later perimenopause
FSH levels	Variable, then increased
LH levels	Normal initially, then increased
Inhibin levels	Correlate with progesterone levels

FP, Follicular phase; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *LP*, luteal phase.

TABLE 24.7

POSTULATED PERIMENOPAUSAL TRANSITION TIME LINE

MENSTRUAL	HORMONAL
-----------	----------

PHASE	PHYSIOLOGY	CHANGES	SYMPTOMATOLOGY
A	Regular, ovulatory cycles Short cycles, short FP	Intermittent ↑ E ₂ FSH usually normal Intermittent ↑ FP FSH Low inhibin	Increased breast tenderness, mood swings, fluid retention, premenstrual symptoms Early morning night sweats (vasomotor symptoms) Weight gain, migraine headaches, heavy flow
B	Regular cycles with disturbances in ovulation Short LP Insufficient LP Anovulatory cycles	Intermittent ↑ FP FSH E ₂ often ↑ Inhibin inappropriately low	Heavy flow ↑ Premenstrual symptoms ↑ Dysmenorrhea Predictable or ↑ vasomotor symptoms before flow
C	Onset of perimenopause Alternating short, long, or skipped cycles	E ₂ often quite ↑ E ₂ normal or low ↑ FSH (slight) ↑ LH Low inhibin	Vasomotor symptoms during waking hours Vasomotor symptoms more persistent, remain cyclic before flow
D	Onset of oligomenorrhea 50% of cycles anovulatory Heavy flow may predict onset of oligomenorrhea	↑ Progesterone with ovulation Persistent ↓ FSH ↑ LH ↑ E ₂ Low inhibin	↑ Vasomotor symptoms ↑ Signs/symptoms of high estrogen after long periods without flow Flow light but unpredictable
E	Final menstrual period plus 1 year	↑ FSH and LH ↓ or normal E ₂ Consistent low inhibin ↓ Progesterone	↑ Intensity and frequency of vasomotor symptoms (although vasomotor symptoms may disappear) ↓ Cramps and premenstrual-type symptoms without subsequent flow ↓ Breast, mood, and fluid symptoms

E₂, Estradiol; FP, follicular phase; FSH, follicle-stimulating hormone; LP, luteal phase.

- *Uterine changes:* Uterine changes occur primarily in the endometrium. The increase in anovulatory cycles allows for proliferative growth of the

endometrium. The longer exposure to estrogen alone results in greater thickness of the endometrium, and 50% of perimenopausal women will experience dysfunctional uterine bleeding that is heavy and unpredictable. Increased endometrial bleeding is correlated with a change from ovulatory to anovulatory cycles and is associated with unopposed high estrogen levels the week before menses. Estrogen causes endometrial tissue to thicken. However, without corresponding stromal support from progesterone, estrogen production leads to heavier periods, menometrorrhagia (excessive bleeding often caused by submucosal myomas and endometrial polyps), or metrorrhagia (midcycle bleeding) (Table 24.8). In the past this has put women at high risk for hysterectomy or endometrial ablation. Medical and hormonal management is the first line of therapy if the uterus is normal.⁵⁶

TABLE 24.8

IMPACT OF HIGH ESTROGEN LEVELS ON MENSTRUAL CYCLE AND SYMPTOMATOLOGY

ASSOCIATED PHYSIOLOGIC CHANGE	SIGNS/SYMPTOMS
Short follicular phase (FP)	Short cycles
Long FP	Long cycles
Thickened endometrium	Heavy, long, or unpredictable flow (including clotting and flooding)*

Increase in glandular cells without stromal support produced by progesterone → unstable endometrium	Midcycle spotting Menorrhagia
Possible increased production of prostaglandins within endometrial tissue	Metrorrhagia Dysmenorrhea Breast tenderness, modularity, enlargement Water retention Emotional stress; new or unpredictable mood swings Weight gain Vasomotor symptoms New onset of migraine headaches; exacerbation of headaches Increased premenstrual symptoms

*Symptoms aggravated by anovulatory cycles; leads to dysfunctional uterine bleeding (see [Chapter 25](#)).

- *Breast tissue changes:* Glandular breast tissue becomes involuted, fat deposits and connective tissue increase, and breasts are reduced in size and firmness. There can be an increase in white adipose tissue inflammation with elevated aromatase levels (decreases circulating estrogen).⁵⁷
- *Genitourinary tract changes:* The ovaries shrink; the uterus atrophies; the vagina shortens, narrows, and loses some elasticity. Lubrication of the vagina diminishes and vaginal pH increases, creating higher incidence of vaginitis. The cervix atrophies and the cervical os shrinks; vaginal epithelium atrophies; labia majora and minora become less prominent; some pubic hair is lost; urethral tone declines along with muscle tone throughout the pelvic area; urinary frequency or urgency, urinary tract infections, and incontinence

may occur. Regular sexual activity and orgasm may diminish some of these changes. Sexually active women have less vaginal atrophy.

- *Skeletal changes:* Bone mass is reduced, leading to increased brittleness and porosity, which increases the risk of osteoporosis and fracture, particularly in the lumbar spine and femoral neck.⁵⁸

- *Cardiovascular changes:* The risk of cardiovascular disease (CVD) increases significantly and is the leading cause of death in postmenopausal women. Blood pressure and total and LDL-cholesterol increase and HDL-cholesterol decreases. There is increased risk for metabolic syndrome.⁶⁰

- *Systemic changes:* **Vasomotor flushes** are characterized by a rise in skin temperature, dilation of peripheral blood vessels, increased blood flow in the hands, increased skin conductance, and a transient increase in heart rate followed by a temperature drop and profuse perspiration over the area of flush distribution. This usually occurs in the face and neck and may radiate into the chest and other parts of the body. Night sweats, dizziness, nausea, headaches, or palpitations may accompany the flush. These flushes can vary in frequency, intensity, and duration and are experienced by up to 85% of perimenopausal to postmenopausal women from

1 to 15 years (mean 1 to 5 years). The physiology of vasomotor flushes is poorly understood. One theory proposes that rapid changes in estrogen levels may result in loss of negative feedback over hypothalamic noradrenaline synthesis, the primary neurotransmitter involved in thermoregulation.⁶¹ Estrogen modulates adrenergic receptors. The decrease in estrogen level in menopause is thought to decrease the number of receptors leading to increased noradrenaline levels and hot flushes. Interestingly, emerging evidence shows that the intensity of vasomotor flushes may be associated with increased risk for cardiovascular disease.⁶²

- *Other changes:* Emotional stress with unpredictable mood swings, weight gain, migraine headaches, insomnia, and depression often accompany the change in estrogen levels.⁶³
- Lower estrogen levels decrease skin thickness and diminish skin elasticity, thereby causing increased skin dryness and wrinkling. Alopecia and unwanted facial hair are common.⁶⁴

Aging and the Male Reproductive System

Men maintain reproductive capacity longer than women. There is no known discrete event, comparable to menopause, that characterizes aging of the male reproductive system, although the term andropause is sometimes used to describe the changes associated with male aging

and lower levels of testosterone. Gradual changes do occur, and aging in the male reproductive system is characterized by hypogonadism, testosterone deficiency, erectile dysfunction, and proliferative disorders of the prostate gland (see [Chapter 26](#)). Aging changes are also influenced by chronic diseases and use of medications.⁶⁵

Components of male sexual behavior include both sexual drive and erectile and ejaculatory capacity. Libido, or sexual drive, is a complex phenomenon that requires a baseline hormonal milieu but is influenced significantly by health status and environmental, social, and psychologic factors. In men older than 40 years, organic factors and chronic disease (e.g., vascular, endocrine, and neurologic disorders) are involved in more than half of the cases of male sexual dysfunction. Aging causes specific physical changes that may influence erectile and ejaculatory capabilities. Alterations in sexual response include the need for longer stimulation to achieve full erection; slower and less forceful ejaculation, with less pelvic muscle involvement; decreased vasocongestive response; and longer refractory period (time during which erection and ejaculation are not possible), up to 24 hours in some men.

The testes undergo several age-related structural changes, including decreased weight, atrophy, and softening. Degenerative changes in the seminiferous tubules may include thickening of the basement membrane; increase in lumen size; germ cell (spermatogonium) arrest and a decrease in spermatogenic activity; and collapse of tubules, followed by complete obstruction caused by sclerosis and fibrosis. Areas of mild to severe degenerative change may be interspersed with areas having intact tubules. These morphologic changes may result from atherosclerosis (arterial clogging) in the testicular vascular bed. Alterations of the seminiferous tubules do not appear to diminish sperm counts (20 million sperm per milliliter of semen is estimated as the minimum concentration for fertility) but they do reduce fertility because a greater percentage of the sperm lack motility or have structural abnormalities.

About 20% of healthy men more than 60 years of age and 30% to 50% older than 80 years of age have testosterone levels below the

reference range and about 2% have hypogonadism. Aging can cause changes in the production of male sex hormones, levels of SHBG, and responsiveness of target tissue receptors. Hormone synthesis by the testes and testicular responsiveness to the gonadotropins (FSH and LH) are diminished, and pituitary secretion of these gonadotropins is elevated. The reduced levels of testosterone may be related to alterations in the Leydig cells, the testosterone producers of the testes. The number of Leydig cells and their function decrease as age increases, perhaps because of decreased arterial perfusion of the testes, and varicoceles and decreased LH or responsiveness to LH.

Even if testosterone levels are not decreased, older men may have less unbound testosterone in their blood, decreasing the amount of unbound hormone available to stimulate target tissues. Decreased testosterone levels have several effects, including functional deterioration of the accessory sex organs (the prostate gland, seminal vesicles, epididymis, and ductus deferens); loss of muscle mass, strength, and endurance; increased visceral fat, osteopenia, and cognitive decline; and, in many men, decrease in libido. This last effect also may be caused by alterations in other variables that affect libido. Modifiable risk factors for low testosterone level and symptoms of androgen deficiency include health status and waist circumference.

Summary Review

Development of the Reproductive Systems

1. Differentiation of female and male genitalia begins around weeks 7 to 8 of embryonic development, when the gonads of genetically male embryos begin secretion of male sex hormones, primarily testosterone; expression of testes-determining factor (TDF); and expression of the *SRY* gene. Until that time the primitive reproductive organs of males and females are homologous (the same).
2. The structure and function of male and female reproductive systems are controlled by the hypothalamic-pituitary-gonadal

(HPG) axis, a set of complex neurologic and hormonal interactions that accelerate at puberty and lead to sexual maturation and reproductive capability.

3. Extrahypothalamic factors cause the hypothalamus to secrete GnRH, which stimulates the anterior pituitary to secrete gonadotropins—FSH and LH—that stimulate the gonads (ovaries or testes) to secrete female or male sex hormones. Paracrine hormones (inhibin, activin, and follistatin) influence the positive and negative feedback loops that occur along the HPG axis.
4. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life. Females release a mature ova at the time of puberty.

The Female Reproductive System

1. The function of the female reproductive system is to produce mature ova and, when fertilized, to protect and nourish them through embryonic and fetal life, and expel them at birth.
2. The external female genitalia are the mons pubis, labia majora, labia minora, clitoris, vestibule (urinary and vaginal openings), Bartholin glands, and Skene glands.
3. The internal female genitalia are the vagina, uterus, fallopian tubes, and ovaries.
4. The vagina is a fibromuscular canal that receives the penis during sexual intercourse and is the exit route for menstrual fluids and products of conception. The vagina leads from the introitus (its external opening) to the cervical portion of the uterus.
5. The uterus is the hollow, muscular organ in which a fertilized ovum develops. The uterine walls have three layers: the endometrium (lining), myometrium (muscular layer), and

perimetrium (outer covering, which is continuous with the pelvic peritoneum). The endometrium proliferates (thickens) and sloughs off in response to cyclic hormonal changes. The cervix is the narrow, lower portion of the uterus that opens into the vagina.

6. The two fallopian tubes extend from the uterus to the ovaries. Their function is to conduct ova from the spaces around the ovaries to the uterus. Fertilization normally occurs in the distal third of the fallopian tubes.
7. From puberty to menopause, the ovaries are the site of (a) ovum maturation and release and (b) production of female sex (estrogen and progesterone) and male (androgens) hormones. Female sex hormones predominate and are involved in sexual differentiation and development, the menstrual cycle, pregnancy, and lactation. Androgens in women contribute to prepubertal growth spurt, pubic and axillary hair growth, and activation of sebaceous glands.
8. Developing ovarian follicles (structures that enclose the ovum) produce estrogen (primarily estradiol). The corpus luteum, the structure that develops from the ruptured ovarian follicle after ovulation or ovum release, produces progesterone. Androgens in women are produced within the ovarian follicle, adrenal glands, and adipose tissue.
9. The average menstrual cycle lasts 27 to 30 days and consists of three phases, which are named for ovarian and endometrial changes: the follicular/proliferative phase, the luteal/secretory phase, and the ischemic/menstrual phase.
10. Ovarian events of the menstrual cycle are controlled by gonadotropins. High FSH levels stimulate follicle and ovum maturation (follicular phase), and then a surge of LH causes ovulation, which is followed by development of the corpus luteum (luteal phase).
11. Ovarian hormones control the uterine (endometrial) events of the menstrual cycle. During the follicular/proliferative phase of the ovarian cycle, estrogen produced by the follicle causes

the endometrium to proliferate (proliferative phase) and induces the LH surge and progesterone production in the granulosa layer. During the luteal/secretory phase, estrogen maintains the thickened endometrium, and progesterone causes it to develop blood vessels and secretory glands (secretory phase). As the corpus luteum degenerates, production of both hormones drops sharply, and the “starved” endometrium degenerates and sloughs off, causing menstruation, the ischemic/menstrual phase.

12. Cyclic changes in hormone levels also cause thinning and thickening of the vaginal epithelium, thinning and thickening of cervical secretions, and changes in basal body temperature.

Structure and Function of the Breast

1. Until puberty the female and male breasts are similar, consisting of a small underdeveloped nipple, some fatty and fibrous tissue, and a few ductlike structures under the areola. At puberty, however, a variety of hormones (estrogen, progesterone, prolactin, growth hormone, insulin, cortisol) cause the female breast to develop into a system of glands and ducts that is capable of producing and ejecting milk.
2. The basic functional unit of the female breast is the lobe, a system of ducts that branches from the nipple to milk-producing units called lobules. The lobules contain alveolar cells, which are convoluted spaces lined with epithelial cells that secrete milk and subepithelial cells that contract, moving the milk into the system of ducts that leads to the nipple.
3. Each breast contains 15 to 20 lobes, which are separated and supported by Cooper ligaments.
4. Milk production occurs in response to prolactin, a hormone that is secreted by alveolar epithelial cells in larger amounts after childbirth. Milk ejection is under the control of oxytocin, which causes contraction of myoepithelial cells.
5. During the reproductive years breast tissue undergoes cyclic

changes in response to hormonal changes of the menstrual cycle.

6. Prior to puberty the male breast development is similar to female development. Lack of high levels of estrogen and progesterone prevents further development of the male breast.

The Male Reproductive System

1. The function of the male reproductive system is to produce male gametes (sperm) and deliver them to the female reproductive tract.
2. The external male genitalia are the testes, epididymides, scrotum, and penis. The internal genitalia are the vas deferens, ejaculatory duct, prostatic and membranous sections of the urethra, seminal vesicles, prostate gland, and Cowper glands.
3. The testes (male gonads) are paired glands suspended within the scrotum. The testes have two functions: spermatogenesis (sperm production) and production of male sex hormones (androgens, chiefly testosterone).
4. The epididymis is a long coiled tube arranged in a comma-shaped compartment that curves over the top and rear of the testis. The epididymis receives sperm from the testis and stores them while they develop further. Sperm travel the length of the epididymis and then are ejaculated into the vas deferens.
5. The scrotum is a skin-covered fibromuscular sac that encloses the testes and epididymides, which are suspended within the scrotum by the spermatic cord. The scrotum keeps these organs at optimal temperatures for sperm survival (about 1°C to 2°C [33.8°F to 35.6°F] lower than body temperature) by contracting in cold environments and relaxing in warm environments.
6. The penis is a cylindrical organ consisting of three longitudinal compartments (two corpora cavernosa and one corpus spongiosum) and the urethra. The urethra runs through the

corpus spongiosum. The corpora cavernosa and corpus spongiosum consist of erectile tissue. Externally the penis consists of a shaft and a tip, which is called the *glans*. The glans contains sebaceous glands and the opening of the urethra and is covered by a flap of skin (the foreskin).

7. The penis has two functions: delivery of sperm to the female vagina and elimination of urine. These two fluids are never in the urethra at the same time.
8. Sexual intercourse is made possible by the erectile reflex, in which tactile or psychogenic stimulation of the parasympathetic nerves causes arterioles in the corpora cavernosa and corpus spongiosum to dilate and fill with blood, causing the penis to enlarge and become firm.
9. Emission, which occurs at the peak of sexual arousal, is the movement of semen from the epididymides to the penis. Ejaculation, which is a continuation of emission, is the pulsatile ejection of semen from the penis. Both emission and ejaculation involve rhythmic contractions of smooth muscle within the internal glands and ducts.
10. The prostate gland is about the size of a walnut and surrounds the urethra. Prostatic secretions are alkaline and contribute to the ejaculate.
11. Cowper glands (bulbourethral glands) secrete mucus in the urethra and add fluid to the ejaculate.
12. Spermatogenesis is a continuous process because spermatogonia, the primitive male gametes, undergo continuous mitosis within the seminiferous tubules of the testes. Some of the spermatogonia develop into primary spermatocytes, which divide meiotically into secondary spermatocytes and then spermatids. The spermatids develop into sperm with the help of nutrients and hormonal signals from Sertoli cells.
13. Production of the male sex hormones is controlled (like production of the female sex hormones) by the HPG axis and by complex feedback mechanisms. The male hormones are

produced steadily, with diurnal variations.

Tests of Reproductive Function

1. Diagnostic tests are performed to evaluate fertility.
2. Evaluation of fertility includes reproductive hormone assays and assessment of structural alteration or infections and the determination of normal ovulation or adequate sperm motility and count.

Aging and Reproductive Function

1. In women the transition from fertility to menopause (perimenopause) starts about 2 to 8 years before the last menstrual period and ends the following year. During this transition period the ovaries produce erratic and high levels of estrogen that contribute to such symptoms as hot flashes, breast tenderness and nodularity, and migraine headaches. Menstrual cycles shorten and then become irregular as anovulation occurs. Menstruation ceases, and women move into menopause.
2. Men maintain reproductive capacity into their later years. In some men there are gradual changes with testosterone deficiency, hypogonadism, proliferative disorders of the prostate, and erectile dysfunction.

Key Terms

Activin, 738

Adrenarche, 730

Androgen, 734

Areola, 740

Bartholin gland (greater vestibular or vulvovaginal gland), 730

Breast, 739
Bulbocavernosus, 730
Cervix (neck of the uterus), 732
Clitoris, 730
Cornification, 739
Corpora cavernosa (*singular*, corpus cavernosum), 743
Corpus luteum, 733
Corpus of the uterus (body of uterus), 732
Corpus spongiosum, 743
Cowper gland (bulbourethral gland), 744
Cul-de-sac, 731
Decornification, 739
Developing fetus, 726
Dihydrotestosterone (DHT), 746
Efferent tubule, 742
Ejaculatory duct, 744
Embryo, 726
Emission, 744
Endocervical canal, 732
Endometrium, 732
Epididymis (*plural*, epididymides), 742
Erectile reflex, 743
Estradiol (E₂), 734
Estrogen, 734
Fallopian tube (oviduct, uterine tube), 733
Fimbriae (*singular*, fimbria), 733
Follicle-stimulating hormone (FSH), 728
Follicular/proliferative phase, 736
Follistatin, 738

CHAPTER 25

Alterations of the Female Reproductive System

Kathleen E. Danhausen, Julia C. Phillippi, Kathryn L. McCance

CHAPTER OUTLINE

Abnormalities of Reproductive Tract Development, 755

Alterations of Sexual Maturation, 756

Delayed Puberty, 757

Precocious Puberty, 757

Disorders of the Female Reproductive System, 759

Hormonal and Menstrual Alterations, 759

Infection and Inflammation, 767

Pelvic Organ Prolapse, 771

Benign Growths and Proliferative Conditions,
773

Cancer, 777

Sexual Dysfunction, 786

Impaired Fertility, 787

Disorders of the Female Breast, 788

Galactorrhea, 788

Benign Breast Disease, 789

Cancer, 792

Alterations of the reproductive system have a wide range of clinical presentations, from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common reproductive disorders carry potentially serious physiologic or psychologic consequences. Sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect ovulation and menstruation, sexual performance, and fertility, and may be risk factors for the development of some types of reproductive tract cancers.^{1,2} Diagnosis and treatment of reproductive system disorders are complicated by the stigma and symbolism associated with the reproductive organs and the emotion-laden beliefs and behaviors related to reproductive health and fertility. Treatment and diagnosis for related problems may be delayed because of embarrassment, guilt, fear, or denial.³

Abnormalities of Reproductive Tract Development

As discussed in [Chapter 24](#), normal development of the female reproductive tract requires absence of testosterone during embryonic/fetal life. The resulting fusion of the two paramesonephric (müllerian) ducts produces the normal cervix and the uterus with an internal cavity. The distal portions of the paramesonephric ducts remain independent and form the two fallopian/uterine tubes. Alterations in the normal process include errors in cellular sensitivity to testosterone (androgen insensitivity) or failures of cell line migration, resulting in changes in the structure of the reproductive organs.

Androgen insensitivity occurs in its most extreme form in about 1 in 20,000 people⁴ and is discussed briefly in this chapter because of the often-resulting female phenotype, despite a male genotype. This

syndrome is caused by an X-linked genetic mutation in cellular androgen receptors that results in an end-organ insensitivity to testosterone, which normally acts as the catalyst for the development of the male reproductive system in embryonic development.⁵ Complete androgen insensitivity syndrome (CAIS) is characterized by external female genitalia with a 46,XY genotype, whereas partial androgen insensitivity syndrome (PAIS) presents with ambiguous genitalia and varying genotype.⁶ Children with CAIS often have testes within the labia majora, inguinal ring, or abdominal cavity that produce testosterone (and estrogen) in normal-range levels. Breast development may be normal, but pubic and axillary hair is often sparse and the cervix, uterus, and ovaries are absent. A short vagina that ends without a cervix also may be present. These individuals are often undiagnosed until puberty when menarche does not occur.⁵ Both CAIS and PAIS carry an increased risk of gonadal tumors and malignancies. Gonadectomy and hormone replacement therapy are recommended for all individuals with CAIS and those with PAIS who are living as females. There remains controversy about the optimal timing of gonadectomy.⁶

Other abnormalities of the uterus, cervix, and fallopian/uterine tubes are caused by müllerian duct abnormalities. These have multifactorial origins, often the result of an interaction between genetic predisposition and environmental factors.⁷ Some medications, chemicals, and toxins have been implicated as a direct cause of uterine abnormalities. For instance, diethylstilbestrol (DES) was prescribed from 1938 until 1971 as a drug to prevent miscarriages.⁸ Although it was not effective at preventing miscarriage, DES affected cell development, causing abnormal internal reproductive anatomy that resulted in uterine malformations and a predisposition to cancer.

Disorders of müllerian tube development include agenesis, a complete absence of uterus and fallopian tubes, or fusion abnormalities resulting in a duplicate, bicornuate, or septate uterus⁷ (Fig. 25.1). About 7% of the general female population has some sort of uterine abnormality, but the rate is much higher in populations of women who have experienced infertility or miscarriage.⁹ Uterine

abnormalities are often diagnosed when the woman has menstrual abnormalities or presents with sexual dysfunction. In other cases, these abnormalities are diagnosed during the diagnostic work-up for infertility, because the uterus is capable of menstruation but may have difficulty supporting a fetus.⁹

FIGURE 25.1 Uterine Malformations. Congenital uterine abnormalities. A, The normal configuration of the uterus and the ovaries. B, Double uterus with a double vagina and C, a single vagina. D, Bicornuate uterus. E, A uterus with a midline septum. F, Unicornuate uterus. (From de Bruyn R: *Pediatric ultrasound*, ed 2, London, 2010, Churchill Livingstone.)

During pregnancy, uterine malformations are usually diagnosed by ultrasound or with magnetic resonance imaging (MRI). The prognosis of these pregnancies depends on the severity of the malformation and the location and size of the placenta and fetus. Some abnormalities can be surgically corrected to improve the outcome of subsequent pregnancies.⁹ Abnormalities of the lower genital tract can also result in women having two vaginas or a vaginal septum (a thin membrane dividing the vaginal vault). For most women this does not create functional problems but can be surgically corrected if needed.⁷

Alterations of Sexual Maturation

The process of sexual maturation, or puberty, is marked by the development of secondary sexual characteristics, rapid growth of the body, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of sexual maturation, causing puberty to occur too late (delayed puberty) or too early (precocious puberty). Both scenarios involve a disrupted onset of sex hormone production by the gonads.

The age of puberty is multifactorial, involving genetic and environmental components. The normal range for the onset of puberty is now 8 to 13 years of age and appears to be decreasing for girls. Girls of African descent and Hispanic/Latina girls may begin puberty up to 1 year sooner than the average young female.^{10,11} This earlier onset appears primarily in breast development, not age of menarche, and 5% of white and 15% of all girls will begin puberty before age 8.¹⁰ Both precocious puberty and delayed puberty have implications for the child's social interactions and self-esteem.¹² In addition, obesity has been shown to accelerate the onset of puberty, making it difficult to determine the impact of race on pubertal timing.

Delayed Puberty

About 2% of children in North America experience delayed development of secondary sex characteristics.¹³ In girls, the onset of
