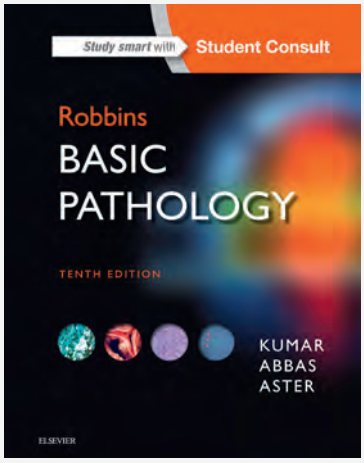
ELSEVIER

Robbins and Cotran.

Where an effective understanding of disease begins.

A current and accurate understanding of pathophysiology is integral to effective practice in every specialty. No source delivers that understanding better than the Robbins and Cotran family! *Robbins Basic Pathology*, *Robbins Essential Pathology*, and their many companion resources provide a clear, up-to-date explanation of disease mechanisms you need to succeed.

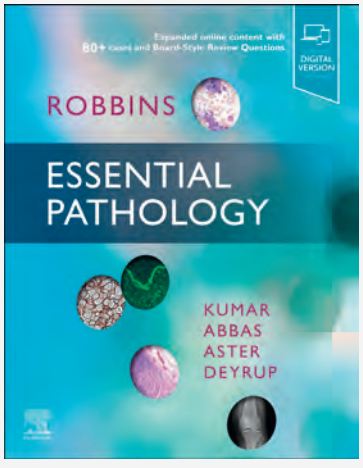


Robbins Basic Pathology, 10th Edition

ISBN: 9780323353175

Key Features:

- Excellent art program boasts high-quality photomicrographs, gross photos, and radiologic images to supplement the world-class illustrations.
- Bulleted summary boxes provide quick access to key information and easy review of key concepts.
- Highlights pathogenesis, morphology, and pathophysiologic content throughout.



Robbins Essential Pathology, 1st Edition

ISBN: 9780323640251

Key Features:

- The most concise Robbins text available, providing high-quality content and a case-based approach in a focused, multimedia learning package for coursework and exam preparation.
- Focuses on the core knowledge of disease mechanisms and essential clinical aspects that medical students need to know.
- Features more than 500 images and tables that illustrate key disorders and concepts.

Preface

As we launch the tenth edition of *Pathologic Basis of Disease* we look to the future of pathology as a discipline and how this textbook can remain most useful to readers in the twenty-first century. It is obvious that an understanding of disease mechanisms is based more than ever on a strong foundation of basic science. We have always woven the relevant basic cell and molecular biology into the sections on pathophysiology in various chapters. In the previous edition we went one step further and introduced a new chapter at the very beginning of the book titled "The Cell as a Unit of Health and Disease." We are delighted that the chapter was found useful by many students and faculty. Because progress in basic cell biology is moving at a very brisk pace, the chapter has been updated significantly.

In the preface of the very first edition (1957), Stanley Robbins wrote:

"The pathologist is interested not only in the recognition of structural alterations, but also in their significance, i.e., *the effects of these changes on cellular and tissue function* and ultimately the effect of these changes on the patient. It is not a discipline isolated from the living patient, but rather *a basic approach to a better understanding of disease and therefore a foundation of sound clinical medicine*."

We hope we continue to illustrate the principles of pathology that Dr. Robbins enunciated with such elegance and clarity over half a century ago.

This edition, like all previous ones, has been extensively revised, and some areas have been completely rewritten. A few examples of significant changes are as follows:

- Chapter 2 has been updated to include novel pathways of cell death beyond the long-established pathways of necrosis and apoptosis. Indeed, the distinction between these two is being blurred. Autophagy, which has begun to take center stage in diseases ranging from aging to cancer and neurodegeneration, has been revised, as have the possible molecular mechanisms of aging.
- In Chapter 3, we have married morphology with molecular mechanisms. Thus, different patterns of inflammation can be related to distinct molecular pathways.
- Chapter 5 includes a discussion of gene editing technology and a revised and updated section on molecular diagnosis.
- Chapter 7 has been extensively revised to incorporate new insights into cancer pathogenesis, the interplay between cancer cells and host immunity, and cancer precision diagnostics.
- Chapter 10, covering pediatric diseases, includes discussion of newly approved therapies targeting specific mutated forms of the CFTR transporter.
- Chapter 11, covering vascular diseases, includes discussion of clonal hematopoiesis, a newly emerging risk factor for atherosclerosis and other inflammatory disorders.
- Chapters 18 and 28, covering diseases of the liver and the central nervous system, have a fresh look brought in by new contributors.
- In addition to the revision and reorganization of the text, many new photographs and schematics have been added and a large number of the older "gems" have been enhanced by digital technology.

We made the changes highlighted above while remaining focused on the same longstanding overarching goals, which serve as our guiding principles:

- To integrate into the discussion of pathologic processes and disorders the newest established information available—morphologic as well as molecular.
- To organize information into logical and uniform presentations, facilitating readability, comprehension, and learning.
- To maintain the book at a reasonable size and yet provide adequate discussion of significant lesions, processes, and disorders. Indeed, despite the addition of new information, we are happy to state that the overall length of the book is unchanged. One of our most challenging tasks is to decide what to eliminate to make room for key new findings.
- To place great emphasis on clarity of writing and proper use of language in the recognition that struggling to comprehend is time-consuming and wearisome and gets in the way of the learning process.
- To make this text useful to students throughout all of their years in medical school and into their residencies—but, at the same time, to provide sufficient detail and depth to meet the needs of more advanced readers.

We have repeatedly been told by readers that up-to-datedness is a special feature that makes this book very valuable. We have strived to remain current by providing new information from the recent literature, up to the current year, and by adding coverage of the COVID-19 epidemic.

We are now into the digital age, and so the text will be available online to those who own the print version. Such access gives the reader the ability to search across the entire text, bookmark passages, add personal notes, use PubMed to view references, and exploit many other exciting features. In addition, also available online are case studies developed by one of us (VK), and revised by Dr. Alex Gallan from the University of Chicago. The cases are designed to enhance and reinforce learning by challenging students to apply their knowledge to solve clinical cases. To assist in the classroom, we have also made the images available for instructors on the Evolve website. Instructors may register

at https://evolve.elsevier.com/ to gain access to the images for teaching purposes.

All three of us have reviewed, critiqued, and edited each chapter to ensure the uniformity of style and flow that have been the hallmarks of the book. Together, we hope that we have succeeded in equipping the readers with the scientific basis for the practice of medicine and in whetting their appetite for learning beyond what can be offered in any textbook.

Vinay Kumar
Abul K. Abbas
Jon C. Aster

Acknowledgments

First and foremost, all four of us offer thanks to our contributing authors for their commitment to this textbook. Many are veterans of previous editions; others are new to the tenth edition. All are acknowledged in the table of contents. Their names lend authority to this book, for which we are grateful. As in previous editions, the four of us have chosen not to add our own names to the chapters we have been responsible for writing, in part or whole. We welcome to this edition Dr. Jerry Turner in the capacity of Associate Editor. Jerry is a veteran of Robbins texts having written the chapter on diseases of the gastrointestinal tract in previous editions. His editing has strengthened several chapters.

Many colleagues have enhanced the text by reading various chapters and providing helpful critiques in their area of expertise. They include Dr. Celeste Thomas, University of Chicago; Dr. Meenakshi Jolly, Rush University, Chicago; Dr. Richard Aster, Blood Research Institute, Milwaukee; and Dr. Suneil Koliwad, UCSF. Many colleagues provided photographic gems from their collections. They are individually acknowledged in the text.

All of the graphic art in this book was created by Mr. James Perkins, Distinguished Professor of Medical Illustration at Rochester Institute of Technology. His ability to convert complex ideas into simple and aesthetically pleasing sketches has considerably enhanced this book.

Many individuals associated with our publisher, Elsevier, need our special thanks. Outstanding among them is Kristine Feeherty, Health Content Management Specialist, and our partner in the production of this book. Her understanding of the needs of the authors, promptness in responding to requests (both reasonable and unreasonable), and cheerful demeanor went a long way in reducing our stress and making our lives less complicated. Jim Merritt handed over the charge to Jeremy Bowes, Publisher. Our thanks also go to Director of Content Development, Rebecca Gruliow, and Designer Brian Salisbury. Undoubtedly there are many others who may have been left out unwittingly—to them we say "thank you" and tender apologies for not acknowledging you individually. We also want to acknowledge many readers—students, residents, and faculty members—scattered around the globe whose comments improve the book. We are impressed by their careful reading of the text.

Efforts of this magnitude take a toll on the families of the authors. We thank our spouses, Raminder Kumar, Ann Abbas, Erin Malone, and Judy Turner, for their patience, love, and support of this venture, and for their tolerance of our absences.

CHAPTER 1

The Cell as a Unit of Health and Disease

Richard N. Mitchell

CHAPTER CONTENTS

Pathology literally translates as the *study of suffering* (Greek *pathos* = suffering, *logos* = study); more prosaically, and as applied to modern medicine, it is the *study of disease.* Virchow was prescient in asserting that disease originates at the cellular level, but we now appreciate that cellular pathologies arise from perturbations in molecules (genes, proteins, and metabolites) that influence cell survival and behaviors. Thus the foundation of modern pathology is understanding the *cellular and molecular* aberrations that give rise to diseases. It is illuminating to consider these abnormalities in the context of normal cellular structure and function, which is the subject of this introductory chapter.

It is unrealistic (and even undesirable) to condense the vast and fascinating field of cell biology into a single chapter. Consequently, rather than attempting a comprehensive review, the goal here is to survey basic principles and highlight recent advances that are relevant to the mechanisms of disease that are emphasized throughout the rest of the book.

THE GENOME

The sequencing of the human genome at the beginning of the 21st century represented a landmark achievement of biomedical science. Since then the rapidly declining cost of sequencing, the burgeoning computational capacity to mine the ensuing data, and the expanding toolkits to analyze functional outputs (genomics, proteomics, and metabolomics) promise to revolutionize our understanding of health and disease. The emerging information has also revealed a breathtaking level of complexity far beyond the linear sequence of the genome. The potential of these powerful innovations to explain disease pathogenesis and drive therapeutic discovery excites and inspires scientists and the lay public alike.

Noncoding DNA

The human genome contains some 3.2 billion DNA base pairs. Yet, within the genome there are only about 20,000 protein-encoding genes, constituting just 1.5% of the genome. These are the blueprints that instruct the assembly of the enzymes, structural elements, and signaling molecules within the 50 trillion cells that make up the human body. Although 20,000 underestimates the actual number of encoded proteins (many genes produce multiple RNA transcripts that translate to different protein isoforms), it is nevertheless startling to realize that worms, which are composed of fewer than 1000 cells and have 30-fold smaller genomes also have about 20,000 protein-encoding genes. Many of these proteins are recognizable homologs of molecules expressed in humans. What then separates humans from worms?

The answer is not completely known, but evidence suggests that much of the difference lies in the 98.5% of the human genome that does not encode proteins. The function of such long stretches of DNA (so-called genome "dark matter") was mysterious for many years. However, over 85% of the human genome is ultimately transcribed; nearly 80% is devoted to regulation of gene expression. It follows that while proteins provide the building blocks and

machinery required for assembling cells, tissues, and organisms, it is the noncoding regions of the genome that provide the critical "architectural planning." Practically stated, the difference between worms and humans apparently lies more in the genomic "blueprints" than in the construction materials.

There are five major classes of functional non–protein-coding sequences in the human genome (Fig. 1.1):

- *Promoter* and *enhancer* regions that provide binding sites for transcription factors.
- Binding sites for factors that organize and maintain higher order *chromatin structures.*
- *Noncoding regulatory RNAs.* Over 60% of the genome is transcribed into RNAs that are never translated but regulate gene expression through a variety of mechanisms. The two best-studied varieties—micro-RNAs (miRNAs) and long noncoding RNAs (lncRNAs)—are described later.
- *Mobile genetic elements* (e.g., *transposons*) make up more than a third of the human genome. These "jumping genes" can move around the genome during evolution, resulting in variable copy number and positioning even among closely related species (e.g., humans and other primates). Although implicated in gene regulation and chromatin organization, the function of mobile genetic elements is not well established.
- Special structural regions of DNA, in particular, *telomeres* (chromosome ends) and *centromeres* (chromosome "tethers"). A major component of centromeres is so-called *satellite DNA,* consisting of large arrays—up to megabases in length—of repeating sequences (from 5 bp up to 5 kb). Although classically associated with spindle apparatus attachment, satellite DNA is also important in maintaining the dense, tightly packed organization of heterochromatin (discussed later).

Many genetic variations (polymorphisms) associated with diseases are located in non–protein-coding regions of the genome. Thus variation in gene regulation may prove to be more important in disease causation than structural changes in specific proteins. Another surprise that emerged from genome sequencing is that any two humans are typically more than 99.5% DNA-identical (and are 99% sequence-identical with chimpanzees)! Thus individual variation, including differential susceptibility to diseases and environmental stimuli, is encoded in less than 0.5% of our DNA (representing about 15 million bp).

The two most common forms of DNA variation in the human genome are single nucleotide polymorphisms (SNPs) and copy number variations (CNVs).

- *SNPs* are variants at single nucleotide positions and are almost always biallelic (only two choices exist at a given

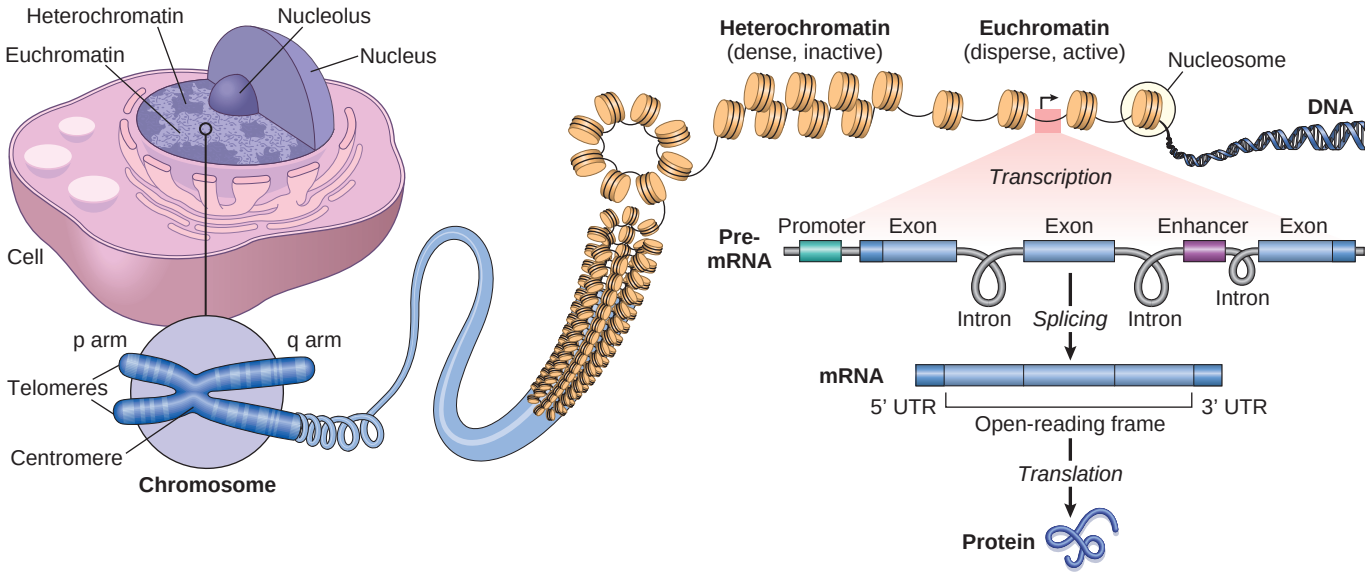

Figure 1.1 The organization of nuclear DNA. At the light microscopic level, the nuclear genetic material is organized into dispersed, transcriptionally active euchromatin and densely packed, transcriptionally inactive heterochromatin; chromatin can also be mechanically connected with the nuclear membrane, and membrane perturbation can thus influence transcription. Chromosomes (as shown) can be visualized only during mitosis. During mitosis, they are organized into paired chromatids connected at centromeres; the centromeres act as the locus for the formation of a kinetochore protein complex that regulates chromosome segregation at metaphase. The *telomeres* are repetitive nucleotide sequences that cap the termini of chromatids and permit repeated chromosomal replication without deterioration of genes near the ends. The chromatids are organized into short "P" ("petite") and long "Q" (next letter in the alphabet) arms. The characteristic banding pattern of chromatids has been attributed to relative GC content (less GC content in bands relative to interbands), with genes tending to localize to interband regions. Individual chromatin fibers are comprised of a string of nucleosomes—DNA wound around octameric histone cores—with the nucleosomes connected via DNA linkers. Promoters are noncoding regions of DNA that initiate gene transcription; they are on the same strand and upstream of their associated gene. Enhancers can modulate gene expression over distances of 100 kb or more by looping back onto promoters and recruiting additional factors that drive the expression of pre–messenger RNA (mRNA) species. Intronic sequences are spliced out of the pre-mRNA to produce the final message that is translated into protein—without the 3′–untranslated region (UTR) and 5′-UTR. In addition to the enhancer, promoter, and UTR sequences, noncoding elements, including short repeats, regulatory factor binding regions, noncoding regulatory RNAs, and transposons, are distributed throughout the genome.

site within the population, such as A or T). Over 6 million human SNPs have been identified, with many showing wide variation in frequency in different populations.
  - SNPs occur across the genome—within exons, introns, intergenic regions, and coding regions.
  - Roughly 1% of SNPs occur in coding regions, which is about what would be expected by chance, since coding regions comprise about 1.5% of the genome.
  - SNPs located in noncoding regions can occur within genomic regulatory elements, thereby altering gene expression; in such instances, SNPs influence disease susceptibility directly.
  - Some SNPs, termed "neutral" variants, are thought to have no effect on gene function or individual phenotype.
  - Even "neutral" SNPs may be useful markers if they happen to be coinherited with a disease-associated polymorphism as a result of physical proximity. In other words, the SNP and the causative genetic factor are in *linkage disequilibrium*.
  - The effect of most SNPs on disease susceptibility is weak, and it remains to be seen if identification of such variants, alone or in combination, can be used to develop effective strategies to identify those at risk and, ultimately, prevent disease.
- *CNVs* are a form of genetic variation consisting of different numbers of large contiguous stretches of DNA; these can range from 1000 base pairs to millions of base pairs. CNVs can be biallelic and simply duplicated or, alternatively, deleted in some individuals. At other sites there are complex rearrangements of genomic material, with multiple variants in the human population.
  - CNVs are responsible for between 5 million and 24 million base pairs of sequence difference between any two individuals.
  - Approximately 50% of CNVs involve gene-coding sequences; thus CNVs may underlie a large portion of human phenotypic diversity.

It is important to note that alterations in DNA sequence cannot by themselves explain the diversity of phenotypes in human populations; moreover, classic genetic inheritance cannot explain differing phenotypes in monozygotic twins. The answers to these conundrums probably lie in *epigenetics*—heritable changes in gene expression that are not caused by variations in DNA sequence (see the following section).

Histone Organization

Even though virtually all cells in the body have the same genetic composition, differentiated cells have distinct structures and functions that arise as a result of lineage-specific gene expression programs. Such cell type–specific differences in transcription and translation depend on *epigenetic factors* (literally, factors that are "above genetics") that can be conceptualized as follows (Fig. 1.2):

- *Histones and histone-modifying factors. Nucleosomes* consist of DNA segments 147 bp long that are wrapped around a central core structure of highly conserved low molecular weight proteins called *histones*. The resulting DNA-histone complex resembles a series of beads joined by short DNA linkers. The naked DNA of a single human cell is about 1.8 m long. By winding around histones, like spools of thread, the entire genome can be packed into a nucleus as small as 7 to 8 μm in diameter. In most cases, this structured DNA, termed chromatin, is not wound uniformly. Thus at the light microscopic level, nuclear chromatin is recognizable as cytochemically dense and transcriptionally inactive heterochromatin and disperse, transcriptionally active euchromatin (see Fig. 1.1). In general, only the regions that are "unwound" are available for transcription. Chromatin structure can therefore regulate transcription independent of traditional promoters and DNA-binding elements and, due to variations between cell types, helps to define cellular identity and activity.

  Histones are not static, but rather are highly dynamic structures regulated by a host of nuclear proteins. Thus chromatin remodeling complexes can reposition nucleosomes on DNA, exposing (or obscuring) gene regulatory elements such as promoters. "Chromatin writer" complexes, on the other hand, carry out over 70 different histone modifications generically denoted as "marks." Such covalent alterations include methylation, acetylation, or phosphorylation of specific amino acids within histones.

  Actively transcribed genes in euchromatin are associated with histone marks that make the DNA accessible to RNA polymerases. In contrast, inactive genes have histone marks that enable DNA compaction into heterochromatin. Histone marks are reversible through the activity of "chromatin erasers." Still other proteins function as "chromatin readers," binding histones that bear particular marks and thereby regulating gene expression.
- *Histone methylation.* Both lysines and arginines can be methylated by specific writer enzymes; methylation of histone lysine residues can lead to transcriptional activation or repression, depending on which histone residue is marked.
- *Histone acetylation.* Lysine residues are acetylated by histone acetyltransferases (HATs), whose modifications tend to open the chromatin and increase transcription. In turn, these changes can be reversed by histone deacetylases (HDACs), leading to chromatin condensation.
- *Histone phosphorylation.* Serine residues can be modified by phosphorylation; depending on the specific residue, the DNA may be opened for transcription or condensed and inactive.
- *DNA methylation.* High levels of DNA methylation in gene regulatory elements typically result in transcriptional silencing. Like histone modifications, DNA methylation is tightly regulated by methyltransferases, demethylating enzymes, and methylated-DNA-binding proteins.
- *Chromatin organizing factors.* Much less is known about these proteins, which are believed to bind to noncoding regions and control long-range looping of DNA, thus regulating the spatial relationships between enhancers and promoters that control gene expression.

Deciphering the mechanisms that allow epigenetic factors to control genomic organization and gene expression in a cell-type-specific fashion is an extraordinarily complex proposition. Despite the intricacies, there is already ample evidence that dysregulation of the "epigenome" has a central role in malignancy (Chapter 7), and emerging data indicate

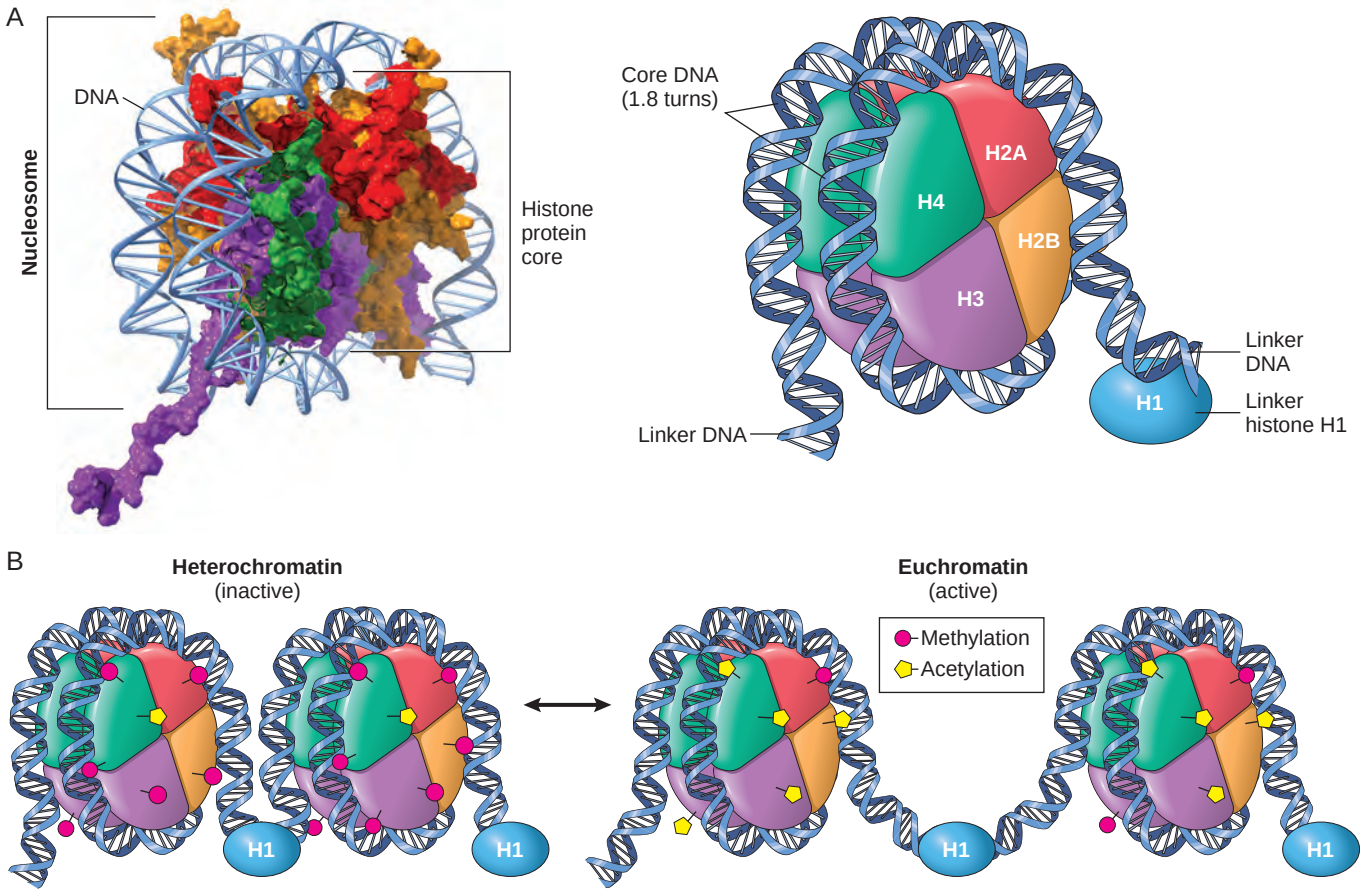

Figure 1.2 Histone organization. (A) Nucleosomes are comprised of octamers of histone proteins (two each of histone subunits H2A, H2B, H3, and H4) encircled by 1.8 147 bp DNA loops. Histones sit on 20- to 80-nucleotide stretches of linker DNA between nucleosomes. Histone subunits are positively charged, thus allowing compaction of negatively charged DNA. (B) The relative state of DNA unwinding (and thus access for transcription factors) is regulated by histone modification, including acetylation, methylation, and/or phosphorylation; these "marks" are dynamically written and erased. Certain marks such as histone acetylation "open up" the chromatin structure, whereas others such as methylation of particular histone residues condense DNA to silence genes. DNA can also be methylated, leading to transcriptional inactivation.

that many other diseases are associated with inherited or acquired epigenetic alterations. Unlike genetic changes, many epigenetic alterations (e.g., histone acetylation and DNA methylation) are reversible and amenable to therapeutic intervention; HDAC and DNA methylation inhibitors are already being tested in the treatment of various forms of cancer.

Micro-RNA and Long Noncoding RNA

Genes can also be regulated by noncoding RNAs. These genomic sequences are transcribed but not translated. Although many distinct families of noncoding RNAs exist, we will discuss only two examples here: small RNA molecules called *microRNAs (miRNAs)* and *long noncoding RNAs (lncRNAs)* (>200 nucleotides in length).

Micro-RNA

miRNAs do not encode proteins; they modulate translation of target messenger RNAs (mRNAs). Posttranscriptional silencing of gene expression by miRNA is a fundamental and well-conserved mechanism of gene regulation present in all eukaryotes (plants, animals, and fungi). Even bacteria have a primitive version of the same machinery that they use to protect themselves against foreign DNA (e.g., phage and virus DNA). The profound influence of miRNAs on protein expression allows these relatively short RNAs (22 nucleotides on average) to be critical regulators of developmental pathways as well as pathologic conditions (e.g., cancer).

The human genome encodes almost 6000 miRNA genes, about 30% of the total number of protein-coding genes. Individual miRNAs can regulate multiple protein-coding genes, allowing each miRNA to coregulate entire programs of gene expression. Transcription of miRNA genes produces a primary transcript (pri-miRNA) that is processed into progressively smaller segments, including trimming by the enzyme *Dicer*. This generates mature single-stranded miRNAs of 21 to 30 nucleotides that associate with a multiprotein aggregate called *RNA-induced silencing complex (RISC)* (Fig. 1.3). Subsequent base pairing between the miRNA strand and its target mRNA directs the RISC to either induce mRNA cleavage or repress its translation. In this way the target mRNA is *posttranscriptionally silenced*.

Small interfering RNAs (siRNAs) are short RNA sequences that can be introduced experimentally into cells where they

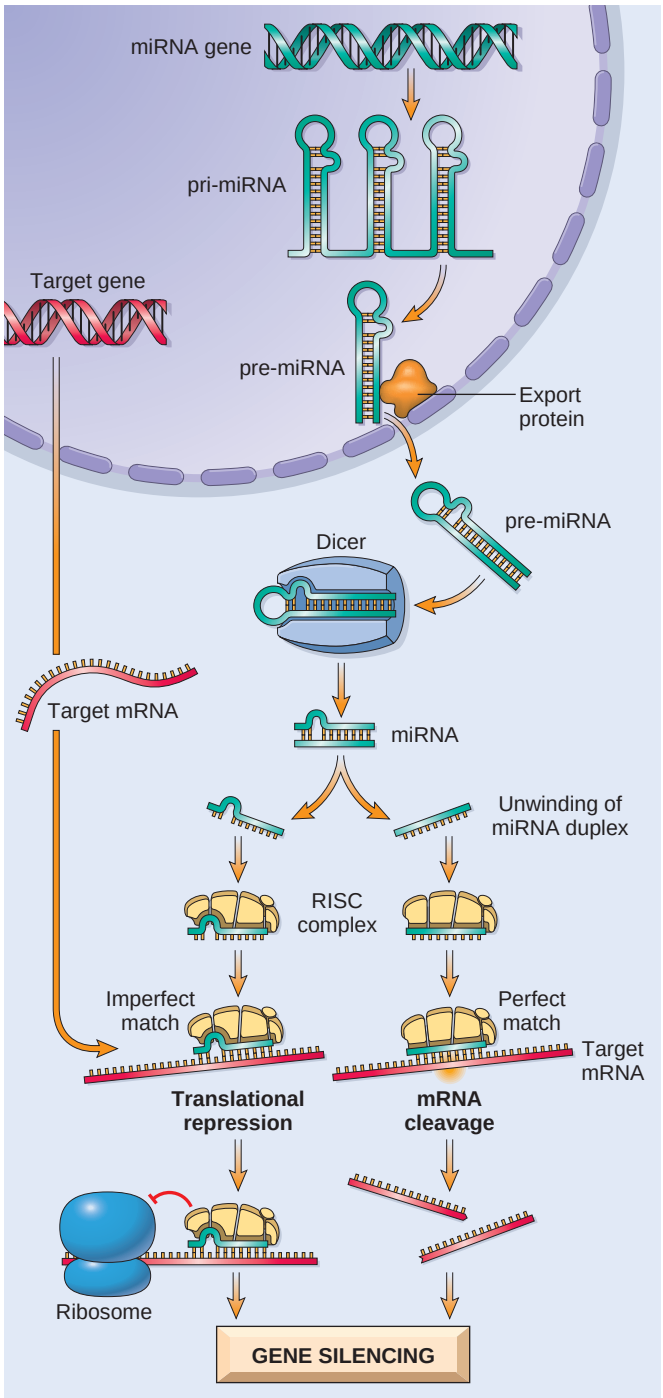

Figure 1.3 Generation of microRNAs (miRNAs) and their mode of action in regulating gene function. Transcription of a miRNA produces a primary miRNA (pri-miRNA), which is processed within the nucleus to form *pre-miRNA* composed of a single RNA strand with secondary hairpin loop structures and stretches of double-stranded RNA. After export out of the nucleus via specific transporter proteins, pre-miRNA is trimmed by the cytoplasmic *Dicer enzyme* to generate mature double-stranded miRNAs of 21 to 30 nucleotides. The miRNA subsequently unwinds and the single strands are incorporated into multiprotein RNA-induced silencing complexes (RISC). Base pairing between single-stranded miRNA and the targeted messenger RNA (mRNA) directs RISC to either cleave or repress translation of the mRNA, resulting in posttranscriptiontional silencing.

serve as substrates for Dicer and interact with RISC, thereby reproducing endogenous miRNAs function. Synthetic siRNAs that target specific mRNA species are powerful laboratory tools to study gene function (so-called knockdown technology) and are also being studied as potential therapeutic agents to silence pathogenic genes (e.g., oncogenes that drive neoplastic transformation).

Long Noncoding RNA

Recent studies have further identified an untapped universe of lncRNAs—by some calculations, the number of lncRNAs may exceed coding mRNAs by 10-fold to 20-fold. lncRNAs modulate gene expression by several mechanisms (Fig. 1.4). As one example, lncRNAs can bind to chromatin and restrict RNA polymerase from accessing coding genes within that region. The best-known example is XIST, which is transcribed from the X chromosome and plays an essential role in the physiologic X chromosome inactivation that occurs in

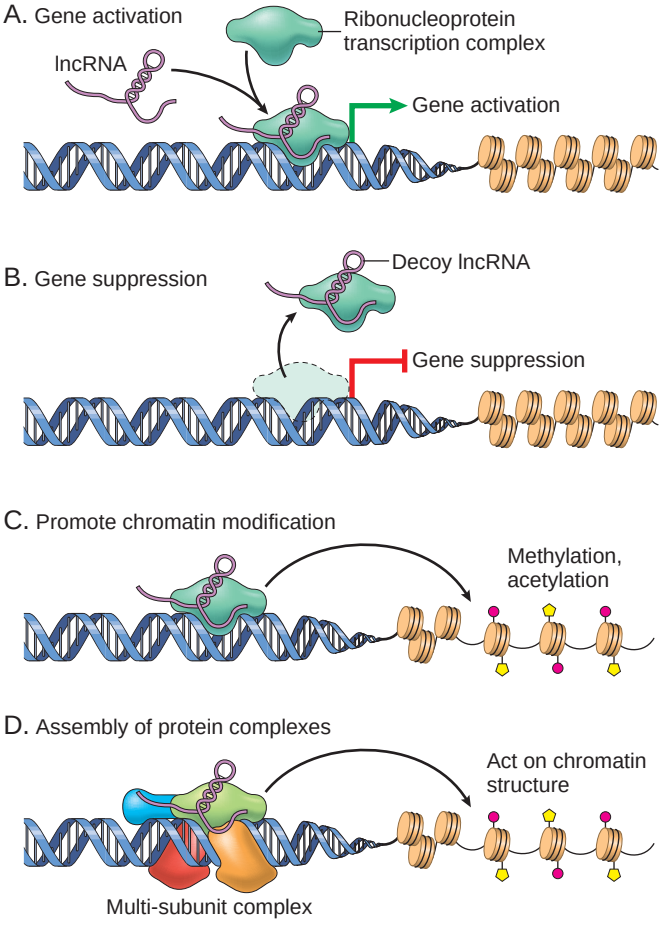

Figure 1.4 Roles of long noncoding RNAs (lncRNAs). (A) lncRNAs can facilitate transcription factor binding and thus promote gene activation. (B) Conversely, lncRNAs can preemptively bind transcription factors to inhibit transcription. (C) Histone and DNA modification by acetylases or methylases (or deacetylases and demethylases) may be directed by lncRNA binding. (D) In other instances, lncRNAs can act as scaffolds to stabilize secondary or tertiary structures and multisubunit complexes that influence chromatin architecture or gene activity. (Modified from Wang KC, Chang HY: Molecular mechanisms of long noncoding RNAs, *Mol Cell* 43:904, 2011.)

females. XIST itself escapes X inactivation but forms a repressive "cloak" on the X chromosome from which it is transcribed, resulting in gene silencing. Conversely, many enhancers are actually sites of lncRNA synthesis. In this case the lncRNAs expand transcription from gene promoters via a variety of mechanisms (see Fig. 1.4).

Gene Editing

An exciting new development that allows high-fidelity genome editing may usher in the next era of the molecular revolution. This advance comes from a wholly unexpected source: the discovery of *clustered regularly interspaced short palindromic repeats (CRISPRs)* and CRISPR-associated genes (Cas), such as the Cas9 nuclease. These are linked genetic elements that endow prokaryotes with a form of acquired immunity to phages and plasmids. Bacteria use the system to sample the DNA of infecting agents and integrate portions into their genomes as CRISPRs. These CRISPR segments are subsequently transcribed and processed into guide RNA sequences that bind and direct the Cas9 nuclease to specific sites (e.g., a phage sequence) so that it can be cleaved to disable the infecting agent.

Gene editing repurposes this process by using artificial 20-base guide RNAs (gRNAs) that bind Cas9 and are complementary to a targeted DNA sequence (Fig. 1.5). Cas9 then induces double-stranded DNA breaks at the site of gRNA binding. Repair of the highly specific cleavages can lead to random disruptive mutations (through nonhomologous end joining) or can introduce new genetic material with precision (by homologous recombination). Both the guide sequences and the Cas enzyme, either as a coding DNA (cDNA) or a protein, can be easily introduced into cells. The potential application to genetic engineering, due to the impressive specificity of the Cas9 system (up to 10,000-fold better than other previous editing systems), has led to great excitement. Applications include inserting specific mutations in cells and tissues to model cancers and other diseases and rapidly generating transgenic animal models from edited embryonic stem cells. CRISPR also makes it possible to selectively edit mutations that cause hereditable disease, or—perhaps more worrisome—to just eliminate less "desirable" traits. Predictably the technology has inspired a vigorous debate regarding the ethics of its use.

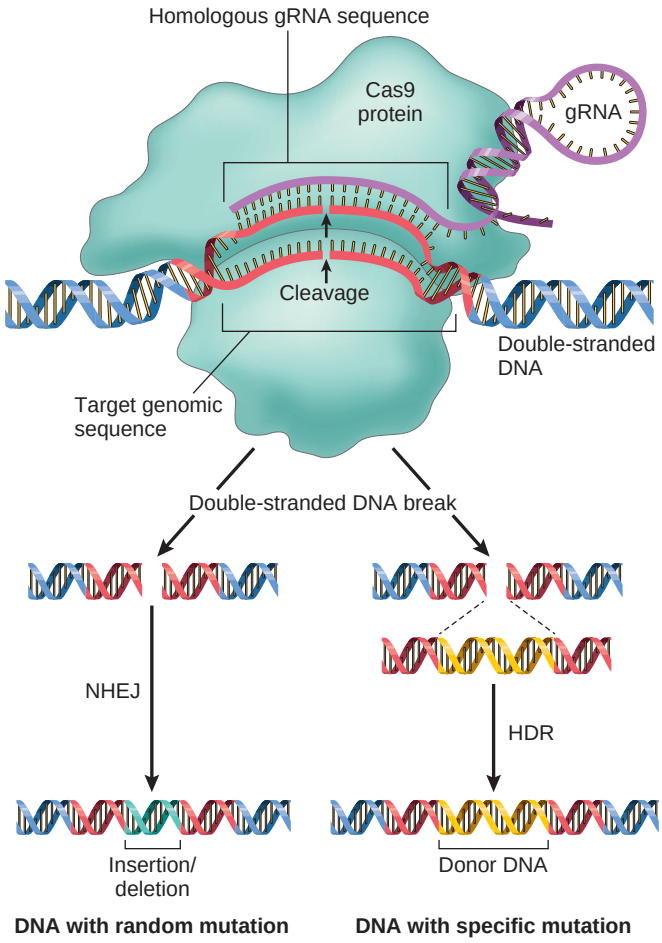

Figure 1.5 Gene editing with clustered regularly interspersed short palindromic repeats (CRISPRs) and the nuclease Cas9. In bacteria, DNA sequences consisting of CRISPRs are transcribed into guide RNAs *(gRNAs)* with a constant region and a variable sequence of approximately 20 bases. The gRNA constant regions bind to Cas9, while the variable regions form heteroduplexes with homologous DNA sequences of interest; the Cas9 nuclease then cleaves the bound DNA to produce a double-stranded DNA break. In nature, bacteria use the CRISPR/Cas9 system to protect against phages and plasmids; CRISPR sequences from previous assaults are transcribed into gRNA from the bacterial genome. These bind to pathogen nucleotide sequences and form a complex with the Cas9 nuclease that leads to cleavage and, ultimately, destruction of the invader's DNA.

To perform *gene editing*, gRNAs are designed with variable regions that are homologous to a specific DNA sequence of interest; coexpression of the gRNA and Cas9 then leads to efficient and highly specific cleavage of the target sequence. In the absence of homologous DNA, the double-stranded break is repaired by nonhomologous end-joining *(NHEJ)*, an error-prone mechanism that typically introduces disruptive insertions or deletions (indels). Conversely, in the presence of homologous "donor" DNA that spans the region target by the CRISPR/Cas9 complex, cells instead can use homologous DNA recombination *(HDR)* to repair the break. HDR is less efficient than NHEJ but has the capacity to introduce precise changes in DNA sequence. Potential applications of CRISPR/Cas9 coupled with HDR include repair of inherited genetic diseases and the creation of pathogenic mutations in inducible pluripotent stem cells.

CELLULAR HOUSEKEEPING

Normal functioning and intracellular homeostasis depend on a variety of fundamental cell housekeeping functions that all differentiated cells must perform to maintain viability and normal activity. These include protection from the environment, nutrient acquisition, metabolism, communication, movement, renewal of senescent molecules, molecular catabolism, and energy generation.

Many of the normal housekeeping functions of the cell are compartmentalized within membrane bound intracellular organelles (Fig. 1.6). By isolating certain cellular functions within distinct compartments, potentially injurious degradative enzymes or toxic metabolites can be kept at usefully high concentrations without risking damage to more delicate intracellular constituents. Moreover, compartmentalization also allows the creation of unique intracellular environments (e.g., low pH or high calcium) that permit more efficient functioning of certain enzymes or metabolic pathways.

New proteins destined for the plasma membrane or secretion are physically assembled in the *rough endoplasmic*

Relative volumes of intracellular organelles (hepatocyte)

Compartment	% total volume	number/cell	role in the cell
Cytosol	54%	1	metabolism, transport, protein translation
Mitochondria	22%	1700	energy generation, apoptosis
Rough ER	9%	1	synthesis of membrane and export protein
Smooth ER, Golgi	6%	1	protein modification, sorting, catabolism
Nucleus	6%	1	cell regulation, proliferation, DNA transcription
Endosomes	1%	200	intracellular transport and export
Lysosomes	1%	300	cellular catabolism
Peroxisomes	1%	400	very long-chain fatty acid metabolism

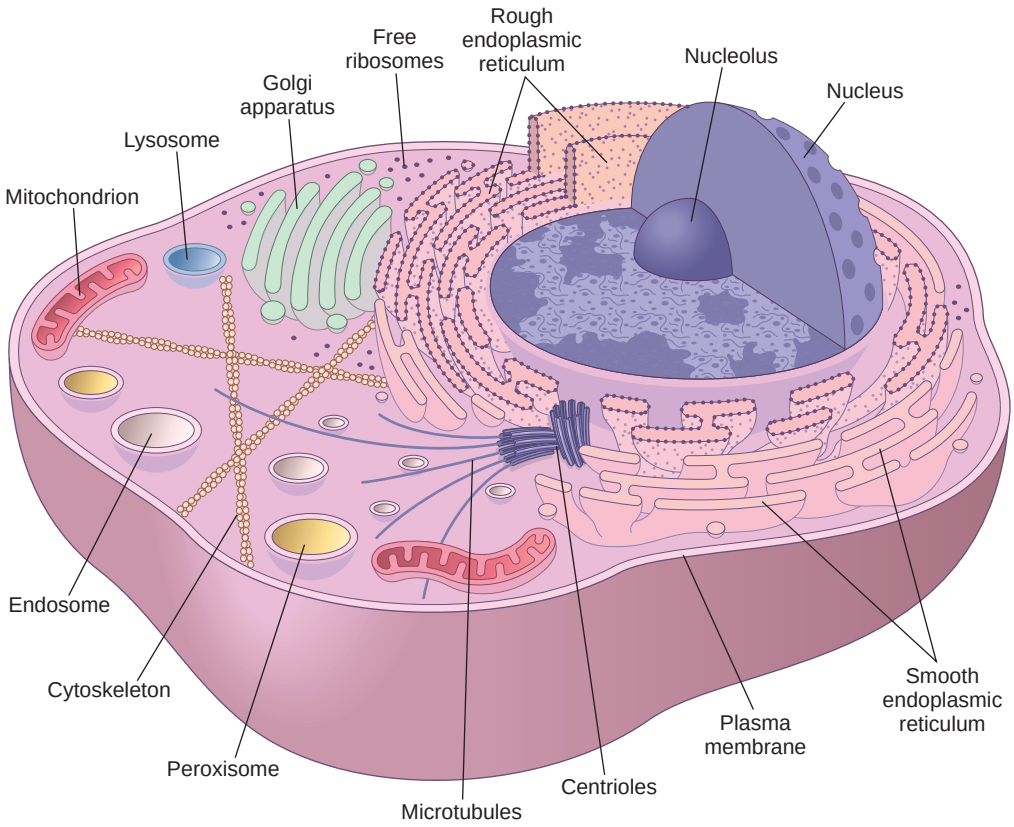

Figure 1.6 Basic subcellular constituents of cells. The table presents the number of the various organelles within a typical hepatocyte, as well as their volume within the cell. The figure shows geographic relationships but is not intended to be accurate to scale. *ER,* Endoplasmic reticulum. (Modified from Weibel ER, Stäubli W, Gnägi HR, et al: Correlated morphometric and biochemical studies on the liver cell. I. Morphometric model, stereologic methods, and normal morphometric data for rat liver. *J Cell Biol* 42:68, 1969.)

reticulum (RER) and *Golgi apparatus;* proteins intended for the cytosol are synthesized on free ribosomes. *Smooth endoplasmic reticulum (SER)* is used for steroid hormone and lipoprotein synthesis and modification of hydrophobic compounds into water-soluble molecules for export.

Cells catabolize the wide variety of molecules that they endocytose, as well as the entire repertoire of their own proteins and organelles—all of which are constantly being degraded and renewed. Breakdown of these constituents takes place at three different sites, ultimately serving different functions.

- *Proteasomes* are "disposal" complexes that degrade denatured or otherwise "tagged" cytosolic proteins. In antigen-presenting cells, the resulting short peptides are presented in the context of class I or class II major histocompatibility molecules to help drive the adaptive immune response (Chapter 6). In other cases, proteasomal degradation of regulatory proteins or transcription factors can trigger initiation or suppression of signaling pathways.
- *Lysosomes* are intracellular organelles containing degradative enzymes that permit digestion of a wide range of macromolecules, including proteins, polysaccharides, lipids, and nucleic acids. They are the site of senescent intracellular organelle breakdown (a process called *autophagy*) and where phagocytosed microbes are killed and catabolized.
- *Peroxisomes* contain catalase, peroxidase, and other oxidative enzymes; they play a specialized role in the breakdown of very long-chain fatty acids, generating hydrogen peroxide in the process.

The contents and location of cellular organelles are also highly regulated. *Endosomal vesicles* shuttle internalized material to the appropriate intracellular site(s), while other

membrane-bound vesicles direct newly synthesized materials to the cell surface or specific organelles. Movement—of both organelles and proteins within the cell, as well as the entire cell in its environment—is accomplished by the *cytoskeleton,* which is composed of filamentous actin (microfilaments), keratins (intermediate filaments), and microtubules. These structural proteins also maintain cellular shape and intracellular organization, which are essential to generation and maintenance of *cell polarity.* This is particularly important in epithelium where the top of the cell *(apical)* and the bottom and sides of the cell *(basolateral)* are exposed to different environments and have distinct functions. Loss of polarity could, for example, disrupt vectorial transcellular transport in the intestine or renal tubule.

Cell growth and maintenance require a constant supply of both energy and the building blocks that are needed for synthesis of macromolecules. Most of the adenosine triphosphate (ATP) that powers cells is generated via *mitochondrial oxidative phosphorylation.* Mitochondria also serve as an important source of metabolic intermediates needed for anabolic metabolism, are sites of synthesis of certain macromolecules (e.g., heme), and contain important sensors of cell damage that can initiate and regulate programmed cell death (e.g., apoptosis).

In growing and dividing cells, all of these organelles have to be replicated *(organellar biogenesis)* and correctly apportioned in daughter cells following mitosis. Moreover, because the macromolecules and organelles have finite lifespans (mitochondria, for example, last only about 10 days), mechanisms must also exist that allow for the recognition and degradation of "worn-out" cellular components.

With this as a primer, we will now move on to discuss cellular components and their function in greater detail.

Plasma Membrane: Protection and Nutrient Acquisition

Plasma membranes (and all other organellar membranes for that matter) are more than just static lipid sheaths. Rather, they are fluid bilayers of amphipathic phospholipids—hydrophilic head groups that face the aqueous environment and hydrophobic lipid tails that interact with each other to form a barrier to passive diffusion of large or charged molecules (Fig. 1.7). The bilayer has a remarkably heterogeneous composition of different phospholipids that vary by location and are also asymmetric—that is, membrane lipids preferentially associate with extracellular or cytosolic faces. Proper localization of these molecules is important for cell health. For example, specific phospholipids interact with particular membrane proteins and modify their distributions and functions.

- *Phosphatidylinositol* on the inner membrane leaflet can be phosphorylated, serving as an electrostatic scaffold for intracellular proteins; alternatively, polyphosphoinositides can be hydrolyzed by phospholipase C to generate intracellular second signals like diacylglycerol and inositol trisphosphate.

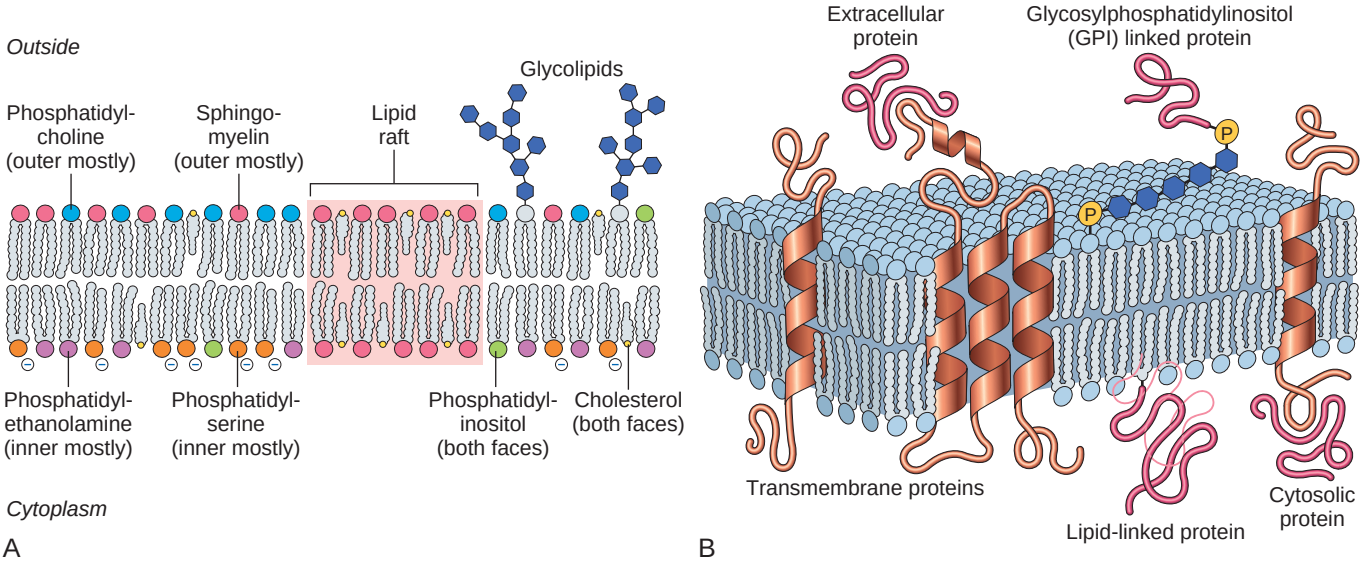

Figure 1.7 Plasma membrane organization and asymmetry. (A) The plasma membrane is a bilayer of phospholipids, cholesterol, and associated proteins. The phospholipid distribution within the membrane is asymmetric due to the activity of flippases; phosphatidylcholine and sphingomyelin are overrepresented in the outer leaflet, and phosphatidylserine (negative charge) and phosphatidylethanolamine are predominantly found on the inner leaflet; glycolipids occur only on the outer face where they contribute to the extracellular glycocalyx. Although the membrane is laterally fluid and the various constituents can diffuse randomly, specific domains, for example cholesterol and glycosphingolipid-rich lipid rafts, can also form. (B) Membrane-associated proteins may traverse the membrane (singly or multiply) via α-helical hydrophobic amino acid sequences; depending on the membrane lipid content and relative hydrophobicity of protein domains, such proteins may have nonrandom distributions within the membrane. Proteins on the cytosolic face can be associated with the plasma membrane through posttranslational modifications (e.g., farnesylation) or addition of palmitic acid. Proteins on the extracytoplasmic face can associate with the membrane via glycosylphosphatidylinositol *(GPI)* linkages. Besides protein-protein interactions within the membrane, membrane proteins can also associate with extracellular and/or intracytoplasmic proteins to generate distinct domains (e.g., the *focal adhesion complex*). Transmembrane proteins can translate mechanical forces (e.g., from the cytoskeleton or extracellular matrix), as well as chemical signals across the membrane.

- *Phosphatidylserine* is normally restricted to the inner face where it confers a negative charge involved in electrostatic protein interactions; however, when flipped to the extracellular leaflet, it becomes a potent "eat me" signal during programmed cell death (e.g., apoptosis). In platelets, phosphatidylserine is also a cofactor in blood clotting.
- *Glycolipids* and *sphingomyelin* are preferentially located on the extracellular face; glycolipids, including gangliosides with complex sugar linkages and terminal sialic acids that confer negative charges, support charge-based interactions that contribute to including inflammatory cell recruitment and sperm-egg fusion.

Despite substantial lateral fluidity, some membrane constituents concentrate into specialized domains (e.g., *lipid rafts*) that are enriched in glycosphingolipids and cholesterol. Since inserted membrane proteins have different intrinsic solubilities in domains with distinct lipid compositions, this membrane organization also impacts protein distribution. This geographic organization of plasma membrane components impacts cell-cell and cell-matrix interactions, intracellular signaling, and the specialized sites of vesicle budding or fusion.

The plasma membrane is liberally studded with a variety of proteins and glycoproteins involved in (1) ion and metabolite transport; (2) fluid-phase and receptor-mediated uptake of macromolecules; and (3) cell-ligand, cell-matrix, and cell-cell interactions. The means by which these proteins associate with membranes frequently reflects function. For example, multiple transmembrane-spanning proteins are often pores or molecular transporters, while proteins that are superficially attached to the membrane via labile linkages are more likely to participate in signaling. In general, proteins associate with the lipid bilayer by one of four mechanisms.

- Most proteins are integral or transmembrane proteins, having one or more relatively hydrophobic α-helical segments that traverse the lipid bilayer.
- Proteins synthesized on free ribosomes in the cytosol may be modified posttranslationally by addition of prenyl groups (e.g., farnesyl, related to cholesterol) or fatty acids (e.g., palmitic or myristic acid) that insert into the cytosolic side of the plasma membrane.
- Proteins on the extracellular face of the membrane may be anchored by glycosylphosphatidylinositol (GPI) tails that are added posttranslationally.
- Peripheral membrane proteins may noncovalently associate with true transmembrane proteins.

Many plasma membrane proteins function as large complexes; these may be aggregated either under the control of chaperone molecules in the RER or by lateral diffusion in the plasma membrane, followed by complex formation in situ. For example, many protein receptors (e.g., cytokine receptors) dimerize or trimerize in the presence of ligand to form functional signaling units. Although lipid bilayers are fluid within the plane of the membrane, components can be confined to discrete domains. This can occur by localization to lipid rafts (discussed earlier) or through intercellular protein-protein interactions (e.g., *tight junctions*) that establish discrete boundaries and also have unique lipid composition. The latter strategy is used to maintain *cell polarity* (e.g., top/apical/free vs. bottom/basolateral/bound to extracellular matrix [ECM]) in epithelial cells. Interactions of other membrane and cytosolic proteins with one another and the cytoskeleton also contributes to cell polarity.

The extracellular face of the plasma membrane is diffusely decorated by carbohydrates, not only as complex oligosaccharides on glycoproteins and glycolipids, but also as polysaccharide chains attached to integral membrane proteoglycans. This *glycocalyx* can form a chemical and mechanical barrier.

Membrane Transport

Although the barrier provided by plasma membranes is critical, transport of selected molecules across the lipid bilayer or to intracellular sites via vesicular transport is essential. Several mechanisms contribute to this transport.

Passive Diffusion. Small, nonpolar molecules like O_2 and CO_2 readily dissolve in lipid bilayers and therefore rapidly diffuse across them. Larger hydrophobic molecules, (e.g., steroid-based molecules like estradiol or vitamin D) can also cross lipid bilayers with relative impunity. While small polar molecules such as water (18 Da) can also diffuse across membranes at low rates, in tissues responsible for significant water movement (e.g., renal tubular epithelium), special integral membrane proteins called aquaporins form transmembrane channels for water, H_2O_2, and other small molecules. In contrast, the lipid bilayer is an effective barrier to the passage of larger polar molecules (>75 Da); at 180 Da, for example, glucose is effectively excluded. Lipid bilayers are also impermeant to ions due to their charge and hydration.

Carriers and Channels (Fig. 1.8)**.** Plasma membrane transport proteins are required for uptake and secretion of ions and larger molecules that are required for cellular function (e.g., nutrient uptake and waste disposal). Ions and small molecules can be transported by channel proteins and carrier proteins. Similar pores and channels also mediate transport across organellar membranes. These transporters that move ions, sugars, nucleotides, etc., frequently have exquisite specificities, and can be either active or passive (see below). For example, some transporters accommodate glucose but reject galactose.

- *Channel proteins* create hydrophilic pores, which, when open, permit rapid movement of solutes (usually restricted by size and charge).
- *Carrier proteins* bind their specific solute and undergo a series of conformational changes to transfer the ligand across the membrane; their transport is relatively slow.

Solute transport across the plasma membrane is frequently driven by a concentration and/or electrical gradient between the inside and outside of the cell via *passive transport* (virtually all plasma membranes have an electrical potential difference across them, with the inside negative relative to the outside). In other cases, *active transport* of certain solutes (against a concentration gradient) is accomplished by carrier molecules (never channels) at the expense of ATP hydrolysis or a coupled ion gradient. For example, most apical nutrient

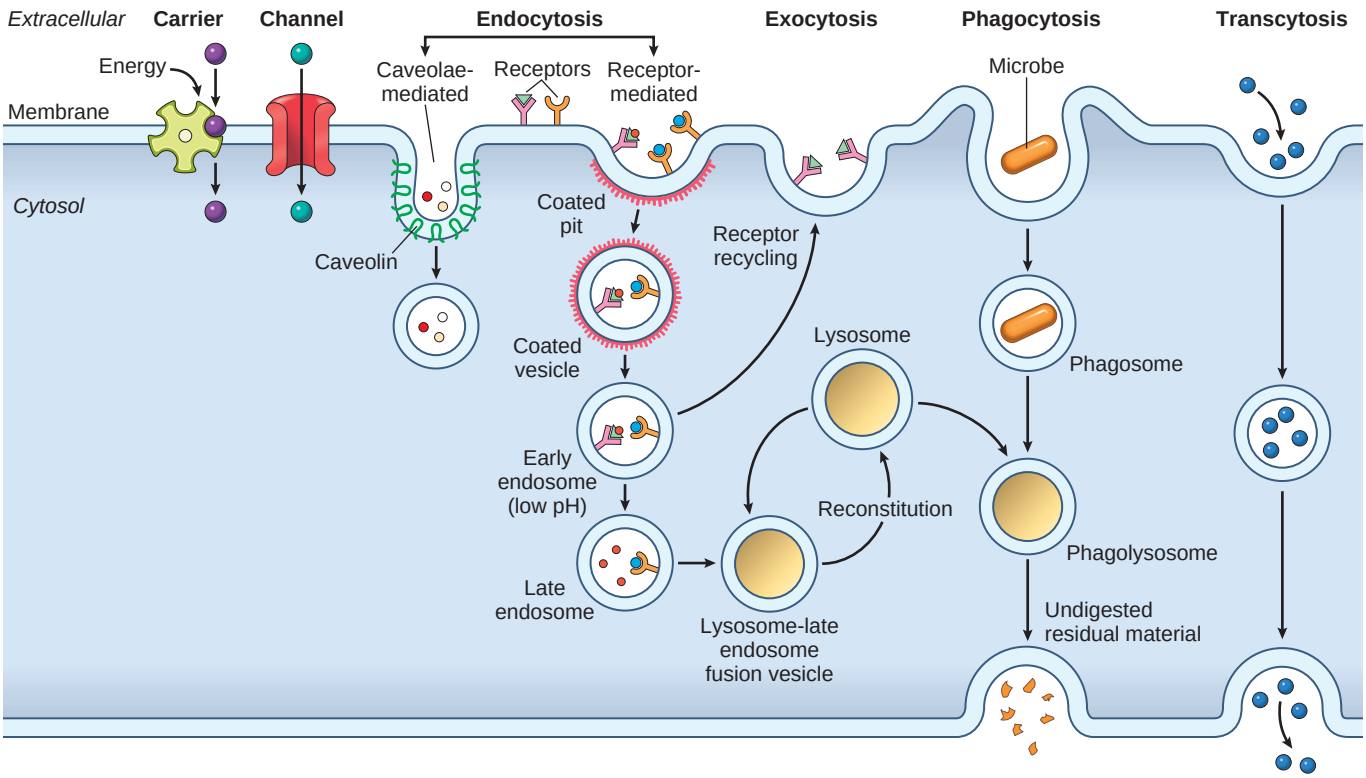

Figure 1.8 Movement of small molecules and larger structures across membranes. The lipid bilayer is relatively impermeable to all but the smallest and/or most hydrophobic molecules. Thus the import or export of charged species requires specific transmembrane transporter proteins, vesicular traffic, or membrane deformations.

From left to right in the figure: Small charged solutes can move across the membrane using either channels or carriers; in general, each molecule requires a unique transporter. Channels are used when concentration gradients can drive the solute movement; activation of the channel opens a hydrophilic pore that allows size-restricted and charge-restricted flow. Carriers are required when solute is moved against a concentration gradient; this typically requires energy expenditure to drive a conformational change in the carrier that facilitates the transmembrane delivery of specific molecules.

Receptor-mediated and fluid-phase uptake of material involves membrane bound vesicles. Caveolae endocytose extracellular fluid, membrane proteins, and some receptor bound molecules (e.g., folate) in a process driven by caveolin proteins concentrated within lipid rafts. They can subsequently fuse with endosomes or recycle to the membrane. Endocytosis of receptor-ligand pairs often involves clathrin-coated pits and vesicles. After internalization the clathrin disassembles and individual components can be re-used. The resulting vesicle becomes part of the endocytic pathway, in which compartments are progressively more acidic. After ligand is released, the receptor can be recycled to the plasma membrane to repeat the process (e.g., iron dissociates from transferin at pH ~5.5; apotransferrin and the transferrin receptor then return to the surface). Alternatively, receptor and ligand complexes can eventually be degraded within lysosomes (e.g., epidermal growth factor and its receptor are both degraded, which prevents excessive signaling). Exocytosis is the process by which membrane-bound vesicles fuse with the plasma membrane and discharge their contents to the extracellular space. This includes endosome recycling (shown), release of undigested residual material from lysosomes, transcytotic delivery of vesicles, and export of secretory vacuole contents (not shown). Phagocytosis involves membrane invagination to engulf large particles and is most common in specialized phagocytes (e.g., macrophages and neutrophils). The resulting phagosomes eventually fuse with lysosomes to facilitate the degradation of the internalized material. Transcytosis can mediate transcellular transport in either apical-to-basal or basal-to-apical directions, depending on the receptor and ligand.

transporters in the intestines and renal tubules exploit the extracellular to intracellular Na^+ gradient to allow absorption even when intracellular nutrient concentrations exceed extracellular concentrations. This form of active transport does not use ATP directly, but depends on the Na^+ gradient generated by Na^+-Ka^+ ATPase. Other transporters are ATPases. One example is the *multidrug resistance (MDR) protein*, which pumps polar compounds (e.g., chemotherapeutic drugs) out of cells and may render cancer cells resistant to treatment.

Water movement into or out of cells is passive and directed by solute concentrations. Thus extracellular salt in excess of that in the cytoplasm *(hypertonicity)* causes net movement of water out of cells, while *hypotonicity* causes net movement of water into cells. Conversely, the charged metabolites and proteins within the cytoplasm attract charged counterions that increase intracellular osmolarity. Thus to prevent overhydration, cells must constantly pump out small inorganic ions (e.g., Na^+)—typically through the activity of the membrane ion-exchanging ATPase. Loss of the ability to generate energy (e.g., in a cell injured by toxins or ischemia) therefore results in osmotic swelling and eventual cell rupture. Similar transport mechanisms also regulate concentrations of other ions (e.g., Ca^{2+} and H^+). This is critical to many processes. For example, cytosolic enzymes are most active at pH 7.4 and are often regulated by Ca^{2+}, whereas lysosomal enzymes function best at pH 5 or less.

Uptake of fluids or macromolecules by the cell is called *endocytosis*. Depending on the size of the vesicle, endocytosis may be denoted pinocytosis ("cellular drinking") or phagocytosis ("cellular eating"). Generally, phagocytosis is restricted to certain cell types (e.g., macrophages and

neutrophils) whose role is to specifically ingest invading organisms or dead cell fragments.

Receptor-Mediated and Fluid-Phase Uptake (see Fig. 1.8)

Certain small molecules—including some vitamins—bind to cell-surface receptors and are taken up through invaginations of the plasma membrane called caveolae. Uptake can also occur through membrane invaginations coated by an intracellular matrix of clathrin proteins that spontaneously assemble into a basket-like lattice which helps drive endocytosis (discussed more later). In both cases, activity of the "pinchase" dynamin is required for vesicle release.

Macromolecules can also be exported from cells by *exocytosis*. In this process, proteins synthesized and packaged within the RER and Golgi apparatus are concentrated in secretory vesicles, which then fuse with the plasma membrane to expel their contents. Common examples include peptide hormones (e.g., insulin) and cytokines.

Transcytosis is the movement of endocytosed vesicles between the apical and basolateral compartments of cells. This is a mechanism for transferring large amounts of intact proteins across epithelial barriers (e.g., ingested antibodies in maternal milk) or for rapid movement of large solute volumes.

We now return to the specifics of endocytosis (see Fig. 1.8).

- *Caveolae-mediated endocytosis. Caveolae* ("little caves") are noncoated plasma membrane invaginations associated with GPI-linked molecules, cyclic adenosine monophosphate (cAMP) binding proteins, src-family kinases, and the folate receptor; *caveolin* is the major structural protein of caveolae, which, like membrane rafts (see above), are enriched in glycosphingolipids and cholesterol. Internalization of caveolae along with bound molecules and associated extracellular fluid is called *potocytosis*—literally "cellular sipping." In addition to supporting transmembrane delivery of some molecules (e.g., folate), caveolae regulate transmembrane signaling and cellular adhesion via internalization of receptors and integrins.
- *Receptor-mediated endocytosis.* Macromolecules bound to membrane receptors (such as transferrin or low-density lipoprotein [LDL] receptors) are taken up at specialized regions of the plasma membrane called *clathrin-coated pits*. The receptors are efficiently internalized by membrane invaginations driven by the associated clathrin matrix, eventually pinching off to form *clathrin-coated vesicles*. Trapped within these vesicles is also a gulp of the extracellular milieu *(fluid-phase pinocytosis)*. The vesicles then rapidly lose their clathrin coating and fuse with an acidic intracellular structure called the *early endosome;* the endosomal vesicles undergo progressive maturation to late endosomes, ultimately fusing with lysosomes. In the acidic environment of the endosomes, LDL and transferrin receptors release their cargo (cholesterol and iron, respectively), which is then transported into the cytosol.

After release of bound ligand, some receptors recycle to the plasma membrane and are reused (e.g., transferrin and LDL receptors), while others are degraded within lysosomes (e.g., epidermal growth factor receptor). In the latter case, degradation after internalization results in receptor downregulation that limits receptor-mediated signaling. Defects in receptor-mediated transport of LDL underlie familial hypercholesterolemia, as described in Chapter 5.

Endocytosis requires recycling of internalized vesicles back to the plasma membrane (exocytosis) for another round of ingestion. This is critical, as a cell will typically ingest from the extracellular space the equivalent of 10% to 20% of its own cell volume each hour—amounting to 1% to 2% of its plasma membrane each minute! Without recycling, the plasma membrane would be rapidly depleted. Endocytosis and exocytosis must therefore be tightly coupled to avoid large changes in plasma membrane area.

Cytoskeleton

The ability of cells to adopt a particular shape, maintain polarity, organize intracellular organelles, and migrate depends on an intracellular scaffold of structural proteins that form the cytoskeleton (Fig. 1.9). Although the cytoskeleton can have an appearance similar to the beams and supports of a building, cytoskeletal structures are constantly elongating and shrinking; microfilaments and microtubules are most active, and their assembly and disassembly can drive cell migration.

In eukaryotic cells, there are three major classes of cytoskeletal proteins.

- *Actin microfilaments* are 5- to 9-nm diameter fibrils formed from the globular protein actin (G-actin), the most

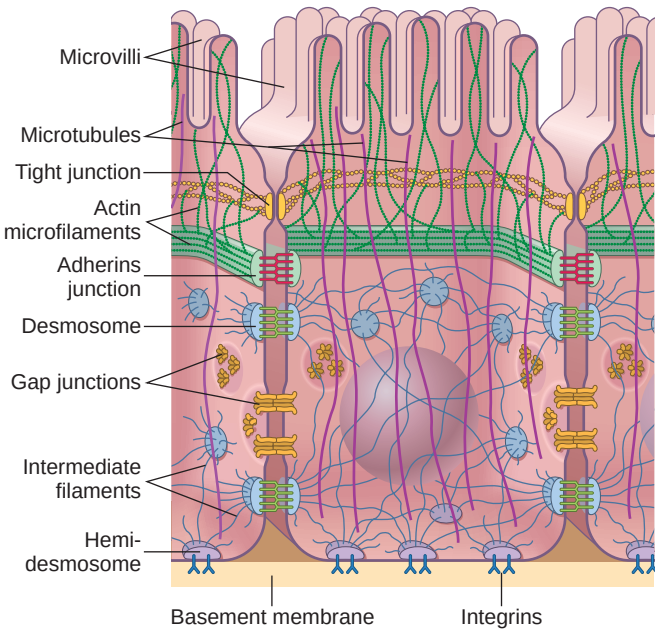

Figure 1.9 Cytoskeletal elements and cell-cell interactions. Interepithelial adhesion involves several different surface protein interactions at tight junctions, adherens junctions, and desmosomes; adhesion to the extracellular matrix involves cellular integrins (and associated proteins) within hemidesmosomes. The various adhesion proteins within the plasma membrane associate with actin microfilaments and intermediate filaments to provide a mechanical matrix for cell structure and signaling. Gap junctions do not impart structural integrity but allow cell-cell communication by the movement of small molecular weight and/or charged species. See text for details.

abundant cytosolic protein in cells. G-actin monomers noncovalently polymerize into long filaments (F-actin) that intertwine to form double-stranded helices with a defined polarity. Although the details are (as always) more nuanced, new subunits are typically added at the "positive" end of the strand and removed from the "negative" end—a process referred to as *actin treadmilling*. Actin nucleating, binding, and regulatory proteins organize polymerization, bundling, and branching to form networks that control cell shape and movement. This complex and its association with motor proteins (e.g., myosin) is so precisely arrayed in skeletal and cardiac muscle that a banding pattern is apparent by light microscopy. ATP hydrolysis by myosin slides the actin filaments relative to one another to cause muscle contraction. Although less coordinated, myosins, of which there are many, are responsible for other functions that depend on actin contraction including vesicular transport, epithelial barrier regulation, and cell migration.

- *Intermediate filaments* are 10-nm diameter fibrils that comprise a large and heterogeneous family that includes keratin proteins and nuclear lamins. Intermediate filaments predominantly form ropelike polymers and do not usually actively reorganize like actin and microtubules. This allows intermediate filaments to provide tensile strength so that cells can bear mechanical stress, e.g., in epithelia where intermediate filaments link *desmosomes* and *hemidesmosomes* (see Fig. 1.9). Individual intermediate filament proteins have characteristic tissue-specific patterns of expression that can be useful for assigning a cell of origin for poorly differentiated tumors. Examples include:
  - *Vimentin*, in mesenchymal cells (fibroblasts, endothelium).
  - *Desmin* in muscle cells forms the scaffold on which actin and myosin contract.
  - *Neurofilaments* are critical for neuronal axon structure and confer both strength and rigidity.
  - *Glial fibrillary acidic protein* is expressed in glial cells.
  - *Cytokeratins* are expressed in epithelial cells. There are at least 30 distinct different cytokeratins that are expressed in different cell lineages (e.g., lung vs. gastrointestinal epithelium).
  - *Lamins* are intermediate filament proteins that form the nuclear lamina, define nuclear shape, and can regulate transcription.
- *Microtubules* are 25-nm-thick fibrils composed of noncovalently polymerized α- and β-tubulin dimers organized into hollow tubes. These fibrils are extremely dynamic and polarized, with "+" and "–" ends. The "–" end is typically embedded in a *microtubule organizing center (MTOC* or *centrosome)* near the nucleus, where it is associated with paired centrioles; the "+" end elongates or recedes in response to various stimuli by the addition or subtraction of tubulin dimers. Microtubules:
  - Serve as mooring lines for molecular motor proteins that use ATP to translocate vesicles, organelles, or other molecules around cells. There are two varieties of these motor proteins, kinesins and dyneins, that typically (but not exclusively) transport cargo in anterograde (– to +) or retrograde (+ to –) directions, respectively.
  - Mediate sister chromatid segregation during mitosis.
  - Form the core of *primary cilia,* single nonmotile projections on many nucleated cells that contribute to the regulation of cellular proliferation and differentiation (mutations in the proteins of the primary cilia complex lead to forms of polycystic kidney disease; see Chapter 20).
  - Can be adapted to form the core of motile cilia (e.g., in bronchial epithelium) or flagella (in sperm).

Cell-Cell Interactions

Cells connect and communicate with each other via junctional complexes that form mechanical links and facilitate receptor-ligand interactions. Similar complexes also mediate interaction with the ECM. Cell-cell junctions are organized into three basic types (see Fig. 1.9):

- *Occluding junctions (tight junctions)* seal adjacent epithelial cells together to create a continuous barrier that restricts the paracellular (between cells) movement of ions and other molecules. Occluding junctions form a tight meshlike network (when viewed en face by freeze-fracture electron microscopy) of macromolecular contacts between neighboring cells; the complexes that mediate the cell-cell interactions are composed of transmembrane proteins including the tetraspanning *claudin* and *tight junction–associated MARVEL protein (TAMP)* families. These connect to a host of intracellular adaptor and scaffolding proteins, including the three members of the *zonula occludens protein family* (ZO-1, ZO-2, ZO-3) and cingulin. Besides forming a selectively permeable barrier that seals the space between cells (i.e., the paracellular space), this zone also represents the boundary that separates apical and basolateral membrane domains and helps to maintain cellular polarity. Nevertheless, these junctions are dynamic structures that can be modified to facilitate epithelial healing and inflammatory cell migration across epithelial-lined mucosal surfaces.
- *Anchoring junctions (adherens junctions* and *desmosomes)* mechanically attach cells—and their cytoskeletons—to other cells or the ECM. Adherens junctions are often closely associated with and beneath tight junctions. Desmosomes are more basal and form several types of junctions. When desmosomes attach the cell to the extracellular matrix (ECM) they are referred to as hemidesmosomes (half a desmosome), since the other half of the desmosome is not present within the ECM. Both adherens junctions and desmosomes are formed by homotypic extracellular interactions between transmembrane glycoproteins called cadherins, on adjacent cells.
  - In adherens junctions the transmembrane adhesion molecules are associated with intracellular actin microfilaments through which they can also influence cell shape and/or motility. Loss of the epithelial adherens junction protein E-cadherin explains the discohesive invasion pattern of some gastric cancers and lobular carcinomas of the breast (Chapters 17 and 23).
  - In desmosomes the cadherins are linked to intracellular intermediate filaments, allowing extracellular forces to be mechanically communicated (and dissipated) over multiple cells.

- In hemidesmosomes the transmembrane connector proteins are called *integrins;* like desmosomal cadherins, these attach to intermediate filaments and link the cytoskeleton to the ECM. *Focal adhesion complexes* are composed of >100 proteins and localize at hemidesmosomes. Their component proteins can generate intracellular signals when cells are subjected to shear stress (e.g., endothelium in the bloodstream or cardiac myocytes in a failing heart).

- *Communicating junctions (gap junctions)* permit the diffusion of chemical or electrical signals from one cell to another. The junction consists of a dense planar array of 1.5- to 2-nm pores (called *connexons*) formed by a pair of hexamers (one on each cell) of transmembrane connexin proteins. These form pores that permit passage of ions, nucleotides, sugars, amino acids, vitamins, and other small molecules; permeability of the junction is rapidly reduced by lowered intracellular pH or increased intracellular calcium. Gap junctions play a critical role in cell-cell communication. For example, gap junctions in cardiac myocytes allow cell-to-cell calcium fluxes that allow the many cells of the myocardium to behave as a functional syncytium with coordinated waves of contraction.

Biosynthetic Machinery: Endoplasmic Reticulum and Golgi Apparatus

All cellular constituents—including structural proteins, enzymes, transcription factors, and even the phospholipid membranes—are constantly renewed in an ongoing process balancing synthesis and degradation. The endoplasmic reticulum (ER) is the site for synthesis of all transmembrane proteins and lipids for plasma membrane and cellular organelles, including the ER itself. It is also the initial site of synthesis for secreted proteins. The ER is organized into a meshlike interconnected maze of branching tubes and flattened lamellae, forming a continuous sheet around a single lumen that is topologically equivalent to the extracellular environment. ER is composed of contiguous but distinct domains that are distinguished by the presence (RER) or absence (SER) of ribosomes (see Fig. 1.6).

- *Rough endoplasmic reticulum (RER):* Membrane-bound ribosomes on the cytosolic face of RER translate mRNA into proteins that are extruded into the ER lumen or become integrated into the ER membrane. This process is directed by specific signal sequences on the N-termini of nascent proteins; synthesis of proteins with signal peptides is initiated on free ribosomes, but the complex then becomes attached to the ER membrane, and the protein is inserted into or passed across the ER membrane as it is translated. For proteins lacking a signal sequence, translation remains on free ribosomes in the cytosol, forming polyribosomes as multiple ribosomes attach to the mRNA; such transcribed proteins remain within the cytoplasm.

  Proteins inserted into the ER fold into their active conformation and can form polypeptide complexes (oligomerize); in addition, disulfide bonds are formed, and N-linked oligosaccharides (sugar moieties attached to asparagine residues) are added. Chaperone molecules assist in folding and retaining proteins in the ER until the modifications are complete and the proper conformation is achieved. If a protein fails to appropriately fold or oligomerize, it is retained and degraded within the ER. A good example of this is the most common mutation of the CFTR protein in cystic fibrosis. In mutant CFTR, a codon deletion leads to the absence of a single amino acid (Phe508) which results in its misfolding, ER retention and catabolism and therefore reduced surface expression. Moreover, excess accumulation of misfolded proteins—exceeding the capacity of the ER to edit and degrade them—leads to the *ER stress response* (also called the *unfolded protein response [UPR]*) (Fig. 1.10B). Detection of excess abnormally folded proteins leads to a reduction in protein synthesis overall with a concurrent increase in chaperone proteins; failure to correct the overload can trigger cell death through *apoptosis* (Chapter 2).

- *Golgi apparatus:* From the RER, proteins and lipids destined for other organelles or extracellular export are shuttled into the Golgi apparatus. This consists of stacked cisternae that progressively modify proteins in an orderly fashion from *cis* (near the ER) to *trans* (near the plasma membrane). Cisternal progression, i.e., movement of *cis*-face cisternae to the *trans* aspect of the Golgi, akin to steps on an escalator, allows sequential processing of newly synthesized proteins and can be facilitated by small membrane-bound vesicles. Similar vesicles shuttle Golgi-resident enzymes from *trans* to *cis* in order to maintain the different cisternal contents along this assembly line. As cisternae mature, the N-linked oligosaccharides originally added in the ER are pruned and extended in a stepwise fashion; O-linked oligosaccharides (sugar moieties linked to serine or threonine) are also appended. Some of this glycosylation is important in sorting molecules to lysosomes (via the mannose-6-phosphate receptor); other glycosylation adducts are important for cell-cell or cell-matrix interactions or for clearing senescent cells (e.g., platelets and erythrocytes). In the *trans Golgi network,* proteins and lipids are sorted and dispatched to other organelles, plasma membrane, or secretory vesicles. The Golgi complex is especially prominent in cells specialized for secretion, including goblet cells of the intestinal or bronchial epithelium, which secrete large amounts of polysaccharide-rich mucus. In plasma cells that secrete antibodies, the Golgi can be recognized as a perinuclear hoff on simple hematoxylin and eosin stains (Chapter 6).

- *Smooth endoplasmic reticulum (SER):* In most cells, the SER is relatively sparse and primarily exists as the transition zone extending from RER to generate transport vesicles that carry newly synthesized proteins to the Golgi apparatus. The SER may, however, be particularly conspicuous in cells that synthesize steroid hormones (e.g., within the gonads or adrenals) or that catabolize lipid-soluble molecules (e.g., hepatocytes). Indeed, repeated exposure to compounds that are metabolized by the SER (e.g., phenobarbital, which is catabolized by the cytochrome P-450 system) can lead to SER hyperplasia. The SER is also responsible for sequestering intracellular calcium, which, when released into the cytosol, can mediate a number of responses to extracellular signals (including apoptotic cell death). In muscle cells, specialized SER called sarcoplasmic reticulum is responsible for the cyclic release and sequestration of calcium ions that regulate muscle contraction and relaxation, respectively.

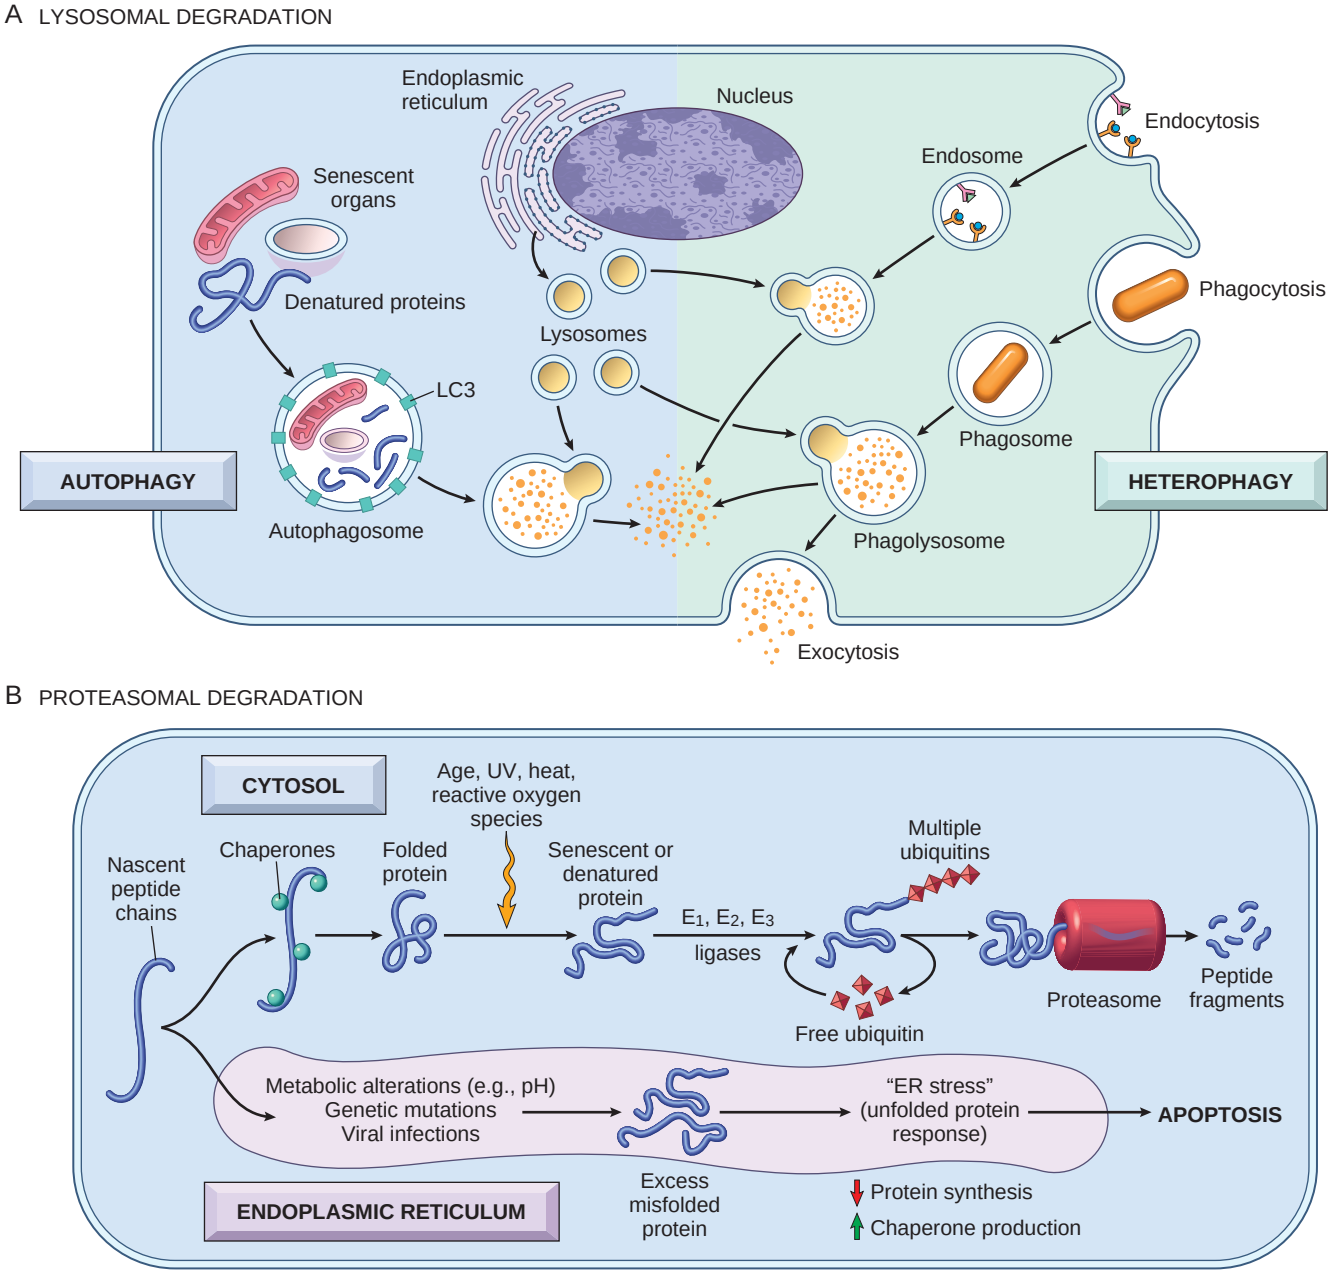

Figure 1.10 Intracellular catabolism. (A) Lysosomal degradation. In heterophagy (right side of panel A), lysosomes fuse with endosomes or phagosomes to facilitate the degradation of their internalized contents (see Fig. 1.8). The end products may be released into the cytosol for nutrition or discharged into the extracellular space (exocytosis). In autophagy (left side of panel A), senescent organelles or denatured proteins are targeted for lysosome-driven degradation as they are encircled within a double membrane vacuole derived from the endoplasmic reticulum and marked by LC3 protein (microtubule-associated protein 1A/1B-light chain 3). Cell stress, such as nutrient depletion or some intracellular infections, can also activate the autophagocytic pathway. (B) Proteosomal degradation. Cytosolic proteins destined for turnover (e.g., transcription factors or regulatory proteins), senescent proteins, or proteins that have become denatured due to extrinsic mechanical or chemical stresses can be tagged by multiple ubiquitin molecules (through the activity of E_1, E_2, and E_3 ubiquitin ligases). This marks the proteins for degradation by proteasomes, cytosolic multi-subunit complexes that degrade proteins to small peptide fragments. High levels of misfolded proteins within the endoplasmic reticulum (ER) trigger a protective unfolded protein response—engendering a broad reduction in protein synthesis, but specific increases in chaperone proteins that can facilitate protein refolding. If this is inadequate to cope with the levels of misfolded proteins it can lead to apoptosis.

Waste Disposal: Lysosomes and Proteasomes

Although cells rely primarily on lysosomes to digest internalized material and accumulated internal waste, there are multiple other routes to degrade intracellular macromolecules (see Fig. 1.10). These include proteosomes and peroxisomes. The latter are responsible for catabolism of long-chained fatty acids.

- *Lysosomes* are membrane-bound organelles containing roughly 40 different acid hydrolases (i.e., that function best at pH ≤5); these include proteases, nucleases, lipases, glycosidases, phosphatases, and sulfatases. Lysosomal

enzymes are initially synthesized in the ER lumen and then tagged with mannose-6-phosphate (M6P) within the Golgi apparatus. These M6P-modified proteins are subsequently delivered to lysosomes through *trans* Golgi vesicles that express M6P receptors. The other macromolecules destined for catabolism in the lysosomes arrive by one of three pathways (see Fig. 1.10).

- Material internalized by *fluid-phase* or *receptor-mediated endocytosis* passes from plasma membrane to early and then late endosomes and ultimately arrives at the lysosome. These compartments are progressively acidified such that proteolytic enzymes become active in late endosome and lysosomes.
- Senescent organelles and/or large, denatured protein complexes can be ferried into lysosomes by a process called *autophagy* (Chapter 2). Through a mechanism involving the products of a number of autophagy-related *(Atg)* genes, obsolete organelles are corralled by a double membrane derived from the ER. The membrane progressively expands to encircle a collection of organelles and cytosolic constituents, forming the definitive *autophagosome;* these structures are targeted for eventual destruction by fusion with lysosomes. In addition to facilitating turnover of aged and/or defunct structures, autophagy can be used to preserve viability during nutrient depletion; is involved in protective responses to intracellular infections; participates in intracellular repair; and, under some circumstances, triggers programmed cell death *(apoptosis)*. Autophagy is discussed in more detail in Chapter 2.
- *Phagocytosis* of microorganisms or large fragments of matrix or debris occurs primarily in professional phagocytes (macrophages or neutrophils). The material is engulfed to form a *phagosome* that subsequently fuses with lysosomes.

- *Proteasomes* play an important role in degrading cytosolic proteins (see Fig. 1.10); these include denatured or misfolded proteins as well as any other macromolecule whose lifespan needs to be regulated (e.g., signaling molecules). Many proteins destined for destruction are identified by covalently binding a small protein called *ubiquitin*. Polyubiquitinated molecules are unfolded and funneled into the polymeric proteasome complex—a cylinder containing multiple protease activities, each with its active site pointed at the hollow core. Proteasomes digest proteins into small (6 to 12 amino acids) fragments that can subsequently be degraded to their constituent amino acids and recycled.

CELLULAR METABOLISM AND MITOCHONDRIAL FUNCTION

Mitochondria evolved from ancestral prokaryotes that were engulfed by primitive eukaryotes about 1.5 billion years ago. Their origin explains why mitochondria contain their own DNA that encodes about 1% of total cellular protein and approximately 20% of the proteins involved in oxidative phosphorylation. Although their genomes are small, mitochondria can carry out all the steps of DNA replication, transcription, and translation using machinery similar to present-day bacteria; for example, mitochondria initiate protein synthesis with N-formylmethionine and are sensitive to some antibacterial antibiotics. Since mitochondria biogenesis requires a genetic contribution from preexisting mitochondria and the ovum contributes the vast majority of cytoplasmic organelles in the fertilized zygote, mitochondrial DNA is almost entirely maternally inherited. Nevertheless, because the protein constituents of mitochondria are encoded by both nuclear and mitochondrial DNA, mitochondrial disorders may be X-linked, autosomal, or maternally inherited.

Mitochondria are impressively dynamic, constantly undergoing fission and fusion with other newly synthesized mitochondria; this supports their renewal and defends against degenerative changes that occur through ongoing oxygen free radical damage. Even so, mitochondria are short-lived—being degraded through autophagy (a process called mitophagy)—with estimated half-lives of 1 to 10 days, depending on the tissue, nutritional status, metabolic demands, and intercurrent injury.

Besides providing the enzymatic machinery for oxidative phosphorylation (and thus the relatively efficient generation of energy from glucose and fatty acid substrates), mitochondria play a fundamental role in regulating apoptosis (Fig. 1.11). Details of mitochondrial functions follow:

- *Energy generation.* Each mitochondrion has two separate membranes with distinct functions; the inner membrane contains the enzymes of the respiratory chain folded into cristae. This encloses a core matrix space that harbors the bulk of the enzymes of the glycolytic and tricarboxylic acid cycles, and these constitute the major working parts of the organelle. Outside the inner membrane is the intermembrane space, which is the site of nucleotide phosphorylation and is, in turn, enclosed by the outer membrane; the latter is studded with porin proteins that form voltage-dependent anion channels that are permeable to small (<5000 Da) molecules. As with other cellular membranes, larger molecules (and even some smaller polar species) require specific transporters.

  The major source of the energy that facilitates all cellular functions derives from oxidative metabolism. Mitochondria oxidize substrates to CO_2, transferring the high-energy electrons from the original molecule (e.g., sugar) to molecular oxygen. Oxidation of various metabolites drives proton pumps that transfer H^+ from the core matrix into the intermembrane space. As the H^+ ions flow down their electrochemical gradient and out of the intermembrane space, the energy released is used to generate ATP.

  Notably, the electron transport chain need not necessarily be coupled to ATP generation. An inner membrane protein enriched in brown fat called *thermogenin* (also called uncoupling protein-1 [UCP-1]) is a hydrogen ion transporter that can dissipate the proton gradient, uncoupling it from oxidative phosphorylation. By this means, there is rapid substrate oxidation without ATP synthesis that allows tissues with high levels of UCP-1 to generate heat (nonshivering thermogenesis). As a natural (albeit usually low-level) by-product of substrate oxidation and electron transport, mitochondria are also an important source of reactive oxygen species (oxygen free radicals, hydrogen peroxide, etc.); importantly, hypoxia, toxic injury, or even mitochondrial aging can

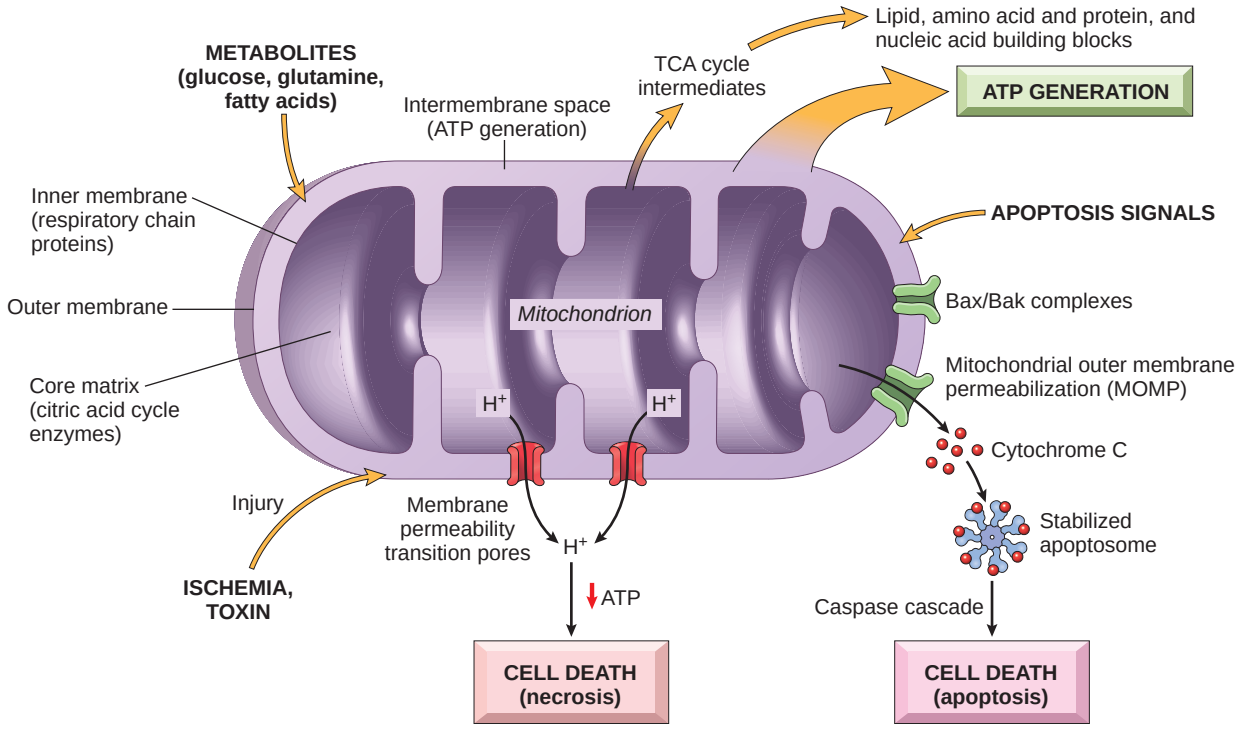

Figure 1.11 Roles of the mitochondria. Besides the efficient generation of adenosine triphosphate (ATP) from carbohydrate and fatty acid substrates, mitochondria also play an important role in intermediary metabolism—serving as the source of substrates used to synthesize lipids, proteins, and nucleotides. Significantly, they are centrally involved in cell life-and-death decisions: (1) toxic or ischemic injury will induce a membrane permeability transition that dissipates the intermembrane proton gradient, leading to cell death through loss of ATP generation; (2) intracellular signaling from both intrinsic and extrinsic sources can also result in the formation of oligomerized Bax and Bak protein pores on mitochondrial outer membrane permeabilization (MOMP) that facilitate release of cytochrome C from the electron transport chain proteins. Cytosolic cytochrome C stabilizes the multisubunit apoptosome to promote caspase activation and ultimately apoptotic cell death. TCA, Tricarboxylic acid.

lead to oxidative stress, characterized by increases in intracellular reactive oxygen species.

- *Intermediate metabolism.* Oxidative phosphorylation efficiently generates 36 to 38 ATP molecules per glucose molecule, but also "burns" substrates to their core CO_2 and H_2O, leaving no carbon moieties to use for building lipids and proteins. Consequently, to ensure the necessary building blocks for growth, rapidly dividing cells (both benign and malignant) increase their uptake of glucose and glutamine and switch to aerobic glycolysis, a phenomenon called the *Warburg effect*. In that setting, each glucose molecule is catabolized to lactic acid (even in the presence of adequate oxygen), generating only two net ATP molecules but "spinning off" intermediates that can be converted into new lipids, amino acids and proteins, and nucleic acids. Thus mitochondrial metabolism can be modulated to support either cellular energy maintenance or cellular proliferation.
- *Cell death.* In addition to providing the ATP that enables the bulk of cellular activity, mitochondria are fundamental to cell survival. The role of mitochondria in cell death is detailed in Chapter 2 and briefly mentioned here.
  - *Necrosis:* External cellular injury (toxin, ischemia, trauma) can damage mitochondria, inducing the formation of mitochondrial permeability transition pores in the outer membrane. These channels allow the dissipation of the proton gradient so that subsequent mitochondrial ATP generation becomes impossible and the cell dies.
  - *Apoptosis:* Programmed cell death is a central feature of normal tissue development and turnover and can be triggered by extrinsic signals (including cytotoxic T cells or inflammatory cytokines) or intrinsic pathways (including DNA damage or intracellular stress). Mitochondria integrate intracellular proapoptotic and antiapoptotic effector signals to generate a final "go" or "no go" signal for apoptosis. A net proapoptotic signal results in mitochondrial outer membrane permeabilization (MOMP)—distinct from the mitochondrial permeability transition—that releases cytochrome C (and other proteins) into the cytoplasm. In turn, these proteins activate intracellular programmed cell death pathways. Notably, a failure of normal proapoptotic signaling (or too many antiapoptotic effectors) can underlie malignancy—even in the face of mutations that would otherwise trigger cellular suicide. Conversely, too strong an apoptotic signal (or lack of antiapoptotic effectors) may lead to premature cell death, as in neurodegenerative disorders (Chapter 28).

CELLULAR ACTIVATION

Intercellular communication is essential to multicellular organisms. At the most basic level, extracellular signals may determine whether a cell lives or dies, remains quiescent,

or becomes active to perform its specific functions. Intercellular signaling is critical in the developing embryo and in maintaining tissue organization; it is also important in adult organisms, where intercellular signaling assures that all tissues act in appropriate concert (e.g., in response to local tissue trauma or a systemic infection). Loss of intercellular communication and "social controls" can also be reflected in unregulated growth (e.g., cancer) or in detrimental responses to extrinsic stress (e.g., shock).

Cell Signaling

Individual cells are chronically exposed to a remarkable cacophony of signals that must be integrated into rational output; some signals may induce a given cell type to differentiate, while others signal proliferation or direct the cell to perform specialized functions. Multiple signals at once, in a certain ratio, may trigger yet another totally unique response. Many cells require certain input just to continue living; in the absence of appropriate exogenous signals, they die by apoptosis.

The signals that most cells respond to can be classified into several groups.

- *Danger and pathogens.* Many cells have an innate capacity to sense and respond to damaged cells (danger signals), as well as foreign invaders such as microbes. The involved receptors are discussed in Chapters 3 and 6.
- *Cell-cell contacts,* mediated through adhesion molecules and/or gap junctions. As mentioned previously, gap junction signaling is accomplished between adjacent cells via hydrophilic connexon channels that permit the movement of small ions (e.g., calcium), metabolites, and second messenger molecules (e.g., cAMP).
- *Cell-ECM contacts,* mediated through integrins. We will return to a consideration of integrins in the context of leukocyte attachment to other cells during inflammation in Chapter 3.
- *Secreted molecules.* The most important secreted molecules include growth factors (discussed later); cytokines, a term reserved for mediators of inflammation and immune responses (discussed also in Chapters 3 and 6); and hormones, which are secreted by endocrine organs (Chapter 24).

Signaling pathways can also be classified based on the spatial relationships between the sending and receiving cells.

- *Paracrine signaling.* Only cells in the immediate vicinity are affected. To accomplish this, there can be only minimal diffusion, after which the secreted signal is rapidly degraded, taken up by other cells, or trapped in the ECM.
- *Autocrine signaling* occurs when molecules secreted by a cell affect that same cell. This can be a means to entrain groups of cells undergoing synchronous differentiation during development, or it can be used to amplify (positive feedback) or dampen (negative feedback) a particular response.
- *Synaptic signaling.* Activated neurons secrete neurotransmitters at specialized cell junctions (i.e., synapses) onto target cells.
- *Endocrine signaling.* A mediator is released into the bloodstream and acts on target cells at a distance.

Regardless of the nature of an extracellular stimulus (paracrine, autocrine, synaptic, or endocrine), the signal that is conveyed is transmitted to the cell via specific receptor proteins. Signaling molecules (ligands) bind their respective receptors and initiate a cascade of intracellular events culminating in the desired cellular response. Ligands usually have high affinities for their receptors ($\leq 10^{-8}$ M) and, at physiologic concentrations, bind receptors with exquisite specificity. Receptors may be present on the cell surface or within the cell (Fig. 1.12).

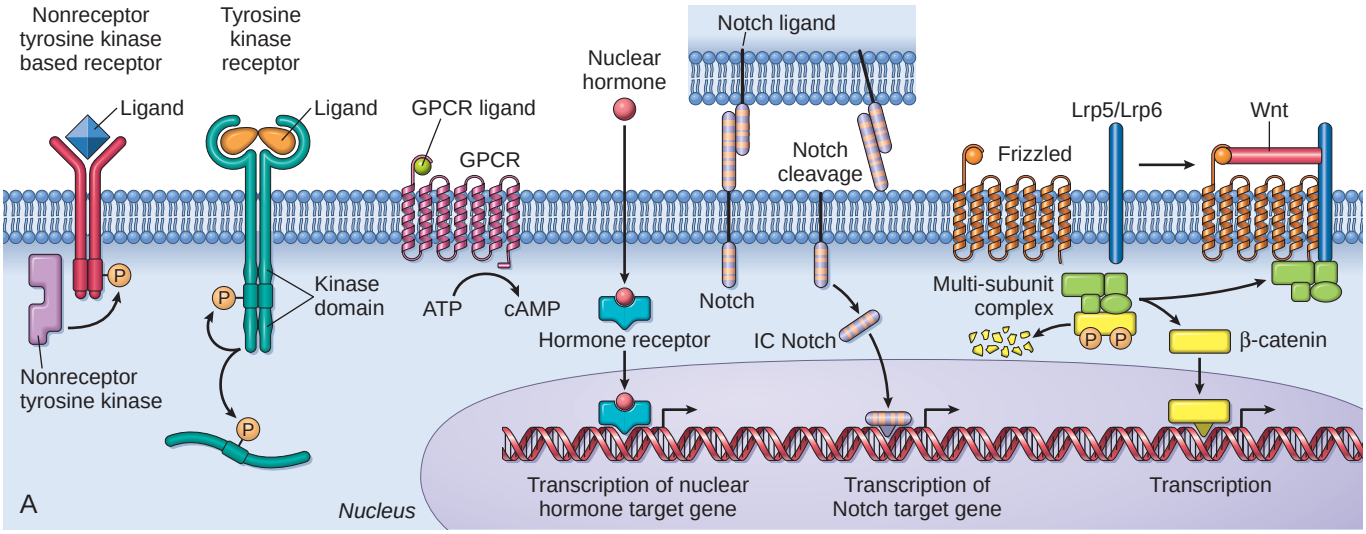
- *Intracellular receptors* include transcription factors that are activated by lipid-soluble ligands that can easily transit plasma membranes; vitamin D and steroid hormones that activate nuclear hormone receptors are good examples. In other cases a small and/or nonpolar signaling ligand produced by one cell type can influence the activity of adjacent cells. Thus nitric oxide produced by endothelial cells diffuses into underlying smooth muscle cells, activating the enzyme guanylyl cyclase to generate cyclic guanosine monophosphate (cGMP) that causes smooth muscle relaxation; endothelium can thereby regulate vasomotor tone.
- *Cell-surface receptors* are generally transmembrane proteins with extracellular domains that bind activating ligands. Depending on the receptor, ligand binding can:
  1. Open ion channels, typically at the synapse between electrically excitable cells.
  2. Activate an associated GTP-binding regulatory protein (G protein).
  3. Activate an endogenous or associated enzyme (often a tyrosine kinase).
  4. Trigger a proteolytic event or change protein binding or stability to activate a latent transcription factor.

G protein–coupled receptors and tyrosine kinase–associated receptors are typically involved in signaling that drives cellular proliferation; proteolytic or conformation changes are common features of multiple pathways (e.g., Notch, Wnt, and Hedgehog) that influence normal development. Secondary intracellular downstream events frequently involve phosphorylation or dephosphorylation of target molecules, with subsequent conformational changes that impact nuclear access or enzymatic activity (see later). Understandably, signals transduced by cell-surface receptors are frequently perturbed in developmental disorders and malignancy.

Signal Transduction Pathways

The interaction of a cell-surface receptor and its ligand can activate signaling through ligand-induced clustering of the receptor (receptor cross-linking) or by inducing a physical change in receptor structure (see Fig. 1.12). Either mechanism results in a conformational change in the cytosolic tail of the receptor that mediates additional intracellular biochemical events.

Cellular receptors are grouped into several types based on the signaling mechanisms they use and the intracellular biochemical pathways they activate (see Fig. 1.12). Receptor signaling most commonly leads to the formation or modification of biochemical intermediates and/or activation of



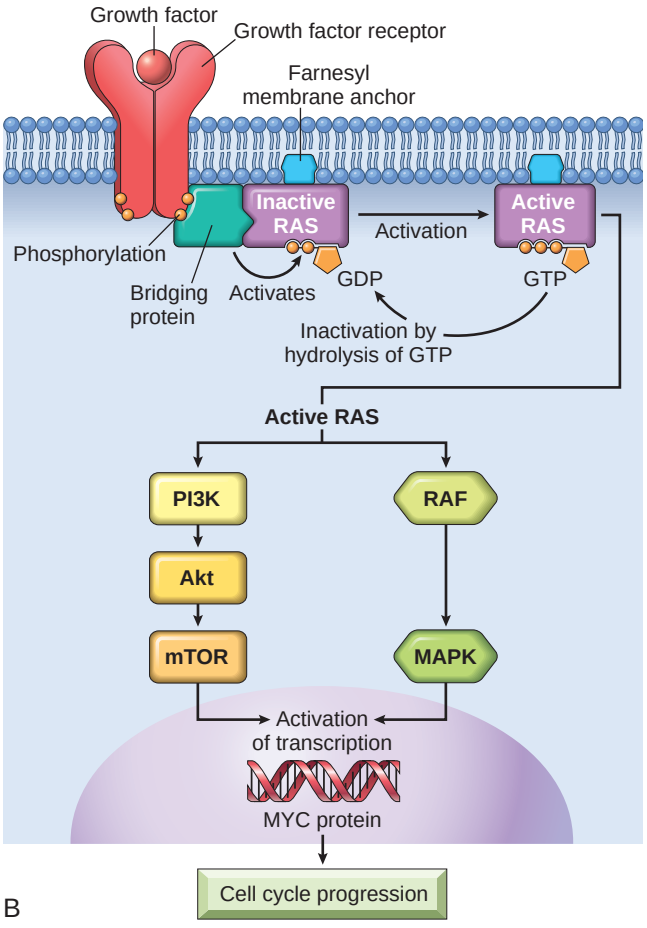


Figure 1.12 Receptor-mediated signaling. (A) Categories of signaling receptors including (from left to right) receptors that utilize a nonreceptor tyrosine kinase; a receptor tyrosine kinase; a G-protein coupled receptor (GPCR) seven-transmembrane protein linked to heterotrimeric G proteins; a nuclear receptor that binds its ligand and can then influence transcription; Notch, which recognizes a ligand on a distinct cell and is cleaved yielding an intracellular Notch (IC Notch) fragment that can enter the nucleus and influence transcription of specific target genes; and the Wnt/Frizzled pathway, where activation releases intracellular β-catenin from a protein complex that normally drives its constitutive degradation. The released β-catenin can then migrate to the nucleus and act as a transcription factor. (B) Signaling from a tyrosine kinase–based growth factor receptor. Binding of the growth factor (ligand) causes receptor dimerization and autophosphorylation of tyrosine residues. Attachment of adaptor (or bridging) proteins couples the receptor to inactive guanosine diphosphate (GDP)–bound RAS, allowing the GDP to be displaced in favor of guanosine triphosphate (GTP) and yielding activated RAS. Activated RAS interacts with and activates RAF (also known as MAP kinase kinase kinase). This kinase then phosphorylates mitogen-activated protein kinases *(MAPK)*, which, in turn, phosphorylates other cytoplasmic proteins and nuclear transcription factors that culminate in cellular responses. The phosphorylated tyrosine kinase receptor can also bind other proteins such as phosphatidylinositol 3-kinase (PI3K), which activates additional signaling pathways. The cascade is inactivated when the activated RAS eventually hydrolyzes GTP to GDP—converting RAS to its inactive form. Mutations in RAS that cause delayed GTP hydrolysis can thus lead to augmented proliferative signaling. *ATP,* Adenosine triphosphate; cAMP, cyclic adenosine monophosphate; Lrp5/Lrp6, low-density lipoprotein receptor–related proteins 5 and 6; mTOR, mammalian target of rapamycin.

enzymes that ultimately lead to generation of active transcription factors that enter the nucleus and alter the pattern of gene expression.

- *Receptors associated with kinase activity.* Downstream phosphorylation is a common pathway of signal transduction. Changes in receptor geometry can stimulate intrinsic receptor protein kinase activity or promote the enzymatic activity of recruited intracellular kinases; these kinases add charged phosphate residues to target molecules. Tyrosine kinases phosphorylate specific tyrosine residues, whereas serine/threonine kinases add phosphates to serine or threonine residues, and lipid kinases phosphorylate lipid substrates. For every phosphorylation event, there is also a phosphatase that removes phosphate residues to modulate signaling; phosphatases usually inhibit signal transduction.

- *Receptor tyrosine kinases (RTKs)* are integral membrane proteins (e.g., receptors for insulin, epidermal growth factor, and platelet-derived growth factor); ligand-induced cross-linking activates intrinsic tyrosine kinase domains located in their cytoplasmic tails.
- Several kinds of receptors have no intrinsic catalytic activity (e.g., immune receptors, some cytokine receptors, and integrins). For these, a separate intracellular protein—known as a *nonreceptor tyrosine* kinase—interacts with receptors after ligand binding and phosphorylates specific motifs on the receptor or other proteins. The cellular homologue of the transforming protein of the Rous sarcoma virus, called Src, is the prototype for an important family of such nonreceptor tyrosine kinases *(Src-family kinases).* Src contains unique functional regions called Src homology (SH) domains; SH2 domains typically bind to receptors phosphorylated by another kinase, allowing the aggregation of multiple enzymes, whereas SH3 domains mediate other protein-protein interactions, often involving proline-rich sequences.

- *G-protein coupled receptors (GPCRs)* characteristically traverse the plasma membrane seven times (hence their designation as seven-transmembrane or serpentine receptors); more than 1500 such receptors have been identified. After ligand binding, the GPCR associates with an intracellular guanosine triphosphate (GTP)–binding protein (G protein) that contains guanosine diphosphate (GDP). G-protein interaction with a GPCR-ligand complex results in activation through the exchange of GDP for GTP. Subsequent GPCR-mediated signaling pathways include the generation of cAMP and inositol-1,4,5-triphosphate (IP_3), with the latter triggering release of calcium from the ER.
- *Nuclear receptors*. Lipid-soluble ligands can diffuse into cells where they interact with intracellular proteins to form a receptor-ligand complex that directly binds to nuclear DNA; the results can be either activation or repression of gene transcription.
- *Other classes of receptors*. Other receptors—originally recognized as important for embryonic development and cell fate determination—are now recognized to participate in the functioning of mature cells, particularly within the immune system. Rather than enzymatic activity, these pathways rely on protein-protein interactions to transduce signals.
  - Receptor proteins of the *Notch* family fall in this category; ligand binding to Notch receptors leads to proteolytic cleavage of the receptor and subsequent nuclear translocation of the cytoplasmic piece (intracellular Notch) to form a transcription complex.
  - *Wnt* protein ligands can also influence cell development through a canonical pathway involving transmembrane *Frizzled* family receptors, a distinct set of GPCRs that regulate intracellular levels of *β-catenin*. Normally, β-catenin is continuously targeted for ubiquitin-directed proteasomal degradation. However, Wnt binding to frizzled (and other coreceptors) recruits yet another intracellular protein *(Dishevelled)* that leads to disruption of the degradation-targeting complex. This stabilizes β-catenin, allowing it to translocate to the nucleus and form a transcription complex.

Modular Signaling Proteins, Hubs, and Nodes

The traditional linear view of signaling—that receptor activation triggers an orderly sequence of biochemical intermediates that ultimately leads to changes in gene expression and the desired biological response—is oversimplified. Instead, it is increasingly clear that any initial signal impacts multiple processes, each of which contributes to the final outcome. This is particularly true of signaling pathways that rely on enzymatic activity. For example, specific phosphorylation of any given protein can allow it to associate with a host of other molecules, resulting in (among other effects):

- Enzyme activation (or inactivation).
- Nuclear (or cytoplasmic) localization of transcription factors (see later).
- Transcription factor activation (or inactivation).
- Actin polymerization (or depolymerization).
- Protein degradation (or stabilization).
- Activation of feedback inhibitory (or stimulatory) loops.

Adaptor proteins play a key role in organizing intracellular signaling pathways. These proteins function as molecular connectors that physically link different enzymes and promote the assembly of complexes; adaptors can be integral membrane proteins or cytosolic proteins. A typical adaptor contains specific domains (e.g., SH2 or SH3) that mediate protein-protein interactions. By influencing which proteins are recruited to signaling complexes, adaptors can determine downstream signaling events.

By analogy with computer networks, the protein-protein complexes can be considered nodes, and the biochemical events feeding into or emanating from these nodes can be thought of as hubs. Signal transduction can therefore be visualized as a kind of networking phenomenon; understanding this higher-order complexity is the province of *systems biology,* involving a melding of biology and computer science, i.e., computational biology.

Transcription Factors

Most signal transduction pathways ultimately induce durable effects on cellular function by modulating gene transcription; this occurs through the activation and/or nuclear localization of transcription factors. Some transcription factors drive expression of a relatively limited set of genes or a specific genetic program, while others have widespread effects. Among the transcription factors that regulate cell division are products of several growth-promoting genes, such as *MYC* and *JUN*, and of cell cycle–inhibiting genes, such as *TP53*. Transcription factors often contain modular domains that bind to DNA, small molecules such as steroid hormones, and intracellular regulatory proteins. Interactions mediated by these domains can be controlled by posttranslational modifications such as phosphorylation. These changes can result in translocation from the cytoplasm into the nucleus, modify transcription factor protein half-life, expose specific DNA binding motifs, or promote binding to components of the RNA polymerase complex to augment transcription factor activity.

- *DNA-binding domains* permit specific binding to short DNA sequences. Whereas some transcription factor

binding sites are found in promoters near the location of transcription initiation, other transcription factor binding sites can be found throughout the genome; in the latter case, transcription factor activation may lead to the simultaneous transcription of a cassette of genes (presumably interrelated and interacting). Transcription factors may also bind to long-range regulatory elements such as enhancers that function by bringing gene promoters into geographic proximity to the genes they regulate. The fact that these sites may be distant from one another based on the linear genetic sequence emphasizes the importance of chromatin organization in regulating gene expression.

- *Protein-protein interaction domains* within transcription factors directly or indirectly recruit additional proteins including coactivators, histone-modifying enzymes, and chromatin-remodeling complexes that unwind and/or otherwise expose initiation sites. Most importantly, they recruit RNA polymerase—the large multiprotein enzymatic complex that is responsible for RNA synthesis.

GROWTH FACTORS AND RECEPTORS

Growth factors stimulate the activity of signaling pathways and genes that augment cell survival, growth, and division. Growth factors bind to specific receptors and, ultimately, influence expression of genes that:

- Promote entry into the cell cycle.
- Relieve blocks on cell cycle progression (thus promoting replication).
- Prevent apoptosis.
- Enhance synthesis of components (nucleic acids, proteins, lipids, carbohydrates) required for cell division.

Although growth factors are characteristically thought of as proteins that "just" stimulate cell proliferation and/or survival, it is important to remember that they can also regulate a host of nongrowth activities including migration, differentiation, and synthetic capacity. Some growth factors relevant to tissue repair and regeneration are listed in Table 1.1 and described further in Chapter 3.

Growth factors regulate cellular proliferation at steady state and in response to injury, when irreversibly damaged cells must be replaced. Uncontrolled proliferation can result when the growth factor activity is dysregulated or when growth factor signaling pathways are altered to become constitutively active. Thus many growth factor pathway genes are *proto-oncogenes;* by virtue of their proliferative effects, gain-of-function mutations convert them into *oncogenes* that lead to unfettered cell division and can be precursors to malignancy. Although the growth factors described here all involve receptors with intrinsic kinase activity, growth factors can signal through each of the pathways shown in Fig. 1.12.

Epidermal Growth Factor (EGF) and Transforming Growth Factor-α (TGF-α). Both factors belong to the EGF family, bind to overlapping sets of receptors, and share many biologic activities. EGF and TGF-α, which are produced by macrophages and some epithelial cells, are mitogenic for hepatocytes, fibroblasts, and a host of epithelial cell types. The "EGF receptor family" includes four membrane receptors with intrinsic tyrosine kinase activity; the best-characterized receptor is EGFR1, also known as ERB-B1, or simply EGFR. EGFR1 mutations and/or amplification frequently occur in a number of cancers including lung, head and neck, breast, and brain. The ERB-B2 receptor (also known as *HER-2*) is overexpressed in a subset of breast cancers. Antibodies and small molecule antagonists that target many of these receptors have proven effective in some cancers.

Hepatocyte Growth Factor (HGF). HGF (also known as scatter factor) has mitogenic effects on hepatocytes and most epithelium including biliary, lung, kidney, breast, and skin.

Table 1.1 Growth Factors Involved in Regeneration and Repair

Growth Factor	Sources	Functions
Epidermal growth factor (EGF)	Activated macrophages, salivary glands, keratinocytes, many other cells	Mitogenic for many cell types; stimulates epithelial cell migration; stimulates formation of granulation tissue
Transforming growth factor-α (TGF-α)	Activated macrophages, keratinocytes, many other cells	Stimulates proliferation of hepatocytes and many other epithelial cells
Hepatocyte growth factor (HGF) (scatter factor)	Fibroblasts, stromal cells in the liver, endothelial cells	Enhances proliferation of hepatocytes and other epithelial cells; increases cell motility
Vascular endothelial growth factor (VEGF)	Mesenchymal cells	Stimulates proliferation of endothelial cells; increases vascular permeability
Platelet-derived growth factor (PDGF)	Platelets, macrophages, endothelial cells, smooth muscle cells, keratinocytes	Chemotactic for neutrophils, macrophages, fibroblasts, and smooth muscle cells; activates and stimulates proliferation of fibroblasts, endothelial cells, and other cells; stimulates ECM protein synthesis
Fibroblast growth factors (FGFs) including acidic (FGF-1) and basic (FGF-2)	Macrophages, mast cells, endothelial cells, many other cell types	Chemotactic and mitogenic for fibroblasts; stimulates angiogenesis and ECM protein synthesis
Transforming growth factor-β (TGF-β)	Platelets, T lymphocytes, macrophages, endothelial cells, epithelial cells, smooth muscle cells, fibroblasts	Chemotactic for leukocytes and fibroblasts; stimulates ECM protein synthesis; suppresses acute inflammation
Keratinocyte growth factor (KGF) (i.e., FGF-7)	Fibroblasts	Stimulates keratinocyte migration, proliferation, and differentiation

ECM, Extracellular matrix.

HGF acts as a *morphogen* in embryonic development (i.e., influences the pattern of tissue differentiation), promotes cell migration (hence the designation scatter factor), and enhances hepatocyte survival. HGF is produced by fibroblasts and most mesenchymal cells, endothelial cells, and non-hepatocyte liver cells. It is synthesized as an inactive precursor (pro-HGF) that is proteolytically activated by serine proteases released at sites of injury. The receptor for HGF is MET, which has intrinsic tyrosine kinase activity. MET is frequently overexpressed or mutated in tumors, particularly renal and thyroid papillary carcinomas. Consequently, MET inhibitors are being evaluated for cancer therapy.

Platelet-derived Growth Factor (PDGF). PDGF is a family of several closely related proteins, each consisting of two chains (designated by pairs of letters). Three isoforms of PDGF (AA, AB, and BB) are directly biologically active; PDGF-CC and PDGF-DD must be activated by proteolytic cleavage. PDGF proteins are stored in cytoplasmic granules and released by activated platelets. Although originally isolated from platelets (hence the name), PDGFs are produced by many cells including activated macrophages, endothelium, smooth muscle cells, and tumors. All PDGF isoforms exert their effects by binding to two cell-surface receptors (PDGFR α and β), both of which have intrinsic tyrosine kinase activity. PDGF induces fibroblast, endothelial, and smooth muscle cell proliferation and is also chemotactic for these cells (and inflammatory cells), thereby promoting their recruitment to sites of inflammation and tissue injury.

Vascular Endothelial Growth Factor (VEGF). VEGFs are a family of homodimeric proteins: VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). VEGF-A is generally referred to simply as VEGF; it is the major *angiogenic* factor (inducing blood vessel development) after injury and in tumors. In comparison, VEGF-B and PlGF are involved in embryonic vessel development, and VEGF-C and VEGF-D stimulate both angiogenesis and lymphatic development *(lymphangiogenesis)*. Separate from their roles in angiogenesis, VEGFs are also involved in the maintenance of normal endothelium, with highest expression in epithelial cells adjacent to fenestrated epithelium (e.g., kidney podocytes, retinal pigment epithelium, and choroid plexus). VEGF induces all the activities necessary for angiogenesis, including endothelial cell migration and proliferation (capillary sprouting), and promotes formation of vascular lumina. VEGF also affects vascular dilation and increases vascular permeability (VEGF was originally called vascular permeability factor to reflect that activity). As might be anticipated, hypoxia is the most important inducer of VEGF production, through pathways that involve activation of the transcription factor *hypoxia-inducible factor 1* (HIF-1). Other VEGF inducers—produced at sites of inflammation or wound healing—include PDGF and TGF-α.

VEGFs bind to a family of tyrosine kinase receptors (VEGFR-1, VEGFR-2, and VEGFR-3); VEGFR-2 is highly expressed in endothelium and is the most important for angiogenesis. Antibodies against VEGF are approved for the treatment of tumors such as renal and colon cancers that require angiogenesis for their spread and growth. Anti-VEGF therapies have had success in ophthalmic disorders including "wet" age-related macular degeneration (a disorder of inappropriate angiogenesis and vascular permeability that causes adult-onset blindness), angiogenesis associated with retinopathy of prematurity, and vascular leakage that leads to diabetic macular edema. Finally, increased levels of soluble VEGFR-1 (also known as s-FLT-1) in pregnant women may cause preeclampsia (hypertension and proteinuria) by sequestering the free VEGF required for maintenance of normal endothelium.

Fibroblast Growth Factor (FGF). FGF refers to a family of growth factors with more than 20 members. Acidic FGF (aFGF) (also known as FGF-1) and basic FGF (bFGF) (also known as FGF-2) are the best characterized; FGF-7 is also referred to as keratinocyte growth factor (KGF). Released FGFs associate with heparan sulfate in the ECM, which serves as a reservoir for inactive factors that can be subsequently released by proteolysis (e.g., at sites of wound healing). FGFs signal through four tyrosine kinase receptors (FGFR1 through FGFR4) to promote wound healing, hematopoiesis, and development; bFGF has all the activities necessary for angiogenesis.

Transforming Growth Factor β (TGF-β). TGF-β has three isoforms (TGF-β1, TGF-β2, TGF-β3) that belong to a larger family of about 30 members including bone morphogenetic proteins (BMPs), activins, inhibins, and Müllerian inhibiting substance. TGF-β1 has the most widespread distribution and is commonly referred to simply as TGF-β; it is a homodimeric protein produced by multiple cell types including platelets, endothelium, epithelial cells, and inflammatory cells. TGF-β is secreted as a precursor that requires proteolysis to yield the biologically active protein. There are two TGF-β receptors (types I and II) both with serine/threonine kinase activity that induce the phosphorylation of a variety of downstream transcription factors called *Smads*. Phosphorylated Smads form heterodimers, allowing nuclear translocation and association with other DNA-binding proteins to activate or inhibit gene transcription. TGF-β signaling has multiple—and often opposing—effects, depending on the tissue type and any concurrent signals. Agents with such multiplicity of effects are called *pleiotropic,* and TGF-β is "pleiotropic with a vengeance." Primarily, however, TGF-β can be conceptualized as driving scar formation and putting a brake on the inflammation that accompanies wound healing.

- TGF-β stimulates the production of collagen, fibronectin, and proteoglycans and inhibits collagen degradation by both decreasing matrix metalloproteinase (MMP) activity and increasing the activity of tissue inhibitors of proteinases (TIMPs) (discussed later). TGF-β is involved not only in scar formation after injury but also drives fibrosis in lung, liver, intestines, and kidneys in the setting of chronic inflammation.
- TGF-β is also an antiinflammatory cytokine that serves to limit and terminate inflammatory responses. It does this by inhibiting lymphocyte proliferation and activity of other leukocytes. Animals lacking TGF-β have widespread and persistent inflammation.

EXTRACELLULAR MATRIX

The ECM is a protein network that constitutes a significant proportion of any tissue. Cell interactions with the ECM are critical for development, healing, and maintenance of

normal tissue architecture (Fig. 1.13). Much more than a simple "space filler" around cells, the ECM functions as a:

- *Mechanical support* for cell anchorage, cell migration, and maintenance of cell polarity.
- *Regulator of cell proliferation* by binding and displaying growth factors and by signaling via cellular integrin family receptors. The ECM provides a depot for latent growth factors that can be activated within foci of injury or inflammation.
- *Scaffolding for tissue renewal*. Because maintenance of normal tissue structure requires a basement membrane or stromal scaffolds, integrity of the basement membrane or the stroma of parenchymal cells is critical for organized tissue regeneration. Thus ECM disruption prevents effective tissue regeneration and repair.
- *Foundation for establishment of tissue microenvironments*. Basement membrane acts as a boundary between epithelium and underlying connective tissue but often does more than just provide structural support; for example, in the kidney, it forms part of the filtration apparatus.

The ECM is constantly being remodeled; its synthesis and degradation accompany morphogenesis, tissue regeneration and repair, chronic fibrosis, and tumor invasion and metastasis.

The ECM occurs in two basic forms: interstitial matrix and basement membrane (Fig. 1.14).

- *Interstitial matrix.* Interstitial matrix occupies the spaces between stromal cells within connective tissue and between parenchymal epithelium and the underlying supportive vascular and smooth muscle structures in some organs. Interstitial matrix is synthesized by mesenchymal cells (e.g., fibroblasts), forming a three-dimensional, relatively amorphous, semi-fluid gel. In some tissues, such as the gastrointestinal tract, urinary bladder, and periarterial soft tissues, fluid within matrix cushions tissue compression associated with peristalsis, urination, and pulsatile arterial blood flow. The major nonfluid constituents of the interstitial matrix are fibrillar and nonfibrillar collagens, as well as *fibronectin, elastin, proteoglycans, hyaluronate,* and other constituents (see later).

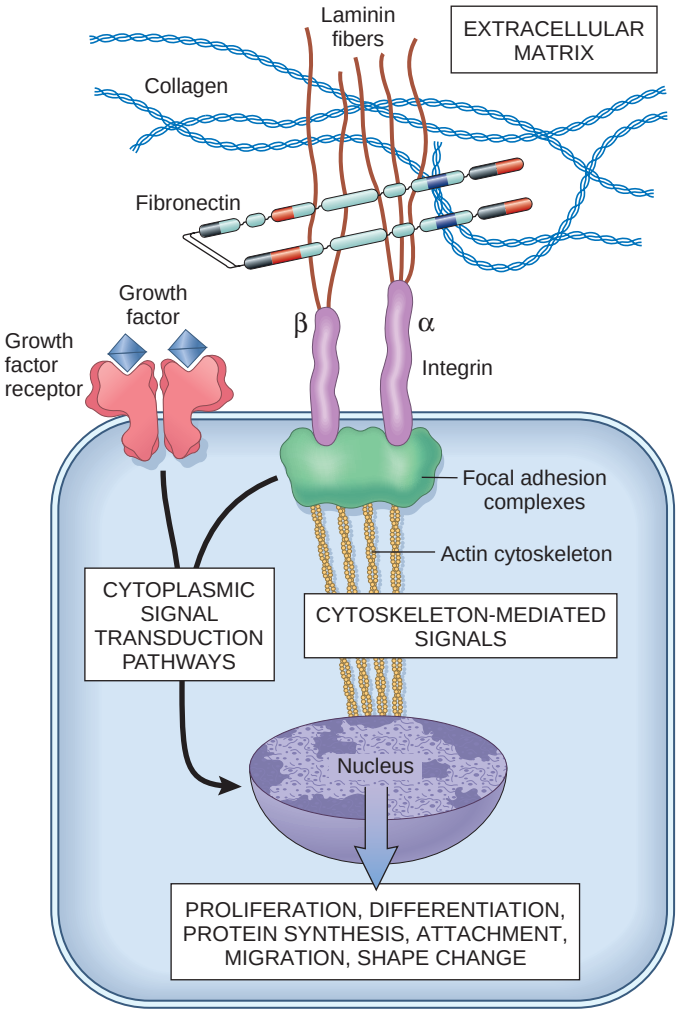

Figure 1.13 Interactions of extracellular matrix (ECM) and growth factors to mediate cell signaling. Cell surface integrins interact with the cytoskeleton at focal adhesion complexes (protein aggregates that include vinculin, α-actinin, and talin; see Fig. 1.17C). This can initiate the production of intracellular messengers or can directly transduce signals to the nucleus. Cell-surface receptors for growth factors can activate signal transduction pathways that overlap with those mediated through integrins. Signals from both ECM interactions and growth factors can be integrated by the cells to produce specific responses, including changes in proliferation, locomotion, or differentiation.

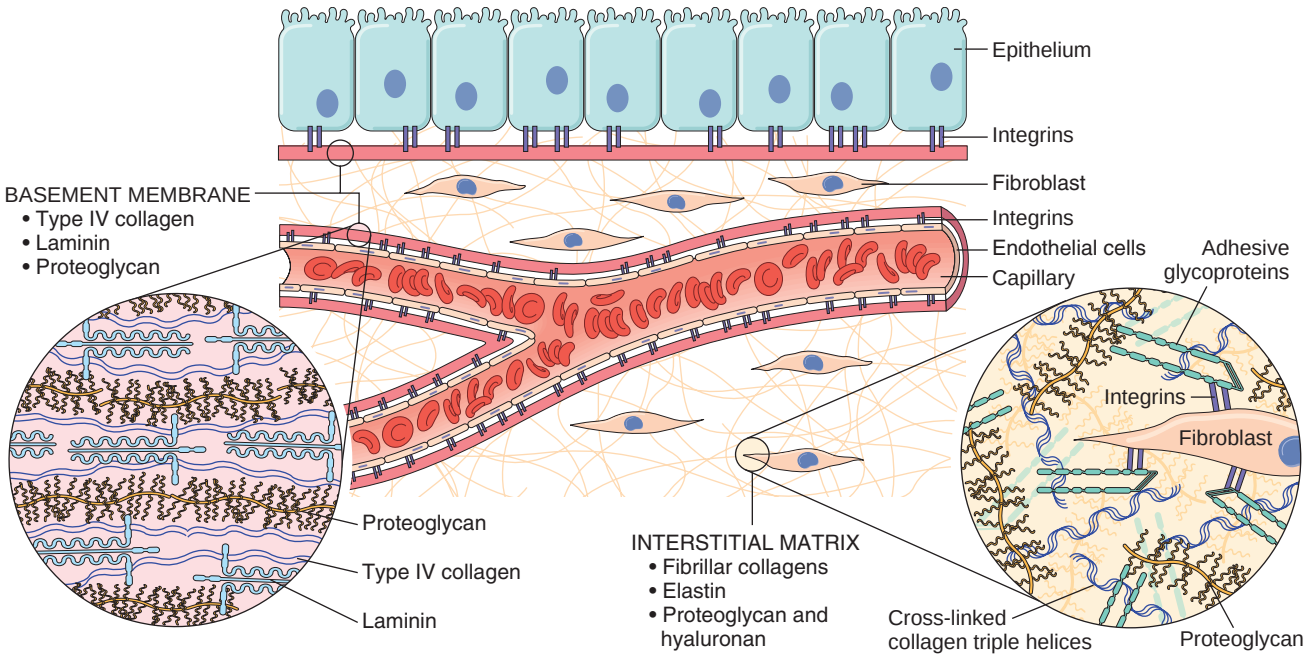

Figure 1.14 Main components of the extracellular matrix (ECM) including collagens, proteoglycans, and adhesive glycoproteins. Both epithelial and mesenchymal cells (e.g., fibroblasts) interact with ECM via integrins. Basement membranes and interstitial ECM have different architecture and general composition, although certain components are present in both. For the sake of clarity, many ECM components (e.g., elastin, fibrillin, hyaluronan, and syndecan) are not shown.

- *Basement membrane*. Interstitial matrix within connective tissues becomes highly organized around epithelial cells, endothelial cells, and smooth muscle cells, where it forms basement membranes, specialized surfaces for cell growth. Basement membrane components, which are synthesized by the overlying epithelium and underlying mesenchymal cells, form a flat lamellar mesh (although labeled as a membrane, it is quite porous). The major constituents are nonfibrillar *type IV collagen* and *laminin*.

Components of the Extracellular Matrix (Fig. 1.15)

ECM components fall into three families:

- *Fibrous structural proteins* such as collagens and elastin that confer tensile strength and recoil
- *Water-hydrated gels* such as proteoglycans and hyaluronan that permit compressive resistance and lubrication
- *Adhesive glycoproteins* that connect ECM elements to one another and to cells

Collagens. Collagens are composed of three separate polypeptide chains braided into a ropelike triple helix (Fig. 1.16). About 30 collagen types have been identified, some of which are unique to specific cells and tissues.

- *Fibrillar collagens:* Some collagen types (e.g., types I, II, III, and V) form linear fibrils stabilized by interchain hydrogen bonding; such fibrillar collagens comprise a major proportion of the connective tissue in bone, tendon, cartilage, blood vessels, and skin, as well as in healing wounds and scars. The tensile strength of the fibrillar collagens derives from lateral cross-linking of the triple helices via covalent bonds that follow lysine hydroxylation. The responsible enzyme, *lysyl hydroxylase,* is dependent on vitamin C, explaining why children with ascorbate deficiency have skeletal deformities and why individuals of any age with vitamin C deficiency heal poorly and bleed easily. Genetic defects, including collagen and lysyl hydroxylase mutations, cause diseases such as *osteogenesis imperfecta* and certain forms of *Ehlers-Danlos syndrome* (Chapter 5).
- *Nonfibrillar collagens* (e.g., type IV collagen) contribute to structures of planar basement membranes; help regulate collagen fibril diameters and collagen-collagen interactions via so-called fibril-associated collagen with interrupted triple helices (FACITs) (e.g., type IX collagen in cartilage); or provide anchoring fibrils that maintain structure of stratified squamous epithelium (e.g., type VII collagen; mutations lead to blistering skin diseases).

Elastin. The ability of tissues to elastically recoil and return to a baseline structure after physical stress is conferred by elastin (see Fig. 1.15A). Elasticity is especially important in cardiac valves and large blood vessels, which need to accommodate recurrent pulsatile flow, as well as in the uterus, skin, and ligaments. Morphologically, elastic fibers consist of a central core of elastin with an associated mesh-like network of *fibrillin* glycoprotein. The latter relationship partially explains why fibrillin synthetic defects lead to skeletal abnormalities and weakened aortic walls, as in patients with Marfan syndrome; fibrillin also controls the availability of free TGF-β, and this function plays a role in pathogenesis of Marfan syndrome (Chapter 5).

Proteoglycans and Hyaluronan (see Fig. 1.15B)**.** Proteoglycans form highly hydrated compressible gels that confer resistance to compressive forces; in joint cartilage, proteoglycans also provide a layer of lubrication between adjacent bony surfaces. Proteoglycans consist of long polysaccharides,

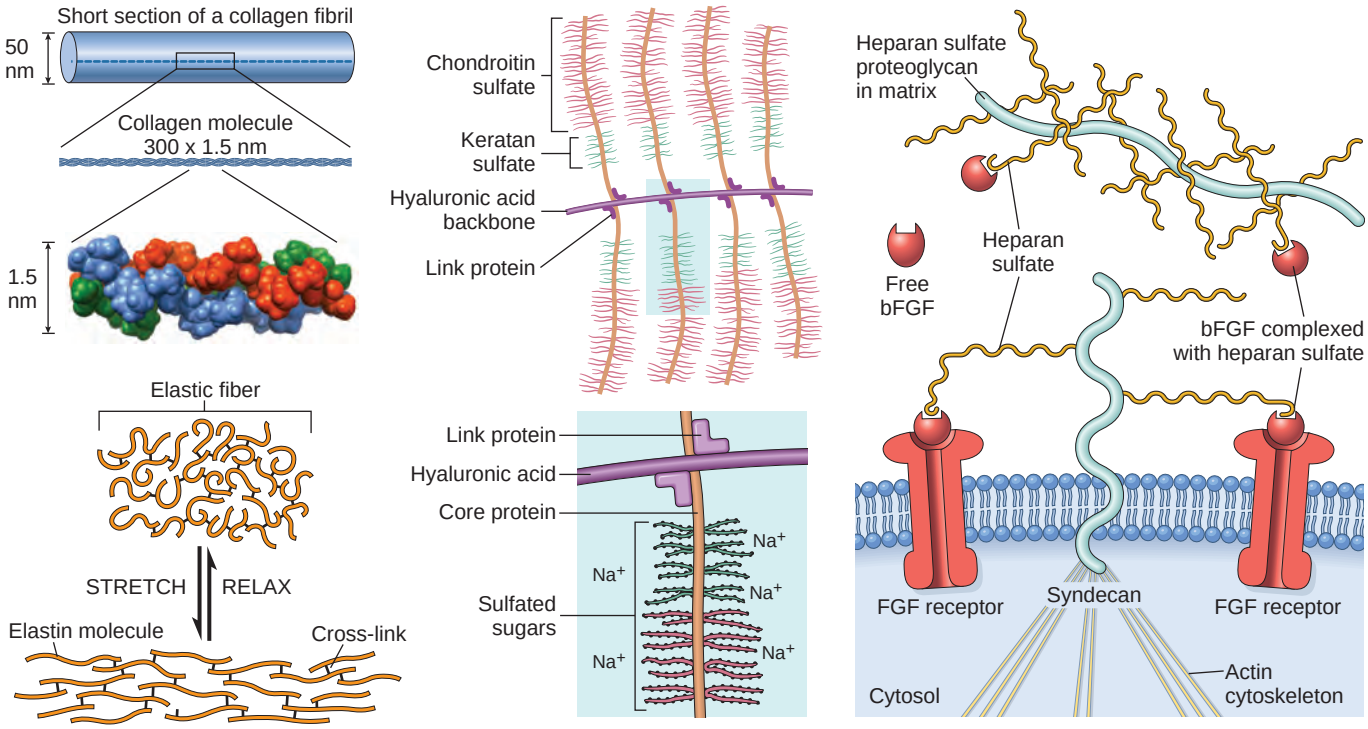

Figure 1.15 Extracellular matrix (ECM) components. (A) Fibrillar collagen and elastic tissue structures. Due to rodlike fibril stacking and extensive lateral cross-linking, collagen fibers have marked tensile strength but do not have much elasticity. Elastin is also cross-linked but differs in having large hydrophobic segments that form a dense globular configuration at rest. As stretch is exerted, the hydrophobic domains are pulled open, but the cross-links keep the tissue intact; release of the stretch tension allows the hydrophobic domains of the proteins to refold. (B) Proteoglycan structure. The highly negatively charged sulfated sugars on the proteoglycan "bristles" attract sodium and water to generate a viscous, but compressible matrix. (C) Regulation of basic fibroblast growth factor (bFGF, also known as FGF-2) activity by ECM and cellular proteoglycans. Heparan sulfate binds bFGF secreted in the ECM. Syndecan is a cell surface proteoglycan with a transmembrane core protein and extracellular glycosaminoglycan side chains that can bind bFGF and a cytoplasmic tail that interacts with the intracellular actin cytoskeleton. Syndecan side chains bind bFGF released from damaged ECM, thus facilitating bFGF interaction with cell-surface receptors. FGF, Fibroblast growth factor.

called *glycosaminoglycans* (examples are keratan sulfate and chondroitin sulfate) attached to a core protein; these are then linked to a long hyaluronic acid polymer called *hyaluronan,* in a manner reminiscent of the bristles on a round brush. The highly negatively charged nature of the densely packed sulfated sugars attracts cations (mostly sodium) and with them, abundant osmotically attracted water—producing a viscous, gel-like matrix. Besides providing compressibility to tissues, proteoglycans also serve as reservoirs for growth factors secreted into the ECM (e.g., FGF and HGF). Some proteoglycans are integral cell membrane proteins that have roles in cell proliferation, migration, and adhesion (e.g., by binding and concentrating growth factors and chemokines) (see Fig. 1.15C).

Adhesive Glycoproteins and Adhesion Receptors. Adhesive glycoproteins and adhesion receptors are structurally diverse molecules variously involved in cell-cell, cell-ECM, and ECM-ECM interactions (Fig. 1.17). Prototypical adhesive glycoproteins include *fibronectin* (a major component of the interstitial ECM) and *laminin* (a major constituent of basement membrane). *Integrins* are representative of the adhesion receptors, also known as cell adhesion molecules (CAMs); the CAMs also include immunoglobulin family members, cadherins, and selectins.

- *Fibronectin* is a large (450-kDa), disulfide-linked heterodimer that exists in tissue and plasma forms; it is synthesized by a variety of cells including fibroblasts, monocytes, and endothelium. Fibronectin has specific domains that can bind to distinct ECM components (e.g., collagen, fibrin, heparin, and proteoglycans), as well as attach to cell integrins (see Fig. 1.17A). In healing wounds, tissue and plasma fibronectin provide the scaffolding for subsequent ECM deposition, angiogenesis, and reepithelialization.
- *Laminin* is the most abundant glycoprotein in basement membranes. It is an 820-kDa cross-shaped heterotrimer that connects cells to underlying ECM components such as type IV collagen and heparan sulfate (see Fig. 1.17B). Besides mediating cell attachment to basement membrane, laminin can also modulate cell proliferation, differentiation, and motility.
- *Integrins* are a large family of transmembrane heterodimeric glycoproteins composed of α- and β-subunits; these allow cells to attach to ECM constituents such as laminin and fibronectin, thus functionally and structurally linking the intracellular cytoskeleton with the outside world. Integrins also facilitate cell-cell adhesive interactions; on leukocytes, they mediate the firm adhesion to and migration across endothelium and epithelium at sites of

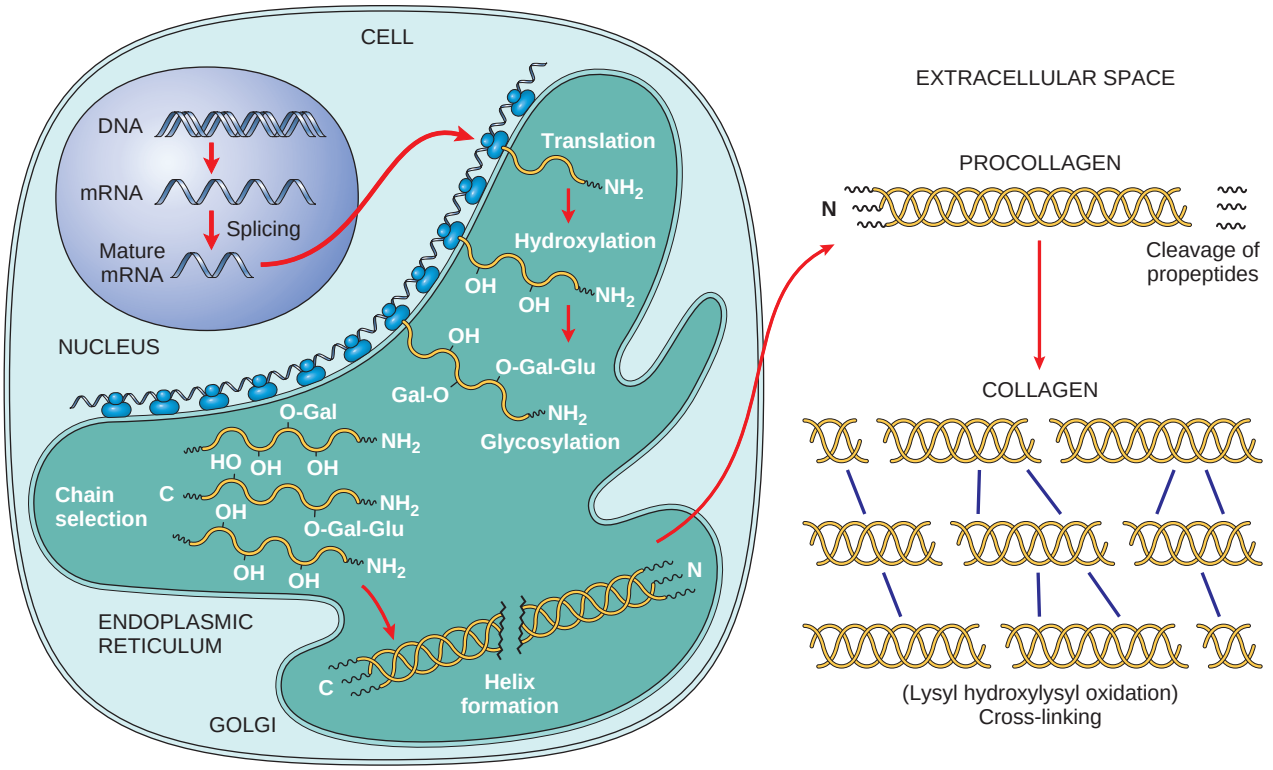

Figure 1.16 Collagen biosynthetic pathway. Some collagen types are heterotrimers (types I, V, and XI), while others are homotrimers (types II and III). The α-chains that make up fibrillar collagen molecules are synthesized as precursor pro-α-chains, with large globular polypeptide regions flanking the central triple-helical domain. After proline and lysine hydroxylation and lysine glycosylation within the endoplasmic reticulum, three procollagen chains align to form a triple helix. For all the fibrillary collagens, the carboxyl end of the propeptide is completely removed by endoproteinase activity after secretion, and the resulting triple helical rodlike domains polymerize in a staggered fashion to form fibrils. The N-terminus propeptide is variably processed depending on the collagen chain. For collagen types I and II, the N-propeptide processing is complete, while for collagens V and XI, a large portion of the N-propeptides remain attached; such "incomplete" processing can regulate fibril size. After secretion, collagen achieves lateral stability through cross-linking involving lysyl oxidase and the previously hydroxylated residues. mRNA, Messenger RNA. Defects in primary sequence, procollagen endopeptidase processing, hydroxylation, or cross-linking can all lead to connective tissue laxity. The specific structures (e.g., blood vessels, skin, bone, ligaments) affected by such disorders are predictable based on the collagen that predominates in that tissue.

inflammation (Chapter 3); they also play a critical role in platelet aggregation (Chapter 4). Integrins attach to ECM components via a tripeptide arginine-glycine-aspartic acid motif (abbreviated RGD). Besides providing focal attachment to underlying substrates, binding through the integrin receptors can trigger signaling cascades that regulate cell locomotion, proliferation, shape, and differentiation (see Fig. 1.17C).

MAINTAINING CELL POPULATIONS

Proliferation and the Cell Cycle

Cell proliferation is fundamental to organism development, to maintenance of steady-state tissue homeostasis, and to replacement of dead or damaged cells. The key elements of cellular proliferation are accurate DNA replication, coordinated synthesis of other cellular components, and equal apportionment of DNA and organelles to daughter cells through the processes of mitosis and cytokinesis.

The sequence of events that results in cell proliferation is called the *cell cycle;* it consists of G_1 (gap 1), S (DNA synthesis), G_2 (gap 2), and M (mitotic) phases; quiescent cells that are not actively cycling are in the G_0 (gap 0) state (Fig. 1.18). Cells can enter G_1 either from the G_0 quiescent cell pool or after completing a round of mitosis. Each stage requires completion of the previous step, as well as activation of necessary factors (see later); nonfidelity of DNA replication or cofactor deficiency results in arrest at various transition points.

The cell cycle is regulated by activators and inhibitors. Cell cycle progression is chaperoned by proteins called *cyclins*—named for the cyclic nature of their production and degradation—and cyclin-associated enzymes called *cyclin-dependent kinases* (CDKs) (Fig. 1.19). Constitutively synthesized CDKs acquire kinase activity—that is, the ability to phosphorylate protein substrates—by forming complexes with the relevant cyclins. Transiently increased synthesis of a particular cyclin thus leads to increased kinase activity of the appropriate CDK binding partner; as the CDK completes its round of phosphorylation, the associated cyclin is degraded and CDK activity abates. Consequently, as cyclin levels rise and fall, activity of associated CDKs will likewise wax and wane.

More than 15 cyclins have been identified; cyclins D, E, A, and B appear sequentially during the cell cycle and bind to one or more CDKs. The cell cycle thus resembles a relay

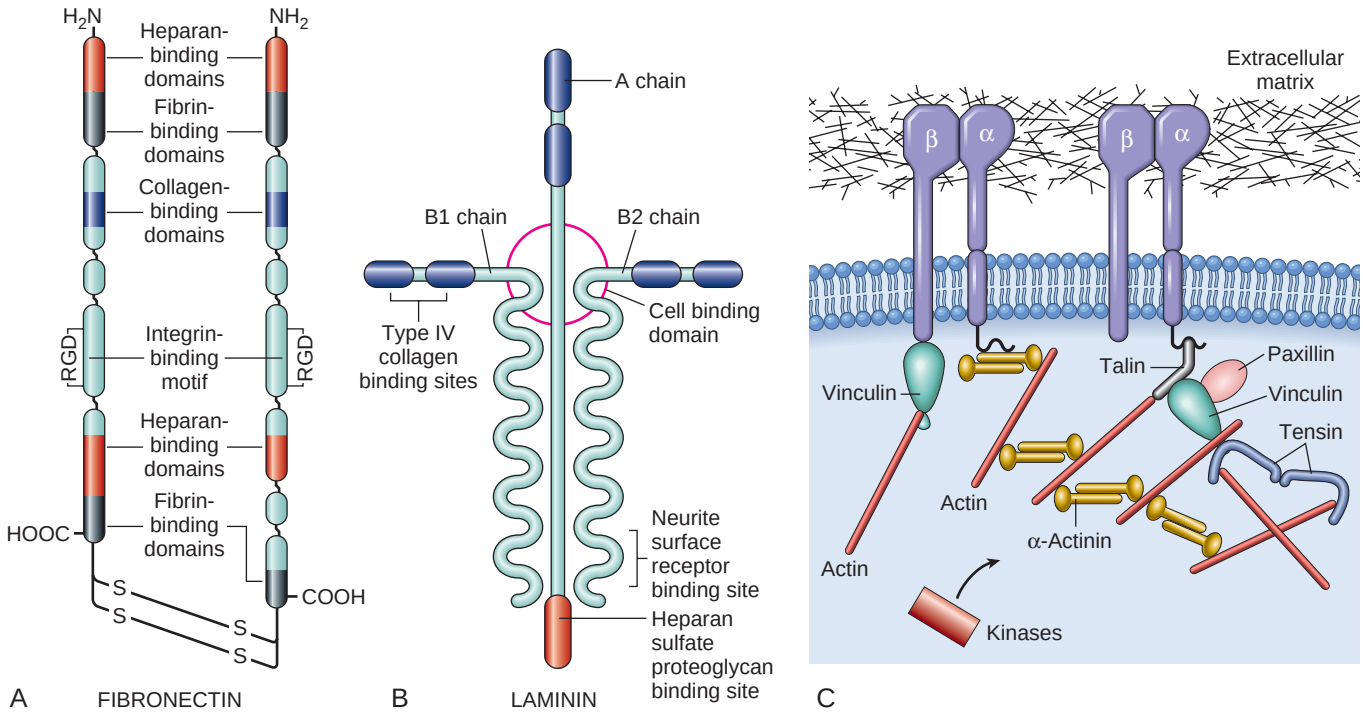

Figure 1.17 Cell and extracellular matrix (ECM) interactions: adhesive glycoproteins and integrin signaling. (A) Fibronectin consists of a disulfide-linked dimer, with several distinct domains that allow binding to ECM and to integrins, the latter through arginine-glycine-aspartic acid (RGD) motifs. (B) The cross-shaped laminin molecule is one of the major components of basement membranes; its multidomain structure allows interactions between type IV collagen, other ECM components, and cell-surface receptors. (C) Integrins and integrin-mediated signaling events at focal adhesion complexes. Each α-β heterodimeric integrin receptor is a transmembrane dimer that links ECM and the intracellular cytoskeleton. Focal adhesion complexes include linking molecules (e.g., vinculin and talin) that can recruit and activate kinases and, ultimately, trigger downstream signaling cascades.

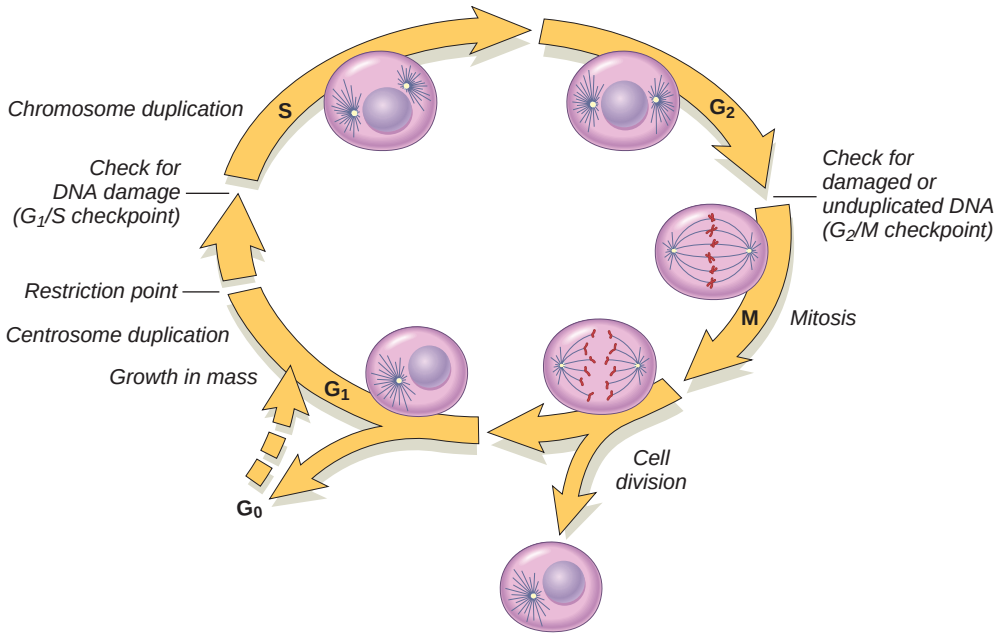

Figure 1.18 Cell cycle landmarks. The figure shows the cell cycle phases (G_0, G_1, G_2, S, and M), the location of the G_1 restriction point, and the G_1/S and G_2/M cell cycle checkpoints. *G_1 restriction point* refers to the stage in G_1 where the cell is committed to advance further into the cell cycle without requiring any more of the growth signal that initiated cell division. Cells from labile tissues such as the epidermis and the gastrointestinal tract may cycle continuously; stable cells such as hepatocytes are quiescent but can enter the cell cycle; permanent cells such as neurons and cardiac myocytes have lost the capacity to proliferate. (Modified from Pollard TD, Earnshaw WC: *Cell Biology,* Philadelphia, 2002, Saunders.)

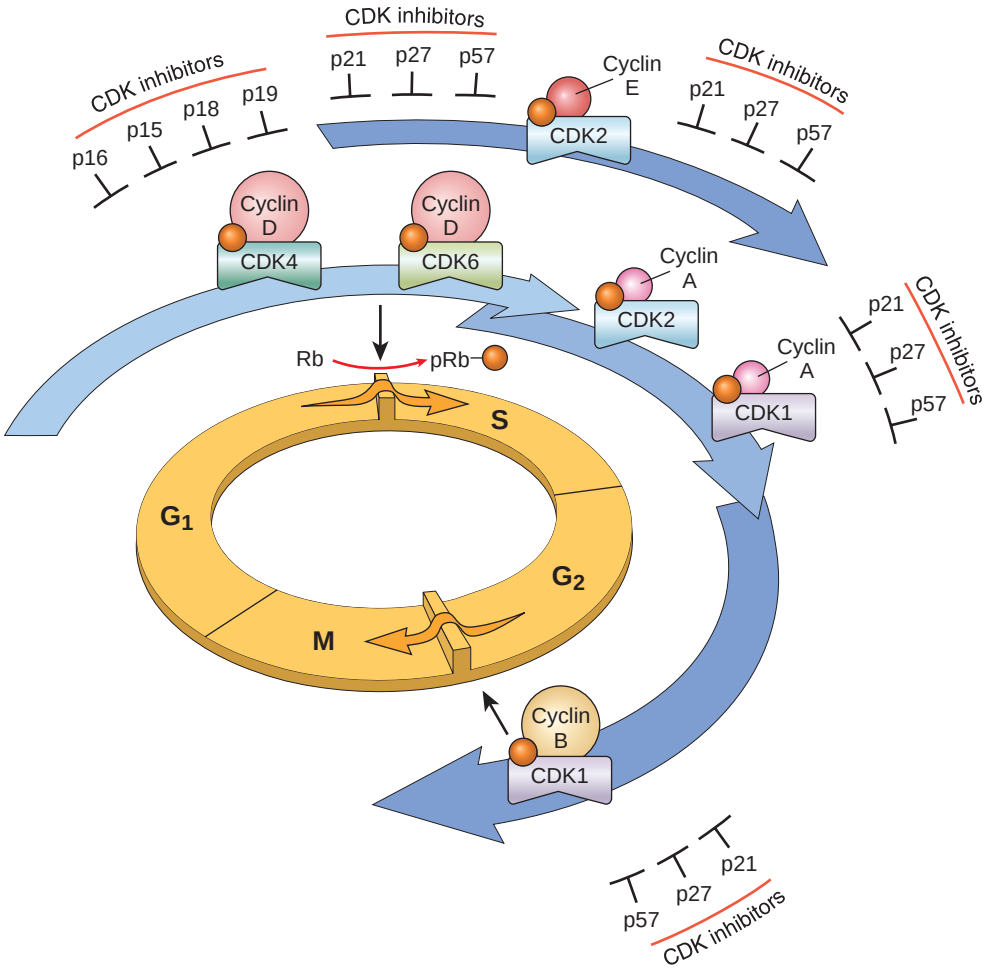

Figure 1.19 Role of cyclins, cyclin-dependent kinases (CDKs) and CDK inhibitors (CDKIs) in regulating the cell cycle. Shaded arrows represent the phases of the cell cycle during which specific cyclin-CDK complexes are active. As illustrated, cyclin D-CDK4, cyclin D-CDK6, and cyclin E-CDK2 regulate the G_1-to-S transition by phosphorylating the Rb protein (pRb). Cyclin A-CDK2 and cyclin A-CDK1 are active in the S phase. Cyclin B-CDK1 is essential for the G_2-to-M transition. Two families of CDK inhibitors can block activity of CDKs and progression through the cell cycle. The so-called INK4 inhibitors, composed of p15, p16, p18, and p19, act on cyclin D-CDK4 and cyclin D-CDK6. The other family of three inhibitors, p21, p27, and p57, can inhibit all CDKs.

race in which each leg is regulated by a distinct set of cyclins: as one collection of cyclins leaves the track, the next set takes over.

Surveillance mechanisms primed to sense DNA or chromosomal damage are embedded within the cell cycle. These quality control *checkpoints* ensure that cells with genetic imperfections do not complete replication. Thus the G_1-S checkpoint monitors DNA integrity before irreversibly committing cellular resources to DNA replication. Later in the cell cycle, the G_2-M restriction point insures that there has been accurate genetic replication before the cell actually divides. When cells do detect DNA irregularities, checkpoint activation delays cell cycle progression and triggers DNA repair mechanisms. If the genetic derangement is too severe to be repaired, cells either undergo apoptosis or enter a nonreplicative state called *senescence*—primarily through p53-dependent mechanisms (see later).

Enforcing the cell cycle checkpoints is the job of *CDK inhibitors* (CDKIs); they accomplish this by modulating CDK-cyclin complex activity. There are several different CDKIs.

- One family of CDKIs—composed of three proteins called p21 (CDKN1A), p27 (CDKN1B), and p57 (CDKN1C)—broadly inhibits multiple CDKs.
- Another family of CDKIs has selective effects on cyclin CDK4 and cyclin CDK6; these proteins are called p15 (CDKN2B), p16 (CDKN2A), p18 (CDKN2C), and p19 (CDKN2D).
- Defective CDKI checkpoint proteins allow cells with damaged DNA to divide, resulting in mutated daughter cells at risk for malignant transformation.

An equally important aspect of cell growth and division is the biosynthesis of the membranes, cytosolic proteins, and organelles necessary to make two daughter cells. Thus as growth factor receptor signaling stimulates cell cycle progression, it also activates events that promote the metabolic changes that support growth. Chief among these is the switch to aerobic glycolysis (with the counter-intuitive reduction in oxidative phosphorylation), also called the *Warburg effect*. These alterations in cell metabolism are an

important element in cancer cell growth and are discussed in greater detail in Chapter 7.

Stem Cells

Stem cells have the dual property of being able to self renew and to give rise to differentiated cells and tissues. During development, *totipotent stem cells* can give rise to the full range of differentiated tissues; in the mature organism, *adult stem cells* only have the capacity to replace damaged cells and maintain cell populations within the tissues where they reside. There are also populations of stem cells between these extremes with varying capacities to differentiate into multiple (but limited) cell lineages. Thus depending on the source and stage of development, there are limits on the cell types that a "stem cell" can generate.

In normal tissues—without healing, degeneration, or neoplasia—there is a homeostatic equilibrium between replication, self-renewal, and differentiation of stem cells and death of mature, fully differentiated cells (Fig. 1.20). The dynamic relationship between stem cells and terminally differentiated parenchyma is particularly evident in the continuously dividing epithelium of the skin; stem cells at the basal layer of the epithelium divide and their daughter cells progressively differentiate as they migrate to the upper layers of the epithelium before dying and being shed.

Under conditions of homeostasis, stem cells are maintained by self-renewal, which can involve two types of cell division:

- *Asymmetric division* refers to cell replication in which one daughter cell enters a differentiation pathway and gives rise to mature cells, while the other remains undifferentiated and retains its self-renewal capacity.
- *Symmetric division* occurs when both daughter cells retain self-renewal capacity. Such replication occurs early in embryogenesis—when stem cell populations are expanding—and under stress conditions, as in bone marrow repopulation after ablative chemotherapy.

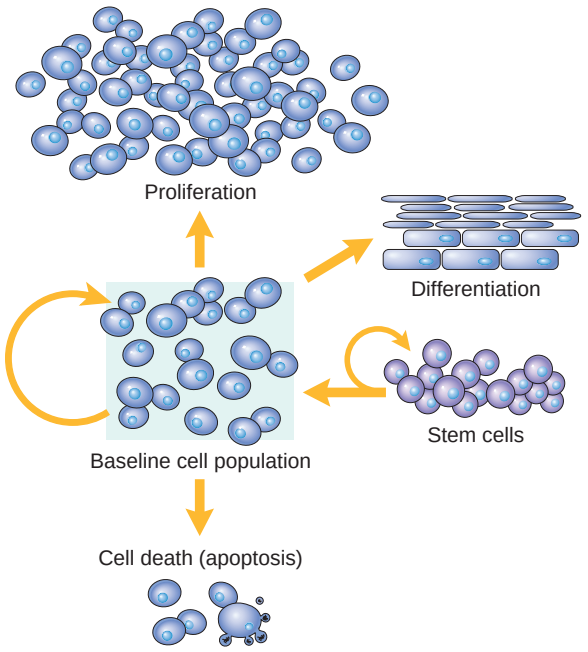

Figure 1.20 Mechanisms regulating cell populations. Cell numbers can be altered by increased or decreased rates of stem cell input, cell death resulting from apoptosis, or changes in the rates of proliferation or differentiation. (Modified from McCarthy NJ, et al: Apoptosis in the development of the immune system: growth factors, clonal selection and bcl-2, *Cancer Metastasis Rev* 11:157, 1992.)

Although some researchers separate stem cells into multiple different subsets, there are fundamentally only two varieties.

- *Embryonic stem (ES) cells* are the most undifferentiated. They are present in the inner cell mass of the blastocyst, have virtually limitless cell renewal capacity, and can give rise to every cell in the body; they are thus said to be *totipotent* (Fig. 1.21). While ES cells can be maintained for extended periods without differentiating, they can be induced under appropriate culture conditions to form specialized cells of all three germ cell layers.
- *Tissue stem cells* (also called *adult stem cells*) are found in intimate association with the differentiated cells of a given tissue. They are normally protected within specialized tissue microenvironments called *stem cell niches*. Such niches have been demonstrated in many organs, most notably the bone marrow, where hematopoietic stem cells characteristically congregate in perivascular niches, and the intestines, where epithelial stem cells are confined to the crypts. Other stem cell niches include the bulge region of hair follicles, the limbus of the cornea, and the subventricular zone in the brain. Soluble factors and other cells within the niches regulate the balance between stem cell quiescence and expansion and differentiation (Fig. 1.22).

Adult stem cells have a limited repertoire *(lineage potential)* of differentiated cells that they can generate. Thus although adult stem cells can maintain tissues with high (e.g., skin, and gastrointestinal tract) or low (e.g., endothelial) cell turnover, the adult stem cells in any given tissue can usually produce only those cells normally found within that tissue.

Hematopoietic stem cells continuously replenish all the cellular elements of the blood as they exit the circulation, senesce, or are otherwise consumed. They can be isolated directly from bone marrow, as well as from the peripheral blood after administration of certain colony-stimulating factors that induce their release from bone marrow niches. Although they are overall rare, hematopoietic stem cells can be purified to virtual purity based on cell surface markers. Clinically, these stem cells can be used to repopulate marrows depleted after chemotherapy (e.g., for leukemia) or to provide normal precursors to correct various blood cell defects (e.g., sickle cell disease; see Chapter 14).

Besides hematopoietic stem cells, the bone marrow (and, notably, other tissues such as fat) also contains a population of *mesenchymal stem cells*. These are multipotent cells that can differentiate into a variety of stromal cells including chondrocytes (cartilage), osteocytes (bone), adipocytes (fat), and myocytes (muscle). Because these cells can be massively expanded and can generate a locally immunosuppressive microenvironment (thus potentially evading rejection), they represent a potential means of manufacturing stromal cellular scaffoldings for tissue regeneration.

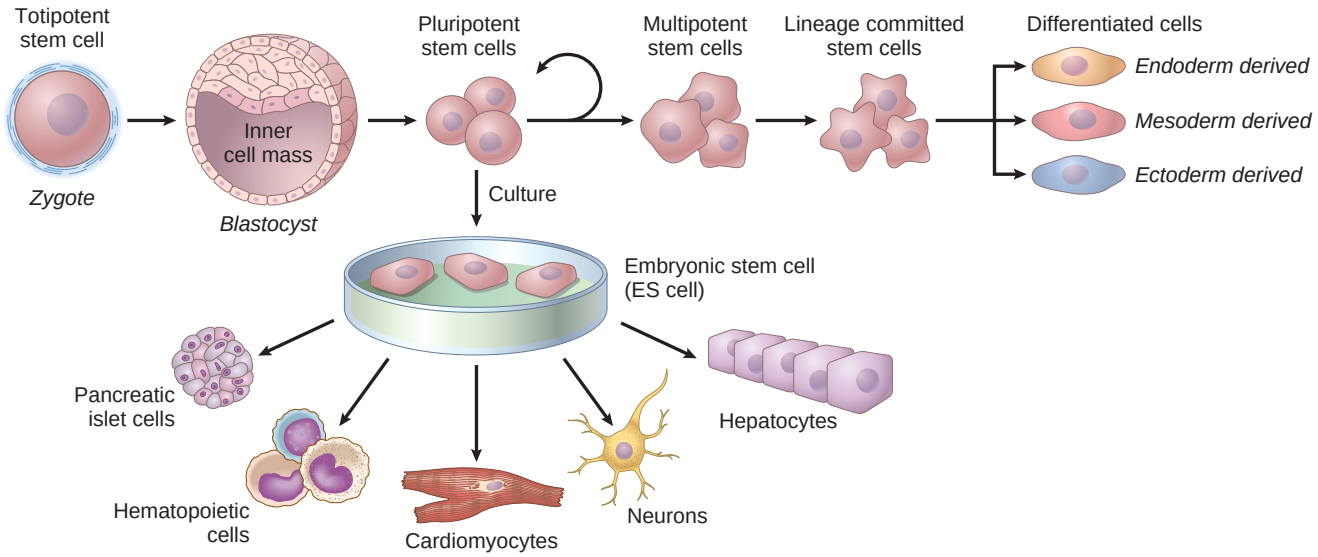

Figure 1.21 Embryonal stem *(ES)* cells. The zygote, formed by the union of sperm and egg, divides to form blastocysts, and the inner cell mass of the blastocyst generates the embryo. The pluripotent cells of the inner cell mass, known as ES cells, can be induced to differentiate into cells of multiple lineages. In the embryo, pluripotent stem cells can asymmetrically divide to yield a residual stable pool of ES cells in addition to generating populations that have progressively more restricted developmental capacity, eventually generating stem cells that are committed to just specific lineages. ES cells can be cultured in vitro and induced to differentiate into cells characteristic of all three germ layers.

Regenerative Medicine

The burgeoning field of regenerative medicine has been made possible by the ability to identify, isolate, expand, and transplant stem cells. Theoretically the differentiated progeny of ES or adult stem cells can be used to repopulate damaged tissues or even to construct entire replacement organs. There is, therefore, considerable interest in therapeutic opportunities for restoring tissues that have low intrinsic regenerative capacity, such as myocardium or neurons, to promote healing after myocardial infarction or stroke, respectively. Despite improved ability to purify and expand stem cells, success has, thus far, been limited by difficulties in introducing and functionally integrating replacement cells at sites of damage.

Another issue arises from the immunologic reactivity of most stem cells. Although mesenchymal stem cells may be relatively immunologically privileged, most other adult stem cells, as well as ES cells (from fertilized blastocysts), express histocompatibility molecules—human leukocyte antigen (HLA) in humans (see Chapters 3 and 6)—that provoke immunologic rejection when transplanted. Hence considerable effort has been expended to generate cells with the totipotential characteristics of ES cells from cells that can be harvested from an individual patient. This would, in principle, allow new tissues to be generated and transplanted

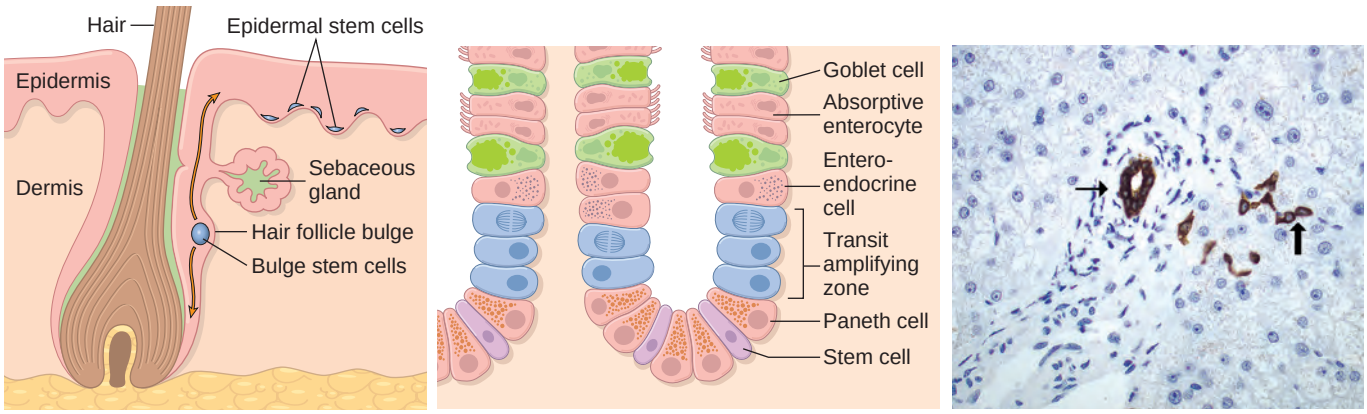

Figure 1.22 Stem cell niches in various tissues. (A) Skin stem cells are located in the bulge area of the hair follicle, in sebaceous glands, and in the lower layer of the epidermis. (B) Small intestinal crypt base columnar (CBC) stem cells are located at the base of the crypt interspersed between Paneth cells. (C) Liver stem cells (oval cells) are located in the canals of Hering (thick arrow), structures that connect bile ductules (thin arrow) to parenchymal hepatocytes. Bile duct cells and canals of Hering are highlighted here by an immunohistochemical stain for cytokeratin 7. (C, Courtesy Tania Roskams, MD, University of Leuven, Belgium.)

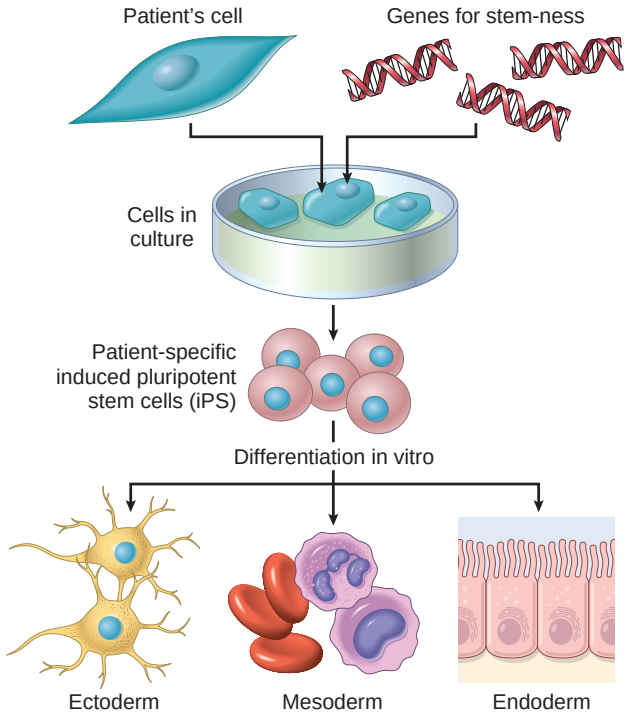

Figure 1.23 Induced pluripotent stem *(iPS)* cells. Genes that confer stem cell properties are introduced into a patient's differentiated cells, giving rise to stem cells that can be induced to differentiate into various lineages. (Modified from Hochedlinger K, Jaenisch R: Nuclear transplantation, embryonic stem cells, and the potential for cell therapy, *N Engl J Med* 349:275, 2003.)

without fear of immunologic graft rejection. To accomplish this, a handful of genes have been identified whose products can—remarkably—reprogram somatic cells to achieve the "stem-ness" of ES cells. When such genes are introduced into fully differentiated cells (e.g., fibroblasts), *induced pluripotent stem (iPS) cells* are generated (Fig. 1.23). While not yet in practice, their differentiated progeny could be remarkable therapeutic agents, e.g., by generating insulin-secreting β cells in a patient with diabetes.

Concluding Remarks. This survey of selected topics in cell biology will serve as a basis for our later discussions of pathology, and we will refer back to it throughout the book. Students should, however, remember that this summary is intentionally brief, and more information about some of the fascinating topics reviewed here can be readily found in textbooks devoted to cell and molecular biology.

CHAPTER 2

Cell Injury, Cell Death, and Adaptations

Scott A. Oakes

CHAPTER CONTENTS

INTRODUCTION TO PATHOLOGY

Pathology is the study of the structural, biochemical, and functional changes in cells, tissues, and organs that underlie disease. By the use of morphologic, microbiologic, immunologic, and molecular techniques, pathology attempts to explain the whys and wherefores of the signs and symptoms manifested by patients while providing a rational basis for clinical care and therapy. It thus serves as the bridge between the basic sciences and clinical medicine, and is the scientific foundation for all of medicine. In Chapter 1 we examined the cellular and molecular properties of healthy cells. In this chapter, we will build on that knowledge to discuss the fundamental mechanisms that underlie various forms of cell injury and death.

Traditionally, the study of pathology is divided into general pathology and systemic pathology. General pathology is concerned with the common reactions of cells and tissues to injurious stimuli. Such reactions are often not tissue specific: thus, acute inflammation in response to bacterial infections produces a very similar reaction in most tissues. On the other hand, systemic pathology examines the alterations and underlying mechanisms in diseases of particular organ systems. In this book, we first cover the principles of general pathology and then proceed to specific disease processes as they affect different organs.

The four aspects of a disease process that form the core of pathology are causation *(etiology)*, biochemical and molecular mechanisms *(pathogenesis)*, the associated structural *(morphologic changes)* and functional alterations in cells and organs, and the resulting clinical consequences *(clinical manifestations).*

- *Etiology is the initiating cause of a disease.* Although there are myriad factors that cause disease, all can be grouped into two broad classes: genetic (e.g., inherited or acquired mutations, and disease-associated gene variants, or polymorphisms) and environmental (e.g., infectious, nutritional, chemical, physical). The idea that one etiologic agent is the cause of one disease arose from the study of infections and inherited disorders caused by single gene anomalies, but the majority of diseases are not this simple. In fact, most common afflictions, such as atherosclerosis and cancer, arise from the effects of various environmental insults on a genetically susceptible individual and hence are referred to as being multifactorial. The relative contribution of inherited susceptibility and environmental influences varies in different diseases, and it is challenging to precisely define their roles in most multifactorial diseases.
- *Pathogenesis refers to the sequence of molecular, biochemical, and cellular events that lead to the development of disease.* Thus, pathogenesis explains how the underlying etiologies produce the morphologic and clinical manifestations of the disease. The study of pathogenesis is a central focus of pathology. Even when the initial cause is known (e.g., infection or mutation), it is many steps removed from the expression of the disease. For example, to truly understand the disorder cystic fibrosis it is essential to know not only the defective gene and gene product, but also the biochemical and morphologic events that lead to clinically significant disease in the lungs, pancreas, and other organs. New technological advances, particularly the use of so-called "omics" technologies (genomics, proteomics, metabolomics) to interrogate diseases, hold great promise for elucidating pathogenic mechanisms. Hopefully, the application of these methods and the analysis of mounds of "big data" so generated will lead not only to better understanding of pathogenesis but also to the identification of *biomarkers* that predict disease progression and therapeutic responses. This, of course, is the goal of *precision medicine*.
- *Morphologic changes refer to the structural alterations in cells or tissues that are characteristic of a disease and hence diagnostic of an etiologic process.* Traditionally, diagnostic pathology has used morphology to determine the nature of disease and to follow its progression. Although morphology remains a cornerstone of diagnosis, it is now routinely supplemented by analysis of protein expression and genetic alterations. Nowhere is this more striking than in the study of neoplasms; breast cancers that are indistinguishable morphologically may result from different genetic abnormalities that result in widely different courses, therapeutic responses, and prognoses. Molecular analysis by techniques such as next-generation sequencing (Chapter 7) has revealed genetic differences that predict the behavior of tumors as well as their response to therapies, an increasing number of which are now chosen on the basis of the presence (or absence) of specific molecular alterations.
- *Clinical manifestations.* The end results of genetic, biochemical, and structural changes in cells and tissues are functional abnormalities that lead to the clinical manifestations (symptoms and signs) of disease, as well as its progression (clinical course and outcome). Hence, clinicopathologic correlations are very important in the study of disease.

Virtually all diseases start with molecular or structural alterations in cells. This concept of the cellular basis of disease was first put forth in the nineteenth century by Rudolf Virchow, known as the father of modern pathology. Virchow emphasized the idea that individuals are sick because their cells are sick. We therefore begin our consideration of pathology with the study of the causes, mechanisms, and morphologic and biochemical correlates of *cell injury*. Injury to cells and to the extracellular matrix ultimately leads to *tissue and organ injury,* which determines the morphologic and clinical patterns of disease.

OVERVIEW OF CELLULAR RESPONSES TO STRESS AND NOXIOUS STIMULI

The normal cell is confined to a fairly narrow range of function and structure dictated by its state of metabolism, differentiation, and specialization; by constraints imposed by neighboring cells; and by the availability of metabolic substrates. It is nevertheless able to handle physiologic demands, maintaining a healthy steady state called *homeostasis*. *Adaptations* are reversible functional and structural responses to changes in physiologic states (e.g., pregnancy) and some pathologic stimuli, during which new but altered

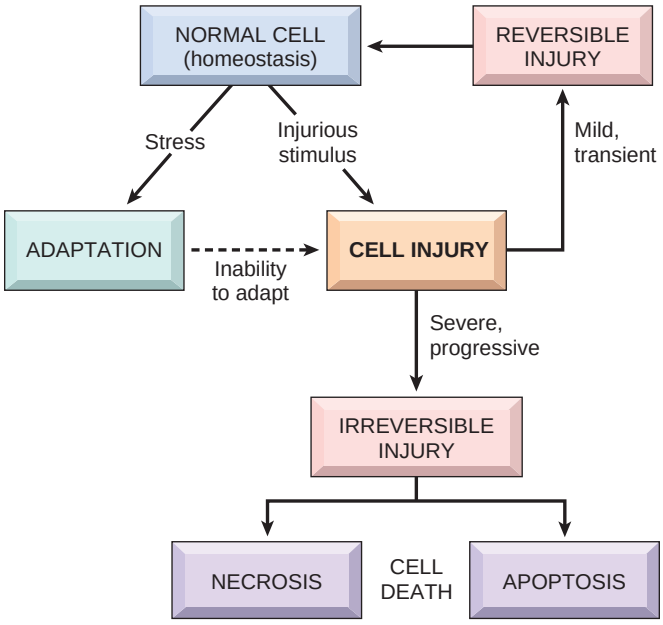

Figure 2.1 Stages of the cellular response to stress and injurious stimuli.

steady states are achieved, allowing the cell to survive and continue to function (Fig. 2.1). The adaptive response may consist of an increase in the size (hypertrophy) and functional activity of cells, an increase in cell number (hyperplasia), a decrease in the size and metabolic activity of cells (atrophy), or a change in the phenotype of cells (metaplasia). If the stress is eliminated, the cell can return to its original state without having suffered any harmful consequences.

If the limits of adaptive responses are exceeded or if cells are exposed to damaging insults, deprived of critical nutrients, or compromised by mutations that affect essential cellular functions, a sequence of events follows that is termed *cell injury* (see Fig. 2.1). Cell injury is *reversible* up to a point, but if the injurious stimulus is persistent or severe, the cell suffers *irreversible injury* and ultimately undergoes *cell death*. *Adaptation, reversible injury,* and *cell death* may be stages of progressive impairment following different types of insults. For instance, in response to increased hemodynamic loads, the heart muscle becomes enlarged, a form of adaptation, which because of increased metabolic demands is more susceptible to injury. If the blood supply to the myocardium is compromised or inadequate, the muscle first suffers reversible injury, manifested by certain cytoplasmic changes (described later). Unless the blood supply is quickly restored, the cells suffer irreversible injury and die (Fig. 2.2).

The removal of damaged, unneeded, and aged cells through *cell death* is a normal and essential process in embryogenesis, the development of organs, and the maintenance of homeostasis into adulthood. Conversely, excessive cell death as a result of progressive injury is one of the most crucial events in the evolution of disease in any tissue or organ. It results from diverse causes, including ischemia (reduced blood flow), infection, and toxins. There are two principal pathways of cell death, *necrosis* and *apoptosis*. Nutrient deprivation triggers an adaptive cellular response called *autophagy* that may also culminate in cell death. A detailed discussion of these and some other, less common pathways of cell death follows later in the chapter.

Stresses of different types may induce changes in cells and tissues other than typical adaptations, cell injury, and death. Metabolic derangements and chronic injury may be associated with *intracellular accumulations* of a number of substances, including proteins, lipids, and carbohydrates. Calcium may be deposited at sites of cell death, resulting in *pathologic calcification*. Finally, the normal process of *aging* is accompanied by characteristic morphologic and functional changes in cells.

This chapter discusses first the causes, mechanisms, and consequences of the various forms of cell damage, including reversible cell injury and cell death. We conclude with cellular adaptations to stress, and three other processes that affect

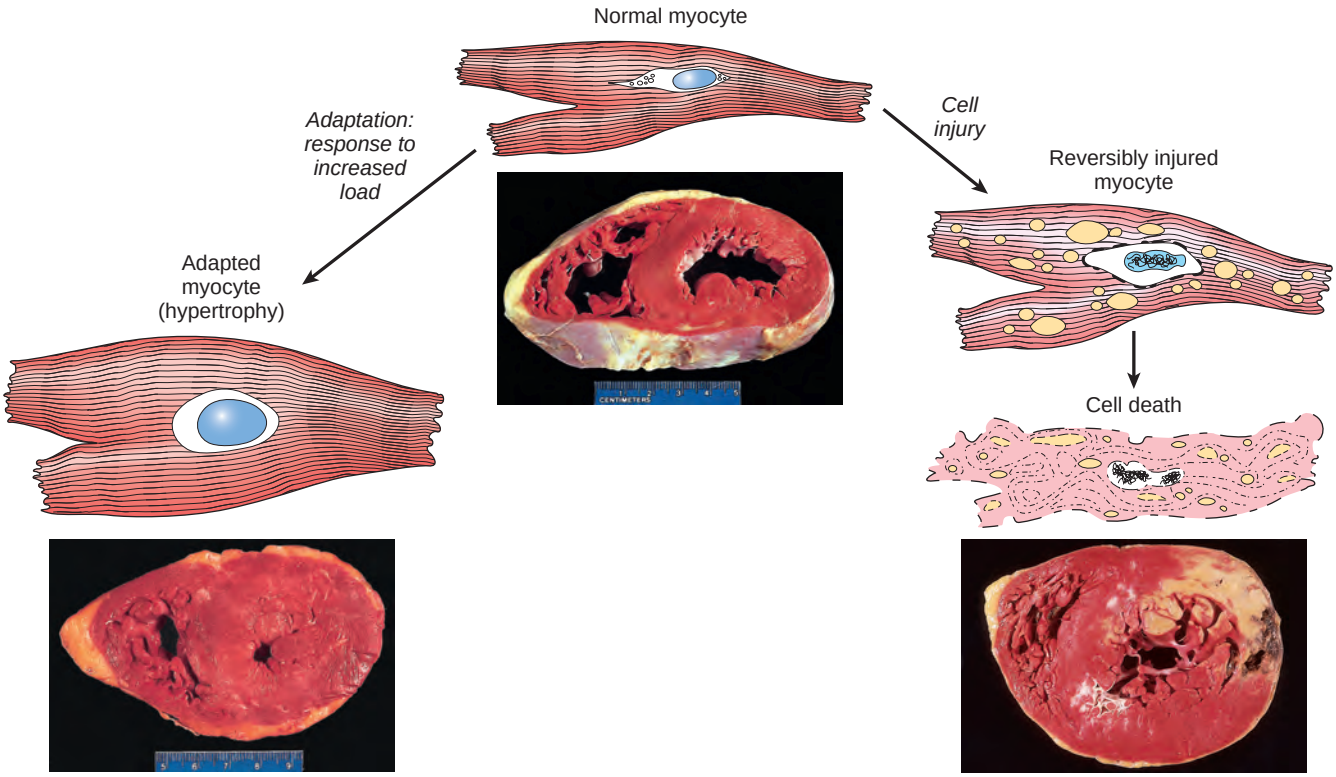

Figure 2.2 The relationship among normal, adapted, reversibly injured, and dead myocardial cells. All three transverse sections of the heart have been stained with triphenyltetrazolium chloride, an enzyme substrate that colors viable myocardium magenta. The cellular adaptation shown here is myocardial hypertrophy *(lower left)*, caused by increased blood pressure requiring greater mechanical effort by myocardial cells. This adaptation leads to thickening of the left ventricular wall (compare with the normal heart). In reversibly injured myocardium (illustrated schematically, *right*), there are functional alterations, usually without any gross or microscopic changes but sometimes with cytoplasmic changes such as cellular swelling and fat accumulation. In the specimen showing necrosis, a form of cell death *(lower right)*, the light area in the posterolateral left ventricle represents an acute myocardial infarction caused by reduced blood flow (ischemia).

cells and tissues: intracellular accumulations, pathologic calcification, and cell aging.

Causes of Cell Injury

The causes of cell injury range from the mechanical trauma of an automobile accident to subtle cellular abnormalities, such as a mutation causing lack of a vital enzyme that impairs normal metabolic function. Most injurious stimuli can be grouped into the following broad categories.

Oxygen Deprivation

Hypoxia is a deficiency of oxygen, which causes cell injury by reducing aerobic oxidative respiration. Hypoxia is an extremely important and common cause of cell injury and cell death. Causes of hypoxia include reduced blood flow *(ischemia);* inadequate oxygenation of the blood due to cardiorespiratory failure; and decreased oxygen-carrying capacity of the blood, as in anemia or carbon monoxide poisoning and severe blood loss. Depending on the severity of the hypoxic state, cells may adapt, undergo injury, or die. For example, if an artery is narrowed, the tissue supplied by that vessel may initially shrink in size (atrophy), whereas more severe or sudden hypoxia induces cell injury and cell death.

Physical Agents

Physical agents capable of causing cell injury include mechanical trauma, extremes of temperature (burns and deep cold), sudden changes in atmospheric pressure, radiation, and electric shock (Chapter 9).

Chemical Agents and Drugs

The list of chemicals that may produce cell injury defies compilation. Simple chemicals such as glucose or salt in hypertonic concentrations may cause cell injury directly or by deranging electrolyte and fluid balance in cells. Even oxygen at high concentrations is toxic. Trace amounts of *poisons,* such as arsenic, cyanide, or mercury, may damage sufficient numbers of cells within minutes or hours to cause death. Other potentially injurious substances are our daily companions: environmental pollutants, insecticides, and herbicides; industrial and occupational hazards, such as carbon monoxide and asbestos; recreational drugs such as alcohol; and the ever increasing variety of therapeutic drugs, many of which have toxic side effects. These are discussed further in Chapter 9.

Infectious Agents

These agents range from submicroscopic viruses to tapeworms several feet in length. In between are rickettsiae, bacteria, fungi, and higher forms of parasites. The ways by which these biologic agents cause injury are diverse (Chapter 8).

Immunologic Reactions

The immune system serves an essential function in defense against infectious pathogens, but immune reactions may also cause cell injury. Injurious reactions to endogenous self antigens are responsible for autoimmune diseases (Chapter 6). Immune reactions to many external agents, such as viruses and environmental substances, are also important causes of cell and tissue injury (Chapters 3 and 6).

Genetic Abnormalities

As described in Chapter 5, genetic aberrations as extreme as an extra chromosome, as in Down syndrome, or as subtle as a single base pair substitution leading to an amino acid substitution, as in sickle cell anemia, may produce highly characteristic clinical phenotypes ranging from congenital malformations to anemias. Genetic defects may cause cell injury because of deficient protein function, such as enzyme defects in inborn errors of metabolism, or accumulation of damaged DNA or misfolded proteins, both of which trigger cell death when they are beyond repair. DNA sequence variants that are common in human populations (polymorphisms) can also influence the susceptibility of cells to injury by chemicals and other environmental insults.

Nutritional Imbalances

Nutritional imbalances continue to be major causes of cell injury. Protein-calorie deficiencies cause an appalling number of deaths, chiefly among lower-income populations. Deficiencies of specific vitamins are found throughout the world (Chapter 9). Nutritional shortages can be self-imposed, as in anorexia nervosa (a psychological disorder of inadequate food consumption) or stem from food shortages or poor diet. Ironically, nutritional excess also is an important cause of cell injury. Obesity is rampant in the United States and is associated with an increased incidence of several important diseases, such as diabetes and cancer. In addition to the problems of undernutrition and overnutrition, the composition of the diet makes a significant contribution to a number of diseases. For example, diets high in certain lipids lead to elevated serum cholesterol and predispose to atherosclerosis, a leading risk factor for cardiovascular disease, the number one killer of adults in the United States.

The Progression of Cell Injury and Death

It is useful to describe the basic alterations that occur in damaged cells before discussing the mechanisms that bring about these changes. All stresses and noxious influences exert their effects first at the molecular or biochemical level. There is a time lag between the stress and the morphologic changes of cell injury or death; understandably, the early changes are subtle and are only detected with highly sensitive methods of examination (Fig. 2.3). With histochemical, ultrastructural, or biochemical techniques, changes may be seen in minutes to hours after injury, whereas changes visible by light microscopy or the naked eye may take considerably longer (hours to days) to appear. As would be expected, the morphologic manifestations of necrosis take more time to develop than those of reversible damage. For example, in ischemia of the myocardium, cell swelling is a reversible morphologic change that may occur in a matter of minutes, and is an indicator of ongoing cellular damage that may progress to irreversibility within 1 or 2 hours. Unmistakable light microscopic evidence of cell death, however, may not be seen until 4 to 12 hours after onset of ischemia.

The sequential structural changes in cell injury progressing to cell death are illustrated in Fig. 2.4 and described later.

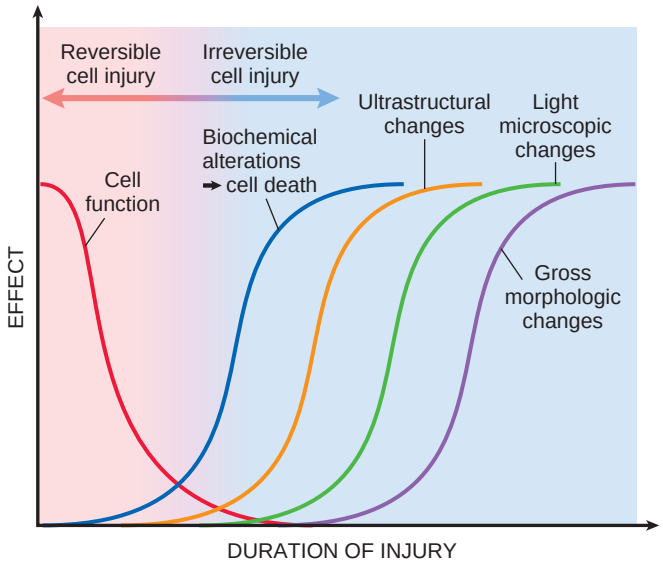

Figure 2.3 Sequential development of biochemical and morphologic changes in cell injury. Cells may become rapidly nonfunctional after the onset of injury, although they may still be viable, with potentially reversible damage; a longer duration of injury may lead to irreversible damage and cell death. Note that irreversible biochemical alterations may cause cell death, and typically this precedes ultrastructural, light microscopic, and grossly visible morphologic changes.

Within limits, the cell can repair the alterations seen in reversible injury and if the injurious stimulus abates, may return to normalcy. Persistent or excessive injury, however, causes cells to pass the rather nebulous "point of no return" into irreversible injury and cell death. Different injurious stimuli induce death mainly by necrosis and/or apoptosis (see Fig. 2.4 and Table 2.1).

REVERSIBLE CELL INJURY

Reversible cell injury is characterized by functional and structural alterations in early stages or mild forms of injury, which are correctable if the damaging stimulus is removed. Two features are consistently seen in reversibly injured cells.

- Early alterations in reversible injury include *generalized swelling of the cell* and its organelles, blebbing of the plasma membrane, detachment of ribosomes from the endoplasmic reticulum (ER), and clumping of nuclear chromatin. Swelling of cells results from influx of water. This is usually caused by failure of the adenosine triphosphate (ATP)-dependent Na^+-K^+ plasma membrane pump due to depletion of ATP resulting from oxygen deficiency, which interferes with mitochondrial oxidative phosphorylation, or mitochondrial damage by radiation or toxins (discussed later).
- *Fatty change* occurs in organs that are actively involved in lipid metabolism (e.g., liver). It results when toxic injury disrupts metabolic pathways and leads to rapid accumulation of triglyceride-filled lipid vacuoles. This is discussed in Chapter 18.
- Other alterations are described in the following sections.

Table 2.1 Features of Necrosis and Apoptosis

Feature	Necrosis	Apoptosis
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis, karyorrhexis, karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No
Physiologic or pathologic role	Usually pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially DNA damage

MORPHOLOGY

Cellular swelling is the earliest manifestation of almost all forms of injury to cells (Fig. 2.5B). When it affects many cells, it causes pallor, increased turgor, and increased weight of the affected organ. On microscopic examination, small clear vacuoles may be seen within the cytoplasm; these represent distended and pinched-off segments of the ER. This pattern of nonlethal injury is sometimes called **hydropic change** or **vacuolar degeneration.** The cytoplasm of injured cells appears red (eosinophilc) when stained with hematoxylin and eosin (H&E) due to loss of RNA, which binds the blue hematoxylin dye. The eosinophilia becomes more pronounced with progression toward necrosis.

The ultrastructural changes of reversible cell injury, visible by electron microscopy (Fig. 2.6B), include the following:

1. Plasma membrane alterations, such as blebbing, blunting, and loss of microvilli
2. Mitochondrial changes, including swelling and the appearance of small amorphous densities
3. Accumulation of "myelin figures" in the cytosol composed of phospholipids derived from damaged cellular membranes
4. Dilation of the ER, with detachment of polysomes
5. Nuclear alterations, with disaggregation of granular and fibrillar elements

CELL DEATH

There are two principal types of cell death, necrosis and apoptosis, which differ in their mechanisms, morphology, and roles in physiology and disease (see Table 2.1). Severe mitochondrial damage with depletion of ATP and rupture of lysosomal and plasma membranes are typically associated with necrosis. Necrosis occurs in many commonly encountered injuries, such as those following ischemia, exposure to toxins, various infections, and trauma. Apoptosis has many unique features (see later).

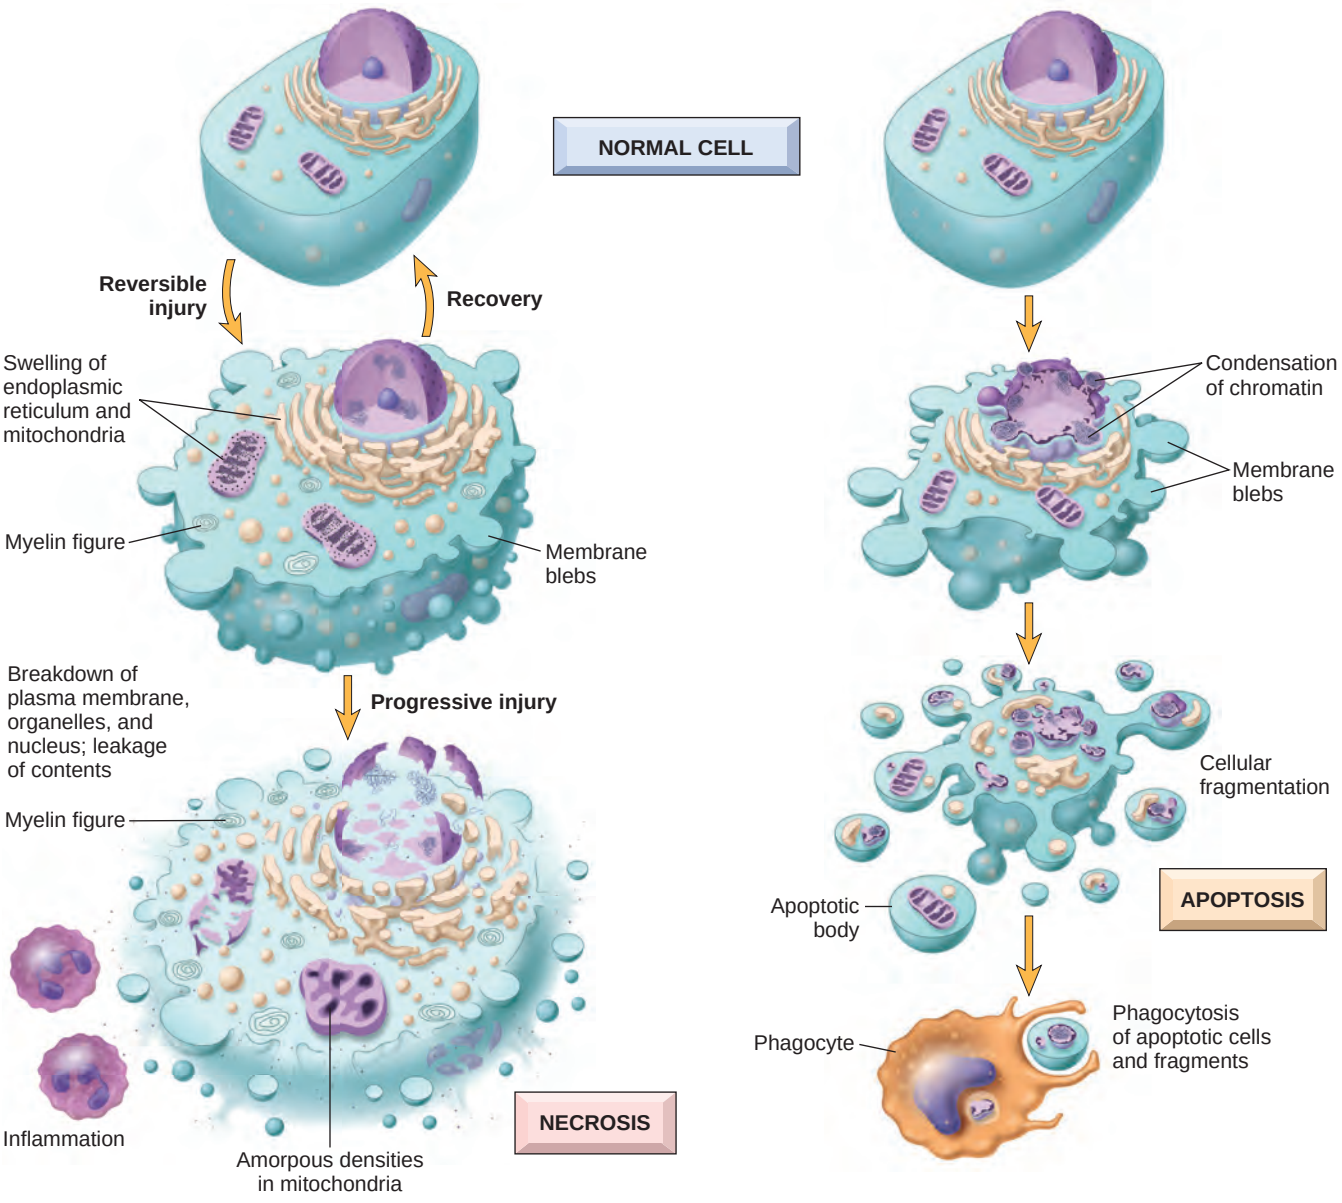

Figure 2.4 Schematic illustration of the morphologic changes in cell injury culminating in necrosis or apoptosis.

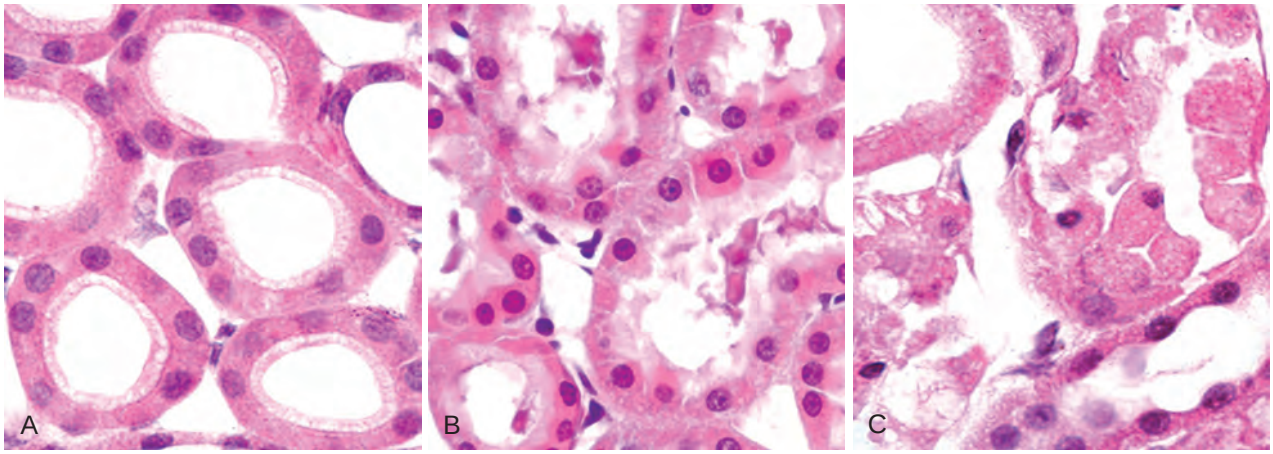

Figure 2.5 Morphologic changes in reversible cell injury and necrosis. (A) Normal kidney tubules with viable epithelial cells. (B) Early (reversible) ischemic injury showing surface blebs, increased eosinophilia of cytoplasm, and swelling of occasional cells. (C) Necrosis (irreversible injury) of epithelial cells, with loss of nuclei, fragmentation of cells, and leakage of contents. The ultrastructural features of these stages of cell injury are shown in Fig. 2.6. (Courtesy Drs. Neal Pinckard and M.A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Tex.)

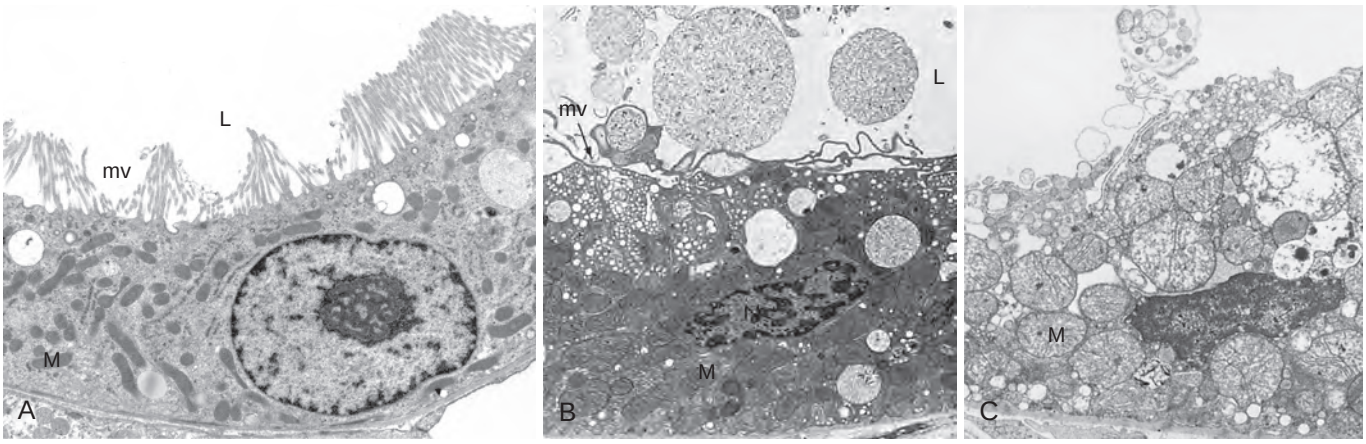

Figure 2.6 Ultrastructural features of reversible and irreversible cell injury (necrosis) in a rabbit kidney. (A) Electron micrograph of a normal epithelial cell of the proximal kidney tubule. Note abundant microvilli *(mv)* lining the luminal surface *(L)*. (B) Epithelial cell of the proximal tubule showing early cell injury resulting from reperfusion following ischemia. The microvilli are lost and have been incorporated in apical cytoplasm; blebs have formed and are extruded in the lumen. Mitochondria *(M)* would have been swollen during ischemia; with reperfusion, they rapidly undergo condensation and become electron-dense. (C) Proximal tubular cell showing late injury, expected to be irreversible. Note the markedly swollen mitochondria containing electron-dense deposits, expected to contain precipitated calcium and proteins. Higher magnification micrographs of the cell would show disrupted plasma membrane and swelling and fragmentation of organelles. (A, Courtesy Dr. Brigitte Kaisslin, Institute of Anatomy, University of Zurich, Switzerland. B, C, Courtesy Dr. M.A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Tex.)

Necrosis has historically been thought of as "accidental" cell death, reflecting severe injury that irreparably damages so many cellular components that the cell simply "falls apart." If early (reversible) injury progresses because the injurious stimulus persists, the end result is death by necrosis. When cells die by necrosis, there is a local inflammatory response that clears the "scene of the accident." In contrast, apoptosis is "regulated" cell death, mediated by defined molecular pathways that are activated under specific circumstances and kill cells with surgical precision, without inflammation or the associated collateral damage. The separation of necrosis and apoptosis is not always so clear, however, and some forms of necrosis are genetically controlled through a defined molecular pathway, called "necroptosis" (discussed later). Moreover, in some situations, cell death may show morphologic features of both apoptosis and necrosis, or progress from one to the other, so the distinctions may not be absolute. Nevertheless, it is useful to consider these as largely non-overlapping pathways of cell death because their principal mechanisms, morphological features, and functional consequences are usually different.

Necrosis

Necrosis is a pathologic process that is the consequence of severe injury. The main causes of necrosis include loss of oxygen supply (ischemia), exposure to microbial toxins, burns and other forms of chemical and physical injury, and unusual situations in which active proteases leak out of cells and damage surrounding tissues (as in pancreatitis). All of these initiating triggers lead to irreparable damage of numerous cellular components.

Necrosis is characterized by denaturation of cellular proteins, leakage of cellular contents through damaged membranes, local inflammation, and enzymatic digestion of the lethally injured cell. When damage to membranes is severe, lysosomal enzymes enter the cytoplasm and digest the cell. Cellular contents also leak through the damaged plasma membrane into the extracellular space, where they elicit a host reaction (inflammation). Some specific substances released from injured cells have been called *damage-associated molecular patterns (DAMPs)*. These include ATP (released from damaged mitochondria), uric acid (a breakdown product of DNA), and numerous other molecules that are normally confined within healthy cells and whose release is an indicator of severe cell injury. These molecules are recognized by receptors present in macrophages and most other cell types, and trigger phagocytosis of the debris as well as the production of cytokines that induce inflammation (Chapter 3). Inflammatory cells produce more proteolytic enzymes, and the combination of phagocytosis and enzymatic digestion usually leads to clearance of the necrotic cells.

Necrosis-associated leakage of intracellular proteins through damaged plasma membranes and ultimately into the circulation is the basis for blood tests that detect tissue-specific cellular injury. Cardiac muscle cells, for example, express cardiac-specific variants of the contractile protein troponin, while bile duct epithelium expresses a specific isoform of the enzyme alkaline phosphatase and hepatocytes express transaminases. Necrosis of these cell types and associated loss of membrane integrity is reflected in increased serum levels of these proteins, which serve as biomarkers that are used clinically to assess and quantify tissue damage. Cardiac-specific troponins can be detected in the blood as early as 2 hours after myocardial cell necrosis, well before histologic evidence of myocardial infarction becomes apparent. Because of their sensitivity and specificity, serial measurement of serum cardiac troponins has a central role in the diagnosis and management of patients with myocardial infarction (Chapter 12).

MORPHOLOGY

Necrotic cells show **increased eosinophilia** in H&E stains, attributable in part to the loss of cytoplasmic RNA and in part to accumulation of denatured cytoplasmic proteins (which bind the red dye eosin). The necrotic cell may have a glassy homogeneous appearance relative to normal cells, mainly as a result of the loss of glycogen particles (see Fig. 2.5C). When enzymes have digested the cell's organelles, the cytoplasm becomes vacuolated and appears moth-eaten. Dead cells may be replaced by large whorled phospholipid precipitates called **myelin figures**, which are either phagocytosed by other cells or further degraded into fatty acids; calcification of such fatty acid residues results in deposition of calcium-rich precipitates. By electron microscopy, necrotic cells are characterized by discontinuities in plasma and organelle membranes, marked dilation of mitochondria with the appearance of large amorphous densities, intracytoplasmic myelin figures, amorphous debris, and aggregates of fluffy material representing denatured protein (see Fig. 2.6C).

Nuclear changes appear in one of three patterns, all due to breakdown of DNA. The basophilia of the chromatin may fade **(karyolysis),** a change that presumably reflects loss of DNA because of enzymatic degradation by endonucleases. A second pattern (also seen in apoptotic cell death) is **pyknosis,** characterized by nuclear shrinkage and increased basophilia. Here the chromatin condenses into a dense, shrunken basophilic mass. In the third pattern, known as **karyorrhexis,** the pyknotic nucleus undergoes fragmentation. With the passage of time (1 or 2 days), the nucleus in the necrotic cell totally disappears.

It is useful to consider the possible events that determine when reversible injury becomes irreversible and progresses to necrosis. The clinical relevance of this question is obvious—if we can answer it, we may be able to devise strategies for preventing cell injury from having permanent deleterious consequences. Although the "point of no return," at which the damage becomes irreversible, is still largely undefined, *two phenomena consistently characterize irreversibility—the inability to reverse mitochondrial dysfunction* (lack of oxidative phosphorylation and ATP generation) even after resolution of the original injury, and *profound disturbances in membrane function*. As mentioned earlier, injury to lysosomal membranes results in the enzymatic dissolution of the injured cell that is characteristic of necrosis.

Patterns of Tissue Necrosis

The discussion of necrosis has focused so far on changes in individual cells. When large numbers of cells die, the tissue or organ is said to be necrotic; thus, a myocardial infarct is necrosis of a portion of the heart caused by death of many myocardial cells. Necrosis of tissues has several morphologically distinct patterns, which are important to recognize because they provide clues about the underlying cause. Although the terms that describe these patterns are somewhat dated, they are often used and their implications are understood by pathologists and clinicians.

MORPHOLOGY

Coagulative necrosis is a form of necrosis in which the architecture of dead tissue is preserved for a span of at least some days (Fig. 2.7). The affected tissue has a firm texture. Presumably, the injury denatures not only structural proteins but also enzymes and so blocks the proteolysis of the dead cells; as a result, intensely eosinophilic cells with indistinct or reddish nuclei may persist for days or weeks. Ultimately, the necrotic cells are broken down by the action of lysosomal enzymes derived from infiltrating leukocytes, which also remove the debris of the dead cells by phagocytosis. Ischemia caused by obstruction in a vessel may lead to coagulative necrosis of the supplied tissue in all organs except the brain (see next paragraph for explanation). A localized area of coagulative necrosis is called an **infarct**.

Liquefactive necrosis, in contrast to coagulative necrosis, is characterized by digestion of the dead cells, resulting in transformation of the tissue into a viscous liquid. It is seen in focal bacterial or, occasionally, fungal infections, because microbes stimulate the accumulation of leukocytes and the liberation of enzymes from these cells. The necrotic material is frequently creamy yellow because of the presence of leukocytes and is called **pus.** For

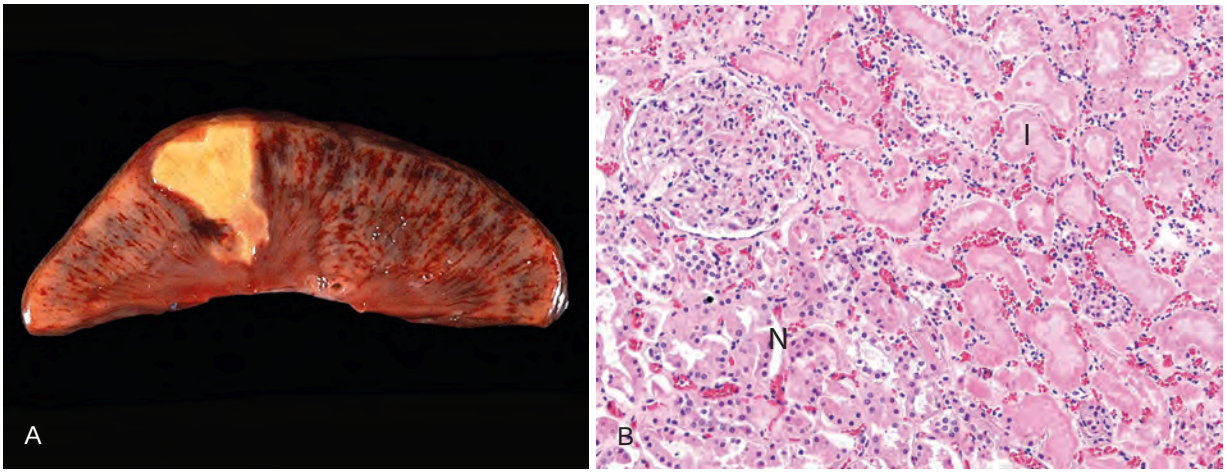

Figure 2.7 Coagulative necrosis. (A) A wedge-shaped kidney infarct *(yellow)*. (B) Microscopic view of the edge of the infarct, with normal kidney *(N)* and necrotic cells in the infarct *(I)* showing preserved cellular outlines with loss of nuclei and an inflammatory infiltrate (seen as nuclei of inflammatory cells in between necrotic tubules).

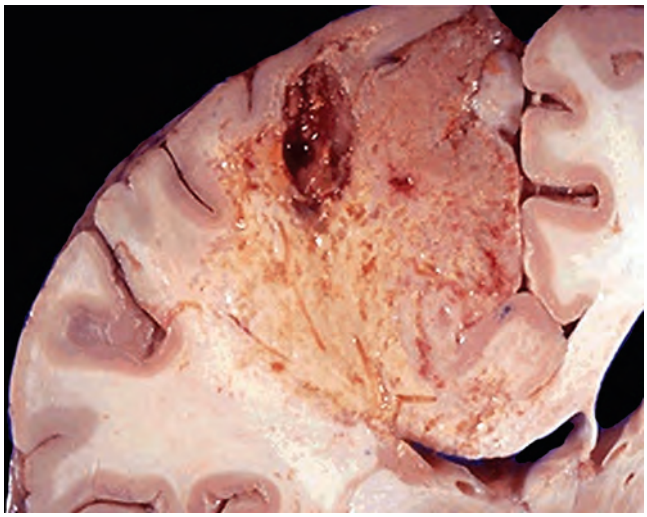

Figure 2.8 Liquefactive necrosis. An infarct in the brain, showing dissolution of the tissue.

unknown reasons, hypoxic death of cells within the central nervous system often manifests as liquefactive necrosis (Fig. 2.8).

Gangrenous necrosis is not a specific pattern of cell death, but the term is commonly used in clinical practice. It is usually applied to a limb, generally the lower leg, that has lost its blood supply and has undergone necrosis (typically coagulative necrosis) involving multiple tissue planes. When bacterial infection is superimposed, there is more liquefactive necrosis because of the actions of degradative enzymes in the bacteria and the attracted leukocytes (giving rise to so-called **wet gangrene**).

Caseous necrosis is encountered most often in foci of tuberculous infection (Chapter 8). The term *caseous* (cheeselike) is derived from the friable white appearance of the area of necrosis (Fig. 2.9). On microscopic examination, the necrotic area appears as a structureless collection of fragmented or lysed cells and amorphous granular debris enclosed within a distinctive inflammatory border; this appearance is characteristic of a focus of inflammation known as a **granuloma** (Chapter 3).

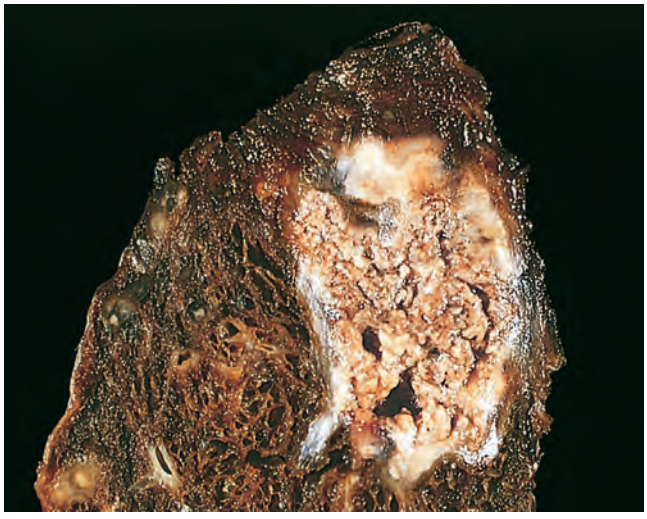

Figure 2.9 Caseous necrosis. Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and "cheesy" appearing debris.

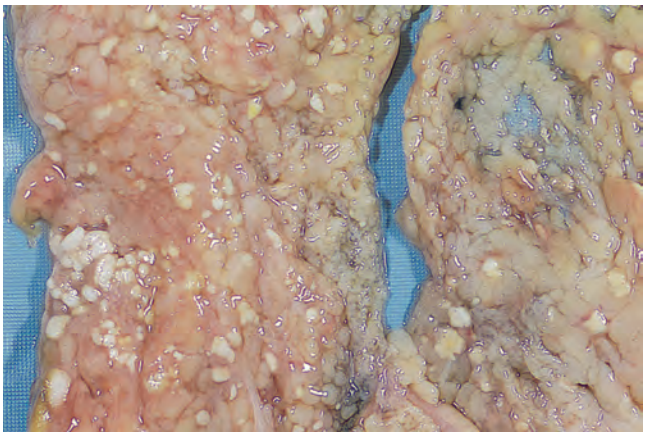

Figure 2.10 Fat necrosis. The areas of white chalky deposits represent foci of fat necrosis with calcium soap formation (saponification) at sites of lipid breakdown in the mesentery.

Fat necrosis refers to focal areas of fat destruction, typically resulting from release of activated pancreatic lipases into the substance of the pancreas and the peritoneal cavity. This occurs in the calamitous abdominal emergency known as acute pancreatitis (Chapter 19). In this disorder, pancreatic enzymes leak out of damaged acinar cells and liquefy the membranes of fat cells in the peritoneum, releasing triglyceride esters that are split by pancreatic lipases. Fatty acids are generated that combine with calcium to produce grossly visible chalky-white areas (fat saponification), which enable the surgeon and the pathologist to identify the underlying disorder (Fig. 2.10). On histologic examination, the necrotic areas contain the shadowy outlines of necrotic fat cells, basophilic calcium deposits, and an inflammatory reaction.

Fibrinoid necrosis is a special form of vascular damage usually seen in immune reactions involving blood vessels. It typically occurs when complexes of antigens and antibodies are deposited in the walls of arteries. Deposits of these immune complexes, together with plasma proteins that has leaked out of vessels, result in a bright pink and amorphous appearance in H&E stains called "fibrinoid" (fibrin-like) by pathologists (Fig. 2.11). The immunologically mediated vasculitis syndromes in which this type of vascular injury is seen are described in Chapter 11.

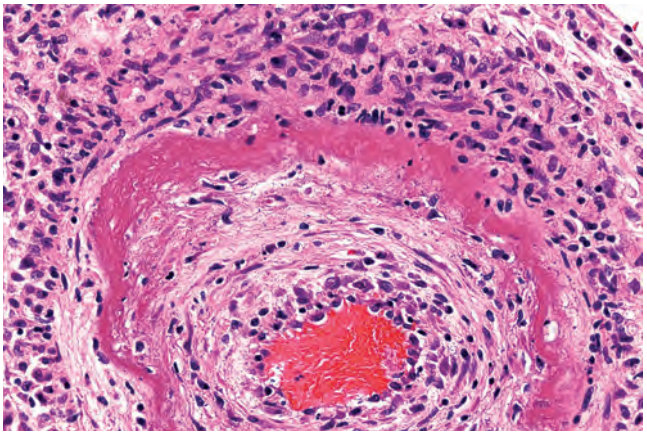

Figure 2.11 Fibrinoid necrosis in an artery. The wall of the artery shows a circumferential bright pink area of necrosis with inflammation (neutrophils with dark nuclei).

Ultimately, in the living patient most necrotic cells and their contents disappear due to enzymatic digestion and phagocytosis of the debris by leukocytes. If necrotic cells and cellular debris are not promptly destroyed and reabsorbed, they provide a nidus for the deposition of calcium salts and other minerals and thus tend to become calcified. This phenomenon, called *dystrophic calcification,* is considered later in the chapter.

KEY CONCEPTS

CELL INJURY AND NECROSIS

- Exposure of cells to stress or noxious agents causes cell injury that is reversible to a point but may progress to death of the cells, principally by necrosis.
- Reversible cell injury: Characterized by cellular swelling, fatty change, plasma membrane blebbing and loss of microvilli, mitochondrial swelling, dilation of the ER, and eosinophilia (due to decreased cytoplasmic RNA)
- Necrosis: A pathologic process in which cellular membranes are destroyed, enzymes and other constituents leak out, and local inflammation is induced to clear the damaged cells. Morphologic features are: eosinophilia; nuclear shrinkage, fragmentation, and dissolution; breakdown of plasma membrane and organellar membranes; abundant myelin figures; and leakage and enzymatic digestion of cellular contents
- Patterns of tissue necrosis: Under different conditions, necrosis in tissues may assume specific patterns: coagulative, liquefactive, gangrenous, caseous, fat, and fibrinoid

Apoptosis

Apoptosis is a type of cell death that is induced by a tightly regulated suicide program in which cells destined to die activate intrinsic enzymes that degrade the cells' genomic DNA and nuclear and cytoplasmic proteins. Apoptotic cells break up into plasma membrane–bound fragments, called *apoptotic bodies,* which contain portions of the cytoplasm and nucleus. While the plasma membrane remains intact, its surface components are altered so as to produce "find me" and "eat me" signals for phagocytes, discussed later. As a result, the dead cell and its fragments are rapidly devoured, before the contents leak out, and therefore apoptosis does not elicit an inflammatory reaction. Apoptosis was first recognized in 1972 by the distinctive morphologic appearance of membrane-bound fragments derived from cells, and named after the Greek designation for "falling off." It was subsequently discovered in model organisms such as worms that certain cells undergo apoptosis at precise times during development. This phenomenon, termed *programmed cell death*, is controlled by the action of a small number of genes and is required for normal embryogenesis. Thus, apoptosis is a unique mechanism of cell death, distinct from necrosis in many respects (see Fig. 2.4 and Table 2.1).

Causes of Apoptosis

Apoptosis occurs in two broad contexts: as part of normal physiologic processes, and as a pathophysiologic mechanism of cell loss in many different diseases.

Apoptosis in Physiologic Situations

Death by apoptosis is a normal phenomenon that serves to eliminate cells that are no longer needed, or as a mechanism to maintain a constant number of various cell populations in tissues. It is estimated that humans turn over almost 1 million cells per second! Central to this process is death of cells by apoptosis and their removal by phagocytes. Apoptosis is important in the following physiologic situations:

- *The removal of supernumerary cells (in excess of the required number) during development*. Cell death is critical for involution of primordial structures and remodeling of maturing tissues. Apoptosis is a generic term for this pattern of cell death, regardless of the context, while programmed cell death refers only to apoptosis during development.
- *Involution of hormone-dependent tissues on hormone withdrawal,* such as endometrial cell breakdown during the menstrual cycle, ovarian follicular atresia in menopause, and regression of the lactating breast after weaning.
- *Cell turnover in proliferating cell populations,* such as immature lymphocytes in the bone marrow and thymus, B lymphocytes in germinal centers that fail to express useful antigen receptors (Chapter 6), and epithelial cells in intestinal crypts, to maintain a constant cell number *(homeostasis)*.
- *Elimination of potentially harmful self-reactive lymphocytes* to prevent immune reactions against one's own tissues (Chapter 6).
- Death of host cells that have served their useful purpose, such as neutrophils in an *acute inflammatory response,* and lymphocytes at the end of an *immune response*.

In all of these situations, cells undergo apoptosis because they are deprived of necessary survival signals, such as growth factors and interactions with the extracellular matrix, or they receive pro-apoptotic signals from other cells or the surrounding environment.

Apoptosis in Pathologic Conditions

Apoptosis eliminates cells that are injured beyond repair without eliciting a host reaction, thus limiting collateral tissue damage. Death by apoptosis is responsible for loss of cells in a variety of pathologic states:

- *DNA damage*. Radiation and cytotoxic anticancer drugs can damage DNA, either directly or via production of free radicals. If repair mechanisms cannot correct the damage, the cell triggers intrinsic mechanisms that induce apoptosis. In these situations, apoptosis has a protective effect by preventing the survival of cells with DNA mutations that can lead to malignant transformation.
- *Accumulation of misfolded proteins*. Cell death triggered by improperly folded intracellular proteins and the subsequent endoplasmic reticulum (ER) stress response is discussed later.
- Apoptosis can be induced during certain *infections,* particularly viral infections, as a result of the virus itself (as in adenovirus and HIV infections) or the host immune response (as in viral hepatitis). An important host response to viruses consists of cytotoxic T lymphocytes

(CTLs) specific for viral proteins, which induce apoptosis of infected cells in an attempt to eliminate reservoirs of infection. During this process, there can be significant tissue damage. The same CTL-mediated mechanism is responsible for killing of *tumor cells,* cellular rejection of *transplants,* and tissue damage in graft-versus-host disease.

- Apoptosis may also contribute to *pathologic atrophy in parenchymal organs after duct obstruction,* such as occurs in the pancreas, parotid gland, and kidney.

Morphologic and Biochemical Changes in Apoptosis

Before discussing underlying mechanisms, the morphologic and biochemical characteristics of apoptosis are described.

MORPHOLOGY

The following morphologic features, some best seen with the electron microscope, characterize cells undergoing apoptosis (Fig. 2.12; see Fig. 2.4).

Cell shrinkage. Cell size is reduced, the cytoplasm is dense and eosinophilic (see Fig. 2.12A), and the organelles, although relatively normal, are more tightly packed. This contrasts with necrosis, in which an early feature is cell swelling, not shrinkage.

Chromatin condensation. This is the most characteristic feature of apoptosis. The chromatin aggregates peripherally, under the nuclear membrane, into dense masses of various shapes and sizes (see Fig. 2.12B). The nucleus itself may break up into two or more fragments.

Formation of cytoplasmic blebs and apoptotic bodies. The apoptotic cell first shows extensive surface membrane blebbing, which is followed by fragmentation of the dead cells into membrane-bound apoptotic bodies composed of cytoplasm and tightly packed organelles, with or without nuclear fragments (see Fig. 2.12C).

Phagocytosis of apoptotic cells or cell bodies, usually by macrophages. The apoptotic bodies are rapidly ingested by phagocytes and degraded by the phagocyte's lysosomal enzymes.

In H&E-stained tissue, the apoptotic cell appears as a round or oval mass of intensely eosinophilic cytoplasm with fragments of dense nuclear chromatin (see Fig. 2.12A). Because the cell shrinkage and formation of apoptotic bodies are rapid and the pieces are quickly cleared by phagocytes, considerable apoptosis may occur in tissues before it is apparent in histologic sections. The absence of an inflammatory response can also make it difficult to detect apoptosis by light microscopy.

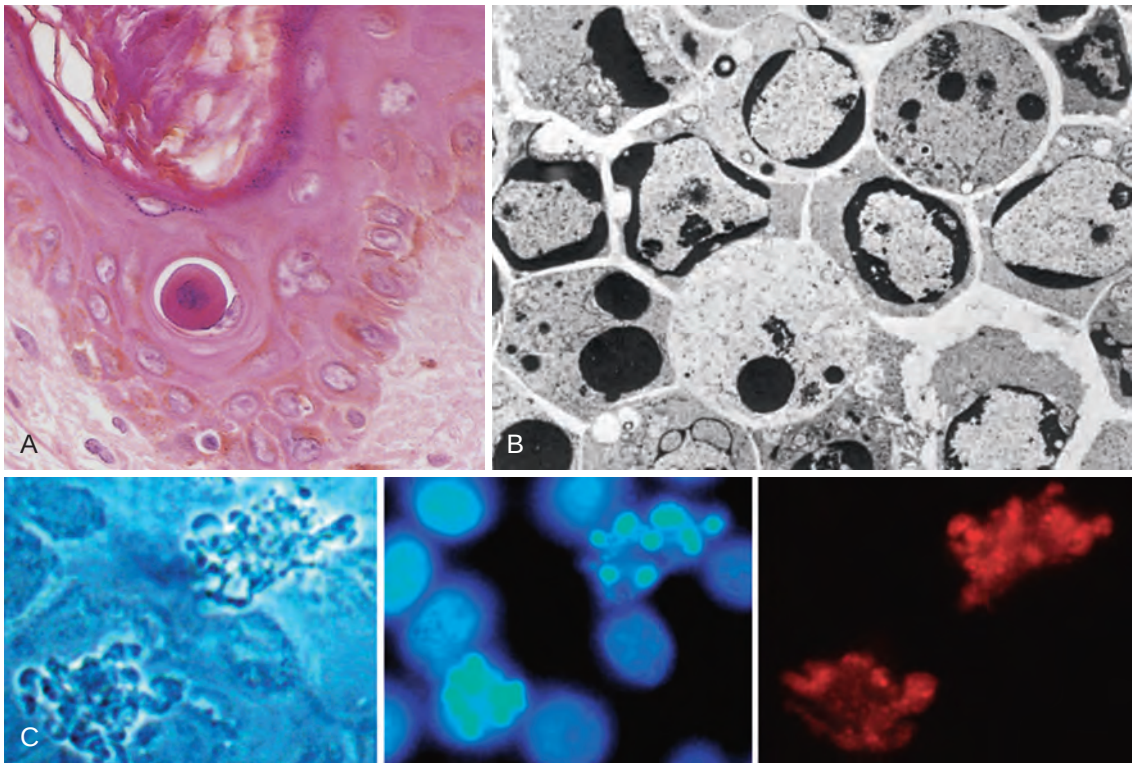

Figure 2.12 Morphologic features of apoptosis. (A) Apoptosis of an epidermal cell in an immune reaction. The cell is reduced in size and contains brightly eosinophilic cytoplasm and a condensed nucleus. (B) This electron micrograph of cultured cells undergoing apoptosis shows some nuclei with peripheral crescents of compacted chromatin, and others that are uniformly dense or fragmented. (C) These images of cultured cells undergoing apoptosis show blebbing and formation of apoptotic bodies (*left panel,* phase contrast micrograph), a stain for DNA showing nuclear fragmentation *(middle panel),* and activation of caspase-3 (*right panel,* immunofluorescence stain with an antibody specific for the active form of caspase-3, revealed as red color). (B, From Kerr JFR, Harmon BV: Definition and incidence of apoptosis: a historical perspective. Mechanisms of Apoptosis

Apoptosis results from the activation of enzymes called *caspases* (so named because they are proteases containing a *c*ysteine in their active site and cleave proteins after *asp*artic residues). Like many proteases, caspases exist as inactive proenzymes and must undergo enzymatic cleavage to become active. The presence of active caspases is therefore a marker for cells undergoing apoptosis (see Fig. 2.12C). The process of apoptosis may be divided into an *initiation phase,* during which some caspases become catalytically active and unleash a cascade of other caspases, and an *execution phase,* during which the terminal caspases trigger cellular fragmentation. Regulation of these enzymes depends on a finely tuned balance between the abundance and activity of pro-apoptotic and anti-apoptotic proteins.

Two distinct pathways converge on caspase activation: the mitochondrial pathway and the death receptor pathway (Fig. 2.13). Although these pathways intersect, they are generally induced under different conditions, involve different initiating molecules, and serve distinct roles in physiology and disease.

The Mitochondrial (Intrinsic) Pathway of Apoptosis

The mitochondrial pathway is responsible for apoptosis in most physiologic and pathologic situations. It results from increased permeability of the mitochondrial outer membrane with consequent release of death-inducing (pro-apoptotic) molecules from the mitochondrial intermembrane space into the cytoplasm (Fig. 2.14). Mitochondria are organelles that contain remarkable proteins such as cytochrome c, a double-edged sword that is essential for producing the energy (e.g., ATP) that sustains cell viability, but that when released into the cytoplasm (an indication that the cell is not healthy) initiates the suicide program of apoptosis. The release of pro-apoptotic proteins such as cytochrome c is determined by the integrity of the outer mitochondrial membrane, which is tightly controlled by the BCL2 family of proteins. This family is named after *BCL2,* a gene that is frequently overexpressed due to chromosomal translocations and other aberrations in certain B cell lymphomas (Chapter 13). There are more than 20 members of the BCL family, which can be divided into three groups based on their pro-apoptotic or anti-apoptotic function and the BCL2 homology (BH) domains they possess.

- *Anti-apoptotic.* BCL2, BCL-X_L, and MCL1 are the principal members of this group; they possess four BH domains (called BH1-4). These proteins reside in the outer mitochondrial membrane as well as in the cytosol and ER membranes. By keeping the mitochondrial outer membrane impermeable, they prevent leakage of cytochrome c and other death-inducing proteins into the cytosol (see Fig. 2.14A).

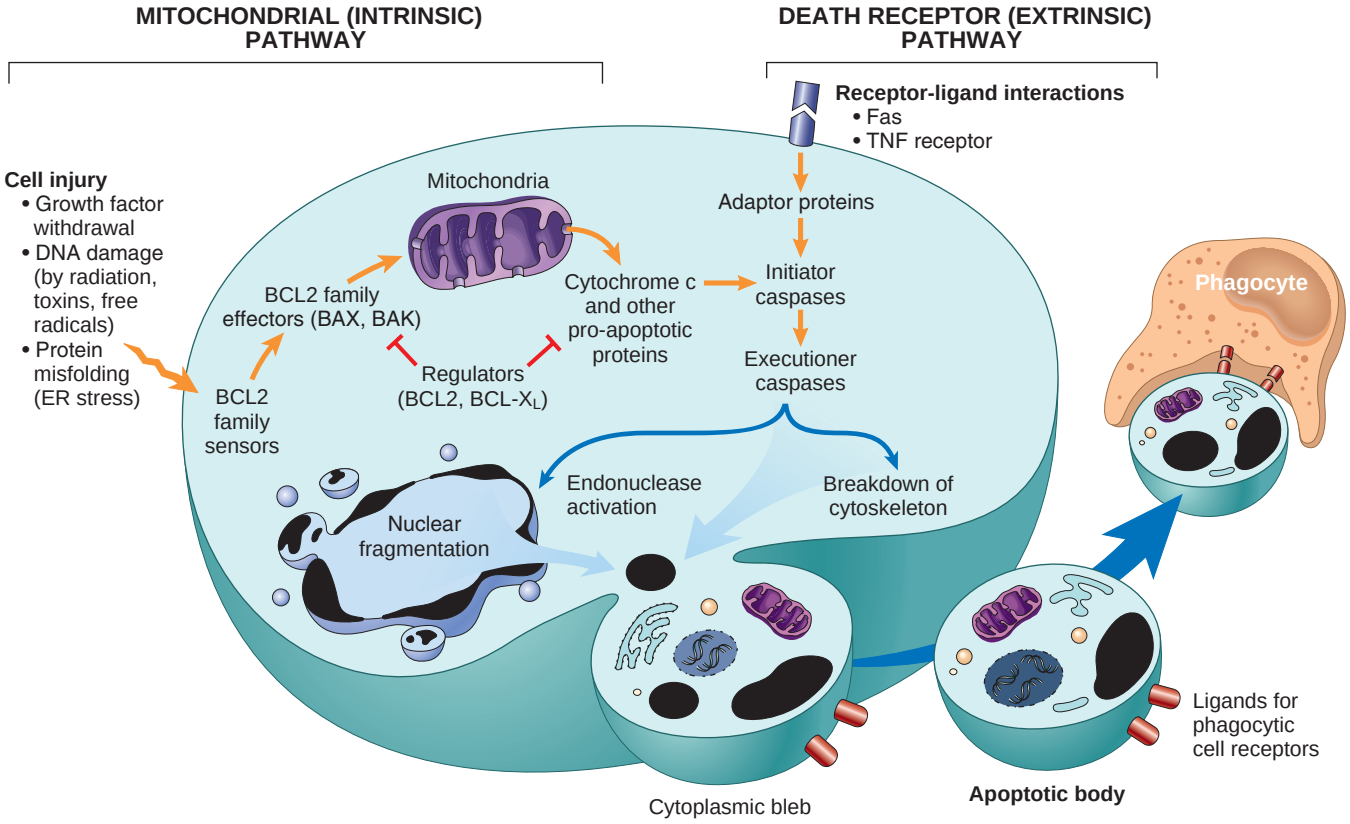

Figure 2.13 Mechanisms of apoptosis. Although the two pathways of apoptosis differ in their induction and regulation, they both culminate in the activation of caspases. In the mitochondrial pathway, proteins of the BCL2 family, which regulate mitochondrial permeability, become imbalanced such that the ratio of pro-apoptotic versus anti-apoptotic proteins results in the leakage of various substances from mitochondria that lead to caspase activation. In the death receptor pathway, signals from plasma membrane receptors lead to the assembly of adaptor proteins into a "death-inducing signaling complex," which activates caspases, and the end result is the same.

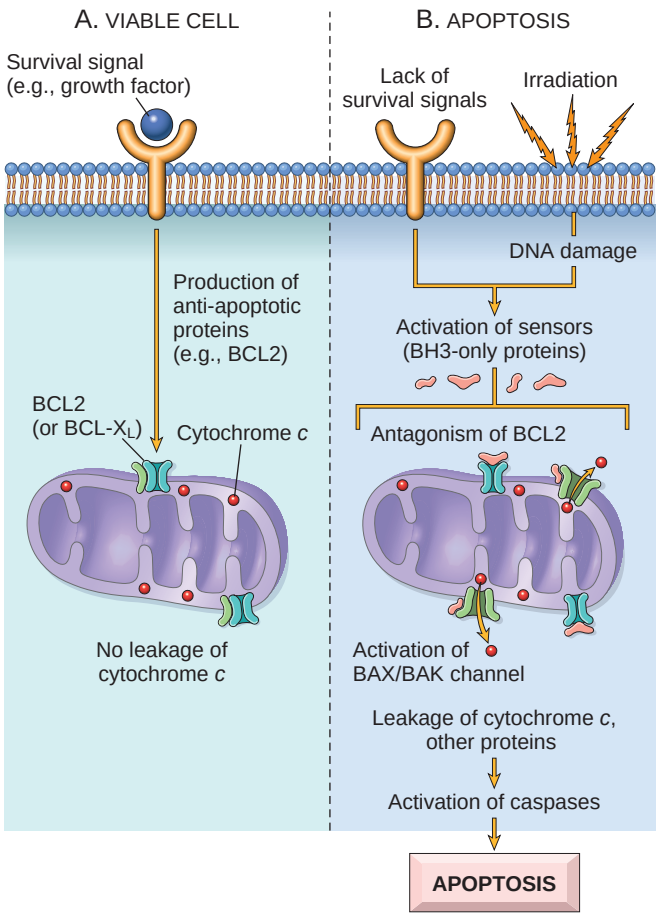

Figure 2.14 The intrinsic (mitochondrial) pathway of apoptosis. (A) Cell viability is maintained by the induction of anti-apoptotic proteins such as BCL2 by survival signals. These proteins maintain the integrity of mitochondrial membranes and prevent leakage of mitochondrial proteins. (B) Loss of survival signals, DNA damage, and other insults activate sensors that antagonize the anti-apoptotic proteins and activate the pro-apoptotic proteins BAX and BAK, which form channels in the mitochondrial membrane. The subsequent leakage of cytochrome c (and other proteins, *not shown*) leads to caspase activation and apoptosis.

- *Pro-apoptotic.* BAX and BAK are the two prototypic members of this group; they contain the first three BH domains (BH1-3). On activation, BAX and/or BAK oligomerize within the outer mitochondrial membrane and enhance its permeability. The precise mechanism by which BAX-BAK oligomers permeabilize membranes is not settled. According to one model illustrated in Fig. 2.14B, they form a channel in the outer mitochondrial membrane that allows cytochrome c leakage from the intermembranous space.
- *Regulated apoptosis initiators.* Members of this group, including BAD, BIM, BID, Puma, and Noxa, contain only one BH domain, the third of the four BH domains, and hence are sometimes called BH3-only proteins. The activity of BH3-only proteins is modulated by sensors of cellular stress and damage; when upregulated and activated, they can initiate apoptosis.

Growth factors and other survival signals stimulate the production of anti-apoptotic proteins such as BCL2, thus protecting cells from apoptosis. When cells are deprived of survival signals, suffer DNA damage, or develop ER stress due to the accumulation of misfolded proteins, BH3-only proteins are upregulated through increased transcription and/or post-translational modifications (e.g., phosphorylation). These BH3-only proteins in turn directly activate the two critical pro-apoptotic family members, BAX and BAK, which form oligomers that insert into the mitochondrial membrane and allow proteins from the inner mitochondrial membrane to leak out into the cytoplasm. BH3-only proteins may also bind to and block the function of BCL2 and BCL-X_L. At the same time, synthesis of BCL2 and BCL-X_L may decline because their transcription relies on survival signals. The net result of BAX-BAK activation coupled with loss of the protective functions of the anti-apoptotic BCL2 family members is the release into the cytoplasm of several mitochondrial proteins such as cytochrome c that can activate the caspase cascade (see Fig. 2.14).

Once released into the cytosol, cytochrome c binds to a protein called APAF-1 (apoptosis-activating factor-1), forming a multimeric structure called the *apoptosome*. This complex binds to caspase-9, the critical initiator caspase of the mitochondrial pathway, and promotes its autocatalytic cleavage, generating catalytically active forms of the enzyme. Active caspase-9 then triggers a cascade of caspase activation by cleaving and thereby activating other pro-caspases (such as caspase-3), which mediate the execution phase of apoptosis (discussed later). Other mitochondrial proteins with arcane names like Smac/DIABLO enter the cytoplasm, where they bind to and neutralize cytoplasmic proteins that function as physiologic inhibitors of apoptosis (IAPs). The normal function of the IAPs is to block the inappropriate activation of caspases, including executioners like caspase-3, and keep cells alive. Thus, IAP inhibition permits initiation of the caspase cascade.

The Extrinsic (Death Receptor–Initiated) Pathway of Apoptosis

This pathway is initiated by engagement of plasma membrane death receptors. Death receptors are members of the tumor necrosis factor (TNF) receptor family that contain a cytoplasmic domain involved in protein-protein interactions. This *death domain* is essential for delivering apoptotic signals. (Some TNF receptor family members do not contain cytoplasmic death domains; their function is to activate inflammatory cascades [Chapter 3], and their role in triggering apoptosis is much less established.) The best-known death receptors are the type 1 TNF receptor (TNFR1) and a related protein called Fas (CD95), but several others have been described. The mechanism of apoptosis induced by these death receptors is well illustrated by Fas, a death receptor expressed on many cell types (Fig. 2.15). The ligand for Fas is called Fas ligand (FasL). FasL is expressed on T cells that recognize self antigens (and functions to eliminate self-reactive lymphocytes that also express the receptor Fas upon recognition of self antigens) and on some CTLs that kill virus-infected and tumor cells. When FasL binds to Fas, three or more molecules of Fas are brought together, and their cytoplasmic death domains form a binding site for an adaptor protein called FADD (*F*as-*a*ssociated *d*eath *d*omain). Once attached to this complex, FADD binds inactive

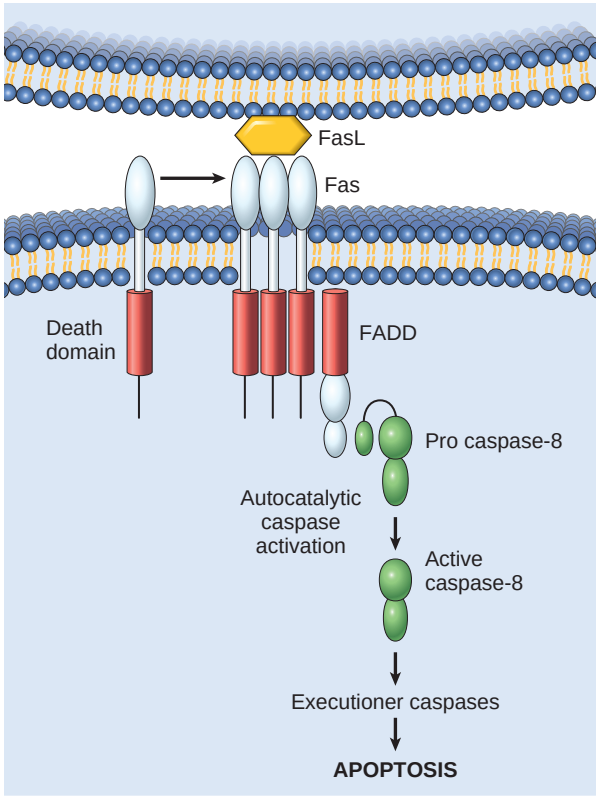

Figure 2.15 The extrinsic (death receptor–initiated) pathway of apoptosis, illustrated by the events following Fas engagement. *FADD,* Fas-associated death domain; *FasL,* Fas ligand.

caspase-8 (or caspase-10), bringing together multiple caspase molecules and leading to autocatalytic cleavage and generation of active caspase-8. In turn, active caspase-8 initiates the same executioner caspase sequence as in the mitochondrial pathway. This extrinsic apoptosis pathway can be inhibited by a protein called FLIP, which binds to procaspase-8, thereby blocking FADD binding, but cannot activate the caspase. Some viruses and normal cells produce FLIP as a mechanism to protect themselves from Fas-mediated apoptosis.

The extrinsic and intrinsic pathways of apoptosis are initiated in fundamentally different ways by distinct molecules, but there may be interconnections between them. For instance, in hepatocytes and pancreatic β cells, caspase-8 produced by Fas signaling cleaves and activates the BH3-only protein BID, which then feeds into the mitochondrial pathway. The combined activation of both pathways delivers a fatal blow to the cells.

The Execution Phase of Apoptosis

The intrinsic and extrinsic pathways converge to activate a caspase cascade that mediates the final phase of apoptosis. The intrinsic mitochondrial pathway activates the initiator caspase-9, whereas the extrinsic death receptor pathway activates caspase-8 and caspase-10. The active forms of these caspases trigger the rapid and sequential activation of the executioner caspases, such as caspase-3 and caspase-6, which then act on many cellular components. For instance, once activated these caspases cleave an inhibitor of a DNase, making the DNase enzymatically active and allowing DNA degradation to commence. Caspases also proteolyze structural components of the nuclear matrix and thus promote fragmentation of nuclei. Other steps in apoptosis are less well-defined. For instance, we do not know how membrane blebs and apoptotic bodies are formed.

Removal of Dead Cells

The formation of apoptotic bodies breaks cells up into "bite-sized" fragments that are edible for phagocytes. Apoptotic cells and their fragments also undergo several changes in their membranes that actively promote their phagocytosis so they are most often cleared before they lose membrane integrity and release their cellular contents. In healthy cells, phosphatidylserine is present on the inner leaflet of the plasma membrane, but in apoptotic cells this phospholipid "flips" out and is expressed on the outer layer of the membrane, where it is recognized by several macrophage receptors. Cells that are dying by apoptosis also secrete soluble factors that recruit phagocytes, and macrophages themselves may produce proteins that bind to apoptotic cells (but not live cells), leading to their engulfment. Apoptotic bodies may also become coated with natural antibodies and proteins of the complement system, notably C1q, which are recognized by phagocytes. Thus, numerous ligands induced on apoptotic cells serve as "eat me" signals and are recognized by receptors on phagocytes that bind and engulf these cells. This process of apoptotic cell phagocytosis is called *efferocytosis*; it is so efficient that dead cells disappear, often within minutes, without leaving a trace. In addition, production of pro-inflammatory cytokines is reduced in macrophages that have ingested apoptotic cells. Together with rapid clearance, this limits inflammatory reactions, even in the face of extensive apoptosis.

KEY CONCEPTS

APOPTOSIS

- Regulated mechanism of cell death that serves to eliminate unwanted and irreparably damaged cells, with the least possible host reaction
- Characterized by enzymatic degradation of proteins and DNA, initiated by caspases, and by recognition and removal of dead cells by phagocytes
- Initiated by two major pathways:
  - Mitochondrial (intrinsic) pathway is triggered by loss of survival signals, DNA damage, and accumulation of misfolded proteins (ER stress), which leads to leakage of pro-apoptotic proteins from mitochondrial membrane into the cytoplasm and subsequent caspase activation; can be inhibited by anti-apoptotic members of the BCL2 family, which are induced by survival signals including growth factors
  - Death receptor (extrinsic) pathway eliminates self-reactive lymphocytes and is a mechanism of cell killing by cytotoxic T lymphocytes; is initiated by engagement of death receptors (members of the TNF receptor family). The responsible ligands can be soluble or expressed on the surface of adjacent cells

Other Mechanisms of Cell Death

Although necrosis and apoptosis are the best-defined mechanisms of cell death, several other ways by which cells die have been described. Their importance in human diseases remains a topic of investigation, but students should be aware of their names and unique features.

- *Necroptosis.* As the name indicates, this form of cell death is a hybrid that shares aspects of both necrosis and apoptosis. Morphologically, and to some extent biochemically, it resembles necrosis, as both are characterized by loss of ATP, swelling of the cell and organelles, generation of reactive oxygen species (ROS), release of lysosomal enzymes, and ultimately rupture of the plasma membrane. Mechanistically, it is triggered by signal transduction pathways that culminate in cell death, a feature similar to apoptosis. Because of these overlapping features, necroptosis is sometimes called *programmed necrosis* to distinguish it from forms of necrosis driven passively by toxic or ischemic injury to the cell. In sharp contrast to apoptosis, the signals leading to necroptosis do not result in caspase activation, and hence it is also sometimes referred to as "caspase-independent" programmed cell death. The process of necroptosis starts in a manner similar to that of the extrinsic form of apoptosis, that is, by ligation of a receptor by its ligand. Ligation of TNFR1 is the most widely studied model of necroptosis, but many other signals, including ligation of Fas and yet to be identified sensors of viral DNA and RNA, can also trigger necroptosis. Since TNF can cause both apoptosis and necroptosis, the mechanisms underlying these effects of TNF are especially illustrative (Fig. 2.16).

  Although the entire set of signaling molecules and their interactions are not known, necroptosis involves two kinases called *receptor-interacting protein kinase 1* and *3* (*RIPK1* and *RIPK3*). As indicated in Fig. 2.16, ligation of TNFR1 recruits these kinases into a multiprotein complex, and RIPK3 phosphorylates a cytoplasmic protein called MLKL. In response to its phosphorylation, MLKL monomers assemble into oligomers, translocate from the cytosol to the plasma membrane, and cause the plasma membrane disruption that is characteristic of necrosis. This explains the morphologic similarity of necroptosis with necrosis initiated by other injuries.

  Necroptosis is postulated to be an important death pathway both in physiologic and pathologic conditions. For example, physiologic necroptosis occurs during the formation of the mammalian bone growth plate. In pathologic states, it is associated with cell death in steatohepatitis, acute pancreatitis, ischemia-reperfusion injury, and neurodegenerative diseases such as Parkinson disease. Necroptosis also acts as a backup mechanism in host defense against certain viruses that encode caspase inhibitors (e.g., cytomegalovirus).
- *Pyroptosis* is a form of apoptosis that is accompanied by the release of the fever-inducing cytokine IL-1 (*pyro* refers to fever). Microbial products that enter infected cells are recognized by cytoplasmic innate immune receptors and can activate the multiprotein complex called the *inflammasome* (Chapter 6). The function of the inflammasome is to activate caspase-1 (also known as interleukin-1β–converting enzyme), which cleaves a precursor form of interleukin-1 (IL-1) and releases its biologically active form. IL-1 is a mediator of many aspects of inflammation, including leukocyte recruitment and fever (Chapter 3). Caspase-1 and the closely related caspases-4 and -5 also induce death of the cells. Unlike classical apoptosis, this pathway of cell death is characterized by release of inflammatory mediators. Pyroptosis is thought to be the mechanism by which some microbes cause the death of infected cells and at the same time trigger local inflammation.
- *Ferroptosis.* Only discovered in 2012, ferroptosis is a distinct form of cell death that is triggered when excessive intracellular levels of iron or reactive oxygen species overwhelm the glutathione-dependent antioxidant defenses (discussed later) to cause unchecked membrane lipid peroxidation. The widespread peroxidation of lipids disrupts many aspects of membrane function, including fluidity, lipid-protein interactions, ion and nutrient transport, and signaling pathways. The overall effect is the loss of plasma membrane permeability, which ultimately leads to cell death resembling necrosis. The process is, however, regulated by specific signals (unlike necrosis) and can be prevented by reducing iron levels (hence its name). Ultrastructurally, the most prominent features are the loss

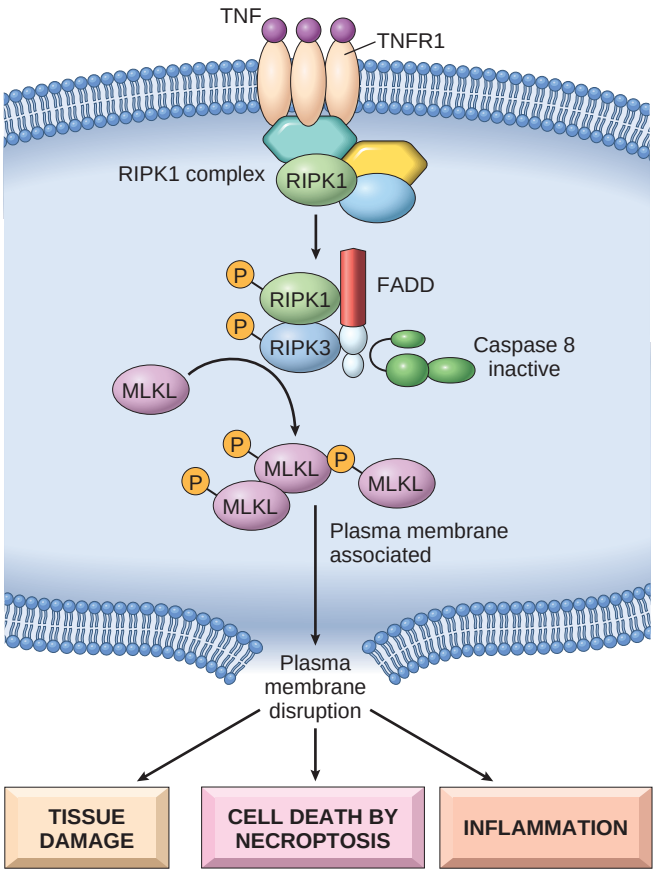

Figure 2.16 Molecular mechanism of TNF-mediated necroptosis. Cross-linking of TNFR1 by TNF initiates the illustrated series of downstream events, which ultimately lead to plasma membrane disruption, cell death, and inflammation. See text for details. (Modified from Galluzi L, et al: Programmed necrosis from molecules to health and disease, *Int Rev Cell Molec Biol* 289:1, 2011.)

of mitochondrial cristae and ruptured outer mitochondrial membrane. While its role in normal development and physiology remain controversial, ferroptosis has been linked to cell death in a variety of human pathologies, including cancer, neurodegenerative diseases, and stroke.

KEY CONCEPTS

NECROPTOSIS AND PYROPTOSIS

- Necroptosis resembles necrosis morphologically, but like apoptosis is a genetically controlled form of cell death.
- Necroptosis is triggered by ligation of TNFR1 and by proteins found in RNA and DNA viruses.
- Necroptosis is caspase-independent and depends on the RIPK1 and RIPK3 complex. RIPK1–RIPK3 signaling leads to the phosphorylation of MLKL, which then forms pores in the plasma membrane.
- Release of cellular contents evokes an inflammatory reaction as in necrosis.
- Pyroptosis occurs in cells infected by microbes. It involves activation of caspase-1, which cleaves the precursor form of IL-1 to generate biologically active IL-1. Caspase-1 along with other closely related caspases also cause death of the infected cell.
- Ferroptosis is an iron-dependent pathway of cell death induced by lipid peroxidation.

Autophagy

Autophagy is a process in which a cell eats its own contents (*Greek: auto,* self; *phagy,* eating). It involves the delivery of cytoplasmic materials to the lysosome for degradation. Autophagy is an evolutionarily conserved survival mechanism whereby, in states of nutrient deprivation, starved cells live by cannibalizing themselves and recycling the digested contents. Autophagy is implicated in many physiologic states (e.g., aging and exercise) and pathologic processes. It proceeds through several steps (Fig. 2.17):

- Nucleation and formation of an isolation membrane, also called a *phagophore;* the isolation membrane is believed to be derived from the ER, though other membrane sources such as the plasma membrane and mitochondria may contribute
- Formation of a vesicle, called the *autophagosome,* from the isolation membrane, inside which intracellular organelles and cytosolic structures are sequestered
- Maturation of the autophagosome by fusion with lysosomes, to deliver digestive enzymes that degrade the contents of the autophagosome

In recent years, more than a dozen "autophagy-related genes" called *Atgs* have been identified whose products are required for the creation of the autophagosome. Environmental cues like nutrient deprivation or depletion of growth factors activate an initiation complex of four proteins that promotes the hierarchical recruitment of *Atgs* to nucleate the initiation membrane. The initiation membrane elongates further, surrounds and captures its cytosolic cargo, and closes to form the autophagosome. The elongation and closure of the initiation membrane require the coordinated action of two ubiquitin-like conjugation systems that result in the covalent linkage of the lipid phosphatidylethanolamine (PE) to microtubule-associated protein light chain 3 (LC3). PE-lipidated LC3 is increased during autophagy, and it is therefore a useful marker for identifying cells in which autophagy is occurring. The newly formed autophagosome fuses with lysosomes to form an autophagolysosome. In the terminal step, the inner membrane and enclosed cytosolic cargoes are degraded by lysosomal enzymes. There is increasing evidence that autophagy is not a random process that engulfs cytosolic contents indiscriminately. Rather, the loading of cargo into the autophagosome is selective, and one of the functions of the lipidated LC3 is to target protein aggregates and effete organelles.

Autophagy functions as a survival mechanism under various stress conditions, maintaining the integrity of cells by recycling essential metabolites and clearing intracellular debris. It is therefore prominent in atrophic cells exposed to severe nutrient deprivation. Autophagy is also involved in the turnover of organelles like the ER, mitochondria, and lysosomes and the clearance of intracellular aggregates that accumulate during aging, stress, and various disease states. Autophagy can trigger cell death if it is inadequate to cope

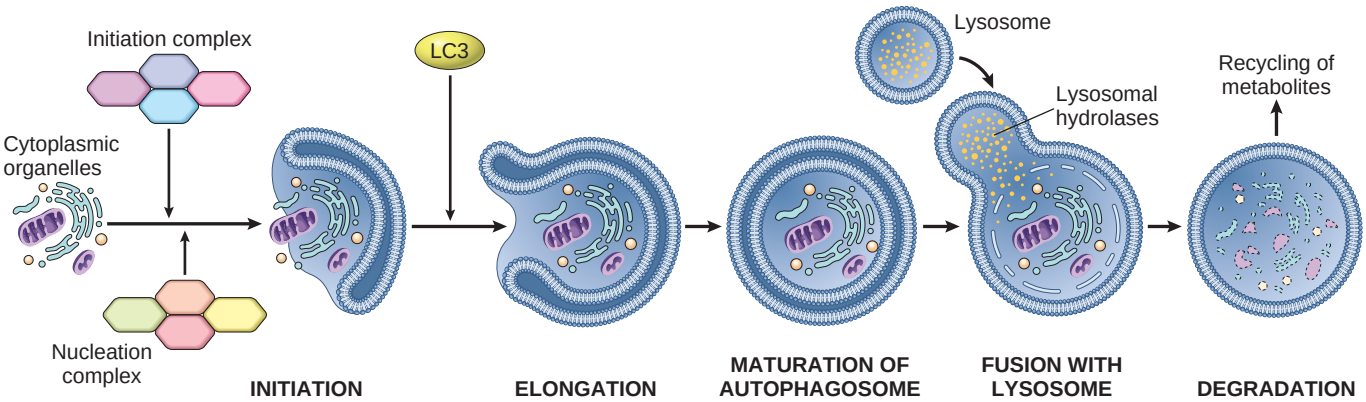

Figure 2.17 Autophagy. Cellular stresses, such as nutrient deprivation, activate an autophagy pathway that proceeds through several phases (initiation, nucleation, and elongation of isolation membrane) and eventually creates double-membrane-bound vacuoles (autophagosome) in which cytoplasmic materials, including organelles, are sequestered and then degraded after fusion of the vesicles with lysosomes. In the final stage, the digested materials are released for recycling of metabolites. See text for details. *LC3,* Light chain 3. (Modified from Choi, AMK, Ryter S, Levine B: Autophagy in human health and disease, *N Engl J Med* 368:651, 2013.)

with the stressor. This pathway of cell death is distinct from necrosis and apoptosis, but the mechanism is unknown. Furthermore, it is not clear whether cell death is caused by autophagy or by the stress that triggered autophagy. Nevertheless, autophagic vacuolization often precedes or accompanies cell death.

There is accumulating evidence that autophagy plays a role in human diseases, including the following:

- *Cancer:* Autophagy can both promote cancer growth and act as a defense against cancers. This is an area of active investigation, as discussed in Chapter 7.
- *Neurodegenerative disorders:* Many neurodegenerative disorders are associated with dysregulation of autophagy. Alzheimer disease is characterized by impaired autophagosome maturation, and in mouse models of the disease genetic defects in autophagy accelerate neurodegeneration. In Huntington disease, mutant huntingtin impairs autophagy.
- *Infectious diseases:* Many pathogens are degraded by autophagy; these include mycobacteria, *Shigella* spp., and HSV-1. This is one way by which microbial proteins are digested and delivered to antigen presentation pathways. Macrophage-specific deletion of Atg5 increases susceptibility to tuberculosis.
- *Inflammatory bowel diseases:* Genome-wide association studies have linked both Crohn disease and ulcerative colitis to single-nucleotide polymorphisms (SNPs) in the autophagy-related gene *ATG16L1*. How these polymorphisms promote intestinal inflammation is not known.

KEY CONCEPTS

AUTOPHAGY

- Autophagy involves sequestration of cellular organelles into cytoplasmic autophagic vacuoles (autophagosomes) that fuse with lysosomes and digest enclosed material.
- Autophagy is an adaptive response that is enhanced during nutrient deprivation, allowing the cell to cannibalize itself to survive.
- Autophagosome formation is regulated by more than a dozen proteins that act in a coordinated and sequential manner.
- Dysregulation of autophagy occurs in many disease states, including cancer, inflammatory bowel diseases, and neurodegenerative disorders. Autophagy plays a role in host defense against certain microbes.

MECHANISMS OF CELL INJURY

The discussion of the pathways of cell injury and death sets the stage for a consideration of the underlying biochemical mechanisms of cell injury. The molecular alterations that lead to cell injury are complex, but several principles are relevant to most forms of cell injury:

- **The cellular response to injurious stimuli depends on the nature of the injury, its duration, and its severity.** Small doses of a chemical toxin or brief periods of ischemia may induce reversible injury, whereas large doses of the same toxin or more prolonged ischemia might result either in rapid cell death or in slowly progressive injury that with time becomes irreversible and leads to cell death.
- **The consequences of cell injury depend on the type, state, and adaptability of the injured cell.** The cell's nutritional and hormonal status, metabolic demands, and functions dictate the response to injury. How vulnerable is a cell, for example, to loss of blood supply and hypoxia? When a skeletal muscle cell in the leg is deprived of its blood supply, it can be rested and preserved; cardiac muscle cells have no such option. Exposure of two individuals to identical concentrations of a toxin, such as carbon tetrachloride, may produce no effect in one and cell death in the other. This may be due to polymorphisms in genes encoding hepatic enzymes that metabolize carbon tetrachloride (CCl_4) to toxic by-products (Chapter 9). With the complete mapping of the human genome, there is great interest in identifying genetic polymorphisms that affect the responses of different individuals to various injurious agents.
- **Any injurious stimulus may simultaneously trigger multiple interconnected mechanisms that damage cells.** This is one reason why it can be difficult to ascribe cell injury in a particular situation to a single or even dominant biochemical derangement.

We start this section with a discussion of general mechanisms that are involved in reversible injury and necrosis caused by diverse stimuli and conclude with a discussion of the pathways of injury in selected clinical situations that illustrate general principles.

General Mechanisms of Cell Injury and Intracellular Targets of Injurious Stimuli

Cell injury results from abnormalities in one or more essential cellular components (Fig. 2.18). The principal targets of injurious stimuli are mitochondria, cell membranes, the machinery of protein synthesis and secretion, and DNA. The consequences of injury of each of these cellular components are distinct but overlapping.

Mitochondrial Damage

Mitochondria are critical players in all pathways leading to cell injury and death. This should be expected because mitochondria supply life-sustaining energy by producing ATP but are also targets of many injurious stimuli. Thus, in many ways, they are the arbiters of life and death of cells. Mitochondria can be damaged by increases of cytosolic Ca^{2+}, ROS (discussed later), and oxygen deprivation, which makes them sensitive to virtually all types of injurious stimuli, including hypoxia and toxins. In addition, mutations in mitochondrial genes are the cause of some inherited diseases (Chapter 5).

There are three major consequences of mitochondrial damage.

- *ATP depletion.* Decreased ATP synthesis and ATP depletion are frequently associated with both hypoxic and chemical (toxic) injury (Fig. 2.19). ATP is produced in two ways. The major pathway in mammalian cells, particularly those that are nondividing (e.g., brain and liver), is oxidative phosphorylation of adenosine diphosphate in a reaction that results in reduction of oxygen by the mitochondrial electron transport system. The second is the glycolytic pathway, which can generate ATP, albeit in far smaller

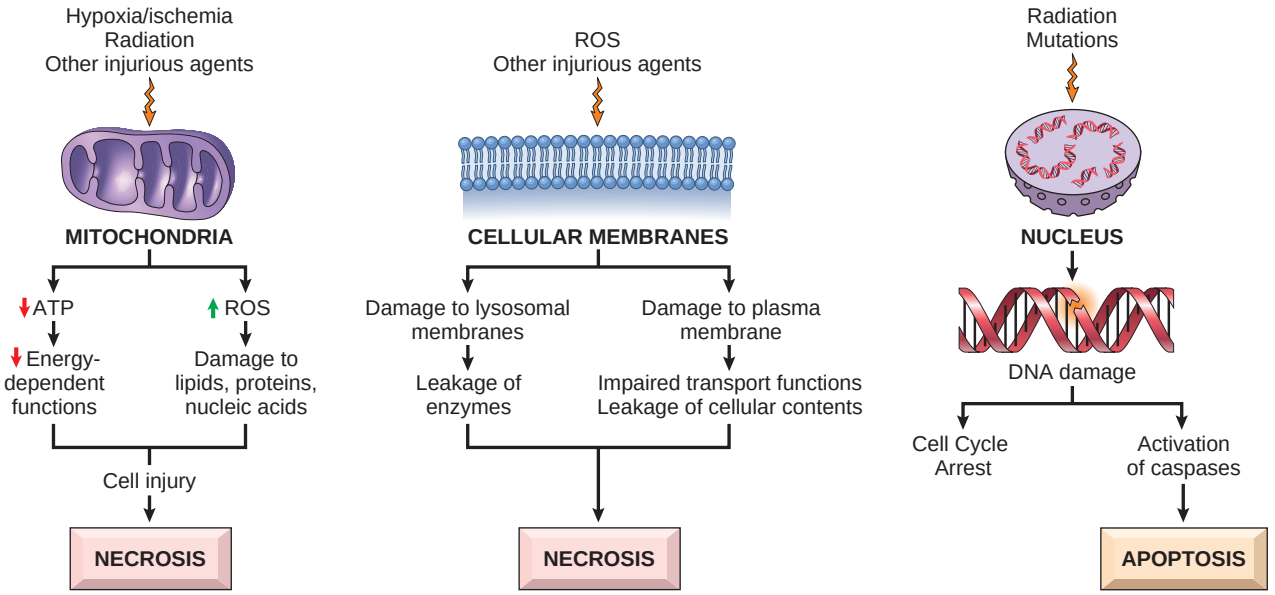

Figure 2.18 The principal forms and sites of damage in cell injury. *ATP*, Adenosine triphosphate; *ROS*, reactive oxygen species.

amounts, in the absence of oxygen using glucose derived either from body fluids or from the hydrolysis of glycogen. In addition to mitochondrial damage, *the major causes of ATP depletion are reduced supply of oxygen and nutrients (because of ischemia and hypoxia), and the actions of some toxins (e.g., cyanide)*. Mitochondrial damage often results in the formation of a high-conductance channel in the mitochondrial membrane, called the *mitochondrial permeability transition pore* (see Fig. 2.19). The opening of this conductance channel leads to the loss of mitochondrial membrane potential, resulting in failure of oxidative phosphorylation and progressive ATP depletion that culminates in necrosis.

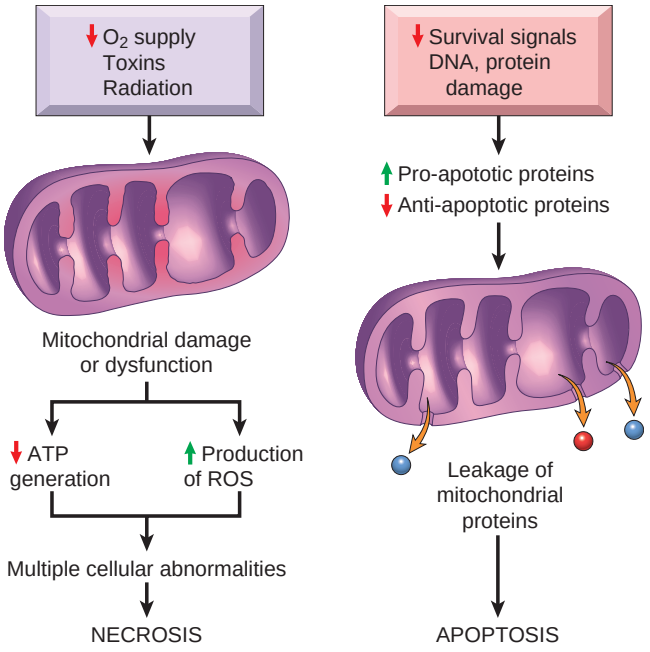

Figure 2.19 Role of mitochondria in cell injury and death. Mitochondria are affected by a variety of injurious stimuli, and their abnormalities lead to necrosis or apoptosis. *ATP*, Adenosine triphosphate; *ROS*, reactive oxygen species.

High-energy phosphate in the form of ATP is required for virtually all synthetic and degradative processes within the cell. These include membrane transport, protein synthesis, lipogenesis, and the deacylation-reacylation reactions necessary for phospholipid turnover. *Hence, depletion of ATP to 5% to 10% of normal levels has widespread effects on many critical cellular systems*.

- The activity of the *plasma membrane energy-dependent sodium pump* (Na^+,K^+-ATPase) is reduced (Chapter 1). Failure of this active transport system causes sodium to enter and accumulate inside cells and potassium concentrations to fall. The net solute gain results in osmotically driven water accumulation that leads to *cell swelling* and ER dilation.
- *Cellular energy metabolism is altered*. If the supply of oxygen to cells is reduced, as in ischemia, oxidative phosphorylation ceases, resulting in a decrease in cellular ATP and associated increase in adenosine monophosphate. These changes stimulate phosphorylase and phosphofructokinase activities, leading to increased rates of glycogenolysis and glycolysis, respectively, in an effort to maintain energy supplies by generating ATP through metabolism of glucose derived from glycogen. As a consequence, *glycogen stores are rapidly depleted*. Glycolysis under anaerobic conditions results in the accumulation of *lactic acid* and inorganic phosphates from the hydrolysis of phosphate esters. This reduces the intracellular pH, resulting in decreased activity of many cytosolic enzymes.
- With prolonged or worsening depletion of ATP, structural disruption of the protein synthetic apparatus occurs, manifest as detachment of ribosomes from the rough ER and dissociation of polysomes, with a consequent *reduction in protein synthesis*. There may

also be increased protein misfolding, with injurious effects that are discussed later.
    - Ultimately, there is irreversible damage to mitochondrial and lysosomal membranes, and the cell undergoes *necrosis*.
- Incomplete oxidative phosphorylation also leads to the formation of ROS, which have many deleterious effects, described later.
- As discussed earlier, leakage of mitochondrial proteins due to channel formation by pro-apoptotic BAX and BAK is the initial step in apoptosis by the intrinsic pathway. This action of BAX and BAK is specific to mitochondrial membranes only and leads to damage of other organelles indirectly.

Membrane Damage

Early loss of selective membrane permeability, leading ultimately to overt membrane damage, is a consistent feature of most forms of cell injury (except apoptosis). Membrane damage may affect the integrity and functions of all cellular membranes. In ischemic cells, membrane defects may be the result of ATP depletion and calcium-mediated activation of phospholipases. The plasma membrane can also be damaged directly by bacterial toxins, viral proteins, lytic complement components, and a variety of physical and chemical agents. Several biochemical mechanisms may contribute to membrane damage (Fig. 2.20):

- *ROS*. Oxygen free radicals cause injury to cell membranes by lipid peroxidation, discussed later.
- *Decreased phospholipid synthesis*. The production of phospholipids in cells may be reduced as a consequence of defective mitochondrial function or hypoxia, both of which decrease ATP production and thus affect energy-dependent biosynthetic pathways. Decreased phospholipid synthesis may affect all cellular membranes, including those of mitochondria.

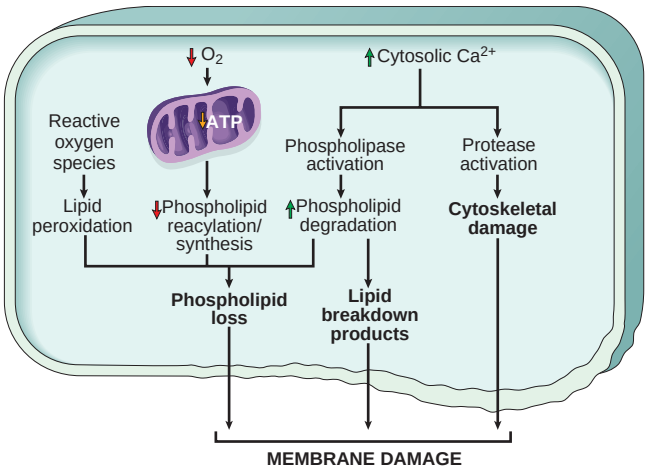

Figure 2.20 Mechanisms of membrane damage in cell injury. Decreased O_2 and increased cytosolic Ca^{2+} are typically seen in ischemia, but may accompany other forms of cell injury. Reactive oxygen species, which are often produced on reperfusion of ischemic tissues, also cause membrane damage *(not shown)*.

- *Increased phospholipid breakdown*. Severe cell injury is associated with increased degradation of membrane phospholipids, probably due to activation of calcium-dependent phospholipases by increased cytosolic and mitochondrial $Ca2^{+}$. Phospholipid breakdown leads to the accumulation of *lipid breakdown products*, including unesterified free fatty acids, acyl carnitine, and lysophospholipids, which have a detergent effect on membranes. They may also either insert into the lipid bilayer of the membrane or exchange with membrane phospholipids, potentially causing changes in permeability and electrophysiologic alterations.
- *Cytoskeletal abnormalities*. Cytoskeletal filaments serve as anchors connecting the plasma membrane to the cell interior, and proteases activated by cytosolic Ca^{2+} may damage these tethers. When exacerbated by cell swelling, particularly in myocardial cells, this damage leads to detachment of the cell membrane from the cytoskeleton, rendering it susceptible to stretching and rupture.

Damage to different cellular membranes has diverse effects on cells.

- *Mitochondrial membrane damage*. As discussed earlier, damage to mitochondrial membranes results in opening of the mitochondrial permeability transition pore, leading to decreased ATP generation and release of proteins that trigger apoptotic death.
- *Plasma membrane damage*. Plasma membrane damage results in loss of osmotic balance and influx of fluids and ions, as well as loss of cellular contents. The cells may also leak metabolites (e.g., glycolytic intermediates) that are vital for the reconstitution of ATP, thus further depleting energy stores.
- *Injury to lysosomal membranes* results in leakage of their enzymes into the cytoplasm and activation of acid hydrolases in the acidic intracellular pH of the injured cell. These lysosomal hydrolases include RNases, DNases, proteases, phosphatases, and glucosidases, which degrade RNA, DNA, proteins, phosphoproteins, and glycogen, respectively, and push cells into necrosis.

Damage to DNA

Damage to nuclear DNA activates sensors that trigger p53-dependent pathways (Chapter 7). DNA damage may be caused by exposure to radiation, chemotherapeutic (anticancer) drugs, and ROS, or may occur spontaneously as a part of aging, due largely to deamination of cytosine residues to uracil residues. DNA damage activates p53, which arrests cells in the G1 phase of the cell cycle and activates DNA repair mechanisms. If these mechanisms fail to correct the DNA damage, p53 triggers apoptosis by the mitochondrial pathway. Thus, the cell chooses to die rather than survive with abnormal DNA that has the potential to induce malignant transformation. Predictably, mutations in p53 that interfere with its ability to arrest cell cycling or to induce apoptosis are associated with numerous cancers (Chapter 7).

In addition to damage to various organelles, some biochemical alterations are involved in many situations that lead to cell injury. Two of these general pathways are discussed next.

Oxidative Stress: Accumulation of Oxygen-Derived Free Radicals

Cell injury induced by free radicals, particularly ROS, is an important mechanism of cell damage in many pathologic conditions, such as chemical and radiation injury, ischemia-reperfusion injury (induced by restoration of blood flow in ischemic tissue), cellular aging, and microbial killing by phagocytes. *Free radicals* are chemical species that have a single unpaired electron in an outer orbit. Unpaired electrons are highly reactive and "attack" and modify adjacent molecules, such as inorganic or organic chemicals—proteins, lipids, carbohydrates, nucleic acids—many of which are key components of cell membranes and nuclei. Some of these reactions are autocatalytic, whereby molecules that react with free radicals are themselves converted into free radicals, thus propagating the chain of damage.

ROS are a type of oxygen-derived free radical whose role in cell injury is well established. ROS are produced normally in cells during mitochondrial respiration and energy generation, but they are degraded and removed by intracellular ROS scavengers. These defense systems allow cells to maintain a steady state in which free radicals may be present at low concentrations but do not cause damage. Increased production or decreased scavenging of ROS may lead to an excess of free radicals, a condition called *oxidative stress*. Oxidative stress has been implicated in a wide variety of pathologic processes, including cell injury, cancer, aging, and some degenerative diseases, such as Alzheimer disease. ROS are also produced in large amounts by activated leukocytes, particularly neutrophils and macrophages, during inflammatory reactions aimed at destroying microbes and cleaning up dead cells and other unwanted substances (Chapter 3).

The following section discusses the generation and removal of ROS, and how they contribute to cell injury. The properties of some of the most important free radicals are summarized in Table 2.2.

Generation of Free Radicals

Free radicals may be generated within cells in several ways (Fig. 2.21):

- *The reduction-oxidation reactions that occur during normal metabolic processes.* As a part of normal respiration, molecular O_2 is reduced by the transfer of four electrons to H_2 to generate two water molecules. This conversion is catalyzed by oxidative enzymes in the ER, cytosol, mitochondria, peroxisomes, and lysosomes. During this process, small amounts of partially reduced intermediates are produced in which different numbers of electrons have been transferred from O_2; these include superoxide anion ($O_2^{\cdot-}$, one electron), hydrogen peroxide (H_2O_2, two electrons), and hydroxyl radicals ($^{\cdot}OH$, three electrons).
- *Absorption of radiant energy* (e.g., ultraviolet light, x-rays). For example, ionizing radiation can hydrolyze water into $^{\cdot}OH$ and hydrogen (H) free radicals.
- Rapid bursts of ROS are produced in activated leukocytes during *inflammation*. This occurs in a precisely controlled reaction carried out by a plasma membrane multiprotein complex that uses NADPH oxidase for the redox reaction (Chapter 3). In addition, some intracellular oxidases (e.g., xanthine oxidase) generate $O_2^{\cdot-}$. Defects in leukocytic superoxide production lead to chronic granulomatous disease (Chapter 6).
- *Enzymatic metabolism of exogenous chemicals or drugs* can generate free radicals that are not ROS but have similar effects (e.g., CCl_4 can generate $^{\cdot}CCl_3$, described later in the chapter).
- *Transition metals* such as iron and copper donate or accept free electrons during intracellular reactions and catalyze free radical formation, as in the Fenton reaction ($H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$). Because most of the intracellular free iron is in the ferric (Fe^{3+}) state, it must be reduced to the ferrous (Fe^{2+}) form to participate in the Fenton reaction. This reduction can be enhanced by $O_2^{\cdot-}$, and

Table 2.2 Properties of the Principal Free Radicals Involved in Cell Injury

Properties	$O_2^{\cdot-}$	H_2O_2	$^{\cdot}OH$	$ONOO^-$
Mechanisms of production	Incomplete reduction of O_2 during oxidative phosphorylation; by phagocyte oxidase in leukocytes	Generated by SOD from $O_2^{\cdot-}$ and by oxidases in peroxisomes	Generated from H_2O by hydrolysis (e.g., by radiation); from H_2O_2 by Fenton reaction; from $O_2^{\cdot-}$	Produced by interaction of $O_2^{\cdot-}$ and NO generated by NO synthase in many cell types (endothelial cells, leukocytes, neurons, others)
Mechanisms of inactivation	Conversion to H_2O_2 and O_2 by SOD	Conversion to H_2O and O_2 by catalase (peroxisomes), glutathione peroxidase (cytosol, mitochondria)	Conversion to H_2O by glutathione peroxidase	Conversion to HNO_2 by peroxiredoxins (cytosol, mitochondria)
Pathologic effects	Stimulates production of degradative enzymes in leukocytes and other cells; may directly damage lipids, proteins, DNA; acts close to site of production	Can be converted to OH and OCl^-, which destroy microbes and cells; can act distant from site of production	Most reactive oxygen-derived free radical; principal ROS responsible for damaging lipids, proteins, and DNA	Damages lipids, proteins, DNA

HNO_2, Nitrite; *H_2O_2,* hydrogen peroxide; *NO,* nitric oxide; *$O_2^{\cdot-}$,* superoxide anion; *OCl^-,* hypochlorite; *OH,* hydroxyl radical; *$ONOO^-$,* peroxynitrite; *ROS,* reactive oxygen species; *SOD,* superoxide dismutase.

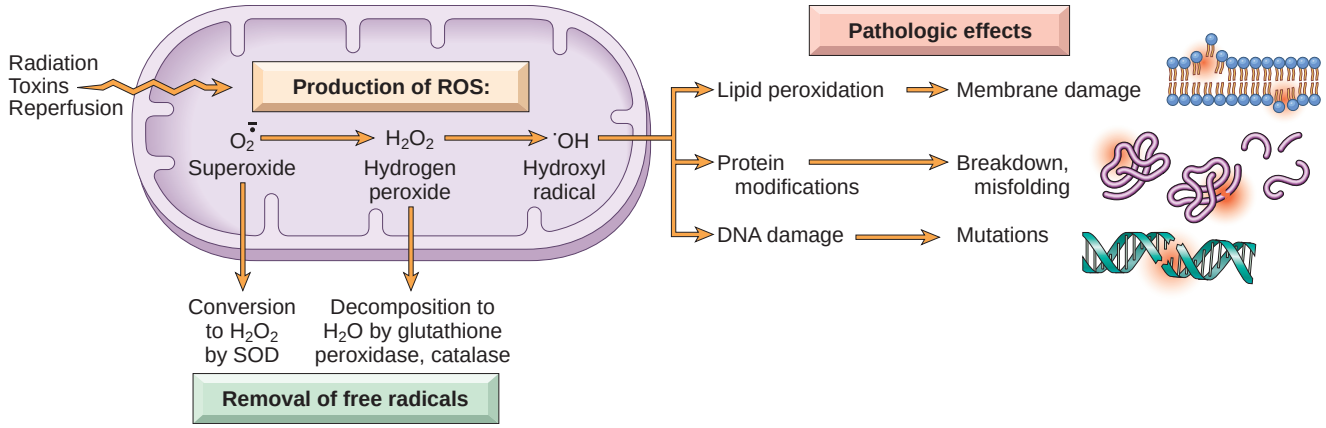

Figure 2.21 The generation, removal, and role of reactive oxygen species *(ROS)* in cell injury. The production of ROS is increased by many injurious stimuli. These free radicals are removed by spontaneous decay and by specialized enzymatic systems. Excessive production or inadequate removal leads to accumulation of free radicals in cells, which may damage lipids (by peroxidation), proteins, and deoxyribonucleic acid *(DNA)*, resulting in cell injury.

thus sources of iron and $O_2^{\cdot-}$ may cooperate in oxidative cell damage.

- *Nitric oxide (NO),* an important chemical mediator generated by endothelial cells, macrophages, neurons, and other cell types (Chapter 3), can act as a free radical and may also be converted to highly reactive peroxynitrite anion ($ONOO^-$) as well as NO_2 and NO_3^-.

Removal of Free Radicals

Free radicals are inherently unstable and generally decay spontaneously. $O_2^{\cdot-}$, for example, is unstable and decays (dismutates) spontaneously to O_2 and H_2O_2 in the presence of water. In addition, cells have developed multiple nonenzymatic and enzymatic mechanisms to remove free radicals and thereby minimize injury (see Fig. 2.21). These include the following:

- *Antioxidants* either block free radical formation or inactivate (e.g., scavenge) free radicals. Examples are the lipid-soluble vitamins E and A as well as ascorbic acid and glutathione in the cytosol.
- As we have seen, free *iron* and *copper* can catalyze the formation of ROS. Under normal circumstances, the reactivity of these metals is minimized by their binding to storage and transport proteins (e.g., transferrin, ferritin, lactoferrin, and ceruloplasmin), which prevents these metals from participating in reactions that generate ROS.
- Several *enzymes* act as free radical–scavenging systems and break down H_2O_2 and $O_2^{\cdot-}$. These enzymes are located near the sites of generation of the oxidants and include the following:
  1. *Catalase,* present in peroxisomes, decomposes H_2O_2 ($2H_2O_2 \rightarrow O_2 + 2H_2O$).
  2. *Superoxidase dismutases* (SODs) are found in many cell types and convert $O_2^{\cdot-}$ to H_2O_2 ($2O_2^{\cdot-} + 2H \rightarrow H_2O_2 + O_2$). This group of enzymes includes both manganese-SOD, which is localized in mitochondria, and copper-zinc-SOD, which is found in the cytoplasm.
  3. *Glutathione peroxidase* also protects against injury by catalyzing free radical breakdown ($H_2O_2 + 2GSH \rightarrow GSSG$ [glutathione homodimer] $+ 2H_2O$, or $2^{\cdot}OH + 2GSH \rightarrow GSSG + 2H_2O$). The intracellular ratio of oxidized glutathione (GSSG) to reduced glutathione (GSH) reflects the oxidative state of the cell and is an important indicator of the cell's ability to detoxify ROS.

Pathologic Effects of Free Radicals

The effects of ROS and other free radicals are wide-ranging, but three reactions are particularly relevant to cell injury (see Fig. 2.21):

- *Lipid peroxidation in membranes.* In the presence of O_2, free radicals may cause peroxidation of lipids within plasma and organellar membranes. Oxidative damage is initiated when the double bonds in unsaturated fatty acids of membrane lipids are attacked by O_2-derived free radicals, particularly by OH. The lipid–free radical interactions yield peroxides, which are themselves unstable and reactive, and an autocatalytic chain reaction ensues (called *propagation*) that can result in extensive membrane damage.
- *Oxidative modification of proteins.* Free radicals promote oxidation of amino acid side chains, formation of covalent protein-protein cross-links (e.g., disulfide bonds), and oxidation of the protein backbone. Oxidative modifications may also damage the active sites of enzymes, disrupt the conformation of structural proteins, and enhance proteasomal degradation of unfolded or misfolded proteins, thereby raising havoc throughout the cell.
- *Lesions in DNA.* Free radicals are capable of causing single- and double-strand breaks in DNA, cross-linking DNA strands, and forming adducts. Oxidative DNA damage has been implicated in cell aging (discussed later in the chapter) and in malignant transformation of cells (Chapter 7).

The traditional thinking about free radicals was that they cause cell injury and death by necrosis, and, in fact, the production of ROS is often a prelude to necrosis. However, it is now clear that free radicals can also trigger apoptosis. It is also possible that these potentially deadly molecules, when produced under controlled conditions in the "right" dose, serve important physiologic functions in signaling by cellular receptors and other pathways.

Disturbance in Calcium Homeostasis

Calcium ions normally serve as second messengers in several signaling pathways, but if released into the cytoplasm of cells in excessive amounts, are also an important source of cell injury. In keeping with this, calcium depletion protects cultured cells from injury induced by a variety of harmful stimuli. Cytosolic free Ca^{2+} is normally maintained at very low concentrations (~0.1 µmol) compared with extracellular levels of 1.3 mmol, and most intracellular Ca^{2+} is sequestered in mitochondria and the ER. Ischemia and certain toxins cause an excessive increase in cytosolic Ca^{2+}, initially because of release from intracellular stores, and later due to increased influx across the plasma membrane (Fig. 2.22). Excessive intracellular Ca^{2+} may cause cell injury by several mechanisms, although the significance of these mechanisms in cell injury in vivo is not established.

- The accumulation of Ca^{2+} in mitochondria results in opening of the mitochondrial permeability transition pore and, as described earlier, failure of ATP generation.
- Increased cytosolic Ca^{2+} activates a number of enzymes with potentially deleterious effects on cells. These enzymes include *phospholipases* (which cause membrane damage), *proteases* (which break down both membrane and cytoskeletal proteins), *endonucleases* (which are responsible for DNA and chromatin fragmentation), and *ATPases* (thereby hastening ATP depletion).

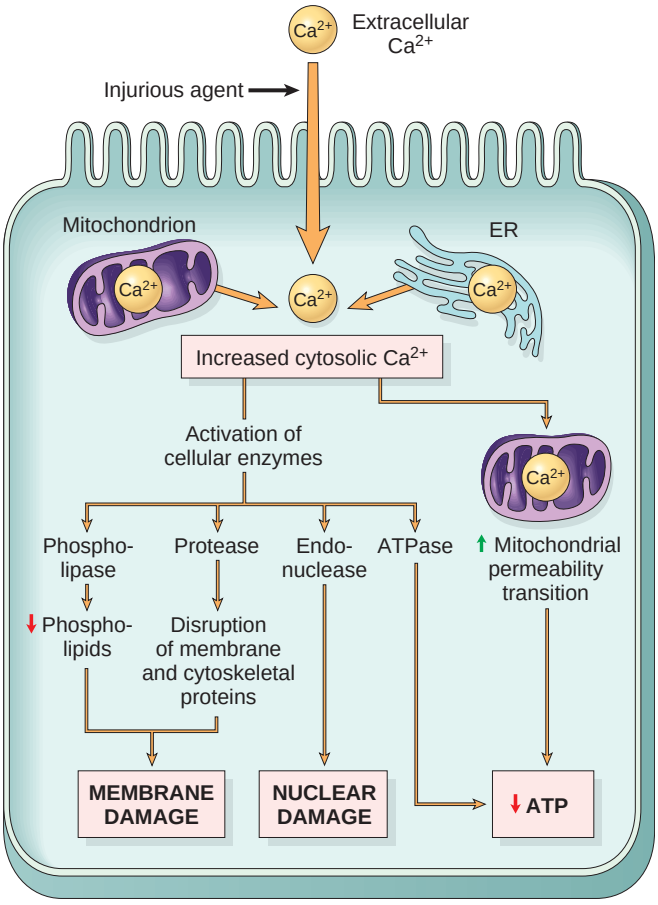

Figure 2.22 The role of increased cytosolic calcium in cell injury. *ER*, Endoplasmic reticulum.

Endoplasmic Reticulum Stress: the Unfolded Protein Response

The accumulation of misfolded proteins in the ER can stress adaptive mechanisms and trigger apoptosis. Chaperones in the ER control the proper folding of newly synthesized proteins, and misfolded polypeptides are shuttled into the cytoplasm where they are ubiquitinated and targeted for proteolysis in proteasomes (Chapter 1). If, however, unfolded or misfolded proteins accumulate in the ER, they trigger a number of alterations that are collectively called the *unfolded protein response*. The unfolded protein response activates signaling pathways that increase the production of chaperones, enhance proteasomal degradation of abnormal proteins, and slow protein translation, thus reducing the load of misfolded proteins in the cell (Fig. 2.23). However, if this cytoprotective response is unable to cope with the accumulation of misfolded proteins, the cell activates caspases and induces apoptosis. This process is called *ER stress.* Intracellular accumulation of misfolded proteins may be caused by an increased rate of misfolding or a reduction in the cell's ability to repair or eliminate them. Increased misfolding may be a consequence of deleterious mutations or decreased capacity to correct misfolded proteins, as occurs in aging. Protein misfolding may also be increased in viral infections when proteins encoded by the viral genome are synthesized in such large quantities that they overwhelm the quality control system that normally ensures proper protein folding. Increased demand for secretory proteins such as insulin in insulin-resistant states, and changes in intracellular pH and redox state are other stressors that result in misfolded protein accumulation. Protein misfolding is thought to be the causative cellular abnormality in several neurodegenerative diseases (Chapter 28). Given that many "foldases" require ATP to function, deprivation of glucose and oxygen, as in ischemia and hypoxia, also may increase the burden of misfolded proteins. Diseases caused by misfolded proteins are listed in Table 2.3.

KEY CONCEPTS

MECHANISMS OF CELL INJURY

- ATP depletion: failure of energy-dependent functions → reversible injury → necrosis
- Mitochondrial damage: ATP depletion → failure of energy-dependent cellular functions → ultimately, necrosis; under some conditions, leakage of mitochondrial proteins that cause apoptosis
- Increased permeability of cellular membranes: may affect plasma membrane, lysosomal membranes, mitochondrial membranes; typically culminates in necrosis
- Accumulation of damaged DNA and misfolded proteins: triggers apoptosis
- Accumulation of ROS: covalent modification of cellular proteins, lipids, nucleic acids
- Influx of calcium: activation of enzymes that damage cellular components and may also trigger apoptosis
- Unfolded protein response and ER stress: Accumulation of misfolded proteins in the ER activates adaptive mechanisms that help the cell to survive, but if their repair capacity is exceeded they trigger apoptosis.

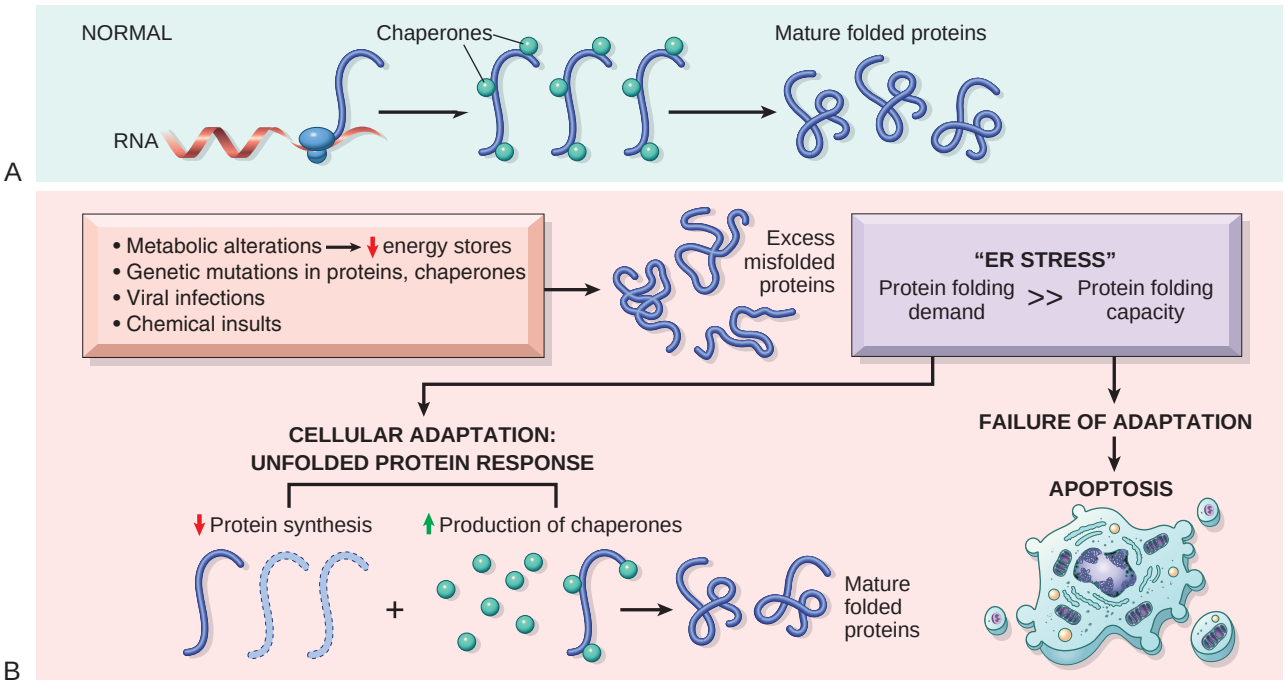

Figure 2.23 The unfolded protein response and endoplasmic reticulum *(ER)* stress. (A) In healthy cells, newly synthesized proteins are folded in the ER with the help of chaperones and are then incorporated into the cell or secreted. (B) Various external stresses or mutations induce a state called *ER stress*, in which the cell is unable to cope with the load of misfolded proteins. Accumulation of these proteins in the ER triggers the unfolded protein response, which tries to restore protein homeostasis; if this response is inadequate, the unfolded protein response actively signals apoptosis.

Table 2.3 Selected Examples of Diseases Caused by Misfolding of Proteins

Disease	Affected Protein	Pathogenesis
Cystic fibrosis	Cystic fibrosis transmembrane conductance regulator (CFTR)	Loss of CFTR leads to defects in chloride transport
Familial hypercholesterolemia	LDL receptor	Loss of LDL receptor leads to hypercholesterolemia
Tay-Sachs disease	Hexosaminidase β subunit	Lack of the lysosomal enzyme leads to storage of GM_2 gangliosides in neurons
α_1-antitrypsin deficiency	α_1-antitrypsin	Storage of nonfunctional protein in hepatocytes causes apoptosis; absence of enzymatic activity in lungs causes destruction of elastic tissue giving rise to emphysema
Creutzfeldt-Jacob disease	Prions	Abnormal folding of PrPsc causes neuronal cell death
Alzheimer disease	Aβ peptide	Abnormal folding of Aβ peptides causes aggregation within neurons and apoptosis

CLINICOPATHOLOGIC CORRELATIONS: SELECTED EXAMPLES OF CELL INJURY AND DEATH

Having briefly reviewed the causes, morphology, and general mechanisms of cell injury and death, we now describe some common and clinically significant forms of cell injury. These examples illustrate many of the mechanisms and sequence of events in cell injury described earlier.

Hypoxia and Ischemia

Ischemia, the most common cause of cell injury in clinical medicine, results from hypoxia induced by reduced blood flow, most often due to a mechanical arterial obstruction. It can also occur due to reduced venous drainage. In contrast to hypoxia, in which blood flow is maintained and during which energy production by anaerobic glycolysis can continue, ischemia compromises the delivery of substrates for glycolysis. Thus, in ischemic tissues, not only does aerobic metabolism cease but anaerobic energy generation also fails after glycolytic substrates are exhausted or glycolysis is inhibited by the accumulation of metabolites, which otherwise would be washed out by flowing blood. For this reason, *ischemia causes more rapid and severe cell and tissue injury than hypoxia*.

Mechanisms of Ischemic Cell Injury

The sequence of events following hypoxia or ischemia reflects many of the biochemical alterations in cell injury, summarized here in Fig. 2.24 and shown earlier in Figs. 2.5 and 2.6. As intracellular oxygen tension falls, oxidative phosphorylation fails and ATP generation decreases. The consequences of ATP depletion were described earlier in the Mitochondrial Damage section. In brief, loss of ATP results

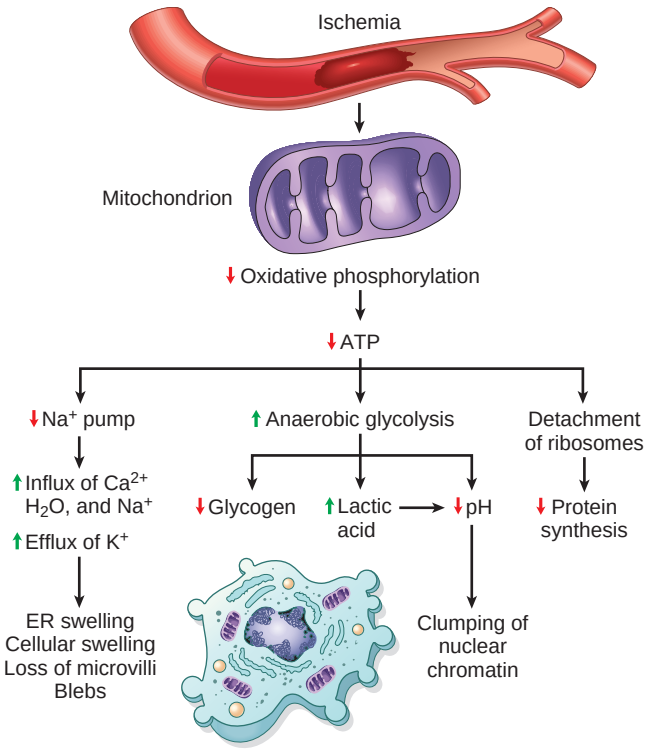

Figure 2.24 Functional and morphologic consequences of decreased intracellular adenosine triphosphate *(ATP)* in ischemic cell injury. The morphologic changes shown here are indicative of reversible cell injury. Further depletion of ATP results in cell death, typically by necrosis. *ER*, Endoplasmic reticulum.

initially in reversible cell injury (cell and organelle swelling) and later in cell death by necrosis.

Mammalian cells have developed protective responses to deal with hypoxic stress. The best defined of these is induction of a transcription factor called *hypoxia-inducible factor-1* (HIF-1), which promotes new blood vessel formation, stimulates cell survival pathways, and enhances glycolysis. Several promising investigational compounds that promote HIF-1 signaling are being developed. Nevertheless, there are still no reliable therapeutic approaches for reducing the injurious consequences of ischemia in clinical situations. The strategy that is perhaps the most useful in ischemic (and traumatic) brain and spinal cord injury is the transient induction of hypothermia (lowering the core body temperature to 92°F). This treatment reduces the metabolic demands of the stressed cells, decreases cell swelling, suppresses the formation of free radicals, and inhibits the host inflammatory response. All of these may contribute to decreased cell and tissue injury.

Ischemia-Reperfusion Injury

Restoration of blood flow to ischemic tissues can promote recovery of cells if they are reversibly injured but can also paradoxically exacerbate cell injury and cause cell death. As a consequence, reperfused tissues may sustain loss of viable cells in addition to those that are irreversibly damaged by the ischemia. This process, called *ischemia-reperfusion injury,* is clinically important because it contributes to tissue damage during myocardial and cerebral infarction following therapies that restore blood flow (Chapters 12 and 28).

How does reperfusion injury occur? The likely answer is that new damaging processes are set in motion during reperfusion, causing the death of cells that might have recovered otherwise. Several mechanisms have been proposed:

- *Oxidative stress.* New damage may be initiated during reoxygenation by increased generation of *reactive oxygen and nitrogen species.* These free radicals may be produced in reperfused tissue as a result of incomplete reduction of oxygen in leukocytes, and in damaged endothelial cells and parenchymal cells. Compromise of cellular antioxidant defense mechanisms during ischemia may sensitize cells to free radical damage.
- *Intracellular calcium overload.* As mentioned earlier, intracellular and mitochondrial calcium overload begins during acute ischemia; it is exacerbated during reperfusion due to influx of calcium resulting from cell membrane damage and ROS-mediated injury to sarcoplasmic reticulum. Calcium overload favors opening of the mitochondrial permeability transition pore with resultant ATP depletion. This, in turn, causes further cell injury.
- *Inflammation*. Ischemic injury is associated with inflammation as a result of "danger signals" released from dead cells, cytokines secreted by resident immune cells such as macrophages, and increased expression of adhesion molecules by hypoxic parenchymal and endothelial cells, all of which act to recruit circulating neutrophils to reperfused tissue. The inflammation causes additional tissue injury (Chapter 3). The importance of neutrophil influx in reperfusion injury has been demonstrated experimentally by the salutary effects of treatment with antibodies that block cytokines or adhesion molecules and thereby reduce neutrophil extravasation.
- Activation of the *complement system* may contribute to ischemia-reperfusion injury. For unknown reasons, some IgM antibodies have a propensity to deposit in ischemic tissues. When blood flow is resumed, complement proteins bind to the deposited antibodies, are activated, and exacerbate cell injury and inflammation.

Chemical (Toxic) Injury

Chemical injury remains a frequent problem in clinical medicine and is a major limitation to drug therapy. Because many drugs are metabolized in the liver, this organ is a major target of drug toxicity. In fact, toxic liver injury is often the reason for terminating the therapeutic use or development of a drug. The mechanisms by which chemicals, certain drugs, and toxins produce injury are described in greater detail in Chapter 9 in the discussion of environmental diseases. Here the major pathways of chemically induced injury with selected examples are described.

Chemicals induce cell injury by one of two general mechanisms:

- *Direct toxicity.* Some chemicals injure cells directly by combining with critical molecular components. For example, in mercuric chloride poisoning, *mercury* binds to the sulfhydryl groups of cell membrane proteins, causing increased membrane permeability and inhibition of ion transport. In such instances, the greatest damage is usually to the cells that use, absorb, excrete, or concentrate the chemicals—in the case of mercuric chloride, the cells of

the gastrointestinal tract and kidney (Chapter 9). *Cyanide* poisons mitochondrial cytochrome oxidase and thus inhibits oxidative phosphorylation. Many antineoplastic chemotherapeutic agents and antibiotics also induce cell damage by direct cytotoxic effects.

- *Conversion to toxic metabolites.* Most toxic chemicals are not biologically active in their native form but must be converted to reactive toxic metabolites, which then act on target molecules. This modification is usually accomplished by the cytochrome P-450 mixed-function oxidases in the smooth ER of the liver and other organs. The toxic metabolites cause membrane damage and cell injury mainly by formation of free radicals and subsequent lipid peroxidation; direct covalent binding to membrane proteins and lipids may also contribute. For instance, CCl_4, which was once widely used in the dry cleaning industry, is converted by cytochrome P-450 to the highly reactive free radical $^{\cdot}CCl_3$, which causes lipid peroxidation and damages many cellular structures. The analgesic drug acetaminophen is also converted to a toxic product during detoxification in the liver, leading to cell injury. These and other examples of chemical injury are described in Chapter 9.

KEY CONCEPTS

EXAMPLES OF CELL INJURY

- Mild ischemia: Reduced oxidative phosphorylation → ATP depletion → failure of Na pump → influx of sodium and water → organelle and cellular swelling (reversible)
- Severe/prolonged ischemia: Severe swelling of mitochondria, calcium influx into mitochondria and into the cell with rupture of lysosomes and plasma membrane. Death by necrosis and apoptosis due to release of cytochrome c from mitochondria.
- Reperfusion injury follows restoration of blood flow to ischemic tissues and is caused by oxidative stress due to release of free radicals from leukocytes and endothelial cells. Blood brings calcium that overloads reversibly injured cells with consequent mitochondrial injury, as well as oxygen and leukocytes, which generate free radicals and cytokines. Complement may be activated locally by IgM antibodies deposited in ischemic tissues.
- Chemicals may cause injury directly or by conversion into toxic metabolites. The organs chiefly affected are those involved in absorption or excretion of chemicals or others such as liver, where the chemicals are converted to toxic metabolites. Direct injury to critical organelles such as mitochondria or indirect injury from free radicals generated from the chemicals/toxins is involved.

ADAPTATIONS OF CELLULAR GROWTH AND DIFFERENTIATION

Adaptations are reversible changes in the size, number, phenotype, metabolic activity, or functions of cells in response to changes in their environment. Such adaptations may take several distinct forms.

Hypertrophy

Hypertrophy is an increase in the size of cells that results in an increase in the size of the affected organ. The hypertrophied organ has no new cells, just larger cells. The increased size of the cells is due to the synthesis and assembly of additional intracellular structural components. Cells capable of division may respond to stress by undergoing both hyperplasia (described later) and hypertrophy, whereas nondividing cells (e.g., myocardial fibers) increase tissue mass due to hypertrophy. In many sites, hypertrophy and hyperplasia may coexist, with both contributing to increased organ size.

Hypertrophy can be *physiologic* or *pathologic;* the former is caused by increased functional demand or stimulation by hormones and growth factors.

- *Pathologic hypertrophy.* The striated muscle cells in the heart and skeletal muscles have only a limited capacity for division, and respond to increased metabolic demands mainly by undergoing hypertrophy. *The most common stimulus for hypertrophy of skeletal and cardiac muscle is increased workload.* In both tissue types, muscle cells respond by synthesizing more protein and increasing the number of myofilaments per cell. This in turn increases the amount of force each myocyte can generate and thus the strength and work capacity of the muscle as a whole. A classic example of pathologic hypertrophy is enlargement of the heart in response to pressure overload, usually resulting from either hypertension or valvular disease (see Fig. 2.2). Initially, cardiac hypertrophy improves function, but over time this adaptation often fails, setting the stage for heart failure and other significant forms of heart disease (Chapter 12).
- *Physiologic hypertrophy.* The massive physiologic growth of the uterus during pregnancy is a good example of hormone-induced enlargement of an organ that results mainly from hypertrophy of smooth muscle fibers (Fig. 2.25). Uterine hypertrophy during pregnancy is stimulated by estrogenic hormone signaling through estrogen receptors that eventually result in increased synthesis of smooth muscle proteins and an increased cell size. The bulging muscles of bodybuilders engaged in "pumping iron" result from enlargement of individual skeletal muscle fibers in response to increased demand.

Mechanisms of Hypertrophy

Hypertrophy is a result of increased cellular protein production. Much of our understanding of hypertrophy is based on studies of the heart. There is great interest in defining the molecular basis of myocardial hypertrophy because beyond a certain point, it becomes maladaptive. Hypertrophy results from the action of growth factors and direct effects on cellular proteins (Fig. 2.26):

- Mechanical sensors in the cell detect the increased load.
- These sensors activate a complex downstream web of signaling pathways, including the phosphoinositide 3-kinase (PI3K)/AKT pathway (postulated to be most important in physiologic, e.g., exercise-induced, hypertrophy) and G-protein–coupled receptor–initiated pathways (activated by many growth factors and vasoactive agents, and thought to be more important in pathologic hypertrophy).
- Some of the signaling pathways stimulate increased production of growth factors (e.g. TGF-β, insulin-like growth factor 1 [IGF1], fibroblast growth factor) and vasoactive agents (e.g., α-adrenergic agonists, endothelin-1, and angiotensin II).

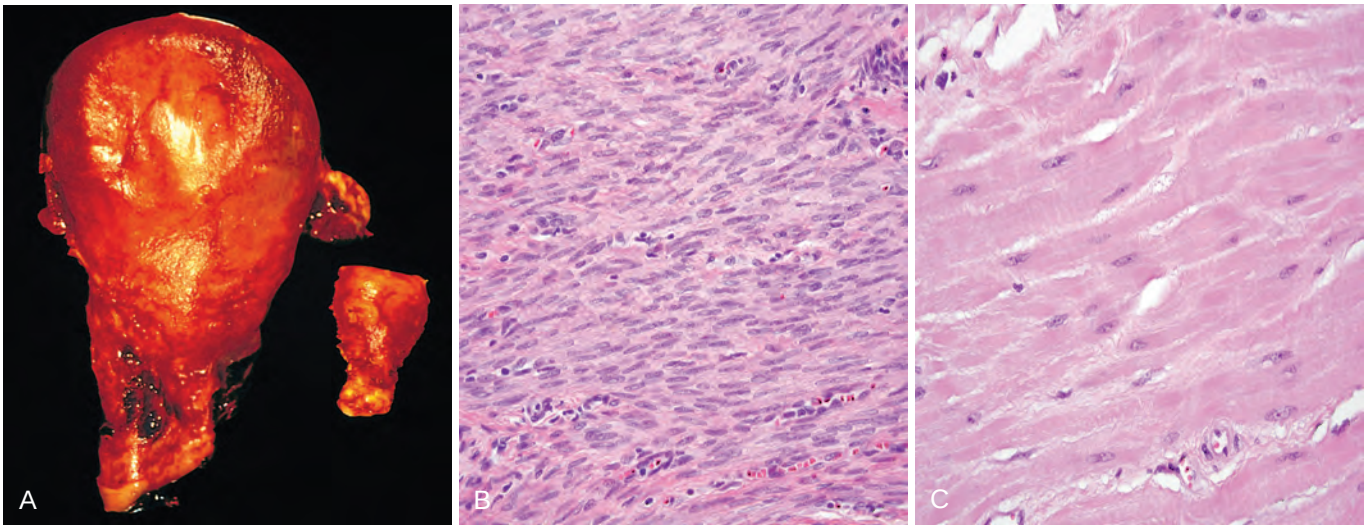

Figure 2.25 Physiologic hypertrophy of the uterus during pregnancy. (A) Gross appearance of a normal uterus *(right)* and a gravid uterus (removed for postpartum bleeding) *(left)*. (B) Small spindle-shaped uterine smooth muscle cells from a normal uterus, compared with (C) large plump cells from the gravid uterus, at the same magnification.

- These and other pathways activate transcription factors, including GATA4, nuclear factor of activated T cells (NFAT), and myocyte enhancer factor 2 (MEF2), which increase the expression of genes that encode muscle proteins.

Cardiac hypertrophy is also associated with a switch in gene expression from genes that encode adult-type contractile proteins to genes that encode functionally distinct fetal isoforms of the same proteins. For example, the α isoform of myosin heavy chain is replaced by the β isoform, which has a slower, more energetically economical contraction. Other proteins that are altered in hypertrophic myocardial cells are the products of genes that participate in the cellular response to stress. For example, cardiac hypertrophy is associated with increased atrial natriuretic factor gene expression. Atrial natriuretic factor is a peptide hormone that causes salt secretion by the kidney, decreases

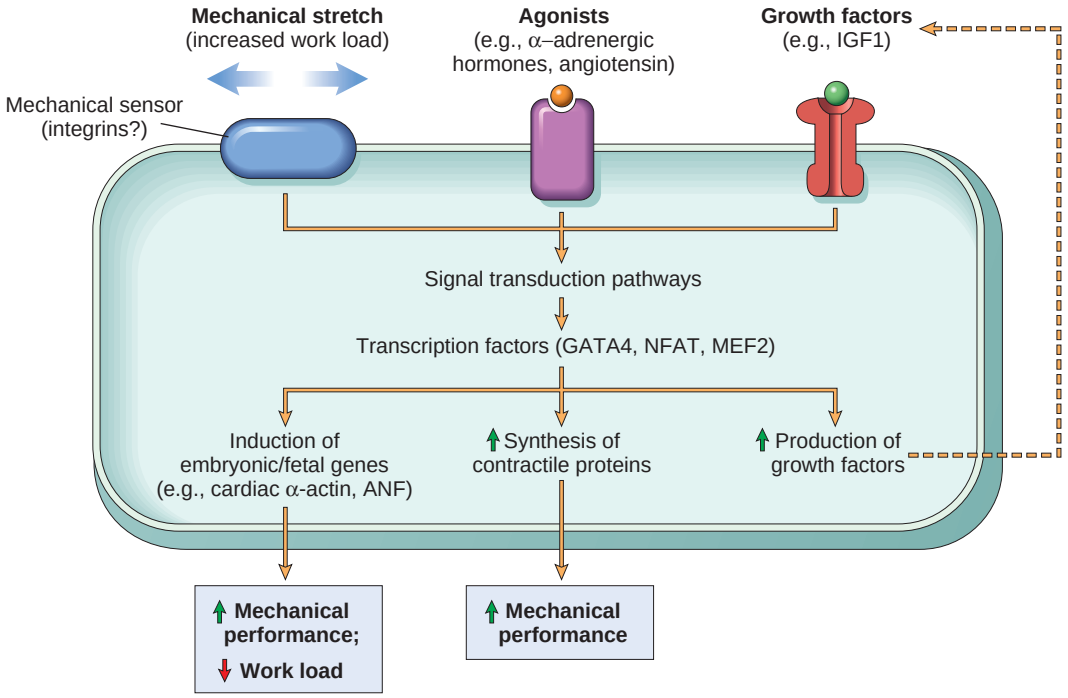

Figure 2.26 Biochemical mechanisms of myocardial hypertrophy. The major known signaling pathways and their functional effects are shown. Mechanical sensors appear to be the major triggers for physiologic hypertrophy, and agonists and growth factors may be more important in pathologic states. *ANF,* Atrial natriuretic factor; *GATA4,* transcription factor that binds to DNA sequence GATA; *IGF1,* insulin-like growth factor; *NFAT,* nuclear factor–activated T cells; *MEF2,* myocardial enhancing factor 2.

blood volume and pressure, and therefore serves to reduce hemodynamic load.

Whatever the exact cause and mechanism of cardiac hypertrophy, it eventually reaches a limit beyond which enlargement of muscle mass is no longer able to cope with the increased burden. At this stage, several regressive changes occur in the myocardial fibers, of which the most important are degradation and loss of myofibrillar contractile elements. In extreme cases, myocyte death can occur. The net result of these changes is cardiac failure, a sequence of events that illustrates how an adaptation to stress can progress to functionally significant cell injury if the stress is not relieved.

Hyperplasia

Hyperplasia is an increase in the number of cells in an organ or tissue in response to a stimulus. Although hyperplasia and hypertrophy are distinct processes, they frequently occur together, and may be triggered by the same external stimuli. Hyperplasia can only take place if the tissue contains cells capable of dividing, thus increasing the number of cells. It can be physiologic or pathologic.

- *Physiologic hyperplasia.* **Physiologic hyperplasia due to the action of hormones or growth factors occurs when there is a need to increase functional capacity of hormone sensitive organs, or when there is need for compensatory increase after damage or resection.** Hormonal hyperplasia is well illustrated by the proliferation of the glandular epithelium of the female breast at puberty and during pregnancy, usually accompanied by enlargement (hypertrophy) of the glandular epithelial cells. The classic illustration of compensatory hyperplasia comes from the study of liver regeneration. In individuals who donate one lobe of the liver for transplantation, the remaining cells proliferate so that the organ soon grows back to its original size. Experimental models of partial hepatectomy have been very useful for defining the mechanisms that stimulate regeneration of the liver (Chapter 3). The bone marrow is also remarkable in its capacity to undergo rapid hyperplasia in response to a deficiency of mature blood cells. For example, in the setting of an acute bleeding or premature breakdown of red blood cells (hemolysis), feedback loops involving the growth factor erythropoietin are activated that stimulate the growth of red blood cell progenitors, allowing red blood cell production to increase as much as eightfold. The regulation of hematopoiesis is discussed further in Chapter 13.
- *Pathologic hyperplasia.* **Most forms of pathologic hyperplasia are caused by excessive or inappropriate actions of hormones or growth factors acting on target cells.** Endometrial hyperplasia is an example of abnormal hormone-induced hyperplasia. Normally, after a menstrual period there is a rapid burst of proliferative activity in the endometrium that is stimulated by pituitary hormones and ovarian estrogen. It is brought to a halt by the rising levels of progesterone, usually about 10 to 14 days before the end of the menstrual period. In some instances, however, the balance between estrogen and progesterone is disturbed, resulting in absolute or relative increases in the amount of estrogen, with consequent hyperplasia of the endometrial glands. This form of pathologic hyperplasia is a common cause of abnormal uterine bleeding. Benign prostatic hyperplasia is another common example of pathologic hyperplasia, in this case as a response to hormonal stimulation by androgens. Although these forms of pathologic hyperplasias are abnormal, the process remains controlled and the hyperplasia can either regress or stabilize if the hormonal stimulation is eliminated. As is discussed in Chapter 7, the increased cell division associated with hyperplasia elevates the risk of acquiring genetic aberrations that drive unrestrained proliferation and cancer. Thus, *although hyperplasia is distinct from cancer, pathologic hyperplasia constitutes a fertile soil in which cancerous proliferations may eventually arise.* For instance, patients with hyperplasia of the endometrium are at increased risk for developing endometrial cancer (Chapter 22).

  Hyperplasia is a characteristic response to certain *viral infections,* such as papillomaviruses, which cause skin warts and several mucosal lesions composed of masses of hyperplastic epithelium. Here, the viruses make factors that interfere with host proteins that regulate cell proliferation. Like other forms of hyperplasia, some of these virally induced proliferations are also precursors to cancer (Chapter 7).

Mechanisms of Hyperplasia

Hyperplasia is the result of growth factor–driven proliferation of mature cells and, in some cases, by increased output of new cells from tissue stem cells. For instance, after partial hepatectomy, growth factors are produced in the liver that engage receptors on the surviving cells and activate signaling pathways that stimulate cell proliferation. But if the proliferative capacity of the liver cells is compromised, as in some forms of hepatitis causing cell injury, hepatocytes can instead regenerate from intrahepatic stem cells. The roles of growth factors and stem cells in cellular replication and tissue regeneration are discussed in more detail in Chapter 3.

Atrophy

Atrophy is a reduction in the size of an organ or tissue due to a decrease in cell size and number. Atrophy can be physiologic or pathologic. *Physiologic atrophy* is common during normal development. Some embryonic structures, such as the notochord and thyroglossal duct, undergo atrophy during fetal development. The decrease in the size of the uterus that occurs shortly after parturition is another form of physiologic atrophy.

Pathologic atrophy has several causes, and it can be local or generalized. Common causes of atrophy include the following:

- *Decreased workload (disuse atrophy).* When a fractured bone is immobilized in a plaster cast or when a patient is restricted to complete bed rest, skeletal muscle atrophy rapidly ensues. The initial decrease in cell size is reversible once activity is resumed. With more prolonged disuse, skeletal muscle fibers decrease in number (due to apoptosis) as well as in size; muscle atrophy can be accompanied by increased bone resorption, leading to osteoporosis of disuse.
- *Loss of innervation (denervation atrophy).* The normal metabolism and function of skeletal muscle are dependent

on its nerve supply. Damage to the nerves leads to atrophy of the muscle fibers supplied by those nerves (Chapter 27).

- *Diminished blood supply.* A gradual decrease in blood supply (chronic ischemia) to a tissue as a result of slowly developing arterial occlusive disease results in tissue atrophy. In late adult life, the brain may undergo progressive atrophy, mainly because of reduced blood supply as a result of atherosclerosis (Fig. 2.27). This is called *senile atrophy*.
- *Inadequate nutrition.* Profound protein-calorie malnutrition (marasmus) is associated with the utilization of skeletal muscle proteins as a source of energy after other reserves such as adipose stores have been depleted. This results in marked muscle wasting (*cachexia;* Chapter 9). Cachexia is also seen in patients with chronic inflammatory diseases and cancer. In some cachectic states, chronic overproduction of the inflammatory cytokine TNF is thought to be responsible for appetite suppression and lipid depletion, culminating in muscle atrophy.
- *Loss of endocrine stimulation.* Many hormone-responsive tissues, such as the breast and reproductive organs, are dependent on endocrine stimulation for normal metabolism and function. The loss of estrogen stimulation after menopause results in atrophy of the endometrium, vaginal epithelium, and breast. Similarly, the prostrate atrophies following chemical or surgical castration (e.g., for treatment of prostate cancer).
- *Pressure.* Tissue compression for any length of time can cause atrophy. An enlarging benign tumor can cause atrophy in the surrounding uninvolved tissues. Atrophy in this setting is probably the result of ischemic changes caused by compromise of the blood supply by the pressure exerted by the expanding mass.

The fundamental cellular changes associated with atrophy are similar in all of these settings. The initial response is a decrease in cell size and organelles, which may reduce the metabolic needs of the cell sufficiently to permit its survival. In atrophic muscle, the cells contain fewer mitochondria and myofilaments and a reduced amount of rough ER. By bringing into balance the cell's metabolic demands and the lower levels of blood supply, nutrition, or trophic stimulation, a new equilibrium is achieved. *Early in the process, atrophic cells and tissues have diminished function, but cell death is minimal*. However, atrophy caused by gradually reduced blood supply may progress to the point at which cells are irreversibly injured and die, often by apoptosis. Cell death by apoptosis also contributes to the atrophy of endocrine organs after hormone withdrawal.

Mechanisms of Atrophy

Atrophy results from decreased protein synthesis and increased protein degradation in cells. Protein synthesis decreases because of reduced trophic signals (e.g., those produced by growth receptors), which enhance uptake of nutrients and increase mRNA translation.

The degradation of cellular proteins occurs mainly by the *ubiquitin-proteasome pathway*. Nutrient deficiency and disuse may activate ubiquitin ligases, which attach the small peptide ubiquitin to cellular proteins and target these proteins for degradation in proteasomes. This pathway is also thought to be responsible for the accelerated proteolysis seen in a variety of catabolic conditions, including cancer cachexia. In many situations, atrophy is also accompanied by increased *autophagy,* marked by the appearance of increased numbers of autophagic vacuoles. Some of the cell debris within the autophagic vacuoles may resist digestion and persist in the cytoplasm as membrane-bound *residual bodies*. An example of residual bodies is *lipofuscin granules,* discussed later in the chapter. When present in sufficient amounts, they impart a brown discoloration to the tissue *(brown atrophy)*. Autophagy is associated with various types of cell injury, as discussed earlier.

Figure 2.27 Atrophy. (A) Normal brain of a young adult. (B) Atrophy of the brain in an 82-year-old man with atherosclerotic cerebrovascular disease, resulting in reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain.

Metaplasia

Metaplasia is a reversible change in which one differentiated cell type (epithelial or mesenchymal) is replaced by another cell type. It often represents an adaptive response in which one cell type that is sensitive to a particular stress is replaced by another cell type that is better able to withstand the adverse environment.

The most common epithelial metaplasia is columnar to squamous (Fig. 2.28), as occurs in the respiratory tract in response to chronic irritation. In the habitual cigarette smoker, the normal ciliated columnar epithelial cells of the trachea and bronchi are often replaced by stratified squamous epithelial cells. Vitamin A (retinoic acid) deficiency can also induce squamous metaplasia in the respiratory epithelium and in the cornea, the latter with highly deleterious effects on vision (Chapter 9). Stones in the excretory ducts of the salivary glands, pancreas, or bile ducts, which are normally lined by secretory columnar epithelium, may also lead to squamous metaplasia. In all these instances, the more rugged stratified squamous epithelium is able to survive under circumstances in which the more fragile specialized columnar epithelium might have succumbed. However, the change to metaplastic squamous cells comes with a price. In the respiratory tract, for example, although the epithelial lining becomes more durable, important mechanisms of protection against infection—mucus secretion and the ciliary action of the columnar epithelium—are lost. Thus, epithelial metaplasia, in most circumstances, represents an undesirable change. Moreover, *the influences that predispose to metaplasia, if persistent, can initiate malignant transformation in metaplastic epithelium*. The development of squamous cell carcinoma in areas of the lungs where the normal columnar epithelium has been replaced by squamous epithelium is one example.

Metaplasia from squamous to columnar type may also occur, as in *Barrett esophagus,* in which the esophageal squamous epithelium is replaced by intestinal-like columnar cells under the influence of refluxed gastric acid. As might be expected, the cancers that arise in these areas are typically glandular (adenocarcinomas) (Chapter 17).

Connective tissue metaplasia is the formation of cartilage, bone, or adipose cells (mesenchymal tissues) in tissues that normally do not contain these elements. For example, bone formation in muscle, designated *myositis ossificans,* occasionally occurs after intramuscular hemorrhage. This type of metaplasia is less clearly seen as an adaptive response, and may be a result of cell or tissue injury. Unlike epithelial metaplasia, this type of metaplasia is not associated with increased cancer risk.

Mechanisms of Metaplasia

Metaplasia does not result from a change in the phenotype of an already differentiated cell type; rather, it results from either reprogramming of local tissue stem cells or, alternatively, colonization by differentiated cell populations from adjacent sites. In either case, the metaplastic change is stimulated by signals generated by cytokines, growth factors, and extracellular matrix components in the cells' environment. In the case of stem cell reprogramming, these external stimuli promote the expression of genes that drive cells toward a specific differentiation pathway. A direct link between transcription factor dysregulation and metaplasia is seen with vitamin A (retinoic acid) deficiency or excess, both of which may cause metaplasia. Retinoic acid regulates gene transcription directly through nuclear retinoid receptors (Chapter 9), which can influence the differentiation of progenitors derived from tissue stem cells.

KEY CONCEPTS

CELLULAR ADAPTATIONS TO STRESS

- Hypertrophy: increased cell and organ size, often in response to increased workload; induced by growth factors produced in response to mechanical stress or other stimuli; occurs in tissues incapable of cell division. It may be physiologic (e.g., enlargement of the uterus in pregnancy) or pathologic (e.g., enlargement of the heart in hypertension of valvular disease).
- Hyperplasia: increased cell numbers in response to hormones and other growth factors; occurs in tissues whose cells are able to divide or contain abundant tissue stem cells. It may be physiologic in response to increased need (e.g., breast acini during lactation) or pathologic in response to inappropriate secretion of hormones (e.g., endometrial hyperplasia due to excessive estrogenic stimulation).
- Atrophy: decreased cell and organ size, as a result of decreased nutrient supply or disuse; associated with decreased synthesis of cellular building blocks and increased breakdown of cellular organelles by increased autophagy
- Metaplasia: change in phenotype of differentiated cells, often in response to chronic irritation, that makes cells better able to withstand the stress; usually induced by altered differentiation pathway of tissue stem cells; may result in reduced functions or increased propensity for malignant transformation

INTRACELLULAR ACCUMULATIONS

One of the manifestations of metabolic derangements in cells is the intracellular accumulation of substances that may be harmless or cause further injury. These accumulations may be located in the cytoplasm, within organelles (typically lysosomes), or in the nucleus, and they may be composed of substances that are synthesized by the affected cells or are produced elsewhere.

There are four main mechanisms leading to abnormal intracellular accumulations (Fig. 2.29):

- *Inadequate removal* of a normal substance secondary to defects in packaging and transport, as in fatty change (steatosis) in the liver (Chapter 18)
- Accumulation of an endogenous substance as a result of genetic or acquired *defects in its folding, packaging, transport, or secretion,* as with certain mutated forms of α_1-antitrypsin (Chapter 15)
- *Failure to degrade* a metabolite due to inherited enzyme deficiencies, typically lysosomal enzymes. The resulting disorders are called *lysosomal storage diseases* (Chapter 5).
- Deposition and accumulation of an *abnormal exogenous substance* when the cell has neither the enzymatic machinery to degrade the substance nor the ability to transport it to other sites. Accumulation of carbon or silica particles is an example of this type of alteration (Chapter 15).

In many cases, if the overload can be controlled or stopped, the accumulation is reversible. In inherited storage diseases, accumulation is progressive and may cause cellular injury, leading in some instances to death of the tissue and the patient.

Lipids

All major classes of lipids can accumulate in cells: triglycerides, cholesterol/cholesterol esters, and phospholipids. Phospholipids are components of the myelin figures found in necrotic cells. In addition, abnormal complexes of lipids and carbohydrates accumulate in the lysosomal storage diseases (Chapter 5). Triglyceride and cholesterol accumulations are discussed here.

Steatosis (Fatty Change)

The terms *steatosis* and *fatty change* describe abnormal accumulations of triglycerides within parenchymal cells. Fatty change is often seen in the liver because it is the major organ involved in fat metabolism (Fig. 2.30), but it also occurs in the heart, muscle, and kidney. The causes of steatosis include toxins, protein malnutrition, diabetes mellitus, obesity, and anoxia. In higher-income nations, the most common causes of significant fatty change in the liver (fatty liver) are alcohol abuse and nonalcoholic fatty liver disease, which is often associated with diabetes and obesity. Fatty liver is discussed in more detail in Chapter 18.

Cholesterol and Cholesterol Esters

The cellular metabolism of cholesterol (Chapter 5) is tightly regulated such that most cells use cholesterol for the synthesis of cell membranes without intracellular accumulation of

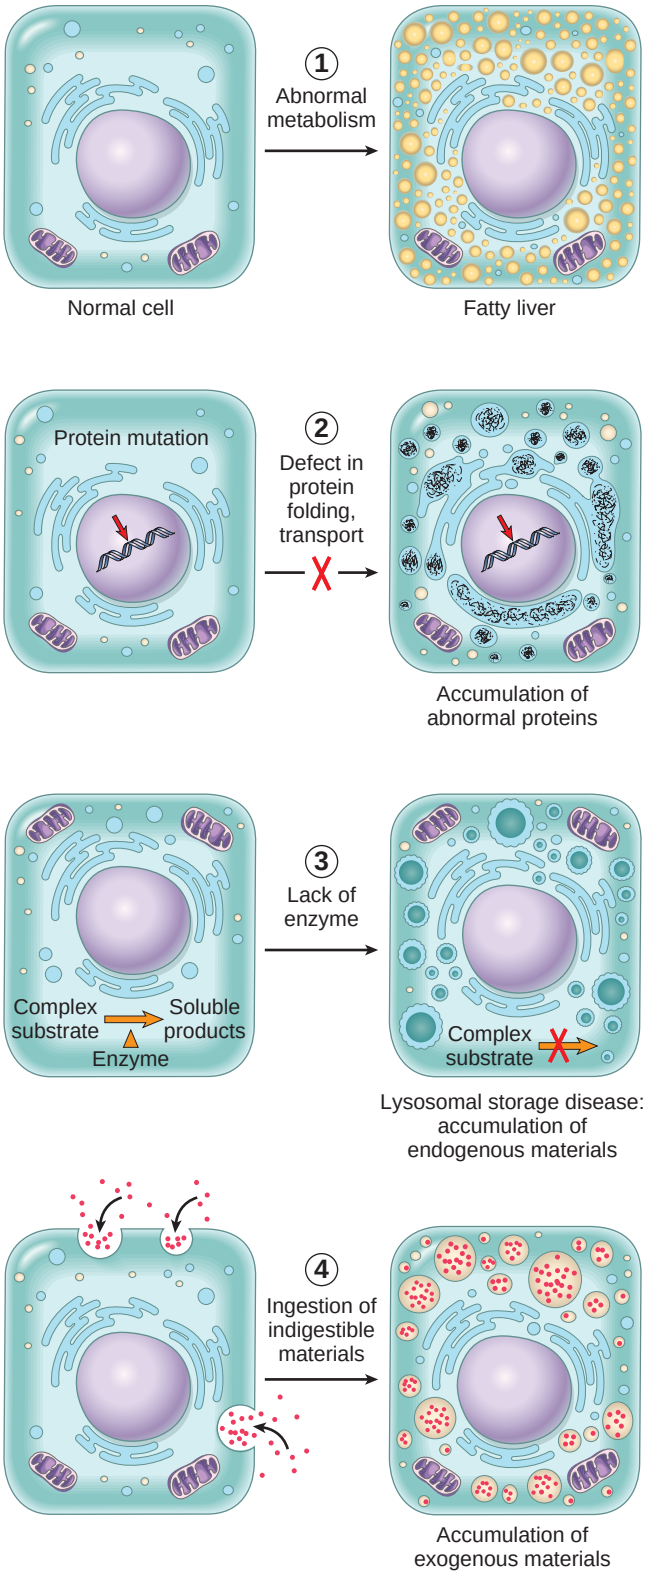

Figure 2.29 Mechanisms of intracellular accumulations discussed in the text.

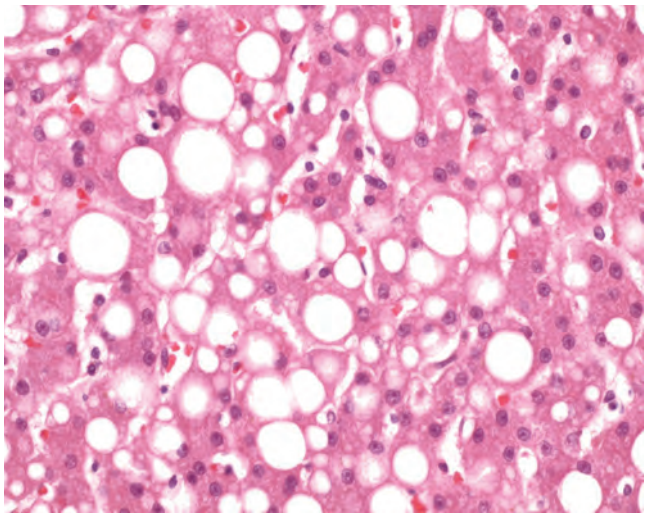

Figure 2.30 Fatty liver. High-power detail of fatty change of the liver. In most cells, the well-preserved nucleus is squeezed into the displaced rim of cytoplasm about the fat vacuole. (Courtesy Dr. James Crawford, Department of Pathology, Hofstra Northwell School of Medicine, NY.)

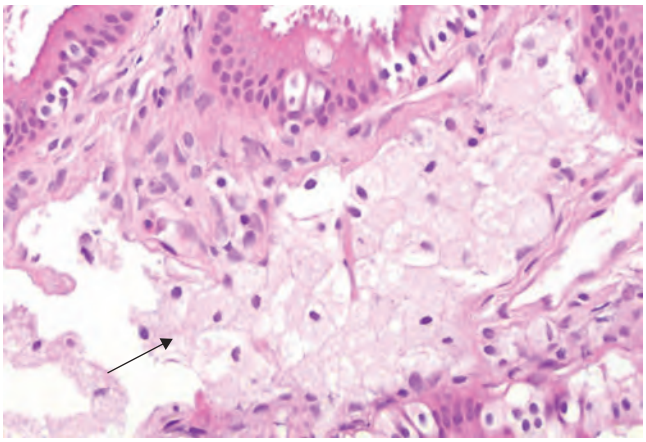

Figure 2.31 Cholesterolosis. Cholesterol-laden macrophages (foam cells, *arrow*) in a focus of gallbladder cholesterolosis. (Courtesy Dr. Matthew Yeh, Department of Pathology, University of Washington, Seattle, Wash.)

cholesterol or cholesterol esters. Accumulations manifested histologically by intracellular vacuoles are seen in several pathologic processes.

- *Atherosclerosis.* In atherosclerotic plaques, smooth muscle cells and macrophages within the intimal layer of the aorta and large arteries are filled with lipid vacuoles, most of which contain cholesterol and cholesterol esters. Such cells have a foamy appearance (foam cells), and aggregates of them in the intima produce the yellow cholesterol-laden atheromas characteristic of this serious disorder. Some of these fat-laden cells may rupture, releasing cholesterol and cholesterol esters into the extracellular space, where they may form crystals. Some form long needles that produce distinct clefts in tissue sections, while other small crystals are phagocytosed by macrophages and activate the inflammasome, contributing to local inflammation. The mechanisms of cholesterol accumulation and its pathogenic consequences in atherosclerosis are discussed in detail in Chapter 11.
- *Xanthomas.* Intracellular accumulation of cholesterol within macrophages is also characteristic of acquired and hereditary hyperlipidemic states. Clusters of foamy cells are found in the subepithelial connective tissue of the skin and in tendons, producing tumorous masses known as *xanthomas*.
- *Cholesterolosis.* This refers to the focal accumulations of cholesterol-laden macrophages in the lamina propria of the gallbladder (Fig. 2.31). The mechanism of accumulation is unknown.
- *Niemann-Pick disease, type C.* This lysosomal storage disease is caused by mutations affecting an enzyme involved in cholesterol trafficking, resulting in cholesterol accumulation in multiple organs (Chapter 5).

Proteins

Intracellular accumulations of proteins usually appear as rounded, eosinophilic droplets, vacuoles, or aggregates in the cytoplasm. By electron microscopy, they can be amorphous, fibrillar, or crystalline in appearance. In some disorders, such as certain forms of amyloidosis, abnormal proteins deposit primarily in extracellular spaces (Chapter 6).

Excesses of proteins within the cells sufficient to cause morphologically visible accumulation have diverse causes.

- *Reabsorption droplets in proximal renal tubules* are seen in renal diseases associated with protein loss in the urine (proteinuria). In the kidney, small amounts of protein filtered through the glomerulus are normally reabsorbed by pinocytosis in the proximal tubule. In disorders with heavy protein leakage across the glomerular filter, there is increased reabsorption of the protein into vesicles, and the protein appears as pink hyaline droplets within the cytoplasm of the tubular cell (Fig. 2.32). The process is reversible; if the proteinuria diminishes, the protein droplets are metabolized and disappear.
- The proteins that accumulate may be normal secreted proteins that are produced in excessive amounts and accumulate within the ER, as occurs in certain

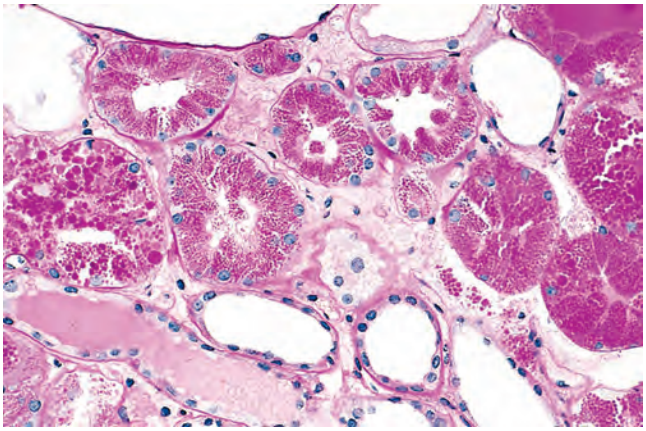

Figure 2.32 Protein reabsorption droplets in the renal tubular epithelium. (Courtesy Dr. Helmut Rennke, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

plasma cells engaged in active synthesis of immunoglobulins. The ER becomes hugely distended, producing large, homogeneous eosinophilic inclusions called *Russell bodies*.

- *Defective intracellular transport and secretion of critical proteins.* In α_1-antitrypsin deficiency, mutations in the protein significantly slow folding, resulting in the buildup of partially folded intermediates, which aggregate in the ER of the hepatocyte and are not secreted. The resultant deficiency of the circulating enzyme where it is needed in the lung causes emphysema (Chapter 15). In many of these protein-folding diseases, the pathology results not only from loss of protein function but also ER stress caused by the misfolded proteins, which initiates the unfolded protein response and culminates in cell death by apoptosis (discussed earlier).
- *Accumulation of cytoskeletal proteins.* There are several types of cytoskeletal proteins, including microtubules (20 to 25 nm in diameter), thin actin filaments (6 to 8 nm), thick myosin filaments (15 nm), and intermediate filaments (10 nm). Intermediate filaments, which provide a flexible intracellular scaffold that organizes the cytoplasm and resists forces applied to the cell, are divided into five classes: keratin filaments (characteristic of epithelial cells), neurofilaments (neurons), desmin filaments (muscle cells), vimentin filaments (connective tissue cells), and glial filaments (astrocytes). Accumulations of keratin filaments and neurofilaments are associated with certain types of cell injury. *Alcoholic hyaline* is an eosinophilic cytoplasmic inclusion in liver cells that is characteristic of alcoholic liver disease and is composed predominantly of keratin intermediate filaments (Chapter 18). The *neurofibrillary tangle* found in the brain in Alzheimer disease contains neurofilaments and other proteins (Chapter 28).
- *Aggregation of abnormal proteins.* Abnormal or misfolded proteins may deposit in tissues and interfere with normal functions. The deposits can be intracellular, extracellular, or both, and the aggregates may either directly or indirectly cause the pathologic changes. Certain forms of *amyloidosis* (Chapter 6) fall in this category of diseases. These disorders are sometimes called *proteinopathies* or *protein-aggregation diseases*.

Hyaline Change

The term *hyaline* usually refers to an alteration within cells or in the extracellular space that gives a homogeneous, glassy, pink appearance in routine histologic sections stained with H&E. It is widely used as a descriptive histologic term rather than a specific marker for cell injury. This morphologic change is produced by a variety of alterations and does not represent a specific pattern of accumulation.

Intracellular hyaline accumulations of protein iclude reabsorption droplets, Russell bodies, and alcoholic hyaline (described earlier). *Extracellular hyaline* has been more difficult to analyze. Collagenous fibers in old scars may appear hyalinized, but the biochemical basis of this change is not clear. In long-standing hypertension and diabetes mellitus, the walls of arterioles, especially in the kidney, become hyalinized, resulting from extravasated plasma protein and deposition of basement membrane material.

Glycogen

Excessive intracellular deposits of glycogen are seen in patients with an abnormality in either glucose or glycogen metabolism. Glycogen is a readily available source of glucose stored in the cytoplasm of healthy cells. Whatever the clinical setting, the glycogen masses appear as clear vacuoles within the cytoplasm because glycogen dissolves in aqueous fixatives; thus, it is most readily identified when tissues are fixed in absolute alcohol. Staining with Best carmine or the PAS reaction imparts a rose-to-violet color to the glycogen, but can also stain protein-bound carbohydrates. Diastase digestion of a parallel section that demonstrates loss of staining due to glycogen hydrolysis is therefore an important validation.

Diabetes mellitus is the prime example of a disorder of glucose metabolism. In this disease, glycogen is found in renal tubular epithelial cells, as well as within liver cells, β cells of the islets of Langerhans within the pancreas, and heart muscle cells.

Glycogen accumulates within select cells in a group of related genetic disorders that are collectively referred to as the *glycogen storage diseases*, or *glycogenoses* (Chapter 5). In these diseases, enzymatic defects in the synthesis or breakdown of glycogen result in massive accumulation, causing cell injury and cell death.

Pigments

Pigments are colored substances, some of which are normal constituents of cells (e.g., melanin), whereas others are abnormal and accumulate in cells under special circumstances. Pigments can be exogenous, coming from outside the body, or endogenous, synthesized within the body itself.

Exogenous Pigments

The most common exogenous pigment is carbon (coal dust), a ubiquitous air pollutant in urban areas. When inhaled, it is picked up by macrophages within the alveoli and then transported through lymphatic channels to lymph nodes in the tracheobronchial region. Accumulations of this pigment blacken the tissues of the lungs *(anthracosis)* and the involved lymph nodes. In coal miners, the aggregates of carbon dust may induce a fibroblastic reaction or even emphysema, and thus cause a serious lung disease known as *coal worker's pneumoconiosis* (Chapter 15). *Tattooing* is a form of localized, exogenous pigmentation of the skin. The pigments inoculated are phagocytosed by dermal macrophages, in which they reside for the remainder of the life of the embellished. The pigments do not usually evoke any inflammatory response.

Endogenous Pigments

Lipofuscin is an insoluble pigment, also known as lipochrome or wear-and-tear pigment. Lipofuscin is composed of polymers of lipids and phospholipids in complex with protein, suggesting that it is derived through lipid peroxidation of polyunsaturated lipids of intracellular membranes. Lipofuscin is not injurious to the cell or its functions. Its importance lies in its being a telltale sign of free radical injury and lipid peroxidation. The term is

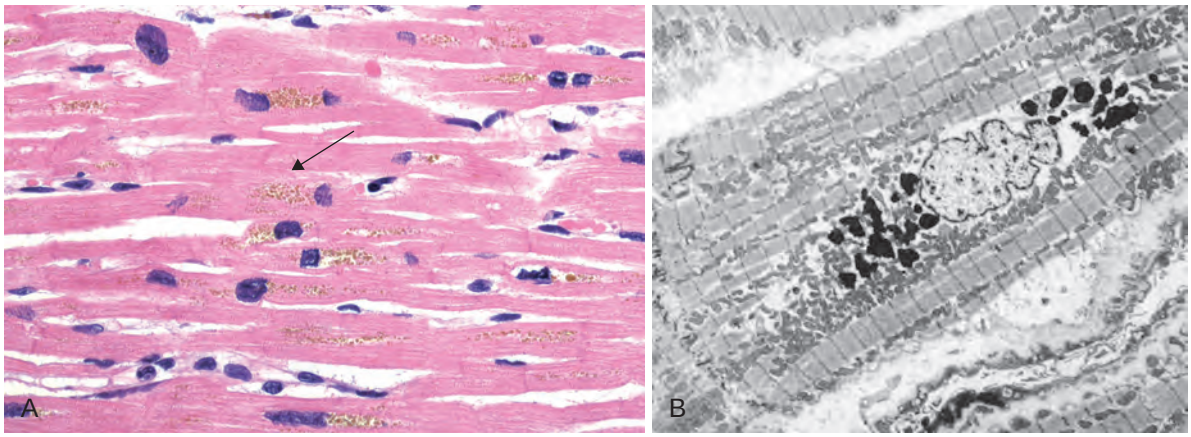

Figure 2.33 Lipofuscin granules in cardiac myocytes shown by (A) light microscopy (deposits indicated by *arrow*), and (B) electron microscopy (note the perinuclear, intralysosomal location).

derived from the Latin (*fuscus,* brown), referring to brown lipid. In tissue sections, it appears as a yellow-brown, finely granular cytoplasmic, often perinuclear, pigment (Fig. 2.33). It is seen in cells undergoing slow, regressive changes and is particularly prominent in the liver and heart of aging patients or patients with severe malnutrition and cancer cachexia.

Melanin, derived from the Greek (*melas*, black), is an endogenous, brown-black, pigment formed when the enzyme tyrosinase catalyzes the oxidation of tyrosine to dihydroxyphenylalanine in melanocytes. It is discussed further in Chapter 25. For practical purposes, melanin is the *only endogenous brown-black pigment*. The only other that could be considered in this category is homogentisic acid, a black pigment that occurs in patients with *alkaptonuria,* a rare metabolic disease. Here the pigment is deposited in the skin, connective tissue, and cartilage, and the pigmentation is known as *ochronosis.*

Hemosiderin, a hemoglobin-derived, golden yellow-to-brown, granular, or crystalline pigment is one of the major storage forms of iron. Iron metabolism and hemosiderin are considered in detail in Chapters 14 and 18. Iron is normally carried by a specific transport protein called transferrin. In cells, it is stored in association with a protein, apoferritin, to form ferritin micelles. Ferritin is a constituent of most cell types. When there is a local or systemic excess of iron, ferritin forms *hemosiderin granules,* which are easily seen with the light microscope. Hemosiderin pigment represents aggregates of ferritin micelles. Under normal conditions, small amounts of hemosiderin can be seen in the mononuclear phagocytes of the bone marrow, spleen, and liver, which are responsible for recycling of iron derived from hemoglobin during the breakdown of effete red blood cells.

Local or systemic excesses of iron cause hemosiderin to accumulate within cells. *Local excesses* result from hemorrhages in tissues. The best example of localized hemosiderosis is the common bruise. Extravasated red blood cells at the site of injury are phagocytosed over several days by macrophages, which break down the hemoglobin and recover the iron. After removal of iron, the heme moiety is converted first to biliverdin ("green bile") and then to bilirubin ("red bile"). In parallel, the iron released from heme is incorporated into ferritin and eventually hemosiderin. These conversions account for the often dramatic play of colors seen in a healing bruise, which typically changes from red-blue to green-blue to golden-yellow before it is resolved.

When there is *systemic iron overload*, hemosiderin may be deposited in many organs and tissues, a condition called *hemosiderosis*. The main causes of hemosiderosis are (1) increased absorption of dietary iron due to an inborn error of metabolism called *hemochromatosis* (Chapter 18), (2) hemolytic anemias, in which excessive lysis of red blood cells leads to release of abnormal quantities of iron (Chapter 14), and (3) repeated blood transfusions, because transfused red blood cells constitute an exogenous iron load.

PATHOLOGIC CALCIFICATION

Pathologic calcification is the abnormal tissue deposition of calcium salts, together with smaller amounts of iron, magnesium, and other mineral salts. There are two forms of pathologic calcification. When the deposition occurs locally in dying tissues, it is known as *dystrophic calcification;* it occurs despite normal serum levels of calcium and in the absence of derangements in calcium metabolism. In contrast, the deposition of calcium salts in otherwise normal tissues is known as *metastatic calcification,* and it almost always results from hypercalcemia secondary to some disturbance in calcium metabolism.

Dystrophic Calcification

Dystrophic calcification is encountered in areas of necrosis, whether they are of coagulative, caseous, or liquefactive type, and in foci of enzymatic necrosis of fat. Calcification is almost always present in the atheromas of advanced atherosclerosis. It also commonly develops in aging or damaged heart valves, further hampering their function (Fig. 2.34). Whatever the site of deposition, the calcium salts appear macroscopically as fine, white granules or clumps, often felt as gritty deposits. Sometimes a tuberculous lymph node is virtually converted to stone.

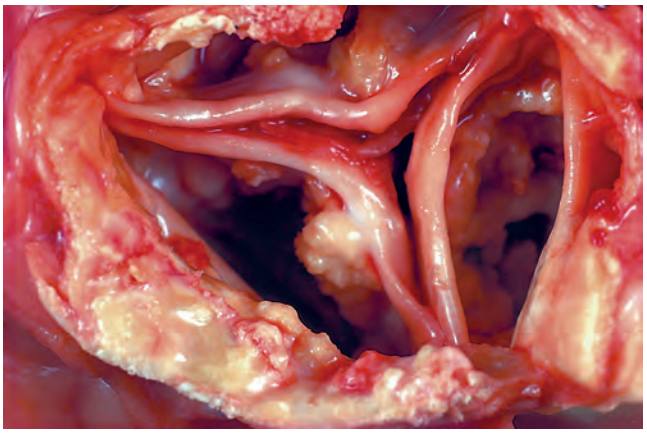

Figure 2.34 Dystrophic calcification of the aortic valve. View looking down onto the unopened aortic valve in a heart with calcific aortic stenosis. It is markedly narrowed (stenosis). The semilunar cusps are thickened and fibrotic, and behind each cusp are irregular masses of piled-up dystrophic calcification.

MORPHOLOGY

Histologically, with the usual H&E stain, calcium salts have a basophilic, amorphous granular, sometimes clumped appearance. They can be intracellular, extracellular, or in both locations. In the course of time, **heterotopic bone** may form in the focus of calcification. On occasion, single necrotic cells may constitute seed crystals that become encrusted by the mineral deposits. The progressive acquisition of outer layers may create lamellated configurations, called **psammoma bodies** because of their resemblance to grains of sand. Some types of papillary cancers (e.g., thyroid) are apt to develop psammoma bodies. In asbestosis, calcium and iron salts gather about long slender spicules of asbestos in the lung, creating exotic, beaded dumbbell forms known as **asbestos bodies** (Chapter 15).

Although dystrophic calcification may simply be a telltale sign of previous cell injury, it is often a cause of organ dysfunction. Such is the case in calcific valvular disease and atherosclerosis, as will become clear in further discussion of these diseases (Chapters 11 and 12). Serum calcium is normal in dystrophic calcification.

Metastatic Calcification

Metastatic calcification may occur in normal tissues whenever there is hypercalcemia. Hypercalcemia also accentuates dystrophic calcification. There are four principal causes of hypercalcemia: (1) *increased secretion of parathyroid hormone (PTH)* with subsequent bone resorption, as in hyperparathyroidism due to parathyroid tumors, and ectopic secretion of PTH-related protein by malignant tumors (Chapter 7); (2) *resorption of bone tissue,* secondary to primary tumors of bone marrow (e.g., multiple myeloma, leukemia) or diffuse skeletal metastasis (e.g., breast cancer), accelerated bone turnover (e.g., Paget disease), or immobilization; (3) *vitamin D–related disorders*, including vitamin D intoxication, sarcoidosis (in which macrophages activate a vitamin D precursor), and idiopathic hypercalcemia of infancy (Williams syndrome), characterized by abnormal sensitivity to vitamin D; and (4) *renal failure,* which causes retention of phosphate, leading to secondary hyperparathyroidism. Less common causes include aluminum intoxication, which occurs in patients on chronic renal dialysis, and milk-alkali syndrome, which is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate.

Metastatic calcification may occur widely throughout the body but principally affects the interstitial tissues of the gastric mucosa, kidneys, lungs, systemic arteries, and pulmonary veins. Although quite different in location, all of these tissues excrete acid and therefore have an internal alkaline compartment that predisposes them to metastatic calcification. In all of these sites, the calcium salts morphologically resemble those described in dystrophic calcification. Thus, they may occur as noncrystalline amorphous deposits or, at other times, as hydroxyapatite crystals.

Usually the mineral salts cause no clinical dysfunction, but on occasion massive involvement of the lungs produces remarkable x-ray images and respiratory compromise. Massive deposits in the kidney (nephrocalcinosis) may in time cause renal damage (Chapter 20).

KEY CONCEPTS

ABNORMAL INTRACELLULAR DEPOSITIONS AND CALCIFICATIONS

Abnormal deposits of materials in cells and tissues are the result of excessive intake or defective transport or catabolism.

- Deposition of lipids
  - Fatty change: Accumulation of free triglycerides in cells, resulting from excessive intake or defective transport (often because of defects in synthesis of transport proteins); manifestation of reversible cell injury
  - Cholesterol deposition: Result of defective catabolism and excessive intake; in macrophages and smooth muscle cells of vessel walls in atherosclerosis
- Deposition of proteins: Reabsorbed proteins in kidney tubules; immunoglobulins in plasma cells
- Deposition of glycogen: In macrophages of patients with defects in lysosomal enzymes that break down glycogen (glycogen storage diseases) and in certain disorders of glycogen metabolism
- Deposition of pigments: Typically indigestible pigments, such as carbon, lipofuscin (breakdown product of lipid peroxidation), or iron (usually due to overload, as in hemosiderosis)
- Pathologic calcifications
  - Dystrophic calcification: Deposition of calcium at sites of cell injury and necrosis
  - Metastatic calcification: Deposition of calcium in normal tissues, caused by hypercalcemia (usually a consequence of parathyroid hormone excess)

CELLULAR AGING

Mankind has pursued immortality from time immemorial. Toth and Hermes, Egyptian and Greek deities, are said to have discovered the elixir of youth and become immortal. Sadly, Toth and Hermes are nowhere to be found, hence

the elixir remains a secret. Shakespeare probably characterized aging best in his elegant description of the seven ages of man. It begins at the moment of conception, involves the differentiation and maturation of the organism and its cells, at some variable point in time leads to the progressive loss of functional capacity characteristic of senescence, and ends in death.

Individuals age because their cells age. Although public attention on the aging process has traditionally focused on its cosmetic manifestations, aging has important health consequences, because age is one of the strongest independent risk factors for many chronic diseases, such as cancer, Alzheimer disease, and ischemic heart disease. Perhaps one of the most striking discoveries about cellular aging is that it is not simply a consequence of cells "running out of steam," but in fact is regulated by genes that are evolutionarily conserved from yeast to worms to mammals.

Cellular aging is the result of a progressive decline in cellular function and viability caused by genetic abnormalities and the accumulation of cellular and molecular damage due to the effects of exposure to exogenous influences (Fig. 2.35). Studies in model systems have clearly established that aging is influenced by a limited number of genes, and genetic anomalies underlie syndromes resembling premature aging in humans as well. Such findings suggest that aging is associated with definable mechanistic alterations. Several mechanisms, some cell intrinsic and others environmentally induced, are believed to play a role in aging.

DNA Damage. A variety of exogenous (physical, chemical, and biologic) agents and endogenous factors such as ROS threaten the integrity of nuclear and mitochondrial DNA. Although most DNA damage is repaired by DNA repair enzymes, some persists and accumulates as cells age. Several lines of evidence point to the importance of DNA repair in the aging process. Next-generation DNA sequencing studies have shown that the average hematopoietic stem cell suffers 14 new mutations per year, and it is likely that this accumulating damage explains why, like most cancers, the most common hematologic malignancies are diseases of the aged. Patients with *Werner syndrome* show premature aging, and the defective gene product is a DNA helicase, a protein involved in DNA replication and repair and other functions requiring DNA unwinding. A defect in this enzyme causes rapid accumulation of chromosomal damage that may mimic some aspects of the injury that normally accumulates during cellular aging. Genetic instability in somatic cells is also characteristic of other disorders in which patients display some of the manifestations of aging at an increased rate, such as *Bloom syndrome* and *ataxia-telangiectasia,* in which the mutated genes encode proteins involved in repairing double-strand breaks in DNA (Chapter 7).

Cellular Senescence. All normal cells have a limited capacity for replication, and after a fixed number of divisions cells become arrested in a terminally nondividing state, known as *replicative senescence.* Aging is associated with progressive replicative senescence of cells. Cells from children have the capacity to undergo more rounds of replication than do cells from older people. Two mechanisms are believed to underlie cellular senescence:

- *Telomere attrition*. One mechanism of replicative senescence involves progressive shortening of telomeres, which ultimately results in cell cycle arrest. *Telomeres* are short repeated sequences of DNA present at the ends of linear chromosomes that are important for ensuring the complete replication of chromosome ends and for protecting the ends from fusion and degradation. When somatic cells replicate, a small section of the telomere is not duplicated and telomeres become progressively shortened. As the telomeres become shorter, the ends of chromosomes cannot be protected and are seen as broken DNA, which signals cell cycle arrest. Telomere length is maintained by nucleotide addition mediated by an enzyme called *telomerase.* Telomerase is a specialized RNA-protein complex that uses its own RNA as a template for adding nucleotides to the ends of chromosomes. Telomerase is expressed in germ cells and is present at low levels in

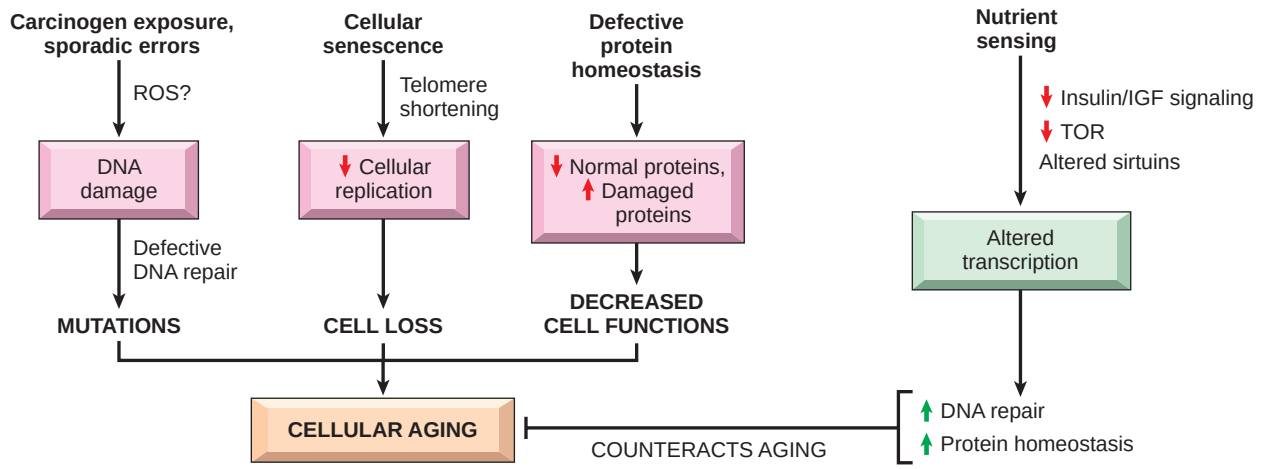

Figure 2.35 Mechanisms that cause and counteract cellular aging. DNA damage, replicative senescence, and decreased and misfolded proteins are among the best described mechanisms of cellular aging. Nutrient sensing, exemplified by caloric restriction, counteracts aging by activating various signaling pathways and transcription factors. *IGF,* Insulin-like growth factor; *ROS,* reactive oxygen species; *TOR,* target of rapamycin.

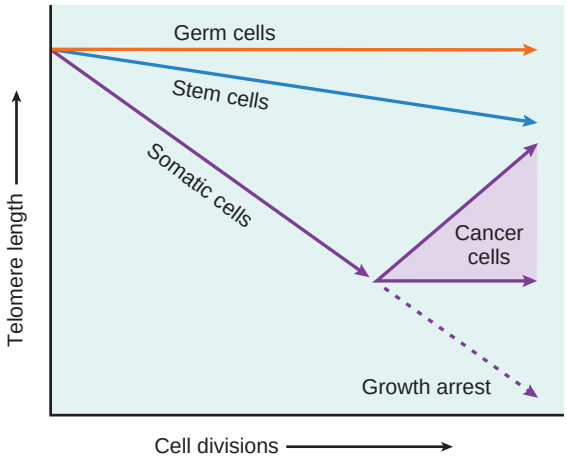

Figure 2.36 The role of telomeres and telomerase in replicative senescence of cells. Telomere length is plotted against the number of cell divisions. In most somatic cells there is no telomerase activity, and telomeres progressively shorten with increasing cell divisions until growth arrest or until senescence occurs. Germ cells and stem cells both contain telomerase, but only germ cells have sufficient levels of the enzyme to stabilize telomere length completely. In cancer cells, telomerase is often reactivated. (Data from Holt SE, Shay JW, Wright WE: Refining the telomere-telomerase hypothesis of aging and cancer, *Nat Biotechnol* 14:836, 1996.)

stem cells, but it is absent in most somatic tissues (Fig. 2.36) Therefore, as most somatic cells age, their telomeres become shorter and they exit the cell cycle, resulting in an inability to generate new cells to replace damaged ones. Conversely, in immortalized cancer cells, telomerase is usually reactivated and telomere length is stabilized, allowing the cells to proliferate indefinitely. This is discussed more fully in Chapter 7. The causal links between telomere length and cellular senescence have been established in mouse models. Genetically engineered mice with shortened telomeres exhibit reduced life spans that can be restored to normal by telomerase activation. As discussed in other chapters, telomere shortening is also associated with premature development of diseases, such as pulmonary fibrosis (Chapter 15) and aplastic anemia (Chapter 14).

- *Activation of tumor suppressor genes.* In addition to telomere attrition, activation of certain tumor suppressor genes, particularly those encoded by the *CDKN2A* locus, also seems to be involved in controlling replicative senescence. The *CDKN2A* locus encodes two tumor suppressor proteins, expression of one of which, known as p16 or INK4a, is correlated with chronologic age in virtually all human and mouse tissues examined. By controlling G1- to S-phase progression during the cell cycle (Chapter 1), p16 protects cells from uncontrolled mitogenic signals and pushes cells along the senescence pathway. This is discussed further in Chapter 7.

Defective Protein Homeostasis. Protein homeostasis involves two mechanisms: maintenance of proteins in their correctly folded conformations (mediated by chaperones) and degradation of misfolded, damaged, or unneeded proteins by the autophagy-lysosome system and ubiquitin-proteasome system. There is evidence that both normal folding and degradation of misfolded proteins are impaired with aging. Mutant mice deficient in chaperones of the heat shock protein family age rapidly, and conversely, those that overexpress such chaperones are long-lived. Similar data exist for the role of autophagy and proteasomal degradation of proteins. Of interest, administration of rapamycin, which inhibits the mTOR (molecular target of rapamycin) pathway, increases the life span of middle-aged mice. Rapamycin has multiple effects, including promotion of autophagy. Abnormal protein homeostasis can have many effects on cell survival, replication, and functions. In addition, it may lead to accumulation of misfolded proteins, which can trigger apoptosis.

Dysregulated Nutrient Sensing. Paradoxical though it may seem, eating less increases longevity. Caloric restriction increases life span in all eukaryotic species in which it has been tested, with encouraging results even in nonhuman primates and in a few unusually disciplined people who are the envy of others! Because of these observations, there has been much interest in deciphering the role of nutrient sensing in aging. Although incompletely understood, there are two major neurohormonal circuits that regulate metabolism.

- *Insulin and insulin-like growth factor 1 (IGF-1) signaling pathway.* IGF-1 is produced in many cell types in response to growth hormone secretion by the pituitary gland. IGF-1, as indicated by its name, mimics intracellular signaling by insulin and thereby informs cells of the availability of glucose, promoting an anabolic state as well as cell growth and replication. IGF-1 signaling has multiple downstream targets; relevant to this discussion are two kinases: AKT and its downstream target, mTOR, which, as the name implies, is inhibited by rapamycin.
- *Sirtuins.* Sirtuins are a family of NAD-dependent protein deacetylases. There are at least seven types of sirtuins in mammals that are distributed in different cellular compartments and have nonredundant functions designed to adapt bodily functions to various environmental stresses, including food deprivation and DNA damage. Sirtuins are thought to promote the expression of several genes whose products increase longevity. These include proteins that inhibit metabolic activity, reduce apoptosis, stimulate protein folding, and counteract the harmful effects of oxygen free radicals. Sirtuins also increase insulin sensitivity and glucose metabolism, and may be targets for the treatment of diabetes.

It is thought that caloric restriction increases longevity both by reducing the signaling intensity of the IGF-1 pathway and by increasing sirtuins. Attenuation of IGF-1 signaling leads to lower rates of cell growth and metabolism and possibly reduced cellular damage. This effect can be mimicked by rapamycin. An increase in sirtuins, particularly sirtuin-6, serves dual functions: the sirtuins (1) contribute to metabolic adaptations of caloric restriction and (2) promote genomic integrity by activating DNA repair enzymes through deacylation. Although the anti-aging effects of sirtuins have been widely publicized, much remains to be known before sirtuin-activating pills will be available to increase longevity. Nevertheless, optimistic wine lovers have been delighted to hear that a constituent of red wine may activate sirtuins and thus increase life span!

KEY CONCEPTS

CELLULAR AGING

- Cellular aging results from a combination of accumulating cellular damage (e.g., by free radicals), reduced capacity to divide (replicative senescence), reduced ability to repair damaged DNA, and defective protein homeostasis.
  - Accumulation of DNA damage: Defective DNA repair mechanisms; conversely, caloric restriction may activate DNA repair and slow aging in model organisms
  - Replicative senescence: Reduced capacity of cells to divide secondary to progressive shortening of chromosomal ends (telomeres)
  - Defective protein homeostasis: Resulting from impaired chaperone and proteasome functions.
  - Nutrient sensing system: Caloric restriction increases longevity. Mediators may be reduced IGF-1 signaling and increased sirtuins.

The various forms of cellular derangements and adaptations described in this chapter cover a wide spectrum, which includes adaptations in cell size, growth, and function; reversible and irreversible forms of acute cell injury; regulated cell death (e.g., in apoptosis); pathologic alterations in cell organelles; and less ominous forms of intracellular accumulations, including pigmentations. Reference is made to all of these alterations throughout this book, because all organ injury and ultimately all clinical disease arise from derangements in cell structure and function.

CHAPTER 3

Inflammation and Repair

CHAPTER CONTENTS

OVERVIEW OF INFLAMMATION: DEFINITIONS AND GENERAL FEATURES

Inflammation is a response of vascularized tissues that delivers leukocytes and molecules of host defense from the circulation to the sites of infection and cell damage in order to eliminate the offending agents. Although in common medical and lay parlance, inflammation suggests a harmful reaction, it is actually a protective response that is essential for survival. It serves to rid the host of both the initial cause of cell injury (e.g., microbes, toxins) and the consequences of such injury (e.g., necrotic cells and tissues). The mediators of defense include phagocytic leukocytes, antibodies, and complement proteins. Most of these normally circulate in a resting state in the blood, from where they can be rapidly recruited to any site in the body. Some of the cells involved in inflammatory responses also reside in tissues, where they function as sentinels on the lookout for threats. The process of inflammation delivers circulating cells and proteins to tissues and activates the recruited and resident cells as well as the soluble molecules, which then function to get rid of the harmful or unwanted substances. Without inflammation, infections would go unchecked, wounds would never heal, and injured tissues might remain permanent festering sores. The suffix *-itis* after an organ denotes inflammation in that site, such as appendicitis, conjunctivitis, or meningitis.

The typical inflammatory reaction develops through a series of sequential steps (Fig. 3.1):

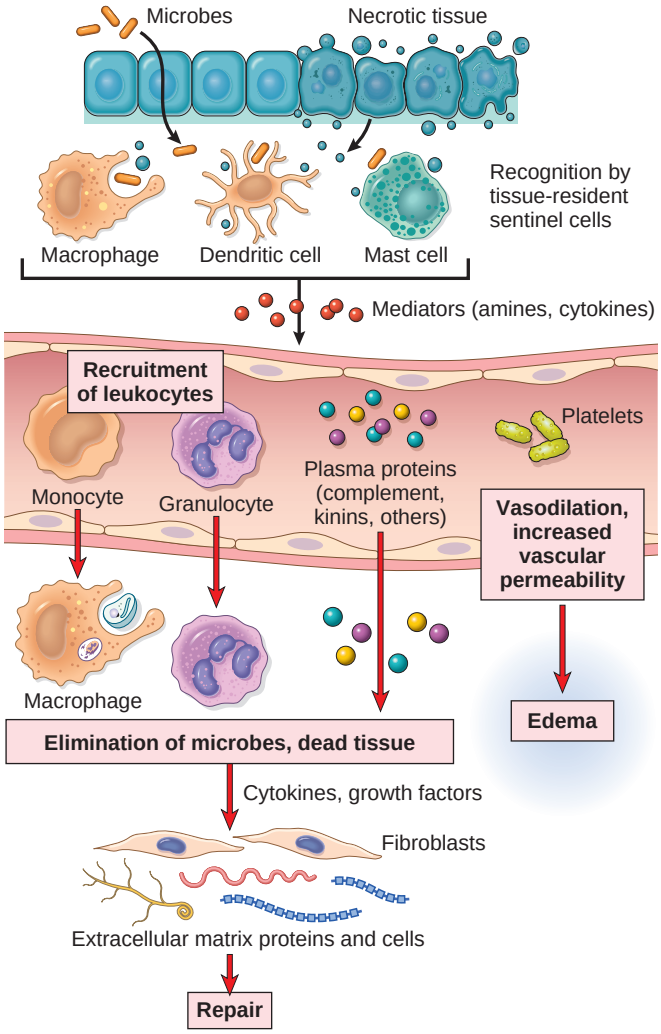

Figure 3.1 Sequence of events in an inflammatory reaction. Sentinel cells in tissues (macrophages, dendritic cells, and other cell types) recognize microbes and damaged cells and liberate mediators, which trigger the vascular and cellular reactions of inflammation.

- *Recognition* of the noxious agent that is the initiating stimulus for inflammation. The cells involved in inflammation (tissue-resident sentinel cells, phagocytes, and others) are equipped with receptors that recognize microbial products and substances released from damaged cells. These receptors are described in more detail later. Engagement of the receptors leads to the production of mediators of inflammation, which then trigger the subsequent steps in the inflammatory response.
- *Recruitment* of leukocytes and plasma proteins into the tissues. Since blood perfuses every tissue, leukocytes and proteins such as complement can be delivered to any site of microbial invasion or tissue injury. When pathogenic microbes invade the tissues, or tissue cells die, leukocytes (first mainly neutrophils, later monocytes and lymphocytes) and plasma proteins are rapidly recruited from the circulation to the extravascular site where the offending agent is located. The exodus of cells and plasma proteins from blood requires coordinated changes in blood vessels and secretion of mediators, described in detail later.
- *Removal* of the stimulus for inflammation is accomplished mainly by phagocytic cells, which ingest and destroy microbes and dead cells.
- *Regulation* of the response is important for terminating the reaction when it has accomplished its purpose.
- *Repair* consists of a series of events that heal damaged tissue. In this process the injured tissue is replaced through regeneration of surviving cells and filling of residual defects with connective tissue (scarring).

Before discussing the mechanisms, functions, and pathology of the inflammatory response, it is useful to review some of its fundamental properties.

- *Components of the inflammatory response.* The major participants in the inflammatory reaction in tissues are blood vessels and leukocytes (see Fig. 3.1). As will be discussed in more detail later, blood vessels respond to inflammatory stimuli by dilating and by increasing their permeability, enabling selected circulating proteins to enter the site of infection or tissue damage. In addition, the endothelium lining blood vessels also changes, such that circulating leukocytes adhere and then migrate into the tissues. Leukocytes, once recruited, are activated and acquire the ability to ingest and destroy microbes and dead cells, as well as foreign bodies and other unwanted materials in the tissues.
- *Harmful consequences of inflammation.* Protective inflammatory reactions to infections are often accompanied by local tissue damage and its associated signs and symptoms (e.g., pain and functional impairment). Typically, however, these harmful consequences are self-limited and resolve as the inflammation abates, leaving little or no permanent damage. In contrast, there are many diseases in which the inflammatory reaction is misdirected (e.g., against self tissues in autoimmune diseases), occurs against normally harmless environmental substances (e.g., in allergies), or is inadequately controlled. In these cases the normally protective inflammatory reaction becomes the cause of the disease, and the damage it causes is the dominant feature. In clinical medicine, great attention is given to the injurious consequences of inflammation (Table 3.1). Inflammatory reactions underlie common chronic diseases such as rheumatoid arthritis, atherosclerosis, and lung fibrosis, as well as life-threatening hypersensitivity reactions to insect bites, foods, drugs, and toxins. For this reason our pharmacies abound with antiinflammatory drugs, which ideally would control the harmful sequelae of inflammation yet not interfere with its beneficial effects. Inflammation also may contribute to a variety of diseases that are thought to be primarily metabolic, degenerative, or genetic, such as type 2 diabetes, Alzheimer disease, and cancer. In recognition of the wide-ranging harmful consequences of inflammation, the lay press has rather melodramatically referred to it as "the silent killer."
- *Local and systemic inflammation.* Much of this discussion focuses on the inflammatory response to a localized infection or tissue damage. Although even local reactions may have systemic manifestations (e.g., fever in the setting

Table 3.1 Diseases Caused by Inflammatory Reactions

Disorders	Cells and Molecules Involved in Injury
Acute	
Acute respiratory distress syndrome	Neutrophils
Asthma	Eosinophils; IgE antibodies
Glomerulonephritis	Antibodies and complement; neutrophils, monocytes
Septic shock	Cytokines
Chronic	
Arthritis	Lymphocytes, macrophages; antibodies?
Asthma	Eosinophils; IgE antibodies
Atherosclerosis	Macrophages; lymphocytes
Pulmonary fibrosis	Macrophages; fibroblasts

IgE, Immunoglobulin E.

Listed are selected examples of diseases in which the inflammatory response plays a significant role in tissue injury. Some, such as asthma, can present with acute inflammation or a chronic illness with repeated bouts of acute exacerbation. These diseases and their pathogenesis are discussed in relevant chapters.

of bacterial or viral pharyngitis), the inflammation is largely confined to the site of infection or damage. In rare situations, such as some disseminated bacterial infections, the inflammatory reaction is systemic and causes widespread pathologic abnormalities. This reaction has been called sepsis, which is one form of the *systemic inflammatory response syndrome*. This serious disorder is discussed in Chapter 4.

- *Mediators of inflammation.* The vascular and cellular reactions of inflammation are triggered by soluble factors that are produced by various cells or derived from plasma proteins and are generated or activated in response to the inflammatory stimulus. Microbes, necrotic cells (whatever the cause of cell death), and even hypoxia can trigger the elaboration of inflammatory mediators and thus elicit inflammation. Such mediators initiate and amplify the inflammatory response and determine its pattern, severity, and clinical and pathologic manifestations.
- *Acute and chronic inflammation.* The distinction between acute and chronic inflammation was originally based on the duration of the reaction, but we now know that they differ in several ways (Table 3.2). Acute inflammation is a rapid, often self-limited, response to offending agents that are readily eliminated, such as many bacteria and fungi, and dead cells. It typically develops within minutes or hours and is of short duration (several hours to a few days). It is characterized by the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes, predominantly neutrophils. If the offending stimulus is eliminated, the reaction subsides, and residual injury is repaired.

  Chronic inflammation may follow acute inflammation or arise de novo. It is a response to agents that are difficult to eradicate, such as some bacteria (e.g., tubercle bacilli) and other pathogens (such as viruses and fungi), as well as self antigens and environmental antigens. Chronic inflammation is of longer duration and is associated with more tissue destruction and scarring (fibrosis). Sometimes, chronic inflammation may coexist with unresolved acute inflammation, as may occur in peptic ulcers.

Table 3.2 Features of Acute and Chronic Inflammation

Feature	Acute	Chronic
Onset	Fast: minutes or hours	Slow: days
Cellular infiltrate	Mainly neutrophils	Monocytes/macrophages and lymphocytes
Tissue injury, fibrosis	Usually mild and self-limited	Often severe and progressive
Local and systemic signs	Prominent	Less

Historical Highlights

Although clinical features of inflammation were described in an Egyptian papyrus dated around 3000 BC, Celsus, a Roman writer of the first century AD, first listed the four cardinal signs of inflammation: *rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain). These signs are hallmarks of acute inflammation. A fifth clinical sign, loss of function *(functio laesa),* was added by Rudolf Virchow in the 19th century. In 1793 the Scottish surgeon John Hunter noted what is now considered an obvious fact: inflammation is not a disease but a stereotypic response that has a salutary effect on its host. In the 1880s Russian biologist Elie Metchnikoff discovered the process of *phagocytosis* by observing the ingestion of rose thorns by amebocytes of starfish larvae and of bacteria by mammalian leukocytes. He concluded that the purpose of inflammation was to bring phagocytic cells to the injured area to engulf invading bacteria. This concept was satirized by George Bernard Shaw in his play *The Doctor's Dilemma,* in which one physician's cure-all is to "stimulate the phagocytes!" Sir Thomas Lewis, studying the inflammatory response in skin, established the concept that chemical substances, such as histamine (produced locally in response to injury), mediate the vascular changes of inflammation. This fundamental concept underlies the important discoveries of chemical mediators of inflammation and the use of antiinflammatory drugs in clinical medicine.

Causes of Inflammation

Inflammatory reactions may be triggered by a variety of stimuli:

- *Infections* (bacterial, viral, fungal, parasitic) and microbial toxins are among the most common and medically important causes of inflammation. Different infectious pathogens elicit varied inflammatory responses, from mild acute inflammation that causes little or no lasting damage and successfully eradicates the infection, to severe systemic reactions that can be fatal, to prolonged chronic reactions that cause extensive tissue injury. The outcomes are determined largely by the type of pathogen and the host response and, to some extent, by other, poorly defined characteristics of the host.

- *Tissue necrosis* elicits inflammation regardless of the cause of cell death. Cells may die because of ischemia (reduced blood flow, the cause of myocardial infarction), trauma, and physical and chemical injury (e.g., thermal injury, as in burns or frostbite; irradiation; exposure to some environmental chemicals). Several molecules released from necrotic cells are known to trigger inflammation; some of these are described later.
- *Foreign bodies* (splinters, dirt, sutures) may elicit inflammation by themselves or because they cause traumatic tissue injury or carry microbes. Even endogenous substances can be harmful if they deposit in tissues; such substances include urate crystals (in gout), cholesterol crystals (in atherosclerosis), and lipids (in obesity-associated metabolic syndrome).
- *Immune reactions* (also called *hypersensitivity*) are reactions in which the normally protective immune system damages the individual's own tissues. The injurious immune responses may be inappropriately directed against self antigens, causing autoimmune diseases, or may be reactions against environmental substances, as in allergies, or against microbes. Inflammation is a major cause of tissue injury in these diseases (Chapter 6). Because the stimuli for the inflammatory responses (e.g., self antigens and environmental antigens) cannot be eliminated, autoimmune and allergic reactions tend to be persistent and difficult to cure, are often associated with chronic inflammation, and are important causes of morbidity and mortality. The inflammation is induced largely by cytokines produced by T lymphocytes and other cells of the immune system (Chapter 6).

Recognition of Microbes and Damaged Cells

Recognition of microbial components or substances released from damaged cells is the initiating step in inflammatory reactions. The cells and receptors that perform this function evolved to protect multicellular organisms from microbes in the environment, and the responses they trigger are critical for the survival of the organisms. Several cellular receptors and circulating proteins are capable of recognizing microbes and products of cell damage and triggering inflammation.

- *Cellular receptors for microbes.* Cells express receptors in the plasma membrane (for extracellular microbes), the endosomes (for ingested microbes), and the cytosol (for intracellular microbes) that enable the cells to sense the presence of foreign invaders in any cellular compartment. The best defined of these receptors belong to the family of *Toll-like receptors (TLRs);* these and other cellular receptors of innate immunity are described in Chapter 6. The receptors are expressed on many cell types including epithelial cells (through which microbes enter from the external environment), dendritic cells, macrophages, and other leukocytes (which may encounter microbes in various tissues). Engagement of these receptors triggers production of molecules involved in inflammation including adhesion molecules on endothelial cells, cytokines, and other mediators.
- *Sensors of cell damage.* All cells have cytosolic receptors, such as *NOD-like receptors (NLRs),* that recognize diverse molecules that are liberated or altered as a consequence of cell damage. These molecules include uric acid (a product of DNA breakdown), adenosine triphosphate (ATP) (released from damaged mitochondria), reduced intracellular K^+ concentrations (reflecting loss of ions because of plasma membrane injury), even DNA when it is released into the cytoplasm and not sequestered in nuclei, as it should be normally, and many others. These receptors activate a multiprotein cytosolic complex called the *inflammasome* (Chapter 6), which induces the production of the cytokine interleukin-1 (IL-1). IL-1 recruits leukocytes and thus induces inflammation (see later). Gain-of-function mutations in the genes encoding some of the receptors are the cause of rare diseases grouped under autoinflammatory syndromes that are characterized by spontaneous IL-1 production and inflammation; IL-1 antagonists are effective treatments for these disorders. The inflammasome has also been implicated in inflammatory reactions to urate crystals (the cause of gout), lipids (in metabolic syndrome and obesity-associated type 2 diabetes), cholesterol crystals (in atherosclerosis), and even amyloid deposits in the brain (in Alzheimer disease). These disorders are discussed later in this and other chapters.
- *Other cellular receptors involved in inflammation.* In addition to directly recognizing microbes, many leukocytes express receptors for the Fc tails of antibodies and for complement proteins. These receptors recognize microbes coated with antibodies and complement (the coating process is called opsonization) and promote ingestion and destruction of the microbes as well as inflammation.
- *Circulating proteins.* The *complement system* reacts against microbes and produces mediators of inflammation (discussed later). A circulating protein called mannose-binding lectin recognizes microbial sugars and promotes ingestion of the microbes and the activation of the complement system. Other proteins called collectins also bind to and combat microbes.

KEY CONCEPTS

GENERAL FEATURES AND CAUSES OF INFLAMMATION

- Inflammation is a beneficial host response to foreign invaders and necrotic tissue, but it may also cause tissue damage.
- The main components of inflammation are a vascular reaction and a cellular response, both activated by mediators that are derived from plasma proteins and various cells.
- The steps of the inflammatory response can be remembered as the five R's: (1) recognition of the injurious agent, (2) recruitment of leukocytes, (3) removal of the agent, (4) regulation (control) of the response, and (5) repair (resolution).
- Acute and chronic inflammation differ in the kinetics of the reaction, the principal cells involved, and the degree of injury. The outcome of acute inflammation is either elimination of the noxious stimulus followed by decline of the reaction and repair of the damaged tissue or persistent injury resulting in chronic inflammation.
- Causes of inflammation include infections, tissue necrosis, foreign bodies, trauma, and immune responses.
- Epithelial cells, tissue macrophages and dendritic cells, leukocytes, and other cell types express receptors that sense the presence of microbes and substances released from damaged cells. Circulating proteins recognize microbes that have entered the blood.

ACUTE INFLAMMATION

Acute inflammation has three major components: (1) dilation of small vessels leading to an increase in blood flow; (2) increased permeability of the microvasculature enabling plasma proteins and leukocytes to leave the circulation; and (3) emigration of leukocytes from the microcirculation, their accumulation in the focus of injury, and their activation to eliminate the offending agent (see Fig. 3.1). When an individual encounters an injurious agent, such as a microbe or dead cells, phagocytes that reside in tissues try to eliminate these agents. At the same time, phagocytes and other sentinel cells in the tissues recognize the presence of the foreign or abnormal substance and react by liberating cytokines, lipid messengers, and other mediators of inflammation. Some of these mediators act on small blood vessels in the vicinity and promote the efflux of plasma and the recruitment of circulating leukocytes to the site where the offending agent is located.

Reactions of Blood Vessels in Acute Inflammation

The vascular reactions of acute inflammation consist of changes in the flow of blood and the permeability of vessels, both designed to maximize the movement of plasma proteins and leukocytes out of the circulation and into the site of infection or injury. The escape of fluid, proteins, and blood cells from the vascular system into the interstitial tissue or body cavities is known as exudation (Fig. 3.2). An *exudate* is an extravascular fluid that has a high protein concentration and contains cellular debris. Its presence implies the existence of an inflammatory process that has increased the permeability of small blood vessels. In contrast, a *transudate* is a fluid with low protein content (most of which is albumin), little or no cellular material, and low specific gravity. It is essentially an ultrafiltrate of blood plasma that is produced as a result of osmotic or hydrostatic imbalance across the vessel wall without an increase in vascular permeability (Chapter 4). Edema denotes an excess of fluid in the interstitial tissue or serous cavities; it can be either an exudate or a transudate. Pus, a purulent exudate, is an inflammatory exudate rich in leukocytes (mostly neutrophils), the debris of dead cells, and, in many cases, microbes.

Changes in Vascular Flow and Caliber

Changes in vascular flow and caliber begin early after injury and consist of the following.

- *Vasodilation* is induced by the action of several mediators, notably histamine, on vascular smooth muscle. It is one of the earliest manifestations of acute inflammation. Vasodilation first involves the arterioles and then leads to opening of new capillary beds in the area. The result is increased blood flow, which is the cause of heat and redness (erythema) at the site of inflammation.
- Vasodilation is quickly followed by *increased permeability of the microvasculature,* with the outpouring of protein-rich fluid into the extravascular tissues; this process is described in detail later.
- The loss of fluid and increased vessel diameter lead to slower blood flow, concentration of red cells in small vessels, and increased viscosity of the blood. These changes result in engorgement of small vessels with slowly moving red cells, a condition termed *stasis,* which is seen

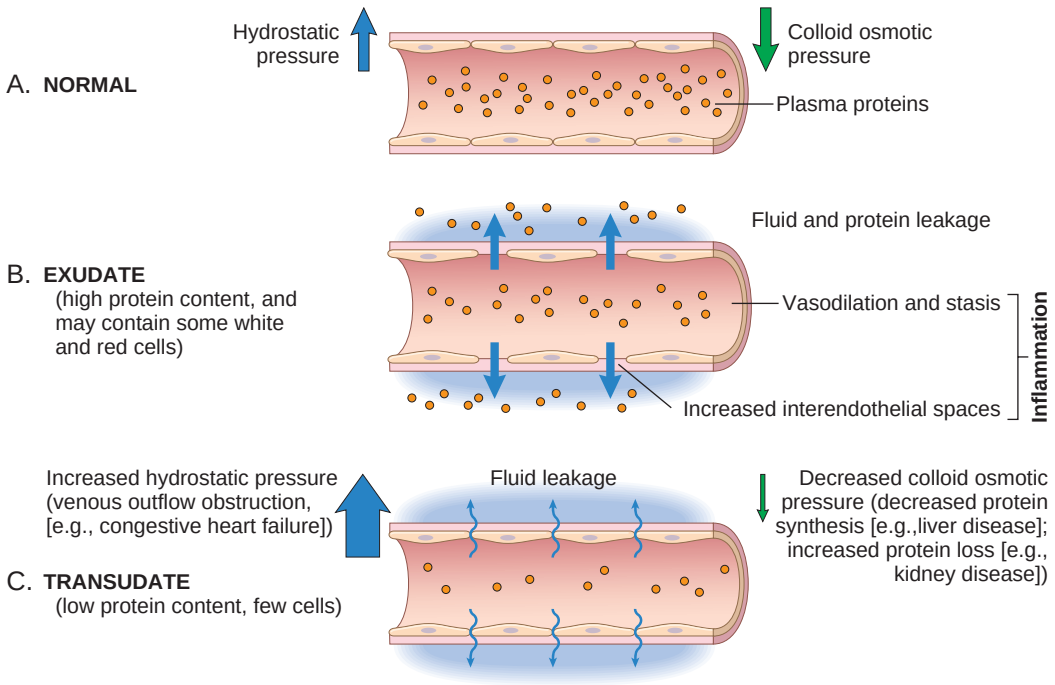

Figure 3.2 Formation of exudates and transudates. (A) Normal hydrostatic pressure *(blue arrow)* is about 32 mm Hg at the arterial end of a capillary bed and 12 mm Hg at the venous end; the mean colloid osmotic pressure of tissues is approximately 25 mm Hg *(green arrow)*, which is equal to the mean capillary pressure. Therefore the net flow of fluid across the vascular bed is almost nil. (B) An exudate is formed in inflammation because vascular permeability increases as a result of increased interendothelial spaces. (C) A transudate is formed when fluid leaks out because of increased hydrostatic pressure or decreased osmotic pressure.

as vascular congestion and localized redness of the involved tissue.

- As stasis develops, blood leukocytes, principally neutrophils, accumulate along the vascular endothelium. At the same time, endothelial cells are activated by mediators produced at sites of infection and tissue damage and express increased levels of adhesion molecules. Leukocytes then adhere to the endothelium, and soon afterward they migrate through the vascular wall into the interstitial tissue in a sequence that is described later.

Increased Vascular Permeability (Vascular Leakage)

Several mechanisms are responsible for the increased permeability of postcapillary venules, a hallmark of acute inflammation (Fig. 3.3).

- *Contraction of endothelial cells* resulting in opening of interendothelial gaps is the most common mechanism of vascular leakage. It is elicited by histamine, bradykinin, leukotrienes, and other chemical mediators. It is called the immediate transient response because it occurs rapidly after exposure to the mediator and is usually short-lived (15 to 30 minutes). In some forms of mild injury (e.g., after burns, irradiation or ultraviolet radiation, and exposure to certain bacterial toxins), vascular leakage begins after a delay of 2 to 12 hours and lasts for several hours or even days; this delayed prolonged leakage may be caused by contraction of endothelial cells or mild endothelial damage. Sunburn is a classic example of damage that results in late-appearing vascular leakage. Often the immediate and delayed responses occur along a continuum.

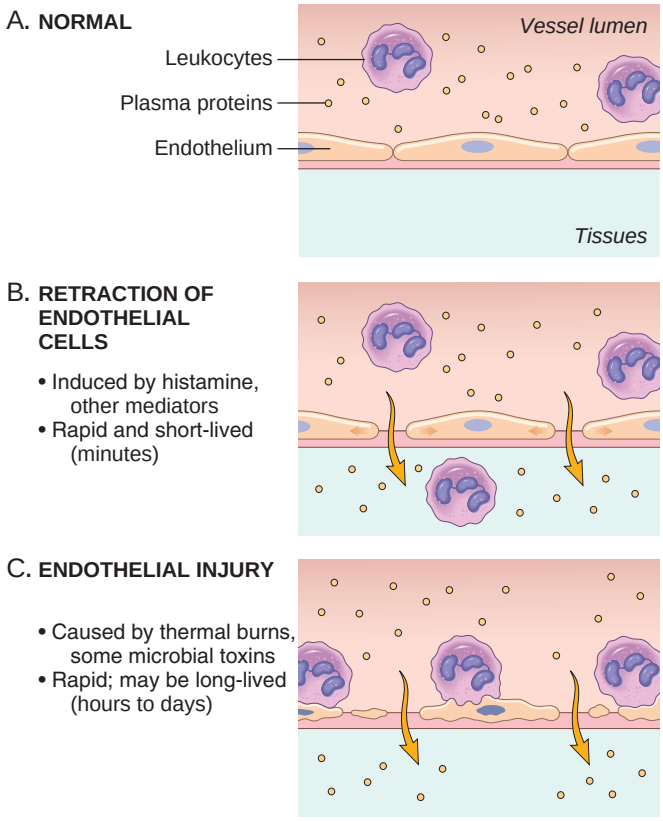

Figure 3.3 Principal mechanisms of increased vascular permeability in inflammation and their features and underlying causes.

- *Endothelial injury* resulting in endothelial cell necrosis and detachment. Direct damage to the endothelium is encountered in severe physical injuries, for example, in thermal burns, or is induced by the actions of microbes and microbial toxins that damage endothelial cells. Neutrophils that adhere to the endothelium during inflammation may also injure endothelial cells and thus amplify the reaction. In most instances leakage starts immediately after injury and is sustained for several hours until the damaged vessels are thrombosed or repaired.

Although these mechanisms of increased vascular permeability are described separately, all probably contribute in varying degrees in responses to most stimuli. For example, at different stages of a thermal burn, leakage results from chemically mediated endothelial contraction and direct and leukocyte-dependent endothelial injury. The vascular leakage induced by these mechanisms can cause life-threatening loss of fluid in severely burned patients.

Responses of Lymphatic Vessels and Lymph Nodes

In addition to blood vessels, lymphatic vessels also participate in acute inflammation. The system of lymphatics and lymph nodes filters and polices the extravascular fluids. Lymphatics drain the small amount of extravascular fluid that seeps out of capillaries in the healthy state. In inflammation, lymph flow is increased and helps drain edema fluid that accumulates because of increased vascular permeability. In addition to fluid, leukocytes and cell debris, as well as microbes, may find their way into lymph. Lymphatic vessels, like blood vessels, proliferate during inflammatory reactions to handle the increased load. The lymphatics may become secondarily inflamed (lymphangitis), as may the draining lymph nodes (lymphadenitis). Inflamed lymph nodes are often enlarged because of hyperplasia of the lymphoid follicles and increased numbers of lymphocytes and macrophages. This constellation of pathologic changes is termed reactive, or inflammatory, lymphadenitis (Chapter 13). The presence of red streaks near a skin wound is a telltale sign of bacterial infection. The streaks represent inflamed lymphatic channels and are diagnostic of lymphangitis; it may be accompanied by painful enlargement of the draining lymph nodes, indicating lymphadenitis.

KEY CONCEPTS

VASCULAR REACTIONS IN ACUTE INFLAMMATION

- Vasodilation is induced by chemical mediators such as histamine (described later) and is the cause of erythema and increased blood flow.
- Increased vascular permeability is induced by histamine, kinins, and other mediators that produce gaps between endothelial cells and by direct or leukocyte-induced endothelial injury.
- Increased vascular permeability allows plasma proteins and leukocytes, the mediators of host defense, to enter sites of infection or tissue damage. Fluid leak from blood vessels results in edema.
- Lymphatic vessels and lymph nodes are also involved in inflammation and often show redness and swelling.

Leukocyte Recruitment to Sites of Inflammation

The changes in blood flow and vascular permeability are quickly followed by an influx of leukocytes into the tissue. These leukocytes perform the key function of eliminating the offending agents. The most important leukocytes in typical inflammatory reactions are the ones capable of phagocytosis, namely neutrophils and macrophages. They ingest and destroy bacteria and other microbes, as well as necrotic tissue and foreign substances. Macrophages also produce growth factors that aid in repair. A price that is paid for the defensive potency of leukocytes is that, when activated, they may induce tissue damage and prolong the inflammatory reaction because the leukocyte products that destroy microbes and help "clean up" necrotic tissues can also injure normal bystander host tissues.

The journey of leukocytes from the vessel lumen to the tissue is a multistep process that is mediated and controlled by adhesion molecules and cytokines called chemokines. This process can be divided into sequential phases (Fig. 3.4).

1. In the lumen: *margination, rolling, and adhesion to endothelium*. Vascular endothelium in its normal state does not bind circulating cells or allow their passage. In inflammation the endothelium is activated and can bind leukocytes as a prelude to their exit from blood vessels.
2. *Migration across the endothelium* and vessel wall.
3. *Migration in the tissues* toward a chemotactic stimulus.

Leukocyte Adhesion to Endothelium

In normally flowing blood in venules, red cells are confined to a central axial column, displacing the leukocytes toward the wall of the vessel. Because of dilation of inflamed postcapillary venules, blood flow slows (stasis), and more white cells assume a peripheral position along the endothelial surface. This process of leukocyte redistribution is called margination. The slowed leukocytes sense signals from the endothelium, resulting first in the cells rolling on the vessel

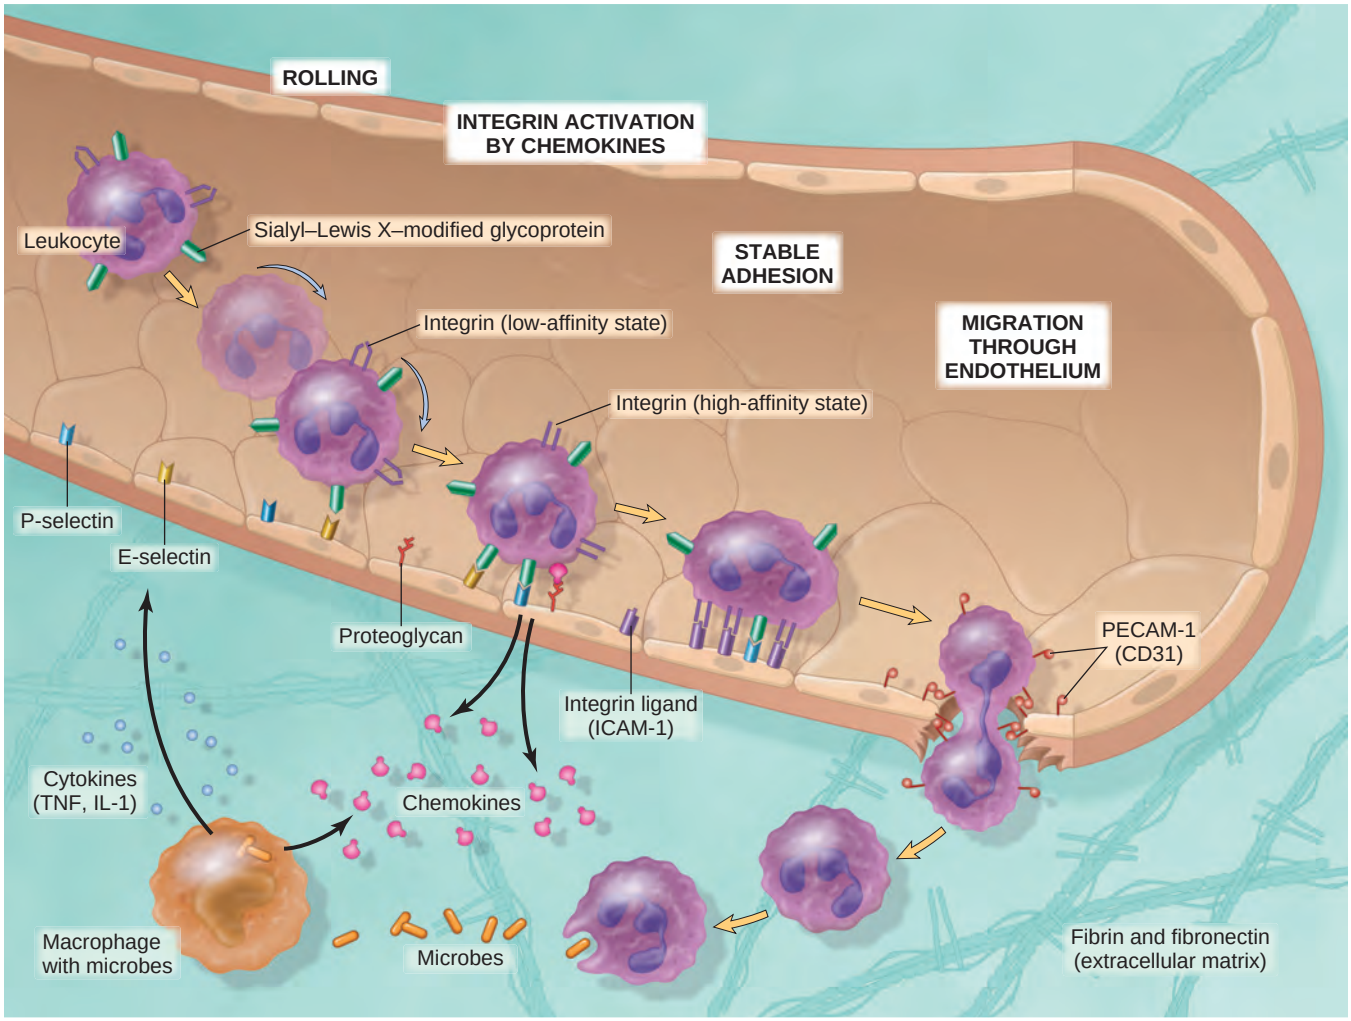

Figure 3.4 The multistep process of leukocyte migration through blood vessels, shown here for neutrophils. The leukocytes first roll, then become activated and adhere to endothelium, then transmigrate across the endothelium, pierce the basement membrane, and migrate toward chemoattractants emanating from the source of injury. Different molecules play predominant roles in different steps of this process: selectins, in rolling; chemokines (usually displayed bound to proteoglycans), in activating the neutrophils to increase avidity of integrins; integrins, in firm adhesion; and CD31 (PECAM-1), in transmigration. *ICAM-1*, Intercellular adhesion molecule 1; *IL-1*, interleukin-1; *PECAM-1*, platelet endothelial cell adhesion molecule (also known as CD31); *TNF*, tumor necrosis factor.

wall and then recognizing adhesion molecules expressed on the endothelium that lead to the cells adhering firmly (resembling pebbles over which a stream runs without disturbing them).

The attachment of leukocytes to endothelial cells is mediated by adhesion molecules whose expression is enhanced by cytokines, which are secreted by sentinel cells in tissues in response to microbes and other injurious agents, thus ensuring that leukocytes are recruited to the tissues where these stimuli are present. The two major families of proteins involved in leukocyte adhesion and migration are the selectins and integrins and their ligands (Table 3.3). They are expressed on leukocytes and endothelial cells.

- *Selectins.* The initial rolling interactions are mediated by selectins, of which there are three types: one expressed on leukocytes (L-selectin), one on endothelium (E-selectin), and one in platelets and on endothelium (P-selectin) (see Table 3.3). The ligands for selectins are sialylated oligosaccharides bound to mucin-like glycoproteins. The expression of selectins and their ligands is regulated by cytokines produced in response to infection and injury. Tissue macrophages, mast cells, and endothelial cells that encounter microbes and dead tissues respond by secreting several cytokines including tumor necrosis factor (TNF), IL-1, and chemokines (*chemo*attractant cyto*kines*). (Cytokines are described in more detail later and in Chapter 6.) TNF and IL-1 act on the endothelial cells of postcapillary venules adjacent to the infection and induce the coordinate expression of numerous adhesion molecules. Within 1 to 2 hours the endothelial cells begin to express E-selectin and the ligands for L-selectin. Other mediators such as histamine and thrombin, described later, stimulate the redistribution of P-selectin from its normal intracellular stores in endothelial cell granules (called *Weibel-Palade bodies*) to the cell surface. Leukocytes express L-selectin at the tips of their microvilli and also express ligands for E-selectin and P-selectin, all of which bind to the complementary molecules on the endothelial cells. These are low-affinity interactions with a fast off-rate, so they are easily disrupted by the flowing blood. As a result, the bound leukocytes bind, detach, and bind again and thus begin to roll along the endothelial surface.
- *Integrins.* The weak rolling interactions slow down the leukocytes and give them the opportunity to bind more firmly to the endothelium. Firm adhesion is mediated by a family of heterodimeric leukocyte surface proteins called integrins (see Table 3.3). TNF and IL-1 induce endothelial expression of ligands for integrins, mainly vascular cell adhesion molecule 1 (VCAM-1), the ligand for the β1 integrin VLA-4, and intercellular adhesion molecule-1 (ICAM-1), the ligand for the β2 integrins LFA-1 and MAC-1. Leukocytes normally express integrins in a low-affinity state. Chemokines that were produced at the site of injury bind to endothelial cell proteoglycans and are displayed at high concentrations on the endothelial surface. These chemokines bind to and activate the rolling leukocytes. One of the consequences of activation is the conversion of VLA-4 and LFA-1 integrins on the leukocytes to a high-affinity state. The combination of cytokine-induced expression of integrin ligands on the endothelium and increased integrin affinity on the leukocytes results in firm integrin-mediated adhesion of the leukocytes to the endothelium at the site of inflammation. The leukocytes stop rolling, their cytoskeleton is reorganized, and they spread out on the endothelial surface.

Leukocyte Migration Through Endothelium

The next step in the process of leukocyte recruitment is migration of the leukocytes through intact endothelium, called *transmigration* or *diapedesis*. Transmigration of leukocytes occurs mainly in postcapillary venules. Chemokines act on the adherent leukocytes and stimulate the cells to migrate through interendothelial gaps toward the chemical

Table 3.3 Endothelial and Leukocyte Adhesion Molecules

Family	Molecule	Distribution	Ligand
Selectin	L-selectin (CD62L)	Neutrophils, monocytes T cells (naïve and central memory) B cells (naïve)	Sialyl-Lewis X/PNAd on GlyCAM-1, CD34, MAdCAM-1, others; expressed on endothelium (HEV)
	E-selectin (CD62E)	Endothelium activated by cytokines (TNF, IL-1)	Sialyl-Lewis X (e.g., CLA) on glycoproteins; expressed on neutrophils, monocytes, T cells (effector, memory)
	P-selectin (CD62P)	Endothelium activated by cytokines (TNF, IL-1), histamine, or thrombin	Sialyl-Lewis X on PSGL-1 and other glycoproteins; expressed on neutrophils, monocytes, T cells (effector, memory)
Integrin	LFA-1 (CD11aCD18)	Neutrophils, monocytes, T cells (naïve, effector, memory)	ICAM-1 (CD54), ICAM-2 (CD102); expressed on endothelium (upregulated on activated endothelium)
	MAC-1 (CD11bCD18)	Monocytes, DCs	ICAM-1 (CD54), ICAM-2 (CD102); expressed on endothelium (upregulated on activated endothelium)
	VLA-4 (CD49aCD29)	Monocytes T cells (naïve, effector, memory)	VCAM-1 (CD106); expressed on endothelium (upregulated on activated endothelium)
	α4β7 (CD49dCD29)	Monocytes T cells (gut homing naïve effector, memory)	VCAM-1 (CD106), MAdCAM-1; expressed on endothelium in gut and gut-associated lymphoid tissues
Ig	CD31	Endothelial cells, leukocytes	CD31 (homotypic interaction)

CLA, Cutaneous lymphocyte antigen-1; *GlyCAM-1,* glycan-bearing cell adhesion molecule-1; *HEV,* high endothelial venule; *Ig,* immunoglobulin; *IL-1,* interleukin-1; *ICAM,* intercellular adhesion molecule; *MAdCAM-1,* mucosal adhesion cell adhesion molecule-1; *PSGL-1,* P-selectin glycoprotein ligand-1; *TNF,* tumor necrosis factor; *VCAM,* vascular cell adhesion molecule.

concentration gradient, that is, toward the site of injury or infection where the chemokines are being produced. Several adhesion molecules present in the intercellular junctions between endothelial cells are involved in the migration of leukocytes. These molecules include a member of the immunoglobulin superfamily called *CD31* or *PECAM-1* (platelet endothelial cell adhesion molecule). After traversing the endothelium, leukocytes pierce the basement membrane, probably by secreting collagenases, and enter the extravascular space. After leukocytes pass through, the basement membranes become continuous again. The cells that have exited the vessel then migrate toward the chemotactic gradient created by chemokines and other chemoattractants and accumulate in the extravascular site.

The most telling proof of the importance of leukocyte adhesion molecules in the host inflammatory response are genetic deficiencies in these molecules, which result in increased susceptibility to bacterial infections. These leukocyte adhesion deficiencies are described in Chapter 6.

Chemotaxis of Leukocytes

After exiting the circulation, leukocytes move in the tissues toward the site of injury by a process called *chemotaxis*, which is defined as locomotion along a chemical gradient. Both exogenous and endogenous substances act as chemoattractants. The most common exogenous factors are bacterial products, including peptides with *N*-formylmethionine terminal amino acids and some lipids. Endogenous chemoattractants include several chemical mediators (described later): (1) cytokines, particularly those of the chemokine family (e.g., IL-8); (2) components of the complement system, particularly C5a; and (3) arachidonic acid (AA) metabolites, mainly leukotriene B_4 (LTB_4). All these chemotactic agents bind to specific seven-transmembrane G protein–coupled receptors on the surface of leukocytes. Signals initiated from these receptors result in activation of second messengers that induce polymerization of actin at the leading edge of the cell and localization of myosin filaments at the back. This reorganization of the cytoskeleton allows the leading edge of the leukocyte to extend filopodia that pull the back of the cell in the direction of extension, much as an automobile with front-wheel drive is pulled by the wheels in front (Fig. 3.5). The net result is that leukocytes migrate in the direction of locally produced chemoattractants emanating from the site of the inflammatory stimulus.

The nature of the leukocyte infiltrate varies with the age of the inflammatory response and the type of stimulus. In most forms of acute inflammation, neutrophils predominate in the inflammatory infiltrate during the first 6 to 24 hours and are replaced by monocytes in 24 to 48 hours (Fig. 3.6). There are several reasons for the early preponderance of neutrophils: they are more numerous than are other leukocytes, respond more rapidly to chemokines, and may attach more firmly to the adhesion molecules that are rapidly induced on endothelial cells such as P-selectin and E-selectin. After entering tissues, neutrophils are short-lived; most neutrophils in extravascular tissues undergo apoptosis within a few days. Monocytes not only survive longer but may also proliferate in the tissues, and thus they become the dominant population in prolonged inflammatory reactions. There are, however, exceptions to this stereotypic pattern of cellular infiltration. In certain infections—for example, those produced by *Pseudomonas* bacteria—the cellular infiltrate is dominated by continuously recruited neutrophils for several days; in viral infections, lymphocytes may be the first cells to arrive; some hypersensitivity reactions are dominated by activated lymphocytes, macrophages, and plasma cells (reflecting the immune response); and in helminthic infections and allergic reactions, eosinophils may be the main cell type.

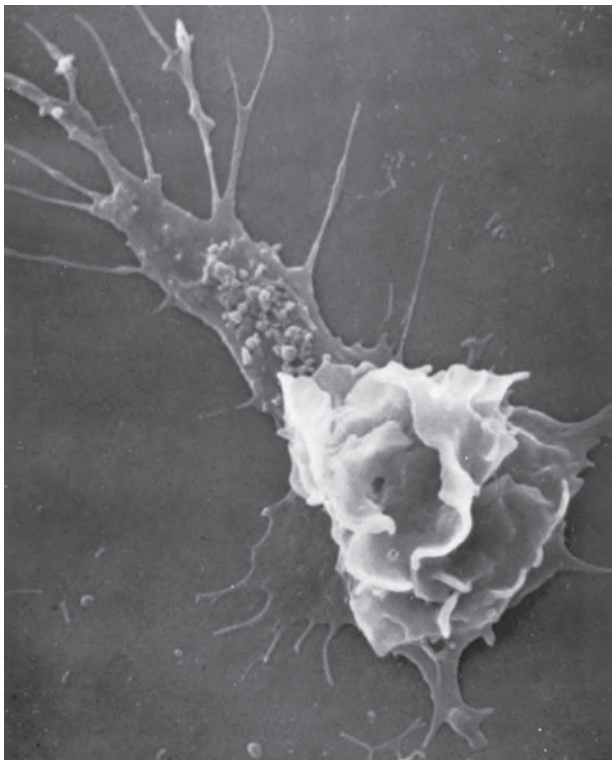

Figure 3.5 Scanning electron micrograph of a moving leukocyte in culture showing a filopodium *(upper left)* and a trailing tail. (Courtesy Dr. Morris J. Karnovsky, Harvard Medical School, Boston, Mass.)

The molecular understanding of leukocyte recruitment and migration has led to development of a large number of drugs for controlling harmful inflammation, including agents that block TNF (discussed later), and antagonists of leukocyte integrins that are approved for inflammatory diseases or are being tested in clinical trials. Predictably, these antagonists not only have the desired effect of controlling the inflammation but can also compromise the ability of treated patients to defend themselves against microbes, which, of course, is the physiologic function of the inflammatory response.

KEY CONCEPTS

LEUKOCYTE RECRUITMENT TO SITES OF INFLAMMATION

- Leukocytes are recruited from the blood into the extravascular tissue, where infectious pathogens or damaged tissues may be located, migrate to the site of infection or tissue injury, and are activated to perform their functions.

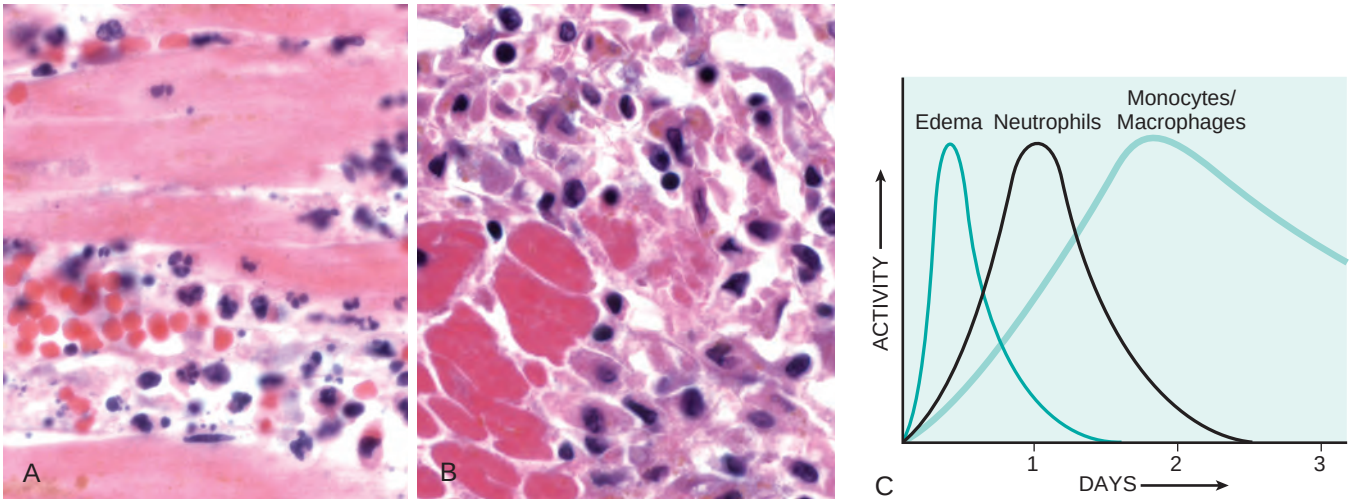

Figure 3.6 Nature of leukocyte infiltrates in inflammatory reactions. The photomicrographs show an inflammatory reaction in the myocardium after ischemic necrosis (infarction). (A) Early (neutrophilic) infiltrates and congested blood vessels. (B) Later (mononuclear) cellular infiltrates. (C) The approximate kinetics of edema and cellular infiltration. For simplicity, edema is shown as an acute transient response, although secondary waves of delayed edema and neutrophil infiltration can also occur.

- Leukocyte recruitment is a multistep process consisting of loose attachment to and rolling on endothelium (mediated by selectins), firm attachment to endothelium (mediated by integrins), and migration through interendothelial spaces.
- Various cytokines promote expression of selectins and integrin ligands on endothelium (e.g., TNF, IL-1), increase the avidity of integrins for their ligands (e.g., chemokines), and promote directional migration of leukocytes (also chemokines); many of these cytokines are produced by tissue macrophages and other cells responding to the pathogens or damaged tissues.
- Neutrophils predominate in the early inflammatory infiltrate and are later replaced by monocytes and macrophages.

Once leukocytes (particularly neutrophils and monocytes) are recruited to a site of infection or cell death, they must be activated to perform their functions. The responses of these leukocytes consist of recognition of the offending agents by TLRs and other receptors, described earlier, which deliver signals that activate the leukocytes to phagocytose and destroy the offending agents.

Phagocytosis and Clearance of the Offending Agent

The two major phagocytes are neutrophils and macrophages. Although these cell types share many functional properties, they also differ in significant ways (Table 3.4).

Recognition of microbes or dead cells induces several responses in leukocytes that are collectively called *leukocyte activation* (Fig. 3.7). Activation results from signaling pathways that are triggered in leukocytes, resulting in increases in cytosolic Ca^{2+} and activation of enzymes such as protein kinase C and phospholipase A_2. The functional responses that are most important for destruction of microbes and other offenders are phagocytosis and intracellular killing. Several other responses aid in the defensive functions of inflammation and may contribute to its injurious consequences.

Phagocytosis

Phagocytosis involves sequential steps (Fig. 3.8):

- Recognition and attachment of the particle to be ingested by the leukocyte;
- Engulfment, with subsequent formation of a phagocytic vacuole; and
- Killing of the microbe and degradation of the ingested material.

Phagocytic Receptors. Mannose receptors, scavenger receptors, and receptors for various opsonins enable phagocytes to bind and ingest microbes. The macrophage mannose receptor is a lectin that binds terminal mannose and fucose residues of glycoproteins and glycolipids. These sugars are typically part of molecules found on microbial cell walls, whereas mammalian glycoproteins and glycolipids contain terminal sialic acid or *N*-acetylgalactosamine. Therefore the mannose receptor recognizes microbes and not host cells. Scavenger receptors were originally defined as molecules that bind and mediate endocytosis of oxidized or acetylated low-density lipoprotein (LDL) particles that do not interact with the conventional LDL receptor. Macrophage scavenger receptors bind a variety of microbes in addition to modified LDL particles. Macrophage integrins, notably MAC-1 (CD11b/CD18), may also bind microbes for phagocytosis. The efficiency of phagocytosis is greatly enhanced when microbes are coated with opsonins for which the phagocytes express high-affinity receptors. The major opsonins are immunoglobulin G (IgG) antibodies, the C3b breakdown product of complement, and certain plasma lectins, notably mannose-binding lectin and collectins, all of which are recognized by specific receptors on leukocytes.

Engulfment. After a particle is bound to phagocyte receptors, extensions of the cytoplasm flow around it, and the plasma membrane pinches off to form an intracellular vesicle (phagosome) that encloses the particle. The phagosome then fuses with a lysosomal granule, which discharges its contents

Table 3.4 Properties of Neutrophils and Macrophages

	Neutrophils	Macrophages
Origin	HSCs in bone marrow	HSCs in bone marrow (in inflammatory reactions) Many tissue-resident macrophages: stem cells in yolk sac or fetal liver (early in development)
Lifespan in tissues	Several days	Inflammatory macrophages: days or weeks Tissue-resident macrophages: years
Responses to activating stimuli	Rapid, short-lived, mostly degranulation and enzymatic activity	More prolonged, slower, often dependent on new gene transcription
Reactive oxygen species	Rapidly induced by assembly of phagocyte oxidase (respiratory burst)	Less prominent
Nitric oxide	Low levels or none	Induced following transcriptional activation of iNOS
Degranulation	Major response; induced by cytoskeletal rearrangement	Not prominent
Cytokine production	Low levels or none	Major functional activity; requires transcriptional activation of cytokine genes
NET formation	Rapidly induced, by extrusion of nuclear contents	No
Secretion of lysosomal enzymes	Prominent	Less

HSC, Hematopoietic stem cells; *iNOS,* inducible nitric oxide synthase; *NET,* neutrophil extracellular trap.

This table lists the major differences between neutrophils and macrophages. The reactions summarized above are described in the text. Note that the two cell types share many features such as phagocytosis, ability to migrate through blood vessels into tissues, and chemotaxis.

into the phagolysosome (see Fig. 3.8). During this process the phagocyte may also release lysosome contents into the extracellular space.

The process of phagocytosis is complex and involves the integration of many receptor-initiated signals that lead to membrane remodeling and cytoskeletal changes. Phagocytosis is dependent on polymerization of actin filaments; it is therefore not surprising that the signals that trigger phagocytosis are many of the same that are involved in chemotaxis.

Intracellular Destruction of Microbes and Debris

Killing of microbes is accomplished by reactive oxygen species (ROS), also called reactive oxygen intermediates, and reactive nitrogen species, mainly derived from nitric

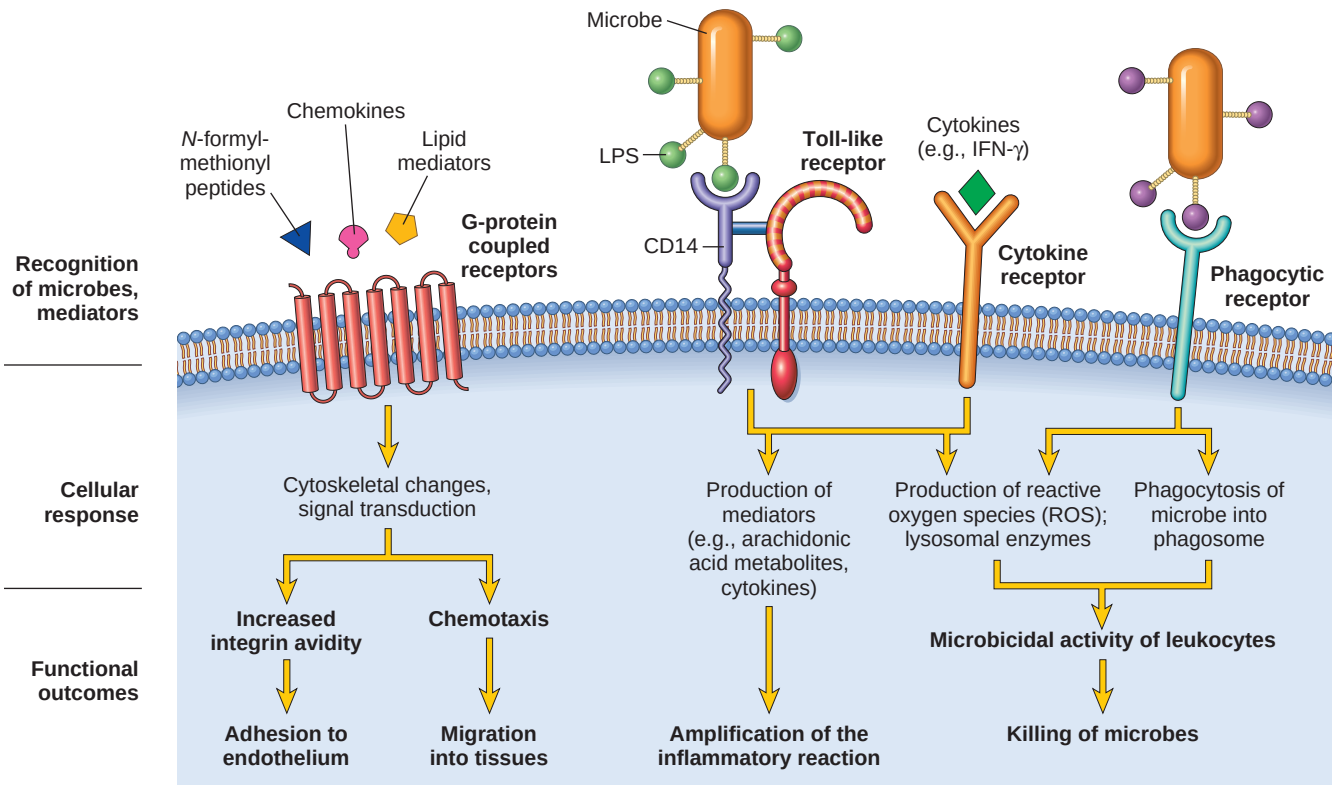

Figure 3.7 Leukocyte activation. Different classes of cell surface receptors of leukocytes recognize different stimuli. The receptors initiate responses that mediate the functions of the leukocytes. Only some receptors are depicted (see text for details). Lipopolysaccharide (*LPS*) first binds to a circulating LPS-binding protein (not shown). *IFN-γ,* Interferon-γ.

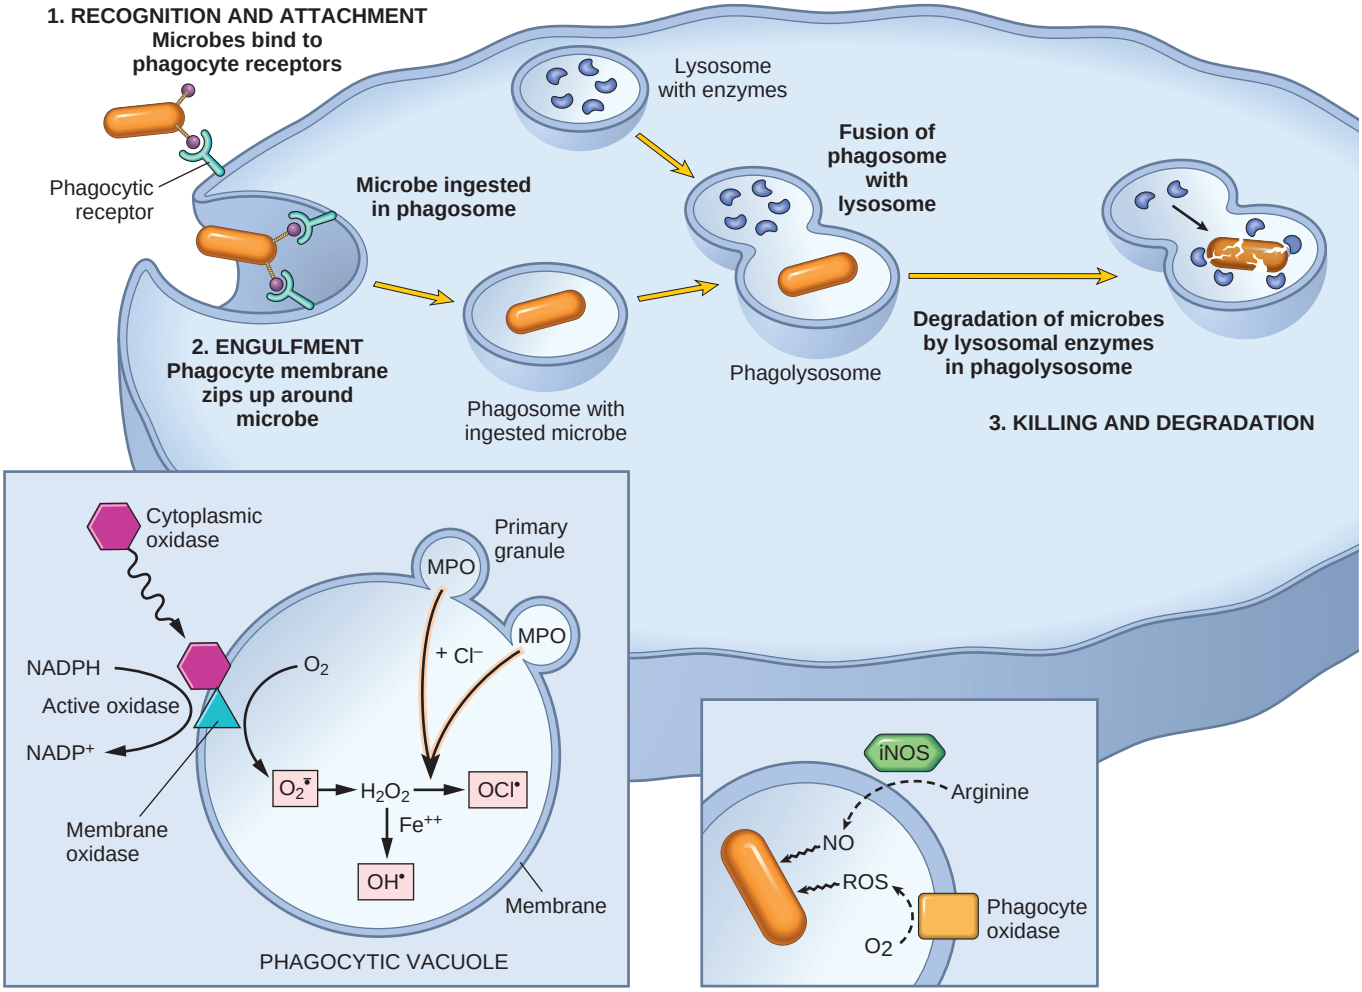

Figure 3.8 Phagocytosis and intracellular destruction of microbes. Phagocytosis of a particle (e.g., a bacterium) involves binding to receptors on the leukocyte membrane, engulfment, and fusion of the phagocytic vacuoles with lysosomes. This is followed by destruction of ingested particles within the phagolysosomes by lysosomal enzymes and by reactive oxygen and nitrogen species. Hypochlorite ($HOCl^{\cdot}$) and hydroxyl radical ($^{\cdot}OH$) are microbicidal products generated from superoxide ($O_2^{\cdot-}$), and peroxynitrite ($OONO^{\cdot}$) is generated from nitric oxide *(NO)*. During phagocytosis, granule contents may be released into extracellular tissues (not shown). *iNOS*, Inducible nitric oxide synthase; *MPO*, myeloperoxidase; *ROS*, reactive oxygen species.

oxide (NO), and these as well as lysosomal enzymes destroy phagocytosed materials (see Fig. 3.8). This is the final step in the elimination of infectious agents and necrotic cells. The killing and degradation of microbes and dead cell debris within neutrophils and macrophages occur most efficiently after activation of the phagocytes. All these killing mechanisms are normally sequestered in lysosomes, to which phagocytosed materials are brought. Thus, potentially harmful substances are segregated from the cell's cytoplasm and nucleus to avoid damage to the phagocyte while it is performing its normal function.

Reactive Oxygen Species. ROS are produced by the rapid assembly and activation of a multicomponent oxidase, NADPH oxidase (also called phagocyte oxidase), which oxidizes reduced nicotinamide-adenine dinucleotide phosphate (NADPH) and, in the process, reduces oxygen to superoxide anion ($O_2^{\cdot-}$). In neutrophils, this oxidative reaction is triggered by activating signals accompanying phagocytosis and is called the *respiratory burst*. Phagocyte oxidase is an enzyme complex consisting of at least seven proteins. In resting neutrophils, different components of the enzyme are located in the plasma membrane and the cytoplasm. In response to activating stimuli, the cytosolic protein components translocate to the phagosomal membrane, where they assemble and form the functional enzyme complex. Thus, the ROS are produced within the phagolysosome, where they can act on ingested particles without damaging the host cell. $O_2^{\cdot-}$ is converted into hydrogen peroxide (H_2O_2), mostly by spontaneous dismutation. H_2O_2 is not able to efficiently kill microbes by itself. However, the azurophilic granules of neutrophils contain the enzyme myeloperoxidase (MPO), which, in the presence of a halide such as Cl^-, converts H_2O_2 to hypochlorite ($HOCl^{\cdot}$), the active ingredient in household bleach. The latter is a potent antimicrobial agent that destroys microbes by halogenation (in which the halide is bound covalently to cellular constituents) or by oxidation of proteins and lipids (lipid peroxidation). The H_2O_2-MPO-halide system is the most potent bactericidal system of neutrophils. Nevertheless, inherited deficiency of MPO by

itself leads to minimal increase in susceptibility to infection, emphasizing the redundancy of microbicidal mechanisms in leukocytes. H_2O_2 is also converted to hydroxyl radical ($^{\cdot}OH$), another powerful destructive agent. As discussed in Chapter 2, these oxygen-derived free radicals bind to and modify cellular lipids, proteins, and nucleic acids and thus destroy cells such as microbes.

Oxygen-derived radicals may be released extracellularly from leukocytes after exposure to microbes, chemokines, and antigen-antibody complexes or following a phagocytic challenge. These ROS are implicated in tissue damage accompanying inflammation.

Plasma, tissue fluids, and host cells possess antioxidant mechanisms that protect healthy cells from these potentially harmful oxygen-derived radicals. These antioxidants are discussed in Chapter 2 and include (1) the enzyme superoxide dismutase, which is found in, or can be activated in, a variety of cell types; (2) the enzyme catalase, which detoxifies H_2O_2; (3) glutathione peroxidase, another powerful H_2O_2 detoxifier; (4) the copper-containing plasma protein ceruloplasmin; and (5) the iron-free fraction of plasma transferrin.

Inherited deficiencies of components of phagocyte oxidase cause an immunodeficiency disease called chronic granulomatous disease (CGD), which is discussed in Chapter 6.

Nitric Oxide. NO, a soluble gas produced from arginine by the action of nitric oxide synthase (NOS), also participates in microbial killing. There are three different types of NOS: endothelial (eNOS), neuronal (nNOS), and inducible (iNOS). eNOS and nNOS are constitutively expressed at low levels, and the NO they generate functions to maintain vascular tone and as a neurotransmitter, respectively. iNOS, the type that is involved in microbial killing, is induced when macrophages (and, to a lesser extent, neutrophils) are activated by cytokines (e.g., interferon-γ [IFN-γ]) or microbial products. In macrophages, NO reacts with superoxide ($O_2^{\cdot-}$) to generate the highly reactive free radical peroxynitrite ($ONOO^-$). These nitrogen-derived free radicals, similar to ROS, attack and damage the lipids, proteins, and nucleic acids of microbes (Chapter 2). Reactive oxygen and nitrogen species have overlapping actions, as shown by the observation that knockout mice lacking either phagocyte oxidase or iNOS are only mildly susceptible to infections, but mice lacking both succumb rapidly to disseminated infections by normally harmless commensal bacteria.

In addition to its role as a microbicidal substance, NO relaxes vascular smooth muscle and promotes vasodilation. It is not clear if this action of NO plays an important role in the vascular reactions of acute inflammation.

Lysosomal Enzymes and Other Lysosomal Proteins. Neutrophils and macrophages contain lysosomal granules that contribute to microbial killing and, when released, may cause tissue damage. Neutrophils have two main types of granules. The smaller specific (or secondary) granules contain lysozyme, collagenase, gelatinase, lactoferrin, plasminogen activator, histaminase, and alkaline phosphatase. The larger azurophil (or primary) granules contain MPO, bactericidal proteins (lysozyme, defensins), acid hydrolases, and a variety of neutral proteases (elastase, cathepsin G, nonspecific collagenases, proteinase 3). Both types of granules can fuse with phagocytic vacuoles containing engulfed material, or the granule contents can be released into the extracellular space during "frustrated phagocytosis" (discussed later).

Different granule enzymes serve different functions. Acid proteases degrade bacteria and debris within the phagolysosomes, which are acidified by membrane-bound proton pumps. Neutral proteases are capable of degrading various extracellular components such as collagen, basement membrane, fibrin, elastin, and cartilage, resulting in the tissue destruction that accompanies inflammatory processes. Neutral proteases can also cleave C3 and C5 complement proteins and release a kinin-like peptide from kininogen. The released components of complement and kinins act as mediators of acute inflammation (discussed later). Neutrophil elastase has been shown to degrade virulence factors of bacteria and thus combat bacterial infections. Macrophages also contain acid hydrolases, collagenase, elastase, phospholipase, and plasminogen activator.

Because of the destructive effects of lysosomal enzymes, the initial leukocytic infiltration, if unchecked, can potentiate further inflammation by damaging tissues. These harmful proteases, however, are normally controlled by a system of antiproteases in the serum and tissue fluids. Foremost among these is α_1-antitrypsin, which is the major inhibitor of neutrophil elastase. A deficiency of these inhibitors may lead to sustained action of leukocyte proteases, as is the case in patients with α_1-antitrypsin deficiency, who are at risk for emphysema due to destruction of elastic support fibers in the lung because of uncontrolled elastase activity (Chapter 15). α_2-Macroglobulin is another antiprotease found in serum and various secretions.

Other microbicidal granule contents include defensins, cationic arginine-rich granule peptides that are toxic to microbes; cathelicidins, antimicrobial proteins found in neutrophils and other cells; lysozyme, which hydrolyzes the muramic acid-*N*-acetylglucosamine bond found in the glycopeptide coat of all bacteria; lactoferrin, an iron-binding protein present in specific granules; and major basic protein, a cationic protein of eosinophils, which has limited bactericidal activity but is cytotoxic to many helminthic parasites.

Neutrophil Extracellular Traps

Neutrophil extracellular traps (NETs) are extracellular fibrillar networks that concentrate antimicrobial substances at sites of infection and trap microbes, helping to prevent their spread. They are produced by neutrophils in response to infectious pathogens (mainly bacteria and fungi) and inflammatory mediators (e.g., chemokines, cytokines [mainly interferons], complement proteins, and ROS). The extracellular traps consist of a viscous meshwork of nuclear chromatin that binds and concentrates granule proteins such as antimicrobial peptides and enzymes (Fig. 3.9). NET formation starts with ROS-dependent activation of an arginine deaminase that converts arginines to citrulline, leading to chromatin decondensation. Other enzymes that are produced in activated neutrophils, such as MPO and elastase, enter the nucleus and cause further chromatin decondensation, culminating in rupture of the nuclear envelope and release of chromatin. In this process, the nuclei of the neutrophils are lost, leading to death of the cells. NETs have also been detected in the blood during sepsis. The nuclear chromatin

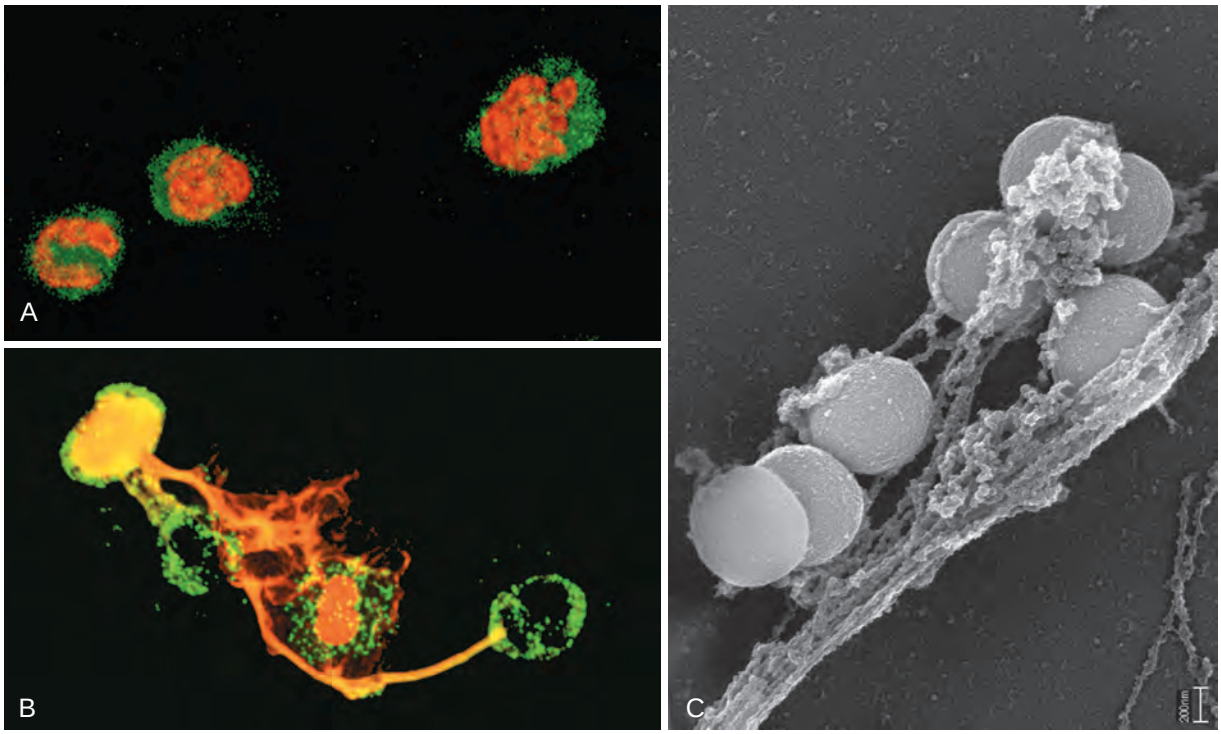

Figure 3.9 Neutrophil extracellular traps (NETs). (A) Healthy neutrophils with nuclei stained red and cytoplasm stained green. (B) Release of nuclear material from neutrophils (note that two have lost their nuclei), forming extracellular traps. (C) Electron micrograph of bacteria (staphylococci) trapped in NETs. (From Brinkmann V, Zychlinsky A: Beneficial suicide: why neutrophils die to make NETs, *Nat Rev Microbiol* 5:577, 2007, with permission.)

in the NETs, which includes histones and associated DNA, has been postulated to be a source of nuclear antigens in systemic autoimmune diseases, particularly lupus, in which individuals react against their own DNA and nucleoproteins (Chapter 6).

Leukocyte-Mediated Tissue Injury

Leukocytes are important causes of injury to normal cells and tissues under several circumstances.

- As part of a normal defense reaction against infectious microbes, when adjacent tissues suffer collateral damage. In some infections that are difficult to eradicate, such as tuberculosis and certain viral diseases, the prolonged host response contributes more to the pathology than does the microbe itself.
- When the inflammatory response is inappropriately directed against host tissues, as in certain autoimmune diseases.
- When the host reacts excessively against usually harmless environmental substances, as in allergic diseases, including asthma.

In all these situations, **the mechanisms by which leukocytes damage normal tissues are the same as the mechanisms involved in antimicrobial defense** because once the leukocytes are activated, their effector mechanisms do not distinguish between offender and host. During activation and phagocytosis, neutrophils and macrophages produce microbicidal substances (ROS, NO, and lysosomal enzymes) within the phagolysosome; under some circumstances, these substances are also released into the extracellular space. These released substances are capable of damaging host cells such as vascular endothelium and may thus amplify the effects of the initial injurious agent. If unchecked or inappropriately directed against host tissues, the leukocyte infiltrate itself becomes the offender, and indeed leukocyte-dependent inflammation and tissue injury underlie many acute and chronic human diseases (see Table 3.1). This fact becomes evident in the discussion of specific disorders throughout this book.

The contents of lysosomal granules are secreted by leukocytes into the extracellular milieu by several mechanisms. Controlled secretion of granule contents is a normal response of activated leukocytes. If phagocytes encounter materials that cannot be easily ingested, such as immune complexes deposited on large surfaces (e.g., glomerular basement membrane), the inability of the leukocytes to surround and ingest these substances (frustrated phagocytosis) triggers strong activation and the release of lysosomal enzymes into the extracellular environment. Some phagocytosed substances, such as urate crystals, may damage the membrane of the phagolysosome, also leading to the release of lysosomal granule contents.

Other Functional Responses of Activated Leukocytes

In addition to eliminating microbes and dead cells, activated leukocytes play several other roles in host defense. Importantly, these cells, especially macrophages, produce cytokines that can either amplify or limit inflammatory reactions, growth factors that stimulate the proliferation of endothelial cells and fibroblasts and the synthesis of collagen, and enzymes that remodel connective tissues. Because of these

activities, macrophages are also critical cells of chronic inflammation and tissue repair after inflammation has subsided. These functions of macrophages are discussed later in the chapter.

In this discussion of acute inflammation, we emphasize the importance of neutrophils and macrophages. However, it has recently become clear that some T lymphocytes, which are cells of adaptive immunity, also contribute to acute inflammation. The most important of these cells are those that produce the cytokine IL-17 (so-called Th17 cells), discussed in more detail in Chapter 6. IL-17 induces the secretion of chemokines that recruit other leukocytes. In the absence of effective Th17 responses, individuals are susceptible to fungal and bacterial infections and tend to develop "cold abscesses," particularly in the skin, that lack the classic features of acute inflammation, such as warmth and redness.

Termination of the Acute Inflammatory Response

Such a powerful system of host defense, with its inherent capacity to cause tissue injury, needs tight controls to minimize damage. In part, inflammation declines after the offending agents are removed simply because the mediators of inflammation are produced for only as long as the stimulus persists, have short half-lives, and are degraded after their release. Neutrophils also have short half-lives in tissues and die by apoptosis within several hours after leaving the blood. In addition, as inflammation develops, the process itself triggers a variety of stop signals that actively terminate the reaction. These active termination mechanisms include a switch in the type of arachidonic acid metabolite produced, from proinflammatory leukotrienes to antiinflammatory lipoxins (described later), and the liberation of antiinflammatory cytokines, including transforming growth factor-β (TGF-β) and IL-10, from macrophages and other cells. Other control mechanisms that have been demonstrated experimentally include neural impulses (cholinergic discharge) that inhibit the production of TNF in macrophages.

KEY CONCEPTS

LEUKOCYTE ACTIVATION AND REMOVAL OF OFFENDING AGENTS

- Leukocytes can eliminate microbes and dead cells by phagocytosis, followed by their destruction in phagolysosomes.
- Destruction is caused by free radicals (ROS, NO) generated in activated leukocytes and lysosomal enzymes.
- Neutrophils can extrude their nuclear contents to form extracellular nets that trap and destroy microbes.
- Enzymes and ROS may be released into the extracellular environment.
- The mechanisms that function to eliminate microbes and dead cells (the physiologic role of inflammation) are also capable of damaging normal tissues (the pathologic consequences of inflammation).
- Antiinflammatory mediators terminate the acute inflammatory reaction when it is no longer needed.

Mediators of Inflammation

Inflammatory mediators are the substances that initiate and regulate inflammatory reactions. Many mediators have been identified and targeted therapeutically to limit inflammation. In this discussion, we review their shared properties and the general principles that govern their production and actions.

- The most important mediators of acute inflammation are vasoactive amines, lipid products (prostaglandins and leukotrienes), cytokines (including chemokines), and products of complement activation (Table 3.5). These mediators induce various components of the inflammatory response, typically by distinct mechanisms, which is why inhibiting each has been therapeutically beneficial. However, there is also some overlap (redundancy) in the actions of the mediators.
- Mediators are either secreted by cells or generated from plasma proteins. *Cell-derived mediators* are normally sequestered in intracellular granules and can be rapidly secreted by granule exocytosis (e.g., histamine in mast cell granules) or are synthesized de novo (e.g., prostaglandins and leukotrienes, cytokines) in response to a stimulus. The major cell types that produce mediators of acute inflammation are the sentinels that detect invaders and tissue damage, that is, macrophages, dendritic cells, and mast cells, but platelets, neutrophils, endothelial cells, and most epithelia can also be induced to elaborate some

Table 3.5 Principal Mediators of Inflammation

Mediator	Source	Action
Histamine	Mast cells, basophils, platelets	Vasodilation, increased vascular permeability, endothelial activation
Prostaglandins	Mast cells, leukocytes	Vasodilation, pain, fever
Leukotrienes	Mast cells, leukocytes	Increased vascular permeability, chemotaxis, leukocyte adhesion and activation
Cytokines (TNF, IL-1, IL-6)	Macrophages, endothelial cells, mast cells	Local: endothelial activation (expression of adhesion molecules) Systemic: fever, metabolic abnormalities, hypotension (shock)
Chemokines	Leukocytes, activated macrophages	Chemotaxis, leukocyte activation
Platelet-activating factor	Leukocytes, mast cells	Vasodilation, increased vascular permeability, leukocyte adhesion, chemotaxis, degranulation, oxidative burst
Complement	Plasma (produced in liver)	Leukocyte chemotaxis and activation, direct target killing (membrane attack complex), vasodilation (mast cell stimulation)
Kinins	Plasma (produced in liver)	Increased vascular permeability, smooth muscle contraction, vasodilation, pain

IL, Interleukin; *TNF,* tumor necrosis factor.

of the mediators. *Plasma-derived mediators* (e.g., complement proteins) are produced mainly in the liver and are present in the circulation as inactive precursors that must be activated, usually by a series of proteolytic cleavages, to acquire their functional properties.

- Active mediators are produced only in response to offending stimuli. These stimuli include microbial products and substances released from necrotic cells. Some of the stimuli trigger well-defined receptors and signaling pathways, described earlier, but we still do not know how other stimuli induce the secretion of mediators (e.g., from mast cells in response to cell injury or mechanical irritation). The usual requirement for microbes or dead tissues as the initiating stimulus ensures that inflammation is normally triggered only when and where it is needed.
- Most mediators are short-lived. They quickly decay, or are inactivated by enzymes, or they are otherwise scavenged or inhibited. There is thus a system of checks and balances that regulates mediator actions. These built-in control mechanisms are discussed with each class of mediator.
- One mediator can stimulate the release of other mediators. For instance, products of complement activation stimulate the release of histamine, and the cytokine TNF acts on endothelial cells to stimulate the production of another cytokine, IL-1, and many chemokines. The secondary mediators may have the same actions as the initial mediators but may also have different and even opposing activities. Such cascades provide mechanisms for amplifying—or, in certain instances, counteracting—the initial action of a mediator.

We next discuss the more important mediators of acute inflammation, focusing on their mechanisms of action and roles in acute inflammation.

Vasoactive Amines: Histamine and Serotonin

The two major vasoactive amines, so named because they have important actions on blood vessels, are *histamine* and *serotonin*. They are stored as preformed molecules in cells and are therefore among the first mediators to be released during inflammation.

The richest source of histamine are mast cells that are normally present in the connective tissue adjacent to blood vessels. It is also found in basophils and platelets. Histamine is stored in mast cell granules and is released by mast cell degranulation in response to a variety of stimuli, including (1) physical injury (such as trauma), cold, and heat, all by unknown mechanisms; (2) binding of antigen to IgE antibodies displayed on the surfaces of mast cells, which underlies immediate hypersensitivity (allergic) reactions (Chapter 6); and (3) products of complement called anaphylatoxins (C3a and C5a), described later. Antibodies and complement products bind to specific receptors on mast cells and trigger signaling pathways that induce rapid degranulation. Neuropeptides (e.g., substance P) and cytokines (IL-1, IL-8) may also trigger release of histamine.

Histamine causes dilation of arterioles and increases the permeability of venules. Histamine is considered to be the principal mediator of the immediate transient phase of increased vascular permeability, producing interendothelial gaps in venules, as discussed earlier. Its vasoactive effects are mediated mainly via binding to receptors on microvascular endothelial cells. The antihistamine drugs that are commonly used to treat some inflammatory reactions, such as allergies, are histamine receptor antagonists that bind to and block the receptor. Histamine also causes contraction of some smooth muscles.

Serotonin (5-hydroxytryptamine) is a preformed vasoactive mediator present in platelets and certain neuroendocrine cells, such as in the gastrointestinal tract. Its primary function is as a neurotransmitter in the gastrointestinal tract and the central nervous system. It is also a vasoconstrictor, but the importance of this action in inflammation is unclear.

Arachidonic Acid Metabolites

The lipid mediators *prostaglandins* and *leukotrienes* are produced from arachidonic acid (AA) present in membrane phospholipids and stimulate vascular and cellular reactions in acute inflammation. AA is a 20-carbon polyunsaturated fatty acid (5,8,11,14-eicosatetraenoic acid) that is derived from dietary sources or by synthesis from a precursor molecule, the essential fatty acid linoleic acid. Active AAs are derived from an esterified precursor found in membrane phospholipids. Mechanical, chemical, and physical stimuli or other mediators (e.g., C5a) release AA from membrane phospholipids through the action of cellular phospholipases, mainly phospholipase A_2. AA-derived mediators, also called eicosanoids (because they are derived from 20-carbon fatty acids; Greek *eicosa* = 20), are synthesized by two major classes of enzymes: cyclooxygenases (which generate prostaglandins) and lipoxygenases (which produce leukotrienes and lipoxins) (Fig. 3.10). Eicosanoids bind to G protein–coupled receptors on many cell types and can mediate virtually every step of inflammation (Table 3.6).

Prostaglandins

Prostaglandins (PGs) are produced by mast cells, macrophages, endothelial cells, and many other cell types, and are involved in the vascular and systemic reactions of inflammation. They are generated by the actions of two cyclooxygenases, called COX-1 and COX-2. COX-1 is constitutively expressed in most tissues, where it may serve various homeostatic functions (e.g., fluid and electrolyte balance in the kidneys, cytoprotection in the gastrointestinal tract), and is also induced by inflammatory stimuli. By contrast, COX-2 expression is mainly confined to cells that are participating in inflammatory reactions.

Prostaglandins are named based on common structural features coded by a letter (PGD, PGE, PGF, PGG, and PGH)

Table 3.6 Principal Actions of Arachidonic Acid Metabolites in Inflammation

Action	Eicosanoid
Vasodilation	Prostaglandins PGI_2 (prostacyclin), PGE_1, PGE_2, PGD_2
Vasoconstriction	Thromboxane A_2, leukotrienes C_4, D_4, E_4
Increased vascular permeability	Leukotrienes C_4, D_4, E_4
Chemotaxis, leukocyte adhesion	Leukotrienes B_4, HETE

HETE, Hydroxyeicosatetraenoic acid.

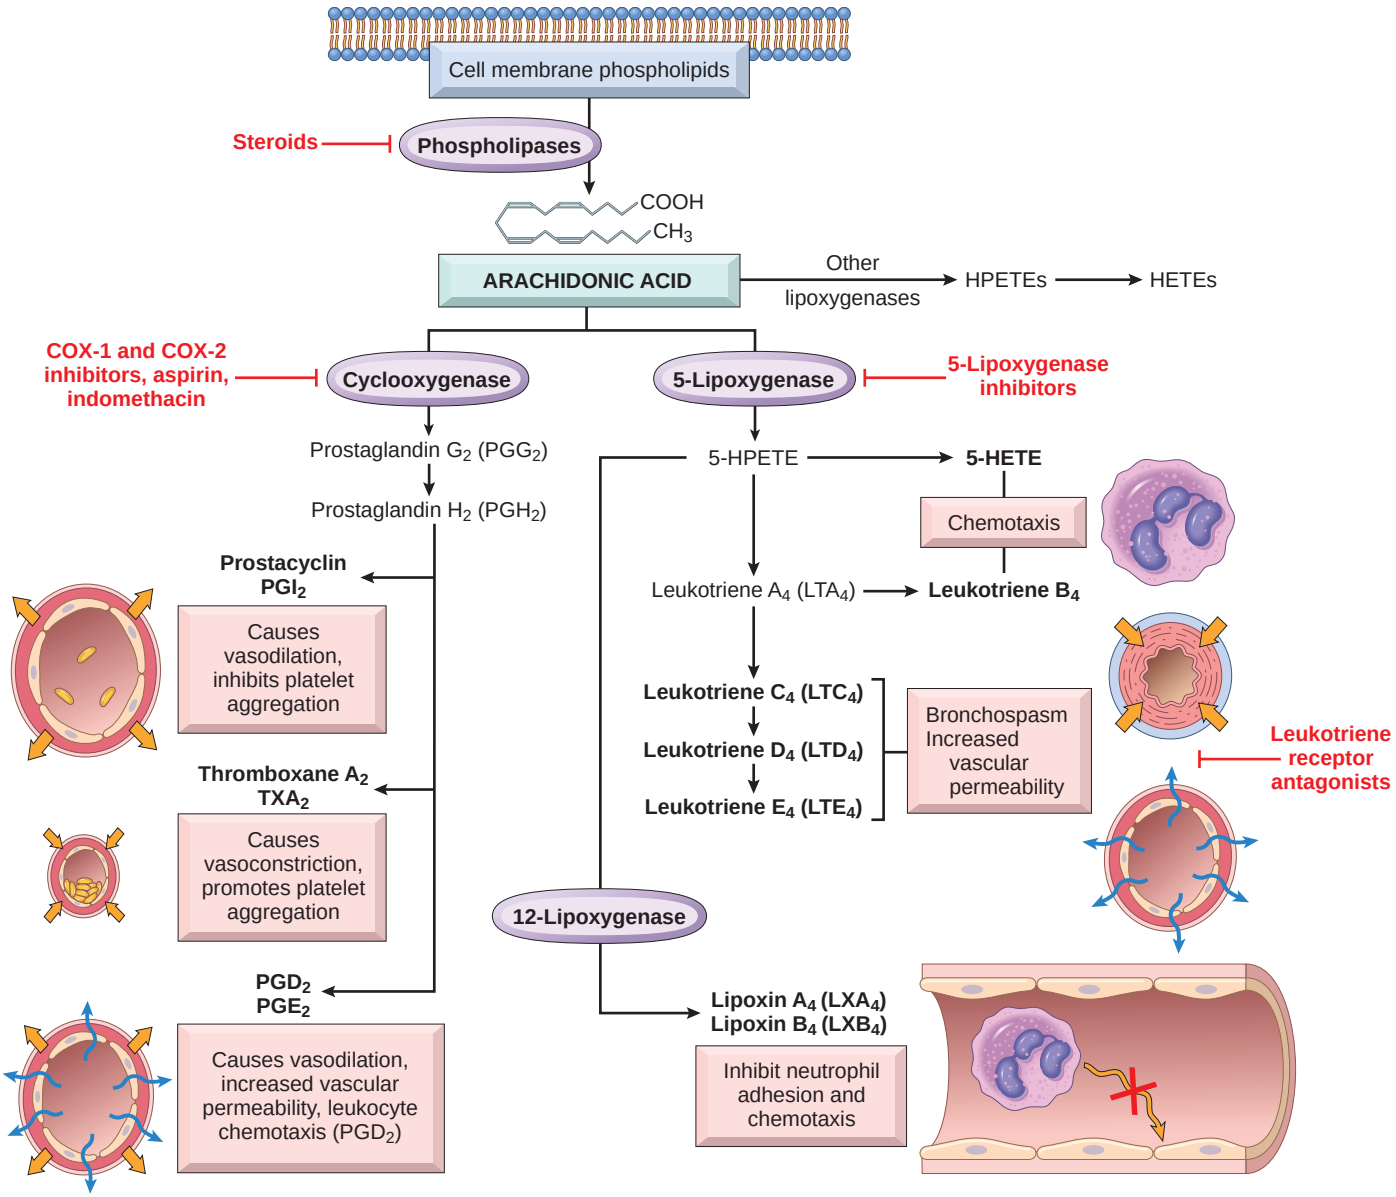

Figure 3.10 Production of arachidonic acid metabolites and their roles in inflammation. Note the enzymatic activities whose inhibition through pharmacologic intervention blocks major pathways (denoted with a red *X*). *COX-1*, *COX-2*, Cyclooxygenase 1 and 2; *HETE*, hydroxyeicosatetraenoic acid; *HPETE*, hydroperoxyeicosatetraenoic acid.

and a subscript numeral (e.g., 1, 2) that indicates the number of double bonds in the compound. The most important ones in inflammation are PGE_2, PGD_2, PGF_{2a}, PGI_2 (prostacyclin), and thromboxane A_2 (TxA_2), each of which is synthesized by a specific enzyme acting on an intermediate in the pathway. Some of these enzymes have restricted tissue distributions. For example, platelets contain the enzyme thromboxane synthase, and hence TxA_2 is the major product in these cells. TxA_2, a potent platelet-aggregating agent and vasoconstrictor, is itself unstable and rapidly converted to its inactive form. Vascular endothelium lacks thromboxane synthase but contains prostacyclin synthase, which is responsible for the formation of prostacyclin (PGI_2) and its stable end product PGF_{1a}. Prostacyclin is a vasodilator and a potent inhibitor of platelet aggregation, and also markedly potentiates the permeability-increasing and chemotactic effects of other mediators. A thromboxane-prostacyclin imbalance has been implicated as an early event in thrombus formation in coronary and cerebral blood vessels. PGD_2 is the major prostaglandin made by mast cells; along with PGE_2 (which is more widely distributed), it causes vasodilation and increases the permeability of postcapillary venules, thus potentiating edema formation. PGD_2 also is a chemoattractant for neutrophils.

In addition to their local effects, prostaglandins are involved in the pathogenesis of pain and fever in inflammation. PGE_2 is hyperalgesic, making the skin hypersensitive to painful stimuli such as intradermal injection of suboptimal concentrations of histamine and bradykinin. It is involved in cytokine-induced fever during infections (described later).

Leukotrienes

Leukotrienes are produced in leukocytes and mast cells by the action of lipoxygenase and are involved in vascular and smooth muscle reactions and leukocyte recruitment. There are three different lipoxygenases, 5-lipoxygenase being the predominant one in neutrophils. This enzyme converts AA to 5-hydroxyeicosatetraenoic acid, which is chemotactic for neutrophils and is the precursor of the leukotrienes. LTB_4 is a potent chemotactic agent and activator of neutrophils, causing aggregation and adhesion of the cells to venular endothelium, generation of ROS, and release of lysosomal enzymes. The cysteinyl-containing leukotrienes LTC_4, LTD_4, and LTE_4 cause intense vasoconstriction, bronchospasm (important in asthma), and increased permeability of venules. Leukotrienes are more potent than histamine in increasing vascular permeability and causing bronchospasm.

Lipoxins

Lipoxins are also generated from AA by the lipoxygenase pathway, but unlike prostaglandins and leukotrienes, the lipoxins suppress inflammation by inhibiting neutrophil chemotaxis and adhesion to endothelium. They are also unusual in that two cell populations are required for the transcellular biosynthesis of these mediators. Neutrophils synthesize precursors of active lipoxins and pass these to platelets, where they are converted to mature lipoxins.

Pharmacologic Inhibitors of Prostaglandins and Leukotrienes

The importance of eicosanoids in inflammation has driven attempts to develop drugs that inhibit their production or actions and thus suppress inflammation. These antiinflammatory drugs include the following.

- *Cyclooxygenase inhibitors* include aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen. They inactivate both COX-1 and COX-2 and thus inhibit prostaglandin synthesis (hence their efficacy in treating pain and fever); aspirin does this by irreversibly acetylating and inactivating cyclooxygenases. Selective COX-2 inhibitors are 200- to 300-fold more potent in blocking COX-2 than COX-1. There has been great interest in COX-2 as a therapeutic target because of the possibility that COX-1 is responsible for the production of prostaglandins that are involved in both inflammation and physiologic protective functions, whereas COX-2 generates prostaglandins that are involved only in inflammatory reactions. If this idea is correct, selective COX-2 inhibitors should be antiinflammatory without having the toxicities of the nonselective inhibitors, such as gastric ulceration. However, these distinctions are not absolute, as COX-2 also seems to play a role in normal homeostasis. Furthermore, selective COX-2 inhibitors may increase the risk of cardiovascular and cerebrovascular events, possibly because they impair endothelial cell production of PGI_2 (prostacyclin), a vasodilator and inhibitor of platelet aggregation, but leave intact the COX-1–mediated production by platelets of TxA_2, an important mediator of platelet aggregation and vasoconstriction. Thus, selective COX-2 inhibition may tilt the balance toward thromboxane and promote vascular thrombosis, especially in individuals with other factors that increase the risk of thrombosis. Nevertheless, these drugs are still used in individuals who do not have risk factors for cardiovascular disease when their benefits outweigh their risks.
- *Lipoxygenase inhibitors.* 5-Lipoxygenase is not affected by NSAIDs, and many new inhibitors of this enzyme pathway have been developed. Pharmacologic agents that inhibit leukotriene production are useful in the treatment of asthma.
- *Corticosteroids* are broad-spectrum antiinflammatory agents that reduce the transcription of genes encoding many proteins involved in inflammation, including COX-2, phospholipase A_2, proinflammatory cytokines (e.g., IL-1 and TNF), and iNOS.
- *Leukotriene receptor antagonists* block leukotriene receptors and prevent the actions of the leukotrienes. These drugs are useful in the treatment of asthma.
- Another approach to manipulating inflammatory responses has been to modify the intake and content of dietary lipids by increasing the consumption of fish oil. The proposed explanation for the effectiveness of this approach is that the polyunsaturated fatty acids in fish oil are poor substrates for conversion to active metabolites by the cyclooxygenase and lipoxygenase pathways but are better substrates for the production of antiinflammatory lipid products, including lipids called resolvins.

Cytokines and Chemokines

Cytokines are proteins produced by many cell types (principally activated lymphocytes, macrophages, and dendritic cells, but also endothelial, epithelial, and connective tissue cells) that mediate and regulate immune and inflammatory reactions. By convention, growth factors that act on epithelial and mesenchymal cells are not grouped under cytokines. The general properties and functions of cytokines are discussed in Chapter 6. The cytokines involved in acute inflammation are reviewed here (Table 3.7).

Tumor Necrosis Factor and Interleukin-1

TNF and IL-1 serve critical roles in leukocyte recruitment by promoting adhesion of leukocytes to endothelium and their migration through blood vessels. These cytokines are produced mainly by activated macrophages and dendritic cells; TNF is also produced by T lymphocytes and mast cells, and IL-1 is produced by some epithelial cells as well. The secretion of TNF and IL-1 can be stimulated by microbial products, dead cells, immune complexes, foreign bodies, physical injury, and a variety of other inflammatory stimuli. The production of TNF is induced by signals through TLRs and other microbial sensors. The synthesis of IL-1 is stimulated by the same signals, but the generation of the biologically active form of this cytokine is dependent on the inflammasome (described earlier).

The actions of TNF and IL-1 contribute to the local and systemic reactions of inflammation (Fig. 3.11). The most important roles of these cytokines in inflammation are the following.

- *Endothelial activation.* Both TNF and IL-1 act on endothelium to induce a spectrum of changes referred to as endothelial activation. These changes include increased expression of endothelial adhesion molecules, mostly

Table 3.7 Cytokines in Inflammation

Cytokine	Principal Sources	Principal Actions in Inflammation
In Acute Inflammation		
TNF	Macrophages, mast cells, T lymphocytes	Stimulates expression of endothelial adhesion molecules and secretion of other cytokines; systemic effects
IL-1	Macrophages, endothelial cells, some epithelial cells	Similar to TNF; greater role in fever
IL-6	Macrophages, other cells	Systemic effects (acute phase response)
Chemokines	Macrophages, endothelial cells, T lymphocytes, mast cells, other cell types	Recruitment of leukocytes to sites of inflammation; migration of cells in normal tissues
IL-17	T lymphocytes	Recruitment of neutrophils and monocytes
In Chronic Inflammation		
IL-12	Dendritic cells, macrophages	Increased production of IFN-γ
IFN-γ	T lymphocytes, NK cells	Activation of macrophages (increased ability to kill microbes and tumor cells)
IL-17	T lymphocytes	Recruitment of neutrophils and monocytes

IFN-γ, Interferon-γ; *IL,* interleukin; *NK,* natural killer; *TNF,* tumor necrosis factor.

The most important cytokines involved in inflammatory reactions are listed. Many other cytokines may play lesser roles in inflammation. There is also considerable overlap between the cytokines involved in acute and chronic inflammation. Specifically, all the cytokines listed under acute inflammation may also contribute to chronic inflammatory reactions.

E-selectin and P-selectin and ligands for leukocyte integrins; increased production of various mediators, including other cytokines and chemokines, growth factors, and eicosanoids; and increased procoagulant activity of the endothelium.

- *Activation of leukocytes and other cells.* TNF augments responses of neutrophils to other stimuli such as bacterial endotoxin and stimulates the microbicidal activity of macrophages, in part by inducing production of NO. IL-1 activates fibroblasts to synthesize collagen and stimulates proliferation of synovial and other mesenchymal cells. IL-1 also stimulates Th17 responses, which in turn induce acute inflammation.
- *Systemic acute-phase response.* IL-1 and TNF (as well as IL-6) induce the systemic acute-phase responses associated with infection or injury, discussed later. TNF regulates energy balance by promoting lipid and protein mobilization and by suppressing appetite. Therefore,

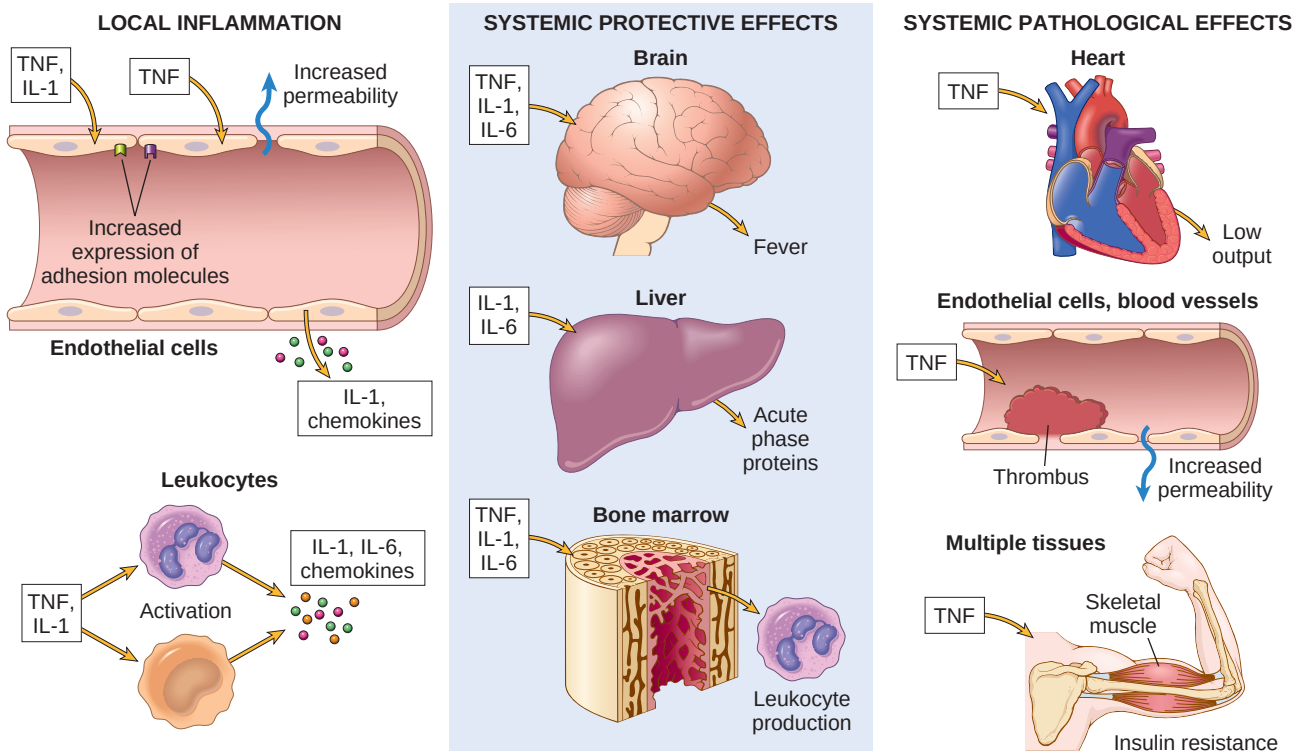

Figure 3.11 Major roles of cytokines in acute inflammation. *IL,* Interleukin; *TNF,* tumor necrosis factor.

sustained production of TNF contributes to cachexia, a pathologic state characterized by weight loss and anorexia that is seen in some chronic infections and neoplastic diseases.

TNF antagonists have been remarkably effective in the treatment of chronic inflammatory diseases, particularly rheumatoid arthritis, psoriasis, and some types of inflammatory bowel disease. One of the complications of this therapy is that patients become susceptible to mycobacterial infection, reflecting the reduced ability of macrophages to kill intracellular microbes. Although many of the actions of TNF and IL-1 seem overlapping, IL-1 antagonists are not as effective for reasons that remain unclear. Also, blocking either cytokine has no effect on the outcome of sepsis, perhaps because other cytokines contribute to this systemic inflammatory reaction.

Chemokines

Chemokines are a family of small (8 to 10 kDa) proteins that act primarily as chemoattractants for specific types of leukocytes. About 40 different chemokines and 20 different receptors for chemokines have been identified. They are classified into four major groups, according to the arrangement of cysteine (C) residues in the proteins.

- *C-X-C chemokines* have one amino acid residue separating the first two of the four conserved cysteine residues. A subset of these chemokines acts primarily on neutrophils. IL-8 (now called CXCL8) is typical of this group. It is secreted by activated macrophages, endothelial cells, and other cell types and causes activation and chemotaxis of neutrophils, with limited activity on monocytes and eosinophils. Its most important inducers are microbial products and other cytokines, mainly IL-1 and TNF.
- *C-C chemokines* have the first two conserved cysteine residues adjacent. The C-C chemokines, which include monocyte chemoattractant protein (MCP-1, CCL2), eotaxin (CCL11), macrophage inflammatory protein-1α (MIP-1α, CCL3), and others, generally attract monocytes, eosinophils, basophils, and lymphocytes, but are less potent chemoattractants for neutrophils. Although most of the chemokines in this class have overlapping actions, eotaxin selectively recruits eosinophils.
- *C chemokines* lack the first and third of the four conserved cysteines. The C chemokines (e.g., lymphotactin, XCL1) are relatively specific for lymphocytes.
- *CX_3C chemokines* contain three amino acids between the two cysteines. The only known member of this class is called fractalkine (CX3CL1). This chemokine exists in two forms: a cell surface–bound protein induced on endothelial cells by inflammatory cytokines that promotes strong adhesion of monocytes and T cells, and a soluble form derived by proteolysis of the membrane-bound protein that has potent chemoattractant activity for the same cells.

Chemokines mediate their activities by binding to seven-transmembrane G protein–coupled receptors. These receptors usually exhibit overlapping ligand specificities, and leukocytes generally express more than one receptor type. As discussed in Chapter 6, certain chemokine receptors (CXCR4, CCR5) act as coreceptors for a viral envelope glycoprotein of human immunodeficiency virus (HIV), the cause of AIDS, and are thus involved in binding and entry of the virus into cells.

Chemokines may be displayed at high concentrations attached to proteoglycans on the surface of endothelial cells and in the extracellular matrix (ECM). They have two main functions.

- *In acute inflammation.* Inflammatory chemokines are the ones whose production is induced by microbes and other stimuli. These chemokines stimulate leukocyte attachment to endothelium by acting on leukocytes to increase the affinity of integrins, and they stimulate migration (chemotaxis) of leukocytes in tissues to the site of infection or tissue damage.
- *Maintenance of tissue architecture.* Some chemokines are produced constitutively in tissues and are sometimes called homeostatic chemokines. These organize various cell types in different anatomic regions of the tissues, such as T and B lymphocytes in discrete areas of the spleen and lymph nodes (Chapter 6).

Although the role of chemokines in inflammation is well established, it has proved difficult to develop antagonists that are effective therapeutic agents.

Other Cytokines in Acute Inflammation

The list of cytokines implicated in inflammation is huge and constantly growing. In addition to the ones described earlier, two that have received considerable recent interest are IL-6, made by macrophages and other cells, which is involved in local and systemic reactions, and IL-17, produced mainly by T lymphocytes, which promotes neutrophil recruitment. Antagonists against both are effective for the treatment of inflammatory diseases, such as juvenile arthritis (anti-IL-6 receptor) and psoriasis (anti-IL-17). Cytokines also play key roles in chronic inflammation; these are described later.

Complement System

The complement system is a collection of plasma proteins that function mainly in host defense against microbes and in pathologic inflammatory reactions. The system consists of more than 20 proteins, some of which are numbered C1 through C9. The complement proteins function in both innate and adaptive immunity for defense against microbial pathogens. In the process of complement activation, several cleavage products of complement proteins are elaborated that cause increased vascular permeability, chemotaxis, and opsonization. The activation and functions of complement are outlined in Fig. 3.12.

Complement proteins are present in inactive forms in the plasma, and many of them are activated to become proteolytic enzymes that degrade other complement proteins, thus forming an enzymatic cascade capable of tremendous amplification. The critical step in complement activation is the proteolysis of the third (and most abundant) component, C3. **Cleavage of C3 can occur by one of three pathways:**

- The *classical pathway,* which is triggered by binding of C1 to antibody (IgM or IgG) that has combined with antigen.

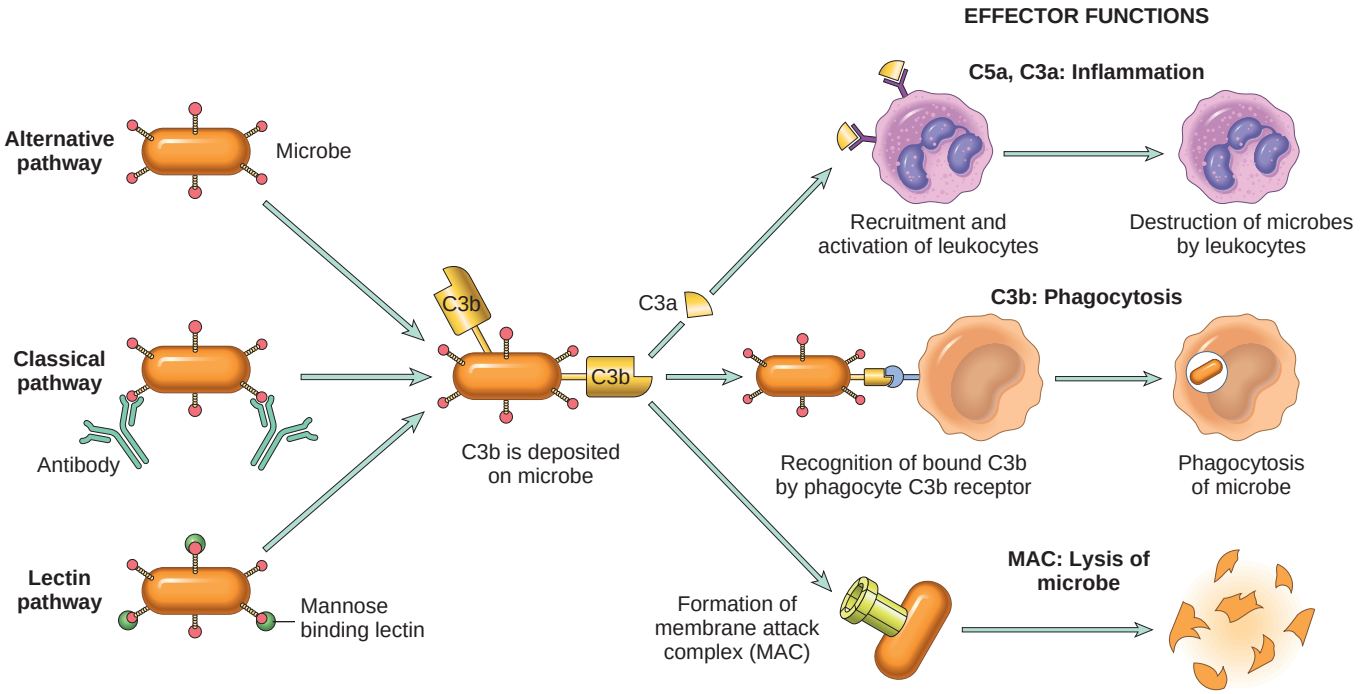

Figure 3.12 Activation and functions of the complement system. Activation of complement by different pathways leads to cleavage of C3. The functions of the complement system are mediated by breakdown products of C3 and other complement proteins and by the membrane attack complex *(MAC)*.

- The *alternative pathway,* which can be triggered by microbial surface molecules (e.g., endotoxin, or lipopolysaccharide [LPS]), complex polysaccharides, cobra venom, and other substances, in the absence of antibody.
- The *lectin pathway,* in which plasma mannose-binding lectin binds to carbohydrates on microbes and directly activates C1.

All three pathways of complement activation lead to the formation of an active enzyme called *C3 convertase,* which splits C3 into two functionally distinct fragments, C3a and C3b. C3a is released, and C3b becomes covalently attached to the cell or molecule where complement is being activated. More C3b then binds to the previously generated fragments to form C5 convertase, which cleaves C5 to release C5a and leave C5b attached to the cell surface. C5b binds the late components (C6–C9), culminating in the formation of the membrane attack complex (composed of multiple C9 molecules).

The complement system has three main functions (see Fig. 3.12).

- *Inflammation.* C5a, C3a, and, to a lesser extent, C4a are cleavage products of the corresponding complement components that stimulate histamine release from mast cells and thereby increase vascular permeability and cause vasodilation. They are called anaphylatoxins because they have effects similar to those of mast cell mediators that are involved in the reaction called anaphylaxis (Chapter 6). C5a is also a chemotactic agent for neutrophils, monocytes, eosinophils, and basophils. In addition, C5a activates the lipoxygenase pathway of AA metabolism in neutrophils and monocytes, causing further release of inflammatory mediators.
- *Opsonization and phagocytosis. C3b* and its cleavage product inactive C3b (iC3b), when fixed to a microbial cell wall, act as opsonins and promote phagocytosis by neutrophils and macrophages, which bear cell surface receptors for the complement fragments.
- *Cell lysis.* The deposition of the membrane attack complex on cells makes these cells permeable to water and ions and results in osmotic lysis of the cells. This role of complement is particularly important for killing microbes with thin cell walls, such as *Neisseria* bacteria, and deficiency of the terminal components of complement predisposes to *Neisseria* infections.

The activation of complement is tightly controlled by cell-associated and circulating regulatory proteins. Different regulatory proteins inhibit the production of active complement fragments or remove fragments that deposit on cells. These regulators are expressed on normal host cells and are thus designed to prevent healthy tissues from being injured at sites of complement activation. Regulatory proteins can be overwhelmed when large amounts of complement are deposited on host cells and in tissues, as happens in autoimmune diseases, in which individuals produce complement-fixing antibodies against their own cell and tissue antigens (Chapter 6). The most important of these regulatory proteins are the following:

- *C1 inhibitor (C1 INH)* blocks the activation of C1, the first protein of the classical complement pathway. Inherited deficiency of this inhibitor is the cause of hereditary angioedema.
- *Decay accelerating factor (DAF)* and *CD59* are two proteins that are linked to plasma membranes by a glycophosphatidylinositol (GPI) anchor. DAF prevents formation of C3 convertases, and CD59 inhibits formation of the

membrane attack complex. An acquired deficiency of the enzyme that creates GPI anchors leads to deficiency of these regulators and excessive complement activation and lysis of red cells (which are sensitive to complement-mediated cell lysis) in the disease called paroxysmal nocturnal hemoglobinuria (PNH) (Chapter 14).

- *Complement Factor H* is a circulating glycoprotein that inhibits the alternative pathway of complement activation by promoting the cleavage and destruction of C3b and the turnover of the C3 convertases. Inherited defects in Factor H and several other regulatory proteins that interact with Factor H cause an atypical form of hemolytic uremic syndrome (Chapter 20), in which complement deposits in glomerular vessels, leading to endothelial damage and formation of platelet-rich thrombi. Polymorphisms in the *Factor H* gene have also been linked to age-related macular degeneration (Chapter 29), an important cause of vision loss in older adults.

The complement system contributes to disease in several ways. The activation of complement by antibodies or antigen-antibody complexes deposited on host cells and tissues is an important mechanism of cell and tissue injury (Chapter 6). Inherited deficiencies of complement proteins cause increased susceptibility to infections (Chapter 6), and, as mentioned earlier, deficiencies of regulatory proteins cause a variety of disorders resulting from excessive complement activation.

Other Mediators of Inflammation

Platelet-Activating Factor

Platelet-activating factor (PAF) is a phospholipid-derived mediator that was discovered as a factor that caused platelet aggregation, but it is now known to have multiple inflammatory effects. A variety of cell types, including platelets, basophils, mast cells, neutrophils, macrophages, and endothelial cells, can elaborate PAF in both secreted and cell-bound forms. In addition to platelet aggregation, PAF causes vasoconstriction and bronchoconstriction, and at low concentrations it induces vasodilation and increased venular permeability. Despite these actions, the use of PAF antagonists in various inflammatory diseases has not been found to be useful.

Products of Coagulation

A link between the coagulation pathway and inflammation is supported by the presence of protease-activated receptors (PARs) on leukocytes that are activated by thrombin (the protease that cleaves fibrinogen to produce fibrin, which forms the clot). It is, however, likely that the major role of the PARs is in platelet activation during clotting (Chapter 4). There is also some evidence that cleavage products of fibrin (fibrinopeptides) can stimulate inflammation. However, many forms of tissue injury are associated with both clotting and inflammation, and it is difficult to establish a cause-and-effect relationship.

Kinins

Kinins are vasoactive peptides derived from plasma proteins, called kininogens, by the action of specific proteases called kallikreins. The enzyme kallikrein cleaves a plasma glycoprotein precursor, high-molecular-weight kininogen, to produce bradykinin. **Bradykinin increases vascular permeability and causes contraction of smooth muscle, dilation of blood vessels, and pain when injected into the skin.** These effects are similar to those of histamine. The action of bradykinin is short-lived because it is quickly inactivated by an enzyme called kininase. Bradykinin has been implicated as a mediator in some forms of allergic reaction, such as anaphylaxis (Chapter 6).

Neuropeptides

Neuropeptides are secreted by sensory nerves and various leukocytes and may play a role in the initiation and regulation of inflammatory responses. These small peptides, such as substance P and neurokinin A, are produced in the central and peripheral nervous systems. Nerve fibers containing substance P are prominent in the lung and gastrointestinal tract. Substance P has many activities that may be important in inflammation, including the transmission of pain signals and increasing vascular permeability. Leukocytes express receptors for many neuropeptides, so these neural products could provide a mechanism for "cross-talk" between the nervous system and immune and inflammatory reactions. For instance, activation of the efferent vagus nerve inhibits the production of proinflammatory cytokines such as TNF, providing a mechanism for suppressing inflammation. This observation has led to clinical trials of vagus nerve stimulation in patients with rheumatoid arthritis.

When Lewis discovered the role of histamine in inflammation, one mediator was thought to be enough. Now, we are wallowing in them! Yet, from this large compendium, it is likely that a few mediators are most important for the reactions of acute inflammation in vivo, and these are summarized in Table 3.8. The redundancy of the mediators and their actions ensures that this protective response is robust and not readily subverted.

Table 3.8 Role of Mediators in Different Reactions of Inflammation

Reaction of Inflammation	Principal Mediators
Vasodilation	Histamine Prostaglandins
Increased vascular permeability	Histamine and serotonin C3a and C5a (by liberating vasoactive amines from mast cells, other cells) Leukotrienes C_4, D_4, E_4
Chemotaxis, leukocyte recruitment and activation	TNF, IL-1 Chemokines C3a, C5a Leukotriene B_4
Fever	IL-1, TNF Prostaglandins
Pain	Prostaglandins Bradykinin Substance P
Tissue damage	Lysosomal enzymes of leukocytes Reactive oxygen species

IL-1, Interleukin-1; *TNF*, tumor necrosis factor.

KEY CONCEPTS

ACTIONS OF THE PRINCIPAL MEDIATORS OF INFLAMMATION

- Vasoactive amines, mainly histamine: Vasodilation and increased vascular permeability.
- Arachidonic acid metabolites (prostaglandins and leukotrienes): Several forms exist and are involved in vascular reactions, leukocyte chemotaxis, and other reactions of inflammation; antagonized by lipoxins.
- Cytokines: Proteins produced by many cell types; usually act at short range; mediate multiple effects, mainly leukocyte recruitment and migration; principal ones in acute inflammation are TNF, IL-1, and chemokines.
- Complement proteins: Activation of the complement system by microbes or antibodies leads to the generation of multiple breakdown products, which are responsible for leukocyte chemotaxis, opsonization, phagocytosis of microbes and other particles, and cell killing.
- Kinins: Produced by proteolytic cleavage of precursors; mediate vascular reaction, pain.

Morphologic Patterns of Acute Inflammation

The morphologic hallmarks of acute inflammatory reactions are dilation of small blood vessels and accumulation of leukocytes and fluid in the extravascular tissue. However, special morphologic patterns are often superimposed on these general features, depending on the severity of the reaction, its specific cause, and the particular tissue and site involved. The importance of recognizing the gross and microscopic patterns is that they often provide valuable clues about the underlying cause.

Serous Inflammation

Serous inflammation is marked by the exudation of cell-poor fluid into spaces created by cell injury or into body cavities lined by the peritoneum, pleura, or pericardium. Typically, the fluid in serous inflammation does not contain microbes or large numbers of leukocytes (which tend to produce purulent inflammation, described later). In body cavities the fluid may be derived from the plasma (as a result of increased vascular permeability) or from the secretions of mesothelial cells (as a result of local irritation); accumulation of fluid in these cavities is called an effusion. (Effusions also occur in noninflammatory conditions, such as reduced blood outflow in heart failure or reduced plasma protein levels in some kidney and liver diseases.) The skin blister resulting from a burn or viral infection represents accumulation of serous fluid within or immediately beneath the damaged epidermis of the skin (Fig. 3.13).

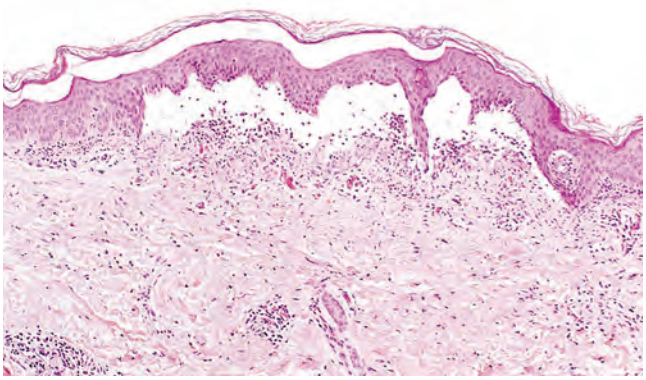

Figure 3.13 Serous inflammation. Low-power view of a cross section of a skin blister showing the epidermis separated from the dermis by a focal collection of serous effusion.

Fibrinous Inflammation

With greater increase in vascular permeability, large molecules such as fibrinogen pass out of the blood, and fibrin is formed and deposited in the extracellular space. **A fibrinous exudate develops when the vascular leaks are large or there is a local procoagulant stimulus** (e.g., caused by cancer cells). A fibrinous exudate is characteristic of inflammation in the lining of body cavities, such as the meninges, pericardium (Fig. 3.14A), and pleura. Histologically, fibrin appears as an eosinophilic meshwork of threads or sometimes as an amorphous coagulum (Fig. 3.14B). Fibrinous exudates may be dissolved by fibrinolysis and cleared by macrophages. If the fibrin is not removed, over time it may stimulate the ingrowth of fibroblasts and blood vessels and thus lead to

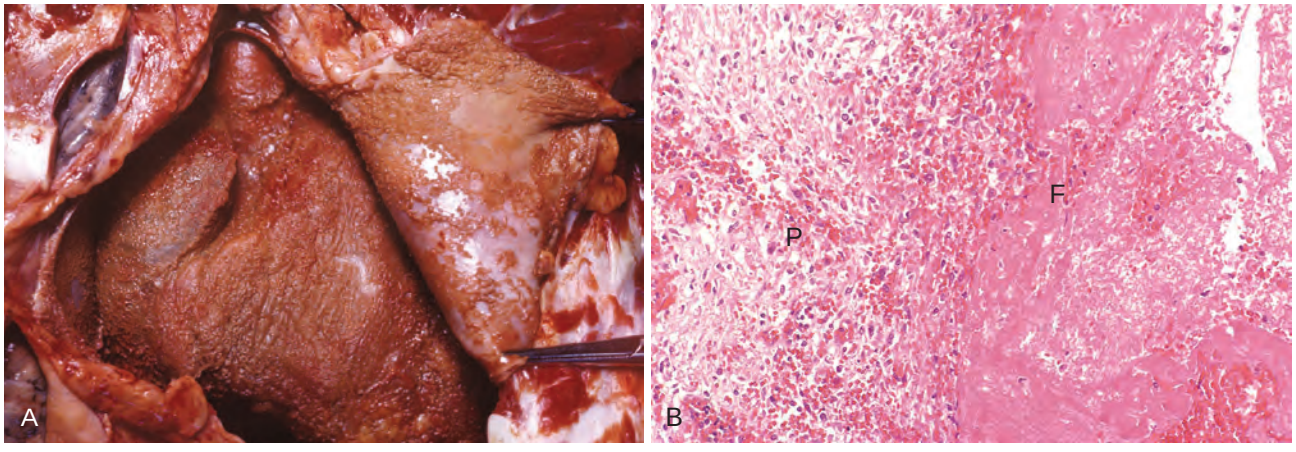

Figure 3.14 Fibrinous pericarditis. (A) Deposits of fibrin on the pericardium. (B) A pink meshwork of fibrin exudate *(F)* overlies the pericardial surface *(P)*.

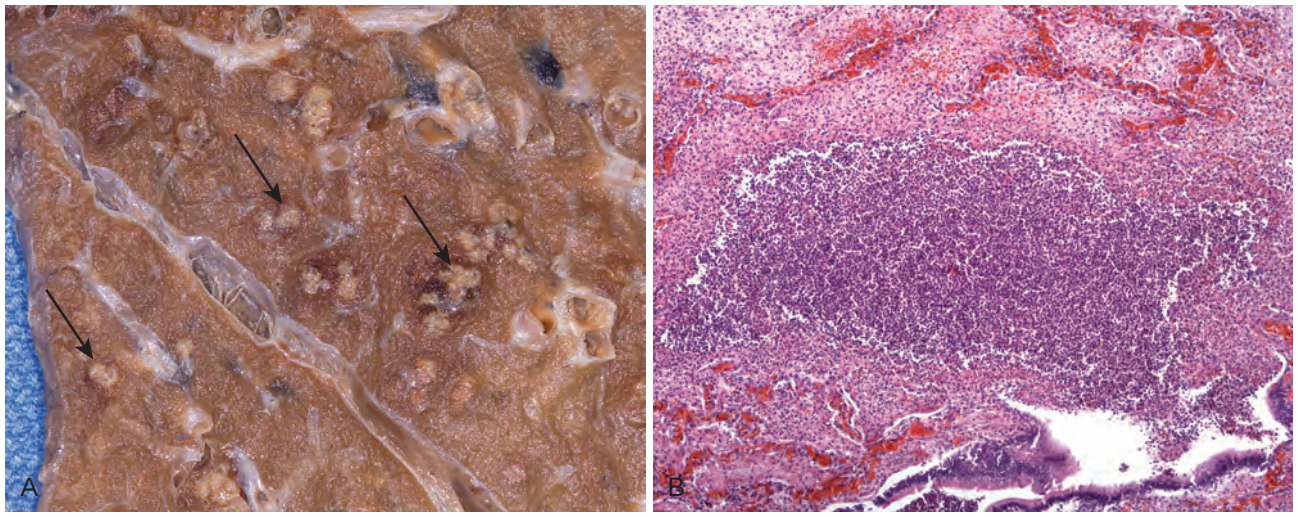

Figure 3.15 Purulent inflammation. (A) Multiple bacterial abscesses *(arrows)* in the lung in a case of bronchopneumonia. (B) The abscess contains neutrophils and cellular debris and is surrounded by congested blood vessels.

scarring. Conversion of the fibrinous exudate to scar tissue (organization) within the pericardial sac leads to opaque fibrous thickening of the pericardium and epicardium in the area of exudation and, if the fibrosis is extensive, obliteration of the pericardial space.

Purulent (Suppurative) Inflammation and Abscess

Purulent inflammation is characterized by the production of pus, an exudate consisting of neutrophils, the liquefied debris of necrotic cells, and edema fluid. The most frequent cause of purulent (also called suppurative) inflammation is infection with bacteria that cause liquefactive tissue necrosis, such as staphylococci; these pathogens are referred to as pyogenic (pus-producing) bacteria. A common example of an acute suppurative inflammation is acute appendicitis.

Abscesses **are localized collections of pus** caused by suppuration buried in a tissue, an organ, or a confined space. They are produced by seeding of pyogenic bacteria into a tissue (Fig. 3.15). Abscesses have a central liquefied region composed of necrotic leukocytes and tissue cells. There is usually a zone of preserved neutrophils around this necrotic focus, and outside this region there may be vascular dilation and parenchymal and fibroblastic proliferation, indicating chronic inflammation and repair. In time the abscess may become walled off and ultimately replaced by connective tissue.

Ulcers

An ulcer is a local defect, or excavation, of the surface of an organ or tissue that is produced by the sloughing (shedding) of inflamed necrotic tissue (Fig. 3.16). Ulceration can occur only when tissue necrosis and resultant inflammation exist on or near a surface. It is most common in (1) the mucosa of the mouth, stomach, intestines, or genitourinary tract, and (2) the skin and subcutaneous tissue of the lower extremities in individuals with disorders that predispose to vascular insufficiency, such as diabetes, sickle cell anemia, and peripheral vascular disease.

Ulcerations are best exemplified by peptic ulcer of the stomach or duodenum, in which acute and chronic inflammation coexist. During the acute stage there is intense polymorphonuclear infiltration and vascular dilation in the margins of the defect. With chronicity, the margins and base of the ulcer develop fibroblastic proliferation, scarring, as well as the accumulation of lymphocytes, macrophages, and plasma cells.

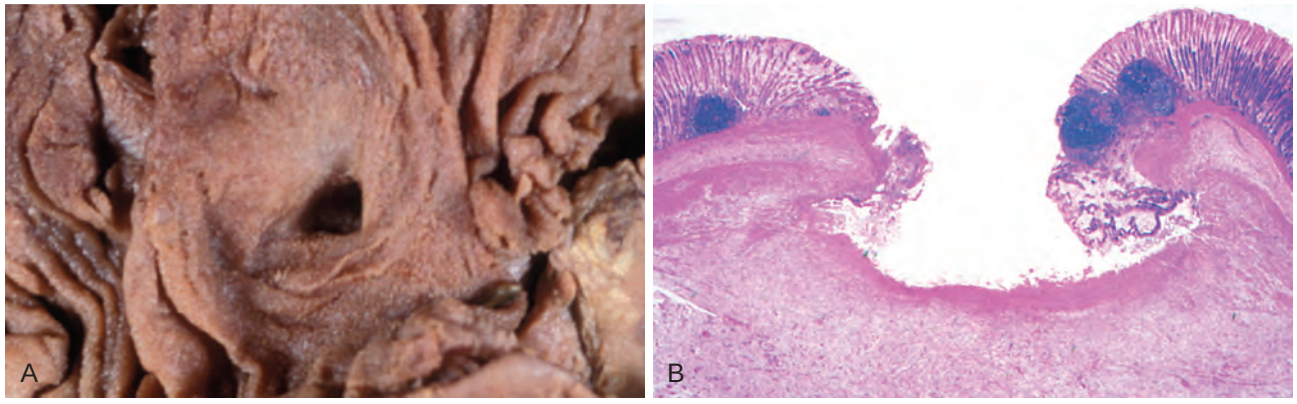

Figure 3.16 The morphology of an ulcer. (A) A chronic duodenal ulcer. (B) Low-power cross-section view of a duodenal ulcer crater with an acute inflammatory exudate in the base.

Outcomes of Acute Inflammation

Although, as might be expected, many variables may modify the basic process of inflammation, including the nature and intensity of the injury, the site and tissue affected, and the responsiveness of the host, **acute inflammatory reactions typically have one of three outcomes** (Fig. 3.17).

- *Complete resolution.* In a perfect world, all inflammatory reactions, once they have succeeded in eliminating the offending agent, would end with restoration of the site of acute inflammation to normal. This is called resolution and is the usual outcome when the injury is limited or short-lived or when there has been little tissue destruction and the damaged parenchymal cells can regenerate. Resolution involves removal of cellular debris and microbes by macrophages and resorption of edema fluid by lymphatics, followed by regeneration of the damaged tissue.
- *Healing by connective tissue replacement (scarring, or fibrosis).* This occurs after substantial tissue destruction, when the inflammatory injury involves tissues that are incapable of regeneration, or when there is abundant fibrin exudation in tissue or in serous cavities (pleura, peritoneum) that cannot be adequately cleared. In all these situations, connective tissue grows into the area of damage or exudate, converting it into a mass of fibrous tissue, a process also called organization.
- Progression of the response to *chronic inflammation* (discussed later). Acute to chronic transition occurs when the acute inflammatory response cannot be resolved, as a result of either the persistence of the injurious agent or some interference with the normal process of healing.

Summary of Acute Inflammation

Now that we have described the components, mediators, and pathologic manifestations of acute inflammatory responses, it is useful to summarize the main features of a typical response of this type. When a host encounters an injurious agent, such as a microbe or dead cells, resident phagocytes and phagocytes recruited from the blood try to eliminate these agents. At the same time, phagocytes and other host cells react to the presence of the foreign or abnormal substance by liberating cytokines, lipid messengers, and other mediators of inflammation. Some of these mediators act on small blood vessels in the vicinity and promote the efflux of plasma proteins and the recruitment of circulating leukocytes to the site where the offending agent is located. The recruited leukocytes are activated by molecules derived from microbes and injured cells and by locally produced mediators, and the activated leukocytes try to remove the offending agent by phagocytosis. As the injurious agent is eliminated and antiinflammatory mechanisms become active, the process subsides and the host returns to a normal state of health. If the injurious agent cannot be quickly eliminated, the result may be chronic inflammation.

The vascular and cellular reactions account for the cardinal signs of inflammation: rubor, calor, tumor, dolor, and functio laesa. The increased blood flow to the injured area and increased vascular permeability lead to the accumulation of extravascular fluid rich in plasma proteins, known as *edema*. The redness *(rubor),* warmth *(calor),* and swelling *(tumor)* are caused by the increased blood flow and edema. Circulating leukocytes, initially predominantly neutrophils, adhere to the endothelium via adhesion

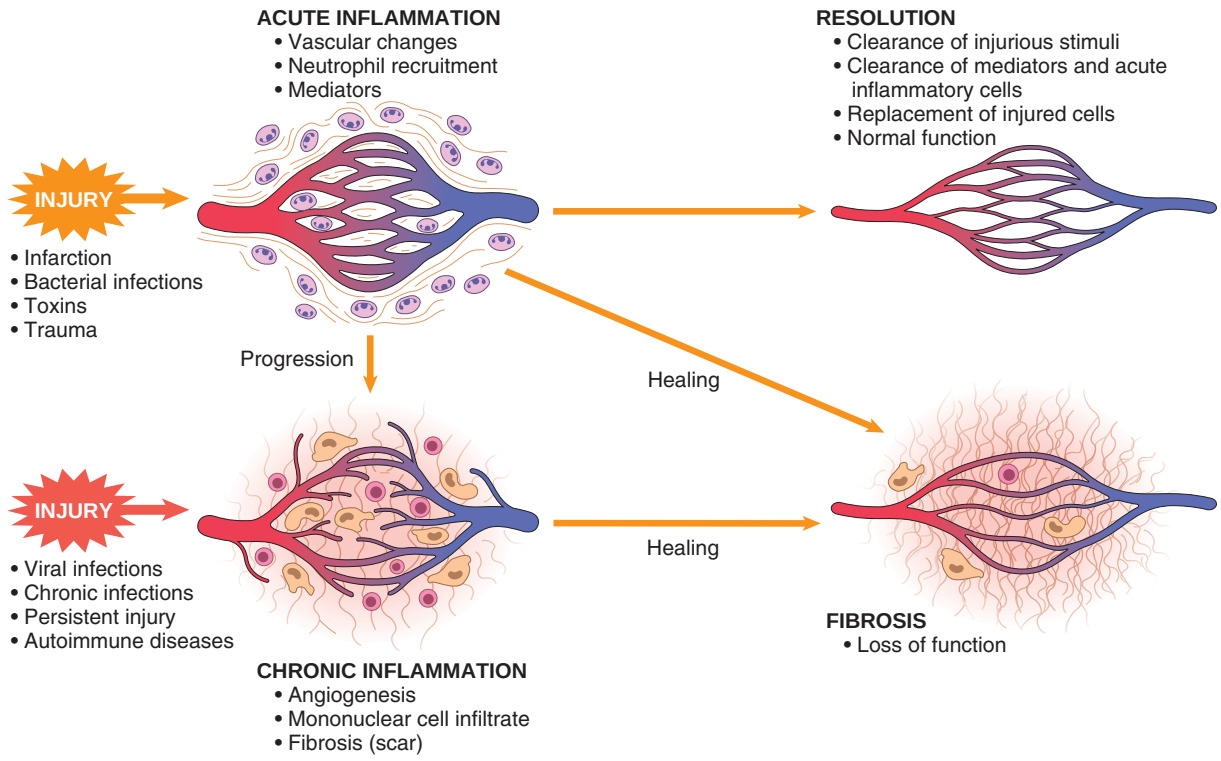

Figure 3.17 Outcomes of acute inflammation: resolution, healing by fibrosis, or chronic inflammation. The components of the various reactions and their functional outcomes are listed.

molecules, traverse the endothelium, and migrate to the site of injury under the influence of chemotactic agents. Leukocytes that are activated by the offending agent and by endogenous mediators may release toxic metabolites and proteases extracellularly, causing tissue damage. Due to the damage and the liberation of prostaglandins, neuropeptides, and cytokines, one of the local symptoms is pain *(dolor)*. Loss of function *(functio laesa)* results from pain and injury to the tissues.

CHRONIC INFLAMMATION

Chronic inflammation is a response of prolonged duration (weeks or months) in which inflammation, tissue injury, and attempts at repair coexist in varying combinations. It may follow acute inflammation, as described earlier, or chronic inflammation may begin insidiously, as a low-grade, smoldering response without any manifestations of a preceding acute reaction.

Causes of Chronic Inflammation

Chronic inflammation arises in the following settings.

- *Persistent infections* by microorganisms that are difficult to eradicate, such as mycobacteria and certain viruses, fungi, and parasites. These organisms often evoke an immune reaction called delayed-type hypersensitivity (Chapter 6). Chronic inflammatory responses sometimes develop a specific pattern called a granulomatous reaction (discussed later). In other cases an unresolved acute inflammation may evolve into chronic inflammation, as may occur in acute bacterial infection of the lung that progresses to a chronic lung abscess. Acute and chronic inflammation may coexist, as in a peptic ulcer.
- *Hypersensitivity diseases.* Chronic inflammation plays an important role in a group of diseases that are caused by excessive and inappropriate activation of the immune system. Under certain conditions, immune reactions develop against the individual's own tissues, leading to autoimmune diseases (Chapter 6). In these diseases, autoantigens evoke a self-perpetuating immune reaction that results in chronic tissue damage and inflammation; examples of such diseases include rheumatoid arthritis and multiple sclerosis. In other cases, chronic inflammation is the result of unregulated immune responses against microbes, as in inflammatory bowel disease. Immune responses against common environmental substances are the cause of allergic diseases, such as bronchial asthma (Chapter 6). Because these autoimmune and allergic reactions are triggered against antigens that are normally harmless, the reactions serve no useful purpose and only cause disease. Such diseases may show morphologic patterns of mixed acute and chronic inflammation because they are characterized by repeated bouts of inflammation. Fibrosis may dominate the late stages.
- Prolonged exposure to potentially *toxic agents*, either exogenous or endogenous. An example of an exogenous agent is particulate silica, a nondegradable inanimate material that, when inhaled for prolonged periods, results in an inflammatory lung disease called silicosis (Chapter 15). Atherosclerosis (Chapter 11) is a chronic inflammatory process of the arterial wall induced, at least in part, by excessive production and tissue deposition of endogenous cholesterol and other lipids.

Morphologic Features

In contrast to acute inflammation, which is manifested by vascular changes, edema, and predominantly neutrophilic infiltration, **chronic inflammation is characterized by** the following:

- *Infiltration with mononuclear cells,* which include macrophages, lymphocytes, and plasma cells (Fig. 3.18).
- *Tissue destruction,* induced by the persistent offending agent or by the inflammatory cells.
- *Attempts at healing* by connective tissue replacement of damaged tissue, accomplished by *angiogenesis* (proliferation of small blood vessels) and, in particular, *fibrosis.*

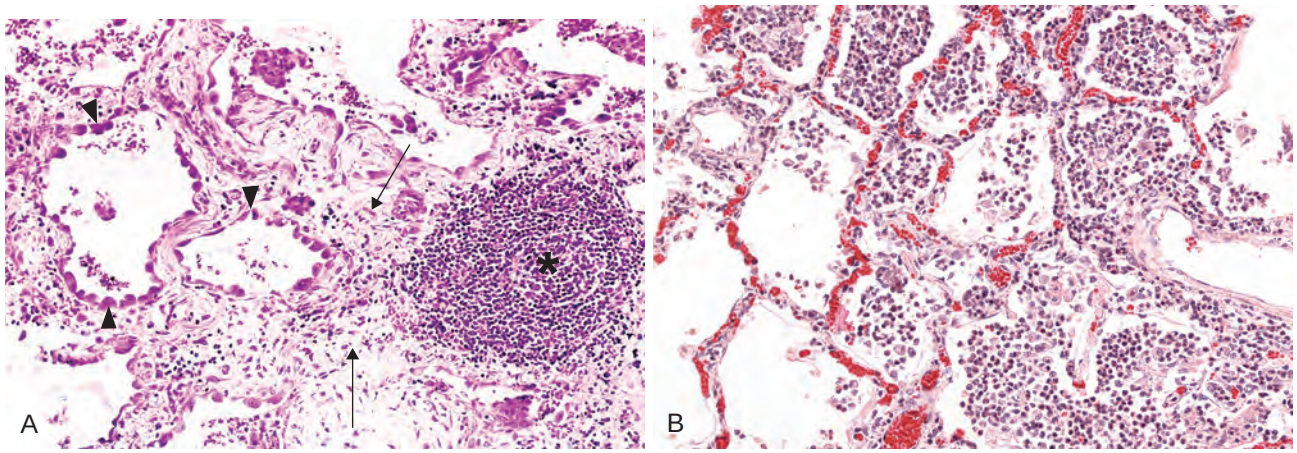

Figure 3.18 (A) Chronic inflammation in the lung, showing all three characteristic histologic features: (1) collection of chronic inflammatory cells *(asterisk)*, (2) destruction of parenchyma (normal alveoli are replaced by spaces lined by cuboidal epithelium) *(arrowheads)*, and (3) replacement by connective tissue (fibrosis) *(arrows)*. (B) In contrast, in acute inflammation of the lung (acute bronchopneumonia), neutrophils fill the alveolar spaces, and blood vessels are congested.

Because angiogenesis and fibrosis are components of wound healing and repair, they are discussed later, in the context of tissue repair.

Cells and Mediators of Chronic Inflammation

The combination of leukocyte infiltration, tissue damage, and fibrosis that characterize chronic inflammation is the result of the local activation of several cell types and the production of mediators.

Role of Macrophages

The dominant cells in most chronic inflammatory reactions are macrophages, which contribute to the reaction by secreting cytokines and growth factors that act on various cells, destroying foreign invaders and tissues, and activating other cells, notably T lymphocytes. Macrophages are professional phagocytes that eliminate microbes and damaged tissues. They also serve important roles in the repair of injured tissues. Here we review the development and functions of macrophages.

Macrophages are tissue cells derived from hematopoietic stem cells in the bone marrow in postnatal life and from progenitors in the embryonic yolk sac and fetal liver during early development (Fig. 3.19). Circulating cells of this lineage are known as monocytes. Macrophages are normally diffusely scattered in most connective tissues. In addition, they are present in specific locations in organs such as the liver (where they are called Kupffer cells), spleen and lymph nodes (called sinus histiocytes), central nervous system (microglial cells), and lungs (alveolar macrophages). Together, these cells comprise the mononuclear phagocyte system, also known by the older (and inaccurate) name reticuloendothelial system.

Committed progenitors in the bone marrow give rise to monocytes, which enter the blood, migrate into various tissues, and differentiate into macrophages. This is typical of macrophages at sites of inflammation and in some tissues such as the skin and intestinal tract. The half-life of blood monocytes is about 1 day, whereas the lifespan of tissue macrophages may be several months or years. Other specialized types of macrophages, such as microglia, Kupffer cells, and alveolar macrophages, arise from progenitors in the yolk sac or fetal liver very early in embryogenesis and migrate to the developing brain, liver, and lung, where they persist throughout life as a stable population of resident cells. As discussed earlier, in inflammatory reactions, monocytes begin to emigrate into extravascular tissues quite early, and within 48 hours they may constitute the predominant cell type. Extravasation of monocytes is governed by the same factors that are involved in neutrophil emigration, that is, adhesion molecules and chemotactic factors.

The products of activated macrophages eliminate injurious agents such as microbes and initiate the process of repair, but are also responsible for much of the tissue injury in chronic inflammation. Several functions of macrophages are central to the development and persistence of chronic inflammation and the accompanying tissue injury.

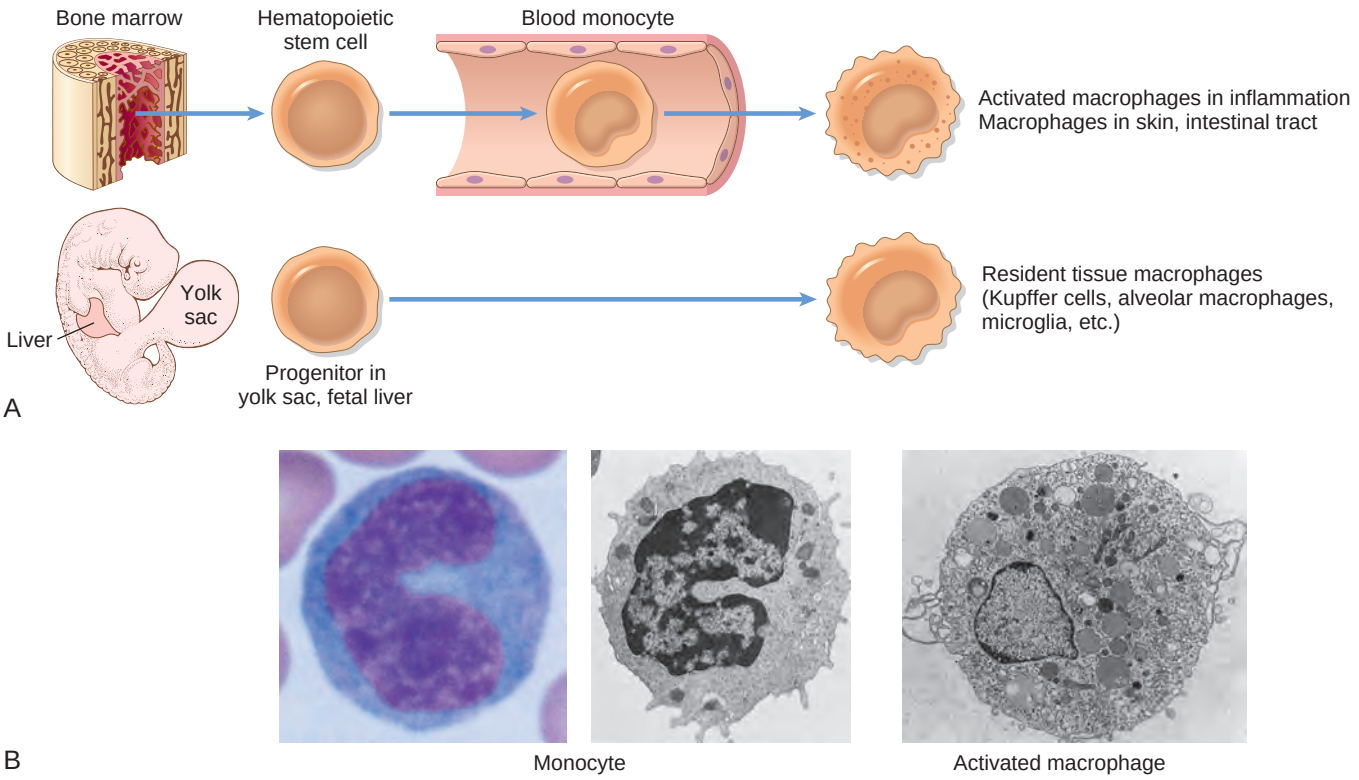

Figure 3.19 Maturation of mononuclear phagocytes. (A) In postnatal life, macrophages arise mainly from bone marrow progenitors and blood monocytes. These cells make up the majority of resident macrophages in some tissues and become more prominent after injury and during inflammation. Some tissue macrophages, including microglia and alveolar macrophages, arise from embryonic precursors and migrate into tissue, where they persist throughout life. (B) The morphology of a monocyte and activated macrophage.

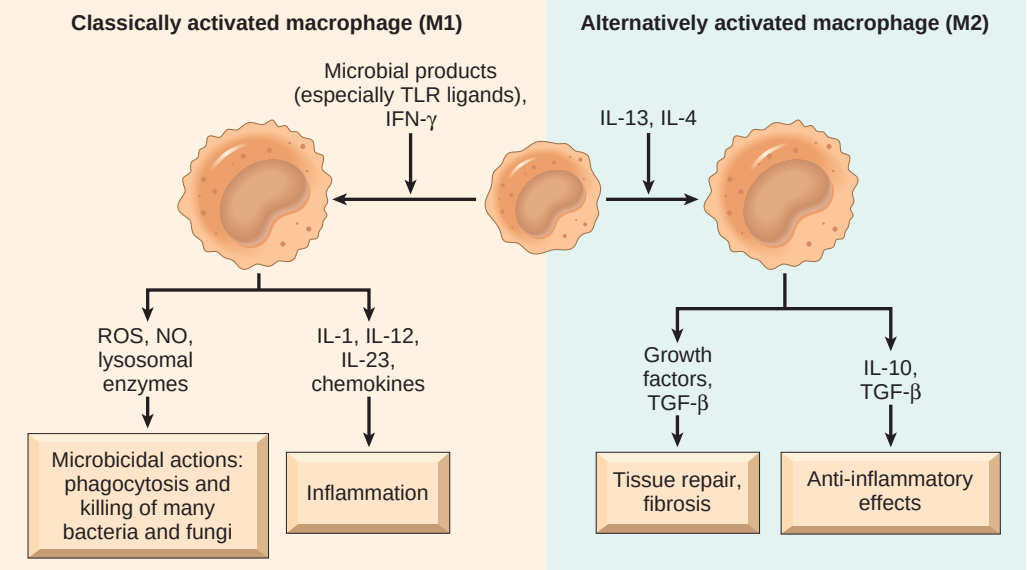

Figure 3.20 Classical and alternative macrophage activation. Different stimuli activate monocytes/macrophages to develop into functionally distinct populations. Classically activated macrophages are induced by microbial products and cytokines, particularly interferon-γ (IFN-γ). They phagocytose and destroy microbes and dead tissues and can potentiate inflammatory reactions. Alternatively activated macrophages are induced by other cytokines and are important in tissue repair and resolution of inflammation. *IL*, Interleukin; *NO*, nitric oxide; *ROS*, reactive oxygen species; *TGF-β*, transforming growth factor-β; *TLR*, Toll-like receptor.

- Macrophages, like the other type of phagocytes, the neutrophils, ingest and eliminate microbes and dead tissues.
- Macrophages initiate the process of tissue repair and are involved in scar formation and fibrosis. These processes are discussed later in the chapter.
- Macrophages secrete mediators of inflammation, such as cytokines (TNF, IL-1, chemokines, and others) and eicosanoids. Thus, macrophages contribute to the initiation and propagation of inflammatory reactions.
- Macrophages display antigens to T lymphocytes and respond to signals from T cells, thus setting up a feedback loop that is essential for defense against many microbes by cell-mediated immune responses. These interactions are described further in the subsequent discussion of the role of lymphocytes in chronic inflammation and in more detail in Chapter 6 where cell-mediated immunity is considered.

There are two major pathways of macrophage activation, called *classical* and *alternative*, that endow macrophages with different functional activities (Fig. 3.20).

- *Classical macrophage activation* may be induced by microbial products such as endotoxin, which engage TLRs and other sensors; by T cell–derived signals, importantly the cytokine IFN-γ, in immune responses; or by foreign substances, including crystals and particulate matter. Classically activated (also called M1) macrophages produce NO and lysosomal enzymes, which enhance their ability to kill ingested organisms, and secrete cytokines that stimulate inflammation. The main role of these macrophages in host defense is to destroy microbes and promote the inflammatory response.
- *Alternative macrophage activation* is induced by cytokines other than IFN-γ, such as IL-4 and IL-13, produced by T lymphocytes and other cells. These macrophages are not actively microbicidal; instead, their principal functions are to terminate inflammation and promote tissue repair.

It seems plausible that in response to most injurious stimuli the first activation pathway is the classical one, designed to destroy the offending agents, and this is followed by alternative activation, which initiates tissue repair. However, such a precise sequence is not documented in most inflammatory reactions, and most reactions contain varying numbers of both types. Also, the M1 and M2 phenotypes are the extreme forms, and there may be many intermediate types that are difficult to characterize as typical M1 or M2.

Their impressive arsenal of mediators makes macrophages powerful allies in the body's defense against unwanted invaders, but the same weaponry can also induce considerable tissue destruction when macrophages are inappropriately or excessively activated. It is largely because of these activities of macrophages that tissue destruction is one of the hallmarks of chronic inflammation.

In some instances, if the irritant is eliminated, macrophages eventually disappear (either dying off or making their way into the lymphatics and lymph nodes). In others, macrophage accumulation persists, as a result of continuous recruitment from the circulation and local proliferation at the site of inflammation.

Role of Lymphocytes

Microbes and other environmental antigens activate T and B lymphocytes, which amplify and propagate chronic inflammation. Activation of these cells is often prominent in chronic inflammatory reactions, and when they are involved, the inflammation tends to be persistent and severe, in part because lymphocyte activation leads to the generation

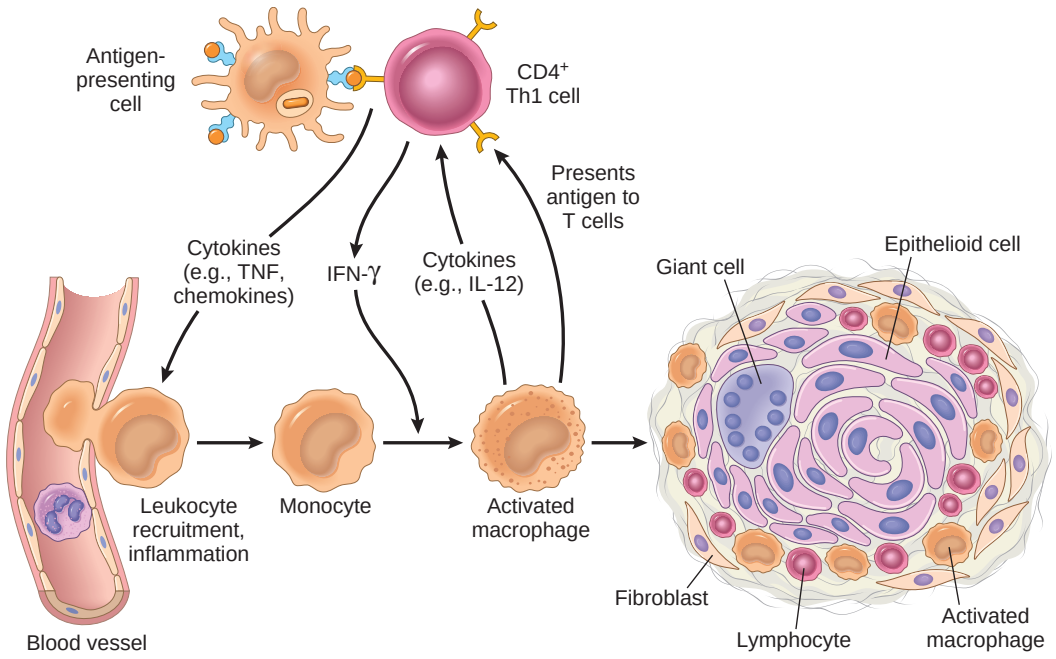

Figure 3.21 Macrophage–lymphocyte interactions in chronic inflammation. Activated T cells produce cytokines that recruit macrophages (tumor necrosis factor *[TNF]*, interleukin-17 *[IL-17]*, chemokines) and others that activate macrophages (interferon-γ *[IFN-γ]*). Activated macrophages in turn stimulate T cells by presenting antigens and via cytokines such as IL-12. Prolonged reactions involving T cells and macrophages may result in granuloma formation.

of long-lived memory cells. Some of the persistent chronic inflammatory reactions, such as granulomatous inflammation, described later, are dependent on generation of memory lymphocyte responses. Lymphocytes may be the dominant population in the chronic inflammation seen in various autoimmune diseases.

By virtue of their ability to secrete cytokines, CD4+ T lymphocytes promote inflammation and influence the nature of the inflammatory reaction. There are three subsets of CD4+ T cells that secrete different types of cytokines and elicit different types of inflammation.

- Th1 cells produce the cytokine IFN-γ, which activates macrophages by the classical pathway.
- Th2 cells secrete IL-4, IL-5, and IL-13, which recruit and activate eosinophils and are responsible for the alternative pathway of macrophage activation.
- Th17 cells secrete IL-17 and other cytokines, which induce the secretion of chemokines responsible for recruiting neutrophils (and monocytes) into the reaction.

Both Th1 and Th17 cells are involved in defense against many types of bacteria and viruses and in autoimmune diseases in which tissue injury is caused by chronic inflammation. Th2 cells are important in defense against helminthic parasites and in allergic inflammation. These T-cell subsets and their functions are described in more detail in Chapter 6.

Lymphocytes and macrophages interact in a bidirectional way, and these interactions play an important role in propagating chronic inflammation (Fig. 3.21). Macrophages display antigens to T cells, express membrane molecules called costimulators, and produce cytokines (IL-12 and others) that stimulate T-cell responses (Chapter 6). Activated T lymphocytes, in turn, produce cytokines, described earlier, which recruit and activate macrophages, promoting more antigen presentation and cytokine secretion. The result is a cycle of cellular reactions that fuel and sustain chronic inflammation. A typical consequence of such a chronic T cell–macrophage reaction is the formation of granulomas, described later.

Activated B lymphocytes and antibody-producing plasma cells are also often present at sites of chronic inflammation. The antibodies produced may be specific for persistent foreign antigens or self antigens in the inflammatory site or against altered tissue components. However, the contribution of antibodies to most chronic inflammatory disorders is unclear.

In some chronic inflammatory reactions, the accumulated lymphocytes, antigen-presenting cells, and plasma cells cluster together to form organized lymphoid follicles resembling those seen in lymph nodes. These are called tertiary lymphoid organs; this type of lymphoid organogenesis is often seen in the synovium of patients with long-standing rheumatoid arthritis and in the thyroid in Hashimoto thyroiditis. It has been postulated that the local formation of lymphoid follicles may perpetuate the immune reaction, but the significance of these structures is not established.

Other Cells in Chronic Inflammation

Other cell types may be prominent in chronic inflammation induced by particular stimuli.

- *Eosinophils* are abundant in immune reactions mediated by IgE and in parasitic infections (Fig. 3.22). Their recruitment is driven by adhesion molecules similar to those used by neutrophils and by specific chemokines (e.g., eotaxin) derived from leukocytes and epithelial cells. Eosinophils have granules that contain major basic protein, a highly cationic protein that is toxic to helminths but

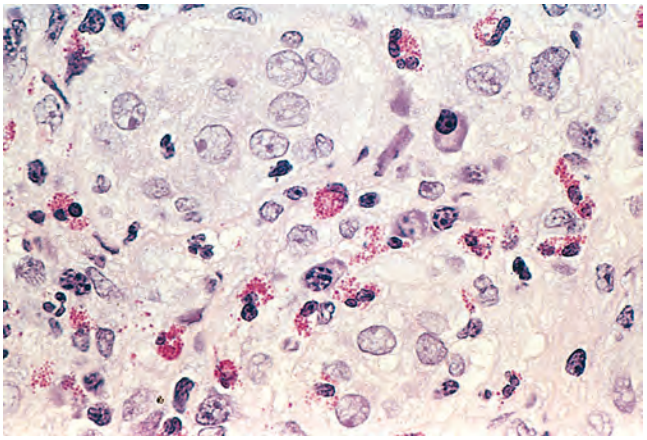

Figure 3.22 Focus of inflammation containing numerous eosinophils.

also may injure host epithelial cells. This is why eosinophils are of benefit in controlling helminth infections, yet they also contribute to tissue damage in immune reactions such as allergies (Chapter 6).

- *Mast cells* are widely distributed in connective tissues and participate in both acute and chronic inflammatory reactions. Mast cells express on their surface the receptor (FcεRI) that binds the Fc portion of IgE antibody. In immediate hypersensitivity reactions, IgE antibodies bound to the cells' Fc receptors specifically recognize antigen, and the cells degranulate and release mediators such as histamine and prostaglandins (Chapter 6). This type of response occurs during allergic reactions to foods, insect venom, or drugs, sometimes with catastrophic results (e.g., anaphylactic shock). Mast cells are also present in chronic inflammatory reactions, and because they secrete a plethora of cytokines, they may promote inflammatory reactions in different situations.
- Although *neutrophils* are characteristic of acute inflammation, many forms of chronic inflammation continue to show large numbers of neutrophils, induced either by persistent microbes or by mediators produced by activated macrophages and T lymphocytes. In chronic bacterial infection of bone (osteomyelitis), a neutrophilic exudate can persist for many months. Neutrophils are also important in the chronic damage induced in lungs by smoking and other irritant stimuli (Chapter 15). This pattern of inflammation has been called acute on chronic.

Granulomatous Inflammation

Granulomatous inflammation is a form of chronic inflammation characterized by collections of activated macrophages, often with T lymphocytes, and sometimes associated with necrosis. Granuloma formation is a cellular attempt to contain an offending agent that is difficult to eradicate. In this attempt there is often strong activation of T lymphocytes leading to macrophage activation, which can cause injury to normal tissues. The activated macrophages may develop abundant cytoplasm and begin to resemble epithelial cells and are called epithelioid cells. Some activated macrophages may fuse, forming multinucleate giant cells.

There are two types of granulomas, which differ in their pathogenesis.

- *Foreign body granulomas* are incited by inert foreign bodies, which induce inflammation in the absence of T cell–mediated immune responses. Typically, foreign body granulomas form around materials such as talc (associated with intravenous drug abuse) (Chapter 9), sutures, or other fibers that are large enough to preclude phagocytosis by a macrophage and are not immunogenic, so they do not incite any specific immune response. Epithelioid cells and giant cells are apposed to the surface of the foreign body. The foreign material can usually be identified in the center of the granuloma, sometimes within the giant cells, particularly if viewed with polarized light, in which it may appear refractile.
- *Immune granulomas* are caused by a variety of agents that are capable of inducing a persistent T cell–mediated immune response. This type of immune response usually produces granulomas when the inciting agent is difficult to eradicate, such as a persistent microbe. In such responses, activated Th1 cells produce cytokines such as IFN-γ, which activates macrophages (see Fig. 3.21). In some parasitic infections, such as schistosomiasis, the granulomas are associated with strong Th2 responses and eosinophils.

MORPHOLOGY

In the usual hematoxylin and eosin preparations, the activated macrophages in granulomas have pink granular cytoplasm with indistinct cell boundaries and are called **epithelioid cells** because of their resemblance to epithelia (Fig. 3.23). The aggregates of epithelioid macrophages are surrounded by a collar of lymphocytes. Older granulomas may have a rim of fibroblasts and connective tissue. Frequently, but not invariably, multinucleated **giant cells** 40 to 50 μm in diameter are found in granulomas; these are called Langhans giant cells. They consist of a large mass of cytoplasm and many nuclei, and they derive from the fusion of multiple activated macrophages. In granulomas associated with certain infectious organisms (most classically *Mycobacterium tuberculosis*), a combination of hypoxia and free radical–mediated injury leads

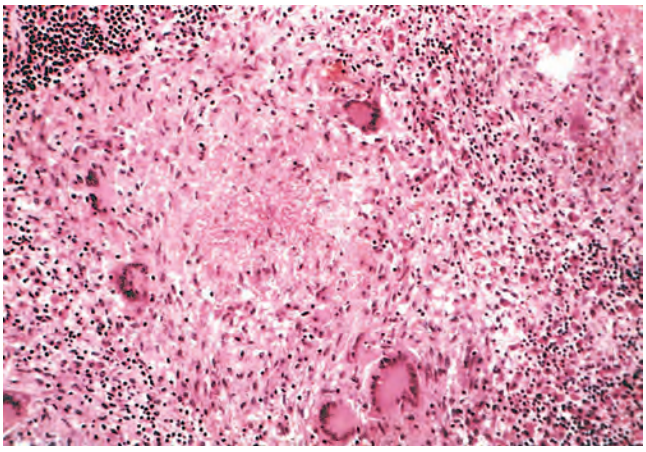

Figure 3.23 Typical tuberculous granuloma showing an area of central necrosis surrounded by multiple Langhans-type giant cells, epithelioid cells, and lymphocytes.

to a central zone of necrosis. Grossly, this has a granular, cheesy appearance and is therefore called **caseous necrosis.** Microscopically, this necrotic material appears as amorphous, structureless, eosinophilic, granular debris, with complete loss of cellular details (as opposed to coagulative necrosis, in which cell outlines are preserved). The granulomas in Crohn disease, sarcoidosis, and foreign body reactions tend to not have necrotic centers and are said to be noncaseating. Healing of granulomas is accompanied by fibrosis that may be extensive in involved organs.

Recognition of granulomatous inflammation is important because of the limited number of conditions (some life-threatening) that cause it (Table 3.9). **Tuberculosis is the prototype of a granulomatous disease caused by infection and should always be excluded as the cause when granulomas are identified.** In this disease the granuloma is referred to as a tubercle. Granulomas may also develop in some immune-mediated inflammatory diseases. Notable among these are Crohn disease, one type of inflammatory bowel disease and an important cause of granulomatous inflammation in the United States, and sarcoidosis, a disorder of unknown etiology. The morphologic patterns in the various granulomatous diseases may be sufficiently different to allow reasonably accurate diagnosis by an experienced pathologist (see Table 3.9); however, there are so many atypical presentations that it is always necessary to identify the specific etiologic agent by special stains for organisms (e.g., acid-fast stains for tubercle bacilli), by culture methods (e.g., in tuberculosis and fungal diseases), by molecular techniques (e.g., the polymerase chain reaction in tuberculosis), and by serologic studies (e.g., in syphilis).

Table 3.9 Examples of Diseases With Granulomatous Inflammation

Disease	Cause	Tissue Reaction
Tuberculosis	*Mycobacterium tuberculosis*	Caseating granuloma (tubercle): focus of activated macrophages (epithelioid cells), rimmed by fibroblasts, lymphocytes, histiocytes, occasional Langhans giant cells; central necrosis with amorphous granular debris; acid-fast bacilli
Leprosy	*Mycobacterium leprae*	Acid-fast bacilli in macrophages; noncaseating granulomas
Syphilis	*Treponema pallidum*	Gumma: microscopic to grossly visible lesion, enclosing wall of histiocytes; plasma cell infiltrate; central cells are necrotic without loss of cellular outline
Cat-scratch disease	Gram-negative bacillus	Rounded or stellate granuloma containing central granular debris and recognizable neutrophils; giant cells uncommon
Sarcoidosis	Unknown etiology	Noncaseating granulomas with abundant activated macrophages
Crohn disease (inflammatory bowel disease)	Immune reaction against intestinal bacteria, possibly self antigens	Occasional noncaseating granulomas in the wall of the intestine, with dense chronic inflammatory infiltrate

KEY CONCEPTS

CHRONIC INFLAMMATION

- Chronic inflammation is a prolonged host response to persistent stimuli.
- It is caused by microbes that resist elimination, immune responses against self antigens and environmental antigens, and some toxic substances (e.g., silica), and it underlies many medically important diseases.
- It is characterized by coexisting inflammation, tissue injury, and attempted repair by scarring.
- The cellular infiltrate consists of macrophages, lymphocytes, plasma cells, and other leukocytes.
- It is mediated by cytokines produced by macrophages and lymphocytes (notably T lymphocytes); bidirectional interactions between these cells tend to amplify and prolong the inflammatory reaction.
- Granulomatous inflammation is a pattern of chronic inflammation induced by T-cell and macrophage activation in response to an agent that is resistant to eradication.

SYSTEMIC EFFECTS OF INFLAMMATION

Inflammation, even if localized, is associated with cytokine-induced systemic reactions that are collectively called the *acute-phase response.* Anyone who has suffered through a severe bout of a viral illness (e.g., influenza) has experienced the systemic manifestations of acute inflammation. These changes are reactions to cytokines whose production is stimulated by bacterial products and by other inflammatory stimuli. The cytokines TNF, IL-1, and IL-6 are important mediators of the acute-phase reaction; other cytokines, notably interferons, also contribute.

The acute-phase response consists of several clinical and pathologic changes.

- *Fever,* characterized by an elevation of body temperature, usually by 1°C to 4°C, is one of the most prominent manifestations of the acute-phase response, especially when inflammation is associated with infection. Substances that induce fever are called pyrogens and include bacterial products (exogenous pyrogens, e.g., LPS) and cytokines, principally IL-1 and TNF (called endogenous pyrogens). Exogenous pyrogens act by stimulating immune cells to release IL-1 and TNF, which upregulate cyclooxygenases, the enzymes that synthesize prostaglandins. Among the cells that respond to IL-1 and TNF are vascular and perivascular cells of the hypothalamus. Prostaglandins released by these cells, especially PGE_2, stimulate the production of neurotransmitters by the hypothalamus that reset the body's steady-state temperature to a higher level by reducing heat loss (via vasoconstriction) and

increasing heat generation (through effects on brown fat and skeletal muscle). NSAIDs, including aspirin, reduce fever by inhibiting prostaglandin synthesis. An elevated body temperature has been shown to help amphibians ward off microbial infections, and although the details are not understood, it is assumed that fever is a protective host response in mammals as well.

- Elevated levels of *acute-phase proteins,* which are plasma proteins, mostly synthesized in the liver, whose plasma concentrations may increase several hundred–fold as part of the response to inflammatory stimuli. Three of the best known of these proteins are C-reactive protein (CRP), fibrinogen, and serum amyloid A (SAA) protein. Synthesis of these molecules in hepatocytes is stimulated by cytokines, especially IL-6 (for CRP and fibrinogen) and IL-1 or TNF (for SAA). Many acute-phase proteins, such as CRP and SAA, bind to microbial cell walls, and they may act as opsonins and fix complement. They also bind chromatin, possibly aiding in clearing necrotic cell nuclei. Fibrinogen binds to red cells and causes them to form stacks (rouleaux) that sediment more rapidly at unit gravity than do individual red cells. This is the basis for measuring the *erythrocyte sedimentation rate* as a simple test for an inflammatory response caused by any stimulus. Acute-phase proteins have beneficial effects during acute inflammation, but prolonged production of these proteins (especially SAA) in states of chronic inflammation causes secondary amyloidosis (Chapter 6). Elevated serum levels of CRP have been proposed as a marker for increased risk of myocardial infarction in patients with coronary artery disease. It is postulated that inflammation involving atherosclerotic plaques in the coronary arteries may predispose to thrombosis and subsequent infarction. Two other liver proteins that are released in increased amounts as part of the acute phase response often lead to altered blood counts. *Hepcidin* is a small protein that reduces the availability of iron to erythroid progenitors in the bone marrow; over time, this effect may lead to the anemia of chronic inflammation (Chapter 14). *Thrombopoietin*, the major growth factor for megakaryocytes (platelet precursors) in the bone marrow, is also upregulated and as a result systemic inflammation may be associated with an elevated platelet count (thrombocytosis).
- *Leukocytosis* is a common feature of inflammatory reactions, especially those induced by bacterial infections. The leukocyte count usually climbs to 15,000 or 20,000 cells/mL, but sometimes it may reach extraordinarily high levels of 40,000 to 100,000 cells/mL. These extreme elevations are sometimes called leukemoid reactions because they are similar to the white cell counts observed in leukemia, from which they must be distinguished. The leukocytosis occurs initially because of accelerated release of granulocytes from the bone marrow (caused by cytokines, including TNF and IL-1) and is therefore associated with a rise in the number of both mature and immature neutrophils in the blood, referred to as a shift to the left (for arcane reasons having to do with the way these cells were counted manually by technicians in days past). Prolonged infection also induces proliferation of precursors in the bone marrow, caused by increased production of colony-stimulating factors (CSFs) mainly from activated macrophages and marrow stromal cells. The increase in the bone marrow output of leukocytes compensates for the loss of these cells in the inflammatory reaction. (See also the discussion of leukocytosis in Chapter 13.) Most bacterial infections induce an increase in the blood neutrophil count, called neutrophilia. Viral infections, such as infectious mononucleosis, mumps, and German measles, cause an absolute increase in the number of lymphocytes (lymphocytosis). In some allergies and helminth infestations, there is an increase in the absolute number of eosinophils, creating eosinophilia. Certain infections (typhoid fever and infections caused by some viruses, rickettsiae, and certain protozoa) are associated with a decreased number of circulating white cells (leukopenia), in part because of sequestration of activated leukocytes in vascular spaces and tissues.
- Other manifestations of the acute-phase response include increased pulse and blood pressure; decreased sweating, mainly because of redirection of blood flow from cutaneous to deep vascular beds, to minimize heat loss through the skin; rigors (shivering), chills (search for warmth), anorexia, somnolence, and malaise, probably because of the actions of cytokines on brain cells.
- In severe bacterial infections (sepsis), the large amounts of bacteria and their products in the blood stimulate the production of enormous quantities of several cytokines, notably TNF and IL-1. High blood levels of cytokines cause various clinical manifestations such as disseminated intravascular coagulation, hypotensive shock, and metabolic disturbances, including insulin resistance and hyperglycemia. This clinical triad is known as *septic shock* and is one form of a severe, often fatal disorder referred to as systemic inflammatory response syndrome; it is discussed in more detail in Chapter 4.

KEY CONCEPTS

SYSTEMIC EFFECTS OF INFLAMMATION

- Fever: cytokines (TNF, IL-1) stimulate production of prostaglandins in hypothalamus.
- Production of acute-phase proteins: C-reactive protein, others; synthesis stimulated by cytokines (IL-6, others) acting on liver cells.
- Leukocytosis: cytokines (CSFs) stimulate production of leukocytes from precursors in the bone marrow.
- In some severe infections, septic shock: fall in blood pressure, disseminated intravascular coagulation, metabolic abnormalities; induced by high levels of TNF and other cytokines.

Whereas excessive inflammation is the underlying cause of many human diseases, defective inflammation results mainly in increased susceptibility to infections. The most common cause of defective inflammation is leukocyte deficiency due to replacement of the bone marrow by leukemias and metastatic tumors and suppression of the marrow by therapies for cancer and graft rejection. Inherited genetic abnormalities of leukocyte adhesion and microbicidal function are rare but informative; these are described in Chapter 6, in the context of immunodeficiency diseases. Deficiencies of the complement system are mentioned earlier and are described further in Chapter 6.

TISSUE REPAIR

Overview of Tissue Repair

Repair, also called healing, refers to the restoration of tissue architecture and function after an injury. By convention, the term *repair* is used for parenchymal and connective tissues and *healing* for surface epithelia, but these distinctions are not based on biology, and we use the terms interchangeably. Critical to the survival of an organism is the ability to repair the damage caused by toxic insults and inflammation. Hence the inflammatory response to microbes and injured tissues not only serves to eliminate these dangers but also sets into motion the process of repair.

Repair of damaged tissues occurs by two processes: regeneration, which restores normal cells, and scarring, the deposition of connective tissue (Fig. 3.24).

- *Regeneration.* Some tissues are able to replace the damaged components and essentially return to a normal state; this process is called regeneration. Regeneration may occur by proliferation of differentiated cells that survive the injury and retain the capacity to proliferate, notably hepatocytes in the liver. In other tissues, particularly the epithelia of the skin and intestines, tissue stem cells and their progenitors contribute to the restoration of damaged tissues. However, mammals have a limited capacity to regenerate most damaged tissues and organs, and only some components of these tissues are able to fully restore themselves.

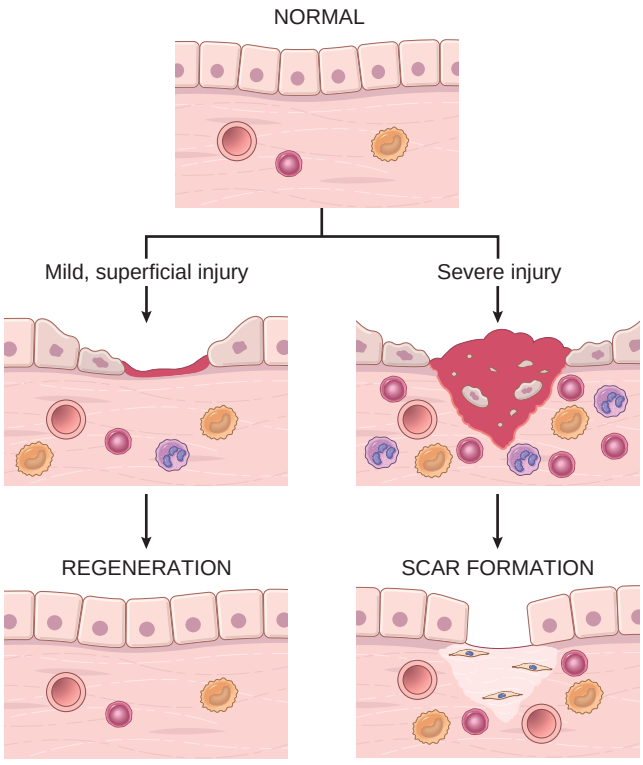

Figure 3.24 Mechanisms of tissue repair: regeneration and scar formation. Following mild injury, which damages the epithelium but not the underlying tissue, resolution occurs by regeneration, but after more severe injury with damage to the connective tissue, repair is by scar formation.

- *Connective tissue deposition (scar formation).* If the injured tissues are incapable of regeneration, or if the supporting structures of the tissue are too severely damaged to support regeneration of the tissue cells, repair occurs by the laying down of connective (fibrous) tissue, a process that may result in scar formation. Although the fibrous scar is not normal, it usually provides enough structural stability that the injured tissue is able to function. The term *fibrosis* is often used to describe the deposition of collagen that occurs in the lungs, liver, kidney, and other organs as a consequence of chronic inflammation or in the myocardium after extensive ischemic necrosis (infarction). If fibrosis develops in a tissue space occupied by an inflammatory exudate, it is called *organization* (as in organizing pneumonia affecting the lung).

After many common types of injury, both regeneration and scar formation contribute in varying degrees to the ultimate repair. Both processes involve the proliferation of cells and close interactions between cells and the ECM. We first discuss the general mechanisms of cellular proliferation and regeneration, then the salient features of healing by scar formation, and we conclude with a description of cutaneous wound healing and fibrosis (scarring) in parenchymal organs as illustrations of the repair process.

Cell and Tissue Regeneration

The regeneration of injured cells and tissues involves cell proliferation, which is driven by growth factors and is critically dependent on the integrity of the ECM, and by the development of mature cells from tissue stem cells. Before describing examples of repair by regeneration, the general principles of cell proliferation are discussed.

Cell Proliferation: Signals and Control Mechanisms

Several cell types proliferate during tissue repair. These include the remnants of the injured tissue (which attempt to restore normal structure), vascular endothelial cells (to create new vessels that provide the nutrients needed for the repair process), and fibroblasts (the source of the fibrous tissue that forms the scar to fill defects that cannot be corrected by regeneration).

The ability of tissues to repair themselves is determined, in part, by their intrinsic proliferative capacity and the presence of tissue stem cells. Based on these criteria, the tissues of the body are divided into three groups.

- *Labile (continuously dividing) tissues.* Cells of these tissues are continuously being lost and replaced by maturation from tissue stem cells and by proliferation of mature cells. Labile cells include hematopoietic cells in the bone marrow and the majority of surface epithelia, such as the stratified squamous epithelia of the skin, oral cavity, vagina, and cervix; the cuboidal epithelia of the ducts draining exocrine organs (e.g., salivary glands, pancreas, biliary tract); the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; and the transitional epithelium of the urinary tract. These tissues can readily regenerate after injury as long as the pool of stem cells is preserved.
- *Stable tissues.* Cells of these tissues are quiescent (in the G_0 stage of the cell cycle) and have only minimal

proliferative activity in their normal state. However, these cells are capable of dividing in response to injury or loss of tissue mass. Stable cells constitute the parenchyma of most solid tissues, such as liver, kidney, and pancreas. They also include endothelial cells, fibroblasts, and smooth muscle cells; the proliferation of these cells is particularly important in wound healing. With the exception of liver, stable tissues have a limited capacity to regenerate after injury.

- *Permanent tissues.* The cells of these tissues are considered to be terminally differentiated and nonproliferative in postnatal life. The majority of neurons and cardiac muscle cells belong to this category. Thus, injury to the brain or heart is irreversible and results in a scar because neurons and cardiac myocytes cannot regenerate. Limited stem cell replication and differentiation occur in some areas of the adult brain, and there is some evidence that heart muscle cells may proliferate after myocardial necrosis. Nevertheless, whatever proliferative capacity may exist in these tissues, it is insufficient to produce tissue regeneration after injury. Skeletal muscle is usually classified as a permanent tissue, but satellite cells attached to the endomysial sheath provide some regenerative capacity for muscle. In permanent tissues, repair is typically dominated by scar formation.

Cell proliferation is driven by signals provided by growth factors and from the ECM. Many different growth factors have been described; some act on multiple cell types, and others are cell-type specific (see Table 1.1 in Chapter 1). Growth factors are typically produced by cells near the site of damage. The most important sources of these growth factors are macrophages that are activated by the tissue injury, but epithelial and stromal cells also produce some of these factors. Several growth factors are displayed at high concentrations bound to ECM proteins. All growth factors activate signaling pathways that stimulate DNA replication (Chapter 1), while also fostering changes in metabolism that promote the biosynthesis of other cellular components (membranes, organelles, proteins) that are needed for a "mother" cell to produce two daughter cells. In addition to responding to growth factors, cells use integrins to bind to ECM proteins, and signals from the integrins can also stimulate cell proliferation.

Mechanisms of Tissue Regeneration

We will consider liver regeneration as a model of tissue regeneration, because it has been studied extensively and illustrates the mechanisms that underlie this process.

Liver Regeneration

The human liver has a remarkable capacity to regenerate, as demonstrated by its growth after partial hepatectomy, which may be performed for tumor resection or for living-donor hepatic transplantation. The mythologic image of liver regeneration is the regrowth of the liver of Prometheus, which was eaten every day by an eagle sent by Zeus as punishment for stealing the secret of fire and grew back overnight. The reality, although less dramatic, is still quite impressive.

Regeneration of the liver occurs by two major mechanisms: proliferation of remaining hepatocytes and repopulation from progenitor cells. Which mechanism plays the dominant role depends on the nature of the injury.

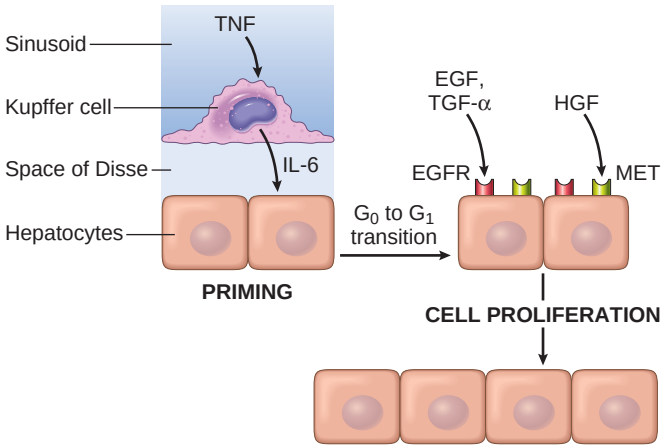

Figure 3.25 Liver regeneration by proliferation of hepatocytes. Following partial hepatectomy, the liver regenerates by proliferation of surviving cells. The process occurs in stages, including priming, followed by growth factor–induced proliferation. The main signals involved in these steps are shown. Once the mass of the liver is restored, the proliferation is terminated (not shown). *EGF*, Epidermal growth factor; *EGFR*, epidermal growth factor receptor; *HGF*, hepatocyte growth factor; *IL-6*, interleukin-6; *TGF-α*, transforming growth factor-α; *TNF*, tumor necrosis factor.

- *Proliferation of hepatocytes following partial hepatectomy.* In humans, resection of up to 90% of the liver can be corrected by proliferation of the residual hepatocytes. This classic model of tissue regeneration has been used experimentally to study the initiation and control of the process.

  Hepatocyte proliferation in the regenerating liver is triggered by the combined actions of cytokines and polypeptide growth factors. The process occurs in distinct stages (Fig. 3.25). In the first, or priming, phase, cytokines such as IL-6 produced mainly by Kupffer cells act on hepatocytes to make the parenchymal cells competent to receive and respond to growth factor signals. In the second, or growth factor, phase, growth factors such as hepatocyte growth factor (HGF) and TGF-α, produced by many cell types, act on primed hepatocytes to stimulate cell metabolism and entry of the cells into the cell cycle. Because hepatocytes are quiescent cells, it takes them several hours to enter the cell cycle, progress from G_0 to G_1, and reach the S phase of DNA replication. Almost all hepatocytes replicate during liver regeneration after partial hepatectomy. During the phase of hepatocyte replication, numerous genes are activated; these include genes encoding transcription factors, cell cycle regulators, regulators of energy metabolism, and others. The wave of hepatocyte proliferation is followed by replication of nonparenchymal cells (Kupffer cells, endothelial cells, and stellate cells). In the final, termination, phase, hepatocytes return to quiescence. The nature of the stop signals is poorly understood; antiproliferative cytokines of the TGF-β family are likely involved.
- *Liver regeneration from progenitor cells.* In situations where the proliferative capacity of hepatocytes is impaired, such as after chronic liver injury or inflammation, progenitor cells in the liver contribute to repopulation. In rodents, these progenitor cells have been called oval cells because

of the shape of their nuclei. Some of these progenitor cells reside in specialized niches called canals of Hering, where bile canaliculi connect with larger bile ducts. The signals that drive proliferation of progenitor cells and their differentiation into mature hepatocytes are topics of active investigation.

Restoration of normal tissue structure can occur only if the residual tissue is structurally intact, as after partial surgical resection. By contrast, if the tissue is damaged by infection or inflammation, regeneration is incomplete and is accompanied by scarring. For example, extensive destruction of the liver with collapse of the reticulin framework, as occurs in a liver abscess, leads to scar formation even though the remaining liver cells have the capacity to regenerate.

KEY CONCEPTS

REPAIR BY REGENERATION

- Tissues are classified as labile, stable, and permanent, according to the proliferative capacity of their cells.
- Continuously dividing tissues (labile tissues) contain stem cells that differentiate to replenish lost cells and maintain tissue homeostasis.
- Cell proliferation is controlled by the cell cycle and is stimulated by growth factors and interactions of cells with the ECM.
- Regeneration of the liver is a classic example of repair by regeneration. It is triggered by cytokines and growth factors produced in response to loss of liver mass and inflammation. In different situations, regeneration may occur by proliferation of surviving hepatocytes or repopulation from progenitor cells.

Repair by Connective Tissue Deposition

If repair cannot be accomplished by regeneration alone, it occurs by replacement of the injured cells with connective tissue, leading to the formation of a scar, or by a combination of regeneration of some residual cells and scar formation. In contrast to regeneration, which involves the restitution of tissue components, scar formation is a response that "patches" rather than restores the tissue. The term scar is most often used in connection to wound healing in the skin, but may also be used to describe the replacement of parenchymal cells in any tissue by collagen, as in the heart after myocardial infarction.

Steps in Scar Formation

Repair by connective tissue deposition consists of sequential processes that follow tissue injury. Within minutes after injury, a hemostatic plug composed of platelets (Chapter 4) is formed, which stops bleeding and provides a scaffold for the deposition of fibrin. The subsequent steps are summarized here (Fig. 3.26):

- *Inflammation.* Breakdown products of complement activation, chemokines released from activated platelets, and other mediators produced at the site of injury function as chemotactic agents to recruit neutrophils and then monocytes over the next 6 to 48 hours. These inflammatory cells eliminate the offending agents, such as microbes that may have entered through the wound, and clear the debris. As the injurious agents and necrotic cells are cleared, the inflammation resolves.
- *Cell proliferation.* In the next stage, which takes up to 10 days, several cell types, including epithelial cells, endothelial and other vascular cells, and fibroblasts, proliferate and migrate to close the now clean wound. Each cell type serves unique functions.
  - *Epithelial cells* respond to locally produced growth factors and migrate over the wound to cover it up.
  - *Endothelial cells and pericytes* proliferate to form new blood vessels, a process known as *angiogenesis*. Because of the importance of this process in physiologic host responses and in many pathologic conditions, it is described in more detail subsequently.
  - *Fibroblasts* proliferate and migrate into the site of injury and lay down collagen fibers that form the scar.
- *Formation of granulation tissue.* Migration and proliferation of fibroblasts and deposition of loose connective tissue,

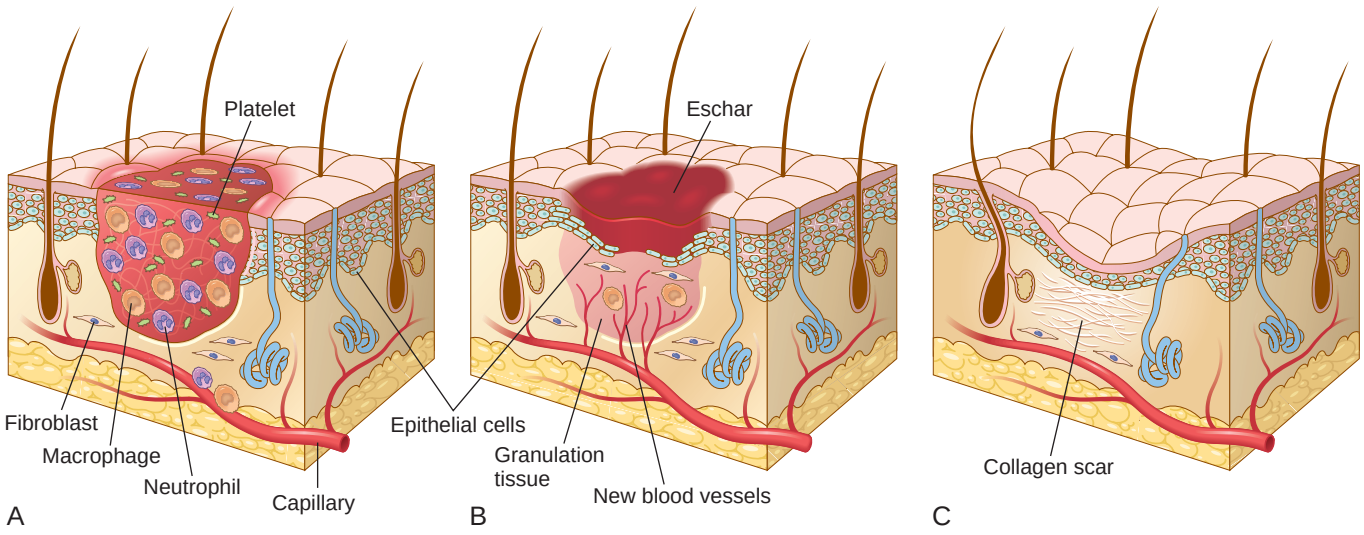

Figure 3.26 Steps in repair by scar formation: wound healing in the skin. (A) Inflammation. (B) Proliferation of epithelial cells; formation of granulation tissue by vessel growth and proliferating fibroblasts. (C) Remodeling to produce the fibrous scar.

together with the vessels and interspersed mononuclear leukocytes, form granulation tissue. The term granulation tissue derives from the pink, soft, granular gross appearance, such as that seen beneath the scab of a skin wound. Its histologic appearance is characterized by proliferation of fibroblasts and new thin-walled, delicate capillaries (angiogenesis) in a loose ECM, often with admixed inflammatory cells, mainly macrophages (Fig. 3.27A). Granulation tissue progressively fills the site of injury; the amount of granulation tissue that is formed depends on the size of the tissue defect created by the wound and the intensity of inflammation.

- *Deposition of connective tissue.* Granulation tissue is progressively replaced by deposition of collagen. The amount of connective tissue increases in the granulation tissue, eventually resulting in the formation of a stable fibrous *scar* (Fig. 3.27B).

Macrophages play a central role in repair by clearing offending agents and dead tissue, providing growth factors for the proliferation of various cells, and secreting cytokines that stimulate fibroblast proliferation and connective tissue synthesis and deposition. The macrophages that are involved in repair are mostly of the alternatively activated (M2) type. It is not clear how the classically activated macrophages that dominate during inflammation, and are involved in getting rid of microbes and dead tissues, are gradually replaced by alternatively activated macrophages that serve to terminate inflammation and induce repair.

We next describe the steps in the formation of granulation tissue and the scar.

Angiogenesis

Angiogenesis is the process of new blood vessel development from existing vessels. It is critical in healing at sites of injury, in the development of collateral circulations at sites of ischemia, and in allowing tumors to increase in size beyond the constraints of their original blood supply. Much work has been done to understand the mechanisms underlying angiogenesis, and therapies to either augment the process (e.g., to improve blood flow to a heart ravaged by coronary atherosclerosis) or inhibit it (to frustrate tumor growth or block pathologic vessel growth such as in diabetic retinopathy) have been developed.

Angiogenesis involves sprouting of new vessels from existing ones and consists of the following steps (Fig. 3.28):

- *Vasodilation* in response to nitric oxide and increased permeability induced by vascular endothelial growth factor (VEGF).
- *Separation of pericytes* from the abluminal surface and breakdown of the basement membrane to allow formation of a vessel sprout.
- *Migration of endothelial cells* toward the area of tissue injury.
- *Proliferation of endothelial cells* just behind the leading front ("tip") of migrating cells.
- Remodeling into capillary tubes.
- *Recruitment of periendothelial cells* (pericytes for small capillaries and smooth muscle cells for larger vessels) to form the mature vessel.
- *Suppression of endothelial proliferation* and migration and deposition of the basement membrane.

Mechanisms of Angiogenesis. The process of angiogenesis involves several signaling pathways, cell–cell interactions, ECM proteins, and tissue enzymes. *VEGFs,* mainly VEGF-A (Chapter 1), stimulate both migration and proliferation of endothelial cells, thus initiating the process of capillary sprouting in angiogenesis. VEGF promotes vasodilation by stimulating the production of NO and contributes to the formation of the vascular lumen. Fibroblast growth factors (FGFs), mainly FGF-2, stimulate the proliferation of endothelial cells. They also promote the migration of macrophages and fibroblasts to the damaged area and stimulate epithelial cell migration to cover epidermal wounds. Angiopoietins 1 and 2 (Ang 1 and Ang 2) are growth factors that play a

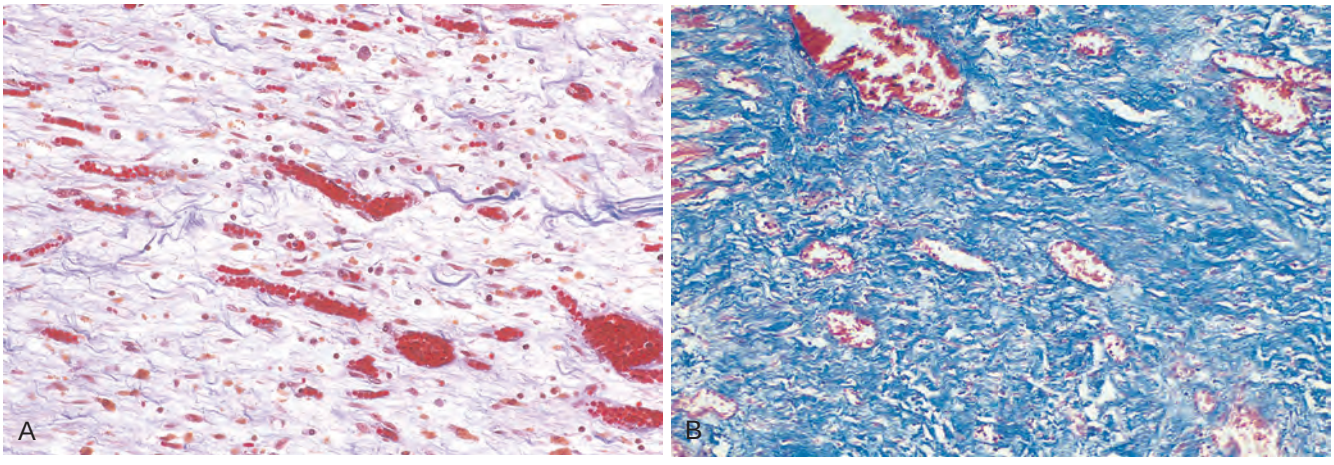

Figure 3.27 (A) Granulation tissue showing numerous blood vessels, edema, and a loose extracellular matrix containing occasional inflammatory cells. Collagen is stained blue by the trichrome stain; minimal mature collagen can be seen at this point. (B) Trichrome stain of mature scar, showing dense collagen, with only scattered vascular channels.

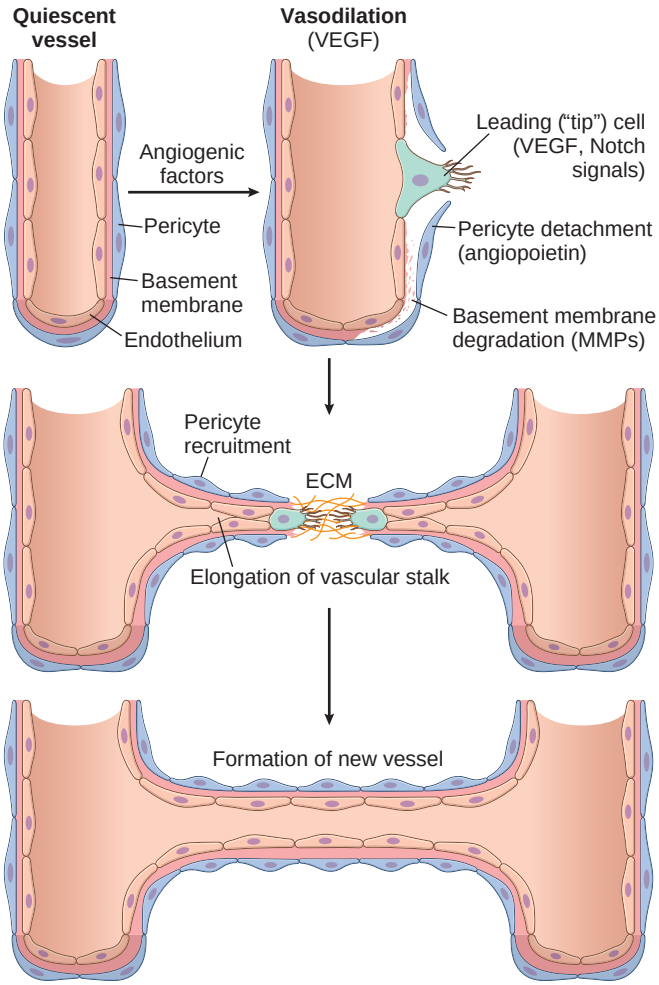

Figure 3.28 Angiogenesis. In tissue repair, angiogenesis occurs mainly by sprouting of new vessels. The steps in the process and the major signals involved are illustrated. The newly formed vessel joins up with other vessels (not shown) to form the new vascular bed. *ECM*, Extracellular matrix; *MMPs*, matrix metalloproteinases; *VEGF*, vascular endothelial growth factor.

role in angiogenesis and the structural maturation of new vessels. Newly formed vessels need to be stabilized by pericytes and smooth muscle cells and by the deposition of connective tissue. The growth factors platelet-derived growth factor (PDGF) and TGF-β also participate in the stabilization process: PDGF recruits smooth muscle cells and TGF-β suppresses endothelial proliferation and migration and enhances the production of ECM proteins.

The Notch signaling pathway regulates the sprouting and branching of new vessels and thus ensures that the new vessels that are formed have the proper spacing to effectively supply the healing tissue with blood. VEGF stimulates the expression of Notch ligands, which bind to the Notch receptor on endothelial cells and regulate the pattern of vessel branching.

ECM proteins participate in the process of vessel sprouting in angiogenesis, largely through interactions with integrin receptors in endothelial cells and by providing the scaffold for vessel growth. Enzymes in the ECM, notably the matrix metalloproteinases (MMPs), degrade the ECM to permit remodeling and extension of the vascular tube.

Deposition of Connective Tissue

The laying down of connective tissue occurs in two steps: migration and proliferation of fibroblasts into the site of injury, and deposition of ECM proteins produced by these cells. These processes are orchestrated by locally produced cytokines and growth factors including PDGF, FGF-2, and TGF-β. The major sources of these factors are inflammatory cells, particularly alternatively activated (M2) macrophages, which are present at sites of injury and in granulation tissue. Sites of inflammation are also rich in mast cells, and in the appropriate chemotactic milieu, lymphocytes may also be present. Each of these can secrete cytokines and growth factors that contribute to fibroblast proliferation and activation.

***TGF-β* is the most important cytokine for the synthesis and deposition of connective tissue proteins.** It is produced by most of the cells in granulation tissue, including alternatively activated macrophages. The levels of TGF-β in tissues are primarily regulated not by the transcription of the gene but by the posttranscriptional activation of latent TGF-β, the rate of secretion of the active molecule, and molecules that make up or that interact with the ECM, notably integrins and microfibrils, that enhance or diminish TGF-β activity. TGF-β stimulates fibroblast migration and proliferation, increases synthesis of collagen and fibronectin, and decreases degradation of ECM by inhibiting metalloproteinases. TGF-β is involved not only in scar formation after injury but also in the development of fibrosis in lung, liver, and kidneys in response to chronic inflammation. TGF-β is also an antiinflammatory cytokine that serves to limit and terminate inflammatory responses. It does this by inhibiting lymphocyte proliferation and the activity of other leukocytes.

As healing progresses, the number of proliferating fibroblasts and new vessels decreases; however, the fibroblasts progressively assume a more synthetic phenotype, and hence there is increased deposition of ECM. Collagen deposition is critical for the development of strength in a healing wound site. As the scar matures, there is progressive vascular regression, which eventually transforms the highly vascularized granulation tissue into a pale, largely avascular scar. Some of the fibroblasts also acquire features of smooth muscle cells, including the presence of actin filaments, and are called *myofibroblasts*. These cells contribute to the contraction of the scar over time.

Remodeling of Connective Tissue

The outcome of the repair process is influenced by a balance between synthesis and degradation of ECM proteins. After its deposition, the connective tissue in the scar continues to be modified and remodeled. The degradation of collagens and other ECM components is accomplished by a family of matrix metalloproteinases (MMPs), so called because they are dependent on metal ions (e.g., zinc) for their activity. MMPs include interstitial collagenases (MMP-1, MMP-2, and MMP-3), which cleave fibrillar collagen; gelatinases,

which degrade amorphous collagen and fibronectin; and stromelysins, which degrade a variety of ECM constituents, including proteoglycans, laminin, fibronectin, and amorphous collagen.

MMPs are produced by a variety of cell types (fibroblasts, macrophages, neutrophils, synovial cells, and some epithelial cells), and their synthesis and secretion are regulated by growth factors, cytokines, and other agents. The activity of the MMPs is tightly controlled. They are produced as inactive precursors (zymogens) that must be first activated; this is accomplished by proteases (e.g., plasmin) likely to be present only at sites of injury. In addition, activated collagenases can be rapidly inhibited by specific tissue inhibitors of metalloproteinases (TIMPs), produced by most mesenchymal cells. Thus, during scar formation, MMPs are activated to remodel the deposited ECM, and then their activity is shut down by the TIMPs.

KEY CONCEPTS

REPAIR BY SCAR FORMATION

- Tissues are repaired by replacement with connective tissue and scar formation if the injured tissue is not capable of proliferation or if the structural framework is damaged and cannot support regeneration.
- The main components of connective tissue repair are angiogenesis, migration and proliferation of fibroblasts, collagen synthesis, and connective tissue remodeling.
- Repair by connective tissue starts with the formation of granulation tissue and culminates in the laying down of fibrous tissue.
- Multiple growth factors stimulate the proliferation of the cell types involved in repair.
- TGF-β is a potent fibrogenic agent; ECM deposition depends on the balance between fibrogenic agents, metalloproteinases (MMPs) that digest ECM, and TIMPs.

Factors That Influence Tissue Repair

Tissue repair may be altered by several factors, which impact the quality or adequacy of the reparative process. Variables that modify healing may be extrinsic (e.g., infection) or intrinsic to the injured tissue and systemic or local:

- *Infection* is clinically one of the most important causes of delayed healing; it prolongs inflammation and potentially increases the local tissue injury.
- *Diabetes* is a metabolic disease that compromises tissue repair for many reasons (Chapter 24) and is one of the most important systemic causes of abnormal wound healing.
- *Nutritional status* has profound effects on repair; protein deficiency and vitamin C deficiency inhibit collagen synthesis and retard healing.
- *Glucocorticoids (steroids)* have well-documented antiinflammatory effects, and their administration may result in weakness of the scar due to inhibition of TGF-β production and diminished fibrosis. In some instances, however, these effects of glucocorticoids are desirable. For example, in corneal infections, glucocorticoids are sometimes prescribed (along with antibiotics) to reduce the likelihood of opacity that may result from scarring.
- *Mechanical factors* such as increased local pressure or torsion may cause wounds to pull apart, or dehisce.
- *Poor perfusion,* due to peripheral vascular disease, arteriosclerosis, and diabetes or due to obstructed venous drainage (e.g., in varicose veins), also impairs healing.
- *Foreign bodies* such as fragments of steel, glass, or even bone impede healing by perpetuating chronic inflammation.
- *The type and extent of tissue injury* and the character of the tissue in which the injury occurs affect the subsequent repair. Complete restoration can occur only in tissues composed of stable and labile cells. Injury to tissues composed of permanent cells inevitably results in scarring and some loss of function.
- The *location of the injury* is also important. For example, inflammation arising in tissue spaces (e.g., pleural, peritoneal, synovial cavities) develops extensive exudates. Subsequent repair may occur by digestion of the exudate, initiated by the proteolytic enzymes of leukocytes, and resorption of the liquefied exudate. This is called resolution, and in the absence of cellular necrosis, normal tissue architecture is generally restored. However, in the setting of larger accumulations, granulation tissue grows into the exudate, and a fibrous scar ultimately forms. This is called organization.

Examples of Tissue Repair and Fibrosis

So far, we have discussed the general principles and mechanisms of repair by regeneration and scar formation. In this section we describe two clinically significant types of repair—the healing of skin wounds (cutaneous wound healing) and fibrosis in injured parenchymal organs.

Healing of Skin Wounds

Based on the nature and size of the wound, the healing of skin wounds is said to occur by first or second intention.

Healing by First Intention

When the injury involves only the epithelial layer, the principal mechanism of repair is epithelial regeneration, also called primary union or healing by first intention. One of the simplest examples of this type of wound repair is the healing of a clean, uninfected surgical incision approximated by surgical sutures (Fig. 3.29). The incision causes only focal disruption of epithelial basement membrane continuity and death of relatively few epithelial and connective tissue cells. The repair consists of the same three connected processes that we have described previously: inflammation, proliferation of epithelial and other cells, and maturation of the connective tissue scar.

- Wounding causes the rapid activation of coagulation pathways, which results in the formation of a blood clot on the wound surface (Chapter 4). The clot serves to stop bleeding and supports migrating cells, which are attracted by growth factors, cytokines, and chemokines released into the area.
- Within 24 hours, neutrophils are seen at the incision margin, migrating toward the fibrin clot. Basal cells at

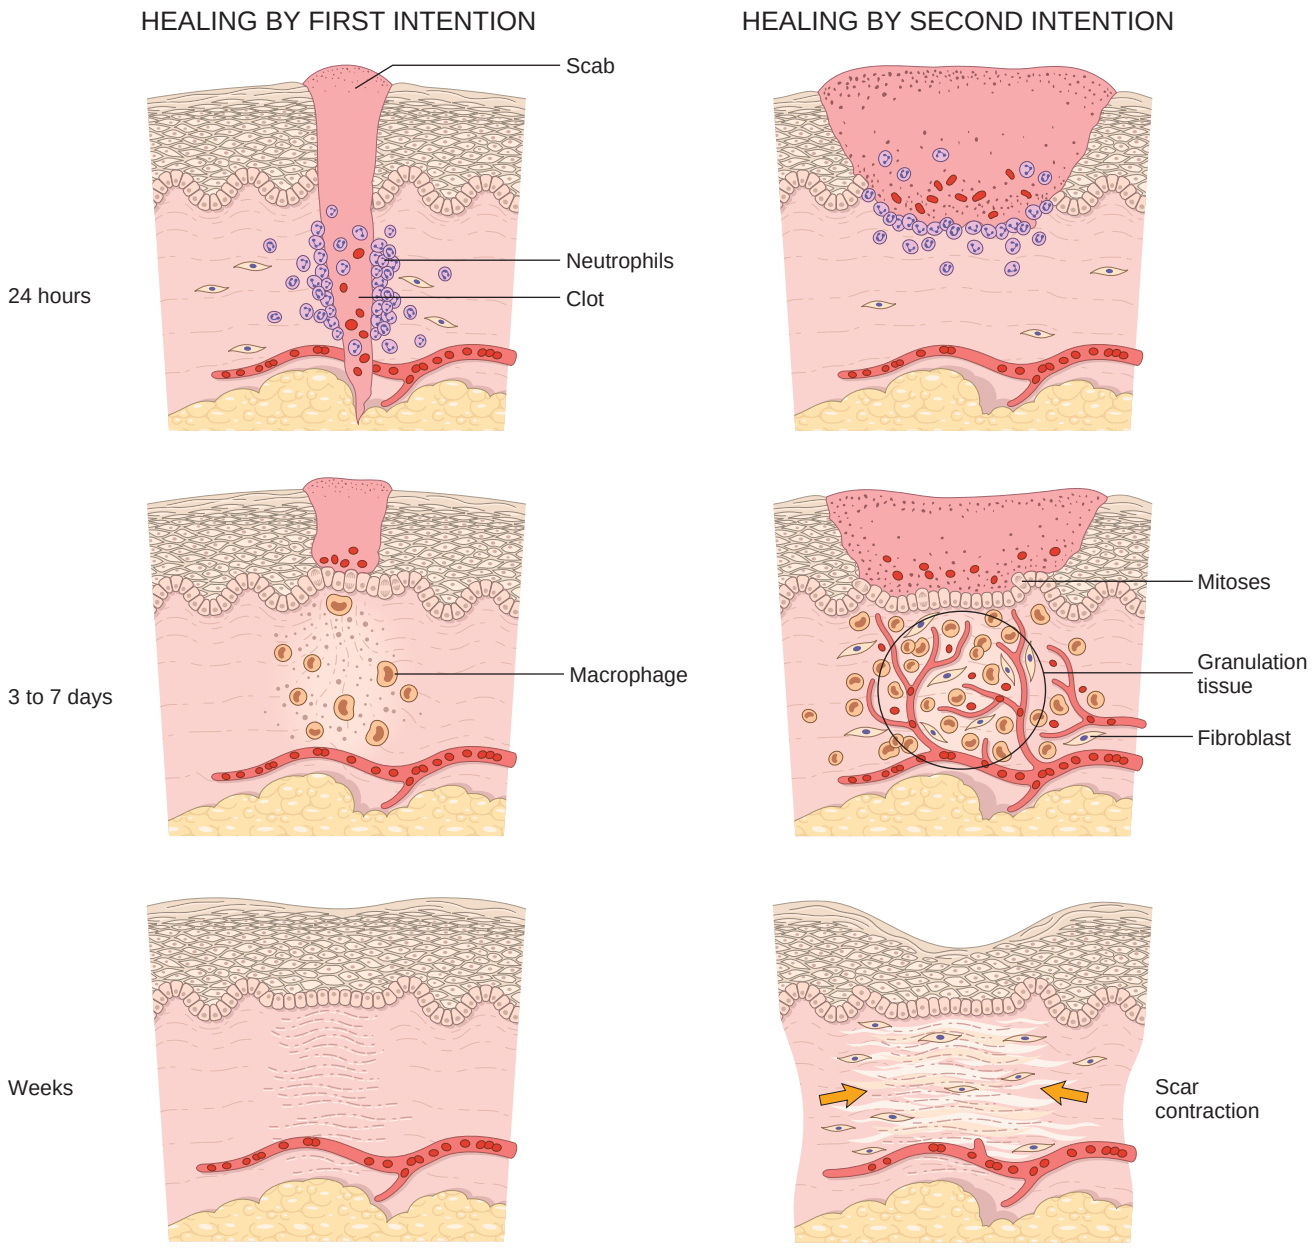

Figure 3.29 Steps in wound healing by first intention (left) and second intention (right). In the latter, note the large amount of granulation tissue and wound contraction.

the edge of the incision begin to show increased mitotic activity. Within 24 to 48 hours, epithelial cells from both edges have begun to migrate and proliferate along the dermis yielding a thin but continuous epithelial layer that closes the wound.

- By day 3, neutrophils have been largely replaced by macrophages, and granulation tissue progressively invades the incision space. The macrophages clear extracellular debris, fibrin, and other foreign material and promote angiogenesis and ECM deposition.
- By day 5, neovascularization reaches its peak as granulation tissue fills the incisional space. The new vessels are leaky, allowing the passage of plasma proteins and fluid into the extravascular space. Thus, new granulation tissue is often edematous. Fibroblasts progressively migrate into the granulation tissue, where they proliferate and lay down collagen and ECM.
- During the second week, there is continued collagen accumulation and fibroblast proliferation. The leukocyte infiltrate, edema, and increased vascularity are substantially diminished.
- By the end of the first month, the scar comprises a cellular connective tissue largely devoid of inflammatory cells and covered by an essentially normal epidermis. The tensile strength of the wound increases with time, as described later.

Healing by Second Intention

Healing by second intention, also called secondary union, differs from primary healing in several respects.

- In wounds causing large tissue deficits, the fibrin clot is larger, and there is more exudate and necrotic debris in the wounded area. Inflammation is more intense because large tissue defects have a greater volume of necrotic debris, exudate, and fibrin that must be removed. Consequently, large defects have a greater potential for secondary, inflammation-mediated injury.
- Much larger amounts of granulation tissue are formed to fill a bigger gap caused by the larger area of deficit. A greater volume of granulation tissue generally results in a greater mass of scar tissue.
- At first a provisional matrix containing fibrin, plasma fibronectin, and type III collagen is formed, but in about 2 weeks this is replaced by a matrix composed primarily of type I collagen. Ultimately the original granulation tissue scaffold is converted into a pale, avascular scar. The dermal appendages that have been destroyed in the line of the incision are permanently lost. By the end of the first month, the scar is made up of acellular connective tissue devoid of inflammatory infiltrate, covered by intact epidermis.
- Wound contraction helps to close the wound by decreasing the gap between its dermal edges and by reducing the wound surface area. Hence it is an important feature in healing by secondary union. Wound contraction involves the formation of a network of *myofibroblasts,* which are modified fibroblasts which have contractile properties. Within 6 weeks, large skin defects may be reduced to 5% to 10% of their original size, largely by contraction.

Wound Strength

Carefully sutured wounds have approximately 70% of the strength of normal skin, largely because of the placement of sutures. The recovery of tensile strength results from the excess of collagen synthesis over collagen degradation during the first 2 months of healing by cross-linking of collagen fibers and increased fiber size. Wound strength reaches approximately 70% to 80% of normal by 3 months but usually does not substantially improve beyond that point.

Fibrosis in Parenchymal Organs

The term fibrosis is used to denote the excessive deposition of collagen and other ECM components in a tissue. As already mentioned, the terms scar and fibrosis are used interchangeably. The basic mechanisms of fibrosis are the same as those of scar formation in the skin during tissue repair. Fibrosis may be responsible for substantial organ dysfunction and even organ failure.

Fibrotic disorders include diverse chronic and debilitating diseases such as liver cirrhosis, systemic sclerosis (scleroderma), fibrosing diseases of the lung (idiopathic pulmonary fibrosis, pneumoconioses, and drug- and radiation-induced pulmonary fibrosis), end-stage kidney disease, and constrictive pericarditis. These conditions are discussed in the appropriate chapters throughout the book. Because of the tremendous functional impairment caused by fibrosis in these conditions, there is great interest in the development of antifibrotic drugs.

Abnormalities in Tissue Repair

Complications in tissue repair can arise from abnormalities in any of the basic components of the process, including deficient scar formation, excessive formation of the repair components, and formation of contractures.

Defects in Healing: Chronic Wounds

These are seen in numerous clinical situations, as a result of local and systemic factors. The following are some common examples.

- *Venous leg ulcers* (Fig. 3.30A) develop most often in elderly people as a result of chronic venous hypertension, which may be caused by severe varicose veins or congestive heart failure. Deposits of iron pigment (hemosiderin) are common, resulting from red cell breakdown, and there may be accompanying chronic inflammation. These ulcers fail to heal because of poor delivery of oxygen to the site of the ulcer.
- *Arterial ulcers* (Fig. 3.30B) develop in individuals with atherosclerosis of peripheral arteries, especially associated with diabetes. The ischemia results in atrophy and then necrosis of the skin and underlying tissues. These lesions can be quite painful.
- *Diabetic ulcers* (Fig. 3.30C) affect the lower extremities, particularly the feet. There is tissue necrosis and failure to heal as a result of vascular disease causing ischemia, neuropathy, systemic metabolic abnormalities, and secondary infections. Histologically, these lesions are characterized by epithelial ulceration (Fig. 3.30E) and extensive granulation tissue in the underlying dermis (Fig. 3.30F).
- *Pressure sores* (Fig. 3.30D) are areas of skin ulceration and necrosis of underlying tissues caused by prolonged compression of tissues against a bone, e.g., in elderly patients with numerous morbidities lying in bed without moving. The lesions are caused by mechanical pressure and local ischemia.

When a surgical incision reopens internally or externally it is called wound dehiscence. The risk factors for such an occurrence are obesity, malnutrition, infections, and vascular insufficiency. In abdominal wounds it can be precipitated by vomiting and coughing.

Excessive Scarring

Excessive formation of the components of the repair process can give rise to hypertrophic scars and keloids. The accumulation of excessive amounts of collagen may give rise to a raised scar known as a hypertrophic scar. These often grow rapidly and contain abundant myofibroblasts, but they tend to regress over several months (Fig. 3.31A). If the scar tissue grows beyond the boundaries of the original wound and does not regress, it is called a *keloid* (Fig. 3.31B, C). Keloid formation seems to be an individual predisposition, and for unknown reasons it is somewhat more common in African Americans. Hypertrophic scars generally develop after thermal or traumatic injury that involves the deep layers of the dermis.

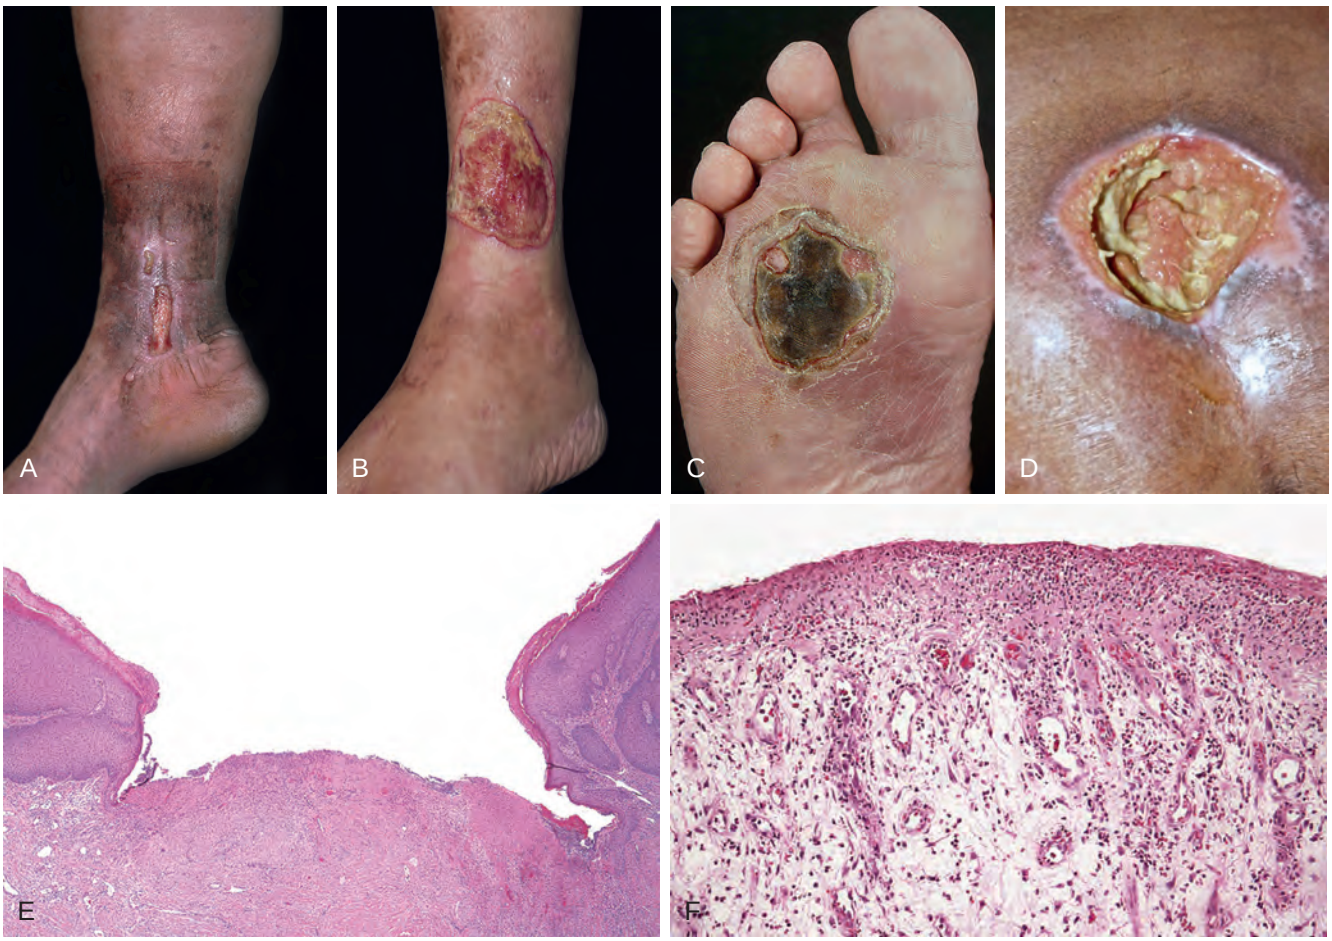

Figure 3.30 Chronic wounds illustrating defects in wound healing. (A–D) External appearance of skin ulcers. (A) Venous leg ulcer; (B) arterial ulcer, with more extensive tissue necrosis; (C) diabetic ulcer; (D) pressure sore. (E, F) Histologic appearance of a diabetic ulcer. (E) Ulcer crater; (F) chronic inflammation and granulation tissue. (A–D, From Eming SA, Margin P, Tomic-Canic M: Wound repair and regeneration: mechanisms, signaling, and translation, *Sci Transl Med* 6:265, 2014.)

Exuberant granulation is another deviation in wound healing consisting of the formation of excessive amounts of granulation tissue, which protrudes above the level of the surrounding skin and blocks reepithelialization (this process has been called, with more literary fervor, proud flesh). Excessive granulation must be removed by cautery or surgical excision to permit restoration of the continuity of the epithelium. Rarely, incisional scars or traumatic injuries may be followed by exuberant proliferation of fibroblasts and other connective tissue elements that may recur after excision. Called desmoids, or aggressive fibromatoses, these neoplasms lie in the interface between benign and malignant (though low-grade) tumors.

Contraction in the size of a wound is an important part of the normal healing process. An exaggeration of this process gives rise to *contracture* and results in deformities of the wound and the surrounding tissues. Contractures are particularly prone to develop on the palms, the soles, and the anterior aspect of the thorax. Contractures are commonly seen after serious burns and can compromise the movement of joints.

KEY CONCEPTS

CUTANEOUS WOUND HEALING AND PATHOLOGIC ASPECTS OF REPAIR

- The main phases of cutaneous wound healing are inflammation, formation of granulation tissue, and ECM remodeling.
- Cutaneous wounds can heal by primary union (first intention) or secondary union (secondary intention); secondary healing involves more extensive scarring and wound contraction.
- Wound healing can be altered by many conditions, particularly infection and diabetes; the type, volume, and location of the injury are important factors that influence the healing process.
- Excessive production of ECM can cause keloids in the skin.
- Persistent stimulation of collagen synthesis in chronic inflammatory diseases leads to fibrosis of the tissue, often with extensive loss of the tissue and functional impairment.

CHAPTER 4

Hemodynamic Disorders, Thromboembolic Disease, and Shock

CHAPTER CONTENTS

The health of cells and tissues depends on the circulation of blood, which delivers oxygen and nutrients and removes wastes generated by cellular metabolism. Under normal conditions, as blood passes through capillary beds, proteins in the plasma are retained within the vasculature, and there is little net movement of water and electrolytes into the tissues. This balance is often disturbed by pathologic conditions that alter endothelial function, increase vascular hydrostatic pressure, or decrease plasma protein content, all of which promote edema—the accumulation of fluid in tissues resulting from a net movement of water into extravascular spaces. Depending on its severity and location, edema may have minimal or profound effects. In the lower extremities, it may only make one's shoes feel snugger after a long sedentary day; in the lungs, however, edema fluid can fill alveoli, causing life-threatening hypoxia.

The structural integrity of blood vessels is frequently compromised by trauma. *Hemostasis* is the process of blood clotting that prevents excessive bleeding after blood-vessel damage. Inadequate hemostasis may result in hemorrhage, which can compromise regional tissue perfusion and, if massive and rapid, may lead to hypotension, shock, and death. Conversely, inappropriate clotting *(thrombosis)* or migration of clots *(embolism)* can obstruct blood vessels, potentially causing ischemic cell death *(infarction)*. Indeed, thromboembolism lies at the heart of three major causes of morbidity and death in high income countries: myocardial infarction, pulmonary embolism (PE), and cerebrovascular accident (stroke).

Herein, we focus on disorders of hemodynamics (edema, effusions, congestion, and shock), provide an overview of disorders of abnormal bleeding and clotting (thrombosis), and discuss the various forms of embolism.

EDEMA AND EFFUSIONS

Disorders that perturb cardiovascular, renal, or hepatic function are often marked by the accumulation of fluid in tissues (edema) or body cavities (effusions). Under normal circumstances, the tendency of vascular hydrostatic pressure to push water and salts out of capillaries into the interstitial space is nearly balanced by the tendency of plasma colloid osmotic pressure to pull water and salts back into vessels. There is usually a small net movement of fluid into the interstitium, but this drains into lymphatic vessels and ultimately returns to the bloodstream via the thoracic duct, keeping the tissues "dry" (Fig. 4.1). **Elevated hydrostatic pressure or diminished colloid osmotic pressure disrupts this balance and results in increased movement of fluid out of vessels.** If the net rate of fluid movement exceeds the rate of lymphatic drainage, fluid accumulates. Within tissues the result is edema, and if a serosal surface is involved, fluid may accumulate within the adjacent body cavity as an effusion.

Edema fluids and effusions may be *inflammatory* or *noninflammatory* (Table 4.1). Inflammation-related edema and effusions are discussed in detail in Chapter 3. These

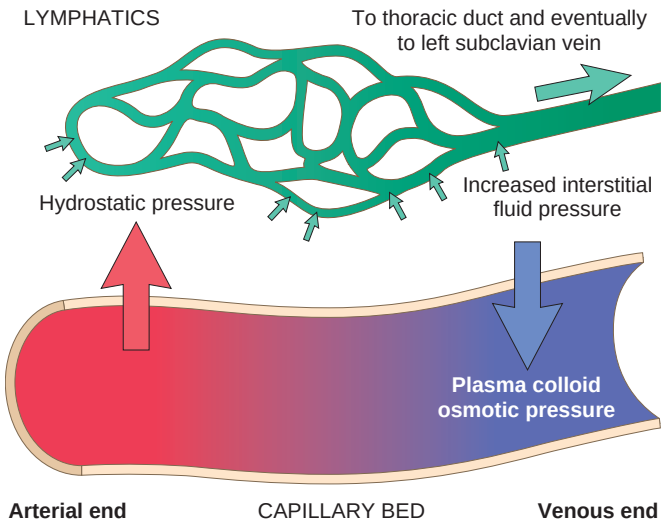

Figure 4.1 Factors influencing fluid movement across capillary walls. Normally, hydrostatic and osmotic forces are nearly balanced so that there is little net movement of fluid out of vessels. Many different pathologic disorders (see Table 4.1) are associated with increases in capillary hydrostatic pressure or decreases in plasma osmotic pressure that lead to the extravasation of fluid into tissues. Lymphatic vessels remove much of the excess fluid, but if the capacity for lymphatic drainage is exceeded, tissue edema results.

protein-rich *exudates* accumulate due to increases in vascular permeability caused by inflammatory mediators. In contrast, noninflammatory edema and effusions are protein-poor fluids called *transudates*. Noninflammatory edema and effusions are common in many disorders, including heart failure, liver failure, renal disease, and malnutrition (Fig. 4.2). We will now discuss the various causes of edema.

Increased Hydrostatic Pressure

Increases in hydrostatic pressure are mainly caused by disorders that impair venous return. If the impairment is localized (e.g., a deep venous thrombosis [DVT] in a lower extremity), then the resulting edema is confined to the affected part. Conditions leading to systemic increases in venous pressure (e.g., congestive heart failure, Chapter 12) are understandably associated with more widespread edema.

Reduced Plasma Osmotic Pressure

Under normal circumstances albumin accounts for almost half of the total plasma protein; it follows that conditions leading to inadequate synthesis or increased loss of albumin from the circulation are common causes of reduced plasma oncotic pressure. Reduced albumin synthesis occurs mainly in severe liver diseases (e.g., end-stage cirrhosis, Chapter 18) and protein malnutrition (Chapter 9). An important cause of albumin loss is the *nephrotic syndrome* (Chapter 20), in which albumin leaks into the urine through abnormally permeable glomerular capillaries. Regardless of cause, reduced plasma osmotic pressure leads in a stepwise fashion to edema, reduced intravascular volume, renal hypoperfusion, and secondary hyperaldosteronism. Not only does the ensuing salt and water retention by the kidney fail to correct the plasma volume deficit, but it also exacerbates the edema, because the primary defect—a low plasma protein level—persists.

Sodium and Water Retention

Increased salt retention—with obligate retention of associated water—causes both increased hydrostatic pressure (due to intravascular fluid volume expansion) and diminished vascular colloid osmotic pressure (due to dilution). Salt retention occurs whenever renal function is compromised, such as in primary kidney disorders and in cardiovascular disorders that decrease renal perfusion. One of the most important causes of renal hypoperfusion is congestive heart failure, which (like hypoproteinemia) results in the activation of the renin-angiotensin-aldosterone axis. In early heart failure, this response is beneficial, as the retention of sodium and water and other adaptations, including increased vascular tone and elevated levels of antidiuretic hormone, improve cardiac output and restore normal renal perfusion. However, as heart failure worsens and cardiac output diminishes, the retained fluid merely increases the hydrostatic pressure, leading to edema and effusions.

Lymphatic Obstruction

Trauma, fibrosis, invasive tumors, and infectious agents can all disrupt lymphatic vessels and impair the clearance of interstitial fluid, resulting in lymphedema in the affected part of the body. A dramatic example is seen in parasitic *filariasis,* in which the organism induces obstructive fibrosis

Table 4.1 Pathophysiologic Categories of Edema

Increased Hydrostatic Pressure
Impaired Venous Return
Congestive heart failure
Constrictive pericarditis
Ascites (liver cirrhosis)
Venous obstruction or compression
Thrombosis
External pressure (e.g., mass)
Lower extremity inactivity with prolonged dependency
Arteriolar Dilation
Heat
Neurohumoral dysregulation
Reduced Plasma Osmotic Pressure (Hypoproteinemia)
Protein-losing glomerulopathies (nephrotic syndrome)
Liver cirrhosis
Malnutrition
Protein-losing gastroenteropathy
Lymphatic Obstruction
Inflammatory
Neoplastic
Postsurgical
Postirradiation
Sodium Retention
Excessive salt intake with renal insufficiency
Increased tubular reabsorption of sodium
Renal hypoperfusion
Increased renin-angiotensin-aldosterone secretion
Inflammation
Acute inflammation
Chronic inflammation
Angiogenesis

Modified from Leaf A, Cotran RS: *Renal Pathophysiology,* ed 3, New York, 1985, Oxford University Press, p 146.

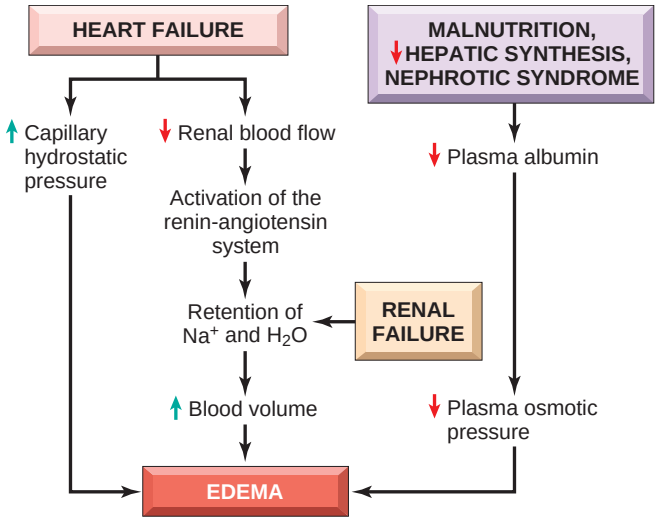

Figure 4.2 Mechanisms of systemic edema in heart failure, renal failure, malnutrition, hepatic failure, and nephrotic syndrome.

of lymphatic channels and lymph nodes. This may result in edema of the external genitalia and lower limbs that is so massive as to earn the appellation *elephantiasis*. Severe edema of the upper extremity may also complicate surgical removal and/or irradiation of the breast and associated axillary lymph nodes in patients with breast cancer.

MORPHOLOGY

Edema is easily recognized grossly; microscopically, it is appreciated as clearing and separation of the extracellular matrix (ECM) and subtle cell swelling. Edema is most commonly seen in subcutaneous tissues, the lungs, and the brain. **Subcutaneous edema** can be diffuse or more conspicuous in regions with high hydrostatic pressures. Its distribution is often influenced by gravity (e.g., it appears in the legs when standing and the sacrum when recumbent), a feature termed **dependent edema.** Finger pressure over markedly edematous subcutaneous tissue displaces the interstitial fluid and leaves a depression, a sign called **pitting edema.**

Edema resulting from **renal dysfunction** often appears initially in parts of the body containing loose connective tissue, such as the eyelids; **periorbital edema** is thus a characteristic finding in severe renal disease. With **pulmonary edema,** the lungs are often two to three times their normal weight, and sectioning yields frothy, blood-tinged fluid—a mixture of air, edema, and extravasated red cells. **Brain edema** can be localized or generalized depending on the nature and extent of the pathologic process or injury. The swollen brain exhibits narrowed sulci and distended gyri, which are compressed by the unyielding skull (Chapter 28).

Effusions involving the pleural cavity **(hydrothorax),** the pericardial cavity **(hydropericardium),** or the peritoneal cavity (**hydroperitoneum** or **ascites**) are common in a wide range of clinical settings. Transudative effusions are typically protein-poor, translucent, and straw colored; an exception are peritoneal effusions caused by lymphatic blockage (chylous effusion), which may be milky due to the presence of lipids absorbed from the gut. In contrast, exudative effusions are protein-rich and often cloudy due to the presence of white cells.

Clinical Features

The consequences of edema range from merely annoying to rapidly fatal. Subcutaneous edema is important primarily because it signals potential underlying cardiac or renal disease; however, when significant, it can also impair wound healing and the clearance of infections. Pulmonary edema is a common clinical problem that is most frequently seen in the setting of left ventricular failure; it can also occur with renal failure, acute respiratory distress syndrome (Chapter 15), and pulmonary inflammation or infection. Edema in the pulmonary interstitium and the alveolar spaces impedes gas exchange (leading to hypoxemia) and also creates a favorable environment for bacterial infection. Pulmonary edema is often exacerbated by pleural effusions, which may further compromise gas exchange by compressing the underlying pulmonary parenchyma. Peritoneal effusions (ascites) resulting most commonly from portal hypertension are prone to seeding by bacteria, leading to serious and sometimes fatal infections. Brain edema is life threatening; if severe, brain substance can herniate (extrude) through the foramen magnum, or the brain stem vascular supply can be compressed. Either condition can injure the medullary centers and cause death (Chapter 28).

KEY CONCEPTS

EDEMA

Edema is the result of the movement of fluid from the vasculature into the interstitial spaces; the fluid may be protein-poor (transudate) or protein-rich (exudate).

Edema may be caused by:

- Increased hydrostatic pressure (e.g., heart failure)
- Decreased colloid osmotic pressure caused by reduced plasma albumin, either due to decreased synthesis (e.g., liver disease, protein malnutrition) or to increased loss (e.g., nephrotic syndrome)
- Increased vascular permeability (e.g., inflammation)
- Lymphatic obstruction (e.g., infection or neoplasia)
- Sodium and water retention (e.g., renal failure)

HYPEREMIA AND CONGESTION

Hyperemia and congestion both stem from increased blood volumes within tissues, but have different underlying mechanisms and consequences. Hyperemia is an active process in which arteriolar dilation (e.g., at sites of inflammation or in skeletal muscle during exercise) leads to increased blood flow. Affected tissues turn red *(erythema)* because of increased delivery of oxygenated blood. Congestion is a passive process resulting from reduced venous outflow of blood from a tissue. It can be systemic, as in cardiac failure, or localized, as in isolated venous obstruction. Congested tissues have an abnormal blue-red color *(cyanosis)* that stems from the accumulation of deoxygenated hemoglobin in the affected area. In long-standing *chronic passive congestion,* the associated chronic hypoxia may result in ischemic tissue injury and scarring. In chronically congested tissues, capillary rupture can also produce small hemorrhagic foci; subsequent catabolism of extravasated red cells can

leave residual telltale clusters of hemosiderin-laden macrophages. As a result of increased hydrostatic pressures, congestion commonly leads to edema.

MORPHOLOGY

Congested tissues take on a dusky reddish-blue color *(cyanosis)* due to red cell stasis and the presence of deoxygenated hemoglobin. Microscopically, **acute pulmonary congestion** is marked by engorged alveolar capillaries, alveolar septal edema, and focal intra-alveolar hemorrhage. In **chronic pulmonary congestion,** which is often caused by congestive heart failure, the septa are thickened and fibrotic, and the alveoli often contain numerous macrophages laden with hemosiderin **(heart failure cells)** derived from phagocytosed red cells. In **acute hepatic congestion,** the central vein and sinusoids are distended. Because the centrilobular area is at the distal end of the hepatic blood supply, centrilobular hepatocytes may undergo ischemic necrosis, and the periportal hepatocytes—better oxygenated because of proximity to hepatic arterioles—may only develop fatty change. In **chronic passive hepatic congestion,** the centrilobular regions are grossly red-brown and slightly depressed (because of cell death) and are accentuated against the surrounding zones of uncongested tan liver **(nutmeg liver)** (Fig. 4.3A). Microscopically, there is centrilobular congestion and hemorrhage, hemosiderin-laden macrophages, and variable degrees of hepatocyte dropout and necrosis (see Fig. 4.3*B*).

HEMOSTASIS, HEMORRHAGIC DISORDERS, AND THROMBOSIS

Hemostasis can be defined simply as the process by which blood clots form at sites of vascular injury. Hemostasis is essential for life and is deranged to varying degrees in a broad range of disorders, which can be divided into two groups. In hemorrhagic disorders, characterized by excessive bleeding, hemostatic mechanisms are either blunted or insufficient to prevent blood loss. By contrast, in thrombotic disorders blood clots (often referred to as thrombi) form within intact blood vessels or within the chambers of the heart. As is discussed in Chapters 11 and 12, thrombosis has a central role in the most common and clinically important forms of cardiovascular disease.

Although useful, it must be recognized that this division between bleeding and thrombotic disorders sometimes breaks down, in that generalized activation of clotting sometimes paradoxically produces bleeding due to the consumption of coagulation factors, as in *disseminated intravascular coagulation (DIC)*. To provide context for understanding disorders of bleeding and clotting, this discussion begins with normal hemostasis, focusing on the contribution of platelets, coagulation factors, and endothelium.

Normal Hemostasis

Hemostasis is a precisely orchestrated process involving platelets, clotting factors, and endothelium that occurs at the site of vascular injury and culminates in the formation of a blood clot, which serves to prevent or limit the extent of bleeding. The general sequence of events leading to hemostasis at a site of vascular injury is shown in Fig. 4.4.

- *Arteriolar vasoconstriction* occurs immediately and markedly reduces blood flow to the injured area (see Fig. 4.4A). It is mediated by reflex neurogenic mechanisms and may be augmented by the local secretion of factors such as *endothelin,* a potent endothelium-derived vasoconstrictor. This effect is transient, however, and bleeding would resume if not for activation of platelets and coagulation factors.
- *Primary hemostasis: the formation of the platelet plug*. Disruption of the endothelium exposes subendothelial von Willebrand factor (vWF) and collagen, which promote platelet adherence and activation. Activation of platelets results in a dramatic shape change (from small rounded discs to flat plates with spiky protrusions that markedly increase surface area), as well as the release of secretory granules. Within a few minutes, the secreted products recruit additional platelets that undergo aggregation to form a primary hemostatic plug (see Fig. 4.4B).
- *Secondary hemostasis: deposition of fibrin.* Vascular injury exposes *tissue factor* at the site of injury. Tissue factor is

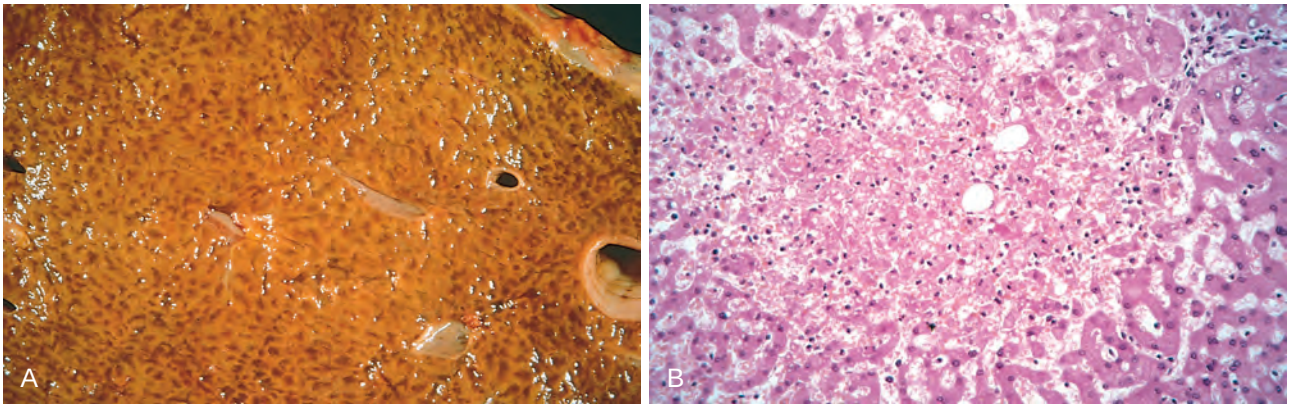

Figure 4.3 Liver with chronic passive congestion and hemorrhagic necrosis. (A) Central areas are red and slightly depressed compared with the surrounding tan viable parenchyma, forming a "nutmeg liver" pattern (so-called because it resembles the cut surface of a nutmeg). (B) Centrilobular necrosis with degenerating hepatocytes and hemorrhage. (Courtesy Dr. James Crawford, Department of Pathology, University of Florida, Gainesville, Fla.)

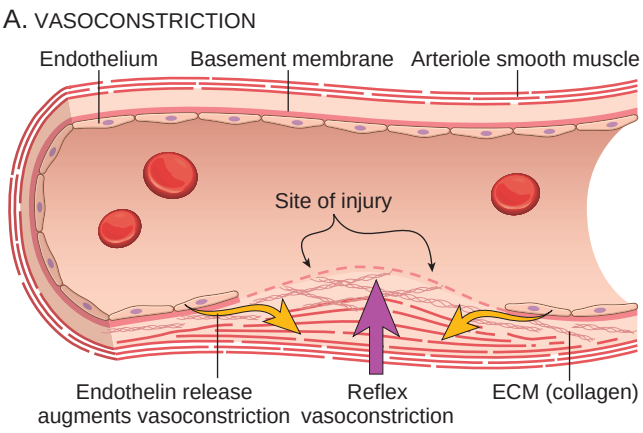
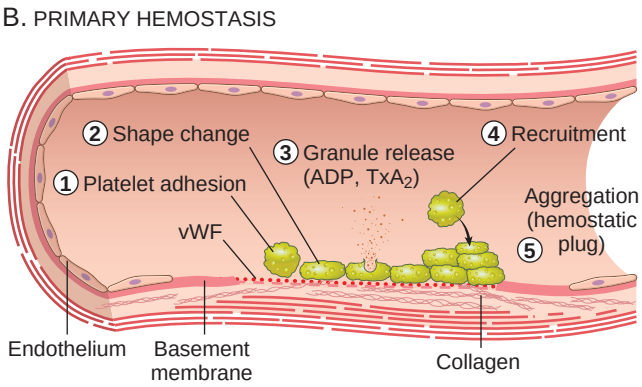
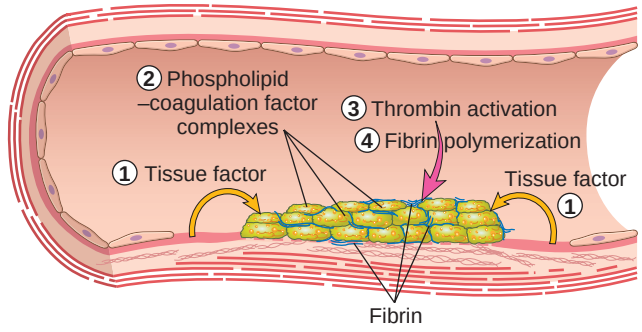
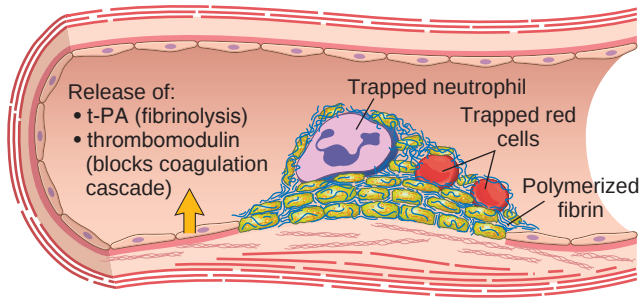
Figure 4.4 Normal hemostasis. (A) After vascular injury, neurohumoral factors induce transient vasoconstriction. (B) Platelets bind via glycoprotein Ib *(GpIb)* receptors to von Willebrand factor *(vWF)* on exposed extracellular matrix *(ECM)* and are activated, undergoing a shape change and granule release. Released adenosine diphosphate *(ADP)* and thromboxane A_2 *(TxA_2)* induce additional platelet aggregation through platelet GpIIb-IIIa receptor binding to fibrinogen, and form the primary hemostatic plug. (C) Local activation of the coagulation cascade (involving tissue factor and platelet phospholipids) results in fibrin polymerization, "cementing" the platelets into a definitive secondary hemostatic plug. (D) Counterregulatory mechanisms, mediated by tissue plasminogen activator (*t-PA*, a fibrinolytic product) and thrombomodulin, confine the hemostatic process to the site of injury.









a membrane-bound procoagulant glycoprotein that is normally expressed by subendothelial cells in the vessel wall, such as smooth muscle cells and fibroblasts. Tissue factor binds and activates factor VII (see later), setting in motion a cascade of reactions that culminates in *thrombin* generation. Thrombin cleaves circulating fibrinogen into insoluble *fibrin,* creating a fibrin meshwork, and also is a potent activator of platelets, leading to additional platelet aggregation at the site of injury. This sequence, referred to as *secondary hemostasis,* consolidates the initial platelet plug (see Fig. 4.4C).

- *Clot stabilization and resorption*. Polymerized fibrin and platelet aggregates undergo contraction to form a solid, permanent plug that prevents further hemorrhage. At this stage, counterregulatory mechanisms (e.g., tissue plasminogen activator [t-PA] made by endothelial cells) are set into motion that limit clotting to the site of injury (see Fig. 4.4D) and eventually lead to clot resorption and tissue repair.

It should be emphasized that endothelial cells are central regulators of hemostasis; the balance between the antithrombic and prothrombotic activities of endothelium determines whether thrombus formation, propagation, or dissolution occur. Normal endothelial cells express a variety of *anticoagulant* factors that inhibit platelet aggregation and coagulation and promote fibrinolysis; after injury or activation, however, this balance shifts, and endothelial cells acquire numerous *procoagulant* activities (activation of platelets and clotting factor, described earlier; see also Fig. 4.10). Besides trauma, endothelium can be activated by microbial pathogens, hemodynamic forces, and pro-inflammatory mediators.

We now describe roles of platelets, coagulation factors, and endothelium in hemostasis in greater detail, following the scheme illustrated in Fig. 4.4.

Platelets

Platelets play a critical role in hemostasis by forming the primary plug that initially seals vascular defects and by providing a surface that binds and concentrates activated coagulation factors. Platelets are disc-shaped anucleate cell fragments that are shed from megakaryocytes in the bone marrow into the bloodstream. Their function depends on several glycoprotein receptors, a contractile cytoskeleton, and two types of cytoplasmic granules. α-*Granules* have the adhesion molecule P-selectin on their membranes (Chapter 3)

and contain proteins involved in coagulation, such as fibrinogen, coagulation factor V, and vWF, as well as protein factors that may be involved in wound healing, such as fibronectin, platelet factor 4 (PF4, a heparin-binding chemokine), platelet-derived growth factor (PDGF), and transforming growth factor-β. *Dense* (or δ) *granules* contain adenosine diphosphate (ADP), adenosine triphosphate, ionized calcium, serotonin, and epinephrine.

After a traumatic vascular injury, platelets encounter constituents of the subendothelial connective tissue, such as vWF and collagen. On contact with these proteins, platelets undergo a sequence of reactions that culminate in the formation of a platelet plug (see Fig. 4.4B).

- *Platelet adhesion* is mediated largely via interactions between the platelet surface receptor glycoprotein Ib (GpIb) and vWF in the subendothelial matrix (Fig. 4.5). Platelets also adhere to exposed collagen via the platelet collagen receptor Gp1a/IIa. Notably, genetic deficiencies of vWF (von Willebrand disease, Chapter 14) or GpIb (Bernard-Soulier syndrome) result in bleeding disorders, attesting to the importance of these factors.
- *Platelets rapidly change shape* following adhesion, being converted from smooth discs to spiky "sea urchins" with greatly increased surface area. This change is accompanied by conformational changes in cell surface *glycoprotein IIb/IIIa* that increase its affinity for fibrinogen and by the translocation of *negatively charged phospholipids* (particularly phosphatidylserine) to the platelet surface. These phospholipids bind calcium and serve as nucleation sites for the assembly of coagulation factor complexes.
- *Secretion (release reaction) of granule contents* occurs along with changes in shape; these two events are often referred to together as platelet activation. Platelet activation is triggered by a number of factors, including the coagulation factor thrombin and ADP. Thrombin activates platelets through a special G-protein–coupled receptor referred to as *protease-activated receptor-1* (PAR-1), which is switched on by a proteolytic cleavage carried out by thrombin. ADP is a component of dense-body granules; thus, platelet activation and ADP release begets additional rounds of platelet activation, a phenomenon referred to as *recruitment*. ADP acts by binding two G-protein–coupled receptors. $P2Y_1$ and $P2Y_{12}$. Activated platelets also produce the prostaglandin *thromboxane* A_2 (TxA_2), a potent inducer of platelet aggregation. An understanding of the biochemical pathways involved in platelet activation has led to the development of drugs with antiplatelet activities. Aspirin, the oldest of all, inhibits platelet aggregation and produces a mild bleeding defect by inhibiting cyclooxygenase, a platelet enzyme that is required for TxA_2 synthesis. More recently, drugs that inhibit platelet function by antagonizing PAR-1 or $P2Y_{12}$ have been developed. All of these antiplatelet drugs are used in the treatment of coronary artery disease.
- *Platelet aggregation* follows their activation. The conformational change in glycoprotein IIb/IIIa that occurs with platelet activation allows binding of fibrinogen, a large bivalent plasma polypeptide that forms bridges between adjacent platelets, leading to their aggregation. Predictably, inherited deficiency of GpIIb-IIIa results in a bleeding disorder called *Glanzmann thrombasthenia*. The initial wave of aggregation is reversible, but concurrent activation of thrombin stabilizes the platelet plug by causing further platelet activation and aggregation, and by promoting irreversible platelet contraction. Platelet contraction is dependent on the cytoskeleton and consolidates the aggregated platelets. In parallel, thrombin also converts fibrinogen into insoluble *fibrin*, cementing the platelets in place and creating the definitive *secondary hemostatic plug*. Entrapped red cells and leukocytes are also found in hemostatic plugs, in part due to adherence of leukocytes to P-selectin expressed on activated platelets.

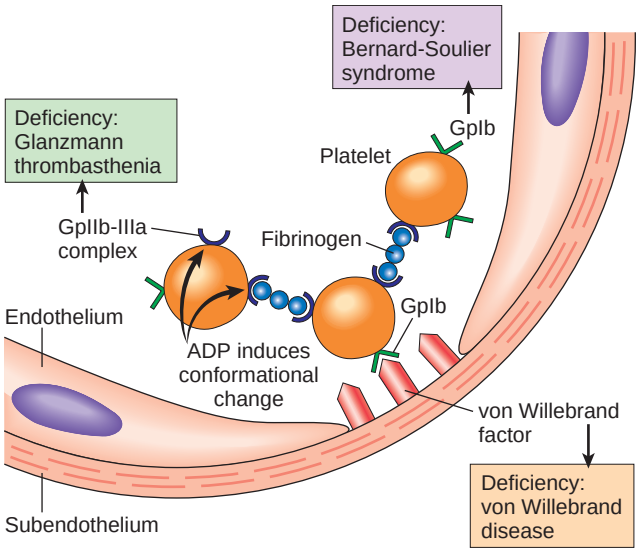


Figure 4.5 Platelet adhesion and aggregation. Von Willebrand factor functions as an adhesion bridge between subendothelial collagen and the glycoprotein Ib *(GpIb)* platelet receptor. Aggregation is accomplished by fibrinogen bridging GpIIb-IIIa receptors on different platelets. Congenital deficiencies in the various receptors or bridging molecules lead to the diseases indicated in the colored boxes. *ADP*, Adenosine diphosphate.

KEY CONCEPTS

PLATELET ADHESION, ACTIVATION, AND AGGREGATION

- Endothelial injury exposes the underlying basement membrane ECM; platelets adhere to the ECM primarily through the binding of platelet GpIb receptors to VWF.
- Adhesion leads to platelet activation, an event associated with secretion of platelet granule contents, including calcium (a cofactor for several coagulation proteins) and ADP (a mediator of further platelet activation); dramatic changes in shape and membrane composition; and activation of GpIIb/IIIa receptors.
- The GpIIb/IIIa receptors on activated platelets form bridging cross-links with fibrinogen, leading to platelet aggregation.
- Concomitant activation of thrombin promotes fibrin deposition, cementing the platelet plug in place.

Coagulation Cascade

The coagulation cascade is a series of amplifying enzymatic reactions that lead to the deposition of an insoluble fibrin clot. As discussed later, the dependency of clot formation on various factors differs in the laboratory test tube and in

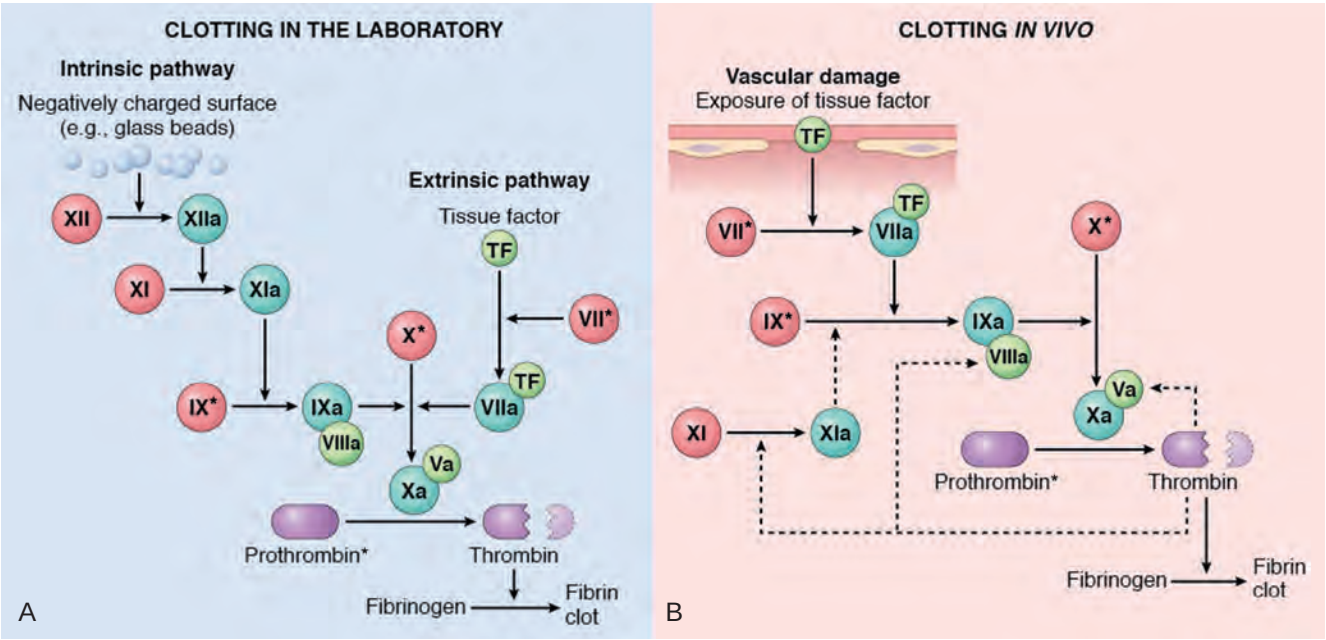

Figure 4.6 The coagulation cascade in the laboratory and in vivo. (A) Clotting is initiated in the laboratory by adding phospholipids, calcium, and either a negatively charged substance such as glass beads (intrinsic pathway) or a source of tissue factor (extrinsic pathway). (B) In vivo, tissue factor is the major initiator of coagulation, which is amplified by feedback loops involving thrombin (dotted lines). The red polypeptides are inactive factors, the dark green polypeptides are active factors, and the light green polypeptides correspond to cofactors (reaction accelerators). Factors marked with an asterisk (*) are vitamin K dependent as are protein C and S (not depicted). Warfarin acts as an anticoagulant by inhibiting the γ-carboxylation of the vitamin K–dependent coagulation factors. Vitamin K is an essential cofactor for the synthesis of all of these vitamin K–dependent clotting factors.

blood vessels in vivo (Fig. 4.6). However, clotting in vitro and in vivo both follow the same general principles, as follows.

The cascade of reactions in the pathway can be likened to a "dance" in which coagulation factors are passed from one partner to the next (Fig. 4.7). Each reaction step involves an enzyme (an activated coagulation factor), a substrate (an inactive proenzyme form of a coagulation factor), and a cofactor (a reaction accelerator). These components are assembled on a negatively charged phospholipid surface, which is provided by activated platelets. Assembly of

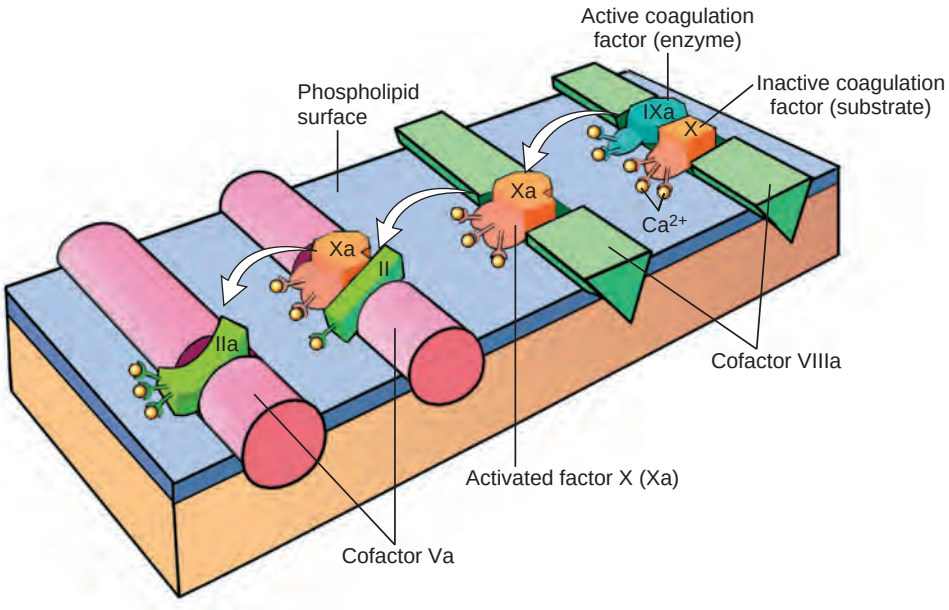

Figure 4.7 Schematic illustration of the conversion of factor X to factor Xa, which in turn converts factor II (prothrombin) to factor IIa (thrombin) (see Fig. 4.6B). The initial reaction complex consists of a proteolytic enzyme (factor IXa), a substrate (factor X), and a reaction accelerator (factor VIIIa), all assembled on a platelet phospholipid surface. Calcium ions hold the assembled components together and are essential for the reaction. Activated factor Xa becomes the protease for the second adjacent complex in the coagulation cascade, converting prothrombin substrate (II) to thrombin (IIa) using factor Va as the reaction accelerator.

reaction complexes also depends on calcium, which binds to γ-carboxylated glutamic acid residues that are present in factors II, VII, IX, and X. The enzymatic reactions that produce γ-carboxylated glutamic acid use vitamin K as a cofactor and are antagonized by drugs such as coumadin, used as an anticoagulant.

Based on assays performed in clinical laboratories, the coagulation cascade can be divided into the *extrinsic* and *intrinsic* pathways (see Fig. 4.6A).

- The *prothrombin time* (PT) assay assesses the function of the proteins in the extrinsic pathway (factors VII, X, V, II [prothrombin], and fibrinogen). In brief, tissue factor, phospholipids, and calcium are added to plasma, and the time for a fibrin clot to form is recorded.
- The *partial thromboplastin time* (PTT) assay screens the function of the proteins in the intrinsic pathway (factors XII, XI, IX, VIII, X, V, II, and fibrinogen). In this assay, clotting of plasma is initiated by the addition of negatively charged particles (e.g., ground glass) that activate factor XII (Hageman factor) together with phospholipids and calcium, and the time to fibrin clot formation is recorded.

Although the PT and PTT assays are of great utility in evaluating coagulation factor function in patients, they do not recapitulate the events that lead to coagulation in vivo. This point is most clearly made by considering the clinical effects of deficiencies of various coagulation factors. Deficiencies of factors V, VII, VIII, IX, and X are associated with moderate to severe bleeding disorders, and prothrombin deficiency is likely incompatible with life. In contrast, factor XI deficiency is only associated with mild bleeding, and individuals with factor XII deficiency do not bleed and in fact may be susceptible to thrombosis. By contrast, there is evidence from experimental models suggesting that in some circumstances factor XII may contribute to thrombosis. These paradoxical findings may stem from involvement of factor XII in several pathways, including the pro-inflammatory bradykinin pathway as well as fibrinolysis (discussed later).

Based on the effects of various factor deficiencies in humans, it is believed that, in vivo, factor VIIa/tissue factor complex is the most important activator of factor IX and that factor IXa/factor VIIIa complex is the most important activator of factor X (see Fig. 4.6B). The mild bleeding tendency seen in patients with factor XI deficiency is likely explained by the ability of thrombin to activate factor XI (as well as factors V and VIII), a feedback mechanism that amplifies the coagulation cascade.

Among the coagulation factors, thrombin is the most important, because its various enzymatic activities control diverse aspects of hemostasis and link clotting to inflammation and repair. Among thrombin's most important activities are the following:

- *Conversion of fibrinogen into cross-linked fibrin.* Thrombin directly converts soluble fibrinogen into fibrin monomers that polymerize into an insoluble fibril, and also amplifies the coagulation process, not only by activating factor XI, but also by activating two critical cofactors: factors V and VIII. It also stabilizes the secondary hemostatic plug by activating factor XIII, which covalently cross-links fibrin.
- *Platelet activation.* Thrombin is a potent inducer of platelet activation and aggregation through its ability to activate PAR-1, thereby linking platelet function to coagulation.

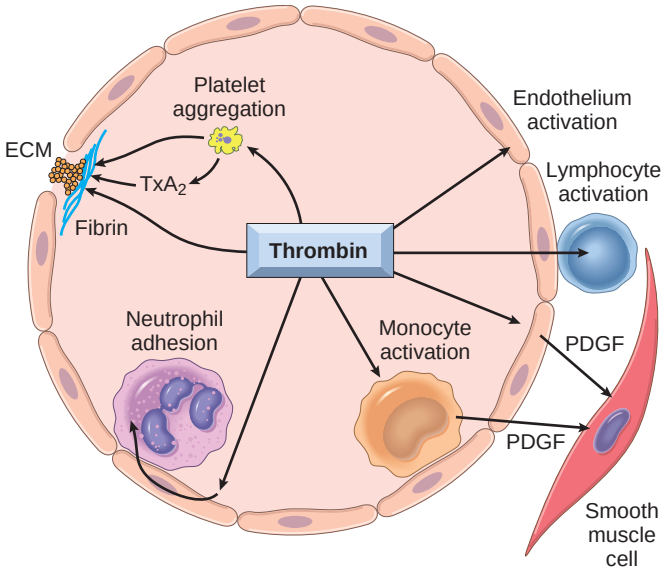

Figure 4.8 Role of thrombin in hemostasis and cellular activation. Thrombin plays a critical role in generating cross-linked fibrin (by cleaving fibrinogen to fibrin and by activating factor XIII), as well as activating several other coagulation factors (see Fig. 4.6B). Through protease-activated receptors (PARs, see text), thrombin also modulates several cellular activities. It directly induces platelet aggregation and TxA_2 production, and activates endothelial cells, which respond by expressing adhesion molecules and cytokine mediators (e.g., *PDGF*). Thrombin also directly activates leukocytes. *ECM*, Extracellular matrix; *PDGF*, platelet-derived growth factor. See Fig. 4.10 for additional anticoagulant activities mediated by thrombin. (Courtesy Shaun Coughlin, MD, PhD, Cardiovascular Research Institute, University of California at San Francisco; modified with permission.)

- *Pro-inflammatory effects.* PARs also are expressed on inflammatory cells, endothelium, and other cell types (Fig. 4.8), and activation of these receptors by thrombin is believed to mediate pro-inflammatory effects that contribute to tissue repair and angiogenesis.
- *Anticoagulant effects.* Remarkably, through mechanisms described later, on encountering normal endothelium, thrombin changes from a procoagulant to an anticoagulant; this reversal in function prevents clots from extending beyond the site of the vascular injury.

Factors That Limit Coagulation

Once initiated, coagulation must be restricted to the site of vascular injury to prevent deleterious consequences. One limiting factor is simple dilution; blood flowing past the site of injury washes out activated coagulation factors, which are rapidly removed by the liver. A second is the requirement for negatively charged phospholipids, which, as mentioned, are mainly provided by platelets that have been activated by contact with subendothelial matrix at sites of vascular injury. However, the most important counter-regulatory mechanisms involve factors that are expressed by intact endothelium adjacent to the site of injury (described later).

Activation of the coagulation cascade also sets into motion a fibrinolytic cascade that limits the size of the clot and contributes to its later dissolution (Fig. 4.9). Fibrinolysis is largely accomplished through the enzymatic activity of

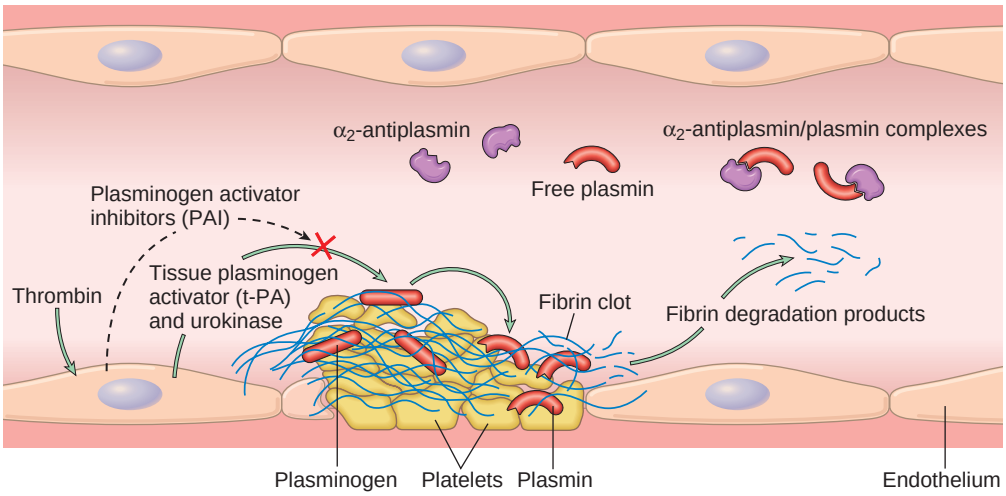

Figure 4.9 The fibrinolytic system, illustrating various plasminogen activators and inhibitors (see text).

plasmin, which breaks down fibrin and interferes with its polymerization. An elevated level of breakdown products of fibrinogen (often called fibrin split products), most notably fibrin-derived *D-dimers,* are a useful clinical marker of several thrombotic states (described later). Plasmin is generated by enzymatic catabolism of the inactive circulating precursor *plasminogen*, either by a factor XII–dependent pathway (possibly explaining the association of factor XII deficiency and thrombosis) or by plasminogen activators. The most important plasminogen activator is t-PA; it is synthesized principally by endothelium and is most active when bound to fibrin. This characteristic makes t-PA a useful therapeutic agent, since its fibrinolytic activity is largely confined to sites of recent thrombosis. Once activated, plasmin is in turn tightly controlled by counterregulatory factors such as α_2-plasmin inhibitor, a plasma protein that binds and rapidly inhibits free plasmin.

KEY CONCEPTS

COAGULATION FACTORS

- Coagulation occurs via the sequential enzymatic conversion of a cascade of circulating and locally synthesized proteins.
- Tissue factor elaborated at sites of injury is the most important initiator of the coagulation cascade in vivo.
- At the final stage of coagulation, thrombin converts fibrinogen into insoluble fibrin that contributes to formation of the definitive hemostatic plug.
- Coagulation normally is restricted to sites of vascular injury by:
  - Limiting enzymatic activation to phospholipid surfaces provided by activated platelets or endothelium
  - Circulating inhibitors of coagulation factors, such as antithrombin III, whose activity is augmented by heparin-like molecules expressed on endothelial cells
  - Expression of thrombomodulin on normal endothelial cells, which binds thrombin and converts it to an anticoagulant
  - Activation of fibrinolytic pathways (e.g., by association of t-PA with fibrin)

Endothelium

The balance between the anticoagulant and procoagulant activities of endothelium often determines whether clot formation, propagation, or dissolution occurs (Fig. 4.10). Normal endothelial cells express a multitude of factors that inhibit the procoagulant activities of platelets and coagulation factors and that augment fibrinolysis. These factors act in concert to prevent thrombosis and to limit clotting to sites of vascular damage. However, if injured or exposed to proinflammatory factors, endothelial cells lose many of their antithrombotic properties. Here, we complete the discussion of hemostasis by focusing on the antithrombotic activities of normal endothelium; we return to the "dark side" of endothelial cells later when discussing thrombosis.

The antithrombotic properties of endothelium can be divided into activities directed at platelets, coagulation factors, and fibrinolysis.

- *Platelet inhibitory effects.* An obvious effect of intact endothelium is to serve as a barrier that shields platelets from subendothelial vWF and collagen. However, normal endothelium also releases a number of factors that inhibit platelet activation and aggregation. Among the most important are *prostacyclin (PGI_2), nitric oxide (NO),* and *adenosine diphosphatase*; the latter degrades ADP, already discussed as a potent activator of platelet aggregation. The major regulator of NO and PGI_2 production appears to be flow; precisely what senses flow is uncertain, though changes in cell shape and cytoskeleton are correlated. PGI_2 is produced by COX-1, which is expressed constitutively by "healthy" endothelium under normal flow conditions. NO is the product of endothelial nitric oxide synthase eNOS.
- *Anticoagulant effects.* Normal endothelium shields coagulation factors from tissue factor in vessel walls and expresses multiple factors that actively oppose coagulation, most notably thrombomodulin, endothelial protein C receptor, heparin-like molecules, and tissue factor pathway inhibitor. Thrombomodulin and endothelial protein C receptor bind thrombin and protein C, respectively, in a complex on the endothelial cell surface. When bound in this complex, thrombin loses its ability to activate coagulation

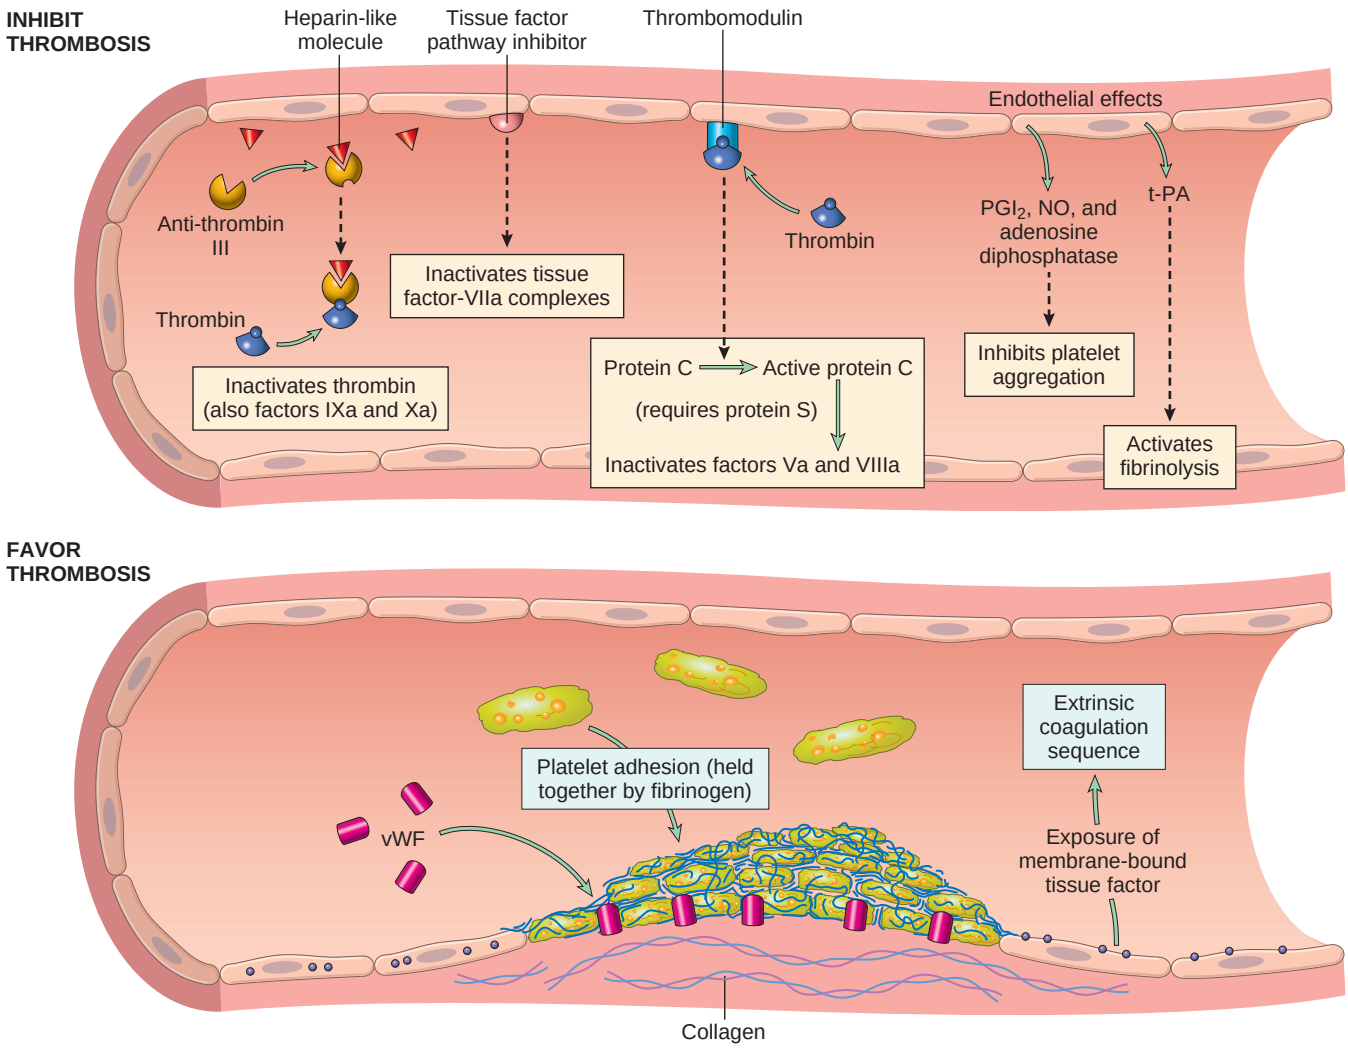

Figure 4.10 Anticoagulant activities of normal endothelium *(top)* and procoagulant properties of injured or activated endothelium *(bottom)*. *NO*, Nitric oxide; *PGI_2*, prostacyclin; *t-PA*, tissue plasminogen activator; *vWF*, von Willebrand factor. The thrombin receptor is one of the protease-activated receptors (PAR).

factors and platelets, and instead cleaves and activates protein C, a vitamin K–dependent protease that requires a cofactor, protein S. Activated protein C/protein S complex is a potent inhibitor of coagulation cofactors Va and VIIIa. *Heparin-like molecules* on the surface of endothelium bind and activate antithrombin III, which then inhibits thrombin and factors IXa, Xa, XIa, and XIIa. The clinical utility of heparin and related drugs is based on their ability to stimulate antithrombin III activity. Tissue factor pathway inhibitor (TFPI), like protein C, requires protein S as a cofactor and, as the name implies, binds and inhibits tissue factor/factor VIIa complexes.

- *Fibrinolytic effects.* Normal endothelial cells synthesize t-PA, as already discussed, a key component of the fibrinolytic pathway.

Hemorrhagic Disorders

Disorders associated with abnormal bleeding inevitably stem from primary or secondary defects in vessel walls, platelets, or coagulation factors, all of which must function properly to ensure hemostasis. The presentation of abnormal bleeding varies widely. At one end of the spectrum are massive bleeds associated with ruptures of large vessels such as the aorta or of the heart; these catastrophic events simply overwhelm hemostatic mechanisms and are often fatal. Diseases associated with sudden, massive hemorrhage include aortic dissection and aortic abdominal aneurysm (Chapter 11) and myocardial infarction (Chapter 12) complicated by rupture of the aorta or the heart. At the other end of the spectrum are subtle defects in clotting that only become evident under conditions of hemostatic stress, such as surgery, childbirth, dental procedures, menstruation, or trauma. Among the most common causes of mild bleeding tendencies are inherited defects in vWF (Chapter 14), aspirin consumption, and uremia (renal failure); the latter alters platelet function through uncertain mechanisms. Between these extremes lie deficiencies of coagulation factors (the hemophilias, Chapter 14), which are usually inherited and lead to severe bleeding disorders if untreated.

Additional specific examples of disorders associated with abnormal bleeding are discussed throughout the book. The

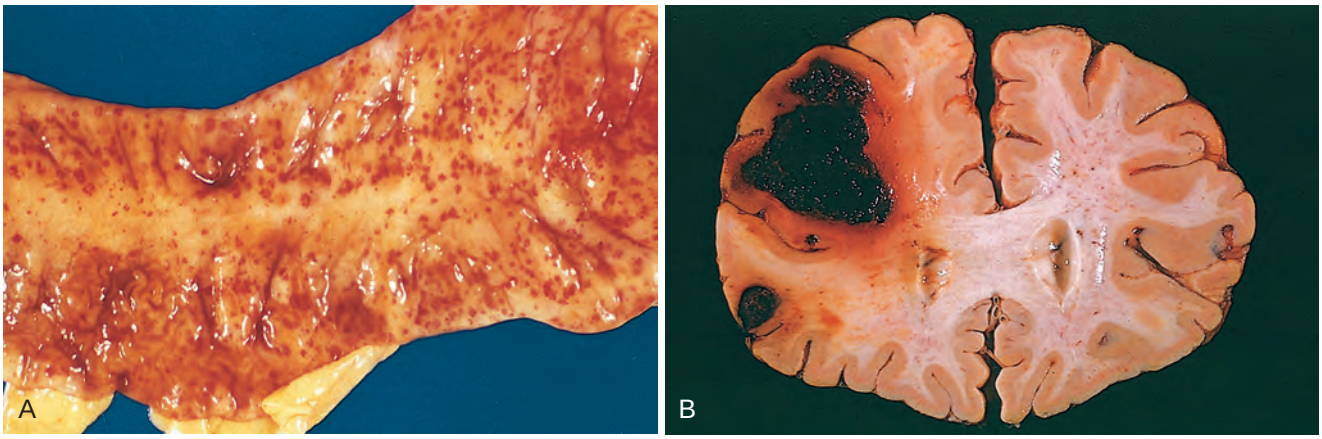

Figure 4.11 (A) Punctate petechial hemorrhages of the colonic mucosa, a consequence of thrombocytopenia. (B) Fatal intracerebral bleed.

following are general principles related to abnormal bleeding and its consequences.

- *Defects of primary hemostasis (platelet defects or von Willebrand disease)* often present with small bleeds in skin or mucosal membranes. These bleeds typically take the form of petechiae, minute 1- to 2-mm hemorrhages (Fig. 4.11A), or *purpura,* which are slightly larger (≥3 mm) than petechiae. It is believed that the capillaries of the mucosa and skin are particularly prone to rupture following minor trauma and that under normal circumstances platelets seal these defects virtually immediately. Mucosal bleeding associated with defects in primary hemostasis may also take the form of epistaxis (nosebleeds), gastrointestinal bleeding, or excessive menstruation (menorrhagia). A feared complication of very low platelet counts *(thrombocytopenia)* is intracerebral hemorrhage, which may be fatal.
- *Defects of secondary hemostasis (coagulation factor defects)* often present with bleeds into soft tissues (e.g., muscle) or joints. Bleeding into joints *(hemarthrosis)* following minor trauma is particularly characteristic of hemophilia (Chapter 14). It is unknown why severe defects in secondary hemostasis present with this peculiar pattern of bleeding; as with severe platelet defects, intracranial hemorrhage, sometimes fatal, may also occur.
- *Generalized defects involving small vessels* often present with "palpable purpura" and ecchymoses. *Ecchymoses* (sometimes simply called *bruises*) are hemorrhages of 1 to 2 cm in size. In both purpura and ecchymoses, the volume of extravasated blood may be large enough to create a palpable mass of blood known as a *hematoma*. Purpura and ecchymoses are particularly characteristic of systemic disorders that disrupt small blood vessels (e.g., vasculitis, Chapter 11) or that lead to blood vessel fragility (e.g., amyloidosis, Chapter 6; scurvy, Chapter 9).

The clinical significance of hemorrhage depends on the volume of the bleed, the rate at which it occurs, and its location. Rapid loss of up to 20% of the blood volume may have little impact in healthy adults; greater losses, however, can cause *hemorrhagic (hypovolemic) shock* (discussed later). Bleeding that is relatively trivial in the subcutaneous tissues can cause death if located in the brain (see Fig. 4.11B); because the skull is unyielding, intracranial hemorrhage may increase intracranial pressure to a level that compromises the blood supply or causes herniation of the brain stem (Chapter 28). Finally, chronic or recurrent external blood loss (e.g., peptic ulcer or menstrual bleeding) causes iron loss and can lead to iron deficiency anemia. In contrast, when red cells are retained (e.g., hemorrhage into body cavities or tissues), iron is recovered and recycled for use in the synthesis of hemoglobin.

Thrombosis

The primary abnormalities that lead to thrombosis are (1) endothelial injury, (2) stasis or turbulent blood flow, and (3) hypercoagulability of the blood (the so-called *Virchow triad*) (Fig. 4.12). Thrombosis is one of the scourges of modern man, because it underlies the most serious and common forms of cardiovascular disease. Here, the focus is on its causes and consequences; its role in cardiovascular disorders is discussed in detail in Chapters 11 and 12.

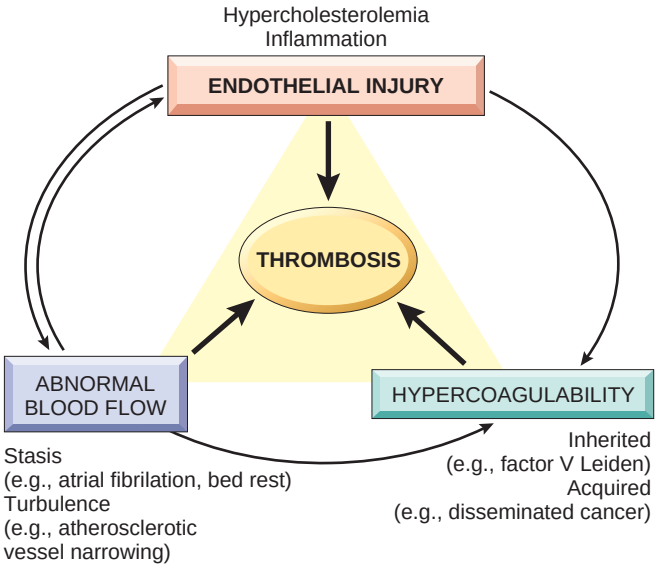

Figure 4.12 The Virchow triad in thrombosis. Endothelial integrity is the most important factor. Injury to endothelial cells can alter local blood flow and affect coagulability. Abnormal blood flow (stasis or turbulence), in turn, can cause endothelial injury. These factors may promote thrombosis independently or in combination.

Endothelial Injury

Endothelial injury leading to platelet activation almost inevitably underlies thrombus formation in the heart and the arterial circulation, where the high rates of blood flow impede clot formation. Notably, cardiac and arterial clots are typically rich in platelets, and it is believed that platelet adherence and activation is a necessary prerequisite for thrombus formation under high shear stress, such as exists in arteries. This insight provides part of the reasoning behind the use of aspirin and other platelet inhibitors in coronary artery disease and acute myocardial infarction.

Obviously, severe endothelial injury may trigger thrombosis by exposing vWF and tissue factor. However, inflammation and other noxious stimuli also promote thrombosis by shifting the pattern of gene expression in endothelium to one that is "prothrombotic." This change is sometimes referred to as *endothelial activation* or *dysfunction* and can be produced by diverse exposures, including physical injury, infectious agents, abnormal blood flow, inflammatory mediators, metabolic abnormalities, such as hypercholesterolemia or homocystinemia, and toxins absorbed from cigarette smoke. Endothelial activation is believed to have an important role in triggering arterial thrombotic events.

The role of endothelial cell activation and dysfunction in arterial thrombosis is discussed in detail in Chapters 11 and 12. Here it suffices to mention several of the major prothrombotic alterations:

- *Procoagulant changes.* Endothelial cells activated by inflammatory cytokines downregulate the expression of *thrombomodulin,* already described as a key modulator of thrombin activity, enhancing the procoagulant and pro-inflammatory actions of thrombin. In addition, inflamed endothelium also downregulates the expression of other anticoagulants, such as protein C and tissue factor protein inhibitor, changes that further promote a procoagulant state.
- *Antifibrinolytic effects.* Activated endothelial cells secrete *plasminogen activator inhibitors* (PAIs), which limit fibrinolysis, and downregulate the expression of t-PA, alterations that also favor the development of thrombi.

Alterations in Normal Blood Flow

Turbulence contributes to arterial and cardiac thrombosis by causing endothelial injury or dysfunction as well as by forming countercurrents that contribute to local pockets of stasis, whereas stasis is a major contributor to the development of venous thrombi Normal blood flow is laminar such that the platelets (and other blood cellular elements) flow centrally in the vessel lumen, separated from the endothelium by a slower moving layer of plasma. Turbulence and stasis therefore:

- *Promote endothelial activation,* enhancing procoagulant activity and leukocyte adhesion, in part through flow-induced changes in the expression of adhesion molecules and pro-inflammatory factors
- *Disrupt laminar flow* and bring platelets into contact with the endothelium
- *Prevent washout and dilution of activated clotting factors* by fresh flowing blood and the inflow of clotting factor inhibitors

Altered blood flow contributes to thrombosis in several clinical settings. Ulcerated atherosclerotic plaques not only expose subendothelial vWF and tissue factor but also cause turbulence. Aortic and arterial dilations called *aneurysms* result in local stasis and are therefore fertile sites for thrombosis (Chapter 11). Acute myocardial infarction results in areas of noncontractile myocardium and sometimes in cardiac aneurysm; both are associated with stasis and flow abnormalities that promote the formation of cardiac mural thrombi (Chapter 12). Rheumatic mitral valve stenosis results in left atrial dilation; in conjunction with atrial fibrillation, a dilated atrium is a site of profound stasis and a prime location for thrombosis (Chapter 12). Hyperviscosity (such as is seen with polycythemia vera; Chapter 13) increases resistance to flow and causes small vessel stasis, and the deformed red cells in *sickle cell anemia* (Chapter 14) impede blood flow through small vessels, with the resulting stasis also predisposing to thrombosis.

Hypercoagulability

Hypercoagulability refers to an abnormally high tendency of the blood to clot, and is typically caused by alterations in coagulation factors. Hypercoagulability has a particularly important role in venous thrombosis and can be divided into primary (genetic) and secondary (acquired) disorders (Table 4.2). Of the inherited causes of hypercoagulability,

Table 4.2 Hypercoagulable States

Primary (Genetic)
Common
Factor V mutation: factor V Leiden (Arg to Gln substitution in amino acid residue 506 leading to resistance to activated protein C)
Prothrombin mutation (G20210A noncoding sequence variant leading to increased prothrombin levels)
Increased levels of factors VIII, IX, XI, or fibrinogen (genetics unknown)
Rare
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Very Rare
Fibrinolysis defects
Homozygous homocystinuria (deficiency of cystathione β-synthetase)
Secondary (Acquired)
Strong Risk Factors for Thrombosis
Prolonged bed rest or immobilization
Myocardial infarction
Atrial fibrillation
Tissue injury (surgery, fracture, burn)
Cancer
Prosthetic cardiac valves
Disseminated intravascular coagulation
Heparin-induced thrombocytopenia
Antiphospholipid antibody syndrome
Other Risk Factors for Thrombosis
Cardiomyopathy
Nephrotic syndrome
Hyperestrogenic states (pregnancy and postpartum)
Oral contraceptive use
Sickle cell anemia
Smoking

point mutations in the factor V gene and prothrombin gene are the most common. These are listed below:

- *Factor V Leiden.* Approximately 2% to 15% of Caucasians carry a single-nucleotide mutation in factor V that is called factor V Leiden, after the city in the Netherlands where it was discovered. Among individuals with recurrent DVT, the frequency of this mutation is considerably higher, approaching 60%. This mutation renders factor V resistant to cleavage and inactivation by protein C. As a result, an important antithrombotic counterregulatory pathway is lost (see Fig. 4.10). The inheritance pattern for factor V Leiden is autosomal dominant. Heterozygotes have a fivefold increased relative risk of venous thrombosis, and homozygotes have a 50-fold increase.
- *Prothrombin gene mutation.* A single nucleotide change (G20210A) in the 3′-untranslated region of the prothrombin gene is another common mutation (1% to 2% of the population) associated with hypercoagulability. It leads to elevated prothrombin levels and an almost threefold increased risk of venous thrombosis.
- *Other inherited causes.* Rare inherited causes of primary hypercoagulability include deficiencies of anticoagulants such as antithrombin III, protein C, or protein S; affected individuals typically present with venous thrombosis and recurrent thromboembolism beginning in adolescence or early adulthood.
- *Homocysteinemia.* Elevated levels of homocysteine may be inherited or acquired. Marked elevations of homocysteine may be caused by an inherited deficiency of cystathione β-synthetase. Acquired causes include deficiency of vitamin B_6, B_{12}, and folic acid. Prothrombotic effects of homocysteine may be due to thioester linkages formed between homocysteine metabolites and a variety of proteins, including fibrinogen.

The most common thrombophilic genotypes found in various populations (heterozygosity for factor V Leiden and heterozygosity for the prothrombin G20210A variant) impart only a moderately increased risk of thrombosis; most individuals with these genotypes, when otherwise healthy, are free from thrombotic complications. However, factor V and prothrombin mutations are frequent enough that homozygosity and compound heterozygosity are not rare, and such genotypes are associated with greater risk. Moreover, individuals with such mutations have a significantly increased frequency of venous thrombosis in the setting of other acquired risk factors (e.g., pregnancy or prolonged bed rest). Thus, factor V Leiden heterozygosity may trigger deep vein thrombosis (DVT) when combined with enforced inactivity, such as during prolonged airplane travel. Consequently, **inherited causes of hypercoagulability must be considered in patients younger than 50 years of age who present with thrombosis—even when acquired risk factors are present.**

Unlike hereditary disorders, the pathogenesis of *acquired thrombophilia* is frequently multifactorial (see Table 4.2). In some cases (e.g., cardiac failure or trauma), stasis or vascular injury may be most important. Hypercoagulability due to oral contraceptive use or the hyperestrogenic state of pregnancy is probably caused by increased hepatic synthesis of coagulation factors and reduced anticoagulant synthesis. In disseminated cancers, release of various procoagulants from tumors predisposes to thrombosis. The hypercoagulability seen with advancing age may be due to reduced endothelial PGI_2 production. Smoking and obesity promote hypercoagulability by unknown mechanisms.

Among the acquired thrombophilic states, heparin-induced thrombocytopenia and antiphospholipid antibody syndrome are particularly important clinical problems that deserve special mention.

Heparin-Induced Thrombocytopenia (HIT) Syndrome

HIT syndrome is a serious, potentially life-threatening disorder that occurs following the administration of *unfractionated heparin*. It results from the formation of antibodies that recognize complexes of heparin and PF4 on the surface of platelets (Chapter 14), as well as complexes of heparin-like molecules and PF4-like proteins on endothelial cells. PF4 protein is normally found in platelet alpha granules and is released on activation of platelets. Released PF4 binds to heparin and undergoes a conformational change that results in the formation of a neoantigen against which IgG antibodies are formed. PF4-IgG immune complex (Fig. 4.13) attaches to and cross-links the Fc receptors on the platelet surface, which leads to platelet activation and aggregation. Platelet activation results in the release of more PF4, creating more target antigen for HIT antibodies. The prothrombotic state may also be augmented by activation of endothelium by binding of HIT antibodies to PF4-like proteins on their surface. Binding of HIT antibodies to platelets results in their removal by macrophages (hence the thrombocytopenia in the syndrome name). Although thrombocytopenia is the most common manifestation, thrombosis is the most serious complication. It occurs in approximately 50% of cases and affects both veins and arteries. Necrosis of the skin, gangrene of the limbs, stroke, and myocardial infarction are some of the sequelae. Diagnosis requires the demonstration of anti–PF4-heparin antibodies. Low-molecular-weight heparin preparations induce HIT less frequently, and other classes of anticoagulants such as direct inhibitors of factor X and thrombin may also obviate the risk.

Antiphospholipid Antibody Syndrome (APS)

APS is an autoimmune disorder characterized by:

- *Presence of one or more antiphospholipid (aPL) autoantibodies*
- *Venous or arterial thromboses, or pregnancy complications such as recurrent miscarriages, unexplained fetal death, and premature birth.*

APS may be primary or secondary. Individuals with a well-defined autoimmune disease, such as systemic lupus erythematosus (Chapter 6), are designated as having secondary antiphospholipid syndrome (hence the earlier term *lupus anticoagulant syndrome*). In primary antiphospholipid syndrome, patients exhibit only the manifestations of a hypercoagulable state and lack evidence of other well-defined autoimmune disorders. Approximately 50% of the patients with APS have the primary form, and the rest occur in association with well-defined autoimmune disease, most commonly SLE. Our focus here is on the primary form.

The clinical manifestations of APS are varied; they include recurrent thromboses, repeated miscarriages, cardiac valve

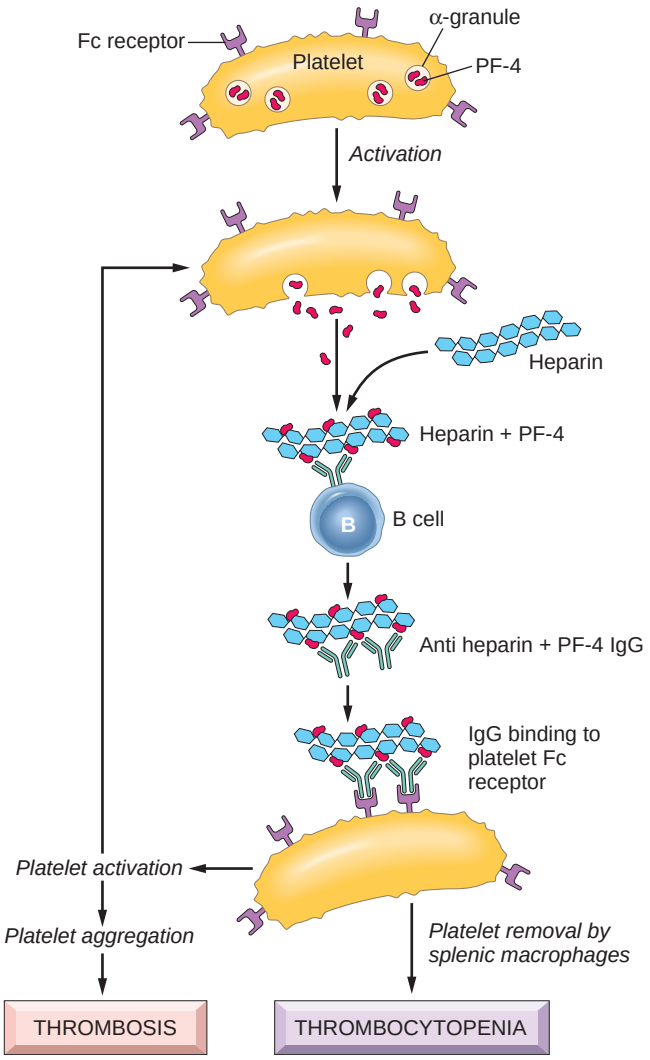

Figure 4.13 Mechanism of heparin-induced thrombocytopenia.

vegetations, and thrombocytopenia. Depending on the vascular bed involved, the clinical presentations can include pulmonary embolism (following lower extremity venous thrombosis), pulmonary hypertension (from recurrent subclinical pulmonary emboli), valvular heart disease, stroke, bowel infarction, or renovascular hypertension.

The pathogenesis of antiphospholipid syndrome is complex and not fully understood. The aPL antibodies are directed against anionic membrane phospholipids or proteins associated with phospholipids. Proteins that are recognized by these antibodies include cardiolipin and β_2-glycoprotein I. This glycoprotein is found in plasma, but it has strong avidity for phospholipids expressed on the surfaces of endothelial cells, monocytes, platelets, thrombin, and trophoblasts. Anti–β_2-glycoprotein antibodies are suspected to have a major role in APS by activating endothelial cells, monocytes, and platelets. Their pathogenicity is supported by the observation that transfer of these antibodies into rodents can induce thrombosis. Patients with APS also show evidence of complement activation and inhibition of fibrinolytic processes, both of which favor the prothrombotic state. As mentioned earlier, pregnancy morbidity is a defining manifestation of APS. However, unlike most other clinical features, fetal loss does not appear to be caused by thrombosis, but rather seems to stem from antibody-mediated interference with the growth and differentiation of trophoblasts, leading to a failure of placentation.

Although antiphospholipid antibodies are clearly associated with thrombotic diatheses, they have also been identified in 5% to 15% of apparently normal individuals, implying that they are not sufficient to cause the full-blown syndrome. It is postulated that a "second hit" is required that may be provided by infection, smoking, or pregnancy, among others. Although these antibodies induce a hypercoagulable state in vivo, they interfere with phospholipids and thus inhibit coagulation in vitro, thereby prolonging the PTT. The antibodies also frequently result in a false-positive serologic test for syphilis because the antigen in the standard assay is embedded in cardiolipin, which cross reacts with phospholipids of *Treponema pallidum*. Diagnosis of APS is based on clinical features and demonstration of aPL antibodies in the serum. Therapy of APS involves various forms of anticoagulation.

MORPHOLOGY

Thrombi can develop anywhere in the cardiovascular system and vary in size and shape depending on the involved site and the underlying cause. Arterial or cardiac thrombi usually begin at sites of turbulence or endothelial injury, whereas venous thrombi characteristically occur at sites of stasis. Thrombi are focally attached to the underlying vascular surface, particularly at the point of initiation. From here, arterial thrombi tend to grow retrograde, and venous thrombi extend in the direction of blood flow; thus both propagate toward the heart. The propagating portion of a thrombus is often poorly attached and therefore prone to fragmentation and embolization.

Thrombi often have grossly and microscopically apparent laminations called **lines of Zahn,** which are pale platelet and fibrin deposits alternating with darker red cell–rich layers. Such laminations signify that a thrombus has formed in flowing blood; their presence can therefore distinguish antemortem clots from the bland nonlaminated clots that occur postmortem (see later).

Thrombi occurring in heart chambers or in the aortic lumen are designated **mural thrombi.** Abnormal myocardial contraction (arrhythmias, dilated cardiomyopathy, or myocardial infarction) or endomyocardial injury (myocarditis or catheter trauma) promotes cardiac mural thrombi (Fig. 4.14A), and ulcerated atherosclerotic plaque and aneurysmal dilation underlie aortic thrombi (see Fig. 4.14B).

Arterial thrombi are frequently **occlusive**; the most common sites in decreasing order of frequency are the coronary, cerebral, and femoral arteries. They typically consist of a friable meshwork of platelets, fibrin, red cells, and degenerating leukocytes. Although these are usually superimposed on a ruptured atherosclerotic plaque, other vascular injuries (vasculitis, trauma) may be the underlying cause.

Venous thrombosis (phlebothrombosis) is almost invariably occlusive, with the thrombus forming a long luminal cast. Because these thrombi form in the sluggish venous circulation, they tend to contain more enmeshed red cells (and relatively few platelets) and are therefore known as **red thrombi** or **stasis thrombi.** Venous thrombi are firm, are focally attached to the

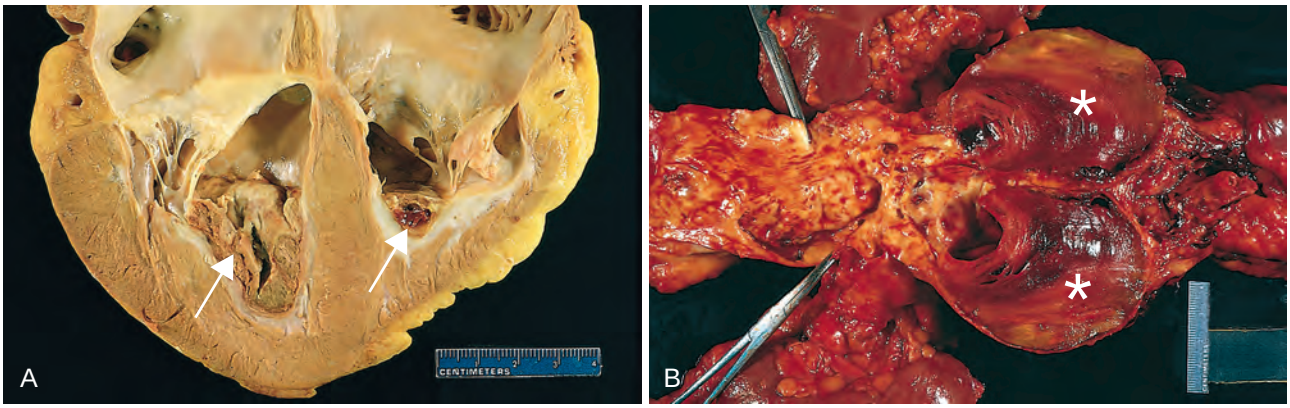

Figure 4.14 Mural thrombi. (A) Thrombus in the left and right ventricular apices *(arrows)*, overlying a white fibrous scar. (B) Laminated thrombus in a dilated abdominal aortic aneurysm *(asterisks)*. Numerous friable mural thrombi are also superimposed on advanced atherosclerotic lesions of the more proximal aorta *(left side of picture)*.

vessel wall, and contain lines of Zahn, features that help distinguish them from postmortem clots (see later). The veins of the lower extremities are most commonly involved (90% of cases); however, upper extremities, periprostatic plexus, or the ovarian and periuterine veins can also develop venous thrombi. Under special circumstances, they can also occur in the dural sinuses, portal vein, or hepatic vein.

Postmortem clots can sometimes be mistaken for antemortem venous thrombi. However, clots that form after death are gelatinous and have a dark-red dependent portion where red cells have settled by gravity and a yellow "chicken fat" upper portion, and are usually not attached to the underlying vessel wall.

Thrombi on heart valves are called **vegetations**, which may be infected or sterile. Blood-borne bacteria or fungi can adhere to previously damaged valves (e.g., due to rheumatic heart disease) or may cause valve damage directly; in either case, endothelial injury and disturbed blood flow can induce the formation of large thrombotic masses (**infective endocarditis**; Chapter 12). Sterile vegetations can also develop on noninfected valves in persons with hypercoagulable states, so-called **nonbacterial thrombotic endocarditis** (Chapter 12). Less commonly, sterile verrucous endocarditis **(Libman-Sacks endocarditis)** can occur in the setting of systemic lupus erythematosus (Chapter 6).

Fate of the Thrombus

If a patient survives the initial thrombosis, in the ensuing days to weeks thrombi undergo some combination of the following four events:

- *Propagation.* Thrombi accumulate additional platelets and fibrin (discussed earlier).
- *Embolization.* Thrombi dislodge and travel to other sites in the vasculature (discussed later).
- *Dissolution.* Dissolution is the result of fibrinolysis, which can lead to the rapid shrinkage and total disappearance of recent thrombi. In contrast, the extensive fibrin deposition and cross-linking in older thrombi render them more resistant to lysis. This distinction explains why therapeutic administration of fibrinolytic agents such as t-PA (e.g., in the setting of acute coronary thrombosis) is generally effective only when given during the first few hours of a thrombotic event.
- *Organization and recanalization.* Older thrombi become organized by the ingrowth of endothelial cells, smooth muscle cells, and fibroblasts (Fig. 4.15). Capillary channels eventually form that reestablish the continuity of the original lumen, albeit to a variable degree. Continued recanalization may convert a thrombus into a smaller mass of connective tissue that becomes incorporated into the vessel wall. Eventually, with remodeling and contraction of the mesenchymal elements, only a fibrous lump may remain to mark the original thrombus (Chapter 11).

Occasionally the centers of thrombi undergo enzymatic digestion, presumably as a result of the release of lysosomal enzymes from trapped leukocytes and platelets. In the setting of bacteremia, such thrombi may become infected, producing an inflammatory mass that erodes and weakens the vessel

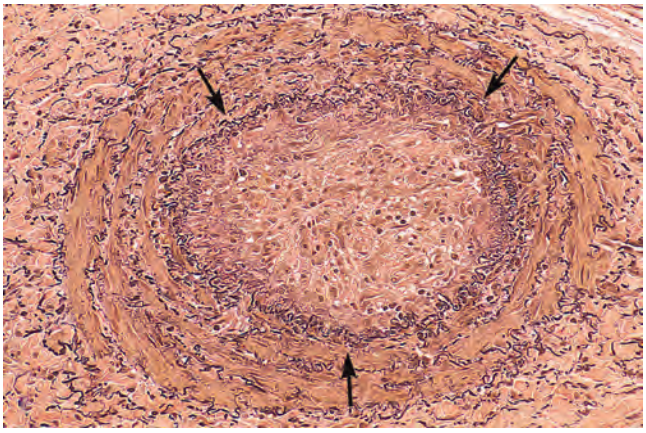

Figure 4.15 Low-power view of a thrombosed artery stained for elastic tissue. The original lumen is delineated by the internal elastic lamina *(arrows)* and is totally filled with organized thrombus, now punctuated by several recanalized endothelium-lined channels *(white spaces)*.

wall. If unchecked, this may result in a mycotic aneurysm (Chapter 11).

Clinical Features

Thrombi come to clinical attention when they obstruct arteries or veins, or give rise to emboli. The clinical presentation depends on the involved site. Venous thrombi can cause painful congestion and edema distal to an obstruction, but are mainly of concern due to their tendency to embolize to the lungs (see later). Conversely, although arterial thrombi can also embolize and cause downstream infarctions, the chief clinical problem is more often related to occlusion of a critical vessel (e.g., a coronary or cerebral artery), which can have serious or fatal consequences.

Venous Thrombosis (Phlebothrombosis). Most venous thrombi occur in the superficial or deep veins of the leg. Superficial venous thrombi typically occur in the saphenous veins in the setting of varicosities. Such thrombi can cause local congestion, swelling, pain, and tenderness, but rarely embolize. Nevertheless, the associated edema and impaired venous drainage predispose the overlying skin to the development of infection and ulcers *(varicose ulcers)*. DVT involving one of the large leg veins—at or above the knee (e.g., the popliteal, femoral, and iliac veins)—is considered serious because such thrombi more often embolize to the lungs and give rise to pulmonary infarction (see later and Chapter 15). Although DVTs may cause local pain and edema due to venous obstruction, these symptoms are often absent due the opening of venous collateral channels. Consequently, DVTs are asymptomatic in approximately 50% of affected individuals and are recognized only in retrospect after embolization.

Lower extremity DVTs are often associated with hypercoagulable states, as described earlier (see Table 4.2). Common predisposing factors include bed rest and immobilization (because they reduce the milking action of the leg muscles, resulting in stasis), and congestive heart failure (also a cause of impaired venous return). Trauma, surgery, and burns not only immobilize a person but are also associated with vascular insults, procoagulant release from injured tissues, increased hepatic synthesis of coagulation factors, and decreased t-PA production. Many elements contribute to the thrombotic diathesis of pregnancy, including decreased venous return from leg veins and systemic hypercoagulability associated with the hormonal changes of late pregnancy and the postpartum period. Tumor-associated inflammation and coagulation factors (tissue factor, factor VIII), as well as procoagulants (e.g., mucin) released from tumor cells, all contribute to the increased risk of thromboembolism in disseminated cancers, so-called *migratory thrombophlebitis* or *Trousseau syndrome*. Regardless of the specific clinical setting, advanced age also increases the risk of DVT.

Arterial and Cardiac Thrombosis. Atherosclerosis is a major cause of arterial thromboses because it is associated with loss of endothelial integrity and with abnormal blood flow (see Fig. 4.14B). Myocardial infarction can predispose to cardiac mural thrombi by causing dyskinetic myocardial contraction and endocardial injury (see Fig. 4.14A), and rheumatic heart disease may engender atrial mural thrombi by causing atrial dilation and fibrillation. Both cardiac and aortic mural thrombi are prone to embolization. Although any tissue can be affected, the brain, kidneys, and spleen are particularly likely targets because of their rich blood supply.

KEY CONCEPTS

THROMBOSIS

- Thrombus development usually is related to one or more components of the Virchow triad:
  - Endothelial injury (e.g., by toxins, hypertension, inflammation, or metabolic products) associated with endothelial activation and changes in endothelial gene expression that favor coagulation
  - Abnormal blood flow—stasis or turbulence (e.g., due to aneurysms, atherosclerotic plaque)
  - Hypercoagulability, either primary (e.g., factor V Leiden, increased prothrombin synthesis, antithrombin III deficiency) or secondary (e.g., bed rest, tissue damage, malignancy, or development of aPL antibodies [antiphospholipid antibody syndrome]) or antibodies against PF4/heparin complexes [heparin-induced thrombocytopenia])
- Thrombi may propagate, resolve, become organized, or embolize.
- Thrombosis causes tissue injury by local vascular occlusion or by distal embolization.

Disseminated Intravascular Coagulation (DIC)

DIC is widespread thrombosis within the microcirculation that may be of sudden or insidious onset. It is not a specific disease but rather a complication of a large number of conditions associated with systemic activation of thrombin. Disorders ranging from obstetric complications to advanced malignancy can be complicated by DIC, which leads to widespread formation of thrombi in the microcirculation. These microvascular thrombi can cause diffuse circulatory insufficiency and organ dysfunction, particularly of the brain, lungs, heart, and kidneys. To complicate matters, the runaway thrombosis "uses up" platelets and coagulation factors (hence the synonym *consumptive coagulopathy*) and often activates fibrinolytic mechanisms. Thus, symptoms initially related to thrombosis can evolve into a bleeding catastrophe, such as hemorrhagic stroke or hypovolemic shock. DIC is discussed in greater detail along with other bleeding diatheses in Chapter 14.

EMBOLISM

An embolus is a detached intravascular solid, liquid, or gaseous mass that is carried by the blood from its point of origin to a distant site, where it often causes tissue dysfunction or infarction. The vast majority of emboli are dislodged thrombi, hence the term *thromboembolism*. Other rare emboli are composed of fat droplets, nitrogen bubbles, atherosclerotic debris *(cholesterol emboli)*, tumor fragments, bone marrow, or even foreign bodies. Emboli travel through

the blood until they encounter vessels too small to permit further passage, causing partial or complete vascular occlusion. Depending on where they originate, emboli can lodge anywhere in the vascular tree; as discussed later, the clinical consequences vary widely depending on the size and the position of the lodged embolus, as well as the vascular bed that is impacted.

Pulmonary Embolism (PE)

Pulmonary emboli originate from DVT and are the most common form of thromboembolic disease. PE is a common and serious disorder with an estimated incidence of 100 to 200 cases per 100,000 people in the United States. It is somewhat more common in males than in females. PE causes about 100,000 deaths per year in the United States. An estimated 20% of individuals with PE die before or shortly after a diagnosis is made. In more than 95% of cases, PE originates from leg DVT. Hence the risk factors for PE are the same as for DVT (see Table 4.2).

Fragmented thrombi from DVT are carried through progressively larger veins and the right side of the heart before slamming into the pulmonary arterial vasculature. Depending on the size of the embolus, it can occlude the main pulmonary artery, straddle the pulmonary artery bifurcation *(saddle embolus),* or pass out into the smaller, branching arteries (Fig. 4.16). Frequently there are multiple emboli, occurring either sequentially or simultaneously as a shower of smaller emboli from a single large mass; in general, **the patient who has had one PE is at high risk for more.** Rarely, a venous embolus passes through an interatrial or interventricular defect and gains access to the systemic arterial circulation *(paradoxical embolism).* A more complete discussion of PEs is presented in Chapter 15; the following is an overview of the major functional consequences of pulmonary emboli.

- *Most pulmonary emboli (60% to 80%) are clinically silent* because they are small. With time they become organized and are incorporated into the vascular wall; in some cases organization of the thromboembolus leaves behind a delicate, bridging fibrous web.

Figure 4.16 Embolus from a lower extremity deep venous thrombosis, lodged at a pulmonary artery branchpoint.

- *Sudden death, acute right heart failure (cor pulmonale),* or cardiovascular collapse occurs when emboli obstruct 60% or more of the pulmonary circulation.
- *Embolic obstruction of medium-sized arteries with subsequent vascular rupture can result in pulmonary hemorrhage* but usually does not cause pulmonary infarction. This is because the lung is supplied by both the pulmonary arteries and the bronchial arteries, and the intact bronchial circulation is usually sufficient to perfuse the affected area. Understandably, if the bronchial arterial flow is compromised (e.g., by left-sided cardiac failure), infarction may occur.
- *Embolic obstruction of small end-arteriolar pulmonary branches often does produce hemorrhage or infarction.*
- *Multiple emboli over time may cause pulmonary hypertension* and right ventricular failure.

Systemic Thromboembolism

Most systemic emboli (80%) arise from intracardiac mural thrombi, two-thirds of which are associated with left ventricular wall infarcts and another one-fourth with left atrial dilation and fibrillation. The remainder originates from aortic aneurysms, atherosclerotic plaques, valvular vegetations, or venous thrombi (paradoxical emboli); 10% to 15% are of unknown origin. In contrast to venous emboli, the vast majority of which lodge in the lung, arterial emboli can travel to a wide variety of sites; the point of arrest depends on the source and the relative amount of blood flow that downstream tissues receive. Most come to rest in the lower extremities (75%) or the brain (10%), but other tissues, including the intestines, kidneys, spleen, and upper extremities, may be involved. The consequences of systemic emboli depend on the vulnerability of the affected tissues to ischemia, the caliber of the occluded vessel, and whether a collateral blood supply exists; in general, however, the outcome is tissue infarction.

Fat Embolism

Fat embolism refers to the presence of microscopic fat globules—sometimes with associated hematopoietic bone marrow—in the vasculature after fractures of long bones or, rarely, in the setting of soft-tissue trauma and burns. It is fairly common, occurring in some 90% of individuals with severe skeletal injuries (Fig. 4.17). Presumably these injuries rupture vascular sinusoids in the marrow or small venules, allowing marrow or adipose tissue to herniate into the vascular space and travel to the lung. Fat embolism syndrome is the term applied to the minority of patients who become symptomatic.

Fat embolism syndrome is characterized by pulmonary insufficiency, neurologic symptoms, anemia, and thrombocytopenia, and is fatal in 5% to 15% of cases. Typically, 1 to 3 days after injury there is a sudden onset of tachypnea, dyspnea, and tachycardia; irritability; and restlessness that can progress to delirium or coma. Thrombocytopenia is attributed to platelet adhesion to fat globules and subsequent aggregation or splenic sequestration; anemia can result from similar red cell aggregation and/or hemolysis. A diffuse petechial rash (seen in 20% to 50% of cases) is related to rapid onset of thrombocytopenia and can be a useful diagnostic clue.

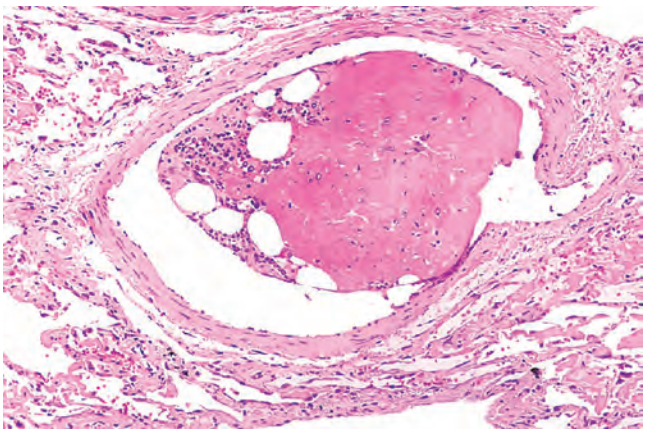

Figure 4.17 Bone marrow embolus in the pulmonary circulation. The cellular elements on the left side of the embolus are hematopoietic cells, and the cleared vacuoles represent marrow fat. The relatively uniform red area on the right of the embolus is an early organizing thrombus.

The pathogenesis of fat embolism syndrome involves both mechanical obstruction and biochemical injury. Fat microemboli and associated red cell and platelet aggregates can occlude the pulmonary and cerebral microvasculature. Release of free fatty acids from the fat globules exacerbates the situation by causing local toxic injury to endothelium, and platelet activation and granulocyte recruitment (with free radical, protease, and eicosanoid release) complete the vascular assault. Because lipids are dissolved out of tissue preparations by solvents routinely used in paraffin embedding, the microscopic demonstration of fat microglobules typically requires specialized techniques, including frozen sections and stains for fat.

Air Embolism

Gas bubbles within the circulation can coalesce to form frothy masses that obstruct vascular flow and cause distal ischemic injury. Air embolism occurs when there is communication between the vasculature and outside air, and a negative pressure gradient that "sucks" in the air. For example, air may be introduced into the cerebral circulation by neurosurgery in the "sitting position," creating a gravitational gradient. Air may also be introduced during endovascular and interventional procedures as well as during mechanical ventilation. A large volume of air, generally more than 100 mL, is necessary to produce a clinical effect in the pulmonary circulation; unless care is taken, this volume of air can be inadvertently introduced during obstetric or laparoscopic procedures, or as a consequence of chest wall injury. Introduction of 300 to 500 mL of air at 100 mL/sec may be fatal. Entry of air in the pulmonary vasculature does not merely block perfusion of downstream region. Microemboli of air trapped in pulmonary capillaries induce an intense inflammatory response with release of cytokines that may injure the alveoli. Bubbles in the central nervous system can cause mental impairment and even sudden onset of coma.

A particular form of gas embolism, called *decompression sickness,* occurs when individuals experience sudden decreases in atmospheric pressure. Scuba and deep sea divers, and underwater construction workers are all at risk. When air is breathed at high pressure (e.g., during a deep sea dive), increased amounts of gas (particularly nitrogen) are dissolved in the blood and tissues. If the diver then ascends (depressurizes) too rapidly, the nitrogen comes out of solution in the tissues and the blood.

The rapid formation of gas bubbles within skeletal muscles and supporting tissues in and about joints is responsible for the painful condition called *the bends* (so named in the 1880s because it was noted that those afflicted characteristically arched their backs in a manner reminiscent of a then-popular women's fashion pose called the *Grecian bend*). In the lungs, gas bubbles in the vasculature cause edema, hemorrhage, and focal atelectasis or emphysema, leading to a form of respiratory distress called the *chokes*. A more chronic form of decompression sickness is called *caisson disease* (named for the pressurized vessels used in bridge construction; workers in these vessels suffered both acute and chronic forms of decompression sickness). In caisson disease, persistence of gas emboli in the skeletal system leads to multiple foci of ischemic necrosis; the more common sites are the femoral heads, tibia, and humeri.

Individuals affected by acute decompression sickness are treated by being placed in a chamber under sufficiently high pressure to force the gas bubbles back into solution. Subsequent slow decompression permits gradual resorption and exhalation of the gases, which prevents the obstructive bubbles from reforming.

Amniotic Fluid Embolism

Amniotic fluid embolism is the fifth most common cause of maternal mortality worldwide; it accounts for roughly 10% of maternal deaths in the United States and results in permanent neurologic deficit in as many as 85% of survivors. Amniotic fluid embolism is an ominous complication of labor and the immediate postpartum period. Although the incidence is only approximately 2 to 6 in 100,000 deliveries, the mortality rate is up to 80%. The onset is characterized by sudden severe dyspnea, cyanosis, and shock, followed by neurologic impairment ranging from headache to seizures and coma, and by DIC. Note that these features differ from those observed with pulmonary embolism from DVT; in fact, much of the morbidity and mortality in amniotic fluid embolism stems from the biochemical activation of coagulation factors, components of the innate immune system, and release of vasoactive substances, rather than the mechanical obstruction of pulmonary vessels by amniotic debris. The vasoactive substances cause acute pulmonary hypertension and right heart failure, which causes hypoxia, left heart failure, pulmonary edema, and diffuse alveolar damage.

The underlying cause is the infusion of amniotic fluid or fetal tissue into the maternal circulation via a tear in the placental membranes or rupture of uterine veins. Classic findings at autopsy include the presence of squamous cells shed from fetal skin, lanugo hair, fat from vernix caseosa, and mucin derived from the fetal respiratory or gastrointestinal tract in the maternal pulmonary microvasculature (Fig. 4.18).

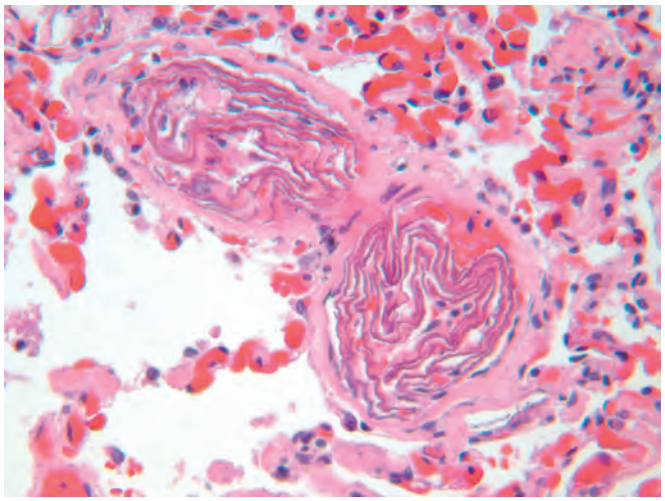

Figure 4.18 Amniotic fluid embolism. Two small pulmonary arterioles are packed with laminated swirls of fetal squamous cells. There is marked edema and congestion. Elsewhere the lung contained small organizing thrombi consistent with disseminated intravascular coagulation. (Courtesy Dr. Beth Schwartz, Baltimore, Md.)

KEY CONCEPTS

EMBOLISM

- An embolus is a solid, liquid, or gaseous mass carried by the blood to a site distant from its origin; most are dislodged thrombi.
- Pulmonary emboli derive primarily from lower extremity DVT; their effects depend on the size of the embolus and the location in which it lodges. Consequences may include right-sided heart failure, pulmonary hemorrhage, pulmonary infarction, or sudden death.
- Systemic emboli derive from cardiac mural or valvular thrombi, aortic aneurysms, or atherosclerotic plaques; whether an embolus causes tissue infarction depends on the site of embolization and the presence or absence of collateral circulation.

INFARCTION

An infarct is an area of ischemic necrosis caused by occlusion of either the arterial supply or the venous drainage. Tissue infarction is a common and extremely important cause of clinical illness. Roughly 40% of all deaths in the United States are caused by cardiovascular disease, and most of these are attributable to myocardial or cerebral infarction. Pulmonary infarction is also a common complication in many clinical settings, bowel infarction is frequently fatal, and ischemic necrosis of the extremities *(gangrene)* is a serious problem in the diabetic population.

Arterial thrombosis or arterial embolism underlies the vast majority of infarctions. Less common causes of arterial obstruction leading to infarction include local vasospasm, hemorrhage into an atheromatous plaque, or extrinsic vessel compression (e.g., by tumor). Other uncommon causes of tissue infarction include torsion of a vessel (e.g., in testicular torsion or bowel volvulus), traumatic vascular rupture, or vascular compromise by edema (e.g., *anterior compartment syndrome* of the leg) or by entrapment in a hernia sac. Although venous thrombosis can cause infarction, the more common outcome is just congestion; in this setting, bypass channels rapidly open and permit vascular outflow, which then improves arterial inflow. Infarcts caused by venous thrombosis are thus more likely in organs with a single efferent vein (e.g., testis and ovary).

MORPHOLOGY

Infarcts are classified according to color and the presence or absence of infection; they are either red (hemorrhagic) or white (anemic) and may be septic or bland.

- **Red infarcts** (Fig. 4.19A) occur (1) with venous occlusions (e.g., testicular torsion, Chapter 19), (2) in loose, spongy tissues (e.g., lung) where blood can collect in the infarcted zone, (3) in tissues with dual circulations (e.g., lung and small intestine) that allow blood to flow from an unobstructed parallel supply into a necrotic zone, (4) in tissues previously congested by sluggish venous outflow, and (5) when flow is reestablished to a site of previous arterial occlusion and necrosis (e.g., following angioplasty of an arterial obstruction).
- **White infarcts** (see Fig. 4.19B) occur with arterial occlusions in solid organs with end-arterial circulation (e.g., heart, spleen, and kidney), and where tissue density limits the seepage of blood from adjoining capillary beds into the necrotic area.

Infarcts tend to be wedge-shaped, with the occluded vessel at the apex and the periphery of the organ forming the base (see Fig. 4.19); when the base is a serosal surface, there may be an overlying fibrinous exudate resulting from an acute inflammatory response to mediator release from injured and necrotic cells. Fresh infarcts are poorly defined and slightly hemorrhagic, but over a few days the margins tend to become better defined by a narrow rim of congestion attributable to inflammation. With further passage of time, infarcts resulting from arterial occlusions in organs without a dual blood supply typically become progressively paler and more sharply defined (see Fig. 4.19B). In comparison, in the lung hemorrhagic infarcts are the rule (see Fig. 4.19A). Extravasated red cells in hemorrhagic infarcts are phagocytosed by macrophages, which convert heme iron into hemosiderin; small

Figure 4.19 Red and white infarcts. (A) Hemorrhagic, roughly wedge-shaped pulmonary red infarct. (B) Sharply demarcated white infarct in the spleen.

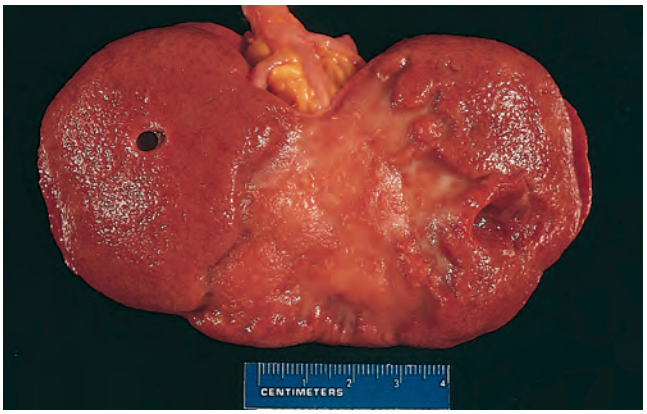

Figure 4.20 Remote kidney infarct replaced by a large fibrotic scar.

amounts do not grossly impart any appreciable color to the tissue, but extensive hemorrhage can leave a firm, brown hemosiderin-rich residuum.

The dominant histologic characteristic of infarction is **ischemic coagulative necrosis** (Chapter 2). Importantly, if the vascular occlusion has occurred shortly (minutes to hours) before the death of the person, histologic changes may be absent; it takes 4 to 12 hours for the dead tissue to show microscopic evidence of necrosis. Acute inflammation is present along the margins of infarcts within a few hours and is usually well defined within 1 to 2 days. Eventually a reparative response begins in the preserved margins (Chapter 3). If the tissue harbors tissue stem cells, parenchymal regeneration can occur at the periphery where underlying stromal architecture is preserved. However, most infarcts are ultimately replaced by scar (Fig. 4.20). The brain is an exception to these generalizations, in that central nervous system infarction results in **liquefactive necrosis** (Chapter 2).

Septic infarctions occur when infected cardiac valve vegetations embolize or when microbes seed necrotic tissue. In these cases the infarct is converted to an abscess, with a correspondingly greater inflammatory response (Chapter 3). The eventual sequence of organization, however, follows the pattern already described.

Factors That Influence Development of an Infarct. A vascular occlusion can cause effects ranging from virtually nothing to tissue dysfunction and necrosis sufficient to result in death. The variables that influence the outcome of vascular occlusion are as follows:

- *Anatomy of the vascular supply.* The availability of an alternative blood supply is the most important determinant of whether vessel occlusion will cause tissue damage. As mentioned earlier, the lungs have a dual pulmonary and bronchial artery blood supply that protects against thromboembolism-induced infarction. Similarly, the liver, with its dual hepatic artery and portal vein circulation, and the hand and forearm, with their dual radial and ulnar arterial supply, are all relatively resistant to infarction. In contrast, renal and splenic circulations are end-arterial, and vascular obstruction generally causes tissue death.
- *Rate of occlusion.* Slowly developing occlusions are less likely to cause infarction, because they provide time for development of collateral pathways of perfusion. For example, small interarteriolar anastomoses—normally with minimal functional flow—interconnect the three major coronary arteries in the heart. If one of the coronaries is occluded slowly (i.e., by an encroaching atherosclerotic plaque), flow within this collateral circulation may increase sufficiently to prevent infarction, even though the larger coronary artery is eventually occluded.
- *Tissue vulnerability to hypoxia.* Neurons undergo irreversible damage when deprived of their blood supply for only 3 to 4 minutes. Myocardial cells, although hardier than neurons, are also quite sensitive and die after only 20 to 30 minutes of ischemia (although, as mentioned earlier, changes in the appearance of the dead cells take 4 to 12 hours to develop). In contrast, fibroblasts within myocardium remain viable even after many hours of ischemia (Chapter 12).
- *Hypoxemia.* Understandably, abnormally low blood oxygen content (regardless of cause) increases both the likelihood and extent of infarction.

KEY CONCEPTS
INFARCTION

- Infarcts are areas of ischemic necrosis most commonly caused by arterial occlusion (typically due to thrombosis or embolization); venous outflow obstruction is a less frequent cause.
- Infarcts caused by venous occlusion or occurring in spongy tissues with dual blood supply and where blood can collect typically are hemorrhagic (red); those caused by arterial occlusion in compact tissues typically are pale (white).
- Whether or not vascular occlusion causes tissue infarction is influenced by collateral blood supply, the rate at which an obstruction develops, intrinsic tissue susceptibility to ischemic injury, and blood oxygenation.

SHOCK

Shock is a state of circulatory failure that impairs tissue perfusion and leads to cellular hypoxia. At the outset, the cellular injury is reversible; however, prolonged shock eventually leads to irreversible tissue injury and can be fatal. Shock may complicate severe hemorrhage, extensive trauma or burns, myocardial infarction, pulmonary embolism, and microbial sepsis. Its causes fall into three general categories (Table 4.3):

- *Cardiogenic shock* results from low cardiac output due to myocardial pump failure. This can be due to intrinsic myocardial damage (infarction), ventricular arrhythmias, extrinsic compression (cardiac tamponade; Chapter 11), or outflow obstruction (e.g., pulmonary embolism).
- *Hypovolemic shock* results from low cardiac output due to low blood volume, such as can occur with massive hemorrhage or fluid loss from severe burns.
- *Sepsis, septic shock, and the systemic inflammatory response syndrome* are interrelated and somewhat overlapping conditions. The definitions that follow are based on The Third International Consensus Definitions for Sepsis and Septic Shock (2016):
  - *Sepsis* is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection.

Table 4.3 Three Major Types of Shock

Type of Shock	Clinical Example	Principle Mechanisms
Cardiogenic	Myocardial infarction Ventricular rupture Arrhythmia Cardiac tamponade Pulmonary embolism	Failure of myocardial pump resulting from intrinsic myocardial damage, extrinsic compression, or obstruction to outflow
Hypovolemic	Fluid loss (e.g., hemorrhage, vomiting, diarrhea, burns, or trauma)	Inadequate blood or plasma volume
Shock associated with systemic inflammation	Overwhelming microbial infections (bacterial and fungal) Superantigens (e.g., toxic shock syndrome) Trauma, burns, pancreatitis	Activation of cytokine cascades; peripheral vasodilation and pooling of blood; endothelial activation/injury; leukocyte-induced damage, disseminated intravascular coagulation

- *Septic shock* is defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone.
- *Systemic inflammatory response syndrome (SIRS)* is a sepsis-like condition associated with systemic inflammation that may be triggered by a variety of nonmicrobial insults, such as burns, trauma, and/or pancreatitis. Pathogenic feature common to SIRS and septic shock is a massive outpouring of inflammatory mediators from innate and adaptive immune cells that produce arterial vasodilation, vascular leakage, and venous blood pooling. With the advent of chimeric antigen receptor T-cell (CAR-T) therapy, a similar iatrogenic syndrome called *cytokine release syndrome* has been observed in cancer patients. The cardiovascular abnormalities associated with SIRS result in tissue hypoperfusion, cellular hypoxia, and metabolic derangements that lead to organ dysfunction and, if severe and persistent, organ failure and death.

- Less commonly, shock can occur in the setting of a spinal cord injury *(neurogenic shock),* or an IgE-mediated hypersensitivity reaction (*anaphylactic shock,* Chapter 6). In both of these forms of shock, acute vasodilation leads to hypotension and tissue hypoperfusion.

Pathogenesis of Septic Shock

Septic shock is responsible for 2% of all hospital admissions in the United States. Of these, 50% require treatment in intensive care units. The number of cases in the United States exceeds 750,000 per year, and the incidence is rising, which is ironically due to improvements in life support for critically ill patients, as well as the growing ranks of immunocompromised hosts (because of chemotherapy, immunosuppression, advanced age, or human immunodeficiency virus infection) and the increasing prevalence of multidrug-resistant organisms in the hospital setting. Despite improvements in care, the mortality rate remains around 50%. Septic shock is most frequently triggered by gram-positive bacterial infections, followed by gram-negative bacteria and fungi.

The ability of diverse microorganisms to cause septic shock is consistent with the idea that a variety of microbial constituents can trigger the process. As mentioned in Chapter 3, macrophages, neutrophils, dendritic cells, endothelial cells, and soluble components of the innate immune system (e.g., complement) recognize and are activated by diverse substances derived from microorganisms. After activation, these cells and factors initiate a number of inflammatory and counter-inflammatory responses that interact in a complex, incompletely understood fashion to produce septic shock and organ failure (Fig. 4.21).

Factors believed to play major roles in the pathophysiology of septic shock include the following:

- *Inflammatory and counter-inflammatory responses*. In sepsis, various microbial cell wall constituents engage receptors on cells of the innate immune system, triggering pro-inflammatory responses. Likely initiators of inflammation in sepsis are signaling pathways that lie downstream of Toll-like receptors (TLRs) (Chapter 5), which recognize a host of microbe-derived substances containing *pathogen-associated molecular patterns* (PAMPs) and *damage-associated molecular patterns* (DAMPs), as well as G-protein–coupled receptors that detect bacterial peptides and C-type lectin receptors such as Dectins. Ligation of these receptors leads to increased expression of the genes encoding inflammatory mediators via activation and nuclear translocation of the transcription factor nuclear factor-κB (NF-κB). The upregulated mediators include numerous cytokines such as tumor necrosis factor (TNF), interleukin 1 (IL-1), IL-12, IL-18, and interferon-γ (IFN-γ), as well as other inflammatory mediators such as high-mobility group box 1 protein (HMGB1). Markers of acute inflammation such as C-reactive protein and *procalcitonin* are also elevated. Reactive oxygen species and lipid mediators such as prostaglandins and platelet-activating factor (PAF) are also elaborated. These effector molecules induce endothelial cells (and other cell types) to upregulate adhesion molecule expression and further stimulate cytokine and chemokine production. The complement cascade is also activated by microbial components, both directly and through the proteolytic activity of plasmin (Chapter 3), resulting in the production of anaphylotoxins (C3a, C5a), chemotactic fragments (C5a), and opsonins (C3b), all of which contribute to the pro-inflammatory state. In addition, microbial components can activate coagulation directly through factor XII and indirectly through altered endothelial function (discussed later). The accompanying widespread activation of thrombin may further augment inflammation by triggering protease-activated receptors on inflammatory cells.

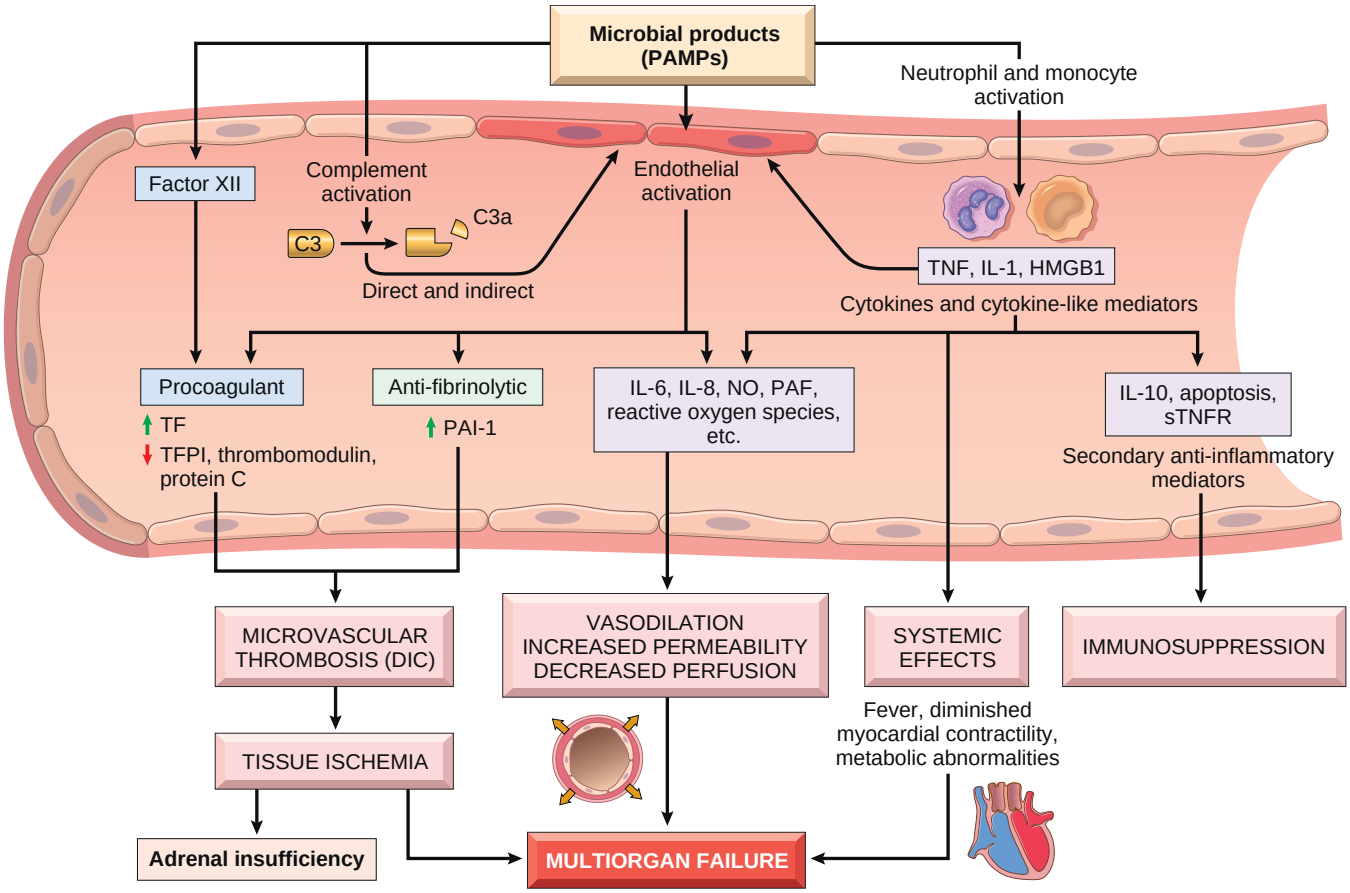

Figure 4.21 Major pathogenic pathways in septic shock. Microbial products (*PAMPs*, or pathogen-associated molecular patterns) activate endothelial cells and cellular and humoral elements of the innate immune system, initiating a cascade of events that lead to end-stage multiorgan failure. Additional details are given in the text. *C3*, Complement component 3; *C3a*, complement component 3a; *DIC*, disseminated intravascular coagulation; *HMGB1*, high-mobility group box 1 protein; *IL*, interleukin; *NO*, nitric oxide; *PAF*, platelet-activating factor; *PAI-1*, plasminogen activator inhibitor 1; *sTNFR*, soluble tumor necrosis factor receptor; *TF*, tissue factor; *TFPI*, tissue factor pathway inhibitor.

The hyperinflammatory state, initiated by sepsis, triggers counter-regulatory immunosuppressive mechanisms, which may involve both innate and adaptive immune cells. As a result, septic patients may oscillate between hyperinflammatory and immunosuppressed states during their clinical course. Proposed mechanisms for the immune suppression include a shift from pro-inflammatory (Th1) to anti-inflammatory (Th2) cytokines (Chapter 5), production of anti-inflammatory mediators (e.g., soluble TNF receptor, IL-1 receptor antagonist, and IL-10), lymphocyte apoptosis, the immunosuppressive effects of apoptotic cells, and the induction of cellular anergy.

Current evidence suggests that both are triggered simultaneously. The intensity of each of these reactions depends on multiple factors both intrinsic to the host (e.g., genetics and underlying diseases) and pathogen (e.g., virulence and burden).

- *Endothelial activation and injury*. The pro-inflammatory state and endothelial cell activation associated with sepsis lead to widespread vascular leakage and tissue edema, which have deleterious effects on both nutrient delivery and waste removal. One effect of inflammatory cytokines is to loosen endothelial cell tight junctions, making vessels leaky and resulting in the accumulation of protein-rich edema fluid throughout the body. This alteration impedes tissue perfusion and may be exacerbated by attempts to support the patient with intravenous fluids. Activated endothelium also upregulates production of NO and other vasoactive inflammatory mediators (e.g., C3a, C5a, and PAF), which may contribute to vascular smooth muscle relaxation and systemic hypotension. Another feature of sepsis is microvascular dysfunction. There is an increase in capillaries with intermittent flow, and heterogeneity of flow in various capillary beds, and the normal autoregulation of flow based on tissue metabolic environment is lost. These changes cause a mismatch in oxygen needs and oxygen delivery.
- *Induction of a procoagulant state*. The derangement in coagulation is sufficient to produce the formidable complication of *DIC* in up to one-half of septic patients. Sepsis alters the expression of many factors so as to favor coagulation. Pro-inflammatory cytokines increase tissue factor production by monocytes and possibly endothelial

cells as well, and decrease the production of endothelial anticoagulant factors, such as tissue factor pathway inhibitor, thrombomodulin, and protein C (see Fig. 4.10). They also dampen fibrinolysis by increasing PAI-1 expression (see Fig. 4.10). Some studies suggest a role for neutrophil extracellular traps (NETs, Chapter 3) in promoting the procoagulant state by stimulating both intrinsic and extrinsic pathways of coagulation. The vascular leak and tissue edema decrease blood flow at the level of small vessels, producing stasis and diminishing the washout of activated coagulation factors. Acting in concert, these effects lead to systemic activation of thrombin and the deposition of fibrin-rich thrombi in small vessels, often throughout the body, further compromising tissue perfusion. In full-blown DIC, the consumption of coagulation factors and platelets is so great that deficiencies of these factors appear, leading to concomitant bleeding and hemorrhage (Chapter 14).

- *Metabolic abnormalities*. Septic patients exhibit insulin resistance and hyperglycemia. Cytokines such as TNF and IL-1, stress-induced hormones (such as glucagon, growth hormone, and glucocorticoids), and catecholamines all drive gluconeogenesis. At the same time, the pro-inflammatory cytokines suppress insulin release while simultaneously promoting insulin resistance in the liver and other tissues, likely by impairing the surface expression of glucose transporter-4 (GLUT-4). Hyperglycemia decreases neutrophil function—thereby suppressing bactericidal activity—and causes increased adhesion molecule expression on endothelial cells. Although sepsis is initially associated with an acute surge in glucocorticoid production, this phase may be followed by adrenal insufficiency and a functional deficit of glucocorticoids. This may stem from depression of the synthetic capacity of intact adrenal glands or frank adrenal necrosis resulting from DIC *(Waterhouse-Friderichsen syndrome)* (Chapter 20). Finally, cellular hypoxia and diminished oxidative phosphorylation lead to increased lactate production and lactic acidosis.
- *Organ dysfunction*. Systemic hypotension, interstitial edema, microvascular dysfunction, and small vessel thrombosis all decrease the delivery of oxygen and nutrients to the tissues that, because of cellular hypoxia, fail to properly use those nutrients that are delivered. Mitochondrial damage resulting from oxidative stress impairs oxygen use. High levels of cytokines and secondary mediators diminish myocardial contractility and cardiac output; increased vascular permeability and endothelial injury can lead to the *acute respiratory distress syndrome* (Chapter 13). Ultimately, these factors may conspire to cause failure of multiple organs, particularly the kidneys, liver, lungs, and heart, culminating in death.

The severity and outcome of septic shock are likely dependent on the extent and virulence of the infection; the immune status of the host; the presence of other comorbid conditions; and the pattern and level of mediator production. The multiplicity of factors and the complexity of the interactions that underlie sepsis explain why most attempts to intervene therapeutically with antagonists of specific mediators have not been effective and even had deleterious effects in some cases. As mentioned earlier, another factor in the failure of neutralization of pro-inflammatory cytokines is the concurrent activation of pro-inflammatory and anti-inflammatory mediators. The standard of care remains antibiotics to treat the underlying infection and intravenous fluids, pressors, and supplemental oxygen to maintain blood pressure and limit tissue hypoxia. Suffice it to say that even in the best of clinical centers, septic shock remains an obstinate clinical challenge.

An additional group of secreted bacterial proteins called *superantigens* also cause a syndrome similar to septic shock (e.g., *toxic shock syndrome*). Superantigens are polyclonal T-lymphocyte activators that induce the release of high levels of cytokines that result in a variety of clinical manifestations, ranging from a diffuse rash to vasodilation, hypotension, shock, and death.

Stages of Shock

Shock is a progressive disorder that leads to death if the underlying problems are not corrected. The exact mechanisms of sepsis-related death are still unclear; aside from increased lymphocyte and enterocyte apoptosis, cellular necrosis is minimal. Death typically follows the failure of multiple organs, which usually offer no morphologic clues to explain their dysfunction. For hypovolemic and cardiogenic shock, however, the pathways leading to a patient's demise are reasonably well understood. Unless the insult is massive and rapidly lethal (e.g., exsanguination from a ruptured aortic aneurysm), shock tends to evolve through three general (albeit somewhat artificial) stages. These stages have been documented most clearly in hypovolemic shock but are common to other forms as well:

- *An initial nonprogressive stage* during which reflex compensatory mechanisms are activated and vital organ perfusion is maintained
- *A progressive stage* characterized by tissue hypoperfusion and onset of worsening circulatory and metabolic derangement, including acidosis
- *An irreversible stage* in which cellular and tissue injury is so severe that even if the hemodynamic defects are corrected, survival is not possible

In the early nonprogressive phase of shock, various neurohumoral mechanisms help maintain cardiac output and blood pressure. These mechanisms include baroreceptor reflexes, release of catecholamines and antidiuretic hormone, activation of the renin-angiotensin-aldosterone axis, and generalized sympathetic stimulation. The net effect is tachycardia, peripheral vasoconstriction, and renal fluid conservation; cutaneous vasoconstriction causes the characteristic "shocky" skin coolness and pallor (notably, septic shock can initially cause cutaneous vasodilation, so the patient may present with warm, flushed skin). Coronary and cerebral vessels are less sensitive to sympathetic signals and maintain relatively normal caliber, blood flow, and oxygen delivery. Thus, blood is shunted away from the skin to the vital organs such as the heart and the brain.

If the underlying causes are not corrected, shock passes imperceptibly to the progressive phase, which as noted is characterized by widespread tissue hypoxia. In the setting

of persistent oxygen deficit, intracellular aerobic respiration is replaced by anaerobic glycolysis with excessive production of lactic acid. The resultant metabolic lactic acidosis lowers the tissue pH, which blunts the vasomotor response; arterioles dilate, and blood begins to pool in the microcirculation. Peripheral pooling not only worsens the cardiac output but also puts endothelial cells at risk for the development of anoxic injury with subsequent DIC. With widespread tissue hypoxia, vital organs are affected and begin to fail.

In the absence of appropriate intervention, or in severe cases, the process eventually enters an irreversible stage. Widespread cell injury is reflected in lysosomal enzyme leakage, further aggravating the shock state. Myocardial contractile function worsens, in part because of increased NO synthesis. The ischemic bowel may allow intestinal flora to enter the circulation, and thus bacteremic shock may be superimposed. Commonly, further progression to renal failure occurs as a consequence of ischemic injury of the kidney (Chapter 14), and despite the best therapeutic interventions, the downward spiral culminates in death.

MORPHOLOGY

The cellular and tissue effects of shock are essentially those of hypoxic injury (Chapter 2) and are caused by a combination of **hypoperfusion** and **microvascular thrombosis.** Although any organ can be affected, the brain, heart, kidneys, adrenals, and gastrointestinal tract are most commonly involved. **Fibrin thrombi** can form in any tissue but typically are most readily visualized in kidney glomeruli. **Adrenal cortical cell lipid depletion** is akin to that seen in all forms of stress and reflects increased use of stored lipids for steroid synthesis. Whereas the lungs are resistant to hypoxic injury in hypovolemic shock occurring after hemorrhage, sepsis or trauma can precipitate diffuse alveolar damage (Chapter 13), leading to so-called **"shock lung."** Except for neuronal and cardiomyocyte loss, affected tissues can recover completely if the patient survives.

Clinical Features

The clinical manifestations of shock depend on the precipitating insult. In hypovolemic and cardiogenic shock, patients exhibit hypotension, a weak rapid pulse, tachypnea, and cool, clammy, cyanotic skin. As already noted, in septic shock, the skin may be warm and flushed owing to peripheral vasodilation. The primary threat to life is the underlying initiating event (e.g., myocardial infarction, severe hemorrhage, bacterial infection). However, the cardiac, cerebral, and pulmonary changes rapidly aggravate the situation. If patients survive the initial insult, worsening renal function can provoke a phase dominated by progressive oliguria, acidosis, and electrolyte imbalances.

Prognosis varies with the origin of shock and its duration. Thus, more than 90% of young, otherwise healthy patients with hypovolemic shock survive with appropriate management; by comparison, septic or cardiogenic shock is associated with substantially poorer outcomes, even with state-of-the-art care.

KEY CONCEPTS

SHOCK

- Shock is defined as a state of systemic tissue hypoperfusion resulting from reduced cardiac output and/or reduced effective circulating blood volume.
- The major types of shock are cardiogenic (e.g., myocardial infarction), hypovolemic (e.g., blood loss), and septic (e.g., infections).
- Shock of any form can lead to hypoxic tissue injury if not corrected.
- Septic shock is caused by a dysregulated host response to bacterial or fungal infections; it is characterized by endothelial cell activation, vasodilation, edema, DIC, and metabolic derangements.

CHAPTER 5

Genetic Disorders

CHAPTER CONTENTS

GENES AND HUMAN DISEASES

In Chapter 1, we discussed the architecture of the normal human genome. Here we build on that knowledge to discuss the genetic basis of human diseases.

Genetic disorders are far more common than is widely appreciated. The lifetime frequency of genetic diseases is estimated to be 670 per 1000. Furthermore, the genetic diseases encountered in medical practice represent only the tip of the iceberg, that is, those with less extreme genotypic errors that permit full embryonic development and live birth. It is estimated that 50% of spontaneous abortuses during the early months of gestation have a demonstrable chromosomal abnormality; there are, in addition, numerous smaller detectable errors and many other genetic lesions that are only now being recognized thanks to advances in DNA sequencing. About 1% of all newborn infants possess a gross chromosomal abnormality, and serious disease with a significant genetic component develops in approximately 5% of individuals younger than age 25 years. How many more mutations remain hidden?

Before discussing specific aberrations that may cause genetic diseases, it is useful to note that **human genetic disorders can be broadly classified into three categories**.

- *Disorders related to mutations in single genes with large effects.* These mutations cause the disease or predispose to the disease and, with some exceptions like hemoglobinopathies, are typically not present in the normal population. Such mutations and their associated disorders are highly

penetrant, meaning that the presence of the mutation is associated with the disease in a large proportion of individuals. Because these diseases are caused by single gene mutations, they usually follow the classic Mendelian pattern of inheritance and are also referred to as Mendelian disorders. A few important exceptions to this rule are noted later.

Study of single genes and mutations with large effects has been extremely informative in medicine, since a great deal of what is known about several physiologic pathways (e.g., cholesterol transport, chloride secretion) has been learned from analysis of single-gene disorders. Although informative, these disorders are generally rare unless they are maintained in a population by strong selective forces (e.g., sickle cell anemia in areas where malaria is endemic; Chapter 14).

- *Chromosomal disorders*. These arise from structural or numerical alteration in the autosomes and sex chromosomes. Like monogenic disease, they are uncommon but associated with high penetrance.
- *Complex multigenic disorders*. These are far more common than diseases in the previous two categories. They are caused by interactions between multiple variant forms of genes and environmental factors. Such variations in genes are common within the population and are also called *polymorphisms*. Each such variant gene confers a small increase in disease risk, and no single susceptibility gene is necessary or sufficient to produce the disease. It is only when several such polymorphisms are present in an individual that disease occurs—hence the term *multigenic* or *polygenic*. Thus, unlike mutant genes with large effects that are highly penetrant and give rise to Mendelian disorders, each polymorphism has a small effect and is of low penetrance. Since environmental interactions are important in the pathogenesis of these diseases, they are also called multifactorial disorders. In this category are some of the most common diseases that afflict humans, including atherosclerosis, diabetes mellitus, hypertension, and autoimmune diseases. Even normal traits such as height and weight are governed by polymorphisms in several genes.

The following discussion describes mutations that affect single genes, which underlie Mendelian disorders, followed by transmission patterns and selected samples of single-gene disorders.

Mutations

A *mutation* is defined as a permanent change in the DNA. Mutations that affect germ cells are transmitted to the progeny and can give rise to inherited diseases. Mutations that arise in somatic cells understandably do not cause hereditary diseases but are important in the genesis of cancers and some congenital malformations.

General principles relating to the effects of gene mutations follow.

- *Point mutations within coding sequences.* A point mutation is a change in which a single base is substituted with a different base. It may alter the code in a triplet of bases and lead to the replacement of one amino acid by another in the gene product. Because these mutations alter the meaning of the sequence of the encoded protein, they are often termed *missense mutations.* If the substituted amino acid is biochemically similar to the original, typically it causes little change in the function of the protein, and the mutation is called a "conservative" missense mutation. On the other hand, a "nonconservative" missense mutation replaces the normal amino acid with a biochemically different one. An excellent example of this type is the sickle mutation affecting the β-globin chain of hemoglobin (Chapter 14). Here the nucleotide triplet CTC (or GAG in mRNA), which encodes glutamic acid, is changed to CAC (or GUG in mRNA), which encodes valine. This single amino acid substitution alters the physicochemical properties of hemoglobin, giving rise to sickle cell anemia. Besides producing an amino acid substitution, a point mutation may change an amino acid codon to a chain terminator, or stop codon *(nonsense mutation).* Taking again the example of β-globin, a point mutation affecting the codon for glutamine (CAG) creates a stop codon (UAG) if U is substituted for C (Fig. 5.1). This change leads to premature termination of β-globin gene translation, and the short peptide that is produced is rapidly degraded. The resulting deficiency of β-globin chains can give rise to a severe form of anemia called β^0-thalassemia (Chapter 14).
- *Mutations within noncoding sequences.* Deleterious effects may also result from mutations that do not involve the exons. Recall that transcription of DNA is initiated and regulated by promoter and enhancer sequences (Chapter 1). Point mutations or deletions involving these regulatory sequences may interfere with binding of transcription factors and thus lead to a marked reduction in or total lack of transcription. Such is the case in certain forms of hereditary anemias called thalassemias (Chapter 14). In addition, point mutations within introns may lead to defective splicing of intervening sequences. This, in turn, interferes with normal processing of the initial mRNA transcripts and results in a failure to form mature mRNA. Therefore translation cannot take place, and the gene product is not synthesized.
- *Deletions and insertions.* Small deletions or insertions involving the coding sequence can have two possible effects on the encoded protein. If the number of base pairs involved is three or a multiple of three, the reading frame will remain intact, and an abnormal protein lacking

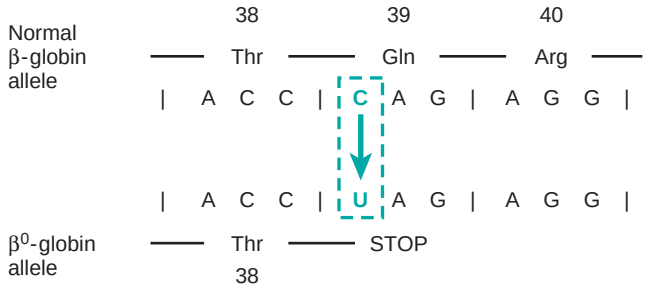

Figure 5.1 Nonsense mutation leading to premature chain termination. Partial mRNA sequence of the β-globin chain of hemoglobin showing codons for amino acids 38 to 40. A point mutation (C → U) in codon 39 changes a glutamine (Gln) codon to a stop codon, and hence protein synthesis stops at amino acid 38.

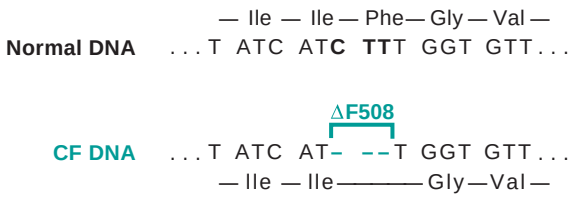

Figure 5.2 Three-base deletion in the common cystic fibrosis *(CF)* allele results in synthesis of a protein that lacks amino acid 508 (phenylalanine). Because the deletion is a multiple of three, this is not a frameshift mutation. (From Thompson MW, et al: *Thompson and Thompson Genetics in Medicine*, ed 5, Philadelphia, 1991, WB Saunders, p 135.)

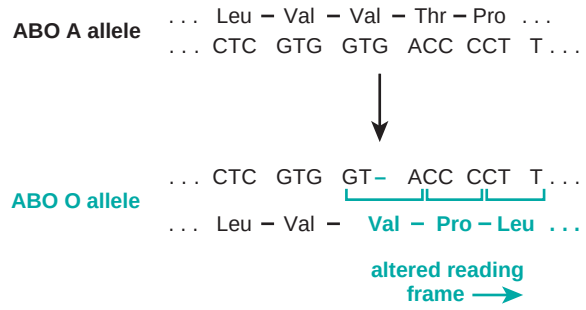

Figure 5.3 Single-base deletion at the ABO (glycosyltransferase) locus, leading to a frameshift mutation responsible for the O allele. (From Thompson MW, et al: *Thompson and Thompson Genetics in Medicine*, ed 5, Philadelphia, 1991, WB Saunders, p 134.)

or gaining one or more amino acids will be synthesized (Fig. 5.2). If the number of affected coding bases is not a multiple of three, this will result in an alteration of the reading frame of the DNA strand, producing what is referred to as a *frameshift mutation* (Figs. 5.3 and 5.4). Typically the result is the incorporation of a variable number of incorrect amino acids followed by truncation resulting from a premature stop codon.

- *Alterations in protein-coding genes other than mutations.* In addition to alterations in DNA sequence, coding genes also can undergo structural variations, such as copy number changes—*amplifications* or *deletions*—or *translocations* that result in aberrant gain or loss of protein function. As with mutations, structural changes may occur in the germline or be acquired in somatic tissues. In many instances, pathogenic germline alterations involve a contiguous portion of a chromosome rather than a single gene, such as in the 22q microdeletion syndrome, discussed later. With the widespread availability of next-generation sequencing (NGS) technology for assessing genome-wide DNA copy number variation at very high resolution, potentially pathogenic structural alterations have now been discovered in common disorders such as autism. Cancers often contain somatically acquired structural alterations, including amplifications, deletions, and translocations. The so-called Philadelphia chromosome—translocation t(9;22) between the *BCR* and *ABL* genes in chronic myeloid leukemia (Chapter 13)—is a classic example.
- *Alterations in noncoding RNAs.* It is worth noting that in the past, the major focus of gene hunting was discovery of genes that encode proteins. We now know that a very large number of genes do not encode proteins but produce transcripts—so-called noncoding RNAs (ncRNAs)—that serve important regulatory functions. Although many distinct families of ncRNAs exist, the two most important examples—small RNA molecules called microRNAs (miRNAs) and long noncoding RNAs (lncRNAs)—are discussed in Chapter 1.
- *Trinucleotide-repeat mutations.* Trinucleotide-repeat mutations belong to a special category of genetic anomaly. These mutations are characterized by amplification of a sequence of three nucleotides. Although the specific nucleotide sequence that undergoes amplification differs in various disorders, almost all affected sequences share the nucleotides guanine (G) and cytosine (C). For example, in fragile X syndrome (FXS), prototypical of this category of disorders, there are 250 to 4000 tandem repeats of the sequence CGG within the regulatory region of a gene called *familial mental retardation 1 (FMR1).* In normal populations the number of repeats is small, averaging 29. Such expansions of the trinucleotide sequences prevent normal expression of the *FMR1* gene, thus giving rise to intellectual disability. Another *distinguishing feature of trinucleotide-repeat mutations is that they are dynamic* (i.e., the degree of amplification increases during gametogenesis). These features, discussed in greater detail later, influence the pattern of inheritance and the phenotypic manifestations of the diseases caused by this class of mutation.

To summarize, mutations can interfere with gene expression at various levels. Transcription may be suppressed by gene deletions and point mutations involving promoter sequences. Abnormal mRNA processing may result from mutations affecting introns or splice junctions or both. Translation is affected if a nonsense mutation creates a stop

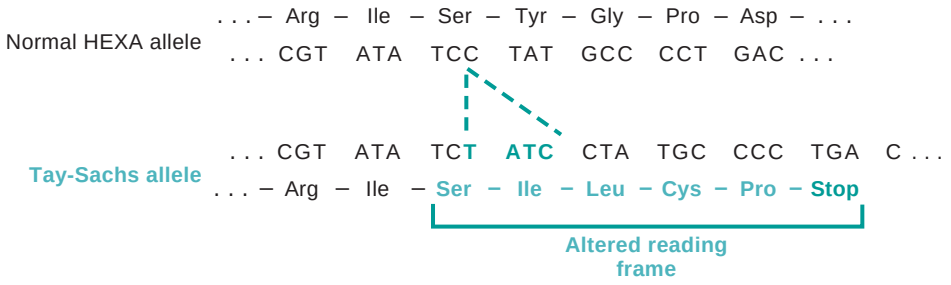

Figure 5.4 Four-base insertion in the hexosaminidase A gene, leading to a frameshift mutation. This mutation is the major cause of Tay-Sachs disease in Ashkenazi Jews. (From Nussbaum RL, et al: *Thompson and Thompson Genetics in Medicine*, ed 6, Philadelphia, 2001, WB Saunders, p 212.)

codon (chain termination mutation) within an exon. Finally, some pathogenic point mutations may lead to expression of normal amounts of a dysfunctional protein.

Against this background, we now turn our attention to the three major categories of genetic disorders: (1) disorders related to mutant genes of large effect, (2) diseases with multifactorial inheritance, and (3) chromosomal disorders. To these three well-known categories must be added a heterogeneous group of *single-gene disorders with nonclassic patterns of inheritance.* This group includes disorders resulting from triplet-repeat mutations, those arising from mutations in mitochondrial DNA (mtDNA), and those in which the transmission is influenced by genomic imprinting or gonadal mosaicism. Diseases within this group are caused by mutations in single genes, but they do not follow the Mendelian pattern of inheritance. These are discussed later in this chapter.

It is beyond the scope of this book to review normal human genetics. Some fundamentals of DNA structure and regulation of gene expressions were described in Chapter 1. It is important here to clarify several commonly used terms—*hereditary, familial,* and *congenital.* Hereditary disorders, by definition, are derived from one's parents and are transmitted in the germline through the generations and therefore are familial. The term *congenital* simply implies "born with." Some congenital diseases are not genetic (e.g., congenital syphilis). Not all genetic diseases are congenital; individuals with Huntington disease, for example, begin to manifest their condition only after their 20s or 30s.

MENDELIAN DISORDERS

Virtually all Mendelian disorders are the result of mutations in single genes that have large effects. It is not necessary to detail Mendel's laws here, since every student in biology, and possibly every garden pea, has learned about them at an early age. Only some comments of medical relevance are made.

It is estimated that every individual is a carrier of several deleterious genes; most of these genes are recessive and therefore do not have serious phenotypic effects. About 80% to 85% of these mutations are familial. The remainder represent new mutations acquired de novo by an affected individual.

Most mutations in autosomal genes produce partial expression in the heterozygote and full expression in the homozygote. Sickle cell anemia is caused by substitution of normal hemoglobin (HbA) by hemoglobin S (HbS). When an individual is homozygous for the mutant gene, all the hemoglobin is of the abnormal, HbS, type, and even with normal saturation of oxygen the disorder is fully expressed (i.e., sickling deformity of all red cells and hemolytic anemia). In the heterozygote, only a proportion of the hemoglobin is HbS (the remainder being HbA), and therefore red cell sickling occurs only under unusual circumstances, such as exposure to lowered oxygen tension. This is referred to as the *sickle cell trait* to differentiate it from full-blown sickle cell anemia.

Although Mendelian traits are usually described as dominant or recessive, in some cases both of the alleles of a gene pair contribute to the phenotype—a condition called *codominance.* Histocompatibility and blood group antigens are good examples of codominant inheritance.

A single mutant gene may lead to many end effects, termed *pleiotropism;* conversely, mutations at several genetic loci may produce the same trait *(genetic heterogeneity).* Sickle cell anemia is an example of pleiotropism. In this hereditary disorder, not only does the point mutation in the gene give rise to HbS, which predisposes the red cells to hemolysis, but also the abnormal red cells tend to cause a logjam in small vessels, inducing, for example, splenic fibrosis, organ infarcts, and bone changes. The numerous differing end-organ derangements all are related to the primary defect in hemoglobin synthesis. On the other hand, profound childhood deafness, an apparently homogeneous clinical entity, results from many different types of autosomal recessive mutations. Recognition of genetic heterogeneity not only is important in genetic counseling but also is relevant in the understanding of the pathogenesis of some common disorders, such as diabetes mellitus.

Transmission Patterns of Single-Gene Disorders

Mutations involving single genes typically follow one of three patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked. The general rules that govern the transmission of single-gene disorders are well known; only a few salient features are summarized. Single-gene disorders with nonclassic patterns of inheritance are described later.

Autosomal Dominant Disorders

Autosomal dominant disorders are manifested in the heterozygous state, so at least one parent of an index case is usually affected; both males and females are affected, and both can transmit the condition. When an affected person marries an unaffected one, every child has one chance in two of having the disease. In addition to these basic rules, autosomal dominant conditions are characterized by the following:

- *With every autosomal dominant disorder, some proportion of patients do not have affected parents.* Such patients owe their disorder to new mutations involving either the egg or the sperm from which they were derived. Their siblings are neither affected nor at increased risk for disease development. The proportion of patients who develop the disease as a result of a new mutation is related to the effect of the disease on reproductive capability. If a disease markedly reduces reproductive fitness, most cases would be expected to result from new mutations. Many new mutations seem to occur in germ cells of relatively older fathers.
- *Clinical features can be modified by variations in penetrance and expressivity.* Some individuals inherit the mutant gene but are phenotypically normal. This is referred to as *incomplete penetrance.* Penetrance is expressed in mathematical terms. Thus 50% penetrance indicates that 50% of those who carry the gene express the trait. In contrast to penetrance, if a trait is seen in all individuals carrying the mutant gene but is expressed differently among individuals, the phenomenon is called *variable expressivity.* For example, manifestations of neurofibromatosis type 1 range from brownish spots on the skin to multiple skin tumors and skeletal deformities. The mechanisms underlying

incomplete penetrance and variable expressivity are not fully understood, but they most likely result from effects of other genes or environmental factors that modify the phenotypic expression of the mutant allele. For example, the phenotype of a patient with sickle cell anemia (resulting from mutation at the β-globin locus) is influenced by the genotype at the α-globin locus because the latter influences the total amount of hemoglobin made (Chapter 14). The influence of environmental factors is exemplified by individuals heterozygous for familial hypercholesterolemia (FH). The expression of the disease in the form of atherosclerosis is conditioned by the dietary intake of lipids.

- In many conditions the age at onset is delayed; symptoms and signs may not appear until adulthood (as in Huntington disease).

The molecular mechanisms of autosomal dominant disorders depend on the nature of the mutation and the type of protein affected. Most mutations lead to the reduced production of a gene product or give rise to a dysfunctional or inactive protein. Whether such a mutation gives rise to dominant or recessive disease depends on whether the remaining copy of the gene is capable of compensating for the loss. Thus, understanding the reasons why particular loss-of-function mutations give rise to dominant versus recessive disease patterns requires an understanding of the biology. Many autosomal dominant diseases arising from deleterious mutations fall into one of a few familiar patterns:

1. *Diseases involved in regulation of complex metabolic pathways that are subject to feedback inhibition.* Membrane receptors such as the low-density lipoprotein (LDL) receptor provide one such example; in FH, discussed later, a 50% loss of LDL receptors results in a secondary elevation of cholesterol that, in turn, predisposes to atherosclerosis in affected heterozygotes.
2. *Key structural proteins, such as collagen and cytoskeletal elements of the red cell membrane* (e.g., spectrin). The biochemical mechanisms by which a 50% reduction in the amounts of such proteins results in an abnormal phenotype are not fully understood. In some cases, especially when the gene encodes one subunit of a multimeric protein, the product of the mutant allele can interfere with the assembly of a functionally normal multimer. For example, the collagen molecule is a trimer in which the three collagen chains are arranged in a helical configuration. Each of the three collagen chains in the helix must be normal for the assembly and stability of the collagen molecule. Even with a single mutant collagen chain, normal collagen trimers cannot be formed, and hence there is a marked deficiency of collagen. In this instance the mutant allele is called *dominant negative* because it impairs the function of a normal allele. This effect is illustrated by some forms of osteogenesis imperfecta, characterized by marked deficiency of collagen and severe skeletal abnormalities (Chapter 26).

Less common than loss-of-function mutations are *gain-of-function* mutations, which can take two forms. Some mutations result in an increase in normal function of a protein, for example, excessive enzymatic activity. In other cases, mutations impart a wholly new activity completely unrelated to the affected protein's normal function. The transmission of disorders produced by gain-of-function mutations is almost always autosomal dominant, as illustrated by Huntington disease (Chapter 28). In this disease the trinucleotide-repeat mutation affecting the Huntington gene (see later) gives rise to an abnormal protein, called *huntingtin,* that is toxic to neurons, and hence even heterozygotes develop a neurologic deficit.

Table 5.1 lists common autosomal dominant disorders. Many are discussed more logically in other chapters. A few conditions not considered elsewhere are discussed later in this chapter to illustrate important principles.

Autosomal Recessive Disorders

Autosomal recessive traits make up the largest category of Mendelian disorders. They occur when both alleles at a given gene locus are mutated. These disorders are characterized by the following features: (1) The trait does not usually affect the parents of the affected individual, but siblings may show the disease; (2) siblings have one chance in four of having the trait (i.e., the recurrence risk is 25% for each birth); and (3) if the mutant gene occurs with a low frequency in the population, there is a strong likelihood that the affected individual (proband) is the product of a consanguineous marriage. The following features generally apply to most autosomal recessive disorders and distinguish them from autosomal dominant diseases:

- The expression of the defect tends to be more uniform than in autosomal dominant disorders.
- Complete penetrance is common.
- Onset is frequently early in life.
- Although new mutations associated with recessive disorders do occur, they are rarely detected clinically. Since the individual with a new mutation is an asymptomatic heterozygote, several generations may pass before the descendants of such a person mate with other heterozygotes and produce affected offspring.
- Many of the mutated genes encode enzymes. In heterozygotes, equal amounts of normal and defective enzyme are synthesized. Usually the natural "margin of safety"

Table 5.1 Autosomal Dominant Disorders

System	Disorder
Nervous	Huntington disease Neurofibromatosis Myotonic dystrophy Tuberous sclerosis
Urinary	Polycystic kidney disease
Gastrointestinal	Familial polyposis coli
Hematopoietic	Hereditary spherocytosis von Willebrand disease

ensures that cells with half the usual complement of the enzyme function normally.

Autosomal recessive disorders include almost all inborn errors of metabolism. The various consequences of enzyme deficiencies are discussed later. The more common of these conditions are listed in Table 5.2. Most are presented elsewhere; a few prototypes are discussed later in this chapter.

X-Linked Disorders

All sex-linked disorders are X-linked, and almost all are recessive. Several genes are located in the male-specific region of Y; all of these are related to spermatogenesis. *Males with mutations affecting the Y-linked genes are usually infertile, and hence there is no Y-linked inheritance.* As discussed later, a few additional genes with homologs on the X chromosome have been mapped to the Y chromosome, but only a few rare disorders resulting from mutations in such genes have been described.

X-linked recessive inheritance accounts for a small number of well-defined clinical conditions. The Y chromosome, for the most part, is not homologous to the X chromosome, and so mutant genes on the X chromosome do not have corresponding alleles on the Y chromosome. Thus, males are said to be *hemizygous* for X-linked mutant genes, so these disorders are expressed in males. Other features that characterize these disorders are as follows:

- An affected male does not transmit the disorder to his sons, but all daughters are carriers. Sons of heterozygous women have, of course, one chance in two of receiving the mutant gene.
- A heterozygous female usually does not express the full phenotypic change because of the paired normal allele. Because of the random inactivation of one of the X chromosomes in the female, however, females have a variable proportion of cells in which the mutant X chromosome is active. Thus it is remotely possible for the normal allele to be inactivated in most cells, permitting full expression of heterozygous X-linked conditions in females. Much more commonly, the normal allele is inactivated in only some of the cells, and thus a heterozygous female expresses the disorder partially. An illustrative condition is *glucose-6-phosphate dehydrogenase (G6PD) deficiency*. Transmitted on the X chromosome, this enzyme deficiency, which predisposes to red cell hemolysis in patients receiving certain types of drugs (Chapter 14), is expressed principally in males. In females, a proportion of the red cells may be derived from precursors with inactivation of the normal allele. Such red cells are at the same risk for undergoing hemolysis as the red cells in hemizygous males. Thus, females are not only carriers of this trait but also are susceptible to drug-induced hemolytic reactions. Because the proportion of defective red cells in heterozygous females depends on the random inactivation of one of the X chromosomes, however, the severity of the hemolytic reaction is almost always less in heterozygous women than in hemizygous men. Most of the X-linked conditions listed in Table 5.3 are covered elsewhere in the text.

There are only a few *X-linked dominant* conditions. They are caused by dominant disease-associated alleles on the X chromosome. These disorders are transmitted by an affected heterozygous female to half her sons and half her daughters and by an affected male parent to all his daughters but none of his sons, if the female parent is unaffected. Vitamin D–resistant rickets and Alport syndrome are examples of this type of inheritance.

KEY CONCEPTS

TRANSMISSION PATTERNS OF SINGLE-GENE DISORDERS

- Autosomal dominant disorders are characterized by expression in heterozygous state; they affect males and females equally, and both sexes can transmit the disorder.
- Enzyme proteins are not affected in autosomal dominant disorders; instead, receptors and structural proteins are involved.
- Autosomal recessive diseases occur when both copies of a gene are mutated; enzyme proteins are frequently involved. Males and females are affected equally.
- X-linked disorders are transmitted by heterozygous females to their sons, who manifest the disease. Female carriers usually are protected because of random inactivation of one X chromosome.

Table 5.3 X-Linked Recessive Disorders

System	Disease
Musculoskeletal	Duchenne muscular dystrophy

Biochemical and Molecular Basis of Single-Gene (Mendelian) Disorders

Mendelian disorders result from alterations involving single genes. The genetic defect may lead to the formation of an abnormal protein or a reduction in the output of the gene product. Virtually any type of protein may be affected in single-gene disorders and by a variety of mechanisms (Table 5.4). To some extent the pattern of inheritance of the disease is related to the kind of protein affected by the mutation. For this discussion, the mechanisms involved in single-gene disorders can be classified into four categories: (1) enzyme defects and their consequences; (2) defects in membrane receptors and transport systems; (3) alterations in the structure, function, or quantity of nonenzyme proteins; and (4) mutations resulting in unusual reactions to drugs.

Enzyme Defects and Their Consequences

Mutations may result in the synthesis of an enzyme with reduced activity or a reduced amount of a normal enzyme. In either case, the consequence is a metabolic block. Fig. 5.5 provides an example of an enzyme reaction in which the substrate is converted by intracellular enzymes, denoted as 1, 2, and 3, into an end product through intermediates 1 and 2. In this model the final product exerts feedback control on enzyme 1. A minor pathway producing small quantities of M1 and M2 also exists. The biochemical consequences of an enzyme defect in such a reaction may lead to three major consequences:

- *Accumulation of the substrate,* depending on the site of block, may be accompanied by accumulation of one or both intermediates. Moreover, an increased concentration of intermediate 2 may stimulate the minor pathway and

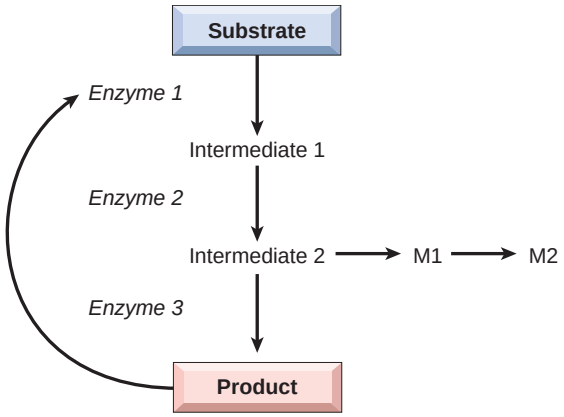

Figure 5.5 A possible metabolic pathway in which a substrate is converted to an end product by a series of enzyme reactions. *M1, M2,* Products of a minor pathway.

Table 5.4 Biochemical and Molecular Basis of Some Mendelian Disorders

Protein Type/Function	Example	Molecular Lesion	Disease
Enzyme	Phenylalanine hydroxylase	Splice-site mutation: reduced amount	Phenylketonuria
	Hexosaminidase A	Splice-site mutation or frameshift mutation with stop codon: reduced amount	Tay-Sachs disease
	Adenosine deaminase	Point mutations: abnormal protein with reduced activity	Severe combined immunodeficiency
Enzyme inhibitor	α_1-Antitrypsin	Missense mutations: impaired secretion from liver to serum	Emphysema and liver disease
Receptor	Low-density lipoprotein receptor	Deletions, point mutations: reduction of synthesis, transport to cell surface, or binding to low-density lipoprotein	Familial hypercholesterolemia
	Vitamin D receptor	Point mutations: failure of normal signaling	Vitamin D–resistant rickets
Transport			
Oxygen	Hemoglobin	Deletions: reduced amount	α-Thalassemia
		Defective mRNA processing: reduced amount	β-Thalassemia
		Point mutations: abnormal structure	Sickle cell anemia
Ion channels	Cystic fibrosis transmembrane conductance regulator	Deletions and other mutations: nonfunctional or misfolded proteins	Cystic fibrosis
Structural			
Extracellular	Collagen	Deletions or point mutations cause reduced amount of normal collagen or normal amounts of defective collagen	Osteogenesis imperfecta Ehlers-Danlos syndromes
	Fibrillin	Missense mutations	Marfan syndrome
Cell membrane	Dystrophin	Deletion with reduced synthesis	Duchenne/Becker muscular dystrophy
	Spectrin, ankyrin, or protein 4.1	Heterogeneous	Hereditary spherocytosis
Hemostasis	Factor VIII	Deletions, insertions, nonsense mutations, and others: reduced synthesis or abnormal factor VIII	Hemophilia A
Growth regulation	Rb protein	Deletions	Hereditary retinoblastoma
	Neurofibromin	Heterogeneous	Neurofibromatosis type I

thus lead to an excess of M1 and M2. Under these conditions tissue injury may result if the precursor, the intermediates, or the products of alternative minor pathways are toxic in high concentrations. For example, in galactosemia, the deficiency of galactose-1-phosphate uridyltransferase (Chapter 10) leads to the accumulation of galactose and consequent tissue damage. Excessive accumulation of complex substrates within the lysosomes as a result of deficiency of degradative enzymes is responsible for a group of diseases generally referred to as *lysosomal storage diseases.*

- *An enzyme defect can lead to a metabolic block and a decreased amount of end product* that may be necessary for normal function. For example, a deficiency of melanin may result from lack of tyrosinase, which is necessary for the biosynthesis of melanin from its precursor, tyrosine, resulting in the clinical condition called *albinism.* If the end product is a feedback inhibitor of the enzymes involved in the early reactions (in Fig. 5.5 it is shown that the product inhibits enzyme 1), the deficiency of the end product may permit overproduction of intermediates and their catabolic products, some of which may be injurious at high concentrations. A prime example of a disease with such an underlying mechanism is Lesch-Nyhan syndrome (Chapter 26).
- *Failure to inactivate a tissue-damaging substrate* is best exemplified by α_1-antitrypsin deficiency. Individuals who have an inherited deficiency of serum α_1-antitrypsin are unable to inactivate neutrophil elastase in their lungs. Unchecked activity of this protease leads to destruction of elastin in the walls of lung alveoli, leading eventually to pulmonary emphysema (Chapter 15).

Defects in Receptors and Transport Systems

As we discussed in Chapter 1, biologically active substances have to be actively transported across the cell membrane. In some cases, transport is achieved by receptor-mediated endocytosis. A genetic defect in a receptor-mediated transport system is exemplified by familial hypercholesterolemia (FH), in which reduced synthesis or function of LDL receptors leads to defective transport of LDL into the cells and secondarily to excessive cholesterol synthesis by complex intermediary mechanisms. In cystic fibrosis the transport system for chloride and bicarbonate ions in exocrine glands, sweat ducts, lungs, and pancreas is defective. By complex mechanisms not fully understood, impaired anion transport leads to serious injury to the lungs and pancreas (Chapter 10).

Alterations in Structure, Function, or Quantity of Nonenzyme Proteins

Genetic defects resulting in alterations of nonenzyme proteins often have widespread secondary effects, as exemplified by sickle cell disease. The hemoglobinopathies, sickle cell disease being one, all of which are characterized by defects in the structure of the globin molecule, best exemplify this category. In contrast to the hemoglobinopathies, the thalassemias result from mutations in globin genes that affect the amount of globin chains synthesized. Thalassemias are associated with reduced amounts of structurally normal α-globin or β-globin chains (Chapter 14). Other examples of genetic disorders involving defective structural proteins include osteogenesis imperfecta (defect in collagen, Chapter 26), hereditary spherocytosis (spectrin, Chapter 14), and muscular dystrophies (dystrophin, Chapter 27).

Genetically Determined Adverse Reactions to Drugs

Certain genetically determined enzyme deficiencies are unmasked only after exposure of the affected individual to certain drugs. This special area of genetics, called *pharmacogenetics,* is of considerable clinical importance. The classic example of drug-induced injury in the genetically susceptible individual is associated with a deficiency of the enzyme G6PD. Under normal conditions, G6PD deficiency does not result in disease, but on administration, for example, of the antimalarial drug primaquine, a severe hemolytic anemia results (Chapter 14). In recent years an increasing number of polymorphisms of genes encoding drug-metabolizing enzymes, transporters, and receptors have been identified. In some cases these genetic factors have a major impact on drug sensitivity and adverse reactions. It is hoped that advances in pharmacogenetics will lead to patient-tailored therapy, an example of personalized medicine.

With this overview of the biochemical basis of single-gene disorders, we now consider selected examples grouped according to the underlying defect.

Disorders Associated With Defects in Structural Proteins

Several diseases caused by mutations in genes that encode structural proteins are listed in Table 5.4. Many are discussed elsewhere in the text. Only Marfan syndrome and Ehlers-Danlos syndromes (EDSs) are discussed here because they affect connective tissue and hence involve multiple organ systems.

Marfan Syndrome

Marfan syndrome is a disorder of connective tissues, manifested principally by changes in the skeleton, eyes, and cardiovascular system. Its prevalence is estimated to be 1 in 5000. Approximately 70% to 85% of cases are familial and transmitted by autosomal dominant inheritance. The remainder are sporadic and arise from new mutations.

Pathogenesis

Marfan syndrome results from an inherited defect in an extracellular glycoprotein called *fibrillin-1*. There are two fundamental mechanisms by which loss of fibrillin leads to the clinical manifestations of Marfan syndrome: loss of structural support in microfibril-rich connective tissue and excessive activation of transforming growth factor (TGF)-β signaling. Each of these is discussed below.

- *Fibrillin is the major component of microfibrils found in the extracellular matrix* (Chapter 1). These fibrils provide a scaffold on which tropoelastin is deposited to form elastic fibers. Although microfibrils are widely distributed in the body, they are particularly abundant in the aorta, ligaments, and the ciliary zonules that support the lens; these tissues are prominently affected in Marfan syndrome. Fibrillin occurs in two homologous forms, fibrillin-1 and fibrillin-2, encoded by two separate genes, *FBN1* and *FBN2,* mapped on chromosomes 15q21.1 and 5q23.31, respectively. Mutations of *FBN1* underlie Marfan syndrome; mutations of the related *FBN2* gene are less

common, and they give rise to *congenital contractural arachnodactyly,* an autosomal dominant disorder characterized by skeletal abnormalities. Mutational analysis has revealed close to 1000 distinct mutations of the *FBN1* gene in individuals with Marfan syndrome. Most of these are missense mutations that give rise to abnormal fibrillin-1. These can inhibit polymerization of fibrillin fibers (dominant negative effect). Alternatively, the reduction of fibrillin content below a certain threshold weakens the connective tissue (haploinsufficiency).

- *TGF-β bioavailability*. While many clinical manifestations of Marfan syndrome can be explained by changes in the mechanical properties of the extracellular matrix resulting from abnormalities of fibrillin, several others such as bone overgrowth and myxoid changes in mitral valves cannot be attributed to changes in tissue elasticity. It is now established that fibrillin-1 controls the bioavailability of TGF-β. Reduced or altered forms of fibrillin-1 give rise to abnormal and excessive activation of TGF-β, since normal microfibrils sequester TGF-β. Excessive TGF-β signaling, in turn, leads to inflammation, has deleterious effects on vascular smooth muscle development, and increases the activity of metalloproteases, causing loss of extracellular matrix. This schema is supported by two sets of observations.
  - First, gain-of-function mutations in the TGF-β type II receptor give rise to a related syndrome, called Marfan syndrome type 2 (MFS2). Furthermore, patients with germline mutations in one isoform of TGF-β, called TGF-β3, present with an inherited predisposition to aortic aneurysm and other cardiovascular manifestations similar to those found in patients with classic Marfan syndrome.
  - Second, angiotensin receptor II blockers, which inhibit TGF-β activity, markedly reduce the aortic root diameter in mouse models of Marfan syndrome. Clinical trials are under way to evaluate the efficacy of angiotensin receptor blockade in patients with Marfan syndrome.

MORPHOLOGY

Skeletal abnormalities are the most striking feature of Marfan syndrome. Typically the patient is unusually tall with exceptionally long extremities and long, tapering fingers and toes. The joint ligaments in the hands and feet are lax, suggesting that the patient is double-jointed; typically the thumb can be hyperextended back to the wrist. The head is commonly dolichocephalic (long-headed) with bossing of the frontal eminences and prominent supraorbital ridges. A variety of spinal deformities may appear, including kyphosis, scoliosis, or rotation or slipping of the dorsal or lumbar vertebrae. The chest is classically deformed, presenting either pectus excavatum (deeply depressed sternum) or a pigeon-breast deformity.

Ocular changes take many forms. Most characteristic is bilateral subluxation or dislocation (usually outward and upward) of the lens, referred to as ectopia lentis. This abnormality, resulting from weakening of ciliary zonules, is so uncommon in persons who do not have this disease that the finding of bilateral ectopia lentis should raise the suspicion of Marfan syndrome.

Cardiovascular lesions are the most life-threatening features of this disorder. The two most common lesions are mitral valve prolapse, which occurs in 40% to 50% of cases and, of greater importance, dilation of the ascending aorta due to cystic medionecrosis. Histologically the changes in the media are virtually identical to those found in cystic medionecrosis not related to Marfan syndrome (Chapter 12). Loss of medial support results in progressive dilation of the aortic valve ring and the root of the aorta, giving rise to severe aortic incompetence. Weakening of the media predisposes to an intimal tear, which may initiate an intramural hematoma that cleaves the layers of the media to produce **aortic dissection.** After cleaving the aortic layers for considerable distances, sometimes back to the root of the aorta or down to the iliac arteries, the hemorrhage often ruptures through the aortic wall.

Clinical Features

Although mitral valve lesions are more frequent, they are clinically less important than aortic lesions. Loss of connective tissue support in the mitral valve leaflets makes them soft and billowy, creating a so-called floppy valve (Chapter 12). Valvular lesions, along with lengthening of the chordae tendineae, frequently give rise to mitral regurgitation. Similar changes may affect the tricuspid and, rarely, the aortic valves. Echocardiography greatly enhances the ability to detect the cardiovascular abnormalities and is therefore extremely valuable in the diagnosis of Marfan syndrome. The great majority of deaths are caused by rupture of aortic dissections, followed in importance by cardiac failure.

While the lesions just described typify Marfan syndrome, it must be emphasized that there is great variation in the clinical expression of this genetic disorder. Patients with prominent eye or cardiovascular changes may have few skeletal abnormalities, whereas others with striking changes in body habitus have no eye changes. Although variability in clinical expression may be seen within a family, interfamilial variability is much more common and extensive. Because of such variations, the clinical diagnosis of Marfan syndrome is currently based on the so-called revised Ghent criteria. These take into account family history, cardinal clinical signs in the absence of family history, and presence or absence of fibrillin mutation. In general, major involvement of two of the four organ systems (skeletal, cardiovascular, ocular, and skin) and minor involvement of another organ is required for diagnosis.

The variable expression of the Marfan defect is best explained on the basis of the many different mutations that affect the fibrillin locus, which number around 1000. This genetic heterogeneity also poses formidable challenges in the diagnosis of Marfan syndrome. The evolving high throughput sequencing technologies discussed later in this chapter may overcome this problem in the future.

Ehlers-Danlos Syndromes (EDSs)

EDSs comprise a clinically and genetically heterogeneous group of disorders that result from some mutations in genes that encode collagen, enzymes that modify collagen, and less commonly other proteins present in the extracellular matrix. Other disorders resulting from mutations affecting collagen synthesis include osteogenesis imperfecta (Chapter 26), Alport syndrome (Chapter 20), and epidermolysis bullosa (Chapter 25).

Biosynthesis of collagen is a complex process (Chapter 1) that can be disturbed by genetic errors that may affect any one of the numerous structural collagen genes or enzymes necessary for posttranscriptional modifications of collagen. Hence the mode of inheritance of EDSs encompasses all three Mendelian patterns. On the basis of clinical and molecular characteristics, six variants of EDS have been recognized. These are listed in Table 5.5. More recently, next-generation sequencing has revealed other subgroups bringing the total to 11 molecular types. Although individually rare, the collective frequency of EDSs is 1 in 5000 births. It is beyond the scope of this book to discuss each variant individually; instead, the important clinical features common to most variants are summarized, and clinical manifestations are correlated with the underlying molecular defects in collagen synthesis or structure.

As might be expected, tissues rich in collagen, such as skin, ligaments, and joints, are frequently involved in most variants of EDS. Because the abnormal collagen fibers lack adequate tensile strength, *skin is hyperextensible, and the joints are hypermobile.* These features permit grotesque contortions, such as bending the thumb backward to touch the forearm and bending the knee forward to create almost a right angle. It is believed that most contortionists have one of the EDSs. A predisposition to joint dislocation, however, is one of the prices paid for this virtuosity. *The skin is extraordinarily stretchable, extremely fragile, and easily bruised.* Minor injuries produce gaping defects, and surgical repair or intervention is accomplished with great difficulty because of the lack of normal tensile strength. *The basic defect in connective tissue may lead to serious internal complications.* These include rupture of the colon and large arteries (vascular EDS), ocular fragility with rupture of cornea and retinal detachment (kyphoscoliosis EDS), and diaphragmatic hernia (classic EDS).

The biochemical and molecular bases of these abnormalities are known in all but one form of EDS—the so-called hypermobility type. Some of the EDS types are described briefly because they offer some insights into the perplexing clinical heterogeneity of these disorders. Perhaps the best characterized is the *kyphoscoliosis type*, the most common autosomal recessive form of EDS. It results from mutations in the *PLOD1* gene encoding lysyl hydroxylase, an enzyme necessary for hydroxylation of lysine residues during collagen synthesis. Affected patients have markedly reduced levels of this enzyme. Because hydroxylysine is essential for intermolecular and intramolecular cross-linking of collagen fibers, a deficiency of lysyl hydroxylase results in the synthesis of collagen that lacks normal structural stability.

The *vascular type of EDS* results from abnormalities of type III collagen. This form is genetically heterogeneous because at least three distinct types of mutations affecting the *COL3A1* gene encoding collagen type III can give rise to this variant. Some affect the rate of synthesis of pro-α1 (III) chains, others affect the secretion of type III procollagen, and still others lead to the synthesis of structurally abnormal type III collagen. Some mutant alleles behave as dominant negatives (see discussion under "Autosomal Dominant Disorders") and thus produce severe phenotypic effects. These molecular studies provide a rational basis for the pattern of transmission and clinical features that are characteristic of this variant. First, because vascular-type EDS results from mutations involving a structural protein (rather than an enzyme protein), an autosomal dominant pattern of inheritance would be expected. Second, because blood vessels and intestines are known to be rich in collagen type III, an abnormality of this collagen is consistent with severe structural defects (e.g., vulnerability to spontaneous rupture) in these organs. Unlike many other EDS subtypes, the skin is not usually hyperextensible.

In two forms of EDS—arthrochalasia type and dermatosparaxis type—the fundamental defect is in the conversion of type I procollagen to collagen. This step in collagen synthesis involves cleavage of noncollagen peptides at the N terminus and C terminus of the procollagen molecule. This is accomplished by N-terminal–specific and C-terminal–specific peptidases. The defect in the conversion of procollagen to collagen in the arthrochalasia type has been traced to mutations that affect one of the two type I collagen genes, *COL1A1* and *COL1A2*. As a result, structurally abnormal pro-α1 (I) or pro-α2 (I) chains that resist cleavage of N-terminal peptides are formed. In patients with a single mutant allele, only 50% of the type I collagen chains are abnormal, but because these chains interfere with the formation of normal collagen helices, heterozygotes manifest the disease. In contrast, the related dermatosparaxis type is caused by mutations in the *ADAMTS2* gene that encodes procollagen-N-peptidase, essential for the cleavage of procollagens. Because in this case the disease is caused by an enzyme deficiency, it follows an autosomal recessive form of inheritance.

Finally, in the *classic type of EDS,* molecular analysis suggests that genes other than those that encode collagen may also be involved. In close to 90% of cases, mutations in the genes for type V collagen (*COL5A1* and *COL5A2*) have been detected. Surprisingly, in the remaining cases, no other collagen gene abnormalities have been found despite clinical similarity with the classic type EDS. It is suspected

Table 5.5 Classification of Ehlers-Danlos Syndromes

EDS Type[a]	Clinical Findings	Inheritance	Gene Defects
Classic (I/II)	Skin and joint hypermobility, atrophic scars, easy bruising	Autosomal dominant	*COL5A1*, *COL5A2*
Hypermobility (III)	Joint hypermobility, pain, dislocations	Autosomal dominant	Unknown
Vascular (IV)	Thin skin, arterial or uterine rupture, bruising, small joint hyperextensibility	Autosomal dominant	*COL3A1*
Kyphoscoliosis (VI)	Hypotonia, joint laxity, congenital scoliosis, ocular fragility	Autosomal recessive	Lysyl hydroxylase
Arthrochalasia (VIIa, VIIb)	Severe joint hypermobility, skin changes (mild), scoliosis, bruising	Autosomal dominant	*COL1A1*, *COL1A2*
Dermatosparaxis (VIIc)	Severe skin fragility, cutis laxa, bruising	Autosomal recessive	Procollagen *N*-peptidase

[a]EDS types were previously classified by Roman numerals. Parentheses show previous numerical equivalents.

that in some cases, genetic defects that affect the biosynthesis of other extracellular matrix molecules that influence collagen synthesis indirectly may be involved. One example is a classic EDS-like condition caused by mutation in the *TNXB* gene encoding tenascin-X, a large multimeric protein that interacts with fibrillar types I, III, and V collagens.

To summarize, the common thread in EDSs is some abnormality of collagen. These disorders, however, are extremely heterogeneous. At the molecular level, a variety of defects, varying from mutations involving structural genes for collagen to those involving enzymes that are responsible for posttranscriptional modifications of mRNA, have been detected. Such molecular heterogeneity results in the expression of EDSs as clinically variable disorders with several patterns of inheritance.

KEY CONCEPTS

MARFAN SYNDROME AND EHLERS-DANLOS SYNDROMES

Marfan Syndrome

- Marfan syndrome is caused by a mutation in the *FBN1* gene encoding fibrillin, which is required for structural integrity of connective tissues and regulation of TGF-β signaling.
- The major tissues affected are the skeleton, eyes, and cardiovascular system.
- Clinical features may include tall stature, long fingers, bilateral subluxation of lens, mitral valve prolapse, aortic aneurysm, and aortic dissection.

Ehlers-Danlos Syndromes

- There are several variants of EDS, all characterized by defects in collagen synthesis or assembly. Each of the variants is caused by a distinct mutation involving one of several collagen genes or genes that encode other ECM proteins like tenascin-X.
- Clinical features may include fragile, hyperextensible skin vulnerable to trauma; hypermobile joints; and ruptures involving the colon, cornea, or large arteries. Wound healing is poor.

Disorders Associated With Defects in Receptor Proteins

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is caused most commonly by mutations in the gene encoding the receptor for LDL, resulting in inadequate removal of plasma LDL by the liver. Mutations in the LDL receptor gene *(LDLR)* account for 80% to 85% of cases of FH. Much less commonly, FH is caused by mutations in two other genes involved in clearance of plasma LDL. They encode (1) apolipoprotein B-100 (ApoB), the ligand for LDL receptor on the LDL particle (5% to 10% cases), and (2) proprotein convertase subtilisin/kexin type 9 (1% to 2% cases). This enzyme, better known by its abbreviation *PCSK9*, reduces expression of LDL receptors by downregulating their recycling and consequent degradation in lysosomes. Each of these three types of mutations impairs hepatic clearance of LDL and increases serum levels of cholesterol, giving rise to premature atherosclerosis and a greatly increased risk of myocardial infarction. The functions of these genes in cholesterol metabolism are discussed below.

FH caused by LDL receptor mutations is one of the most frequently occurring Mendelian disorders. Heterozygotes with one mutant gene, representing about 1 in 200 individuals, have from birth a twofold to threefold elevation of plasma cholesterol level, leading to tendinous xanthomas and premature atherosclerosis in adult life (Chapter 11). Homozygotes, having a double dose of the mutant gene, are much more severely affected and may have fivefold to sixfold elevations in plasma cholesterol levels. Skin xanthomas and coronary, cerebral, and peripheral vascular atherosclerosis may develop in these individuals at an early age. Myocardial infarction may occur before age 20 years. Large-scale studies have found that FH is present in 3% to 6% of survivors of myocardial infarction.

Normal Cholesterol Metabolism and Transport

Cholesterol may be derived from the diet or from endogenous synthesis. Dietary triglycerides and cholesterol are incorporated into chylomicrons in the intestinal mucosa and travel by way of the gut lymphatics to the blood. These chylomicrons are hydrolyzed by an endothelial lipoprotein lipase in the capillaries of muscle and fat. The chylomicron remnants, rich in cholesterol, are then delivered to the liver. Some of the cholesterol enters the metabolic pool (to be described), and some is excreted as free cholesterol or as bile acids into the biliary tract. The endogenous synthesis of cholesterol and LDL begins in the liver (Fig. 5.6). The first step in this process is the secretion of very-low-density

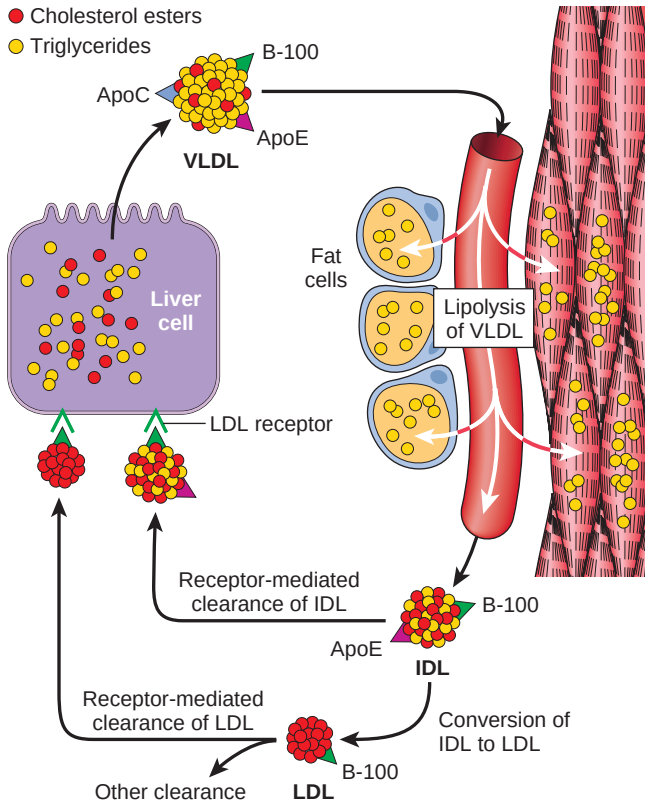

Figure 5.6 Low-density lipoprotein *(LDL)* metabolism and the role of the liver in its synthesis and clearance. Lipolysis of very-low-density lipoprotein *(VLDL)* by lipoprotein lipase in the capillaries releases triglycerides, which are then stored in fat cells and used as a source of energy in skeletal muscles. *ApoC*, Apolipoprotein C; *ApoE*, apolipoprotein E; *B-100*, apolipoprotein B-100 (ApoB); *IDL*, intermediate-density lipoprotein.

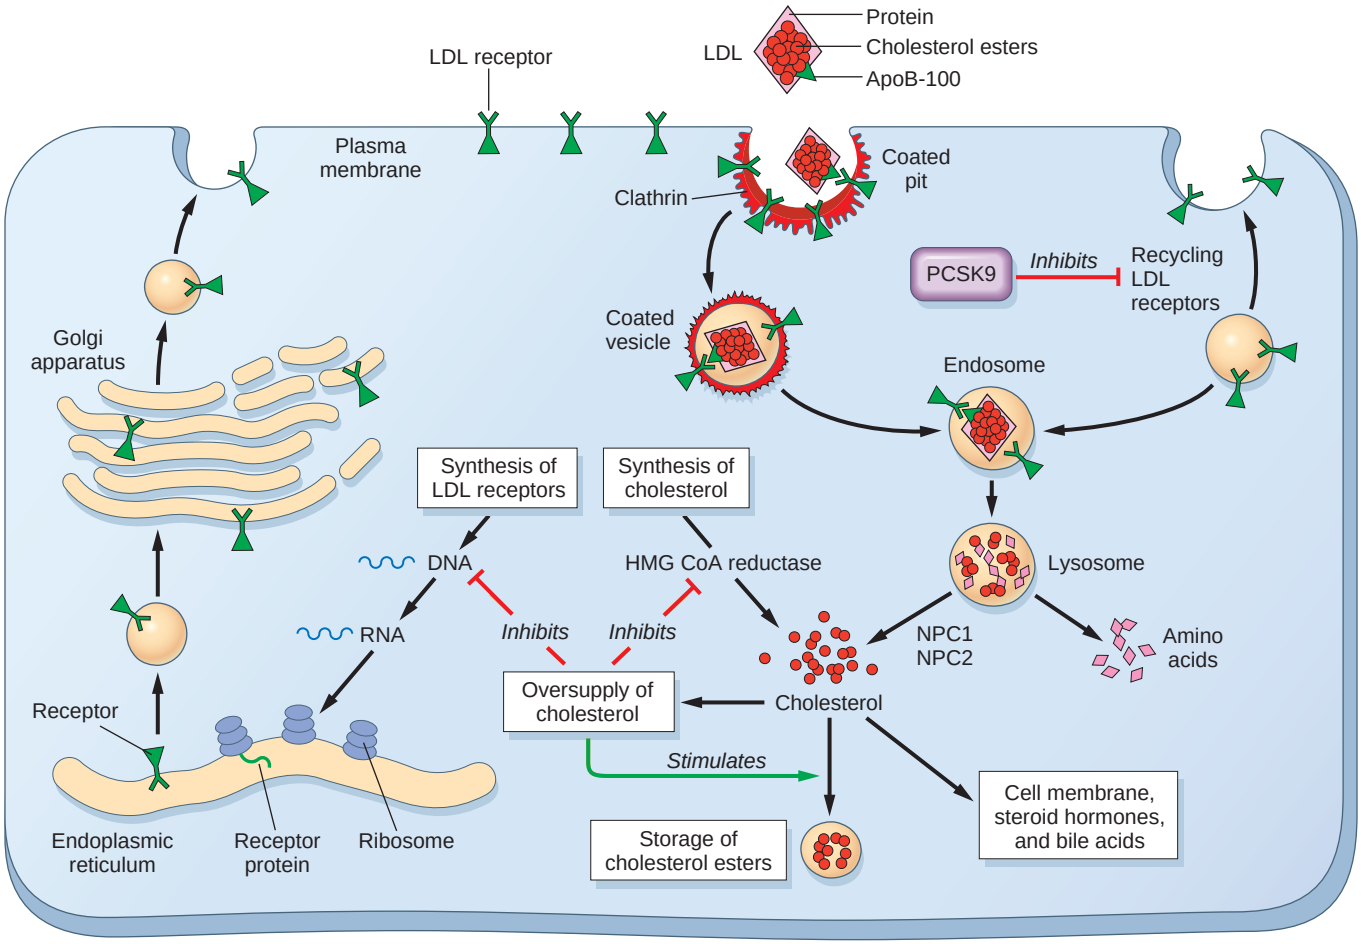

Figure 5.7 The low-density lipoprotein *(LDL)* receptor pathway and regulation of cholesterol metabolism. *ApoB-100*, Apolipoprotein B-100 (ApoB); *HMG CoA*, 3-hydroxy-3-methylglutaryl coenzyme A.

lipoprotein (VLDL) from the liver into the blood. VLDL particles are rich in triglycerides, but they contain lesser amounts of cholesteryl esters. In addition, they carry apolipoproteins ApoB, ApoC, and ApoE on their surface. In the capillaries of adipose tissue and muscle, the VLDL particle undergoes lipolysis and is converted to VLDL remnant, also called intermediate-density lipoprotein (IDL). Compared with VLDL, IDL particles have reduced content of triglycerides and an increase in cholesteryl esters. ApoC is lost, but ApoB and ApoE are retained. After release from the capillary endothelium, the IDL particles have one of two fates. Approximately 50% of newly formed IDL is rapidly taken up by the liver by receptor-mediated transport. The receptor responsible for the binding of IDL to the liver cell membrane recognizes both ApoB and ApoE. It is called ApoB/E, or more commonly the LDL receptor, because it is also involved in the hepatic clearance of LDL (described later). In the liver cells, IDL is recycled to generate VLDL. The IDL particles not taken up by the liver are subjected to further metabolic processing that removes most of the remaining triglycerides and ApoE, yielding ApoB carrying cholesterol-rich LDL particles.

Although many cell types, including fibroblasts, lymphocytes, smooth muscle cells, hepatocytes, and adrenocortical cells, possess high-affinity LDL receptors, approximately 70% of the plasma LDL is cleared by the liver, using a quite sophisticated transport process (Fig. 5.7). The first step involves binding of LDL to cell-surface receptors, which are clustered in specialized regions of the plasma membrane called *coated pits* (Chapter 1). After binding, the coated pits containing the receptor-bound LDL are internalized by invagination to form coated vesicles, after which they migrate within the cell to fuse with the lysosomes. Here the LDL dissociates from the receptor, which is recycled to the surface. The recycling of LDL receptors is regulated by PCSK9, which binds to LDL receptors on the surface of hepatocytes and causes their degradation after endocytosis. In the lysosomes the LDL molecule is enzymatically degraded; the apoprotein part is hydrolyzed to amino acids, whereas the cholesteryl esters are broken down to free cholesterol. This free cholesterol, in turn, crosses the lysosomal membrane to enter the cytoplasm, where it is used for membrane synthesis and as a regulator of cholesterol homeostasis. The exit of cholesterol from the lysosomes requires the action of two proteins, called NPC1 and NPC2 (see "Niemann-Pick Disease Type C"). Four separate processes are affected by the released intracellular cholesterol, as follows (see Fig. 5.7):

- Cholesterol *suppresses* cholesterol synthesis within the cell by inhibiting the activity of the enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, which is the rate-limiting enzyme in the synthetic pathway.

- Cholesterol *activates* the enzyme acyl-coenzyme A:cholesterol acyltransferase, favoring esterification and storage of excess cholesterol.
- Cholesterol *suppresses* the synthesis of LDL receptors, thus protecting the cells from excessive accumulation of cholesterol.
- Cholesterol *upregulates* the expression of PCSK9, which reduces recycling of LDL receptors and causes degradation of endocytosed LDL receptors. This provides an additional mechanism of protecting the cells from excessive accumulation of cholesterol.

As mentioned earlier, FH results from mutations in the gene encoding the receptor for LDL or the two genes that compromise its function. The impact of mutations in these genes is as follows:

- *Mutations in* LDLR *gene*. Heterozygotes with FH due to mutation in the *LDLR* gene possess only 50% of the normal number of high-affinity LDL receptors because they have only one normal gene. As a result of this defect in transport, the catabolism of LDL by the receptor-dependent pathways is impaired, and the plasma level of LDL increases two- to three-fold. Homozygotes have virtually no normal LDL receptors in their cells and have much higher levels of circulating LDL. In addition to defective LDL clearance, both the homozygotes and the heterozygotes have increased synthesis of LDL. The increased synthesis that contributes to hypercholesterolemia also results from a lack of LDL receptors (see Fig. 5.6). As mentioned above, IDL, the immediate precursor of plasma LDL, also uses hepatic LDL receptors (apoB/E receptors) for its transport into the liver. In FH, impaired IDL transport into the liver secondarily diverts a greater proportion of plasma IDL into the precursor pool for plasma LDL.
- *Mutations in gene encoding ApoB*. Since ApoB on the surface of LDL particles is the ligand for LDL receptors, mutant ApoB reduces the binding of LDL molecules with LDL receptors. This compromise in the binding of LDL particles to its receptors increases serum LDL cholesterol.
- *Activating mutation in the PCSK9 gene*. This mutation greatly reduces the number of LDL receptors on the cell surface because of their increased degradation during the recycling process.

The transport of LDL via the scavenger receptor seems to occur at least in part into the cells of the mononuclear phagocyte system. Monocytes and macrophages have receptors for chemically altered (e.g., acetylated or oxidized) LDL. Normally the amount of LDL transported along this scavenger receptor pathway is less than that mediated by the LDL receptor–dependent mechanisms. In the face of hypercholesterolemia, however, there is a marked increase in the scavenger receptor–mediated traffic of LDL cholesterol into the cells of the mononuclear phagocyte system and possibly the vascular walls (Chapter 11). This increase is responsible for the appearance of xanthomas and contributes to the pathogenesis of premature atherosclerosis.

The molecular genetics of FH is extremely complex. More than 2000 mutations involving the LDL receptor gene, including DNA copy number variations, insertions, deletions, and missense and nonsense mutations, have been identified.

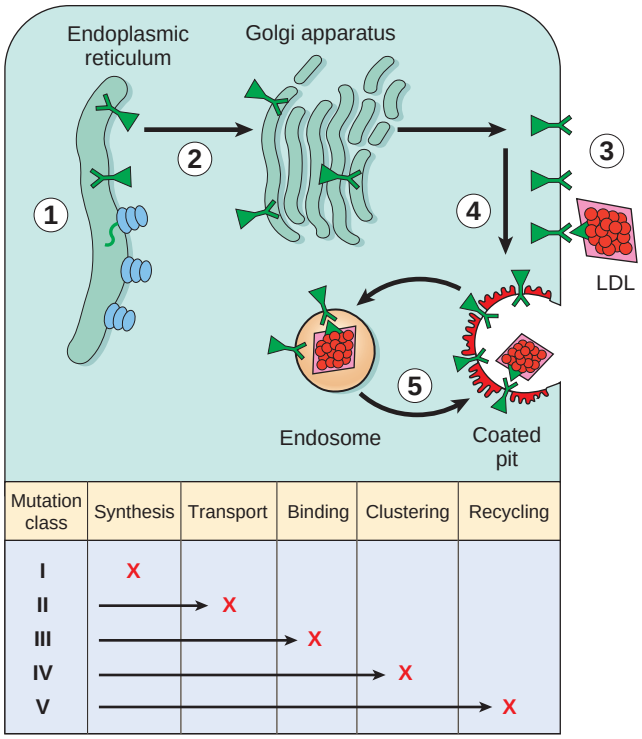

Figure 5.8 Classification of low-density lipoprotein *(LDL)* receptor mutations based on abnormal function of the mutant protein. These mutations disrupt the receptor's synthesis in the endoplasmic reticulum, transport to the Golgi complex, binding of apoprotein ligands, clustering in coated pits, and recycling in endosomes. Not shown is class VI mutation, in which initial targeting of the receptor to basolateral membrane fails to occur. Each class is heterogeneous at the DNA level. (Modified with permission from Hobbs HH, et al: The LDL receptor locus in familial hypercholesterolemia: mutational analysis of a membrane protein, *Annu Rev Genet* 24:133–170, 1990. © 1990 by Annual Reviews.)

These can be classified into six groups (Fig. 5.8). *Class I mutations* are relatively uncommon and lead to a complete failure of synthesis of the LDL receptor protein (null allele). *Class II mutations* are fairly common; they encode LDL receptor proteins that accumulate in the endoplasmic reticulum because their folding defects make it impossible for them to be transported to the Golgi complex. *Class III mutations* affect the ApoB binding site of the receptor; the mutant LDL receptors reach the cell surface but fail to bind LDL or do so poorly. *Class IV mutations* encode LDL receptors that are synthesized and transported to the cell surface efficiently. They bind LDL normally, but they fail to localize in coated pits, and hence the bound LDL is not internalized. *Class V mutations* encode LDL receptors that are expressed on the cell surface, can bind LDL, and can be internalized; however, the pH-dependent dissociation of the receptor and the bound LDL fails to occur. Such receptors are trapped in the endosome, where they are degraded, and hence they fail to recycle to the cell surface. *Class VI mutations* result in the failure of initial targeting of the LDL receptor to the basolateral membrane.

The discovery of the critical role of LDL receptors in cholesterol homeostasis has led to the rational design of drugs that lower plasma cholesterol by increasing the number of LDL receptors (see Fig. 5.8). One strategy is

based on the ability of certain drugs (statins) to suppress intracellular cholesterol synthesis by inhibiting the enzyme HMG CoA reductase. The reduction in intracellular cholesterol allows greater synthesis of LDL receptors by removing the braking action of cholesterol on LDL receptor synthesis. In another strategy, antibodies that inhibit PCSK9 function reduce the degradation of LDL receptors, thereby increasing their abundance on the cell membrane and consequent increased clearance of LDL cholesterol from the blood. These agents have profound cholesterol-lowering effects, and large clinical trials have shown the benefits of using this class of drugs in the treatment of patients who do not respond adequately to statins alone. Interestingly, PCSK9 was discovered accidentally in individuals with exceedingly low serum cholesterol who were found to have loss-of-function variants of the *PCSK9* gene.

KEY CONCEPTS

FAMILIAL HYPERCHOLESTEROLEMIA

- FH is an autosomal dominant disorder caused by mutations in the genes encoding the (1) LDL receptor (85% cases), (2) ApoB protein (5% to 10% cases), or (3) activating mutations of PCSK9 (1% to 2% cases).
- Patients develop hypercholesterolemia as a consequence of impaired transport of LDL into the cells.
- In heterozygotes for mutations in the *LDLR* gene, elevated serum cholesterol greatly increases the risk of atherosclerosis and resultant coronary artery disease; homozygotes have an even greater increase in serum cholesterol and a higher frequency of ischemic heart disease. Cholesterol also deposits along tendon sheaths to produce xanthomas.

Disorders Associated With Enzyme Defects

Lysosomal Storage Diseases

Lysosomes are key components of the intracellular digestive system. They contain a battery of hydrolytic enzymes, which have two special properties. First, they function in the acidic milieu of the lysosomes. Second, these enzymes constitute a special category of secretory proteins that are destined not for the extracellular fluids but for intracellular organelles. This latter characteristic requires special processing within the Golgi apparatus, which merits brief discussion.

Similar to all other secretory proteins, lysosomal enzymes (or *acid hydrolases,* as they are sometimes called) are synthesized in the endoplasmic reticulum and transported to the Golgi apparatus. Within the Golgi complex they undergo a variety of posttranslational modifications including the attachment of terminal mannose-6-phosphate groups to some of the oligosaccharide side chains. The phosphorylated mannose residues serve as an "address label" that is recognized by specific receptors found on the inner surface of the Golgi membrane. Lysosomal enzymes bind these receptors and are thereby segregated from the numerous other secretory proteins within the Golgi. Subsequently, small transport vesicles containing the receptor-bound enzymes are pinched off from the Golgi and proceed to fuse with the lysosomes. Thus the enzymes are targeted to their intracellular abode, and the vesicles are shuttled back to the Golgi (Fig. 5.9). As indicated later, genetically determined errors in this remarkable sorting mechanism may give rise to one form of lysosomal storage disease. Recent studies have established a close link between lysosomal storage diseases and several neurodegenerative disorders. The cellular and molecular mechanisms of this linkage will be discussed below.

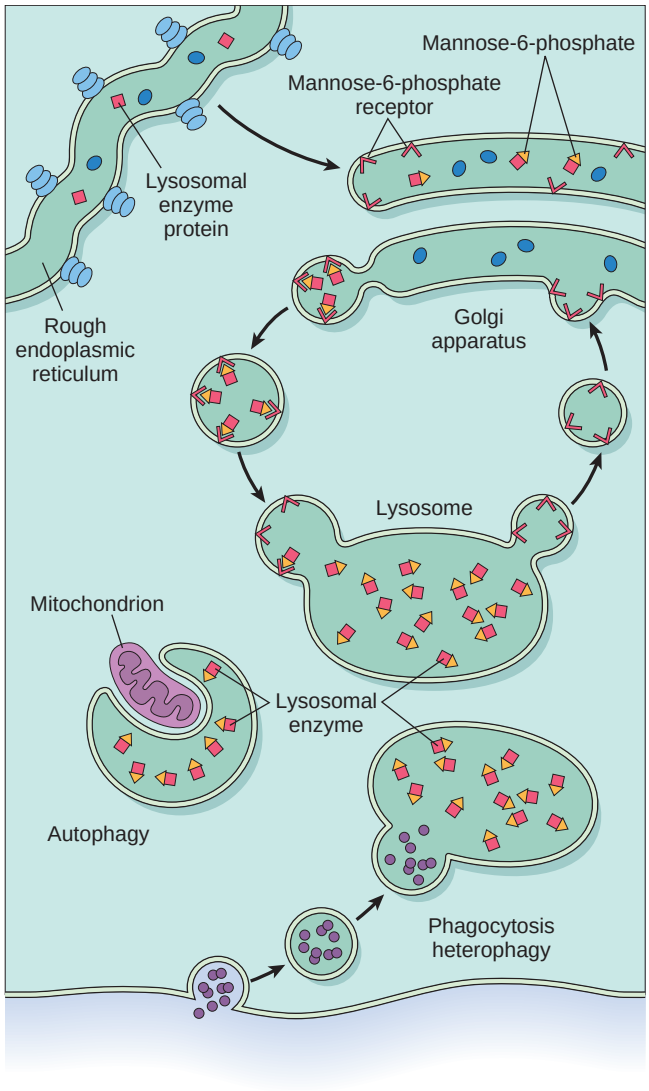

Figure 5.9 Synthesis and intracellular transport of lysosomal enzymes.

The lysosomal enzymes catalyze the breakdown of a variety of complex macromolecules. These large molecules may be derived from the metabolic turnover of intracellular organelles (autophagy), or they may be acquired from outside the cells by phagocytosis (heterophagy). An inherited deficiency of a functional lysosomal enzyme gives rise to two pathologic consequences (Fig. 5.10).

- *Catabolism of the substrate of the missing enzyme remains incomplete,* leading to the accumulation of the partially degraded insoluble metabolite within the lysosomes. This is called "primary accumulation." Stuffed with incompletely digested macromolecules, lysosomes become large and numerous enough to interfere with normal cell functions.

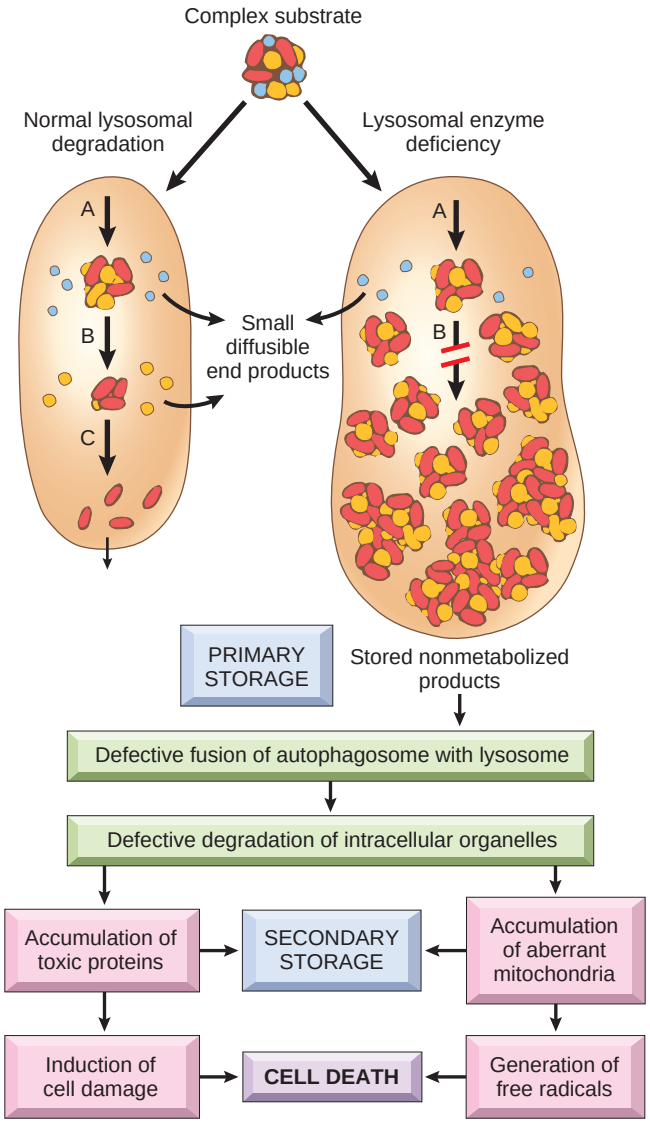

Figure 5.10 Pathogenesis of lysosomal storage diseases. In the example shown, a complex substrate is normally degraded by a series of lysosomal enzymes (*A*, *B*, and *C*) into soluble end products. If there is a deficiency or malfunction of one of the enzymes (e.g., *B*), catabolism is incomplete, and insoluble intermediates accumulate in the lysosomes. In addition to this primary storage, secondary storage and toxic effects result from defective autophagy.

- *There is a tight linkage between autophagy, mitochondrial functions, and lysosomes*. As discussed in Chapter 2, a diverse range of cellular organelles and molecules are degraded by autophagy including complex lipids, polyubiquitinated proteins, mitochondria, and fragments of the endoplasmic reticulum. In particular, autophagy is essential for turnover of mitochondria by a process termed *mitophagy*. This serves as a quality control system whereby dysfunctional mitochondria are degraded. Because of the accumulation of undigested macromolecules in the lysosomes, the rate at which lysosomes process organelles delivered by autophagocytic vacuoles is markedly reduced. This leads to persistence of dysfunctional and leaky mitochondria with poor calcium-buffering capacity and altered membrane potentials in the lysosomes. Damaged mitochondria generate free radicals and release molecules that trigger the intrinsic pathway of apoptosis. Impaired autophagy gives rise to secondary accumulation of autophagic substrates including ubiquitinated and aggregate-prone polypeptides such as α-synuclein and Huntingtin protein. This provides a molecular link between neurodegenerative disorders and lysosomal storage diseases such as Gaucher disease (discussed below).

There are three general approaches to the treatment of lysosomal storage diseases. The most obvious is enzyme replacement therapy, currently in use for several of these diseases. Another approach, substrate reduction therapy, is based on the premise that if the substrate to be degraded by the lysosomal enzyme can be reduced, the residual enzyme activity may be sufficient to catabolize it and prevent accumulation. A more recent strategy is based on the understanding of the molecular basis of enzyme deficiency. In many disorders, exemplified by Gaucher disease, the enzyme activity is low because the mutant proteins are unstable and prone to misfolding and hence degraded in the endoplasmic reticulum. In such diseases an exogenous competitive inhibitor of the enzyme can, paradoxically, bind to the mutant enzyme and act as the folding template that assists proper folding of the enzyme and thus prevents its degradation. Such *molecular chaperone therapy* is under active investigation. In addition to the aforementioned, hematopoietic stem cell transplants and gene therapy are also being evaluated in specific cases.

Although the combined frequency of lysosomal storage disorders is about 1 in 5000 live births, lysosomal dysfunction may be involved in the etiology of several more common diseases. For example, an important genetic risk factor for developing Parkinson disease is the carrier state for Gaucher disease, and virtually all patients with Gaucher disease develop Parkinson disease. Niemann-Pick type C disease is another lysosomal storage disorder that increases the risk for Alzheimer disease. Such interconnectedness stems from the multifunctionality of the lysosome. For example, lysosomes play critical roles in (1) autophagy, resulting from fusion with the autophagosome; (2) immunity, because they fuse with phagosomes; and (3) membrane repair, through fusion with the plasma membrane.

Approximately 70 lysosomal storage diseases have been identified. These may result from abnormalities of lysosomal enzymes or proteins involved in substrate degradation, endosomal sorting, or lysosomal membrane integrity. Lysosomal storage disorders are divided into categories based on the biochemical nature of the substrates and the accumulated metabolites (Table 5.6). Within each group are several entities, each resulting from the deficiency of a specific enzyme.

In general, the distribution of the stored material, and hence the organs affected, is determined by two interrelated factors: (1) the tissue where most of the material to be degraded is found and (2) the location where most of the degradation normally occurs. For example, the brain is rich in gangliosides, and hence defective hydrolysis of gangliosides, as occurs in G_{M1} and G_{M2} gangliosidoses, results primarily in accumulation within neurons and consequent neurologic symptoms. Defects in degradation of mucopolysaccharides affect virtually every organ because mucopolysaccharides are

Table 5.6 Lysosomal Storage Diseases

Disease	Enzyme Deficiency	Major Accumulating Metabolites
Glycogenosis	Type 2—Pompe disease α-1,4-Glucosidase (lysosomal glucosidase)	Glycogen
Sphingolipidoses		
G_{M1} gangliosidosis	G_{M1} ganglioside β-galactosidase	G_{M1} ganglioside, galactose-containing oligosaccharides
Type 1—infantile, generalized		
Type 2—juvenile		
G_{M2} gangliosidosis		
Tay-Sachs disease	Hexosaminidase A	G_{M2} ganglioside
Sandhoff disease	Hexosaminidase A and B	G_{M2} ganglioside, globoside
G_{M2} gangliosidosis variant AB	Ganglioside activator protein	G_{M2} ganglioside
Sulfatidoses		
Metachromatic leukodystrophy	Arylsulfatase A	Sulfatide
Multiple sulfatase deficiency	Arylsulfatase A, B, C; steroid sulfatase; iduronate sulfatase; heparan *N*-sulfatase	Sulfatide, steroid sulfate, heparan sulfate, dermatan sulfate
Krabbe disease	Galactosylceramidase	Galactocerebroside
Fabry disease	α-Galactosidase A	Ceramide trihexoside
Gaucher disease	Glucocerebrosidase	Glucocerebroside
Niemann-Pick disease: types A and B	Sphingomyelinase	Sphingomyelin
Mucopolysaccharidoses (MPSs)		
MPS I-H (Hurler)	α-L-Iduronidase	Dermatan sulfate, heparan sulfate
MPS II (Hunter)	Iduronate 2-sulphatase	
Mucolipidoses (MLs)		
I-cell disease (ML II) and pseudo-Hurler polydystrophy	Deficiency of phosphorylating enzymes essential for the formation of mannose-6-phosphate recognition marker; acid hydrolases lacking the recognition marker cannot be targeted to the lysosomes, but are secreted extracellularly	Mucopolysaccharide, glycolipid
Other diseases of complex carbohydrates		
Fucosidosis	α-Fucosidase	Fucose-containing sphingolipids and glycoprotein fragments
Mannosidosis	α-Mannosidase	Mannose-containing oligosaccharides
Aspartylglycosaminuria	Aspartylglycosamine amide hydrolase	Aspartyl-2-deoxy-2-acetamido-glycosylamine
Other lysosomal storage diseases		
Wolman disease	Acid lipase	Cholesterol esters, triglycerides

widely distributed in the body. Because cells of the mononuclear phagocyte system are especially rich in lysosomes and are involved in the degradation of a variety of substrates, organs rich in phagocytic cells, such as the spleen and liver, are frequently enlarged in several forms of lysosomal storage disorders. The ever-expanding number of lysosomal storage diseases can be divided into rational categories based on the biochemical nature of the accumulated metabolite, thus creating such subgroups as *glycogenoses, sphingolipidoses (lipidoses), mucopolysaccharidoses (MPSs),* and *mucolipidoses* (see Table 5.6).

Most of these conditions are very rare, and their detailed description is better relegated to specialized texts and reviews. Only a few of the more common conditions are considered here.

Tay-Sachs Disease (G_{M2} Gangliosidosis: Hexosaminidase α-Subunit Deficiency)

G_{M2} gangliosidoses are a group of three lysosomal storage diseases caused by deficiency of the enzyme β-hexosaminidase resulting in an inability to catabolize G_{M2} gangliosides. There are two isoenzymes of β-hexosaminidase: Hex A, consisting of two subunits, α and β, and Hex B, a homodimer of β-subunits. Degradation of G_{M2} gangliosides requires three polypeptides encoded by three distinct genes—*HEXA* (on chromosome 15), which encodes the α-subunit of Hex A; *HEXB* (on chromosome 5), which encodes the β-subunit of Hex A and Hex B; and *GM2A* (on chromosome 5), which encodes the activator of hexosaminidase. The phenotypic effects of mutations affecting these genes are fairly similar because they result from accumulation of G_{M2} gangliosides. The underlying enzyme defect, however, is different for each. Tay-Sachs disease, the most common form of G_{M2} gangliosidosis, results from mutations in the α-subunit locus on chromosome 15 that cause a severe deficiency of hexosaminidase A. This disease is especially prevalent among Jews, particularly among those of Eastern European (Ashkenazic) origin, in whom a carrier rate of 1 in 30 has been reported.

The molecular basis for neuronal injury resulting from hexosaminidase deficiency is not fully understood. More than 100 mutations have been described in the *HEXA*

α-subunit gene; most affect protein folding. Because the mutant protein is misfolded, it induces the so-called unfolded protein response (Chapter 2). If such misfolded enzymes are not stabilized by chaperones, they undergo proteasomal degradation, leading to accumulation of toxic substrates and intermediates within neurons. These findings have spurred clinical trials of molecular chaperone therapy for some variants of later-onset Tay-Sachs and other selected lysosomal storage diseases. Such therapy involves the use of synthetic chaperones that can cross the blood–brain barrier, bind to the mutated protein, and enable its proper folding. Sufficient functional enzyme can then be rescued to ameliorate the effects of the inborn error.

MORPHOLOGY

Hexosaminidase A is absent from virtually all the tissues, so G_{M2} ganglioside accumulates in many tissues (e.g., heart, liver, spleen, nervous system), but the **involvement of neurons in the central and autonomic nervous systems and retina dominates the clinical picture.** On histologic examination, the neurons are ballooned with cytoplasmic vacuoles, each representing a markedly distended lysosome filled with gangliosides (Fig. 5.11A). With the electron microscope, several types of **cytoplasmic inclusions** can be visualized, the most prominent being whorled configurations within lysosomes composed of onion-skin layers of membranes (Fig. 5.11B). In time there is progressive destruction of neurons, proliferation of microglia, and accumulation of complex lipids in phagocytes within the brain substance. The ganglion cells in the retina are similarly swollen with G_{M2} ganglioside, particularly at the margins of the macula. A **cherry-red spot thus appears in the macula,** representing accentuation of the normal color of the macular choroid contrasted with the pallor produced by the swollen ganglion cells in the remainder of the retina (Chapter 29). This finding is characteristic of Tay-Sachs disease and other storage disorders affecting the neurons.

Clinical Features

Affected infants appear normal at birth but begin to manifest signs and symptoms at about age 6 months. There is relentless motor and mental deterioration, resulting in motor incoordination and intellectual disability leading eventually to muscular flaccidity, blindness, and increasing dementia. Sometime during the early course of the disease, the characteristic, but not pathognomonic, cherry-red spot appears in the macula of the eye in almost all patients. Over the span of 1 or 2 years a complete vegetative state is reached, followed by death at age 2 to 3 years. Antenatal diagnosis and carrier detection are possible by enzyme assays and DNA-based analysis.

Niemann-Pick Disease Types A and B

Niemann-Pick disease types A and B are two related disorders that are characterized by lysosomal accumulation of sphingomyelin due to an inherited deficiency of sphingomyelinase. Type A is a severe infantile form with extensive neurologic involvement, marked visceral accumulations of sphingomyelin, and progressive wasting and early death within the first 3 years of life. In contrast, patients with type B disease have organomegaly but generally no central nervous system involvement. Patients usually survive into adulthood. As with Tay-Sachs disease, Niemann-Pick disease types A and B are common in Ashkenazi Jews. The gene for acid sphingomyelinase maps to chromosome 11p15.4 and is one of the imprinted genes that is preferentially expressed from the maternal chromosome as a result of epigenetic silencing of the paternal gene (discussed later). Although this disease is typically inherited as an autosomal recessive, heterozygotes who inherit the mutant allele from the mother can develop Niemann-Pick disease. More than 180 mutations have been found in the acid sphingomyelinase gene, and there seems to be a correlation between the type of mutation, the severity of enzyme deficiency, and the phenotype.

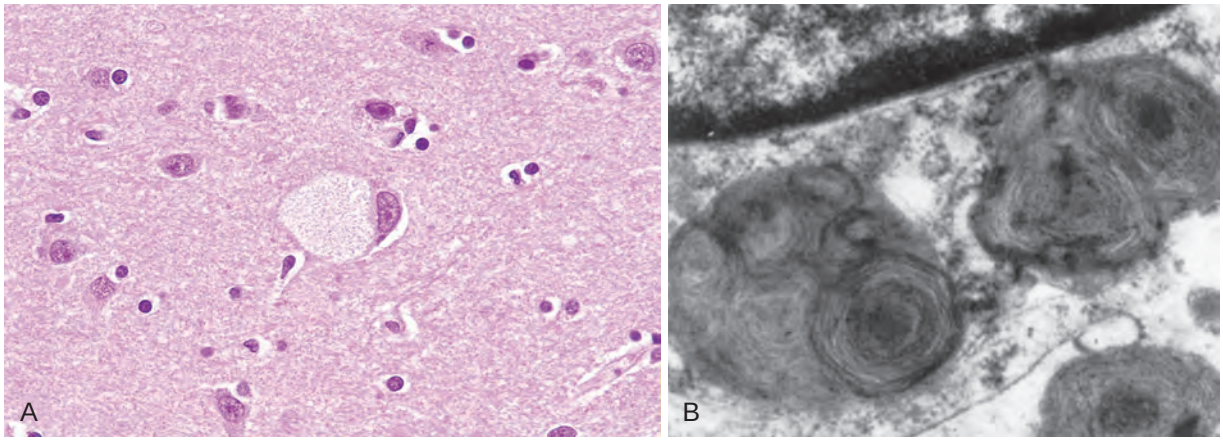

Figure 5.11 Ganglion cells in Tay-Sachs disease. (A) Under the light microscope, a large neuron has obvious lipid vacuolation. (B) A portion of a neuron under the electron microscope shows prominent lysosomes with whorled configurations. Part of the nucleus is shown above. (A, Courtesy Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.; B, Courtesy Dr. Joe Rutledge, University of Texas Southwestern Medical Center, Dallas, Tex.)

MORPHOLOGY

In the classic infantile type A variant, a missense mutation causes almost complete deficiency of sphingomyelinase. Sphingomyelin is a ubiquitous component of cellular (including organellar) membranes, and so the enzyme deficiency blocks degradation of the lipid, resulting in its progressive accumulation within lysosomes, particularly within cells of the mononuclear phagocyte system. **Affected cells become enlarged, sometimes to 90 μm in diameter, due to the distention of lysosomes with sphingomyelin and cholesterol.** Innumerable small vacuoles of relatively uniform size are created, imparting foaminess to the cytoplasm (Fig. 5.12). Electron microscopy confirms that the vacuoles are engorged secondary lysosomes that often contain membranous cytoplasmic bodies resembling concentric lamellated myelin figures, sometimes called zebra bodies.

The lipid-laden phagocytic foam cells are widely distributed in the spleen, liver, lymph nodes, bone marrow, tonsils, gastrointestinal tract, and lungs. **The involvement of the spleen generally produces massive enlargement,** sometimes to 10 times its normal weight, but the hepatomegaly is usually not quite so striking. The lymph nodes are generally moderately to markedly enlarged throughout the body.

The neuronal involvement is diffuse, affecting all parts of the nervous system. **Vacuolation and ballooning of neurons** constitute the dominant histologic change, which in time leads to cell death and loss of brain substance. A **retinal cherry-red spot** similar to that seen in Tay-Sachs disease is present in about one-third to one-half of affected individuals.

Clinical manifestations in type A disease may be present at birth and almost invariably become evident by age 6 months. Infants typically have a protuberant abdomen because of hepatosplenomegaly. Once the manifestations appear, they are followed by progressive failure to thrive, vomiting, fever, and generalized lymphadenopathy as well as progressive deterioration of psychomotor function. Death occurs usually within the first or second year of life.

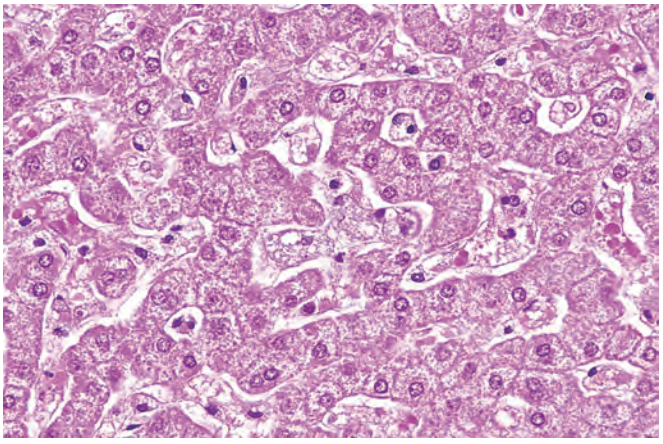

Figure 5.12 Niemann-Pick disease in liver. The hepatocytes and Kupffer cells have a foamy, vacuolated appearance due to deposition of lipids. (Courtesy Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.)

The diagnosis is established by biochemical assays for sphingomyelinase activity in leukocytes or bone marrow biopsy. Individuals affected with types A and B as well as carriers can be detected by DNA analysis.

Niemann-Pick Disease Type C

Although previously considered to be related to types A and B, Niemann-Pick disease type C is distinct at the biochemical and genetic levels and is more common than types A and B combined. Mutations in two related genes, *NPC1* and *NPC2*, can give rise to Niemann-Pick disease type C, with *NPC1* being responsible for 95% of cases. Unlike most other storage diseases, Niemann-Pick disease type C is due to a primary defect in nonenzymatic lipid transport. NPC1 is membrane bound, whereas NPC2 is soluble. Both are involved in the transport of free cholesterol from the lysosomes to the cytoplasm. Niemann-Pick disease type C is clinically heterogeneous. It may present as hydrops fetalis and stillbirth, as neonatal hepatitis, or, most commonly, as a chronic form characterized by progressive neurologic damage. The clinical course is marked by ataxia, vertical supranuclear gaze palsy, dystonia, dysarthria, and psychomotor regression.

Gaucher Disease

Gaucher disease refers to a cluster of autosomal recessive disorders resulting from mutations in the gene encoding glucocerebrosidase. It is the most common lysosomal storage disorder. The affected gene encodes glucocerebrosidase, an enzyme that normally cleaves the glucose residue from ceramide. As a result of the enzyme defect, glucocerebrosides accumulate principally in phagocytes but in some subtypes also in the central nervous system. Glucocerebrosides are continually formed from the catabolism of glycolipids derived mainly from the cell membranes of senescent leukocytes and red cells. It is clear now that the pathologic changes in Gaucher disease are caused not just by the burden of storage material but also by activation of macrophages and the consequent secretion of cytokines such as interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF).

Three clinical subtypes of Gaucher disease have been distinguished:

- The most common, accounting for 99% of cases, is type I, or the chronic nonneuronopathic form. In this type, storage of glucocerebrosides is limited to the mononuclear phagocytes throughout the body without involving the brain. Splenic and skeletal involvements dominate this pattern of the disease. It is found principally in Jews of European stock. Individuals with this disorder have reduced but detectable levels of glucocerebrosidase activity. Longevity is shortened, but not markedly.
- Type II, or acute neuronopathic Gaucher disease, is the infantile acute cerebral pattern. This form has no predilection for Jews. In these patients there is virtually no detectable glucocerebrosidase activity in the tissues. Hepatosplenomegaly is also seen in this form of Gaucher disease, but the clinical picture is dominated by progressive central nervous system involvement leading to death at an early age.
- A third pattern, type III, is intermediate between types I and II. These patients have the systemic involvement characteristic of type I but have progressive central

nervous system disease that usually begins in adolescence or early adulthood.

MORPHOLOGY

Glucocerebrosides accumulate in massive amounts within phagocytic cells throughout the body in all forms of Gaucher disease. The **distended phagocytic cells, known as Gaucher cells, are found in the spleen, liver, bone marrow, lymph nodes, tonsils, thymus, and Peyer patches.** Similar cells may be found in both the alveolar septa and the air spaces in the lung. In contrast to other lipid storage diseases, Gaucher cells rarely appear vacuolated, but instead have a fibrillary type of cytoplasm likened to crumpled tissue paper (Fig. 5.13). Gaucher cells are often enlarged, sometimes up to 100 μm in diameter, and have one or more dark, eccentrically placed nuclei. Periodic acid–Schiff staining is usually intensely positive. With the electron microscope **the fibrillary cytoplasm can be resolved as elongated, distended lysosomes,** containing the stored lipid in stacks of bilayers.

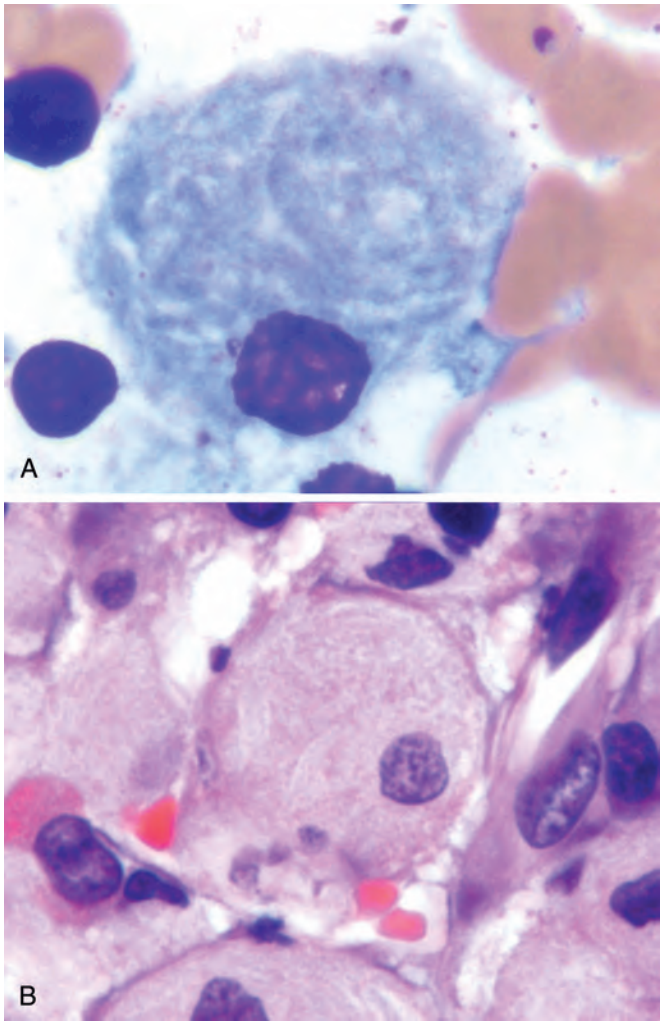

Figure 5.13 Gaucher disease involving the bone marrow. (A–B) Gaucher cells are plump macrophages that characteristically have the appearance in the cytoplasm of crumpled tissue paper due to accumulation of glucocerebroside. (A) Wright stain; (B) hematoxylin and eosin. (Courtesy Dr. John Anastasi, Department of Pathology, University of Chicago, Chicago, Ill.)

In type I disease, the **spleen is enlarged, sometimes up to 10 kg.** The lymphadenopathy is mild to moderate and is body-wide. Accumulation of Gaucher cells in the bone marrow occurs in 70% to 100% of cases of type I Gaucher disease. It produces areas of **bone erosion** that are sometimes small but in other cases sufficiently large to give rise to pathologic fractures. Bone destruction occurs due to the secretion of cytokines by activated macrophages. In patients with cerebral involvement, Gaucher cells are seen in the Virchow-Robin spaces, and arterioles are surrounded by swollen adventitial cells. There is no storage of lipids in the neurons, yet neurons appear shriveled and are progressively destroyed. It is suspected that the lipids that accumulate in the phagocytic cells around blood vessels secrete cytokines that damage nearby neurons.

Mutation of the glucocerebrosidase gene is the most common known genetic risk factor for development of Parkinson disease. Patients with Gaucher disease have a 20-fold higher risk of developing Parkinson disease (compared with controls), and 5% to 10% of patients with Parkinson disease have mutations in the gene encoding glucocerebrosidase. There is a reciprocal relationship between the level of this enzyme and aggregation of α-synuclein, the protein involved in the pathogenesis of Parkinson disease (Chapter 24). As discussed earlier, patients with lysosomal diseases have impairment in autophagy, which allows aggregation and persistence of proteins like α-synuclein.

The level of glucocerebrosides in leukocytes or cultured fibroblasts is helpful in diagnosis and in the detection of heterozygote carriers. DNA testing is also available in select populations.

Clinical Features

The course of Gaucher disease depends on the clinical subtype. In type I, symptoms and signs first appear in adult life and are related to splenomegaly or bone involvement. Most commonly there is pancytopenia or thrombocytopenia secondary to hypersplenism. Pathologic fractures and bone pain occur if there has been extensive expansion of the marrow space. Although the disease is progressive in adults, it is compatible with long life. In types II and III, central nervous system dysfunction, convulsions, and progressive mental deterioration dominate, although organs such as the liver, spleen, and lymph nodes are also affected. The diagnosis in homozygotes can be made by measurement of glucocerebrosidase activity in peripheral blood leukocytes or in extracts of cultured skin fibroblasts. The enzyme assay cannot identify heterozygotes because the levels of glucocerebrosidase are difficult to distinguish from those in normal cells. In principle, heterozygotes can be identified by detection of mutations. However, because more than 150 mutations in the glucocerebrosidase gene can cause Gaucher disease, currently it is not possible to use a single genetic test. However, when the causative mutation in a patient is known, a heterozygote can be identified with molecular tests. The landscape of genetic testing is rapidly changing with the application of next-generation sequencing.

Replacement therapy with recombinant enzymes is the mainstay for treatment of Gaucher disease; it is effective, and

those with type I disease can expect normal life expectancy. However, such therapy is extremely expensive. Because the fundamental defect resides in mononuclear phagocytic cells originating from marrow stem cells, allogeneic hematopoietic stem cell transplantation can be curative. Other work is directed toward correction of the enzyme defect by transfer of the normal glucocerebrosidase gene into the patient's hematopoietic stem cells. Substrate reduction therapy with inhibitors of glucosylceramide synthetase is also being evaluated.

Mucopolysaccharidoses

MPSs are a group of closely related syndromes that result from genetically determined deficiencies of enzymes involved in the degradation of mucopolysaccharides (glycosaminoglycans). Chemically, mucopolysaccharides are long-chain complex carbohydrates that are linked with proteins to form proteoglycans. They are abundant in extracellular matrix, joint fluid, and connective tissue. The glycosaminoglycans that accumulate in MPSs are dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. Eleven enzymes involved in the degradation of these molecules cleave terminal sugars from the polysaccharide chains disposed along a polypeptide or core protein. In the absence of enzymes, these chains accumulate within lysosomes in various tissues and organs of the body.

There are 11 clinical variants of MPS, each resulting from the deficiency of one specific enzyme (some variants have subvariants). All the MPSs except one are inherited as autosomal recessive traits; the exception, *Hunter syndrome,* is an X-linked recessive trait. Within a given group (e.g., MPS I, characterized by a deficiency of α-L-iduronidase), subgroups exist that result from different mutant alleles at the same genetic locus. Thus the severity of enzyme deficiency and the clinical picture even within subgroups are often different.

In general, MPSs are progressive disorders, characterized by *coarse facial features, clouding of the cornea, joint stiffness, and intellectual disability.* Urinary excretion of the accumulated mucopolysaccharides is often increased and is used as a diagnostic tool.

MORPHOLOGY

The accumulated **mucopolysaccharides are generally found in mononuclear phagocytic cells, endothelial cells, intimal smooth muscle cells, and fibroblasts** throughout the body. Common sites of involvement are thus the spleen, liver, bone marrow, lymph nodes, blood vessels, and heart.

Microscopically, affected cells are distended and have apparent clearing of the cytoplasm to create so-called balloon cells. Under the electron microscope, the clear cytoplasm can be resolved as numerous minute vacuoles. These are swollen lysosomes containing a finely granular periodic acid–Schiff–positive material that can be identified biochemically as mucopolysaccharide. Similar lysosomal changes are found in the neurons of those syndromes characterized by central nervous system involvement. In addition, however, some of the lysosomes in neurons are replaced by lamellated zebra bodies similar to those seen in Niemann-Pick disease. **Hepatosplenomegaly, skeletal deformities, valvular lesions and subendothelial arterial deposits, particularly in the coronary arteries, and lesions in the brain are common threads that run through all the MPSs.** In many of the more protracted syndromes, coronary subendothelial lesions lead to myocardial ischemia. Thus myocardial infarction and cardiac decompensation are important causes of death.

Clinical Features

Of the 11 recognized variants, only 2 well-characterized syndromes are described briefly here. *Hurler syndrome,* also called MPS I-H, results from a deficiency of α-L-iduronidase. It is one of the most severe forms of MPS. Affected children appear normal at birth but develop hepatosplenomegaly by age 6 to 24 months. Their growth is retarded, and, as in other forms of MPS, they develop coarse facial features and skeletal deformities. Death occurs by age 6 to 10 years and is often due to cardiovascular complications. *Hunter syndrome,* also called MPS II, differs from Hurler syndrome in mode of inheritance (X-linked), absence of corneal clouding, and milder clinical course.

KEY CONCEPTS

LYSOSOMAL STORAGE DISEASES

Inherited mutations leading to defective lysosomal enzyme functions gives rise to accumulation and storage of complex substrates in the lysosomes and defects in autophagy resulting in cellular injury.

- Tay-Sachs disease is caused by an inability to metabolize G_{M2} gangliosides due to lack of the α-subunit of lysosomal hexosaminidase. G_{M2} gangliosides accumulate in the central nervous system and cause severe intellectual disability, blindness, motor weakness, and death by 2 to 3 years of age.
- Niemann-Pick disease types A and B are caused by a deficiency of sphingomyelinase. In the more severe type A variant, accumulation of sphingomyelin in the nervous system results in neuronal damage. Lipid also is stored in phagocytes within the liver, spleen, bone marrow, and lymph nodes, causing their enlargement. In type B, neuronal damage is not present.
- Niemann-Pick disease type C is caused by a defect in cholesterol transport and resultant accumulation of cholesterol and gangliosides in the nervous system. Affected children most commonly exhibit ataxia, dysarthria, and psychomotor regression.
- Gaucher disease results from lack of the lysosomal enzyme glucocerebrosidase and accumulation of glucocerebroside in mononuclear phagocytic cells. In the most common, type I variant, affected phagocytes become enlarged (Gaucher cells) and accumulate in liver, spleen, and bone marrow, causing hepatosplenomegaly and bone erosion. Types II and III are characterized by variable neuronal involvement. Gaucher disease has a strong association with Parkinson disease.
- MPSs result in accumulation of mucopolysaccharides in many tissues including liver, spleen, heart, blood vessels, brain, cornea, and joints. Affected patients in all forms have coarse facial features. Manifestations of Hurler syndrome include corneal clouding, coronary arterial and valvular deposits, and death in childhood. Hunter syndrome is associated with a milder clinical course.

Glycogen Storage Diseases (Glycogenoses)

The glycogen storage diseases result from a hereditary deficiency of one of the enzymes involved in the synthesis or sequential degradation of glycogen. Depending on the

normal tissue or organ distribution of the specific enzyme, glycogen storage in these disorders may be limited to a few tissues, may be more widespread while not affecting all tissues, or may be systemic.

The significance of a specific enzyme deficiency is best understood from the perspective of the normal metabolism of glycogen (Fig. 5.14). Glycogen is a storage form of glucose. Glycogen synthesis begins with the conversion of glucose to glucose-6-phosphate by the action of a hexokinase (glucokinase). A phosphoglucomutase then transforms the glucose-6-phosphate to glucose-1-phosphate, which, in turn, is converted to uridine diphosphoglucose. A highly branched, large polymer is then built (molecular weight as high as 100 million), containing as many as 10,000 glucose molecules linked together by α-1,4-glucoside bonds. The glycogen chain and branches continue to be elongated by the addition of glucose molecules mediated by glycogen synthetases. During degradation, distinct phosphorylases in the liver and muscle split glucose-1-phosphate from the glycogen until about four glucose residues remain on each branch, leaving a branched oligosaccharide called limit dextrin. This can be further degraded only by the debranching enzyme. In addition to these major pathways, glycogen is also degraded in the lysosomes by acid alpha-glucosidase. If the lysosomes are deficient in this enzyme, the glycogen contained within them is not accessible to degradation by cytoplasmic enzymes such as phosphorylases.

On the basis of specific enzyme deficiencies and the resultant clinical pictures, glycogenoses have traditionally been divided into a dozen or so syndromes designated by

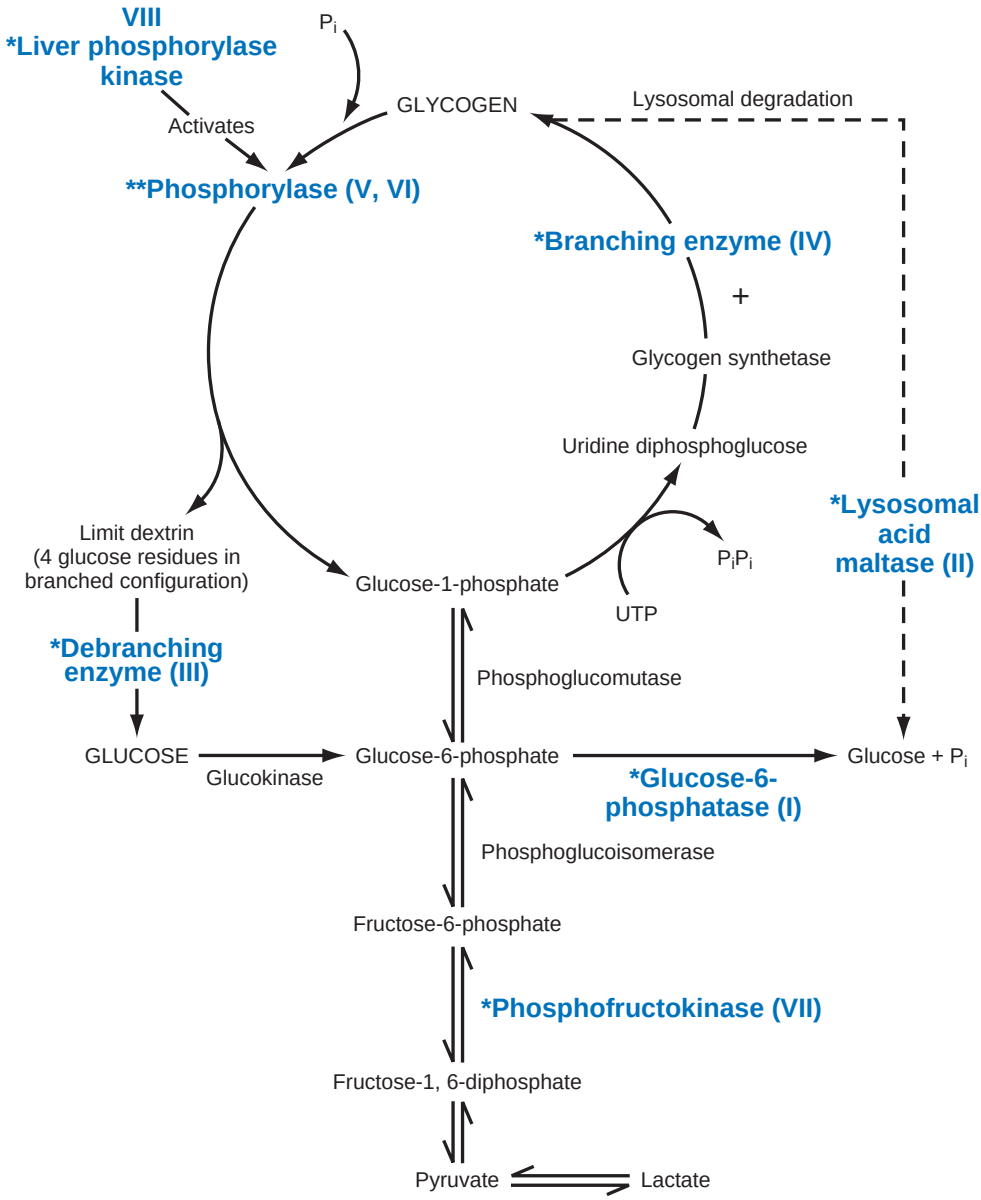

Figure 5.14 Pathways of glycogen metabolism. *Asterisks* mark the enzyme deficiencies associated with glycogen storage diseases. Roman numerals indicate the type of glycogen storage disease associated with the given enzyme deficiency. Types V and VI result from deficiencies of muscle and liver phosphorylases, respectively. (Modified from Hers H, et al: Glycogen storage diseases. In Scriver CR, et al, editors: *The Metabolic Basis of Inherited Disease*, ed 6, New York, 1989, McGraw-Hill, p 425.)

Table 5.7 Principal Subgroups of Glycogenoses

Clinicopathologic Category	Specific Type	Enzyme Deficiency	Morphologic Changes	Clinical Features
Hepatic type	Hepatorenal—von Gierke disease (type I)	Glucose-6-phosphatase	Hepatomegaly—intracytoplasmic accumulations of glycogen and small amounts of lipid; intranuclear glycogen Renomegaly—intracytoplasmic accumulations of glycogen in cortical tubular epithelial cells	In untreated patients: failure to thrive, stunted growth, hepatomegaly, and renomegaly Hypoglycemia due to failure of glucose mobilization, often leading to convulsions Hyperlipidemia and hyperuricemia resulting from deranged glucose metabolism; many patients develop gout and skin xanthomas Bleeding tendency due to platelet dysfunction With treatment: most survive and develop late complications (e.g., hepatic adenomas)
Myopathic type	McArdle disease (type V)	Muscle phosphorylase	Skeletal muscle only—accumulations of glycogen predominant in subsarcolemmal location	Painful cramps associated with strenuous exercise; myoglobinuria occurs in 50% of cases; onset in adulthood (>20 years); muscular exercise fails to raise lactate level in venous blood; serum creatine kinase always elevated; compatible with normal longevity
Miscellaneous types	Generalized glycogenosis—Pompe disease (type II)	Lysosomal acid alpha-glucosidase	Mild hepatomegaly—ballooning of lysosomes with glycogen, creating lacy cytoplasmic pattern Cardiomegaly—glycogen within sarcoplasm as well as membrane-bound Skeletal muscle—similar to changes in heart	Massive cardiomegaly, muscle hypotonia, and cardiorespiratory failure within 2 years; a milder adult form with only skeletal muscle involvement, presenting with chronic myopathy; enzyme replacement therapy available

Roman numerals, and the list continues to grow. On the basis of pathophysiology glycogenoses can be divided into three major subgroups (Table 5.7).

- *Hepatic forms.* The liver is a key player in glycogen metabolism. It contains enzymes that synthesize glycogen for storage and ultimately break it down into free glucose, which is then released into the blood. An inherited deficiency of hepatic enzymes that are involved in glycogen degradation therefore leads not only to the accumulation of glycogen in the liver but also to a reduction in blood glucose concentrations (hypoglycemia) (Fig. 5.15). Deficiency of the enzyme glucose-6-phosphatase (von Gierke disease, or type I glycogenosis) is a prime example of the hepatic-hypoglycemic form of glycogen storage disease (see Table 5.7). Other examples include deficiencies of liver phosphorylase and debranching enzyme, both involved in the breakdown of glycogen (see Fig. 5.15). In all these disorders, glycogen is stored in many organs, but hepatic enlargement and hypoglycemia dominate the clinical picture.
- *Myopathic forms.* In the skeletal muscles, as opposed to the liver, glycogen is used predominantly as a source of energy during physical activity. Adenosine triphosphate (ATP) is generated by glycolysis, which leads ultimately to the formation of lactate (Fig. 5.16). If the enzymes that fuel the glycolytic pathway are deficient, glycogen storage occurs in the muscles and is associated with muscular weakness due to impaired energy production. Examples in this category include deficiencies of muscle phosphorylase (McArdle disease, or type V glycogenosis), muscle phosphofructokinase (type VII glycogen storage disease), and several others. Typically, individuals with the myopathic forms present with muscle cramps after exercise, and lactate levels in the blood fail to rise after exercise due to a block in glycolysis.
- *Glycogen storage diseases associated with (1) deficiency of acid alpha-glucosidase (acid maltase) and (2) lack of branching enzyme* do not fit into the hepatic or myopathic categories. They are associated with glycogen storage in many organs and death early in life. Acid alpha-glucosidase is a lysosomal enzyme, and hence its deficiency leads to lysosomal storage of glycogen (type II glycogenosis, or *Pompe disease*) in all organs, but *cardiomegaly is the most prominent feature* (see Fig. 5.16).

KEY CONCEPTS

GLYCOGEN STORAGE DISEASES

- Inherited deficiency of enzymes involved in glycogen metabolism can result in storage of normal or abnormal forms of glycogen, predominantly in liver or muscles, but also in other tissues as well.
- In the most common hepatic form (von Gierke disease), liver cells store glycogen because of a lack of hepatic glucose-6-phosphatase. The liver is enlarged, and patients have hypoglycemia.
- There are several myopathic forms, including McArdle disease, in which lack of muscle phosphorylase gives rise to storage in skeletal muscles and cramps after exercise.
- In Pompe disease there is lack of lysosomal acid alpha-glucosidase, and all organs are affected, but heart involvement is predominant.

Disorders Associated With Defects in Proteins That Regulate Cell Growth

Normal growth and differentiation of cells are regulated by two classes of genes: proto-oncogenes and tumor suppressor genes, whose products promote or restrain cell growth (Chapter 7). It is well established that mutations in these two classes of genes are important in the pathogenesis of tumors. In the vast majority of cases, cancer-causing mutations affect somatic cells and hence are not passed in the germline. In approximately 5% of all cancers, however, mutations transmitted through the germline contribute to the development of cancer. Most familial cancers are inherited in an autosomal dominant fashion, but a few recessive disorders have also been described. This subject is discussed in Chapter 7. Specific forms of familial tumors are described in various chapters.

COMPLEX MULTIGENIC DISORDERS

As discussed previously, such disorders are caused by interactions between variant forms of genes and environmental factors. A gene that has at least two alleles, each of which occurs at a frequency of at least 1% in the population, is polymorphic, and each variant allele is referred to as a polymorphism. According to the common disease/common variant hypothesis, complex genetic disorders occur when many polymorphisms, each with a modest effect and low penetrance, are coinherited. Two additional facts have emerged from studies of common complex disorders, such as type 1 diabetes:

- While complex disorders result from the collective inheritance of many polymorphisms, different polymorphisms vary in significance. For example, of the 20 to 30 genes implicated in type 1 diabetes, 6 or 7 are most important, and a few HLA alleles contribute more than 50% of the risk (Chapter 24).

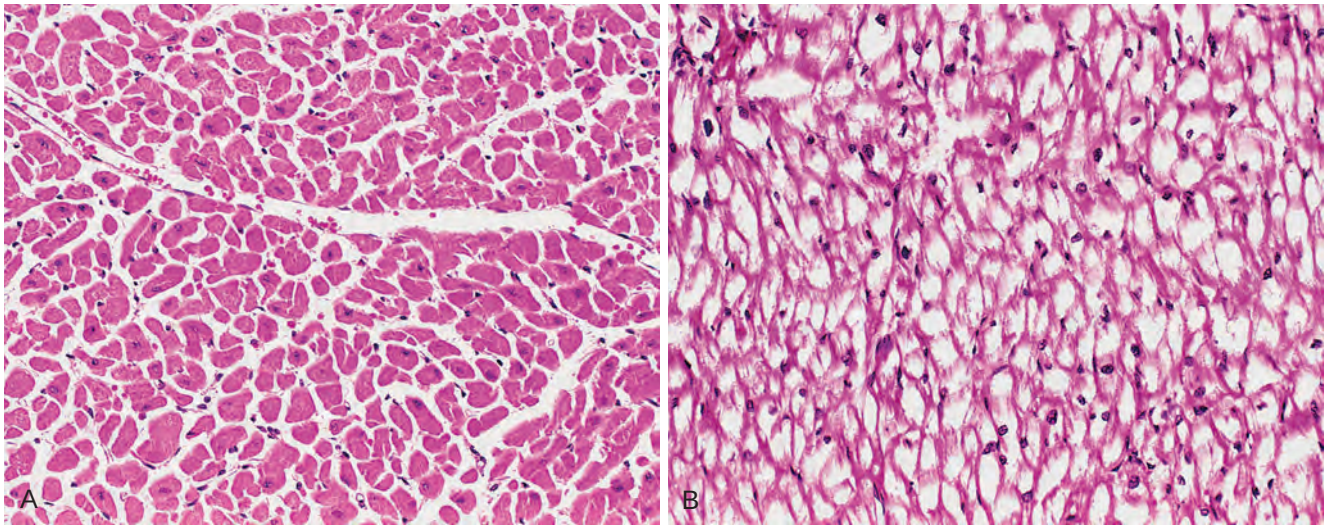

Figure 5.16 Pompe disease (glycogen storage disease type II). (A) Normal myocardium with abundant eosinophilic cytoplasm. (B) Patient with Pompe disease (same magnification) showing the myocardial fibers full of glycogen seen as clear spaces. (Courtesy Dr. Trace Worrell, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.)

- Some polymorphisms are common to multiple diseases of the same type, while others are disease specific. This is best illustrated in autoimmune diseases (Chapter 6).

Several normal phenotypic characteristics are governed by multifactorial inheritance such as hair color, eye color, skin color, height, and intelligence. These characteristics show a continuous variation in population groups, producing the standard bell-shaped curve of distribution. Environmental influences, however, significantly modify the phenotypic expression of complex traits. For example, type 2 diabetes has many of the features of a multifactorial disorder. It is well recognized that individuals often first manifest this disease after weight gain. Thus, obesity as well as other environmental influences unmask the diabetic genetic trait. Nutritional influences may cause even monozygous twins to achieve different heights. A culturally deprived child cannot achieve his or her full intellectual capacity.

Assigning a disease to this mode of inheritance must be done with caution. It depends on many factors but first on familial clustering and the exclusion of Mendelian and chromosomal modes of transmission. A range of levels of severity of a disease is suggestive of a complex multigenic disorder, but, as pointed out earlier, variable expressivity and reduced penetrance of single mutant genes may also account for this phenomenon. Because of these problems, sometimes it is difficult to distinguish between Mendelian and multifactorial disease.

CHROMOSOMAL DISORDERS

Normal Karyotype

As you will remember, human somatic cells contain 46 chromosomes—22 homologous pairs of autosomes and two sex chromosomes, XX in the female and XY in the male. The study of chromosomes—*karyotyping*—is the basic tool of the cytogeneticist. The usual procedure to examine chromosomes is to arrest dividing cells in metaphase with mitotic spindle inhibitors (e.g., *N*-diacetyl-*N*-methylcolchicine [colcemid]) and then to stain the chromosomes. In a metaphase spread, the individual chromosomes take the form of two chromatids connected at the centromere. A karyotype is obtained by arranging each pair of autosomes according to length, followed by sex chromosomes.

A variety of staining methods have been developed that allow identification of individual chromosomes on the basis of distinctive and reliable patterns of alternating light and dark bands. The one most commonly used involves a Giemsa stain and is hence called *G banding*. A normal male karyotype with G banding is illustrated in Fig. 5.17. With standard G banding, approximately 400 to 800 bands per haploid set can be detected. The resolution obtained by banding can be markedly improved by obtaining the cells in prophase. The individual chromosomes appear markedly elongated, and as many as 1500 bands per karyotype can be recognized. The use of these banding techniques permits certain identification

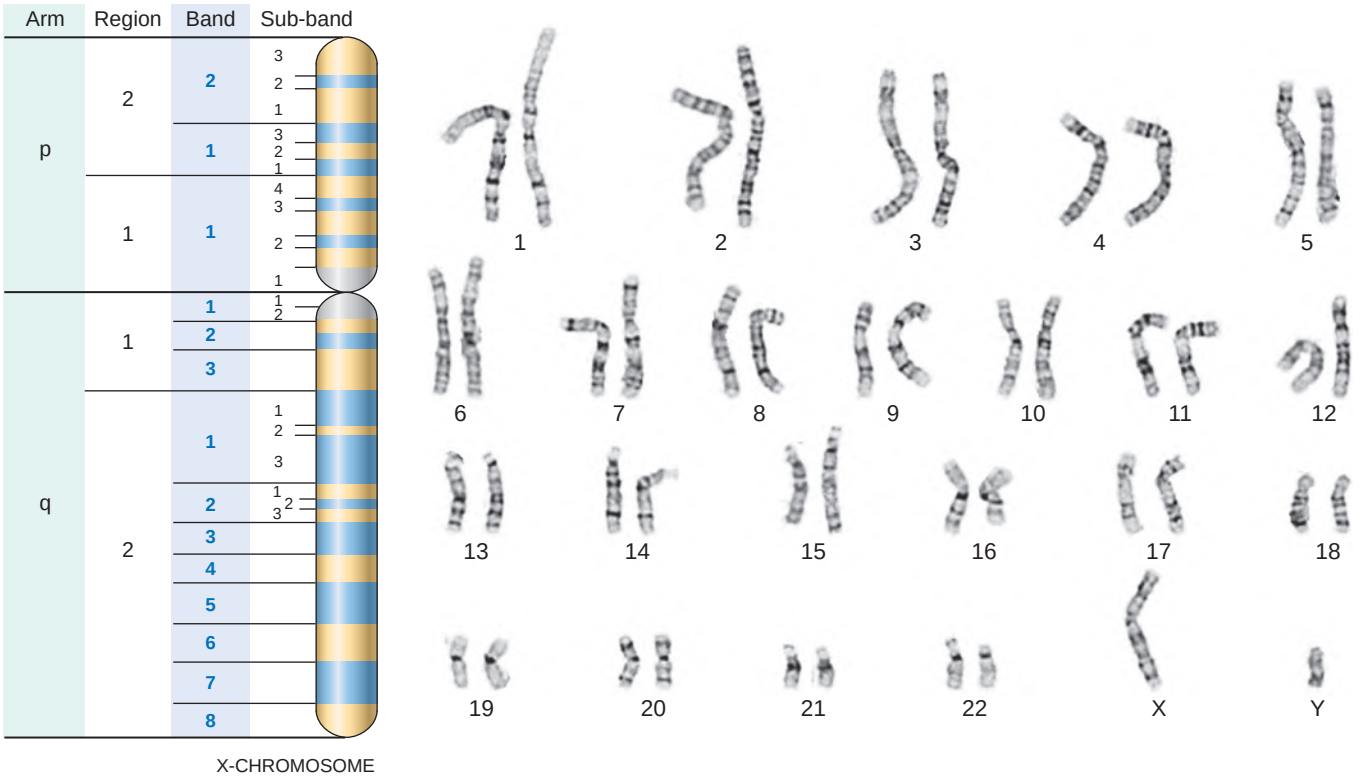

Figure 5.17 G-banded karyotype from a normal male (46,XY). Also shown is the banding pattern of the X chromosome with nomenclature of arms, regions, bands, and sub-bands. (Courtesy Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, Ill.)

of each chromosome and roughly delineates breakpoints and other gross alterations (described later).

Commonly Used Cytogenetic Terminology

Karyotypes are usually described using a shorthand system of notations in the following order: total number of chromosomes is given first, followed by the sex chromosome complement, and finally the description of abnormalities in ascending numerical order. For example, a male with trisomy 21 is designated *47,XY,+21*. Notations denoting structural alterations of chromosomes and their corresponding abnormalities are described later.

The short arm of a chromosome is designated *p* (for petit), and the long arm is referred to as *q* (the next letter of the alphabet). In a banded karyotype, each arm of the chromosome is divided into two or more regions bordered by prominent bands. The regions are numbered (e.g., 1, 2, 3) from the centromere outward. Each region is further subdivided into bands and sub-bands, and these are ordered numerically as well (see Fig. 5.17). Thus the notation *Xp21.2* refers to a chromosomal segment located on the short arm of the X chromosome, in region 2, band 1, and sub-band 2.

Structural Abnormalities of Chromosomes

The aberrations underlying cytogenetic disorders may take the form of an abnormal number of chromosomes or alterations in the structure of one or more chromosomes. The normal chromosome complement is expressed as 46,XX for females and 46,XY for males. Any exact multiple of the haploid number of chromosomes (23) is called *euploid.* If an error occurs in meiosis or mitosis and a cell acquires a chromosome complement that is not an exact multiple of 23, it is referred to as *aneuploidy*. The usual causes for aneuploidy are *nondisjunction* and *anaphase lag*. When nondisjunction occurs during gametogenesis, the gametes formed have either an extra chromosome (n + 1) or one less chromosome (n – 1). Fertilization of such gametes by normal gametes results in two types of zygotes—trisomic (2n + 1) or monosomic (2n – 1). In anaphase lag, one homologous chromosome in meiosis or one chromatid in mitosis lags behind and is left out of the cell nucleus. The result is one normal cell and one cell with monosomy. As discussed later, monosomies or trisomies involving the sex chromosomes, or even more bizarre aberrations, are compatible with life and are usually associated with variable degrees of phenotypic abnormalities. Monosomy involving an autosome generally causes loss of too much genetic information to permit live birth or even embryogenesis, but several autosomal trisomies do permit survival. With the exception of trisomy 21, all exhibit severe malformations and almost invariably die at an early age.

Occasionally, mitotic errors in early development give rise to two or more populations of cells with different chromosomal complement in the same individual, a condition referred to as *mosaicism*. Mosaicism can result from mitotic errors during the cleavage of the fertilized ovum or in somatic cells. Mosaicism affecting the sex chromosomes is relatively common. In the division of the fertilized ovum, an error may lead to one of the daughter cells receiving three sex chromosomes, whereas the other receives only one, yielding, for example, a 45,X/47,XXX mosaic. All descendant cells derived from each of these precursors thus have either a 47,XXX complement or a 45,X complement. Such a patient is a mosaic variant of Turner syndrome, with the extent of phenotypic expression dependent on the number and distribution of the 45,X cells.

Autosomal mosaicism seems to be much less common than that involving the sex chromosomes. An error in an early mitotic division affecting the autosomes usually leads to a nonviable mosaic due to autosomal monosomy. Rarely, the nonviable cell population is lost during embryogenesis, yielding a viable mosaic (e.g., 46,XY/47,XY,+21). Such a patient is a trisomy 21 mosaic with variable expression of Down syndrome, depending on the proportion of cells containing the trisomy.

A second category of chromosomal aberrations is associated with changes in the structure of chromosomes. To be visible by routine banding techniques, a fairly large amount of DNA (approximately 2 to 4 million bp), containing many genes, must be involved. The resolution is much higher with fluorescence in situ hybridization (FISH), which can detect changes as small as kilobases. Structural changes in chromosomes usually result from chromosome breakage followed by loss or rearrangement of material. In the next section the more common forms of alterations in chromosome structure and the notations used to signify them are reviewed.

Deletion refers to loss of a portion of a chromosome (Fig. 5.18). Most deletions are interstitial, but rarely terminal deletions may occur. Interstitial deletions occur when there are two breaks within a chromosome arm, followed by loss of the chromosomal material between the breaks and fusion of the broken ends. One can specify in which regions and at what bands the breaks have occurred. For example, *46,XY,del(16)(p11.2p13.1)* describes breakpoints in the short arm of chromosome 16 at 16p11.2 and 16p13.1 with loss of material between breaks. Terminal deletions result from a single break in a chromosome arm, producing a fragment with no centromere, which is then lost at the next cell division. The deleted end of the retained chromosome is protected by acquiring telomeric sequences.

A *ring chromosome* is a special form of deletion. It is produced when a break occurs at both ends of a chromosome with fusion of the damaged ends (see Fig. 5.18). If significant genetic material is lost, phenotypic abnormalities result. This might be expressed as *46,XY,r(14)*. Ring chromosomes do not behave normally in meiosis or mitosis and usually result in serious consequences.

Inversion refers to a rearrangement that involves two breaks within a single chromosome with reincorporation of the inverted, intervening segment (see Fig. 5.18). An inversion involving only one arm of the chromosome is known as *paracentric.* If the breaks are on opposite sides of the centromere, it is known as *pericentric.* Inversions are often fully compatible with normal development.

Isochromosome formation results when one arm of a chromosome is lost and the remaining arm is duplicated, resulting in a chromosome consisting of two short arms only or of two long arms (see Fig. 5.18). An isochromosome has morphologically identical genetic information in both arms. The most common isochromosome present in live births involves the long arm of the X chromosome and is designated *i(X)(q10)*. The Xq isochromosome is associated

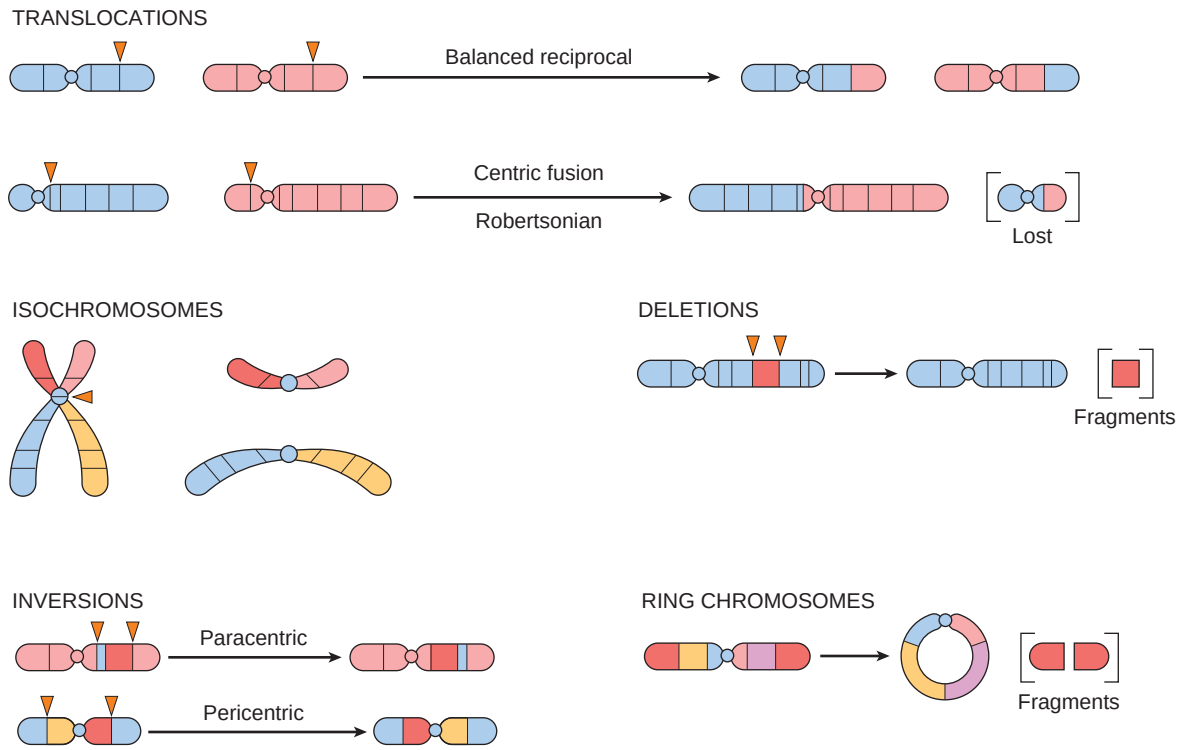

Figure 5.18 Types of chromosomal rearrangements.

with monosomy for genes on the short arm of X and with trisomy for genes on the long arm of X.

In a *translocation,* a segment of one chromosome is transferred to another (see Fig. 5.18). In one form, called *balanced reciprocal translocation,* there are single breaks in each of two chromosomes, with exchange of material. A balanced reciprocal translocation between the long arm of chromosome 2 and the short arm of chromosome 5 would be written *46,XX,t(2;5)(q31;p14)*. This individual has 46 chromosomes with altered morphology of one of the chromosomes 2 and one of the chromosomes 5. Because there has been no or very little loss of genetic material, the individual is likely to be phenotypically normal. A balanced translocation carrier, however, is at increased risk for producing abnormal gametes. For example, in the case cited earlier, a gamete containing one normal chromosome 2 and a translocated chromosome 5 may be formed. Such a gamete would be unbalanced because it would not contain the normal complement of genetic material. Subsequent fertilization by a normal gamete would lead to the formation of an abnormal (unbalanced) zygote, resulting in spontaneous abortion or birth of a malformed child. The other important pattern of translocation is called a *robertsonian translocation* (or centric fusion), a translocation between two acrocentric chromosomes. Typically the breaks occur close to the centromeres of each chromosome. Transfer of the segments then leads to one very large chromosome and one extremely small one. Usually the small product is lost (see Fig. 5.18); however, because it carries only highly redundant genes (e.g., ribosomal RNA genes), this loss is compatible with a normal phenotype. Robertsonian translocation between two chromosomes is encountered in 1 in 1000 apparently normal individuals. The significance of this form of translocation also lies in the production of abnormal progeny, as discussed later with Down syndrome.

As pointed out earlier, the clinically detected chromosome disorders represent only the "tip of the iceberg." It is estimated that approximately 7.5% of all conceptions have a chromosomal abnormality, most of which are not compatible with survival or live birth. Even in live-born infants the frequency is approximately 0.5% to 1.0%. It is beyond the scope of this book to discuss most of the clinically recognizable chromosomal disorders. Hence we focus attention on those few that are most common.

Cytogenetic Disorders Involving Autosomes

Trisomy 21 (Down Syndrome)

Down syndrome is the most common of the chromosomal disorders and is a major cause of intellectual disability. In the United States the incidence in newborns is about 1 in 700. Approximately 95% of affected individuals have trisomy 21, so their chromosome count is 47. FISH with chromosome 21–specific probes reveals the extra copy of chromosome 21 in such cases (Fig. 5.19). As mentioned earlier, the most common cause of trisomy and therefore of Down syndrome is meiotic nondisjunction. The parents of such children have a normal karyotype and are normal in all respects.

Maternal age has a strong influence on the incidence of trisomy 21. It occurs once in 1550 live births in women under age 20, in contrast to 1 in 25 live births for mothers

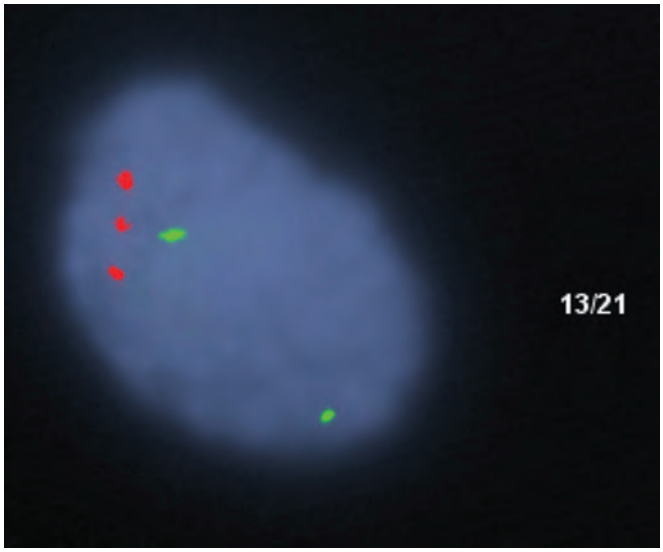

Figure 5.19 Fluorescence in situ hybridization analysis of an interphase nucleus using locus-specific probes to chromosome 13 (green) and chromosome 21 (red), revealing three red signals consistent with trisomy 21. (Courtesy Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)

older than age 45. The correlation with maternal age suggests that in most cases the meiotic nondisjunction of chromosome 21 occurs in the ovum. Indeed, studies in which DNA polymorphisms were used to trace the parental origin of chromosome 21 have revealed that in 95% of the cases with trisomy 21 the extra chromosome is of maternal origin. Although many hypotheses have been advanced, the reason for the increased susceptibility of the ovum to nondisjunction remains unknown.

In about 4% of cases of Down syndrome the extra chromosomal material derives from the presence of a robertsonian translocation of the long arm of chromosome 21 to another acrocentric chromosome (e.g., 22 or 14). Because the fertilized ovum already possesses two normal autosomes 21, the translocated material provides the same triple gene dosage as in trisomy 21. Such cases are frequently (but not always) familial, and the translocated chromosome is inherited from one of the parents (usually the mother), who is a carrier of a robertsonian translocation, for example, a mother with karyotype 45,XX,der(14;21)(q10;q10). In cells with robertsonian translocations, the genetic material normally found on long arms of two pairs of chromosomes is distributed among only three chromosomes. This affects chromosome pairing during meiosis, and as a result the gametes have a high probability of being aneuploid.

Approximately 1% of patients with Down syndrome are mosaics, having a mixture of cells with 46 or 47 chromosomes. This mosaicism results from mitotic nondisjunction of chromosome 21 during an early stage of embryogenesis. Symptoms in such cases are variable and milder, depending on the proportion of abnormal cells. Clearly, in cases of translocation or mosaic Down syndrome, maternal age is of no importance.

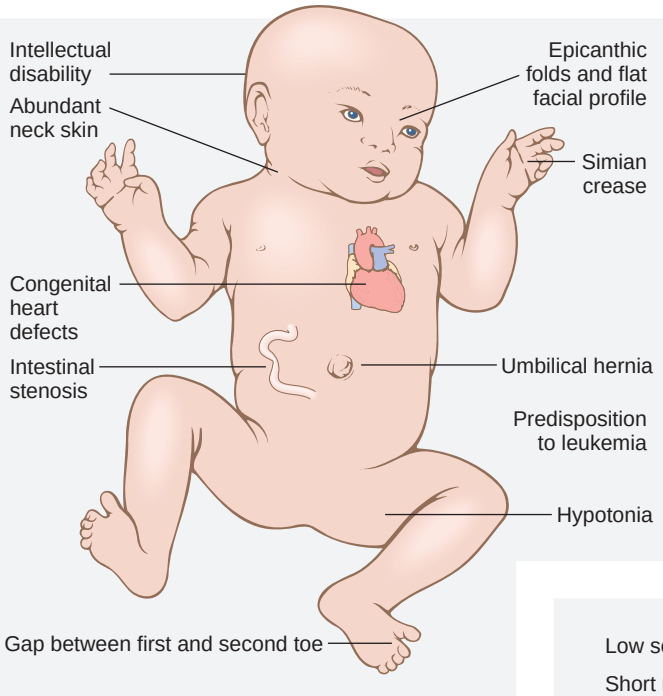
The diagnostic clinical features of this condition—flat facial profile, oblique palpebral fissures, and epicanthic folds (Fig. 5.20)**—are usually readily evident, even at birth.** Down syndrome is a leading cause of severe intellectual disability. It should be pointed out that some mosaics with Down syndrome have mild phenotypic changes and may even have normal or near-normal intelligence. In addition to the phenotypic abnormalities and the intellectual disability already noted, some other clinical features are worthy of note.

- *Approximately 40% of the patients have congenital heart disease.* The most frequent forms of congenital heart diseases in Down syndrome are atrioventricular septal defects constituting 43% of cases, whereas ventricular septal defects, atrial septal defects, and tetralogy of Fallot constitute 32%, 19%, and 6%, respectively. Cardiac problems are responsible for the majority of the deaths in infancy and early childhood. Several other congenital malformations, including atresias of the esophagus and small bowel, are also common.
- *Children with trisomy 21 have a high risk of developing leukemia;* there is 20-fold increased risk of developing acute B lymphoblastic leukemias and 500-fold increased risk of acute myeloid leukemias. The latter, most commonly, is acute megakaryoblastic leukemia.
- Virtually all patients with trisomy 21 older than age 40 develop *neuropathologic changes* characteristic of Alzheimer disease, a degenerative disorder of the brain.
- Patients with Down syndrome *have abnormal immune responses* that predispose them to serious infections, particularly of the lungs, and to thyroid autoimmunity. Although several abnormalities, affecting mainly T-cell functions, have been reported, the basis of immunologic disturbances is not clear.

Despite all these problems, improved medical care has increased the longevity of individuals with trisomy 21. Currently the median age at death is 47 years (up from 25 years in 1983).

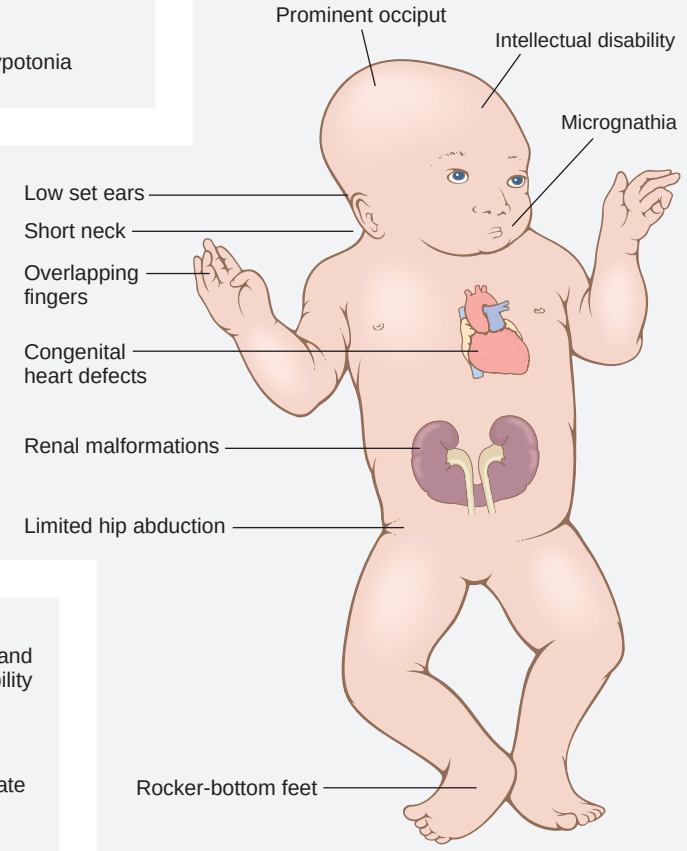
Although the long arm of chromosome 21 was fully sequenced in 2000, progress in unraveling the molecular basis of Down syndrome has been quite slow. This stems in part from the fact that Down syndrome results from gene dosage imbalance rather than the action of a few genes. A sampling of some of the observations follows.

- *Gene dosage*. The majority of the protein coding genes mapped to chromosome 21 are overexpressed. Included among these is the gene for amyloid-beta precursor protein (*APP*). As discussed in Chapter 28, aggregation of amyloid-beta proteins is the critical initiating event in the development of Alzheimer disease and could contribute to the early onset of Alzheimer disease that occurs in individuals with Down syndrome.
- *Mitochondrial dysfunction.* Approximately 10% of the genes overexpressed in Down syndrome are directly or indirectly involved in regulation of mitochondrial functions. In keeping with this, mitochondria are abnormal both morphologically and functionally in several tissues. For example, cristae are broken or swollen; there is evidence of mitochondrial stress with generation of reactive oxygen species and activation of apoptosis.
- *Noncoding RNAs*. Chromosome 21 has the highest density of lncRNAs whose target sequences are widely expressed



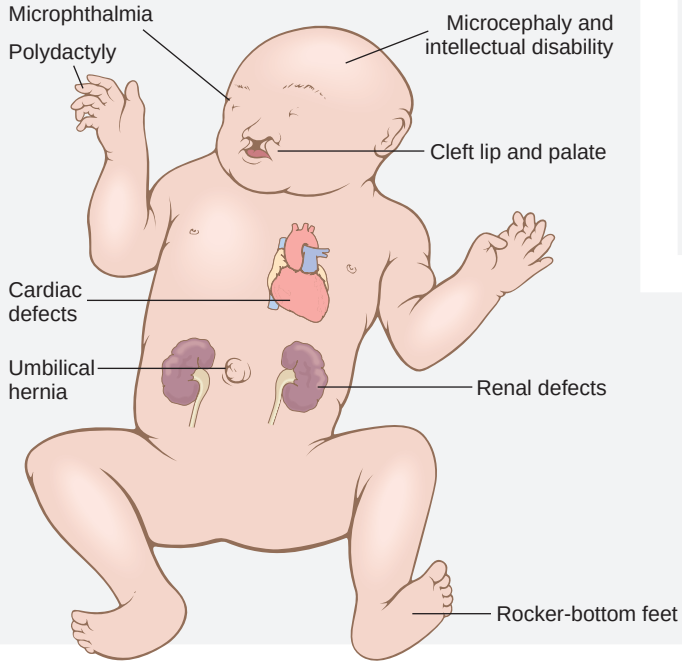
TRISOMY 21: DOWN SYNDROME

Incidence: 1 in 700 births
Karyotypes:
Trisomy 21 type: 47,XX, +21
Translocation type: 46,XX,der(14;21)(q10;q10),+21
Mosaic type: 46,XX/47,XX, +21



TRISOMY 18: EDWARDS SYNDROME

Incidence: 1 in 8000 births
Karyotypes:
Trisomy 18 type: 47,XX, +18
Mosaic type: 46,XX/47,XX, +18



TRISOMY 13: PATAU SYNDROME

Incidence: 1 in 15,000 births
Karyotypes:
Trisomy 13 type: 47,XX, +13
Translocation type: 46,XX,+13,der(13;14)(q10;q10)
Mosaic type: 46,XX/47,XX, +13

Figure 5.20 Clinical features and karyotypes of selected autosomal trisomies.

on other chromosomes, making the task of identification of genes whose products dictate the phenotype of trisomy 21 exceedingly difficult.

Much progress is being made in the molecular diagnosis of Down syndrome prenatally. Approximately 5% to 10% of the total cell free DNA in maternal blood is derived from the fetus and can be identified by polymorphic genetic markers. By using next-generation sequencing, the gene dosage of chromosome 21 linked genes in fetal DNA can be determined with great precision. This is a powerful noninvasive screening test for prenatal diagnosis of trisomy 21 as well as other trisomies. Most laboratories require confirmation of a positive screening test with conventional karyotyping.

Other Trisomies

A variety of other trisomies involving chromosomes 8, 9, 13, 18, and 22 have been described. Only trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome) are common enough to merit brief mention here. As noted in Fig. 5.20, they share several karyotypic and clinical features with trisomy 21. Thus most cases result from meiotic nondisjunction and therefore carry a complete extra copy of chromosome 13 or 18. As in Down syndrome, an association with increased maternal age is also noted. In contrast to trisomy 21, however, the malformations are much more severe and wide ranging. As a result, only rarely do infants survive beyond the first year of life. Most succumb within a few weeks to months.

Chromosome 22q11.2 Deletion Syndrome

Chromosome 22q11.2 deletion syndrome encompasses a spectrum of disorders that result from a small deletion of band q11.2 on the long arm of chromosome 22. The syndrome is fairly common, occurring in as many as 1 in 4000 births, but it is often missed because of variable clinical features. These include congenital heart defects, abnormalities of the palate, facial dysmorphism, developmental delay, and variable degrees of T-cell immunodeficiency and hypocalcemia. Previously, these clinical features were considered to represent two different disorders—*DiGeorge syndrome* and *velocardiofacial syndrome*. In a very small number of cases there is a deletion of 10p13-14.

Patients with DiGeorge syndrome have thymic hypoplasia, with resultant T-cell immunodeficiency (Chapter 6), parathyroid hypoplasia giving rise to hypocalcemia, a variety of cardiac malformations affecting the outflow tract, and mild facial anomalies. Atopic disorders (e.g., allergic rhinitis) and autoimmunity (e.g., thrombocytopenia) may also be seen. The clinical features of the so-called velocardiofacial syndrome include facial dysmorphism (prominent nose, retrognathia), cleft palate, cardiovascular anomalies, and learning disabilities. Less frequently, these patients also have immunodeficiency.

Despite the overlapping clinical features of these two conditions (e.g., cardiac malformations, facial dysmorphology) it was only after these two apparently unrelated syndromes were found to be associated with a similar cytogenetic abnormality that the clinical overlap came into focus. Recent studies indicate that, in addition to the numerous structural malformations, individuals with the 22q11.2 deletion syndrome are at a particularly high risk for psychotic illnesses, such as *schizophrenia and bipolar disorders.* In fact, it is estimated that schizophrenia develops in approximately 25% of adults with this syndrome. Conversely, deletions of the region can be found in 2% to 3% of individuals with childhood-onset schizophrenia. In addition, attention-deficit/hyperactivity disorder is seen in 30% to 35% of affected children.

The diagnosis of this condition may be suspected on clinical grounds but can be established only by detection of the deletion by FISH (Fig. 5.21). By this test, approximately 90% of individuals previously diagnosed as having DiGeorge syndrome and 80% of those with the velocardiofacial syndrome have a deletion of 22q11.2. Thirty percent of individuals with conotruncal cardiac defects but no other features of this syndrome also reveal deletions of the same chromosomal region.

The molecular basis of this syndrome is not fully understood. The deleted region is large (approximately 1.5 Mb) and includes 30 to 40 genes. The clinical heterogeneity, with predominant immunodeficiency in some cases (DiGeorge syndrome) and predominant dysmorphology and cardiac malformations in other cases, probably reflects the variable position and size of the deleted segment from this genetic region. Approximately 30 candidate genes have been mapped to the deleted region. Among these, *TBX1,* a T-box transcription factor, is most closely associated with the phenotypic features of this syndrome. This gene is expressed in the pharyngeal mesenchyme and endodermal pouch from which facial structures, thymus, and parathyroid are derived. The targets of *TBX1* include *PAX9,* a gene that controls the development of the palate, parathyroids, and thymus. Clearly there are other genes that contribute to the behavioral and psychiatric disorders that remain to be identified.

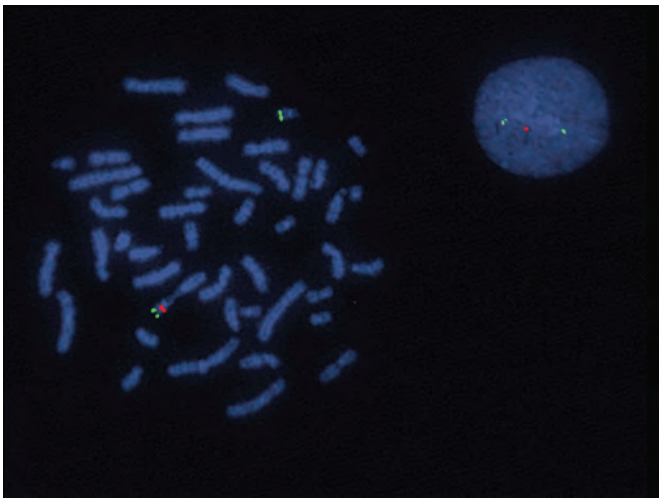


Figure 5.21 Fluorescence in situ hybridization of both metaphase chromosomes and an interphase cell from a patient with DiGeorge syndrome demonstrating the deletion of a probe that maps to chromosome 22q11.2. The 22q11.2 probe is in red, and the control probe, localized to 22q, is in green. The metaphase spread shows one chromosome 22 with both a green signal (control probe) and a red signal (from the 22q11.2 probe). The other chromosome 22 shows only hybridization with the control probe (green), but no red 22q11.2 signal since there is a deletion on this chromosome. The interphase cell also shows a hybridization pattern consistent with a deletion of chromosome 22q11.2. (Courtesy Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, Ill.)

KEY CONCEPTS

CYTOGENETIC DISORDERS INVOLVING AUTOSOMES

- Down syndrome is associated with an extra copy of genes on chromosome 21, most commonly due to trisomy 21 and less frequently from translocation of extra chromosomal material from chromosome 21 to other chromosomes or from mosaicism.
- Patients with Down syndrome have severe intellectual disability, flat facial profile, epicanthic folds, cardiac malformations, higher risk of leukemia and infections, and premature development of Alzheimer disease.
- Deletion of genes at chromosomal locus 22q11.2 gives rise to malformations affecting the face, heart, thymus, and parathyroids. The resulting disorders are recognized as DiGeorge syndrome (thymic hypoplasia with diminished T-cell immunity and parathyroid hypoplasia with hypocalcemia) and velocardiofacial syndrome (congenital heart disease involving outflow tracts, facial dysmorphism, and developmental delay).

Cytogenetic Disorders Involving Sex Chromosomes

Genetic diseases associated with changes involving the sex chromosomes are far more common than those related to autosomal aberrations. Furthermore, imbalances (excess or loss) of sex chromosomes are much better tolerated than are similar imbalances of autosomes. In large part, this latitude relates to two factors that are peculiar to the sex chromosomes: (1) lyonization or inactivation of all but one X chromosome and (2) the modest amount of genetic material carried by the Y chromosome. These features are discussed briefly in relation to sex chromosomal disorders.

In 1961, Mary Lyon outlined the idea of X-inactivation, now commonly known as the Lyon hypothesis. It states that (1) *only one of the X chromosomes is genetically active,* (2) *the other X chromosome of either maternal or paternal origin undergoes heteropyknosis and is rendered inactive,* (3) *inactivation of either the maternal or the paternal X chromosome occurs at random among all the cells of the blastocyst on or about day 5.5 of embryonic life,* and (4) *inactivation of the same X chromosome persists in all the cells derived from each precursor cell.* Thus, the great preponderance of normal females are in reality mosaics and have two populations of cells, one with an inactivated maternal X chromosome and the other with an inactivated paternal X chromosome. Herein lies the explanation of why females have the same dosage of X-linked active genes as males. The inactive X chromosome can be seen in the interphase nucleus as a darkly staining small mass in contact with the nuclear membrane known as the *Barr body,* or X chromatin. The molecular basis of X inactivation involves a unique gene called *XIST,* whose product is a lncRNA (Chapter 1) that is retained in the nucleus, where it "coats" the X chromosome that it is transcribed from and initiates a gene-silencing process by chromatin modification and DNA methylation. The *XIST* allele is switched off in the active X chromosome.

Although it was initially thought that all the genes on the inactive X chromosome are "switched off," it is now established that many genes escape X inactivation. Molecular studies suggest that 30% of genes on Xp and a smaller number (3%) on Xq escape X inactivation. At least some of the genes that are expressed from both X chromosomes are important for normal growth and development. This notion is supported by the fact that patients with monosomy of the X chromosome (Turner syndrome: 45,X) have severe somatic and gonadal abnormalities. If a single dose of X-linked genes were sufficient, no detrimental effect would be expected in such cases. Furthermore, although one X chromosome is inactivated in all cells during embryogenesis, it is selectively reactivated in oogonia before the first meiotic division. Thus, it seems that both X chromosomes are required for normal growth as well as oogenesis. The tips of short and long arms of X and Y chromosomes have regions of homology that recombine during meiosis and are therefore inherited as autosomal loci. For this reason they are called pseudoautosomal regions. These genes also escape X inactivation. These mechanisms ensure that males and females have equivalent doses of genes that map on X and Y chromosomes.

With respect to the Y chromosome, it is well known that this chromosome is both necessary and sufficient for male development. **Regardless of the number of X chromosomes, the presence of a single Y chromosome determines the male sex.** The gene that dictates testicular development (*SRY* [sex-determining region Y gene]) is located on its distal short arm. For quite some time this was considered to be the only gene of significance on the Y chromosome. Recent studies, however, have yielded a rich harvest of several gene families in the so-called male-specific Y region, or MSY region, harboring 75 protein coding genes. All of these are believed to be testis-specific and are involved in spermatogenesis. In keeping with this, all Y chromosome deletions are associated with azoospermia. By comparison, the X chromosome has 840 coding genes. The following features are common to all sex chromosome disorders.

- In general, sex chromosome disorders cause subtle, chronic problems relating to sexual development and fertility.
- Sex chromosome disorders are often difficult to diagnose at birth, and many are first recognized at the time of puberty.
- In general, the greater the number of X chromosomes, in both males and females, the greater the likelihood of intellectual disability.

The two most important disorders arising in aberrations of sex chromosomes are described briefly here.

Klinefelter Syndrome

Klinefelter syndrome is best defined as male hypogonadism that occurs when there are two or more X chromosomes and one or more Y chromosomes. It is one of the most frequent forms of genetic diseases involving the sex chromosomes as well as one of the most common causes of hypogonadism in males. The incidence of this condition is reported to be approximately 1 in 660 live male births. This is an underestimate since Klinefelter syndrome has a range of phenotypic manifestations, and those with mild features are never seen by health care providers. The clinical features of Klinefelter syndrome can be attributed to two major factors: (1) aneuploidy and the impact of increased gene

dosage by the supernumerary X and (2) the presence of hypogonadism. Klinefelter syndrome is rarely diagnosed before puberty, particularly because manifestations of hypogonadism do not develop before early puberty.

Most patients have a distinctive body habitus with an increase in length between the soles and the pubic bone, which creates the appearance of an elongated body. Also characteristic are eunuchoid body habitus with abnormally long legs; small atrophic testes often associated with a small penis; and lack of such secondary male characteristics as deep voice, beard, and male distribution of pubic hair. Gynecomastia may be present. The cognitive abilities range from average to below average with modest deficit in verbal skills particularly those that are used in reading and language comprehension. Patients with Klinefelter syndrome develop several comorbid conditions. There is increased incidence of type 2 diabetes and the metabolic syndrome that gives rise to insulin resistance. Patients are at a higher risk for congenital heart disease, particularly mitral valve prolapse, which is seen in about 50% of adults. In addition there is a higher prevalence of atrial and ventricular septal defects. There is also an increased incidence of osteoporosis and fractures due to sex hormonal imbalance. Patients with Klinefelter syndrome have a 20- to 30-fold higher risk of developing extragonadal germ cell tumors, mostly mediastinal teratomas. In addition, breast cancer and autoimmune diseases such as systemic lupus erythematosus occur more frequently. It should be noted that the physical attributes described here are quite variable, the only consistent finding being hypogonadism.

Klinefelter syndrome is an important genetic cause of reduced spermatogenesis and male infertility. In some patients the testicular tubules are totally atrophied and replaced by pink, hyaline, collagenous ghosts. In others, apparently normal tubules are interspersed with atrophic tubules. In some patients, all tubules are primitive and appear embryonic, consisting of cords of cells that never developed a lumen or progressed to mature spermatogenesis. Leydig cells appear prominent, as a result of the atrophy and crowding of the tubules and elevation of gonadotropin concentrations. Plasma gonadotropin concentrations, particularly follicle-stimulating hormone (FSH), are consistently elevated, whereas testosterone levels are variably reduced. Mean plasma estradiol levels are elevated by an as yet unknown mechanism. The ratio of estrogens and testosterone determines the degree of feminization in individual cases.

Classic Klinefelter syndrome is associated with a 47,XXY karyotype (90% of cases). This complement of chromosomes results from nondisjunction during the meiotic divisions in the germ cells of one of the parents. Maternal and paternal nondisjunction at the first meiotic division is roughly equally involved. There is no phenotypic difference between those who receive the extra X chromosome from their father and those who receive it from their mother. Advanced maternal age (>40 years) is a risk factor. In addition to this classic karyotype, approximately 15% of patients with Klinefelter syndrome have a variety of mosaic patterns, most of them being 46,XY/47,XXY; in some there is a cell line with structurally abnormal X chromosome (e.g., 47,iXq,Y). As is the case with normal females, all but one X chromosome undergoes inactivation in patients with Klinefelter syndrome. Why then, do the patients with this disorder have hypogonadism and associated features? The explanation for this lies in genes on the X chromosome that escape lyonization and in the pattern of X inactivation.

- One pathogenic mechanism is related to uneven dosage compensation during X inactivation. It is now known that about 35% of the X-linked genes escape inactivation. Thus there is an extra dose of these genes compared with normal males in whom only one copy of the X chromosome is active; it appears that "overexpression" of one or more of these genes leads to hypogonadism. A similar mechanism may also dictate some somatic features. The *Short-stature HomeobOX (SHOX)* gene that maps on the pseudoautosomal region of Xp is one of the genes that is not subject to X inactivation. An extra copy of this growth-related gene is probably responsible for the tall stature and long legs typical of Klinefelter syndrome. It should be noted that most genes whose expression is upregulated in Klinefelter syndrome lie outside the X chromosome. This implies that the supernumerary X chromosome can regulate gene expression on autosomes.
- A second mechanism involves the gene encoding the androgen receptor, through which testosterone mediates its effects. The androgen receptor gene maps to the X chromosome and contains highly polymorphic CAG (trinucleotide) repeats. The functional response of the receptor to any particular dose of androgen is dictated, in part, by the number of CAG repeats, as receptors with shorter CAG repeats are more sensitive to androgens than those with long CAG repeats. In persons with Klinefelter syndrome, the X chromosome bearing the androgen receptor allele with the shortest CAG repeat is preferentially inactivated. In XXY males with low testosterone levels, expression of androgen receptors with long CAG repeats exacerbates the hypogonadism and appears to account for certain aspects of the phenotype, such as small penis size.

Turner Syndrome

Turner syndrome results from complete or partial monosomy of the X chromosome and is characterized by hypogonadism in phenotypic females. It is the most common sex chromosome abnormality in females, affecting about 1 in 2000 live-born females.

With routine cytogenetic methods, three types of karyotypic abnormalities are seen in individuals with Turner syndrome.

- *Approximately 57% are missing an entire X chromosome, resulting in a 45,X karyotype.* Of the remaining 43%, approximately one-third (14%) have structural abnormalities of the X chromosomes, and two-thirds (29%) are mosaics.
- *The common feature of the structural abnormalities is to produce partial monosomy of the X chromosome.* In order of frequency, the structural abnormalities of the X chromosome include (1) an isochromosome of the long arm, 46,X,i(X)(q10), resulting in the loss of the short arm; (2) deletion of portions of both long and short arms, resulting in the formation of a ring chromosome, 46,X,r(X); and (3) deletion of portions of the short or long arm, 46X,del(Xq) or 46X,del(Xp).
- *The mosaic patients have a 45,X cell population along with one or more karyotypically normal or abnormal cell types.*

Examples of karyotypes that mosaic Turner females may have are the following: (1) 45,X/46,XX, (2) 45,X/46,XY, (3) 45,X/47,XXX, or (4) 45,X/46,X,i(X)(q10). Studies suggest that the prevalence of mosaicism in Turner syndrome may be much higher than the 30% detected by conventional cytogenetic studies. With the use of more sensitive techniques, the prevalence of mosaic Turner syndrome increases to 75%. Because 99% of conceptuses with an apparent 45,X karyotype are nonviable, many authorities believe that there are no truly nonmosaic Turner syndrome patients. While this issue remains controversial, it is important to appreciate the karyotypic heterogeneity associated with Turner syndrome because it is responsible for significant variations in phenotype. In patients in whom the proportion of 45,X cells is high, the phenotypic changes are more severe than in those who have readily detectable mosaicism. The latter may have an almost normal appearance and may present only with primary amenorrhea. A very small number of patients are able to conceive.

Five percent to 10% of patients with Turner syndrome have Y chromosome sequences either as a complete Y chromosome (e.g., 45,X/46,XY karyotype) or as fragments of Y chromosomes translocated on other chromosomes. These patients are at a higher risk for development of a gonadal tumor (gonadoblastoma).

The most severely affected patients generally present during infancy with edema of the dorsum of the hand and foot due to lymph stasis and sometimes *swelling of the nape of the neck*. The latter is related to markedly distended lymphatic channels, producing a so-called cystic hygroma (Chapter 10). As these infants develop, the swellings subside but often leave bilateral *neck webbing* and persistent looseness of skin on the back of the neck. *Congenital heart disease* is also common, affecting 25% to 50% of patients. Left-sided cardiovascular abnormalities, particularly preductal coarctation of the aorta and bicuspid aortic valve, are seen most frequently. Approximately 5% of young women initially diagnosed with coarctation of aorta have Turner syndrome. Aortic root dilatation is present in 30% of cases, and there is a 100-fold higher risk of aortic dissection. Cardiovascular abnormalities are the most important cause of increased mortality in children with Turner syndrome.

The principal clinical features in adolescents and adults are illustrated in Fig. 5.22. At puberty there is failure to develop normal secondary sex characteristics. The genitalia remain infantile, breast development is inadequate, and there is little pubic hair. The mental status of patients is usually normal, but subtle defects in nonverbal, visual-spatial information processing have been noted. Of particular importance in establishing the diagnosis in an adult is the shortness of stature (rarely exceeding 150 cm in height) and amenorrhea. Turner syndrome is the single most important cause of primary

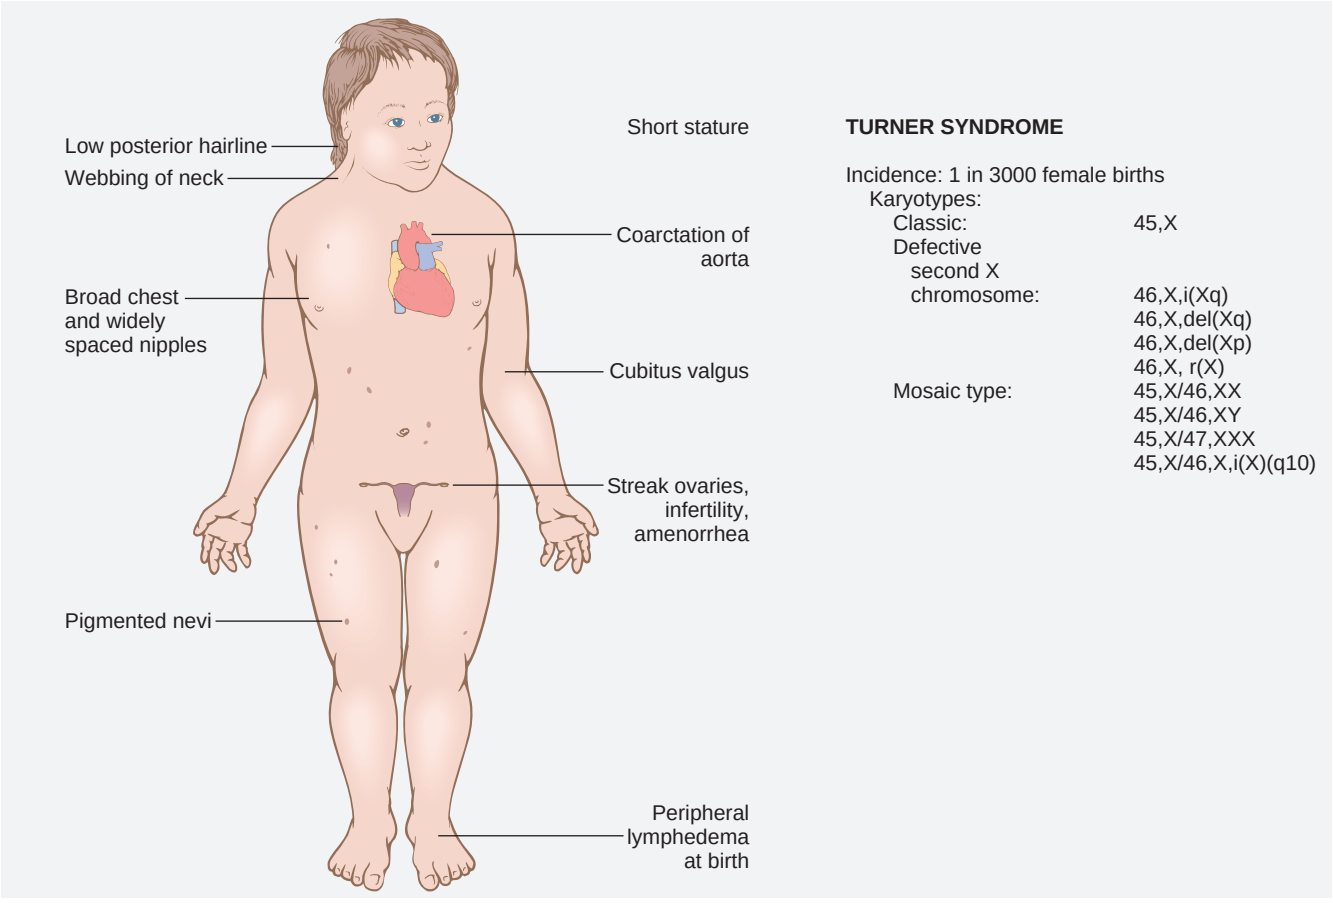

Figure 5.22 Clinical features and karyotypes of Turner syndrome.

amenorrhea, accounting for approximately one-third of the cases. For reasons that are not clear, approximately 50% of patients develop autoantibodies that react with the thyroid gland, and up to half of these develop clinically manifest hypothyroidism. Equally mysterious is the presence of glucose intolerance, obesity, nonalcoholic fatty liver disease, and insulin resistance in a subset of patients. Some have full-fledged metabolic syndrome. The occurrence of insulin resistance is significant because therapy with growth hormone, commonly used in these patients, worsens insulin resistance.

The molecular pathogenesis of Turner syndrome is not completely understood, but studies have begun to shed some light. In approximately 80% of cases the X chromosome is maternal in origin, suggesting that there is an abnormality in paternal gametogenesis. As mentioned earlier, both X chromosomes are active during oogenesis and are essential for normal development of the ovaries. During normal fetal development, ovaries contain as many as 7 million oocytes. The oocytes gradually disappear so that by menarche their numbers have dwindled to a mere 400,000, and when menopause occurs fewer than 10,000 remain. In Turner syndrome, fetal ovaries develop normally early during the first 18 weeks of gestation, but the absence of the second X chromosome leads to an accelerated loss of oocytes, which is complete by age 2 years. In a sense, therefore, "menopause occurs before menarche," and the ovaries are reduced to atrophic fibrous strands, devoid of ova and follicles *(streak ovaries)*. Studies of patients with Turner syndrome with deletions affecting the short or long arm have revealed that many of the somatic features are determined by genes on the short arm, whereas genes on the long arm affect fertility and menstruation. Among the genes involved in the Turner phenotype is the *SHOX* gene at Xp22.33. As mentioned earlier, *SHOX* maps at the pseudo autosomal region of the X and Y chromosomes and escapes X inactivation. Thus both normal males and normal females have two copies of this gene. Haploinsufficiency of *SHOX* in Turner syndrome is believed to give rise to short stature. Indeed, deletions of the *SHOX* gene are noted in 2% to 5% of otherwise normal children with short stature. In keeping with its role as a critical regulator of growth, *SHOX* is expressed during fetal life in the growth plates of several long bones including the radius, ulna, tibia, and fibula. It is also expressed in the first and second pharyngeal arches. Just as the loss of *SHOX* is always associated with short stature, excess copies of this gene (in Klinefelter syndrome) are associated with tall stature. Whereas haploinsufficiency of *SHOX* can explain growth deficit in Turner syndrome, it cannot explain other clinical features such as cardiac malformations and metabolic abnormalities. Clearly several other genes located on the short arm of X chromosome are involved. Growth hormone and estradiol are used to treat Turner syndrome with a reasonable degree of success.

Hermaphroditism and Pseudohermaphroditism

The problem of sexual ambiguity is exceedingly complex, and only limited observations are possible here; for more details, the reader should refer to specialized sources. It will be no surprise to medical students that the sex of an individual can be defined on several levels. *Genetic sex* is determined by the presence or absence of a Y chromosome. No matter how many X chromosomes are present, a single Y chromosome dictates testicular development and the genetic male sex. The initially indifferent gonads of both male and female embryos have an inherent tendency to feminize, unless influenced by Y chromosome–dependent masculinizing factors. *Gonadal sex* is based on the histologic characteristics of the gonads. *Ductal sex* depends on the presence of derivatives of the müllerian or wolffian ducts. *Phenotypic,* or *genital, sex* is based on the appearance of the external genitalia. Sexual ambiguity is present whenever there is disagreement among these various criteria for determining sex.

The term *true hermaphrodite* implies the presence of both ovarian and testicular tissue. In contrast, a pseudohermaphrodite represents a disagreement between the phenotypic and gonadal sex (i.e., a female pseudohermaphrodite has ovaries but male external genitalia; a male pseudohermaphrodite has testicular tissue but female-type genitalia). The genetic bases of these conditions are quite variable and beyond the scope of our discussion here.

KEY CONCEPTS

CYTOGENETIC DISORDERS INVOLVING SEX CHROMOSOMES

- In females, one X chromosome, maternal or paternal, is randomly inactivated during development (Lyon hypothesis).
- In Klinefelter syndrome, there are two or more X chromosomes with one Y chromosome as a result of nondisjunction of sex chromosomes. Patients have testicular atrophy, sterility, reduced body hair, gynecomastia, and eunuchoid body habitus. It is the most common cause of male sterility.
- In Turner syndrome, there is partial or complete monosomy of genes on the short arm of the X chromosome, most commonly due to absence of one X chromosome (45,X), mosaicism, or deletions involving the short arm of the X chromosome. Short stature, webbing of the neck, cubitus valgus, cardiovascular malformations, amenorrhea, lack of secondary sex characteristics, and fibrotic ovaries are typical clinical features.

SINGLE-GENE DISORDERS WITH NONCLASSIC INHERITANCE

It has become increasingly evident that transmission of certain single-gene disorders does not follow classic Mendelian principles. This group of disorders can be classified into four categories.

- Diseases caused by trinucleotide-repeat mutations
- Disorders caused by mutations in mitochondrial genes
- Disorders associated with genomic imprinting
- Disorders associated with gonadal mosaicism

Clinical and molecular features of some single-gene diseases that exemplify nonclassic patterns of inheritance are described next.

Diseases Caused by Trinucleotide-Repeat Mutations

Expansion of trinucleotide repeats is an important genetic cause of human disease, particularly neurodegenerative

Table 5.8 Examples of Trinucleotide-Repeat Disorders

Disease	Gene	Locus	Protein	Repeat	No. Repeats	
					Normal	Disease
Expansions Affecting Noncoding Regions						
Fragile X syndrome	*FMRI (FRAXA)*	Xq27.3	FMR-I protein (FMRP)	CGG	6–55	55–200 (pre); >230 (full)
Friedreich ataxia	*FXN*	9q21.1	Frataxin	GAA	7–34	34–80 (pre); >100 (full)
Myotonic dystrophy	*DMPK*	19q13.3	Myotonic dystrophy protein kinase (DMPK)	CTG	5–37	34–80 (pre); >100 (full)
Expansions Affecting Coding Regions						
Spinobulbar muscular atrophy (Kennedy disease)	*AR*	Xq12	Androgen receptor (AR)	CAG	5–34	37–70
Huntington disease	*HTT*	4p16.3	Huntingtin	CAG	6–35	39–250
Dentatorubral-pallidoluysian atrophy (Haw River syndrome)	*ATNL*	12p13.31	Atrophin-I	CAG	7–35	49–88
Spinocerebellar ataxia type I	*ATXN1*	6p23	Ataxin-I	CAG	6–44	>39
Spinocerebellar ataxia type 2	*ATXN2*	12q24.1	Ataxin-2	CAG	13–33	>31
Spinocerebellar ataxia type 3 (Machado-Joseph disease)	*ATXN3*	14q21	Ataxin-3	CAG	12–40	55–84
Spinocerebellar ataxia type 6	*Ataxin-6*	19p13.3	α_{1A}-Voltage-dependent calcium channel subunit	CAG	4–18	21–33
Spinocerebellar ataxia type 7	*Ataxin-7*	3p14.1	Ataxin-7	CAG	4–35	37–306

disorders. The discovery in 1991 of expanding trinucleotide repeats as a cause of fragile X syndrome (FXS) was a landmark in human genetics. Since then the origins of about 40 human diseases (Table 5.8) have been traced to unstable nucleotide repeats, and the number continues to grow. All the disorders discovered so far are associated with neurodegenerative changes. Some general principles apply to these diseases.

- The causative mutations are associated with the expansion of a stretch of trinucleotides that usually share the nucleotides G and C. In all cases the DNA is unstable, and an expansion of the repeats above a certain threshold impairs gene function in various ways, discussed later. In recent years, diseases associated with unstable tetranucleotides, pentanucleotides, and hexanucleotides have also been found, establishing this as a fundamental mechanism of neuromuscular diseases.
- The proclivity to expand depends strongly on the sex of the transmitting parent. In FXS, expansions occur during oogenesis, whereas in Huntington disease they occur during spermatogenesis.
- There are three key mechanisms by which unstable repeats cause diseases: (1) *Loss of function* of the affected gene, typically by transcription silencing, as in FXS; in such cases the repeats are generally in the noncoding part of the gene. (2) *A toxic gain of function* by alterations of protein structure, as in Huntington disease and spinocerebellar ataxias; in such cases the expansions occur in the coding regions of the genes. (3) *A toxic gain of function mediated by RNA* as is seen in fragile X–associated tremor/ataxia syndrome; as in FXS, the noncoding parts of the gene are affected (Fig. 5.23).

The pathogenetic mechanisms underlying disorders caused by mutations that affect coding regions seem to be distinct from those in which the expansions affect noncoding regions. The former usually involve CAG repeats coding for polyglutamine tracts in the corresponding proteins. Such polyglutamine diseases are characterized by progressive neurodegeneration, typically striking in midlife. Polyglutamine expansions lead to toxic gain of function, whereby the abnormal protein may interfere with the function of the normal protein (a dominant negative activity) or acquire a novel pathophysiologic toxic activity. The precise mechanisms by which expanded polyglutamine proteins cause disease are not fully understood. In most cases the proteins are misfolded and tend to aggregate; the aggregates may suppress transcription of other genes, cause mitochondrial dysfunction, or trigger the unfolded-protein stress response and apoptosis (Chapters 1 and 2). *A morphologic hallmark of these diseases is the accumulation of aggregated mutant proteins in large intranuclear inclusions.* While formation of aggregates is common to many polyglutamine diseases, evidence of a direct toxic role of aggregates is not universal. In fact, some observers believe that aggregation may be protective by sequestration of the misfolded protein. Other models of pathogenicity implicate downstream effects mediated by proteolytic fragments of the polyglutamine fragment. Much more needs to be learned before therapeutic strategies can be developed.

Fragile X Syndrome (FXS)

FXS is the most common genetic cause of intellectual disability in males and overall the second most common cause after Down syndrome. It results from a trinucleotide expansion mutation in the *familial mental retardation 1 (FMR1)* gene. Although discovered initially as the cause of FXS, expansion mutations affecting the *FMR1* gene are now known to be present in two other well-defined disorders—fragile X–associated tremor/ataxia syndrome and fragile X–associated primary ovarian insufficiency. We begin our discussion of these disorders with consideration of FXS.

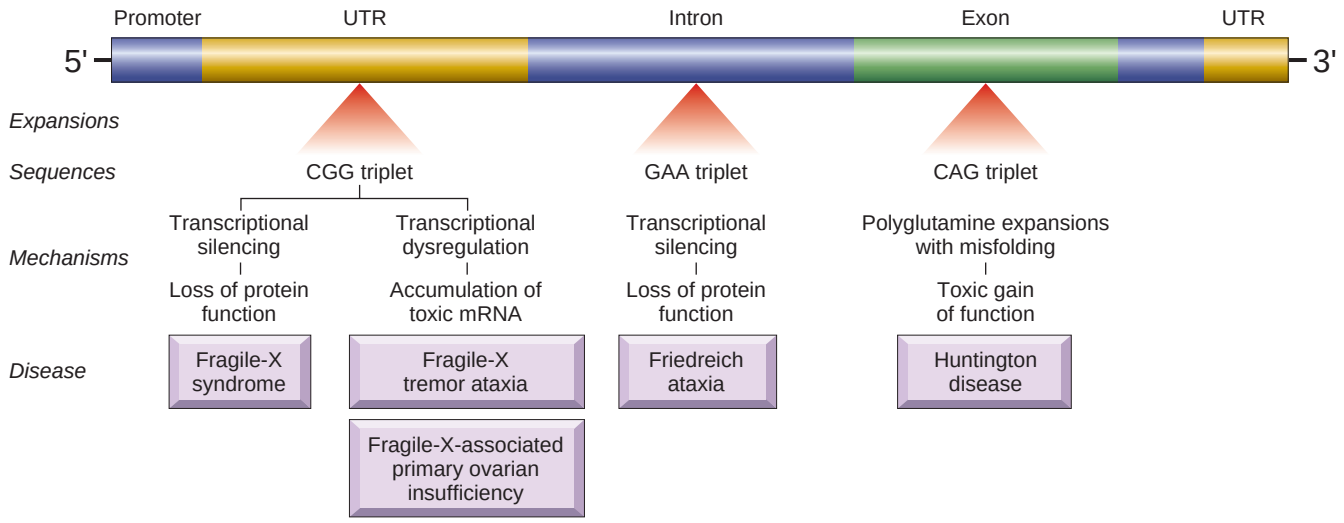

Figure 5.23 Sites of expansion and the affected sequence in selected diseases caused by nucleotide-repeat mutations. *UTR,* Untranslated region.

FXS has a frequency of 1 in 1550 for affected males and 1 in 8000 for affected females. Its name derives from an inducible cytogenetic abnormality in the X chromosome within which the *FMR1* gene maps. The cytogenetic alteration was discovered as a discontinuity of staining or as a constriction in the long arm of the X chromosome when cells are cultured in a folate-deficient medium. Because it appears that the chromosome is "broken" at this locale, it was named as a *fragile site* (Fig. 5.24). This method of detection has now been supplanted by DNA-based analysis of triplet repeat size, as discussed later.

Males with FXS have marked *intellectual disability.* They have a characteristic physical phenotype that includes a long face with a large mandible, large everted ears, and large testicles (macro-orchidism). Hyperextensible joints, a high arched palate, and mitral valve prolapse noted in some patients mimic a connective tissue disorder. These and other physical abnormalities described in this condition, however, are not always present and, in some cases, are quite subtle. The most distinctive feature is *macro-orchidism,* which is observed in at least 90% of affected postpubertal males.

In addition to intellectual disability, several neurologic and neuropsychiatric manifestations have been recognized in patients with FXS. These include epilepsy in 30% of cases, aggressive behavior in 90% of cases, autism spectrum disorder (includes several conditions such as autism and Asperger syndrome), and anxiety disorder/hyperactivity disorder. The latter two affect 50% to 75% of males with FXS. Two percent to 5% of patients diagnosed first with nonsyndromic autism have a mutation in the *FMR1* gene.

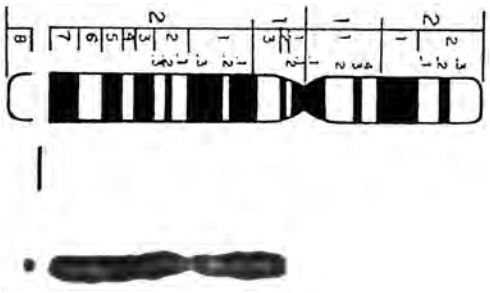

Figure 5.24 Fragile X seen as discontinuity of staining. (Courtesy Dr. Patricia Howard-Peebles, University of Texas Southwestern Medical Center, Dallas, Tex.)

As with other X-linked diseases, FXS affects males predominantly. Analysis of several pedigrees, however, reveals some patterns of transmission not typically associated with other X-linked recessive disorders (Fig. 5.25).

- *Carrier males:* Approximately 20% of males who, by pedigree analysis and by molecular tests, are known to carry a fragile X mutation are clinically normal. Because carrier males transmit the trait through all their phenotypically normal daughters to affected grandchildren, they are called *normal transmitting males.*
- *Affected females:* Thirty percent to 50% of carrier females are affected (i.e., have intellectual disability as well as other features described here), a number much higher than that in other X-linked recessive disorders.
- *Risk of phenotypic effects:* Risk depends on the position of the individual in the pedigree. For example, brothers of transmitting males are at a 9% risk of having intellectual disability, whereas grandsons of transmitting males incur a 40% risk.
- *Anticipation:* This refers to the observation that clinical features of FXS worsen with each successive generation, as if the mutation becomes increasingly deleterious as it is transmitted from a man to his grandsons and great-grandsons (through daughters).

The first breakthrough in resolving these perplexing observations came when linkage studies localized the mutation responsible for this disease to Xq27.3, within the cytogenetically abnormal region. At this locale lies the *FMR1* gene, characterized by multiple tandem repeats of the nucleotide sequence CGG in its 5′ untranslated region. In the normal population, the number of CGG repeats is small, ranging from 6 to 55 (average, 29). The presence and severity of clinical symptoms is related to the amplification of the CGG repeats. Thus, normal transmitting males and carrier females carry 55 to 200 CGG repeats. Expansions of this size are called *premutations.* In contrast, patients with FXS

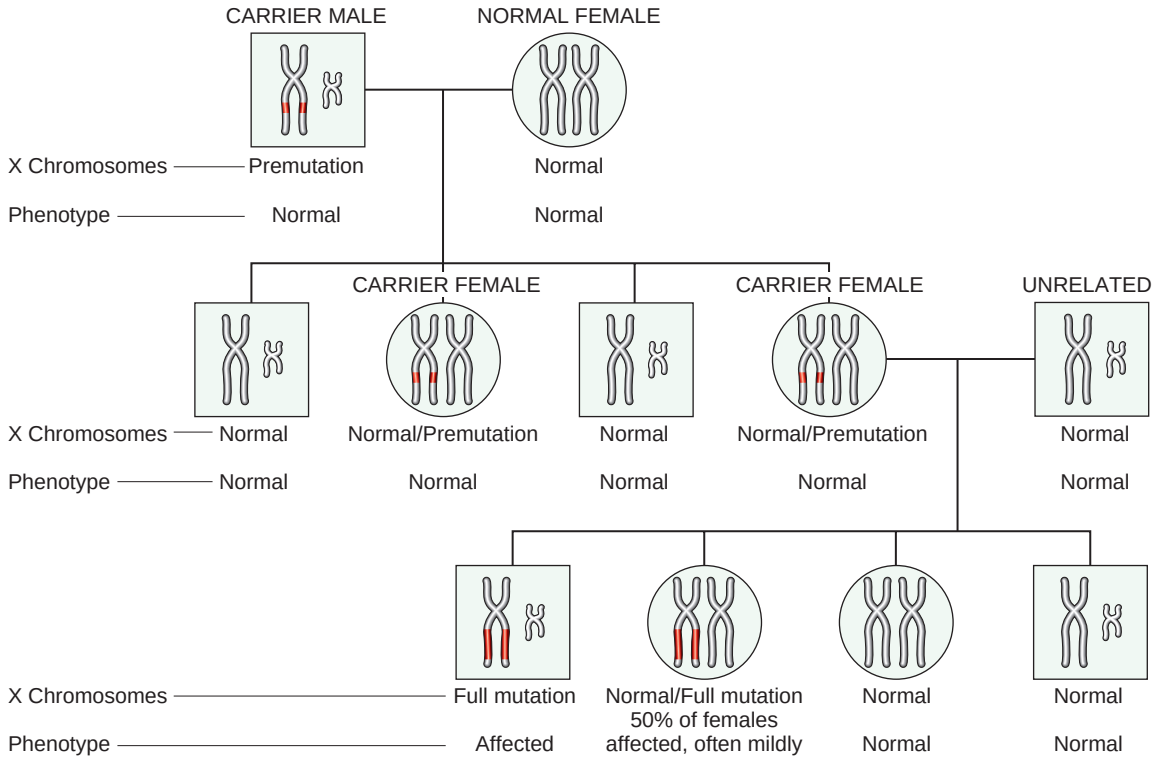

Figure 5.25 Fragile X pedigree. Note that in the first generation all sons are normal and all females are carriers. During oogenesis in the carrier female, premutation expands to full mutation; hence, in the next generation all males who inherit the X with full mutation are affected. However, only 50% of females who inherit the full mutation are affected and only mildly. Not shown are fragile X–associated ataxia/tremor and fragile X–associated primary ovarian failure that can occur in permutation careers. (Courtesy Dr. Nancy Schneider, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.)

have an extremely large expansion of the repeat region (200 to 4000 repeats, or *full mutations*). Full mutations are believed to arise by further amplification of the CGG repeats seen in premutations. How this process takes place is quite peculiar. Carrier males transmit the repeats to their progeny with small changes in repeat number. When the premutation is passed on by a carrier female, however, there is a high probability of a dramatic amplification of the CGG repeats, leading to intellectual disability in most male offspring and 50% of female offspring. Thus *it seems that during the process of oogenesis, but not spermatogenesis, premutations can be converted to mutations by triplet-repeat amplification*. This explains the unusual inheritance pattern; that is, the likelihood of intellectual disability is much higher in grandsons than in brothers of transmitting males because grandsons incur the risk of inheriting a premutation from their grandfather that is amplified to a full mutation in their mothers' ova. By comparison, brothers of transmitting males, being higher up in the pedigree, are less likely to have a full mutation. These molecular details also provide a satisfactory explanation of anticipation—a phenomenon that remained unexplained until triplet-repeat mutations were identified. Why only 50% of the females with the full mutation are clinically affected is not clear. Presumably in those who are clinically affected, there is unfavorable lyonization (i.e., there is a higher frequency of cells in which the X chromosome carrying the mutation is active).

The molecular basis of intellectual disability and other somatic changes is related to loss of function of the fragile X mental retardation protein (FMRP), the product of *FMR1* gene. As mentioned earlier, the normal *FMR1* gene contains up to 55 CGG repeats in its 5′ untranslated region. When the trinucleotide repeats in the *FMR1* gene exceed approximately 230, the DNA of the entire 5′ region of the gene becomes abnormally methylated. Methylation also extends upstream into the promoter region of the gene, resulting in transcriptional suppression of *FMR1*. The resulting absence of FMRP is believed to cause the phenotypic changes.

FMRP is a widely expressed cytoplasmic protein, most abundant in the brain and testis, the two organs most affected in this disease. Its proposed functions in the brain are the following:

- *FMRP selectively binds mRNAs associated with polysomes and regulates their intracellular transport to dendrites.* Unlike other cells, in neurons, protein synthesis occurs both in the perinuclear cytoplasm and in dendritic spines. Newly made FMRP translocates to the nucleus, where it assembles into a complex containing mRNA transcripts that encode presynaptic and postsynaptic proteins. The FRMP-mRNA complexes are then exported to the cytoplasm, from where they are trafficked to dendrites near neuronal synapses (Fig. 5.26).
- *FRMP is a translation regulator.* At synaptic junctions, FMRP suppresses protein synthesis from the bound mRNAs in response to signaling through group I metabotropic glutamate receptors (mGlu-R). Thus a reduction in FMRP in FXS results in increased translation of the bound mRNAs at synapses. This leads to an imbalance

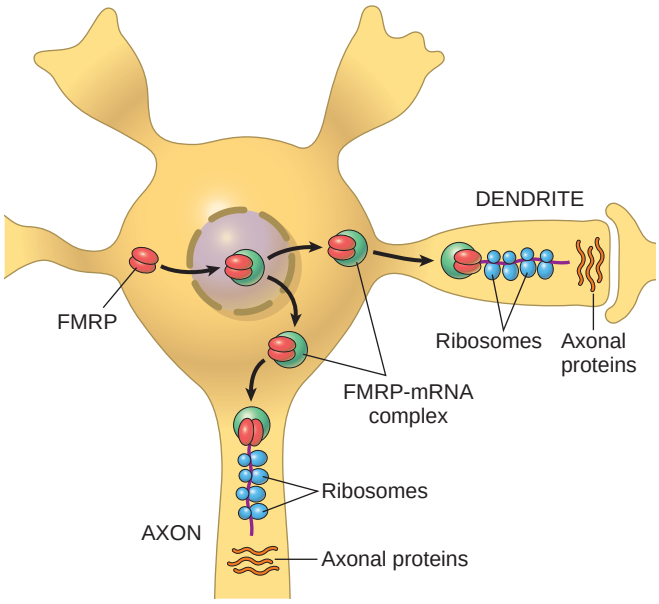

Figure 5.26 A model for the action of familial mental retardation protein *(FMRP)* in neurons. (Modified from Hin P, Warren ST: New insights into fragile X syndrome: from molecules to neurobehavior, *Trends Biochem Sci* 28:152, 2003.)

in the production of proteins at the synapses resulting in loss of synaptic plasticity—the ability of synapses to change and adapt in response to specific signals. Synaptic plasticity is essential for learning and memory.

Although demonstration of an abnormal karyotype led to the identification of this disorder, polymerase chain reaction (PCR)–based detection of the repeats is now the method of choice for diagnosis.

Fragile X–Associated Tremor/Ataxia Syndrome and Fragile X–Associated Primary Ovarian Failure

Although initially assumed to be innocuous, CGG premutations in the *FMR1* gene can cause two disorders that are phenotypically different from FXS and occur through a distinct mechanism involving a toxic gain of function. A decade after the discovery that CGG repeat expansions cause FXS, it became clear that approximately 20% of females carrying the premutation (carrier females) have premature ovarian failure (before the age of 40 years). This condition is called *fragile X–associated primary ovarian failure.* Affected women have menstrual irregularities and decreased fertility. FSH levels are elevated, and antimüllerian hormone levels are decreased—both markers of declining ovarian function. They develop menopause approximately 5 years earlier than controls. Approximately 50% of premutation-carrying males (transmitting males) exhibit a progressive neurodegenerative syndrome starting in their sixth decade. This syndrome, referred to as *fragile X–associated tremor/ataxia,* is characterized by intention tremors and cerebellar ataxia and may progress to parkinsonism.

How do premutations cause disease? In these patients, the *FMR1* gene instead of being methylated and silenced continues to be transcribed. CGG-containing *FMR1* mRNAs, so formed, are "toxic." They recruit RNA-binding proteins and impair their function by sequestration from their normal locales. The expanded *FMR1* mRNA and the sequestered RNA-binding proteins aggregate in the nucleus and form intranuclear inclusions in both the central and the peripheral nervous systems. As in FXS, males are affected much more frequently and more severely than female permutation carriers. The pathogenesis of fragile X–associated primary ovarian insufficiency is less well understood. Aggregates containing *FMR1* mRNA have been detected in granulosa cells and ovarian stromal cells. Perhaps these aggregates cause premature death of ovarian follicles.

KEY CONCEPTS

FRAGILE X SYNDROME (FXS)

- Pathologic amplification of trinucleotide repeats causes loss-of-function (FXS) or gain-of-function (Huntington disease) mutations. Most such mutations produce neurodegenerative disorders.
- FXS results from loss of *FMR1* gene function and is characterized by severe intellectual disability and a variety of neuropsychiatric conditions such as autism spectrum disorders.
- In the normal population, there are about 29 to 55 CGG repeats in the *FMR1* gene. The genomes of carrier males and females contain premutations with 55 to 200 CGG repeats that can expand to 4000 repeats (full mutations) during oogenesis. When full mutations are transmitted to progeny, FXS occurs.
- Carriers of premutations develop fragile X–associated tremor/ataxia and fragile X–associated primary ovarian failure due to toxic gain of function by the abnormal *FMR1* mRNA.

Mutations in Mitochondrial Genes—Leber Hereditary Optic Neuropathy

The vast majority of genes are located on chromosomes in the cell nucleus and are inherited in classic Mendelian fashion. Several mitochondrial genes exist, however, that are inherited in quite a different manner. *A feature unique to mtDNA is maternal inheritance.* This peculiarity exists because ova contain numerous mitochondria within their abundant cytoplasm, whereas spermatozoa contain few, if any. Hence the mtDNA complement of the zygote is derived entirely from the ovum. Thus, mothers transmit mtDNA to all their offspring, male and female; daughters, but not sons, transmit the DNA further to their progeny (Fig. 5.27). Several other features apply to mitochondrial inheritance.

- *Human mtDNA contains 37 genes,* of which 22 are transcribed into transfer RNAs and two into ribosomal RNAs. The remaining 13 genes encode subunits of the respiratory chain enzymes. Because mtDNA encodes enzymes involved in oxidative phosphorylation, mutations affecting these genes exert their deleterious effects primarily on the organs most dependent on oxidative phosphorylation such as the central nervous system, skeletal muscle, cardiac muscle, liver, and kidneys.
- *Each mitochondrion contains thousands of copies of mtDNAs,* and typically deleterious mutations of mtDNA affect some, but not all, of these copies. Thus tissues and, indeed, individuals may harbor both wild-type and mutant mtDNA, a situation called *heteroplasmy.* A minimum number of mutant mtDNAs must be present in a cell or

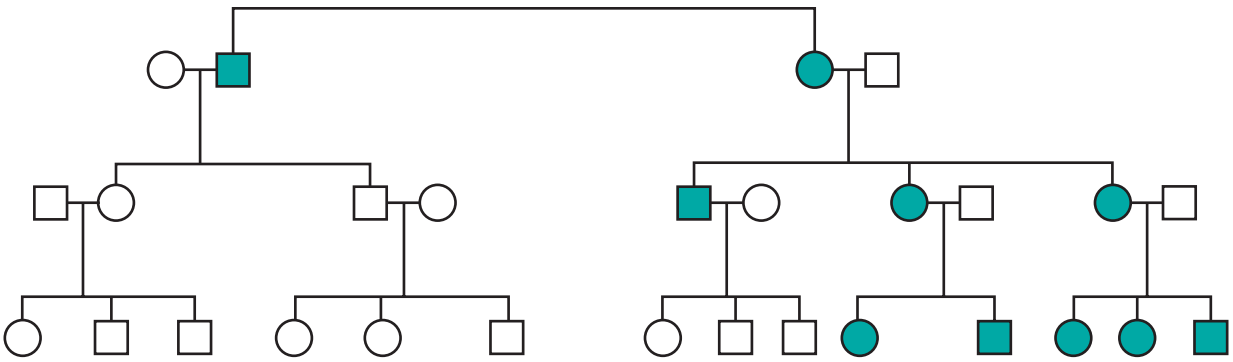

Figure 5.27 Pedigree of Leber hereditary optic neuropathy, a disorder caused by mutation in mitochondrial DNA. Note that all progeny of an affected male *(shaded squares)* are normal, but all children, male and female, of the affected female *(shaded circles)* manifest disease to a variable degree as discussed in the text.

tissue before oxidative dysfunction gives rise to disease. This is called the "threshold effect." Not surprisingly, the threshold is reached most easily in the metabolically active tissues listed earlier.

- *During cell division, mitochondria and their contained DNA are randomly distributed* to the daughter cells. Thus when a cell containing normal and mutant mtDNA divides, the proportion of the normal and mutant mtDNA in daughter cells is extremely variable. Therefore the expression of disorders resulting from mutations in mtDNA is quite variable.

Diseases associated with mitochondrial inheritance are rare, and, as mentioned earlier, many of them affect the neuromuscular system. *Leber hereditary optic neuropathy* is a prototype of this type of disorder. It is a neurodegenerative disease that manifests as progressive bilateral loss of central vision. Visual impairment is first noted between ages 15 and 35, leading eventually to blindness. Cardiac conduction defects and minor neurologic manifestations have also been observed in some families.

Genomic Imprinting

We all inherit two copies of each autosomal gene, carried on homologous maternal and paternal chromosomes. In the past, it had been assumed that there is no functional difference between the alleles derived from the mother or the father. Studies have now provided definite evidence that, at least with respect to some genes, important functional differences exist between the paternal allele and the maternal allele. These differences result from an epigenetic process called *imprinting.* In most cases, imprinting selectively inactivates either the maternal or the paternal allele. Thus, *maternal imprinting* refers to transcriptional silencing of the maternal allele, whereas *paternal imprinting* implies that the paternal allele is inactivated.

Imprinting occurs in the ovum or the sperm, before fertilization, and then is stably transmitted to all somatic cells through mitosis. As with other instances of epigenetic regulation, imprinting is associated with differential patterns of DNA methylation at CG nucleotides. Other mechanisms include histone H4 deacetylation and methylation (Chapter 1). Regardless of the mechanism, it is believed that such marking of paternal and maternal chromosomes occurs during gametogenesis, and thus it seems that from the moment of conception some chromosomes remember where they came from. The exact number of imprinted genes is not known; estimates range from 200 to 600. Although imprinted genes may occur in isolation, more commonly they are found in groups that are regulated by common *cis*-acting elements called imprinting control regions. Genomic imprinting is best illustrated by two uncommon genetic disorders: Prader-Willi syndrome and Angelman syndrome, which were originally believed to be unrelated until the genetic lesions responsible for them were mapped to the same location. They are described next.

Prader-Willi Syndrome and Angelman Syndrome

Prader-Willi syndrome is characterized by intellectual disability, short stature, hypotonia, profound hyperphagia, obesity, small hands and feet, and hypogonadism. In 65% to 70% of cases, an interstitial deletion of band q12 in the long arm of chromosome 15, del(15)(q11.2q13), can be detected. In most cases the breakpoints are the same, causing a 5-Mb deletion. *It is striking that in all cases the deletion affects the paternally derived chromosome 15.* In contrast to Prader-Willi syndrome, patients with the phenotypically distinct Angelman syndrome are *born with a deletion of the same chromosomal region derived from their mothers.* **Patients with Angelman syndrome also have intellectual disability, but in addition they present with microcephaly, ataxic gait, seizures, and inappropriate laughter.** Because of their laughter and ataxia, they have been referred to as "happy puppets." A comparison of these two syndromes clearly demonstrates the *parent-of-origin* effects on gene function.

The molecular basis of these two syndromes lies in the process of genomic imprinting (Fig. 5.28). Three mechanisms are involved.

- *Deletions.* It is known that a gene or set of genes on maternal chromosome 15q12 is imprinted (and hence silenced), and thus the only functional alleles are provided by the paternal chromosome. When these are lost as a result of a deletion, the person develops Prader-Willi syndrome. Conversely, a distinct gene that also maps to the same region of chromosome 15 is imprinted on the paternal chromosome. Only the maternally derived allele of this gene is normally active. Deletion of this maternal

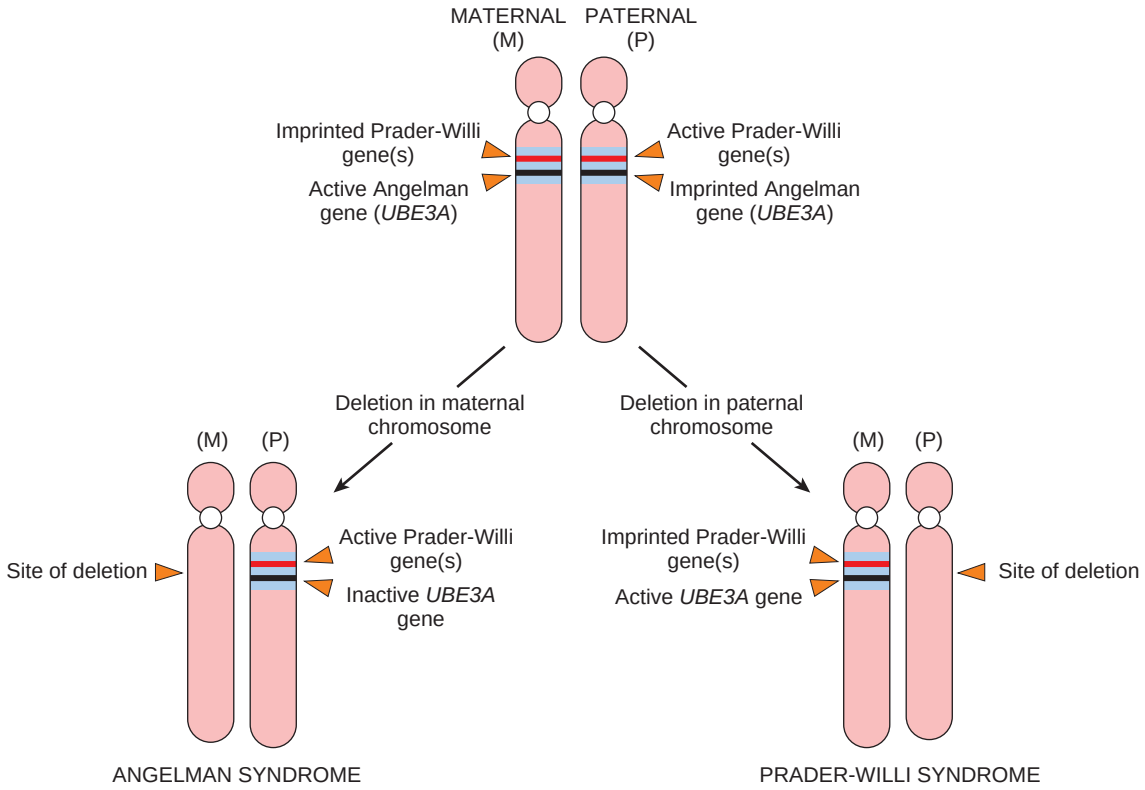

Figure 5.28 Diagrammatic representation of Prader-Willi and Angelman syndromes.

gene on chromosome 15 gives rise to the Angelman syndrome. Deletions account for about 70% cases.

- *Uniparental disomy.* Molecular studies of cytogenetically normal individuals with Prader-Willi syndrome (i.e., those without the deletion) have revealed that they have two maternal copies of chromosome 15. Inheritance of both chromosomes of a pair from one parent is called *uniparental disomy.* The net effect is the same (i.e., the person does not have a functional set of genes from the [nonimprinted] paternal chromosomes 15). Angelman syndrome, as might be expected, can also result from uniparental disomy of paternal chromosome 15. This is the second most common mechanism, responsible for 20% to 25% cases.
- *Defective imprinting.* In a small minority of patients (1% to 4%), there is an imprinting defect. In some patients with Prader-Willi syndrome, the paternal chromosome carries the maternal imprint, and conversely in Angelman syndrome, the maternal chromosome carries the paternal imprint (hence there are no functional alleles).

The genetic basis of these two imprinting disorders is now being unraveled.

- In Angelman syndrome, the affected gene is a ubiquitin ligase that is involved in catalyzing the transfer of activated ubiquitin to target protein substrates. The gene, called *UBE3A,* maps within the 15q12 region, is imprinted on the paternal chromosome, and is expressed from the maternal allele primarily in specific regions of the brain. Absence of *UBE3A* inhibits synapse formation and synaptic plasticity. The imprinting is tissue-specific in that *UBE3A* is expressed from both alleles in most tissues.
- In contrast to Angelman syndrome, no single gene has been implicated in Prader-Willi syndrome. Instead, a series of genes located in the 15q11.2-q13 interval (which are imprinted on the maternal chromosome and expressed from the paternal chromosome) are believed to be involved. These include the SNORP family of genes that encode small nucleolar RNAs. These RNAs are noncoding molecules that are involved in posttranscriptional modifications of ribosomal RNAs and other small nuclear RNAs. Loss of SNORP functions is believed to contribute to Prader-Willi syndrome, but the precise mechanisms are unclear.

Molecular diagnosis of these syndromes is based on assessment of methylation status of marker genes and FISH. The importance of imprinting is not restricted to rare chromosomal disorders. Parent-of-origin effects have been identified in a variety of inherited diseases such as Huntington disease and myotonic dystrophy and in tumorigenesis.

KEY CONCEPTS

GENOMIC IMPRINTING

- Imprinting involves transcriptional silencing of the paternal or maternal copies of certain genes during gametogenesis. For such genes, only one functional copy exists in the individual. Loss of the functional (not imprinted) allele by deletion gives rise to diseases.

- In Prader-Willi syndrome there is deletion of band q12 on the long arm of paternal chromosome 15. Genes in this region of maternal chromosome 15 are imprinted, so there is complete loss of their functions. Patients have intellectual disability, short stature, hypotonia, hyperphagia, small hands and feet, and hypogonadism.
- In Angelman syndrome there is deletion of the same region from the maternal chromosome, and genes on the corresponding region of paternal chromosome 15 are imprinted. These patients have intellectual disability, ataxia, seizures, and inappropriate laughter.

Gonadal Mosaicism

It was mentioned earlier that with every autosomal dominant disorder some patients do not have affected parents. In such patients the disorder results from a new mutation in the egg or the sperm from which they were derived; as such, their siblings are neither affected nor at increased risk for development of the disease. This is not always the case, however. *In some autosomal dominant disorders, exemplified by osteogenesis imperfecta, phenotypically normal parents have more than one affected child.* This clearly violates the laws of Mendelian inheritance. Studies indicate that gonadal mosaicism may be responsible for such unusual pedigrees. Such mosaicism results from a mutation that occurs postzygotically during early (embryonic) development. If the mutation affects only cells destined to form the gonads, the gametes carry the mutation, but the somatic cells of the individual are completely normal. A phenotypically normal parent who has gonadal mosaicism can transmit the disease-causing mutation to the offspring through their mutated gametes. Because the progenitor cells of the gametes carry the mutation, there is a possibility that more than one child of such a parent would be affected. Obviously the likelihood of such an occurrence depends on the proportion of germ cells carrying the mutation.

MOLECULAR GENETIC DIAGNOSIS

The field of molecular genetic diagnostics emerged in the latter half of the 20th century in the form of labor-intensive, low throughput methods such as conventional karyotyping for diagnosis of cytogenetic disorders (e.g., Down syndrome) and DNA-based assays such as Southern blotting for the diagnosis of Huntington disease. Over time, a steady stream of technologic breakthroughs has led to ever-increasing capabilities, particularly in the area of nucleic acid sequencing. These advances began with the development of Sanger DNA sequencing in 1977 and PCR in 1983 and accelerated rapidly with the advent of high throughput, massively parallel sequencing strategies (often lumped together under the rubric next-generation sequencing [NGS]) in the late 1990s. NGS has continued to improve in terms of speed and cost, and it is now possible to sequence an entire genome for less than $1000 in a few days. As a result, nucleic acid–based testing is taking a central role in the diagnosis and management of many diseases, and we currently are in a transition period during which many simple, single-gene tests using "old" technologies are being slowly but surely supplanted by more comprehensive NGS-based approaches. That said, certain types of genetic lesions are difficult to detect by NGS, and for the foreseeable future older technologies will continue to have an important role in testing for genetic diseases. An exhaustive discussion of molecular diagnostics is beyond the scope of this book; here, we highlight some of the most useful and widely deployed approaches.

When considering molecular genetic testing, it is important to remember that genetic markers can be either constitutional (i.e., present in every cell of the affected person, as with a *CFTR* mutation in a patient with cystic fibrosis) or somatic (i.e., restricted to specific tissue types or lesions, as with mutations in *RAS* in a variety of human cancers). Similarly, in suspected infections, nucleic acids that are specific to the infectious agent may be confined to particular cells or body sites. These considerations determine the nature of the sample used for the assay (e.g., peripheral blood cells, tumor tissue, nasopharyngeal swab).

Diagnostic Methods and Indications for Testing

There are a dizzying number of techniques and indications for performing molecular genetic diagnostic tests on patient specimens. The burden of choice is often problematic, both for molecular pathologists who design tests and for clinicians who need to choose the optimal test for their patients.

Laboratory Considerations

Pathologists developing tests focus on the sensitivity, specificity, accuracy, and reproducibility of different methods as well as practical factors like cost, labor, reliability, and turnaround time. To choose the most appropriate diagnostic technique, one must have a thorough knowledge of the spectrum of genetic anomalies that are responsible for the disease in the patient population under study. Disease-causing genetic anomalies range in size from single base substitutions to gains or losses of entire chromosomes and often vary widely in frequency among ethnic groups. Proper test design requires careful consideration of these factors. For example, standard cystic fibrosis testing for pathogenic mutations in *CFTR* has a sensitivity of 94% in Ashkenazi Jews, but identifies less than 50% of affected patients in Asian populations. In cases with negative standard test results and a high clinical suspicion, further testing is indicated. However, even with extensive sequencing of *CFTR,* no pathogenic mutations are identified in approximately 10% of patients with classic cystic fibrosis; this is likely because NGS assays miss certain genetic lesions (e.g., kilobase scale deletions and gene rearrangements) that are better detected with other methods. Issues like this arise frequently in genetic testing, and close communication between primary care clinicians, medical genetics specialists, and diagnosticians is required to select the optimal test strategy in difficult cases.

Indications for Analysis of Inherited Genetic Alterations

Although it is not unusual for inherited genetic disorders to present in adulthood, most testing is performed during the prenatal or postnatal/childhood periods. Mendelian disorders caused by mutations in specific genes number in the thousands, and definitive diagnosis of most of them is possible by DNA sequencing tests.

Other inherited disorders are the result of chromosomal aberrations that usually present prenatally or at birth. Prenatal testing should be offered for all fetuses at risk for a cytogenetic abnormality. Possible indications include the following:

- Advanced maternal age
- A parent known to carry a balanced chromosomal rearrangement, which greatly increases the frequency of abnormal chromosome segregation during meiosis and the risk of aneuploidy in the fertilized ovum
- Fetal anomalies observed on ultrasound
- Routine maternal blood screening indicating an increased risk of Down syndrome (trisomy 21) or another trisomy

Prenatal testing may also be considered for fetuses at known risk for Mendelian disorders (e.g., cystic fibrosis, spinal muscular atrophy) based on family history. At present it is usually performed on cells obtained by amniocentesis, chorionic villus biopsy, or umbilical cord blood. However, as much as 10% of the free DNA in a pregnant mother's blood is of fetal origin, and new sequencing technologies have opened the door to an era of noninvasive prenatal diagnostics utilizing this source of DNA.

Following birth, testing is ideally done as soon as the possibility of constitutional genetic disease arises. It is most commonly performed on peripheral blood DNA and is targeted based on clinical suspicion. In newborns or children, indications are as follows:

- Multiple congenital anomalies
- Suspicion of a metabolic syndrome
- Unexplained intellectual disability, and/or developmental delay
- Suspected aneuploidy (e.g., features of Down syndrome) or other syndromic chromosomal abnormality (e.g., deletions, inversions)
- Suspected monogenic disease, whether previously described in the family or new

In older patients, testing logically becomes more focused toward genetic diseases that manifest at later stages of life. Again, the possibilities are vast, but the more common indications include the following:

- Inherited cancer syndromes (triggered by either family history or an unusual cancer presentation, such as multiple cancer types or unusually young age at diagnosis)
- Atypically mild monogenic disease (e.g., attenuated cystic fibrosis)
- Neurodegenerative disorders (e.g., familial Alzheimer disease, Huntington disease)

Indications for Analysis of Acquired Genetic Alterations

In this era of molecularly targeted therapies it is increasingly important to identify nucleic acid sequences or aberrations that are specific for acquired diseases (e.g., cancer and infectious disease). The technical approaches are the same as those used for germline Mendelian disorders. Common indications include the following:

- *Diagnosis and management of cancer* (Chapter 7)
  - Detection of tumor-specific mutations and cytogenetic alterations that are the hallmarks of specific tumors (e.g., *BCR-ABL* fusion genes in chronic myeloid leukemia [CML])
  - Determination of clonality as an indicator of a neoplastic condition
  - Identification of specific genetic alterations that can direct therapeutic choices (e.g., amplification of *HER2* [official gene name *ERBB2*] in breast cancer or mutation of *EGFR* [official gene name *ERBB1*] in lung cancer)
  - Determination of treatment efficacy (e.g., minimal residual disease detection in patients with CML by quantitative PCR for BCR-ABL)
  - Detection of drug-resistant secondary mutations in malignancies treated with therapies that target specific proteins (e.g., mutated EGFR)
- *Diagnosis and management of infectious disease* (Chapter 8)
  - Detection of microorganism-specific genetic material for definitive diagnosis (e.g., human immunodeficiency virus [HIV], mycobacteria, human papillomavirus, herpesvirus in central nervous system)
  - Identification of genetic alterations in the genomes of microbes that are associated with drug resistance
  - Determination of treatment efficacy (e.g., assessment of viral loads in HIV, Epstein-Barr virus, and hepatitis C virus infection)

PCR and Detection of DNA Sequence Alterations

PCR analysis, which involves synthesis of relatively short DNA fragments from a DNA template, has been a mainstay of molecular diagnostics for the last few decades. By using appropriate heat-stable DNA polymerases and thermal cycling, the target DNA (usually <1000 bp) lying between designed primer sites is exponentially amplified from as little as one original copy, greatly simplifying secondary sequence analysis. Many options exist for subsequent analysis, each with different strengths and weaknesses. A few of the more common options are described below:

- *Sanger sequencing.* A single PCR product is mixed with a DNA polymerase, a specific primer, nucleotides, and four dead-end (di-deoxy terminator) nucleotides (A, T, G, and C) labeled with different fluorescent tags. The ensuing reaction produces a ladder of DNA molecules of all possible lengths, each labeled with a tag corresponding to the base at which the reaction stopped due to incorporation of a terminator nucleotide. After size separation by electrophoresis, the sequence is "read" and compared with the normal sequence to detect mutations.
- *Next-generation sequencing (NGS).* PCR using primers for many different genomic regions is performed simultaneously, and the resulting mixture of PCR products enriched for regions of interest are subjected to NGS (described in more detail later). NGS is more sensitive than Sanger sequencing, as it can reliably identify the presence of mutations in only a small percentage of the individual sequencing reads. This situation is encountered frequently in cancers, either because the mutation in question is only present in a small fraction of tumor cells or because the tumor cells are heavily contaminated with genetically normal stromal cells.
- *Single-base primer extension.* This is a useful approach for identifying mutations at a specific nucleotide position (e.g., an oncogenic mutation in codon 600 of the *BRAF* gene). A primer is added to the PCR product that

hybridizes one base upstream of the target, differently colored terminator fluorescent nucleotides are added (corresponding to normal and variant bases), and a single base polymerase extension is performed. The relative amounts of normal/variant fluorescence are then detected (Fig. 5.29). This technique is very sensitive, but has the obvious disadvantage of only producing 1 bp of sequence data.

- *Restriction fragment length analysis.* This simple approach takes advantage of the digestion of DNA with endonucleases known as restriction enzymes that recognize and cut DNA at specific sequences. If the specific mutation is known to affect a restriction site, the amplified PCR product may be digested, and the normal and mutant PCR products will yield fragments of different sizes that are easily distinguished. Needless to say, this approach is considerably less comprehensive than direct sequencing but remains useful for molecular diagnosis when the causal mutation always occurs at an invariant nucleotide position.

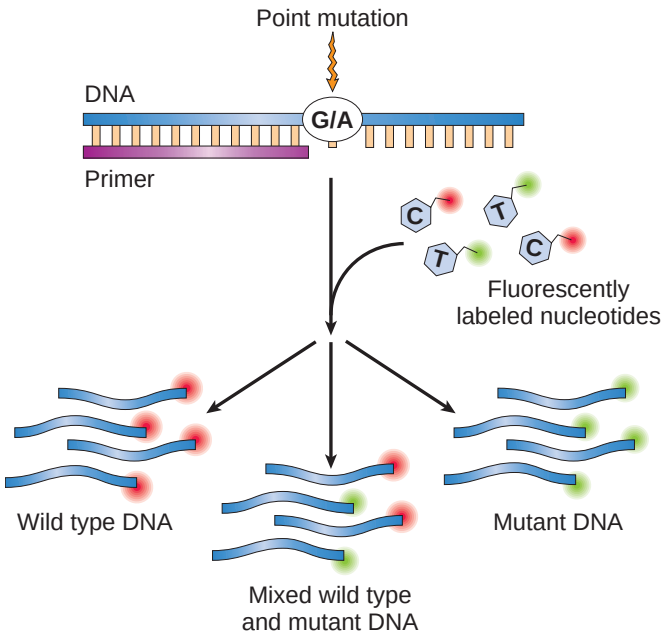

Figure 5.29 Single-base extension analysis of a polymerase chain reaction product, using a primer to interrogate a single base position. Nucleotides complementary to the mutant and wild-type bases at the queried position are labeled with different fluorophores, such that incorporation yields fluorescent signals of varying intensity based on the ratio of mutant to wild-type DNA present.

- *Amplicon length analysis.* Mutations that affect the length of DNA (e.g., deletions or expansions) can be easily detected by PCR. As discussed earlier, several diseases, such as FXS, are associated with alterations in trinucleotide repeats. Fig. 5.30 reveals how PCR analysis can be used to detect this mutation. Two primers that flank the region containing the trinucleotide repeats at the 5′ end of the *FMR1* gene are used to amplify the intervening sequences. Because there are large differences in the number of repeats, the size of the PCR products obtained from the DNA of normal individuals, or those with a premutation, is quite different and can be easily distinguished by gel electrophoresis. An important caveat is that if the trinucleotide expansion is so large that it cannot be amplified by convention PCR, Southern blot analysis of genomic DNA may have to be performed. As discussed earlier, large expansions are not uncommon in FXS.

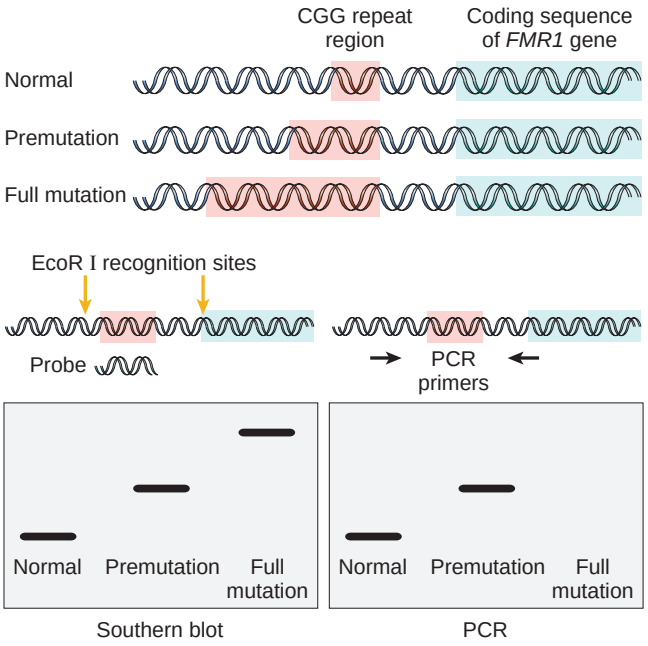

Figure 5.30 Diagnostic application of polymerase chain reaction *(PCR)* and Southern blot analysis in fragile X syndrome. With PCR, the differences in the size of CGG repeats between normal and premutation give rise to products of different sizes and mobility. With a full mutation, the region between the primers is too large to be amplified by conventional PCR. In Southern blot analysis the DNA is cut by enzymes that flank the CGG repeat region and is then probed with complementary DNA that binds to the affected part of the gene. A single small band is seen in normal males, a band of higher molecular weight is seen in males with premutation, and a very large (usually diffuse) band is seen in males with the full mutation.

- *Real-time PCR.* A variety of PCR-based technologies that use fluorophore indicators can detect and quantify the presence of particular nucleic acid sequences in real time (i.e., during the exponential phase of DNA amplification rather than post-PCR). It is most often used to monitor the frequency of cancer cells bearing characteristic genetic lesions in the blood or in tissues (e.g., the level of *BCR-ABL* fusion gene sequences in patients with CML), or the infectious load of certain viruses (e.g., HIV, Epstein-Barr virus).

Molecular Analysis of Genomic Alterations

A significant number of genetic lesions involve large deletions, duplications, or more complex rearrangements that are not readily amenable to detection using PCR or DNA sequencing approaches. Such genomic-scale alterations can be studied using a variety of hybridization-based techniques.

Fluorescence in Situ Hybridization (FISH)

FISH uses DNA probes that recognize sequences specific to particular chromosomal regions. To perform FISH, large fragments of cloned genomic DNA spanning up to 200 kb are labeled with fluorescent dyes and applied to

metaphase chromosome preparations or interphase nuclei that are pretreated so as to "melt" the genomic DNA. The probe hybridizes to its homologous genomic sequence and thus labels a specific chromosomal region that can be visualized under a fluorescent microscope. FISH can be performed on prenatal samples, peripheral blood cells, touch preparations from cancer biopsies, and even fixed archival tissue sections. It is used to detect numeric abnormalities of chromosomes (aneuploidy) (see Fig. 5.19), subtle microdeletions (see Fig. 5.21) and complex translocations that are not demonstrable by routine karyotyping, and gene amplification (e.g., *HER2* in breast cancer or *NMYC* amplification in neuroblastomas). It is also used in certain circumstances when rapid diagnosis is essential (e.g., when deciding to treat a patient with suspected acute promyelocytic leukemia with retinoic acid, which is effective only when a particular chromosomal translocation involving the retinoic acid receptor gene is present in the tumor cells; Chapter 13).

Cytogenomic Array Technology

FISH requires prior knowledge of the one or few specific chromosomal regions suspected of being altered in the test sample. However, **genomic abnormalities can also be detected without prior knowledge by using microarray technology to perform a global genomic survey.** First-generation platforms were designed for comparative genomic hybridization (CGH), while newer platforms incorporate single nucleotide polymorphism (SNP) genotyping approaches, offering multiple benefits.

- *Array-based comparative genomic hybridization.* In array CGH, the test DNA and a reference (normal) DNA are labeled with two different fluorescent dyes. The samples are then mixed and hybridized to an array spotted with DNA probes that span the human genome at regularly spaced intervals. At each chromosomal probe location, the binding of the labeled DNA from the two samples is compared. If the two samples are equal (i.e., the test sample is diploid), all spots on the array will fluoresce yellow due to equal admixture of green and red dyes. In contrast, if the test sample has a deletion or duplication, the probe spots corresponding to it will show skewing toward red or green (depending on gain or loss of material), allowing highly accurate determination of even focal copy number gain or loss anywhere across the genome.
- *Single nucleotide polymorphism genotyping arrays.* Newer types of genomic arrays are based on a similar concept, but some or all of the probes are designed to identify SNP sites genome-wide, which provides a number of advantages. As discussed in Chapter 1, SNPs are the most common type of DNA polymorphism, occurring on average approximately every 1000 nucleotides throughout the genome. They serve both as a physical landmark within the genome and as a genetic marker whose transmission can be followed from parent to child.

There are several testing platforms using different methodologies that allow SNPs to be analyzed genome-wide on arrays; details of these methods are beyond the scope of this discussion. Like CGH probes, these methods involving SNPs can be used to make copy number variation (CNV) calls, but by discriminating between SNP alleles at each particular location they also provide zygosity data (Fig. 5.31). The current generation of SNP arrays is quite comprehensive, with the largest containing greater than 4 million SNP probes.

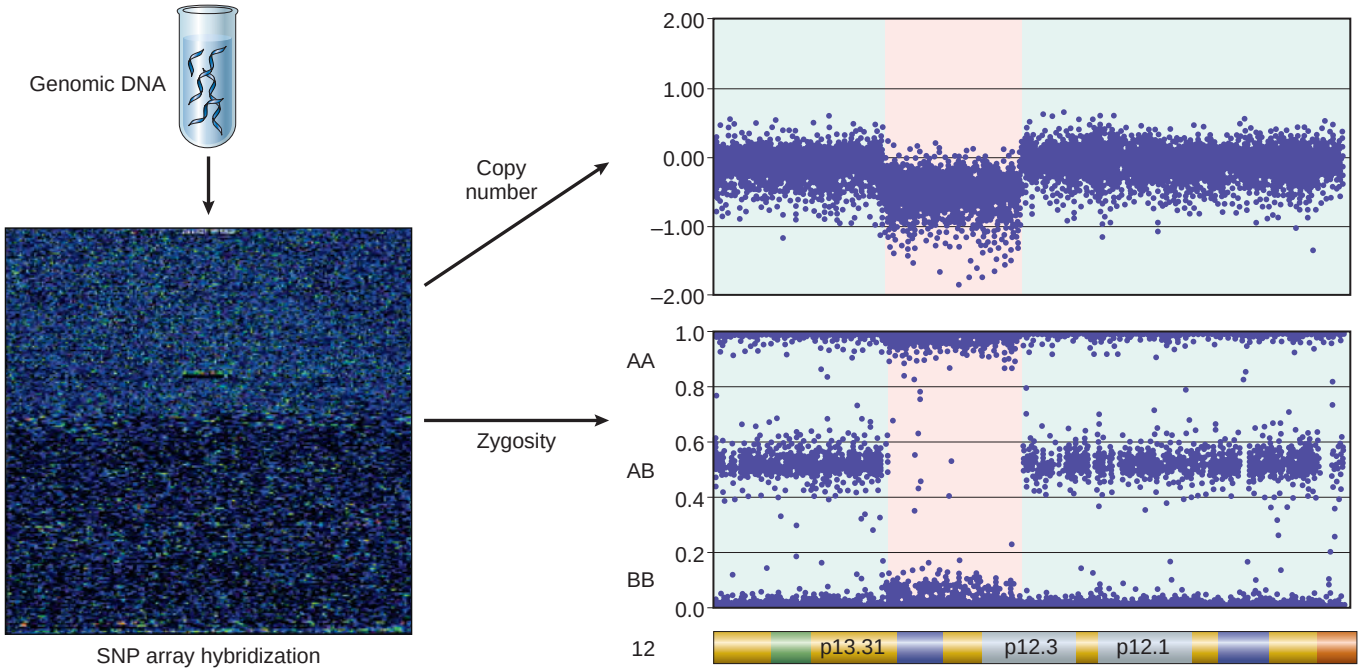

Figure 5.31 Analysis of copy number variation via single nucleotide polymorphism *(SNP)* cytogenomic array. Genomic DNA is labeled and hybridized to an array containing potentially millions of probe spots. Copy number is determined by overall intensity, and genotype is determined by allelic ratio. The example shown is the p arm of chromosome 12 in a patient with pediatric leukemia. The normal areas (green) show neutral (diploid) DNA content, and the zygosity plot shows the expected ratio of AA, AB, and BB SNP genotypes. The anomalous area (red) shows decreased overall intensity, and the zygosity plot shows absence of the mixed AB genotype, indicating a full heterozygous deletion. (Modified from Paulsson K, et al: Genetic landscape of high hyperdiploid childhood acute lymphoblastic leukemia, *Proc Natl Acad Sci U S A* 107:21719–21724, 2010.)

In the clinical laboratory, SNP arrays are routinely used to uncover copy number abnormalities in pediatric patients when the karyotype is normal but a structural chromosomal abnormality is still suspected. Common indications include congenital abnormalities, dysmorphic features, developmental delay, and autism. Notably, unlike CGH arrays, SNP arrays can identify loss of heterozygosity. This capability is important in the diagnosis of disorders caused by uniparental disomy (e.g., in Prader-Willi syndrome and Angelman syndrome), where despite diploid genomic copy number, the SNP calls in the affected chromosomal regions showed reduction to homozygosity. SNP data can also help uncover other anomalies, such as mosaicism, which produces complex but distinctive skewing of zygosity plots.

Polymorphic Markers and Molecular Diagnosis

Clinical detection of disease-specific mutations is possible only if the gene responsible for the disorder is known and its sequence has been identified. If the exact nature of the genetic aberration is not known, or if testing for the primary defect is technically challenging or unfeasible, diagnostic laboratories can take advantage of the phenomenon of *linkage*. In humans, two DNA loci even 100,000 bp apart on the same chromosome are almost certain to cosegregate during meiosis due to the extremely low chance of a crossover event happening between them. Thus, the closer two loci are, the higher the probability that they will travel together in family pedigrees. In the event of a challenging or unknown pathogenic allele, a diagnostic laboratory can instead choose as a surrogate approach to examine nearby marker loci in the context of the family pedigree.

The two types of genetic polymorphisms most useful for linkage analysis are SNPs (described earlier) and repeat-length polymorphisms known as minisatellite and microsatellite repeats. Human DNA contains short repetitive sequences of DNA giving rise to what are called repeat-length polymorphisms. These polymorphisms are often subdivided on the basis of their length into microsatellite repeats and minisatellite repeats. Microsatellites are usually less than 1 kb and are characterized by a repeat size of 2 to 6 bp. Minisatellite repeats, by comparison, are larger (1 to 3 kb), and the repeat motif is usually 15 to 70 bp. The number of repeats, both in microsatellites and in minisatellites, is extremely variable within a given population, and hence these stretches of DNA can be used to establish genetic identity for linkage analysis. Different microsatellites and minisatellites are readily distinguishable on the basis of size, which can be measured by doing PCR amplification using primers that flank the repeat region. Fig. 5.32 depicts the application of microsatellite linkage analysis to the *PKD1* gene (historically very difficult to sequence) for the familial diagnosis of adult polycystic kidney disease. It can be seen that the longest microsatellite allele is linked in the family to the disease allele and can be used to track its transmission.

Assays to detect genetic polymorphisms are also important in many other areas of medicine, including in the determination of relatedness and identity in transplantation, cancer genetics, paternity testing, and forensic medicine. Since microsatellite markers are scattered throughout the human genome and have such a high level of polymorphism, they are ideal for differentiating between two individuals and to follow transmission of the marker from parent to child. Assays employing PCR amplification of informative microsatellite markers are now routinely used for determining paternity and for criminal investigations. PCR can be performed even with highly degraded biologic samples, allowing DNA testing to play a central role in forensic identifications. The same assays are used in patients following allogeneic hematopoietic stem cell transplant to detect and quantify chimerism, which is evaluated by assessing the relative amounts of donor-specific and host-specific microsatellite markers in the patient's blood cells.

Epigenetic Alterations

Epigenetics is defined as the study of heritable chemical modification of DNA or chromatin that does not alter the protein-encoding DNA sequence itself. Examples of such modifications include methylation of DNA and methylation and acetylation of histones (Chapter 1). Our understanding of the importance of these types of molecular alterations is rapidly growing, and it is clear that epigenetic modifications are critical for normal human development—including the regulation of tissue-specific gene expression, X chromosome inactivation, and imprinting—as well as for understanding the cellular perturbations in aging and cancer.

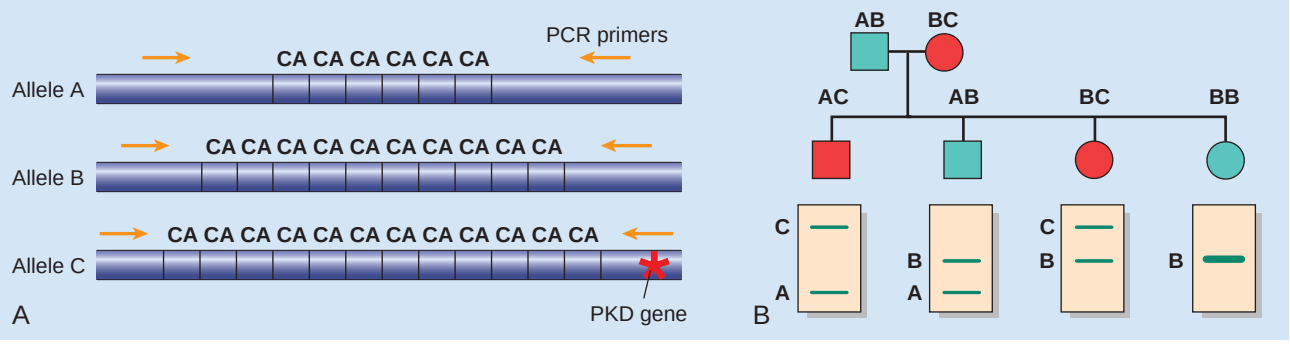

Figure 5.32 DNA polymorphisms resulting from a variable number of CA repeats. The three alleles (A) produce polymerase chain reaction *(PCR)* products of different sizes (B), thus identifying their origins from specific chromosomes. In the example depicted, allele C is linked to a mutation responsible for autosomal dominant polycystic kidney disease *(PKD)*. Application of this to detect progeny carrying the disease-related gene (red symbols) is illustrated in one hypothetical pedigree. Males (squares); females (circles).

Gene expression frequently correlates negatively with the level of methylation of DNA, particularly of cytosine residues in CG dinucleotide-rich promoter regions known as CpG islands. As discussed earlier in the section on genomic imprinting, increased methylation of CpG islands is associated with decreased gene expression and is accompanied by concomitant alterations of histone methylation and acetylation. Diagnosis of an increasing number of diseases involves the analysis of promoter methylation—for example, FXS, in which hypermethylation results in *FMR1* silencing. Methylation analysis is also essential in the diagnosis of Prader-Willi syndrome and Angelman syndrome.

Special techniques are needed to detect DNA methylation. One approach is to treat genomic DNA with sodium bisulfite, a chemical that converts unmethylated cytosine to uracil, which acts like thymine in downstream reactions. Methylated cytosines are protected from modification and remain unchanged. After treatment, it is then straightforward to discriminate the unmethylated (modified) DNA from the methylated (unmodified) DNA by DNA sequencing.

RNA Analysis

Because DNA exerts its effects on the cell through RNA expression and mature mRNA contains the coding sequences of all expressed genes, RNA can in principle substitute for DNA in a wide range of diagnostic applications. From a practical standpoint, DNA-based diagnosis is usually preferred, since DNA is much more stable. Nonetheless, RNA analysis is critical in several areas of molecular diagnostics. The most important applications are the detection and quantification of RNA viruses such as HIV and hepatitis C virus, but increasingly RNA analysis is also being used to evaluate cancer. mRNA expression profiling (described for breast cancer in Chapter 23) has become an important tool for molecular stratification of certain tumors. In some instances, cancer cells bearing particular chromosomal translocations are detected with greater sensitivity by analyzing mRNA (e.g., the *BCR-ABL* fusion transcript in CML). The principal reason for this is that most translocations occur in scattered locations within particular introns, which can be very large, complicating detection by PCR amplification of DNA. Since introns are removed by splicing during the formation of mRNA, PCR analysis is possible if RNA is first converted to complementary DNA (cDNA) by reverse transcriptase. Real-time PCR performed on cDNA is the method of choice for monitoring residual disease in patients with CML and certain other hematologic malignancies (Chapter 13).

Next-Generation Sequencing (NGS)

***Next-generation sequencing* is a term used to describe several newer DNA sequencing technologies that produce very large amounts of sequence data in a massively parallel manner.** These technologies have revolutionized biomedical research and are increasingly impacting molecular diagnostics. The factors propelling rapid adoption of NGS are price and performance: NGS allows us to perform previously impossible analyses at extremely low relative cost.

One feature that makes NGS far more clinically applicable than Sanger sequencing is its input sample requirement. Whereas Sanger sequencing requires a single homogeneous template DNA (usually a specific PCR product), NGS has no such requirement: any DNA from almost any source can be used. Because Sanger sequencing essentially provides an "average" result for a particular DNA region in a sample, samples with substantial sequence heterogeneity among input DNA molecules produce uninterpretable results. NGS, by contrast, is well suited to analysis of heterogeneous DNA samples due to the application of three common basic principles (Fig. 5.33).

- *Spatial separation.* At the beginning of the procedure, individual DNA molecules are physically isolated from each other in space. The specifics of this process are platform-dependent.
- *Local amplification.* After separation, the individual DNA molecules are amplified in place using a limited number of PCR cycles. Amplification is necessary so that sufficient signal can be generated to ensure detection and accuracy.
- *Parallel sequencing.* The amplified DNA molecules are then simultaneously sequenced by the addition of polymerases and other reagents, with each spatially separated and amplified original molecule yielding a "read" corresponding to its sequence. Sequence reads from NGS instruments are generally short, less than 500 bp.

Bioinformatics

Each NGS analysis generates a staggering amount of sequence data; for high throughput sequencing instruments, this amounts to 400 billion bp or more of sequence per day, enough to produce a high-quality sequence spanning an entire human genome. The downstream analysis necessary to make sense of these enormous data sets is sufficiently complex that specialized training in bioinformatics is needed to ensure its proper interpretation. Bioinformatics computational "pipelines" vary widely across applications and sample types, and a detailed discussion is beyond the scope of this text. However, it is worth describing the basic steps necessary to process this type of data.

- *Alignment.* Alignment is the process by which the sequencing reads from a sample are mapped onto a reference genome, allowing them to be viewed and interpreted in context.
- *Variant calling.* This process involves a systematic comparison of all of the sequence data from a sample with the reference sequence. The more reads that cover a particular location (sequencing depth), the more likely that a variant will be detected if present. If a locus shows sufficient evidence of a difference from the reference sequence, a variant call is made.
- *Variant annotation and interpretation.* Called variants can be annotated with various features (e.g., gene name, coding change and protein effect predictions, information from databases listing benign and pathogenic variants, clinical information). Once completed by the clinical laboratory, the annotated data are ready for reporting. Because the pace of advances in genetics and genomics has far outpaced the knowledge of the typical clinician, an important part of this report is a brief description of the biological and clinical significance of each pathogenic variant, which can be numerous in the case of some cancers.

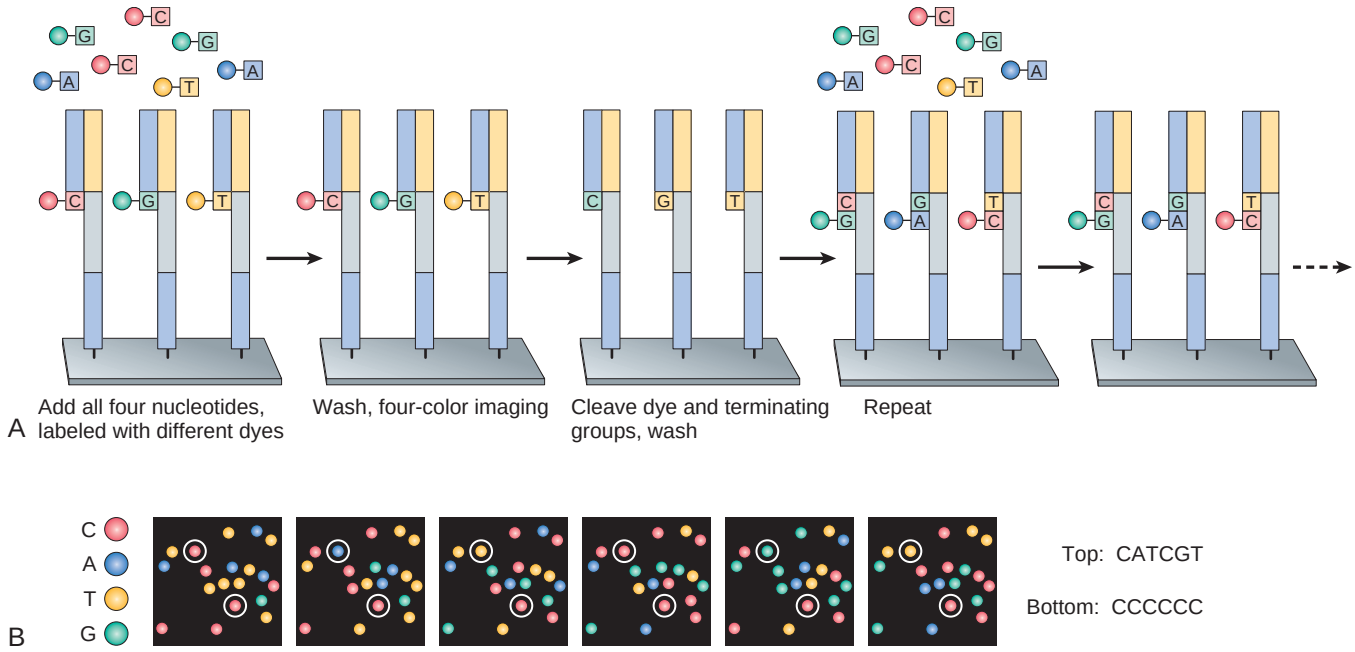

Figure 5.33 Principle of next-generation sequencing. Several alternative approaches currently are available for next-generation sequencing, and one of the more commonly used platforms is illustrated. (A) Short fragments of genomic DNA (template) 100 to 500 bp in length are immobilized on a solid-phase platform such as a glass slide, using universal capture primers that are complementary to adaptors that have previously been added to ends of the template fragments. The addition of fluorescently labeled complementary nucleotides, one per template DNA per cycle, occurs in a "massively parallel" fashion, at millions of templates immobilized on the solid phase at the same time. A four-color imaging camera captures the fluorescence emanating from each template location (corresponding to the specific incorporated nucleotide), following which the fluorescent dye is cleaved and washed away, and the entire cycle is repeated. (B) Powerful computational programs can decipher the images to generate sequences complementary to the template DNA at the end of one run, and these sequences are then mapped back to the reference genomic sequence to identify alterations. (Reproduced with permission from Metzker M: Sequencing technologies—the next generation, *Nat Rev Genet* 11:31–46, 2010, © Nature Publishing Group.)

- *Mutational signature calling*. In addition to totaling up individual mutations, informatics algorithms have been developed that detect patterns of mutations that point to particular environmental exposures (e.g., ultraviolet light) or underlying defects in DNA repair. The latter has become clinically relevant with the discovery that cancers with acquired defects in mismatch repair genes that lead to microsatellite instability (MSI) are highly responsive to immune checkpoint inhibitors (Chapter 7). Based on this observation, many clinical laboratories are now "calling" the MSI status of cancers based on NGS results.

Clinical Applications of Next-Generation DNA Sequencing

As discussed, any DNA sample can be analyzed by NGS. However, the DNA needs to first be prepared for sequencing by preparing a *library* of short DNA sequences that are enriched for genomic regions of interest (e.g., particular exons). There are several methods for NGS library preparation from genomic DNA, depending on the question and desired result. In the clinical laboratories, most applications of NGS are targeted toward constitutional genetic disease and cancer diagnostics, using a few different basic approaches:

- *Targeted sequencing*. Most current clinical laboratory NGS tests fall in this category. Targeted sequencing is focused on a carefully selected panel of genes, which maximizes sequencing depth while minimizing costs and the time and expense required for interpretation and clinical reporting. Sample preparation for targeted sequencing can be performed either by enriching for sequences of interest through a method called hybrid capture via custom complementary probes or by multiplex PCR. Single-gene NGS assays for inherited disorders are also becoming more common, and many laboratories that previously performed costly Sanger sequencing of multiple PCR products (i.e., to enable comprehensive *CFTR* sequencing) are now moving these assays to NGS platforms. Targeted NGS with gene panels is also now commonplace in evaluating individuals with genetic diseases such as cardiomyopathy and congenital deafness. In cancer testing, gene panels are widely used to perform detailed tumor profiling. Each tumor has a unique set of somatic mutations, and these assays aim to detect as many treatable or prognostic mutations as possible to offer individually tailored patient care. Increasingly, repeat testing at the time of disease recurrence is also being performed to understand mechanisms of drug resistance, which can serve to guide the selection of second-line therapies.
- *Whole-exome sequencing (WES)*. WES is a more expansive type of targeted sequencing, in which hundreds of thousands of custom probes are used to enrich for the roughly 1.5% of the genome that consists of protein-encoding exons prior to NGS. It is not routinely used in the evaluation of suspected germline disorders, but has

led to some wonderful success stories, allowing physicians to deliver answers and even therapies for children with orphan diseases who had suffered through prolonged and unsuccessful diagnostic odysseys. WES is also used in oncology to perform a very broad analysis, mostly in the research setting.

- *Whole-genome sequencing (WGS).* WGS is the most comprehensive type of DNA analysis that can be performed on an individual. Current indications for use in medical genetics are mostly limited to cases where exome sequencing has failed to provide an answer, but the clinical suspicion of genetic disease remains high. For cancer applications, WGS is the only form of NGS that can detect novel structural rearrangements (e.g., insertions, deletions, translocations) that may be clinically relevant, but relatively high costs, slow turnaround times, and significant informatics challenges still preclude its routine use in clinical practice.

Future Applications

Because NGS can be used to detect genetic anomalies of essentially any size scale, from SNPs to very large rearrangements and even aneuploidy, almost all of today's genetic diagnostic test modalities could in principle be supplanted by NGS. This includes RNA analysis because NGS-based analysis of the transcriptome (RNA-seq) is straightforward. As costs continue to drop, it is reasonable to expect NGS to occupy an increasingly prominent place in the diagnostics laboratory. Additionally, NGS has great promise for clinical applications in a number of other areas including microbiome analysis, blood screening for early markers of diseases (e.g., cancer), and vastly more sensitive methods of gauging the response of cancers to therapy (i.e., using circulating "free" DNA released from tumor cells that is harvested from the blood). Continuing technologic advances may even extend the applications further. For example, third-generation ("single molecule" or "next next-generation") technologies are emerging that can rapidly sequence single molecules in parallel without the need for focal amplification, and these could soon have an impact in the clinical laboratory.

ACKNOWLEDGMENT

The assistance of Jeremy Segal, MD, PhD, Director, Division of Genomic and Molecular Pathology, University of Chicago, in the revision of the section on molecular diagnosis is greatly appreciated.

CHAPTER 6

Diseases of the Immune System

CHAPTER CONTENTS

The immune system is vital for survival because it protects us from infectious pathogens that abound in the environment and from the development of cancer. Predictably, immune deficiencies render individuals easy prey to infections and increase the incidence of certain cancers. But the immune system is itself capable of causing tissue injury and disease. Examples of disorders caused by immune responses include reactions to environmental substances that cause *allergies* and reactions against an individual's own tissues and cells *(autoimmunity)*.

This chapter is devoted to diseases caused by too little or too much immunologic reactivity. We also consider amyloidosis, a disease in which an abnormal protein, derived in many cases from immunoglobulins, is deposited in tissues.

First, we review some of the important features of normal immune responses, to provide a foundation for understanding the abnormalities that give rise to immunologic diseases.

THE NORMAL IMMUNE RESPONSE

The classic definition of immunity is protection from infectious pathogens, and the normal immune response is best understood in this context. However, immunity in its broader sense includes host reactions against cancers (tumor immunity), tissue transplants, and even self antigens (autoimmunity). The mechanisms of immunity fall into two broad categories (Fig. 6.1). *Innate immunity* (also called natural, or native, immunity) refers to intrinsic mechanisms that are poised to react immediately, and thus constitute the first line of defense. It is mediated by cells and molecules that recognize products of microbes and dead cells and induce rapid protective host reactions. *Adaptive immunity* (also called acquired, or specific, immunity) consists of mechanisms that are stimulated by ("adapt to") exposure to microbes and other foreign substances. It develops more slowly than innate immunity, but is even more powerful in combating infections. By convention, the term immune response usually refers to adaptive immunity.

Innate Immunity

Innate immunity is always present, ready to provide immediate defense against microbes and to eliminate damaged cells. The receptors and components of innate immunity have evolved to serve these purposes.

Components of Innate Immunity

The major components of innate immunity are epithelial barriers that block entry of microbes, phagocytic cells (mainly neutrophils and macrophages), dendritic cells, natural killer cells and other innate lymphoid cells, and several plasma proteins, including the proteins of the complement system.

- *Epithelia* of the skin and gastrointestinal and respiratory tracts act as mechanical barriers to the entry of microbes from the external environment. Epithelial cells also produce antimicrobial molecules such as defensins, and lymphocytes located in the epithelia combat microbes at these sites. If microbes breach epithelial boundaries, other defense mechanisms come into play.
- *Monocytes* and *neutrophils* are phagocytes in the blood that can be rapidly recruited to any site of infection; monocytes that enter the tissues and mature are called *macrophages*. Some tissue-resident macrophages (Kupffer cells in the liver, microglia in the brain, and alveolar macrophages in the lungs) develop from the yolk sac or fetal liver early in life and populate various tissues. Phagocytes sense the presence of microbes and other offending agents, ingest (phagocytose) these invaders, and destroy them. Because macrophages are the dominant cells of chronic inflammation, we described them in more detail in Chapter 3 in the discussion of chronic inflammation.
- *Dendritic cells (DCs)* are specialized cells present in epithelia, lymphoid organs, and most tissues. They capture protein antigens and display peptides for recognition by T lymphocytes. In addition to their antigen-presenting function, DCs are endowed with a rich collection of receptors that sense microbes and cell damage and stimulate the secretion of cytokines, mediators that play critical roles in inflammation and antiviral defense. Thus, DCs serve as sentinels that detect danger and initiate innate immune responses, but, unlike macrophages, they are not key participants in the destruction of microbes and other offending agents.
- *Innate lymphoid cells (ILCs)* are tissue-resident lymphocytes that lack T-cell antigen receptors and cannot respond to

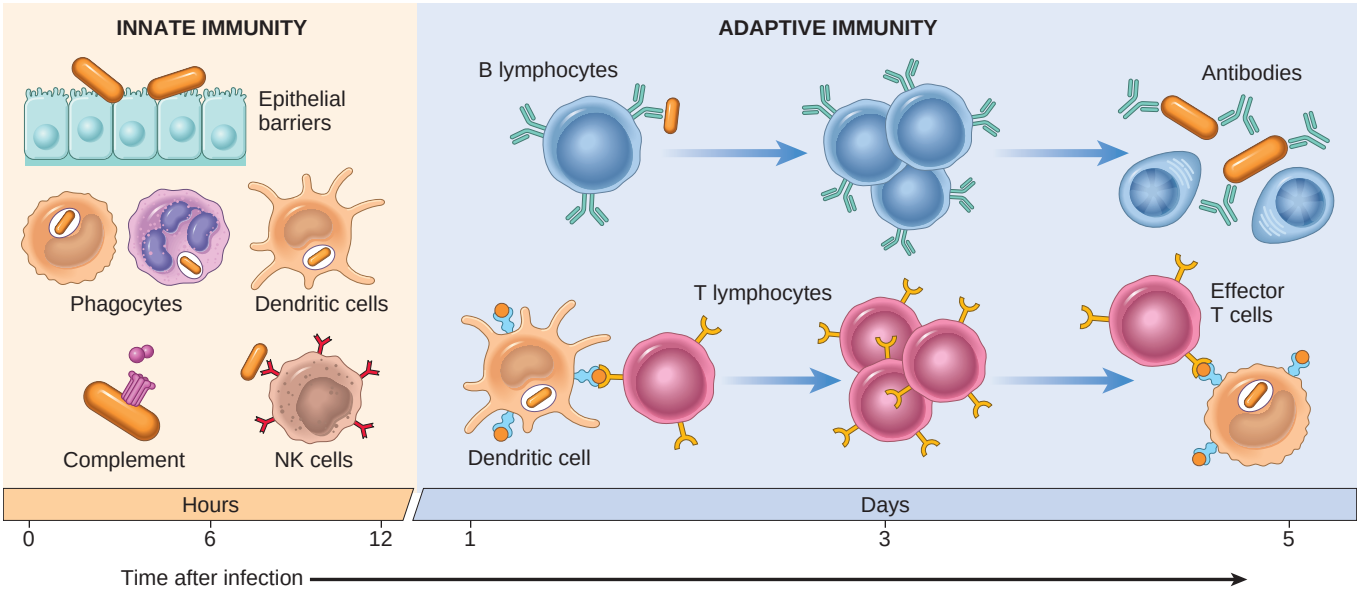

Figure 6.1 The principal components of innate and adaptive immunity. *NK*, Natural killer.

antigens, but instead are activated by cytokines and other mediators produced at sites of tissue damage. They are thought to be sources of inflammatory cytokines during early phases of immune reactions. ILCs are classified into groups based on the dominant cytokines they produce: groups 1, 2, and 3 ILCs produce many of the same cytokines as Th1, Th2, and Th17 subsets of CD4+ T cells, described later. *Natural killer (NK) cells* are one type of ILC that provide early protection against many viruses and intracellular bacteria; their properties and functions are described later.

- *Other cell types.* Several other cell types can sense and react to microbes. These include *mast cells*, which are capable of producing many mediators of inflammation (discussed later), and even epithelial and endothelial cells.
- *Plasma proteins.* In addition to these cells, several soluble proteins play important roles in innate immunity. The *complement system* (described in Chapter 3) consists of plasma proteins that are activated by microbes. Complement activation may occur through the alternative and lectin pathways as part of innate immune responses or through the classical pathway, which involves antibody-antigen complexes, as part of adaptive immune responses (Chapter 3). Other circulating proteins of innate immunity are mannose-binding lectin and C-reactive protein, both of which coat microbes and promote phagocytosis. Lung surfactant is also a component of innate immunity, providing protection against inhaled microbes.

Cellular Receptors for Microbes, Products of Damaged Cells, and Foreign Substances

Cells that participate in innate immunity are capable of recognizing certain components that are shared among related microbes and that are often essential for infectivity (and thus cannot be mutated to allow the microbes to evade the defense mechanisms). These microbial structures are called pathogen-associated molecular patterns. Leukocytes also recognize molecules released by injured and necrotic cells, which are called damage-associated molecular patterns. Collectively, the cellular receptors that recognize these molecules are called pattern recognition receptors.

Pattern recognition receptors are located in all cellular compartments where microbes may be present: plasma membrane receptors detect extracellular microbes, endosomal receptors detect ingested microbes, and cytosolic receptors detect microbes in the cytoplasm (Fig. 6.2). Several classes of these receptors have been identified.

Toll-like receptors. The best known of the pattern recognition receptors are the Toll-like receptors (TLRs), whose founding member, *Toll,* was discovered in *Drosophila* as a gene involved in development of the fly. A family of related proteins was later shown to be essential for host defense against microbes. Mammals have 10 TLRs, each recognizing a different set of microbial molecules. The TLRs are present in the plasma membrane and endosomal vesicles (see Fig. 6.2). All TLRs signal by a common pathway that culminates in the activation of two sets of transcription factors: (1) NF-κB, which stimulates the synthesis and secretion of cytokines and the expression of adhesion molecules, both of which are critical for the recruitment and activation of leukocytes (Chapter 3), and (2) interferon regulatory factors (IRFs), which stimulate the production of the antiviral cytokines, type I interferons. Inherited loss-of-function mutations affecting TLRs and their signaling pathways are associated with rare but serious immunodeficiency syndromes, described later in the chapter.

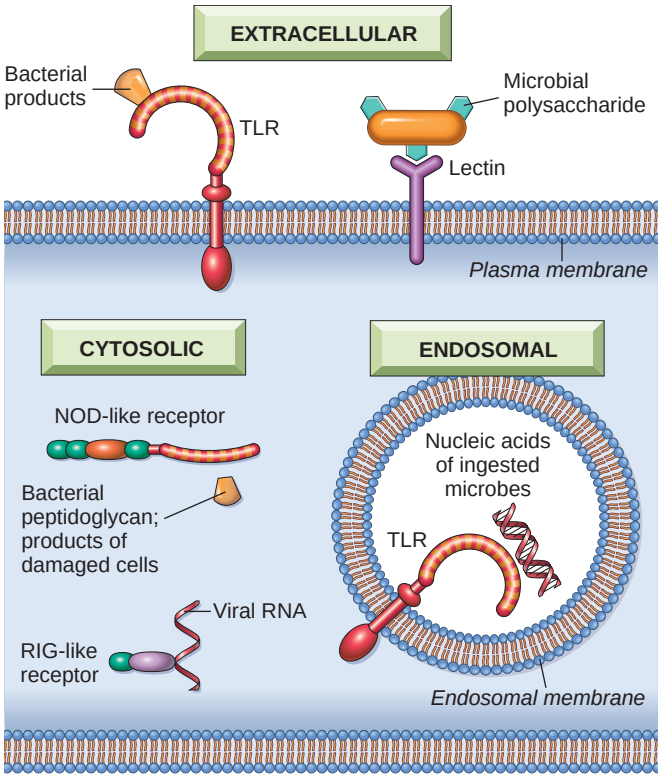

Figure 6.2 Cellular receptors for microbes and products of cell injury. Phagocytes, dendritic cells, and many types of epithelial cells express different classes of receptors that sense the presence of microbes and dead cells. Toll-like receptors *(TLRs)* located in different cellular compartments, as well as other cytoplasmic and plasma membrane receptors, recognize products of different classes of microbes. Major classes of innate immune receptors are TLRs, NOD-like receptors (NLRs) in the cytosol, C-type lectin receptors (CLRs), RIG-like receptors (RLRs) for viral nucleic acids, and cytosolic receptors for DNA (not shown). *RIG,* retinoic acid-inducible gene.

NOD-like receptors and the inflammasome. NOD-like receptors (NLRs) are cytosolic receptors named after the founding member NOD-2. They recognize a wide variety of substances, including products released from necrotic or damaged cells (e.g., uric acid and adenosine triphosphate [ATP]), loss of intracellular K^+ ions, and some microbial products. How this family of sensors is capable of detecting so many diverse signs of danger or damage is not known. Several of the NLRs signal via a cytosolic multiprotein complex called the *inflammasome,* which activates an enzyme (caspase-1) that cleaves a precursor form of the cytokine interleukin-1 (IL-1) to generate the biologically active form (Fig. 6.3). As discussed later, IL-1 is a mediator of inflammation that recruits leukocytes and induces fever. Gain-of-function mutations in NLRs and related proteins, and loss-of-function mutations in regulators of the inflammasome, result in periodic fever syndromes called *autoinflammatory syndromes* (to be distinguished from autoimmune diseases,

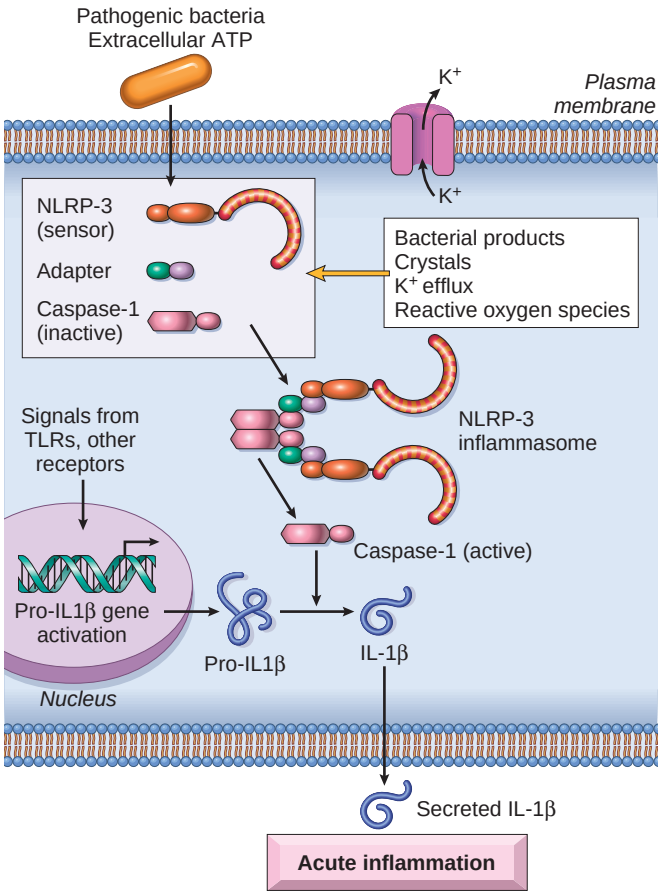

Figure 6.3 The inflammasome. The inflammasome is a protein complex that recognizes products of dead cells and some microbes and induces the secretion of biologically active interleukin 1. The inflammasome consists of a sensor protein (an example is the leucine-rich protein NLRP3), an adapter, and the enzyme caspase-1, which is converted from an inactive to an active form. *ATP*, Adenosine triphosphate; *IL*, interleukin; *TLR*, Toll-like receptor.

which result from T and B lymphocyte reactions against self antigens). The autoinflammatory syndromes respond very well to treatment with IL-1 antagonists. The inflammasome pathway may also play a role in many common disorders. For example, recognition of urate crystals by a class of NLRs underlies the inflammation associated with gout. These receptors are also capable of detecting lipids and cholesterol crystals that are deposited in abnormally large amounts in tissues, and the resulting inflammation appears to contribute to obesity-associated type 2 diabetes and atherosclerosis, respectively.

Other cellular receptors for microbial products. C-type lectin receptors (CLRs) expressed on the plasma membrane of macrophages and DCs detect fungal glycans and elicit inflammatory reactions to fungi. RIG-like receptors (RLRs), named after the founding member RIG-I (retinoic acid-inducible gene-I), are located in the cytosol of most cell types and detect nucleic acids of viruses that replicate in the cytoplasm of infected cells. These receptors stimulate the production of antiviral cytokines. Cytosolic receptors for microbial DNA, often derived from viruses in the cell, activate a pathway called STING (for stimulator of interferon genes), which leads to the production of the antiviral cytokine interferon-α. Excessive activation of the STING pathway causes systemic inflammatory disorders collectively called *interferonopathies*. Plasma membrane G protein–coupled receptors on neutrophils, macrophages, and most other types of leukocytes recognize short bacterial peptides containing *N*-formylmethionyl residues. Because all bacterial proteins and few mammalian proteins (only those synthesized within mitochondria) are initiated by *N*-formylmethionine, this receptor enables neutrophils to detect bacterial proteins and move toward their source (chemotaxis). Mannose receptors recognize microbial sugars (which often contain terminal mannose residues, unlike mammalian glycoproteins) and induce phagocytosis of the microbes.

Natural Killer Cells

The function of NK cells is to recognize and destroy severely stressed or abnormal cells, such as virus-infected cells and tumor cells. NK cells make up approximately 5% to 10% of peripheral blood lymphocytes. NK cells express CD16, a receptor for IgG Fc tails that confers on NK cells the ability to lyse IgG-coated target cells. This phenomenon is known as antibody-dependent cellular cytotoxicity (ADCC).

Killing of target cells by NK cells is regulated by signals from activating and inhibitory receptors (Fig. 6.4). There are many types of activating receptors, which recognize surface molecules that are induced by various kinds of stress, such as infection and DNA damage. Thus, these receptors enable NK cells to recognize damaged or infected cells. NK cell inhibitory receptors recognize self class I MHC molecules, which are expressed on all healthy cells. The inhibitory receptors prevent NK cells from killing normal cells. Virus infection or neoplastic transformation often enhances expression of ligands for activating receptors and at the same time reduces the expression of class I MHC molecules. As a result, when NK cells engage these abnormal cells the balance is tilted toward activation, and the infected or tumor cell is killed.

NK cells also secrete cytokines such as interferon-γ (IFN-γ), which activates macrophages to destroy ingested microbes, and thus NK cells provide an early defense against intracellular microbial infections. The activity of NK cells is regulated by many cytokines, including the interleukins IL-2, IL-15, and IL-12. IL-2 and IL-15 stimulate proliferation of NK cells, whereas IL-12 activates the killing of target cells and the secretion of IFN-γ.

Reactions of Innate Immunity

The innate immune system provides host defense by two main reactions.

- *Inflammation.* Cytokines and products of complement activation, as well as other mediators, are produced during innate immune reactions and trigger the vascular and cellular components of inflammation. The recruited leukocytes destroy microbes and ingest and eliminate damaged cells. The innate immune response also triggers the repair of damaged tissues. These processes are described in Chapter 3.
- *Antiviral defense.* Type I interferons produced in response to viruses act on infected and uninfected cells and activate

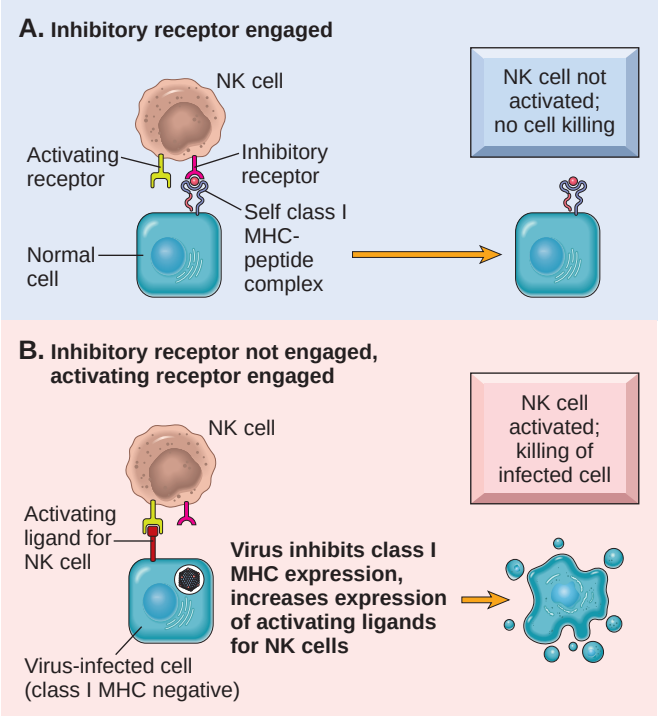

Figure 6.4 Activating and inhibitory receptors of natural killer *(NK)* cells. (A) Healthy cells express self class I major histocompatibility complex *(MHC)* molecules, which are recognized by inhibitory receptors, thus ensuring that NK cells do not attack normal cells. Note that healthy cells may express ligands for activating receptors *(not shown)* or may not express such ligands *(as shown)*, but they do not activate NK cells because they engage the inhibitory receptors. (B) In infected and stressed cells, class I MHC expression is reduced so that the inhibitory receptors are not engaged, and ligands for activating receptors are expressed. The result is that NK cells are activated and the infected cells are killed.

enzymes that degrade viral nucleic acids and inhibit viral replication, inducing what has been called an antiviral state. NK cells recognize virus-infected cells, as described above.

In addition to these direct defense functions, innate immunity produces the danger signals that stimulate the subsequent more powerful adaptive immune response. The nature of some of these signals is described later.

Innate immunity, unlike adaptive immunity, does not have memory or fine antigen specificity. It is estimated that innate immunity uses about 100 different receptors to recognize 1000 molecular patterns. In contrast, adaptive immunity uses two types of receptors (antibodies and T-cell receptors [TCRs], described later), each with millions of variations, to recognize millions of antigens.

Adaptive Immunity

The adaptive immune system consists of lymphocytes and their products, including antibodies. The lymphocytes of adaptive immunity use highly diverse receptors to recognize a vast array of foreign substances. In the remainder of this introductory section, we focus on lymphocytes and the reactions of the adaptive immune system.

There are two types of adaptive immunity: humoral immunity, which protects against extracellular microbes and their toxins, and cell-mediated (or cellular) immunity, which is responsible for defense against intracellular microbes and against cancers. Humoral immunity is mediated by B (bone marrow–derived) lymphocytes and their secreted products, *antibodies* (also called *immunoglobulins*, Ig), and cellular immunity is mediated by T (thymus-derived) lymphocytes. Both classes of lymphocytes express highly specific receptors for a wide variety of substances, which are called *antigens*.

Cells of the Adaptive Immune System

Although T and B lymphocytes and their subsets are morphologically unimpressive and appear quite similar to one another, they are actually remarkably heterogeneous and specialized in molecular properties and functions. The major classes of lymphocytes and their functions in adaptive immunity are illustrated in Fig. 6.5. Lymphocytes and other cells involved in immune responses are not fixed in particular tissues (as are cells in most of the organs of the body) but constantly circulate among lymphoid and other tissues via the blood and the lymphatic system. This feature promotes immune surveillance throughout the body and allows lymphocytes to home to any site of infection. In lymphoid organs, different classes of lymphocytes are anatomically segregated in such a way that they interact with one another only when stimulated to do so by encounters with antigens and other stimuli. Mature lymphocytes that have not encountered the antigen for which they are specific are said to be *naïve* (immunologically inexperienced). After they are activated by recognition of antigens and other signals described later, lymphocytes differentiate into *effector cells,* which perform the function of eliminating microbes, and *memory cells,* which live in a state of heightened awareness and are able to react rapidly and strongly to combat the microbe in case it returns. The process of lymphocyte differentiation into effector and memory cells is summarized later. We start with a consideration of the diversity of T and B lymphocytes.

Lymphocyte Diversity

Lymphocytes specific for a large number of antigens exist before exposure to antigen, and when an antigen appears it selectively activates the antigen-specific cells. This fundamental concept is called *clonal selection*. Lymphocytes of the same specificity are said to constitute a clone; all members of one clone express identical antigen receptors, which are different from the receptors in all other clones. There are about 10^{12} lymphocytes in a healthy adult, and it is estimated that there are 10^7 to 10^9 clones, each expressing receptors specific for a different antigen. It follows that the number of cells specific for any one antigen is very small, probably fewer than 1 in 100,000 lymphocytes. It is remarkable that so few cells with a particular specificity can accomplish the difficult task of combating various microbes; as discussed later, the immune system has developed many mechanisms for optimizing reactions to microbial antigens. It is also remarkable that the system is capable of producing so many receptors, far more than could be individually

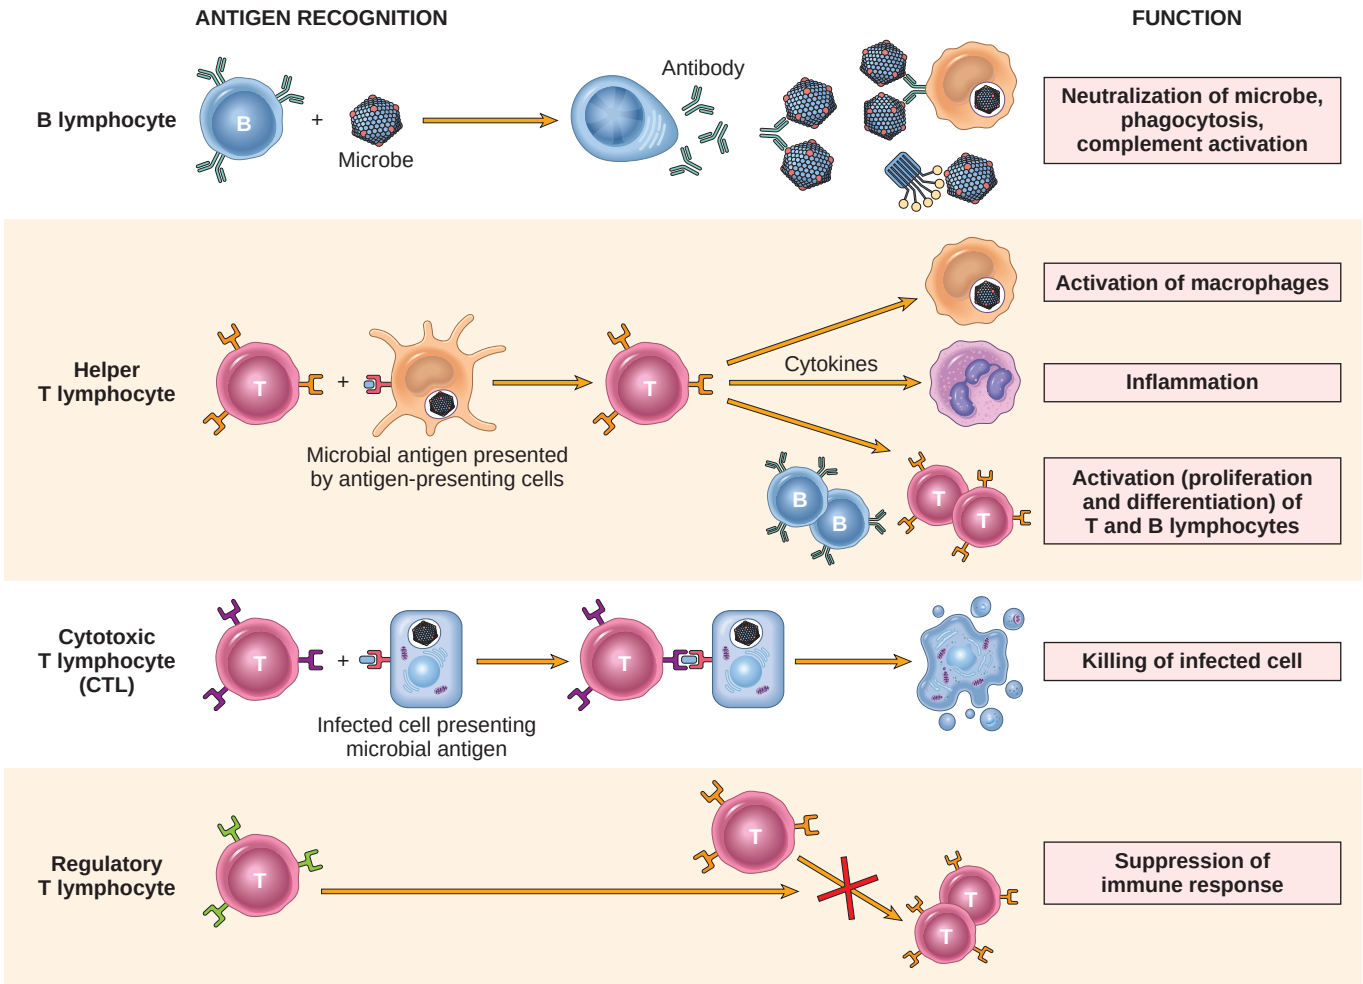

Figure 6.5 The principal classes of lymphocytes and their functions. B and T lymphocytes are the cells of adaptive immunity. Several other classes of lymphocytes have been identified, including NK-T cells and so-called innate lymphoid cells (ILCs); the functions of these cells are not as well established as those of B and T lymphocytes. NK cells are discussed earlier.

encoded in the genome. The mechanisms by which this happens are now well understood and have many interesting clinical implications.

Antigen receptor diversity is generated by somatic recombination of the genes that encode antigen receptors. All cells of the body, including lymphocyte progenitors, contain antigen receptor genes in the germline (inherited) configuration, in which the genes encoding these receptors consist of spatially separated segments that cannot be expressed as mRNAs. During lymphocyte maturation (in the thymus for T cells and the bone marrow for B cells), these gene segments are assembled by recombination, and DNA sequence variation is introduced at the sites where the gene segments are joined. This creates many different genes that can be transcribed and translated into antigen receptors with diverse amino acid sequences, particularly in the regions of the receptors that recognize and bind antigen. The enzyme in developing lymphocytes that mediates recombination of these gene segments is the product of *RAG-1* and *RAG-2* (recombination-activating genes); inherited defects in RAG proteins result in a failure to generate mature lymphocytes. It is important to note that germline antigen receptor genes are present in all cells in the body, but only T and B cells contain recombined (also called rearranged) antigen receptor genes (the TCR in T cells and Ig in B cells). Hence, the presence of recombined TCR or Ig genes, which can be demonstrated by molecular analysis, is a marker of T- or B-lineage cells. Furthermore, because each T or B cell and its clonal progeny have a unique DNA rearrangement (and hence a unique antigen receptor), it is possible to distinguish polyclonal (nonneoplastic) lymphocyte proliferations from monoclonal (neoplastic) lymphoid tumors by assessing the diversity of antigen receptor rearrangements within a population of lymphocytes. Thus, **assays that assess the clonality of antigen receptor gene rearrangements are useful in diagnosing lymphoid neoplasms** (Chapter 13).

T Lymphocytes

There are three major populations of T cells, which serve distinct functions. **Helper T lymphocytes stimulate B lymphocytes to make antibodies and activate other leukocytes (e.g., phagocytes) to destroy microbes; cytotoxic (killer) T lymphocytes (CTLs) kill infected cells; and**

regulatory T lymphocytes limit immune responses and prevent reactions against self antigens.

T lymphocytes develop in the thymus from precursors that arise from hematopoietic stem cells (HSCs). Mature T cells are found in the blood, where they constitute 60% to 70% of lymphocytes, and in T-cell zones of secondary lymphoid organs (described later). Each T cell recognizes a specific cell-bound antigen by means of an antigen-specific TCR. In approximately 95% of T cells, the TCR consists of a disulfide-linked heterodimer made up of an α and a β polypeptide chain (Fig. 6.6), each having a variable (antigen-binding) region and a constant region. **The αβ TCR recognizes peptide antigens that are bound to and presented by major histocompatibility complex (MHC) molecules on the surfaces of antigen-presenting cells (APCs).** By limiting the specificity of T cells for peptides displayed by cell surface MHC molecules, called MHC restriction, the immune system ensures that T cells see only cell-associated antigens (e.g., those derived from microbes in cells or from proteins ingested by cells).

Each TCR is noncovalently linked to six polypeptide chains, which form the CD3 complex and the ζ chain dimer (see Fig. 6.6). The CD3 and ζ proteins are invariant (i.e., identical) in all T cells. They are involved in the transduction of signals into the T cell that are triggered by binding of antigen to the TCR. Together with the TCR, these proteins form the TCR complex.

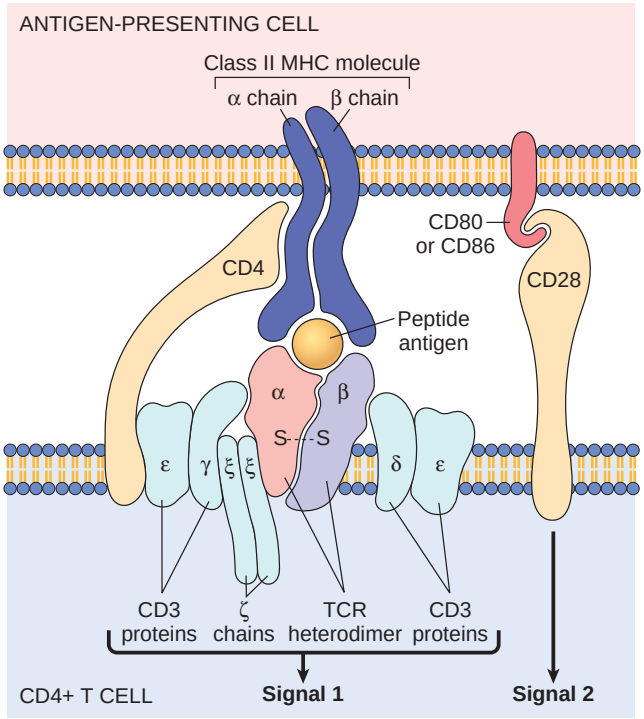

Figure 6.6 The T-cell receptor *(TCR)* complex and other molecules involved in T-cell activation. The TCR heterodimer, consisting of an α and a β chain, recognizes antigen (in the form of peptide-MHC complexes expressed on antigen-presenting cells, or APCs), and the linked CD3 complex and ζ chains initiate activating signals. CD4 and CD28 are also involved in T-cell activation. (Note that some T cells express CD8 and not CD4; these molecules serve analogous roles.) The sizes of the molecules are not drawn to scale. *MHC*, Major histocompatibility complex.

A small population of mature T cells expresses another type of TCR composed of γ and δ polypeptide chains. The γδ TCR recognizes peptides, lipids, and small molecules, without a requirement for display by MHC proteins. γδ T cells tend to aggregate at epithelial surfaces, such as the skin and mucosa of the gastrointestinal and urogenital tracts, suggesting that these cells are sentinels that protect against microbes that try to enter through epithelia. However, the functions of γδ T cells are not established. Another small subset of T cells expresses markers that are also found on NK cells; these cells are called NK-T cells. NK-T cells express a very limited diversity of TCRs, and they recognize glycolipids that are displayed by the MHC-like molecule CD1. The functions of NK-T cells are also not well defined.

In addition to CD3 and ζ proteins, T cells express several other proteins that assist the TCR complex in functional responses. These include CD4, CD8, CD28, and integrins. CD4 and CD8 are expressed on two mutually exclusive subsets of αβ T cells. Normally, approximately 60% of mature T cells are CD4+, and about 30% are CD8+. Most CD4+ T cells function as cytokine-secreting helper cells that assist macrophages and B lymphocytes to combat infections. Most CD8+ cells function as CTLs that destroy host cells harboring microbes. CD4 and CD8 serve as coreceptors in T-cell activation. During antigen recognition, CD4 molecules bind to class II MHC molecules that are displaying antigen (see Fig. 6.6); CD8 molecules bind to class I MHC molecules; and the CD4 or CD8 coreceptor initiates signals that are necessary for activation of the T cells. Because of this requirement for coreceptors, CD4+ helper T cells can recognize and respond to antigen displayed only by class II MHC molecules, whereas CD8+ cytotoxic T cells recognize cell-bound antigens only in association with class I MHC molecules; this segregation is described later. Integrins are adhesion molecules that promote the attachment of T-cells to APCs.

To respond, T cells have to not only recognize antigen-MHC complexes, but also have to receive additional signals provided by antigen-presenting cells. This process, in which CD28 plays an important role, is described later, when the steps in cell-mediated immune responses are summarized.

B Lymphocytes

B lymphocytes are the only cells in the body capable of producing antibodies, the mediators of humoral immunity. B lymphocytes develop from precursors in the bone marrow. Mature B cells constitute 10% to 20% of lymphocytes in the blood and are also present in peripheral lymphoid tissues such as lymph nodes, spleen, and mucosa-associated lymphoid tissues. B cells recognize antigen via the B-cell antigen receptor complex. Membrane-bound antibodies of the IgM and IgD isotypes, present on the surface of all mature, naïve B cells, are the antigen-binding component of the B-cell receptor (BCR) complex (Fig. 6.7). After stimulation by antigen and other signals (described later), B cells develop into *plasma cells,* veritable protein factories for producing antibodies, as well as long-lived memory cells. It is estimated that a single plasma cell can secrete hundreds to thousands of antibody molecules per second, a remarkable measure of the power of the immune response for combating pathogens.

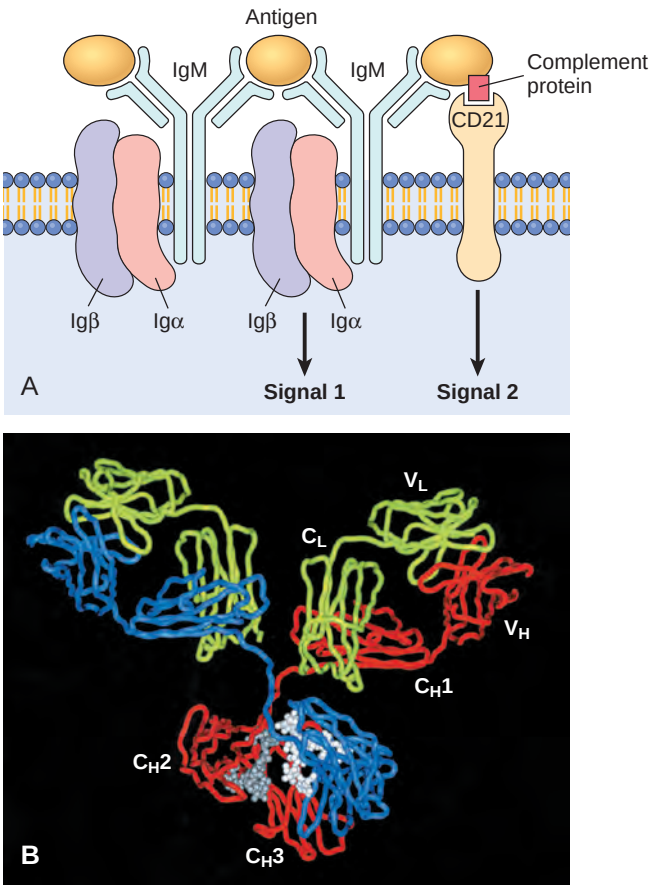

Figure 6.7 Structure of antibodies and the B-cell antigen receptor. (A) The B-cell antigen receptor complex is composed of membrane immunoglobulin M (*IgM;* or IgD, *not shown*), which recognizes antigens, and the associated signaling proteins Igα and Igβ. CD21 is a receptor for a complement component that also promotes B-cell activation. (B) Crystal structure of a secreted IgG molecule, showing the arrangement of the variable *(V)* and constant *(C)* regions of the heavy *(H)* and light *(L)* chains. (Courtesy Dr. Alex McPherson, University of California, Irvine, Calif.)

In addition to membrane Ig, the B-cell antigen receptor complex contains a heterodimer of two invariant proteins called Igα and Igβ. Similar to the CD3 and ζ proteins of the TCR complex, Igα (CD79a) and Igβ (CD79b) are essential for signal transduction in response to antigen recognition. B cells also express several other molecules that are essential for their responses. These include the type 2 complement receptor (CR2, or CD21), which recognizes complement products generated during innate immune responses to microbes, and CD40, which receives signals from helper T cells. CR2 is also used by Epstein-Barr virus (EBV) as a receptor to enter and infect B cells.

Dendritic Cells (DCs)

DCs (sometimes called interdigitating DCs) **are the most important antigen-presenting cells for initiating T-cell responses against protein antigens.** These cells have numerous fine cytoplasmic processes that resemble dendrites, from which they derive their name. Several features of DCs account for their key role in antigen presentation. First, these cells are located at the right place to capture antigens—under epithelia, the common site of entry of microbes and foreign antigens, and in the interstitia of all tissues, where antigens may be produced. Immature DCs within the epidermis are called *Langerhans cells*. Second, DCs express many receptors for capturing and responding to microbes (and other antigens), including TLRs and lectins. Third, in response to microbes, DCs are recruited to the T-cell zones of lymphoid organs, where they are ideally located to present antigens to naïve T cells. Fourth, DCs express high levels of MHC and other molecules needed for antigen presentation and T-cell activation.

A second type of cell with dendritic morphology is present in the germinal centers of lymphoid follicles in the spleen and lymph nodes and is called the *follicular dendritic cell (FDC)*. These cells bear Fc receptors for IgG and receptors for C3b and can trap antigen bound to antibodies or complement proteins. They play a role in humoral immune responses by presenting antigens to B cells in the germinal center, part of a process through which only B cells that express antibodies with high affinity for antigen survive and go on to mature into plasma cells or memory cells.

Macrophages

Macrophages are a part of the mononuclear phagocyte system; their origin, differentiation, and role in inflammation are discussed in Chapter 3. Here, their important functions in the induction and effector phases of adaptive immune responses are discussed.

- *Macrophages that have phagocytosed microbes and protein antigens process the antigens and present peptide fragments to T cells.* Thus, macrophages function as antigen-presenting cells in T-cell activation.
- *Macrophages are key effector cells in certain forms of cell-mediated immunity, the reaction that serves to eliminate intracellular microbes.* In this type of response, T cells activate macrophages and enhance their ability to kill ingested microbes (discussed later).
- *Macrophages also participate in the effector phase of humoral immunity.* Macrophages efficiently phagocytose and destroy microbes that are opsonized (coated) by IgG or C3b.

Tissues of the Immune System

The tissues of the immune system consist of the *primary* (also called *generative*, or *central*) lymphoid organs, in which T and B lymphocytes mature and become competent to respond to antigens, and the *secondary* (or *peripheral*) lymphoid organs, in which adaptive immune responses to microbes are initiated.

Primary Lymphoid Organs. **The principal primary lymphoid organs are the thymus, where T cells develop, and the bone marrow, the site of production of all other blood cells, including naïve B cells.** These organs are described in Chapter 13.

Secondary Lymphoid Organs. **The secondary lymphoid organs—lymph nodes, spleen, and the mucosal and cutaneous lymphoid tissues—are the tissues where adaptive immune responses occur**. Several features of these organs promote the generation of adaptive immunity—antigens are concentrated in these organs, naïve lymphocytes circulate through them searching for the antigens, and different

lymphocyte populations (such as T and B cells) are brought together when they need to interact.

- *Lymph nodes* are nodular aggregates of lymphoid tissues located along lymphatic channels throughout the body (Fig. 6.8). As lymph slowly suffuses through lymph nodes, antigen-presenting cells are positioned to recognize antigens (e.g., derived from microbes that may enter through epithelia into tissues and are carried in the lymph). In addition, DCs pick up and transport antigens of microbes from epithelia and tissues via lymphatic vessels to the lymph nodes. Thus, the antigens of microbes that enter through epithelia or colonize tissues become concentrated in draining lymph nodes. Because most foreign antigens enter through epithelia or are produced in tissues, lymph nodes are the site of generation of the majority of adaptive immune responses.
- The *spleen* is an abdominal organ that serves the same role in immune responses to blood-borne antigens as the lymph nodes do in responses to lymph-borne antigens. Blood entering the spleen flows through a network of sinusoids lined by macrophages and DCs. Blood-borne antigens are trapped in the spleen by these cells, which can then initiate adaptive immune responses to these antigens.
- The *cutaneous and mucosal lymphoid systems* are located under the epithelia of the skin and the gastrointestinal and respiratory tracts, respectively. They respond to antigens that enter through breaches in the epithelium. Pharyngeal tonsils and Peyer patches of the intestine are two anatomically defined mucosal lymphoid tissues. At any time, a large fraction of the body's lymphocytes are in the mucosal tissues (reflecting the large size of these tissues), and many of these are memory cells.

Within the secondary lymphoid organs, naïve T and B lymphocytes are segregated into different regions (see Fig. 6.8). In lymph nodes, the B cells are concentrated in discrete structures, called follicles, located around the periphery, or cortex, of each node. If the B cells in a follicle have recently responded to an antigen, this follicle may contain a central region called a germinal center. The T lymphocytes are concentrated in the paracortex, adjacent to the follicles. The follicles contain the FDCs that are involved in the activation of B cells, and the paracortex contains the DCs that present antigens to T lymphocytes. In the spleen, T lymphocytes are concentrated in periarteriolar lymphoid sheaths surrounding small arterioles, and B cells reside in follicles akin to those found in lymph nodes (the so-called splenic white pulp).

Lymphocyte Recirculation

Lymphocytes constantly recirculate between tissues and home to particular sites; naïve lymphocytes traverse the secondary lymphoid organs where immune responses are initiated, and effector lymphocytes migrate to sites of infection and inflammation. This process of lymphocyte recirculation is most important for T cells, because naïve T cells have to circulate through the secondary lymphoid organs where antigens are concentrated and effector T cells have to migrate to sites of infection to eliminate microbes. In contrast, plasma cells remain in lymphoid organs and the bone marrow and do not need to traffic to sites of infection because they secrete

antibodies that are carried through the blood to distant tissues.

Major Histocompatibility Complex Molecules: the Peptide Display System of Adaptive Immunity

The function of MHC molecules is to display peptide fragments of protein antigens for recognition by antigen-specific T cells. Because MHC molecules are fundamental to antigen recognition by T cells and are linked to many autoimmune diseases, it is important to briefly review their structure and function. MHC molecules were discovered as products of genes that evoke rejection of transplanted organs, and their name derives from their role in determining tissue compatibility between individuals. In humans, the MHC molecules are called *human leukocyte antigens* (HLA) because they were initially detected on leukocytes. The genes encoding HLA molecules are clustered on a small segment of chromosome 6 (Fig. 6.9). The HLA system is highly polymorphic; there are thousands of distinct MHC gene alleles in humans, and as a result each individual's HLA alleles differ from those inherited by most other individuals in the population. This, as we see subsequently, constitutes a formidable barrier in organ transplantation.

On the basis of their structure, cellular distribution, and function, MHC gene products are divided into two major classes.

- *Class I MHC molecules* are expressed on all nucleated cells and platelets. They are heterodimers consisting of a polymorphic α, or heavy, chain (44-kD) linked noncovalently to a smaller (12-kD) nonpolymorphic protein called β_2-microglobulin. The α chains are encoded by three genes, designated *HLA-A, HLA-B,* and *HLA-C,* that lie close to one another in the MHC locus (see Fig. 6.9). The extracellular region of the α chain is divided into three domains: α_1, α_2, and α_3. The α_1 and α_2 domains form a cleft, or groove, where peptides bind. The polymorphic amino acid residues line the sides and the base of the peptide-binding groove, explaining why different class I alleles bind different peptides.

  Class I MHC molecules display peptides that are derived from cytoplasmic proteins, including normal proteins and virus- and tumor-specific antigens, which are all recognized bound to class I MHC molecules by CD8+ T cells. Cytoplasmic proteins are degraded in proteasomes, and peptides are transported into the endoplasmic reticulum (ER), where they bind to newly synthesized class I molecules. Peptide-loaded MHC

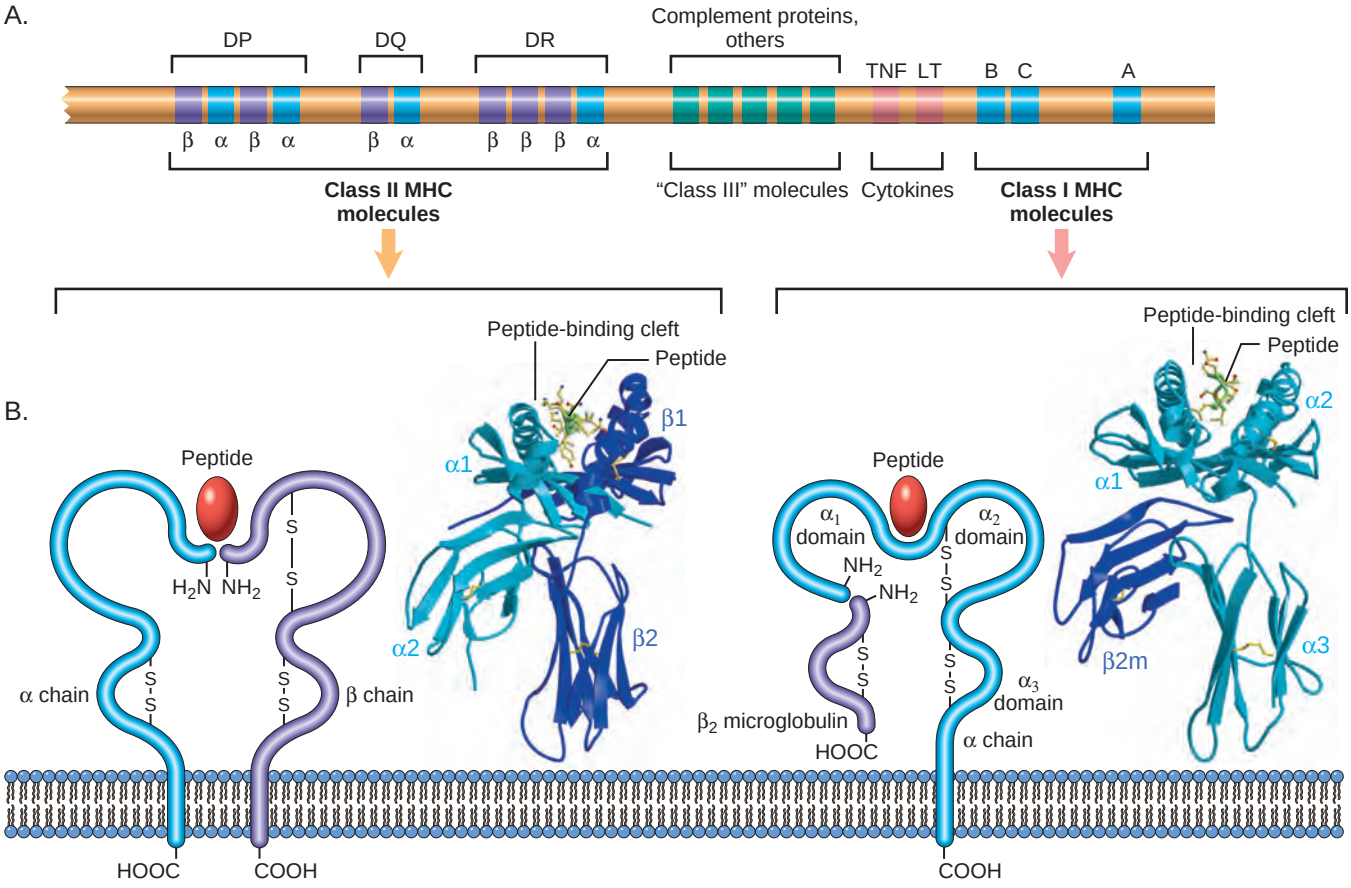

Figure 6.9 The human leukocyte antigen (HLA) complex and the structure of HLA molecules. (A) The location of genes in the HLA complex. The relative locations, sizes, and distances between genes are not to scale. Genes that encode several proteins involved in antigen processing (the TAP transporter, components of the proteasome, and HLA-DM) are located in the class II region *(not shown).* (B) Schematic diagrams and crystal structures of class I and class II HLA molecules. (Crystal structures are courtesy Dr. P. Bjorkman, California Institute of Technology, Pasadena, Calif.)

molecules then associate with β_2-microglobulin to form a stable complex, which is transported to the cell surface. The nonpolymorphic α_3 domain of class I MHC molecules has a binding site for CD8, and therefore the peptide-class I complexes are recognized by CD8+ T cells, which function as CTLs. In this interaction, the TCR recognizes the MHC-peptide complex, and the CD8 molecule, acting as a coreceptor, binds to the class I heavy chain. Since CD8+ T cells recognize peptides only if presented as a complex with class I MHC molecules, CD8+ T cells are said to be class I MHC-restricted. Because important functions of CD8+ CTLs include the elimination of viruses, which may infect any nucleated cell, and killing of tumor cells, which may arise from any nucleated cell, it makes good sense that all nucleated cells express class I MHC molecules and can be surveyed by CD8+ T cells.

- *Class II MHC molecule*s are encoded in a region called *HLA-D*, which has three subregions: *HLA-DP, HLA-DQ,* and *HLA-DR*. Each class II molecule is a heterodimer consisting of a noncovalently associated α chain and β chain, both of which are polymorphic. The extracellular portions of the α and β chains both have two domains designated α_1 and α_2, and β_1 and β_2. The crystal structure of class II molecules has revealed that, similar to class I molecules, they have peptide-binding clefts facing outward (see Fig. 6.9). This cleft is formed by an interaction of the α_1 and β_1 domains, and it is in this portion that most class II alleles differ. Thus, as with class I molecules, polymorphism of class II molecules is associated with differential binding of antigenic peptides.

  Class II MHC molecules present antigens derived from extracellular microbes and proteins following their internalization into endosomes or lysosomes. Here, the internalized proteins are proteolytically digested, producing peptides that then associate with class II heterodimers in the vesicles, from which they are transported to the cell surface as stable peptide-MHC complexes. The class II β_2 domain has a binding site for CD4, and therefore, the class II-peptide complex is recognized by CD4+ T cells, which function as helper cells. Because CD4+ T cells can recognize antigens only in the context of self class II molecules, they are referred to as class II MHC-restricted. In contrast to class I molecules, class II molecules are mainly expressed on cells that present ingested antigens and respond to T-cell help (macrophages, B lymphocytes, and DCs).

The combination of HLA alleles in each individual is called the HLA haplotype. Any given individual inherits one set of HLA genes from each parent and (assuming the parents are unrelated) typically expresses two different molecules for every locus. Because of the polymorphism of the HLA genes, virtually innumerable combinations of molecules exist in the population, and each individual expresses an MHC profile on his or her cell surface that is different from the haplotypes of most other individuals. It is believed that this degree of polymorphism evolved to ensure that at least some individuals in a species would be able to display any microbial peptide and thus provide protection against any infection. This polymorphism also means that no two individuals (other than identical twins) are likely to express the same MHC molecules, and therefore grafts exchanged between these individuals are recognized as foreign and attacked by the immune system. Because each haplotype is inherited as a block, and there are two sets of genes from each parent, the chance that siblings will have the same MHC is 1 in 4. This is why siblings are screened first as potential donors for patients in need of a kidney or hematopoietic stem cell transplant.

MHC molecules play several key roles in regulating T cell–mediated immune responses. First, because different antigenic peptides bind to different MHC molecules, it follows that an individual mounts an immune response against a protein antigen only if he or she inherits an MHC variant that can bind peptides derived from the antigen and present it to T cells. The consequences of inheriting a given MHC (e.g., class II) variant depend on the nature of the antigen bound by the class II molecule. For example, if the antigen is a peptide from ragweed pollen, the individual who expresses class II molecules capable of binding the antigen would be genetically prone to allergic reactions against ragweed. In contrast, an inherited capacity to bind a bacterial peptide may provide resistance to the infection by evoking a protective antibody response. Second, by segregating cytoplasmic and internalized antigens, MHC molecules ensure that the correct immune response is mounted against different microbes—CTL-mediated killing of cells harboring cytoplasmic microbes and tumor antigens, and helper T cell–mediated antibody production and macrophage activation to combat extracellular and phagocytosed microbes.

Interest in HLA molecules was spurred by the realization, in the 1960s and 1970s, that a number of autoimmune and other diseases are associated with the inheritance of particular HLA alleles. These associations are discussed when the pathogenesis of autoimmune diseases is considered later in the chapter.

Cytokines: Messenger Molecules of the Immune System

The induction and regulation of immune responses involve multiple interactions among lymphocytes, DCs, macrophages, other inflammatory cells (e.g., neutrophils), and endothelial cells. Some of these interactions depend on cell-to-cell contact; however, **many functions of leukocytes are stimulated and regulated by secreted proteins called cytokines.** Molecularly defined cytokines are called interleukins because they mediate communications between leukocytes (although many also act on cells other than leukocytes). Most cytokines have a wide spectrum of effects, and some are produced by several different cell types. The majority of these cytokines act on the cells that produce them (autocrine actions) or on neighboring cells (paracrine) and rarely at a distance (endocrine).

Cytokines contribute to different types of immune responses.

- In innate immune responses, cytokines are produced rapidly after encounter with microbes and other stimuli, and they function to induce inflammation and inhibit virus replication. These cytokines include TNF, IL-1, IL-12, type I IFNs, IFN-γ, and chemokines (Chapter 3). Their major sources are macrophages, DCs, ILCs, and NK cells, but endothelial and epithelial cells can also produce them.
- In adaptive immune responses, cytokines are produced principally by CD4+ T lymphocytes activated by antigen

and other signals, and they function to promote lymphocyte proliferation and differentiation and to activate effector cells. The main ones in this group are IL-2, IL-4, IL-5, IL-17, and IFN-γ; their roles in immune responses are described later. Some cytokines serve mainly to limit and terminate immune responses; these include TGF-β and IL-10.

- Some cytokines stimulate hematopoiesis and are called colony-stimulating factors (CSFs) because they are assayed by their ability to stimulate formation of blood cell colonies from bone marrow progenitors (Chapter 13). Their functions are to increase leukocyte production during immune and inflammatory responses, both to increase their numbers and to replace leukocytes that die during such responses. They are produced by marrow stromal cells, T lymphocytes, macrophages, and other cells. Examples include GM-CSF and other CSFs, and IL-3.

The knowledge gained about cytokines has numerous practical therapeutic applications. Inhibiting cytokine production or actions is an approach for controlling the harmful effects of inflammation and tissue-damaging immune reactions. Patients with rheumatoid arthritis often show dramatic responses to TNF antagonists, an elegant example of rationally designed and molecularly targeted therapy. Many other cytokine antagonists are now approved for the treatment of various inflammatory disorders. Conversely, administration of cytokines is used to boost reactions that are normally dependent on these proteins, such as hematopoiesis and defense against some viruses. An important therapeutic application of cytokines is to mobilize hematopoietic stem cells from bone marrow to peripheral blood, from which they can be collected for stem cell transplantation.

Overview of Lymphocyte Activation and Immune Responses

All adaptive immune responses develop in steps, consisting of: antigen recognition; activation of specific lymphocytes to proliferate and differentiate into effector and memory cells; elimination of the antigen; and decline of the response, with memory cells being the long-lived survivors. The major events in each step are summarized next; these general principles apply to protective responses against microbes as well as pathologic responses that injure the host.

Display and Recognition of Antigens

Microbes and other foreign antigens can enter the body anywhere. It is obviously impossible for lymphocytes to effectively patrol every possible portal of antigen entry, because there are not enough antigen-specific lymphocytes to constantly cover all of this "terrain." To overcome this problem, antigens are captured and concentrated in secondary lymphoid organs through which naïve lymphocytes circulate, thus increasing the likelihood of a lymphocyte finding antigens it can recognize. Microbes and their protein antigens are captured by DCs that are resident in epithelia and tissues. These cells carry their antigenic cargo to draining lymph nodes (Fig. 6.10). Here the antigens are processed and displayed complexed with MHC molecules on the cell surface, where the antigens are recognized by T cells.

B lymphocytes use their antigen receptors (membrane-bound antibody molecules) to recognize antigens of many different chemical types, including proteins, polysaccharides, and lipids.

Even before the antigens of a microbe are recognized by T and B lymphocytes, the microbe elicits an immune response through pattern recognition receptors expressed on innate immune cells; this is the first line of defense that also serves to activate adaptive immunity. In the case of immunization with a protein antigen, microbial mimics, called adjuvants, are given with the antigen, and these stimulate innate immune responses. During the innate response, the microbe or adjuvant activates antigen-presenting cells to express molecules called *costimulators* and to secrete cytokines that stimulate the proliferation and differentiation of T lymphocytes. The principal costimulators for T cells are the B7 proteins (CD80 and CD86) that are expressed on antigen-presenting cells and are recognized by the CD28 receptor on naïve T cells. Thus, antigen ("signal 1") and costimulatory molecules produced during innate immune responses to microbes ("signal 2") function cooperatively to activate antigen-specific lymphocytes (see Fig. 6.6). The requirement for microbe-triggered signal 2 ensures that the adaptive immune response is induced by microbes and not by harmless substances. In immune responses to tumors and transplants, "signal 2" may be provided by substances released from necrotic cells (the "damage-associated molecular patterns" mentioned earlier).

The reactions and functions of T and B lymphocytes differ in important ways and are best considered separately even though both may be activated concurrently in an immune response.

Cell-Mediated Immunity: Activation of T Lymphocytes and Elimination of Intracellular Microbes

Naïve T lymphocytes are activated by antigen and costimulators in peripheral lymphoid organs, and proliferate and differentiate into effector cells that migrate to any site where microbial antigens are present (see Fig. 6.10). One of the earliest responses of CD4+ helper T cells is secretion of the cytokine IL-2 and expression of high-affinity receptors for IL-2. This creates an autocrine loop wherein IL-2 acts as a growth factor that stimulates T-cell proliferation, leading to an increase in the number of antigen-specific lymphocytes. The functions of helper T cells are mediated by the combined actions of CD40-ligand (CD40L) and cytokines. When CD4+ helper T cells recognize antigens being displayed by macrophages or B lymphocytes, the T cells express CD40L, which engages CD40 on the macrophages or B cells and activates these cells.

Some of the activated CD4+ T cells differentiate into effector cells that secrete distinct sets of cytokines and perform different functions (Fig. 6.11). Cells of the Th1 subset secrete the cytokine IFN-γ, which is a potent macrophage activator. The combination of CD40- and IFN-γ-mediated activation results in "classical" macrophage activation (Chapter 3), leading to the production of microbicidal substances in macrophages and the destruction of ingested microbes. Th2 cells produce IL-4, which stimulates B cells to differentiate into IgE-secreting plasma cells, and IL-5, which stimulates the production of eosinophils in the marrow and activates eosinophils at sites of immune responses. Eosinophils and mast cells bind to IgE-coated microbes such as helminthic parasites, and function to eliminate helminths. Th2 cells also induce the "alternative"

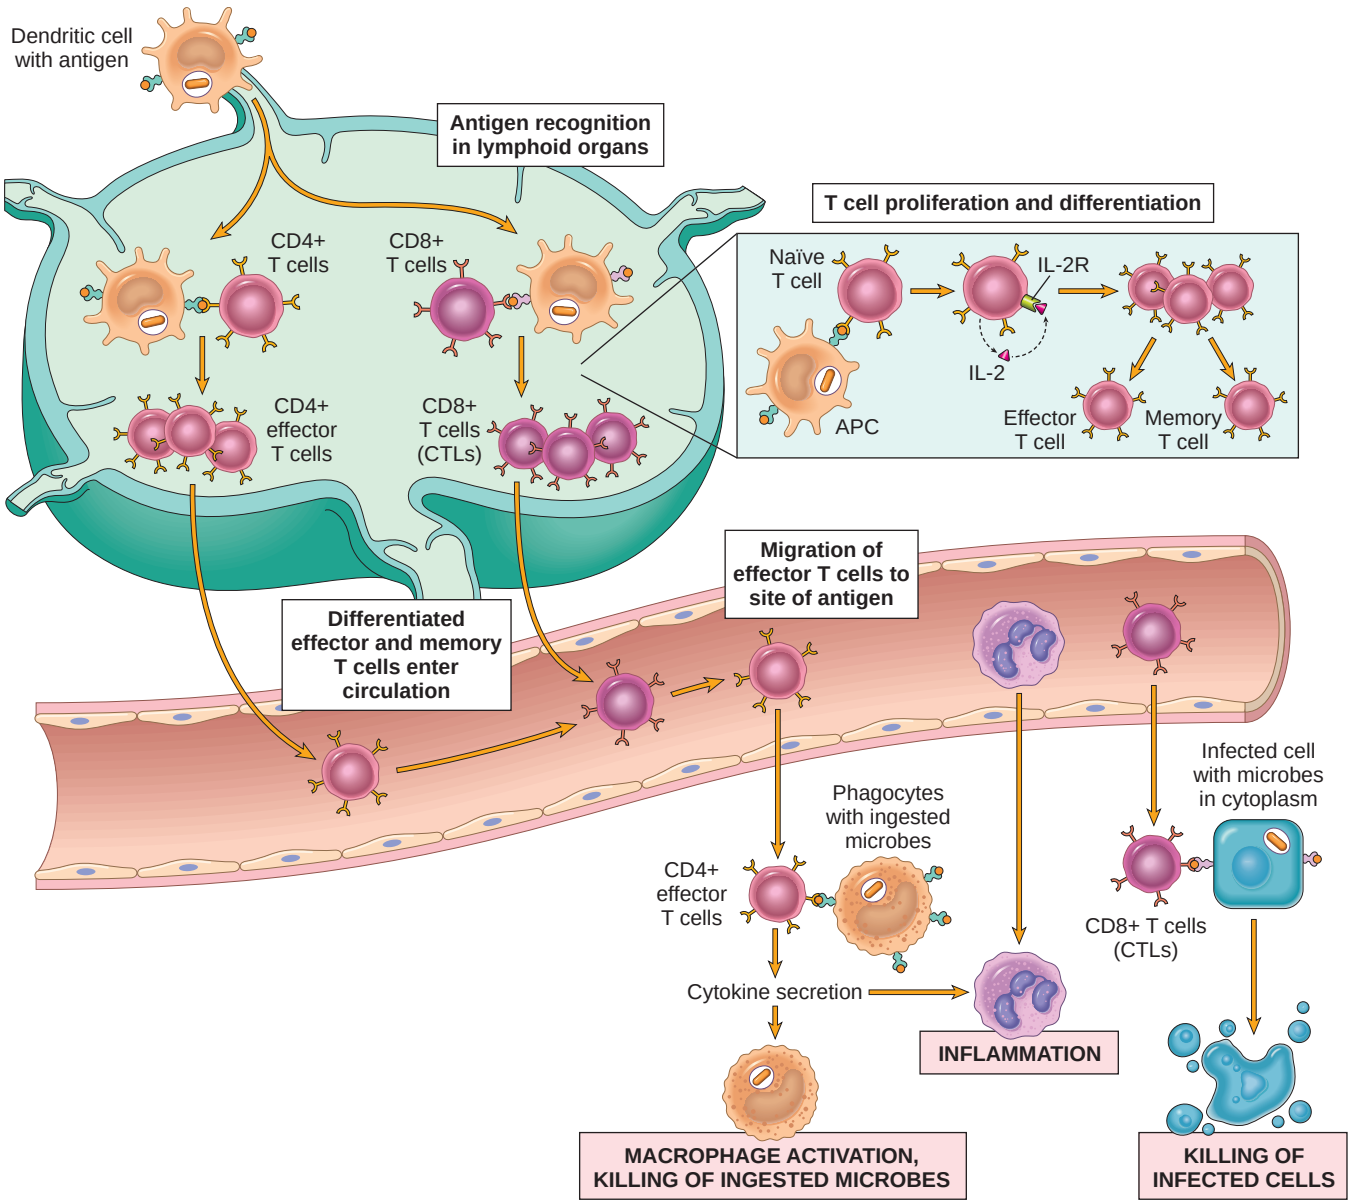

Figure 6.10 Cell-mediated immunity. Dendritic cells capture microbial antigens from epithelia and tissues and transport the antigens to lymph nodes. During this process, the dendritic cells mature, and express high levels of MHC molecules and costimulators. Naïve T cells recognize MHC-associated peptide antigens displayed on dendritic cells. The T cells are activated to proliferate and to differentiate into effector and memory cells, which migrate to sites of infection and serve various functions in cell-mediated immunity. CD4+ effector T cells of the Th1 subset recognize the antigens of microbes ingested by phagocytes and activate the phagocytes to kill the microbes; other subsets of effector cells enhance leukocyte recruitment and stimulate different types of immune responses. CD8+ cytotoxic T lymphocytes *(CTLs)* kill infected cells harboring microbes in the cytoplasm. Some activated T cells remain in the lymphoid organs and help B cells to produce antibodies, and some T cells differentiate into long-lived memory cells (not shown). *APC,* Antigen-presenting cell.

pathway of macrophage activation, which is associated with tissue repair and fibrosis (Chapter 3). Th17 cells, so called because the signature cytokine of these cells is IL-17, recruit neutrophils and monocytes, which destroy extracellular bacteria and fungi and are involved in some inflammatory diseases.

Activated CD8+ T lymphocytes differentiate into CTLs that kill cells harboring microbes in the cytoplasm. By destroying the infected cells, CTLs eliminate the reservoirs of infection. CTLs also kill tumor cells by recognizing tumor-specific antigens derived from mutated or abnormal cytoplasmic proteins.

Humoral Immunity: Activation of B Lymphocytes and Elimination of Extracellular Microbes

Upon activation, B lymphocytes proliferate and then differentiate into plasma cells that secrete different classes of antibodies with distinct functions (Fig. 6.12). Antibody responses to most protein antigens require T cell help and are said to be T-dependent. In these responses, B cells that recognize protein antigens by their Ig receptors endocytose these antigens into vesicles, degrade them, and display peptides bound to class II MHC molecules for recognition by helper T cells. The helper T cells are activated and express CD40L

	Th1	Th2	Th17
Cytokines produced	IFN-γ	IL-4, IL-5, IL-13	IL-17, IL-22
Cytokines that induce this subset	IFN-γ, IL-12	IL-4	TGF-β, IL-6, IL-1, IL-23
Immunological reactions triggered	Macrophage activation	Stimulation of IgE production, activation of mast cells and eosinophils	Recruitment of neutrophils, monocytes
Host defense against	Intracellular microbes	Helminthic parasites	Extracellular bacteria, fungi
Role in disease	Immune-mediated chronic inflammatory diseases (often autoimmune)	Allergies	Immune-mediated chronic inflammatory diseases (often autoimmune)

Figure 6.11 Subsets of helper T *(Th)* cells. In response to stimuli (mainly cytokines) present at the time of antigen recognition, naïve CD4+ T cells may differentiate into populations of effector cells that produce distinct sets of cytokines and perform different functions. The dominant immune reactions elicited by each subset, and its role in host defense and immunologic diseases, are summarized. These populations may be capable of converting from one to another. Some activated T cells produce multiple cytokines and do not fall into a distinct subset.

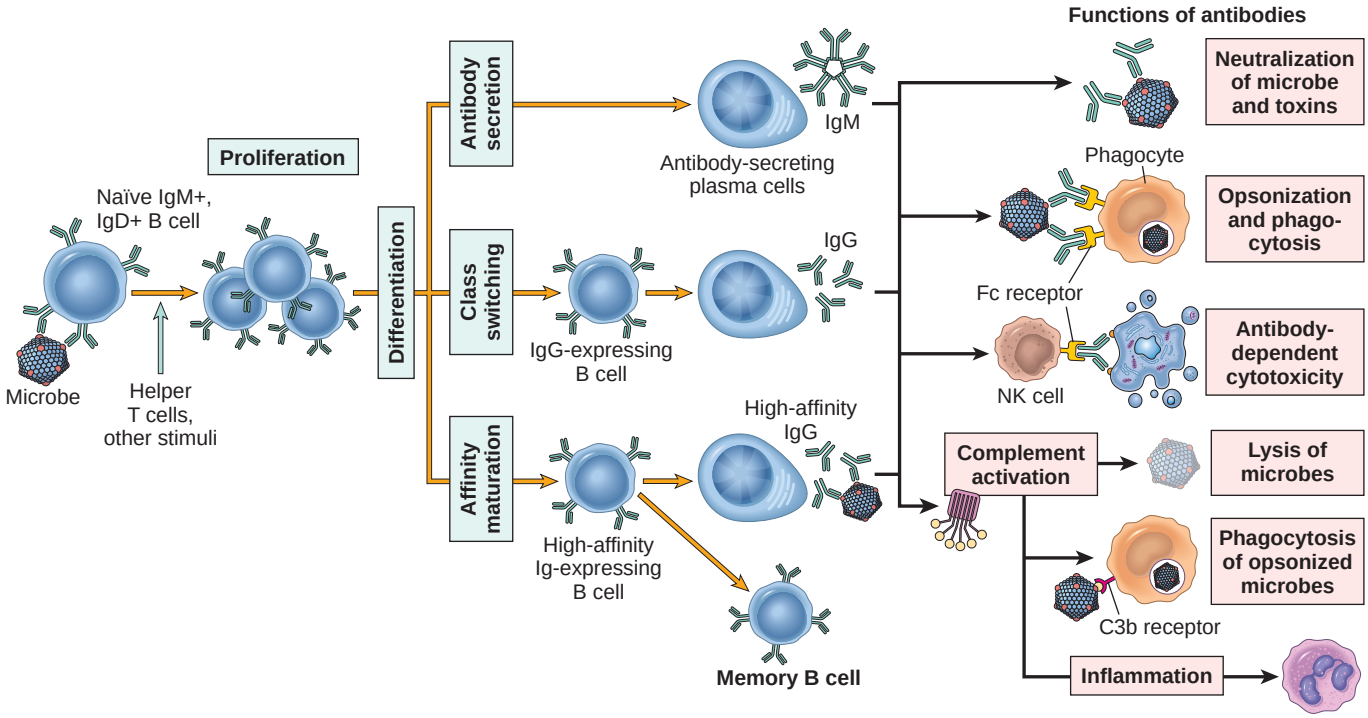

Figure 6.12 Humoral immunity. Naïve B lymphocytes recognize antigens, and under the influence of helper T cells and other stimuli *(not shown)*, the B cells are activated to proliferate and to differentiate into antibody-secreting plasma cells. Some of the activated B cells undergo heavy-chain class switching and affinity maturation, and some become long-lived memory cells. Antibodies of different heavy-chain classes (isotypes) perform different effector functions, shown on the right. Note that the antibodies shown are IgG; these and IgM activate complement; and the specialized functions of IgA (mucosal immunity) and IgE (mast cell and eosinophil activation) are not shown.

and secrete cytokines, which work together to stimulate the B cells. Many polysaccharide and lipid antigens cannot be recognized by T cells (because they cannot bind to MHC molecules) but have multiple identical antigenic determinants (epitopes) that are able to engage many antigen receptor molecules on each B cell and initiate the process of B-cell activation; these responses are said to be T-independent. T-independent responses are relatively simple, whereas T-dependent responses show features such as Ig isotype switching and affinity maturation (described later), which require T cell help and lead to responses that are more varied and effective.

Each plasma cell is derived from an antigen-stimulated B cell and secretes antibodies that recognize the same antigen that was bound by the BCR to initiate the response. Polysaccharides and lipids stimulate secretion mainly of IgM antibody. Protein antigens, by virtue of CD40L- and cytokine-mediated helper T-cell actions, induce the production of antibodies of different classes, or isotypes (IgG, IgA, IgE), a process called *isotype switching*. Helper T cells also stimulate the production of antibodies with high affinities for the antigen. This process, called *affinity maturation,* improves the quality of the humoral immune response. These two processes are initiated when activated B cells that receive signals from helper T cells during responses to protein antigens migrate into follicles and begin to proliferate to form germinal centers, which are the major sites of isotype switching and affinity maturation. The helper T-cells that stimulate these processes in B lymphocytes also migrate to and reside in the germinal centers and are called T follicular helper (TFH) cells.

The humoral immune response combats microbes in many ways (see Fig. 6.12). Antibodies bind to microbes and prevent them from infecting cells, thus neutralizing the microbes. IgG antibodies coat (opsonize) microbes and target them for phagocytosis, since phagocytes (neutrophils and macrophages) express receptors for the Fc tails of IgG. IgG and IgM activate the complement system by the classical pathway, and complement products promote phagocytosis and destruction of microbes. Some antibodies serve special roles at particular anatomic sites. IgA is secreted from mucosal epithelia and neutralizes microbes in the lumens of the respiratory and gastrointestinal tracts (and other mucosal tissues). IgG is actively transported across the placenta and protects the newborn until the immune system becomes mature. IgE and eosinophils cooperate to kill parasites, mainly by release of eosinophil granule contents that are toxic to the worms. As mentioned earlier, Th2 cytokines stimulate the production of IgE and activate eosinophils, and thus the response to helminths is orchestrated by Th2 cells.

Most circulating IgG antibodies have half-lives of about 3 weeks. Some antibody-secreting plasma cells, particularly those that are generated in germinal centers, migrate to the bone marrow and take up residence for months or even years, continuously producing antibodies during this time.

Decline of Immune Responses and Immunologic Memory

The majority of effector lymphocytes induced by an infectious pathogen die by apoptosis after the microbe is eliminated, thus returning the immune system to its resting state. The initial activation of lymphocytes also generates long-lived memory cells, which may survive for many years after the infection. Memory cells are an expanded pool of antigen-specific lymphocytes (more numerous than the naïve cells specific for any antigen that are present before encounter with that antigen), and they respond faster and more effectively when reexposed to the antigen than do naïve cells. Generation of memory cells underlies the effectiveness of vaccination.

KEY CONCEPTS

THE NORMAL IMMUNE RESPONSE: OVERVIEW OF CELLS, TISSUES, RECEPTORS, AND MEDIATORS

- The innate immune system uses several families of receptors (e.g., Toll-like receptors) to recognize molecules present in and shared by various types of microbes and produced by damaged cells.
- Lymphocytes are the mediators of adaptive immunity and the only cells that produce specific and diverse receptors for antigens.
- T (thymus-derived) lymphocytes express antigen receptors called TCRs that recognize peptide fragments of protein antigens that are displayed by MHC molecules on the surface of antigen-presenting cells.
- B (bone marrow–derived) lymphocytes express membrane-bound antibodies that recognize a wide variety of antigens. B cells are activated to become plasma cells, which secrete antibodies.
- NK cells destroy cells that are infected by some microbes, or are stressed and damaged beyond repair. NK cells express inhibitory receptors that recognize MHC molecules that are normally expressed on healthy cells, and are thus prevented from killing normal cells.
- Antigen-presenting cells (APCs) capture microbes and other antigens, transport them to secondary lymphoid organs, and display them for recognition by lymphocytes. The most efficient APCs are dendritic cells (DCs), which are present in epithelia and most other tissues.
- The cells of the immune system are organized in tissues, some of which are the sites of production of mature lymphocytes (the primary, or generative, lymphoid organs, the bone marrow and thymus), and others are the sites of immune responses (the secondary, or peripheral, lymphoid organs, including lymph nodes, spleen, and mucosal lymphoid tissues).
- The early reaction to microbes is mediated by the mechanisms of innate immunity, which are always ready to respond to microbes. These mechanisms include epithelial barriers, phagocytes, innate lymphoid cells (ILCs), NK cells, and certain plasma proteins (e.g., the complement system). Innate immune reactions often manifest as inflammation. Innate immunity, unlike adaptive immunity, does not have fine antigen specificity or memory.
- The defense reactions of adaptive immunity develop over several days, but are more potent and specialized.
- Microbes and other foreign antigens are captured by DCs and transported to lymph nodes, where the antigens are recognized by naïve lymphocytes. The lymphocytes are activated to proliferate and differentiate into effector and memory cells.
- Cell-mediated immunity is the reaction of T lymphocytes, designed to combat cell-associated microbes (e.g., phagocytosed microbes and microbes in the cytoplasm of infected cells). Humoral immunity is mediated by antibodies and is effective against extracellular microbes (in the circulation and mucosal lumens).
- CD4+ helper T cells help B cells to make antibodies, activate macrophages to destroy ingested microbes, stimulate recruitment

of leukocytes, and regulate all immune responses to protein antigens. The functions of CD4+ T cells are mediated by secreted proteins called cytokines. CD8+ cytotoxic T lymphocytes kill cells that express antigens in the cytoplasm that are seen as foreign (e.g., virus-infected and tumor cells) and can also produce cytokines.
- Antibodies secreted by plasma cells neutralize microbes and block their infectivity, and they promote the phagocytosis and destruction of pathogens. Antibodies also confer passive immunity to neonates.

The brief outline of basic immunology presented here provides a foundation for considering the diseases of the immune system. We first discuss the immune reactions that cause injury, called hypersensitivity reactions, and then disorders caused by the failure of tolerance to self antigens, called autoimmune disorders, and the rejection of transplants. This is followed by diseases caused by a defective immune system, called immunodeficiency diseases. We close with a consideration of amyloidosis, a disorder that is often associated with immune and inflammatory diseases.

HYPERSENSITIVITY: IMMUNOLOGICALLY MEDIATED TISSUE INJURY

Injurious immune reactions, called hypersensitivity, are responsible for the pathology associated with immunologic diseases. This term arose from the idea that individuals who have been previously exposed to an antigen manifest detectable reactions to that antigen and are therefore said to be sensitized. Hypersensitivity implies an excessive or harmful reaction to an antigen. There are several important general features of hypersensitivity disorders.

- Hypersensitivity reactions can be elicited by exogenous environmental antigens (microbial and nonmicrobial) or endogenous self antigens. Exogenous antigens include those in dust, pollen, food, drugs, microbes, and various chemicals. The immune responses against such exogenous antigens may take several forms, ranging from annoying but trivial discomforts, such as itching of the skin, to potentially fatal diseases, such as anaphylaxis. Some of the most common reactions to environmental antigens cause the group of diseases known as allergy. Immune responses against self, or autologous, antigens, cause autoimmune diseases.
- Hypersensitivity usually results from an imbalance between the effector mechanisms of immune responses and the control mechanisms that serve to limit such responses. In fact, in many hypersensitivity diseases, it is suspected that the underlying cause is a failure of normal regulation. We will return to this concept when we consider autoimmunity.
- The development of hypersensitivity diseases (both allergic and autoimmune) is often associated with the inheritance of particular susceptibility genes. HLA genes and many non-HLA genes have been implicated in different diseases; specific examples will be described in the context of the diseases.
- The mechanisms of tissue injury in hypersensitivity reactions are the same as the effector mechanisms of defense against infectious pathogens. The problem in hypersensitivity is that these reactions are poorly controlled, excessive, or misdirected (e.g., against normally harmless environmental and self antigens).

Classification of Hypersensitivity Reactions

Hypersensitivity reactions can be classified on the basis of the underlying immunologic mechanism (Table 6.1). This classification is of value in distinguishing the manner in which an immune response causes tissue injury and disease, and the accompanying pathologic and clinical manifestations. However, it is now increasingly recognized that multiple mechanisms may be operative in any one disease. The main types of hypersensitivity reactions are as follows:

- In *immediate hypersensitivity (type I hypersensitivity)*, the injury is caused by Th2 cells, IgE antibodies, and mast cells and other leukocytes. Mast cells release mediators

Table 6.1 Mechanisms of Hypersensitivity Reactions

Type	Immune Mechanisms	Histopathologic Lesions	Prototypical Disorders
Immediate (type I) hypersensitivity	Production of IgE antibody → immediate release of vasoactive amines and other mediators from mast cells; later recruitment of inflammatory cells	Vascular dilation, edema, smooth muscle contraction, mucus production, tissue injury, inflammation	Anaphylaxis; allergies; bronchial asthma (atopic forms)
Antibody-mediated (type II) hypersensitivity	Production of IgG, IgM → binds to antigen on target cell or tissue → phagocytosis or lysis of target cell by activated complement or Fc receptors; recruitment of leukocytes	Phagocytosis and lysis of cells; inflammation; in some diseases, functional derangements without cell or tissue injury	Autoimmune hemolytic anemia; Goodpasture syndrome
Immune complex–mediated (type III) hypersensitivity	Deposition of antigen-antibody complexes → complement activation → recruitment of leukocytes by complement products and Fc receptors → release of enzymes and other toxic molecules	Inflammation, necrotizing vasculitis (fibrinoid necrosis)	Systemic lupus erythematosus; some forms of glomerulonephritis; serum sickness; Arthus reaction
Cell-mediated (type IV) hypersensitivity	Activated T lymphocytes → (1) release of cytokines, inflammation and macrophage activation; (2) T cell–mediated cytotoxicity	Perivascular cellular infiltrates; edema; granuloma formation; cell destruction	Contact dermatitis; multiple sclerosis; type 1 diabetes; tuberculosis

Ig, Immunoglobulin.

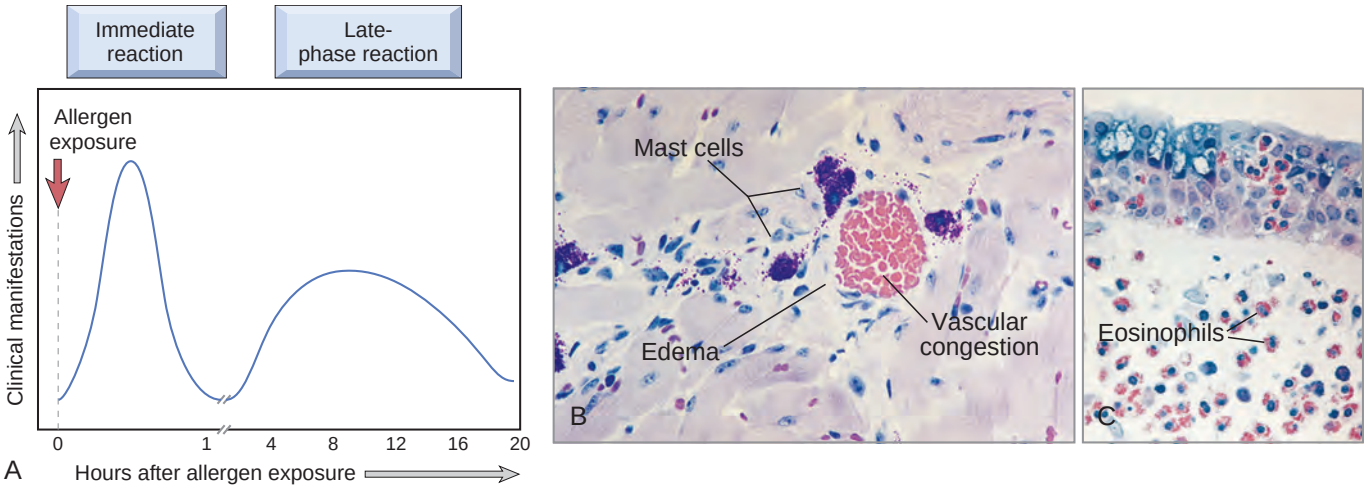

Figure 6.13 Phases of immediate hypersensitivity reactions. (A) Kinetics of the immediate and late-phase reactions. The immediate vascular and smooth muscle reaction to allergen develops within minutes after challenge (allergen exposure in a previously sensitized individual), and the late-phase reaction develops 2 to 24 hours later. The immediate reaction (B) is characterized by vasodilation, congestion, and edema, and the late-phase reaction (C) is characterized by an inflammatory infiltrate rich in eosinophils, neutrophils, and T cells. (Courtesy Dr. Daniel Friend, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

that act on vessels and smooth muscle and proinflammatory cytokines that recruit inflammatory cells.

- In *antibody-mediated disorders (type II hypersensitivity)*, secreted IgG and IgM antibodies injure cells by promoting their phagocytosis or lysis and injure tissues by inducing inflammation. Antibodies may also interfere with cellular functions and cause disease without tissue injury.
- In *immune complex–mediated disorders (type III hypersensitivity)*, IgG and IgM antibodies bind antigens usually in the circulation, and the antigen-antibody complexes deposit in tissues and induce inflammation. The leukocytes that are recruited (neutrophils and monocytes) produce tissue damage by release of lysosomal enzymes and generation of toxic free radicals.
- In *cell-mediated immune disorders (type IV hypersensitivity)*, T lymphocytes (Th1 and Th17 cells and CD8+ CTLs) are the cause of the tissue injury.

Immediate (Type I) Hypersensitivity

Immediate, or type I, hypersensitivity is a rapid immunologic reaction occurring in a previously sensitized individual that is triggered by the binding of an antigen to IgE antibody on the surface of mast cells. These reactions are often called *allergy,* and the antigens that elicit them are allergens. Immediate hypersensitivity may occur as a systemic disorder or as a local reaction. The systemic reaction most often follows injection of an antigen into a sensitized individual (e.g., by a bee sting), but can also follow antigen ingestion (e.g., peanut allergens). Sometimes, within minutes the patient goes into a state of shock, which may be fatal. Local reactions are diverse and vary depending on the portal of entry of the allergen. They may take the form of localized cutaneous rash or blisters (skin allergy, hives), nasal and conjunctival discharge (allergic rhinitis and conjunctivitis), hay fever, bronchial asthma, or allergic gastroenteritis (food allergy).

Many local type I hypersensitivity reactions have two well-defined phases (Fig. 6.13). The immediate reaction is characterized by vasodilation, vascular leakage, and, depending on the tissue, smooth muscle spasm or glandular secretions. These changes usually become evident within minutes after exposure to an allergen and tend to subside in a few hours. In many instances (e.g., allergic rhinitis and bronchial asthma), a second, late-phase reaction sets in 2 to 24 hours later without additional exposure to antigen and may last for several days. This late-phase reaction is characterized by infiltration of tissues with eosinophils, neutrophils, basophils, monocytes, and CD4+ T cells, as well as tissue destruction, typically in the form of mucosal epithelial cell damage.

Most immediate hypersensitivity disorders are caused by excessive Th2 responses, and these cells play a central role by stimulating IgE production and promoting inflammation. These Th2-mediated disorders show a characteristic sequence of events (Fig. 6.14), described next.

Activation of Th2 Cells and Production of IgE Antibody

The first step in the generation of Th2 cells is the presentation of the antigen to naïve CD4+ helper T cells, probably by DCs that capture the antigen from its site of entry. For reasons that are still not understood, only some environmental antigens elicit strong Th2 responses and thus serve as allergens. In response to antigen and other stimuli, including cytokines such as IL-4 produced at the local site, the T cells differentiate into Th2 cells. The newly minted Th2 cells produce a number of cytokines on subsequent encounter with the antigen; as mentioned earlier, the signature cytokines of this subset are IL-4, IL-5, and IL-13. IL-4 acts on B cells to stimulate class switching to IgE and promotes the development of additional Th2 cells. IL-5 is involved in the development and activation of eosinophils, which are important effectors of type I hypersensitivity (discussed later). IL-13 enhances IgE production and acts on epithelial cells to stimulate mucus secretion. In addition, Th2 cells (as well as mast cells and epithelial cells) produce chemokines that attract more Th2 cells, as well as other leukocytes, to the reaction site. Patients with chronic atopic diseases such as

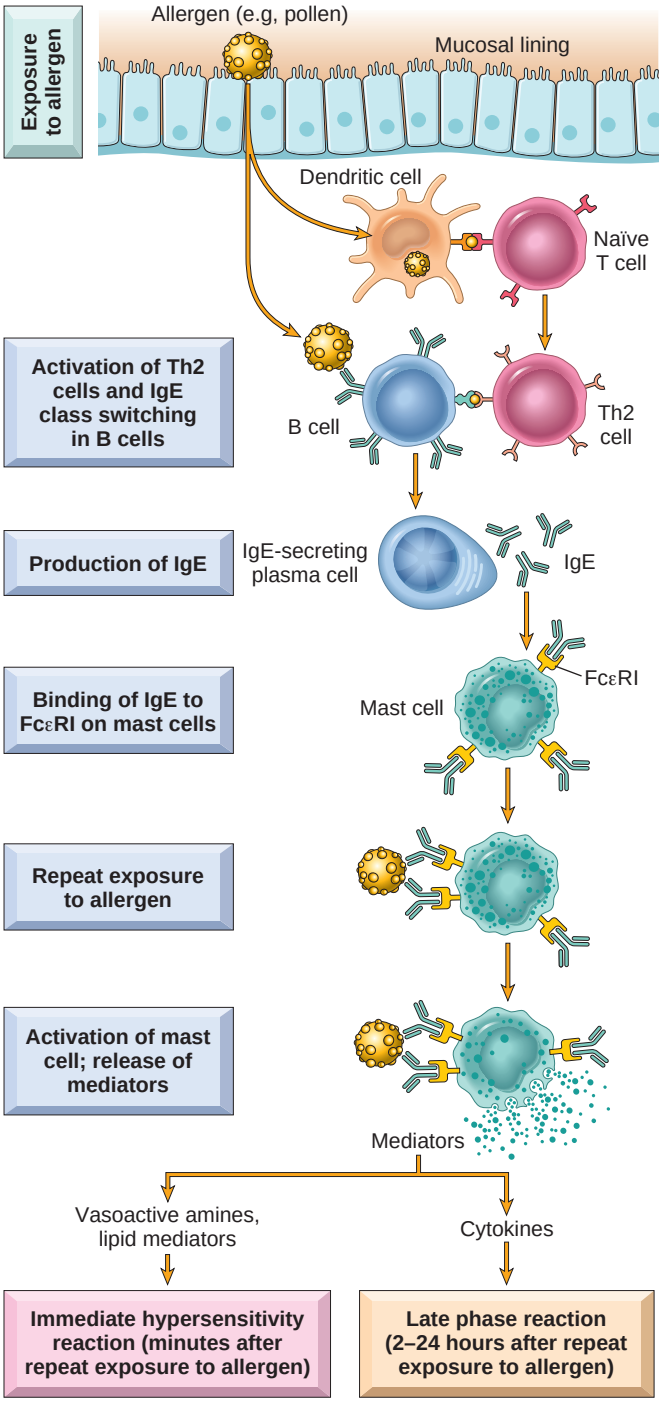

Figure 6.14 Sequence of events in immediate (type I) hypersensitivity. Immediate hypersensitivity reactions are initiated by the introduction of an allergen, which stimulates Th2 responses and IgE production in genetically susceptible individuals. IgE binds to Fc receptors (FcεRI) on mast cells, and subsequent exposure to the allergen activates the mast cells to secrete the mediators that are responsible for the pathologic manifestations of immediate hypersensitivity.

asthma and atopic dermatitis are sometimes classified into Th2-high and Th2-low based on biomarkers that reflect the intensity of the pathologic T-cell response in individual patients. This separation may serve as a guide to therapy, as antagonists of Th2 cytokines (IL-4, IL-5) are predictably most effective in the Th2-high group.

Before Th2 responses develop, type 2 ILCs in tissues may respond to cytokines produced by damaged epithelia. These ILCs secrete IL-5 and IL-13 and are thus able to induce the same tissue reactions as the classical Th2 cells. Over time, the Th2 cells become the dominant contributors to the local cytokine response.

Sensitization and Activation of Mast Cells

Because mast cells are central to the development of immediate hypersensitivity, we first review some of their salient characteristics. Mast cells are bone marrow–derived cells that are widely distributed in the tissues. They are abundant near small blood vessels and nerves and in subepithelial tissues, which explains why local immediate hypersensitivity reactions often occur at these sites. Mast cells have cytoplasmic membrane-bound granules that contain a variety of biologically active mediators, described later. The granules also contain acidic proteoglycans that bind basic dyes such as toluidine blue. (*Mast* in German refers to fattening of animals, and the name of these cells came from the erroneous belief that their granules fed the tissue where the cells were located.) As detailed next, mast cells (and their circulating counterpart, basophils) are activated by the cross-linking of high-affinity IgE Fc receptors; in addition, mast cells may also be triggered by several other stimuli, such as complement components C5a and C3a (called anaphylatoxins because they elicit reactions that mimic anaphylaxis), both of which act by binding to receptors on the mast cell membrane. Other mast cell secretagogues include some chemokines (e.g., IL-8), drugs such as codeine and morphine, adenosine, melittin (present in bee venom), and physical stimuli (e.g., heat, cold, sunlight). Basophils are similar to mast cells in many respects, including the presence of cell surface IgE Fc receptors as well as cytoplasmic granules. In contrast to mast cells, however, basophils are not normally present in tissues but rather circulate in the blood in small numbers. Similar to other granulocytes, basophils can be recruited to inflammatory sites.

When a mast cell armed with IgE antibodies previously produced in response to an antigen is exposed to the same antigen, the cell is activated, leading to the release of an arsenal of powerful mediators that are responsible for immediate hypersensitivity reactions. Mast cells and basophils express a high-affinity receptor called FcεRI that is specific for the Fc portion of IgE and avidly binds IgE antibodies. IgE-coated mast cells are said to be sensitized because they are activated by subsequent encounters with antigen. In the first step of activation, the antigen binds to the IgE antibodies on the mast cell surface. Multivalent antigens bind to and cross-link adjacent IgE antibodies, bringing the underlying Fcε receptors together. This triggers signal transduction pathways from the cytoplasmic portion of the receptors that lead to the release of preformed mediators and de novo production of mediators that are responsible for the initial, sometimes explosive, symptoms of immediate hypersensitivity, and they also set into motion the events that lead to the late-phase reaction.

Mediators of Immediate Hypersensitivity

Mast cell activation leads to degranulation, with the discharge of preformed mediators that are stored in the granules, and

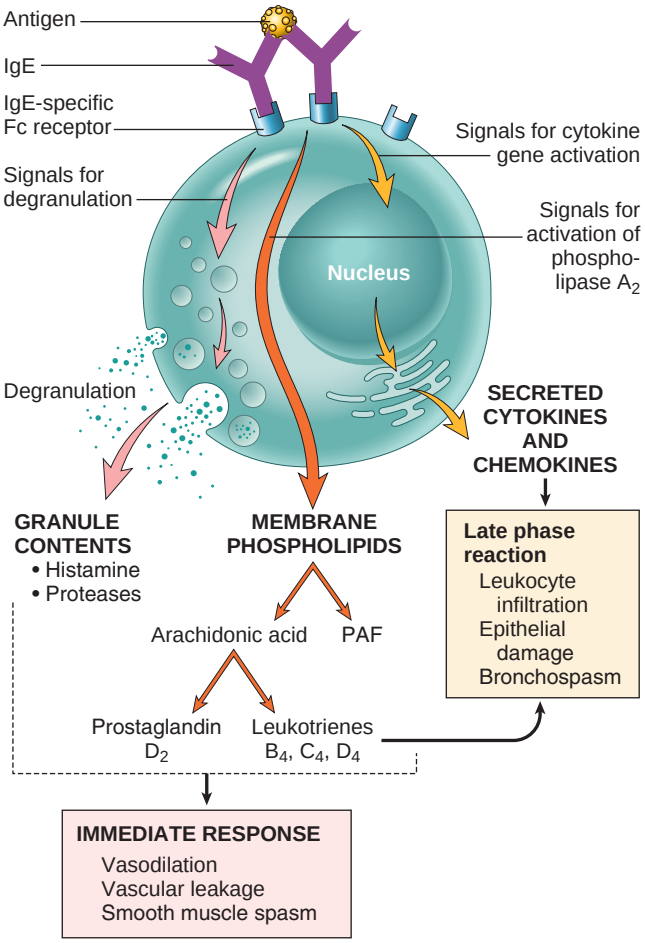

Figure 6.15 Mast cell mediators. On activation, mast cells release various classes of mediators that are responsible for the immediate and late-phase reactions. *PAF,* Platelet-activating factor.

de novo synthesis and release of additional mediators including lipid products and cytokines (Fig. 6.15).

Granule contents. Mediators contained within mast cell granules are the first to be released and can be divided into three categories:

- *Vasoactive amines*. The most important mast cell–derived amine is *histamine* (Chapter 3). Histamine causes intense smooth muscle contraction, increases vascular permeability, and stimulates mucus secretion by nasal, bronchial, and gastric glands.
- *Enzymes.* These are contained in the granule matrix and include neutral proteases (chymase, tryptase) and several acid hydrolases. The enzymes cause tissue damage and lead to the generation of kinins and activated components of complement (e.g., C3a) by acting on their precursor proteins.
- *Proteoglycans.* These include heparin, a well-known anticoagulant, and chondroitin sulfate. The proteoglycans serve to package and store the amines in the granules.

Lipid mediators. The major lipid mediators are arachidonic acid–derived products (Chapter 3). Mast cell activation is associated with activation of phospholipase A_2, an enzyme that converts membrane phospholipids to arachidonic acid. This is the parent compound from which leukotrienes and prostaglandins are produced by the 5-lipoxygenase and the cyclooxygenase pathways, respectively.

- *Leukotrienes.* Leukotrienes C_4 and D_4 are the most potent vasoactive and spasmogenic agents known. On a molar basis, they are several thousand times more active than histamine in increasing vascular permeability and causing bronchial smooth muscle contraction. Leukotriene B_4 is highly chemotactic for neutrophils, eosinophils, and monocytes.
- *Prostaglandin D_2.* This is the most abundant mediator produced in mast cells by the cyclooxygenase pathway. It causes intense bronchospasm and increases mucus secretion.
- *Platelet-activating factor (PAF).* PAF (Chapter 3) is a lipid mediator produced by some mast cell populations that is not derived from arachidonic acid. It causes platelet aggregation, histamine release, bronchospasm, increased vascular permeability, and vasodilation. Its role in immediate hypersensitivity reactions is not well established.

Cytokines. Mast cells are sources of many cytokines, which may play an important role at several stages of immediate hypersensitivity reactions. The cytokines include: TNF, IL-1, and chemokines, which promote leukocyte recruitment (typical of the late-phase reaction); IL-4, which amplifies the Th2 response; and numerous others. The inflammatory cells that are recruited by mast cell–derived TNF and chemokines are additional sources of cytokines.

The mediators produced by mast cells are responsible for most of the manifestations of immediate hypersensitivity reactions. Some, such as histamine and leukotrienes, are released rapidly from sensitized mast cells and trigger the intense immediate reactions characterized by edema, mucus secretion, and smooth muscle spasm; others, exemplified by cytokines, including chemokines, set the stage for the late-phase response by recruiting additional leukocytes. Not only do these inflammatory cells release additional waves of mediators (including cytokines), but they also cause epithelial cell damage. Epithelial cells themselves are not passive bystanders in this reaction; they can also produce soluble mediators, such as chemokines.

Late-Phase Reaction

In the late-phase reaction, leukocytes are recruited that amplify and sustain the inflammatory response without additional exposure to the triggering antigen. *Eosinophils* are often an abundant leukocyte population in these reactions (see Fig. 6.13C). They are recruited to sites of immediate hypersensitivity by chemokines, such as eotaxin, and others that may be produced by epithelial cells, Th2 cells, and mast cells. The Th2 cytokine IL-5 is the most potent eosinophil-activating cytokine known. Upon activation, eosinophils liberate proteolytic enzymes as well as two unique proteins called major basic protein and eosinophil cationic protein, which damage tissues. Eosniophils contain crystals called Charcot-Leyden crystals composed of the protein galectin-10, which are sometimes released into the extracellular space and can be detected in the sputum of patients with asthma. These crystals promote inflammation and enhance Th2 responses, so they may contribute to allergic reactions. It is now believed that the late-phase reaction is a major cause of symptoms in some type I hypersensitivity disorders, such as allergic asthma. Therefore, treatment of these diseases

requires the use of broad-spectrum antiinflammatory drugs, such as steroids, rather than antihistamine drugs, which are of benefit only in the immediate reaction as occurs in allergic rhinitis (hay fever).

Development of Allergies

Susceptibility to immediate hypersensitivity reactions is genetically determined. A propensity to develop immediate hypersensitivity reactions is called *atopy*. Atopic individuals tend to have higher serum IgE levels and more IL-4–producing Th2 cells than does the general population. A positive family history of allergy is found in 50% of atopic individuals. The basis of familial predisposition is not clear, but studies in patients with asthma reveal linkage to polymorphisms in several genes encoding cytokines with important roles in allergic reaction, including the genes for the cytokines IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF. How the disease-associated polymorphisms influence the development of allergies is not known. Linkage has also been noted to polymorphisms lying within the HLA genes located on chromosome 6, suggesting that the inheritance of certain HLA alleles permits reactivity to certain allergens.

Environmental factors are also important in the development of allergic diseases. Exposure to environmental pollutants, which is common in industrialized societies, is an important predisposing factor for allergy. For example, dogs and cats diverged from humans about 95 million years ago and are genetically distant from humans compared with chimpanzees, which diverged only about 4 to 5 million years ago and are >95% identical to humans genetically; yet dogs and cats, who live in the same environment as humans, develop allergies, and chimps do not. This observation suggests that environmental factors may be more important in the development of allergic disease than genetics. Viral infections of the airways are triggers for bronchial asthma, an allergic disease affecting the lungs (Chapter 15).

It is estimated that 20% to 30% of immediate hypersensitivity reactions are triggered by non-antigenic stimuli such as temperature extremes and exercise, and do not involve Th2 cells or IgE; such reactions are sometimes called *nonatopic allergy*. It is believed that in these cases mast cells are abnormally sensitive to activation by various nonimmune stimuli.

The incidence of many allergic diseases has increased in high income countries, as populations have urbanized and exposure to the natural environment has diminished. These observations have led to an idea, sometimes called the *hygiene hypothesis,* that early childhood and even prenatal exposure to microbial antigens "educates" the immune system in such a way that subsequent pathologic responses against common environmental allergens are prevented. Thus, paradoxically, improved hygiene in early childhood may increase allergies later in life. This hypothesis, however, is difficult to prove, and the underlying mechanisms are not defined.

With this consideration of the basic mechanisms of type I hypersensitivity, we turn to some clinically important examples of IgE-mediated disease. These reactions can lead to a wide spectrum of injury and clinical manifestations (Table 6.2).

Table 6.2 Examples of Disorders Caused by Immediate Hypersensitivity

Clinical Syndrome	Clinical and Pathologic Manifestations
Anaphylaxis (may be caused by drugs, bee sting, food)	Fall in blood pressure (shock) caused by vascular dilation; airway obstruction due to laryngeal edema
Bronchial asthma	Airway obstruction caused by bronchial smooth muscle hyperactivity; inflammation and tissue injury caused by late-phase reaction
Allergic rhinitis, sinusitis (hay fever)	Increased mucus secretion; inflammation of upper airways, sinuses
Food allergies	Increased peristalsis due to contraction of intestinal muscles

Systemic Anaphylaxis

Systemic anaphylaxis is characterized by vascular shock, widespread edema, and difficulty in breathing. It may occur in sensitized individuals in hospital settings after administration of foreign proteins (e.g., antisera), hormones, enzymes, polysaccharides, and drugs (e.g., the antibiotic penicillin), or in the community setting following exposure to food allergens (e.g., peanuts, shellfish) or insect toxins (e.g., those in bee venom). Extremely small doses of antigen may trigger anaphylaxis, for example, the tiny amounts used in skin testing for allergies. Because of the risk of severe allergic reactions to minute quantities of peanuts in confined quarters, commercial airlines have largely stopped serving peanuts or foods containing peanuts. Within minutes after exposure to allergens, itching, hives, and skin erythema appear, followed shortly thereafter by a striking contraction of pulmonary bronchioles and respiratory distress. Laryngeal edema results in hoarseness and further compromises breathing. Vomiting, abdominal cramps, diarrhea, and laryngeal obstruction follow, and the patient may go into shock and even die within the hour. The risk of anaphylaxis must be borne in mind when certain therapeutic agents are administered. Although patients at risk often have a previous history of some form of allergy, the absence of such a history does not preclude the possibility of an anaphylactic reaction.

Local Immediate Hypersensitivity Reactions

About 10% to 20% of the population suffers from allergies involving localized reactions to common environmental allergens, such as pollen, animal dander, house dust, foods, and the like. Specific diseases include urticaria, allergic rhinitis (hay fever), bronchial asthma, atopic dermatitis, and food allergies; these are discussed elsewhere in this text.

KEY CONCEPTS

IMMEDIATE (TYPE I) HYPERSENSITIVITY

- These are also called allergic reactions, or allergies.
- They are induced by environmental antigens (allergens) that stimulate strong Th2 responses and IgE production in genetically susceptible individuals.
- IgE attaches to mast cells by binding to Fcε receptors; reexposure to the allergen leads to cross-linking of the IgE and FcεRI, activation of mast cells, and release of mediators.
- The principal mediators are histamine, proteases, and other granule contents; prostaglandins and leukotrienes; and cytokines.

- The mediators are responsible for the immediate vascular and smooth muscle reactions and the late-phase reaction (inflammation).
- The clinical manifestations may be local or systemic, and range from mildly annoying rhinitis to fatal anaphylaxis.

Antibody-Mediated (Type II) Hypersensitivity

Antibodies that react with antigens present on cell surfaces or in the extracellular matrix cause disease by destroying these cells, triggering inflammation, or interfering with normal functions. The antibodies may be specific for normal cell or tissue antigens (autoantibodies) or for exogenous antigens, such as chemical or microbial proteins, that bind to a cell surface or tissue matrix. The antibody-dependent mechanisms that cause tissue injury and disease are illustrated in Fig. 6.16 and described next. These reactions are the cause of several important diseases (Table 6.3).

Opsonization and Phagocytosis

Phagocytosis is largely responsible for depletion of cells coated with antibodies. Cells opsonized by IgG antibodies are recognized by phagocyte Fc receptors, which are specific for the Fc portions of some IgG subclasses. In addition, when IgM or IgG antibodies are deposited on the surfaces of cells, they may activate the complement system by the classical pathway. Complement activation generates cleavage products of C3, mainly C3b and C4b, which are deposited on the surfaces of the cells and recognized by phagocytes that express receptors for these proteins. The net result is phagocytosis of the opsonized cells and their destruction inside the phagocytes (see Fig. 6.16A). Complement activation on cells also leads to the formation of the membrane attack complex, which disrupts membrane integrity by "drilling holes" through the lipid bilayer, thereby causing osmotic lysis of the cells. This mechanism is probably effective in destroying only cells and microbes with thin cell walls.

Antibody-mediated destruction of cells also may occur by another process called antibody-dependent cellular

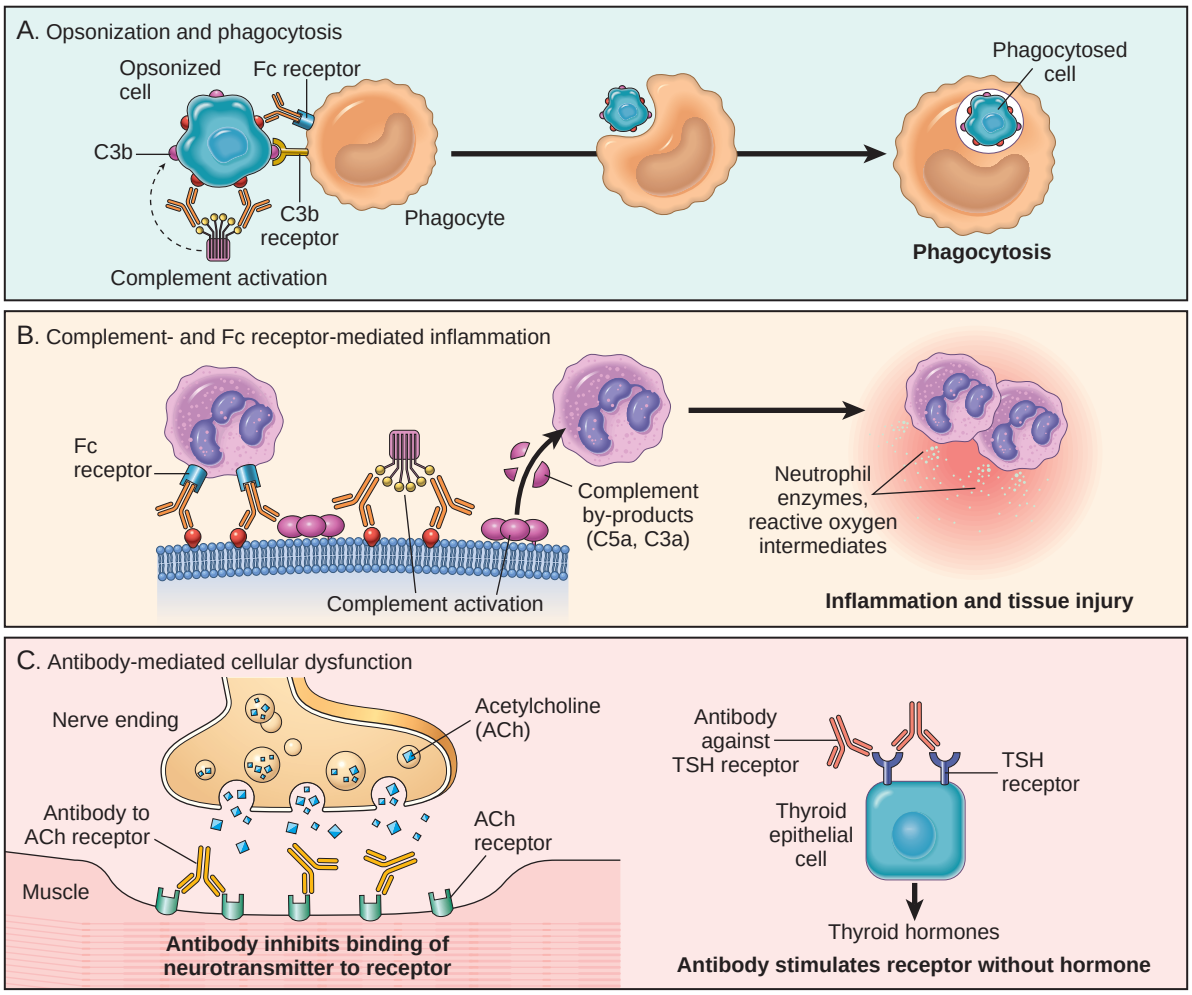

Figure 6.16 Mechanisms of antibody-mediated injury. (A) Opsonization of cells by antibodies and complement components and ingestion by phagocytes. (B) Inflammation induced by antibody binding to Fc receptors of leukocytes and by complement breakdown products. (C) Antireceptor antibodies disturb the normal function of receptors. In these examples, antibodies to the acetylcholine *(ACh)* receptor impair neuromuscular transmission in myasthenia gravis, and antibodies against the thyroid-stimulating hormone *(TSH)* receptor activate thyroid cells in Graves disease.

Table 6.3 Examples of Antibody-Mediated Diseases (Type II Hypersensitivity)

Disease	Target Antigen	Mechanisms of Disease	Clinicopathologic Manifestations
Autoimmune hemolytic anemia	Red cell membrane proteins (Rh blood group antigens, I antigen)	Opsonization and phagocytosis of red cells	Hemolysis, anemia
Autoimmune thrombocytopenic purpura	Platelet membrane proteins (GpIIb:IIIa integrin)	Opsonization and phagocytosis of platelets	Bleeding
Pemphigus vulgaris	Proteins in intercellular junctions of epidermal cells (desmogleins)	Antibody-mediated activation of proteases, disruption of intercellular adhesions	Skin vesicles (bullae)
Vasculitis caused by ANCA	Neutrophil granule proteins, presumably released from activated neutrophils	Neutrophil degranulation and inflammation	Vasculitis
Goodpasture syndrome	Noncollagenous protein in basement membranes of kidney glomeruli and lung alveoli	Complement- and Fc receptor–mediated inflammation	Nephritis, lung hemorrhage
Acute rheumatic fever	Streptococcal cell wall antigen; antibody cross-reacts with myocardial antigen	Inflammation, macrophage activation	Myocarditis, arthritis
Myasthenia gravis	Acetylcholine receptor	Antibody inhibits acetylcholine binding, down-modulates receptors	Muscle weakness, paralysis
Graves disease (hyperthyroidism)	TSH receptor	Antibody-mediated stimulation of TSH receptors	Hyperthyroidism
Pernicious anemia	Intrinsic factor of gastric parietal cells	Neutralization of intrinsic factor, decreased absorption of vitamin B_{12}	Abnormal erythropoiesis, anemia

ANCA, Antineutrophil cytoplasmic antibodies; *TSH*, thyroid-stimulating hormone.

cytotoxicity (ADCC). Cells that are coated with IgG antibody are killed by effector cells, mainly NK cells and macrophages, which bind to the target by their receptors for the Fc fragment of IgG, and cell lysis proceeds without phagocytosis. The contribution of ADCC to common hypersensitivity diseases is uncertain.

Clinically, antibody-mediated cell destruction and phagocytosis occur in the following situations: (1) transfusion reactions, in which cells from a blood group mismatched donor react with and are opsonized by preformed antibody in the host (Chapter 14); (2) hemolytic disease of the fetus and newborn (erythroblastosis fetalis), in which there is an antigenic difference between the mother and the fetus, and IgG anti-erythrocyte antibodies from the mother cross the placenta and cause destruction of fetal red cells (Chapter 10); (3) autoimmune hemolytic anemia, agranulocytosis, and thrombocytopenia, in which individuals produce antibodies to their own blood cells, which are then destroyed (Chapter 14); and (4) certain drug reactions. In some cases of drug-induced antibody-mediated destruction of blood cells, the drug binds to plasma membrane proteins on host cells, and antibodies are produced against the drug-protein complex. In other instances, the offending drug modifies the conformation of an antigen, generating new antigenic epitopes against which the individual reacts.

Inflammation

When antibodies deposit in fixed tissues, such as basement membranes and extracellular matrix, the resultant injury is due to inflammation. The deposited antibodies activate complement, generating cleavage products, including chemotactic agents (mainly C5a), which direct the migration of granulocytes and monocytes, and anaphylatoxins (C3a and C5a), which increase vascular permeability (see Fig. 6.16B). The leukocytes are activated by engagement of their C3b and Fc receptors. This results in the release of substances from the leukocytes that damage tissues, such as lysosomal enzymes, including proteases capable of digesting basement membrane, collagen, elastin, and cartilage, and by generation of reactive oxygen species.

Antibody-mediated inflammation is the mechanism responsible for tissue injury in some forms of glomerulonephritis, vascular rejection in organ grafts, and numerous other disorders (see Table 6.3).

Cellular Dysfunction

In some cases, antibodies directed against cell surface receptors impair or dysregulate function without causing cell injury or inflammation (see Fig. 6.16C). For example, in myasthenia gravis, antibodies reactive with acetylcholine receptors in the motor end plates of skeletal muscles block neuromuscular transmission and therefore cause muscle weakness. The converse (i.e., antibody-mediated stimulation of cell function) is the basis of Graves disease. In this disorder, antibodies against the thyroid-stimulating hormone receptor on thyroid epithelial cells stimulate the cells, resulting in hyperthyroidism.

Immune Complex–Mediated (Type III) Hypersensitivity

Antigen-antibody complexes produce tissue damage mainly by eliciting inflammation at the sites of deposition. The pathologic reaction is usually initiated when antigen combines

Table 6.4 Examples of Immune Complex–Mediated Diseases

Disease	Antigen Involved	Clinicopathologic Manifestations
Systemic lupus erythematosus	Nuclear antigens	Nephritis, skin lesions, arthritis, others
Poststreptococcal glomerulonephritis	Streptococcal cell wall antigen(s); may be "planted" in glomerular basement membrane	Nephritis
Polyarteritis nodosa	Hepatitis B virus antigens in some cases	Systemic vasculitis
Reactive arthritis	Bacterial antigens (e.g., *Yersinia*)	Acute arthritis
Serum sickness	Various proteins, e.g., foreign serum protein (horse antithymocyte globulin)	Arthritis, vasculitis, nephritis
Arthus reaction (experimental)	Various foreign proteins	Cutaneous vasculitis

with antibody in the circulation, creating immune complexes that typically deposit in vessel walls. Less frequently, the complexes may be formed at sites where antigen has been "planted" previously (called in situ immune complexes). The antigens that form immune complexes may be exogenous, such as a foreign protein that is injected or produced by an infectious microbe, or endogenous, if the individual produces antibody against self antigens (autoimmunity). Examples of immune complex disorders and the antigens involved are listed in Table 6.4. Immune complex–mediated diseases tend be systemic, but often preferentially involve the kidney (glomerulonephritis), joints (arthritis), and small blood vessels (vasculitis), all of which are common sites of immune complex deposition for reasons mentioned below.

Systemic Immune Complex Disease

Serum sickness is the prototype of a systemic immune complex disease; it was once a frequent sequela to the administration of large amounts of foreign serum (e.g., serum from immunized horses used for protection against diphtheria). In modern times, the disease is infrequent and usually seen in individuals who receive antibodies from other individuals or species. Nevertheless, it is an informative model that has taught us a great deal about systemic immune complex disorders.

The pathogenesis of systemic immune complex disease can be divided into three phases (Fig. 6.17).

1. *Formation of immune complexes.* The introduction of a protein antigen triggers an immune response that results in the formation of antibodies, typically about 1 week after the injection of the protein. These antibodies are secreted into the blood, where they react with the antigen still present in the circulation and form antigen-antibody complexes.
2. *Deposition of immune complexes.* In the next phase, the circulating antigen-antibody complexes are deposited in vessels. The factors that determine whether immune complex formation will lead to tissue deposition and disease are not fully understood, but the major influences seem to be the characteristics of the complexes and local vascular alterations. In general, complexes that are of medium size, formed under conditions of slight antigen excess, are the most pathogenic. Organs where blood is filtered at high pressure to form other fluids, like urine and synovial fluid, are sites where immune complexes become concentrated and tend to deposit; hence, immune complex disease often affects glomeruli and joints.

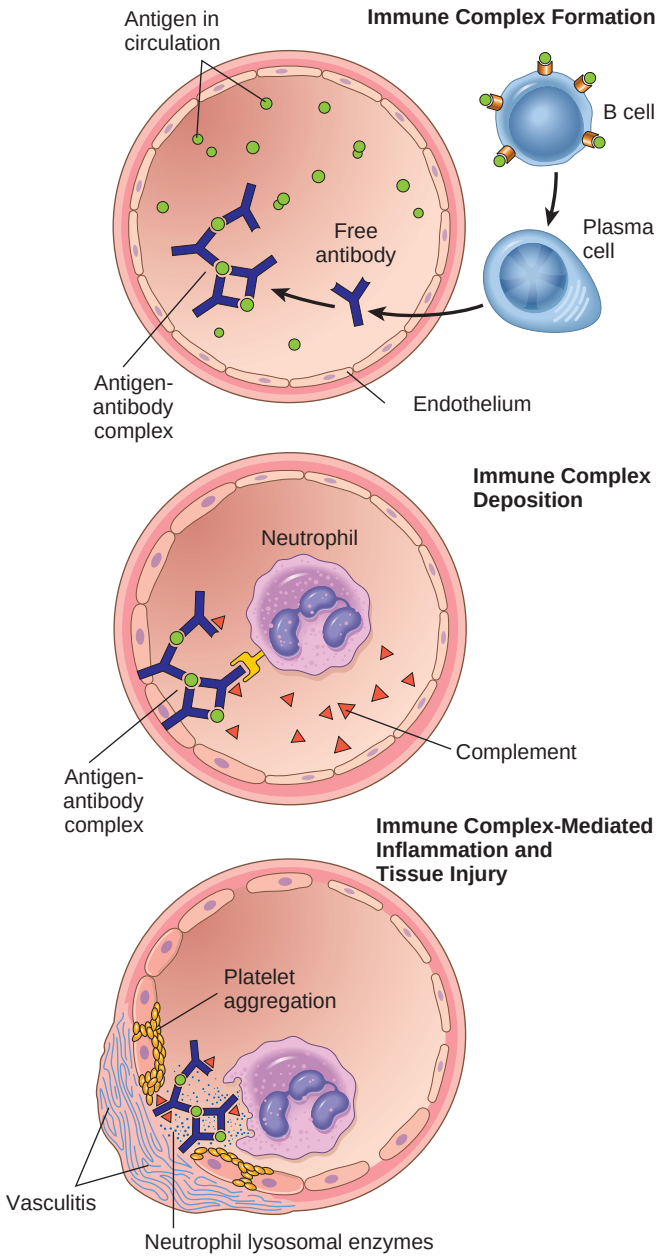

Figure 6.17 Immune complex disease. The sequential phases in the induction of systemic immune complex–mediated diseases (type III hypersensitivity).

3. *Inflammation and tissue injury.* Once immune complexes are deposited in the tissues, they initiate an acute inflammatory reaction. During this phase (approximately 10 days after antigen administration), clinical features such as fever, urticaria, joint pain, lymph node enlargement, and proteinuria appear. Wherever complexes deposit, inflammation and tissue injury occur through the antibody-mediated mechanisms that were discussed earlier. The important role of complement in the pathogenesis of the tissue injury is supported by the observations that complement proteins can be detected at the site of injury and, during the active phase of the disease, consumption of complement leads to a decrease in serum levels of C3. In fact, serum C3 levels can, in some cases, be used to monitor disease activity.

MORPHOLOGY

The principal morphologic manifestation of immune complex injury is acute vasculitis, associated with necrosis of the vessel wall and intense neutrophilic infiltration. The necrotic tissue and deposits of immune complexes, complement, and plasma protein appear as a smudgy eosinophilic area of tissue destruction, an appearance termed **fibrinoid necrosis** (see Fig. 2.15). When deposited in the kidney, the complexes can be seen on immunofluorescence microscopy as granular lumpy deposits of immunoglobulin and complement and on electron microscopy as electron-dense deposits along the glomerular basement membrane (see Figs. 6.31 and 6.32).

In *acute serum sickness*, caused by a single exposure to a large amount of antigen, the lesions tend to resolve as a result of catabolism of the immune complexes. A form of *chronic serum sickness* results from repeated or prolonged exposure to an antigen. This occurs in several diseases, such as systemic lupus erythematosus (SLE), which is associated with persistent antibody responses to autoantigens. In many diseases, the morphologic changes and other findings suggest immune complex deposition, but the inciting antigens are unknown. Included in this category are membranous glomerulonephritis and several vasculitides.

Local Immune Complex Disease

The *Arthus reaction* is a localized area of tissue necrosis resulting from acute immune complex vasculitis, usually elicited in the skin. The reaction can be produced experimentally by intracutaneous injection of antigen in a previously immunized animal that contains circulating antibodies against the antigen. As the antigen diffuses into the vascular wall, it binds the preformed antibody, and large immune complexes are formed locally. These complexes precipitate in the vessel walls and cause fibrinoid necrosis, and superimposed thrombosis worsens the ischemic injury.

KEY CONCEPTS

PATHOGENESIS OF DISEASES CAUSED BY ANTIBODIES AND IMMUNE COMPLEXES

- Antibodies can coat (opsonize) cells, with or without complement proteins, and target these cells for phagocytosis by phagocytes (macrophages), which express receptors for the Fc tails of IgG and for complement proteins. The result is depletion of the opsonized cells.
- Antibodies and immune complexes may deposit in tissues or blood vessels and elicit an acute inflammatory reaction by activating complement, with release of breakdown products, or by engaging Fc receptors of leukocytes. The inflammatory reaction causes tissue injury.
- Antibodies can bind to cell surface receptors or other essential molecules and cause functional derangements (either inhibition or unregulated activation) without cell injury.

T Cell–Mediated (Type IV) Hypersensitivity

Cell-mediated hypersensitivity is caused mainly by inflammation resulting from cytokines produced by CD4+ T cells (Fig. 6.18). CD4+ T cell–mediated hypersensitivity induced by environmental and self antigens is the cause of many autoimmune and other chronic inflammatory diseases (Table 6.5). Cell killing by CD8+ cells may also be involved in some autoimmune diseases and may be the dominant mechanism of tissue injury in certain reactions, especially those that follow viral infections.

CD4+ T Cell–Mediated Inflammation

In CD4+ T cell–mediated hypersensitivity reactions, cytokines produced by T cells induce inflammation that may be chronic and destructive. The prototype of T cell–mediated inflammation is *delayed-type hypersensitivity (DTH),* a tissue reaction to antigens given to immune individuals. In this reaction, an antigen administered into the skin of a previously immunized individual results in a detectable cutaneous reaction within 24 to 48 hours (hence the term delayed, in contrast to immediate hypersensitivity). Both Th1 and Th17 cells contribute to organ-specific diseases in which inflammation is a prominent aspect of the pathology. The inflammatory reaction associated with Th1 cells is dominated by activated macrophages, and that triggered by Th17 cells has a greater neutrophil component.

The inflammatory reactions stimulated by CD4+ T cells can be divided into sequential stages.

Activation of CD4+ T Cells

As described earlier, naïve CD4+ T cells recognize peptides displayed by DCs and secrete IL-2, which functions as an autocrine growth factor to stimulate proliferation of the antigen-responsive T cells. The subsequent differentiation of antigen-stimulated T cells to Th1 or Th17 cells is driven by the cytokines produced by APCs at the time of T-cell activation. In some situations, the APCs (DCs and macrophages) produce IL-12, which induces differentiation of CD4+ T cells to the Th1 subset. IFN-γ produced by these effector cells promotes further Th1 development, thus amplifying the reaction. If the APCs produce the inflammatory cytokines IL-1, IL-6, and a close relative of IL-12 called IL-23, the T cells are induced to differentiate to the Th17 subset. Some of the differentiated effector cells enter the circulation and join the pool of memory T cells, where they persist for long periods, sometimes years.

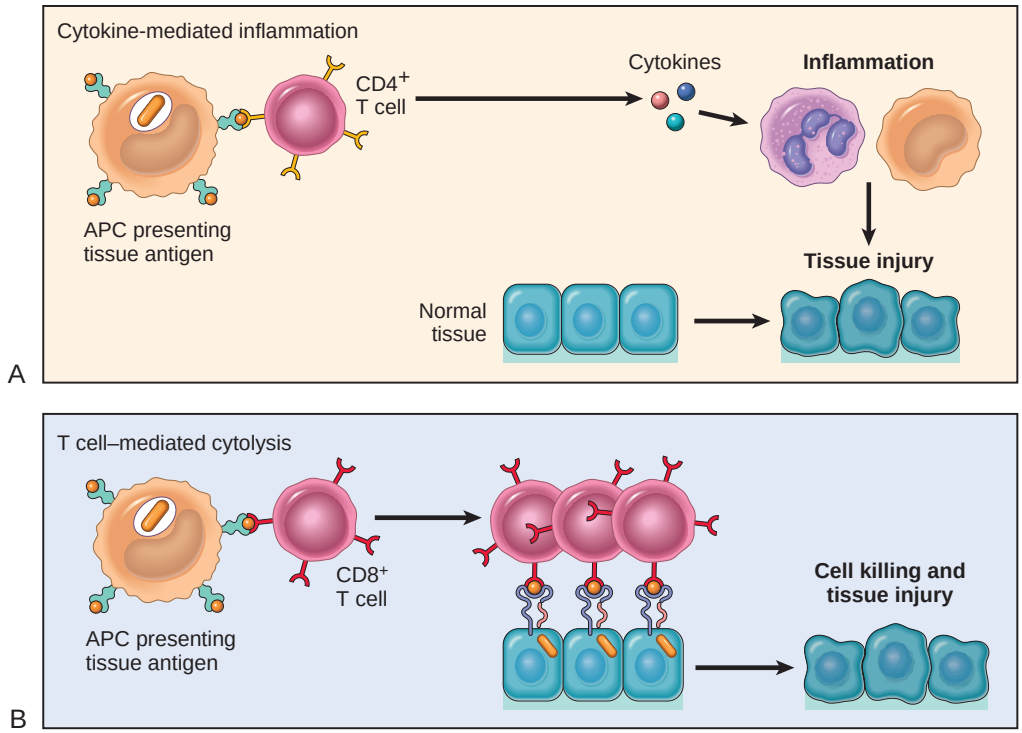

Figure 6.18 Mechanisms of T-cell–mediated (type IV) hypersensitivity reactions. (A) CD4+ Th1 cells (and sometimes CD8+ T cells, *not shown*) respond to tissue antigens by secreting cytokines that stimulate inflammation and activate phagocytes, leading to tissue injury. CD4+ Th17 cells contribute to inflammation by recruiting neutrophils (and, to a lesser extent, monocytes). (B) In some diseases, CD8+ cytotoxic T lymphocytes directly kill tissue cells. *APC*, Antigen-presenting cell.

Responses of Differentiated Effector T Cells

On repeat exposure to an antigen, Th1 cells secrete cytokines, mainly IFN-γ, which are responsible for many of the manifestations of delayed-type hypersensitivity. IFN-γ-activated ("classically activated") macrophages are altered in several ways: their ability to phagocytose and kill microorganisms is markedly augmented; they express more class II MHC molecules on the surface, enhancing antigen presentation; they secrete TNF, IL-1, and chemokines, which promote inflammation (Chapter 3); and they produce more IL-12, amplifying the Th1 response. Thus, activated macrophages serve to eliminate the offending antigen; if the activation is sustained, continued inflammation and tissue injury result.

Table 6.5 T Cell–Mediated Diseases

Disease	Specificity of Pathogenic T Cells	Principal Mechanisms of Tissue Injury	Clinicopathologic Manifestations
Rheumatoid arthritis	Collagen? Citrullinated self proteins?	Inflammation mediated by Th17 (and Th1?) cytokines; role of antibodies and immune complexes?	Chronic arthritis with inflammation, destruction of articular cartilage
Multiple sclerosis	Protein antigens in myelin (e.g., myelin basic protein)	Inflammation mediated by Th1 and Th17 cytokines, myelin destruction by activated macrophages	Demyelination in CNS with inflammation; paralysis, optic neuritis
Type 1 diabetes	Antigens of pancreatic islet β cells (insulin, glutamic acid decarboxylase, others)	T-cell–mediated inflammation, destruction of islet cells by CTLs	Insulitis (chronic inflammation in islets), destruction of β cells; diabetes
Inflammatory bowel disease	Enteric bacteria; self antigens?	Inflammation mediated by Th1 and Th17 cytokines	Chronic intestinal inflammation, obstruction
Psoriasis	Unknown	Inflammation mediated mainly by Th17 cytokines	Destructive plaques in the skin
Contact sensitivity	Various environmental chemicals (e.g., urushiol from poison ivy or poison oak)	Inflammation mediated by Th1 (and Th17?) cytokines	Epidermal necrosis, dermal inflammation, causing skin rash and blisters

Examples of human T cell–mediated diseases are listed. In many cases, the specificity of the T cells and the mechanisms of tissue injury are inferred based on the similarity with experimental animal models of the diseases. *CTLs*, Cytotoxic T lymphocytes.

Activated Th17 cells secrete IL-17, IL-22, chemokines, and several other cytokines. Collectively, these cytokines recruit neutrophils and monocytes to the reaction, thus promoting inflammation.

Clinical Examples of CD4+ T Cell–Mediated Inflammatory Reactions

The classic example of DTH is the tuberculin reaction, which is produced by the intracutaneous injection of purified protein derivative (PPD, also called tuberculin), a protein-containing antigen of the tubercle bacillus. In a previously sensitized individual, reddening and induration of the site appear in 8 to 12 hours, reach a peak in 24 to 72 hours, and thereafter slowly subside. Morphologically, delayed-type hypersensitivity is characterized by the accumulation of mononuclear cells, mainly CD4+ T cells and macrophages, around venules, producing perivascular "cuffing" (Fig. 6.19). In fully developed lesions, the venules show marked endothelial hypertrophy, reflecting cytokine-mediated endothelial activation.

With certain persistent or nondegradable antigens, such as tubercle bacilli colonizing the lungs or other tissues, the infiltrate is dominated by macrophages over a period of 2 or 3 weeks. With sustained activation, macrophages often undergo a morphologic transformation into epithelioid cells, large cells with abundant cytoplasm. Aggregates of epithelioid cells, usually surrounded by lymphocytes, form grossly visible small nodules called *granulomas* (Fig. 6.20). This pattern of chronic inflammation, called granulomatous inflammation (Chapter 3), is commonly associated with strong Th1-cell activation and production of cytokines such as IFN-γ. It can also be caused by indigestible foreign bodies, which activate macrophages without eliciting an adaptive immune response. In some helminthic infections, such as schistosomiasis, the worms lay eggs that elicit granulomatous reactions. These reactions are usually rich in eosinophils and are elicited by strong Th2 responses, which are typical of many helminthic infections.

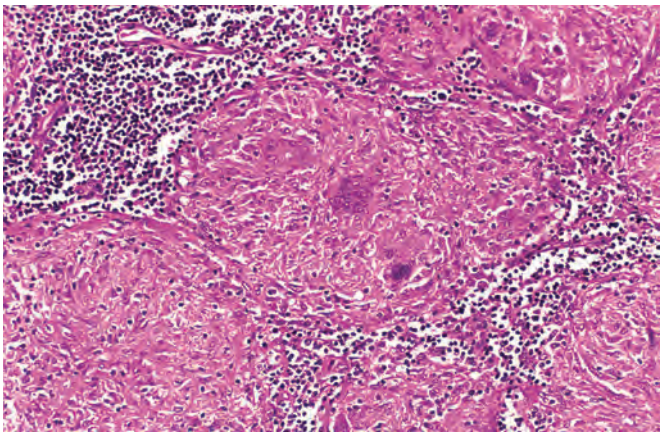

Figure 6.20 Granulomatous inflammation. A section of a lymph node shows several granulomas, each made up of an aggregate of epithelioid cells and surrounded by lymphocytes. The granuloma in the center shows several multinucleate giant cells. (Courtesy Dr. Trace Worrell, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

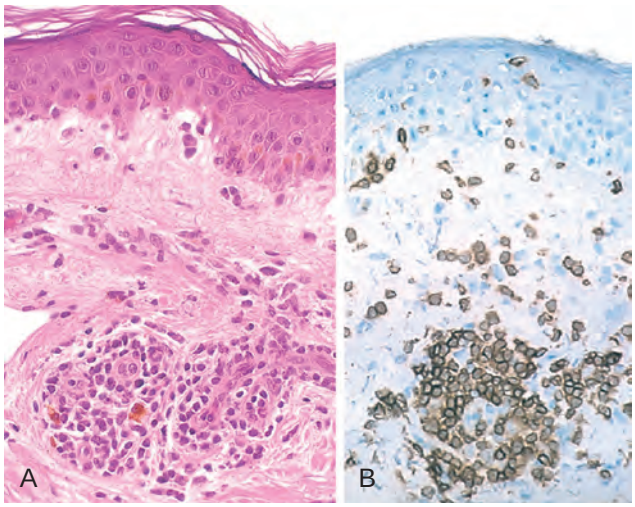

Figure 6.19 Delayed type hypersensitivity reaction in the skin. (A) Perivascular accumulation ("cuffing") of mononuclear inflammatory cells (lymphocytes and macrophages), with associated dermal edema and fibrin deposition. (B) Immunoperoxidase staining reveals a predominantly perivascular cellular infiltrate that marks positively with anti-CD4 antibodies. (Courtesy Dr. Louis Picker, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Contact dermatitis is a common example of tissue injury resulting from DTH reactions. It may be evoked by contact with urushiol, the antigenic component of poison ivy or poison oak, and presents as an itchy, vesicular (blistering) dermatitis. It is thought that in these reactions, the environmental chemical binds to and structurally modifies self proteins, and peptides derived from these modified proteins are recognized by T cells and elicit the reaction. Chemicals may also modify HLA molecules, making them appear foreign to T cells. The same mechanism is responsible for most *drug reactions,* among the most common immunologic reactions of humans. These often manifest as skin rashes.

CD4+ T cell–mediated inflammation is the basis of tissue injury in many organ-specific and systemic autoimmune diseases, such as rheumatoid arthritis and multiple sclerosis, as well as diseases linked to uncontrolled reactions to bacterial commensals, such as inflammatory bowel disease (see Table 6.5).

CD8+ T Cell–Mediated Cytotoxicity

In this type of T cell–mediated reaction, CD8+ CTLs kill antigen-expressing target cells. Tissue destruction by CTLs may be a component of some T cell–mediated diseases, such as type 1 diabetes. CTLs directed against cell surface histocompatibility antigens play an important role in graft rejection, to be discussed later. They also play a role in reactions against viruses. In a virus-infected cell, viral peptides are displayed by class I MHC molecules, and the complex is recognized by the TCR of CD8+ T lymphocytes. The killing of infected cells leads to the elimination of the infection, but in some cases it is responsible for cell damage that accompanies the infection (e.g., in viral hepatitis). Tumor antigens are also presented on the surface of tumor cells, and CTLs are involved in the host response to transformed cells (Chapter 7).

The principal mechanism of T cell–mediated killing of targets involves perforins and granzymes, preformed mediators contained in the lysosome-like granules of CTLs. CTLs that recognize the target cells secrete a complex consisting of perforin, granzymes, and other proteins that enters target cells by endocytosis. In the target cell cytoplasm, perforin facilitates the release of the granzymes from the complex. Granzymes are proteases that cleave and activate caspases, which induce apoptosis of the target cells (Chapter 2). Activated CTLs also express Fas ligand, a molecule with homology to TNF, which also can trigger apoptosis by binding and activating Fas receptor expressed on target cells.

CD8+ T cells also produce cytokines, notably IFN-γ, and are involved in inflammatory reactions resembling DTH, especially following viral infections and exposure to some contact sensitizing agents.

KEY CONCEPTS

MECHANISMS OF T CELL–MEDIATED HYPERSENSITIVITY REACTIONS

- Cytokine-mediated inflammation: CD4+ T cells are activated by exposure to a protein antigen and differentiate into Th1 and Th17 effector cells. Subsequent exposure to the antigen results in the secretion of cytokines. IFN-γ activates macrophages to produce substances that cause tissue damage and promote fibrosis, and IL-17 and other cytokines recruit leukocytes, thus promoting inflammation. The classical T cell–mediated inflammatory reaction is DTH.
- T cell–mediated cytotoxicity: CD8+ cytotoxic T lymphocytes (CTLs) specific for an antigen recognize cells expressing the target antigen and kill these cells. CD8+ T cells also secrete IFN-γ.

Now that we have described how the immune system can cause tissue damage, we turn to diseases in which normal mechanisms of immune regulation fail. The prototypes of such diseases are autoimmune disorders, which are the result of failure of tolerance to self antigens.

AUTOIMMUNE DISEASES

Immune reactions against self antigens—autoimmunity—are an important cause of certain diseases in humans, estimated to affect 5% to 10% of the US population, and the incidence is increasing, especially in high income countries. A growing number of diseases have been attributed to autoimmunity (Table 6.6). It should be noted, however, that the mere presence of autoantibodies does not indicate that an autoimmune disease exists. Autoantibodies can be found in the serum of apparently normal individuals, particularly in older age groups. Furthermore, innocuous autoantibodies are sometimes produced after damage to tissues and may serve a physiologic role in the removal of tissue breakdown products. How, then, does one define pathologic autoimmunity? Ideally, at least three requirements should be met before a disorder is categorized as truly caused by autoimmunity: (1) the presence of an immune reaction specific for some self antigen or self tissue; (2) evidence that such a reaction is not secondary to tissue damage but is of primary pathogenic significance; and (3) the absence of another well-defined cause of the disease. Similarity with experimental models of proven autoimmunity is also often used to support this mechanism in human diseases. Disorders in which chronic inflammation is a prominent component are sometimes grouped under immune-mediated inflammatory diseases; these may be autoimmune, or the immune response may be directed against normally harmless microbes such as gut commensal bacteria.

Table 6.6 Autoimmune Diseases

Organ-Specific	Systemic
Diseases Mediated by Antibodies	
Autoimmune hemolytic anemia	Systemic lupus erythematosus
Autoimmune thrombocytopenia	
Autoimmune atrophic gastritis of pernicious anemia	
Myasthenia gravis	
Graves disease	
Goodpasture syndrome	
Diseases Mediated by T Cells[a]	
Type 1 diabetes mellitus	Rheumatoid arthritis
Multiple sclerosis	Systemic sclerosis (scleroderma)[b]
	Sjögren syndrome[b]
Diseases Postulated to Be Autoimmune	
Inflammatory bowel diseases (Crohn disease, ulcerative colitis)[c]	Polyarteritis nodosa[b]
Primary biliary cirrhosis[b]	Inflammatory myopathies[b]
Autoimmune (chronic active) hepatitis	

[a]A role for T cells has been demonstrated in these disorders, but antibodies may also be involved in tissue injury.

[b]An autoimmune basis of these disorders is suspected, but the supporting evidence is not strong.

[c]These disorders may result from excessive immune responses to commensal enteric microbes, autoimmunity, or a combination of the two.

The clinical manifestations of autoimmune disorders are extremely varied. On one end are conditions in which the immune responses are directed against a single organ or tissue, resulting in *organ-specific disease,* and on the other end are diseases in which the autoimmune reactions are against widespread antigens, resulting in *systemic disease*. Examples of organ-specific autoimmune diseases are type 1 diabetes, in which the autoreactive T cells and antibodies are specific for β cells of the pancreatic islets, and multiple sclerosis, in which autoreactive T cells react against central nervous system (CNS) myelin. The best example of systemic autoimmune disease is SLE, in which a diversity of antibodies directed against DNA, platelets, red cells, and protein-phospholipid complexes result in widespread lesions throughout the body. In the middle of the spectrum falls Goodpasture syndrome, in which antibodies to basement membranes of lung and kidney induce lesions in these organs.

It is obvious that autoimmunity results from the loss of self-tolerance, and the question arises as to how this happens. Before we look for answers to this question, we review the mechanisms of immunologic tolerance to self antigens.

Immunologic Tolerance

Immunologic tolerance is the phenomenon of unresponsiveness to an antigen induced by exposure of lymphocytes to that antigen. *Self-tolerance* refers to lack of responsiveness to an individual's own antigens, and it underlies our ability to live in harmony with our cells and tissues.

The mechanisms of self-tolerance can be broadly classified into two groups: central tolerance and peripheral tolerance (Fig. 6.21). Each of these is considered briefly.

Central Tolerance

In this process, immature self-reactive T and B lymphocyte clones that recognize self antigens during their maturation in the central (primary, or generative) lymphoid organs (the thymus for T cells and the bone marrow for B cells) are killed or rendered harmless. In developing lymphocytes, random somatic antigen receptor gene rearrangements generate diverse antigen receptors, many of which by chance may have high affinity for self antigens. The mechanisms of central tolerance eliminate these potentially dangerous lymphocytes.

- When immature T cells expressing TCRs specific for self antigens encounter these antigens in the thymus, signals are produced that result in killing of the cells by apoptosis. This process is called *negative selection* or *clonal deletion*. A wide variety of autologous protein antigens, including antigens thought to be restricted to peripheral tissues, are processed and presented by thymic antigen-presenting cells in association with self MHC molecules and can, therefore, be recognized by potentially self-reactive T cells. A protein called AIRE (autoimmune regulator) stimulates expression of some peripheral tissue–restricted self antigens in the thymus and is thus critical for deletion of immature T cells specific for these antigens. The importance of this mechanism is emphasized by rare patients with germline loss-of-function mutations in the *AIRE* gene, who develop an autoimmune disorder called *autoimmune polyendocrine syndrome* that leads to destruction of multiple endocrine organs (Chapter 24). In the CD4+ T-cell lineage, some of the cells that see self antigens in the thymus do not die but develop into regulatory T cells (described later). What determines the choice between deletion and development of regulatory T cells in the thymus is not established; it may be partly related to the affinity of the antigen receptor on immature T cells for antigens present in the thymus.
- When developing B cells strongly recognize self antigens in the bone marrow, many of the cells reactivate the machinery of antigen receptor gene rearrangement and begin to express new antigen receptors, not specific for self antigens. This process is called *receptor editing*; it is estimated that one-fourth to one-half of all B cells in the body may have undergone receptor editing during their maturation. If receptor editing does not occur, the self-reactive cells undergo apoptosis, thus purging potentially dangerous lymphocytes from the mature pool.

Central tolerance, however, is imperfect. Not all self antigens may be present in the thymus and bone marrow, and hence lymphocytes bearing receptors for such autoantigens escape into the periphery. Self-reactive lymphocytes that

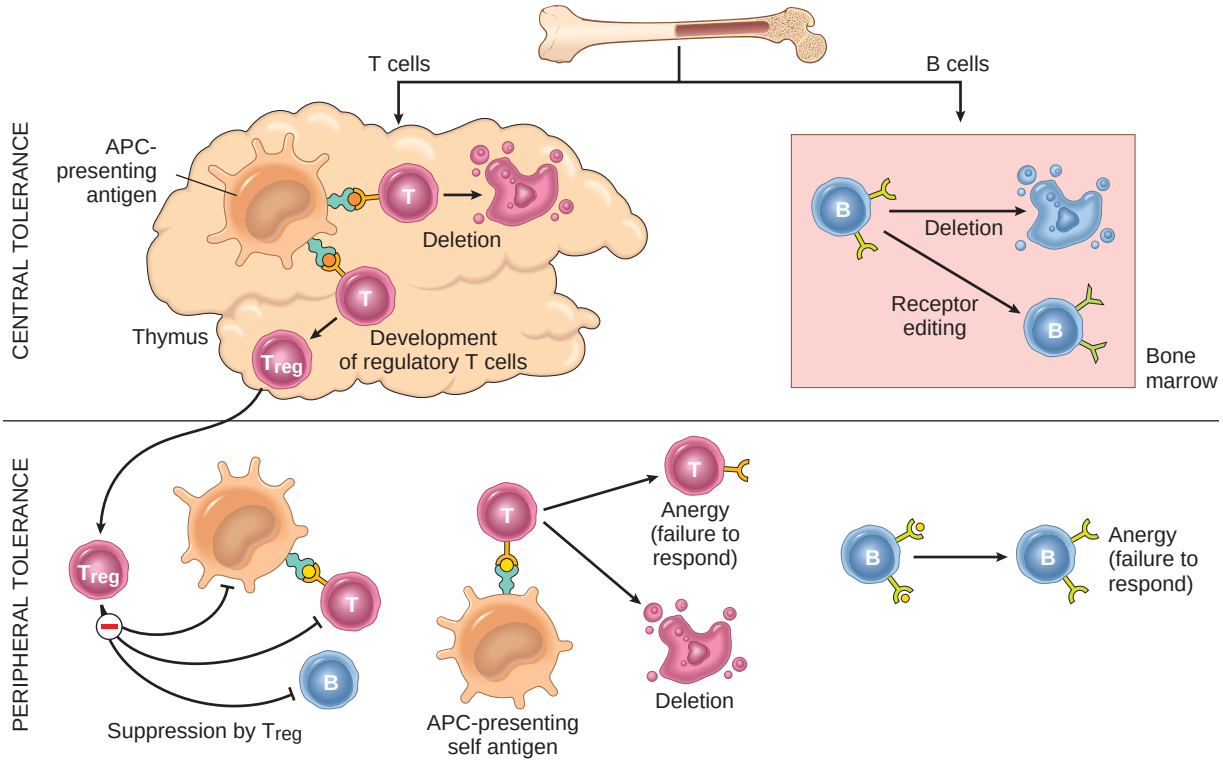

Figure 6.21 Mechanisms of immunologic tolerance to self antigens. The principal mechanisms of central and peripheral self-tolerance in T and B cells are illustrated. *APC*, Antigen-presenting cell.

escape negative selection can inflict tissue injury unless they are deleted or muzzled in the peripheral tissues.

Peripheral Tolerance

Several mechanisms silence potentially autoreactive T and B cells in peripheral tissues; these are best defined for T cells. These mechanisms include the following:

- *Anergy.* Lymphocytes that recognize self antigens may be rendered functionally unresponsive, a phenomenon called anergy. We discussed earlier that activation of antigen-specific T cells requires two signals: recognition of peptide antigen in association with self MHC molecules on the surface of APCs and a set of costimulatory signals ("second signals") from APCs. These second signals are provided by certain T cell–associated molecules, such as CD28, that bind to their ligands (the costimulators B7-1 and B7-2) on APCs. If the antigen is presented to T cells without adequate levels of costimulators, the cells become anergic. Because costimulatory molecules are not expressed or are weakly expressed on resting DCs in normal tissues, the encounter between autoreactive T cells and their specific self antigens displayed by these DCs may lead to anergy. Several mechanisms of T-cell anergy have been demonstrated in various experimental systems. One of these, which has clinical implications, is that T cells that recognize self antigens receive an inhibitory signal from receptors that are structurally homologous to CD28 but serve the opposite functions. Two of these inhibitory receptors, sometimes called coinhibitors (to contrast them with costimulators mentioned earlier), are CTLA-4, which (like CD28) binds to B7 molecules, and PD-1, which binds to two ligands, PD-L1 and PD-L2, that are expressed on a wide variety of cells. The importance of these inhibitory mechanisms has been established by study of CTLA-4 and PD-1 "knockout" mice and humans with inherited mutations in *CTLA4,* all of which lead to systemic inflammatory diseases. Interestingly, some tumors and viruses use the same pathways of immune regulation to evade immune attack. This realization has led to the development of antibodies that block CTLA-4, PD-1, and its ligand PD-L1 for tumor immunotherapy; by removing the brakes on the immune response, these antibodies promote responses against tumors.

  Anergy also affects mature B cells in peripheral tissues. It is believed that if B cells encounter self antigen in peripheral tissues, especially in the absence of specific helper T cells, the B cells become unable to respond to subsequent antigenic stimulation and may be excluded from lymphoid follicles, resulting in their death.
- *Suppression by regulatory T cells.* A population of T cells called regulatory T cells functions to prevent immune reactions against self antigens. Regulatory T cells develop mainly in the thymus, as a result of recognition of self antigens (see Fig. 6.21), but they may also be induced in peripheral lymphoid tissues. The best-defined regulatory T cells are CD4+ cells that express high levels of CD25, the α chain of the IL-2 receptor, and FOXP3, a transcription factor of the forkhead family. Both IL-2 and FOXP3 are required for the development and maintenance of functional CD4+ regulatory T cells. Mutations in *FOXP3* result in severe autoimmunity in humans and mice; in humans these mutations are the cause of a systemic autoimmune disease called *IPEX* (an acronym for *i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked). Mutation of the gene encoding IL-2 or the IL-2 receptor α or β chain also results in a rare multiorgan autoimmune disease because IL-2 is essential for the maintenance of regulatory T cells. Recent genome-wide association studies have revealed that polymorphisms in the promoter of the *CD25* gene are associated with type 1 diabetes, multiple sclerosis, and other autoimmune diseases, raising the possibility of a regulatory T-cell defect contributing to these diseases. Regulatory T cells may suppress immune responses by multiple mechanisms. Their inhibitory activity may be mediated in part by the secretion of immunosuppressive cytokines such as IL-10 and TGF-β, which inhibit lymphocyte activation and effector functions.

  Regulatory T cells prevent immune responses not only against self antigens but also against the fetus and commensal microbes. Placental mammals face a unique challenge because the developing fetus expresses paternal antigens that are foreign to the mother yet have to be tolerated. There is emerging evidence that regulatory T cells prevent immune reactions against fetal antigens that are inherited from the father and therefore foreign to the mother. In line with this idea, during evolution, placentation appeared simultaneously with the ability to stably express the FOXP3 transcription factor. Experiments in mice have shown that fetal antigens induce long-lived FOXP3+ regulatory T cells, and depletion of these cells results in fetal loss. There is great interest in determining the contribution of regulatory T cells in human pregnancy and possible defects in these cells as the basis for recurrent spontaneous abortions.
- *Deletion by apoptosis.* T cells that recognize self antigens may receive signals that promote their death by apoptosis. Depletion of T cells occurs not only in the thymus, discussed earlier, but also in the periphery. Two mechanisms of deletion of mature T cells in the periphery have been proposed, based mainly on studies in mice. It is postulated that if T cells recognize self antigens, they may express a pro-apoptotic member of the Bcl family, called Bim, without antiapoptotic members of the family like Bcl-2 and Bcl-x (whose induction requires the full set of signals for lymphocyte activation). Unopposed Bim triggers apoptosis by the mitochondrial pathway (Chapter 2). A second mechanism involves the Fas-Fas ligand system. Upon recognition of self antigens, lymphocytes express the death receptor Fas (CD95), a member of the TNF-receptor family. Fas ligand (FasL), a membrane protein that is structurally homologous to the cytokine TNF, is expressed mainly on activated T lymphocytes. The engagement of Fas by FasL induces apoptosis by the death receptor pathway (Chapter 2). If self antigens engage antigen receptors of self-reactive T cells, Fas and FasL are co-expressed, leading to elimination of the cells via Fas-mediated apoptosis. Self-reactive B cells may also be deleted by FasL on T cells engaging Fas on the B cells. Mutations in Fas or FasL in mice and humans result in an autoimmune disease reminiscent of human SLE called the *autoimmune lymphoproliferative syndrome (ALPS).*

  Some antigens are hidden (sequestered) from the immune system, because the tissues in which these

antigens are located do not communicate with the blood and lymph. As a result, self antigens in these tissues fail to elicit immune responses and are essentially ignored by the immune system. This is believed to be the case for the testis, eye, and brain, all of which are called *immune-privileged sites* because antigens introduced into these sites tend to elicit weak or no immune responses. If the antigens of these tissues are released, for example, as a consequence of trauma or infection, the result may be an immune response that leads to prolonged tissue inflammation and injury. This is the postulated mechanism for post-traumatic orchitis and uveitis.

Mechanisms of Autoimmunity: General Principles

The immune system normally exists in an equilibrium in which lymphocyte activation, which is required for defense against pathogens, is balanced by the mechanisms of tolerance, which prevent reactions against self antigens. The underlying cause of autoimmune diseases is the failure of tolerance, which allows responses to develop against self antigens. Understanding why tolerance fails in these diseases is an important goal of immunologists.

Autoimmunity arises from a combination of the inheritance of susceptibility genes, which may contribute to the breakdown of self-tolerance, and environmental triggers, such as infections and tissue damage, which promote the activation of self-reactive lymphocytes (Fig. 6.22). Although much remains unknown about the enigma of autoimmunity, the following abnormalities appear to contribute to its development:

- *Defective tolerance or regulation.* Some clues about how tolerance mechanisms are disrupted have come from the analysis of patients with rare inherited (Mendelian) autoimmune disorders and from gene knockout mice that develop autoimmune lesions, mentioned earlier and discussed in more detail later. However, despite these advances, it is still not known why self-tolerance fails in the majority of common autoimmune diseases.
- *Abnormal display of self antigens.* Abnormalities may include increased expression and persistence of self antigens that are normally cleared, or structural changes in these antigens resulting from posttranslational enzymatic modifications or from cellular stress or injury. If these changes lead to the display of "neoantigens" (new epitopes that are not expressed normally), the immune system may not be tolerant to these epitopes, and anti-self responses may develop.
- *Inflammation or an initial innate immune response.* As discussed earlier, the innate immune response is a strong stimulus for the subsequent activation of lymphocytes and the generation of adaptive immune responses. Microbes or cell injury may elicit local inflammatory reactions that may be triggers for subsequent autoimmunity.

Although these are appealing hypotheses, which of these abnormalities actually play a role in specific autoimmune diseases in humans remains largely a matter of speculation.

Role of Susceptibility Genes

Most autoimmune diseases are complex multigenic disorders. It has been known for decades that autoimmunity has a genetic component. The incidence of many autoimmune diseases is greater in twins of affected individuals than in the general population, and greater in monozygotic than in dizygotic twins, proof that genetics contributes to the development of these disorders.

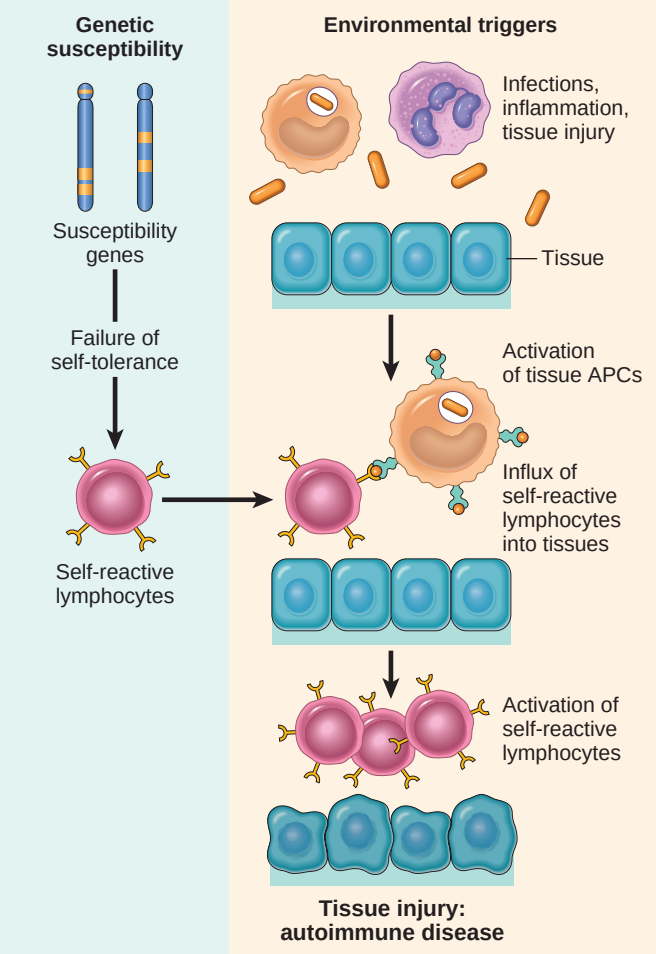

Figure 6.22 Pathogenesis of autoimmunity. Autoimmunity results from multiple factors, including susceptibility genes that may interfere with self-tolerance and environmental triggers (such as infections, tissue injury, and inflammation) that promote lymphocyte entry into tissues, activation of self-reactive lymphocytes, and tissue damage.

Association of HLA Alleles With Disease

Among the genes known to be associated with autoimmunity, the greatest contribution is that of HLA genes (Table 6.7). The most striking of these associations is between ankylosing spondylitis and *HLA-B27;* individuals who inherit this class I HLA allele have a 100- to 200-fold greater chance (odds ratio, or relative risk) of developing the disease compared with those who do not carry *HLA-B27.* Many autoimmune diseases are associated with different class II *HLA* alleles. Although it is reasonable to postulate that these associations reflect the ability of some HLA molecules to preferentially display natural or modified self peptides, it has been difficult to prove that this is the case. It is also important to understand that although different HLA alleles may contribute to a disease, their presence is not, by itself, the cause of any disease. Thus, in the example of HLA-B27,

Table 6.7 Association of HLA Alleles and Inflammatory Diseases

Disease	HLA Allele	Odds Ratio[a]
Rheumatoid arthritis (anti-CCP Ab positive)[b]	DRB1, 1 SE allele[c] DRB1, 2 SE alleles	4 12
Type 1 diabetes	DRB1*0301-DQA1*0501-DQB1*0201 haplotype DRB1*0401-DQA1*0301-DQB1*0302 haplotype DRB1*0301/0401 haplotype heterozygotes	4 8 35
Multiple sclerosis	DRB1*1501	3
Systemic lupus erythematosus	DRB1*0301 DRB1*1501	2 1.3
Ankylosing spondylitis	B*27 (mainly B*2705 and B*2702)	100–200
Celiac disease	DQA1*0501-DQB1*0201 haplotype	7

[a]The odds ratio reflects approximate values of increased risk of the disease associated with the inheritance of particular HLA alleles. The data are from European-derived populations.

[b]Anti-CCP Ab = antibodies directed against cyclic citrullinated peptides. Data are from patients who test positive for these antibodies in the serum.

[c]SE refers to *shared epitope*, so called because the susceptibility alleles map to one region of the DRB1 protein (positions 70–74).

Courtesy Dr. Michelle Fernando, Imperial College London.

the vast majority of individuals who inherit this allele never develop ankylosing spondylitis.

Association of Non-MHC Genes With Autoimmune Diseases

Genome-wide association studies and family studies have shown that multiple non-MHC genes are associated with various autoimmune diseases (Table 6.8). Some of these genes are disease-specific, but many of the associations are seen in multiple disorders, suggesting that the products of these genes affect general mechanisms of immune regulation and self-tolerance. Three recently described genetic associations are especially interesting.

- Polymorphisms in a gene called *PTPN22,* which encodes a protein tyrosine phosphatase, are associated with rheumatoid arthritis, type 1 diabetes, and several other autoimmune diseases. Because these disorders have a fairly high prevalence (especially rheumatoid arthritis), *PTPN22* is said to be the non-HLA gene that is most frequently implicated in autoimmunity. It is postulated that the disease-associated variants encode forms of the phosphatase that are functionally defective and thus unable to dampen the activity of tyrosine kinases that are involved in many responses of lymphocytes. The net result is excessive lymphocyte activation.
- Polymorphisms in the gene for NOD2 are associated with Crohn disease, a form of inflammatory bowel disease, especially in certain ethnic populations. NOD2, a member of the NOD-like receptor (NLR) family (discussed earlier), is a cytoplasmic sensor of microbes that is expressed in intestinal epithelial and other cells. According to one hypothesis, the disease-associated variant is ineffective at sensing gut microbes, including commensal bacteria, resulting in entry of and chronic inflammatory responses against these normally well-tolerated organisms.
- Polymorphisms in the gene encoding the IL-2 receptor (CD25) are associated with multiple sclerosis and other autoimmune diseases. These variants may influence the expression and activity of this key receptor and thereby affect the balance between regulatory and effector T cells.

Many other polymorphisms have been described in different autoimmune diseases, and we will mention some of these when we describe specific disorders. We have previously mentioned that in mice and humans, gene

Table 6.8 Selected Non–HLA Genes Associated With Autoimmune Diseases

Putative Gene Involved	Diseases	Postulated Function of Encoded Protein and Role of Mutation/Polymorphism in Disease
Genes Involved in Immune Regulation		
PTPN22	RA, T1D, IBD	Protein tyrosine phosphatase, may affect signaling in lymphocytes and may alter negative selection or activation of self-reactive T cells
IL23R	IBD, PS, AS	Receptor for the Th17-inducing cytokine IL-23; may alter differentiation of CD4+ T cells into pathogenic Th17 effector cells
CTLA4	T1D, RA	Inhibits T-cell responses by terminating activation and promoting activity of regulatory T cells; may interfere with self-tolerance
IL2RA	MS, T1D	α chain of the receptor for IL-2, which is a growth and survival factor for activated and regulatory T cells; may affect development of effector cells and/or regulation of immune responses
Genes Involved in Immune Responses to Microbes		
NOD2	IBD	Cytoplasmic sensor of bacteria expressed in Paneth and other intestinal epithelial cells; may control resistance to gut commensal bacteria
ATG16	IBD	Involved in autophagy; possible role in defense against microbes and maintenance of epithelial barrier function
IRF5, IFIH1	SLE	Role in type I interferon production; type I interferon is involved in the pathogenesis of SLE (see text)

AS, Ankylosing spondylitis; *IBD,* inflammatory bowel disease; *MS,* multiple sclerosis; *PS,* psoriasis; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus.

The probable linkage of these genes with various autoimmune diseases has been defined by genome-wide association studies and other methods for studying disease-associated polymorphisms.

Modified from Zenewicz LA, Abraham C, Flavell RA, Cho JH: Unraveling the genetics of autoimmunity. *Cell* 140:791, 2010.

knockouts and sporadic mutations affecting several individual genes result in autoimmunity. These genes include *AIRE, CTLA4, PD1, FAS, FASL,* and *IL2* and its receptor *CD25*. In addition, B cells express an Fc receptor that recognizes IgG antibodies bound to antigens and switches off further antibody production (a normal negative-feedback mechanism). Knockout of this receptor results in autoimmunity, presumably because the B cells can no longer be controlled. These examples provide valuable information about pathways of self-tolerance and immune regulation, but the diseases caused by these single-gene mutations are rare, and mutations in these genes are not the cause of most common autoimmune disorders.

Role of Infections and Other Environmental Factors

Autoimmune reactions may be triggered by infections. Two mechanisms have been postulated to explain the link between infections and autoimmunity (Fig. 6.23). First, infections may upregulate the expression of costimulators on APCs. If these cells are presenting self antigens, the result may be a breakdown of anergy and activation of T cells specific for the self antigens. Second, some microbes may express antigens that share amino acid sequences with self antigens. Immune responses against the microbial antigens may result in the activation of self-reactive lymphocytes. This phenomenon is called *molecular mimicry*. A clear example of such mimicry is rheumatic heart disease, in which antibodies against streptococcal proteins cross-react with myocardial proteins and cause myocarditis (Chapter 12). More subtle molecular mimicry may be involved in classic autoimmune diseases as well.

Microbes may induce other abnormalities that promote autoimmune reactions. Some viruses, such as EBV and HIV, cause polyclonal B-cell activation, which may result in production of autoantibodies. The tissue injury that is common in infections may release and structurally modify self antigens, creating neoantigens that are able to activate T cells. Infections may induce the production of cytokines that recruit lymphocytes, including potentially self-reactive lymphocytes, to sites of self antigens.

Infections may protect against some autoimmune diseases. Although the role of infections in triggering autoimmunity has received a great deal of attention, epidemiologic studies suggest that the incidence of autoimmune diseases is increasing in high income countries in parallel with better infection control. In some animal models (e.g., of type 1 diabetes) infections greatly reduce the incidence of disease. The underlying mechanisms are unclear; one possibility is that infections promote low-level IL-2 production, and this is essential for maintaining regulatory T cells.

Recently, there has been great interest in the idea that the normal gut and skin microbiome influences the development of autoimmunity. It is possible that different nonpathogenic microbes affect the relative proportions of effector and regulatory T cells and shape the host response toward or away from aberrant activation. However, it is still not clear which microbes actually contribute to specific diseases in humans, or if the microbiome can be manipulated to prevent or treat these disorders.

In addition to infections, the display of tissue antigens also may be altered by a variety of environmental insults. As discussed later, ultraviolet (UV) radiation causes cell death and may lead to the exposure of nuclear antigens, which elicit pathologic immune responses in lupus; this mechanism is the proposed explanation for the association of lupus flares with exposure to sunlight. Smoking is a risk factor for rheumatoid arthritis, perhaps because it leads to chemical modification of self antigens. Local tissue injury for any reason may lead to the release of self antigens and autoimmune responses.

Finally, autoimmunity has a strong gender bias, with many of these diseases being more common in women than

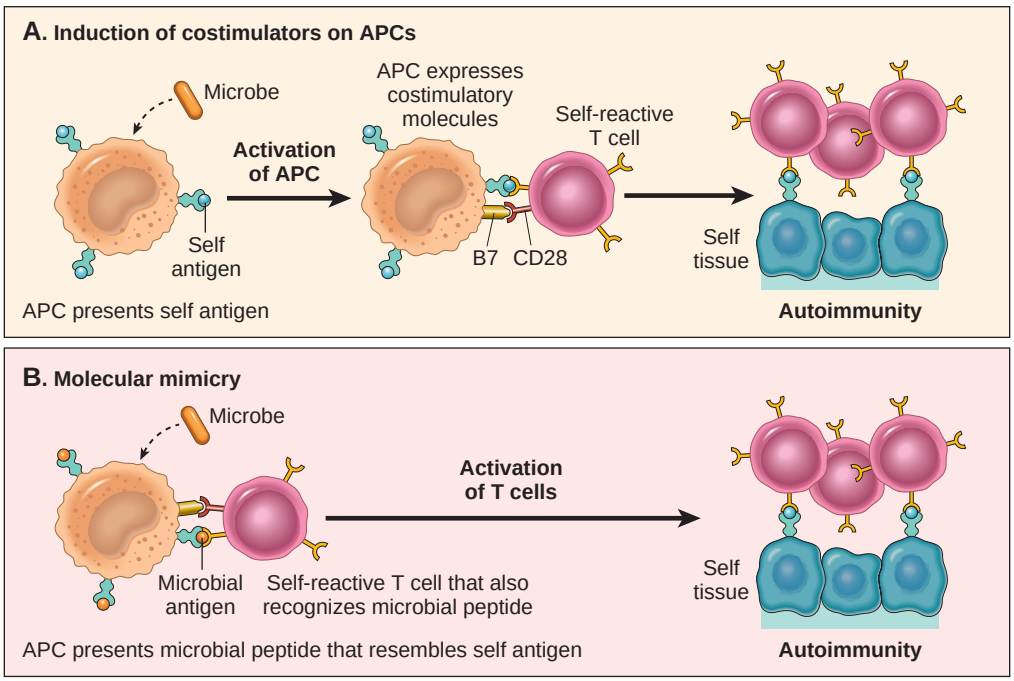

Figure 6.23 Postulated role of infections in autoimmunity. Infections may promote activation of self-reactive lymphocytes by inducing the expression of costimulators (A), or microbial antigens may mimic self antigens and activate self-reactive lymphocytes as a cross-reaction (B).

in men. The underlying mechanisms are not understood but may involve the effects of hormones and currently unknown genes on the X chromosome.

General Features of Autoimmune Diseases

Diseases caused by autoimmunity have some important general features.

- Autoimmune diseases tend to be chronic, sometimes with relapses and remissions, and the damage is often progressive. One reason for the chronicity is that the immune system contains many intrinsic amplification loops that allow small numbers of antigen-specific lymphocytes to accomplish the task of eradicating complex infections. When the response is inappropriately directed against self tissues, the same amplification mechanisms exacerbate and prolong the injury. Another reason for the persistence and progression of autoimmune disease is the phenomenon of *epitope spreading,* in which an immune response against one self antigen causes tissue damage, releasing other antigens, and resulting in the activation of lymphocytes that recognize these newly encountered epitopes.
- The clinical and pathologic manifestations of an autoimmune disease are determined by the nature of the underlying immune response. Some of these diseases are caused by autoantibodies, whose formation may be associated with dysregulated germinal center reactions. Most chronic inflammatory diseases are caused by abnormal and excessive Th1 and Th17 responses; examples of these diseases include psoriasis, multiple sclerosis, and some types of inflammatory bowel disease. In some autoimmune diseases, such as rheumatoid arthritis, both antibodies and T cell–mediated inflammation may be involved.

With this background, we can proceed to a discussion of specific autoimmune diseases. Table 6.6 lists both systemic and organ-specific autoimmune disorders. The systemic diseases tend to involve blood vessels and connective tissues, and therefore, they are often called *collagen vascular diseases* or *connective tissue diseases*. Our focus here is on selected systemic autoimmune diseases; organ-specific disorders are covered in relevant chapters.

KEY CONCEPTS

IMMUNOLOGIC TOLERANCE AND AUTOIMMUNITY

- Tolerance (unresponsiveness) to self antigens is a fundamental property of the immune system, and breakdown of tolerance is the basis of autoimmune diseases.
- Central tolerance: immature lymphocytes that recognize self antigens in the central (generative) lymphoid organs are killed by apoptosis; in the B-cell lineage, some of the self-reactive lymphocytes switch to new antigen receptors that are not self-reactive.
- Peripheral tolerance: mature lymphocytes that recognize self antigens in peripheral tissues become functionally inactive (anergic) or are suppressed by regulatory T lymphocytes, or they die by apoptosis.
- The factors that lead to a failure of self-tolerance and the development of autoimmunity include (1) inheritance of susceptibility genes that may disrupt different tolerance pathways and (2) infections and tissue injury that may expose self antigens and activate APCs and lymphocytes in the tissues.
- Autoimmune diseases are usually chronic and progressive, and the type of tissue injury is determined by the nature of the dominant immune response.

Systemic Lupus Erythematosus (SLE)

SLE is an autoimmune disease involving multiple organs, characterized by a vast array of autoantibodies, particularly antinuclear antibodies (ANAs), in which injury is caused mainly by deposition of immune complexes and binding of antibodies to various cells and tissues. The disease may be acute or insidious in its onset, and is typically a chronic, remitting and relapsing, often febrile, illness. Injury to the skin, joints, kidney, and serosal membranes is most prominent, but virtually any organ in the body may be affected. Because of this, the disease is very heterogeneous, and any patient may present with any number of clinical features. In recognition of this, the American College of Rheumatology has established a complex set of criteria for this disorder, which is helpful for clinicians and for the assessment of patients in clinical trials (Table 6.9).

SLE is a fairly common disease, with a prevalence that may be as high as 1 in 2500 in certain populations. Similar to many autoimmune diseases, SLE predominantly affects women, with a frequency of 1 in 700 among women of childbearing age and a female-to-male ratio of 9:1 in the reproductive age group of 17 to 55 years. By comparison, the female-to-male ratio is only 2:1 for disease developing during childhood or after 65 years of age. The prevalence of the disease is twofold to threefold higher in blacks and Hispanics than in whites. Although SLE most often presents in the twenties and thirties, it may manifest at any age, even in early childhood.

Spectrum of Autoantibodies in Systemic Lupus Erythematosus

The hallmark of SLE is the production of autoantibodies, several of which (antibodies to double-stranded DNA and the so-called Smith [Sm] antigen) are virtually diagnostic. These and other autoantibodies are pathogenic, either by forming immune complexes or by attacking their target cells. The levels of these autoantibodies in the blood are also helpful for the diagnosis and management of patients with SLE. Autoantibodies are found in many diseases in addition to SLE, and antibodies of different specificities tend to be associated with different autoimmune disorders (Table 6.10).

ANAs. These are directed against nuclear antigens and can be grouped into four categories based on their specificity for: (1) DNA, (2) histones, (3) nonhistone proteins bound to RNA, and (4) nucleolar antigens. Table 6.10 lists several ANAs and their association with SLE as well as with other autoimmune diseases to be discussed later. The most widely used method for detecting ANAs is indirect immunofluorescence, which can identify antibodies that bind to a variety of nuclear antigens, including DNA, RNA, and proteins (collectively called generic ANAs). The pattern of nuclear fluorescence suggests the type of antibody present in the patient's serum. Four basic patterns are recognized (Fig. 6.24):

Table 6.9 1997 Revised Criteria for Classification of Systemic Lupus Erythematosus[a]

Criterion	Definition
Clinical Criteria	
Acute cutaneous lupus	Malar rash (fixed erythema, flat or raised, over the malar eminences), photosensitivity
Chronic cutaneous lupus	Discoid rash: erythematous raised patches with adherent keratotic scaling and follicular plugging
Nonscarring alopecia	Diffuse thinning or hair fragility in the absence of other causes
Oral or nasal ulcers	Oral or nasopharyngeal ulceration, usually painless
Joint disease	Nonerosive synovitis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis (pleuritic pain or rub or evidence of pleural effusion), pericarditis
Renal disorder	Persistent proteinuria >0.5 g/24 hours, or red cell casts
Neurologic disorder	Seizures, psychosis, myelitis, or neuropathy, in the absence of offending drugs or other known causes
Hemolytic anemia	Hemolytic anemia
Leukopenia or lymphopenia	Leukopenia: $<4.0 \times 10^9$ cells/L (4000 cells/mm^3) total on two or more occasions, *or* Lymphopenia: $<1.5 \times 10^9$ cells/L (1500 cells/mm^3) on two or more occasions
Thrombocytopenia	Thrombocytopenia: $<100 \times 10^9$ cells/L (100×10^3 cells/mm^3) in the absence of offending drugs and other conditions
Immunologic Criteria	
Antinuclear antibody (ANA)	Abnormal titer of antinuclear antibody by immunofluorescence
Anti-dsDNA antibody	Abnormal titer
Anti-Sm antibody	Presence of antibody to Sm nuclear antigen
Antiphospholipid antibody	Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anti-cardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard test, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by negative *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Low complement	Low C3, C4, or CH50
Direct Coombs test	Assay for anti–red cell antibody, in the absence of clinically evident hemolytic anemia

[a]This classification was initially proposed in 1997 by the American College of Rheumatology for the purpose of identifying patients in clinical studies. It was updated in 2012 by the Systemic Lupus International Collaborating Clinics. A patient is classified as having SLE if four of the clinical and immunologic criteria are present at any time (not necessarily concurrently), including at least one clinical and one immunologic criterion. Some details have been omitted from the table.

Modified from Petri M, Orbai AM, Alarcón GS, et al: Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus, *Arthritis Rheum* 64:2677, 2012.

Table 6.10 Autoantibodies in Systemic Autoimmune Diseases

Disease	Specificity of Autoantibody	% Positive	Association With Specific Disease Features
Systemic lupus erythematosus (SLE)	Double-stranded DNA	40–60	Nephritis; specific for SLE
	U1-RNP	30–40	
	Smith (Sm) antigen (core protein of small RNP particles)	20–30	Specific for SLE
	Ro (SS-A)/La (SS-B) nucleoproteins	30–50	Congenital heart block; neonatal lupus
	Phospholipid-protein complexes (anti-PL)	30–40	Antiphospholipid syndrome (in ~10% of SLE patients)
	Multiple nuclear antigens ("generic ANAs")	95–100	Found in other autoimmune diseases, not specific
Systemic sclerosis	DNA topoisomerase I	30–70	Diffuse skin disease, lung disease; specific for systemic sclerosis
	Centromeric proteins (CENPs) A, B, C	20–40	Limited skin disease, ischemic digital loss, pulmonary hypertension
	RNA polymerase III	15–20	Acute onset, scleroderma renal crisis, cancer
Sjögren syndrome	Ro/SS-A La/SS-B	70–95	
Autoimmune myositis	Histidyl aminoacyl-tRNA synthetase, Jo1	25	Interstitial lung disease, Raynaud phenomenon
	Mi-2 nuclear antigen	5–10	Dermatomyositis, skin rash
	MDA5 (cytoplasmic receptor for viral RNA)	20–35 (Japanese)	Vascular skin lesions, interstitial lung disease
	TIF1γ nuclear protein	15–20	Dermatomyositis, cancer
Rheumatoid arthritis	CCP (cyclic citrullinated peptides); various citrullinated proteins	60–80	Specific for rheumatoid arthritis
	Rheumatoid factor (not specific)	60–70	

"Generic" antinuclear antibodies (ANAs), which may react against many nuclear antigens, are positive in a large fraction of patients with SLE but are also positive in other autoimmune diseases. % positive refers to the approximate % of patients who test positive for each antibody.

The table was compiled with the help of Dr. Antony Rosen, Johns Hopkins University, Baltimore, Md.

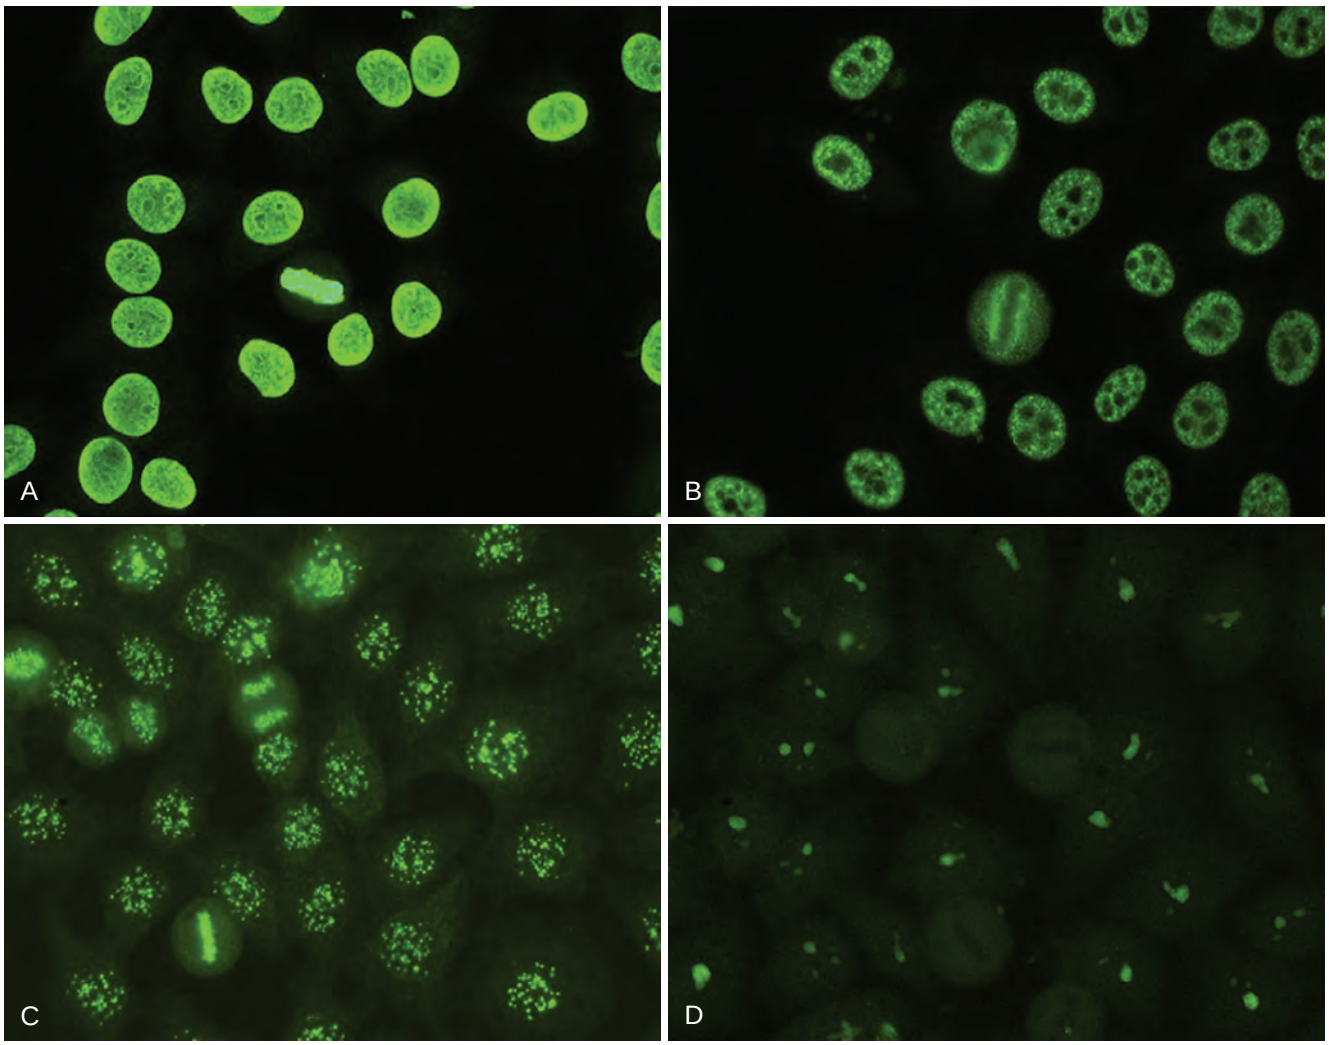

Figure 6.24 Staining patterns of antinuclear antibodies. (A) Homogeneous or diffuse staining of nuclei is typical of antibodies reactive with dsDNA, nucleosomes, and histones, and is common in systemic lupus erythematosus. (B) Speckled pattern is seen with antibodies against various nuclear antigens, including Sm and RNPs. (C) The pattern of staining of anti-centromere antibodies is seen in some cases of systemic sclerosis, Sjögren syndrome, and other diseases. (D) Nucleolar pattern is typical of antibodies against nucleolar proteins. (Images reproduced with permission from Wiik AS, Høier-Madsen M, Forslid J, et al: Antinuclear antibodies: a contemporary nomenclature using Hep-2 cells, *J Autoimm* 35:276–290, 2010.)

- *Homogeneous or diffuse nuclear staining* usually reflects antibodies to chromatin, histones, and, occasionally, double-stranded DNA.
- *Rim or peripheral staining* patterns are most often indicative of antibodies to double-stranded DNA and sometimes to nuclear envelope proteins.
- *Speckled pattern* refers to the presence of uniform or variable-sized speckles. This is one of the most commonly observed patterns of fluorescence and therefore the least specific. It reflects the presence of antibodies to non-DNA nuclear constituents such as Sm antigen, ribonucleoprotein, and SS-A and SS-B reactive antigens.
- *Nucleolar pattern* refers to the presence of a few discrete spots of fluorescence within the nucleus and represents antibodies to RNA. This pattern is reported most often in patients with systemic sclerosis.
- *Centromeric pattern.* Patients with systemic sclerosis often contain antibodies specific for centromeres, which give rise to this pattern.

The fluorescence patterns are not absolutely specific for the type of antibody, and because many autoantibodies may be present, combinations of patterns are frequent. Concerns have been raised about the sensitivity and subjective nature of this assay, and attempts are ongoing to replace it with ELISAs (enzyme linked immunosorbent assays) for specific nuclear and other antigens. Nevertheless, the staining pattern is considered of diagnostic value, and the test remains in use.

In addition to ANAs, lupus patients have a host of other autoantibodies. Some are directed against blood cells, such as red cells, platelets, and lymphocytes; others react with proteins in complex with phospholipids. *Antiphospholipid antibodies* are present in 30% to 40% of lupus patients. They are actually specific for epitopes of plasma proteins that are revealed when the proteins are in complex with phospholipids. Included among these proteins are prothrombin, annexin V, β_2-glycoprotein I, protein S, and protein C. Antibodies against the phospholipid-β_2-glycoprotein complex

also bind to cardiolipin antigen, used in syphilis serology, and therefore lupus patients may have a false-positive test result for syphilis. Some of these antibodies interfere with in vitro clotting tests, such as partial thromboplastin time. Therefore, these antibodies are sometimes referred to as *lupus anticoagulant*. Despite the observed clotting delays in vitro, however, patients with antiphospholipid antibodies have complications related to excessive clotting (a hypercoagulable state), such as thrombosis (Chapter 4).

Pathogenesis

The fundamental defect in SLE is a failure of the mechanisms that maintain self-tolerance. Although what causes this failure of self-tolerance remains unknown, as is true of most autoimmune diseases, both genetic and environmental factors play a role.

Genetic Factors. SLE is a genetically complex disease with contributions from MHC and multiple non-MHC genes. Many lines of evidence support a genetic predisposition.

- Family members of patients have an increased risk of developing SLE. In addition, laboratory testing has revealed that as many as 20% of clinically unaffected first-degree relatives of SLE patients have autoantibodies and other immune abnormalities.
- There is a higher rate of concordance (>20%) in monozygotic twins when compared with dizygotic twins (1% to 3%).
- Studies of HLA associations support the concept that MHC genes regulate production of particular autoantibodies. Specific alleles of the *HLA-DQ* locus have been linked to the production of anti–double-stranded DNA, anti-Sm, and antiphospholipid antibodies, although the relative risk is small.
- Some lupus patients have inherited deficiencies of early complement components, such as C2, C4, or C1q. Lack of complement may impair removal of circulating immune complexes by the mononuclear phagocyte system, thus favoring tissue deposition. Knockout mice lacking C4 or certain complement receptors are also prone to develop lupus-like autoimmunity. Various mechanisms have been invoked, including failure to clear immune complexes and loss of B-cell self-tolerance. It has also been proposed that deficiency of C1q results in defective phagocytic clearance of apoptotic cells. Many cells normally undergo apoptosis, and if they are not cleared their nuclear components may elicit immune responses.
- Genome-wide association studies have identified several genetic loci that may be associated with the disease. Many of these loci encode proteins involved in lymphocyte signaling and interferon responses, both of which may play a role in lupus pathogenesis, as discussed later. The relative risk for each locus is small, and even taken together these loci account for 20% or less of the disease predisposition, suggesting an important role for environmental factors, discussed later.

Immunologic Factors. Recent studies in animal models and patients have revealed several immunologic aberrations that collectively may result in the persistence and uncontrolled activation of self-reactive lymphocytes.

- Failure of self-tolerance in B cells results from defective elimination of self-reactive B cells in the bone marrow or defects in peripheral tolerance mechanisms.
- Activation of CD4+ helper T cells specific for nucleosomal antigens that escape tolerance and help B cells to produce high-affinity pathogenic autoantibodies.
- TLR engagement by nuclear DNA and RNA contained in immune complexes may activate B lymphocytes. These TLRs function normally to sense microbial products, including nucleic acids. Thus, B cells specific for nuclear antigens may get second signals from TLRs and may be activated, resulting in increased production of antinuclear autoantibodies.
- Type I interferons play a role in lymphocyte activation in SLE. High levels of circulating type I interferons and a molecular signature in blood cells suggesting exposure to these cytokines has been reported in SLE patients and correlates with disease severity. Type I interferons are antiviral cytokines that are normally produced during innate immune responses to viruses. It may be that nucleic acids engage TLRs on DCs and stimulate the production of interferons. In other words, self nucleic acids mimic their microbial counterparts. How interferons contribute to the development of SLE is unclear; these cytokines may activate DCs and B cells and promote Th1 responses, all of which may stimulate the production of pathogenic autoantibodies and induce inflammation.

Environmental Factors. There are many indications that environmental factors must also be involved in the pathogenesis of SLE.

- Exposure to ultraviolet (UV) light exacerbates the disease in many individuals. UV irradiation may induce apoptosis in cells and may alter the DNA in such a way that its recognition by TLRs is enhanced. In addition, UV light may modulate the immune response, for example, by stimulating keratinocytes to produce IL-1, a cytokine known to promote inflammation.
- The gender bias of SLE is partly attributable to actions of sex hormones and partly related to unknown genes on the X chromosome, independent of hormone effects.
- Drugs such as hydralazine, procainamide, and D-penicillamine can induce an SLE-like response in humans.

A Model for the Pathogenesis of SLE. It is clear from this discussion that the immunologic abnormalities in SLE—both documented and postulated—are varied and complex. Nevertheless, an attempt can be made to synthesize results from patients and animal studies into a model of the pathogenesis of SLE (Fig. 6.25). UV irradiation and other environmental insults lead to the apoptosis of cells. Inadequate clearance of the nuclei of these cells results in a large burden of nuclear antigens. Underlying abnormalities in B and T lymphocytes are responsible for defective tolerance, because of which self-reactive lymphocytes survive and remain functional. These lymphocytes are stimulated by nuclear self antigens, and antibodies are produced against the antigens. Complexes of the antigens and antibodies bind to Fc receptors on B cells and DCs, and may be internalized. The nucleic acid components engage TLRs and stimulate B cells to produce more autoantibodies. TLR stimuli also activate DCs to produce interferons and other cytokines,

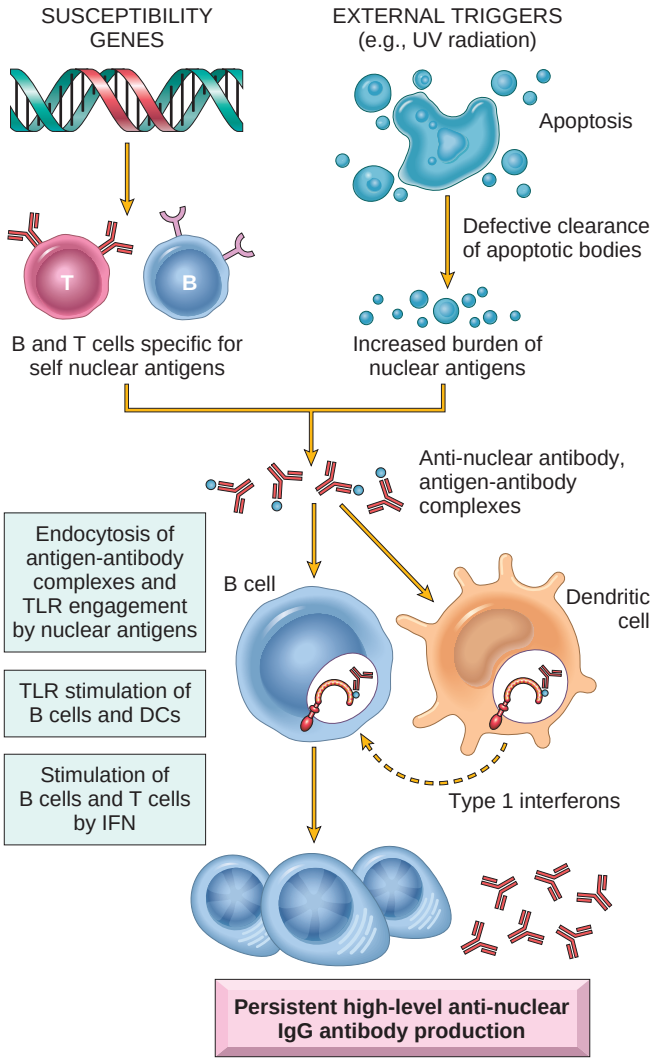

Figure 6.25 Model for the pathogenesis of systemic lupus erythematosus. In this hypothetical model, susceptibility genes interfere with the maintenance of self-tolerance, and external triggers lead to persistence of nuclear antigens. The result is an antibody response against self nuclear antigens, which is amplified by the action of nucleic acids on dendritic cells *(DCs)* and B cells, and the production of type I interferons. *IFN,* Interferon; *TLRs,* Toll-like receptors.

which further enhance the immune response and cause more apoptosis. The net result is a cycle of antigen release and immune activation resulting in the production of high-affinity autoantibodies.

Mechanisms of Tissue Injury. Different autoantibodies are the cause of most of the lesions of SLE.

- Most of the systemic lesions are caused by *immune complexes (type III hypersensitivity).* DNA–anti-DNA complexes can be detected in the glomeruli and small blood vessels in animal models. Low levels of serum complement (secondary to consumption of complement proteins) and granular deposits of complement and immunoglobulins in the glomeruli further support the role of immune complex deposition. T-cell infiltrates are also frequently seen in the kidneys and may be involved in tissue damage. There is no evidence that ANAs, which are present in immune complexes, can penetrate intact cells. If cell nuclei are exposed, however, the ANAs can bind to them. In tissues, nuclei of damaged cells react with ANAs, lose their chromatin pattern, and become homogeneous, to produce so-called LE bodies or hematoxylin bodies. Related to this phenomenon is the *LE cell,* which is readily seen when blood is agitated in vitro. The LE cell is any phagocytic leukocyte (blood neutrophil or macrophage) that has engulfed the denatured nucleus of an injured cell. The demonstration of LE cells in vitro was used in the past as a test for SLE. With new techniques for detection of ANAs, however, this test is now largely of historical interest. Sometimes, LE cells are found in pericardial or pleural effusions in patients.
- Autoantibodies specific for red blood cells, white blood cells, and platelets opsonize these cells and promote their phagocytosis and destruction, resulting in cytopenias. These are examples of antibody-mediated (type II) hypersensitivity. The most common disorder caused by this type of autoantibody is immune thromobocytopenic purpura (ITP; Chapter 14), which occurs in up to 10% of patients with SLE. ITP is most commonly due to autoantibodies that bind platelet membrane glycoproteins, leading to removal of platelets by macrophages, particularly in splenic sinusoids.
- *Antiphospholipid antibody syndrome.* Patients with antiphospholipid antibodies may develop venous and arterial thromboses, which may be associated with recurrent spontaneous miscarriages and focal cerebral or ocular ischemia. This constellation of clinical features, in association with lupus, is referred to as the secondary antiphospholipid antibody syndrome. The mechanisms of thrombosis are not defined, and antibodies against clotting factors, platelets, and endothelial cells have all been proposed as being responsible for thrombosis (Chapter 4). Some patients develop these autoantibodies and the clinical syndrome without associated SLE. They are said to have the primary antiphospholipid antibody syndrome (Chapter 4).
- The *neuropsychiatric manifestations* of SLE have been attributed to antibodies that cross the blood-brain barrier and react with neurons or receptors for various neurotransmitters. Other immune factors, such as cytokines, may also be involved in the cognitive dysfunction and CNS abnormalities that are associated with SLE.

MORPHOLOGY

The morphologic changes in SLE are extremely variable. The frequency of individual organ involvement is shown in Table 6.11. The most characteristic lesions result from immune complex deposition in blood vessels, kidneys, connective tissue, and skin.

Blood Vessels. An acute necrotizing vasculitis involving capillaries, small arteries, and arterioles may be present in any tissue. The arteritis is characterized by fibrinoid necrosis of the vessel walls. In chronic stages, vessels undergo fibrous thickening with luminal narrowing.

Kidney. Up to 50% of SLE patients have clinically significant renal involvement mainly in the form of glomerulonephritis and tubulointerstitial nephritis. The glomerular lesions are the result

Table 6.11 Clinical and Pathologic Manifestations of Systemic Lupus Erythematosus

Clinical Manifestation	Prevalence in Patients (%)[a]
Hematologic	100
Arthritis, arthralgia or myalgia	80–90
Skin	85
Fever	55–85
Fatigue	80–100
Weight loss	60
Renal	50–70
Neuropsychiatric	25–35
Pleuritis	45
Pericarditis	25
Gastrointestinal	20
Raynaud phenomenon	15–40
Ocular	5–15
Peripheral neuropathy	15

[a]Percentages are approximate and may vary with age, ethnicity, and other factors. Table compiled with the assistance of Dr. Meenakshi Jolly, Rush Medical Center, Chicago, Ill.

of deposition of immune complexes on the glomerular basement membrane, in the mesangium, and sometimes throughout the glomerulus. According to the currently accepted classification, six patterns of glomerular disease are seen in SLE. It should be noted that there is some overlap between these classes, and over time lesions may evolve from one class to another. Thus, the exact percentage of patients with each of the six classes of lesions is difficult to determine. Suffice it to say that class I is the least common and class IV is the most common pattern.

- *Minimal mesangial lupus nephritis* (class I) is very uncommon and is characterized by immune complex deposition in the mesangium, identified by immunofluorescence and by electron microscopy, but without structural changes by light microscopy.
- *Mesangial proliferative lupus nephritis* (class II) is characterized by mesangial cell proliferation, often accompanied by accumulation of mesangial matrix, and granular mesangial deposits of immunoglobulin and complement without involvement of glomerular capillaries.
- *Focal lupus nephritis* (class III) is defined by involvement of fewer than 50% of glomeruli. The lesions may be segmental (affecting only a portion of the glomerulus) or global (involving the entire glomerulus). Affected glomeruli may exhibit swelling and proliferation of endothelial and mesangial cells, leukocyte accumulation, capillary necrosis, and hyaline thrombi. There is also often extracapillary proliferation associated with focal necrosis and crescent formation (Fig. 6.26A). The clinical presentation ranges from mild hematuria and proteinuria to acute renal insufficiency. Red blood cell casts in the urine are common when the disease is active. Some patients progress to diffuse glomerulonephritis. The active (or proliferative) inflammatory lesions can heal completely or lead to chronic global or segmental glomerular scarring.
- *Diffuse lupus nephritis* (class IV) is the most common and severe form of lupus nephritis. The lesions are similar to those in class III, but differ in extent; typically, in class IV nephritis half or more of the glomeruli are affected. As in class III, the lesions may be segmental or global and on the basis of this, it can be subclassified as Class IV segmental (IV-S) or Class IV global (IV-G). Involved glomeruli show proliferation of endothelial, mesangial, and epithelial cells (Fig. 6.26B), with the latter producing cellular crescents that fill Bowman's space (Chapter 20). Subendothelial immune complex deposits may cause circumferential thickening of the capillary wall, forming "wire loop" structures on light microscopy (Fig. 6.26C). Immune complexes can be readily detected by electron microscopy (Fig. 6.26D) and immunofluorescence (Fig. 6.26E). Lesions may progress to scarring of glomeruli. Patients with diffuse glomerulonephritis are usually symptomatic, showing hematuria as well as proteinuria. Hypertension and mild to severe renal insufficiency are also common.
- *Membranous lupus nephritis* (class V) is characterized by diffuse thickening of the capillary walls due to deposition of subepithelial immune complexes, similar to idiopathic membranous nephropathy, described in Chapter 20. The immune complexes are usually accompanied by increased production of basement membrane–like material. This lesion typically causes severe proteinuria or nephrotic syndrome and may occur concurrently with focal or diffuse lupus nephritis.
- *Advanced sclerosing lupus nephritis* (class VI) is characterized by sclerosis of more than 90% of the glomeruli and represents end-stage renal disease.

Changes in the interstitium and tubules are frequently present in lupus nephritis. Rarely, **tubulointerstitial lesions** may be the dominant abnormality. Immune complexes similar to those in glomeruli are present in the tubular or peritubular capillary basement membranes in many lupus nephritis patients. Occasionally, there are well-organized B-cell follicles in the interstitium, with plasma cells that may be sources of autoantibodies.

Skin. Characteristic erythema affects the face along the bridge of the nose and cheeks (the "butterfly" rash) in approximately 50% of patients, and a similar rash may be seen on the extremities and trunk. Urticaria, bullae, maculopapular lesions, and ulcerations also occur. Exposure to sunlight incites or accentuates the erythema. Histologically the involved areas show vacuolar degeneration of the basal layer of the epidermis (Fig. 6.27A). In the dermis, there is variable edema and perivascular inflammation. Vasculitis with fibrinoid necrosis may be prominent. Immunofluorescence microscopy shows deposition of immunoglobulin and complement along the dermoepidermal junction (Fig. 6.27B), which may also be present in uninvolved skin. This finding is not specific for SLE and is sometimes seen in scleroderma or dermatomyositis.

Joints. Joint involvement is typically a nonerosive synovitis with little deformity, which contrasts with rheumatoid arthritis.

CNS. No clear morphologic abnormalities account for the neuropsychiatric symptoms of SLE. Noninflammatory occlusion of small vessels by intimal proliferation is sometimes noted, which may be due to endothelial damage by autoantibodies or immune complexes.

Pericarditis and Other Serosal Cavity. Inflammation of the serosal lining membranes may be acute, subacute, or chronic. During the acute phases, the mesothelial surfaces are sometimes covered with fibrinous exudate. Later they become thickened, opaque, and coated with a shaggy fibrous tissue that may lead to partial or total obliteration of the serosal cavity. Pleural and pericardial effusions may be present.

Cardiovascular System. Involvement may manifest as damage to any layer of the heart. Symptomatic or asymptomatic pericardial involvement is present in up to 50% of patients. Myocarditis, or

mononuclear cell infiltration, is less common and may cause resting tachycardia and electrocardiographic abnormalities. Valvular abnormalities, primarily of the mitral and aortic valves, manifest as diffuse leaflet thickening that may be associated with dysfunction (stenosis and/or regurgitation). Valvular endocarditis (called Libman-Sacks endocarditis) was more common before the widespread use of steroids. This nonbacterial verrucous endocarditis takes the form of single or multiple 1- to 3-mm warty deposits on any heart valve, distinctively on either surface of the leaflets (Fig. 6.28). By comparison, the vegetations in infective endocarditis are considerably larger, and those in rheumatic heart disease (Chapter 12) are smaller and confined to the lines of closure of the valve leaflets.

An increasing number of SLE patients have evidence of coronary artery disease (angina, myocardial infarction) resulting from coronary atherosclerosis. This complication is particularly notable in young patients with long-standing disease, and especially prevalent in those who have been treated with corticosteroids. The pathogenesis of accelerated coronary atherosclerosis is unclear but is probably multifactorial. Risk factors for atherosclerosis, including hypertension, obesity, and hyperlipidemia, are more commonly present in SLE patients than in the population at large. In addition, immune complexes and antiphospholipid antibodies may cause endothelial damage and promote atherosclerosis.

Spleen. Splenomegaly, capsular thickening, and follicular hyperplasia are common features. Central penicilliary arteries may show concentric intimal and smooth muscle cell hyperplasia, producing so-called onion-skin lesions.

Lungs. In addition to pleuritis and pleural effusions, which are present in almost 50% of patients, in some cases, there is chronic interstitial fibrosis and secondary pulmonary hypertension. None of these changes is specific for SLE.

Other Organs and Tissues. LE, or hematoxylin, bodies in the bone marrow or other organs are strongly indicative of SLE. Lymph nodes may be enlarged due to the presence of hyperplastic germinal centers, or may even demonstrate necrotizing lymphadenitis, usually associated with the presence of activated CTLs and macrophages. The activated T cells may be so prominent in such cases as to mimic certain features of T-cell lymphoma but are polyclonal and reactive in nature.

Clinical Features

SLE is a multisystem disease that is highly variable in its presentation, and its diagnosis relies on a constellation of clinical, serologic, and morphologic changes (see Table 6.9). It may be acute or insidious in its onset. Often, the patient is a young woman with some, but not necessarily all, of the following features: a butterfly rash over the face, fever, pain but no deformity in one or more peripheral joints (feet, ankles, knees, hips, fingers, wrists, elbows, shoulders), pleuritic chest pain, and photosensitivity. In many patients, however, the presentation of SLE is subtle and puzzling, taking forms such as a febrile illness of unknown origin, abnormal urinary findings, or joint disease masquerading

as rheumatoid arthritis or rheumatic fever. "Generic" ANAs, detected by immunofluorescence assays, are found in virtually 100% of patients, but these are not specific for SLE. A variety of clinical findings may point toward renal involvement, including hematuria, red cell casts, proteinuria, and in some cases the classic nephrotic syndrome (Chapter 20). Laboratory evidence of some hematologic derangement is seen in virtually every case, but in some patients anemia or thrombocytopenia may be the presenting manifestation as well as the dominant clinical problem. In still others, mental aberrations, including psychosis or convulsions, or coronary artery disease may be prominent clinical problems. Patients with SLE are also prone to infections, presumably because of their underlying immune dysfunction and treatment with immunosuppressive drugs.

The course of the disease is variable and unpredictable. Rarely, death ensues within weeks to months. More often, with appropriate therapy, the disease follows a relapsing and remitting course spanning a period of years or even decades. During acute flareups, increased formation of immune complexes results in complement activation, often leading to hypocomplementemia. Disease flares are usually treated with corticosteroids or other immunosuppressive drugs. Even without therapy, in some patients the disease runs an indolent course with relatively mild manifestations, such as skin changes and mild hematuria, for years. The outcome has improved significantly, and an approximately 90% 5-year and 80% 10-year survival can be expected. The most common causes of death are renal failure and intercurrent infections. Coronary artery disease is also becoming an important cause of death. Patients treated with steroids and immunosuppressive drugs incur the usual risks associated with such therapy.

As mentioned earlier, involvement of skin along with multisystem disease is fairly common in SLE. The following sections describe two syndromes in which the cutaneous involvement is the exclusive or most prominent feature.

Chronic Discoid Lupus Erythematosus

Chronic discoid lupus erythematosus is a disease in which the skin manifestations may mimic SLE, but systemic manifestations are rare. It is characterized by the presence of skin plaques showing varying degrees of edema, erythema, scaliness, follicular plugging, and skin atrophy surrounded by an elevated erythematous border. The disease usually remains confined to the skin, but 5% to 10% of patients develop multisystem manifestations after many years. Approximately 35% of patients test positive for generic ANAs, but antibodies to double-stranded DNA are rarely present. Immunofluorescence studies of skin biopsy specimens show deposition of immunoglobulin and C3 at the dermoepidermal junction, similar to what is seen in SLE.

Subacute Cutaneous Lupus Erythematosus

Subacute cutaneous lupus erythematosus appears to define a group of patients with features intermediate between SLE and chronic discoid lupus erythematosus. The condition presents with predominant skin involvement and is distinguished from chronic discoid lupus erythematosus by several criteria. Firstly, the skin rash tends to be widespread, superficial, and nonscarring (though exceptions occur). Secondly, most patients have mild systemic symptoms consistent with SLE. There is a strong association with antibodies to the SS-A antigen and with the *HLA-DR3* genotype.

Drug-Induced Lupus Erythematosus

An SLE-like syndrome may develop in patients receiving a variety of drugs, including hydralazine, procainamide, isoniazid, and D-penicillamine, to name only a few. Somewhat surprisingly, anti-TNF therapy, which is effective in rheumatoid arthritis and other autoimmune diseases, can also cause drug-induced lupus. Many of these drugs are associated with the development of ANAs, but most patients do not have symptoms of SLE. For example, 80% of patients receiving procainamide test positive for ANAs, but only one-third of these manifest clinical symptoms, such as arthralgias, fever, and serositis. Although multiple organs are affected, renal and CNS involvement is distinctly uncommon. There are serologic and genetic differences from classic SLE, as well. Antibodies specific for double-stranded DNA are rare, but there is an extremely high frequency of antibodies specific for histones.

KEY CONCEPTS

SYSTEMIC LUPUS ERYTHEMATOSUS

- SLE is a systemic autoimmune disease caused by autoantibodies produced against numerous self antigens and the formation of immune complexes.
- The major autoantibodies, and the ones responsible for the formation of circulating immune complexes, are directed against nuclear antigens. Other autoantibodies react with red cells, platelets, and various complexes of phospholipids with proteins.
- Disease manifestations include nephritis, skin lesions, arthritis (all caused by the deposition of immune complexes), and hematologic and neurologic abnormalities.

The underlying cause of the breakdown in self-tolerance in SLE is unknown; it may include excess or persistence of nuclear antigens, multiple inherited susceptibility genes, and environmental triggers (e.g., UV irradiation, which results in cellular apoptosis and release of nuclear proteins).

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease that primarily affects the joints, but may also involve extraarticular tissues such as the skin, blood vessels, lungs, and heart. Abundant evidence supports the autoimmune nature of the disease. Because the principal manifestations of the disease are in the joints, it is discussed in Chapter 26.

Sjögren Syndrome

Sjögren syndrome is a chronic disease characterized by dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia) resulting from immunologically mediated destruction of the lacrimal and salivary glands. It occurs as an isolated disorder (primary form), also known as the *sicca syndrome,* or more often in association with another autoimmune disease (secondary form). Among the associated disorders, rheumatoid arthritis is the most common, but some patients have SLE, polymyositis, scleroderma, vasculitis, mixed connective tissue disease, or thyroiditis.

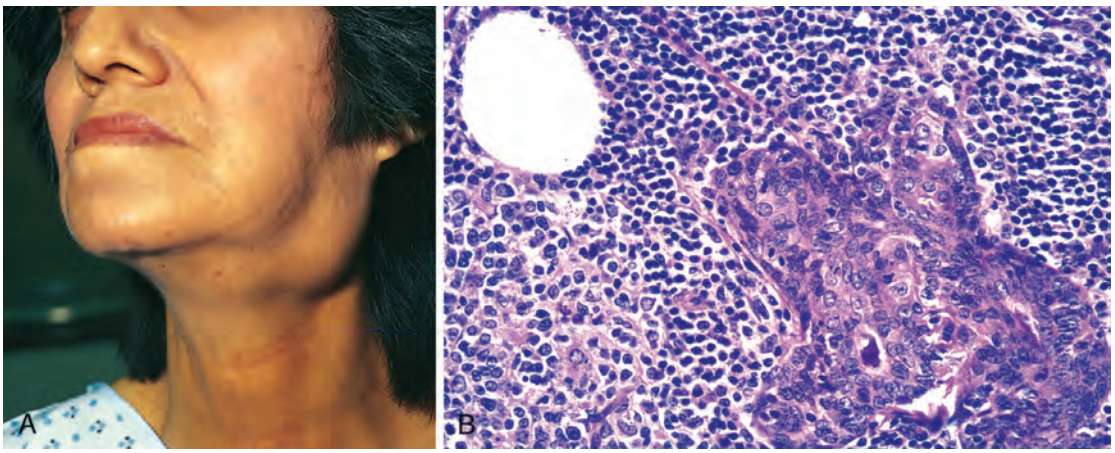

Figure 6.29 Sjögren syndrome. (A) Enlargement of the salivary gland. (B) Intense lymphocytic and plasma cell infiltration with ductal epithelial hyperplasia in a salivary gland. (A) Courtesy Dr. Richard Sontheimer, Department of Dermatology, University of Texas Southwestern Medical School, Dallas, Tex. (B) Courtesy Dr. Dennis Burns, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Pathogenesis

The characteristic decrease in tears and saliva (sicca syndrome) is the result of lymphocytic infiltration and fibrosis of the lacrimal and salivary glands. The infiltrate contains predominantly activated CD4+ helper T cells and some B cells, including plasma cells. About 75% of patients have rheumatoid factor (an antibody reactive with self IgG) whether or not coexisting rheumatoid arthritis is present. ANAs are detected in 50% to 80% of patients by immunofluorescence assay. A host of other organ-specific and non–organ-specific antibodies have also been identified. Most important, however, are antibodies directed against two ribonucleoprotein antigens, SS-A (Ro) and SS-B (La) (see Table 6.10), which can be detected in as many as 90% of patients by sensitive techniques. These antibodies are thus considered serologic markers of the disease. These autoantibodies are also present in a smaller percentage of patients with SLE and hence are not entirely specific for Sjögren syndrome.

As with other autoimmune diseases, Sjögren syndrome shows some association, albeit weak, with certain HLA alleles. The significance of such associations in disease causation or manifestations is not clear.

Although the pathogenesis of Sjögren syndrome remains obscure, aberrant T-cell and B-cell activation are both implicated. The initiating trigger may be a viral infection of the salivary glands, which causes local cell death and release of tissue self antigens. In genetically susceptible individuals, CD4+ T cells and B cells specific for these self antigens may have escaped tolerance and are able to react. The result is inflammation, tissue damage, and, eventually, fibrosis. However, the role of particular cytokines or T cell subsets in the development of the lesions is not established. The nature of the autoantigens recognized by these lymphocytes is also mysterious. Sjögren syndrome–like disease is seen in some patients with human T-lymphotropic virus (HTLV), human immunodeficiency virus (HIV), and hepatitis C virus infections, but the link between these viruses and the autoimmune disorder is obscure.

MORPHOLOGY

Lacrimal and salivary glands are the major targets of the disease, but other exocrine glands, including those lining the respiratory and gastrointestinal tracts and the vagina, may also be involved. The earliest histologic finding in involved salivary glands is periductal and perivascular lymphocytic infiltration. Eventually the lymphocytic infiltrate becomes extensive (Fig. 6.29B), and lymphoid follicles with germinal centers may appear. The ductal lining epithelial cells may show hyperplasia, thus obstructing the ducts. Later there is atrophy of the acini, fibrosis, and hyalinization; still later in the course, atrophy and replacement of parenchyma with fat are seen. In some cases, the lymphoid infiltrate may be so intense as to give the appearance of a lymphoma. Indeed, these patients are at high risk for development of B-cell lymphomas.

The lack of tears leads to drying of the corneal epithelium, which becomes inflamed, eroded, and ulcerated; the oral mucosa may atrophy, with inflammatory fissuring and ulceration; and dryness and crusting of the nose may lead to ulcerations and even perforation of the nasal septum.

Clinical Features

Sjögren syndrome occurs most commonly in women between 50 and 60 years of age. As might be expected, symptoms result from inflammatory destruction of the exocrine glands. The keratoconjunctivitis produces blurring of vision, burning, and itching, and thick secretions accumulate in the conjunctival sac. The xerostomia results in difficulty in swallowing solid foods, a decrease in the ability to taste, cracks and fissures in the mouth, and dryness of the buccal mucosa. Parotid gland enlargement is present in one-half of patients; dryness of the nasal mucosa, epistaxis, recurrent bronchitis, and pneumonitis are other symptoms. Manifestations of extraglandular disease are seen in one-third of patients and include synovitis, diffuse pulmonary fibrosis, and peripheral neuropathy. These are more common in patients with high titers of antibodies specific for SS-A. In contrast to SLE, glomerular lesions are extremely rare in Sjögren syndrome. Defects of tubular function, however, including renal tubular

acidosis, uricosuria, and phosphaturia, are often seen and are associated with tubulointerstitial nephritis (Chapter 20). About 60% of patients have another accompanying autoimmune disorder, such as rheumatoid arthritis, and these patients also have the symptoms and signs of that disorder.

The combination of lacrimal and salivary gland inflammation was once called Mikulicz disease. The name has now been replaced by *Mikulicz syndrome,* broadened to include lacrimal and salivary gland enlargement from any cause, including sarcoidosis, IgG4-related disease (described later), lymphoma, and other tumors.

As mentioned earlier, the involved glands show intense inflammatory infiltrates. In early stages of the disease, this immune infiltrate consists of a mixture of polyclonal T and B cells. However, if the reaction continues unabated, there is a strong tendency over time for individual clones within the population of B cells to gain a growth advantage, presumably because of the acquisition of somatic mutations. Emergence of a dominant B-cell clone is usually indicative of the development of a marginal zone lymphoma, a specific type of B-cell malignancy that often arises in the setting of chronic lymphocytic inflammation. About 5% of Sjögren patients develop lymphoma, an incidence that is 40-fold greater than normal. Certain other autoimmune disorders (e.g., Hashimoto thyroiditis) are also associated with a high risk of marginal zone lymphoma (Chapter 13), which typically arises within the organ or tissue that is the target of the autoimmune inflammation.

KEY CONCEPTS

SJÖGREN SYNDROME

- Sjögren syndrome is an inflammatory disease that affects primarily the salivary and lacrimal glands, causing dryness of the mouth and eyes.
- The disease is believed to be caused by an autoimmune T-cell reaction against an unknown self antigen expressed in these glands, or immune reactions against the antigens of a virus that infects the tissues.

Systemic Sclerosis (Scleroderma)

Systemic sclerosis is characterized by: (1) chronic inflammation thought to be the result of autoimmunity, (2) widespread damage to small blood vessels, and (3) progressive interstitial and perivascular fibrosis in the skin and multiple organs. Although the term *scleroderma* is ingrained in clinical medicine, this disease is better named *systemic sclerosis* because it is characterized by excessive fibrosis throughout the body. The skin is most commonly affected, but the gastrointestinal tract, kidneys, heart, muscles, and lungs also are frequently involved. In some patients, the disease seems to remain confined to the skin for many years, but in the majority it progresses to visceral involvement with death from renal failure, cardiac failure, pulmonary insufficiency, or intestinal malabsorption. The clinical heterogeneity of systemic sclerosis has been recognized by classifying the disease into two major categories: *diffuse scleroderma,* characterized by widespread skin involvement at onset, with rapid progression and early visceral involvement; and *limited scleroderma,* in which the skin involvement is often confined to fingers, forearms, and face. Visceral involvement occurs late; hence, the clinical course is relatively benign. Some patents with the limited disease develop a combination of calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia, called the *CREST syndrome*. Several other variants and related conditions, such as eosinophilic fasciitis, occur far less frequently and are not described here.

Pathogenesis

The cause of systemic sclerosis is not known, but the **disease likely results from three interrelated processes—autoimmune responses, vascular damage, and collagen deposition** (Fig. 6.30).

- *Autoimmunity.* It is proposed that CD4+ T cells responding to an as yet unidentified antigen accumulate in the skin and release cytokines that activate inflammatory cells and fibroblasts. Although inflammatory infiltrates are typically sparse in the skin of patients with systemic sclerosis, activated CD4+ T cells can be found in many patients,

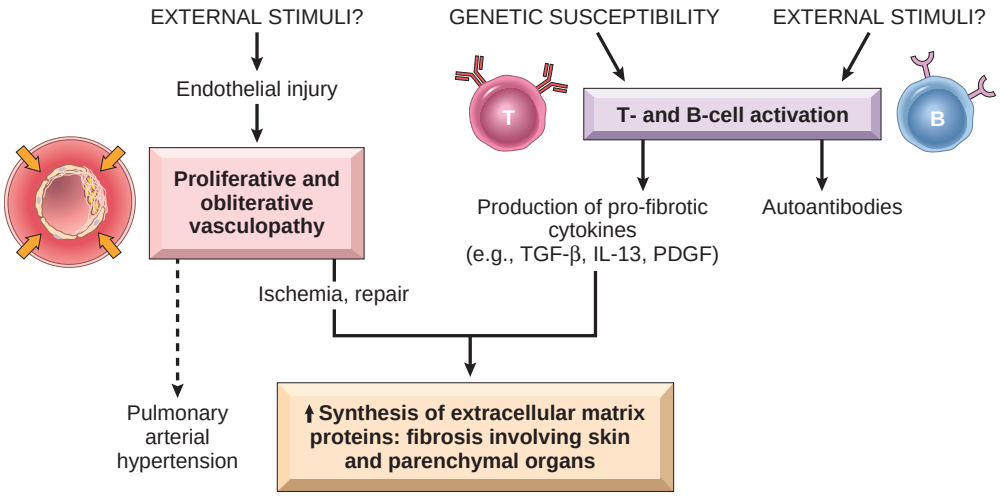

Figure 6.30 A model for the pathogenesis of systemic sclerosis. Unknown external stimuli cause vascular abnormalities and immune activation in genetically susceptible individuals, and both contribute to the excessive fibrosis.

and Th2 cells have been isolated from the skin. Several cytokines produced by these T cells, including TGF-β and IL-13, can stimulate the transcription of genes encoding collagen and other extracellular matrix proteins (e.g., fibronectin) in fibroblasts. Other cytokines recruit leukocytes and propagate the chronic inflammation. There is also evidence for inappropriate activation of humoral immunity, and the presence of various autoantibodies, notably ANAs, provides diagnostic and prognostic information. The role of these ANAs in the pathogenesis of the disease is unclear; it has been postulated that some of these antibodies may stimulate fibrosis, but the evidence in support of this idea is not convincing.

- *Vascular damage.* Microvascular disease is consistently present early in the course of systemic sclerosis and may be the initial lesion. Intimal proliferation is evident in the digital arteries of patients with systemic sclerosis. Capillary dilation with leaking, as well as destruction, is also common. Nailfold capillary loops are distorted early in the course of disease, and later they disappear. Telltale signs of endothelial activation and injury (e.g., increased levels of von Willebrand factor) and increased platelet activation (increased circulating platelet aggregates) have also been noted. However, what causes the vascular injury is not known; it could be the initiating event or the result of chronic inflammation, with mediators released by inflammatory cells inflicting damage on microvascular endothelium. Repeated cycles of endothelial injury followed by platelet aggregation lead to release of platelet and endothelial factors (e.g., PDGF, TGF-β) that trigger perivascular fibrosis. Vascular smooth muscle cells also show abnormalities, such as increased expression of adrenergic receptors. Eventually, widespread narrowing of the microvasculature leads to ischemic injury and scarring.
- *Fibrosis.* The progressive fibrosis characteristic of the disease may be the culmination of multiple abnormalities, including the accumulation of alternatively activated macrophages, actions of fibrogenic cytokines produced by infiltrating leukocytes, hyperresponsiveness of fibroblasts to these cytokines, and scarring following ischemic damage caused by the vascular lesions. There is some evidence that fibroblasts from patients with systemic sclerosis have an intrinsic abnormality that causes them to produce excessive amounts of collagen. This idea is based on studies with cultured fibroblasts, and whether or how this abnormality relates to pathogenesis in vivo is unknown.

MORPHOLOGY

Virtually all organs may be involved in systemic sclerosis. Prominent changes occur in the skin, alimentary tract, musculoskeletal system, and kidney, and lesions also are often present in the blood vessels, heart, lungs, and peripheral nerves.

Skin. The majority of patients have diffuse, sclerotic atrophy of the skin, which usually begins in the fingers and distal regions of the upper extremities and extends proximally to involve the upper arms, shoulders, neck, and face. Histologically, there are perivascular infiltrates containing CD4+ T cells and edema, together with degeneration of collagen fibers, which become eosinophilic. Capillaries and small arteries (150 to 500 μm in diameter) may show thickening of the basal lamina, endothelial cell damage, and partial occlusion. With progression of the disease, there is increasing fibrosis of the dermis, which becomes tightly bound to the subcutaneous structures. There is marked increase of compact collagen in the dermis, usually with thinning of the epidermis, loss of rete pegs, atrophy of the dermal appendages, and hyaline thickening of the walls of dermal arterioles and capillaries (Fig. 6.31B). Focal and sometimes diffuse subcutaneous calcifications may develop, especially in patients with the CREST syndrome. In advanced stages, the fingers take on a tapered clawlike appearance, joint motion is limited, and the face becomes a drawn mask. Loss of blood supply may lead to cutaneous ulcerations and to atrophic changes in the terminal phalanges (Fig. 6.31C). Sometimes the tips of the fingers undergo autoamputation.

Alimentary Tract. The alimentary tract is affected in approximately 90% of patients. Progressive atrophy and collagenous fibrous replacement of the muscularis may develop at any level of the gut but are most severe in the esophagus. The lower two-thirds of the esophagus often develops a rubber-hose–like inflexibility. The associated dysfunction of the lower esophageal sphincter gives rise to gastroesophageal reflux and its complications, including Barrett esophagus (Chapter 17) and strictures. The mucosa is thinned and may be ulcerated, and there is excessive collagenization of the lamina propria and submucosa. Loss of villi and microvilli in the small bowel sometimes produces a malabsorption syndrome.

Musculoskeletal System. Inflammation of the synovium, associated with synovial hypertrophy and hyperplasia, is common in the early stages; fibrosis later ensues. These changes are reminiscent of rheumatoid arthritis, but joint destruction is not common in systemic sclerosis. In a small subset of patients (approximately 10%), inflammatory myositis may develop.

Kidneys. Renal abnormalities occur in two-thirds of patients with systemic sclerosis, most prominently vascular lesions. Interlobular arteries show intimal thickening as a result of deposition of mucinous or finely collagenous material, which stains histochemically for glycoprotein and acid mucopolysaccharides. There is also concentric proliferation of intimal cells. These changes may resemble those seen in malignant hypertension, but in scleroderma the alterations are restricted to vessels 150 to 500 μm in diameter and are not always associated with hypertension. Hypertension, however, does occur in 30% of patients with scleroderma, and in 20% it takes an ominously rapid, downhill course (malignant hypertension). In hypertensive patients, vascular alterations are more pronounced and are often associated with fibrinoid necrosis of arterioles, thrombosis, and infarction. Such patients often die of renal failure, which overall accounts for about 50% of deaths from systemic sclerosis. There are no specific glomerular changes.

Lungs. Pulmonary involvement is seen in more than 50% of individuals with systemic sclerosis and may manifest as interstitial fibrosis and pulmonary hypertension. Pulmonary vasospasm, secondary to pulmonary vascular endothelial dysfunction, is considered important in the pathogenesis of pulmonary hypertension. Pulmonary fibrosis, when present, is indistinguishable from that seen in idiopathic pulmonary fibrosis (Chapter 15).

Heart. Pericarditis with effusion, myocardial fibrosis, and thickening of intramyocardial arterioles occur in one-third of patients. Clinical impairment by myocardial involvement, however, is less common.

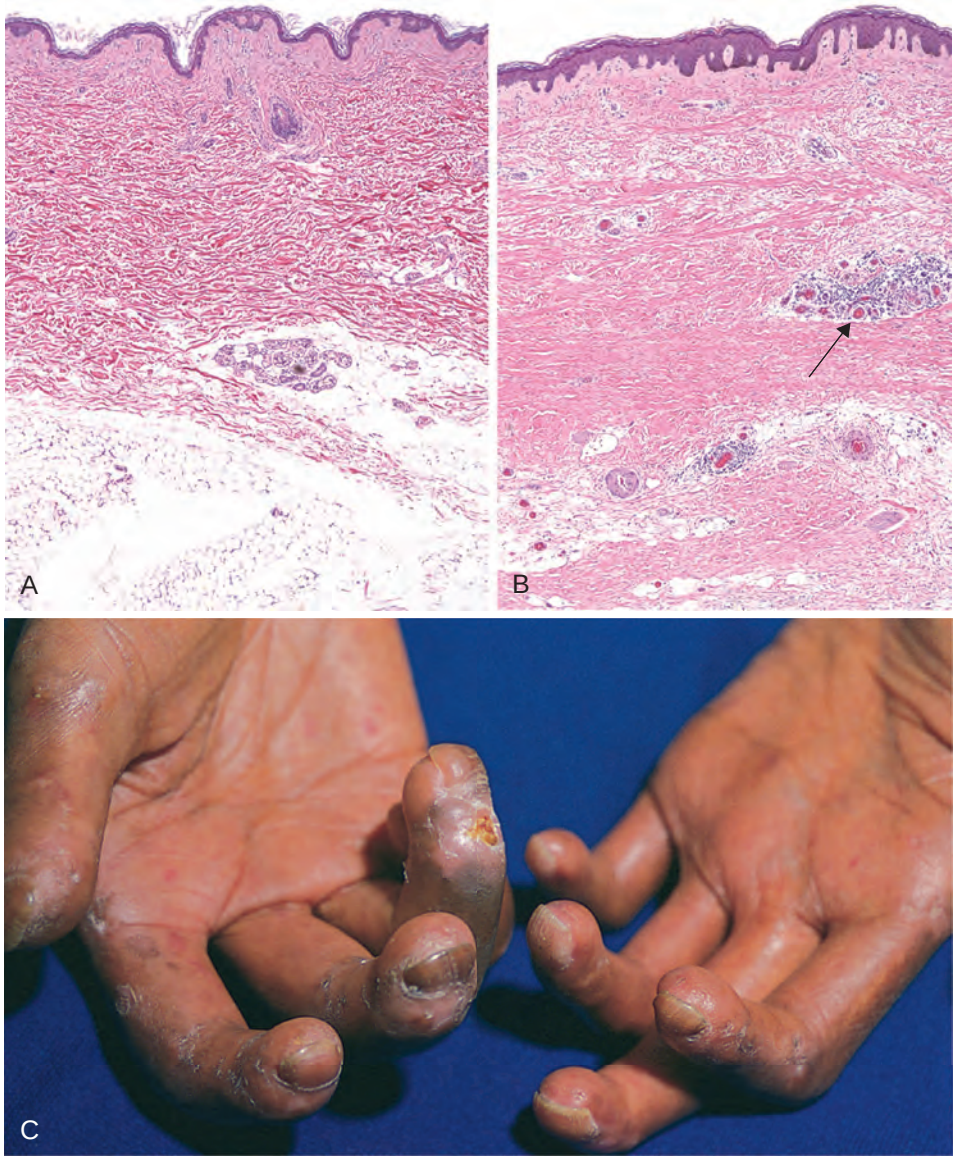

Figure 6.31 Systemic sclerosis. (A) Normal skin. (B) Skin biopsy from a patient with systemic sclerosis. Note the extensive deposition of dense collagen in the dermis with virtual absence of appendages (e.g., hair follicles) and foci of inflammation *(arrow)*. (C) The extensive subcutaneous fibrosis has virtually immobilized the fingers, creating a clawlike flexion deformity. Loss of blood supply has led to cutaneous ulcerations. (C, Courtesy Dr. Richard Sontheimer, Department of Dermatology, University of Texas Southwestern Medical School, Dallas, Tex.)

Clinical Features

Systemic sclerosis has a female-to-male ratio of 3:1, with a peak incidence in the 50- to 60-year age group. Although systemic sclerosis shares many features with SLE, rheumatoid arthritis (Chapter 26), and polymyositis (Chapter 27), its distinctive features are the striking cutaneous changes, notably skin fibrosis (Fig. 6.31C). *Raynaud phenomenon,* manifested as numbness and tingling of the fingers and toes caused by episodic vasoconstriction of arteries and arterioles, is seen in virtually all patients and precedes other symptoms in 70% of cases. Dysphagia attributable to esophageal fibrosis and its resultant hypomotility are present in more than 50% of patients. Eventually, destruction of the esophageal wall leads to atony and dilation, especially at its lower end. Abdominal pain, intestinal obstruction, or malabsorption syndrome with weight loss and anemia due to nutritional deficiencies reflect involvement of the small intestine. Respiratory difficulties caused by the pulmonary fibrosis may result in right-sided cardiac dysfunction, and myocardial fibrosis may cause either arrhythmias or cardiac failure. Proteinuria occurs in as many as 30% of patients, but rarely is severe enough to cause nephrotic syndrome. The most ominous manifestation is malignant hypertension (Chapter 11), with the subsequent development of renal failure, but in its absence progression of the disease may be slow. The disease tends to be more severe in people of African descent, especially women. As treatment of the renal crises has improved, pulmonary disease has become the major cause of death in systemic sclerosis.

Virtually all patients have ANAs that react with a variety of nuclear antigens. Two ANAs strongly associated with systemic sclerosis have been described. One of these, directed

against DNA topoisomerase I (anti-Scl 70), is highly specific. Depending on the ethnic group and the assay, it is present in 10% to 20% of patients with diffuse systemic sclerosis. Patients who have this antibody are more likely to have pulmonary fibrosis and peripheral vascular disease. The other, an anticentromere antibody, is found in 20% to 30% of patients, who tend to have the CREST syndrome. Patients with this syndrome have relatively limited involvement of skin, often confined to fingers, forearms, and face, and calcification of the subcutaneous tissues. Involvement of the viscera, including esophageal lesions, pulmonary hypertension, and biliary cirrhosis, may not occur at all or occur late. In general, these patients live longer than those with diffuse visceral involvement at the outset.

KEY CONCEPTS

SYSTEMIC SCLEROSIS

- Systemic sclerosis (commonly called scleroderma) is characterized by progressive fibrosis involving the skin, gastrointestinal tract, and other tissues.
- Fibrosis may be the result of activation of fibroblasts by cytokines produced by T cells, but what triggers T-cell responses is unknown.
- Endothelial injury and microvascular disease are commonly present in the lesions of systemic sclerosis, perhaps causing chronic ischemia, but the pathogenesis of vascular injury is not known.

Inflammatory Myopathies

Inflammatory myopathies comprise an uncommon, heterogeneous group of disorders characterized by injury and inflammation of mainly the skeletal muscles that are probably immunologically mediated. These diseases are described in Chapter 27.

Mixed Connective Tissue Disease

The term mixed connective tissue disease is used to describe a disease with clinical features that overlap with those of SLE, systemic sclerosis, and polymyositis. The disease is characterized serologically by high titers of antibodies to U1 ribonucleoprotein. Typically, mixed connective tissue disease presents with synovitis of the fingers, Raynaud phenomenon, myositis, and renal involvement, which is modest and responds well to corticosteroids, at least in the short term. It is debated whether mixed connective tissue disease is a truly distinct entity, or if different patients represent subsets of SLE, systemic sclerosis, and myositis. The disease may, over time, evolve into classic SLE or systemic sclerosis. However, in other patients the mixture of features are maintained over time, and the salutary response to steroids is not universal, suggesting that there is a form of mixed connective tissue disease that is distinct from other autoimmune diseases.

Polyarteritis Nodosa and Other Vasculitides

Polyarteritis nodosa belongs to a group of diseases characterized by necrotizing inflammation of the walls of blood vessels and showing strong evidence of an immunologic pathogenic mechanism. The general term *noninfectious vasculitis* differentiates these conditions from those due to direct infection of the blood vessel wall (such as occurs in the wall of an abscess). Noninfectious vasculitis is encountered in many clinical settings. A detailed classification and description of vasculitides is presented in Chapter 11, where the immunologic mechanisms are also discussed.

IgG4-Related Disease

IgG4-related disease (IgG4-RD) is a constellation of disorders characterized by tissue infiltrates dominated by IgG4 antibody–producing plasma cells and lymphocytes (particularly T cells), fibrosis, obliterative phlebitis, and usually increased serum IgG4. Although recognized only recently when extrapancreatic manifestations were identified in patients with autoimmune pancreatitis, IgG4-related disease has now been described in virtually every organ system: the biliary tree, salivary glands, periorbital tissues, kidneys, lungs, lymph nodes, meninges, aorta, breast, prostate, thyroid, pericardium, and skin (Fig. 6.32). Many medical conditions long viewed as confined to single organs are part of the IgG4-RD spectrum. These include some forms of Mikulicz syndrome, Riedel thyroiditis, idiopathic retroperitoneal fibrosis, autoimmune pancreatitis, and inflammatory pseudotumors of the orbit, lungs, and kidneys, to name a few. The disease most often affects middle-age and older men.

The pathogenesis of this condition is not understood, and although IgG4 production in lesions is a hallmark of the disease it is not known if this antibody type contributes to the pathology. The key role of B cells is supported by initial clinical trials in which depletion of B cells with anti–B-cell reagents such as rituximab provided clinical benefit. It is unclear if the disease is truly autoimmune in nature, and no target autoantigens have been identified.

REJECTION OF TISSUE TRANSPLANTS

Transplant rejection is discussed here because it involves several of the immunologic reactions that underlie immune-mediated inflammatory diseases. A major barrier to transplantation is the process of rejection, in which the recipient's immune system recognizes the graft as being foreign and attacks it.

Mechanisms of Recognition and Rejection of Allografts

Rejection is a process in which T lymphocytes and antibodies produced against graft antigens react against and destroy tissue grafts. Grafts exchanged between individuals of the same species (the usual clinical situation) are called *allografts*, and grafts from one species to another (still an experimental procedure) are called *xenografts*. Since most clinical transplants are allografts, the discussion is focused on these.

Recognition of Graft Alloantigens by T and B Lymphocytes

The major antigenic differences between a donor and recipient that result in rejection of transplants are differences in HLA alleles. Because HLA genes are highly

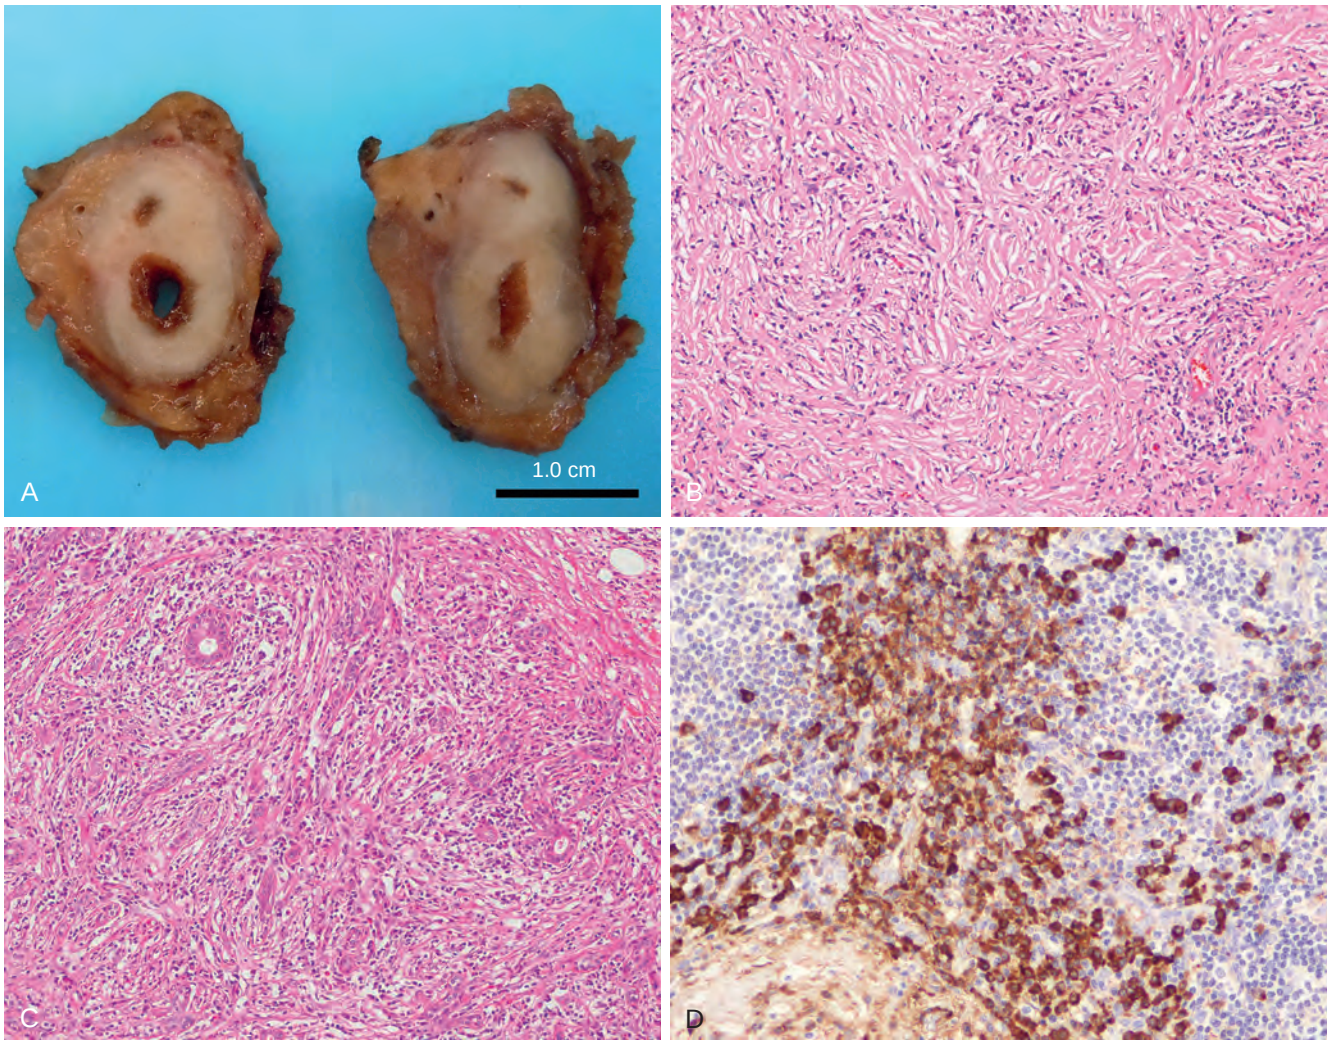

Figure 6.32 IgG4-related disease: representative lesions. (A) Bile duct showing sclerosing cholangitis. (B) Sclerotic area of the bile duct with storiform fibrosis. (C) Submandibular gland with infiltrates of lymphocytes and plasma cells and whorls of fibrosis. (D) Section of an involved lacrimal gland stained with an antibody against IgG_4, showing large numbers of IgG4-producing plasma cells. (From Kamisawa T, Zen Y, Pillai S, et al: IgG4-related disease, *Lancet* 385:1460, 2015.)

polymorphic, there are always some differences between individuals (except, of course, identical twins). Following transplantation, the recipient's T cells recognize donor HLA antigens from the graft (the allogeneic antigens, or alloantigens) by two pathways. The graft antigens are either presented directly to recipient T cells by graft APCs, or the graft antigens are picked up by host APCs, processed (like any other foreign antigen), and presented to host T cells. These are called the direct and indirect pathways of recognition of alloantigens. Both lead to the activation of CD8+ T cells, which develop into CTLs, and CD4+ T cells, which become cytokine-producing effector cells, mainly Th1 cells. The direct pathway may be most important for CTL-mediated acute rejection, and the indirect pathway may play a greater role in chronic rejection.

The frequency of T cells that can recognize the foreign antigens in a graft is much higher than the frequency of T cells specific for any microbe. For this reason, immune responses to allografts are stronger than responses to pathogens. Predictably, these strong reactions can destroy grafts rapidly, and their control requires powerful immunosuppressive agents.

B lymphocytes also recognize antigens in the graft, including HLA and other antigens that differ between donor and recipient. The activation of these B cells typically requires T cell help.

Patterns and Mechanisms of Graft Rejection

Graft rejection is classified into hyperacute, acute, and chronic, on the basis of clinical and pathologic features. This historical classification was devised by clinicians based on rejection of kidney allografts, and has stood the test of time remarkably well. Each type of rejection is mediated by a particular kind of immune response. In the following discussion, the description of the morphology of rejection is limited to kidney allografts, but similar changes are seen in other organ transplants.

- **Hyperacute rejection is mediated by preformed antibodies specific for antigens on graft endothelial cells.** The preformed antibodies may be natural IgM antibodies

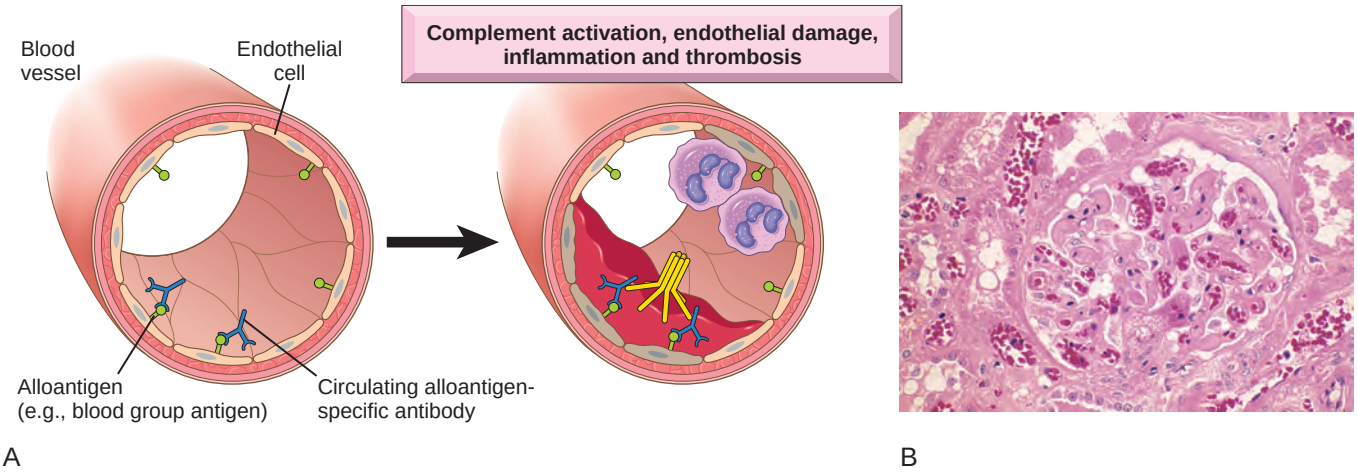

Figure 6.33 Hyperacute rejection. (A) Deposition of antibody on endothelium and activation of complement causes thrombosis. (B) Hyperacute rejection of a kidney allograft showing platelet fibrin thrombi and severe ischemic injury in a glomerulus.

specific for blood group antigens, or may be antibodies specific for allogeneic MHC molecules that were induced by prior exposure of the organ recipient to allogeneic cells through blood transfusions, pregnancy, or transplantation of another organ. Immediately after the graft is implanted and blood flow is restored, the antibodies bind to antigens on the graft vascular endothelium and activate the complement system, leading to endothelial injury, thrombosis, and ischemic necrosis of the graft (Fig. 6.33A). Hyperacute rejection is rare because every donor and recipient are matched for blood type, and potential recipients are tested for antibodies against the cells of the prospective donor, a test called a cross-match.

MORPHOLOGY

In hyperacute rejection, the affected kidney rapidly becomes cyanotic, mottled, and anuric. Virtually all arterioles and arteries exhibit acute fibrinoid necrosis of their walls and narrowing or complete occlusion of their lumens by thrombi (Fig. 6.33B). Neutrophils rapidly accumulate within arterioles, glomeruli, and peritubular capillaries. As these changes intensify and become diffuse, the glomerular capillaries also undergo thrombotic occlusion, and eventually the kidney cortex undergoes outright necrosis (infarction). Affected kidneys are nonfunctional and have to be removed.

- **Acute rejection is mediated by T cells and antibodies that are activated by alloantigens in the graft**. It occurs within days or weeks after transplantation and is the principal cause of early graft failure. It also may appear suddenly much later after transplantation if immunosuppression is tapered or terminated. Based on the role of T cells or antibodies, acute rejection is divided into two types, although in most rejecting grafts, both patterns are present.

  In *acute cellular rejection,* CD8+ CTLs may directly destroy graft cells, or CD4+ cells secrete cytokines and induce inflammation, which damages the graft (Fig. 6.34A). T cells may also react against graft vessels, leading to vascular damage. Current immunosuppressive therapy is designed mainly to prevent and reduce acute rejection by blocking the activation of alloreactive T cells.

MORPHOLOGY

Acute cellular (T cell–mediated) rejection may produce two different patterns of injury.

- In the tubulointerstitial pattern (sometimes called type I), there is extensive interstitial inflammation and tubular inflammation (tubulitis) associated with focal tubular injury (Fig. 6.34B). As might be expected, the inflammatory infiltrates contain activated CD4+ and CD8+ T lymphocytes.
- The vascular pattern shows inflammation of vessels (type II) (Fig. 6.34C) and sometimes necrosis of vessel walls (type III). The affected vessels have swollen endothelial cells, and lymphocytes are seen between the endothelium and the vessel wall, a finding termed endotheliitis or intimal arteritis. The recognition of cellular rejection is important because, in the absence of accompanying humoral rejection, most patients respond well to immunosuppressive therapy.

In acute *antibody-mediated (vascular, or humoral) rejection,* antibodies bind to vascular endothelium and activate complement via the classical pathway (Fig. 6.35A). The resultant inflammation and endothelial damage cause graft failure.

MORPHOLOGY

Acute antibody-mediated rejection is manifested mainly by damage to glomeruli and small blood vessels. Typically, there is inflammation of glomeruli and peritubular capillaries (Fig. 6.35B), associated with deposition of complement products due to activation of the complement system by the antibody-dependent classical pathway (Fig. 6.35C). Small vessels also may show focal thrombosis.

- **Chronic rejection is an indolent form of graft damage that occurs over months or years, leading to progressive**

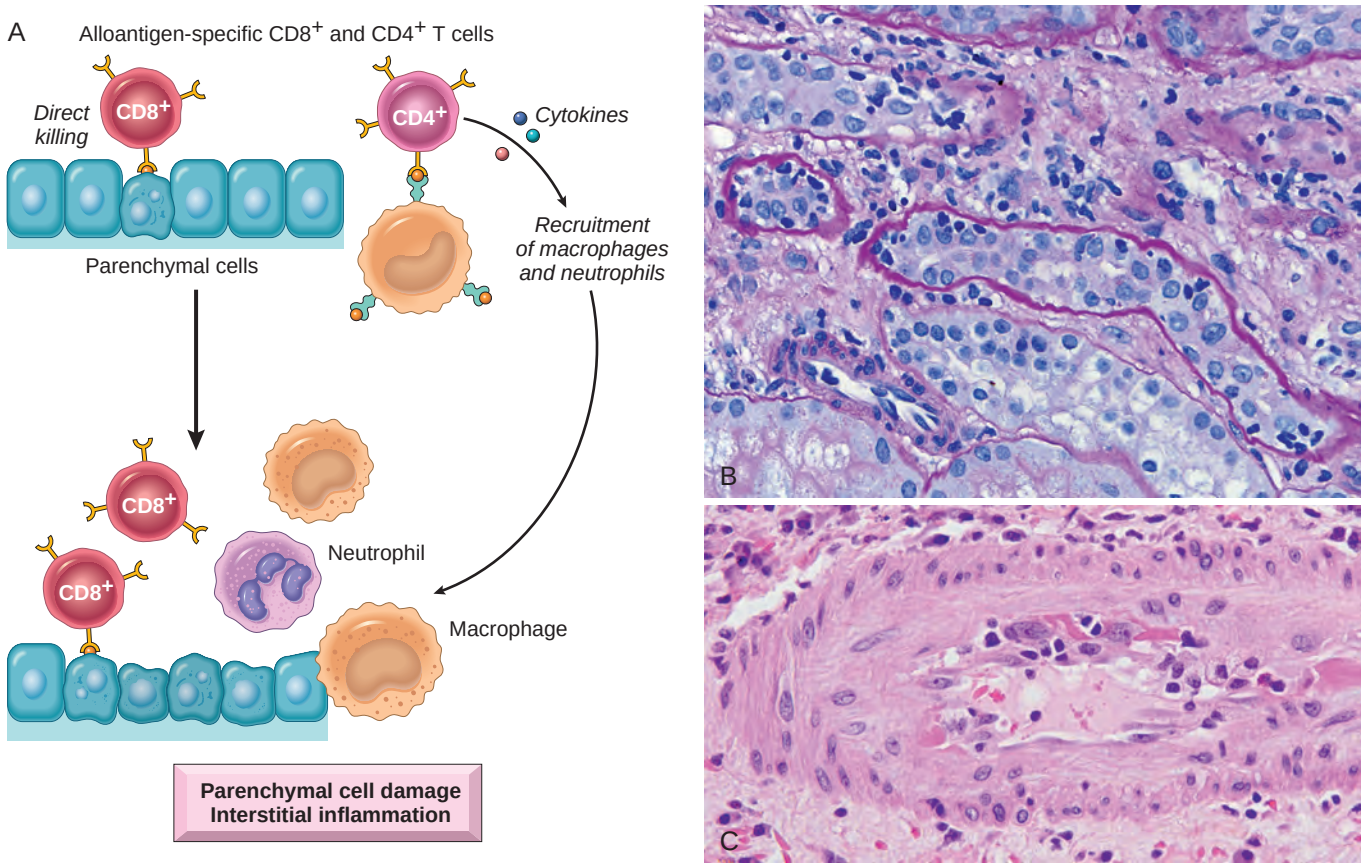

Figure 6.34 Acute cellular rejection. (A) Destruction of graft cells by T cells. Acute T-cell–mediated rejection involves direct killing of graft cells by CD8+ CTLs and inflammation caused by cytokines produced by CD4 T cells. (B) Acute cellular rejection of a kidney graft, manifested by inflammatory cells in the interstitium and between epithelial cells of the tubules (tubulitis). Collapsed tubules are outlined by wavy basement membranes. (C) Rejection vasculitis in a kidney graft. Zoltan Laszik and Kuang-Yu Jen, Department of Pathology, University of California, San Francisco, Calif.)

loss of graft function. Chronic rejection manifests as interstitial fibrosis and gradual narrowing of graft blood vessels *(graft arteriosclerosis)*. In both lesions, the culprits are believed to be T cells that react against graft alloantigens and secrete cytokines, which stimulate the proliferation and activities of fibroblasts and vascular smooth muscle cells in the graft (Fig. 6.36A). Alloantibodies also contribute to chronic rejection. Although treatments to prevent or curtail acute rejection have steadily improved, leading to better 1-year survival of transplants, chronic rejection is refractory to most therapies and is becoming the principal cause of graft failure.

MORPHOLOGY

Chronic rejection is dominated by vascular changes, often with intimal thickening and vascular occlusion (Fig. 6.36B). Chronically rejecting kidney grafts show glomerulopathy, with duplication of the basement membrane, likely secondary to chronic endothelial injury (Fig. 6.36C), and peritubular capillaritis with multilayering of peritubular capillary basement membranes. Interstitial fibrosis and tubular atrophy with loss of renal parenchyma may occur secondary to the vascular lesions (Fig. 6.36D). Interstitial mononuclear cell infiltrates are typically sparse.

In addition to the kidney, a variety of organs, such as the liver (Chapter 18), heart (Chapter 12), lungs, and pancreas, are also transplanted. The rejection of these grafts is described in the relevant chapters.

Methods of Increasing Graft Survival

The value of HLA matching between donor and recipient varies in different solid-organ transplants. In kidney transplants, there is substantial benefit if all the polymorphic HLA alleles are matched (both inherited alleles of *HLA-A*, *-B*, and *DR*). However, HLA matching is usually not done for transplants of liver, heart, and lungs, because other considerations, such as anatomic compatibility, severity of the underlying illness, and the need to minimize the time of organ storage, override the potential benefits of HLA matching.

Except for identical twins, immunosuppressive therapy is essential in all donor-recipient combinations. Immunosuppressive drugs in current use include steroids (which reduce inflammation), mycophenolate mofetil (which inhibits lymphocyte proliferation), and tacrolimus (FK506). Tacrolimus, like its predecessor cyclosporine, is an inhibitor of the phosphatase calcineurin, which is required for activation of a transcription factor called nuclear factor of activated T cells (NFAT). NFAT stimulates transcription of cytokine

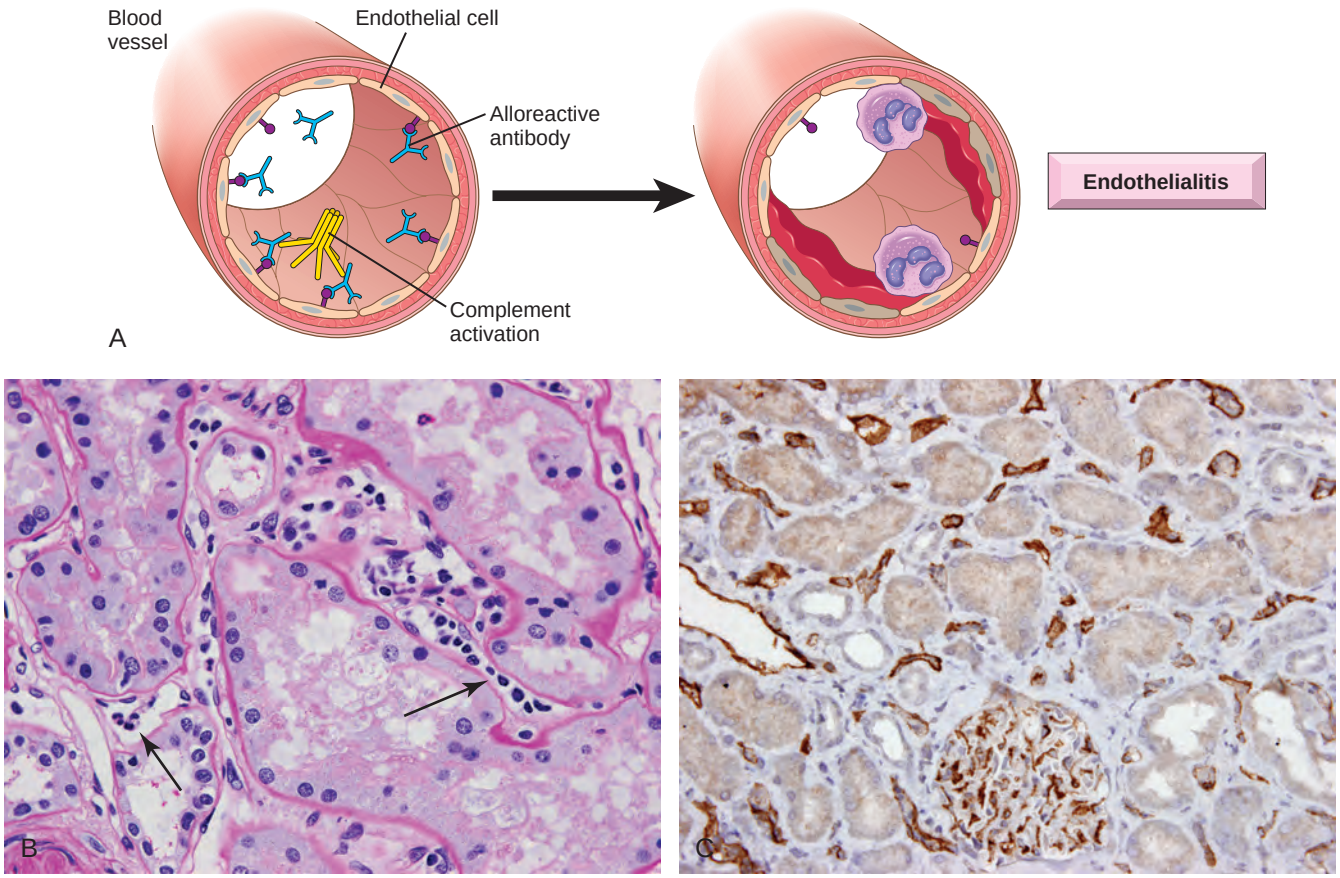

Figure 6.35 Acute antibody-mediated (humoral) rejection. (A) Graft damage caused by antibody deposition in vessels. (B) Light micrograph showing inflammation (capillaritis) in peritubular capillaries *(arrows)* in a kidney graft. genes, in particular the gene that encodes the growth factor IL-2. Thus, tacrolimus inhibits T cell responses. Additional drugs that are used to treat rejection include T cell– and B cell–depleting antibodies, and pooled intravenous IgG (IVIG), which suppresses inflammation by unknown mechanisms. Plasmapheresis is used in cases of severe antibody-mediated rejection. Another more recent strategy for reducing antigraft immune responses is to prevent host T cells from receiving costimulatory signals from DCs during the initial phase of sensitization. This can be accomplished by interrupting the interaction between the B7 molecules on the DCs of the graft donor with the CD28 receptors on host T cells, for example, by administration of proteins that bind to B7 costimulators.

Although immunosuppression prolongs graft survival, it carries its own risks. The price paid in the form of increased susceptibility to opportunistic infections is not small. One of the most frequent infectious complications is reactivation of polyoma virus. The virus establishes latent infection of epithelial cells in the lower genitourinary tract of healthy individuals, and on immunosuppression, it is reactivated, infects renal tubules, and may even cause graft failure. These patients are also at increased risk for developing EBV-induced lymphomas, human papillomavirus–induced squamous cell carcinomas, and Kaposi sarcoma (KS; Chapter 11), all probably the result of reactivation of latent viral infections because of diminished host defenses. To circumvent the untoward effects of immunosuppression, much effort is being devoted to induce donor-specific tolerance in graft recipients. Strategies being tested include injecting regulatory T cells and blocking the costimulatory signals that are required for lymphocyte activation, as mentioned earlier.

Transplantation of Hematopoietic Stem Cells (HSCs)

Use of HSC transplants to treat hematologic malignancies, bone marrow failure syndromes (such as aplastic anemia), and inherited bone marrow disorders (such as sickle cell anemia, thalassemia, and immunodeficiency states) is increasing each year. Transplantation of genetically "reengineered" HSCs obtained from affected patients may also be useful for somatic cell gene therapy, and is being evaluated in some immunodeficiencies and hemoglobinopathies. Historically, HSCs were obtained from the bone marrow, but now they usually are harvested from peripheral blood after they are mobilized from the bone marrow by administration of hematopoietic growth factors, or from the umbilical cord blood of newborn infants, a rich source of HSCs. In most of the conditions in which HSC transplantation is indicated, the recipient is irradiated or treated with high doses of chemotherapy to destroy the immune system (and sometimes, cancer cells) and to "open up" niches in the microenvironment of the marrow that nurture HSCs, thus

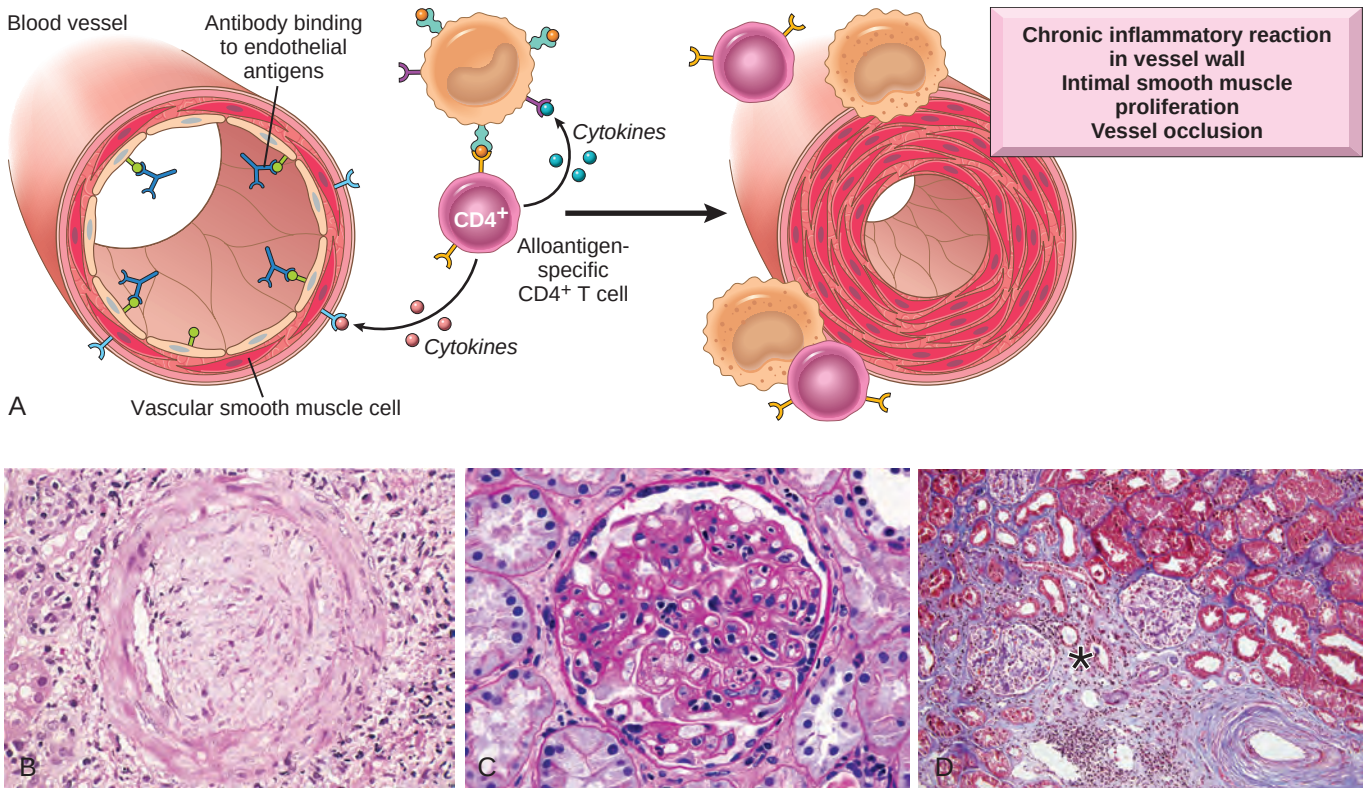

Figure 6.36 Chronic rejection. (A) Graft arteriosclerosis caused by T-cell cytokines and antibody deposition. (B) Graft arteriosclerosis in a cardiac transplant. (C) Transplant glomerulopathy, the characteristic manifestation of chronic antibody-mediated rejection in the kidney. The glomerulus shows inflammatory cells within the capillary loops (glomerulitis), accumulation of mesangial matrix, and duplication of the capillary basement membrane. (D) Interstitial fibrosis and tubular atrophy, resulting from arteriosclerosis of arteries and arterioles in a chronically rejecting kidney allograft. In this trichrome stain, the blue area *(asterisk)* shows fibrosis, contrasted with the normal kidney *(top right)*. An artery showing prominent arteriosclerosis is shown *(bottom right)*. allowing the transplanted HSCs to engraft. Several features distinguish HSC transplants from solid-organ transplants. Two problems that are unique to HSC transplantation are graft-versus-host disease (GVHD) and immunodeficiency.

GVHD occurs when immunologically competent cells or their precursors are transplanted into immunologically compromised recipients, and the transferred cells recognize alloantigens in the host and attack host tissues. It is seen most commonly in the setting of HSC transplantation but, rarely, may occur following transplantation of solid organs rich in lymphoid cells (e.g., the liver) or transfusion of unirradiated blood. When immune-compromised recipients receive HSC preparations from allogeneic donors, the immunocompetent T cells present in the donor inoculum recognize the recipient's HLA antigens as foreign and react against them. To try to minimize GVHD, HSC transplants are done between donor and recipient who are HLA-matched using precise DNA sequencing–based methods for molecular typing of HLA alleles.

- *Acute GVHD* occurs within days to weeks after allogeneic HSC transplantation. Although any organ may be affected, the major clinical manifestations result from involvement of the immune system and epithelia of the skin, liver, and intestines. Involvement of skin in GVHD is manifested by a generalized rash that may lead to desquamation in severe cases (Fig. 6.37A). Destruction of small bile ducts gives rise to jaundice, and mucosal ulceration of the gut results in bloody diarrhea. Although tissue injury may be severe, the affected tissues are usually not heavily infiltrated by lymphocytes. It is believed that in addition to direct cytotoxicity by CD8+ T cells, considerable damage is inflicted by cytokines released by the sensitized donor T cells.
- *Chronic GVHD* may follow the acute syndrome or may occur insidiously. These patients have extensive cutaneous injury, with destruction of skin appendages and fibrosis of the dermis (Fig. 6.37B). The changes may resemble systemic sclerosis (discussed earlier). Chronic liver disease manifested by cholestatic jaundice is also frequent. Damage to the gastrointestinal tract may cause esophageal strictures. The immune system is devastated, with involution of the thymus and depletion of lymphocytes in the lymph nodes. Not surprisingly, patients experience recurrent and life-threatening infections. Other patients develop manifestations of autoimmunity, postulated to result from the grafted CD4+ helper T cells reacting with host B cells and stimulating these cells, some of which may be capable of producing autoantibodies.

Because GVHD is mediated by T lymphocytes contained in the transplanted donor cells, depletion of donor T cells before transfusion virtually eliminates the disease. This protocol, however, is a decidedly mixed blessing: GVHD is ameliorated, but the recurrence of tumor in leukemic

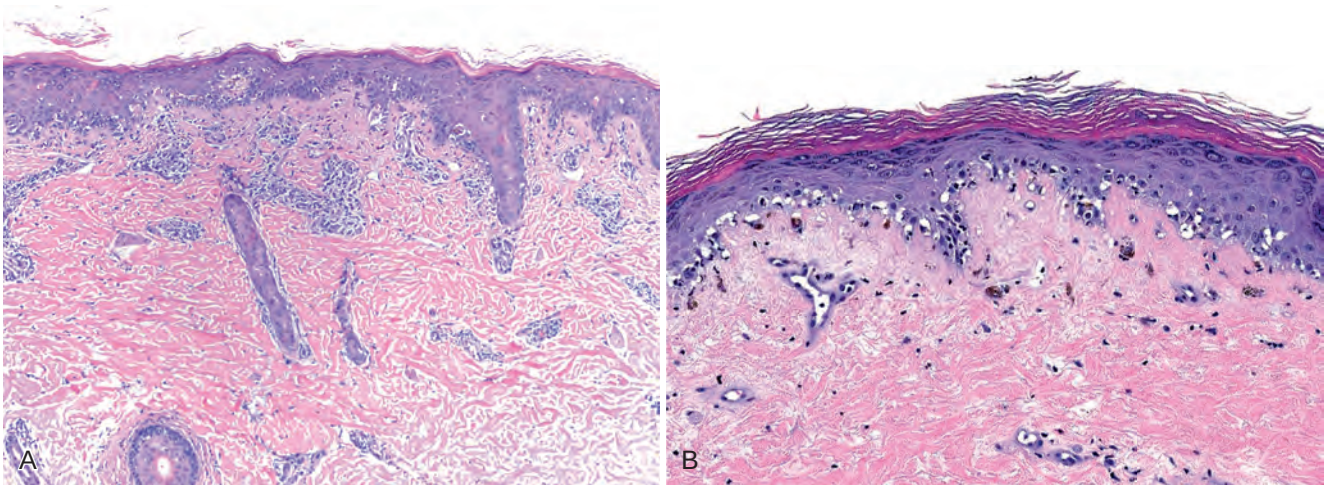

Figure 6.37 Graft-versus-host disease (GVHD) involving the skin. (A) Acute GVHD showing patchy epithelial cell death and dermal infiltrates of mononuclear cells (lymphocytes and macrophages). (B) Chronic GVHD showing a sparse lymphocytic infiltrate at the dermal-epidermal junction, which has resulted in a vacuolar interface reaction and occasional damaged keratinocytes. The epidermis is thinned, signifying atrophy. The underlying dermis shows thickening of collagen bundles, indicative of sclerosis. (B, Courtesy Dr. Jarish Cohen, Department of Pathology, University of California, San Francisco, Calif.)

patients as well as the incidence of graft failures and EBV-related B-cell lymphoma increase. It seems that the multifaceted T cells not only mediate GVHD but also are required for engraftment of the transplanted HSCs, suppression of EBV-infected B-cell clones, and control of leukemia cells. The latter graft-versus-leukemia effect can be quite dramatic. In fact, deliberate induction of graft-versus-leukemia effect by infusion of allogeneic T cells is used to treat chronic myeloid leukemia that has relapsed after HSC transplantation.

Immunodeficiency is a frequent complication of HSC transplantation. The immunodeficiency may be a result of prior treatment (e.g., for leukemia), myeloablation prior to HSC transplantation, a delay in repopulation of the recipient's immune system, and attack on the host's immune cells by grafted lymphocytes. Affected individuals are profoundly immunosuppressed and are easy prey to infections. Although many different types of organisms may infect patients, infection with cytomegalovirus is particularly important. This usually results from activation of latent infection. Cytomegalovirus-induced pneumonitis can be a fatal complication.

KEY CONCEPTS

RECOGNITION AND REJECTION OF TRANSPLANTS (ALLOGRAFTS)

- The rejection response against solid organ transplants is initiated mainly by host T cells that recognize the foreign HLA antigens of the graft, either directly (on APCs in the graft) or indirectly (after uptake and presentation by host APCs).
- Types and mechanisms of rejection of solid organ grafts:
  - Hyperacute rejection. Preformed antidonor antibodies bind to graft endothelium immediately after transplantation, leading to thrombosis, ischemic damage, and rapid graft failure.
  - Acute cellular rejection. T cells destroy graft parenchyma (and vessels) by cytotoxicity and inflammatory reactions.
  - Acute humoral rejection. Antibodies damage graft vasculature.
  - Chronic rejection. Dominated by arteriosclerosis, this type is caused by T-cell activation and antibodies. The T-cells may secrete cytokines that induce proliferation of vascular smooth muscle cells, and the antibodies cause endothelial injury. The vascular lesions and T-cell reactions cause parenchymal fibrosis.
- Treatment of graft rejection relies on immunosuppressive drugs, which inhibit immune responses against the graft.
- Transplantation of HSCs requires careful matching of donor and recipient and is often complicated by GVHD and immune deficiency.

IMMUNODEFICIENCY DISEASES

Immunodeficiency diseases can be divided into primary (or congenital) immunodeficiencies, which are genetically determined, and secondary (or acquired) immunodeficiencies, which may arise as complications of cancers, infections, malnutrition, or side effects of immunosuppression, irradiation, or chemotherapy for cancer and other diseases. Immunodeficiencies are manifested clinically by increased infections, which may be newly acquired or a reactivation of latent infection. The primary immunodeficiency syndromes are accidents of nature that provide valuable insights into some of the critical molecules of the human immune system. Here we briefly discuss the more important and best-defined primary immunodeficiencies, to be followed by a more detailed description of acquired immunodeficiency syndrome (AIDS), the most devastating example of secondary immunodeficiency.

Primary Immunodeficiencies

Primary immunodeficiency diseases are caused by genetic (inherited) defects that affect the defense mechanisms of innate immunity (phagocytes, NK cells, or complement) or the humoral and/or cellular arms of adaptive immunity (mediated by B and T lymphocytes, respectively). Most of

these diseases are detected in infancy, between 6 months and 2 years of life, the telltale signs being susceptibility to recurrent infections. Here we present selected examples of primary immunodeficiencies, beginning with defects in innate immunity and then defects in the maturation and activation of B and T lymphocytes. We conclude with immune defects associated with some systemic diseases.

Defects in Innate Immunity

Inherited defects in the early innate immune response typically affect leukocyte functions or the complement system, and all lead to increased vulnerability to infections (Table 6.12). Some of the defects whose molecular basis is defined are summarized next.

Defects in Leukocyte Function

- *Inherited defects in leukocyte adhesion.* Individuals with *leukocyte adhesion deficiency type 1* have a defect in the biosynthesis of the β_2 chain shared by the integrins LFA-1 and Mac-1. *Leukocyte adhesion deficiency type 2* is caused by the absence of sialyl-Lewis X, the fucose-containing ligand for E- and P-selectins, as a result of a defect in a fucosyl transferase, an enzyme that attaches fucose moieties to protein backbones. Both conditions result in a failure of leukocyte adhesion to endothelium, preventing the cells from migrating into tissues and making patients prone to bacterial infections, which are often recurrent and frequently life threatening.
- *Inherited defects in phagolysosome function.* One such disorder is *Chédiak-Higashi syndrome,* an autosomal recessive condition characterized by defective fusion of phagosomes and lysosomes, resulting in defective phagocyte function and susceptibility to infections. The main leukocyte abnormalities are neutropenia (decreased numbers of neutrophils), defective degranulation, and delayed microbial killing. Leukocytes contain giant granules, which can be readily seen in peripheral blood smears and are thought to result from aberrant phagolysosome fusion. In addition, there are abnormalities in melanocytes (leading to albinism), cells of the nervous system (associated with nerve defects), and platelets (causing bleeding disorders). The dysfunctional gene underlying this disorder encodes a cytosolic protein called LYST, which is believed to regulate lysosomal trafficking.
- *Inherited defects in microbicidal activity.* The importance of oxygen-dependent bactericidal mechanisms is shown by the existence of a group of congenital disorders called *chronic granulomatous disease* (CGD), which are characterized by defects in bacterial killing that render patients susceptible to recurrent bacterial infection. CGD results from inherited defects in the genes encoding components of phagocyte oxidase, the phagolysosomal enzyme that generates superoxide ($O_2^{\cdot-}$). The most common variants are an X-linked defect in one of the membrane-bound components (gp91phox) and autosomal recessive defects in the genes encoding two of the cytoplasmic components (p47phox and p67phox). The name of this disease comes from the macrophage-rich chronic inflammatory reaction that tries to control the infection when the initial neutrophil defense is inadequate. This often leads to collections of activated macrophages that wall off the microbes, forming granulomas.
- *Defects in TLR signaling.* Rare defects have been described in various TLRs and their signaling molecules. Defects in TLR3, a receptor for viral RNA, result in recurrent herpes simplex encephalitis, and defects in MyD88, the adaptor protein downstream of multiple TLRs, are associated with destructive bacterial pneumonias.

Deficiencies Affecting the Complement System

Hereditary deficiencies have been described for virtually all components of the complement system and several of the regulators. In addition, one disease, paroxysmal nocturnal hemoglobinuria, is caused by an acquired deficiency of complement regulatory factors.

- Deficiency of C2 is the most common complement protein deficiency. A deficiency of C2 or C4, early components of the classical pathway, is associated with increased bacterial or viral infections. However, many patients have no clinical manifestations, presumably because the alternative complement pathway is adequate for the control of most infections. Surprisingly, in some of these patients, as well as in patients with C1q deficiency, the dominant manifestation is SLE-like autoimmune disease, as discussed earlier.

Table 6.12 Defects in Innate Immunity

Disease	Defect
Defects in Leukocyte Function	
Leukocyte adhesion deficiency 1	Defective leukocyte adhesion because of mutations in β chain of CD11/CD18 integrins
Leukocyte adhesion deficiency 2	Defective leukocyte adhesion because of mutations in fucosyl transferase required for synthesis of sialylated oligosaccharide (receptor for selectins)
Chédiak-Higashi syndrome	Decreased leukocyte functions because of mutations affecting protein involved in lysosomal membrane traffic
Chronic granulomatous disease	Decreased oxidative burst
X-linked	Phagocyte oxidase (membrane component)
Autosomal recessive	Phagocyte oxidase (cytoplasmic components)
Myeloperoxidase deficiency	Decreased microbial killing because of defective MPO-H_2O_2 system
Defects in the Complement System	
C2, C4 deficiency	Defective classical pathway activation results in reduced resistance to infection and reduced clearance of immune complexes
C3 deficiency	Defects in all complement functions
Deficiency of complement regulatory proteins	Excessive complement activation; clinical syndromes include angioedema, paroxysmal hemoglobinuria, others

The table lists some of the more common inherited immune deficiencies affecting phagocytic leukocytes and the complement system.

Modified in part from Gallin JI: Disorders of phagocytic cells. In Gallin JI, Goldstein IM, Snyderman R, editors: *Inflammation: Basic Principles and Clinical Correlates,* ed 2, New York, 1992, Raven Press, pp 860–861.

- Deficiency of components of the alternative pathway (properdin and factor D) is rare. It is associated with recurrent pyogenic infections.
- The C3 component of complement is required for both the classical and alternative pathways, and hence a deficiency of this protein results in susceptibility to serious and recurrent pyogenic infections. There is also an increased incidence of immune complex–mediated glomerulonephritis. Complement is involved in the removal of immune complexes, and in its absence inflammation is presumably caused by Fc receptor–dependent leukocyte activation.
- The terminal components of complement (C5, 6, 7, 8, and 9) are required for the assembly of the membrane attack complex involved in the lysis of organisms. Deficiency of these late-acting components is associated with increased susceptibility to recurrent *Neisseria* (gonococcal and meningococcal) infections; *Neisseria* bacteria have thin cell walls that make them susceptible to the lytic actions of complement.
- Other patients inherit a defective form of mannose-binding lectin, the plasma protein that initiates the lectin pathway of complement. These individuals also show increased susceptibility to infections.
- A deficiency of C1 inhibitor (C1 INH) gives rise to *hereditary angioedema*. This autosomal dominant disorder is more common than complement deficiency states. The C1 inhibitor's targets are proteases, specifically C1r and C1s of the complement cascade, factor XII of the coagulation pathway, and the kallikrein system. With deficiency of C1 INH, unregulated activation of kallikrein may lead to increased production of vasoactive peptides such as bradykinin. Although the exact nature of the bioactive compound produced in hereditary angioedema is uncertain, these patients have episodes of edema affecting skin and mucosal surfaces such as the larynx and the gastrointestinal tract. This may result in life-threatening asphyxia or nausea, vomiting, and diarrhea after minor trauma or emotional stress. Acute attacks of hereditary angioedema can be treated with C1 inhibitor concentrates prepared from human plasma.
- Deficiencies of other complement regulatory proteins are causes of paroxysmal nocturnal hemoglobinuria (Chapter 14), chronic forms of hemolytic uremic syndrome (Chapter 20), and age-related macular degeneration.

Defects in Adaptive Immunity

Defects in adaptive immunity are often subclassified on the basis of the primary component involved (i.e., B cells or T cells, or both). However, these distinctions are not clear-cut; for instance, T-cell defects almost always lead to impaired antibody synthesis, and hence isolated deficiencies of T cells are often indistinguishable clinically from combined deficiencies of T and B cells. These immunodeficiencies result from abnormalities in lymphocyte maturation or activation. The mutations responsible for many of these diseases have now been identified (Fig. 6.38).

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) spans a constellation of genetically distinct syndromes, all having in common defects in both humoral and cell-mediated immune responses. Affected infants present with prominent thrush (oral candidiasis), extensive diaper rash, and failure to thrive. Some patients develop a morbilliform rash shortly after birth because maternal T cells are transferred across the placenta and attack the fetus, causing GVHD. Persons with SCID are extremely susceptible to recurrent, severe infections by a wide range of pathogens, including *Candida albicans, Pneumocystis jirovecii, Pseudomonas,* cytomegalovirus, varicella, and a host of bacteria. Without HSC transplantation, death occurs within the first year of life. Despite the common clinical manifestations, the underlying genetic defects are quite varied and in many cases are unknown. Often, the SCID defect resides in the T-cell compartment, with a secondary impairment of humoral immunity.

X-linked SCID. The most common form, accounting for 50% to 60% of cases, is X-linked, and hence SCID is more common in boys than in girls. The genetic defect in the X-linked form is a mutation in the common γ-chain (γc) subunit of cytokine receptors. This transmembrane protein is a signal-transducing component of the receptors for IL-2, IL-4, IL-7, IL-9, IL-11, IL-15, and IL-21. IL-7 is required for the survival and proliferation of lymphoid progenitors, particularly T-cell precursors. As a result of defective IL-7 receptor signaling, there is a profound defect in the earliest stages of lymphocyte development, especially T-cell development. T-cell numbers are greatly reduced, and although B cells may be normal in number, antibody synthesis is impaired because of lack of T-cell help. IL-15 is important for the maturation and proliferation of NK cells, and because the common γ chain is a component of the receptor for IL-15, these individuals often have a deficiency of NK cells as well.

Autosomal Recessive SCID. The remaining forms of SCID are autosomal recessive disorders. The most common cause of autosomal recessive SCID is a deficiency of the enzyme adenosine deaminase (ADA). Although the mechanisms by which ADA deficiency causes SCID are not entirely clear, it has been proposed that deficiency of the enzyme leads to accumulation of deoxyadenosine and its derivatives (e.g., deoxy-ATP), which are toxic to rapidly dividing immature lymphocytes, especially those of the T-cell lineage. Hence there may be a greater reduction in the number of T lymphocytes than of B lymphocytes.

Several other less common causes of autosomal recessive SCID have been identified:

- Mutations in recombinase-activating genes (RAG) or other components of the antigen receptor gene recombination machinery prevent the somatic gene rearrangements that are essential for the assembly of TCR and Ig genes. This blocks the development of T and B cells.
- An intracellular kinase called JAK3 is essential for signal transduction through cytokine receptors containing the common γ chain (which is mutated in X-linked SCID, as discussed earlier). Mutations of JAK3 therefore have the same effects as mutations in the γc chain.
- Several mutations have been described in signaling molecules, including kinases associated with the T-cell antigen receptor and components of calcium channels that are required for entry of calcium and activation of many signaling pathways.

The histologic findings in SCID depend on the underlying defect. In the two most common forms (γc mutation and ADA deficiency), the thymus is small and devoid of

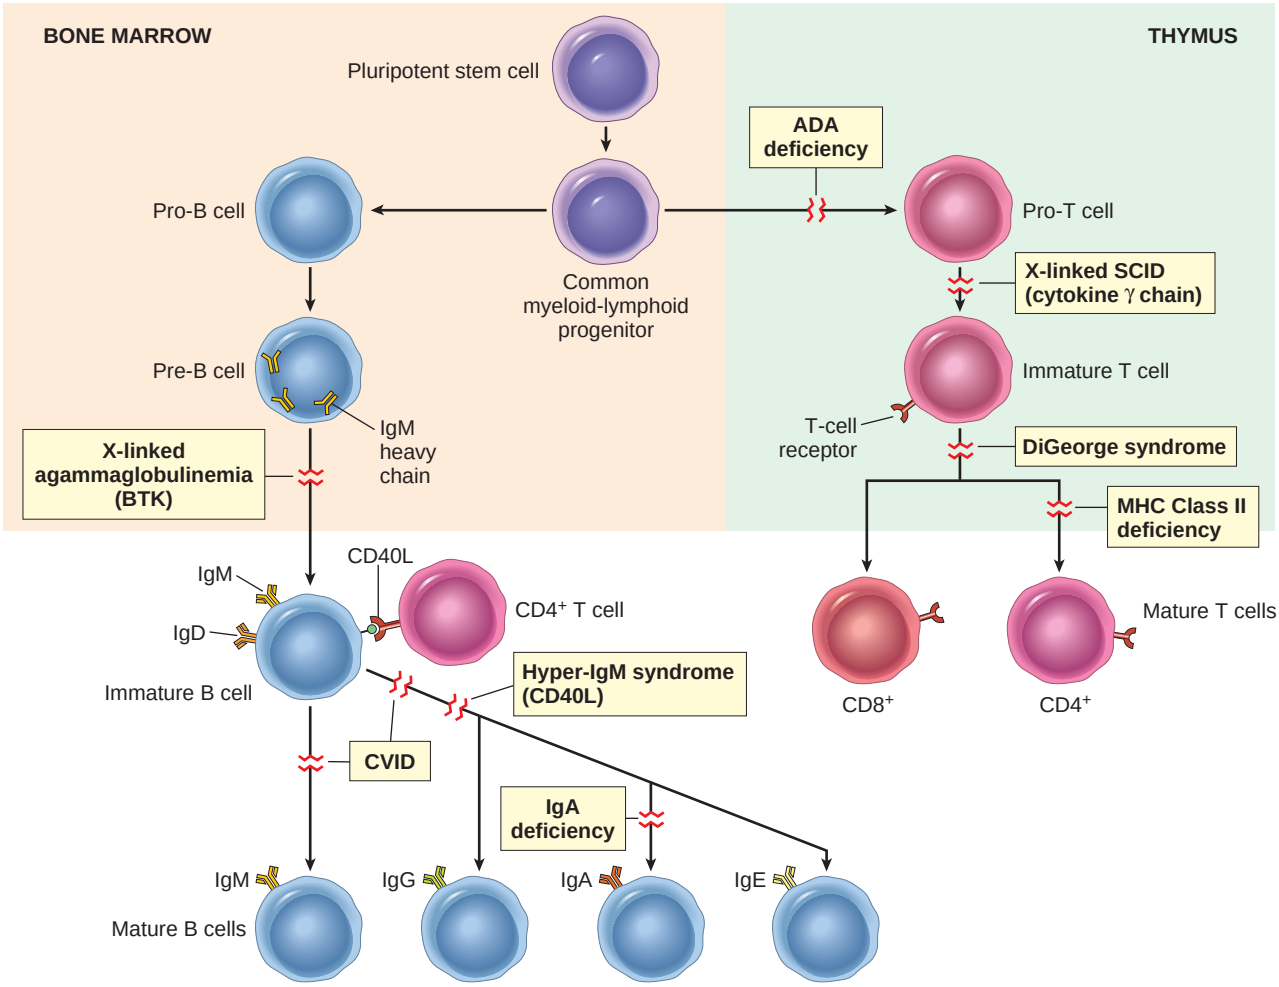

Figure 6.38 Primary immune deficiency diseases. Shown are the principal pathways of lymphocyte development and the blocks in these pathways in selected primary immune deficiency diseases. The affected genes are indicated in parentheses for some of the disorders. *ADA*, Adenosine deaminase; *CD40L*, CD40 ligand (also known as *CD154*); *CVID*, common variable immunodeficiency; *SCID*, severe combined immunodeficiency.

lymphoid cells. In X-linked SCID, the thymus contains lobules of undifferentiated epithelial cells resembling fetal thymus, whereas in SCID caused by ADA deficiency, remnants of Hassall's corpuscles can be found. In both diseases, other lymphoid tissues are hypoplastic as well, with marked depletion of T-cell areas and in some cases both T-cell and B-cell zones.

Currently, HSC transplantation is the mainstay of treatment, but X-linked SCID is the first human disease in which gene therapy has been successful. In this type of ex vivo gene therapy, a normal γc gene is expressed using a viral vector in HSCs taken from patients, and the cells are then transplanted back into the patients. The clinical experience is small, but some patients have shown reconstitution of their immune systems for over 10 years after therapy. Unfortunately, about 20% of patients in the initial clinical trials developed T-cell lymphoblastic leukemia, highlighting the dangers of this particular approach to gene therapy. The uncontrolled T-cell proliferation was triggered by the activation of oncogenes by the integrated virus, an effect that may have been augmented by a growth advantage conferred by the introduced γc gene. Current trials are using new vectors with safety features built in. Patients with ADA deficiency have also been treated with HSC transplantation and, more recently, with administration of the enzyme or gene therapy involving the introduction of a normal *ADA* gene into T-cell precursors.

X-Linked Agammaglobulinemia (Bruton Agammaglobulinemia)

X-linked agammaglobulinemia is characterized by the failure of B-cell precursors (pro–B cells and pre–B cells) to develop into mature B cells. It is one of the more common forms of primary immunodeficiency. During normal B-cell maturation in the bone marrow, the Ig heavy-chain genes are rearranged first, in pre–B cells. These form a complex with a "surrogate" light chain on the cell surface called the pre–B cell receptor (pre-BCR) that delivers signals that induce rearrangement of the Ig light-chain genes and further maturation. This need for Ig-initiated signals is a quality-control mechanism that ensures that maturation will proceed only if functional Ig proteins are expressed. X-linked agammaglobulinemia is caused by mutations in a cytoplasmic tyrosine kinase, called Bruton tyrosine kinase (BTK); the gene that encodes it is located on the long arm of the X chromosome at Xq21.22. BTK is a protein tyrosine kinase that is associated with the pre-BCR and with the B-cell receptor (BCR) complexes that are found on mature B

cells. When BTK is mutated, the pre-BCR cannot deliver the signals that are needed for light chain rearrangement, and maturation is arrested. BTK is also an important transducer of BCR signals that stimulate growth and increase cell survival in benign and malignant mature B cells, and inhibitors of BTK are effective therapies for several B cell malignancies (Chapter 13).

As an X-linked disease, this disorder is seen almost exclusively in males, but sporadic cases have been described in females, possibly caused by mutations in other genes that function in the same pathway. The disease usually does not become apparent until about 6 months of age, as maternal immunoglobulins are depleted. In most cases, recurrent bacterial infections of the respiratory tract, such as acute and chronic pharyngitis, sinusitis, otitis media, bronchitis, and pneumonia, call attention to the underlying immune defect. Almost always the causative organisms are *Haemophilus influenzae, Streptococcus pneumoniae,* or *Staphylococcus aureus*. These organisms are normally opsonized by antibodies and cleared by phagocytosis. Because antibodies are important for neutralizing infectious viruses, individuals with this disease are also susceptible to certain viral infections, especially those caused by enteroviruses, such as echovirus, poliovirus, and coxsackievirus. These viruses infect the gastrointestinal tract, and from here they can disseminate to the nervous system via the blood. Thus, immunization with live poliovirus carries the risk of paralytic poliomyelitis, and echovirus can cause fatal encephalitis. For similar reasons, *Giardia lamblia,* an intestinal protozoan that is normally resisted by secreted IgA, causes persistent infections in persons with this disorder. In general, however, most fungal, protozoal, and intracellular viral infections are handled quite well by the intact T cell–mediated immunity.

The classic form of this disease has the following characteristics:

- B cells are absent or markedly decreased in the circulation, and serum levels of all classes of immunoglobulins are depressed. Pre–B cells, which express the B-lineage marker CD19 but not membrane Ig, are found in normal numbers in the bone marrow.
- Germinal centers of lymph nodes, Peyer patches, the appendix, and tonsils are underdeveloped.
- Plasma cells are absent throughout the body.
- T cell–mediated reactions are normal.

Paradoxically, autoimmune diseases, such as arthritis and dermatomyositis, occur in as many as 30% of individuals with this disease. It is likely that these autoimmune disorders are caused by a breakdown of self-tolerance resulting in autoimmunity, but chronic infections associated with the immune deficiency may play a role in inducing the inflammatory reactions. The treatment of X-linked agammaglobulinemia is replacement therapy with immunoglobulins. In the past, most patients succumbed to infection in infancy or early childhood. Prophylactic IVIG therapy allows most individuals to reach adulthood.

DiGeorge Syndrome (Thymic Hypoplasia)

DiGeorge syndrome is a T-cell deficiency that results from failure of development of the thymus. The third and fourth pharyngeal pouches, which give rise to the thymus, the parathyroids, some of the C cells of the thyroid, and the ultimobranchial body, do not develop normally. Thus, individuals with this syndrome have a variable loss of T cell–mediated immunity (resulting from hypoplasia or lack of the thymus), tetany (resulting from lack of the parathyroids), and congenital defects of the heart and great vessels. In addition, the appearance of the mouth, ears, and facies may be abnormal. Absence of cell-mediated immunity is caused by low numbers of T lymphocytes in the blood and lymphoid tissues and poor defense against certain fungal and viral infections. The T-cell zones of lymphoid organs—paracortical areas of the lymph nodes and the periarteriolar sheaths of the spleen—are depleted. Ig levels may be normal or reduced, depending on the severity of the T-cell deficiency.

In the vast majority (90%) of cases, DiGeorge syndrome is caused by a small germline deletion that maps to chromosome 22q11, and DiGeorge syndrome is now considered a component of the 22q11 deletion syndrome, discussed in Chapter 5. One gene in the deleted region is *TBX1,* which is required for development of the branchial arch and the great vessels. Notably, *TBX1* is involved by loss-of-function mutations in a few cases of DiGeorge syndrome that lack 22q11 deletions, strongly suggesting that its loss contributes to the observed phenotype.

Other Defects in Lymphocyte Maturation

Many other rare causes of immunodeficiency resulting from defective lymphocyte maturation have been documented. One of these, *bare lymphocyte syndrome,* is usually caused by mutations in transcription factors that are required for class II MHC gene expression. The lack of class II MHC molecules prevents the development of CD4+ T cells, which are involved in cellular immunity and provide help to B cells; hence, class II MHC deficiency results in combined immunodeficiency. Other defects are caused by mutations in antigen receptor chains or signaling molecules involved in T- or B-cell maturation.

Hyper-IgM Syndrome

In this disorder, affected patients have IgM antibodies but are deficient in IgG, IgA, and IgE antibodies. Mature B cells are present, but they are incapable of Ig class switching and affinity maturation, because of a defect in CD4+ helper T cells or an intrinsic B-cell defect. As discussed earlier in the chapter, many of the functions of CD4+ helper T cells require the engagement of CD40 on B cells, macrophages, and DCs by CD40L (also called CD154) expressed on antigen-activated T cells. This interaction triggers Ig class switching and affinity maturation in B cells, and also stimulates the microbicidal functions of macrophages. Approximately 70% of individuals with hyper-IgM syndrome have the X-linked form of the disease, caused by mutations in the gene encoding CD40L located on Xq26 that interfere with CD4+ helper T cell function. In the remaining patients, the disease is inherited in an autosomal recessive pattern. Most of these patients have loss-of-function mutations involving either CD40 or activation-induced cytidine deaminase (AID), a DNA-editing enzyme expressed in B cells that is required for Ig class switching and affinity maturation.

The serum of persons with this syndrome contains normal or elevated levels of IgM but no IgA or IgE and extremely low levels of IgG. The numbers of B and T cells in the blood are normal. Clinically, patients present with recurrent pyogenic

infections, because the level of opsonizing IgG antibodies is low, and also because affinity maturation, a process necessary for production of high-affinity antibodies, is impaired. In addition, those with CD40L mutations are susceptible to pneumonia caused by the intracellular organism *Pneumocystis jirovecii* because CD40L-mediated macrophage activation, a key reaction of cell-mediated immunity, is also defective. Occasionally, the IgM antibodies react with blood cells, giving rise to autoimmune hemolytic anemia, thrombocytopenia, and neutropenia. In older patients, there may be a proliferation of IgM-producing plasma cells that infiltrates the mucosa of the gastrointestinal tract.

Common Variable Immunodeficiency

This relatively frequent entity encompasses a heterogeneous group of disorders in which the common feature is hypogammaglobulinemia, generally affecting all the antibody classes but sometimes only IgG. The diagnosis of common variable immunodeficiency is based on exclusion of other well-defined causes of decreased antibody production.

Both sporadic and inherited forms of the disease occur. In familial forms, there is no single pattern of inheritance. Relatives of such patients have a high incidence of selective IgA deficiency (see later), suggesting that at least in some cases, selective IgA deficiency and common variable immunodeficiency represent different expressions of a common genetic defect in antibody synthesis. In contrast to X-linked agammaglobulinemia, most individuals with common variable immunodeficiency have normal or near-normal numbers of B cells in the blood and lymphoid tissues. These B cells, however, are not able to differentiate into plasma cells.

Both intrinsic B-cell defects and abnormalities in helper T cell–mediated activation of B cells may account for the antibody deficiency in this disease. Families have been reported in which the underlying abnormality is in a receptor for a cytokine called *BAFF* that promotes the survival and differentiation of B cells, or in a molecule called *ICOS* (inducible costimulator) that is homologous to CD28 and is involved in T-cell activation and in interactions between T and B cells. However, the known mutations explain less than 10% of cases.

The clinical manifestations of common variable immunodeficiency are caused by antibody deficiency, and hence they resemble those of X-linked agammaglobulinemia. Patients typically present with recurrent sinopulmonary pyogenic infections. In addition, about 20% of patients have recurrent herpesvirus infections. Serious enterovirus infections causing meningoencephalitis may also occur. Individuals with this disorder are also prone to the development of persistent diarrhea caused by *G. lamblia.* Common variable immunodeficiency affects both sexes equally, and the onset of symptoms is later than in X-linked agammaglobinemina, in childhood or adolescence. Histologically, the germinal centers in lymphoid tissues (i.e., nodes, spleen, and gut) are hyperplastic due to the presence of cells that can proliferate in response to antigen but are defective in further maturation in some respect.

As in X-linked agammaglobulinemia, these patients have a high frequency of autoimmune diseases (approximately 20%), including rheumatoid arthritis. The risk of lymphoid malignancy is also increased, and an increase in gastric cancer has been reported.

Isolated IgA Deficiency

Isolated IgA deficiency is a common immunodeficiency caused by impaired differentiation of naïve B lymphocytes to IgA-producing plasma cells. In the United States, it occurs in about 1 in 600 individuals of European descent. It is far less common in people of African descent and Asians. Affected individuals have extremely low levels of both serum and secretory IgA. The molecular basis of this defect in most patients is unknown; defects in a receptor for a B cell–activating cytokine, BAFF, have been described in some patients.

Most individuals with IgA deficiency are asymptomatic. Because IgA is the major antibody in mucosal secretions, mucosal defenses are weakened, and infections occur in the respiratory, gastrointestinal, and urogenital tracts. Symptomatic patients commonly present with recurrent sinopulmonary infections and diarrhea. In addition, IgA-deficient patients have a high frequency of respiratory tract allergy and a variety of autoimmune diseases, particularly SLE and rheumatoid arthritis. The basis of the increased frequency of autoimmune and allergic diseases is not known. When transfused with blood containing normal IgA, some patients develop severe, even fatal, anaphylactic reactions, because the IgA behaves like a foreign antigen.

X-Linked Lymphoproliferative Disease

X-linked lymphoproliferative disease is characterized by an inability to eliminate EBV, eventually leading to fulminant infectious mononucleosis and the development of B-cell tumors. In about 80% of cases, the disease is due to mutations in the gene encoding an adapter molecule called SLAM-associated protein (SAP). SAP binds to a family of cell surface molecules involved in the activation of NK cells and T and B lymphocytes, including the signaling lymphocyte activation molecule (SLAM). Defects in SAP attenuate NK and T-cell activation and result in increased susceptibility to viral infections. SAP is also required for the development of T follicular helper cells, and because of this defect X-linked lymphoproliferative disease patients are unable to form germinal centers or produce high-affinity antibodies, additional abnormalities that also likely contribute to susceptibility to viral infection. This immunodeficiency is most commonly manifested by severe EBV infection, including severe and often fatal infectious mononucleosis (Chapter 8), but not other viral infections, for reasons that are not clear.

Other Defects in Lymphocyte Activation

Many rare cases of lymphocyte activation defects have been described, affecting antigen receptor signaling and various biochemical pathways. Mutations affecting Th1 responses are associated with atypical mycobacterial infections; the syndrome is called *Mendelian susceptibility to mycobacterial disease*. Inherited defects in Th17 responses lead to chronic mucocutaneous candidiasis and bacterial infections of the skin (a disorder called *Job syndrome*).

Immunodeficiencies Associated With Systemic Diseases

In some inherited systemic disorders, immune deficiency is a prominent clinical problem. Two representative examples of such diseases are described next.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked disease characterized by thrombocytopenia, eczema, and a marked vulnerability to recurrent infection, resulting in early death. The thymus is morphologically normal, at least early in the course of the disease, but there is progressive loss of T lymphocytes in the peripheral blood and in the T-cell zones (paracortical areas) of the lymph nodes, with variable defects in cellular immunity. Patients do not make antibodies to polysaccharide antigens, and the response to protein antigens is poor. IgM levels in the serum are low, but levels of IgG are usually normal. Paradoxically the levels of IgA and IgE are often elevated. Patients are also prone to developing B-cell lymphomas. Wiskott-Aldrich syndrome is caused by mutations in the gene located at Xp11.23 that encodes Wiskott-Aldrich syndrome protein (WASP). WASP belongs to a family of proteins that are believed to link membrane receptors, such as antigen receptors, to cytoskeletal elements. WASP may be involved in cytoskeleton-dependent responses, including cell migration and signal transduction, but the essential functions of this protein in lymphocytes and platelets are unclear. The only treatment is HSC transplantation.

Ataxia Telangiectasia

Ataxia telangiectasia is an autosomal-recessive disorder characterized by abnormal gait (ataxia), vascular malformations (telangiectases), neurologic deficits, increased incidence of tumors, and immunodeficiency. The immunologic defects are of variable severity and may affect both B and T cells. The most prominent humoral immune abnormalities are defective production of isotype-switched antibodies, mainly IgA and IgG_2. The T-cell defects, which are usually less pronounced, are associated with thymic hypoplasia. Patients experience upper and lower respiratory tract bacterial infections, multiple autoimmune phenomena, and increasingly frequent cancers with advancing age. The gene responsible for this disorder is located on chromosome 11 and encodes a protein kinase called ATM (ataxia telangiectasia mutated). In response to DNA damage (double-strand breaks), ATM activates p53 by phosphorylation, which in turn can activate cell cycle checkpoints and apoptosis in cells with damaged DNA. ATM has also been shown to contribute to the stability of DNA double-strand break complexes during V(D)J recombination. The abnormalities in DNA repair resulting from ATM deficiency may impair the generation of antigen receptors. In addition, defective DNA repair may lead to abnormalities in the DNA recombination events that are involved in Ig isotype switching. Like several other immunodeficiency syndromes, patients with ataxia telangiectasia have a markedly increased incidence of lymphoma.

KEY CONCEPTS

PRIMARY (INHERITED) IMMUNODEFICIENCIES

- These diseases are caused by inherited mutations in genes involved in lymphocyte maturation or function, or in innate immunity.
- Deficiencies in innate immunity include defects of phagocyte function, complement, and innate immune receptors.
- Some of the common disorders affecting lymphocytes and the adaptive immune response are:
  - X-SCID: failure of T-cell and B-cell maturation; mutation in the common γ chain of a cytokine receptor, leading to failure of IL-7 signaling and defective lymphopoiesis
  - Autosomal recessive SCID: failure of T-cell development, secondary defect in antibody responses; approximately 50% of cases caused by mutation in the gene encoding ADA, leading to accumulation of toxic metabolites during lymphocyte maturation and proliferation
  - X-linked agammaglubulinemia: failure of B-cell maturation, absence of antibodies; caused by mutations in the *BTK* gene, which encodes B-cell tyrosine kinase, required for maturation signals from the pre-BCRs and BCRs
  - Common variable immunodeficiency: defects in antibody production; cause unknown in most cases
  - Selective IgA deficiency: failure of IgA production; cause unknown
  - X-linked hyper-IgM syndrome: failure to produce isotype-switched high-affinity antibodies (IgG, IgA, IgE); mutation in gene encoding CD40L
  - X-linked lymphoproliferative disease: defect in a signaling molecule causing defective responses against Epstein-Barr virus and lymphoproliferation
- These diseases present clinically with increased susceptibility to infections in early life.

Secondary Immunodeficiencies

Secondary (acquired) immune deficiencies may be encountered in individuals with cancer, diabetes and other metabolic diseases, malnutrition, chronic infection, and in persons receiving chemotherapy or radiation therapy for cancer, or immunosuppressive drugs to prevent graft rejection or to treat autoimmune diseases (Table 6.13). As a group, the secondary immune deficiencies are more common than the disorders of primary genetic origin. Some of these secondary immunodeficiency states can be caused by defective lymphocyte maturation (when the bone marrow is damaged by radiation or chemotherapy or involved by tumors, such as leukemias), inadequate Ig synthesis (as in malnutrition), or lymphocyte depletion (from drugs or severe infections). The most serious secondary immunodeficiency is AIDS, which is described next.

Table 6.13 Causes of Secondary (Acquired) Immunodeficiencies

Cause	Mechanism
Human immunodeficiency virus infection	Depletion of CD4+ helper T cells
Irradiation and chemotherapy treatments for cancer	Decreased bone marrow precursors for all leukocytes
Involvement of bone marrow by cancers (metastases, leukemias)	Reduced site of leukocyte development
Protein-calorie malnutrition	Metabolic derangements inhibit lymphocyte maturation and function
Removal of spleen	Decreased phagocytosis of microbes

Acquired Immunodeficiency Syndrome (AIDS)

AIDS is caused by the retrovirus human immunodeficiency virus (HIV) and is characterized by profound immunosuppression that leads to opportunistic infections, secondary neoplasms, and neurologic manifestations. The magnitude of this modern plague is truly staggering. In the United States, AIDS is the second leading cause of death in men between 25 and 44 years of age, and the third leading cause of death in women in this age group. Although initially recognized in the United States, AIDS is a global problem. It has now been reported from more than 190 countries around the world, and the pool of HIV-infected persons in Africa and Asia is large and expanding. By 2016, HIV had infected 60 million people worldwide, and nearly 30 million adults and children have died of the disease. There are about 37 million people living with HIV (1.1 million in the United States), of whom 70% are in Africa and more than 20% in Asia; the prevalence rate of infection in adults in sub-Saharan Africa is 7% overall and exceeds 25% in some countries. It is estimated that 1.7 million people were newly infected with HIV in 2018, and about 800,000 deaths were caused by AIDS. Only about 80% of HIV-infected people living worldwide know their status.

There is some good news. Because of public health measures, the infection rate seems to be decreasing, and some authorities believe it may have peaked in the late 1990s. Furthermore, improved antiviral therapies have resulted in fewer people dying of the disease. However, these newer treatments are not readily available in many low income countries, and toxic side effects remain a problem. The advent of these drugs raises its own tragic concern; because more people are living with HIV, the risk of spreading the infection will increase if vigilance is relaxed.

The enormous medical and social burden of AIDS has led to an explosion of research aimed at understanding HIV and its remarkable ability to cripple host defenses. The literature on HIV and AIDS is vast. Here we summarize the currently available data on the epidemiology, pathogenesis, and clinical features of HIV infection.

Epidemiology

Epidemiologic studies in the United States have identified five groups of adults at high risk for developing AIDS. The case distribution in these groups is as follows:

- *Men who have sex with men* account for more than 50% of the reported cases. This includes about 5% who are intravenous drug users as well. Transmission of HIV in this category appears to be on the decline, but in 2016 this remained the largest affected group, constituting about 70% of new cases.
- *Heterosexual transmission,* chiefly due to contact with members of other high-risk groups (e.g., intravenous drug users), is responsible for approximately 20% of cases in the United States. Heterosexual transmission has declined modestly since 2011 in the United States. Globally, however, heterosexual transmission is by far the most common mode by which HIV is spread, and as a result, women are much more frequently infected outside of the United States. In sub-Saharan Africa, where the infection rate is estimated to be about 10,000 new cases every day, more than one-half of infected individuals are women. Heterosexual spread of the virus is occurring most rapidly in female sex workers and in women in long-term marital or cohabitating relationships, particularly among adolescents.
- *Intravenous drug users* with no previous history of homosexuality are the next largest group, representing about 20% of infected individuals.
- *HIV infection of the newborn.* Children of HIV-positive women are at risk for infection in utero, at birth, or through breast milk (discussed later). Close to 2% of all AIDS cases occur in children, and it is estimated that worldwide there are 1.7 million HIV-infected individuals younger than 15 years of age.
- Patients with *hemophilia,* especially those who received large amounts of factor VIII or factor IX concentrates before 1985, make up about 0.5% of all cases.
- *Recipients of blood and blood components* who are not hemophiliacs but who received transfusions of HIV-infected whole blood or components (e.g., platelets, plasma) account for about 1% of patients. (Organs obtained from HIV-infected donors can also transmit the virus.)
- In approximately 5% of cases, the risk factors cannot be determined.

It should be apparent from the preceding discussion that transmission of HIV occurs under conditions that facilitate exchange of blood or body fluids containing the virus or virus-infected cells. **The three major routes of transmission are sexual contact, parenteral inoculation, and passage of the virus from infected mothers to their newborns.**

- *Sexual transmission* is the dominant mode of infection worldwide, accounting for more than 75% of all cases of HIV transmission. Because the majority of infected people in the United States are men who have sex with men, most sexual transmission has occurred among homosexual men. The virus is carried in the semen, and it enters the recipient's body through abrasions in rectal or oral mucosa or by direct contact with mucosal lining cells. Viral transmission occurs in two ways: (1) direct inoculation into the blood vessels breached by trauma and (2) infection of DCs or CD4+ cells within the mucosa. In addition to male-to-male and male-to-female transmission, female-to-male transmission also occurs.

  Sexual transmission of HIV is enhanced by coexisting sexually transmitted diseases, especially those associated with genital ulceration. In this regard, syphilis, chancroid, and herpes are particularly important. Other sexually transmitted diseases, including gonorrhea and chlamydia, are also cofactors for HIV transmission, perhaps because in these genital inflammatory states there is greater concentration of the virus and virus-containing cells in genital fluids, as a result of increased numbers of inflammatory cells in the semen.
- *Parenteral transmission* of HIV has occurred in three groups of individuals: intravenous drug users, hemophiliacs who received factor VIII and factor IX concentrates, and random recipients of blood transfusion. Of these three, intravenous drug users constitute by far the largest group. Transmission occurs by sharing of needles, syringes, and other paraphernalia contaminated with HIV-containing blood.

Transmission of HIV by transfusion of blood or blood products, such as lyophilized factor VIII and factor IX concentrates, has been virtually eliminated. This fortunate outcome resulted from increasing use of recombinant clotting factors and from three public health measures: screening of donated blood and plasma for antibody to HIV, stringent purity criteria for factor VIII and factor IX preparations, and screening of donors on the basis of history. However, an extremely small risk of acquiring AIDS through transfusion of seronegative blood persists, because a recently infected individual may be antibody-negative. Currently, this risk is estimated to be 1 in more than 2 million units of blood transfused.

- As alluded to earlier, *mother-to-infant transmission* is the major cause of pediatric AIDS. Infected mothers can transmit the infection to their offspring by three routes: (1) in utero by transplacental spread, (2) during delivery through an infected birth canal, and (3) after birth by ingestion of breast milk. Of these, transmission during birth (intrapartum) and in the immediate period thereafter (peripartum) is considered to be the most common mode in the United States. The reported transmission rates vary from 7% to 49% in different parts of the world. Higher risk of transmission is associated with high maternal viral load and low CD4+ T-cell counts as well as chorioamnionitis. Fortunately, antiretroviral therapy (ART) given to infected pregnant women in the United States has virtually eliminated mother-to-child transmission, but it remains a major source of infection in areas where these treatments are not readily available.

Much concern has arisen in the lay public and among health care workers about the spread of HIV infection outside the high-risk groups. Extensive studies indicate that HIV infection cannot be transmitted by casual personal contact in the household, workplace, or school. Spread by insect bites is virtually impossible. Regarding transmission of HIV infection to health care workers, an extremely small but definite risk is present. Seroconversion has been documented after accidental needle-stick injury or exposure of nonintact skin to infected blood in laboratory accidents. After needle-stick accidents, the risk of seroconversion is believed to be about 0.3%, and antiretroviral therapy given within 24 to 48 hours of a needle stick can reduce the risk of infection eightfold. By comparison, approximately 30% of those accidentally exposed to hepatitis B–infected blood become seropositive.

Etiology: the Properties of HIV

HIV is a nontransforming human retrovirus belonging to the lentivirus family. Included in this group are feline immunodeficiency virus, simian immunodeficiency virus, visna virus of sheep, bovine immunodeficiency virus, and the equine infectious anemia virus.

Two genetically different but related forms of HIV, called *HIV-1 and HIV-2,* have been isolated from patients with AIDS. HIV-1 is the most common type associated with AIDS in the United States, Europe, and Central Africa, whereas HIV-2 causes a similar disease principally in West Africa and India. Specific tests for HIV-2 are available, and blood collected for transfusion is routinely screened for both HIV-1 and HIV-2 seropositivity. The ensuing discussion relates primarily to HIV-1 and diseases caused by it, but the information is generally applicable to HIV-2 as well.

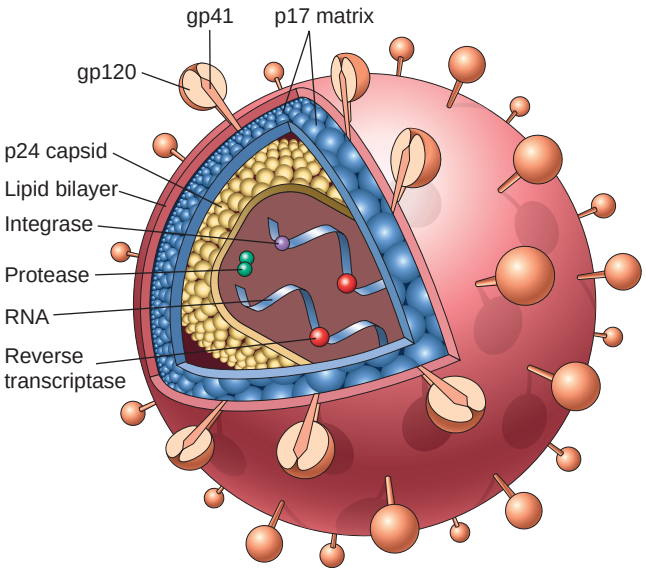

Figure 6.39 The structure of the HIV-1 virion. The viral particle is covered by a lipid bilayer derived from the host cell and studded with viral glycoproteins gp41 and gp120.

Structure of HIV

Similar to most retroviruses, the HIV-1 virion is spherical and contains an electron-dense, cone-shaped core surrounded by a lipid envelope derived from the host cell membrane (Fig. 6.39). **The virus core contains (1) the major capsid protein p24; (2) nucleocapsid protein p7/p9; (3) two copies of viral genomic RNA; and (4) the three viral enzymes (protease, reverse transcriptase, and integrase).** p24 is the most abundant viral antigen and is detected by an ELISA that is widely used to diagnose HIV infection. The viral core is surrounded by a matrix protein called *p17,* which lies underneath the virion envelope. Studding the viral envelope are two viral glycoproteins, gp120 and gp41, which are critical for HIV infection of cells.

The HIV-1 RNA genome contains the *gag, pol,* and *env* genes, which are typical of retroviruses (Fig. 6.40). The products of the *gag* and *pol* genes are large precursor proteins that are cleaved by the viral protease to yield the mature proteins. In addition to these three standard retroviral genes, HIV contains several other accessory genes, including *tat, rev, vif, nef, vpr,* and *vpu,* which regulate the synthesis and assembly of infectious viral particles and the pathogenicity of the virus. For example, the product of the *tat* (transactivator) gene causes a 1000-fold increase in the transcription of viral genes and is critical for virus replication. The functions of other accessory proteins are indicated in Fig. 6.40.

Pathogenesis of HIV Infection and AIDS

Although HIV can infect many tissues, **the major target of HIV infection is the immune system.** The central nervous system (CNS) is also affected.

Profound immune deficiency, primarily affecting cell-mediated immunity, is the hallmark of AIDS. This results chiefly from infection and subsequent death of CD4+ T cells

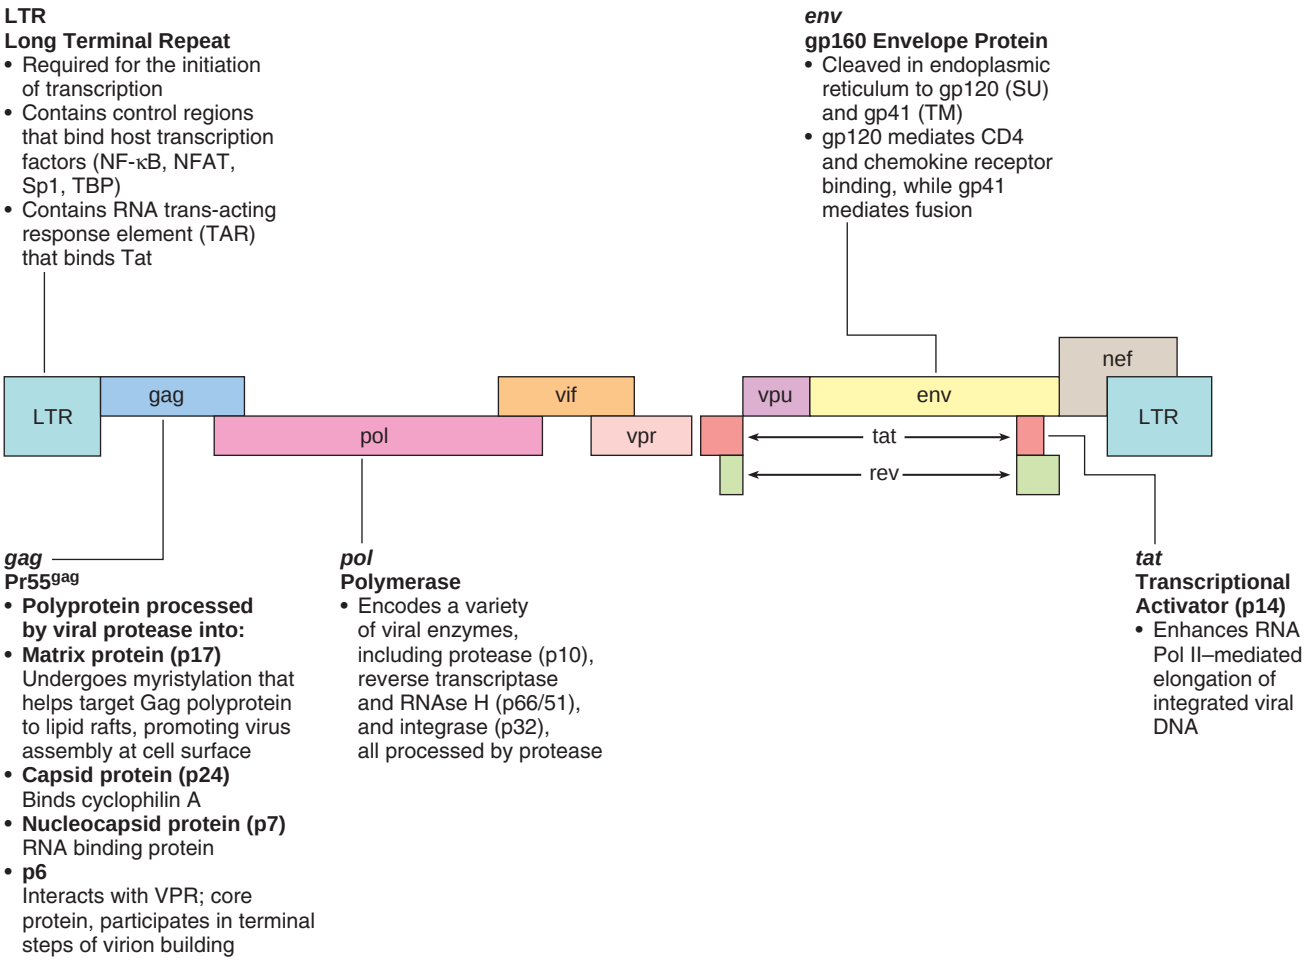

Figure 6.40 The HIV genome. The functions of selected genes are shown.

as well as impairment in the function of surviving helper T cells, but infection of macrophages and DCs also contributes (discussed later). HIV enters the body through mucosal tissues and blood and first infects T cells as well as DCs and macrophages. The infection becomes established in lymphoid tissues, where the virus may remain latent for long periods. Active viral replication is associated with more infection of cells and progression to AIDS. We first describe the mechanisms involved in viral entry into T cells and macrophages and the replicative cycle of the virus within cells. This is followed by a more detailed review of the interaction between HIV and its cellular targets.

Life Cycle of HIV

The life cycle of HIV consists of infection of cells, integration of the provirus into the host cell genome, activation of viral replication, and production and release of infectious virus (Fig. 6.41). The molecules and mechanisms of each of these steps are understood in considerable detail.

Infection of Cells by HIV. **HIV infects cells by using the CD4 molecule as a receptor and various chemokine receptors as coreceptors** (see Fig. 6.41). The requirement for CD4 binding explains the selective tropism of the virus for CD4+ T cells and other CD4+ cells, particularly monocytes/macrophages and DCs. Binding to CD4 is not sufficient for infection, however. HIV gp120 must also bind to other cell surface molecules (coreceptors) for entry into the cell. Chemokine receptors, particularly CCR5 and CXCR4, serve this role. HIV isolates can be distinguished by their use of these receptors: R5 strains use CCR5, X4 strains use CXCR4, and some strains (R5X4) use both. R5 strains preferentially infect cells of the monocyte/macrophage lineage and are thus referred to as M-tropic, whereas X4 strains are T-tropic, preferentially infecting T cells. In approximately 90% of cases, the R5 (M-tropic) type of HIV is the dominant virus found in the blood of acutely infected individuals and early in the course of infection. Over the course of infection, however, T-tropic viruses gradually accumulate; these are especially virulent because T-tropic viruses are capable of infecting many T cells and even thymic T-cell precursors and cause greater T-cell depletion and impairment.

Molecular details of the deadly handshake between HIV glycoproteins and their cell surface receptors have been elucidated and are important to understand because they may provide the basis for additional anti-HIV therapies. The HIV envelope contains two noncovalently associated glycoproteins, surface gp120 and the transmembrane protein gp41. The initial step in infection is the binding of the gp120 envelope glycoprotein to CD4, which leads to a conformational change that produces a new recognition site on gp120 for the coreceptors CCR5 or CXCR4. Binding

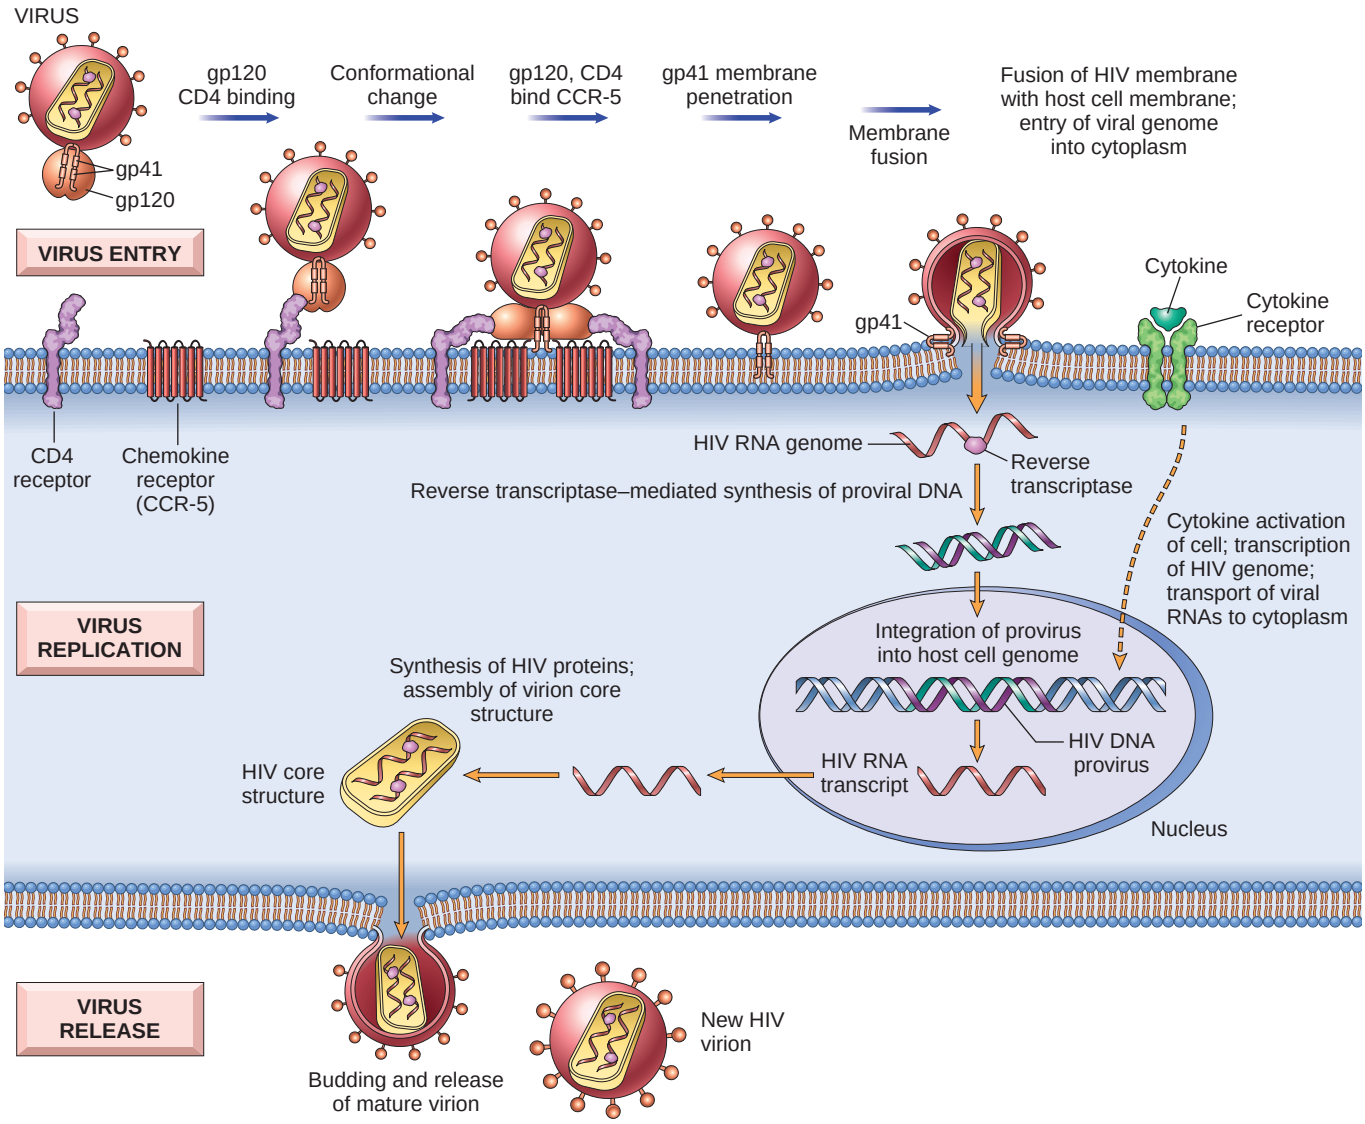

Figure 6.41 The life cycle of HIV showing the steps from viral entry to production of infectious virions. (Modified with permission from Wain-Hobson S: HIV. One on one meets two, *Nature* 384:117, 1996. Copyright 1996, Macmillan Magazines Limited.)

to the coreceptors induces conformational changes in gp41 that result in the exposure of a hydrophobic region called the fusion peptide at the tip of gp41. This peptide inserts into the cell membrane of the target cells (e.g., T cells or macrophages), leading to fusion of the virus and the host cell membrane, an event that allows the virus core containing the HIV genome to enter the cell. The requirement for HIV binding to coreceptors may have important implications for the pathogenesis of AIDS. Chemokines sterically hinder HIV infection of cells in culture by occupying their receptors, and therefore, the level of chemokines in the tissues may influence the efficiency of viral infection in vivo. Also, polymorphisms in the gene encoding CCR5 are associated with different susceptibility to HIV infection. About 1% of white Americans inherit two mutant copies of the *CCR5* gene and are resistant to infection and the development of AIDS associated with R5 HIV isolates. About 20% of individuals are heterozygous for this protective CCR5 allele; these persons are not protected from AIDS, but the onset of their disease after infection is somewhat delayed. Only rare homozygotes for the mutation have been found in African or East Asian populations.

Viral Replication. Once internalized, the RNA genome of the virus undergoes reverse transcription, leading to the synthesis of double-stranded complementary DNA (cDNA; proviral DNA) (see Fig. 6.41). In quiescent T cells, HIV cDNA may remain in the cytoplasm in a linear episomal form. In dividing T cells, the cDNA circularizes, enters the nucleus, and integrates into the host genome. After integration, the provirus may be silent for months or years, a form of latent infection. Alternatively, proviral DNA may be transcribed, with the formation of complete viral particles that bud from the cell membrane. Such productive infection, when associated with extensive viral budding, leads to death of infected cells.

HIV infects memory and activated T cells but is inefficient at productively infecting naïve (resting) T cells.

Naïve T cells contain an active form of an enzyme that introduces mutations in the HIV genome. This enzyme has the cumbersome name APOBEC3G (for apolipoprotein B mRNA-editing, enzyme-catalytic, polypeptide-like 3G). It is a cytidine deaminase that introduces cytosine-to-uracil mutations in the viral DNA that is produced by reverse transcription. These mutations inhibit further DNA replication by mechanisms that are not fully defined. Activation of T cells converts APOBEC3G into an inactive, high-molecular-mass complex, explaining why the virus can replicate in previously activated (e.g., memory) T cells. HIV has also evolved to counteract this cellular defense mechanism; the viral protein Vif binds to APOBEC3G and promotes its degradation by cellular proteases.

Completion of the viral life cycle in latently infected cells occurs only after cell activation, and in the case of most CD4+ T cells, viral replication and shedding result in cell lysis. Activation of T cells by antigens or cytokines upregulates several transcription factors, including NF-κB, that stimulate transcription of genes encoding cytokines such as IL-2 and its receptor. In resting T cells, NF-κB is held inactive in the cytoplasm in a complex with the IκB (inhibitor of κB) protein. Stimulation of cells by antigen or cytokines activates cytoplasmic kinases that phosphorylate IκB and target it for enzymatic degradation, thus releasing NF-κB and allowing it to translocate to the nucleus. In the nucleus, NF-κB binds to the regulatory sequences of several genes, including those of cytokines that are expressed in activated T cells. The long-terminal-repeat sequences that flank the HIV genome also contain NF-κB–binding sites that can drive the expression of viral RNA. Imagine now a latently infected CD4+ cell that encounters an environmental antigen. Induction of NF-κB in such a cell (a physiologic response) activates the expression of HIV genes (a pathologic outcome) and leads ultimately to the production of virions and to cell lysis. Furthermore, TNF and other cytokines produced by activated macrophages also stimulate NF-κB activity in T cells. Thus, it seems that HIV thrives when the host T cells and macrophages are physiologically activated, an act that can be best described as "subversion from within." Such activation in vivo may result from antigenic stimulation by HIV itself or by other infecting microorganisms. HIV-infected people are at increased risk for other infections, which lead to increased lymphocyte activation and production of proinflammatory cytokines. These, in turn, stimulate more HIV production, loss of additional CD4+ T cells, and more infection. Thus, it is easy to visualize how in individuals with AIDS a vicious cycle is set up that culminates in inexorable destruction of the immune system.

Mechanism of T-Cell Depletion in HIV Infection

Loss of infected CD4+ T cells is mainly because of the direct cytopathic effects of the replicating virus. In infected individuals, approximately 100 billion new viral particles are produced every day, and 1 to 2 billion CD4+ T cells die each day. Because the frequency of infected cells in the circulation is very low, for many years it was suspected that the immunodeficiency is out of proportion to the level of infection and cannot be attributed to death of infected cells. In fact, many infected cells are within tissues (e.g., secondary lymphoid organs and mucosal sites), and death of these cells is a major cause of the relentless, and eventually profound, cell loss. Also, up to a point the immune system can replace the dying T cells, and hence the rate of T cell loss may appear deceptively low, but as the disease progresses, renewal of CD4+ T cells cannot keep up with their loss.

In addition to direct killing of cells by the virus, other mechanisms may contribute to the loss of T cells. These include the following:

- Chronic activation of uninfected cells, responding to HIV itself or to infections that are common in individuals with AIDS, leads to apoptosis of these cells by the process of activation-induced cell death. Thus, the numbers of CD4+ T cells that die may be considerably more than the numbers of infected cells. The molecular mechanism of this type of cell death is not known.
- Noncytopathic (abortive) HIV infection activates the inflammasome pathway and leads to a form of cell death that has been called pyroptosis (Chapter 2). During this process, inflammatory cytokines and cellular contents are released, thus potentiating recruitment of new cells and increasing the numbers of cells that can be infected. This form of cell death may play a role in spread of the infection.
- HIV infects cells in secondary lymphoid organs (spleen, lymph nodes, tonsils) and may cause progressive destruction of the architecture and cellular composition of lymphoid tissues.
- Loss of immature precursors of CD4+ T cells can also occur, either by direct infection of thymic progenitor cells or by infection of accessory cells that secrete cytokines essential for CD4+ T-cell maturation.
- Fusion of infected and uninfected cells with formation of syncytia (giant cells) can occur. In tissue culture, the gp120 expressed on productively infected cells binds to CD4 molecules on uninfected T cells, followed by cell fusion. Fused cells usually die within a few hours. This property of syncytia formation is generally confined to the T-tropic X4 type of HIV-1. For this reason, this type is often referred to as syncytia-inducing (SI) virus, in contrast to the R5 virus.
- Although marked reduction in CD4+ T cells, a hallmark of AIDS, can account for most of the immunodeficiency late in the course of HIV infection, there is evidence of qualitative defects in T cells even in asymptomatic HIV-infected persons. These include reduced antigen-induced T-cell proliferation, decreased Th1-type responses, defects in intracellular signaling, and many more. The loss of Th1 responses results in a profound deficiency of cell-mediated immunity, leading to increased susceptibility to infections by viruses and other intracellular microbes. There is also a selective loss of the memory subset of CD4+ helper T cells early in the course of disease, which explains poor recall responses to previously encountered antigens.

Low-level chronic or latent infection of T cells is an important feature of HIV infection. It is widely believed that integrated provirus, without viral gene expression (latent infection), can remain in the cells for months to years. Even with potent antiviral therapy, which practically sterilizes the peripheral blood, latent virus lurks within the CD4+ cells (both T cells and macrophages) in the lymph nodes. According to some estimates, 0.05% of CD4+ T cells in the

Table 6.14 Major Abnormalities of Immune Function in AIDS

Lymphopenia
Predominantly caused by death of the CD4+ helper T-cell subset
Decreased T-Cell Function in Vivo
Preferential loss of activated and memory T cells Decreased delayed-type hypersensitivity Susceptibility to opportunistic infections Susceptibility to neoplasms
Altered T-Cell Function in Vitro
Decreased proliferative response to mitogens, alloantigens, and soluble antigens Decreased cytotoxicity Decreased helper function for B-cell antibody production Decreased IL-2 and IFN-γ production
Polyclonal B-Cell Activation
Hypergammaglobulinemia and circulating immune complexes Inability to mount de novo antibody response to new antigens Poor responses to normal B-cell activation signals in vitro
Altered Monocyte or Macrophage Functions
Decreased chemotaxis and phagocytosis Decreased class II HLA expression Diminished capacity to present antigen to T cells

HLA, Human leukocyte antigen; *IFN-γ*, interferon-γ; *IL-2*, interleukin-2; *TNF*, tumor necrosis factor.

lymph nodes are latently infected. Because most of these CD4+ T cells are memory cells, they are long-lived, with a life span of months to years, and thus provide a persistent reservoir of virus.

CD4+ T cells play a pivotal role in regulating both cellular and humoral immune responses. Therefore, loss of this "master regulator" has ripple effects on virtually every other component of the immune system, as summarized in Table 6.14.

HIV Infection of Non–T Cells

In addition to infection and loss of CD4+ T cells, **infection of macrophages and DCs is also important in the pathogenesis of HIV infection**. Similar to T cells, the number of macrophages infected by HIV in the tissues greatly exceeds the number of infected blood monocytes. In certain tissues, such as the lungs and brain, as many as 10% to 50% of macrophages are infected. Several aspects of HIV infection of macrophages should be emphasized:

- Although cell division is required for nuclear entry and replication of most retroviruses, HIV-1 can infect and multiply in terminally differentiated nondividing macrophages. This property of HIV-1 is dependent on the viral *vpr* gene. The Vpr protein allows nuclear targeting of the HIV pre-integration complex through the nuclear pore.
- Infected macrophages bud relatively small amounts of virus from the cell surface, but these cells contain large numbers of virus particles, often located in intracellular vesicles. Even though macrophages allow viral replication, they are quite resistant to the cytopathic effects of HIV, in contrast to CD4+ T cells. Thus, in late stages of HIV infection, when CD4+ T-cell numbers decline greatly, macrophages may be an important site of continued viral replication and a reservoir for viral persistence.
- Macrophages may act as portals of infection because in more than 90% of cases acute HIV infection is by M-tropic strains.
- Even uninfected monocytes are reported to have unexplained functional defects that may have important consequences for host defense. These defects include impaired microbicidal activity, decreased chemotaxis, decreased secretion of IL-1, inappropriate secretion of TNF, and poor capacity to present antigens to T cells. Also, infected monocytes may carry HIV from the blood to various parts of the body, including the nervous system, where infiltrating infected monocytes may be a source of the virus that infects resident microglial cells (described later).

Studies have documented that, in addition to macrophages, two types of DCs are also important targets for the initiation and maintenance of HIV infection: mucosal and follicular DCs. It is thought that mucosal DCs are infected by the virus and may transport it to regional lymph nodes, where the virus is transmitted to CD4+ T cells. DCs also express a lectin-like receptor that binds HIV and displays it in an intact, infectious form to T cells, thus promoting infection of the T cells.

FDCs in the germinal centers of lymph nodes are potential reservoirs of HIV. Although some FDCs may be susceptible to HIV infection, most virus particles are found on the surface of their dendritic processes. FDCs have receptors for the Fc portion of immunoglobulins, and hence they trap HIV virions coated with anti-HIV antibodies. The antibody-coated virions localized to FDCs retain the ability to infect CD4+ T cells as they traverse the intricate meshwork formed by the dendritic processes of the FDCs. Infected T follicular helper cells in the germinal centers are also reservoirs of HIV. Since CTLs are largely excluded from germinal centers, these viral reservoirs cannot be readily eliminated by the host immune response.

B-Cell Function in HIV Infection

Although HIV infects T cells, macrophages, and DCs, individuals with AIDS also display profound abnormalities of B-cell function. Paradoxically, early in the disease course there is polyclonal activation of B cells, resulting in germinal center B-cell hyperplasia, sometimes accompanied by autoimmune phenomena like immune thromoboctyopenic purpura. B-cell activation may result from multiple mechanisms: reactivation of or reinfection with EBV, which is a polyclonal B-cell activator; viral gp41, which can promote B-cell growth and differentiation; and increased production of IL-6, which stimulates proliferation of B cells, by HIV-infected macrophages. Plasma cells also increase in number, leading to hypergammaglobulinemia and bone marrow plasmacytosis.

Despite the increased activation of B cells and risk of autoimmunity, patients with AIDS are unable to mount effective antibody responses to newly encountered pathogens. This could be due, in part, to lack of T-cell help, but antibody responses against T-independent antigens are also suppressed, and hence there may be intrinsic defects in B cells as well. Impaired humoral immunity renders these patients

prey to disseminated infections caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, both of which require antibodies for effective opsonization and clearance.

Pathogenesis of Central Nervous System Involvement

The pathogenesis of neurologic manifestations deserves special mention because, in addition to the lymphoid system, the nervous system is a target of HIV infection. The clinical syndrome of CNS abnormalities is called HIV-associated neurocognitive disorder (HAND). Microglia, cells in the CNS that belong to the macrophage lineage, are the predominant cell types in the brain that are infected with HIV. It is believed that HIV is carried into the brain by infected T cells or monocytes. The mechanism of HIV-induced damage of the brain remains obscure. Because neurons are not infected by HIV and the extent of neuropathologic changes is less than might be expected from the severity of neurologic symptoms, most workers believe that the neurologic deficit is caused indirectly by viral products and by soluble factors produced by infected microglia. Included among the soluble factors are the usual culprits, such as IL-1, TNF, and IL-6. In addition, nitric oxide induced in neuronal cells by gp41 has been implicated. Direct damage of neurons by soluble HIV gp120 has also been postulated.

Natural History of HIV Infection

The virus typically enters through mucosal epithelia. The subsequent pathologic and clinical manifestations of the infection can be divided into several phases: (1) an acute retroviral syndrome; (2) a middle, chronic phase, in which most individuals are asymptomatic; and (3) clinical AIDS (Figs. 6.42 and 6.43).

Primary Infection, Virus Dissemination, and the Acute Retroviral Syndrome

Acute (early) infection is characterized by infection of memory CD4+ T cells (which express CCR5) in mucosal lymphoid tissues, and death of many infected cells. Because the mucosal tissues are the largest reservoir of memory T cells in the body, and memory T cells are susceptible to HIV infection, this local loss results in considerable depletion of lymphocytes. Few infected cells are detectable in the blood and other tissues. Mucosal infection is often associated with damage to the epithelium, defects in mucosal barrier functions, and translocation of other microbes across the epithelium.

Mucosal infection is followed by dissemination of the virus and the development of host immune responses. DCs in epithelia at sites of virus entry capture the virus and then migrate into the lymph nodes. Once in lymphoid tissues, DCs may pass HIV on to CD4+ T cells through direct cell-to-cell contact. Within days after the first exposure to HIV, viral replication can be detected in the lymph nodes. This replication leads to viremia, during which high numbers of HIV particles are present in the patient's blood. The virus disseminates throughout the body and infects helper T cells, macrophages, and DCs in peripheral lymphoid tissues.

As the HIV infection spreads, the individual mounts antiviral humoral and cell-mediated immune responses. These responses lead to seroconversion (usually within 3 to 7 weeks of presumed exposure) and the development of

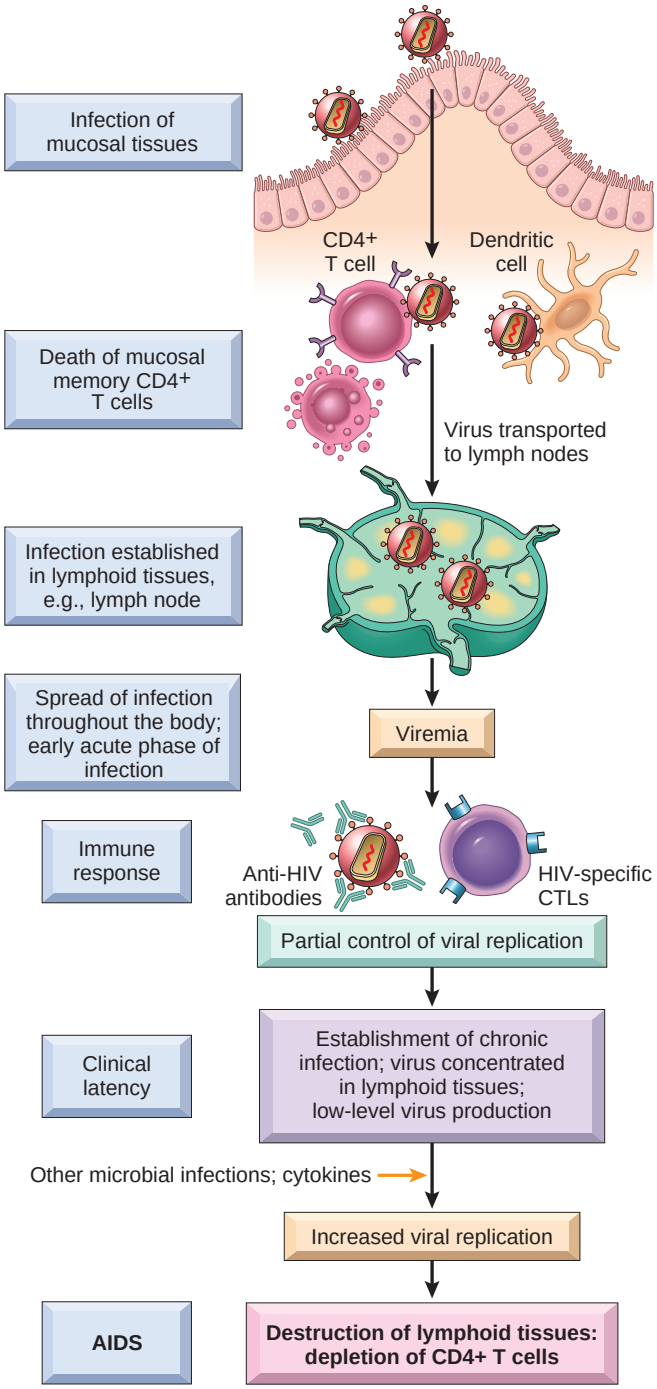

Figure 6.42 Pathogenesis of HIV-1 infection. The initial infection starts in mucosal tissues, involving mainly memory CD4+ T cells and dendritic cells, and spreads to lymph nodes. Viral replication leads to viremia and widespread seeding of lymphoid tissue. This corresponds to the early acute phase of HIV infection. The viremia is controlled by the host immune response, and the patient then enters a phase of clinical latency. During this phase, viral replication in both T cells and macrophages continues unabated, but there is some immune containment of virus *(not illustrated)*. There continues a gradual erosion of CD4+ cells, and ultimately CD4+ T-cell numbers decline, and the patient develops clinical symptoms of full-blown AIDS. *CTL,* Cytotoxic T lymphocyte.

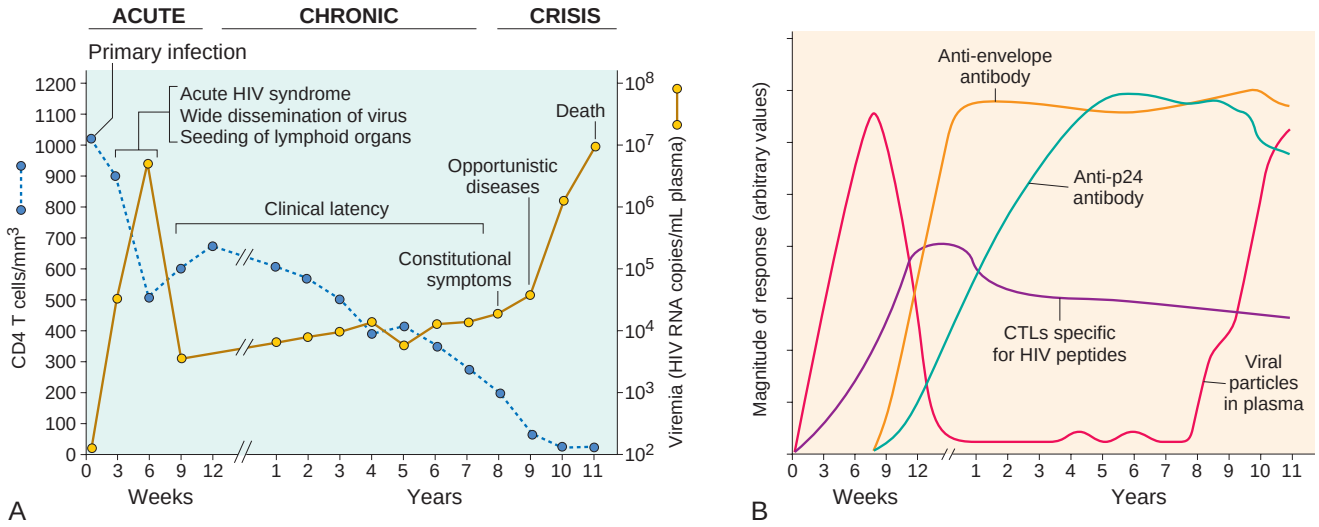

Figure 6.43 Clinical course of HIV infection. (A) During the early period after primary infection, there is dissemination of virus, development of an immune response to HIV, and often an acute viral syndrome. During the period of clinical latency, viral replication continues, and the CD4+ T-cell count gradually decreases until it reaches a critical level below which there is a substantial risk of AIDS-associated diseases. (B) Immune response to HIV infection. A cytotoxic T lymphocyte *(CTL)* response to HIV is detectable by 2 to 3 weeks after the initial infection, and it peaks by 9 to 12 weeks. Marked expansion of virus-specific CD8+ T-cell clones occurs during this time, and up to 10% of a patient's CTLs may be HIV specific at 12 weeks. The humoral immune response to HIV peaks at about 12 weeks. (A, Redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS, et al., editors: *Harrison's Principles of Internal Medicine*, ed 14, New York, 1997, McGraw-Hill, p 1791.)

virus-specific CD8+ cytotoxic T cells. HIV-specific CD8+ T cells are detected in the blood at about the time viral titers begin to fall and are most likely responsible for the initial containment of HIV infection. These immune responses partially control the infection and viral production, as reflected by a drop in viremia to low but detectable levels by about 12 weeks after the primary exposure.

The *acute retroviral syndrome* is the clinical presentation of the initial spread of the virus and the host response. It is estimated that 40% to 90% of individuals who acquire a primary infection develop this syndrome. This typically occurs 3 to 6 weeks after infection, and resolves spontaneously in 2 to 4 weeks. This phase is marked by a nonspecific self-limited acute illness with flulike symptoms, including sore throat, myalgias, fever, weight loss, and fatigue, sometimes accompanied by rash, cervical adenopathy, diarrhea, and vomiting.

The level of HIV-1 RNA in the blood (viral load) is a useful marker of HIV disease progression and is of clinical value in the management of people with HIV infection. The viral load at the end of the acute phase reflects the equilibrium reached between the virus and the host response, and in a given patient it may remain fairly stable for several years. This level of steady-state viremia, called the viral set point, is a predictor of the rate of decline of CD4+ T cells, and, therefore, progression of HIV disease. In one study, only 8% of patients with a viral load of less than 4350 copies of viral mRNA per microliter of blood progressed to clinical AIDS in 5 years, whereas 62% of those with a viral load of greater than 36,270 copies developed AIDS in the same period.

Because the loss of immune containment is associated with declining CD4+ T-cell counts, the Centers for Disease Control and Prevention (CDC) classification stratifies HIV infection into three categories on the basis of CD4+ cell counts: CD4+ cells greater than or equal to 500 cells/μL, 200 to 499 cells/μL, and fewer than 200 cells/μL (Table 6.15). For clinical management, the blood CD4+ T-cell count is perhaps the most reliable short-term indicator of disease progression. For this reason, the CD4+ cell count (rather than viral load) is the primary clinical measurement used to determine when to start antiretroviral therapy (ART).

Chronic Infection: Phase of Clinical Latency

In the next, chronic phase of the disease, lymph nodes and the spleen are sites of continuous HIV replication and cell destruction (see Fig. 6.42). During this period of the disease, few or no clinical manifestations of the HIV infection are present. Therefore, this phase of HIV disease is called the *clinical latency* period. Although the majority of peripheral blood T cells do not harbor the virus, destruction of CD4+ T cells within lymphoid tissues continues and the number of CD4+ T cells in the blood steadily declines. More than 90% of the body's approximately 10^{11} T cells are normally found in secondary lymphoid organs, and it is estimated that HIV destroys up to 2×10^9 CD4+ T cells every day. Early in the course of the disease, the T cells can be replaced almost as quickly as they are destroyed. At this stage, up to 10% of CD4+ T cells in lymphoid organs may be infected, but the frequency of infected CD4+ T cells in the blood may be less than 0.1% of the total circulating CD4+ T cells. Eventually, over a period of years, the slowly amplifying cycle of virus infection, T-cell death, and new infection leads to a steady decline in the number of CD4+ T cells in the lymphoid tissues and the circulation.

Concomitant with this loss of CD4+ T cells, host defenses wane, and the proportion of the surviving CD4+ cells infected with HIV increases, as does the viral burden per CD4+ cell. Not unexpectedly, HIV RNA levels increase as the host begins to lose the battle with the virus. How HIV escapes

Table 6.15 CDC Classification Categories of HIV Infection

Clinical Categories	CD4+ T-Cell Categories		
	1 ≥500 Cells/μL	2 200–499 Cells/μL	3 <200 Cells/μL
A. Asymptomatic, acute (primary) HIV, or persistent generalized lymphadenopathy	A1	A2	A3
B. Symptomatic, not A or C conditions	B1	B2	B3
C. AIDS indicator conditions: including opportunistic infections, neurologic disease, and tumors			

Data from Centers for Disease Control and Prevention: 1993 revised classification system and expanded surveillance definition for AIDS among adolescents and adults, *MMWR* 41(RR-17):1, 1992.

immune control is not entirely clear, but several mechanisms have been proposed. These include destruction of the CD4+ T cells that are critical for effective immunity, antigenic variation, and down-modulation of class I MHC molecules on infected cells so that viral antigens are not recognized by CD8+ CTLs. During this period, the virus may evolve and switch from relying solely on CCR5 to enter its target cells to relying on either CXCR4 or both CCR5 and CXCR4. This coreceptor switch is associated with more rapid decline in CD4+ T-cell counts, presumably because of greater infection of T cells.

In this chronic phase of infection, patients are either asymptomatic or develop minor opportunistic infections, such as oral candidiasis (thrush), vaginal candidiasis, herpes zoster, and perhaps tuberculosis (the latter being particularly common in resource-poor regions such as sub-Saharan Africa). Autoimmune thrombocytopenia may also be noted (Chapter 14).

AIDS

The final phase is progression to AIDS, characterized by a breakdown of host defense, a dramatic increase in viral load, and severe, life-threatening clinical disease. The typical patient presents with long-lasting fever (>1 month), fatigue, weight loss, diarrhea, and generalized lymph node enlargement. After a variable period, serious opportunistic infections, secondary neoplasms, or clinical neurologic disease (grouped under the rubric AIDS indicator diseases, discussed later) emerge, and the patient is said to have developed AIDS.

In the absence of treatment, most patients with HIV infection progress to AIDS after a chronic phase lasting from 7 to 10 years. Exceptions to this typical course are rapid progressors and long-term nonprogressors. In *rapid progressors,* the middle, chronic phase is telescoped to 2 to 3 years after primary infection. About 5% to 15% of infected individuals are *long-term nonprogressors,* defined as untreated HIV-1–infected individuals who remain asymptomatic for 10 years or more, with stable CD4+ T-cell counts and low viral loads (usually <500 viral RNA copies per milliliter). Remarkably, about 1% of infected individuals have undetectable plasma virus (<50 to 75 RNA copies/mL); these have been called *elite controllers*. Individuals with such an uncommon clinical course have attracted great attention in the hope that studying them may shed light on host and viral factors that influence disease progression. Studies thus far indicate that this group is heterogeneous with respect to the variables that influence the course of the disease. In most cases, the viral isolates do not show qualitative abnormalities, suggesting that the course of the disease cannot be attributed to a "wimpy" virus. In all cases, there is evidence of a vigorous anti-HIV immune response, but the immune correlates of protection are still unknown. Some of these individuals have high levels of HIV-specific CD4+ and CD8+ T-cell responses, and these levels are maintained over the course of infection. The inheritance of particular HLA alleles seems to correlate with resistance to disease progression, perhaps reflecting the ability to mount antiviral T-cell responses. Further studies, it is hoped, will provide the answers to this and other questions critical to understanding disease progression.

Clinical Features of AIDS

The salient clinical features of the acute early and chronic middle phases of HIV infection were described earlier; here we summarize the clinical manifestations of the terminal phase, AIDS. At the outset, it should be pointed out that the clinical manifestations and opportunistic infections associated with HIV infection vary in different parts of the world. Also, the course of the disease has been greatly modified by new antiretroviral therapies, and many devastating complications that were once common are now infrequent.

In the United States, the typical adult patient with AIDS presents with fever, weight loss, diarrhea, generalized lymphadenopathy, multiple opportunistic infections, neurologic disease, and, in many cases, secondary neoplasms. The infections and neoplasms listed in Table 6.16 are included in the surveillance definition of AIDS.

Opportunistic Infections

Opportunistic infections account for the majority of deaths in untreated patients with AIDS. Many of these infections represent reactivation of latent infections, which are normally kept in check by a robust immune system but are not completely eradicated because the infectious agents have evolved to coexist with their hosts. The frequency of infections varies in different regions of the world, and has been markedly reduced by ART, which relies on a combination of three or four drugs that block different steps of the HIV life cycle. A brief summary of selected opportunistic infections is provided here.

- Approximately 15% to 30% of untreated HIV-infected people develop pneumonia caused by the fungus *Pneumocystis jirovecii* (reactivation of a prior latent infection) during the course of the disease. Before the advent of ART, this infection was the presenting feature in about 20% of cases, but the incidence is much less in patients who respond to ART.

Table 6.16 AIDS-Defining Opportunistic Infections and Neoplasms Found in Patients With HIV Infection

Infections
Protozoal and Helminthic Infections
Cryptosporidium or *Cystoisospora* (enteritis)
Pneumocystis (pneumonia or disseminated infection)
Toxoplasma (pneumonia or CNS infection)
Fungal Infections
Candida (esophageal, tracheal, or pulmonary)
Cryptococcus (CNS infection)
Coccidioides (disseminated)
Histoplasma (disseminated)
Bacterial Infections
Mycobacterium ("atypical," e.g., *Mycobacterium avium-intracellulare*, disseminated or extrapulmonary; *Mycobacterium tuberculosis*, pulmonary or extrapulmonary)
Nocardia (pneumonia, meningitis, disseminated)
Salmonella infections, disseminated
Viral Infections
Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS infections)
Herpes simplex virus (localized or disseminated infection)
Varicella-zoster virus (localized or disseminated infection)
Progressive multifocal leukoencephalopathy
Neoplasms
Kaposi sarcoma
Primary lymphoma of brain
Invasive cancer of the uterine cervix

CNS, Central nervous system.

- Many patients present with other opportunistic infections. Among the most common pathogens are *Candida,* cytomegalovirus, atypical and typical mycobacteria, *Cryptococcus neoformans, Toxoplasma gondii, Cryptosporidium,* herpes simplex virus, papovaviruses, and *Histoplasma capsulatum*.
- *Candidiasis* is the most common fungal infection in patients with AIDS, and infection of the oral cavity, vagina, and esophagus are its most common clinical manifestations. In asymptomatic HIV-infected individuals, oral candidiasis is a sign of immunologic decompensation and often heralds the transition to AIDS. Invasive candidiasis is infrequent in patients with AIDS, and it usually occurs when there is drug-induced neutropenia or use of indwelling catheters.
- *Cytomegalovirus* (CMV) may cause disseminated disease or may be localized to the eye and gastrointestinal tract. At one time, CMV chorioretinitis was seen in approximately 25% of patients, but its incidence has decreased dramatically due to ART. Cytomegalovirus retinitis occurs almost exclusively in patients with CD4+ T cell counts less than 50/μL. Gastrointestinal disease, seen in 5% to 10% of cases, manifests as esophagitis and colitis, the latter associated with multiple mucosal ulcerations.
- Disseminated bacterial infection with *atypical mycobacteria* (mainly *Mycobacterium avium-intracellulare*) also occurs late, in the setting of severe immunosuppression. Coincident with the AIDS epidemic, the incidence of tuberculosis has risen dramatically. Worldwide, almost one-third of all deaths in AIDS patients are attributable to tuberculosis, but this complication remains uncommon in the United States. Patients with AIDS are at risk for reactivation of latent pulmonary disease as well as primary infection. In contrast to infection with atypical mycobacteria, *M. tuberculosis* infection manifests early in the course of AIDS. As with tuberculosis in other settings, the infection may be confined to lungs or may involve multiple organs. The extent of infection depends on the degree of immunosuppression; dissemination is more common in patients with very low CD4+ T-cell counts. Most worrisome are reports indicating that a growing number of isolates are resistant to multiple antimycobacterial drugs.
- A variety of opportunistic infections target the CNS. *Cryptococcosis* occurs in about 10% of AIDS patients. As in other settings with immunosuppression, meningitis is the major clinical manifestation of cryptococcosis. *Toxoplasma gondii,* another frequent invader of the CNS in AIDS, causes encephalitis and is responsible for 50% of all mass lesions in the CNS. *JC virus,* a human papovavirus, is another important cause of CNS infections in HIV-infected patients. It causes progressive multifocal leukoencephalopathy (Chapter 28).
- Other infections preferentially involve the gastrointestinal tract and genitalia. *Herpes simplex virus infection* is manifested by mucocutaneous ulcerations involving the mouth, esophagus, external genitalia, and perianal region. *Persistent diarrhea,* which is common in untreated patients with advanced AIDS, is often caused by infections with protozoans such as *Cryptosporidium, Isospora belli,* or microsporidia. These patients have chronic, profuse, watery diarrhea with massive fluid loss. Diarrhea may also result from infection with enteric bacteria, such as *Salmonella* and *Shigella,* as well as *M. avium-intracellulare.*

Tumors

Patients with AIDS have a high incidence of certain tumors, especially Kaposi sarcoma (KS), B-cell lymphoma, cervical cancer in women, and anal cancer in men. It is estimated that 25% to 40% of untreated HIV-infected individuals will eventually develop a malignancy. A common feature of these tumors is that they are caused by oncogenic DNA viruses, specifically human herpesvirus-8 (KS), EBV (B-cell lymphoma), and human papillomavirus (cervical and anal carcinoma). These viruses may establish latent infections even in healthy people, but they are usually kept in check by a competent immune system. The risk of malignancy in AIDS patients is increased mainly because of failure to contain the infections and decreased immunity against the tumors.

Kaposi Sarcoma. KS, a vascular tumor that is otherwise rare in the United States, is the most common neoplasm in patients with AIDS. The morphology of KS and its occurrence in patients not infected with HIV are discussed in Chapter 11. At the onset of the AIDS epidemic, up to 30% of infected homosexual or bisexual men had KS, but in recent years, with use of ART there has been a dramatic decline in its incidence. In contrast, in areas of sub-Saharan Africa where HIV infection is both frequent and largely untreated, KS is one of the most common tumors.

The lesions of KS are characterized by the proliferation of spindle-shaped cells that express markers of both

endothelial cells (vascular or lymphatic) and smooth muscle cells. There is also a profusion of slitlike vascular spaces, suggesting that the lesions may arise from primitive mesenchymal precursors of vascular channels. In addition, KS lesions display chronic inflammatory cell infiltrates. Many of the features of KS suggest that it is not a malignant tumor (despite its ominous name). For instance, spindle cells in many KS lesions are polyclonal or oligoclonal, although more advanced lesions occasionally show monoclonality. The current model of KS pathogenesis is that the spindle cells produce proinflammatory and angiogenic factors, which recruit the inflammatory and neovascular components of the lesion, and the latter components supply signals that aid in spindle cell survival and growth.

There is compelling evidence that KS is caused by *human herpesvirus 8* (HHV8), also called KS herpesvirus (KSHV). Exactly how HHV8 infection leads to KS is still unclear. Like other herpesviruses, HHV8 establishes latent infection, during which several proteins are produced with potential roles in stimulating spindle cell proliferation and preventing apoptosis. These include a viral homologue of cyclin D and several inhibitors of p53. However, HHV8 infection, although necessary for KS development, is not sufficient, and additional cofactors are needed. In the AIDS-related form, that cofactor is clearly HIV (the relevant cofactors for HIV-negative KS remain unknown). HIV-mediated immune suppression may aid in widespread dissemination of HHV8 in the host.

HHV8 infection is not restricted to endothelial cells. The virus is related phylogenetically to the lymphotropic subfamily of herpesviruses (γ-herpesvirus); in keeping with this, its genome is found in B cells of infected subjects. In fact, HHV8 infection is also linked to rare B-cell lymphomas in AIDS patients (called primary effusion lymphoma) and to multicentric Castleman disease, a B-cell lymphoproliferative disorder.

Clinically, AIDS-associated KS is quite different from the sporadic form (Chapter 11). In HIV-infected individuals, the tumor is usually widespread, affecting the skin, mucous membranes, gastrointestinal tract, lymph nodes, and lungs. These tumors also tend to be more aggressive than classic KS.

Lymphomas. Lymphoma occurs at a markedly increased rate in individuals with AIDS, making it one of several AIDS-defining conditions. Roughly 5% of AIDS patients present with lymphoma, and approximately another 5% develop lymphoma during their subsequent course, virtually all of which originate from transformed B cells. With the advent of effective ART, the incidence of lymphoma has fallen substantially in some HIV-infected populations. However, lymphoma continues to occur in HIV-infected people at an incidence that is at least 10-fold greater than the population average. These epidemiologic findings suggest that the association of lymphoma and HIV infection is only partially explained by T-cell immunodeficiency. Indeed, based on molecular characterization of HIV-associated lymphomas and these epidemiologic considerations, at least two mechanisms appear to underlie the increased risk of B-cell tumors in HIV-infected individuals (Fig. 6.44).

- Unchecked proliferation of B cells infected with oncogenic herpesviruses in the setting of profound T cell depletion (AIDS). T-cell immunity is required to restrain the proliferation of B cells infected with oncogenic viruses such as EBV and HHV8. With the appearance of severe T-cell depletion late in the course of HIV infection, this control is lost. As a result, AIDS patients are at high risk of developing aggressive B cell lymphomas composed of tumor cells infected by oncogenic viruses, particularly EBV.

  By adulthood, most normal individuals are infected with EBV. Once immunity is established, EBV persists in such individuals as a latent infection in approximately 1 in 100,000 B cells, most of which have a memory B-cell phenotype. Activation of such cells, by antigen or by cytokines, reawakens an EBV-encoded program of gene expression that drives B-cell proliferation. Patients with AIDS have high levels of several cytokines, some of which, including IL-6, are growth factors for B cells. These patients are also chronically infected with pathogens that may lead to B-cell stimulation. In the absence of T-cell immunity, these activated, EBV-infected clones proliferate and eventually acquire additional somatic mutations, leading to their outgrowth as full-blown EBV-positive B-cell lymphomas. The tumors often occur in extranodal

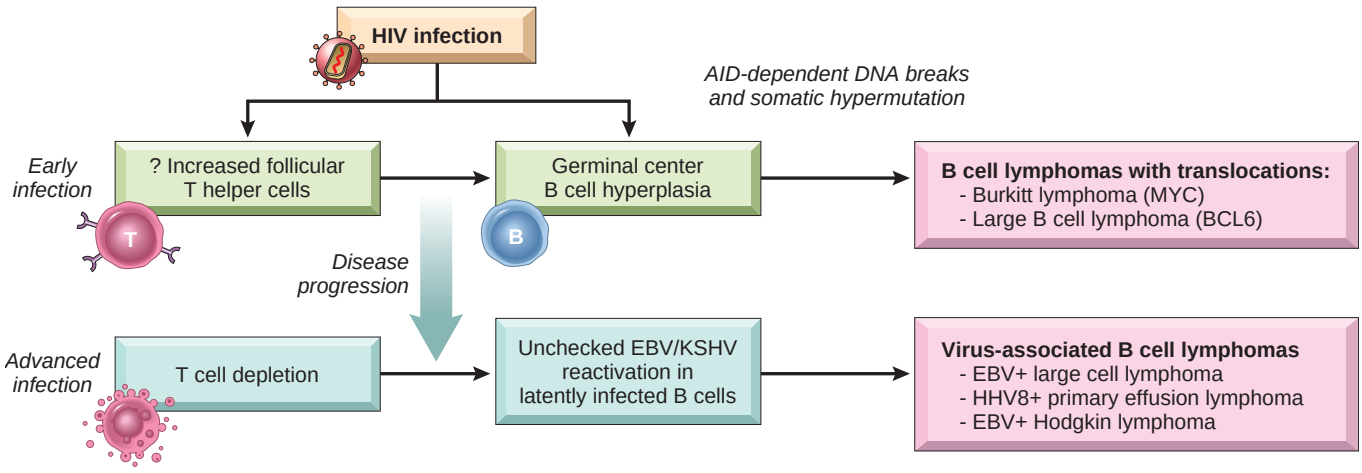

Figure 6.44 A model for the pathogenesis of B-cell lymphomas in HIV infection. HIV infection results in several changes that may cooperate to produce B-cell lymphomas. An increase in T follicular helper cells early in the course of the disease is postulated, but its basis is unknown.

sites, such as the CNS, but also the gut, the orbit, the lungs, and elsewhere. The primary effusion lymphomas mentioned earlier present as malignant effusions and are remarkable in that the tumor cells are typically coinfected by both EBV and HHV8, an unusual example of cooperativity between two oncogenic viruses.

- Germinal center B-cell hyperplasia in the setting of early HIV infection. As mentioned, even in the face of effective ART, the overall rate of lymphoma in the HIV-infected population remains elevated, even in those with normal CD4+ T-cell counts. The majority of the lymphomas that arise in patients with preserved CD4 T-cell counts are not associated with EBV or HHV8. What then explains the increased risk of lymphoma? The answer is not known, but it may be related to the profound germinal center B-cell hyperplasia that occurs early in HIV infection. Recall that in germinal centers, B cells undergo class switching and somatic hypermutation in their immunoglobulin genes. Both processes introduce breaks in DNA and are error-prone, sometimes leading to translocation of oncogenes. Of note, B cell tumors that arise outside of the setting of full-blown AIDS in HIV-infected individuals, such as Burkitt lymphoma and diffuse large B-cell lymphoma, are often associated with translocations of oncogenes into Ig gene loci. Thus, the striking germinal center B-cell hyperplasia that occurs early in HIV infection may contribute to lymphomagenesis in part by increasing the number of B cells that are at-risk for acquiring lymphoma-initiating events.

Several other EBV-related proliferations also merit mention. Hodgkin lymphoma, an unusual B cell tumor associated with a pronounced tissue inflammatory response (Chapter 13), occurs at increased frequency in HIV-infected individuals. In virtually all instances of HIV-associated Hodgkin lymphoma, the characteristic tumor cells (Reed-Sternberg cells) are infected with EBV. Many (but not all) HIV patients with Hodgkin lymphoma have low CD4 counts at the time of disease presentation. EBV infection also is responsible for oral hairy leukoplakia (white projections on the tongue), which results from EBV-driven squamous cell proliferation of the oral mucosa (Chapter 16).

Other Tumors. In addition to KS and lymphoma, patients with AIDS are at increased risk of human papilloma virus (HPV)-associated carcinomas of the uterine cervix and the anus. HPV is intimately associated with squamous cell carcinoma of the cervix and its precursor, squamous intraepithelial lesion (SIL; Chapters 7 and 22). HPV-associated SIL is 10 times more common in HIV-infected women as compared with uninfected women attending family planning clinics, and is confined to HIV-infected women with CD4 counts of less than 500 cells/μL, suggesting that the risk is attributable to diminished immune surveillance. The rate of progression from SIL to overt cervical carcinoma also appears to be accelerated in HIV-infected women. Hence, gynecologic examination is a particularly important part of a routine workup for HIV-infected women.

Central Nervous System Disease

Involvement of the CNS is a common and important manifestation of AIDS. Ninety percent of patients demonstrate some form of neurologic involvement at autopsy, and 40% to 60% have clinically apparent neurologic dysfunction. Importantly, in some patients, neurologic manifestations may be the sole or earliest presenting feature of HIV infection. In addition to opportunistic infections and neoplasms, several HIV-related neuropathologic changes occur. These include a self-limited meningoencephalitis occurring at the time of seroconversion, aseptic meningitis, vacuolar myelopathy, peripheral neuropathies, and, most commonly, a progressive encephalopathy designated clinically as HIV-associated neurocognitive disorder (Chapter 28). It is believed to result from a combination of HIV infection of microglia and an immune response in the CNS.

Effect of Antiretroviral Drug Therapy

Fortunately for those affected, ART with drugs that target the viral reverse transcriptase, protease, and integrase have altered the clinical course of HIV infection quite dramatically. These drugs are given in combination to reduce the emergence of drug-resistant mutants. Over 25 antiretroviral drugs from six distinct drug classes have been developed for the management of HIV infection. When a combination of at least three effective drugs is used in a motivated, compliant patient, HIV viral load is reduced to below the level of detection (<50 copies RNA/mL) and remains there indefinitely (as long as the patient adheres to therapy). Even when a drug-resistant virus breaks through, there are several second- and third-line options to combat the virus. Once the virus is suppressed, the progressive loss of CD4+ T cells is halted, and over a period of several years the peripheral blood CD4+ T-cell count slowly increases and often returns to normal. With the use of ART, in the United States the annual death rate from AIDS has decreased from its peak of 16 to 18 per 100,000 people in 1995 to 1996 to less than 4 per 100,000. Many AIDS-associated disorders, such as *P. jirovecii* infection and KS, are very uncommon now. ART also has reduced the transmission of the virus, especially from infected mothers to newborns. However, because of the reduced mortality, more people are living with HIV, and the risk of HIV spread in the population will inevitably increase if vigilance is relaxed. Indeed, there is compelling evidence that even patients who have virtually undetectable viral loads for years on ART develop active infection if they stop drug treatment.

Despite these dramatic improvements, several new complications associated with HIV infection and its treatment have emerged. Some patients with advanced disease who are given ART have a paradoxical deterioration in their clinical condition as the immune system recovers. This occurs despite increasing CD4+ T-cell counts and decreasing viral load. This disorder, called *immune reconstitution inflammatory syndrome,* is not understood but is postulated to be a poorly regulated host response to the high antigenic burden of persistent microbes. Perhaps a more important complication of long-term ART pertains to adverse side effects of the drugs. These include lipoatrophy (loss of facial fat), lipoaccumulation (excess fat deposition centrally), elevated lipids, insulin resistance, peripheral neuropathy, and potentially deleterious effects on cardiovascular, renal, and hepatic function. Because CD4+ T-cell counts are normalized, non-AIDS morbidity is far more common than classic AIDS-related morbidity in long-term ART-treated patients. Major causes of morbidity are cancer, and accelerated cardiovascular, kidney, and

liver disease. The mechanism for these non–AIDS-related complications is not known, but persistent inflammation and immune dysfunction may play a role.

MORPHOLOGY

The anatomic changes in the tissues are neither specific nor diagnostic. Common pathologic features of AIDS include opportunistic infections, KS, and B-cell lymphomas. Most of these lesions are discussed elsewhere, because they also occur in individuals who do not have HIV infection. Lesions in the CNS are described in Chapter 28.

Biopsy specimens from enlarged lymph nodes in the early stages of HIV infection reveal a marked hyperplasia of B-cell follicles. The follicles are enlarged and often take on unusual, serpiginous shapes. The mantle zones that surround the follicles are attenuated, and the germinal centers impinge on interfollicular T-cell areas. This hyperplasia of B cells is the morphologic reflection of the polyclonal B-cell activation that is seen in HIV-infected individuals.

With disease progression, the frenzy of B-cell proliferation subsides and gives way to a pattern of severe lymphoid involution. The lymph nodes are depleted of lymphocytes, and the organized network of FDCs is disrupted. The germinal centers may even become hyalinized. These small, atrophic, "burnt-out" lymph nodes may harbor numerous opportunistic pathogens, often within macrophages. Because of profound immunosuppression, inflammatory responses to infections, both in the lymph nodes and at extranodal sites, may be sparse or atypical. For example, mycobacteria may not evoke granuloma formation because CD4+ cells are deficient. In the empty-looking lymph nodes and in other organs, the presence of infectious agents may not be readily apparent without special stains. As might be expected, lymphoid involution is not confined to the nodes; in later stages of AIDS, the spleen and thymus also are converted to "wastelands" that are virtually devoid of lymphocytes.

Despite spectacular advances in our understanding of HIV infection, the long-term prognosis of HIV-positive patients remains guarded. With ART, the mortality rate has declined in the United States, but treated patients still carry viral DNA in their lymphoid tissues, and a cure remains elusive. Although a considerable effort has been mounted to develop a vaccine, many hurdles remain to be crossed before vaccine-based prophylaxis becomes a reality. Molecular analyses have revealed an alarming degree of variation in viral isolates from patients; this renders the task of producing a vaccine extremely difficult. Recent efforts have focused on producing broadly neutralizing antibodies against relatively invariant portions of HIV proteins. The task of developing an effective vaccine is complicated by the fact that the correlates of immune protection are not fully understood. At present, therefore, prevention, public health measures, and antiretroviral drugs remain the mainstays in the fight against AIDS.

KEY CONCEPTS

PATHOGENESIS AND COURSE OF HIV INFECTION AND AIDS

- Virus entry into cells: requires CD4 and co-receptors, which are receptors for chemokines; involves binding of viral gp120 and fusion with the cell mediated by viral gp41 protein; main cellular targets are CD4+ helper T cells, macrophages, and DCs
- Viral replication: provirus genome integrates into host cell DNA; viral gene expression is triggered by stimuli that activate infected cells (e.g., infectious microbes, cytokines produced during normal immune responses)
- Progression of infection: acute infection of mucosal T cells and DCs; viremia with dissemination of virus; latent infection of cells in lymphoid tissue; continuing viral replication and progressive loss of CD4+ T cells
- Mechanisms of immune deficiency
  - Loss of CD4+ T cells: T-cell death during viral replication and budding (similar to other cytopathic infections); apoptosis as a result of chronic stimulation; decreased thymic output; functional defects
  - Defective macrophage and DC functions
  - Destruction of architecture of lymphoid tissues (late)
- Clinical manifestations of AIDS include opportunistic infections, tumors such as B-cell lymphomas, and CNS abnormalities.

AMYLOIDOSIS

Amyloidosis is a condition associated with a number of inherited and inflammatory disorders in which extracellular deposits of fibrillar proteins are responsible for tissue damage and functional compromise. These abnormal fibrils are produced by the aggregation of misfolded proteins (which are soluble in their normal folded configuration). The fibrillar deposits bind a wide variety of proteoglycans and glycosaminoglycans, including heparan sulfate and dermatan sulfate, and plasma proteins, notably serum amyloid P. The presence of abundant charged sugar groups in these adsorbed proteins give the deposits staining characteristics that were thought to resemble starch (amylose). Therefore, the deposits were called *amyloid,* a name that is firmly entrenched despite the realization that the deposits are unrelated to starch.

Amyloid is deposited in the extracellular space in various tissues and organs in several clinical settings. With progressive accumulation, it encroaches on and produces pressure atrophy of adjacent cells. Because amyloid deposition appears insidiously and sometimes mysteriously, its clinical recognition ultimately depends on morphologic identification of this distinctive substance in appropriate biopsy specimens. With the light microscope and hematoxylin and eosin stains, amyloid appears as an amorphous, eosinophilic, hyaline, extracellular substance. To differentiate amyloid from other hyaline materials (e.g., collagen, fibrin), a variety of histochemical techniques, described later, are employed. Perhaps most widely used is the Congo red stain, which under ordinary light imparts a pink or red color to tissue deposits, but far more striking and specific is the green birefringence of the stained amyloid when observed by polarizing microscopy (see later).

Properties of Amyloid Proteins

Even though all amyloid deposits have a similar microscopic appearance, amyloid is not a single chemical entity. In fact, more than 20 different proteins can aggregate to form amyloid. There are three major and several minor biochemical

forms, which are deposited by different pathogenic mechanisms. Therefore, amyloidosis is not a single disease, but rather a group of diseases having in common the deposition of similar-appearing proteins. At the heart of the morphologic similarity is the remarkably uniform physical organization of amyloid, which we consider first.

Physical Nature of Amyloid. By electron microscopy, all types of amyloid, regardless of clinical setting or chemical composition, consist of continuous, nonbranching fibrils with a diameter of approximately 7.5 to 10 nm. X-ray crystallography and infrared spectroscopy demonstrate a characteristic cross-β-pleated sheet conformation (Fig. 6.45). This conformation is responsible for the distinctive Congo red staining and birefringence of amyloid.

Chemical Nature of Amyloid. Approximately 95% of the amyloid consists of fibril proteins, with the remaining 5% being the P component and other glycoproteins. The three most common forms of amyloid are as follows:

- *Amyloid light chain (AL) protein* is made up of complete immunoglobulin light chains, the amino-terminal fragments of light chains, or both. Most of the AL proteins analyzed are composed of λ light chains or their fragments, but κ chains are present in some cases. The amyloid fibril protein of the AL type is produced from free Ig light chains secreted by a monoclonal population of plasma cells, and its deposition is associated with certain plasma cell tumors (Chapter 13).
- *Amyloid-associated (AA) protein* is a form of amyloid derived from a unique non-Ig protein made by the liver. The AA protein found in the fibrils is created by proteolysis of a larger precursor called SAA (serum amyloid-associated) protein that is synthesized in the liver and circulates in the blood bound to high-density lipoproteins. The production of SAA protein is increased in inflammatory states as part of the acute phase response; therefore, this form of amyloidosis is associated with chronic inflammation, and is often called secondary amyloidosis.
- *β-amyloid (Aβ) protein* constitutes the core of cerebral plaques found in Alzheimer disease as well as the amyloid deposited in walls of cerebral blood vessels in individuals with this disease. The Aβ protein is derived by proteolysis from a much larger transmembrane glycoprotein called amyloid precursor protein. This form of amyloid is discussed in Chapter 28.

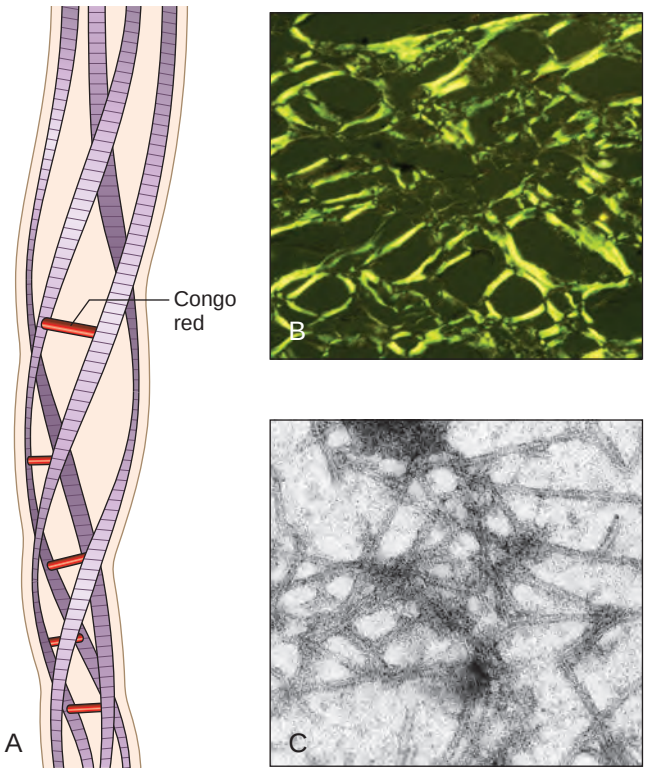

Figure 6.45 Structure of amyloid. (A) A schematic diagram of an amyloid fiber showing four fibrils (there can be as many as six in each fiber) wound around one another with regularly spaced binding of the Congo red dye. (B) Congo red staining shows apple-green birefringence under polarized light, a diagnostic feature of amyloid. (C) Electron micrograph of 7.5- to 10-nm amyloid fibrils. (From Merlini G, Bellotti V: Molecular mechanisms of amyloidosis, *N Engl J Med* 349:583–596, 2003, with permission of the Massachusetts Medical Society.)

As mentioned, multiple other biochemically distinct proteins can also deposit as amyloid in a variety of clinical settings. Among these rare forms of amyloid, the proteins most often involved are as follows:

- *Transthyretin* (TTR) is a normal serum protein that binds and transports thyroxine and retinol. Several distinct mutant forms of TTR (and its fragments) form amyloid in a group of genetically determined disorders referred to as *familial amyloid polyneuropathies.* Unmutated TTR may also deposit as amyloid in the heart of aged individuals (senile systemic amyloidosis).
- *β_2-microglobulin,* a component of MHC class I molecules and a normal serum protein, has been identified as the major component of a form of amyloid ($A\beta_2m$) that deposits in or around the joints or soft tissues of patients on long-term hemodialysis.
- In a minority of cases of prion disease in the CNS, the misfolded prion proteins aggregate in the extracellular space and acquire the structural and staining characteristics of amyloid.

Pathogenesis and Classification of Amyloidosis

Amyloidosis results from abnormal folding of proteins, which become insoluble, aggregate, and deposit as fibrils in extracellular tissues. Normally, misfolded proteins are degraded intracellularly in proteasomes, or extracellularly by macrophages. It appears that in amyloidosis, these quality-control mechanisms fail, leading to accumulation of a misfolded protein outside cells. The proteins that form amyloid fall into two general categories (Fig. 6.46): (1) normal proteins that have an inherent tendency to fold improperly, associate and form fibrils, and do so when they are produced in increased amounts and (2) mutant proteins that are prone to misfolding and subsequent aggregation. The mechanisms of deposition of different types of amyloid are discussed here along with classification.

Because a given biochemical form of amyloid (e.g., AA) may be associated with amyloid deposition in diverse clinical settings, we follow a combined biochemical-clinical classification for our discussion (Table 6.17). Amyloid may be *systemic* (generalized), involving several organ systems, or it may

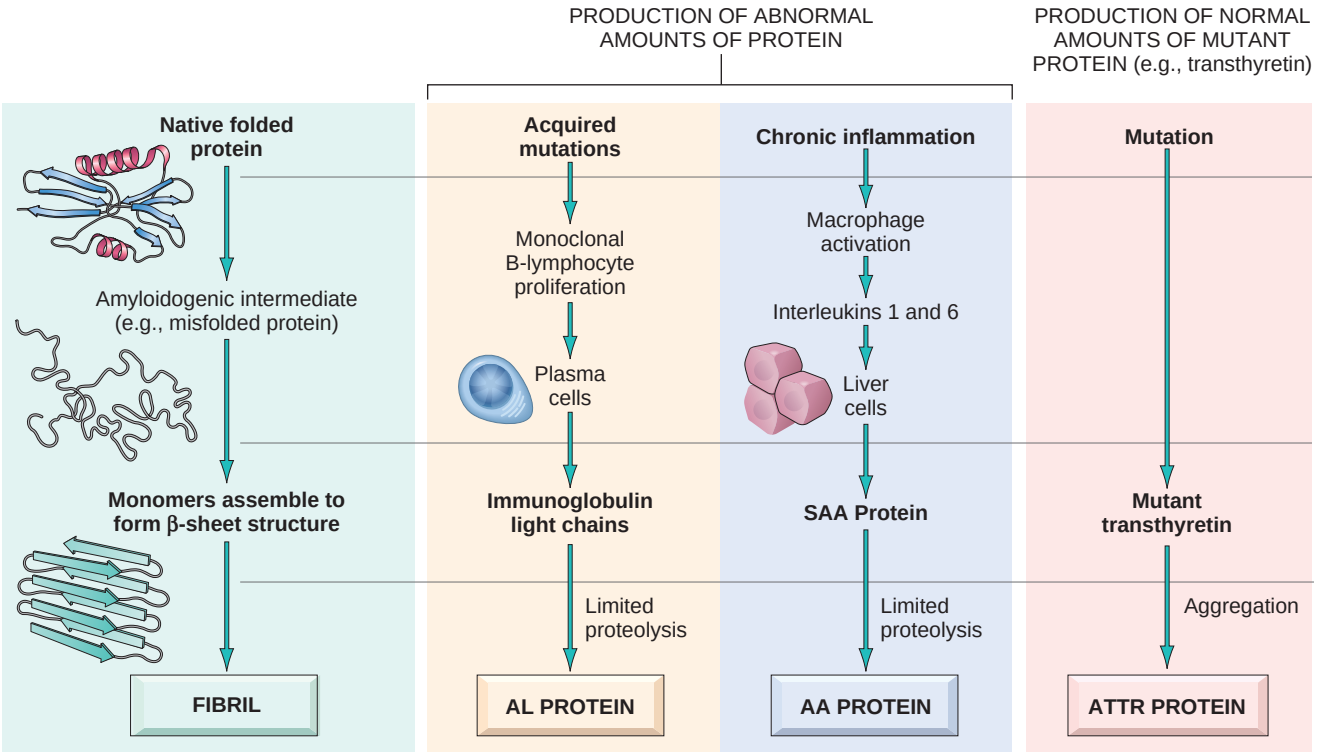

Figure 6.46 Pathogenesis of amyloidosis, showing the proposed mechanisms underlying deposition of the major forms of amyloid fibrils.

be *localized* to a single organ, such as the heart. On clinical grounds, the systemic, or generalized, pattern is subclassified into *primary amyloidosis,* when it is associated with clonal plasma cell proliferations, or *secondary amyloidosis,* when it occurs as a complication of an underlying chronic inflammatory process. *Hereditary* or *familial amyloidosis* constitutes a separate, albeit heterogeneous, group, with several distinctive patterns of organ involvement.

Primary Amyloidosis: Plasma Cell Disorders Associated With Amyloidosis

Amyloid in this category is usually systemic in distribution and is of the AL type. With approximately 2000 to 3000 new cases every year in the United States, this is the most common form of amyloidosis. In all cases, the disorder is caused by a clonal proliferation of plasma cells that

Table 6.17 Classification of Amyloidosis

Clinicopathologic Category	Associated Diseases	Major Fibril Protein	Chemically Related Precursor Protein
Systemic (Generalized) Amyloidosis			
Immunoglobulin light chain amyloidosis (primary amyloidosis)	Multiple myeloma and other monoclonal plasma cell proliferations	AL	Immunoglobulin light chains, chiefly λ type
Reactive systemic amyloidosis (secondary amyloidosis)	Chronic inflammatory conditions	AA	SAA
Hemodialysis-associated amyloidosis	Chronic renal failure	$A\beta_2m$	β_2-microglobulin
Hereditary Amyloidosis			
Familial Mediterranean fever		AA	SAA
Familial amyloidotic neuropathies (several types)		ATTR	Transthyretin
Systemic senile amyloidosis		ATTR	Transthyretin
Localized Amyloidosis			
Senile cerebral	Alzheimer disease	Aβ	APP
Endocrine Medullary carcinoma of thyroid Islets of Langerhans	Type 2 diabetes	 A Cal AIAPP	 Calcitonin Islet amyloid peptide
Isolated atrial amyloidosis		AANF	Atrial natriuretic factor

synthesize an Ig light chain that is prone to form amyloid due to its intrinsic physiochemical properties. Best defined is the occurrence of systemic amyloidosis in 5% to 15% of individuals with multiple myeloma, a plasma-cell tumor characterized by multiple osteolytic lesions throughout the skeletal system (Chapter 13). The malignant plasma cells synthesize abnormal amounts of a single Ig, producing an M (myeloma) protein "spike" on serum electrophoresis. In addition to the synthesis of whole Ig molecules, the malignant plasma cells often secrete free, unpaired κ or λ light chains (referred to as Bence-Jones protein). These are often found in the serum, and due to their small molecular size, Bence-Jones proteins are excreted and concentrated in the urine. In primary amyloidosis, the free light chains are not only present in serum and urine but are also deposited in tissues as amyloid. It should be noted, however, that the majority of myeloma patients who have free light chains in serum and urine do not develop amyloidosis. Clearly, not all free light chains are equally likely to produce amyloid, and it is believed that the amyloidogenic potential of any particular light chain is largely determined by its specific amino acid sequence.

Most persons with AL amyloid do not have classic multiple myeloma or any other overt B-cell neoplasm; such cases have been traditionally classified as primary amyloidosis, because their clinical features derive from the effects of amyloid deposition without any other associated disease. In virtually all such cases, however, monoclonal immunoglobulins or free light chains, or both, can be found in the serum or urine. Most of these patients also have a modest increase in the number of plasma cells in the bone marrow, which presumably secrete the precursors of AL protein. Thus, these patients have an underlying monoclonal proliferation of Ig-producing cells *(monoclonal gammopathy)* in which production of an abnormal protein, rather than presence of tumor masses, is the dominant manifestation.

Reactive Systemic Amyloidosis

The amyloid deposits in this pattern are systemic in distribution and are composed of AA protein. This category was previously referred to as *secondary amyloidosis* because it is secondary to an associated inflammatory condition. At one time, tuberculosis, bronchiectasis, and chronic osteomyelitis were the most important underlying conditions, but with the advent of effective antibiotic therapy, the importance of these conditions has diminished. More commonly now, reactive systemic amyloidosis complicates rheumatoid arthritis, other connective tissue disorders such as ankylosing spondylitis, and inflammatory bowel disease, both Crohn disease and ulcerative colitis. Among these, the most frequently associated condition is rheumatoid arthritis. Amyloidosis is reported to occur in approximately 3% of patients with rheumatoid arthritis and is clinically significant in one-half of those affected. Heroin users who inject the drug subcutaneously also have a high occurrence rate of generalized AA amyloidosis. The chronic skin infections associated with "skin-popping" of narcotics seem to be responsible for the amyloidosis. Reactive systemic amyloidosis may also occur in association with solid tumors, the most common being renal cell carcinoma and Hodgkin lymphoma.

In this form of amyloidosis, SAA synthesis by liver cells is stimulated by cytokines such as IL-6 and IL-1 that are produced during inflammation; thus, long-standing inflammation leads to a sustained elevation of SAA levels. However, increased production of SAA by itself is not sufficient for the deposition of amyloid. There are two possible explanations for this. According to one view, SAA is normally degraded to soluble end products by the action of monocyte-derived enzymes. Conceivably, individuals who develop amyloidosis have an enzyme defect that results in incomplete breakdown of SAA, thus generating insoluble AA molecules. Alternatively, a genetically determined structural abnormality in the SAA molecule may render it resistant to degradation by macrophages.

Heredofamilial Amyloidosis

A variety of familial forms of amyloidosis have been described. Most of them are rare and occur in limited geographic areas. The most common and best studied is an autosomal recessive condition called *familial Mediterranean fever*. This is an autoinflammatory syndrome associated with excessive production of the cytokine IL-1 in response to inflammatory stimuli. It is characterized clinically by attacks of fever accompanied by inflammation of serosal surfaces, including peritoneum, pleura, and synovial membrane. The gene for familial Mediterranean fever encodes a protein called pyrin (for its relation to fever), which is one of a complex of proteins that regulate inflammatory reactions via activation of the inflammasome (Chapter 3). This disorder is encountered largely in individuals of Armenian, Sephardic Jewish, and Arabic origins. It is sometimes associated with widespread amyloidosis. The amyloid fibril proteins are made up of AA proteins, reflecting the increased production of SAA in response to excessive IL-1 secretion.

In contrast to familial Mediterranean fever, a group of autosomal dominant familial disorders is characterized by deposition of amyloid predominantly in peripheral and autonomic nerves. These familial amyloidotic polyneuropathies have been described in different parts of the world. As mentioned earlier, in all of these genetic disorders, the fibrils are made up of mutant TTR. In these disorders, TTR is deposited as amyloid fibrils because genetically determined alterations of its structure render it prone to misfolding and aggregation, and resistant to proteolysis.

Hemodialysis-Associated Amyloidosis

Patients on long-term hemodialysis for renal failure can develop amyloidosis as a result of deposition of β_2-microglobulin. This protein is present in high concentrations in the serum of persons with renal disease, and in the past it was retained in the circulation because it could not be filtered through dialysis membranes. Patients usually present with symptoms related to β_2-microglobulin deposition in joints, muscle, tendons, or ligaments; one relatively common presentation is as carpal tunnel syndrome. With new dialysis filters, the incidence of this complication has decreased substantially.

Localized Amyloidosis

Sometimes, amyloid deposits are limited to a single organ or tissue without involvement of any other site in the body. The deposits may produce grossly detectable nodular masses or be evident only on microscopic examination. Nodular deposits of amyloid are most often encountered in the lung,

larynx, skin, urinary bladder, tongue, and the region around the eye. Frequently, there are infiltrates of lymphocytes and plasma cells in the periphery of these amyloid masses. At least in some cases, the amyloid consists of AL protein and may therefore represent a localized form of plasma cell–derived amyloid.

Endocrine Amyloid

Microscopic deposits of localized amyloid may be found in certain endocrine tumors, such as medullary thyroid carcinoma, pancreatic islet tumor, and pheochromocytoma, and in the islets of Langerhans in individuals with type 2 diabetes mellitus. In these settings, the amyloidogenic proteins seem to be derived either from polypeptide hormones (e.g., medullary carcinoma) or from unique proteins (e.g., islet amyloid polypeptide). In medullary carcinoma of the thyroid, the presence of amyloid is a helpful diagnostic feature.

Amyloid of Aging

Several well-documented forms of amyloid deposition occur with aging. Senile systemic amyloidosis refers to the systemic deposition of amyloid in elderly patients (usually in their seventies and eighties). Because of the dominant involvement and related dysfunction of the heart, this form was previously called senile cardiac amyloidosis. Those who are symptomatic present with a restrictive cardiomyopathy and arrhythmias (Chapter 12). The amyloid in this form is derived from normal TTR. In addition to the sporadic senile systemic amyloidosis, another form affecting predominantly the heart that results from the deposition of a mutant form of TTR has also been recognized. Approximately 4% of people of African descent in the United States express this mutant form of TTR, and cardiomyopathy has been identified in both homozygous and heterozygous patients. The precise prevalence of patients with this mutation who develop clinically manifest cardiac disease is not known.

MORPHOLOGY

There are no consistent or distinctive patterns of organ or tissue distribution of amyloid deposits in any of the categories cited. Nonetheless, a few generalizations can be made. In amyloidosis secondary to chronic inflammatory disorders, the kidneys, liver, spleen, lymph nodes, adrenals, and thyroid, as well as many other tissues, are typically affected. Although amyloidosis associated with plasma cell proliferations cannot reliably be distinguished from the secondary form by its organ distribution, it more often involves the heart, gastrointestinal tract, respiratory tract, peripheral nerves, skin, and tongue. The localization of amyloid deposits in the hereditary syndromes is varied. In familial Mediterranean fever, the amyloidosis may be widespread, involving the kidneys, blood vessels, spleen, respiratory tract, and (rarely) liver. The localization of amyloid in the remaining hereditary syndromes can be inferred from the designation of these entities.

Whatever the clinical disorder, the amyloid may or may not be apparent on macroscopic examination. When amyloid accumulates in larger amounts, the organ is frequently enlarged and the tissue appears gray with a waxy, firm consistency. Histologically, the amyloid deposition is always extracellular and begins between cells, often closely adjacent to basement membranes (Fig. 6.47A). As the amyloid accumulates, it encroaches on the cells, in time surrounding and destroying them. In the form associated with plasma cell proliferation, perivascular and vascular deposits are common.

The histologic diagnosis of amyloid is based almost entirely on its staining characteristics. The most common staining technique uses the dye Congo red, which under ordinary light imparts a pink or red color to amyloid deposits. Under polarized light, the Congo red–stained amyloid shows so-called apple-green birefringence (Fig. 6.47B). This reaction is shared by all forms of amyloid and is caused by the cross-β-pleated configuration of amyloid fibrils. Confirmation can be obtained by electron microscopy, which reveals amorphous nonoriented thin fibrils. AA, AL, and ATTR types of amyloid can also be distinguished by specific immunohistochemical staining.

The pattern of organ involvement in different clinical forms of amyloidosis is variable.

Kidney. Amyloidosis of the kidney is the most common and potentially the most serious form of organ involvement. Grossly, the kidneys may be of normal size and color, or, in advanced cases, they may be shrunken because of ischemia caused by vascular narrowing induced by the deposition of amyloid within arterial and arteriolar walls.

Histologically, the amyloid is deposited primarily in the glomeruli, but the interstitial peritubular tissue, arteries, and arterioles are also affected. The glomerular deposits first appear as subtle thickenings of the mesangial matrix, accompanied usually by uneven widening of the basement membranes of the glomerular capillaries.

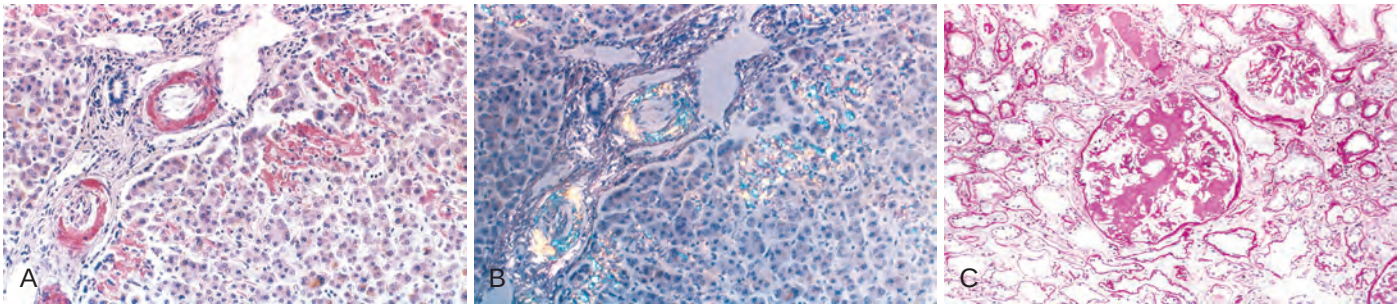

Figure 6.47 Amyloidosis. (A) A section of the liver stained with Congo red reveals pink-red deposits of amyloid in the walls of blood vessels and along sinusoids. (B) Note the yellow-green birefringence of the deposits when observed by polarizing microscope. (C) Amyloidosis of the kidney. The glomerular architecture is almost totally obliterated by the massive accumulation of amyloid. (A, B, Courtesy Dr. Trace Worrell and Sandy Hinton, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

In time, the mesangial depositions and the deposits along the basement membranes cause capillary narrowing and distortion of the glomerular vascular tuft. With progression of the glomerular amyloidosis, the capillary lumens are obliterated, and the obsolescent glomerulus is flooded by confluent masses or interlacing broad ribbons of amyloid (Fig. 6.47C).

Spleen. Amyloidosis of the spleen may be inapparent grossly or may cause moderate to marked splenomegaly (up to 800 g). For completely mysterious reasons, one of two patterns of deposition is seen. In one, the deposits are largely limited to the splenic follicles, producing tapioca-like granules on gross inspection, designated *sago spleen.* In the other pattern, the amyloid involves the walls of the splenic sinuses and connective tissue framework in the red pulp. Fusion of the early deposits gives rise to large, maplike areas of amyloidosis, creating what has been designated *lardaceous spleen.*

Liver. The deposits may be inapparent grossly or may cause moderate to marked hepatomegaly. Amyloid appears first in the space of Disse and then progressively encroaches on adjacent hepatic parenchymal cells and sinusoids (see Fig. 6.47). In time, deformity, pressure atrophy, and disappearance of hepatocytes occur, causing total replacement of large areas of liver parenchyma. Vascular involvement is frequent. Even with extensive involvement, liver function is usually preserved.

Heart. Amyloidosis of the heart (Chapter 12) may occur in any form of systemic amyloidosis. It is also the major organ involved in senile systemic amyloidosis. The heart may be enlarged and firm, but more often it shows no significant changes on gross inspection. The deposits begin as focal subendocardial accumulations and within the myocardium between the muscle fibers. Expansion of these myocardial deposits eventually causes pressure atrophy of myocardial fibers. When the amyloid deposits are subendocardial, the conduction system may be damaged, accounting for the electrocardiographic abnormalities noted in some patients.

Other Organs. Nodular deposits in the tongue may cause macroglossia, giving rise to the designation *tumor-forming amyloid of the tongue.* The respiratory tract may be involved focally or diffusely from the larynx down to the smallest bronchioles. As mentioned earlier, a distinct form of amyloid is found in the brains of patients with Alzheimer disease. It may be present in so-called *plaques* as well as blood vessels (Chapter 28). Amyloidosis of peripheral and autonomic nerves is a feature of several familial amyloidotic neuropathies. Depositions of amyloid in patients on long-term hemodialysis are most prominent in the carpal ligament of the wrist, resulting in compression of the median nerve (carpal tunnel syndrome). These patients may also have extensive amyloid deposition in the joints.

Clinical Features

Amyloidosis may be found as an unsuspected anatomic change, having produced no clinical manifestations, or it may cause serious clinical problems and even death. The symptoms depend on the magnitude of the deposits and on the sites or organs affected. Clinical manifestations at first are often nonspecific, such as weakness, weight loss, lightheadedness, or syncope. Somewhat more specific findings appear later and most often relate to renal, cardiac, and gastrointestinal involvement.

Renal involvement gives rise to proteinuria that may be severe enough to cause the nephrotic syndrome (Chapter 20). Progressive obliteration of glomeruli in advanced cases ultimately leads to renal failure and uremia. Renal failure is a common cause of death. *Cardiac amyloidosis* may present as an insidious congestive heart failure. The most serious aspects of cardiac amyloidosis are conduction disturbances and arrhythmias, which may prove fatal. Occasionally, cardiac amyloidosis produces a restrictive pattern of cardiomyopathy and masquerades as chronic constrictive pericarditis (Chapter 12). *Gastrointestinal amyloidosis* may be entirely asymptomatic, or it may present in a variety of ways. Amyloidosis of the tongue may cause sufficient enlargement and inelasticity to hamper speech and swallowing. Depositions in the stomach and intestine may lead to malabsorption, diarrhea, and disturbances in digestion. *Vascular amyloidosis* causes vascular fragility that may lead to bleeding, sometimes massive, that can occur spontaneously or following seemingly trivial trauma. Additionally, in some cases AL amyloid binds and inactivates factor X, a critical coagulation factor, leading to a life-threatening bleeding disorder.

The diagnosis of amyloidosis depends on the histologic demonstration of amyloid deposits in tissues. The most common sites biopsied are the kidney, when renal manifestations are present, or rectal or gingival tissues in patients suspected of having systemic amyloidosis. Examination of abdominal fat aspirates stained with Congo red can also be used for the diagnosis of systemic amyloidosis. The test is quite specific, but its sensitivity is low. In suspected cases of AL amyloidosis, serum and urine protein electrophoresis and immunoelectrophoresis should be performed. Bone marrow aspirates in such cases often show monoclonal plasmacytosis, even in the absence of overt multiple myeloma. Scintigraphy with radiolabeled serum amyloid P component is a rapid and specific test, since it binds to the amyloid deposits and reveals their presence. It also gives a measure of the extent of amyloidosis and can be used to follow patients undergoing treatment.

The prognosis for individuals with generalized amyloidosis is poor. Those with AL amyloidosis have an overall median survival of 2 years after diagnosis, and the prognosis is even poorer with myeloma-associated AL amyloidosis. Nevertheless, many new, more effective drugs have recently been deployed to treat plasma cell tumors and offer some hope. The outlook for individuals with reactive systemic amyloidosis is somewhat better and depends to some extent on the control of the underlying condition. Resorption of amyloid after treatment of the associated condition has been reported, but this is a rare occurrence. New therapeutic strategies aimed at correcting protein misfolding and inhibiting fibrillogenesis are being developed.

KEY CONCEPTS

AMYLOIDOSIS

- Amyloidosis is a disorder characterized by the extracellular deposits of misfolded proteins that aggregate to form insoluble fibrils.
- The deposition of these proteins may result from: excessive production of proteins that are prone to misfolding and aggregation; mutations that produce proteins that cannot fold properly and tend to aggregate; and defective or incomplete proteolytic degradation of extracellular proteins.

- Amyloidosis may be localized or systemic. It is seen in association with a variety of primary disorders, including monoclonal B-cell proliferations (in which the amyloid deposits consist of immunoglobulin light chains); chronic inflammatory diseases such as rheumatoid arthritis (deposits of amyloid A protein, derived from an acute-phase protein produced in inflammation); Alzheimer disease (amyloid β protein); familial conditions in which the amyloid deposits consist of mutants of normal proteins (e.g., transthyretin in familial amyloid polyneuropathies); and amyloidosis associated with dialysis (deposits of β_2-microglobulin, whose clearance is defective).
- Amyloid deposits cause tissue injury and impair normal function by causing pressure on cells and tissues. They do not evoke an inflammatory response.

CHAPTER 7

Neoplasia

CHAPTER CONTENTS

Cancer is the second leading cause of death in the United States; only cardiovascular diseases exact a higher toll. Even more agonizing than the mortality rate is the emotional and physical suffering inflicted by cancers. Patients and the public often ask, "When will there be a cure for this scourge?" The answer to this simple question is difficult because cancer is not one disease but many disorders with widely different pathogeneses, natural histories, and responses to treatments. Some cancers, such as Hodgkin lymphoma, are curable, whereas others, such as pancreatic adenocarcinoma, are virtually always fatal. The only hope for controlling cancer lies in learning more about its causes and pathogenesis. Fortunately, great strides have been made in understanding its molecular basis, and some good news has emerged: cancer mortality for both men and women in the United States declined during the last decade of the 20th century and has continued its downward course in the 21st century.

In this chapter, we describe the vocabulary of tumor biology and pathology and then review the morphologic characteristics that define neoplasia and allow benign and malignant tumors to be identified and distinguished. Also reviewed is the epidemiology of cancer, which provides a measure of the impact of cancer on human populations as well as clues to its environmental causes, insights that have led to effective prevention campaigns against certain cancers. Building on this foundation, we then discuss the biologic properties of tumors and the molecular basis of carcinogenesis, emphasizing the critical role that genetic alterations play in the development of neoplasia. Finally, we turn to cancer diagnosis, focusing on new technologies that are helping to direct the use of cancer drugs that are targeted at particular molecular lesions. Throughout, we give examples of new analytic methods and therapies that are not only changing our approach to cancer treatment but also providing new insights into cancer pathophysiology.

NOMENCLATURE

Neoplasia means "new growth," and the collection of cells and stroma composing new growths are referred to as *neoplasms*. *Tumor* originally described swelling caused by inflammation, but is now equated with neoplasm. *Oncology* (Greek *oncos* = tumor) is the study of tumors or neoplasms. Although physicians know what they mean when they use the term *neoplasm,* it has been difficult to develop a precise definition. In the modern era, a neoplasm is defined as a genetic disorder of cell growth that is triggered by acquired or less commonly inherited mutations affecting a single cell and its clonal progeny. As discussed later, these causative mutations alter the function of particular genes and give the neoplastic cells a survival and growth advantage, resulting in excessive proliferation that is independent of physiologic growth signals and controls.

All tumors are composed of two components: (1) neoplastic cells that constitute the tumor parenchyma and (2) reactive stroma made up of connective tissue, blood vessels, and cells of the adaptive and innate immune system. The classification of tumors and their biologic behavior are based primarily on the parenchymal component, but their growth and spread are critically dependent on their stroma. In some tumors, connective tissue is scant, and the neoplasm is soft and fleshy. In others, parenchymal cells stimulate the formation of abundant collagenous stroma, referred to as *desmoplasia.* Some desmoplastic tumors—for example, some cancers of the female breast—are stony hard or *scirrhous.*

Benign Tumors

Benign tumors remain localized at their site of origin and are generally amenable to surgical removal. Predictably, the patient generally survives. Exceptions arise, however, when benign tumors occur in vulnerable locations such as the brain; here, even "benign" tumors may cause significant morbidity and are sometimes even fatal.

Naming of benign tumors of mesenchymal cells is relatively simple; in general, the suffix "-oma" is attached to the name of the cell type from which the tumor arises. Thus a benign tumor of fibroblast-like cells is called a *fibroma,* a benign cartilaginous tumor is a *chondroma,* and so on. The nomenclature of benign epithelial tumors is more complex; some are classified based on their cell of origin, others on their microscopic appearance, and still others on their macroscopic architecture. *Adenoma* is applied to benign epithelial neoplasms derived from glandular tissues even if the tumor cells fail to form glandular structures. Thus, a benign epithelial neoplasm that arises from renal tubular cells and forms tightly clustered glands and a mass of adrenal cortical cells growing as a solid sheet are both referred to as adenomas. Benign epithelial neoplasms producing fingerlike or warty projections from epithelial surfaces are called *papillomas,* whereas those that form large cystic masses, such as in the ovary, are referred to as *cystadenomas.* Some tumors produce papillary projections that protrude into cystic spaces and are called papillary cystadenomas. When a neoplasm—benign or malignant—produces a grossly visible projection above a mucosal surface, for example, into the gastric or colonic lumen, it is termed a *polyp*. If the polyp has glandular tissue, it is called an adenomatous polyp (Fig. 7.1).

Malignant Tumors

Malignant tumors can invade and destroy adjacent structures and spread to distant sites (metastasize). Malignant tumors are collectively referred to as *cancers,* derived from the Latin word for crab, because they tend to adhere to any part that they seize on in an obstinate manner. Not all cancers pursue a deadly course; some are discovered at early stages

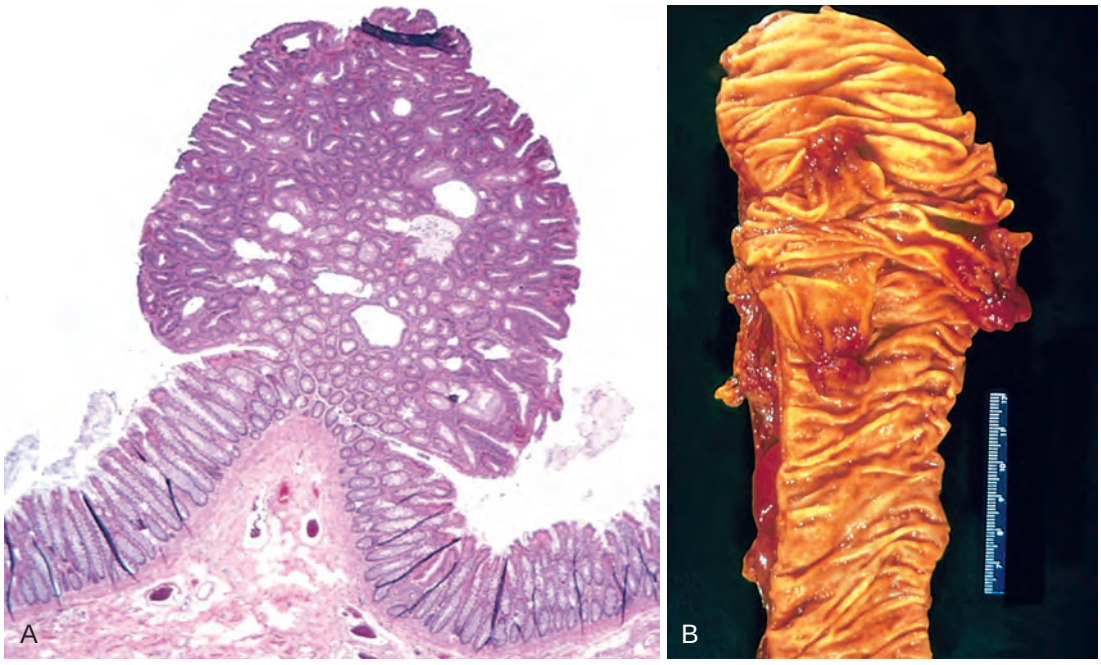

Figure 7.1 Colonic polyp. (A) An adenomatous (glandular) polyp is projecting into the colonic lumen and is attached to the mucosa by a distinct stalk. (B) Gross appearance of several colonic polyps.

that allow for surgical excision, and others are cured with systemically administered drugs or therapeutic antibodies. Nevertheless, the designation "malignant" always raises a red flag.

The nomenclature of malignant tumors follows essentially the same schema used for benign neoplasms, with certain additions. Malignant tumors arising in solid mesenchymal tissues are usually called *sarcomas* (Greek *sar* = fleshy; e.g., fibrosarcoma and chondrosarcoma), whereas those arising from blood-forming cells are designated *leukemias* (literally, white blood) or *lymphomas* (tumors of lymphocytes or their precursors). Malignant neoplasms of epithelial cell origin are called *carcinomas.* Carcinomas may be further qualified. In *squamous cell carcinoma* the tumor cells resemble stratified squamous epithelium, whereas in *adenocarcinoma* the neoplastic epithelial cells grow in a glandular pattern. Sometimes the tissue or organ of origin can be identified and is added as a descriptor, as in renal cell adenocarcinoma or bronchogenic squamous cell carcinoma. In approximately 2% of cases, cancers are composed of cells of unknown origin and must be designated merely as undifferentiated malignant tumors.

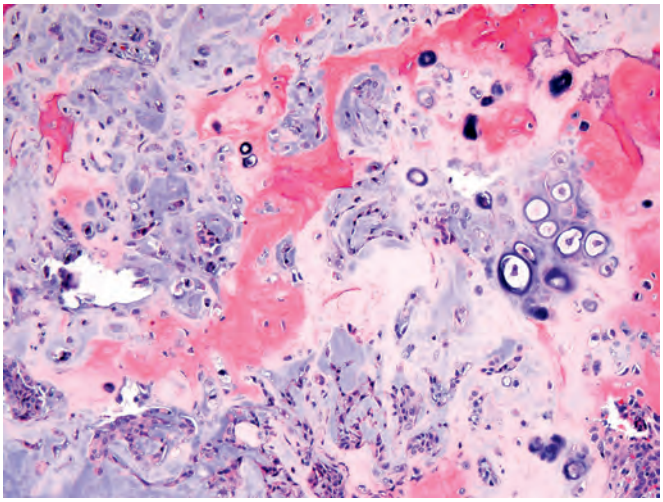

Figure 7.2 Mixed tumor of the parotid gland. Small nests of epithelial cells and myxoid stroma forming cartilage and bone (an unusual feature) are present in this field. (Courtesy Dr. Vicky Jo, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

Mixed Tumors

In most neoplasms, all parenchymal cells closely resemble one another, but in some types of tumors more than one line of differentiation is evident, creating distinct subpopulations of cells. A classic example is the mixed tumor of the salivary gland, which contains epithelial components scattered within a myxoid stroma that may contain islands of cartilage or bone (Fig. 7.2). All of these elements arise from a single neoplastic clone capable of producing both epithelial and mesenchymal cells; thus the preferred designation of this neoplasm is *pleomorphic adenoma.* The great majority of neoplasms, including mixed tumors, are composed of cells from a single germ layer (mesoderm, endoderm, or ectoderm). An exception is a tumor called a *teratoma,* which contains recognizable mature or immature cells or tissues belonging to more than one germ cell layer (and sometimes all three). Teratoma originates from totipotential germ cells that are normally present in the ovary and testis and sometimes also found in abnormal midline embryonic rests. Such cells can differentiate into any cell type found in the body and so, not surprisingly, may give rise to neoplasms that contain, in a helter-skelter fashion, bone, epithelium, muscle, fat, nerve, and other tissues. A particularly common pattern is seen in the *ovarian cystic teratoma (dermoid cyst),* which differentiates principally along ectodermal lines to create a cystic tumor lined by squamous epithelium that is replete with hair, sebaceous glands, and tooth structures (Fig. 7.3).

The nomenclature of the more common types of tumors is presented in Table 7.1. Included in this list are some inappropriate but deeply entrenched names. For instance, the benign-sounding designations lymphoma, melanoma, mesothelioma, and seminoma are used for malignant neoplasms. Alternatively, ominous-sounding terms are applied to some trivial lesions. *Hamartomas* are disorganized masses composed of cells indigenous to the involved tissue. Once thought to be a developmental malformation unworthy

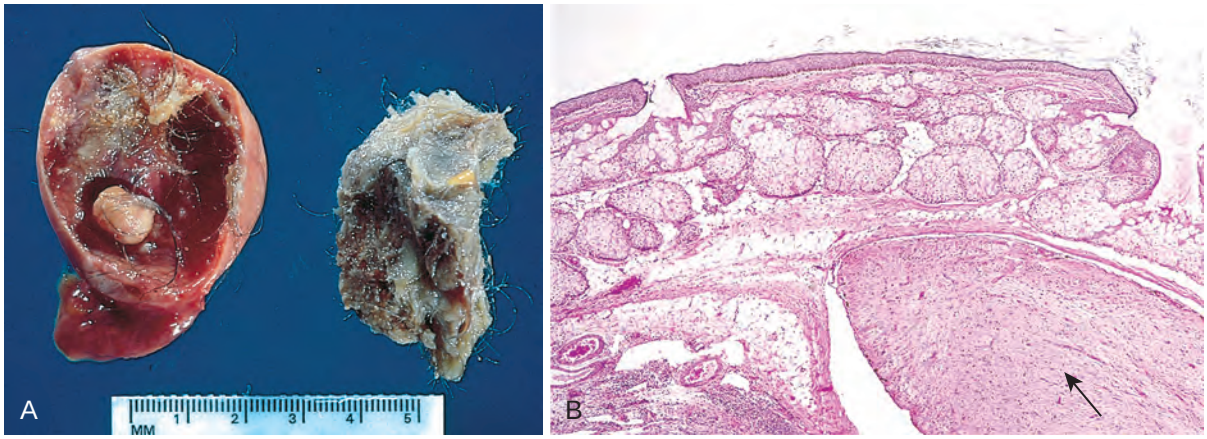

Figure 7.3 (A) Gross appearance of an opened cystic teratoma of the ovary. Note the presence of hair, sebaceous material, and a tooth. (B) Microscopic view of a similar tumor shows skin, sebaceous glands, fat cells, and a tract of neural tissue *(arrow).*

Table 7.1 Nomenclature of Tumors

Tissue of Origin	Benign	Malignant
Composed of One Parenchymal Cell Type		
Tumors of Mesenchymal Origin		
Connective tissue and derivatives	Fibroma Lipoma Chondroma Osteoma	Fibrosarcoma Liposarcoma Chondrosarcoma Osteogenic sarcoma
Vessels and Surface Coverings		
Blood vessels	Hemangioma	Angiosarcoma
Lymph vessels	Lymphangioma	Lymphangiosarcoma
Mesothelium	Benign fibrous tumor	Mesothelioma
Brain coverings	Meningioma	Invasive meningioma
Blood Cells and Related Cell Types		
Hematopoietic cells		Leukemias
Lymphoid tissue		Lymphomas
Muscle		
Smooth	Leiomyoma	Leiomyosarcoma
Striated	Rhabdomyoma	Rhabdomyosarcoma
Tumors of Epithelial Origin		
Stratified squamous	Squamous cell papilloma	Squamous cell carcinoma
Basal cells of skin or adnexa		Basal cell carcinoma
Melanocytes	Nevus	Malignant melanoma
Epithelial lining of glands or ducts	Adenoma Papilloma Cystadenoma	Adenocarcinoma Papillary carcinomas Cystadenocarcinoma
Respiratory passages	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cells	Hepatic adenoma	Hepatocellular carcinoma
Urinary tract epithelium (transitional epithelium)	Transitional cell papilloma	Transitional cell carcinoma
Placenta epithelium	Hydatidiform mole	Choriocarcinoma
Testicular epithelium (germ cells)		Seminoma Embryonal carcinoma
More Than One Neoplastic Cell Type—Mixed Tumors, Usually Derived From One Germ Cell Layer		
Salivary glands	Pleomorphic adenoma (mixed tumor of salivary origin)	Malignant mixed tumor of salivary gland origin
Renal anlage		Wilms tumor
More Than One Neoplastic Cell Type Derived From More Than One Germ Cell Layer—Teratogenous		
Totipotential cells in gonads or in embryonic rests	Mature teratoma, dermoid cyst	Immature teratoma, teratocarcinoma

of the "-oma" designation, most hamartomas have clonal chromosomal aberrations that are acquired through somatic mutation and on this basis are now considered benign neoplasms. *Choristoma* is the term applied to a heterotopic (misplaced) rest of cells. For example, a small nodule of well-developed, normally organized pancreatic tissue may be found in the submucosa of the stomach or small intestine. The term *choristoma,* suggesting a neoplasm, imparts a gravity to these lesions that far exceeds their actual significance.

CHARACTERISTICS OF BENIGN AND MALIGNANT NEOPLASMS

The differentiation between benign and malignant tumors is one of the most important distinctions a pathologist can make, as nothing is more important to an individual with a tumor than being told, "It is benign." Although an innocent face may mask an ugly nature, benign and malignant tumors usually can be distinguished on the basis of various histologic and anatomic features (described later). Malignant tumors also tend to grow more rapidly than benign tumors, but there are so many exceptions that growth rate is not a reliable discriminator between benignity and malignancy. In fact, even cancers exhibit remarkably varied growth rates, from slow-growing tumors associated with survival for many years, often without treatment, to rapidly growing tumors that may be lethal within months or weeks.

Differentiation and Anaplasia

Differentiation refers to the extent to which neoplastic parenchymal cells resemble the corresponding normal parenchymal cells, both morphologically and functionally; lack of differentiation is called *anaplasia*. In general, benign tumors are well differentiated (Figs. 7.4 and 7.5). The neoplastic cells of a lipoma, a proliferation of benign adipocytes, may so closely resemble normal adipocytes as to be unrecognizable as a tumor by microscopic examination. Only the growth of these cells into a discrete mass discloses

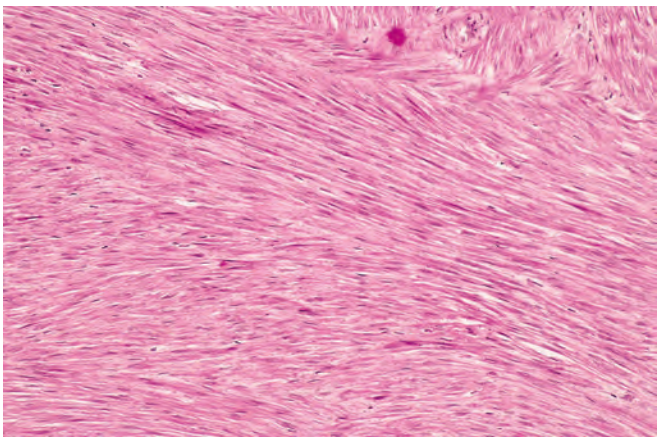

Figure 7.4 Leiomyoma of the uterus. This benign, well-differentiated tumor contains interlacing bundles of neoplastic smooth muscle cells that are virtually identical in appearance to normal smooth muscle cells in the myometrium.

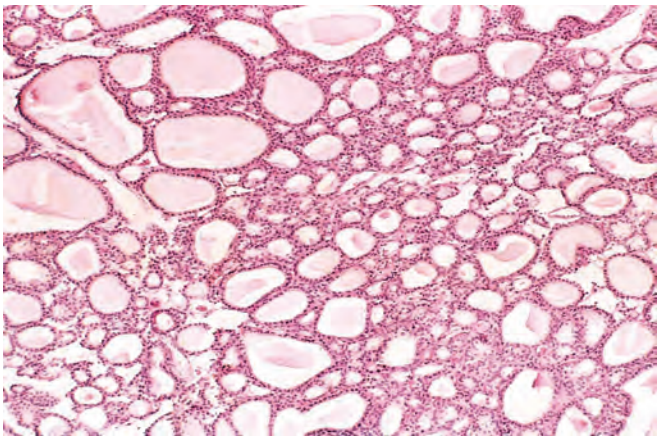

Figure 7.5 Benign tumor (adenoma) of the thyroid. Note the normal-looking (well-differentiated), colloid-filled thyroid follicles. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.)

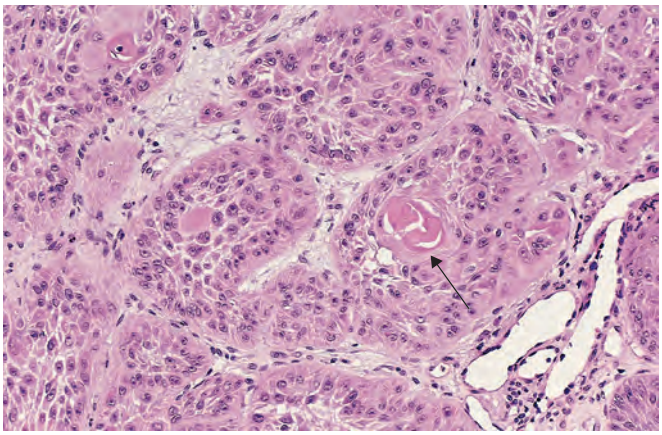

Figure 7.6 Well-differentiated squamous cell carcinoma of the skin. The tumor cells are strikingly similar to normal squamous epithelial cells, with intercellular bridges and nests of keratin pearls *(arrow)*. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.)

their neoplastic nature. One may get so close to the tree that one loses sight of the forest. In well-differentiated benign tumors, mitoses are usually rare and are of normal configuration.

By contrast, **most malignant neoplasms exhibit morphologic alterations that betray their potential for aggressive behavior**. In well-differentiated tumors, these features may be quite subtle. Well-differentiated adenocarcinomas of the thyroid, for example, form normal-appearing follicles, and some squamous cell carcinomas contain cells that appear identical to normal squamous epithelial cells (Fig. 7.6). The malignant nature of such tumors is revealed by invasion of adjacent tissues and their ability to metastasize. At the other end of the spectrum lie highly anaplastic, poorly differentiated tumors exhibiting little or no evidence of differentiation (Fig. 7.7), a morphologic appearance that is highly predictive of malignant behavior. In between these two extremes lie tumors that are loosely referred to as moderately well differentiated (Fig. 7.8).

In addition to anaplasia, cancer cells often exhibit other telltale morphologic changes:

- *Pleomorphism.* Pleomorphism refers to variation in cell size and shape. Thus, cells within the same tumor are not uniform, but range from small cells with an undifferentiated appearance to *tumor giant cells* many times larger than their neighbors. Some tumor giant cells possess only a single huge polymorphic nucleus, while others may have two or more large, hyperchromatic nuclei (Fig. 7.9). These giant cells are not to be confused with inflammatory Langhans or foreign body giant cells, which are derived from macrophages and contain many small, normal-appearing nuclei.
- *Abnormal nuclear morphology.* Characteristically, cancer cells have nuclei that are disproportionately large, with a nuclear-to-cytoplasm ratio that may approach 1:1 instead of the normal 1:4 to 1:6. The nuclear shape is variable and often irregular, and the chromatin is often coarsely clumped and distributed along the nuclear

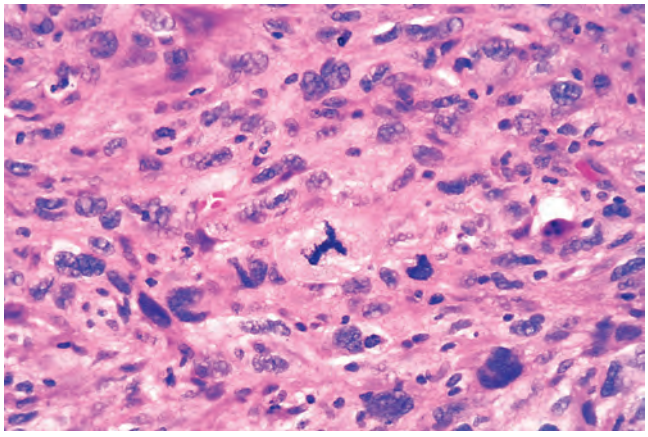

Figure 7.7 Anaplastic tumor showing cellular and nuclear variation in size and shape. The prominent cell in the center field has an abnormal tripolar spindle.

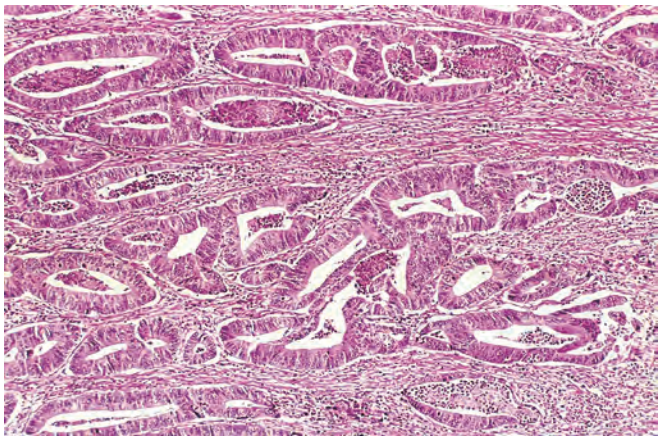

Figure 7.8 Malignant tumor (adenocarcinoma) of the colon. Note that compared with the well-formed and normal-looking glands characteristic of a benign tumor, the cancerous glands are irregular in shape and size and do not resemble the normal colonic glands. This tumor is considered moderately well differentiated because gland formation is seen. The malignant glands have invaded the muscular layer of the colon. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.)

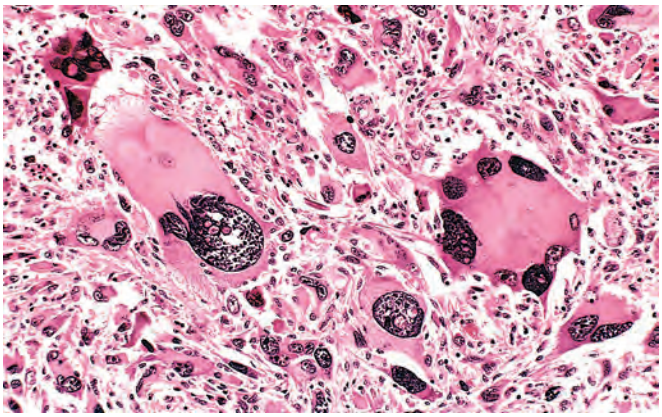

Figure 7.9 Pleomorphic tumor of the skeletal muscle (rhabdomyosarcoma). Note the marked cellular and nuclear pleomorphism, hyperchromatic nuclei, and tumor giant cells. (Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.)

membrane or more darkly stained than normal *(hyperchromatic)*. Abnormally large nucleoli are also commonly seen.

- *Mitoses.* Unlike benign tumors and some well-differentiated malignant neoplasms, undifferentiated cancers often contain many cells in mitosis, reflecting their high rate of proliferation. The presence of mitoses, however, does not equate with malignancy. For example, cells in mitosis are often seen in normal tissues exhibiting rapid turnover, such as the epithelial lining of the gut and nonneoplastic proliferations such as hyperplasias. More important as a morphologic feature of malignancy are *atypical, bizarre mitotic figures* (see Fig. 7.8).
- *Loss of polarity.* In addition to cytologic abnormalities, the orientation of anaplastic cells with respect to each other or to supporting structures like basement membranes is markedly disturbed. Sheets or large masses of tumor cells grow in a disorganized fashion.
- *Other changes.* While growing tumor cells must have a blood supply, the vascular stroma is often insufficient; as a result, many rapidly growing cancers develop areas of ischemic necrosis.

As one might surmise, well-differentiated transformed cells have a greater likelihood of retaining the functional capabilities of their normal counterparts. Benign tumors are almost always well differentiated and often retain normal functions, as do many well-differentiated cancers. Thus, well-differentiated tumors of endocrine glands frequently secrete hormones characteristic of their origin into the blood, where they can be detected and quantified to diagnose and follow the response of such tumors to treatment. Similarly, well-differentiated squamous cell carcinomas synthesize keratin, and well-differentiated hepatocellular carcinomas elaborate bile. By contrast, highly anaplastic undifferentiated tumors typically lose the specialized functional activities of their tissue of origin, but sometimes acquire new and unanticipated functions. Thus some malignant tumors express fetal proteins that are not produced by their normal adult counterparts, while others express proteins that are normally found only in other types of cells. For example, bronchogenic carcinomas may produce corticotropin, parathyroid-like hormone, insulin, glucagon, and other hormones, giving rise to paraneoplastic syndromes (described later).

Metaplasia, Dysplasia, and Carcinoma In Situ

These terms describe morphologically recognizable changes in differentiation that variously represent an adaptation to chronic injury (metaplasia), a premalignant change (dysplasia), or a cancer that has yet to invade (carcinoma in situ).

- *Metaplasia* is defined as the replacement of one type of cell with another type (Chapter 2). Metaplasia is nearly always found in association with tissue damage, repair, and regeneration. Often the replacing cell type is better suited to some alteration in the local environment. For example, in Barrett esophagus, gastroesophageal reflux damages the squamous epithelium of the esophagus, leading to its replacement by glandular (gastric or intestinal) epithelium better suited to an acidic environment. Unfortunately, the metaplastic epithelium is prone to malignant transformation. The same is true of squamous metaplasia of the bronchial epithelium in chronic smokers, often a prelude to the development of lung cancer.
- *Dysplasia* is a term that literally means "disordered growth." It is encountered principally in epithelial cells and is recognized on the basis of several morphologic changes. Dysplastic cells may exhibit considerable pleomorphism and often contain large hyperchromatic nuclei with a high nuclear-to-cytoplasmic ratio. Dysplastic epithelial surfaces also typically show architectural disarray and a loss of orderly differentiation. For example, in dysplastic squamous epithelium the normal progressive maturation of tall cells in the basal layer to flattened squames on the surface may fail in part or entirely, leading to replacement of the epithelium by basal-like cells with hyperchromatic nuclei. In addition, mitotic figures are more abundant than in the normal squamous epithelium and may be seen throughout dysplastic epithelium, rather than being confined to the basal layer, as is the normal case.
- *Carcinoma in situ.* When dysplasia is severe and involves the full thickness of the epithelium but the lesion does not penetrate the basement membrane, it is referred to as *carcinoma in situ* (Fig. 7.10). Carcinoma in situ is often seen in the skin, breast, bladder, and uterine cervix. In situ epithelial cancers display all of the cytologic features of malignancy and unless treated have high probability of progression to invasive cancers.

Dysplastic changes are often found adjacent to foci of invasive carcinoma, and in some situations, such as in the cervix, severe epithelial dysplasia or carcinoma in situ frequently antedates the appearance of cancer. Moreover, some mutations associated with full-blown cancer (described later) may be present in even "mild" dysplasias. Nevertheless, **although dysplasia may be a precursor to malignant transformation, it does not always progress to cancer.** With removal of inciting causes, even moderately severe dysplasias may be completely reversible. Even carcinoma in situ may persist for years before it becomes invasive. As discussed later, cancers arise by accumulation of mutations, and the time interval for evolution of full-blown cancers from in situ lesions relates most likely to the time required for

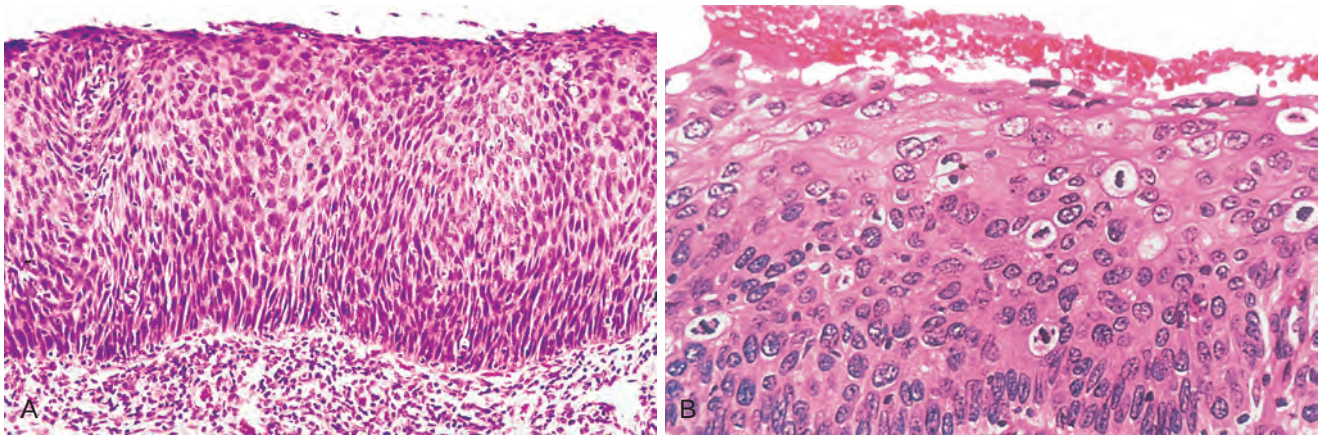

Figure 7.10 (A) Carcinoma in situ. Low-power view shows that the epithelium is entirely replaced by atypical dysplastic cells. There is no orderly differentiation of squamous cells. The basement membrane is intact, and there is no tumor in the subepithelial stroma. (B) High-power view of another region shows failure of normal differentiation, marked nuclear and cellular pleomorphism, and numerous mitotic figures extending toward the surface.

accumulation of all the mutations that are needed to induce a fully malignant phenotype. Finally, it should be noted that while dysplasia often occurs in metaplastic epithelium, not all metaplastic epithelium is dysplastic.

Local Invasion

The growth of cancers is accompanied by progressive invasion, destruction of surrounding tissue, and eventually systemic spread, whereas nearly all benign tumors grow as cohesive, expansile masses that remain localized to their site of origin and lack the capacity to invade or metastasize to distant sites. Because benign tumors grow and expand slowly, they usually develop a rim of compressed fibrous tissue called a capsule that separates them from the surrounding normal tissue. The tumor capsule consists of extracellular matrix (ECM) deposited by stromal cells such as fibroblasts, which are activated by hypoxic damage resulting from the pressure of the expanding tumor. Such encapsulation creates a tissue plane that makes the tumor discrete, readily palpable, movable (nonfixed), and easily excisable by surgical enucleation (Fig. 7.11). There are a few exceptions to this rule, however. For example, hemangiomas (benign neoplasms composed of tangled blood vessels) are often unencapsulated and permeate the site in which they arise (e.g., the dermis of the skin and the liver); when such lesions are extensive, they may be unresectable.

In contrast, malignant tumors are, in general, poorly demarcated from the surrounding normal tissue and lack well-defined cleavage planes (Fig. 7.12). Slowly expanding malignant tumors may develop an apparently enclosing fibrous capsule and push along a broad front into adjacent normal structures. However, histologic examination of such "pseudoencapsulated" masses almost always shows rows of tumor cells penetrating the margin and infiltrating adjacent structures, a crablike pattern of growth that fits the popular image of cancer.

Next to the development of metastases, invasiveness is the most reliable discriminator of malignant and benign tumors. Most malignant tumors do not recognize normal anatomic boundaries. Given time, they will penetrate the wall of the colon or uterus, for example, or fungate through the surface of the skin. This invasiveness makes their complete surgical resection difficult or impossible, and even if the tumor appears well circumscribed it is necessary to remove a large margin of adjacent, apparently normal tissue to ensure complete local excision.

Metastasis

Metastasis is defined as the spread of a tumor to sites that are physically discontinuous with the primary tumor, an

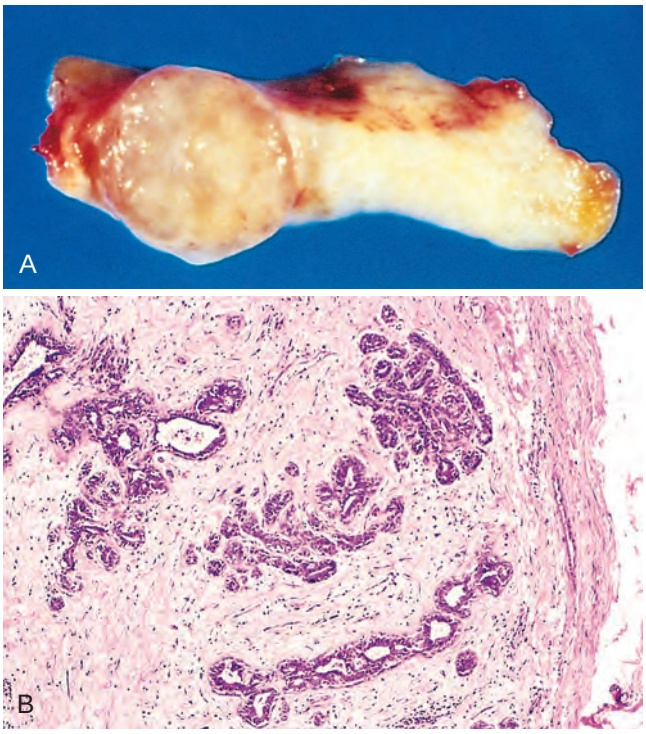

Figure 7.11 Fibroadenoma of the breast. (A) The tan-colored, encapsulated small tumor is sharply demarcated from the whiter breast tissue. (B) Microscopic view shows that the fibrous capsule *(right)* delimits the tumor from the surrounding tissue. (B, Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.)

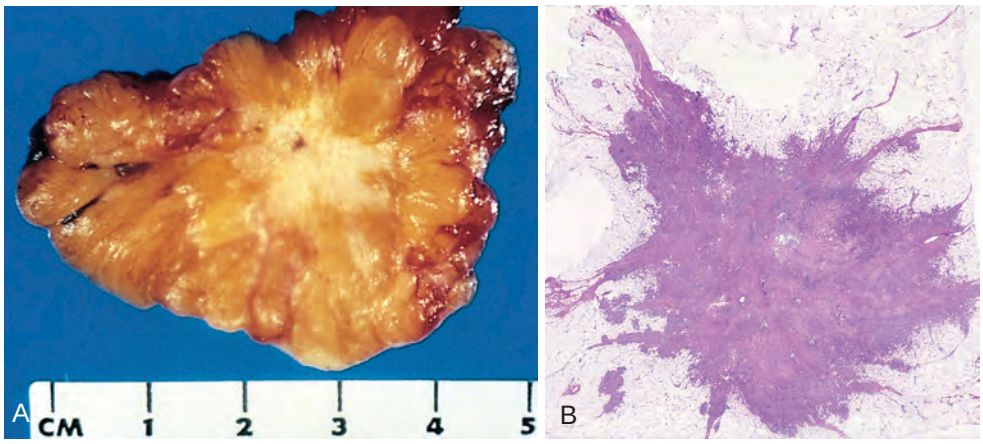

Figure 7.12 Invasive ductal carcinoma of the breast. (A) On cut section, the lesion is retracted and infiltrates the surrounding breast substance and would be stony hard on palpation. (B) Low-power microscopic view shows irregular infiltrative borders without a well-defined capsule and intense stromal reaction. (A, Courtesy Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, Tex.; B, Courtesy Dr. Susan Lester, Brigham and Women's Hospital, Boston, Mass.)

event that unequivocally marks a tumor as malignant. The invasiveness of cancers permits them to penetrate blood vessels, lymphatics, and body cavities, providing the opportunity for spread. All malignant tumors can metastasize, but some do so very infrequently. Examples include malignant neoplasms of the glial cells in the central nervous system, called *gliomas,* and basal cell carcinomas of the skin, both of which invade early in their course but rarely metastasize. It is evident then that the properties of invasiveness and metastasis are separable. Blood cancers (leukemias and lymphomas) are a special case. These tumors are derived from cells that normally have the capacity to enter the bloodstream and travel to distant sites. As a result, leukemias and lymphomas (sometimes referred to as "liquid tumors") are often disseminated at diagnosis and are always taken to be malignant, unlike all other tumors (so-called "solid" tumors), which are derived from cells that do not normally circulate in the bloodstream.

Overall, approximately 30% of solid tumors (excluding skin cancers other than melanomas) present as metastatic disease. In general, the likelihood of metastasis of a solid tumor correlates with other features of malignancy, including lack of differentiation, aggressive local invasion, rapid growth, and large size. There are innumerable exceptions, however. Small, well-differentiated, slow-growing lesions sometimes metastasize widely; conversely, some rapidly growing, large lesions remain localized for years. Metastasis is thus a complex and unpredictable process that involves many factors relating to both invader and host (discussed later). Metastatic spread strongly reduces the possibility of cure; hence, short of prevention of cancer, no achievement would be of greater benefit to patients than an effective means to block metastasis, with the important caveat that many tumors that kill the patient have already spread by the time of initial diagnosis.

Pathways of Spread

Dissemination of cancers occurs through three pathways: (1) direct seeding of body cavities or surfaces, (2) lymphatic spread, and (3) hematogenous spread. Although iatrogenic spread of tumor cells on surgical instruments may occur—it is the reason, for example, why biopsies of testicular masses are never done—it is rare and not discussed further.

Seeding of Body Cavities and Surfaces. Seeding of body cavities and surfaces occurs when a malignant neoplasm penetrates into a natural "open field" lacking physical barriers. Most often involved is the peritoneal cavity (Fig. 7.13), but any body cavity—pleural, pericardial, subarachnoid, and joint spaces—may be affected. Such seeding is particularly characteristic of carcinomas arising in the ovaries, which often spread to peritoneal surfaces, producing a heavy cancerous coating. Remarkably, the tumor cells may remain confined to the surface of the abdominal viscera without penetrating into the substance. Sometimes, mucus-secreting

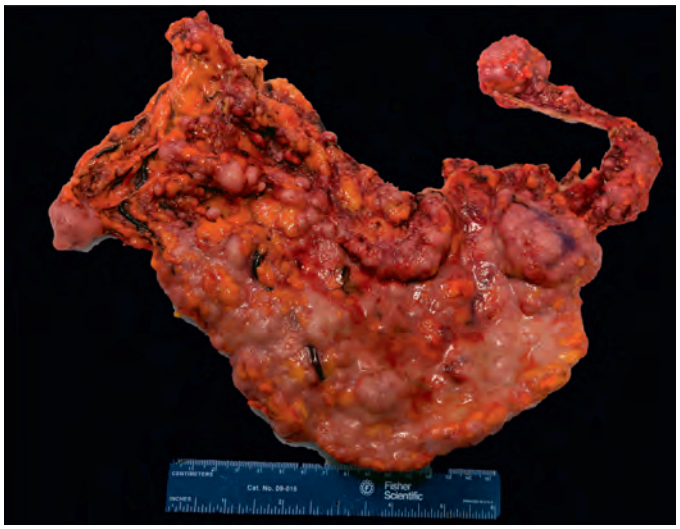

Figure 7.13 Involvement of omentum by metastatic ovarian carcinoma. Innumerable nodules and more subtle "glazing" are evident due to seeding by carcinoma cells via the peritoneal cavity. (Courtesy Dr. Sarah Hill, Brigham and Women's Hospital, Boston, Mass.)

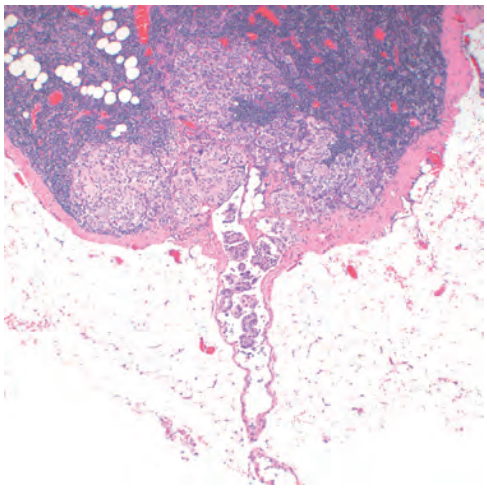

Figure 7.14 Axillary lymph node with metastatic breast carcinoma. Note the aggregates of tumor cells within the substance of the node and the dilated lymphatic channel. (Courtesy Dr. Susan Lester, Brigham and Women's Hospital, Boston, Mass.)

appendiceal carcinomas or ovarian carcinomas fill the peritoneal cavity with a gelatinous neoplastic mass referred to as *pseudomyxoma peritonei*.

Lymphatic Spread. **Transport through lymphatic vessels is the most common pathway for the initial dissemination of carcinomas** (Fig. 7.14). Sarcomas also sometimes use this route. Tumors do not contain functional lymphatic vessels, but lymphatic vessels located at the margins of invading cancers are apparently sufficient for the lymphatic spread of tumor cells. The pattern of spread follows the natural routes of lymphatic drainage. For example, because carcinomas of the breast usually arise in the upper outer quadrants, they generally disseminate first to the axillary lymph nodes and then to infraclavicular and supraclavicular lymph nodes. Carcinomas of the lung arising in the major respiratory passages metastasize first to perihilar tracheobronchial and mediastinal lymph nodes. Local lymph nodes, however, may be bypassed—so-called skip metastasis—possibly because microscopic metastases are missed or because of variation in normal patterns of lymphatic drainage.

In breast cancer, axillary lymph node examination is used to determine the prognosis and select the most suitable therapeutic options. To avoid the surgical morbidity associated with a full axillary lymph node dissection, biopsy of sentinel nodes is often used to assess the presence or absence of metastatic lesions. **A sentinel lymph node is defined as "the first node in a regional lymphatic basin that receives lymph flow from the primary tumor."** Sentinel node mapping can be done by injection of radiolabeled tracers or colored dyes, and examination of frozen sections of the sentinel lymph node performed during surgery can guide the surgeon to the appropriate therapy. Sentinel node examination has also been used to assess the spread of melanomas, colon cancers, and other tumors.

In many cases the regional nodes serve as effective barriers against further dissemination of the tumor, at least for a while. Conceivably, after arrest within the node the cells may be destroyed by a tumor-specific immune response. The immune response to tumor cells or antigens in draining lymph nodes may lead to enlargement (hyperplasia) of the nodes. Thus, enlarged lymph nodes do not always harbor metastases, which can be assessed definitively only by microscopic examination.

Hematogenous Spread. **Hematogenous spread is typical of sarcomas but is also seen with carcinomas**. In general, histologic evidence of penetration of small vessels at the site of the primary neoplasm is an ominous feature associated with hematogenous metastasis. The involved vessels are usually small veins, as arteries, with their thicker walls, are more resistant to penetration. Arterial spread may occur, however, when tumor cells pass through pulmonary capillary beds or pulmonary arteriovenous shunts or when cancers in the lung (primary or metastatic) give rise to tumor emboli.

Several factors influence the patterns of vascular metastasis. With venous invasion, the blood-borne tumor cells often come to rest in the first capillary bed they encounter. Understandably, the liver and the lungs (Fig. 7.15) are most frequently involved by hematogenous dissemination because all portal area drainage flows to the liver and all caval blood

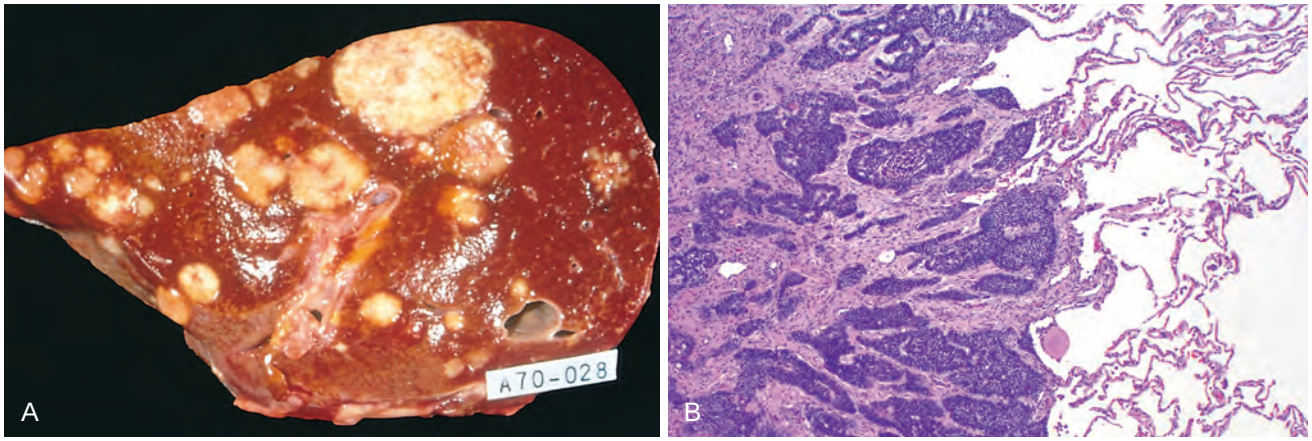

Figure 7.15 Cancer metastasis. (A) Liver studded with metastatic cancer. (B) Microscopic view of lung metastasis. A colonic adenocarcinoma has formed a metastatic nodule in the lung. (B, Courtesy Dr. Shuji Ogino, Dana Farber Cancer Institute, Boston, Mass.)

Table 7.2 Comparisons Between Benign and Malignant Tumors

Characteristics	Benign	Malignant
Differentiation/ anaplasia	Well differentiated; structure sometimes typical of tissue of origin	Some lack of differentiation (anaplasia); structure often atypical
Rate of growth	Usually progressive and slow; may come to a standstill or regress; mitotic figures rare and normal	Erratic, may be slow to rapid; mitotic figures may be numerous and abnormal
Local invasion	Usually cohesive, expansile, well-demarcated masses that do not invade or infiltrate surrounding normal tissues	Locally invasive, infiltrating surrounding tissue; sometimes may be misleadingly cohesive and expansile
Metastasis	Absent	Frequent; more likely with large undifferentiated primary tumors

flows to the lungs. Cancers arising in close proximity to the vertebral column often embolize through the paravertebral plexus; this pathway produces frequent vertebral metastases from carcinomas of the thyroid and prostate. Nonetheless, many observations suggest that the location of the primary tumor and its natural pathways of venous drainage do not wholly explain the observed patterns of metastatic spread, which are often cancer-specific. Unfortunately, most cancers have not read pathology textbooks! The basis of tissue-specific patterns of metastasis is discussed later.

Certain cancers have a curious propensity for growth within large veins. Renal cell carcinoma often invades the branches of the renal vein and then the renal vein itself, growing in a snakelike fashion up the inferior vena cava until it sometimes reaches the right side of the heart. Similarly, hepatocellular carcinomas often penetrate portal and hepatic radicles and then grow into the main venous channels. Remarkably, such intravenous growth may not be accompanied by widespread metastasis.

The distinguishing features of benign and malignant tumors are summarized in Table 7.2 and Fig. 7.16. Having completed our overview of the morphology and behavior of neoplasms, we now discuss the pathogenesis of neoplasia, starting with clues gleaned from studies of the epidemiology of cancer.

KEY CONCEPTS

CHARACTERISTICS OF BENIGN AND MALIGNANT NEOPLASMS

- Benign and malignant tumors can be distinguished from one another based on the degree of differentiation, local invasiveness, and distant spread.
- Benign tumors resemble the tissue of origin and are well differentiated; malignant tumors are less well differentiated or completely undifferentiated (anaplastic).

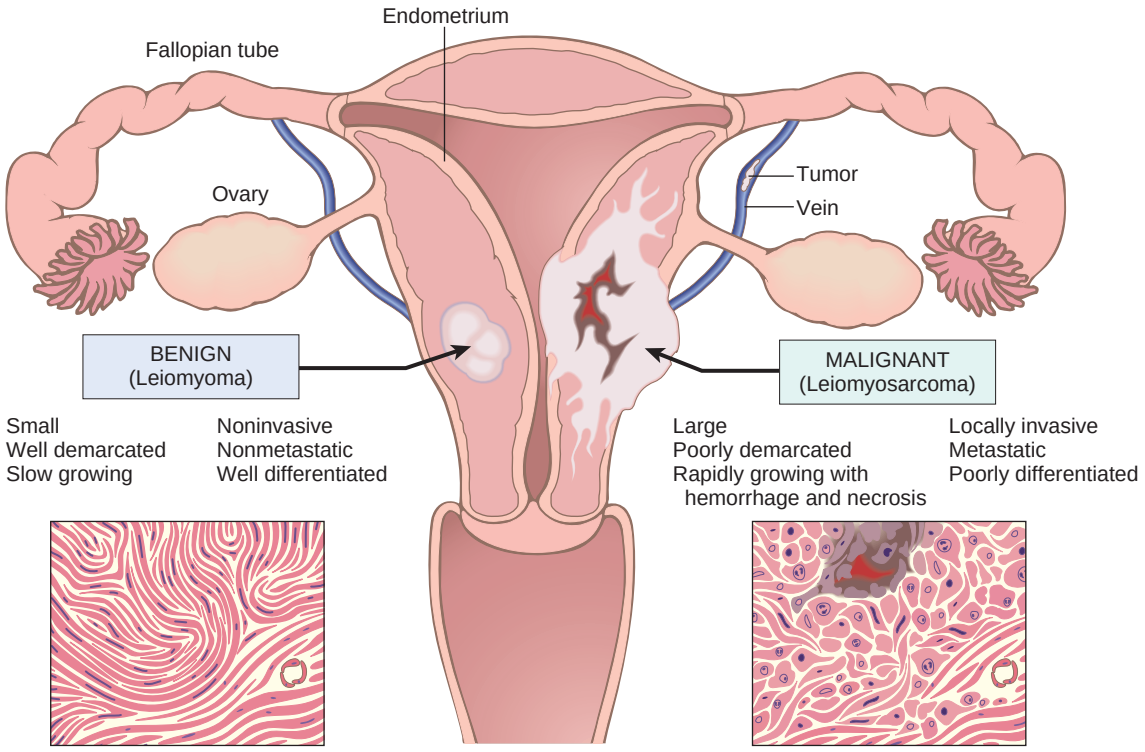

Figure 7.16 Comparison between a benign tumor of the myometrium (leiomyoma) and a malignant tumor of the same origin (leiomyosarcoma).

- Benign tumors are more likely to retain functions of their cells of origin, whereas malignant tumors sometimes acquire unexpected functions due to derangements in differentiation.
- Benign tumors are slow growing, while malignant tumors generally grow faster.
- Benign tumors are circumscribed and have a capsule; malignant tumors are poorly circumscribed and invade surrounding normal tissues.
- Benign tumors remain localized at the site of origin; malignant tumors metastasize to distant sites. Carcinomas tend to spread via lymphatics, whereas sarcomas prefer the hematogenous route.

EPIDEMIOLOGY OF CANCER

Study of cancer in defined populations has contributed substantially to knowledge about its origins. Epidemiologic studies have established the causative link between smoking and lung cancer, and comparison of diet and cancer rates in different regions of the world has linked diets high in fat and low in fiber to colon cancer. It is hoped that additional insights into the causes of cancer will be obtained by studies that relate particular environmental, racial (possibly hereditary), and cultural influences to specific neoplasms. The strong association of certain inflammatory and other diseases with cancer also provides clues to its pathogenesis. In the following sections, we discuss the overall incidence of cancer and then review environmental and host factors that influence the predisposition to cancer.

The Global Impact of Cancer

In 2018 it was estimated that there were over 9.5 million deaths caused by cancer worldwide, representing nearly 1 in 6 of all deaths. Moreover, due to increasing population size and age, cancer cases and cancer-related deaths worldwide are projected to increase to 21.4 million and 13.2 million, respectively by the year 2030. The major organ sites affected and the estimated frequency of cancer deaths in the United States are shown in Fig. 7.17. The most common tumors in men arise in the prostate, lung, and colon/rectum. In women, cancers of the breast, lung, and colon/rectum are the most frequent. Cancers of the lung, female breast, prostate, and colon/rectum constitute more than 50% of cancer diagnoses and cancer deaths in the United States.

Most longitudinal data pertaining to cancer incidence come from higher income countries, where age-adjusted death rates (deaths per 100,000 population) for many cancers have changed significantly over the years. In the last 50 years of the 20th century, the age-adjusted cancer death rate increased significantly in both men and women. However, since 1995 the cancer incidence rate in men has been stable, and since 1990 the cancer death rate has decreased by approximately 20%. Similarly, the cancer incidence rate also stabilized in women in 1995, and the cancer death rate has fallen by approximately 10% since 1991. Among men, nearly 80% of the decrease is accounted for by lower death rates from lung, prostate, and colorectal cancers; among women, nearly 60% of the decrease is due to reductions in death rates from breast and colorectal cancers. Decreased use of tobacco products is responsible for the reduction in lung cancer deaths, while improved detection and treatment are responsible for the decrease in death rates for colorectal, female breast, and prostate cancer.

The last half-century has also seen a sharp decline in deaths caused by cervical cancer in the United States. This decrease is largely attributable to the Papanicolaou (Pap) smear test, which enables detection of "precursor lesions" (discussed later) and early, curable cancers. By contrast,

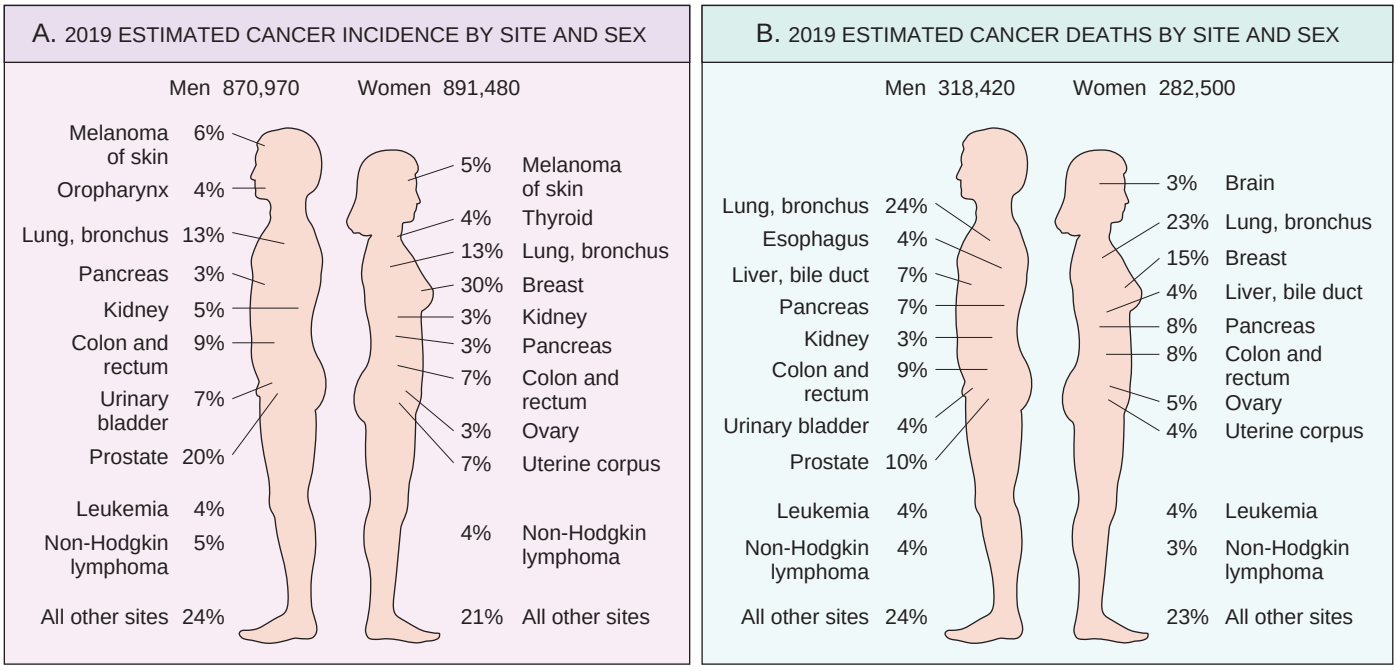

Figure 7.17 Cancer incidence (A) and mortality (B) by site and sex. Excludes basal cell and squamous cell skin cancers and in situ carcinomas except urinary bladder. (Modified from Siegel RL, Miller KD, Jemal A: Cancer statistics, 2017, *CA Cancer J Clin* 67:7–30, 2017.)

between 1990–1991 and 2004, lung cancer death rates in women and liver and intrahepatic bile duct cancer death rates in men increased substantially, offsetting some of the improvement in survival from other cancers. Indeed, although carcinomas of the breast occur about 2.5 times more frequently than those of the lung in women, lung cancer now causes more deaths in women.

Race is not a discrete biologic variable, but it can define groups at risk for certain cancers. The disparity in cancer mortality rates between Americans who are Caucasian or of African descent persists, but African Americans had the largest decline in cancer mortality during the past decade. People identifying as Hispanic living in the United States have a lower frequency of the most common cancers affecting the Caucasian non-Hispanic population and a higher incidence of cancers of the stomach, liver, uterine cervix, and gallbladder as well as certain leukemias.

Environmental Factors

Although both genetic and environmental factors contribute, environmental influences are the dominant risk factors for most cancers. One line of evidence supporting this idea comes from longitudinal changes in cancer incidence in the United States. Examples include the tight tracking of lung cancer incidence with changes in smoking habits over time; the sharp drop in stomach cancer incidence during the 20th century, believed to stem from decreased exposure to unknown environmental carcinogens; and a recent increase in the incidence of liver cancer, which is likely due to rising rates of chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infection and obesity. Other evidence is found in the wide geographic variation that exists in the incidence of specific cancers (Fig. 7.18). For example, the most common cancer of men in the United States and in most other higher income countries is prostate cancer, but in other countries or regions, cancers of the liver, stomach, esophagus, bladder, lung, oropharynx, and the immune system rise to the top of the list. Similarly, the incidence of breast cancer is generally much higher in women living in higher income countries than in lower income countries. Although racial predisposition may factor in, it is believed that environmental influences—some known, some not—underlie most of these differences in cancer incidence.

Among the best-established environmental factors affecting cancer risk are the following.

- *Infectious agents.* About 15% of all cancers worldwide are caused directly or indirectly by infectious agents, with the burden of cancers linked to infections being roughly three times higher in the developing world than in the developed world. For example, *human papillomavirus (HPV),* an agent spread through sexual contact, has a causative role in the majority of cervical carcinomas and an increasing fraction of head and neck cancers. Specific infectious agents and their associated cancers are discussed later in this chapter.
- *Smoking.* Cigarette smoking is the single most important environmental factor contributing to premature death in the United States. Smoking, particularly of cigarettes, is implicated in cancer of the mouth, pharynx, larynx, esophagus, pancreas, and bladder and, most significantly, in about 90% of lung cancers (Chapter 9).
- *Alcohol consumption.* Alcohol abuse increases the risk of carcinoma of the oropharynx (excluding lip), larynx, and esophagus and, by the development of alcoholic cirrhosis, hepatocellular carcinoma. Moreover, the risk of cancers in the upper airways and digestive tract imposed by alcohol is increased synergistically when combined with tobacco use.
- *Diet.* Although the precise dietary factors that affect cancer risk remain a matter of debate, wide geographic variation in the incidences of colorectal carcinoma, prostate carcinoma, and breast carcinoma has been ascribed to differences in diet.
- *Obesity.* Given that the obesity epidemic in the United States is spreading to other parts of the world (Chapter 9), it is concerning that obesity is associated with increased cancer risk. The most overweight individuals in the U.S. population have 52% (men) to 62% (women) higher death rates from cancer than do their slimmer counterparts; it follows that approximately 14% of cancer deaths in men and 20% in women are associated with obesity.
- *Reproductive history.* Lifelong cumulative exposure to estrogen stimulation, particularly if unopposed by progesterone, increases the risk of cancers of the breast and endometrium, tissues that are responsive to these hormones. It is likely that some of the geographic variation in breast cancer incidence is related to differing cultural mores that influence the timing and number of pregnancies a woman has during her lifetime.
- *Environmental carcinogens.* There is no paucity of well-characterized environmental carcinogens: they lurk in the ambient environment, in the workplace (Table 7.3), in food, and in personal practices. Individuals may be exposed to carcinogenic factors when they go outside (e.g., ultraviolet [UV] rays, smog), drink well water (e.g., arsenic, particularly in Bangladesh), take certain medications (e.g., methotrexate), go to work (e.g., asbestos), or lounge at home (e.g., grilled meat, high-fat diet, alcohol).

It appears that almost everything one does to earn a livelihood or for pleasure is fattening, immoral, illegal, or, even worse, carcinogenic!

Age

Age has an important influence on the risk of cancer. Most carcinomas occur in adults older than 55 years of age. Cancer is the leading cause of death among women aged 40 to 79 and among men aged 60 to 79; the decline in cancer deaths after age 80 is due to the lower number of individuals who reach this age. The rising incidence of cancer with age is likely explained by the accumulation of somatic mutations that accompanies the aging of cells (discussed later). A decline in immune competence in older individuals may also be a factor.

Tragically, children are not spared; cancer accounts for approximately 10% of all deaths in children younger than age 15 in the United States, second only to accidents. However, the types of cancers that predominate in children are different from those seen in adults; in part, this is because pediatric cancers are more likely to be caused by inherited mutations (particularly in tumor suppressor genes, described later) and much less likely to stem from exposure to

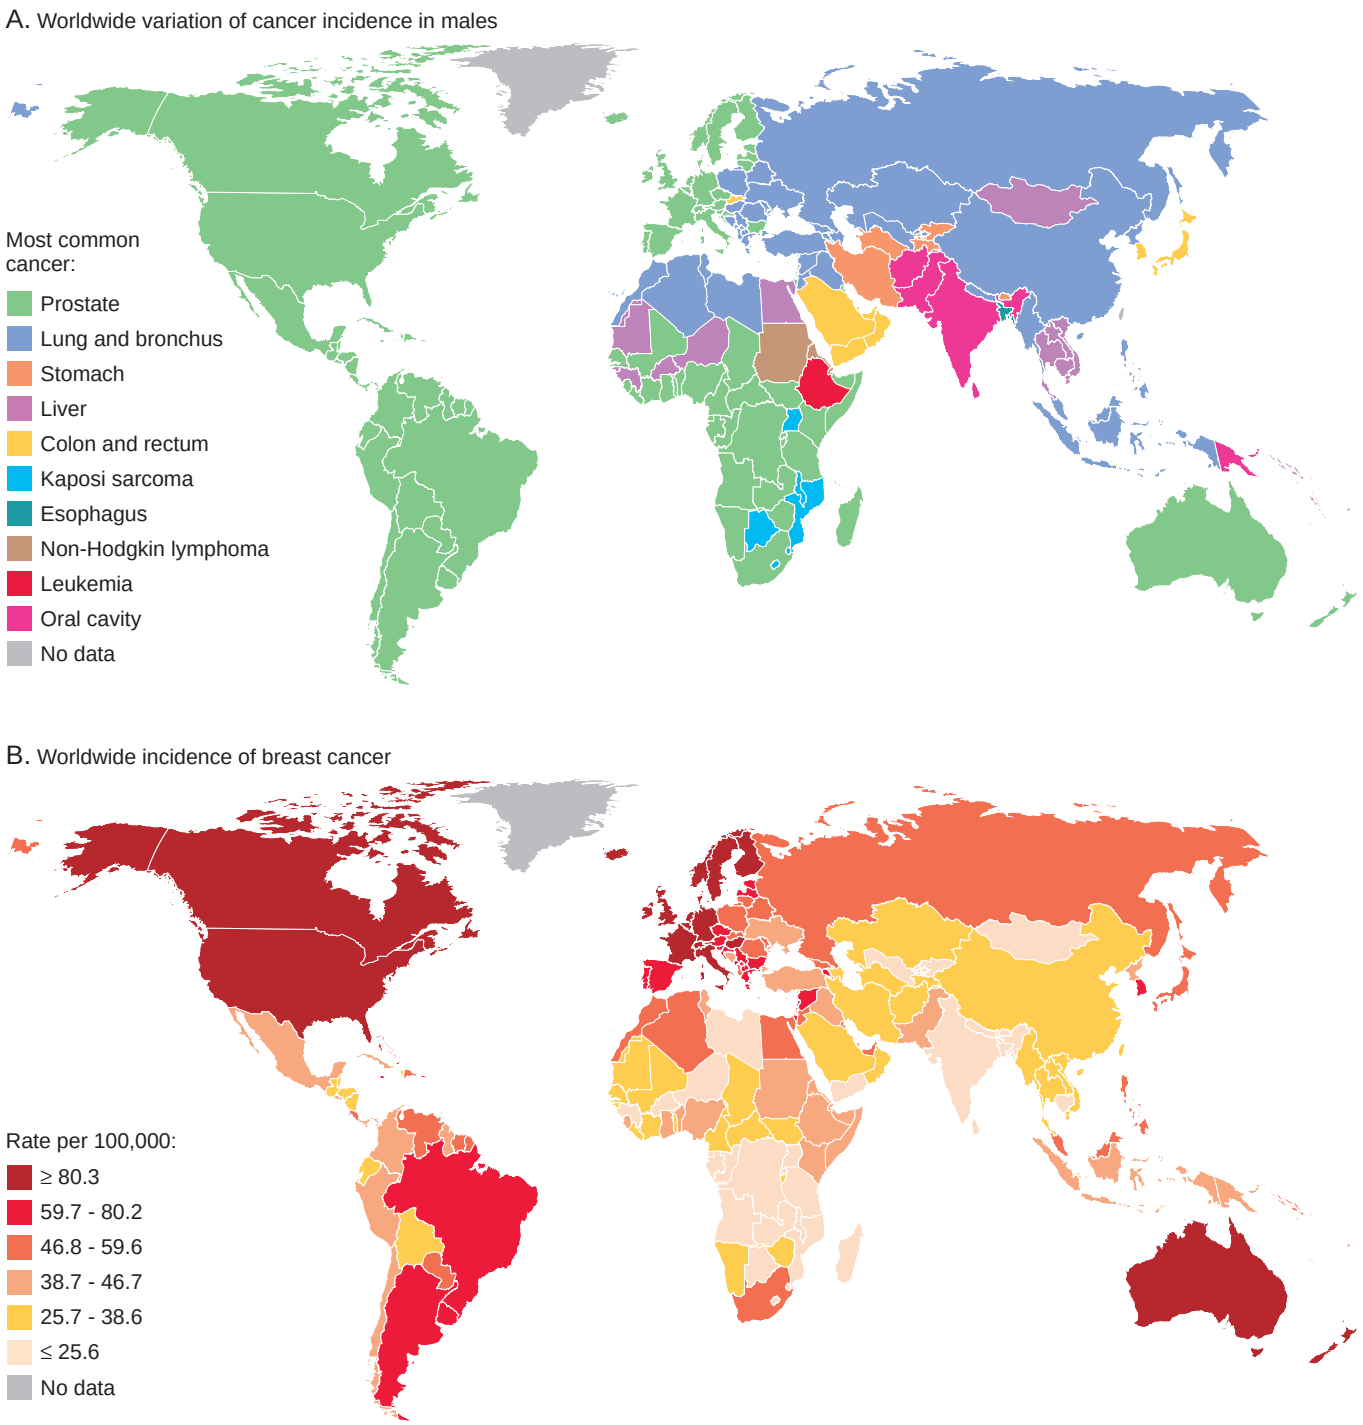

Figure 7.18 Geographic variation in cancer incidence. (A) Most common cancers in men by country. (B) Variation in breast cancer incidence in women by country. (Modified from American Cancer Society: *Global Cancer Facts & Figures*, ed 3, Atlanta, 2015, American Cancer Society.)

environmental carcinogens (e.g., cigarette smoking). This difference explains why carcinomas, which are frequently caused by carcinogens and are the most common general type of tumor in adults, are very rare in children. Instead, acute leukemia and distinctive neoplasms of the central nervous system cause approximately 60% of childhood cancer deaths. The common neoplasms of infancy and childhood include the so-called small round blue cell tumors such as neuroblastoma, Wilms tumor, retinoblastoma, acute lymphoblastic leukemia, and rhabdomyosarcoma. These are discussed in Chapter 10 and elsewhere in the text.

Acquired Predisposing Conditions

Acquired conditions that predispose to cancer can be divided into chronic inflammatory disorders, precursor

Table 7.3 Occupational Cancers

Agents or Groups of Agents	Human Cancers for Which Reasonable Evidence Is Available	Typical Use or Occurrence
Arsenic and arsenic compounds	Lung carcinoma, skin carcinoma	By-product of metal smelting; component of alloys, electrical and semiconductor devices, medications and herbicides, fungicides, and animal dips
Asbestos	Lung, esophageal, gastric, and colon carcinoma; mesothelioma	Formerly used for many applications because of fire, heat, and friction resistance; still found in existing construction as well as fire-resistant textiles, friction materials (i.e., brake linings), underlayment and roofing papers, and floor tiles
Benzene	Acute myeloid leukemia	Principal component of light oil; despite known risk, many applications exist in printing and lithography, paint, rubber, dry cleaning, adhesives and coatings, and detergents; formerly widely used as solvent and fumigant
Beryllium and beryllium compounds	Lung carcinoma	Missile fuel and space vehicles; hardener for lightweight metal alloys, particularly in aerospace applications and nuclear reactors
Cadmium and cadmium compounds	Prostate carcinoma	Uses include yellow pigments and phosphors; found in solders; used in batteries and as alloy and in metal platings and coatings
Chromium compounds	Lung carcinoma	Component of metal alloys, paints, pigments, and preservatives
Nickel compounds	Lung and oropharyngeal carcinoma	Nickel plating; component of ferrous alloys, ceramics, and batteries; by-product of stainless-steel arc welding
Radon and its decay products	Lung carcinoma	From decay of minerals containing uranium; potentially serious hazard in quarries and underground mines
Vinyl chloride	Hepatic angiosarcoma	Refrigerant; monomer for vinyl polymers; adhesive for plastics; formerly inert aerosol propellant in pressurized containers

Modified from Stellman JM, Stellman SD: Cancer and workplace, *CA Cancer J Clin* 46:70, 1996.

lesions, and immunodeficiency states. Chronic inflammatory disorders and precursor lesions span a diverse set of conditions that are all associated with increased cellular replication, which appears to create a "fertile" soil for the development of malignant tumors. Indeed, repeated rounds of cell division may be required for neoplastic transformation, as proliferating cells are most at risk for somatic mutations that lead to carcinogenesis. Immunodeficiency states predispose to virus-induced cancers. Each of these acquired predisposing conditions is described next.

- *Chronic inflammation.* Virchow first proposed a cause-and-effect relationship between chronic inflammation and cancer in 1863. The scope of this association is now clear; cancer risk is increased in individuals affected by a wide variety of chronic inflammatory diseases, both infectious and noninfectious (Table 7.4). Tumors arising in the context of chronic inflammation are mostly carcinomas, but also include mesothelioma and several kinds of lymphoma. As with any cause of tissue injury, these disorders are accompanied by a compensatory proliferation of cells that serves to repair the damage. In some cases, chronic inflammation may increase the pool of tissue stem cells, which may be particularly susceptible to transformation. Additionally, activated immune cells produce reactive oxygen species that may damage DNA and inflammatory mediators that may promote cell survival, even in the face of genomic damage. Whatever the precise mechanism, the link between chronic inflammation and cancer has practical implications. For instance, diagnosis and effective treatment of *Helicobacter pylori* gastritis with antibiotics can quell a chronic inflammatory condition that might otherwise lead to the development of a gastric cancer.
- *Precursor lesions.* Precursor lesions are defined by localized morphologic changes that identify a field of epithelium that is at increased risk for malignant transformation. These changes may take the form of hyperplasia, metaplasia, or dysplasia. The link between epithelial dysplasia and metaplasia with various forms of carcinoma has already been mentioned. Precursor lesions consisting of hyperplasias often stem from chronic exposure to trophic factors. One of the most common precursors of this type is *endometrial hyperplasia,* which is caused by sustained estrogenic stimulation of the endometrium. Other "at risk" lesions consist of benign neoplasms. A classic lesion of this type is the colonic *villous adenoma,* which progresses to cancer in about 50% of cases if left untreated. It should be emphasized, however, that most benign tumors transform rarely (e.g., uterine leiomyomas, pleomorphic adenoma) and others not at all (e.g., lipomas). Why most benign tumors have a negligible risk of malignant transformation is an unsettled question; one possibility is that benign tumors at high risk for malignant transformation possess the cancer-enabling property of genomic instability (discussed later), whereas other benign tumors do not.
- *Immunodeficiency and cancer.* Patients who are immunodeficient, particularly those with deficits in T-cell immunity, are at increased risk for cancer, especially types caused by oncogenic viruses, presumably because

Table 7.4 Chronic Inflammatory States and Cancer

Pathologic Condition	Associated Neoplasm(s)	Etiologic Agent(s)
Asbestosis, silicosis	Mesothelioma, lung carcinoma	Asbestos fibers, silica particles
Inflammatory bowel disease	Colorectal carcinoma	
Lichen sclerosis	Vulvar squamous cell carcinoma	
Pancreatitis	Pancreatic carcinoma	Alcoholism, germline mutations (e.g., in the trypsinogen gene)
Chronic cholecystitis	Gallbladder cancer	Bile acids, bacteria, gallbladder stones
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma	Gastric acid
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma	
Opisthorchis, cholangitis	Cholangiocarcinoma, colon carcinoma	Liver flukes (*Opisthorchis viverrini*)
Gastritis/ulcers	Gastric adenocarcinoma, MALT lymphoma	*Helicobacter pylori*
Hepatitis	Hepatocellular carcinoma	Hepatitis B and/or C virus
Osteomyelitis	Carcinoma in draining sinuses	Bacterial infection
Chronic cervicitis	Cervical carcinoma	Human papillomavirus
Chronic cystitis	Bladder carcinoma	Schistosomiasis

MALT, Mucosa-associated lymphoid tissue.

Modified from Tlsty TD, Coussens LM: Tumor stroma and regulation of cancer development, *Ann Rev Pathol Mech Dis* 1:119, 2006.

these individuals have a higher than normal incidence of chronic infection with viruses. These virus-associated tumors include lymphomas, certain carcinomas, and some sarcomas and sarcoma-like proliferations. The relationship between infections, immunity, and cancer is discussed later in this chapter.

Genetic Predisposition and Interactions Between Environmental and Inherited Factors

In some families, cancer is an inherited trait, usually due to germline mutations in a tumor suppressor gene (described later). What then can be said about the influence of heredity on sporadic malignant neoplasms, which constitute roughly 95% of cancers in the United States? While the evidence suggests that these cancers are largely attributable to environmental factors or acquired predisposing conditions, lack of family history does not preclude an inherited component. It is generally difficult to sort out hereditary and nonhereditary contributions because their interactions are often complex, particularly when tumor development depends on the action of multiple genes. Even in cancers with a well-defined inherited component, the risk of cancer development may be greatly influenced by nongenetic factors. For instance, breast cancer risk in females who inherit mutated copies of the *BRCA1* or *BRCA2* tumor suppressor genes (discussed later) has been observed to be almost threefold higher for women born after 1940 than for women born before that year, perhaps because of changes in reproductive history. Conversely, genetic factors can alter the likelihood of cancers that are primarily induced by environmental carcinogens. This is because genetic variation (polymorphisms) in certain enzymes, such as the cytochrome P-450 system, influences the conversion of procarcinogens to active carcinogens. A cardinal example, discussed later, is a polymorphism in one of the P-450 genes that confers susceptibility to smoking-induced lung cancer.

KEY CONCEPTS

EPIDEMIOLOGY OF CANCER

- The incidence of cancer varies with geography, age, race, and genetic background. Cancers are most common in adults older than 55 years of age, but occur in adults at all ages and in children and infants. The geographic variation is thought to mainly stem from different environmental exposures.
- Important environmental factors implicated in carcinogenesis include infectious agents, smoking, alcohol, diet, obesity, reproductive history, and exposure to environmental carcinogens.
- The risk of cancer is increased by reparative proliferations caused by chronic inflammation or tissue injury, certain forms of hyperplasia, and immunodeficiency.
- Interactions between environmental factors and genetic factors may be important determinants of cancer risk.

MOLECULAR BASIS OF CANCER: ROLE OF GENETIC AND EPIGENETIC ALTERATIONS

Evidence for the genetic origins of cancer has been building for decades. However, a full accounting of the extent of these genetic aberrations is only now nearing completion, made possible by technologic advances in DNA sequencing and other methods that permit genome-wide analysis of cancer cells. The complexity of these data is daunting, and the messages hidden within them have yet to be fully decoded, but certain "genomic themes" have emerged that are likely relevant to every cancer.

- *Nonlethal genetic damage lies at the heart of carcinogenesis.* The initial damage (or mutation) may be caused by environmental exposures, may be inherited in the germline, or may be spontaneous and random, falling into the category of "bad luck." The term environmental, used in this context, refers to any acquired mutation caused by exogenous agents such as viruses or environmental chemicals or by endogenous products of cellular metabolism that have the potential to damage DNA (such as reactive oxygen species) or alter gene expression through epigenetic mechanisms (e.g., so-called oncometabolites, described later).

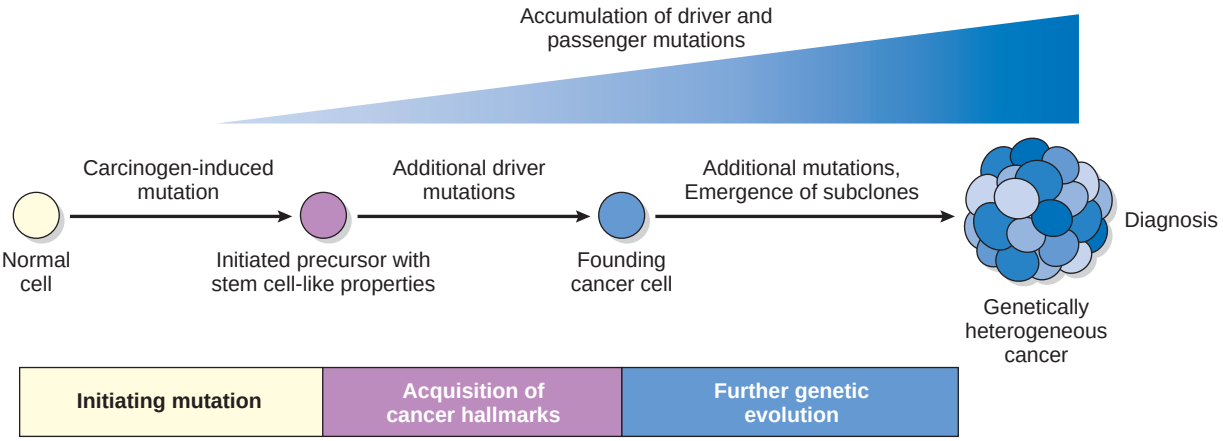

Figure 7.19 Development of a cancer through stepwise acquisition of complementary mutations. The order in which various driver mutations occur in initiated precursor cells is not known and may vary from tumor to tumor. See text for details.

- *A tumor is formed by the clonal expansion of a single precursor cell that has incurred genetic damage (i.e., tumors are clonal).* Alterations in DNA are heritable, being passed to daughter cells, and thus all cells within an individual tumor share the same set of mutations that were present at the moment of transformation. Such tumor-specific mutations are most often identified by DNA sequencing (e.g., point mutations) or by chromosomal analyses (e.g., chromosomal translocations and copy number changes, discussed later).
- *Four classes of genes—growth-promoting proto-oncogenes, growth-inhibiting tumor suppressor genes, genes that regulate programmed cell death (apoptosis), and genes that are responsible for DNA repair—are the principal targets of cancer-causing mutations.* Mutations that activate proto-oncogenes may either cause an increase in one or more normal functions of the encoded gene product that promote tumorigenesis or the appearance of a completely new function that is oncogenic. Because these mutations cause a "gain of function," they can transform cells despite the presence of a normal copy of the same gene. Thus, in genetic parlance, oncogenes are dominant over their normal counterparts. Mutations that affect tumor suppressor genes generally cause a "loss of function," and in most instances both alleles must be damaged before transformation can occur. As a result, mutated tumor suppressor genes usually behave in a recessive fashion. However, there are exceptions: sometimes loss of only a single tumor suppressor gene allele (a state termed haploinsufficiency) reduces the quantity of the encoded protein enough to release the brakes on cell proliferation and survival. Such a finding indicates that two "doses" of the gene are essential for normal function. Apoptosis-regulating genes may acquire abnormalities that result in less cell death and therefore enhanced survival. These abnormalities include gain-of-function mutations in genes whose products suppress apoptosis and loss-of-function mutations in genes whose products promote cell death. Loss-of-function mutations affecting DNA repair genes contribute to carcinogenesis indirectly by impairing the ability of the cell to recognize and repair nonlethal genetic damage in other genes. As a result, affected cells acquire mutations at an accelerated rate, a state referred to as a *mutator phenotype* that is marked by *genomic instability.*
- *Carcinogenesis results from the accumulation of complementary mutations in a stepwise fashion over time* (Fig. 7.19). Malignant neoplasms have several phenotypic attributes referred to as *cancer hallmarks* (discussed in detail later), such as excessive growth, local invasiveness, and the ability to form distant metastases, which stem from genomic alterations that change the expression and function of key genes and thereby impart a malignant phenotype.
  - *Mutations that contribute to the acquisition of cancer hallmarks are referred to as driver mutations.* The first driver mutation that starts a cell on the path to malignancy is the *initiating mutation,* which is typically maintained in all the cells of the subsequent cancer. However, because no single mutation appears to be fully transforming, development of a cancer requires that the "initiated" cell acquire a number of additional driver mutations, each of which also contributes to the development of the cancer. The time over which this occurs is unknown in most cancers, but appears to be lengthy; even in aggressive cancers that clinically seem to appear "out of the blue," such as childhood acute lymphoblastic leukemia, cells bearing initiating mutations may be found in blood samples taken as long as a decade before diagnosis. The persistence of initiated cells during this long preclinical prodrome is consistent with the idea that cancers arise from cells with stem cell–like properties, so-called *cancer stem cells,* that have a capacity for self-renewal and long-term persistence.
  - *Loss-of-function mutations in genes that maintain genomic integrity appear to be a common early step on the road to malignancy, particularly in solid tumors.* Mutations that lead to genomic instability not only increase the likelihood of acquiring driver mutations, but also greatly increase the frequency of mutations that have no phenotypic consequence, so-called *passenger mutations,* which are much more common than driver mutations. As a result, by the time a cell acquires all of the driver mutations that are needed for malignant behavior, it may bear hundreds or even thousands of passenger mutations.

- Mutations in many other genes contribute to tumorigenesis by interfering with host immune responses or altering interactions with the stroma, or by other mechanisms. By convention, these are not classified under driver and passenger mutations, since the terms are largely restricted to genes that influence the behavior of the cells in a cell-intrinsic manner.

Once established, tumors evolve genetically during their outgrowth and progression under the pressure of Darwinian selection (survival of the fittest). Early on, all the cells in a tumor are genetically identical, being the progeny of a single founding transformed cell. However, by the time a tumor comes to clinical attention (generally when it attains a mass of about 1 g, or about 10^9 cells), it has gone through a minimum of 30 cell doublings (this number is actually a substantial underestimation because a fraction of cells in all tumors dies by apoptosis during preclinical stages of tumor development). During the expansion process, individual tumor cells acquire additional mutations at random; this is particularly true in tumors with driver mutations conferring a mutator phenotype. As a result of this tumor evolution, even though cancers are clonal in origin, by the time they become clinically evident their constituent cells are often extremely heterogeneous genetically (see Fig. 7.19). These diverse tumor subclones compete for access to nutrients and microenvironmental niches, and those that are most fit "win" this Darwinian struggle and come to dominate the tumor mass. This pernicious tendency of tumors to become more aggressive over time is referred to as *tumor progression*.

A skeptical student might well ask, "How do we know that genetically distinct subclones really exist in any particular cancer?" Supportive data have emerged from studies of solid cancers such as renal cell carcinoma, in which multiple regions of the primary tumor and metastatic deposits from the same patient have been subjected to DNA sequencing (Fig. 7.20). As predicted, two types of mutations were identified in these studies: (1) mutations that are present in all tumor sites tested, which were presumably present in the founding cell at the moment of transformation, and (2) mutations that are unique to a subset of tumor sites, which were likely acquired after transformation during the outgrowth and spread of the tumor. This second type of mutation can be used to create tumor "family trees" showing the genetic relationships of various subclones. Remarkably, subclones within tumors appear to diverge genetically in a fashion that is very similar to the manner in which new species are thought to emerge in complex ecosystems; a cardinal example of the latter are the finches on the Galapagos Islands that inspired Darwin, in part, to propose evolution as the origin of the species. In the case of species, this genetic divergence occurs over a period of many millennia, whereas in tumors, subclones may arise and diverge on a timescale of years, months, or even weeks.

Selection of the fittest cells can explain not only the natural history of cancer, but also changes in tumor behavior following therapy. One of the most profound selective pressures that cancer cells face is effective therapy given by treating physicians. Tumors that recur after therapy are almost always found to be resistant if the same treatment is given again, presumably because therapy selects for subclones that, by chance, have a genotype that allows them to survive.

In addition to DNA mutations, epigenetic aberrations also contribute to the malignant properties of cancer cells. Epigenetic modifications include DNA methylation, which tends to silence gene expression, and modifications of histones, the proteins that package DNA into chromatin, which depending on their nature may either enhance or dampen gene expression. The epigenetic state of the cell dictates which genes are expressed, which in turn determines the lineage commitment and differentiation state of both normal and neoplastic cells. Epigenetic modifications are

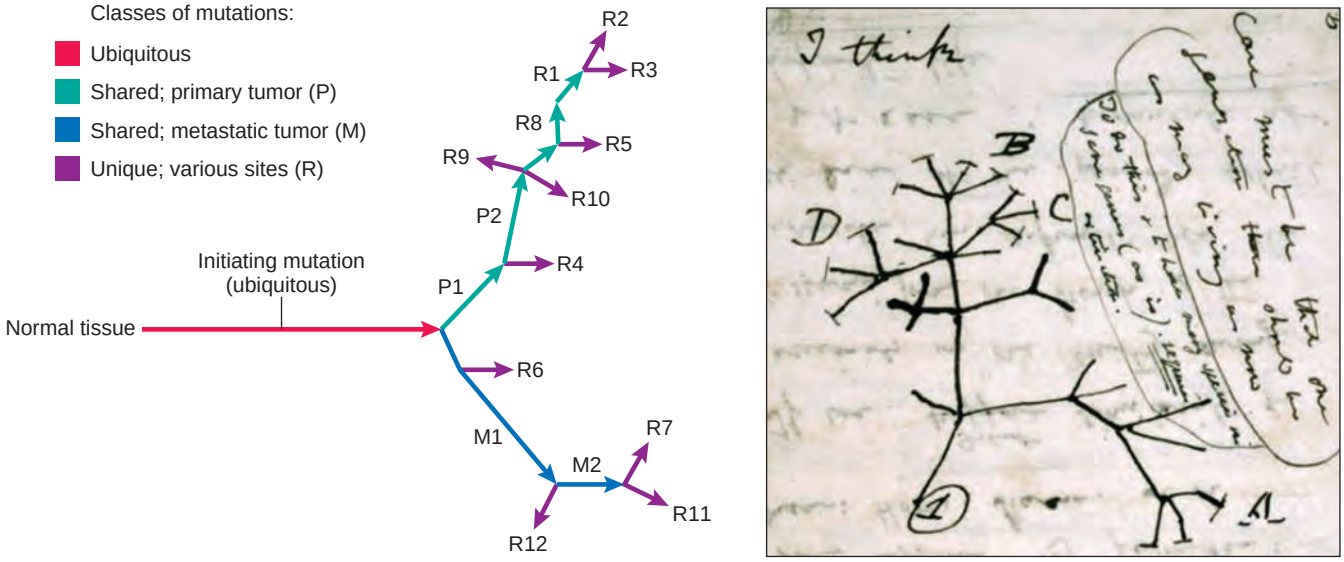

Figure 7.20 Tumor evolution. Evolution of a renal cell carcinoma *(left panel)* and Darwin's finches *(right panel)*. The renal cell carcinoma evolutionary tree is based on genetic comparisons drawn from sequencing of DNA obtained from different tumor sites; the finch evolutionary tree was surmised by Darwin based on morphologic comparisons of different species of finches on the Galapagos Islands. (*right panel*, from Darwin CR: Notebook B: Transmutation of species, 1837–1838, p 26.)

usually passed on faithfully to daughter cells, but on occasion (just as with DNA mutations) alterations may occur that result in changes in gene expression. Aberrant DNA methylation in cancer cells is responsible for the silencing of some tumor suppressor genes, while tumor-specific changes in histone modifications may have far-ranging effects on gene expression (see later). The increasing awareness of the role of epigenetic alterations in cancer has revealed a new path forward for cancer treatment; unlike DNA mutations, epigenetic changes are potentially reversible by drugs that inhibit DNA-modifying or histone-modifying factors. Thus, there is great interest in treating cancers with drugs that correct epigenetic abnormalities.

We will come back to these themes throughout the subsequent discussion, which next turns to the cellular and molecular properties that underlie the malignant behavior of cancer cells.

Cellular and Molecular Hallmarks of Cancer

Over the past several decades, hundreds of genes that are mutated in cancer have been discovered. Traditionally, the functional consequences of these alterations were described one gene at a time. However, the blizzard of mutated genes emerging from the sequencing of cancer genomes has blanketed the landscape and revealed the limitations of trying to grasp the fundamental properties of cancer gene by gene. For example, compilation of a partially complete catalog of recurrent genetic alterations in breast carcinoma required whole genomic sequencing of thousands of tumors and led to the identification of hundreds of distinct driver mutations—and this is just one of hundreds of different kinds of cancer, some of which are substantially more genetically complex than breast carcinoma.

A more tractable and conceptually satisfying way to think about the biology of cancer is to consider the common biologic properties that are imparted to cancer cells by their diverse genomic and epigenomic alterations. It appears that **all cancers display eight fundamental changes in cell physiology, which are considered the hallmarks of cancer.** These changes are illustrated in Fig. 7.21 and consist of the following:

- *Self-sufficiency in growth signals.* Tumors have the capacity to proliferate without external stimuli, usually as a consequence of oncogene activation.
- *Insensitivity to growth-inhibitory signals.* Tumors may not respond to molecules that inhibit the proliferation of normal cells, usually because of inactivation of tumor suppressor genes that encode components of growth inhibitory pathways.
- *Altered cellular metabolism.* Tumor cells undergo a metabolic switch to aerobic glycolysis (called the *Warburg effect*), which enables the synthesis of the macromolecules and organelles that are needed for rapid cell growth.
- *Evasion of apoptosis.* Tumors are resistant to programmed cell death.
- *Limitless replicative potential (immortality).* Tumors have unrestricted proliferative capacity, a stem cell–like property that permits tumor cells to avoid cellular senescence and mitotic catastrophe.
- *Sustained angiogenesis.* Tumor cells, like normal cells, are not able to grow without a vascular supply to bring nutrients and oxygen and remove waste products. Hence, tumors must induce angiogenesis.
- *Ability to invade and metastasize.* Tumor metastases are the cause of the vast majority of cancer deaths and arise from the interplay of processes that are intrinsic to tumor cells and signals that are initiated by the tissue environment.
- *Ability to evade the host immune response.* You will recall that the cells of the innate and adaptive immune system can recognize and eliminate cells displaying abnormal antigens (e.g., a mutated oncoprotein). Cancer cells exhibit a number of alterations that allow them to evade the host immune response.

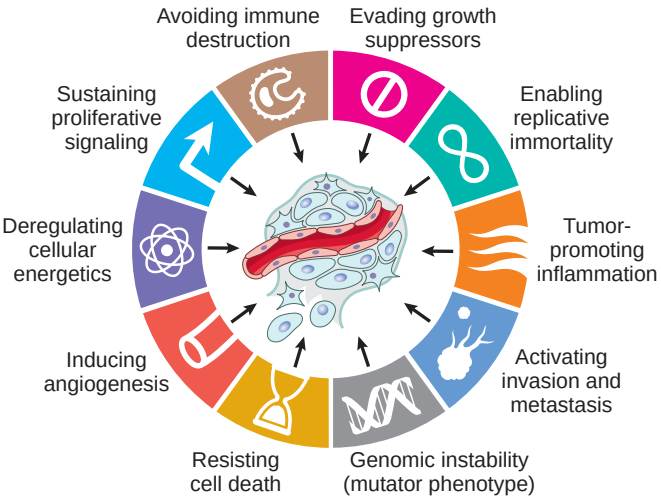

Figure 7.21 Hallmarks of cancer. (Modified from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation, *Cell* 144:646, 2011.)

The acquisition of the genetic and epigenetic alterations that confer these hallmarks may be accelerated by *genomic instability* and by *cancer-promoting inflammation*. These are considered enabling characteristics because they promote cellular transformation and subsequent tumor progression.

In the following sections, each of the hallmarks and enabling characteristics of cancer cells is discussed, focusing on the most important contributing genes and cellular pathways. The discussion of cancer pathophysiology ends with a review of the roles that epigenetic changes and noncoding RNAs play in the disease.

Self-Sufficiency in Growth Signals: Oncogenes

Oncogenes are mutated genes that cause excessive cell growth, even in the absence of growth factors and other growth-promoting external cues. A major discovery in cancer was that oncogenes are mutated or overexpressed versions of normal cellular genes, which are called proto-oncogenes. Through a variety of mechanisms, discussed later, these mutations increase or alter the function of oncoproteins, which are constitutively active and resistant to control by external signals. Cells expressing oncoproteins are thus freed from normal checkpoints and proliferate excessively.

To aid in the understanding of the nature and functions of oncoproteins and their role in cancer, it is necessary to briefly describe how normal cells respond to growth factors.

Physiologic growth factor–induced signaling can be resolved into the following steps:

- The binding of a growth factor to its specific receptor
- Transient and limited activation of the growth factor receptor, which in turn activates several cytoplasmic signal-transducing proteins
- Transmission of the transduced signal to the nucleus via additional cytoplasmic effector proteins and second messengers or by a cascade of signal transduction molecules
- Induction and activation of transcription factors and epigenetic alterations that initiate and sustain DNA transcription
- Expression of genes and encoded factors that promote entry and progression of the cell into the cell cycle, ultimately resulting in cell division
- In parallel, changes in the expression of other genes that support cell survival and metabolic alterations that are needed for optimal growth

Aberrations in multiple signaling pathways have been identified in neoplasms, and many components of these pathways act as oncoproteins when mutated (Table 7.5). Conversely, many tumor suppressors act by inhibiting one or more components of these same pro-growth pathways (discussed later). In Chapter 1, the major signaling pathways

Table 7.5 Selected Oncogenes, Their Mode of Activation, and Associated Human Tumors

Category	Proto-Oncogene	Mode of Activation in Tumor	Associated Human Tumor
Growth Factors			
PDGF-β	*PDGFB*	Overexpression	Astrocytoma
Fibroblast growth factors	*HST1* *FGF3*	Overexpression Amplification	Osteosarcoma Stomach cancer Bladder cancer Breast cancer Melanoma
TGF-α	*TGFA*	Overexpression	Astrocytomas
HGF	*HGF*	Overexpression	Hepatocellular carcinomas Thyroid cancer
Growth Factor Receptors			
EGF-receptor family	*ERBB1 (EGFR)* *ERBB2 (HER)*	Mutation Amplification	Adenocarcinoma of lung Breast carcinoma
FMS-like tyrosine kinase 3	*FLT3*	Point mutation or small duplications	Leukemia
Receptor for neurotrophic factors	*RET*	Point mutation	Multiple endocrine neoplasia 2A and B, familial medullary thyroid carcinomas
PDGF receptor	*PDGFRB*	Amplification, translocation	Gliomas, leukemias
Receptor for KIT ligand	*KIT*	Point mutation	Gastrointestinal stromal tumors, seminomas, leukemias
ALK receptor	*ALK*	Translocation Point mutation	Adenocarcinoma of lung, certain lymphomas Neuroblastoma
Proteins Involved in Signal Transduction			
GTP-binding (G) proteins	*KRAS* *HRAS* *NRAS* *GNAQ* *GNAS*	Point mutation Point mutation Point mutation Point mutation Point mutation	Colon, lung, and pancreatic tumors Bladder and kidney tumors Melanomas, hematologic malignancies Uveal melanoma Pituitary adenoma, other endocrine tumors
Nonreceptor tyrosine kinase	*ABL*	Translocation	Chronic myelogenous leukemia Acute lymphoblastic leukemia
RAS signal transduction	*BRAF*	Point mutation	Melanomas, leukemias, colon carcinoma, others
Notch signal transduction	*NOTCH1*	Point mutation, translocation	Leukemias, lymphomas, breast carcinoma
JAK/STAT signal transduction	*JAK2*	Point mutation, translocation	Myeloproliferative disorders Acute lymphoblastic leukemia
Nuclear Regulatory Proteins			
Transcriptional activators	*MYC* *NMYC*	Translocation Amplification	Burkitt lymphoma Neuroblastoma
Cell Cycle Regulators			
Cyclins	*CCND1* (cyclin D1)	Translocation Amplification	Mantle cell lymphoma, multiple myeloma Breast and esophageal cancers
Cyclin-dependent kinase	*CDK4*	Amplification or point mutation	Glioblastoma, melanoma, sarcoma

that regulate cellular behavior are laid out, including the receptor tyrosine kinase pathway, the G protein–coupled receptor pathway, the JAK/STAT pathway, the WNT pathway, the Notch pathway, the Hedgehog pathway, the TGF-β/SMAD pathway, and the NF-κB pathway. Abnormalities in each of these pathways are implicated in the development and progression of various cancers.

Traditionally, discussion of oncoproteins and tumor suppressors has centered on their ability to accelerate or inhibit, respectively, DNA replication and cell cycle progression. This view has merit, and we will follow it in our initial description of their activities. However, the proliferation of cells requires not only DNA replication but also sufficient biosynthesis of membrane, protein, and various macromolecules and organelles to enable a "mother" cell to divide and produce two complete daughter cells. Cell growth pathways implicated in oncogenesis also initiate signals that promote and coordinate the biosynthesis of all essential cellular components (discussed later). This insight has generated interest in therapeutic targeting of many aspects of oncogenic pro-growth signaling including the altered cellular metabolism that is characteristic of cancer cells.

Building on this framework, we next discuss some of the most important oncoproteins and the mechanisms by which they contribute to the autonomous growth of cancer cells.

Oncoproteins and Cell Growth

Oncogenes have multiple roles, but virtually all encode constitutively active oncoproteins that participate in signaling pathways that drive the proliferation of cells. Thus proto-oncogenes, the normal regulated versions of oncogenes, may encode growth factors, growth factor receptors, signal transducers, transcription factors, or cell cycle components. In most instances, the corresponding oncogenes encode oncoproteins that serve functions similar to their normal counterparts, with the important difference that they are usually constitutively active and thereby relieve cells of their normal dependency on growth factors.

In the following sections, we "walk down" a prototypical growth factor signaling pathway from the membrane to the nucleus (Fig. 7.22), discussing at each step along the way some of the genes and factors that are most commonly dysregulated (and therefore most important) in cancer.

Growth Factors. Most growth factors are made by one cell type and act on a neighboring cell of a differing type expressing the appropriate growth factor receptor (paracrine action). Some cancer cells, however, synthesize the same growth factor to which they are responsive, creating an autocrine loop. For example, brain tumors called *glioblastomas* (Chapter 28) often express both platelet-derived growth factor (PDGF) and PDGF receptor (PDGFR), and many sarcomas overexpress transforming growth factor α (TGF-α) and its receptor, epidermal growth factor receptor (EGFR).

Growth Factor Receptors. A large number of oncogenes encode growth factor receptors, of which receptor tyrosine kinases are arguably the most important in cancer. Recall that receptor tyrosine kinases are transmembrane proteins with an extracellular growth factor–binding domain and a cytoplasmic tyrosine kinase domain (Chapter 1). Normally the receptor is activated transiently by binding of a specific growth factor, an event that induces a rapid change in receptor conformation to an active dimeric state. The activated receptor then autophosphorylates tyrosine residues in its own intracellular tail, and these modified residues serve as sites for recruitment of other signaling molecules including RAS and PI3K, key players in receptor tyrosine kinase signaling (described later). The oncogenic versions of these receptors are associated with mutations that lead to constitutive, growth factor–independent tyrosine kinase activity. Hence, the mutant receptors deliver mitogenic signals to the cell continuously, even in the absence of growth factor in the environment.

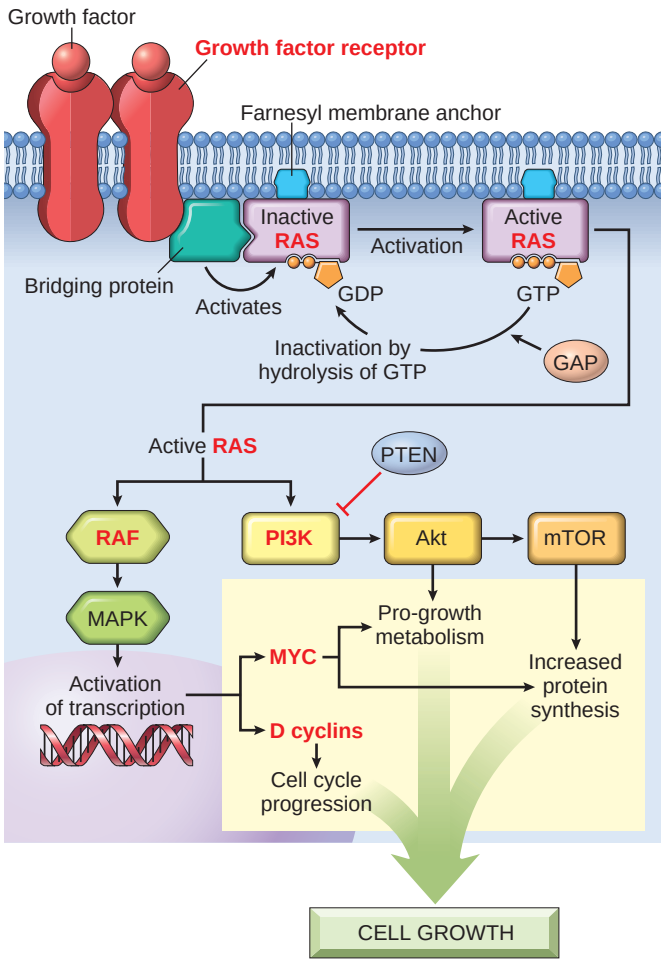

Figure 7.22 Growth factor signaling pathways in cancer. Growth factor receptors RAS, PI3K, MYC, and D cyclins are oncoproteins that are activated by mutations in various cancers. GTPase-activating proteins *(GAPs)* apply brakes to RAS activation, and phosphatase and tensin homologue *(PTEN)* serves the same function for PI3K. *GDP,* Guanosine diphosphate; *GTP,* guanosine triphosphate.

Receptor tyrosine kinases are constitutively activated in tumors by multiple mechanisms including point mutations, gene rearrangements, and gene amplifications. A few of the best-characterized oncogenic mutations involving growth factor receptors are listed in Table 7.5; the following are salient examples of particular clinical importance.

- *ERBB1* encodes EGFR. Several different *ERBB1* point mutations found in a subset of lung adenocarcinomas produce constitutive activation of the EGFR tyrosine kinase.
- *ERBB2* encodes a different member of the receptor tyrosine kinase family, HER2. Rather than being activated by point mutations, the *ERBB2* gene is amplified in certain breast carcinomas, leading to overexpression of the HER2 receptor and constitutive tyrosine kinase activity.
- *ALK* is a receptor tyrosine kinase that may be produced in a constitutively active form as a result of a gene rearrangement. For example, in a subset of lung adenocarcinomas, a deletion on chromosome 5 fuses part of the *ALK* gene with part of another gene called *EML4*. The resulting *EML4-ALK* fusion gene encodes a chimeric EML4-ALK protein with constitutive tyrosine kinase activity.

The importance of these mutated receptor tyrosine kinases has been proven in no small part by the therapeutic effectiveness of agents that inhibit their enzymatic activities. Breast cancers with *ERBB2* amplification and overexpression of HER2 respond well to antibodies or drugs that inhibit HER2 activity. These inhibitors not only block tumor growth but also induce apoptosis and tumor regression, reflecting the ability of receptor tyrosine kinase signaling to augment cell survival as well as proliferation. Inhibitors of EGFR and ALK produce similar therapeutic responses in patients with lung adenocarcinomas harboring *ERBB1* mutations or *EML4-ALK* fusion genes, respectively.

Unfortunately, these targeted therapies are usually not curative in advanced cancers. The tumor cells that withstand therapy typically are found to have other acquired mutations that sidestep the effects of the drug. For example, lung cancers that develop resistance to EGFR inhibitors often have mutations in EGFR that prevent inhibitors from binding, or amplifications in a gene called *MET,* which encodes yet another receptor tyrosine kinase. This experience highlights one of the most daunting clinical problems in the treatment of advanced cancers—the presence of subclones within the genetically heterogeneous tumor cell population that afford resistance to targeted therapies.

Downstream Components of the Receptor Tyrosine Kinase Signaling Pathway. As mentioned, receptor tyrosine kinase activation stimulates RAS and two major downstream signaling "arms," the MAPK cascade and the PI3K/AKT pathway. In line with the importance of these pathways in mediating cell growth, RAS, PI3K, and other components of these pathways are frequently involved by gain-of-function mutations in different types of cancer. Of interest, when *RAS* mutations are present in a tumor, activating mutations in receptor tyrosine kinases are almost always absent, at least within the dominant tumor clone, implying that in such tumors activated RAS can completely substitute for tyrosine kinase activity. Thus, lung adenocarcinomas fall into mutually exclusive molecular subtypes that are associated with mutations involving *RAS* or various tyrosine kinase genes, an insight that has important implications for targeted therapies in this type of cancer.

Point mutations of *RAS* family genes constitute the most common type of abnormality involving proto-oncogenes in human tumors. The RAS genes, of which there are three in humans (*HRAS*, *KRAS*, and *NRAS*), were discovered initially within the genomes of transforming retroviruses. Approximately 15% to 20% of all human tumors have RAS mutations, but in some types of cancers the frequency of RAS mutations is much higher. For example, 90% of pancreatic adenocarcinomas contain RAS mutations, as do about 50% of colon, endometrial, and thyroid cancers and 30% of lung adenocarcinomas and myeloid leukemias.

Recall that RAS proteins are members of a family of membrane-associated small G proteins that bind guanosine nucleotides (guanosine triphosphate [GTP] and guanosine diphosphate [GDP]), similar to the larger trimolecular G proteins. RAS normally flips back and forth between an excited signal-transmitting state in which it is bound to GTP and a quiescent state in which it is bound to GDP. Stimulation of receptor tyrosine kinases by growth factors leads to exchange of GDP for GTP and subsequent conformational changes that generate active RAS. Activation of RAS is transient because RAS has an intrinsic GTPase activity that is accelerated by GTPase-activating proteins (GAPs), which bind to active RAS and augment its GTPase activity by more than 1000-fold, thereby terminating signal transduction. Thus, GAPs prevent uncontrolled RAS activity.

Several distinct *RAS* point mutations have been identified in cancer cells that markedly reduce the GTPase activity of the RAS protein. These mutated forms of RAS are trapped in the activated GTP-bound form, and as a result the cell receives pro-growth signals continuously. It follows from this scenario that the consequences of gain-of-function mutations in RAS proteins should be mimicked by loss-of-function mutations in GAPs that normally restrain RAS activity. Indeed, disabling mutations of neurofibromin 1, a GAP encoded by the *NF1* gene, are associated with the inherited cancer syndrome *familial neurofibromatosis type 1* (Chapter 25). *NF1* is therefore an example of a tumor suppressor gene that acts through negative regulation of RAS signaling.

The MAPK and PI3K/AKT cascades both lie downstream of RAS and consist of a series of kinases, many of which are mutated in cancer cells. Components positioned close to the top of each cascade are frequently involved by oncogenic gain-of-function mutations in various cancers, as follows:

- *Mutations in BRAF,* a member of the RAF family of serine/threonine protein kinases, are found in close to 100% of hairy cell leukemias, 60% of melanomas, and a smaller percentage of a wide variety of other neoplasms including colon carcinomas. Like activating RAS mutations, activating mutations in BRAF stimulate downstream kinases and ultimately activate transcription factors. Mutations in other MAPK family members downstream of BRAF are less common in cancer, suggesting mutations affecting factors near the top of the cascade are most effective at producing pro-growth effects.
- *Mutations in kinases of the PI3K family* are also very common in certain cancers. For example, about 30% of breast carcinomas have PI3K gain-of-function mutations. In other instances, PI3K is "unbridled" by loss-of-function mutations in its negative regulator, called PTEN, a tumor suppressor that is commonly mutated in endometrial carcinoma. Under normal circumstances, following

receptor tyrosine kinase activation, PI3K is recruited to plasma membrane–associated protein complexes. Here, like BRAF, it activates a cascade of serine/threonine kinases, including AKT. AKT phosphorylates more than 150 proteins and constitutes a major signaling node. Its substrates include key regulators of protein synthesis (mTOR) and apoptosis (BAD, FOXO transcription factors, MDM2, and IAP, all described elsewhere).

Because RAS proteins are so frequently mutated in cancer, much effort has been spent trying to develop drugs that inhibit RAS. Unfortunately, none of these strategies has been successful, in large part because what is required is the restoration of a missing enzymatic activity (GTPase activity), an effect that is generally difficult to achieve with drugs. In contrast, treatment of patients with advanced melanomas with BRAF inhibitors has produced striking clinical responses. Such responses are strictly limited to tumors with *BRAF* mutations since these are dependent on BRAF signaling, whereas melanomas with wild-type *BRAF* genes do not respond. This phenomenon, termed *oncogene addiction* (described below), highlights the need for molecular analysis to guide appropriate therapy. Multiple drugs that inhibit various PI3K isoforms have also been developed, and some are now approved for treatment of particular cancers.

Nonreceptor Tyrosine Kinases. Oncogenic mutations also occur in several nonreceptor tyrosine kinases that normally localize to the cytoplasm or the nucleus. In many instances the mutations take the form of chromosomal translocations or rearrangements that create fusion genes encoding constitutively active tyrosine kinases. Despite their nonmembranous localization, these oncoproteins seem to activate the same signaling pathways as receptor tyrosine kinases. An important example of this oncogenic mechanism involves the ABL tyrosine kinase. In chronic myeloid leukemia (CML) and a subset of acute lymphoblastic leukemia, the *ABL* gene is translocated from its normal abode on chromosome 9 to chromosome 22 (Fig. 7.23), where it fuses with the *BCR* gene (see discussion of chromosomal translocations later in this chapter). The resultant fusion gene encodes a chimeric BCR-ABL protein with constitutive tyrosine kinase activity. The most important contribution of the BCR moiety is to promote self-association of BCR-ABL, which appears to be sufficient to unleash the tyrosine kinase activity of ABL. This represents a recurrent story in cancer, as many different oncogenic tyrosine kinases consist of chimeric proteins in which the non–tyrosine kinase partner drives self-association.

Treatment of CML has been revolutionized by the development of BCR-ABL kinase inhibitors, another example of rational drug design emerging from an understanding of the molecular basis of cancer. The remarkable therapeutic response of CML to BCR-ABL inhibitors is one of the first and best examples of *oncogene addiction,* in which tumor cells are highly dependent on the activity of one oncoprotein. Despite accumulation of mutations in other cancer-associated genes in CML cells, signaling through the BCR-ABL tyrosine kinase is required for most CML tumor cells to proliferate and survive; hence, inhibition of its activity is a highly effective therapy. The presence of a *BCR-ABL* fusion gene defines CML and must be the initiating event in this disease;

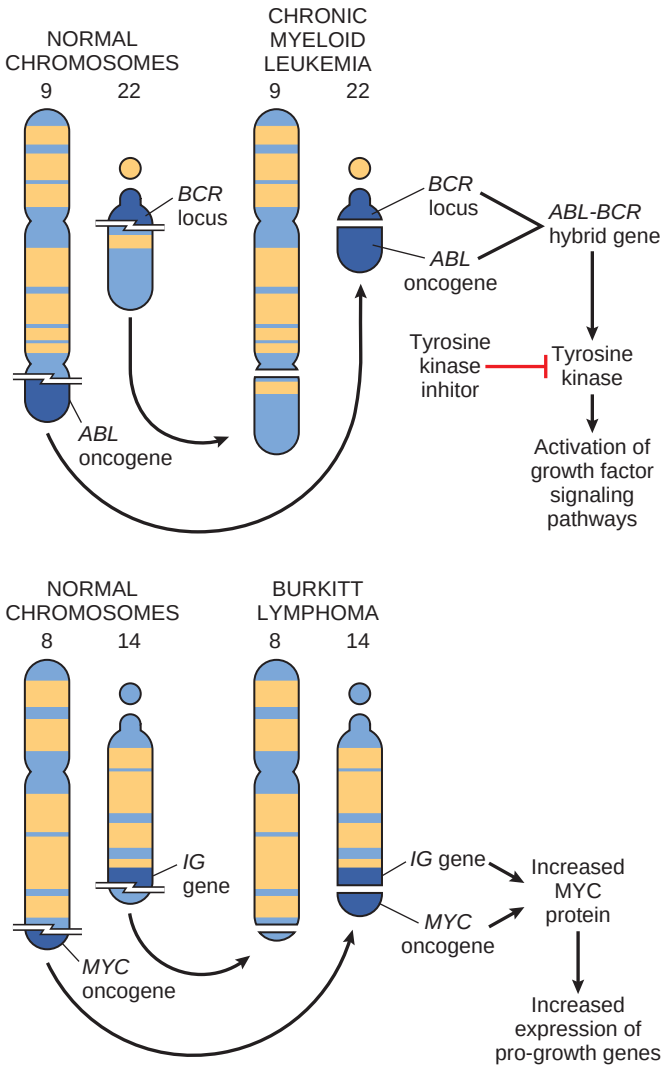

Figure 7.23 Chromosomal translocation and associated oncogenes in Burkitt lymphoma and chronic myeloid leukemia.

thus, additional mutations acquired by the founding clone are selected for their ability to complement the effects of incessant BCR-ABL signaling. BCR-ABL can be seen as the central lodgepole around which an oncogenic signaling "structure" is built. If the lodgepole is removed by treatment with BCR-ABL kinase inhibitors, the entire structure collapses. Unfortunately, treatment of this "addiction" to BCR-ABL does not lead to cure. Even though the proliferating component of the tumor is suppressed by BCR-ABL inhibitors and the patient seems completely well, rare CML "stem cells" harboring the *BCR-ABL* fusion gene persist, apparently because these cells do not require BCR-ABL signals for their survival. As a result, therapy with BCR-ABL inhibitors must be continued indefinitely; otherwise, the malignant stem cells spawn rapidly proliferating offspring, and the full-blown leukemia returns. This outcome highlights a second important concept that we will return to: the existence of "stem-like" cells in certain cancers that may be particularly resistant to therapeutic targeting.

In other instances, nonreceptor tyrosine kinases are activated by point mutations that abrogate the function of negative autoregulatory domains that normally hold enzyme

activity in check. An example of this type of mutation is found in the nonreceptor tyrosine kinase JAK2. JAK2 participates in the JAK/STAT signaling pathway, which transduces mitogenic signals from growth factor and cytokine receptors that lack tyrosine kinase activity (as described in Chapter 1). JAK/STAT activation alters the expression of target genes that bind STAT transcription factors. Several myeloid neoplasms are frequently associated with activating point mutations in JAK2 that relieve the tumor cells of their normal dependence on hematopoietic growth factors such as erythropoietin (Chapter 13). Recognition of this molecular lesion has led to the clinical development of JAK2 inhibitors and has stimulated searches for activating mutations in other nonreceptor tyrosine kinases.

Transcription Factors. Just as all roads lead to Rome, all signal transduction pathways converge on the nucleus, where the expression of target genes that orchestrate the cell's orderly advance through the cell cycle is activated. Indeed, the ultimate consequence of deregulated mitogenic signaling pathways is inappropriate and continuous stimulation of nuclear transcription factors that drive growth-promoting genes. Thus not surprisingly, growth autonomy may also occur as a consequence of mutations affecting transcription factors that regulate the expression of pro-growth genes and cyclins. Transcription factors of this class include the products of the *MYC, MYB, JUN, FOS,* and *REL* proto-oncogenes. Of these, *MYC* is most commonly affected in cancer, and hence a brief overview of its regulation and function follows.

MYC. The *MYC* proto-oncogene is expressed in virtually all eukaryotic cells and belongs to the immediate early response genes, which are rapidly and transiently induced by RAS/MAPK signaling following growth factor stimulation of quiescent cells. Under normal circumstances, MYC protein concentrations are tightly controlled at the level of transcription, translation, and protein stability, and virtually all pathways that regulate growth impinge on MYC through one or more of these mechanisms.

How MYC promotes normal and neoplastic cell growth is incompletely understood, but a multitude of studies have shown that **MYC has remarkably broad activities, several of which contribute not only to deregulated cell growth but also to several other hallmarks of cancer**.

- *MYC activates the expression of many genes that are involved in cell growth.*
  - Some MYC target genes, like D cyclins, are directly involved in cell cycle progression.
  - MYC also upregulates the expression of ribosomal RNA (rRNA) genes and rRNA processing, thereby enhancing the assembly of ribosomes needed for protein synthesis.
  - MYC upregulates a program of gene expression that leads to metabolic reprogramming and the Warburg effect, another cancer hallmark (discussed later). Among the genes involved in metabolism that are upregulated by MYC are multiple glycolytic enzymes and factors involved in glutamine metabolism, both of which contribute to the generation of metabolic intermediates that are needed for synthesis of macromolecules such as DNA, proteins, and lipids.
  - Based on these protean effects, MYC can be considered a master transcriptional regulator of cell growth. Indeed, the fastest growing human tumors, such as Burkitt lymphoma, which virtually always bears a chromosomal translocation involving *MYC* (see Fig. 7.23), are those with the highest levels of MYC.
- *In some contexts, MYC upregulates expression of telomerase.* As discussed later, telomerase is one of several factors that contribute to the endless replicative capacity (the immortalization) of cancer cells.
- *MYC is one of a handful of transcription factors that can act together to reprogram somatic cells into pluripotent stem cells* (Chapter 1). This capacity has led to suspicions that MYC also contributes to cancer cell "stemness," another important aspect of the immortality of cancers.

Given the importance of MYC in regulation of cell growth, it should come as no surprise that it is deregulated in cancer through a large variety of mechanisms. Sometimes deregulation involves genetic alterations of *MYC* itself. In Burkitt lymphoma and a subset of other B- and T-cell tumors, the *MYC* gene is translocated into an antigen receptor gene locus, which contains gene regulatory elements called enhancers that are highly active in lymphocytes. Rather than driving the expression of B- or T-cell receptors, these misplaced enhancers instead cause the deregulation and overexpression of MYC protein. Alternatively the *MYC* gene is amplified in cancers of the breast, colon, lung, and other tissues, again resulting in overexpression of MYC. The functionally identical *NMYC* and *LMYC* genes are also amplified in neuroblastomas (Fig. 7.24) and small cell cancers of the lung, respectively. In many other instances, oncogenic

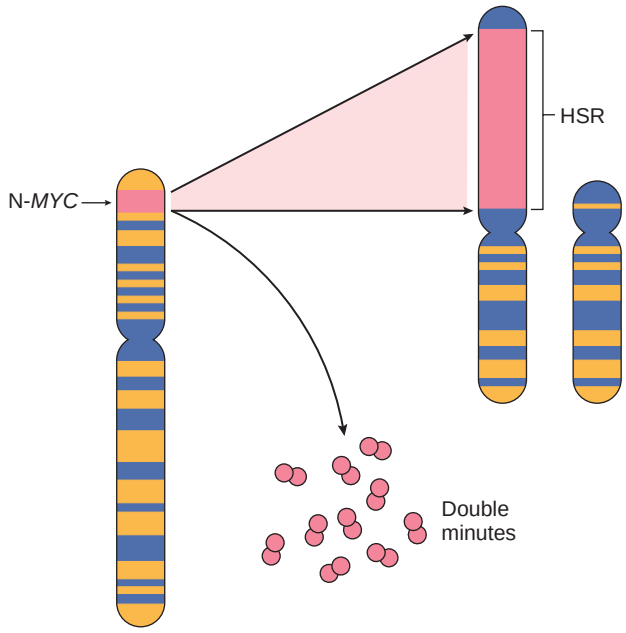

Figure 7.24 Amplification of the *NMYC* gene in human neuroblastomas. The *NMYC* gene, normally present on chromosome 2p, becomes amplified and is seen either as extra chromosomal double minutes or as a chromosomally integrated, homogeneous staining region *(HSR)*. The integration involves other autosomes such as 4, 9, or 13. (Modified from Brodeur GM: Molecular correlates of cytogenetic abnormalities in human cancer cells: implications for oncogene activation. In Brown EB, editor: *Progress in Hematology,* vol 14, Orlando, Fla, 1986, Grune & Stratton, pp 229–256.)

mutations involving components of upstream signaling pathways elevate MYC protein levels by increasing *MYC* transcription, enhancing *MYC* messenger RNA (mRNA) translation, and/or stabilizing MYC protein. Thus, constitutive RAS/MAPK signaling (many cancers), Notch signaling (several cancers), Wnt signaling (colon carcinoma), and Hedgehog signaling (medulloblastoma) all transform cells in part through upregulation of *MYC*. Finally, several single nucleotide polymorphisms (SNPs) associated with an inherited risk for cancers such as prostate and ovarian carcinoma and certain leukemias lie within enhancer elements that flank *MYC;* these variants appear to stimulate higher levels of *MYC* RNA expression in response to growth-promoting signals. Thus, there is seemingly no end to the ways in which MYC may be deregulated in cancer cells.

Cyclins and Cyclin-Dependent Kinases. As mentioned in Chapter 1, growth factors transduce signals that stimulate the orderly progression of cells through the various phases of the cell cycle, the process by which cells replicate their DNA in preparation for cell division. Progression of cells through the cell cycle is orchestrated by cyclin-dependent kinases (CDKs), which are activated by binding to cyclins, so called because of the cyclic nature of their production and degradation. The CDK-cyclin complexes phosphorylate crucial target proteins that drive cells forward through the cell cycle. While cyclins arouse the CDKs, CDK inhibitors, of which there are many, silence the CDKs and exert negative control over the cell cycle (Table 7.6). Expression of these inhibitors is downregulated by mitogenic signaling pathways, thus promoting the progression of the cell cycle.

There are two main cell cycle checkpoints, one at the G_1/S transition and the other at the G_2/M transition, both of which are tightly regulated by a balance of growth-promoting and growth-suppressing proteins, as well as by sensors of DNA damage (Chapter 1). If activated, these DNA-damage sensors transmit signals that arrest cell cycle progression and, if the damage cannot be repaired, initiate apoptosis. Understandably, defects in the G_1/S checkpoint are more important in cancer because these not only lead to dysregulated growth but may also impair DNA repair, creating a "mutator" phenotype that (as mentioned) enables cancer development and progression.

The major cancer-associated mutations that affect the G_1/S checkpoint can be broadly grouped into two classes.

- *Gain-of-function mutations in D cyclin genes and CDK4, which promote unregulated G_1/S progression and thus function as oncogenes.* There are three D cyclin genes, D1, D2, and D3, which are functionally interchangeable and often dysregulated by acquired mutations in cancer, including chromosomal translocations in lymphoid tumors and gene amplification in a variety of solid tumors. Amplification of the *CDK4* gene also occurs in melanomas, sarcomas, and glioblastomas. CDK4 inhibitors are effective in treatment of advanced breast cancers associated with excessive CDK4 activity. Mutations affecting other CDKs and cyclin E also occur in cancers, but they are infrequent, presumably because these factors are less important in control of the G_1/S transition, which has a preeminent role in regulating tumor growth rates.
- *Loss-of-function mutations in genes that inhibit G_1/S progression.* Examples of these tumor suppressor genes are those encoding CDK inhibitors, which inhibit cyclin D/CDK complexes and are frequently mutated or otherwise silenced in many human malignancies. For example, germline mutations of *p16 (CDKN2A)* are present in 25% of melanoma-prone kindreds, and somatically acquired deletion or inactivation of p16 is seen in 75% of pancreatic carcinomas, 40% to 70% of glioblastomas, 50% of esophageal cancers, 20% to 70% of acute lymphoblastic leukemias, and 20% of non–small cell lung carcinomas, soft tissue sarcomas, and bladder cancers. Furthermore, the two most important tumor suppressor genes, *RB* and *TP53,* both encode proteins that inhibit G_1/S progression.

Table 7.6 Cell Cycle Components and Inhibitors That Are Frequently Mutated in Cancer

Cell Cycle Component	Main Function
Cyclins and Cyclin-Dependent Kinases	
CDK4; D cyclins	Form a complex that phosphorylates RB, allowing the cell to progress through the G_1 restriction point
Cell Cycle Inhibitors	
CIP/KIP family: p21, p27 (CDKN1A–D)	Block the cell cycle by binding to cyclin-CDK complexes p21 is induced by tumor suppressor p53 p27 responds to growth suppressors such as TGF-β
INK4/ARF family (CDKN2A–C)	p16/INK4a binds to cyclin D–CDK4 and promotes the inhibitory effects of RB p14/ARF increases p53 levels by inhibiting MDM2 activity
Cell Cycle Checkpoint Components	
RB	Tumor suppressive "pocket" protein that binds E2F transcription factors in its hypophosphorylated state, preventing G_1/S transition Interacts with transcription factors that regulate differentiation
p53	Tumor suppressor altered in the majority of cancers Induced by DNA damage Causes cell cycle arrest by upregulating the CDK inhibitor p21 Induces apoptosis by upregulating BAX and other pro-apoptotic genes

KEY CONCEPTS

ONCOGENES, ONCOPROTEINS, AND UNREGULATED CELL PROLIFERATION

Proto-oncogenes: normal cellular genes whose products promote cell proliferation.

Oncogenes: mutated or overexpressed versions of proto-oncogenes that function autonomously, having lost dependence on normal growth-promoting signals.

Oncoprotein: a protein encoded by an oncogene that drives increased cancer cell proliferation, which may result from a variety of aberrations.

- Constitutive expression of growth factors and their cognate growth factor receptors, setting up an autocrine cell signaling loop.
- Mutations in growth factor receptors, nonreceptor tyrosine kinases, or downstream signaling molecules that lead to constitutive signaling, such as:
  - Activation of the EGF receptor tyrosine kinase by point mutations (lung cancer), activation of the HER2 receptor tyrosine kinase by gene amplification (breast cancer), and activation of the JAK2 tyrosine kinase by point mutations (myeloproliferative neoplasms).
  - Activation of the ABL nonreceptor tyrosine kinase by chromosomal translocation and creation of a *BCR-ABL* fusion gene (chronic myeloid leukemia, acute lymphoblastic leukemia).
  - Activation of RAS by point mutations (many cancers).
  - Activation of PI3K and BRAF serine/threonine kinases by point mutations (many cancers).
  - Increased expression of MYC, a master transcription factor that regulates genes needed for rapid cell growth by deregulation through chromosomal translocations (Burkitt lymphoma, other hematologic malignancies), gene amplication (neuroblastoma), and increased activity of upstream signaling pathways (many cancers).
  - Mutations that increase the activity of cyclin-dependent kinase 4 (CDK4)/D cyclin complexes, which promote cell cycle progression.

Insensitivity to Growth Inhibition: Tumor Suppressor Genes

Whereas oncogenes drive the proliferation of cells, the products of most tumor suppressor genes apply brakes to cell proliferation, and abnormalities in these genes lead to failure of growth inhibition, another fundamental hallmark of carcinogenesis. Tumor suppressor proteins control a series of checkpoints that prevent uncontrolled growth. Many tumor suppressors, such as RB and p53, are part of a regulatory network that recognizes genotoxic stress from any source and responds by shutting down proliferation. Indeed, expression of an oncogene in normal cells with intact tumor suppressor genes leads to quiescence or permanent cell cycle arrest (oncogene-induced senescence, discussed later), rather than uncontrolled proliferation. Ultimately, the growth inhibitory pathways may prod the cells into apoptosis. Another set of tumor suppressors seems to be involved in cell differentiation, causing cells to enter a postmitotic, differentiated pool without replicative potential. Similar to mitogenic signals, signals that induce growth inhibition and differentiation originate outside the cell and use receptors, signal transducers, and nuclear transcription regulators to accomplish their effects; tumor suppressors form a portion of these networks. Thus the protein products of tumor suppressor genes may function as transcription factors, cell cycle inhibitors, signal transduction molecules, cell surface receptors, and regulators of cellular responses to DNA damage.

In this section, we describe tumor suppressor genes, their products, and mechanisms by which loss of their function contributes to unregulated cell growth (Table 7.7). Many of our current concepts of tumor suppressors evolved from studies of the retinoblastoma (*RB*) gene, the first tumor suppressor gene discovered, which remains a prototype of genes of this type. Like many discoveries in medicine, *RB* was identified by studying a rare inherited disease, familial retinoblastoma. Approximately 40% of retinoblastomas are familial, with the predisposition to develop the tumor being transmitted as an autosomal dominant trait. Carriers of this trait have a 10,000-fold increased risk of developing retinoblastoma (often in both eyes) compared with the general population and are at greatly increased risk of developing osteosarcoma and other soft tissue sarcomas. The remaining 60% of retinoblastomas occur sporadically (virtually always in only one eye), and such patients are not at increased risk for other forms of cancer. To explain these two patterns of occurrence of retinoblastoma, Knudson proposed his now canonic "two-hit" hypothesis of oncogenesis. In molecular terms, Knudson's hypothesis can be stated as follows (Fig. 7.25):

- Two mutations (hits), involving both alleles of *RB* are required to produce retinoblastoma.
- In familial cases, children inherit one defective copy of *RB* (the first hit) and one normal copy of *RB* in the germline. Retinoblastoma develops when the normal *RB* allele is mutated in retinoblasts as a result of a spontaneous somatic mutation (the second hit). Because second hits seem to be virtually inevitable in a small fraction of retinoblasts, most individuals inheriting a germline defect in one *RB* allele develop unilateral or bilateral retinoblastoma, and the disease is inherited as an autosomal dominant trait.
- In sporadic cases both normal *RB* alleles must undergo somatic mutation in the same retinoblast (two hits). The probability of this event is low (explaining why retinoblastoma is uncommon in the general population), but the end result is the same: a retinal cell loses *RB* function and becomes cancerous.

A child carrying an inherited mutant *RB* allele in all somatic cells is perfectly normal (except for the increased risk of developing cancer); it follows that one defective *RB* gene does not have adverse effects on cell behavior. Thus, although the genetic trait (increased cancer risk) associated with germline *RB* mutations is inherited in an autosomal dominant fashion, at the level of individual cells the phenotype associated with *RB* loss of function behaves like a recessive trait.

Following the identification of *RB,* a large number of other tumor suppressor genes were discovered, often through study of other types of familial cancer. In general, the major themes that emerged from the study of familial retinoblastoma hold for other familial cancers: the risk of cancer is inherited as an autosomal dominant trait due to a germline mutation in a tumor suppressor gene; tumors have second "hits" in the sole normal tumor suppressor gene allele; and the same tumor suppressor gene is frequently mutated in sporadic tumors of the same type.

Some of the most important tumor suppressor genes, their associated familial syndromes, and their normal

Table 7.7 Selected Tumor Suppressor Genes and Associated Familial Syndromes and Cancers, Sorted by Cancer Hallmarks[a]

Gene	Protein	Function	Familial Syndromes	Sporadic Cancers
Inhibitors of Mitogenic Signaling Pathways				
APC	Adenomatous polyposis coli protein	Inhibitor of WNT signaling	Familial colonic polyps and carcinomas	Carcinomas of stomach, colon, pancreas; melanoma
NF1	Neurofibromin-1	Inhibitor of RAS/MAPK signaling	Neurofibromatosis type 1 (neurofibromas and malignant peripheral nerve sheath tumors)	Neuroblastoma, juvenile myeloid leukemia
NF2	Merlin	Cytoskeletal stability, Hippo pathway signaling	Neurofibromatosis type 2 (acoustic schwannoma and meningioma)	Schwannoma, meningioma
PTCH	Patched	Inhibitor of Hedgehog signaling	Gorlin syndrome (basal cell carcinoma, medulloblastoma, several benign tumors)	Basal cell carcinoma, medulloblastoma
PTEN	Phosphatase and tensin homologue	Inhibitor of PI3K/AKT signaling	Cowden syndrome (variety of benign skin, GI, and CNS growths; breast, endometrial, and thyroid carcinoma)	Diverse cancers, particularly carcinomas and lymphoid tumors
SMAD2, SMAD4	SMAD2, SMAD4	Component of the TGF-β signaling pathway, repressors of MYC and CDK4 expression, inducers of CDK inhibitor expression	Juvenile polyposis	Frequently mutated (along with other components of the TGF-β signaling pathway) in colonic and pancreatic carcinoma
Inhibitors of Cell Cycle Progression				
RB	Retinoblastoma (RB) protein	Inhibitor of G_1/S transition during cell cycle progression	Familial retinoblastoma syndrome (retinoblastoma, osteosarcoma, other sarcomas)	Retinoblastoma; osteosarcoma; carcinomas of breast, colon, lung
CDKN2A	p16/INK4a and p14/ARF	p16: Negative regulator of cyclin-dependent kinases; p14, indirect activator of p53	Familial melanoma	Pancreatic, breast, and esophageal carcinoma; melanoma; certain leukemias
Inhibitors of Pro-growth Programs of Metabolism and Angiogenesis				
VHL	von Hippel–Lindau (VHL) protein	Inhibitor of hypoxia-induced transcription factors (e.g., HIF1α)	von Hippel–Lindau syndrome (cerebellar hemangioblastoma, retinal angioma, renal cell carcinoma)	Renal cell carcinoma
STK11	Liver kinase B1 (LKB1) or STK11	Activator of AMPK family of kinases; suppresses cell growth when cell nutrient and energy levels are low	Peutz-Jeghers syndrome (GI polyps, GI cancers, pancreatic carcinoma, and other carcinomas)	Diverse carcinomas (5%–20% of cases, depending on type)
SDHB, SDHD	Succinate dehydrogenase complex subunits B and D	TCA cycle, oxidative phosphorylation	Familial paraganglioma, familial pheochromocytoma	Paraganglioma
Inhibitors of Invasion and Metastasis				
CDH1	E-cadherin	Cell adhesion, inhibition of cell motility	Familial gastric cancer	Gastric carcinoma, lobular breast carcinoma
Enablers of Genomic Stability				
TP53	p53 protein	Cell cycle arrest and apoptosis in response to DNA damage	Li-Fraumeni syndrome (diverse cancers)	Most human cancers
DNA Repair Factors				
BRCA1, BRCA2	Breast cancer-1 and breast cancer-2 (BRCA1 and BRCA2)	Repair of double-stranded breaks in DNA	Familial breast and ovarian carcinoma; carcinomas of male breast; chronic lymphocytic leukemia (BRCA2)	Rare
MSH2, MLH1, MSH6	MSH1, MLH1, MSH6	DNA mismatch repair	Hereditary nonpolyposis colon carcinoma	Colonic and endometrial carcinoma
Unknown Mechanisms				
WT1	Wilms tumor-1 (WT1)	Transcription factor	Familial Wilms tumor	Wilms tumor, certain leukemias
MEN1	Menin	Transcription factor	Multiple endocrine neoplasia-1 (MEN1) (pituitary, parathyroid, and pancreatic endocrine tumors)	Pituitary, parathyroid, and pancreatic endocrine tumors

[a]Some tumor suppressors impact multiple cancer phenotypes (e.g., p53 affects cell cycle progression, genomic stability, susceptibility to cell death, and cellular metabolism); only a subset of major effects are given for each tumor suppressor gene listed.

CNS, Central nervous system; *GI,* gastrointestinal; *TCA,* tricarboxylic acid.

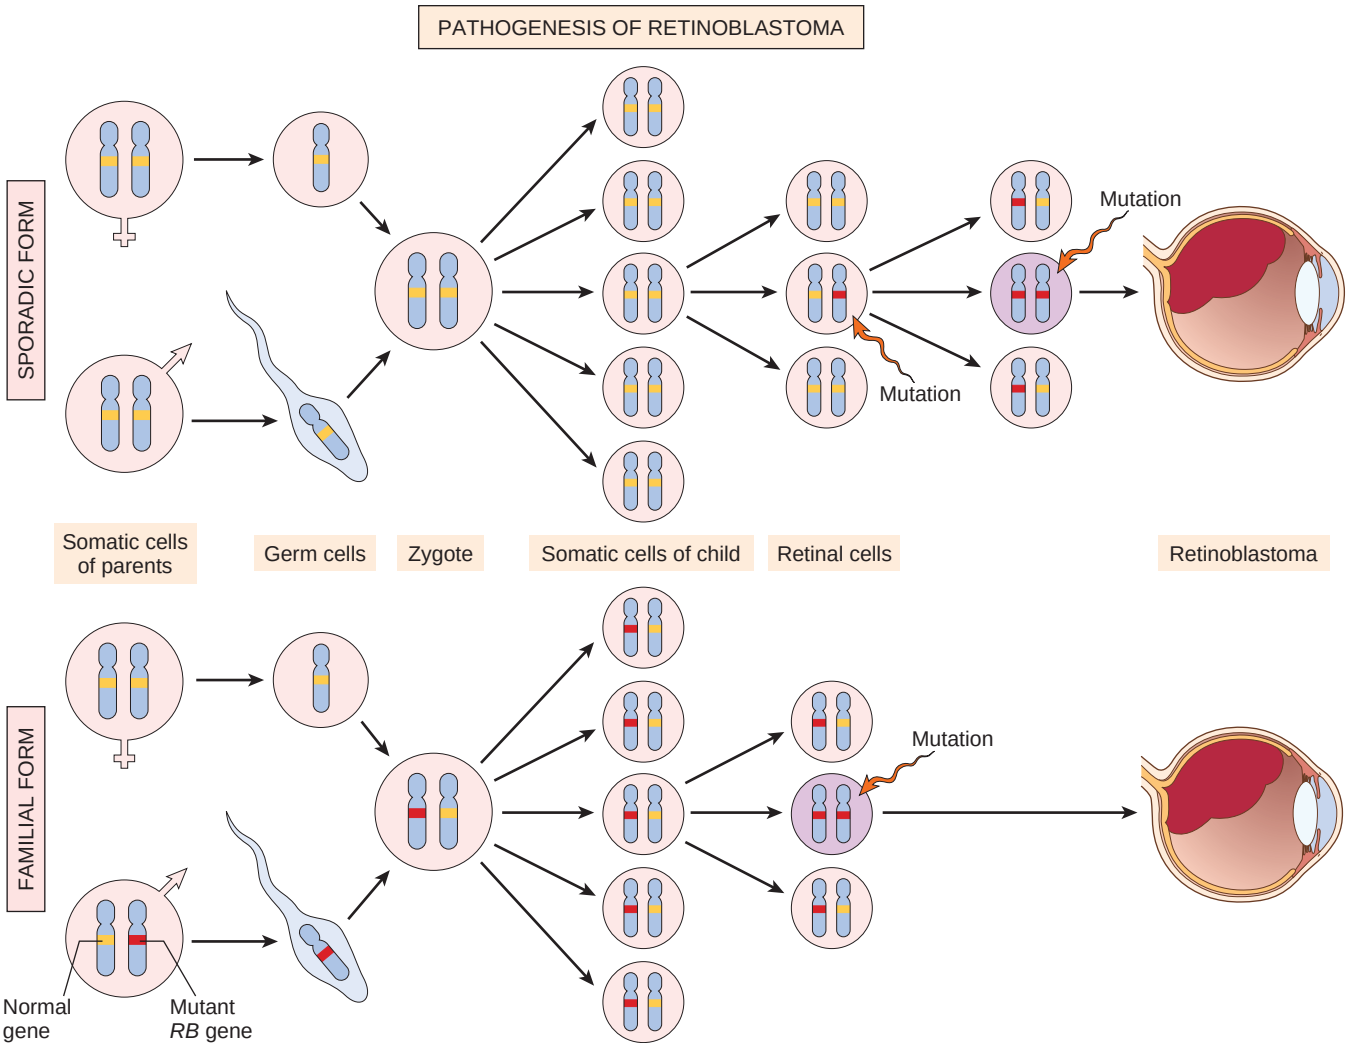

Figure 7.25 Pathogenesis of retinoblastoma. Two mutations of the *RB* locus on chromosome 13q14 lead to neoplastic proliferation of the retinal cells. In the sporadic form, both *RB* mutations in the tumor-founding retinal cell are acquired. In the familial form, all somatic cells inherit one mutated copy of *RB* gene from a carrier parent, and as a result only one additional *RB* mutation in a retinal cell is required for complete loss of RB function.

functions are listed in Table 7.7. Note that while tumor suppressors were initially thought of narrowly as proteins that put the brakes on cell cycle progression and DNA replication, it is now appreciated that some tumor suppressors prevent cellular transformation through other mechanisms such as by altering cell metabolism or by ensuring genomic stability. Thus, while most tumor suppressors have inhibitory effects on cell growth through one mechanism or another, a more inclusive definition of a tumor suppressor is simply a protein or gene that opposes any of the various hallmarks of cancer.

We next consider how specific tumor suppressors function, focusing on factors that are frequently mutated in cancer or that highlight pathogenically important molecular mechanisms.

RB: Governor of Proliferation. **RB, a key negative regulator of the G_1/S cell cycle transition, is directly or indirectly inactivated in most human cancers.** RB exists in an active hypophosphorylated state in quiescent cells and an inactive hyperphosphorylated state in cells passing through the G_1/S cell cycle transition (Chapter 1). Its function may be compromised in two different ways.

- Loss-of-function mutations involving both *RB* alleles.
- A shift from the active hypophosphorylated state to the inactive hyperphosphorylated state caused by gain-of-function mutations that upregulate CDK/cyclin D activity or by loss-of-function mutations that abrogate the activity of CDK inhibitors.

As discussed previously, the "decision" of a cell to progress from G_1 into S is of great importance, as once a cell enters S phase it is obligated to complete mitosis. High levels of CDK4/cyclin D, CDK6/cyclin D, and CDK2/cyclin E complexes lead to hyperphosphorylation and inhibition of RB, releasing E2F transcription factors that drive the expression of genes that are needed for progression to S phase (Fig. 7.26). Growth factor signaling pathways generally upregulate the activity of CDK/cyclin complexes and drive cells through the G_1/S transition, whereas growth inhibitors

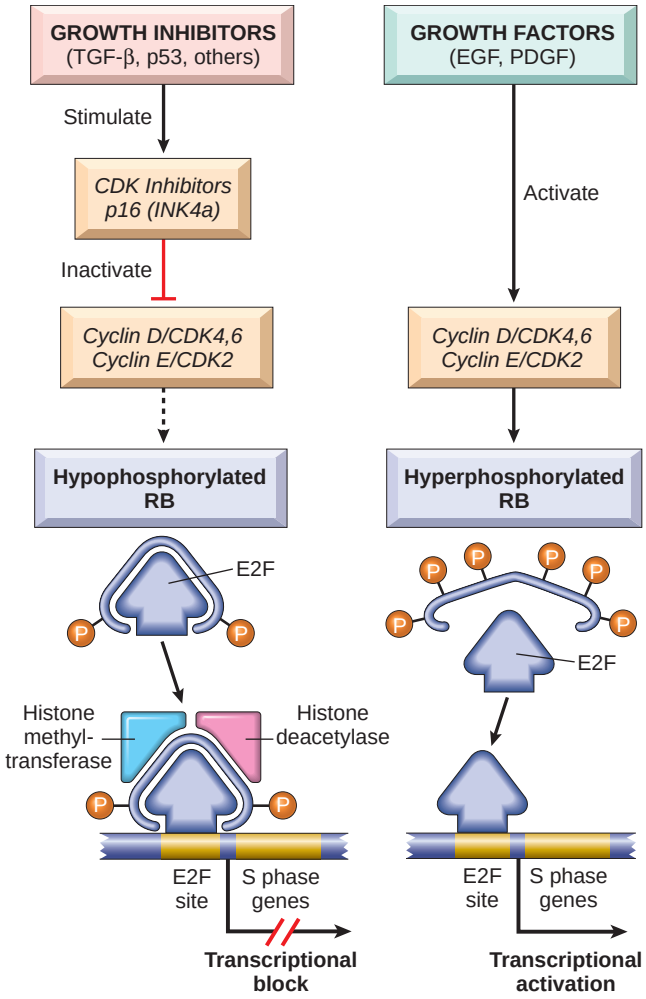

Figure 7.26 The role of RB in regulating the G_1-S checkpoint of the cell cycle. Hypophosphorylated RB in complex with the E2F transcription factors binds to DNA, recruits chromatin-modifying factors (histone deacetylases and histone methyltransferases), and inhibits transcription of genes whose products are required for the S phase of the cell cycle. When RB is phosphorylated by the cyclin D–CDK4, cyclin D–CDK6, and cyclin E–CDK2 complexes, it releases E2F. The latter then activates transcription of S-phase genes. Phosphorylation of RB is inhibited by cyclin-dependent kinase inhibitors because they inactivate cyclin–CDK complexes. In most cancers, the G_1-S checkpoint is defective as a result of mutation of one of four genes that regulate the phosphorylation of RB; these genes are *RB*, *CDK4*, the genes encoding cyclin D proteins, and *CDKN2A* (p16). *EGF,* Epidermal growth factor; PDGF, platelet-derived growth factor; *TGF-β,* transforming growth factor-β.

tip the balance the other way by upregulating CDK inhibitors. RB is the point of integration of these opposing signals, making it a key regulator of cell cycle progression.

It was mentioned previously that germline and somatic loss-of-function *RB* mutations are associated with retinoblastoma and osteosarcoma, and analyses of cancer cell genomes have identified similar somatic *RB* mutations in subsets of glioblastoma and lung, breast, and bladder carcinoma. However, given that RB is expressed in all cells, one may ask, why do patients with germline *RB* mutations preferentially develop retinoblastoma instead of other cancers? And, conversely, why are acquired mutations of *RB* not found in all kinds of cancer?

The reason why persons who inherit one defective allele of *RB* develop retinoblastoma and not other tumors is not understood, but a possible explanation is that other RB family members exist with RB-like activities; these proteins may fulfill the role of RB in cell types other than retinoblasts. With respect to the second question, the answer is much simpler: mutations in other genes that control RB phosphorylation can mimic the effect of *RB* loss, and such genes are mutated in many cancers that have normal *RB* genes. Thus, for example, mutational activation of cyclin D or CDK4 and mutational inactivation of CDK inhibitors favors cell proliferation by facilitating the hyperphosphorylation and inactivation of RB. The current paradigm is that **loss of normal cell cycle control is central to malignant transformation and that at least one of four key regulators of the cell cycle (p16/INK4a, cyclin D, CDK4, RB) is dysregulated in the vast majority of human cancers**. In cells that harbor mutations in any one of these genes or in upstream factors that regulate their expression and function (e.g., receptor tyrosine kinases, RAS), RB may be functionally inactivated even if the *RB* gene itself is not mutated.

The transforming proteins of several oncogenic animal and human DNA viruses also neutralize the growth inhibitory activities of RB. Of greatest relevance to human cancer, polyomavirus large T antigens and E7 proteins from high-risk types of HPV (such as HPV16) bind to hypophosphorylated RB through the same "pocket" that RB uses to bind and sequester E2F transcription factors. Binding of the viral proteins thus inactivates RB and releases E2F transcription factors, freeing them to cause cell cycle progression.

KEY CONCEPTS

RB, GOVERNOR OF THE CELL CYCLE

- When hypophosphorylated, RB exerts antiproliferative effects by binding and inhibiting E2F transcription factors that regulate genes required for cells to pass through the G_1/S phase cell cycle checkpoint. Normal growth factor signaling leads to RB hyperphosphorylation and inactivation, thus promoting cell cycle progression.
- The antiproliferative effect of RB is abrogated in cancers through a variety of mechanisms, including:
  - Loss-of-function *RB* mutations
  - Amplifications of the CDK4 and cyclin D genes
  - Loss-of-function mutations affecting cyclin-dependent kinase inhibitors (e.g., p16/INK4a)
  - Viral oncoproteins that bind and inhibit RB (E7 protein of HPV)

TP53: Guardian of the Genome. ***TP53,* a tumor suppressor gene that regulates cell cycle progression, DNA repair, cellular senescence, and apoptosis, is the most frequently mutated gene in human cancers.** Loss-of-function mutations in *TP53,* located on chromosome 17p13.1, are found in more than 50% of cancers. Moreover, *TP53* mutations occur in virtually every type of cancer, including carcinomas of the lung, colon, and breast—the three leading causes of cancer death. In most cases, mutations are present in both *TP53* alleles and are acquired in somatic cells (not inherited in

the germline). Less commonly, individuals inherit one mutated *TP53* allele. As in the case of the *RB* tumor suppressor and retinoblastoma, inheritance of a mutated copy of *TP53* predisposes individuals to malignant tumors because only one additional "hit" in the remaining normal allele is needed to abrogate *TP53* function. Individuals with these inherited mutations, said to have the *Li-Fraumeni syndrome,* have a 25-fold greater chance of developing a malignant tumor by age 50 than the general population. In contrast to individuals who inherit a mutant *RB* allele, the spectrum of tumors that develop in persons with Li-Fraumeni syndrome is broad; the most common types are sarcomas, breast cancers, leukemias, brain tumors, and carcinomas of the adrenal cortex. Persons with Li-Fraumeni syndrome often develop cancer at younger ages and are more likely to suffer from multiple primary tumors of varying types than are normal individuals.

These mutational data, while impressive, only begin to tell the tale of altered *TP53* function in cancer. *TP53* encodes the protein p53, which is tightly regulated at several levels. Analogous to RB, many tumors lacking *TP53* mutations have instead other mutations affecting proteins that regulate p53 function. For example, MDM2 and related proteins of the MDM2 family stimulate the degradation of p53; these proteins are frequently overexpressed in malignancies with normal *TP53* alleles. Indeed, the *MDM2* gene is amplified in 33% of human sarcomas, leading to a functional deficiency of p53 in these tumors. Like RB, the transforming proteins of several DNA viruses bind p53 and promote its degradation. Best known of these viral oncoproteins is the E6 protein of high-risk HPVs, which have causative roles in cervical carcinoma and a subset of squamous cell carcinomas of the head and neck.

The frequent loss of p53 function in human tumors reflects its critical role in preventing cancer development. p53 is the focal point of a large network of signals that sense cellular stress, primarily DNA damage, but also shortened telomeres, hypoxia, and stress caused by excessive pro-growth signaling, as may occur in cells bearing mutations in genes such as *RAS* and *MYC*. In nonstressed, healthy cells, p53 is held at bay through its aforementioned association with MDM2, an enzyme that ubiquitinates p53, leading to its degradation by the proteasome. As a result, p53 is virtually undetectable in normal cells. In stressed cells, however, p53 is released from the inhibitory effects of MDM2 via two major mechanisms, which vary depending on the nature of the stress.

- *DNA damage and hypoxia*. The key initiators of p53 activation following DNA damage or hypoxic stress are two related protein kinases, ataxia-telangiectasia mutated (ATM) and ataxia-telangiectasia and Rad3 related (ATR). As the name implies, *ATM* was originally identified in individuals with ataxia-telangiectasia, which is caused by germline mutations in *ATM*. Affected patients suffer from an inability to repair certain kinds of DNA damage and have an increased incidence of cancer. The types of damage sensed by ATM and ATR are different, but the downstream effects are similar. Once triggered, both ATM and ATR stimulate the phosphorylation of p53 and MDM2. These posttranslational modifications disrupt the binding and degradation of p53 by MDM2, allowing p53 to accumulate.
- *"Oncogenic" stress*. Activation of oncoproteins such as RAS leads to sustained, supraphysiologic signaling through pro-growth pathways such as the MAPK and PI3K/AKT cascades. Through incompletely understood mechanisms, these aberrant signals create cellular stress and lead to increased expression of p14/ARF, which is encoded by the *CDKN2A* tumor suppressor gene. p14/ARF binds MDM2 and displaces p53, again allowing p53 levels to rise in the cell.

Once activated, p53 thwarts neoplastic transformation by inducing transient cell cycle arrest, senescence (permanent cell cycle arrest), or programmed cell death (apoptosis) (Fig. 7.27). p53 is a transcription factor that binds DNA in a sequence-specific fashion and activates the transcription of hundreds of target genes with p53-binding regulatory elements. The target genes that execute the functions of p53 are not completely defined but appear to fall into three major categories: (1) genes that cause cell cycle arrest, (2) genes that cause apoptosis, and (3) genes that enhance catabolic metabolism or inhibit anabolic metabolism. The last group of genes makes intuitive sense; there is no need for a cell that has stopped its cell cycle progression to continue to synthesize macromolecules (e.g., lipids and proteins) that are needed for cell growth and division.

Once p53 accumulates in a cell to levels that are sufficient to activate the transcription of target genes, several different outcomes are possible, each more serious than the last with respect to the ultimate fate of the affected cell.

- *Transient p53-induced cell cycle arrest.* Rapid onset, p53-mediated cell cycle arrest may be considered a primordial response to DNA damage. It occurs late in G_1 phase and is caused in part by p53-dependent transcription of the *CDKN1A* gene, which encodes the CDK inhibitor p21. p21 (like p16) inhibits CDK4/D cyclin complexes, thereby maintaining RB in an active, hypophosphorylated state and blocking the progression of cells from G_1 phase to S phase. This pause in cell cycling is welcome, as it gives the cells "breathing time" to repair DNA damage. p53 also helps the process by inducing proteins such as GADD45 (growth arrest and DNA damage) that enhance DNA repair. If DNA damage is repaired successfully, the signals responsible for p53 stabilization cease and p53 levels fall, releasing the cell cycle block. The cells may then revert to a normal state.
- *p53-induced senescence.* Senescence is a state of permanent cell cycle arrest characterized by specific changes in morphology and gene expression that differentiate it from reversible cell cycle arrest. How cells become fixed in the senescence state is unclear. One plausible idea is that senescence is the product of epigenetic changes that result in the formation of heterochromatin at key loci, including genes that are required for progression of cells from G_1 phase to S phase. Like other p53 responses, senescence may be stimulated in response to a variety of stresses, such as unopposed oncogene signaling, hypoxia, and shortened telomeres. Senescent cells, while not normal, cannot divide and therefore cannot develop into tumors.
- *p53-induced apoptosis.* Apoptosis of cells with irreversible DNA damage is the ultimate protective mechanism against neoplastic transformation. p53 directs the transcription

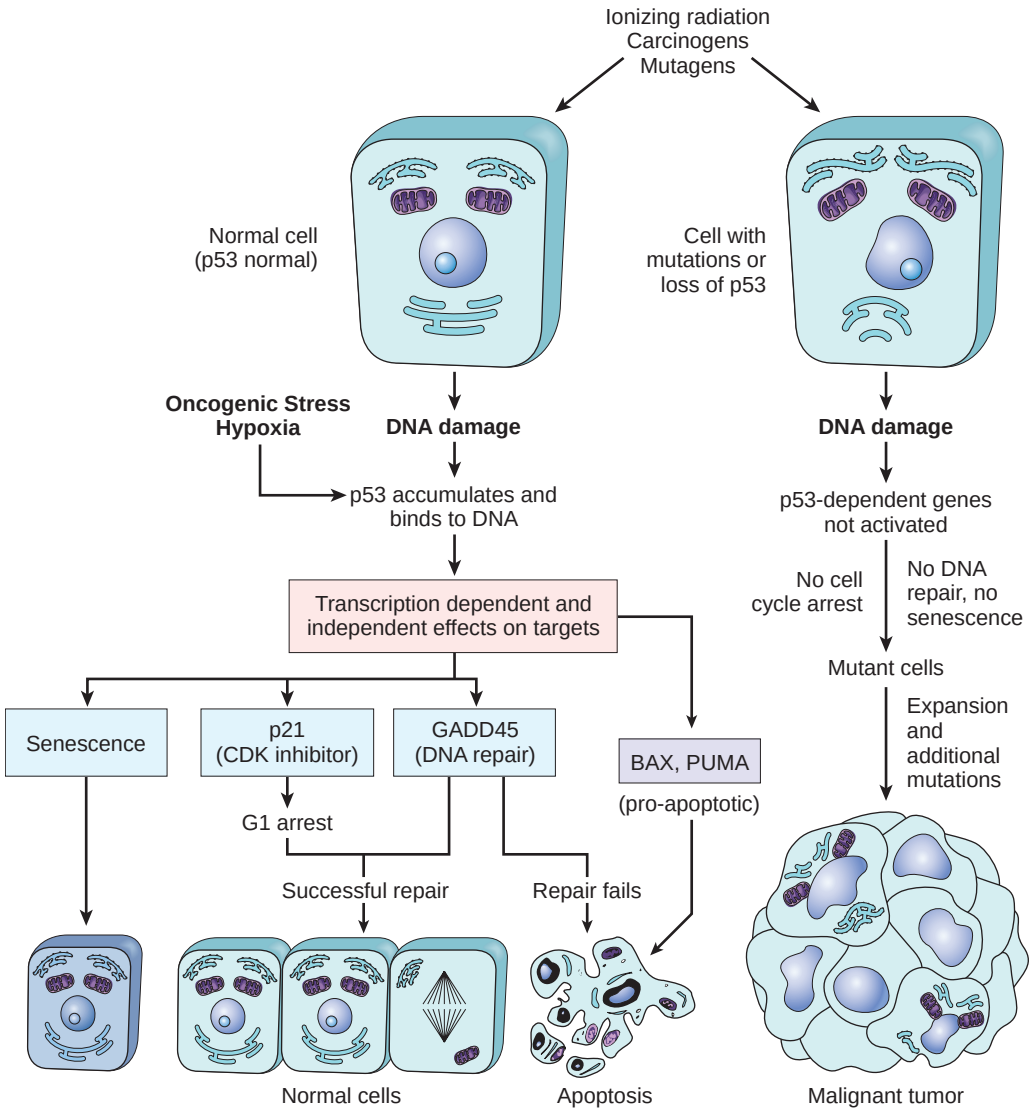

Figure 7.27 The role of p53 in maintaining the integrity of the genome. Activation of normal p53 by DNA-damaging agents or by hypoxia leads to cell cycle arrest in G_1 and induction of DNA repair by transcriptional upregulation of the cyclin-dependent kinase inhibitor *CDKN1A* (encoding the cyclin-dependent kinase inhibitor p21) and *GADD45* genes. Successful repair of DNA allows cells to proceed with the cell cycle; if DNA repair fails, p53 triggers either apoptosis or senescence. In cells with loss or mutations of the p53 gene, DNA damage does not induce cell cycle arrest or DNA repair, and genetically damaged cells proliferate, giving rise eventually to malignant neoplasms.

of several pro-apoptotic genes such as *BAX* and *PUMA* (described later), which are believed to tip the balance in favor of cell death via the intrinsic (mitochondrial) pathway.

What determines whether a cell repairs its DNA, becomes senescent, or undergoes apoptosis is uncertain, but both the duration and the level of p53 activation may be deciding factors. It appears that the affinity of p53 for its binding sites in the promoters and enhancers of DNA repair genes is higher than its affinity for binding sites in pro-apoptotic genes. Thus the DNA repair pathway is stimulated first as p53 begins to accumulate. If p53 is sustained at this level due to ineffective DNA repair or other chronic stresses (e.g., that induced by a potentially oncogenic RAS mutation), epigenetic silencing of genes that are needed for cell cycle progression occurs, leading to senescence. Alternatively, if enough p53 accumulates to stimulate the transcription of the pro-apoptotic genes, the cell dies. While this scheme seems to be generally correct, cell type–specific variations in response to p53 activation have been observed that are not easily explained, with some cell types succumbing rapidly to apoptosis and others opting mainly for senescence. Thus there is still much to be learned about the nuances of p53 function.

With loss of p53 function, DNA damage goes unrepaired, driver mutations accumulate in oncogenes and other cancer genes, and the cell marches along a dangerous path leading to malignant transformation. Moreover, once a cancer is established, its p53 status has important therapeutic implications. Irradiation and conventional chemotherapy, the two common modalities of cancer treatment, mediate their effects

by inducing DNA damage and subsequent apoptosis. Tumors with wild-type *TP53* alleles are more likely to be killed by such therapy than tumors with mutated *TP53* alleles. Such is the case with testicular germ cell tumors and childhood acute lymphoblastic leukemias, cancers with excellent clinical outcomes that usually have wild-type *TP53* alleles. In contrast, tumors such as lung cancers and colorectal cancers, which frequently carry *TP53* mutations, are relatively resistant to chemotherapy and irradiation. A second, less obvious but even more nefarious effect is that cells with defective p53 acquire a mutator phenotype, a tendency to acquire mutations at a high rate. Particularly in advanced stage tumors with mutator phenotypes, it is very likely (and perhaps inevitable) that genetically distinct subclones will arise by chance that are resistant to any single therapy, whether radiation, conventional chemotherapy, or molecularly targeted cancer drugs. This theme is discussed later when the enabling properties of genomic instability are discussed more broadly.

KEY CONCEPTS

P53, GUARDIAN OF THE GENOME

- The p53 protein is the central monitor of stress in the cell and can be activated by anoxia, inappropriate signaling by mutated oncoproteins, or DNA damage. p53 controls the expression and activity of proteins involved in cell cycle arrest, DNA repair, cellular senescence, and apoptosis.
- DNA damage is sensed by complexes containing kinases of the ATM/ATR family; these kinases phosphorylate p53, liberating it from inhibitors such as MDM2. Active p53 then upregulates the expression of proteins such as the cyclin-dependent kinase inhibitor p21, thereby causing cell-cycle arrest at the G_1/S checkpoint. This pause allows cells to repair DNA damage.
- If DNA damage cannot be repaired, p53 induces additional events that lead to cellular senescence or apoptosis.
- The majority of human cancers demonstrate biallelic loss-of-function mutations in *TP53*. Rare patients with Li-Fraumeni syndrome inherit one defective copy of *TP53* and have a very high incidence of a wide variety of cancers.
- Like RB, p53 is inactivated by viral oncoproteins, such as the E6 protein of HPV.

Other Tumor Suppressor Genes. The full panoply of tumor suppressor genes is still being defined. Often, they are disabled because they are the targets of recurrent chromosomal deletions, which are now being systematically identified and characterized by sequencing of cancer genomes. Tumor suppressor genes all appear to impact one or more of the hallmarks of cancer. Some that are associated with well-defined clinical syndromes (Table 7.7) or that serve to highlight mechanisms by which tumor suppressors function are described next; others that are organ- or tumor-specific are mentioned in the relevant chapters that follow.

APC: Gatekeeper of Colonic Neoplasia. **Adenomatous polyposis coli (APC) is a member of the class of tumor suppressors that function by downregulating growth-promoting signaling pathways.** Germline loss-of-function mutations involving the *APC* locus on chromosome 5q21 are associated with *familial adenomatous polyposis*, an autosomal dominant disorder in which individuals inheriting one mutant allele develop thousands of adenomatous polyps in the colon during their teens or 20s (Chapter 17). Almost invariably, one or more of these polyps undergoes malignant transformation, giving rise to colon cancer. As with other tumor suppressor genes, both copies of *APC* must be lost for an adenoma to arise. As discussed later, several additional mutations must then occur for adenomas to progress to cancers. In addition to these hereditary forms of colon cancer, 70% to 80% of nonfamilial colorectal carcinomas and sporadic adenomas also show acquired defects involving both APC genes, firmly implicating APC loss of function in the pathogenesis of colonic tumors.

APC is a component of the WNT signaling pathway, which has a major role in controlling cellular growth and differentiation during embryonic development (Fig. 7.28). WNT molecules signal by binding to cell surface receptors of the frizzled (FRZ) family. This stimulates several pathways, the central one involving APC and β-catenin. A major function of the APC protein is to hold β-catenin activity in check. In the absence of WNT signaling, APC participates in the formation a "destruction complex" that leads to the proteasomal degradation of β-catenin. WNT signaling blocks the formation of the destruction complex, stabilizing β-catenin and allowing it to translocate from the cytoplasm to the nucleus. Here, it forms a transcription activation complex with a DNA-binding factor called TCF that promotes the growth of colonic epithelial cells by increasing the expression of *MYC, cyclin D1,* and other genes. Because loss of APC function disrupts the destruction complex, cells that lose APC behave as if they are being continuously stimulated by WNT and show elevated expression of genes that are regulated by β-catenin. The importance of the β-catenin complex in tumorigenesis is attested to by the fact that many colon tumors with normal *APC* genes harbor β-catenin mutations that prevent its APC-dependent destruction, again leading to its accumulation and increased expression of β-catenin–dependent target genes. Thus β-catenin, the target of APC, is itself a proto-oncoprotein. Dysregulation of the APC/β-catenin pathway is not restricted to colon cancers; for example, gain-of-function mutations in β-catenin are present in approximately 20% of hepatocellular carcinomas.

E-Cadherin. β-catenin also binds to the cytoplasmic tail of E-cadherin, a cell surface protein that maintains intercellular adhesiveness. Loss of cell-cell contact, such as following epithelial wounding or injury, disrupts the interaction between E-cadherin and β-catenin. Like WNT signaling, this in turn allows β-catenin to translocate to the nucleus and stimulate genes that promote proliferation, an appropriate response to injury that can help repair a wound. Reestablishment of these E-cadherin contacts as the wound heals leads to sequestration of β-catenin at the membrane and reduces proliferative signaling; these cells are said to be "contact-inhibited." Loss of contact inhibition, by mutation of the E-cadherin/β-catenin axis or by other changes, is a characteristic of many carcinomas. Furthermore, loss of E-cadherin can contribute to the malignant phenotype by allowing easy disaggregation of cells, which can then invade locally or metastasize. Reduced cell surface expression of E-cadherin has been noted in many carcinomas including

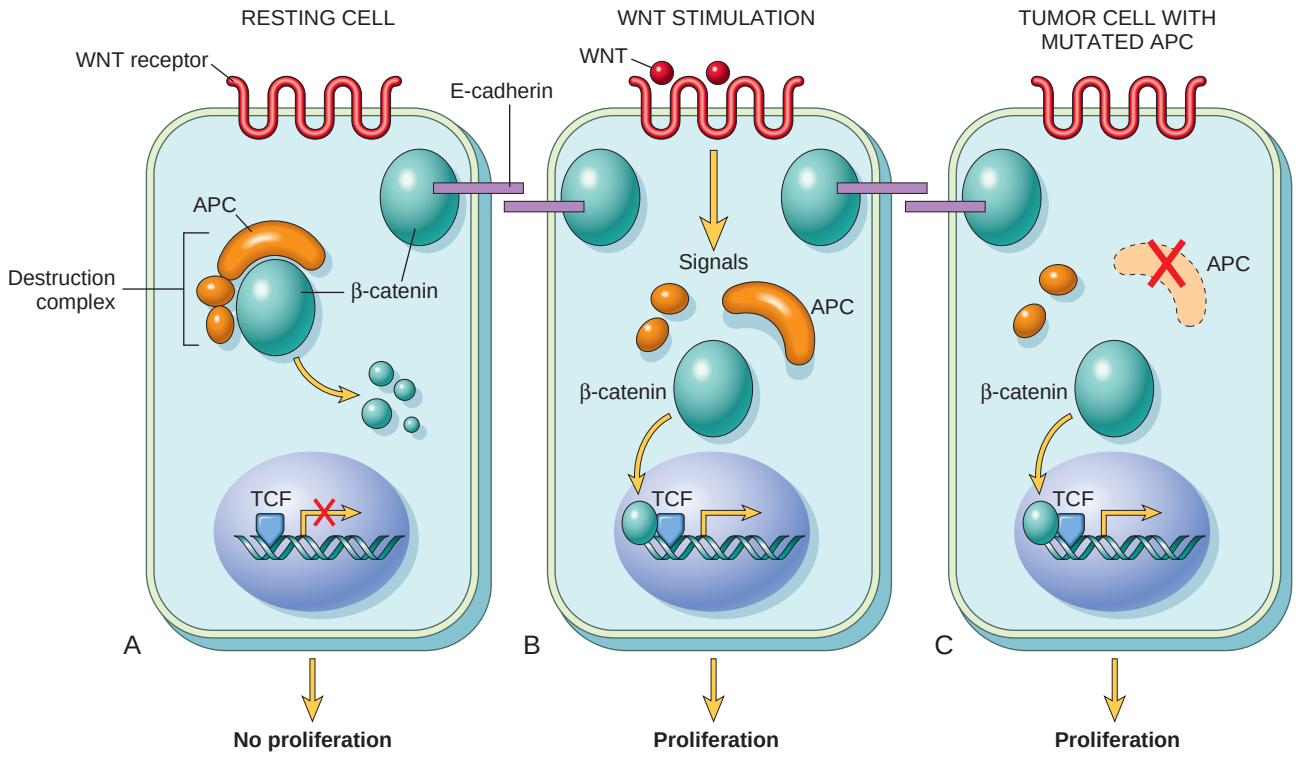

Figure 7.28 The role of adenomatous polyposis coli *(APC)* in regulating the stability and function of β-catenin. APC and β-catenin are components of the WNT signaling pathway. (A) In resting colonic epithelial cells (not exposed to WNT), β-catenin forms a macromolecular complex containing the APC protein. This complex leads to the destruction of β-catenin, and intracellular levels of β-catenin are low. (B) When normal colonic epithelial cells are stimulated by WNT molecules, the *destruction complex* is deactivated, β-catenin degradation does not occur, and cytoplasmic levels increase. β-Catenin translocates to the nucleus, where it binds to TCF, a transcription factor that activates genes involved in cell cycle progression. (C) When *APC* is mutated or absent, as frequently occurs in colonic polyps and cancers, the destruction of β-catenin cannot occur. β-Catenin translocates to the nucleus and coactivates genes that promote entry into the cell cycle, and cells behave as if they are under constant stimulation by the WNT pathway.

those that arise in the esophagus, colon, breast, ovary, and prostate. Germline loss-of-function mutations of the E-cadherin gene, known as *CDH1,* are associated with familial gastric carcinoma, and a proportion of sporadic gastric carcinomas are also associated with loss of E-cadherin expression, which can occur due to mutation of the *CDH1* gene or other indirect mechanisms.

CDKN2A. As mentioned earlier, the *CDKN2A* gene encodes two protein products: the p16/INK4a cyclin-dependent kinase inhibitor, which blocks CDK4/cyclin D–mediated phosphorylation of RB, thereby reinforcing the G_1/S checkpoint; and p14/ARF, which activates the p53 pathway by inhibiting MDM2 and preventing destruction of p53. p16 also appears to be important in induction of cellular senescence (described later). Germline mutations in *CDKN2A* are associated with familial forms of melanoma, and sporadic mutations of this locus have been detected in bladder cancer, head and neck tumors, acute lymphoblastic leukemia, and cholangiocarcinoma. In some tumors, such as cervical cancer, p16 is often silenced by hypermethylation of the gene rather than mutation (see "Epigenetic Changes"). Other cyclin-dependent kinase inhibitors also function as tumor suppressors and are frequently mutated or otherwise silenced in many human malignancies.

TGF-β Pathway. In most normal epithelial, endothelial, and hematopoietic cells, TGF-β is a potent inhibitor of proliferation. It regulates cellular processes by binding to TGF-β receptors, thereby stimulating intracellular signals that involve transcriptional regulators of the SMAD protein family. Under normal circumstances, these signals turn on antiproliferative genes (e.g., genes for cyclin-dependent kinase inhibitors) and turn off genes that drive cell growth (e.g., *MYC,* cyclins, and cyclin-dependent kinases). As can be inferred from our earlier discussion, these changes result in decreased phosphorylation of RB and cell cycle arrest.

In many forms of cancer these growth-inhibiting effects are impaired by loss-of-function mutations in the TGF-β signaling pathway. Mutations affecting TGF-β receptors are common in cancers of the colon, stomach, and endometrium, while mutational inactivation of SMAD4 is common in pancreatic cancers. In many other cancers, loss of TGF-β–mediated growth inhibition occurs at the level of key target genes; examples include mutations that lead to loss of p21 function and/or persistent expression of *MYC*. In such cases, other preserved elements of the TGF-β–induced program of gene expression may actually facilitate acquisition of cancer hallmarks, such as immune evasion or angiogenesis. Thus TGF-β signaling is a double-edged sword that can prevent or promote tumor growth, depending on the state of other genes in the cell.

PTEN. Phosphatase and tensin homologue (PTEN) is a membrane-associated phosphatase encoded by a gene on chromosome 10q23 that is mutated in Cowden syndrome,

an autosomal dominant disorder marked by frequent benign growths such as skin appendage tumors and an increased incidence of epithelial cancers, particularly of the breast (Chapter 21), endometrium, and thyroid. As already mentioned, PTEN acts as a tumor suppressor by serving as a brake on the PI3K/AKT signaling cascade. *PTEN* gene function is lost in many cancers through deletion, deleterious point mutations, or epigenetic silencing.

VHL. Germline loss-of-function mutations of the von Hippel–Lindau *(VHL)* gene on chromosome 3p are associated with hereditary renal cell carcinoma and several other tumors and proliferations. Somatic mutations of *VHL* also occur in a subset of sporadic renal cell carcinomas (Chapter 20). VHL is a component of a protein complex that covalently links ubiquitin chains to specific protein substrates, thereby promoting their degradation by the proteasome. A critical substrate for the VHL ubiquitin ligase is the transcription factor hypoxia-inducible transcription factor 1α (HIF1α). In the presence of oxygen, HIF1α is hydroxylated and binds to VHL, leading to its ubiquitination and degradation. In hypoxic environments the hydroxylation reaction does not occur, and HIF1α escapes recognition by VHL. As a result, HIF1α accumulates in the nuclei of hypoxic cells and turns on target genes, including genes encoding vascular endothelial growth factor (VEGF), a critical angiogenesis factor; PDGF, a potent mitogen; and the glucose transporter GLUT1 and several glycolytic enzymes, factors that contribute to Warburg metabolism (described later). Thus, VHL is part of the system that regulates cellular responses to oxygen levels. Loss-of-function mutations in *VHL* prevent the ubiquitination and degradation of HIF1α, even under normoxic conditions, and are accordingly associated with increased levels of angiogenic growth factors and alterations in cellular metabolism that favor growth.

STK11. The *STK11* gene, also known as *LKB1,* encodes a serine/threonine kinase that is an important regulator of cellular metabolism. Germline loss-of-function *STK11* mutations cause Peutz-Jeghers syndrome, an autosomal dominant disorder associated with benign polyps of the gastrointestinal tract and an increased risk of multiple epithelial cancers, particularly gastrointestinal and pancreatic carcinomas. STK11 has pleiotropic effects on multiple facets of cellular metabolism including glucose uptake, gluconeogenesis, protein synthesis, mitochondrial biogenesis, and lipid metabolism. Sporadic *STK11* loss-of-function mutations are found in diverse carcinomas, a finding pointing to the important role of altered cellular metabolism in the establishment and maintenance of the transformed state (discussed later).

KEY CONCEPTS

MECHANISM OF ACTION OF MAJOR TUMOR SUPPRESSOR GENES

APC: encodes a factor that negatively regulates the WNT pathway in colonic epithelium by promoting the formation of a complex that degrades β-catenin.
- Germline loss-of-function mutations cause familial adenomatous polyposis, an autosomal dominant disorder associated with development of thousands of colonic polyps and early-onset colon carcinoma.
- Acquired somatic *APC* mutations are found in about 70% of sporadic colon carcinomas.

E-cadherin: cell adhesion molecule that plays an important role in contact-mediated growth inhibition of epithelial cells; also binds and sequesters β-catenin, a signaling protein that functions in the WNT pathway.
- Germline loss-of-function mutations in the E-cadherin gene *(CDH1)* cause autosomal dominant familial gastric carcinoma.
- Loss of *CDH1* expression is seen in many sporadic carcinomas; these are associated with loss of contact inhibition, loss of cohesiveness, increased invasiveness, and increased WNT signaling.

CDKN2A: a complex locus that encodes two tumor suppressive proteins, p16/INK4a, a cyclin-dependent kinase inhibitor that augments RB function, and ARF, which stabilizes p53.
- Germline loss-of-function mutations cause autosomal dominant familial melanoma.
- Biallelic loss of function is seen in diverse cancers including leukemias, melanomas, and carcinomas.

TGF-β pathway: potent inhibitor of cellular proliferation in normal tissues.
- Frequent loss-of-function mutations involving TGF-β receptors (colon, stomach, endometrium) or downstream signal transducers (SMADs, pancreas) in diverse carcinomas.
- Complex role in carcinogenesis; may also have a pro-oncogenic role by enhancing the immune evasiveness of tumors.

PTEN: encodes a lipid phosphatase that is an important negative regulator of PI3K/AKT signaling.
- Germline loss-of-function mutations cause Cowden syndrome, an autosomal dominant disorder associated with a high risk of breast and endometrial carcinoma.
- Biallelic loss of function common in diverse cancers.

VHL: encodes a component of a ubiquitin ligase complex that is responsible for degradation of hypoxia-induced factors (HIFs), transcription factors that alter gene expression in response to hypoxia.
- Germline loss-of-function mutations cause von Hippel–Lindau syndrome, an autosomal dominant disorder associated with a high risk of renal cell carcinoma and pheochromocytoma.
- Acquired biallelic loss-of-function mutations are common in sporadic renal cell carcinoma.

Growth-Promoting Metabolic Alterations: The Warburg Effect

Even in the presence of ample oxygen, cancer cells demonstrate a distinctive form of cellular metabolism characterized by high levels of glucose uptake and increased conversion of glucose to lactose (fermentation) via the glycolytic pathway. This phenomenon, called the *Warburg effect* and also known as *aerobic glycolysis,* has been recognized for many years (Otto Warburg received the Nobel Prize in 1931 for discovery of the effect that bears his name). Clinically the "glucose hunger" of tumors is used to visualize them via positron emission tomography (PET) scanning, in which patients are injected with ^{18}F-fluorodeoxyglucose, a nonmetabolizable derivative of glucose that is preferentially taken up into tumor cells (as well as normal, actively dividing

tissues such as the bone marrow). Most tumors are PET-positive, and rapidly growing ones are markedly so.

At the heart of the Warburg effect lies a simple question: why is it advantageous for a cancer cell to rely on seemingly inefficient glycolysis (which generates two molecules of ATP per molecule of glucose) instead of oxidative phosphorylation (which generates 36 molecules of ATP per molecule of glucose)? While pondering this question, it is important to recognize that rapidly growing normal cells, such as in embryonic tissues, also rely on aerobic fermentation. Thus, "Warburg metabolism" is not cancer-specific, but instead is a general property of growing cells that is exploited by cancer cells.

The answer to this riddle is surprisingly simple: **aerobic glycolysis provides rapidly dividing tumor cells with metabolic intermediates that are needed for the synthesis of cellular components, whereas mitochondrial oxidative phosphorylation does not.** The reason growing cells rely on aerobic glycolysis becomes readily apparent when one considers that a growing cell has a strict biosynthetic requirement; it must duplicate all of its cellular components—DNA, RNA, proteins, lipid, and organelles—before it can divide and produce two daughter cells. Recall that the net effect of oxidative phosphorylation is to take a molecule of glucose, $C_6H_{12}O_6$, and combine it with six molecules of O_2 to produce six molecules of H_2O and six molecules of CO_2, which are lost through respiration. Thus, while "pure" oxidative phosphorylation yields abundant ATP, it fails to produce any carbon moieties that can be used to build cellular components that are needed for growth (proteins, lipids, and nucleic acids). Even cells that are not actively growing must shunt some metabolic intermediates away from oxidative phosphorylation to synthesize macromolecules that are needed for cellular maintenance.

By contrast, in actively growing cells, only a small fraction of the cellular glucose is shunted through the oxidative phosphorylation pathway, such that on average each molecule of glucose that is metabolized produces approximately four molecules of ATP (instead of the two molecules that would be produced by "pure" glycolysis). Presumably, this balance in glucose utilization (heavily biased toward aerobic fermentation, with a bit of oxidative phosphorylation) hits a metabolic "sweet spot" that is optimal for growth. It follows that growing cells do rely on mitochondrial metabolism. However, the main metabolic function of mitochondria in growing cells is not to generate ATP, but rather to carry out reactions that generate intermediates that can be diverted for use as precursors in the synthesis of cellular building blocks. For example, lipid biosynthesis requires acetyl coenzyme A (acetyl-CoA), and acetyl-CoA is largely synthesized in growing cells from intermediates such as citrate that are generated in mitochondria.

So how is this reprogramming of metabolism triggered in growing normal and malignant cells? As might be guessed, **metabolic reprogramming is produced by signaling cascades downstream of growth factor receptors, the very same pathways that are deregulated by mutations in oncogenes and tumor suppressor genes in cancers.** Thus, whereas in rapidly growing normal cells aerobic glycolysis ceases when the tissue is no longer growing, in cancer cells this reprogramming persists due to the action of oncogenes and the loss of tumor suppressor gene function. Some of the important points of crosstalk between pro-growth signaling factors and cellular metabolism are shown in Fig. 7.29 and include the following:

- *Receptor tyrosine kinase/PI3K/AKT signaling.* PI3K/AKT signaling upregulates the activity of glucose transporters and multiple glycolytic enzymes, thus increasing glycolysis; promotes shunting of mitochondrial intermediates to pathways leading to lipid biosynthesis; and stimulates factors that are required for protein synthesis. In addition, receptor tyrosine kinases phosphorylate and inhibit pyruvate kinase, which catalyzes the last step in the glycolytic pathway, the conversion of phosphoenolpyruvate to pyruvate. This creates a damming effect that leads to the buildup of upstream glycolytic intermediates, which are siphoned off for synthesis of DNA, RNA, and protein.
- *MYC.* As mentioned, pro-growth pathways upregulate expression of the transcription factor MYC, which drives changes in gene expression that support anabolic metabolism and cell growth. Among the most important metabolic factors that are upregulated by MYC are multiple glycolytic enzymes and glutaminase, which is required for mitochondrial utilization of glutamine, another important source of intermediates needed for biosynthesis of cellular components.

The flip side of the coin is that tumor suppressors often inhibit metabolic pathways that support growth. We have already discussed how the STK11 tumor suppressor antagonizes metabolic changes that produce Warburg metabolism. Indeed, it may be that many (and perhaps all) tumor suppressors that induce growth arrest suppress the Warburg effect. For example, p53, arguably the most important tumor suppressor, upregulates target genes that collectively inhibit glucose uptake, glycolysis, lipogenesis, and the generation of NADPH (a key cofactor needed for the biosynthesis of macromolecules). Thus, it is clear that the functions of many oncoproteins and tumor suppressors are inextricably intertwined with cellular metabolism.

Autophagy. Autophagy is a state of severe nutrient deficiency in which cells not only arrest their growth but also cannibalize their own organelles, proteins, and membranes as carbon sources for energy production (see Fig. 7.29 and Chapter 2). If this adaptation fails, the cells die of starvation. Tumor cells often seem to be able to grow under marginal environmental conditions without triggering autophagy, suggesting that the pathways that induce autophagy are disabled. In keeping with this, several genes that promote autophagy are tumor suppressors, meaning that the loss of autophagy enhances tumor growth. Whether autophagy is always bad from the vantage point of the tumor, however, is a matter of active investigation and debate. For example, under conditions of severe nutrient deprivation, tumor cells may use autophagy to become "dormant," a state of metabolic hibernation that allows cells to survive hard times for long periods. Such cells are believed to be resistant to therapies that kill actively dividing cells and could therefore be responsible for therapeutic failures. Thus, autophagy may be a tumor's friend or foe depending on how the signaling pathways that regulate it are "wired" in a given tumor.

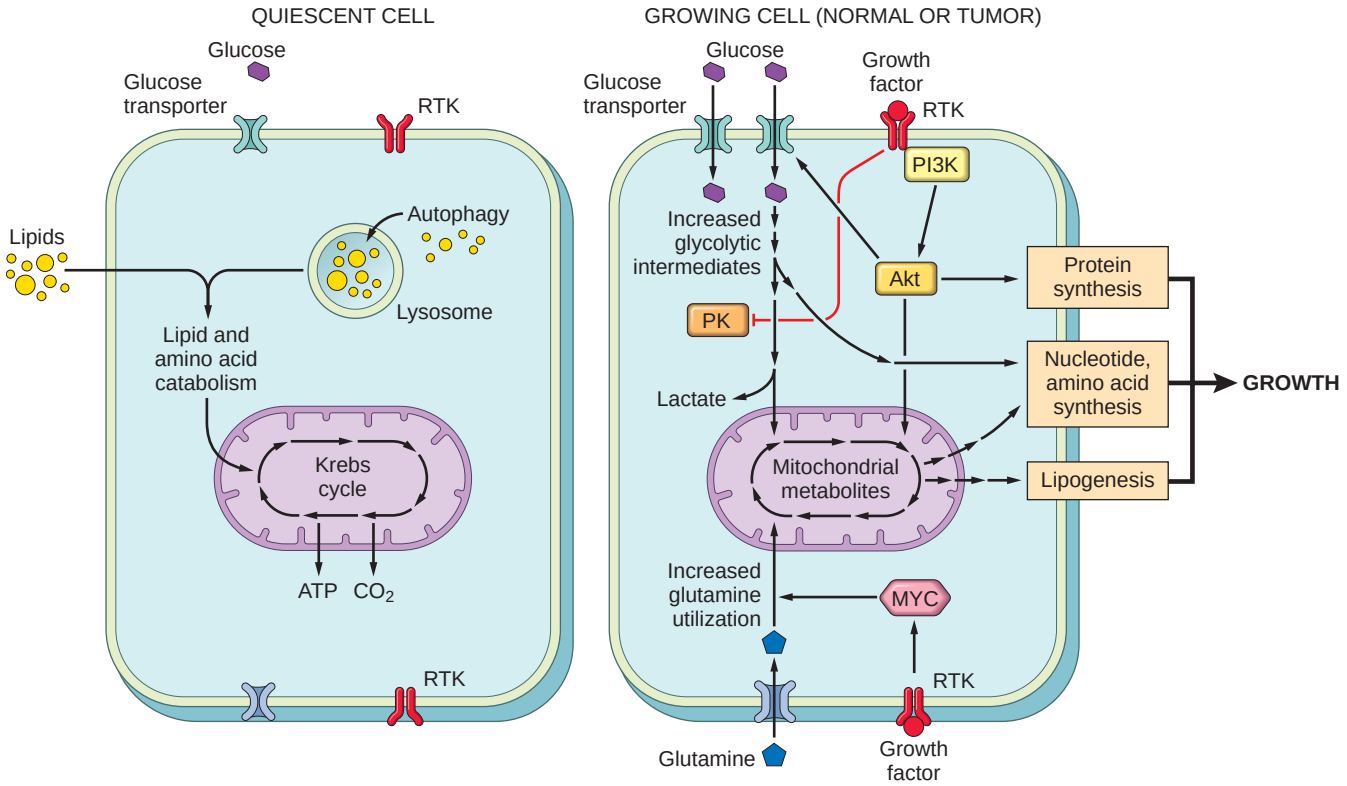

Figure 7.29 Metabolism and cell growth. Quiescent cells rely mainly on the Krebs cycle for adenosine triphosphate *(ATP)* production; if starved, autophagy (self-eating) is induced to provide a source of fuel. When stimulated by growth factors, normal cells markedly upregulate glucose and glutamine uptake, yielding glycolytic and Krebs cycle metabolic intermediates that provide carbon sources for synthesis of nucleotides, proteins, and lipids. In cancers, oncogenic mutations involving growth factor signaling pathways and other key factors such as MYC deregulate these metabolic pathways.

Oncometabolism. A surprising group of genetic alterations discovered through tumor genome sequencing studies consists of mutations in enzymes that participate in the Krebs cycle. Of these, mutations in isocitrate dehydrogenase (IDH) have garnered the most interest, as they have revealed a new mechanism of oncogenesis termed *oncometabolism* (Fig. 7.30).

The proposed steps in the oncogenic pathway involving IDH are as follows:

- IDH acquires a mutation that leads to a specific amino acid substitution involving residues in its active site. As a result, the mutated protein loses it IDH function and instead acquires a new enzymatic activity that catalyzes the production of 2-hydroxyglutarate (2-HG).
- 2-HG in turn acts as an inhibitor of several other enzymes that require a metabolite called α-ketoglutarate as a cofactor. Among the proteins that are inhibited by 2-HG are several members of the TET family, including TET2.
- TET2 is one of several factors that enhance DNA methylation, which you will recall is an epigenetic modification that controls normal gene expression and often goes awry in cancer. According to the model, loss of TET2 activity leads to abnormal patterns of DNA methylation.
- Abnormal DNA methylation in turn leads to misexpression of cancer genes, which drive cellular transformation and oncogenesis. Some data suggest that the net effect of TET2 loss in lineages in which TET2 is a tumor suppressor is the upregulation of RAS and receptor tyrosine kinase signaling.

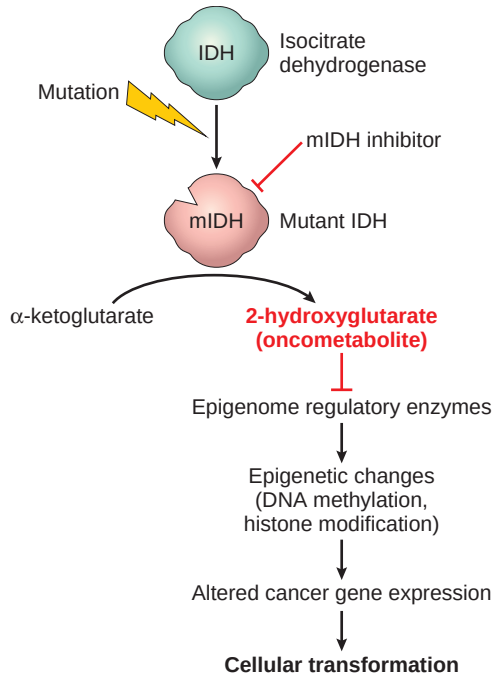

Figure 7.30 Proposed action of the oncometabolite 2-hydroxyglutarate in cancer cells with mutated isocitrate dehydrogenase *(mIDH)*. *IDH*, Isocitrate dehydrogenase.

Thus, according to this scenario, mutated IDH acts by producing 2-HG, which is considered a prototypical *oncometabolite*. Oncogenic IDH mutations occur in a diverse collection of cancers including a sizable fraction of cholangiocarcinomas, gliomas, acute myeloid leukemias, and sarcomas. Of clinical significance, because the mutated IDH proteins have an altered structure, it has been possible to develop drugs that inhibit mutated IDH and not the normal IDH enzyme. These drugs are now being used to treat leukemias with IDH mutations. This story exemplifies how detailed understanding of oncogenic mechanisms can yield entirely new kinds of anticancer drugs.

KEY CONCEPTS

ALTERED CELLULAR METABOLISM

- Warburg metabolism is a form of pro-growth metabolism favoring glycolysis over oxidative phosphorylation. It is induced in normal cells by exposure to growth factors and becomes fixed in cancer cells due to the action of certain driver mutations.
- Many oncoproteins (RAS, MYC, mutated growth factor receptors) induce or contribute to Warburg metabolism, and many tumor suppressors (*PTEN*, *NF1*, *p53*) oppose it.
- Stress may induce cells to consume their components in a process called autophagy. Cancer cells may accumulate mutations to avoid autophagy or may corrupt the process to provide nutrients for continued growth and survival.
- Some oncoproteins such as mutated IDH act by causing the formation of high levels of "oncometabolites" that alter the epigenome, thereby leading to changes in gene expression that are oncogenic.

Evasion of Cell Death

Tumor cells frequently contain mutations in genes that result in resistance to apoptotic cell death. As discussed in Chapter 2, apoptosis, or regulated cell death, refers to an orderly dismantling of cells into component pieces, which are then efficiently consumed by macrophages without stimulating inflammation. You will recall there are two pathways that lead to apoptosis: (1) the extrinsic (death receptor) pathway, triggered by death receptors of the tumor necrosis factor (TNF) receptor family, such as FAS, and their ligands; and (2) the intrinsic (mitochondrial) pathway, initiated by various stresses, such as the absence of growth factors and DNA damage. The intrinsic pathway appears to be the primary arbitrator of life and death in cancer cells, as cancer cells are subject to a number of intrinsic stresses that can initiate apoptosis, particularly DNA damage, but also metabolic disturbances stemming from dysregulated growth, hypoxia caused by insufficient blood supply, and in some cancers increased amounts of misfolded proteins. These stresses are enhanced manyfold when tumors are treated with chemotherapy or radiation (which kill tumor cells mainly by inducing apoptosis). Thus there is strong selective pressure, both before and after therapy, for cancer cells to develop mechanisms to evade apoptosis. This occurs mainly by way of acquired mutations and changes in gene expression that disable key components of the intrinsic pathway or that reset the balance of regulatory factors so as to favor cell survival in the face of intrinsic stresses (Fig. 7.31).

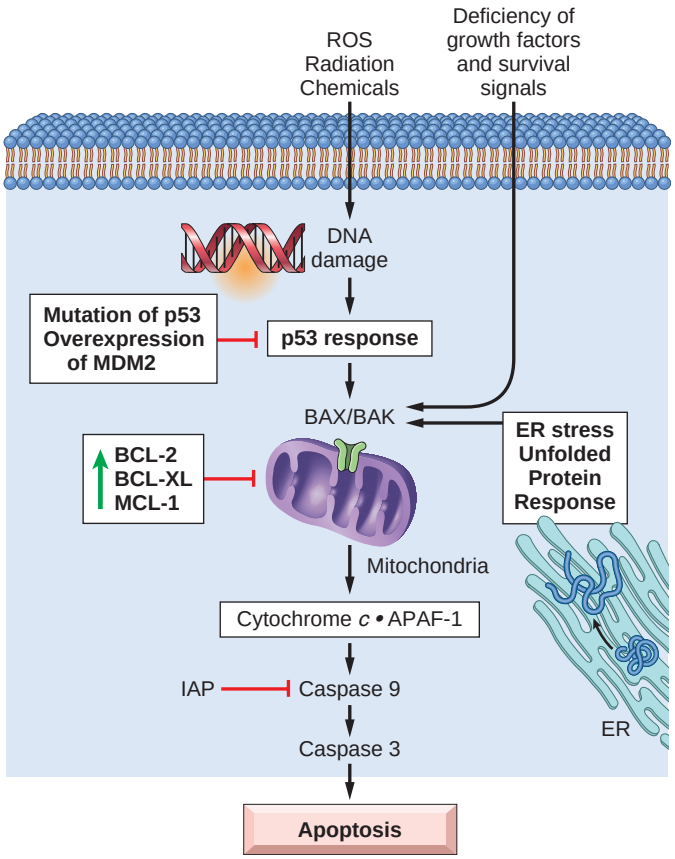

Figure 7.31 Intrinsic pathway of apoptosis and major mechanisms used by tumor cells to evade cell death. The most important mechanisms involve loss of p53 function, either through mutation or through antagonism by MDM2, and reduced egress of cytochrome *c* from mitochondria as a result of upregulation of anti-apoptotic factors that stabilize the mitochondrial membrane such as BCL2, BCL-XL, and MCL-1. Less commonly, tumors suppress apoptosis by unregulating members of the inhibitor of apoptosis *(IAP)* family.

Before delving into modes of resistance to apoptosis, a brief review of the intrinsic pathway is in order. Activation of this pathway leads to permeabilization of the mitochondrial outer membrane and release of molecules, such as cytochrome *c,* that initiate apoptosis. The integrity of the mitochondrial outer membrane is determined by a delicate balancing act between pro-apoptotic and anti-apoptotic members of the BCL2 protein family. The pro-apoptotic proteins BAX and BAK are required for apoptosis and directly promote mitochondrial permeabilization. Their action is inhibited by the anti-apoptotic members of this family, which are exemplified by BCL2 and BCL-XL. A third set of proteins, so-called *BH3-only proteins,* which include BIM, BAD, BID, and PUMA, shift the balance between the pro-apoptotic and anti-apoptotic family members by neutralizing the actions of anti-apoptotic proteins like BCL2 and BCL-XL, thereby promoting apoptosis. When the sum total of all BH3 proteins expressed "overwhelms" the anti-apoptotic BCL2/ BCL-XL protein barrier, BAX and BAK are activated and form pores in the mitochondrial membrane. This allows cytochrome *c* to leak into the cytosol, where it

binds to APAF-1 and activates caspase-9, which in turn cleaves and activates the executioner caspases. Another check on this system consists of a group of proteins called *inhibitor of apoptosis proteins (IAPs),* which block the action of caspase-9.

Within this framework, it is possible to illustrate the two major mechanisms by which apoptosis is avoided by cancer cells (see Fig. 7.31):

- *Loss of TP53 function*. While *TP53* is commonly mutated in cancers at diagnosis, the frequency of *TP53* mutations is even higher in tumors that relapse after therapy, probably because of their ability to convey resistance to genotoxic therapies. Other lesions in cancer impair p53 function indirectly, most notably amplification of *MDM2,* which encodes an inhibitor of p53. Loss of p53 function prevents the upregulation of PUMA, a pro-apoptotic BH3-only protein, in response to DNA damage and other stresses, allowing cells to survive that otherwise would be killed.
- *Overexpression of anti-apoptotic members of the BCL2 family*. Overexpression of BCL2 is a common event leading to the protection of tumor cells from apoptosis. One of the best-understood examples is found in follicular lymphoma (Chapter 12), a B-cell tumor carrying a characteristic (14;18)(q32;q21) translocation that fuses the *BCL2* gene to the transcriptionally active immunoglobulin heavy chain gene. The resulting overabundance of BCL2 protects the transformed lymphocytes from apoptosis. Because BCL2-overexpressing follicular lymphomas arise in large part through reduced cell death rather than explosive cell proliferation, they tend to be indolent (slow-growing). In other tumors such as chronic lymphocytic leukemia (Chapter 12), it appears that BCL2 is upregulated due to loss of specific micro-RNAs that normally restrain BCL2 levels. Many other mechanisms leading to overexpression of anti-apoptotic members of the BCL2 family have been proposed in a wide variety of cancers.

Recognition of the mechanisms by which cancers evade cell death has stimulated several lines of targeted drug development. Restoration of p53 function in *TP53*-mutated tumors is a daunting problem (because of the inherent difficulty of "fixing" defective genes) but is possible in tumors in which p53 is inactive because of overexpression of its inhibitor, MDM2. Indeed, inhibitors of MDM2 that reactivate p53 and induce apoptosis in tumors with *MDM2* gene amplification are being tested in clinical trials. Even more impressive results have been generated with drugs that inhibit the function of anti-apoptotic members of the BCL2 family, particularly BCL2 itself. These drugs have potent activity against certain tumors characterized by BCL2 overexpression (such as chronic lymphocytic leukemia) and are beoming a standard part of the treatment of particular cancers.

KEY CONCEPTS

EVASION OF CELL DEATH

- Apoptosis can be initiated through intrinsic or extrinsic pathways, both of which result in the activation of a proteolytic cascade of caspases that destroys the cell.
- Lesions that incapacitate the intrinsic (mitochondrial) pathway appear to be most common in cancers.
- In greater than 85% of follicular B-cell lymphomas, the anti-apoptotic gene *BCL2* is overexpressed due to a (14;18) translocation.
- Overexpression of other BCL2 family members is also linked to cancer cell survival and drug resistance.

Limitless Replicative Potential: The Stem Cell–Like Properties of Cancer Cells

All cancers contain cells that are immortal and have limitless replicative potential. Some cell lines established from cancers have now been proliferating ceaselessly in laboratories for more than 60 years, and it is reasonable to expect that they will continue to grow for as long as there are scientists to tend to them. How can it be that cancer cells have seemingly discovered the proverbial fountain of eternal youth? The answers are not completely known, but three interrelated factors appear to be critical to the immortality of cancer cells: (1) evasion of senescence, (2) evasion of mitotic crisis, and (3) the capacity for self-renewal.

- *Evasion of senescence.* As discussed in Chapter 2, most normal human cells have the capacity to divide 60 to 70 times. After this, the cells become senescent, permanently leaving the cell cycle and never dividing again. The mechanisms that produce senescence are not well understood, but the senescent state is associated with upregulation of p53 and INK4a/p16 (perhaps in response to the accumulation of DNA damage over time). These are believed to contribute to senescence in part by maintaining RB in a hypophosphorylated state, which favors cell cycle arrest. As already discussed, the RB-dependent G_1/S cell cycle checkpoint is disrupted in virtually all cancers by a wide variety of acquired genetic and epigenetic aberrations that may allow cells to bypass senescence.
- *Evasion of mitotic crisis.* While cells that are resistant to senescence have increased replicative capacity, they are not immortal; instead, they eventually enter a phase referred to as *mitotic crisis* and die. Mitotic crisis has been ascribed to progressive shortening of *telomeres,* special DNA sequences at the ends of chromosomes that bind several types of protective protein complexes (Chapter 2). Most somatic cells do not express *telomerase,* the enzyme that is responsible for the maintenance of telomeres, and with each cell division their telomeres shorten. When the telomeric DNA is completely eroded, the exposed chromosome ends are "sensed" as double-stranded DNA breaks. If the affected cells have functional p53, the cell arrests its growth and may undergo apoptosis, but if p53 is dysfunctional, the nonhomologous end-joining pathway is activated and may join the "naked" ends of two chromosomes. The resulting dicentric chromosomes are broken during attempted mitotic segregation during anaphase, producing new double-stranded DNA breaks. The snowballing genomic damage caused by repeated "bridge-fusion-breakage" cycles eventually produces mitotic catastrophe and cell death (Fig. 7.32). Telomerase is expressed at very low levels in most somatic cells, and thus proliferating cells that escape from senescence are

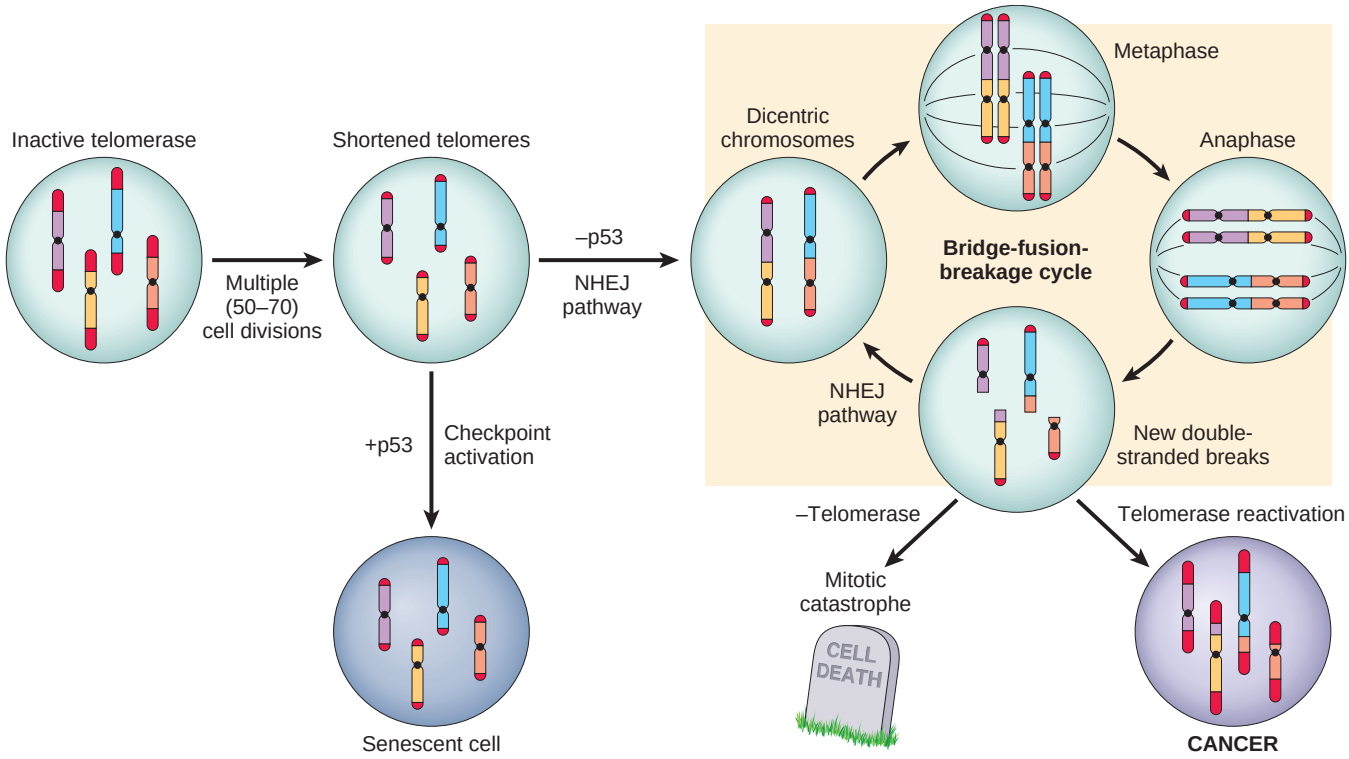

Figure 7.32 Escape of cells from senescence and mitotic catastrophe caused by telomere shortening. Replication of somatic cells, which do not express telomerase, leads to shortened telomeres. In the presence of competent checkpoints, cells undergo arrest and enter nonreplicative senescence. In the absence of checkpoints, DNA repair pathways such as the nonhomologous end joining *(NHEJ)* pathway are inappropriately activated, leading to the formation of dicentric chromosomes. At mitosis the dicentric chromosomes are pulled apart, generating random double-stranded breaks, which then activate DNA repair pathways, leading to the random association of double-stranded ends and the formation, again, of dicentric chromosomes. Cells undergo numerous rounds of this bridge-fusion-breakage cycle, which generates massive chromosomal instability and numerous mutations. If cells fail to reexpress telomerase, they eventually undergo mitotic catastrophe and death. Reexpression of telomerase allows the cells to escape the bridge-fusion-breakage cycle, thus promoting their survival and tumorigenesis.

likely to expire in this fashion. However, cells in crisis that reactivate telomerase can restore their telomeres and survive. Such cells may have suffered damage to oncogenes and tumor suppressor genes during crisis and are at high risk for malignant transformation. Alternatively, cancers may arise from stem cells (described later), which are long-lived in part because they express telomerase. Whatever the mechanism, telomere maintenance is seen in virtually all types of cancers. In 85% to 95% of tumors it is due to expression of telomerase. The remaining tumors use another mechanism to maintain their telomeres termed alternative lengthening of telomeres that depends on DNA recombination.

- *Self-renewal.* Unlike most cells, tissue stem cells and germ cells express telomerase, making them resistant to mitotic crisis, and also somehow avoid the genetic and epigenetic alterations that trigger senescence. In addition, long-lived stem cells possess another critical property, the capacity for self-renewal. In simple terms, self-renewal means that each time a stem cell divides at least one of the two daughter cells remains a stem cell. In a symmetric division, both daughter cells remain stem cells; such divisions may occur during embryogenesis, when stem cell pools are expanding, or during times of stress. In an asymmetric division, only one daughter cell remains a stem cell; in such circumstances, the non–stem cell daughter proceeds along some differentiation pathway, losing "stemness" but gaining one or more functions in the process. Cells in "transit" to a differentiated state are often highly proliferative, but they eventually differentiate, stop dividing, and may eventually become senescent or undergo apoptosis. The continued growth and maintenance of many tissues that contain short-lived cells, such as the formed elements of the bone marrow and blood and the epithelial cells of the gastrointestinal tract and skin, depend on a resident population of tissue stem cells that are capable of self-renewal. Following on this logic, because cancers are immortal and have limitless proliferative capacity, they too must contain cells that self-renew—so-called *cancer stem cells*. While there remains debate about the identity and number of stemlike cells in particular cancers, it is accepted that cells resembling stem cells must exist in all cancers.

Another open question is whether cancer stem cells arise from the transformation of tissue stem cells or from the conversion of conventional somatic cells to transformed cells with the acquired property of "stemness." The answer seems to be that both scenarios occur in different types of tumors, as exemplified by chronic myeloid leukemia and acute promyelocytic leukemia (Fig. 7.33). Recall also that expression of a small number of transcription factors can

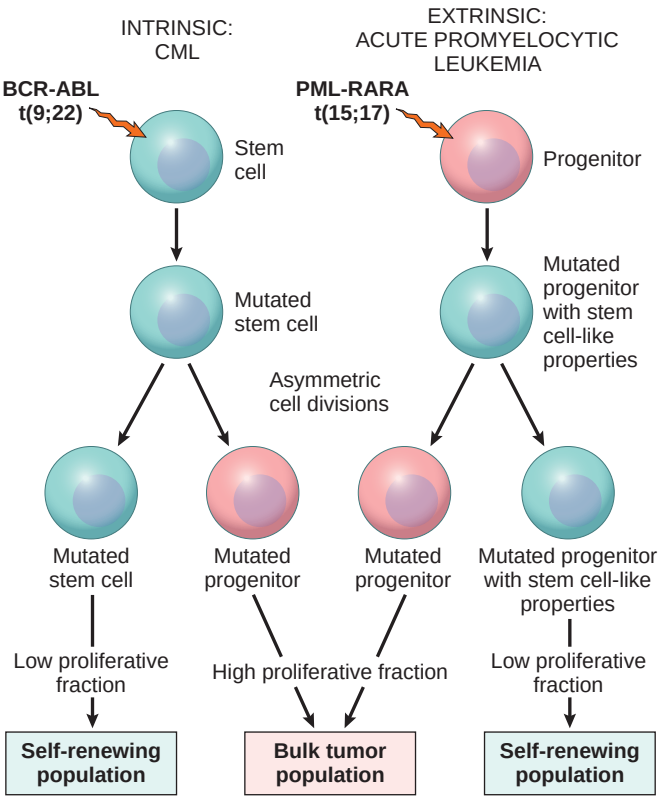

Figure 7.33 Origins of cells with self-renewing capacity in cancer. Cancer stem cells can arise from transformed tissue stem cells (e.g., hematopoietic stem cells in chronic myeloid leukemia *[CML]*) with intrinsic "stemness" or from proliferating cells that acquire a mutation that confers stemness (e.g., granulocyte progenitors in acute promyelocytic leukemia). In both instances, the cancer stem cells undergo asymmetric cell divisions that give rise to committed progenitors that proliferate more rapidly than the cancer stem cells; as a result, most of the malignant cells in both tumors lack self-renewing capacity.

result in the epigenetic reprogramming of a differentiated somatic cell such as a fibroblast into a pluripotent stem cell. Thus it is easy to imagine how mutations leading to misexpression of certain key transcription factors, such as MYC, might convert a somatic cell into a transformed cell with a capacity for self-renewal. A corollary of this idea is that, unlike normal stem cells and their more differentiated progeny, which have a fixed parent–offspring relationship, cancer cells within a tumor may be able to dedifferentiate to a stem cell–like state. Indeed, there is evidence that cancers can repopulate their stem cell pools from non–stem cell populations, further complicating efforts to precisely define and selectively target cancer stem cells.

Despite these uncertainties, the concept of cancer stem cells has important implications for cancer therapy. Most notably, if cancer stem cells are essential for tumor persistence, it follows that these cells must be eliminated to eradicate the tumor. It is hypothesized that like normal stem cells, cancer stem cells have a high intrinsic resistance to conventional therapies due to a low rate of cell division and the expression of factors such as multiple drug resistance-1 (MDR1) that counteract the effects of chemotherapeutic drugs. Thus the limited success of current therapies may in part be explained by their failure to kill the malignant stem cells that lie at the root of cancer.

KEY CONCEPTS

LIMITLESS REPLICATIVE POTENTIAL

- At least some cells in all cancers must be stem cell–like; these cells are sometimes referred to as cancer stem cells. These may arise through transformation of a normal stem cell or through acquired genetic lesions that impart a stem-like state on a more mature cell.
- Cancer cells acquire lesions that inactivate senescence signals and reactivate telomerase, which act together to convey limitless replicative potential.

Angiogenesis

Even if a solid tumor possesses all the genetic aberrations that are required for malignant transformation, it cannot enlarge beyond 1 to 2 mm in diameter unless it has the capacity to induce angiogenesis. Like normal tissues, the "health" of tumors requires delivery of oxygen and nutrients and removal of waste products; presumably the 1- to 2-mm size limit is the maximal distance across which oxygen, nutrients, and waste can diffuse from existing blood vessels. Growing cancers stimulate neoangiogenesis, during which new vessels sprout from capillaries (Chapter 3). Neovascularization supplies needed nutrients and oxygen, and proliferating endothelial cells also stimulate the growth of adjacent tumor cells by secreting growth factors such as insulin-like growth factors (IGFs) and PDGF. While the resulting tumor vasculature is effective at delivering nutrients and removing wastes, it is not entirely normal; the vessels are leaky and dilated and have a haphazard pattern of connection, features that can be appreciated on angiograms. By permitting tumor cells ready access to these abnormal vessels, angiogenesis also contributes to metastasis. Angiogenesis is thus an essential facet of malignancy.

How do growing tumors develop a blood supply? The current paradigm is that **angiogenesis is controlled by a balance between angiogenesis promoters and inhibitors; in angiogenic tumors this balance is skewed in favor of promoters.** Early in their development, most human tumors do not induce angiogenesis. Starved of nutrients, these tumors remain small or in situ, possibly for years, until an *angiogenic switch* terminates this stage of quiescence. The molecular basis of the angiogenic switch involves increased local production of angiogenic factors and/or loss of angiogenic inhibitors. The sources of these factors include tumor cells, infiltrating inflammatory cells (e.g., macrophages) or other tumor-associated stromal cells, and the ECM. In the case of tumor cells, several alterations enhance the production of pro-angiogenic factors:

- *Relative lack of oxygen due to hypoxia stabilizes HIF1α,* an oxygen-sensitive transcription factor mentioned earlier that activates the transcription of the pro-angiogenic cytokines VEGF and basic fibroblast growth factor (bFGF). These factors create an angiogenic gradient that stimulates the proliferation of endothelial cells and guides the growth of new vessels toward the tumor (Chapter 3).
- *Driver mutations in certain tumor suppressors and oncogenes favor angiogenesis.* For example, p53 stimulates the expression of anti-angiogenic molecules such as thrombospondin-1

and represses the expression of pro-angiogenic molecules such as VEGF. Thus, loss of p53 not only removes cell cycle checkpoints and alters tumor cell metabolism but also provides a more permissive environment for angiogenesis. Conversely, gain-of-function mutations in *RAS* or *MYC* upregulate the production of VEGF.

- *Proteases,* which may be elaborated by either tumor cells or by stromal cells, also influence the local balance of angiogenic and antiangiogenic factors. Many proteases release bFGF from the ECM, which constitutes a storage site for this factor, while other proteases release anti-angiogenic factors such as angiostatin and endostatin through proteolytic cleavage of plasminogen and collagen, respectively.

The idea that angiogenesis is essential for solid tumors to grow to clinically significant sizes provided a powerful impetus for the development of therapeutic agents that block angiogenesis. These agents are now a part of the armamentarium that oncologists use against cancers. A cardinal example is bevacizumab, a monoclonal antibody that neutralizes VEGF activity and is approved for treatment of multiple cancers. However, angiogenesis inhibitors have not been nearly as effective as was hoped; they can prolong life, but usually for only a few months and at very high financial cost. The mechanisms that underlie the persistence and ultimate progression of cancers in the face of angiogenesis inhibitors are not yet clear. Improvements will be possible only with greater understanding of the "escape routes" through which tumor cells sidestep the effects of the angiogenesis inhibitors that are now in use.

KEY CONCEPTS

ANGIOGENESIS

- Vascularization of tumors is essential for their growth and is controlled by the balance between angiogenic and anti-angiogenic factors that are produced by tumor and stromal cells.
- Hypoxia triggers angiogenesis through the actions of HIF1α on the transcription of the pro-angiogenic factor VEGF.
- Many other factors regulate angiogenesis; for example, p53 induces synthesis of the angiogenesis inhibitor thombospondin-1, while RAS, MYC, and MAPK signaling all upregulate VEGF expression and stimulate angiogenesis.
- VEGF inhibitors are used to treat a number of advanced cancers and prolong the clinical course, but are not curative.

Invasion and Metastasis

Invasion and metastasis are the major causes of cancer-related morbidity and mortality and hence are the subjects of intense investigation. Local invasion of tumor cells may damage or destroy vital structures and is a prerequisite for distant spread. Studies in mice and humans reveal that although many of these locally invasive cells enter the bloodstream each day, very few produce metastases. Why is the metastatic process so inefficient? The answer is uncertain but undoubtedly relates to the complexity of the process. For cancer cells to emerge from a primary mass, enter blood vessels or lymphatics, and produce a secondary growth at a distant site, they must go through a series of steps that involve an intricate interplay between tumor cells and many different types of host cells and factors (summarized in Fig. 7.34). At each point in this sequence, the breakaway cells must overcome the challenges of avoiding immune defenses (discussed later) and adapting to a microenvironment (e.g., lymph node, bone marrow, or brain) that is quite different from that of the site of origin of the tumor. The complexity of this series of events may explain why individual "metastasis genes" have not been found; it may be that the "metastatic phenotype" requires the

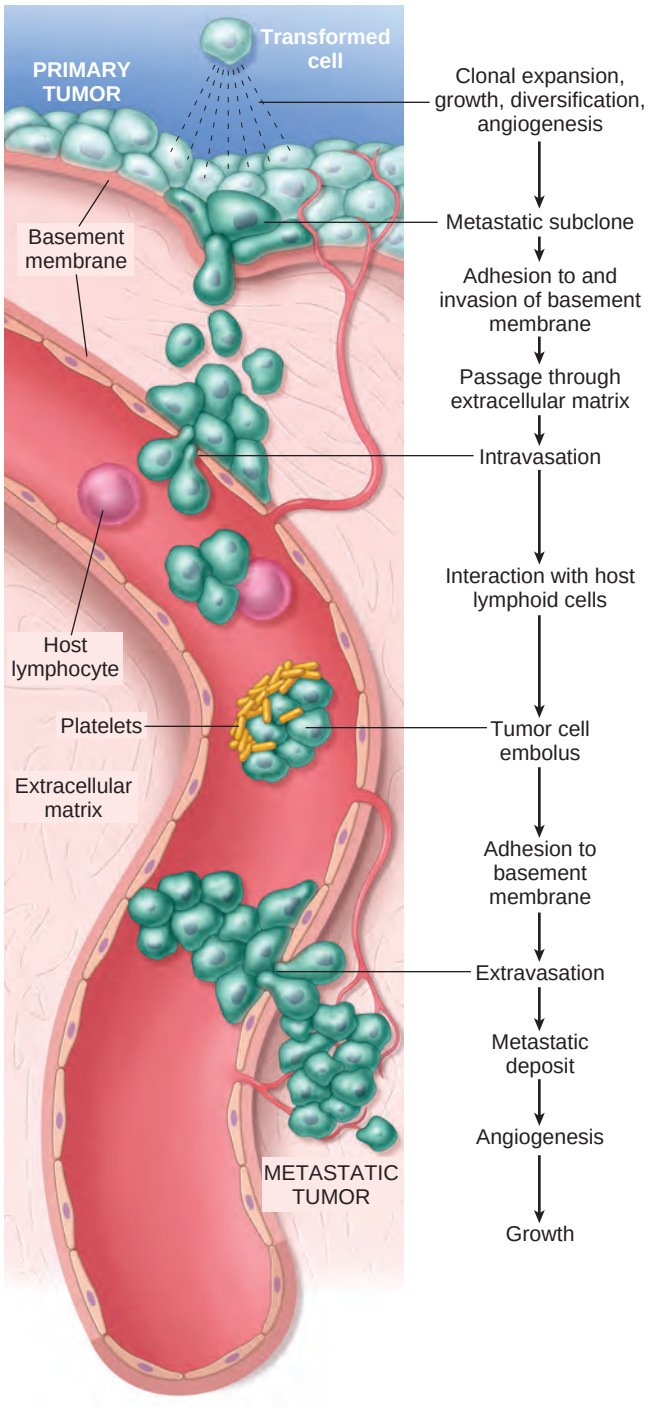

Figure 7.34 The metastatic cascade. Sequential steps involved in the hematogenous spread of a tumor.

accumulate complementary genetic and epigenetic alterations that collectively promote the metastatic cascade. This set of "skills" may be present only in rare cells, or might even require a collaboration between subclones, with each providing some needed function. This latter idea implies that successful metastases may arise from cells that migrate as cohesive groups, for which there is some evidence.

In the discussion that follows, the metastatic cascade is divided into two phases: (1) invasion of the ECM and (2) vascular dissemination, tissue homing, and colonization. Throughout, we touch on some of the proposed molecular mechanisms that underlie the process.

Invasion of Extracellular Matrix

The structural organization and function of normal tissues is determined by interactions between cells and the ECM. As discussed in Chapter 1, tissue compartments are separated from each other by two types of ECM, basement membrane and interstitial connective tissue, each made up of different combinations of collagens, glycoproteins, and proteoglycans. As shown in Fig. 7.34, tumor cells interact with the ECM at several stages in the metastatic cascade. To metastasize, carcinoma cells must breach the underlying basement membrane, traverse the interstitial connective tissue, and ultimately gain access to the circulation by penetrating the vascular basement membrane. This process is repeated in reverse when tumor cells extravasate at a distant site. Invasion of the ECM initiates the metastatic cascade and is an active process that can be resolved into several steps (Fig. 7.35):

- "Loosening up" of tumor cell–tumor cell interactions
- Degradation of ECM
- Attachment to "remodeled" ECM components
- Migration and invasion of tumor cells

Dissociation of cancer cells from one another is often the result of alterations in intercellular adhesion molecules and is the first step in the process of invasion. Normal epithelial cells are tightly glued to each other and to the ECM by a variety of adhesion molecules. As discussed earlier, *E-cadherins* are transmembrane glycoproteins that mediate the homotypic adhesion of epithelial cells, serving both to hold the cells together and to relay signals between cells. In several epithelial tumors including certain adenocarcinomas of the stomach and breast, E-cadherin function is lost due to pathogenic mutations, and in many other epithelial cancers it is hypothesized that E-cadherin expression is silenced, at least transiently, through a process called *epithelial-mesenchymal transition (EMT)*. It is postulated that EMT is integral to the metastasis of carcinomas, particularly breast and prostate cancers. EMT is controlled by the transcription factors SNAIL and TWIST and is defined not only by the downregulation of epithelial markers (e.g., E-cadherin) but also by the concomitant upregulation of mesenchymal markers (e.g., vimentin and smooth muscle actin), changes that are believed to favor the development of a promigratory phenotype that is essential for metastasis.

Degradation of the basement membrane and interstitial connective tissue is the second step in invasion. Tumor cells may accomplish this by secreting proteolytic enzymes or by inducing stromal cells (e.g., fibroblasts and inflammatory cells) to do so. Many different proteases such as matrix metalloproteinases (MMPs), cathepsin D, and urokinase plasminogen activator are overexpressed in tumors and have been implicated in tumor cell invasion. MMPs regulate tumor invasion not only by remodeling the basement membrane and interstitial connective tissue, but also by releasing factors that contribute to the malignant behavior

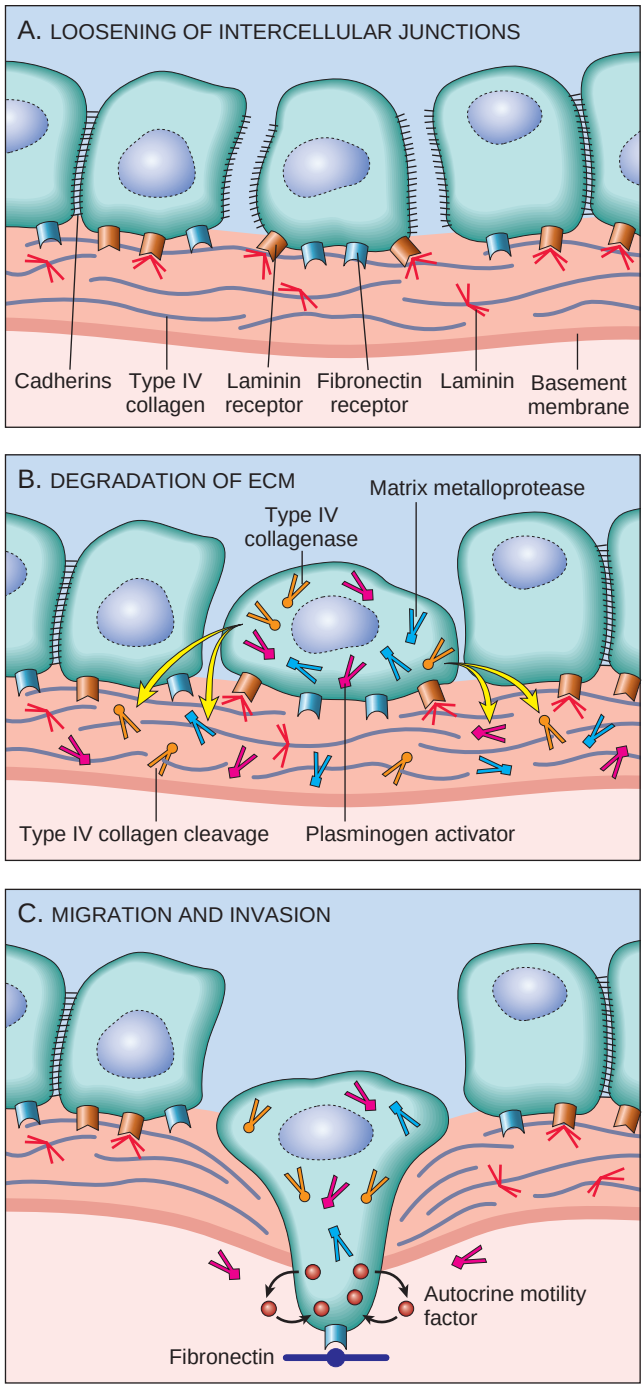

Figure 7.35 Sequence of events in the invasion of epithelial basement membranes by tumor cells. Tumor cells detach from each other because of reduced adhesiveness and attract inflammatory cells. Proteases secreted from tumor cells and inflammatory cells degrade the basement membrane. Binding of tumor cells to proteolytically generated binding sites and tumor cell migration follow. *ECM*, Extracellular matrix.

of cancers. For example, MMP-9, a gelatinase that cleaves type IV collagen found within the epithelial and vascular basement membrane, also stimulates the release of VEGF from ECM-sequestered pools and generates collagen and proteoglycan cleavage products with chemotactic, angiogenic, and growth-promoting effects. Benign tumors of the breast, colon, and stomach have little MMP-9 activity, whereas their malignant counterparts overexpress this enzyme. Concurrently the concentrations of metalloproteinase inhibitors are also reduced in many cancers, further tilting the balance toward tissue degradation.

The third step in invasion involves changes in how tumor cells attach to ECM proteins. Tumor cells demonstrate complex changes in the expression of integrins, which you will recall are transmembrane proteins that participate in adhesion of cells to other cells and to ECM (Chapter 3). In normal epithelial cells, integrins that bind basement membrane laminin and collagens are strictly restricted to the basal aspect of the cell; these receptors help to maintain the cells in a resting, polarized state. Loss of adhesion in normal cells leads to induction of apoptosis, but free tumor cells are resistant to this form of cell death (termed *anoikis,* meaning without a home), in part because of expression of other integrins that mitigate the loss of adhesion to ECM, apparently by transmitting signals that promote cell survival. Additionally, the matrix itself is modified in ways that promote invasion and metastasis. For example, cleavage of the basement membrane proteins collagen IV and laminin by MMP-2 or MMP-9 generates novel sites that bind to receptors on tumor cells and stimulate migration.

Locomotion is the final step of invasion, propelling tumor cells through the degraded basement membranes and zones of matrix proteolysis. Migration is a multistep process that involves many families of receptors and several signaling pathways that eventually impinge on the actin cytoskeleton. Cells must attach to the matrix at their leading edge, detach from the matrix at their trailing edge, and contract the actin cytoskeleton to ratchet forward. Such movement seems to be stimulated and directed by several types of factors, which likely vary among different types of tumors. These include:

- Tumor cell–derived cytokines including chemokines and growth factors (e.g., insulin-like growth factors), which act as autocrine motility factors
- Cleavage products of matrix components (e.g., collagen, laminin)
- Stromal cell–derived paracrine factors such as hepatocyte growth factor/scatter factor, which binds to the receptor tyrosine kinase MET on tumor cells and stimulates motility

This initial phase of metastasis culminates in penetration through the endothelial basement membrane and transmigration into the vascular space. Throughout this phase of the process, tumor cells interact not only with ECM but also with several types of stromal cells, including innate and adaptive immune cells, fibroblasts, and endothelial cells. Details remain to be worked out, but it is clear that "successful" invaders induce signals that modify stromal cells in ways that support their malignant behavior. For example, under the influence of invading cancer cells, so-called cancer-associated fibroblasts alter their expression of genes that encode ECM molecules, proteases, protease inhibitors, and various growth factors. It is easy to imagine that as tumors evolve over time, they come to be dominated by cancer cells that are most effective at co-opting the complex, ever-changing tumor microenvironment to serve their malignant purposes.

Vascular Dissemination, Homing, and Colonization

Once in the circulation, tumor cells are vulnerable to destruction by a variety of mechanisms including mechanical shear stress, apoptosis due to anoikis, and innate and adaptive immune defenses. Nevertheless, viable circulating tumor cells are not rare in patients with solid tumors such as carcinomas. What then separates those few cells that give rise to metastases from the large number of cells that fail? Also, what determines why metastases ultimately appear where they do in the body?

While definitive answers to these questions are not known, clues have emerged. One idea that has gained support proposes that the circulating cells that establish metastases are much more likely to migrate as multicellular aggregates than as single cells. Clumping of tumor cells in the blood is promoted by homotypic interactions as well as heterotypic interactions between tumor cells and blood elements, particularly platelets (see Fig. 7.34), which are believed to enhance tumor cell survival in the circulation. Tumor cells may also express anionic substances such as polyphosphate that activate factor XII (contact factor), resulting in fibrin deposition and further stabilization of tumor emboli, which may enhance the ability of the cells to arrest en masse within capillary beds. Another potential advantage possessed by tumor cells circulating as a group is that they may be far more likely than any single cell to possess all the properties that are needed to establish a metastasis. Among these essential attributes is the presence of cells with stem cell–like properties, which may contribute not only to the relentless growth of metastatic lesions but also to the "plasticity" that is needed for metastatic cells to adapt to growth in a new microenvironment.

Where circulating tumor cells arrest and eventually form clinically significant metastatic deposits appears to relate to three factors: (1) location and vascular drainage of the primary tumor; (2) tropism of particular kinds of tumor cells for specific tissues; and (3) escape from tumor dormancy. The first is a matter of simple anatomy; thus colon carcinomas are far more likely to give rise to metastases in the liver, the first organ downstream of the tumor, than to metastases elsewhere. However, many exceptions to this "rule" exist. For example, carcinomas of the prostate and breast preferentially spread to bone, bronchogenic carcinomas tend to involve the adrenals and the brain, and neuroblastomas spread to the liver and bones. Such organ tropism may be related to the following mechanisms:

- Tumor cells may express adhesion molecules whose ligands are found preferentially on the endothelial cells of the target organ. Of interest in this regard is the CD44 adhesion molecule, which is expressed on normal T lymphocytes and is used by these cells to migrate to selective sites in lymphoid tissues. Such migration is accomplished by the binding of CD44 to hyaluronate on high endothelial venules. Solid tumors also often express

CD44, which appears to enhance their spread to lymph nodes and other metastatic sites.
- Some cancer cells express chemokine receptors, which may guide tumor cells to tissues expressing chemokines, much in the way chemokines normally act as attractants for cells of the immune system.
- Some tissues may provide a favorable "soil" for the growth of tumor seedlings. According to this "seed-soil" hypothesis, originally proposed by Paget, the ability of tumor cells originating from a particular site to adapt to a foreign environment may be limited to certain tissue types. A corollary of this idea is that target tissues in which metastasis is rare despite a rich vascular supply (e.g., skeletal muscle, spleen) constitute nonpermissive environments—"unfavorable soil," so to speak.

Once arrested at distant sites, extravasation of tumor cells involves transmigration between endothelial cells followed by egress through the basement membrane. Little is known about how this process occurs, and the mechanisms may differ depending on whether the endothelium is fenestrated (as in tissues such as the liver and bone marrow) or is held together by tight junctions (as in the brain). Extravasation requires the action of adhesion molecules (integrins, laminin receptors), proteolytic enzymes, and chemokines, which may be derived from tumor cells or from innate immune cells such as monocytes and neutrophils.

Even when metastatic cells take root and survive within distant tissues, they may fail to grow. This phenomenon, called *tumor dormancy,* is well described in melanoma and in breast and prostate cancer. Although the molecular mechanisms of productive colonization are still being unraveled, a consistent theme seems to be that tumor cells secrete cytokines, growth factors, and ECM molecules that act on the resident stromal cells, which in turn make the metastatic site habitable for the cancer cell. For example, breast cancer cells that are metastatic to bone often secrete parathyroid hormone–related protein (PTHRP), which stimulates osteoblasts to make RANK ligand (RANKL). RANKL then activates osteoclasts, which degrade the bone matrix and release growth factors embedded within it, like IGF and TGF-β. These in turn bind to receptors on the cancer cells, activating signaling pathways that support the growth and survival of the cancer cells. It is likely that many similar feedback loops between metastatic tumor cells and stromal cells await discovery.

KEY CONCEPTS

INVASION AND METASTASIS

- Ability to invade tissues, a hallmark of malignancy, occurs in four steps: loosening of cell-cell contacts, degradation of ECM, attachment to novel ECM components, and migration of tumor cells.
- Cell-cell contacts are lost by the inactivation of E-cadherin through a variety of pathways.
- Basement membrane and interstitial matrix degradation is mediated by proteolytic enzymes secreted by tumor cells and stromal cells, such as MMPs and cathepsins.
- Proteolytic enzymes also release growth factors sequestered in the ECM and generate chemotactic and angiogenic fragments from cleavage of ECM glycoproteins.
- The metastatic site of many tumors can be predicted by the location of the primary tumor. Many tumors arrest in the first capillary bed they encounter (lung and liver, most commonly).
- Some tumors show organ tropism, probably due to expression of adhesion or chemokine receptors whose ligands are expressed by endothelial cells at the metastatic site.
- Genes that promote epithelial-mesenchymal transition (EMT), like *TWIST* and *SNAIL*, may be important metastasis genes in epithelial tumors.

Evasion of Immune Surveillance

Long one of the "holy grails" of oncology, the promise of therapies that enable the host immune system to recognize and destroy cancer cells is finally coming to fruition, largely due to a clearer understanding of the ways by which cancer cells evade the host response. Paul Ehrlich first conceived the idea that tumor cells can be recognized as "foreign" and eliminated by the immune system. Subsequently, Lewis Thomas and Macfarlane Burnet formalized this concept by coining the term *immune surveillance,* which implies that a normal function of the immune system is to constantly "scan" the body for emerging malignant cells and destroy them. This idea has been supported by many observations—the direct demonstration of tumor-specific T cells and antibodies in patients; data showing that the density and quality of immune infiltrates in cancers often correlate with outcome; the increased incidence of certain cancers in immunodeficient people and mice; and most recently and most directly, the response of advanced cancers to therapeutic agents that act by stimulating latent host T-cell responses (described later).

Assuming the immune system is capable of recognizing and eliminating nascent cancers, it follows that the tumors that grow out in immunocompetent individuals must be composed of cells that are either invisible to the host immune system or that activate mechanisms that suppress host immunity. In support of this concept, it is now evident that therapeutic agents that neutralize these mechanisms can lead to tumor regression, even in patients with advanced cancers. These encouraging clinical responses constitute strong evidence that evasion of host immunity is indeed a hallmark of many, if not all, human cancers.

The following section explores some of the important questions about tumor immunity: What is the nature of tumor antigens? What host effector systems recognize tumor cells? How do tumors evade these host mechanisms? And how can immune reactions against tumors be exploited therapeutically?

Tumor Antigens

Malignant tumors express various types of molecules that may be recognized by the immune system as foreign antigens (Fig. 7.36). Tumor antigens that elicit an immune response have been demonstrated in many experimentally induced tumors and in some human cancers. It appears that protein antigens that elicit CD8+ cytotoxic T-cell

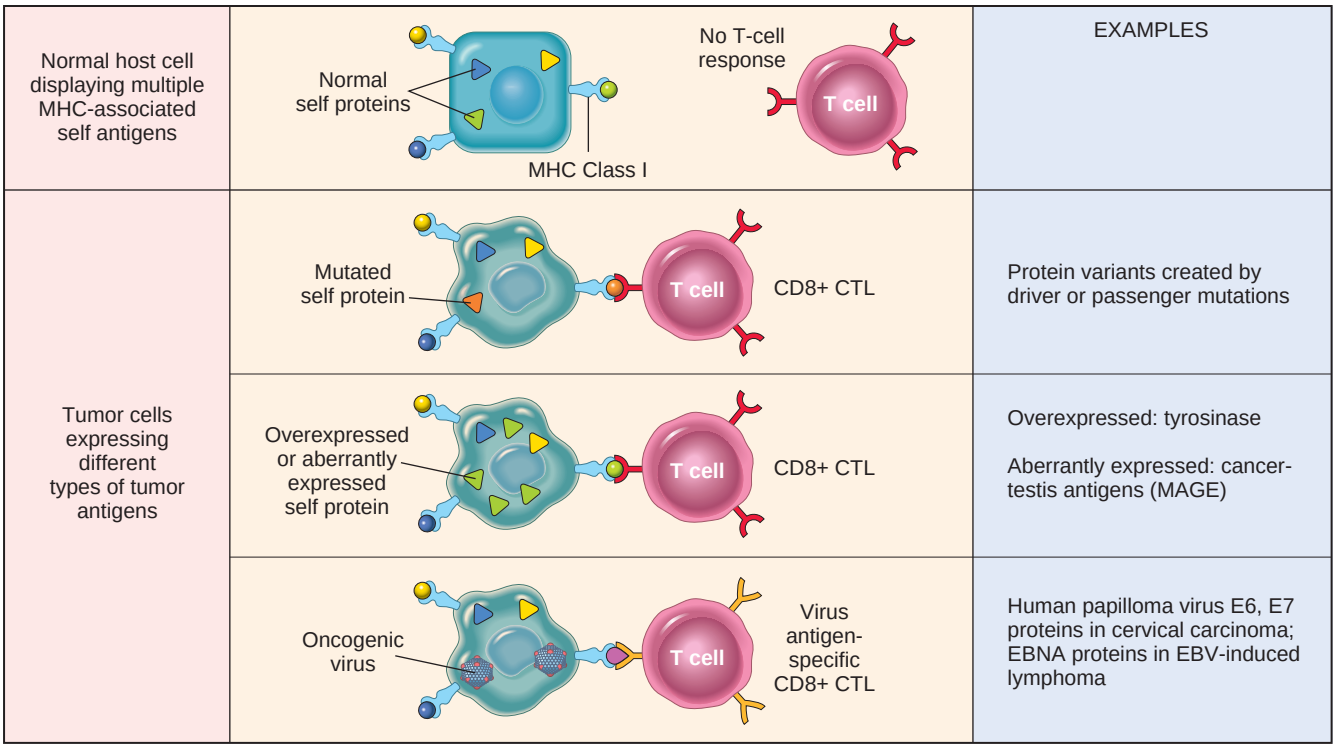

Figure 7.36 Tumor antigens recognized by CD8+ T cells. *EBV,* Epstein-Barr virus; *MHC,* major histocompatibility complex. (Modified from Abbas AK, Lichtman AH: *Cellular and Molecular Immunology,* ed 5, Philadelphia, 2003, WB Saunders.)

responses are most relevant for protective antitumor immunity. These protein antigens can be classified according to their source and molecular structure as follows:

- *Neoantigens produced from genes bearing passenger and driver mutations.* As discussed earlier, neoplastic transformation results from driver mutations in cancer genes; these mutated genes encode variant proteins that have never been seen by the immune system and may thus be recognized as nonself. Additionally, because of the enabling hallmark feature of genetic instability, cancers often have a high burden of passenger mutations throughout their genomes. Although these mutations are neutral in terms of cancer cell fitness and thus unrelated to the transformed phenotype, some by chance fall in the coding sequences of genes and give rise to protein variants that serve as tumor antigens (provided the mutation is in an epitope that binds to the MHC molecules of the individual). Notably, the size of the mutational load in a particular tumor, as deduced from DNA sequencing of tumor genomes, correlates well with the strength of the host CD8+ cytotoxic T-cell response and the effectiveness of immunomodulatory therapies (described later).
- *Overexpressed or aberrantly expressed normal cellular proteins.* Tumor antigens may also be normal cellular proteins that are overexpressed or aberrantly expressed in tumor cells. An example of an overexpressed protein that may be antigenic is tyrosinase, an enzyme involved in melanin biosynthesis that is expressed only in normal melanocytes and melanomas. It may be surprising that the immune system is able to respond to this normal self antigen. The probable explanation is that tyrosinase is normally produced in such small amounts and in so few healthy cells that it is not recognized by the immune system and fails to induce tolerance. Another group of tumor antigens are proteins that are aberrantly expressed in cancer cells at levels much greater than those seen in normal tissues. This may occur because of gene amplification or because of acquired epigenetic alterations that reactivate genes that are normally silenced in adult tissues. Some genes in this class encode *cancer-testis antigens,* proteins that are normally expressed only in testicular germ cells. Although the protein is present in the testis, it is not expressed on the cell surface in an antigenic form because sperm do not express major histocompatibility complex (MHC) class I antigens. Thus, for all practical purposes, these antigens are tumor-specific. Prototypic of this group is the melanoma antigen gene (MAGE) family. Although originally described in melanomas, MAGE antigens are expressed by a variety of tumor types.
- *Tumor antigens produced by oncogenic viruses.* In several cancers associated with ongoing active or latent viral infections (described later), the responsible viruses encode viral proteins that are recognized as foreign by the immune system. Cytotoxic T lymphocytes (CTLs) play a vital role in surveillance against virus-induced tumors by recognizing viral antigens and killing virus-infected cells. The importance of this immune mechanism is made evident by the high incidence of virally induced cancers that is observed in patients with inherited or acquired T-cell immunodeficiency. Many of these tumors are caused by Epstein-Barr virus (EBV) or HPV, DNA viruses that carry potent viral oncogenes.

Antitumor Effector Mechanisms

The principal immune mechanism of tumor eradication is killing of tumor cells by CTLs specific for tumor antigens. This mechanism predominates because the majority of tumor neoantigens consist of mutated gene products or viral proteins that are endogenously synthesized and presented in the context of MHC class I molecules, enabling their recognition by CTLs. Although sera from cancer patients may contain antibodies that recognize tumors, there is little evidence that they have any protective role under physiologic conditions. The cellular effectors that mediate immunity are described in Chapter 6. Here we focus on the CTL response to tumor antigens.

CTL responses against tumors are initiated by recognition of tumor antigens on host antigen presenting cells (APCs). Many cancers, particularly those that are rapidly growing, have a high fraction of cells that are undergoing cell death, either by apoptosis or necrosis. Dendritic cells and macrophages in the tumor microenvironment ingest tumor cells or released tumor antigens and migrate to draining lymph nodes. Here, they present the antigens in the context of MHC class II molecules and, through a mechanism called cross-presentation, in the context of MHC class I molecules (Fig. 7.37), allowing the antigens to be recognized by naïve CD8+ CTLs. Activation of antigen-specific CTLs also requires costimulatory molecules, which are upregulated on APCs presumably by "danger signals" released from damaged or necrotic tumor cells (DAMPs). Once activated by interaction with APCs, tumor-specific CTLs can migrate from lymph nodes to the tumor and kill tumor cells, directly and serially, without any assistance from other cell types.

The ability of CTLs to kill tumor cells independent of other cell types and factors underlies the ferocious antitumor activity of CTLs engineered to express chimeric antigen receptors (so-called CAR-T cells) against lineage-specific surface antigens found on certain tumors. For example, CAR-T cells specific for B-cell antigens are highly active against B-cell tumors but also annihilate normal B cells and release sufficient inflammatory cytokines to cause substantial morbidity and sometimes the death of the patient.

Although CTLs appear to have a preeminent role, other mechanisms also may play a role in tumor immunity. Antitumor CD4+ T-cell responses have been detected in patients, and increased numbers of CD4+ effector T cells, especially Th1 cells, in tumor infiltrates have been associated with a better prognosis in certain cancers, such as colorectal carcinoma. In experimental systems, natural killer (NK) cells and activated macrophages are capable of killing tumor cells. After activation with interleukin (IL)-2 and IL-15, NK cells can lyse a wide range of human tumors, including those that are nonimmunogenic for T cells due to loss of expression of MHC class I molecules. The ability of NK cells to kill tumor cells requires no prior sensitization, suggesting that they might constitute a first line of defense. While the importance of NK cells in host responses against spontaneous tumors is still not well established, cytokines that activate NK cells are being used for immunotherapy. Activated macrophages also exhibit cytotoxicity against tumor cells in vitro. Interferon-γ, a cytokine secreted by T cells and NK cells, is a potent activator of macrophages and may allow macrophages to kill tumors by mechanisms similar to those used to kill microbes (e.g., production of reactive oxygen species; see Chapter 3).

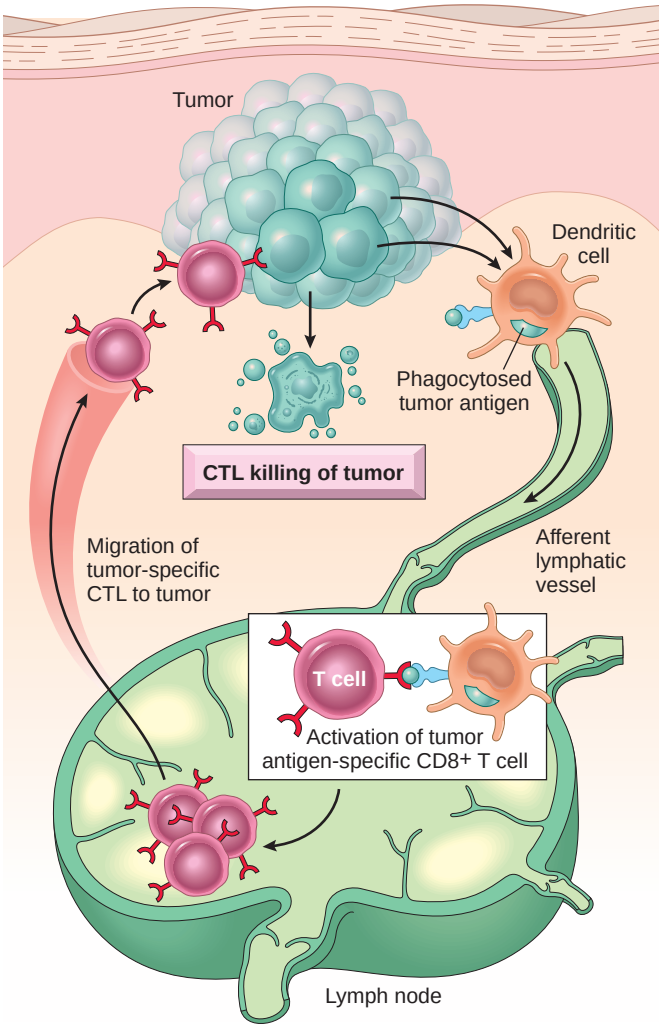

Figure 7.37 Cross-presentation of tumor antigens and induction of CD8+ cytotoxic T cell antitumor response. (Modified from Abbas AK, Lichtman AH: *Cellular and Molecular Immunology*, ed 8, Philadelphia, 2017, Elsevier.)

Mechanisms of Immune Evasion by Cancers

Immune responses often fail to check tumor growth because cancers evade immune recognition or resist immune effector mechanisms. Since cancer is all too common in persons who do not suffer from any overt immunodeficiency, it is evident that tumor cells must have ways to escape or evade the immune system in immunocompetent hosts. Several mechanisms appear to be operative (Fig. 7.38).

- *Selective outgrowth of antigen-negative variants.* During tumor progression, strongly immunogenic antigen-expressing subclones may be eliminated, and tumor cells that survive are those that have lost their antigens. If tumor cells express a large number of neoantigens, it is unlikely that all can be lost, but the same goal may be accomplished by other strategies.

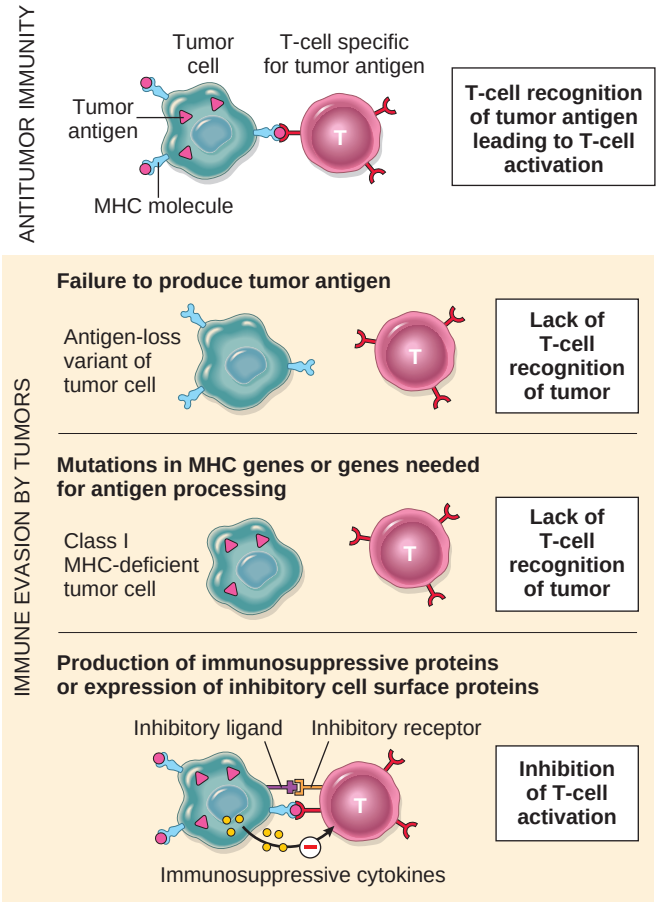

Figure 7.38 Mechanisms by which tumors evade the immune system. Tumors may evade immune responses by losing expression of antigens or major histocompatibility complex *(MHC)* molecules or by producing immunosuppressive cytokines or ligands such as PD-L1 for inhibitory receptors on T cells. (From Abbas AK, Lichtman AH, Pillai S: *Cellular and Molecular Immunology*, ed 7, Philadelphia, 2012, WB Saunders.)

- *Loss or reduced expression of MHC molecules.* Tumor cells may fail to express normal levels of HLA class I molecules, thereby losing the ability to display cytosolic antigens and escaping attack by cytotoxic T cells. Such cells, however, may trigger NK cells if the tumor cells express ligands for NK cell activating receptors.
- *Engagement of pathways that inhibit T-cell activation.* Tumor cells actively inhibit tumor immunity by upregulating negative regulatory "checkpoints" that suppress immune responses. Through a variety of mechanisms, tumor cells may promote the expression of the inhibitory receptor CTLA-4 on tumor-specific T cells. CTLA-4 binds to and removes its ligands, the B7 molecules, from APCs, thus reducing the engagement of the activating costimulatory receptor CD28. This not only prevents sensitization but also may induce long-lived unresponsiveness in tumor-specific T cells. Tumor cells also may upregulate the expression of PD-L1 and PD-L2, cell surface proteins that activate the programmed death-1 (PD-1) receptor on effector T cells. PD-1, like CTLA-4, inhibits T-cell activation. In some instances, overexpression of PD-L1 and PD-L2 is caused by amplification or translocation of the PD-L1 and PD-L2 genes, placing them in the pantheon of true oncogenes. Based on promising results in clinical trials, antibodies that restore T-cell function by blocking CTLA-4, PD-L1, or inhibitory PD-1 receptors are now approved for treatment of patients with advanced stage solid tumors and certain forms of lymphoma. The success of these agents has led to a new paradigm in cancer immunotherapy, sometimes called "checkpoint blockade," which is centered on the idea that agents that remove the "brakes" (checkpoints) imposed by tumors on host antitumor immune responses can be highly effective in treating cancer (Fig. 7.39).
- *Secretion of immunosuppressive factors.* Tumors may secrete several products that inhibit the host immune response. TGF-β is secreted in large quantities by many tumors and is a potent immunosuppressant. Many other soluble factors produced by tumors are also suspected of inhibiting the host immune response, including IL-10, prostaglandin E_2, certain metabolites derived from tryptophan, and VEGF, which can inhibit the movement of T cells from the vasculature into the tumor bed.
- *Induction of regulatory T cells (Tregs).* Some studies suggest that tumors produce factors that favor the development of immunosuppressive Tregs, which could also contribute to "immunoevasion."

Thus, it seems that there is no dearth of mechanisms by which tumor cells can outwit the host immune system. Nevertheless, the aforementioned response of tumors to immunomodulatory agents, such as antibodies that block CTLA-4 and PD-1, has generated tremendous excitement around the potential of rationally designed cancer immunotherapy. One of the remarkable features of this therapy is that it can achieve long-term remission and possibly even cures (which is not likely with any other treatment), perhaps because long-lived tumor-specific memory T cells are activated in the treated patients. The major challenges now are to determine which immune evasion mechanisms are most important in the cancers of individual patients and to develop a broader set of therapies that stymie various evasion mechanisms and thereby induce effective host immunity. In this regard, the treatment of human cancers with highly specific checkpoint inhibitor antibodies affords the opportunity to develop a mechanistic understanding of certain aspects of tumor response and resistance. Lessons learned to date from clinical trials conducted with these inhibitors include the following:

- *Tumor neoantigen burden is a good predictor of response.* Tumors that have deficiencies in mismatch repair enzymes, which normally correct errors in DNA replication that lead to point mutations, have the highest mutation burdens of all cancers, and these cancers are most likely to respond to checkpoint blockade therapy. Based on this observation, anti–PD-1 therapy is now approved for all metastatic tumors that have mismatch repair deficiency, which leads to a high mutational burden, regardless of histologic type.
- *Only a subset of tumors (25% to 40%) responds to checkpoint inhibitors,* probably because nonresponding tumors rely on evasion strategies other than engaging checkpoint pathways. For example, tumors that do not express PD-L1, or do not have exhausted PD-1–positive CD8+ T-cell infiltrates, are not likely to respond to anti–PD-1 or

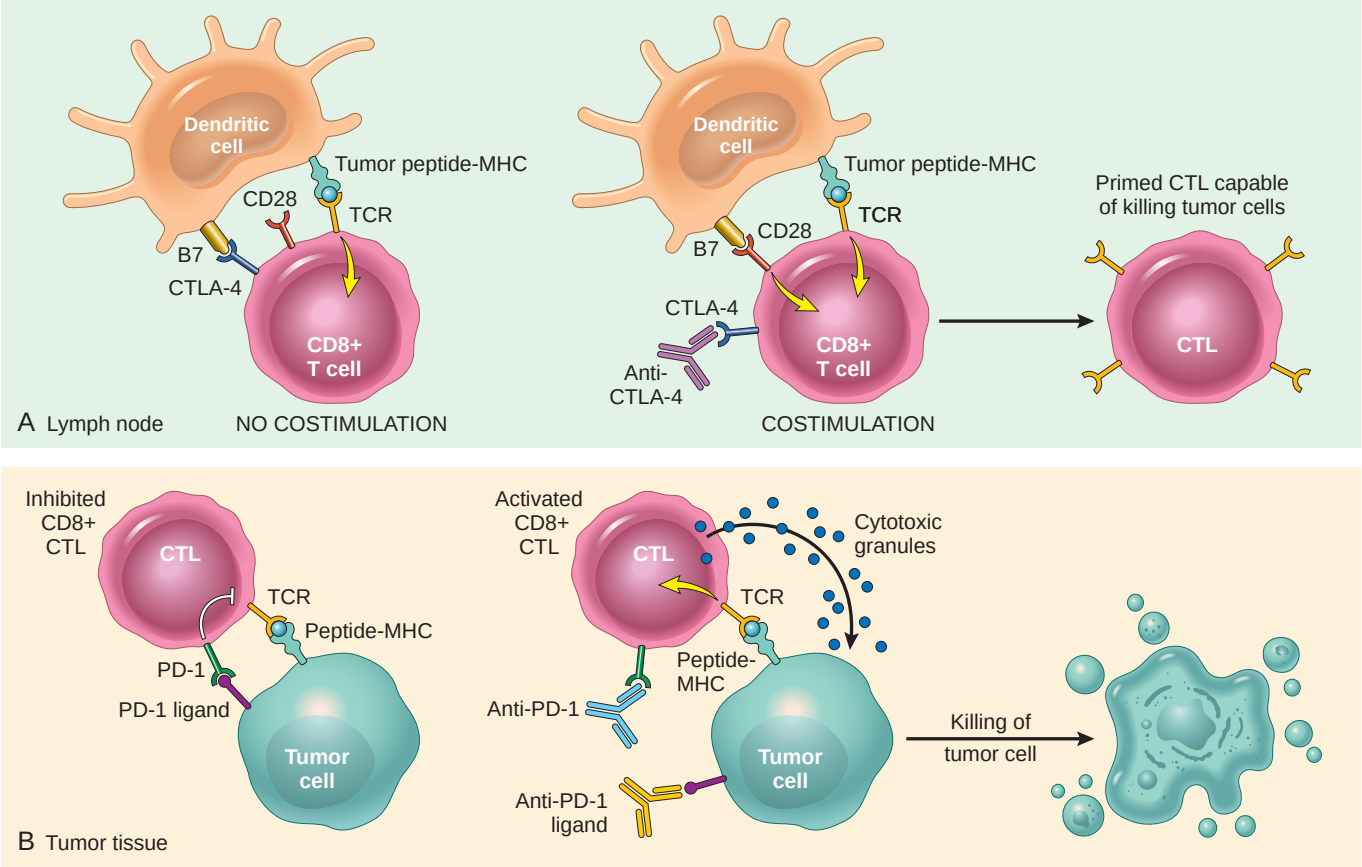

Figure 7.39 Activation of host antitumor immunity by checkpoint inhibitors. (A) Blockade of the CTLA4 surface molecule with an inhibitor antibody allows cytotoxic CD8+ T cells *(CTLs)* to engage B7 family coreceptors, leading to T-cell activation. (B) Blockade of PD-1 receptor or PD-1 ligand by inhibitory antibodies abrogates inhibitory signals transmitted by PD-1, again leading to activation of CTLs. *MHC,* Major histocompatibility complex. (From Abbas AK, Lichtman AH, Pillai S: *Cellular and Molecular Immunology*, ed 9, Philadelphia, 2017, Elsevier.)

anti–PD-L1 therapy. Investigators are currently studying which biomarkers will predict responsiveness to different checkpoint blockade approaches.

- *Combination of checkpoint inhibitors with other therapeutic agents.* The combined use of different checkpoint inhibitors, or of checkpoint inhibitors with other types of therapeutic agents (e.g., drugs that target oncoproteins like tyrosine kinases), will likely be necessary to achieve higher rates of therapeutic success. The first successful example of this is the combined use of anti–CTLA-4 and anti–PD-1 to treat melanoma, an approach that is more effective than anti–CTLA-4 alone. This reflects the fact that the mechanisms by which CTLA-4 and PD-1 inhibit T-cell activation are different (Fig. 7.39). There are numerous ongoing or planned clinical trials using combinations of checkpoint blockade together with other kinds of therapeutic agents.
- *The most common toxicities associated with checkpoint blockade are autoimmunity and/or inflammatory damage to organs.* This is predictable because the physiologic function of inhibitory receptors and ligands is to maintain tolerance to self antigens. A wide range of organs may be affected including colon, lungs, endocrine organs, heart, and skin, each requiring different clinical interventions, sometimes including cessation of the potentially life-saving checkpoint blockade therapy.

KEY CONCEPTS

EVASION OF IMMUNE SURVEILLANCE

- Tumor cells can be recognized by the immune system as nonself and destroyed.
- Antitumor activity is mediated by predominantly cell-mediated mechanisms. Tumor antigens are presented on the cell surface by MHC class I molecules and are recognized by CD8+ CTLs.
- The different classes of tumor antigens include products of mutated proto-oncogenes, tumor suppressor genes, overexpressed or aberrantly expressed proteins, and tumor antigens produced by oncogenic viruses.
- Immunosuppressed patients have an increased risk for development of cancer, particularly types caused by oncogenic DNA viruses.
- In immunocompetent patients, tumors may avoid the immune system by several mechanisms including selective outgrowth of antigen-negative variants, loss or reduced expression of histocompatibility antigens, and immunosuppression mediated by expression of certain factors (e.g., TGF-β, PD-1 ligand) by the tumor cells.
- Antibodies that overcome mechanisms of immune evasion involving "immune checkpoints" are approved for treatment of patients with advanced cancer and are most likely to be effective against cancers with a high mutational burden.

Genomic Instability

Genetic aberrations that increase mutation rates are very common in cancers and expedite the acquisition of driver mutations that are required for transformation and subsequent tumor progression. Although exposure to environmental agents that are mutagenic (e.g., chemicals, radiation, sunlight) is unavoidable, cancers are relatively rare outcomes of these encounters. This state of affairs results from the ability of normal cells to repair DNA damage, the death of cells with irreparable damage (see "Evasion of Cell Death" earlier), and other mechanisms such as oncogene-induced senescence and immune surveillance.

Several mechanisms contribute to genomic instability in cancer cells. We previously discussed how p53 protects the genome from potentially oncogenic damage by arresting cell division to provide time for repair of DNA damage and by initiating apoptosis in irreparably damaged cells. Cancers with loss of p53 function not only accumulate point mutations but also are strongly associated with aneuploidy, which may take the form of deletions, amplifications, and complex chromosomal rearrangements. These genomic aberrations may occur in cells with defective telomeres during break-fusion-breakage cycles (see Fig. 7.32) or may be created by other types of chromosomal "catastrophes" (such as chromothrypsis, described later) that lead to DNA breaks in multiple chromosomes. In the absence of p53 function, cells with severely damaged genomes that normally would be eliminated persist and stitch their chromosome back together in an error-prone way using the nonhomologous end-joining pathway.

TP53 is the most commonly mutated gene in cancer, and loss of p53 function is thus the preeminent source of genomic instability in cancers. In the following sections, we discuss two other classes of proteins that normally function to protect against genomic instability: DNA repair factors and DNA polymerase itself. As with p53, dysfunction of these factors leads to more rapid accumulation of genomic damage (a "mutator" phenotype), speeding cancer development and progression. Finally, we will describe a special type of regulated genomic instability specific to lymphoid cells that also is a source of oncogenic mutations.

DNA Mismatch Repair Factors. DNA mismatch repair proteins work together to act as "spell checkers" during the process of DNA replication. For example, if there is an erroneous pairing of G with T rather than the normal A with T, the mismatch-repair factors correct the defect. With "proofreading" function lost, errors accumulate throughout the genome. Some of these errors may by chance create driver mutations, and with time a cancer may result. One of the hallmarks of mismatch-repair defects is *microsatellite instability*. Microsatellites are tandem repeats of one to six nucleotides found throughout the genome. In normal people the length of these microsatellites remains constant. However, if mismatch repair is defective, these satellites are unstable and increase or decrease in length, creating mutated alleles.

Hereditary nonpolyposis colon cancer (HNPCC) syndrome (also known as Lynch syndrome) is an autosomal dominant disorder associated with carcinomas that arise predominantly in the cecum and proximal colon (Chapter 17). Individuals with HNPCC syndrome inherit one abnormal copy of a mismatch repair gene. Trouble arises when cells acquire somatic loss-of-function mutations, presumably at random, in their single normal alleles. Germline loss-of-function mutations in at least four different genes can produce HNPCC syndrome. The most commonly affected genes are *MSH2* and *MLH1*, each accounting for approximately 30% of HNPCC syndrome. Microsatellite instability also is observed in about 15% of sporadic colon cancers and less frequently in many other cancer types. In sporadic cancers, defects in mismatch repair usually stem from epigenetic silencing of the *MLH1* gene, rather than somatic mutations.

Nucleotide Excision Repair Factors. UV radiation causes cross-linking of pyrimidine residues, preventing normal DNA replication. Such DNA damage is repaired by the nucleotide excision repair system. Several genes are involved in nucleotide excision repair. Inherited loss-of-function mutations in any of these genes gives rise to a syndrome called *xeroderma pigmentosum* that is marked by an extraordinarily high risk of skin cancers, specifically squamous cell carcinoma and basal cell carcinoma.

Homologous Recombination Repair Factors. Other types of DNA damage, particularly covalent DNA cross-links and double-stranded DNA breaks, are repaired through a complex process called homologous recombination. Several disorders caused by defects in homologous recombination factors are associated with an increased risk of cancer, as follows:

- *Bloom syndrome* is an autosomal recessive disorder caused by loss-of-function mutations in a helicase that is required for homologous recombination repair. Affected individuals have developmental anomalies and an increased risk of developing many different types of cancer.
- *Ataxia telangiectasia* is an autosomal recessive disorder caused by defects in *ATM,* a gene encoding a kinase that acts upstream of p53. This syndrome is characterized by neurodegeneration (particularly of the cerebellum, hence the ataxia), immunodeficiency, hypersensitivity to radiation (due to an inability to repair double-stranded DNA breaks), and predisposition to cancer, particularly certain forms of leukemia and lymphoma. Somatic driver mutations in *ATM* also are common in certain types of lymphoid neoplasms.
- *Fanconi anemia* is an autosomal recessive disorder that may be caused by mutations in more than a dozen different genes, each encoding a protein that participates in a pathway that repairs DNA cross-links through homologous recombination. It is characterized by developmental abnormalities (short stature, skeletal abnormalities), hypersensitivity to chemotherapeutic agents that cross-link DNA, and increased risk of bone marrow failure (aplasia) and leukemia.
- *Familial breast cancer* often is associated with inherited defects in genes that are required for homologous recombination repair. Mutations in two genes, *BRCA1* and *BRCA2,* account for 25% of cases. Certain germline *BRCA2* mutations cause Fanconi anemia, and it appears that BRCA proteins and Fanconi proteins function cooperatively in a DNA damage response network linked to homologous recombination repair. Defects in this pathway lead to the activation of the salvage

nonhomologous end-joining pathway, formation of dicentric chromosomes, bridge-fusion-breakage cycles, and aneuploidy, just as occurs in p53-deficient cells that undergo telomere shortening (see Fig. 7.32). In addition to breast cancer, women with *BRCA1* mutations have a substantially higher risk of epithelial ovarian cancers, and men have a slightly higher risk of prostate cancer. Mutations in the *BRCA2* gene are associated with a broader spectrum of cancers including breast cancer in men and women as well as cancers of the ovary, prostate, pancreas, bile ducts, stomach, melanocytes, and B lymphocytes.

DNA Polymerase. Under normal circumstances, cellular DNA polymerases involved in DNA replication have a very low rate of error, defined as addition of nucleotide that does not match its partner on the template strand of DNA. This fidelity stems in part from an inherent exonuclease activity that allows DNA polymerase to pause, excise mismatched bases, and insert the proper nucleotide before proceeding down the template strand. Subsets of certain cancers, most often endometrial carcinomas and colon cancers, harbor mutations in DNA polymerase that result in a loss of this "proofreading" function and the accumulation of numerous point substitutions. Cancers with DNA polymerase mutations are the most heavily mutated of all human cancers and, presumably because of a high burden of neoantigens, appear to have excellent responses to immune checkpoint inhibitors.

Regulated Genomic Instability in Lymphoid Cells. A special type of DNA damage plays a central role in the pathogenesis of tumors of B and T lymphocytes. As described in Chapter 6, adaptive immunity relies on the ability of B and T cells to diversify their antigen receptor genes. Developing B and T cells both express a pair of gene products, RAG1 and RAG2, that carry out V(D)J segment recombination, permitting the assembly of functional antigen receptor genes. In addition, after encountering antigen, mature B cells express a specialized enzyme called activation-induced cytosine deaminase (AID), which is required for both immunoglobulin gene class switch recombination and somatic hypermutation. These processes are associated with AID-induced DNA breaks or nucleotide substitutions, both of which are prone to errors such as translocations and mutations that cause lymphoid neoplasms (Chapter 13).

KEY CONCEPTS

GENOMIC INSTABILITY AS ENABLER OF MALIGNANCY

- Persons with inherited mutations of genes involved in DNA repair systems are at greatly increased risk for the development of cancer.
- Patients with HNPCC syndrome have defects in the mismatch repair system, leading to development of carcinomas of the colon. These patients' genomes show microsatellite instability, characterized by changes in length of short repeats throughout the genome.
- Patients with xeroderma pigmentosum have a defect in the nucleotide excision repair pathway and are at increased risk for the development of cancers of the skin exposed to UV light because of an inability to repair pyrimidine dimers.
- Syndromes involving defects in the homologous recombination DNA repair system constitute a group of disorders—Bloom syndrome, ataxia-telangiectasia, and Fanconi anemia—that are characterized by developmental disorders and hypersensitivity to DNA-damaging agents, such as ionizing radiation. *BRCA1* and *BRCA2*, which are mutated in familial breast cancers, are involved in DNA repair.
- Mutations in DNA polymerase that abolish proofreading function leads to genomic instability in subsets of colonic and endometrial carcinomas.
- T and B cells undergo regulated genomic instability during somatic gene rearrangements. Errors in this process are an important cause of lymphoid neoplasms.

Cancer-Enabling Inflammation

Infiltrating cancers provoke a chronic inflammatory reaction, leading some to liken them to "wounds that do not heal." In patients with advanced cancers, this inflammatory reaction can be so extensive as to cause systemic signs and symptoms such as anemia (Chapter 14), fatigue, and cachexia (described later). However, studies carried out on cancers in animal models suggest that inflammatory cells also modify the tumor cells and the local microenvironment to enable many of the hallmarks of cancer. These effects may stem from direct interactions between inflammatory cells and tumor cells or through indirect effects of inflammatory cells on other resident stromal cells, particularly cancer-associated fibroblasts and endothelial cells. Proposed cancer-enabling effects of inflammatory cells and resident stromal cells include the following:

- *Release of factors that promote proliferation.* Infiltrating leukocytes and activated stromal cells secrete a wide variety of growth factors such as EGF, as well as proteases that can liberate growth factors from the ECM.
- *Removal of growth suppressors.* The growth of epithelial cells is normally suppressed by cell–cell and cell–ECM interactions. Proteases released by inflammatory cells can degrade the adhesion molecules that mediate these interactions, removing a barrier to growth.
- *Enhanced resistance to cell death.* Recall that detachment of epithelial cells from basement membranes and from cell–cell interactions leads to a form of cell death called *anoikis*. It is suspected that tumor-associated macrophages prevent anoikis by expressing adhesion molecules such as integrins that promote direct physical interactions with the tumor cells. There is also substantial evidence that stromal cell–cancer cell interactions increase the resistance of cancer cells to chemotherapy, presumably by activating signaling pathways that promote cell survival in the face of stresses such as DNA damage.
- *Inducing angiogenesis.* Inflammatory cells release numerous factors, including VEGF, which stimulate angiogenesis.
- *Activating invasion and metastasis.* Proteases released from macrophages foster tissue invasion by remodeling the ECM, while factors such as TNF and EGF may directly stimulate tumor cell motility. As mentioned, other factors released from stromal cells, such as TGF-β, may promote

EMT, which is considered to be a key event in the process of invasion and metastasis.

- *Evading immune destruction.* A variety of soluble factors released by macrophages and other stromal cells may contribute to the immunosuppressive microenvironment of tumors, including TGF-β and a number of other factors that either favor the recruitment of immunosuppressive Tregs or suppress the function of CD8+ cytotoxic T cells. Furthermore, there is abundant evidence in murine cancer models and emerging evidence in human disease that advanced cancers contain alternatively activated (M2) macrophages (Chapter 3), cells induced by cytokines such as IL-4 and IL-13. These macrophages produce cytokines that promote angiogenesis, fibroblast proliferation, and collagen deposition, all of which are commonly observed in invasive cancers. In addition, macrophages may suppress effective host immune responses to cancer cells by expressing the immune checkpoint factor PD-L1 and through other mechanisms that remain to be fully elucidated.

Although a thorough understanding of how cancers "manipulate" inflammatory cells to support their growth and survival remains elusive, there is substantial interest in the development of therapies directed at tumor-induced inflammation and its downstream consequences. Of note in this regard, antiinflammatory cyclooxygenase-2 (COX-2) inhibitors have been shown to decrease the incidence of colonic adenomas and are approved for treatment of patients with familial adenomatous polyposis.

Dysregulation of Cancer-Associated Genes

The genetic damage that activates oncogenes or inactivates tumor suppressor genes may be subtle (e.g., point mutations) or may involve segments of chromosomes large enough to be detected in a routine karyotype. Activation of oncogenes and loss of function of tumor suppressor genes by mutations were discussed earlier in this chapter. Here we discuss chromosomal abnormalities and epigenetic changes that contribute to carcinogenesis and then briefly touch on the role of noncoding RNAs.

Chromosomal Changes

Certain chromosomal abnormalities are highly associated with particular neoplasms and inevitably lead to the dysregulation of genes with an integral role in the pathogenesis of that tumor type. Specific recurrent chromosomal abnormalities have been identified in most leukemias and lymphomas, many sarcomas, and an increasing number of carcinomas. In addition, whole chromosomes may be gained or lost. Although changes in chromosome number (aneuploidy) and structure are generally considered to be late phenomena in cancer progression, in some cases (e.g., in cells that have lost their telomeres; see Fig. 7.32), it can be an early event that initiates the transformation process.

Historically, chromosomal changes in cancer were identified through karyotyping, the morphologic identification of metaphase chromosomes prepared from clinical specimens. Today, however, cancer cell karyotypes are being reconstructed in research laboratories from deep sequencing of cancer cell genomes, and it is possible that conventional karyotyping will be supplanted by other methods even in clinical laboratories in the years to come. Whatever technology is used, the study of chromosomal changes in tumor cells is important. First, genes in the vicinity of recurrent chromosomal breakpoints or deletions are very likely to be either oncogenes (e.g., *MYC, BCL2, ABL*) or tumor suppressor genes (e.g., *APC, RB*). Second, certain karyotypic abnormalities have diagnostic value or important prognostic or therapeutic implications. For example, tests that detect and quantify *BCR-ABL* fusion genes or their mRNA products are essential for the diagnosis of CML and are used to monitor the response to BCR-ABL kinase inhibitors. Many other chromosomal aberrations that are characteristic of specific tumor types are presented in later chapters.

Table 7.8 Selected Examples of Oncogenes Created by Translocations

Malignancy	Translocation	Affected Genes
Chronic myeloid leukemia (CML)	(9;22)(q34;q11)	*ABL* 9q34 *BCR* 22q11
Acute myeloid leukemia (AML)	(8;21)(q22;q22) (15;17)(q22;q21)	*AML* 8q22 *ETO* 21q22 *PML* 15q22 *RARA* 17q21
Burkitt lymphoma	(8;14)(q24;q32)	*MYC* 8q24 *IGH* 14q32
Mantle cell lymphoma	(11;14)(q13;q32)	*CCND1* 11q13 *IGH* 14q32
Follicular lymphoma	(14;18)(q32;q21)	*IGH* 14q32 *BCL2* 18q21
Ewing sarcoma	(11;22)(q24;q12)	*FLI1* 11q24 *EWSR1* 22q12
Prostatic adenocarcinoma	(7;21)(p22;q22) (17;21)(p21;q22)	*TMPRSS2* (21q22.3) *ETV1* (7p21.2) *ETV4* (17q21)

Chromosomal Translocations. Any type of chromosomal rearrangement—translocations, inversions, amplifications, and even small deletions—can activate proto-oncogenes, but chromosomal translocation is the most common mechanism. Notable examples of oncogenes activated by chromosomal translocations are listed in Table 7.8. Translocations can activate proto-oncogenes in two ways:

- By promoter or enhancer substitution, in which the translocation results in overexpression of a proto-oncogene by swapping its regulatory elements with those of another gene, typically one that is highly expressed.
- By formation of a fusion gene in which the coding sequences of two genes are fused in part or in whole, leading to the expression of a novel chimeric protein with oncogenic properties.

Overexpression of a proto-oncogene caused by translocation is exemplified by Burkitt lymphoma. Virtually all Burkitt lymphomas have a translocation involving chromosome 8q24, where the *MYC* gene resides, and one of the three chromosomes that carry an immunoglobulin gene. At its normal locus, *MYC* is tightly controlled and is most highly expressed in actively dividing cells. In Burkitt lymphoma the most common translocation moves the *MYC*-containing

segment of chromosome 8 to chromosome 14q32 (see Fig. 7.23), placing it close to the immunoglobulin heavy chain *(IGH)* gene. The genetic notation for the translocation is t(8;14)(q24;q32). The molecular mechanisms of the translocation-mediated overexpression of *MYC* are variable, as are the precise breakpoints within the *MYC* gene. In most cases the translocation removes regulatory sequences of the *MYC* gene and replaces them with the control regions of the *IGH* gene, which is highly expressed in B cells. The *MYC* coding sequences remain intact, and the MYC protein is constitutively expressed at high levels. The almost invariable presence of *MYC* translocations in Burkitt lymphomas attests to the importance of *MYC* overactivity in the pathogenesis of this tumor.

There are many other examples of translocations involving oncogenes and antigen receptor loci in lymphoid tumors. For these (or any other) translocations to occur, double-stranded DNA breaks must occur simultaneously in at least two places in the genome, and the free DNA ends must then be joined to create two new derivative chromosomes. In lymphoid cells, most of these molecular misadventures are believed to occur during attempts at normal antigen receptor gene recombination (which occurs in both B- and T-cell progenitors) or class-switch recombination (which is confined to antigen-stimulated mature B cells). Not unexpectedly, tumors with translocations involving immunoglobulin genes are always of B-cell origin, and tumors with translocations involving T-cell receptor genes are always of T-cell origin. The affected genes are diverse, but as with translocations involving *MYC,* the net effect is overexpression of some protein with oncogenic activity.

The *Philadelphia chromosome,* characteristic of CML and a subset of B-cell acute lymphoblastic leukemias (Chapter 13), provides the prototypic example of a chromosomal rearrangement that creates a fusion gene encoding a chimeric oncoprotein. In this instance the two chromosome breaks lie within the *ABL* gene on chromosome 9 and within the *BCR (b*reakpoint *c*luster *r*egion) gene on chromosome 22 (see Fig. 7.23). Nonhomologous end-joining then leads to a reciprocal translocation that creates an oncogenic *BCR-ABL* fusion gene on the derivative chromosome 22 (the so-called Philadelphia chromosome). *BCR-ABL* fusion genes encode chimeric BCR-ABL proteins with constitutive tyrosine kinase activity. Since the discovery of *BCR-ABL* in CML, many other fusion oncogenes encoding constitutively active tyrosine kinases have been described in a broad array of human cancers. Like BCR-ABL, these fusion proteins drive oncogenic signaling pathways and have sometimes proven to be targets of effective therapies.

Other oncogenic fusion genes encode nuclear factors that regulate transcription or chromatin structure. In contrast to overactive tyrosine kinases, less is known about how nuclear fusion oncoproteins contribute to cancer. An exception with important clinical consequences is found in *acute promyelocytic leukemia* (APML). APML is virtually always associated with a reciprocal translocation between chromosomes 15 and 17 that produces a *PML-RARA* fusion gene (Fig. 7.40). How this fusion gene functions is now reasonably well understood.

- The fusion gene encodes a chimeric protein consisting of part of a protein called PML and part of the retinoic acid receptor-α (RARα). Normal RARα binds to DNA and activates transcription in the presence of retinoids. Among the RARα responsive genes are a number that are needed for the differentiation of myeloid progenitors into neutrophils.
- The PML-RARα oncoprotein has diminished affinity for retinoids, such that at physiologic levels retinoids do not bind to PML-RARα to any significant degree. In this "unliganded" state, it retains the capacity to bind DNA, but instead of activating transcription, it inhibits transcription through recruitment of transcriptional repressors. This interferes with the expression of genes that are needed for differentiation, leading to a "pile-up" of proliferating myeloid progenitors that replace normal bone marrow elements.
- When given in pharmacologic doses, all-*trans* retinoic acid (ATRA) binds to PML-RARα and causes a conformational change that results in the displacement of repressor complexes and the recruitment of different complexes that activate transcription. There also is evidence that ATRA-bound PML-RARA complexes are degraded more rapidly. These changes overcome the block in gene expression, causing the neoplastic myeloid progenitors to differentiate into neutrophils and die (as normal mature neutrophils do), clearing the marrow over several days and allowing for recovery of normal hematopoiesis.

This highly effective therapy is the first example of *differentiation therapy,* in which immortal tumor cells are induced to differentiate into their mature progeny, which have limited lifespans. It has also spurred efforts to develop drugs that target other nuclear oncoproteins, despite the inherent difficulty of the problem.

Deletions. Chromosomal deletions are another very common structural abnormality in tumor cells. Deletion of specific regions of chromosomes is associated with the loss of particular tumor suppressor genes.

As we discussed earlier, deletions involving chromosome 13q14, the site of the *RB* gene, are associated with retinoblastoma, and deletion of the *VHL* tumor suppressor gene on chromosome 3p is a common event in renal cell carcinomas. Sequencing of cancer cell genomes has revealed many more examples of deletions involving tumor suppressor genes, as well as small insertions of DNA from one site into another. Not all deletions lead to loss of gene function, however; a subset activates oncogenes through the same mechanisms as chromosomal translocations. For example, about 25% of T-cell acute lymphoblastic leukemias have small deletions of chromosome 1 that juxtapose the *TAL1* proto-oncogene with a nearby active promoter, leading to overexpression of the TAL1 transcription factor. Many other examples of "addition by genomic subtraction" have now been discovered through sequencing of cancer genomes.

Gene Amplification. Overexpression of oncogenes may also result from reduplication and amplification of their DNA sequences. Such amplification may produce up to several hundred copies of the oncogene in the tumor cell. In some cases the amplified genes produce chromosomal changes that can be identified microscopically. Two mutually exclusive patterns are seen: (1) multiple small extrachromosomal structures called *double minutes* and (2) *homogeneous*

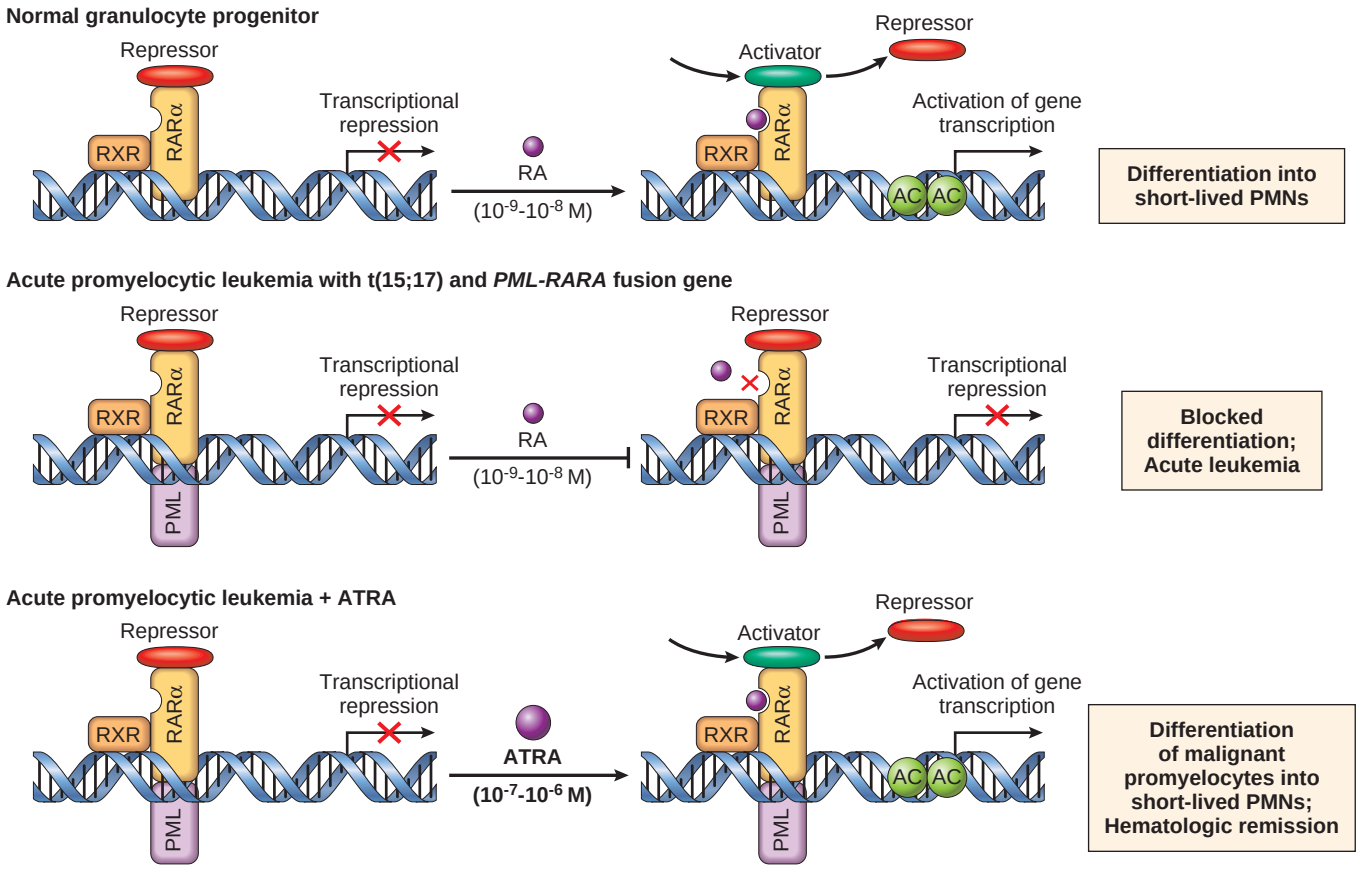

Figure 7.40 Molecular pathogenesis of acute promyelocytic leukemia *(PML)* and basis for response to all-*trans* retinoic acid *(ATRA)*. *PMN*, Polymorphonuclear neutrophil; *RA*, retinoic acid; *RXR*, binding partner for normal RARa and PML-RARa fusion protein encoded by a chimeric gene created by the (15;17) translocation in acute promyelocytic leukemia.

staining regions. The latter derive from the insertion of the amplified genes into new chromosomal locations, which may be distant from the normal location of the involved oncogene. The affected chromosomal regions lack a normal pattern of light- and dark-staining bands, appearing homogeneous in karyotypes (see Fig. 7.24). From a clinical perspective the most important amplifications are *NMYC* in neuroblastoma and *ERBB2* in breast cancers. *NMYC* is amplified in 25% to 30% of neuroblastomas, and its amplification is associated with poor prognosis. *ERBB2* amplification occurs in about 20% of breast cancers. As already mentioned, antibody therapy directed against the HER2 receptor encoded by *ERBB2* is an effective therapy for this molecular subset of breast cancers.

Complex Chromosomal Rearrangements. The true extent of chromosome rearrangements in cancer is only now coming into view thanks to sequencing of entire cancer cell genomes, which allows for comprehensive "reconstruction" of chromosomes from DNA sequences. This exercise has revealed not only a large number of simple rearrangements (e.g., small deletions, duplications, or inversions), but also much more dramatic chromosomal "catastrophes" that stem from chromothrypsis (literally, chromosome shattering). *Chromothrypsis* is observed in 1% to 2% of cancers as a whole and is particularly common in osteosarcomas and gliomas. It appears to result from a single event in which dozens to hundreds of chromosome breaks occur in a single chromosome or several chromosomes. The genesis of these breaks is uncertain, but DNA repair mechanisms are activated that stitch the pieces together in a haphazard way, creating many rearrangements, deletions, and even amplifications. It is hypothesized that such catastrophic events may by chance mutate multiple cancer genes simultaneously thereby expediting the process of carcinogenesis.

KEY CONCEPTS

GENETIC LESIONS IN CANCER

- Tumor cells may acquire several types of oncogenic mutations including point mutations and other nonrandom chromosomal abnormalities, such as translocations, deletions, and gene amplifications.
- Translocations contribute to carcinogenesis by overexpression of oncogenes or generation of novel fusion proteins with altered signaling capacity. Deletions frequently cause loss of tumor suppressor gene function and occasionally activate proto-oncogenes. Gene amplification generally increases the expression and function of oncogenes.
- Genomic sequencing has revealed numerous "cryptic" (subcytogenetic) rearrangements, mainly small deletions and insertions ("indels"), as well as chromothrypsis, in which a chromosome is "shattered" and then reassembled in a haphazard way.

Epigenetic Changes

Epigenetic changes have been implicated in many aspects of the malignant phenotype including the expression of cancer genes, the control of differentiation and self-renewal, and drug sensitivity and drug resistance. As discussed in Chapter 1, "epigenetics" refers to factors other than the sequence of DNA that regulate gene expression (and thereby cellular phenotype). Recall that epigenetic mechanisms include histone modifications catalyzed by enzymes associated with chromatin regulatory complexes; DNA methylation, a modification created by DNA methyltransferases; and other alterations that regulate the higher order organization of DNA (e.g., looping of enhancer elements onto gene promoters).

It has been recognized for more than a hundred years that the nuclei of cancer cells display abnormal morphologies, which (as discussed earlier) may take the form of hyperchromasia, chromatin clumping, or chromatin clearing (so-called vesicular nuclear chromatin). These altered appearances stem from disturbances of chromatin organization. One of the most notable findings emerging from the sequencing of cancer genomes has been the identification of numerous mutations involving genes that encode epigenetic regulatory proteins (Table 7.9). As a result, it is now suspected that the altered morphologic appearance of cancer cells reflects acquired genetic defects in factors that maintain the epigenome. Indeed, methods that allow genome-wide assessments have begun to reveal widespread alterations in cancer cell epigenomes, which can be broadly divided into the following categories:

- *Silencing of tumor suppressor genes by local hypermethylation of DNA.* Some cancer cells exhibit selective hypermethylation of the promoters of tumor suppressor genes that results in their transcriptional silencing. Typically, hypermethylation occurs on only one allele, and the function of the other copy of the affected tumor suppressor gene is lost through another mechanism, such as a disabling point mutation or a deletion. One of several examples of a tumor suppressor gene that is hypermethylated in several cancers is *CDKN2A,* which you will recall is a complex locus that encodes two tumor suppressors, p14/ARF and p16/INK4a, that enhance p53 and RB activity, respectively.
- *Global changes in DNA methylation.* In addition to local hypermethylation of tumor suppressor genes, many tumors exhibit abnormal patterns of DNA methylation throughout their genomes. Tumors commonly exhibiting abnormal DNA methylation, such as acute myeloid leukemia, sometimes have mutations in genes encoding DNA methyltransferases or other proteins that influence DNA methylation (see Table 7.9), suggesting that the observed alterations have a genetic basis. The most obvious potential consequence of global changes in methylation is altered expression of multiple genes, which may be overexpressed or underexpressed compared to normal depending on the nature of local changes.
- *Changes in histones.* You will recall that histones are responsible for "packaging" of DNA and that changes in histone positioning or posttranslational modifications (so-called histone marks) regulate gene transcription. Cancer cells often demonstrate changes in histones near genes that influence cellular behavior. As with DNA methylation, in many instances these alterations appear to have a genetic basis, being attributable to mutations in proteins that "write," "read," and "erase" histone marks or that position nucleosomes on DNA (see Table 7.9). Remarkably, in some cancers, driver mutations occur in the histone genes themselves. Details have yet to emerge, but it is certain that these lesions alter the expression of genes that contribute to the malignant phenotype.

Table 7.9 Examples of Epigenomic Regulatory Genes That Are Mutated in Cancer

Gene(s)	Function	Tumor (Approximate Frequency of Mutation)
DNMT3A	DNA methylation	Acute myeloid leukemia (20%)
MLL1	Histone methylation	Acute leukemia in infants (90%)
MLL2	Histone methylation	Follicular lymphoma (90%)
CREBBP/EP300	Histone acetylation	Diffuse large B-cell lymphoma (40%)
ARID1A	Nucleosome positioning/chromatin remodeling	Ovarian clear cell carcinoma (60%), endometrial carcinoma (30%–40%)
SNF5	Nucleosome positioning/chromatin remodeling	Malignant rhabdoid tumor (100%)
PBRM1	Nucleosome positioning/chromatin remodeling	Renal carcinoma (30%)
H3F3A, HIST1H3B	Histone H3 variants (nucleosome components)	Pediatric gliomas (30%–80%, depending on anatomic location)

Much remains to be deciphered about the state of the "epigenome" in various cancers and its contribution to the malignant state, but several aspects of the relationship merit emphasis.

- *The lineage-specificity of certain oncogenes and tumor suppressor genes has an epigenetic basis.* You may have noticed that tumor suppressors and oncoproteins can be broadly divided into two classes, those that are mutated or otherwise dysregulated in many cancers (e.g., RAS, MYC, p53) and those that are mutated in a restricted subset of tumors (e.g., RB in retinoblastoma, VHL in renal cell carcinoma, APC in colon carcinoma) and are thus lineage-restricted. A cancer cell's lineage or differentiation state, like that of normal cells, is dependent on epigenetic modifications that produce a pattern of gene expression that characterizes that particular cell type. It follows that lineage-restricted cancer genes act only within epigenetic contexts in which key oncogenic targets are controlled by these genes. At its extremes, this allows some genes, such as those encoding Notch receptors, to act as a tumor suppressor in one lineage and behave as an oncogene in another. Thus, the *NOTCH1* gene is one of the most commonly mutated tumor suppressor genes in squamous

cell carcinoma of the skin (in which the mutations result in loss of function and lead to impaired differentiation) and is also the most commonly mutated oncogene in T-cell acute lymphoblastic leukemia (in which mutations in different parts of the gene result in gain of function and drive the expression of pro-growth genes such as *MYC*).

- *The epigenome is a therapeutic target.* Because the epigenetic state of a cell depends on reversible modifications that are carried out by enzymes (which are generally good drug targets), there is intense interest in developing drugs that target epigenomic modifiers in cancer and other diseases. Inhibitors of histone deacetylases, chromatin erasers that remove acetyl groups from histones, are approved for use in certain lymphoid tumors, and DNA methylation inhibitors are used to treat myeloid tumors, based in part on the idea that these drugs may reactivate tumor suppressor genes. Other drugs that target specific chromatin writers and chromatin readers are now being tested in clinical trials.
- *Cancers likely exhibit considerable epigenetic heterogeneity.* Just as genomic instability gives rise to genetic heterogeneity in cancers, it is feared that cancers will also prove to have extensive epigenetic heterogeneity from cell to cell within individual tumors. One consequence of such heterogeneity may be drug resistance. For example, epigenetic alterations can lead to the resistance of lung cancer cells to inhibitors of EGF receptor signaling. When the inhibitors are removed, the lung cancer cells revert to their prior inhibitor-sensitive state. If widespread, such epigenetic plasticity may join genetic heterogeneity as yet another barrier to the development of curative cancer therapies.

Noncoding RNAs and Cancer

Noncoding RNAs participate in carcinogenesis by regulating the expression of protein-coding cancer-associated genes. The best characterized of these noncoding RNAs are microRNAs. As discussed in Chapter 1, microRNAs (miRs) are small noncoding, single-stranded RNAs, approximately 22 nucleotides in length, that mediate sequence-specific inhibition of mRNAs. Given that miRs control normal cell survival, growth, and differentiation, it is not surprising that they play a role in carcinogenesis. Altered miR expression, sometimes stemming from amplifications and deletions of miR loci, has been identified in many cancers. Decreased expression of certain miRs increases the translation of oncogenic mRNAs; such miRs have tumor suppressive activity. For example, deletions affecting miR-15 and miR-16 are among the most frequent genetic lesions in chronic lymphocytic leukemia, a common tumor of older adults (Chapter 13). In this tumor, loss of these mIRs leads to upregulation of the anti-apoptotic protein BCL-2, enhancing tumor cell survival. Conversely, overexpression of other miRs represses the expression of tumor suppressor genes; such miRs promote tumor development and are referred to as *onco-miRs.* One example of an onco-miR is miR-155, which is overexpressed in many human B-cell lymphomas and indirectly upregulates a large number of genes that promote proliferation, including *MYC*.

The involvement of miRs may be the proverbial tip of the iceberg with respect to the role of noncoding RNAs in cancer. Systematic genomic analyses have revealed that more than 60% of the genome is transcribed into RNAs, most of which are noncoding and believed to have regulatory functions (Chapter 1).

Molecular Basis of Multistep Carcinogenesis

Given that malignant tumors must acquire multiple "hallmarks" of cancer, it follows that cancers result from the stepwise accumulation of multiple mutations that act in complementary ways to produce a fully malignant tumor. The notion that malignant tumors arise from a sequential accumulation of cancer-promoting alterations is supported by epidemiologic, experimental, and molecular studies, and the study of oncogenes and tumor suppressor genes has provided a firm molecular footing for the concept of multistep carcinogenesis. Genome-wide sequencing of cancers has revealed as few as 10 or so mutations in certain leukemias to many thousands of mutations (most of which are passengers rather than drivers) in tumors that arise following chronic exposure to carcinogens, such as lung cancers associated with cigarette smoking. A more direct answer to the question "how many mutations does it take to establish a fully malignant tumor?" comes from experimental attempts to transform normal human cells with combinations of oncogenes, some derived from transforming viruses (described later). For example, normal human epithelial cells can be transformed by the following combination of events: (1) activation of RAS; (2) inactivation of RB; (3) inactivation of p53; (4) inactivation of PP2A, a tumor suppressive phosphatase that is a negative regulator of many signaling pathways; and (5) constitutive expression of telomerase. Cells bearing all of these alterations are immortal and produce invasive, fully malignant growths when injected into immunodeficient mice.

Unlike in the laboratory, these events presumably never occur simultaneously during the natural development of a human cancer, but instead occur in a stepwise fashion. What is the evidence that this is so? A classic example of incremental acquisition of the malignant phenotype is found in colon carcinoma. Many of these cancers evolve through a series of morphologically identifiable stages, most notably the formation of adenomas that progressively enlarge and ultimately undergo malignant transformation (Chapter 17). Molecular analyses of proliferations at each stage has indeed shown that precancerous lesions have fewer mutations than adenocarcinomas and that certain mutations tend to occur early (e.g., mutations in the tumor suppressor gene *APC*) or late (e.g., mutations in *TP53*) in the process (discussed in detail in Chapter 17). Similar evidence for stepwise progression exists for other recognizable precursor lesions to epithelial cancers, such as dysplasias of the cervix, epidermis, and oral mucosa, and hyperplasias of the endometrium. These are also described in subsequent chapters.

CARCINOGENIC AGENTS AND THEIR CELLULAR INTERACTIONS

More than 200 years ago the London surgeon Sir Percival Pott correctly attributed scrotal skin cancer in chimney sweeps to chronic exposure to soot. Based on this observation,

Table 7.10 Major Chemical Carcinogens

Direct-Acting Carcinogens
Alkylating Agents
β-Propiolactone Dimethyl sulfate Diepoxybutane Anticancer drugs (cyclophosphamide, chlorambucil, nitrosoureas, and others)
Acylating Agents
1-Acetyl-imidazole Dimethylcarbamyl chloride
Procarcinogens That Require Metabolic Activation
Polycyclic and Heterocyclic Aromatic Hydrocarbons
Benz[*a*]anthracene Benzo[*a*]pyrene Dibenz[*a,h*]anthracene 3-Methylcholanthrene 7,12-Dimethylbenz[*a*]anthracene
Aromatic Amines, Amides, Azo Dyes
2-Naphthylamine (β-naphthylamine) Benzidine 2-Acetylaminofluorene Dimethylaminoazobenzene (butter yellow)
Natural Plant and Microbial Products
Aflatoxin B_1 Griseofulvin Cycasin Safrole Betel nuts
Others
Nitrosamine and amides Vinyl chloride, nickel, chromium Insecticides, fungicides Polychlorinated biphenyls

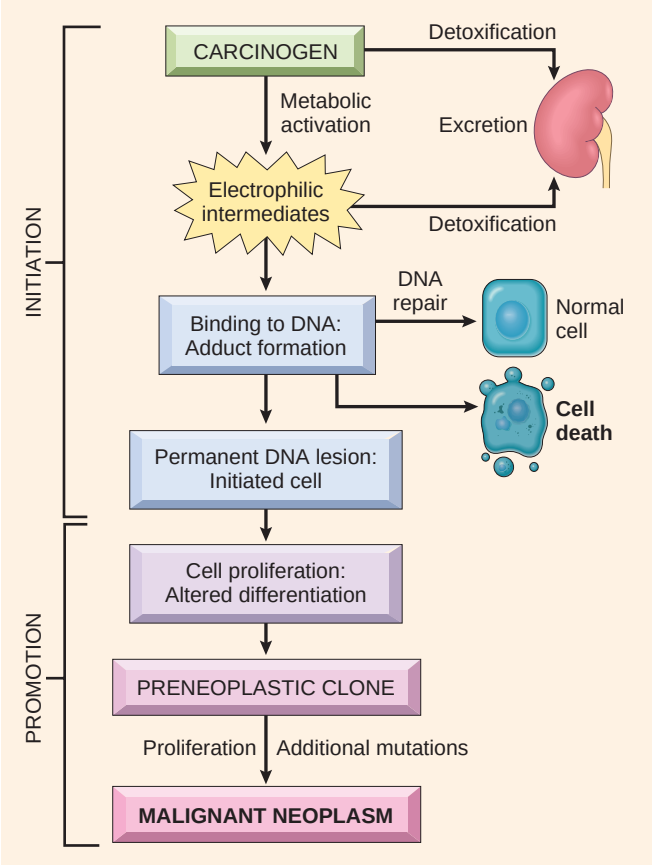

Figure 7.41 General schema of events in chemical carcinogenesis. Note that promoters cause clonal expansion of the initiated cell, thus producing a preneoplastic clone. Further proliferation induced by the promoter or other factors causes accumulation of additional mutations and emergence of a malignant tumor.

the Danish Chimney Sweeps Guild ruled that its members must bathe daily. No public health measure since that time has achieved as much in controlling a form of cancer! Subsequently, hundreds of chemicals have been shown to be carcinogenic in animals. Some of the major agents are listed in Table 7.10.

Chemical Carcinogenesis

As discussed earlier, carcinogenesis is a multistep process. This is readily demonstrated in experimental models of chemical carcinogenesis, in which the stages of initiation and promotion during cancer development were first described. The classic experiments that allowed the distinction between initiation and promotion were performed on mouse skin and revealed the following concepts relating to the initiation-promotion sequence: *Initiation* results from exposure of cells to a sufficient dose of a carcinogenic agent. It causes permanent DNA damage (mutations). *Promoters* can induce tumors to arise from initiated cells, but they are not tumorigenic by themselves. Application of promoters leads to proliferation and clonal expansion of initiated (mutated) cells. Driven to proliferate, subclones of the initiated cells suffer various additional mutations, and eventually a cancerous clone with all the hallmark characteristics emerges. It is likely that many factors contributing to oncogenesis in humans also act by stimulating proliferation and thus can be thought of conceptually as tumor promoters; examples include unopposed estrogenic stimulation of the endometrium and breast and chronic inflammatory processes associated with tissue repair (e.g., inflammatory bowel disease, chronic hepatitis, and Barrett esophagus).

Although the concepts of initiation and promotion have been derived largely from experiments in mice, they are useful concepts when considering the roles of certain factors that contribute to human cancers. With this brief overview, initiation and promotion can be examined in more detail (Fig. 7.41). All initiating chemical carcinogens are highly reactive electrophiles (have electron-deficient atoms) that can react with nucleophilic (electron-rich) atoms in the cell. Their targets are DNA, RNA, and proteins, and in some cases these interactions cause cell death. Initiation, obviously, inflicts nonlethal damage to the DNA that is repaired in some error-prone fashion. The mutated cell then passes on the DNA lesions to its daughter cells. Chemicals that can cause initiation of carcinogenesis fall into two categories: direct acting and indirect acting.

Direct-Acting Carcinogens

***Direct-acting carcinogens* do not require metabolic conversion to become carcinogenic.** Most are weak carcinogens, but some are important because they are cancer chemotherapeutic drugs (e.g., alkylating agents). Tragically, in some instances these agents have cured, controlled, or delayed recurrence of certain types of cancer (e.g., leukemia, lymphoma, or breast carcinoma), only to evoke a second form of cancer, usually acute myeloid leukemia. The risk of induced cancer is low, but its existence dictates judicious use of such agents.

Indirect-Acting Carcinogens

***Indirect-acting carcinogens* require metabolic conversion to become active carcinogens; the carcinogenic products are called *ultimate carcinogens*.** Most chemical carcinogens act indirectly and require metabolic activation for conversion into ultimate carcinogens (Fig. 7.41). Some of the most potent indirect chemical carcinogens—the polycyclic hydrocarbons—are present in fossil fuels. Others, for example, benzo[*a*]pyrene (the active component of soot, which Potts showed to be carcinogenic), are formed during the high-temperature combustion of tobacco in cigarettes and are implicated in the causation of lung cancer. Polycyclic hydrocarbons also are produced from animal fats during the process of broiling or grilling meats and are present in smoked meats and fish. The aromatic amines and azo dyes are another class of indirect-acting carcinogens that were widely used in the past in the aniline dye and rubber industries. Many other occupational carcinogens are listed in Table 7.10.

Most indirect carcinogens are metabolized by *cytochrome P-450–dependent monooxygenases*. The genes that encode these enzymes are polymorphic, and the activity and inducibility of these enzymes vary significantly among individuals (described further in Chapter 9). Because these enzymes are essential for the activation of procarcinogens, the susceptibility to carcinogenesis is related in part to the particular polymorphic variants that an individual inherits. Thus it may be possible to assess cancer risk in a given individual by genetic analysis of such enzyme polymorphisms.

The metabolism of polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene by the product of the P-450 gene, *CYP1A1,* provides an instructive example. Approximately 10% of the white population carry a highly inducible form of this gene. Light smokers with the susceptible *CYP1A1* genotype have a sevenfold higher risk of developing lung cancer compared with smokers without the permissive genotype. Metabolic pathways also are involved in the inactivation (detoxification) of certain procarcinogens or their derivatives, and variation in these pathways also may influence cancer risk.

Molecular Targets of Chemical Carcinogens. Because malignant transformation results from mutations, it comes as no surprise that most chemical initiating agents target DNA and are mutagenic. There is no single or unique alteration associated with cancer initiation. Nor is there any apparent predisposition for initiators to cause mutations in particular genes; presumably, mutations occur throughout the genome, and cells that by chance suffer damage to the "usual suspects"—oncogenes and tumor suppressors such as *RAS* and *TP53*—gain a potential selective advantage and are at risk for subsequent transformation.

This is not to say that mutations induced by carcinogens occur in an entirely random fashion. Because of their chemical structures, some carcinogens interact preferentially with particular DNA sequences or bases and thus produce mutations that are clustered at "hotspots" or that are enriched for particular base substitutions. This phenomenon is illustrated by a mutational "hotspot" associated with exposure to *aflatoxin* B_1, a naturally occurring agent produced by some strains of the mold *Aspergillus*. *Aspergillus* grows on improperly stored grains and nuts, and there is a strong correlation between the dietary level of this food contaminant and the incidence of hepatocellular carcinoma in parts of Africa and the Far East. Interestingly, aflatoxin B_1–associated hepatocellular carcinomas tend to have a particular mutation in *TP53*, a G:C→T:A transversion in codon 249 that produces an arginine-to-serine substitution in the p53 protein that interferes with its function. In contrast, *TP53* mutations are infrequent in liver tumors from areas where aflatoxin contamination of food does not occur, and few of these mutations involve codon 249. Similarly, lung cancers associated with smoking have a 10-fold higher mutational burden on average than lung cancers in nonsmokers, and these excess mutations are strongly skewed toward particular base substitutions known to be caused by carcinogens in cigarette smoke (the proverbial "smoking gun"). Sequencing of cancer genomes has revealed several dozen other mutational "signatures." One of these signatures reflects exposure to chemotherapeutic agents, but the rest are largely unexplained, suggesting that other carcinogenic agents lurk in the environment, awaiting discovery.

Additional potential carcinogens in the workplace and at home include vinyl chloride, arsenic, nickel, chromium, insecticides, fungicides, and polychlorinated biphenyls. Nitrites used as food preservatives also have caused concern, as they react with amines contained in the food to form nitrosoamines, which are suspected carcinogens.

KEY CONCEPTS

CHEMICAL CARCINOGENESIS

- Chemical carcinogens have highly reactive electrophile groups that directly damage DNA, leading to mutations and eventually cancer.
- Direct-acting agents do not require metabolic conversion to become carcinogenic, while indirect-acting agents are not active until converted to an ultimate carcinogen by endogenous metabolic pathways. Hence, polymorphisms of endogenous enzymes such as cytochrome P-450 may influence carcinogenesis.
- After exposure of a cell to a mutagen or an initiator, tumorigenesis can be enhanced by exposure to promoters, which stimulate proliferation of the mutated cells.
- Examples of human carcinogens are direct-acting agents (e.g., alkylating agents used for chemotherapy), indirect-acting agents (e.g., benzo[*a*]pyrene, azo dyes, aflatoxin), and promoters or agents that cause pathologic hyperplasias of the endometrium or regenerative activity in the liver.

Radiation Carcinogenesis

Radiant energy, in the form of the UV rays of sunlight or as ionizing electromagnetic and particulate radiation, is mutagenic and carcinogenic. UV light exposure causes skin cancers, and ionizing radiation exposure from medical or occupational exposure, nuclear plant accidents, and atomic bomb detonations is associated with a variety of cancers. Although the contribution of ionizing radiation to the total human burden of cancer is probably small, those cancers that do occur may arise decades later, and long periods of observation are necessary to ascertain its full effect. An increased incidence of breast cancer has become apparent decades after women were exposed during childhood to atomic bomb tests. The incidence peaked during 1988–1992 and then declined. Moreover, radiation may have additive or synergistic effects with other potentially carcinogenic factors.

Ultraviolet Rays

Exposure to UV rays derived from the sun, particularly in fair-skinned individuals, is associated with an increased incidence of squamous cell carcinoma, basal cell carcinoma, and melanoma of the skin. The degree of risk depends on the type of UV rays, the intensity of exposure, and skin pigmentation, the latter reflecting the quantity of light-absorbing melanin in the skin. Thus, persons of European origin with fair skin that sunburns easily and stalwartly refuses to tan and who live in locales receiving a great deal of sunlight (e.g., Queensland, Australia, close to the equator) have the highest incidence of skin cancers in the world. The UV portion of the solar spectrum can be divided into three wavelength ranges: UVA (320–400 nm), UVB (280–320 nm), and UVC (200–280 nm). Of these, UVB is believed to be responsible for the induction of cutaneous cancers. UVC, although a potent mutagen, is not considered significant because it is filtered out by the ozone layer surrounding the earth (hence concerns about ozone depletion).

UVB light is carcinogenic because of its ability to cause pyrimidine dimers to form in DNA. Absorption of the energy in a photon of UV light by DNA produces a chemical reaction that leads to covalent cross-linking of pyrimidine bases, particularly adjacent thymidine residues in the same strand of DNA. This distorts the DNA helix and prevents proper pairing of the dimer with bases in the opposite DNA strand. Pyrimidine dimers are repaired by the nucleotide excision repair pathway, a process that may involve 30 or more proteins. It is postulated that with excessive sun exposure, the capacity of the nucleotide excision repair pathway is overwhelmed, and error-prone nontemplated DNA repair mechanisms become operative. These allow the cell to survive but also introduce mutations that, in some instances, lead to cancer. The importance of the nucleotide excision repair pathway of DNA repair is most graphically illustrated by the high frequency of cancers in individuals with the hereditary disorder *xeroderma pigmentosum* (discussed previously). Controversy about the role of UV exposure in the etiology of melanoma was put to rest by sequencing of melanoma genomes. This revealed that melanomas arising in sun-exposed skin harbor enormous numbers of mutations bearing the signature of error-prone repair of pyrimidine dimers, confirming that UV light has an important causative role in this potentially lethal cancer.

Ionizing Radiation

Electromagnetic (x-rays, γ rays) and particulate (α particles, β particles, protons, neutrons) radiations are all carcinogenic. The evidence is voluminous, and a few examples suffice. Many individuals pioneering the use of x-rays developed skin cancers. Miners of radioactive elements in central Europe and the Rocky Mountain region of the United States have a 10-fold higher incidence of lung cancers than the rest of the population. Most telling is the follow-up of survivors of the atomic bombs dropped on Hiroshima and Nagasaki. Initially there was a marked increase in the incidence of certain forms of leukemia after an average latent period of about 7 years. Subsequently the incidence of many solid tumors with longer latent periods (e.g., carcinomas of the breast, colon, thyroid, and lung) increased. Of great concern in the current era of widespread use of computed tomography (CT) scans are studies that have shown that children who get two or three CT scans have a threefold higher risk of leukemia, and those who receive five to 10 such scans have a threefold higher risk of brain tumors. The overall risk in children is very low (roughly one excess leukemia and one excess brain tumor over 10 years per 10,000 CT scans), but nevertheless emphasizes the need to minimize radiation exposure whenever possible.

In humans, for reasons that are not clear, there is a hierarchy of tissue vulnerability to radiation-induced cancers. Most frequent are myeloid leukemias (tumors of granulocytes and their precursors; see Chapter 13). Cancer of the thyroid follows closely but only in young patients. In the intermediate category are cancers of the breast, lungs, and salivary glands. In contrast, skin, bone, and the gastrointestinal tract are relatively resistant to radiation-induced neoplasia, even though gastrointestinal epithelial cells are vulnerable to the acute cell-killing effects of radiation, and the skin is "first in line" for all external radiation. Nonetheless, the physician must not forget: practically *any* cell can be transformed into a cancer cell by sufficient exposure to radiant energy.

KEY CONCEPTS

RADIATION CARCINOGENESIS

- Ionizing radiation causes chromosome breakage, translocations, and, less frequently, point mutations, leading to genetic damage and carcinogenesis.
- UV rays induce the formation of pyrimidine dimers within DNA, leading to mutations. Therefore UV rays can give rise to skin cancers. Individuals with defects in the repair of pyrimidine dimers suffer from xeroderma pigmentosa and are at particularly high risk.
- Exposure to radiation during imaging procedures such as CT scans is linked to a very small, but measurable, increase in cancer risk in children.

Microbial Carcinogenesis

Many RNA and DNA viruses have proved to be oncogenic in animals as disparate as frogs and primates. Despite intense scrutiny, however, only a few viruses have been linked with human cancer. Our discussion focuses on human oncogenic viruses as well as the role of the bacterium *H. pylori* in gastric cancer. A common theme in the pathogenesis

of microbial carcinogenesis is that the infecton triggers cell proliferation, which is initially polyclonal but with time becomes monoclonal by acquisition of driver mutations in rapidly dividing cells.

Oncogenic RNA Viruses

Human T-Cell Leukemia Virus Type 1. Although the study of animal retroviruses has provided spectacular insights into the molecular basis of cancer, only one human retrovirus, human T-cell leukemia virus type 1 (HTLV-1), is firmly implicated in the pathogenesis of cancer in humans.

HTLV-1 causes adult T-cell leukemia/lymphoma (ATLL), a tumor that is endemic in certain parts of Japan, the Caribbean basin, South America, and Africa and found sporadically elsewhere, including the United States. Worldwide, it is estimated that 15 to 20 million people are infected with HTLV-1. Similar to human immunodeficiency virus (HIV), which causes AIDS, HTLV-1 has tropism for CD4+ T cells, and hence this subset of T cells is the major target for neoplastic transformation. Human infection requires transmission of infected T cells via sexual intercourse, blood products, or breastfeeding. Leukemia develops in only 3% to 5% of the infected individuals, typically after a long latent period of 40 to 60 years.

There is little doubt that HTLV-1 infection of T lymphocytes is necessary for leukemogenesis, but the molecular mechanisms of transformation are not defined. In contrast to several murine retroviruses, HTLV-1 does not contain an oncogene, and no consistent integration next to a proto-oncogene has been discovered. In leukemic cells, however, viral integration shows a clonal pattern. In other words, although the site of viral integration in host chromosomes is random (the viral DNA is found at different locations in different cancers), the site of integration is identical within all cells of a given cancer. This would not occur if HTLV-1 were merely a passenger that infects cells after transformation; rather, it means that HTLV-1 must have been present at the moment of transformation, placing it at the "scene of the crime."

The HTLV-1 genome contains the *gag, pol, env,* and long-terminal-repeat regions typical of all retroviruses, but, in contrast to other leukemia viruses, it contains two other genes referred to as *tax* and *HBZ*. Several aspects of HTLV-1's transforming activity may be attributable to the protein products of these genes. Tax is essential for viral replication because it stimulates transcription of viral RNA from the 5′ long terminal repeat. HBZ is a transcription factor, and Tax and HBZ alter the transcription of host cell genes and interact with certain host cell signaling proteins. In doing so, they appear to contribute to the acquisition of cancer hallmarks, though the mechanisms remain unclear; effects on intracellular signals that regulate growth and cell survival, induction of genomic instability, and inhibition of senescence all have been suggested. Whatever the actual mechanism, it is quite inefficient, given the typical latency period of many decades between infection and the development of leukemia, which appears in only a small subset of infected individuals.

Oncogenic DNA Viruses

As with RNA viruses, several oncogenic DNA viruses that cause tumors in animals have been identified. Of the various human DNA viruses, five—HPV, EBV, HBV, Merkel cell polyomavirus, and human herpesvirus 8 (HHV8, also called Kaposi sarcoma herpesvirus)—have been implicated in the causation of human cancer. Merkel cell polyomavirus has been identified in Merkel cell carcinomas and is described in Chapter 25. HHV8 is discussed in Chapters 6 and 11. Although not a DNA virus, HCV is also associated with cancer and is discussed here briefly.

Human Papillomavirus. At least 70 genetically distinct types of HPV have been identified. Some types (e.g., 1, 2, 4, and 7) cause benign squamous papillomas (warts) in humans. In contrast, high-risk HPVs (e.g., types 16 and 18) have been implicated in the genesis of squamous cell carcinomas of the cervix, anogenital region, and head and neck (particularly tumors arising in the tonsillar mucosa). These cancers are sexually transmitted diseases caused by chronic HPV infection. In contrast to cervical cancers, genital warts have low malignant potential and are associated with low-risk HPVs, predominantly HPV-6 and HPV-11.

What explains the variation in cancer risk among HPV strains? In benign warts, the HPV genome is maintained in a nonintegrated episomal form, while in cancers the HPV genome is integrated into the host genome, suggesting that integration of viral DNA is one factor. As with HTLV-1, the site of viral integration in host chromosomes is random, but the pattern of integration is clonal. Integration always occurs in a fashion that interrupts the viral DNA within the E1/E2 open reading frame, leading to loss of the E2 viral repressor and increased expression of the HPV E6 and E7 genes, which are responsible for the oncogenic potential of HPV (Fig. 7.42).

- *Oncogenic activities of E6.* The E6 protein binds to and mediates the degradation of p53 and stimulates the expression of telomerase reverse transcriptase (TERT), the catalytic subunit of telomerase, which you will recall contributes to the immortalization of cells. E6 from high-risk HPV types has a higher affinity for p53 than E6 from

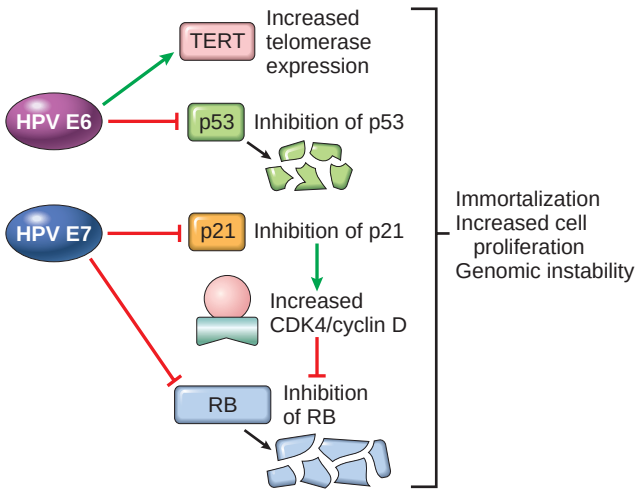

Figure 7.42 Transforming effects of human papillomavirus *(HPV)* E6 and E7 proteins. The net effect of HPV E6 and E7 proteins is to immortalize cells and remove the restraints on cell proliferation (see Fig. 7.26). *TERT,* Telomerase reverse transcriptase. (Modified from Münger K, Howley PM: Human papillomavirus immortalization and transformation functions, *Virus Res* 89:213–228, 2002.)

low-risk HPV types, a distinction that likely accounts for the difference in cancer risk.

- *Oncogenic activities of E7.* The E7 protein has effects that complement those of E6, all of which are centered on speeding cells through the G_1/S cell cycle checkpoint. It binds to the RB protein and displaces the E2F transcription factors that are normally sequestered by RB, promoting progression through the cell cycle. As with E6 proteins and p53, E7 proteins from high-risk HPV types have a higher affinity for RB than do E7 proteins from low-risk HPV types. E7 also inactivates the CDK inhibitors p21 and p27. Finally, E7 proteins from high-risk HPVs (types 16, 18, and 31) also bind and presumably activate cyclins A and E.

To summarize, **high-risk HPV types express oncogenic proteins that inactivate tumor suppressors, activate cyclins, inhibit apoptosis, and combat cellular senescence.** Thus, it is evident that HPV proteins promote many of the hallmarks of cancer. The primacy of HPV infection in the causation of cervical cancer is confirmed by the effectiveness of HPV vaccines in preventing cervical cancer. However, infection with HPV itself is not sufficient for carcinogenesis. For example, when human keratinocytes are transfected with DNA from HPV types 16, 18, or 31 in vitro, they are immortalized but do not form tumors. Cotransfection with a mutated *RAS* gene results in full malignant transformation. In addition to such genetic cofactors, HPV in all likelihood also acts in concert with environmental factors. These include cigarette smoking, coexisting microbial infections, dietary deficiencies, and hormonal changes, all of which have been implicated in the pathogenesis of cervical cancers. A high proportion of women infected with HPV clear the infection by immunologic mechanisms, but others do not because of acquired immune abnormalities, such as those that result from HIV infection, or for unknown reasons. As might be expected, women who are coinfected with high-risk HPV types and HIV have an elevated risk of cervical cancer.

Epstein-Barr Virus. EBV, a member of the herpesvirus family, was the first virus linked to a human tumor, Burkitt lymphoma. Since its initial discovery 50 years ago, EBV has been implicated in the pathogenesis of a diverse collection of human tumors including various lymphomas, several carcinomas, and even rare sarcomas. The most common EBV-associated tumors are lymphomas derived from B cells and nasopharyngeal carcinoma; other EBV-associated neoplasms are discussed elsewhere in this book.

The manner in which EBV causes B-cell tumors such as Burkitt lymphoma is complex and incompletely understood, but best appreciated by considering its effects on normal B cells. EBV has surface glycoproteins that recognize and bind the complement receptor CD21, allowing the virus to attach to and infect B cells. This probably occurs in the tonsils following exposure to the virus in saliva. Viral infection of B cells is latent; that is, there is no viral replication, and the cells are not killed. However, EBV proteins are expressed in latently infected B cells that allow the cells to grow indefinitely (immortalization). The molecular basis of B-cell growth and immortalization is complex, but as with other viruses it involves the "hijacking" of several normal signaling pathways. One EBV gene, latent membrane protein-1 *(LMP-1),* is an oncogene capable of inducing B-cell lymphomas in mice. LMP-1 behaves like a constitutively active CD40 receptor, a key recipient of helper T-cell signals that stimulate B-cell growth (Chapter 6). LMP-1 activates the NF-κB and JAK/STAT signaling pathways and promotes B-cell survival and proliferation, all of which occur autonomously (i.e., without T cells or other outside signals) in EBV-infected B cells. Concurrently, LMP-1 prevents apoptosis by activating BCL2. Thus, the virus "borrows" normal B-cell activation pathways to expand the pool of latently infected cells. Another EBV gene, *EBNA-2,* encodes a nuclear protein that mimics a constitutively active Notch receptor. EBNA-2 transactivates several host genes, including cyclin D and the *SRC* family of proto-oncogenes. In addition, the EBV genome contains a gene encoding a homologue of IL-10 (vIL-10) that was "borrowed" from the host genome. vIL-10 suppresses the activation of T cells by macrophages and contributes to EBV-dependent transformation of B cells.

The EBV proteins that are required for B-cell immortalization and proliferation are highly immunogenic, and in normal individuals the EBV-driven polyclonal B-cell proliferation is readily controlled by a cytotoxic T-cell response. Depending on the timing and intensity of this response, the individual either remains asymptomatic or develops a self-limited episode of infectious mononucleosis (Chapter 8). If T-cell immunity is defective, however, EBV transformed B cells can produce a rapidly progressive, fatal lymphoma.

Burkitt lymphoma is a neoplasm of B lymphocytes that is endemic in central Africa and New Guinea, areas where it is the most common tumor of childhood. A morphologically identical lymphoma occurs sporadically throughout the world. The association between endemic Burkitt lymphoma and EBV is strong:

- More than 90% of endemic tumors carry the EBV genome.
- All affected patients have elevated antibody titers against viral capsid antigens.
- Serum antibody titers against viral capsid antigens are correlated with the risk of developing the tumor.

Although EBV is intimately involved in the causation of Burkitt lymphoma, several observations suggest that additional factors are involved. (1) EBV infection is not limited to the geographic locales where Burkitt lymphoma is found; in fact, it is a ubiquitous virus that infects almost all humans worldwide. (2) The EBV genome is found in only 15% to 20% of Burkitt lymphomas outside of endemic regions. (3) There are significant differences in the patterns of viral gene expression in EBV-transformed (but not tumorigenic) B-cell lines and Burkitt lymphoma cells. Most notably, Burkitt lymphoma cells do not express LMP-1, EBNA2, and other EBV proteins that drive B-cell growth and immortalization.

Given these observations, how then does EBV contribute to the genesis of endemic Burkitt lymphoma? One possibility is shown in Fig. 7.43. In regions where Burkitt lymphoma is endemic, concomitant infections such as malaria impair immune competence, allowing sustained B-cell proliferation. Eventually, T-cell immunity directed against EBV antigens such as EBNA2 and LMP-1 eliminates most of the EBV-infected B cells, but a small number of cells downregulate expression of these immunogenic antigens. These cells persist indefinitely, even in the face of normal immunity. Lymphoma cells may

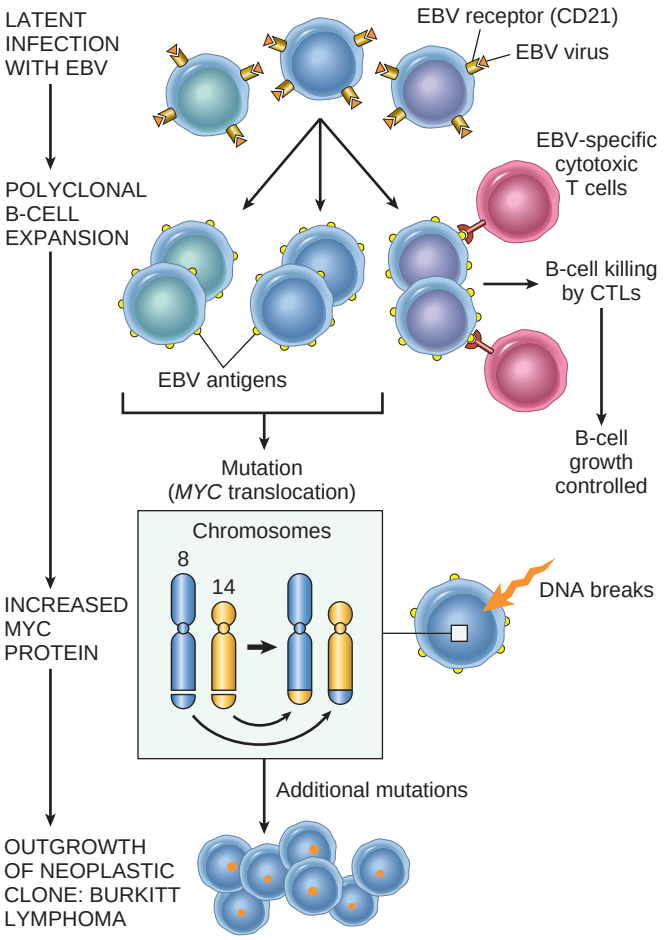

Figure 7.43 Pathogenesis of Epstein-Barr virus *(EBV)*–induced Burkitt lymphoma. *CTLs*, Cytotoxic T lymphocytes.

emerge from this population only with the acquisition of specific mutations, most notably translocations involving the *MYC* oncogene, as virtually all endemic and sporadic tumors possess the t(8;14) or other translocations that dysregulate *MYC*. Thus although sporadic Burkitt lymphomas are triggered by mechanisms other than EBV, they appear to develop through similar oncogenic pathways.

In summary, **in the case of Burkitt lymphoma, it seems that EBV is not directly oncogenic, but by acting as a polyclonal B-cell mitogen sets the stage for the acquisition of the (8;14) translocation and other mutations that ultimately produce a full-blown cancer.** In most individuals, EBV infection is readily controlled by effective immune responses, and lymphomagenesis is rare. By contrast, in regions where Burkitt lymphoma is endemic, cofactors such as chronic malaria may favor the acquisition of additional genetic events (e.g., t(8;14)) that lead to transformation.

The role played by EBV is more direct in B-cell lymphomas arising in immunosuppressed patients. Some persons with AIDS or who receive immunosuppressive therapy for preventing allograft rejection develop EBV-positive B-cell tumors, often at multiple sites and within extranodal tissues such as the gut or the central nervous system. These proliferations are polyclonal at the outset but can evolve into monoclonal neoplasms. In contrast to Burkitt lymphoma, tumors in immunosuppressed patients usually express LMP-1 and EBNA2, which are antigenic and would normally be recognized by cytotoxic T cells. Also, in contrast to Burkitt lymphoma, B-cell tumors in immunosuppressed individuals usually lack *MYC* translocations. These potentially lethal proliferations can be subdued if T-cell immunity can be restored, as may occur with withdrawal of immunosuppressive drugs in transplant recipients.

Nasopharyngeal carcinoma also is strongly associated with EBV. This tumor is endemic in southern China, parts of Africa, and the Inuit population of the Arctic. In contrast to Burkitt lymphoma, all nasopharyngeal carcinomas obtained from all parts of the world contain EBV, and antibody titers to viral capsid antigens are uniformly elevated in affected patients. The structure of the viral genome is identical (clonal) within individual tumors, indicating that EBV infection occurred before tumor development. EBV thus has a central role in the genesis of nasopharyngeal carcinoma, but (as with Burkitt lymphoma) its restricted geographic distribution indicates that genetic or environmental cofactors also contribute to its development. Unlike Burkitt lymphoma, LMP-1 is expressed in nasopharyngeal carcinoma cells and (as in B cells) activates the NF-κB pathway, which upregulates the expression of factors such as VEGF, FGF-2, MMP-9, and COX-2 that may contribute to oncogenesis. Nasopharyngeal carcinomas typically contain prominent infiltrates composed of T cells, which may be responding to viral antigens such as LMP-1, but this response is ineffective, suggesting that immune evasion mechanisms are likely to be important in this cancer. In line with this idea, nasopharyngeal carcinoma cells often express the immune checkpoint molecule PD-L1 and are responsive to PD-L1 inhibitors. Interestingly, EBV-positive carcinomas resembling nasopharyngeal carcinoma occasionally arise at other sites, such as the stomach and the thymus.

The relationship of EBV to the pathogenesis of Hodgkin lymphoma, yet another EBV-associated tumor, is discussed in Chapter 13.

***Hepatitis B and C Viruses.* Worldwide, 70% to 85% of hepatocellular carcinomas are associated with infection with HBV or HCV.** HBV is endemic in countries of the Far East and Africa; correspondingly, these areas have the highest incidence of hepatocellular carcinoma. Despite compelling evidence incriminating HBV and HCV, the mode of action of these viruses in liver tumorigenesis is not fully elucidated. Oncogenes have yet to be identified in HBV or HCV genomes, and although the HBV DNA is integrated within the human genome, there is no consistent pattern of integration in liver cells. Indeed, while the oncogenic effects of HBV and HCV are multifactorial, the dominant effect seems to be immunologically mediated chronic inflammation and hepatocyte death leading to hepatocyte proliferation during regeneration and, over time, genomic damage.

As with any cause of hepatocellular injury, chronic viral infection leads to the compensatory proliferation of hepatocytes. This regenerative process is aided and abetted by a plethora of growth factors, cytokines, chemokines, and other bioactive substances. These are produced by activated immune cells and promote cell survival, tissue remodeling, and angiogenesis (Chapter 3). The activated immune cells

also produce other mediators, such as reactive oxygen species, that are genotoxic and mutagenic. One key molecular step may be activation of the NF-κB pathway, which blocks apoptosis, allowing the dividing hepatocytes to incur genotoxic stress and to accumulate mutations. Although this seems to be a dominant mechanism in the pathogenesis of virus-induced hepatocellular carcinoma, the HBV genome also contains genes that may directly promote the development of cancer. For example, an HBV gene known as *HBx* can activate a variety of transcription factors and several signal transduction pathways. In addition, viral integration can cause structural changes in chromosomes that dysregulate oncogenes and tumor suppressor genes.

Although not a DNA virus, HCV is also strongly linked to the pathogenesis of liver cancer. The molecular mechanisms used by HCV are less well defined than are those of HBV. In addition to chronic liver cell injury and compensatory regeneration, components of the HCV genome, such as the HCV core protein, may have a direct effect on tumorigenesis, possibly by activating a variety of growth-promoting signal transduction pathways.

Helicobacter pylori

First incriminated as a cause of peptic ulcers, *H. pylori* now has acquired the dubious distinction of being the first bacterium classified as a carcinogen. Indeed, *H. pylori* infection is implicated in the genesis of both gastric adenocarcinomas and gastric lymphomas.

The proposed scenario for the development of gastric adenocarcinoma in the setting of *H. pylori* infection is similar to that of HBV- and HCV-induced liver cancer, as it involves increased epithelial cell proliferation in a background of chronic inflammation. As in viral hepatitis, the inflammatory milieu contains numerous genotoxic agents, such as reactive oxygen species. The *H. pylori* genome also contains genes directly implicated in oncogenesis. Strains associated with gastric adenocarcinoma have been shown to contain a "pathogenicity island" that contains cytotoxin-associated A *(CagA)* gene. Although *H. pylori* is noninvasive, *CagA* penetrates into gastric epithelial cells, where it has a variety of effects including the initiation of a signaling cascade that mimics unregulated growth factor stimulation. The infection initially leads to development of chronic gastritis, followed by gastric atrophy, intestinal metaplasia of the lining cells, dysplasia, and cancer. This sequence takes decades to complete and occurs in only 3% of infected patients.

H. pylori is specifically associated with the development of gastric lymphomas of B-cell origin (also discussed in Chapters 13 and 17). Their molecular pathogenesis is incompletely understood but seems to involve strain-specific *H. pylori* factors as well as host genetic factors, such as polymorphisms in the promoters of inflammatory cytokines such as IL-1β and TNF. It is thought that *H. pylori* infection leads to the appearance of *H. pylori*–reactive T cells, which in turn stimulate a polyclonal B-cell proliferation. In chronic infections, currently unknown mutations may be acquired that give individual cells a growth advantage. These cells grow out into a monoclonal MALToma that nevertheless remains dependent on T-cell stimulation of B-cell pathways that activate the transcription factor NF-κB. At this stage, eradication of *H. pylori* by antibiotic therapy "cures" the lymphoma by removing the antigenic stimulus for T cells. At later stages, however, additional mutations may be acquired that cause constitutive NF-κB activation. At this point, the MALToma no longer requires the antigenic stimulus of the bacterium for growth and survival and develops the capacity to spread beyond the stomach to other tissues.

KEY CONCEPTS

VIRAL AND BACTERIAL ONCOGENESIS``

HTLV-1: a retrovirus that is endemic in Japan, the Caribbean, and parts of South America and Africa that causes adult T-cell leukemia/lymphoma.

- HTLV-1 encodes two viral proteins, Tax and HBX, which are suspected to contribute to leukemogenesis through uncertain mechansisms.
- After a long latent period (decades), a small fraction of HTLV-1–infected individuals develop adult T-cell leukemia/lymphoma, a CD4+ tumor that arises from an HTLV-1–infected cell, presumably due to acquisition of additional mutations in the host cell genome.

HPV: an important cause of benign warts, cervical cancer, and oropharyngeal cancer.

- Oncogenic types of HPV encode the viral oncoproteins E6 and E7, which bind to p53 and Rb, respectively, with high affinity and neutralize their function.
- Development of cancer is associated with integration of HPV into the host genome and additional mutations needed for acquisition of cancer hallmarks.
- HPV cancers can be prevented by vaccination against high-risk HPV types.

EBV: ubiquitous herpesvirus implicated in the pathogenesis of Burkitt lymphomas, B-cell lymphomas in patients with T-cell immunosuppression (HIV infection, transplant recipients), and several other cancers.

- The EBV genome harbors several genes encoding proteins that trigger B-cell signaling pathways; in concert, these signals are potent inducers of B-cell growth and transformation.
- In the absence of T-cell immunity, EBV-infected B cells can rapidly "grow out" as aggressive B-cell tumors.
- In the presence of normal T-cell immunity, a small fraction of infected patients develop EBV-positive B-cell tumors (Burkitt lymphoma, Hodgkin lymphoma) or carcinomas (e.g., nasopharyngeal carcinoma).

HBV and HCV: cause of 70% to 85% of hepatocellular carcinomas worldwide.

- Oncogenic effects are multifactorial; dominant effect seems to be immunologically mediated chronic inflammation, hepatocellular injury, and reparative hepatocyte proliferation.
- HBx protein of HBV and the HCV core protein can activate signal transduction pathways that also may contribute to carcinogenesis.

H. pylori: implicated in gastric adenocarcinoma and MALToma.

- Pathogenesis of *H. pylori*–induced gastric cancers is multifactorial including chronic inflammation and reparative gastric cell proliferation.
- *H. pylori* pathogenicity genes, such as *CagA*, also may contribute by stimulating growth factor pathways.
- Chronic *H. pylori* infection leads to polyclonal B-cell proliferations that may give rise to a B-cell lymphoma (MALToma) of the stomach as a result of accumulation of mutations.

CLINICAL ASPECTS OF NEOPLASIA

Clinical Manifestations

Ultimately the importance of neoplasms lies in their effects on patients. Although malignant tumors are of course more threatening than benign tumors, any tumor, even a benign one, may cause morbidity and mortality.

Local and Hormonal Effects

Location is a critical determinant of the clinical effects of benign and malignant tumors. Tumors may impinge upon vital tissues and impair their function, cause death of involved tissues, and provide a nidus for infection. A small (1 cm) pituitary adenoma, although benign and possibly nonfunctional, can compress and destroy the surrounding normal gland and thus lead to serious hypopituitarism. Cancers arising within or metastatic to an endocrine gland may cause an endocrine insufficiency by destroying the gland. Neoplasms in the gut, both benign and malignant, may cause obstruction as they enlarge. Infrequently, peristaltic movement telescopes the neoplasm and its affected segment into the downstream segment, producing an obstructing intussusception (Chapter 17). Symptoms produced by a cancer due to its position can (ironically) be life-saving; for example, the few survivors of pancreatic cancer are those whose tumors "fortuitously" obstruct bile ducts early in their course, leading to the appearance of jaundice and other symptoms at a stage of the disease when surgical cure is possible.

Benign and malignant neoplasms arising in endocrine glands can cause clinical problems by producing hormones. Such functional activity is more typical of benign than of malignant tumors, which are more likely to be poorly differentiated and nonfunctional. A benign beta-cell adenoma of the pancreatic islets less than 1 cm in diameter may produce sufficient insulin to cause fatal hypoglycemia. In addition, nonendocrine tumors may elaborate hormones or hormone-like products and give rise to paraneoplastic syndromes (discussed later). The erosive and destructive growth of cancers or the expansile pressure of a benign tumor on any natural surface, such as the skin or mucosa of the gut, may cause ulcerations, secondary infections, and bleeding. Melena (blood in the stool) and hematuria, for example, are characteristic of neoplasms of the gut and urinary tract.

Cancer Cachexia

Cancer cachexia is a hypercatabolic state defined by a loss of muscle mass (with or without loss of fat) that cannot be explained by diminished food intake. It occurs in about 50% of cancer patients, most commonly in individuals with advanced gastrointestinal, pancreatic, and lung cancers, and is responsible for about 30% of cancer deaths. It is a highly debilitating condition characterized by extreme weight loss, fatigue, muscle atrophy, anemia, anorexia, and edema. Mortality is generally the consequence of atrophy of the diaphragm and other respiratory muscles.

The precise causes of cancer cachexia are not known, but inflammatory mediators, particularly TNF, IL-1, and IL-6, appear to have important roles. Administration of any of these cytokines to mice induces cachexia, whereas tumor-bearing mice are protected from cachexia by knockout of the TNF receptor. These observations are bolstered by clinical studies showing that cachexia in cancer patients is associated with higher levels of inflammatory cytokines. Evidence suggests that muscle loss occurs through a direct effect of inflammatory cytokines on skeletal muscle cells. Specifically, it appears that cytokines increase the degradation of major skeletal muscle structural proteins, such as myosin heavy chain, through signaling pathways that lead to ubiquitination of target proteins followed by proteolysis via the proteasome. It is also worth noting that similar cachetic states may be seen in patients without cancer, such as in those with chronic disseminated infections and AIDS, presumably at least in part due to the effects of inflammatory cytokines.

However, it must also be recognized that therapies directed against individual cytokines (e.g., TNF) in cancer patients have not been effective in reversing cachexia, suggesting that either a multiplicity of inflammatory cytokines, or other factors entirely, are also involved in its pathogenesis. In line with the latter possibility, while muscle wasting is the cardinal feature of cancer cachexia, many patients lose fat stores as well. One factor that may contribute to fat loss is a protein called lipid mobilizing factor, which has been detected in the sera and urine of patients with advanced cancer and which appears to sensitize adipocytes to lipolytic stimuli. It is likely that additional mechanisms underlying cancer cachexia await discovery.

Paraneoplastic Syndromes

Some cancer-bearing individuals develop signs and symptoms that cannot readily be explained by the anatomic distribution of the tumor or by the elaboration of hormones indigenous to the tissue from which the tumor arose; these are known as paraneoplastic syndromes. These occur in about 10% of persons with cancer. Paraneoplastic syndromes are important to recognize for several reasons:

- They may be the earliest manifestation of an occult neoplasm.
- In affected patients they can cause significant clinical problems and may even be lethal.
- They may mimic metastatic disease and therefore confound treatment.

A classification of paraneoplastic syndromes and their presumed origins is presented in Table 7.11. A few comments on some of the more common and interesting syndromes follow.

Endocrinopathies are frequently encountered paraneoplastic syndromes. By definition, the responsible cancers are not of endocrine origin and the secretory activity of such tumors is referred to as ectopic hormone production. *Cushing syndrome* is the most common endocrinopathy. Approximately 50% of affected individuals have carcinoma of the lung, chiefly the small-cell type. It is caused by excessive production of corticotropin (adrenocorticotropic hormone [ACTH]) or corticotropin-like peptides. The precursor of corticotropin is a large molecule known as pro-opiomelanocortin. Lung cancer patients with Cushing syndrome have elevated serum levels of both pro-opiomelanocortin and corticotropin. The former is not found in serum of patients with excess corticotropin produced by the pituitary.

Table 7.11 Paraneoplastic Syndromes

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
Endocrinopathies		
Cushing syndrome	Small cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone secretion	Small cell carcinoma of lung Intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma	Parathyroid hormone-related protein (PTHRP), TGF-α, TNF, IL-1
Hypoglycemia	Ovarian carcinoma Fibrosarcoma Other mesenchymal sarcomas	Insulin or insulin-like substance
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Osteomalacia	Phosphaturic mesenchymal tumor	FGF-23
Nerve and Muscle Syndromes		
Myasthenia	Bronchogenic carcinoma Thymic neoplasms	Immunologic
Disorders of the central and peripheral nervous systems	Breast carcinoma	
Dermatologic Disorders		
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic carcinoma Breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma Thymic neoplasms	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Disseminated intravascular coagulation	Acute promyelocytic leukemia Prostatic carcinoma	Tumor products that activate clotting
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Red cell aplasia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

ACTH, Adrenocorticotropic hormone; *IL*, interleukin; *TGF*, transforming growth factor; *TNF*, tumor necrosis factor; *FGF-23*, fibroblast growth factor-23.

Hypercalcemia is probably the most common paraneoplastic syndrome; in fact, symptomatic hypercalcemia is more often related to cancer than to hyperparathyroidism. Two general processes are involved in cancer-associated hypercalcemia: (1) *osteolysis* induced by cancer, whether primary in bone, such as multiple myeloma, or metastatic to bone from any primary lesion, and (2) the production of *calcemic humoral substances* by extraosseous neoplasms. Only the second mechanism is considered to be paraneoplastic.

The humoral factor that is most commonly associated with paraneoplastic hypercalcemia is *parathyroid hormone–related protein* (PTHRP). As its name implies, PTHRP has partial structural homology to parathyroid hormone (PTH). PTHRP and PTH bind to the same G protein–coupled receptor, known as the PTH/PTHRP receptor (often referred to as PTH-R or PTHRP-R), and share some, but not all, biologic activities. Like PTH, PTHRP increases bone resorption and renal calcium uptake, while inhibiting renal phosphate transport, effects that raise serum calcium levels. In contrast to PTH, PTHRP is produced in small amounts by many normal tissues, including epithelial cell types such as keratinocytes, which may explain the relatively frequent

association of squamous cell carcinomas with PTHRP-induced hypercalcemia. In addition to PTHRP, several other factors, such as IL-1, TGF-α, TNF, and dihydroxyvitamin D, have been causally implicated in the hypercalcemia of malignancy.

The tumors that are most often associated with paraneoplastic hypercalcemia are carcinomas of the breast, lung, kidney, and ovary. In breast cancers, paraneoplastic hypercalcemia is often exacerbated by osteolytic bone metastases. The most common lung neoplasm associated with hypercalcemia is squamous cell carcinoma, typically because of release of PTHRP.

The *neuromyopathic paraneoplastic syndromes* take diverse forms, such as peripheral neuropathies, encephalitis, cortical cerebellar degeneration, a polymyopathy resembling polymyositis, and a myasthenic syndrome similar to *myasthenia gravis* (Chapter 27). The cause of these syndromes is poorly understood, but appears to involve a cancer-induced immunologic attack on normal tissues. The initiating event may be the ectopic expression of antigens that normally are restricted to the neuromuscular system by tumor cells. For unknown reasons, the immune system recognizes these antigens as foreign and mounts a response that leads to tissue damage. This often takes the form of T-cell responses; in some cases, antibodies that cross-react with neuronal cell antigens are detected.

Acanthosis nigricans is a disorder characterized by gray-black patches of thickened, hyperkeratotic skin with a velvety appearance. It occurs rarely as a genetically determined disease in juveniles or adults (Chapter 25). In about 50% of the cases, particularly in adults older than age 40, the appearance of such lesions is associated with cancer, most commonly carcinoma of the stomach. Acanthosis nigricans is sometimes accompanied by the abrupt development of multiple seborrheic keratoses (Leser-Trélat sign). These skin changes may appear before the cancer is discovered.

Hypertrophic osteoarthropathy is encountered in 1% to 10% of patients with lung carcinoma. Rarely, other forms of cancer are involved. This disorder is characterized by (1) periosteal new bone formation, primarily at the distal ends of long bones, metatarsals, metacarpals, and proximal phalanges; (2) arthritis of the adjacent joints; and (3) clubbing of the digits. Although osteoarthropathy is seldom seen in non-cancer patients, clubbing of the fingertips may be encountered in patients with liver diseases, diffuse lung disease, congenital cyanotic heart disease, ulcerative colitis, and other disorders. The cause is unknown.

Several vascular and hematologic manifestations may appear in association with a variety of cancers. As mentioned in the discussion of thrombosis (Chapter 4), *migratory thrombophlebitis* (Trousseau syndrome) may be encountered in association with deep-seated cancers, most often carcinomas of the pancreas or lung. *Disseminated intravascular coagulation* may complicate a diversity of clinical disorders (Chapter 14); among cancers, it is most commonly associated with acute promyelocytic leukemia and prostatic adenocarcinoma. Bland, small, nonbacterial fibrinous vegetations sometimes form on the cardiac valve leaflets (more often on left-sided valves), particularly in individuals with advanced mucin-secreting adenocarcinomas. These lesions, called *nonbacterial thrombotic endocarditis,* are described further in Chapter 12. The vegetations are potential sources of emboli that can further complicate the course of the cancer.

Grading and Staging of Tumors

Methods to quantify the probable clinical aggressiveness of a given neoplasm and its apparent extent and spread are necessary for accurate prognostication and for comparing results of various treatments. For instance, the results of treating well-differentiated thyroid adenocarcinoma that is localized to the thyroid gland will be different from those obtained from treating highly anaplastic thyroid cancers that have invaded surrounding tissues. Systems have been developed that use the level of differentiation, or grade, and the extent of cancer spread, or stage, as parameters of the clinical gravity of the disease.

- *Grading.* Grading of a cancer is based on the degree of differentiation of the tumor cells and, in some cancers, the number of mitoses or architectural features. Grading schemes have evolved for each type of malignancy and generally range from two (low grade and high grade) to four categories. Criteria for the individual grades vary in different types of tumors and so are not detailed here, but all attempt, in essence, to judge the extent to which the tumor cells resemble or fail to resemble their normal counterparts. Although histologic grading is useful, the correlation between histologic appearance and biologic behavior is less than perfect. In recognition of this problem and to avoid spurious quantification, it is common practice to characterize a particular neoplasm in descriptive terms, for example, well-differentiated, mucin-secreting adenocarcinoma of the stomach, or poorly differentiated pancreatic adenocarcinoma.
- *Staging.* The staging of solid cancers is based on the size of the primary lesion, whether it has spread to regional lymph nodes, and the presence or absence of blood-borne metastases. The major staging system currently in use is the American Joint Committee on Cancer Staging. This system uses a classification called the *TNM system—T* for primary tumor, *N* for regional lymph node involvement, and *M* for metastases. TNM staging varies for specific forms of cancer, but there are general principles. The primary lesion is characterized as T1 to T4 based on increasing size. T0 is used to indicate an in situ lesion. N0 would mean no nodal involvement, whereas N1 to N3 would denote involvement of an increasing number and range of nodes. M0 signifies no distant metastases, whereas M1 or sometimes M2 indicates the presence of metastases and some judgment as to their number.

It is increasingly apparent, however, that the molecular features of solid tumors provide important complementary prognostic information that is independent of anatomic staging of cancers. In recognition of this, the American Joint Committee on Cancer (AJCC) has included molecular characterization as an essential part of the standard work-up of early breast cancers (T1–2, N0, M0) in the latest edition of the cancer staging manual. It can be anticipated that as molecular characterization of all cancers becomes widespread, many more prognostic schemes incorporating both anatomic and molecular information will become a routine part of standard-of-care clinical and pathologic practice.

KEY CONCEPTS

CLINICAL ASPECTS OF TUMORS

Cachexia: progressive loss of body fat and lean body mass, accompanied by profound weakness, anorexia, and anemia, that is caused by release of factors by the tumor or host immune cells.

Paraneoplastic syndromes: symptom complexes in individuals with cancer that cannot be explained by tumor spread or release of hormones that are indigenous to the tumor "cell of origin." For example:

- Endocrinopathies (Cushing syndrome, hypercalcemia)
- Neuropathic syndromes (polymyopathy, peripheral neuropathies, encephalopathy, neural degeneration, myasthenic syndromes)
- Skin disorders (acanthosis nigricans)
- Skeletal and joint abnormalities (hypertrophic osteoarthritis)
- Hypercoagulability (migratory thrombophlebitis, disseminated intravascular coagulation, nonbacterial thrombotic endocarditis)
- Grading: determined by cytologic appearance; based on the idea that behavior and differentiation are related, with poorly differentiated tumors having more aggressive behavior.
- Staging: determined by surgical exploration or imaging, is based on size, local and regional lymph node spread, and distant metastases; of greater clinical value than grading.

Laboratory Diagnosis of Cancer

Every year the laboratory diagnosis of cancer becomes more complex, more sophisticated, and more "personalized," increasingly allowing patients to receive therapy that is tailored to the molecular characteristics of their specific tumor. The following sections present the current state of this rapidly evolving art, starting with older standard methods and then moving to new molecular approaches, avoiding technologic details throughout.

Histologic and Cytologic Methods. The laboratory diagnosis of cancer is, in most instances, not difficult. The two ends of the benign-malignant spectrum pose no problem; however, in the middle is a gray zone where even experts tread cautiously. The focus here is on the roles of the clinician (often a surgeon) and the pathologist in facilitating the correct diagnosis.

Clinical data are invaluable for accurate pathologic diagnosis, but clinicians often underestimate its value. Radiation changes in the skin or mucosa can be similar to those associated with cancer. Sections taken from a healing fracture can mimic an osteosarcoma. Moreover, the laboratory evaluation of a lesion is only as good as the specimen made available for examination. It must be adequate, representative, and properly preserved. Several sampling approaches are available: (1) excision or biopsy, (2) needle aspiration, and (3) cytologic smears. When excision is not possible, selection of an appropriate site for biopsy of a mass requires awareness that the periphery may not be representative and the center may be largely necrotic. Appropriate preservation involves such actions as prompt immersion of at least a portion of the specimen in a fixative (usually a formalin solution) and (depending on the differential diagnosis) rapid allocation of tissue for other studies such as cytogenetics, flow cytometry, and molecular diagnostics (described later). Requesting "quick-frozen section" diagnosis is sometimes desirable, for example, in determining the nature of a mass lesion, in evaluating the margins of an excised cancer to ascertain that the entire neoplasm has been removed, or in making decisions about what additional studies beyond histology are needed. This method permits histologic evaluation within minutes. In experienced, competent hands, frozen-section diagnosis is highly accurate, but there are particular instances in which the superior morphologic detail provided by standard histology is needed—for example, when extremely radical surgery, such as the amputation of an extremity, may be indicated. Better to wait a day or two, despite the delay, than to perform inadequate or unnecessary surgery.

Fine-needle aspiration of tumors is another approach that is widely used. The procedure involves aspirating cells and attendant fluid with a small-bore needle, followed by cytologic examination of the stained smear. This method is used most commonly for assessment of readily palpable lesions in sites such as the breast, thyroid, and lymph nodes. With guidance from imaging, the method can also be used to evaluate lesions in deep-seated structures, such as pelvic lymph nodes and pancreas. Fine-needle aspiration is less invasive and more rapidly performed than needle biopsies, and it obviates surgery and its attendant risks. While it may be confounded by sampling errors, in experienced hands it is rapid and quite reliable.

Cytologic smears provide yet another method for cancer detection (Chapter 22). This approach is most widely used to screen for carcinoma of the cervix and its precursor lesions, but it is suitable for evaluation of any form of suspected malignancy in which tumor cells are shed into fluids or are easily accessible. Types of specimens that are commonly examined in cytologic smears for cancer cells include urine, cerebrospinal fluid, pleural effusions, and bronchial washes.

As pointed out earlier, cancer cells have lowered cohesiveness and exhibit a range of morphologic changes encompassed by the term *anaplasia.* Thus shed cells can be evaluated for the features of anaplasia indicative of their origin from a tumor (Fig. 7.44). In these cases, judgment must be rendered based on the features of individual cells or, at most, a clump of cells, without the supporting evidence of loss of orientation of one cell to another, and (most importantly) evidence of invasion. This method permits differentiation among normal, dysplastic, and malignant cells and, in addition, permits the recognition of cellular changes characteristic of carcinoma in situ. The gratifying control of cervical cancer through screening with Pap smears is the best testament to the value of cytology.

Although histology and exfoliative cytology remain the foundation of cancer diagnosis, they have inherent limits; for example, it can be difficult to determine the nature and tissue of origin of a poorly differentiated tumor, and some specific tumor types are notoriously difficult to distinguish based on their morphologic appearance alone (e.g., various acute leukemias and lymphomas). These limitations have spurred the widespread application of immunohistochemistry and flow cytometry, which can be used to make more accurate diagnoses. Another rapidly expanding modality is molecular diagnostics, which is being used increasingly to identify cancers that are amenable to treatment with

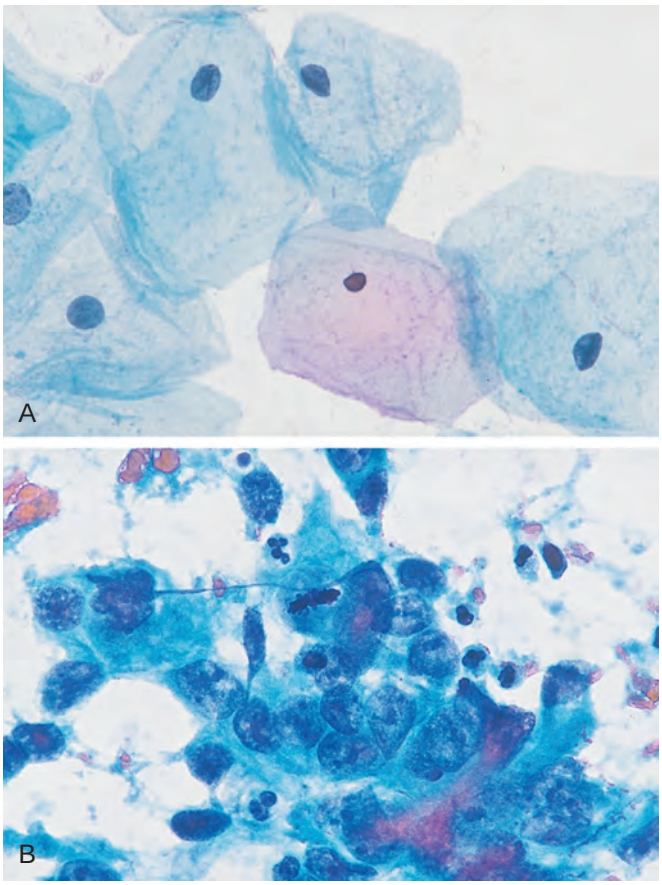

Figure 7.44 Cytology of cervical smears. (A) Normal cervicovaginal smear shows large, flattened squamous cells and groups of metaplastic cells; interspersed are neutrophils. There are no malignant cells. (B) Abnormal cervicovaginal smear shows numerous malignant cells that have pleomorphic, hyperchromatic nuclei; interspersed are normal polymorphonuclear leukocytes. (Courtesy Dr. P. K. Gupta, University of Pennsylvania, Philadelphia, Pa.)

so-called targeted therapies, drugs that are directed at mutated oncoproteins. Only some highlights of these diagnostic modalities are presented.

Immunohistochemistry. The availability of specific antibodies has greatly facilitated the identification of cell products or surface markers. Examples of the utility of immunohistochemistry in the diagnosis or management of malignant neoplasms follow.

- *Categorization of undifferentiated malignant tumors.* In many cases malignant tumors of diverse types resemble each other morphologically because of limited differentiation. Such tumors may be impossible to distinguish in routine hematoxylin and eosin (H&E)–stained tissue sections. For example, certain anaplastic carcinomas, lymphomas, melanomas, and sarcomas may look quite similar, but they must be accurately identified because their treatment and prognosis are different. Antibodies specific to intermediate filaments have proved to be of particular value in such cases because solid tumor cells often contain intermediate filaments characteristic of their cell of origin. For example, the presence of cytokeratins, detected by immunohistochemistry, points to an epithelial origin (carcinoma) (Fig. 7.45), whereas desmin is specific for neoplasms of muscle cell origin, and hematologic malignancies lack these cytoskeletal structures. Other useful immunohistochemical markers include lineage-specific membrane proteins (e.g., CD20, a marker of B-cell tumors) and transcription factors.
- *Determination of site of origin of metastatic tumors.* Many cancer patients present with metastases. In some the primary site is obvious or readily detected on the basis of clinical or radiologic features. In cases in which the origin of the tumor is obscure, immunohistochemical detection of tissue-specific or organ-specific antigens in a biopsy specimen of the metastatic deposit can lead to the identification of the tumor source. For example, prostate-specific antigen (PSA) and thyroglobulin are markers of carcinomas of the prostate and thyroid, respectively.
- *Detection of molecules that have prognostic or therapeutic significance.* Immunohistochemical detection of hormone (estrogen/progesterone) receptors in breast cancer cells is of prognostic and therapeutic value because these cancers are susceptible to antiestrogen therapy (Chapter 23). In general, receptor-positive breast cancers have a better prognosis than receptor-negative tumors. Protein products of oncogenes such as *ERBB2* in breast cancers can also be detected by immunostaining. Breast cancers with strong immunohistochemical staining for the protein product of the *ERBB2* gene product, HER2, generally have a poor prognosis but are amenable to treatment with antibodies that block the activity of the HER2 receptor. Because high-level expression of HER2 is caused by amplification of the *ERBB2* gene, fluorescent in situ hybridization (FISH) to confirm *ERBB2* gene amplification is sometimes used as an adjunct to immunohistochemical studies. Similarly, immunohistochemical stains for ALK protein can be used to identify lung cancers and lymphomas expressing constitutively active ALK fusion proteins, which is an indication for treatment with drugs that inhibit the ALK tyrosine kinase.

Flow Cytometry. Flow cytometry rapidly and quantitatively measures several cell characteristics but requires viable cells

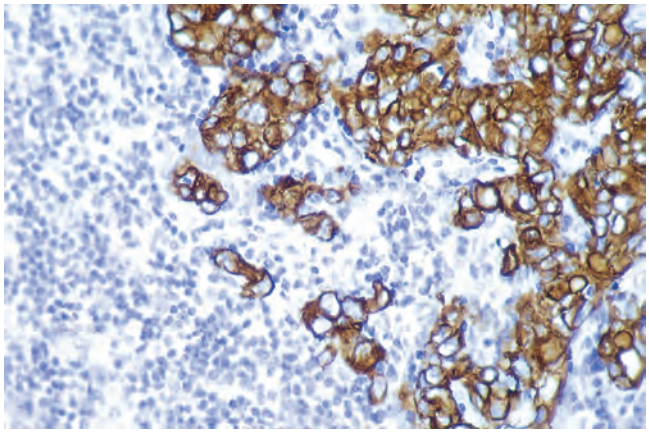

Figure 7.45 Anticytokeratin immunoperoxidase stain of a tumor of epithelial origin (carcinoma). (Courtesy Dr. Melissa Upton, University of Washington, Seattle, Wash.)

in suspension. It is mainly used to identify cellular antigens expressed by "liquid" tumors, those that arise from blood-forming tissues. These include B-cell and T-cell lymphomas and leukemias as well as myeloid neoplasms. An advantage of flow cytometry over immunohistochemistry is that multiple antigens are assessed simultaneously on individual cells using combinations of specific antibodies linked to different fluorescent dyes. Monoclonal antibodies directed against antigens found on blood cells and their progenitors that are frequently detected by flow cytometry are listed in Chapter 13.

Circulating Tumor Cells. Instrumentation that permits detection, quantification, and characterization of rare solid tumor cells (e.g., carcinoma, melanoma) circulating in the blood is being developed as a diagnostic modality. Some of the devices rely on three-dimensional flow cells coated with antibodies specific for tumor cells of interest (e.g., carcinoma cells) that efficiently capture rare tumor cells present in the blood. Such methods have the potential to permit earlier diagnosis, to gauge the risk of metastasis, and to provide a minimally invasive means of assessing the response of tumor cells to therapy, but are mainly being used currently in the realm of clinical research.

Molecular Diagnostics and Cytogenetics. Several molecular or cytogenetic techniques—some established, others emerging—have been used for diagnosis and, in some cases, for predicting behavior of tumors.

- *Diagnosis of malignant neoplasms.* Although molecular methods are not the primary modality of cancer diagnosis, they are of considerable value in selected cases. T- and B-cell tumors are derived from single cells with unique antigen receptor gene rearrangements, whereas reactive lymphoid proliferations contain many different lymphocyte clones, each with a different set of rearrangements antigen receptor genes. For this reason, polymerase chain reaction (PCR)–based evaluation of rearranged T-cell receptor or immunoglobulin genes allows distinction between monoclonal (neoplastic) and polyclonal (reactive) proliferations. Many hematopoietic neoplasms (leukemias and lymphomas) are associated with specific translocations that activate oncogenes. Detection of such translocations, usually by routine cytogenetic analysis or by FISH (Chapter 5), is often extremely helpful in diagnosis. Diagnosis of sarcomas (Chapter 26) with characteristic translocations is also aided by molecular techniques, in part because chromosome preparations are often difficult to obtain from solid tumors. For example, many sarcomas of childhood, so-called round blue cell tumors (Chapter 10), can be difficult to distinguish from each other on the basis of morphology. However, the presence of the characteristic (11;22)(q24;q12) translocation, established by PCR, in such tumors can help to confirm the diagnosis of Ewing sarcoma. Another diagnostic platform with some utility is *DNA microarrays,* either tiling arrays, which cover the entire human genome, or SNP arrays (SNP chips), which allow high-resolution mapping of copy number changes (either deletions or amplifications) genome-wide.
- *Prognosis of malignant neoplasms.* Certain genetic alterations are associated with poor prognosis, and hence their detection allows stratification of patients for therapy. For example, amplification of the *NMYC* gene and deletions of chromosome 1p bode poorly for patients with neuroblastoma, and oligodendrogliomas in which the only genomic abnormality is the loss of chromosomes 1p and 19q respond well to therapy and are associated with long-term survival when compared to tumors without 1p and 19q deletion and with EGF receptor amplification instead.
- *Detection of minimal residual disease.* After treatment of patients with leukemia or lymphoma, the presence of minimal disease or the onset of relapse can be monitored by PCR-based amplification of nucleic acid sequences unique to the malignant clone. For example, detection of *BCR-ABL* transcripts by PCR gives a measure of the residual leukemia cells in treated patients with CML. The prognostic importance of minimal residual disease has been established in acute leukemia and is being evaluated in other neoplasms.
- *Diagnosis of hereditary predisposition to cancer.* As discussed earlier, germline mutations in several tumor suppressor genes, including *BRCA1* and *BRCA2,* as well as the *RET* proto-oncogene, are associated with a high risk of developing specific cancers. Thus, detection of these mutated alleles may allow the patient and physician to devise an aggressive screening program, consider the option of prophylactic surgery, and counsel relatives, who may also be at risk. Such analysis usually requires detection of a specific mutation or sequencing of the entire gene. The latter is necessary when several different cancer-associated mutations are known to exist. Although the detection of mutations in such cases is relatively straightforward, the ethical issues surrounding presymptomatic diagnosis are complex.
- *Guiding therapy with oncoprotein-directed drugs.* An increasing number of chemotherapeutic agents target oncoproteins that are present only in a subset of cancers of a particular type. Thus the molecular identification of genetic lesions that produce these oncoproteins is essential for optimal treatment of patients. Current examples of genetic lesions that guide therapy and are frequently tested for in molecular diagnostic laboratories include the *PML-RARA* fusion gene in acute promyelocytic leukemia, the *BCR-ABL* fusion gene in chronic myeloid leukemia and acute lymphoblastic leukemia, *ERBB1* (EGFR) mutations and *ALK* gene rearrangements in lung cancer, and *BRAF* mutations in melanoma.
- *Identifying mechanisms of drug resistance: liquid biopsies.* These tests rely on circulating tumor cells or, increasingly, cell-free DNA that is shed from dying tumor cells into the blood. The most advanced tests of this type analyze cell-free tumor DNA for the presence of specific driver mutations that create targetable oncoproteins, for example, in lung cancers. These tests use extremely sensitive PCR-based approaches and can be performed on peripheral blood at multiple timepoints after treatment has begun, avoiding the need for repeat tissue biopsies. It is hoped that such approaches will make it possible to detect the early emergence of new genetic variants that convey drug resistance, thereby allowing oncologists to select alternative, more effective drugs before relapse becomes evident clinically.

Molecular Profiles of Tumors: The Future of Cancer Diagnostics

Until recently, molecular studies of tumors involved the analysis of individual genes. However, the past few years have seen the introduction of revolutionary technologies that can rapidly sequence an entire genome; assess epigenetic modifications genome-wide (the epigenome); quantify all of the RNAs expressed in a cell population (the transcriptome); measure many proteins simultaneously (the proteome); and take a snapshot of all of the cell's metabolites (the metabolome). Thus, we are living in the age of "omics"!

Among these various "omic" technologies, DNA sequencing has had the greatest impact on the evaluation of cancer. RNA sequencing is also being widely employed in research laboratories, but RNA is prone to degradation and is a more difficult analyte to work with than DNA in clinical practice. By contrast, DNA sequencing can be routinely performed using DNA retrieved from routinely fixed and processed tissues, the type that exists in most pathology departments.

These advances have enabled the systematic sequencing and cataloging of genomic alterations in various human cancers, much of it within a large consortium sponsored by the National Cancer Institute called The Cancer Genome Atlas (TCGA). The complexity of the genetic aberrations identified in these genome-wide studies has inspired informaticians to create new ways of displaying the data, such as circos plots (Fig. 7.46), which provide a snapshot of all of the genetic alterations that exist in a particular tumor.

The main impact of cancer genome sequencing to date has been in the area of research. However, next-generation DNA sequencing of cancer genomes is rapidly transitioning to standard clinical practice. "Targeted" sequencing is being performed routinely in many academic cancer centers and reference laboratories, at reasonable costs and with turnaround times of a few days to a few weeks. These tests typically cover the exons of several hundred key genes at sufficient "depth" (fold coverage of the sequence in question) to reliably detect any mutation that might be present in as few as 5% of tumor cells. One goal of these analyses is to identify therapeutically "actionable" genetic lesions. Such approaches are particularly applicable to tumors such as lung carcinomas, which are genetically diverse and require a "personalized" approach if targeted therapy is to succeed. Other clinically useful information is obtained, however. For example, the observed pattern of mutations (including passenger as well as driver mutations) can be used to identify the mutational signature (microsatellite instability) that is associated with mismatch repair defects, which as mentioned earlier is an indication for treatment with immune checkpoint inhibitors, regardless of cancer type. Other identified mutations may help guide therapy; for example, *TP53* mutations portend a very poor prognosis in acute leukemias, which otherwise might be expected to respond well to chemotherapy.

Fewer tests measuring RNA levels have entered into the clinical domain, but breast cancers are routinely subjected to RNA profiling to determine whether chemotherapy is likely to be beneficial. Newer test platforms that allow easier and more reliable measurement of RNAs retrieved from fixed tissue samples may expedite the development of additional tests of this type. Certain assays aimed at detecting driver mutations that use RNA have advantages over DNA-based tests, including assays designed to identify chimeric RNAs produced from fusion genes, which are now in various stages of development and clinical application.

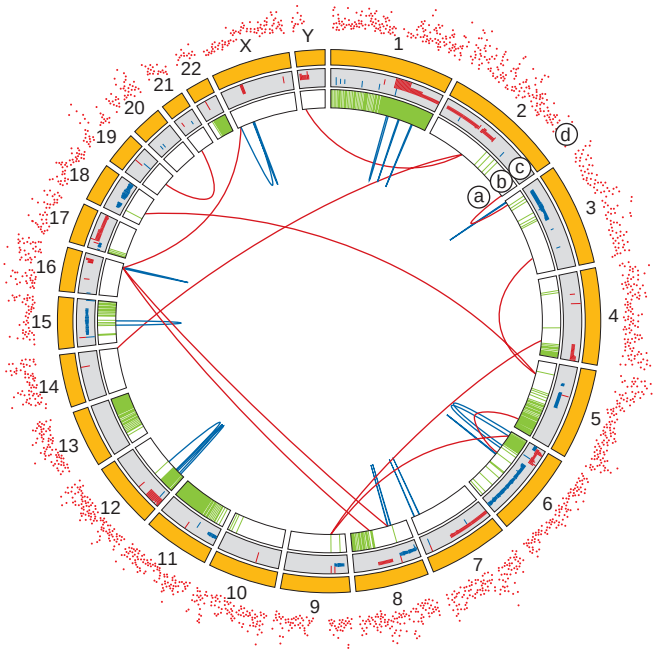

Figure 7.46 Circos plot showing genetic alterations in a single lung cancer in a male patient. Each of the 24 chromosomes in the cancer is displayed in a circle. The positions of various tumor-specific aberrations are mapped onto these chromosomes as follows: *a*, Structural rearrangements in chromosomes. The blue lines denote intrachromosomal rearrangements, while the red lines denote interchromosomal rearrangements. *b*, Regions of loss of heterozygosity and allelic imbalance (overrepresentation of one allele versus the second) are in green. *c*, Copy number profiles, showing copy number losses (in red) and copy gains (in blue). *d*, Point mutations, represented as red dots.

The excitement created by the development of new techniques for the global molecular analysis of tumors has led some scientists to predict that the end of histopathology is in sight. Indeed, with the advent of targeted therapies, it can be argued that we are in the midst of a paradigm shift in which the most important part of the work-up of a cancer sample is the identification of molecular targets, rather than histopathologic diagnosis (Fig. 7.47). For example, it is now appreciated that histopathologically distinct cancers may harbor the same gain-of-function mutation in the serine/threonine kinase BRAF, a component of the RAS signaling pathway (Fig. 7.48). In principle, all of these diverse "BRAFomas" are candidates for treatment with BRAF inhibitors. However, clinical studies have shown that the effectiveness of BRAF inhibitors (for reasons that remain to be determined) vary widely depending on histologic subtype: hairy cell leukemias with *BRAF* mutations typically show sustained responses, melanomas respond transiently, and colon carcinomas respond little, if at all, emphasizing the value of morphologic diagnosis. An example of a treatment based entirely on molecular features is the use of checkpoint inhibitors in patients with recurrent and metastatic tumors based on defects in mismatch repair genes and not on histologic features, which we mentioned earlier.

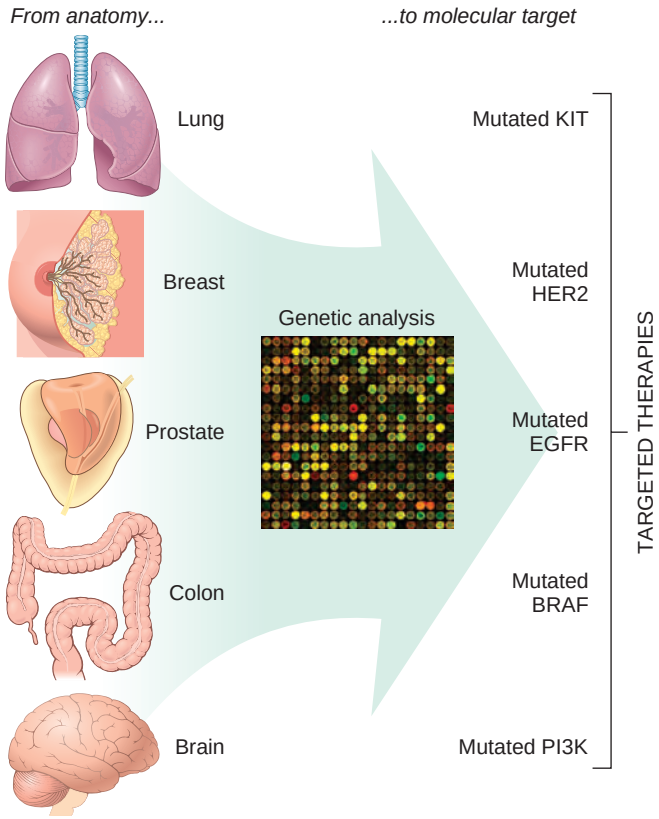

Figure 7.47 A paradigm shift: classification of cancer according to therapeutic targets rather than cell of origin and morphology. (Courtesy Dr. Levi Garraway, Dana Farber Cancer Institute, Boston, Mass.)

In most cases, however, histopathologic inspection of tumors provides information about other important cancer characteristics, such as anaplasia, invasiveness, and tumor heterogeneity, and when coupled with in situ biomarker tests performed on tissue sections, also remains the best way to assess tumor–stromal cell interactions such as angiogenesis and host immune responses. The latter may have an increasingly important role in guiding therapeutic interventions that are designed to counteract immune evasion by tumors. Thus, what lies ahead is not the replacement of one set of techniques by another. On the contrary, for the foreseeable future the most accurate diagnosis and assessment of prognosis in cancer patients will be arrived at by a combination of morphologic and molecular techniques.

Tumor Markers

Biochemical assays for tumor-associated enzymes, hormones, and other tumor markers in the blood lack the sensitivity and specificity necessary to diagnose cancer; however, in concert with other tests, they may contribute to the detection of cancer, and in many instances they are useful in following a tumor's response to therapy and in detecting tumor recurrence.

A host of tumor markers have been described, and new candidates are identified every year. Only a few have stood the test of time and proved to have clinical usefulness.

The application of several markers, listed in Table 7.12, is considered in the discussion of specific forms of neoplasia in other chapters, so only a few widely used examples suffice here. Blood tests for *prostate-specific antigen (PSA),* a marker for prostatic adenocarcinoma, are frequently used in clinical practice. Prostatic carcinoma can be suspected when elevated levels of PSA are found in the blood. However, PSA screening highlights problems encountered with virtually every tumor marker. Although PSA levels are often elevated by cancer, PSA levels also may be elevated by benign prostatic hyperplasia (Chapter 18). Furthermore, there is no PSA level that ensures that a person does not have prostate cancer. These limitations are discussed in detail in Chapter 18.

Other tumor markers occasionally used in clinical practice include *carcinoembryonic antigen* (CEA), which is elaborated by carcinomas of the colon, pancreas, stomach, and breast; and *alpha-fetoprotein* (AFP), which is produced

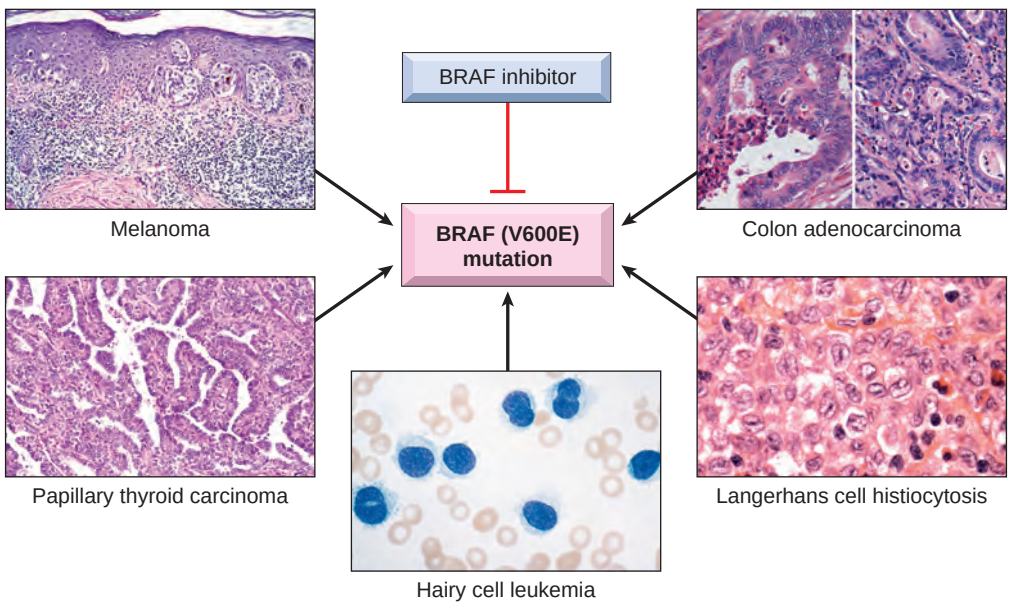

Figure 7.48 Diverse tumor types with a common molecular pathogenesis.

Table 7.12 Selected Tumor Markers

Tumor Markers	Tumor Types
Hormones	
Human chorionic gonadotropin	Trophoblastic tumors, nonseminomatous testicular tumors
Calcitonin	Medullary carcinoma of thyroid
Catecholamine and metabolites	Pheochromocytoma and related tumors
Ectopic hormones	See Table 7.11
Oncofetal Antigens	
α-Fetoprotein	Liver cell cancer, nonseminomatous germ cell tumors of testis
Carcinoembryonic antigen	Carcinomas of the colon, pancreas, lung, stomach, and heart
Lineage-Specific Proteins	
Immunoglobulins	Multiple myeloma and other gammopathies
Prostate-specific antigen and prostate-specific membrane antigen	Prostate cancer
Mucins and Other Glycoproteins	
CA-125	Ovarian cancer
CA-19-9	Colon cancer, pancreatic cancer
CA-15-3	Breast cancer
Cell-Free DNA Markers	
EGFR mutants in serum	Lung cancer
TP53, *APC*, *RAS* mutants in stool and serum	Colon cancer
TP53, *RAS* mutants in stool and serum	Pancreatic cancer
TP53, *RAS* mutants in sputum and serum	Lung cancer
TP53 mutants in urine	Bladder cancer

by hepatocellular carcinomas, yolk sac tumors, and occasionally teratocarcinomas and embryonal cell carcinomas. Unfortunately, serum levels of CEA and AFP can be elevated in a variety of nonneoplastic conditions, limiting their value as screening tests. Their utility lies in their ability to follow response to therapy. With successful resection of the tumor, these markers disappear from the serum; their persistence or reappearance almost always signifies tumor lurking within. Other widely used markers include *human chorionic gonadotropin* (HCG) for testicular tumors, *CA-125* for ovarian tumors, and monoclonal *immunoglobulin* in multiple myeloma and other secretory plasma cell tumors.

The development of accurate, sensitive, and specific screening tests to detect cancer markers in blood and body fluids remains an active area of research, as it is evident that early detection of cancer would greatly improve clinical outcomes. Sensitive tests that identify specific driver mutations in DNA isolated from urine, blood, or stool have been developed for this purpose. Nevertheless, it has been difficult to find a test focused on any single marker that has sufficient specificity to allow screening of populations, and it may be (given that cancer is the product of multiple genetic and epigenetic events rather than singular events) that such markers simply do not exist. An alternative approach is to measure many cancer-associated markers simultaneously. In principle, for example, it may be possible to detect multiple driver mutations in a single "liquid biopsy," and there is evidence that RNA shed from tumor cells into the blood is amenable to molecular profiling. These "circulating RNAs" are enriched in exosomes, membrane vesicles that can be found in the blood and other body fluids that are released from the cells of some tumors.

With all the advances in genomic analyses and targeted therapies and immunotherapies, one can confidently predict that we are on the cusp of the golden age of tumor diagnosis and treatment. Those of you who are in medical school now can safely assume that the expectations for rapid advances in cancer diagnosis and therapy will be realized while you are still in practice. Get ready!

KEY CONCEPTS

LABORATORY DIAGNOSIS OF CANCER

- Several sampling approaches exist for the diagnosis of tumors including excision, biopsy, fine-needle aspiration, and cytologic smears.
- Immunohistochemistry and flow cytometry studies help in the diagnosis and classification of tumors because distinct protein expression patterns define different entities.
- Molecular analyses are used to determine diagnosis and prognosis, to detect minimal residual disease, and to diagnose hereditary predisposition to cancer.
- Molecular profiling of tumors by DNA sequencing, RNA profiling, and DNA copy number arrays is useful in molecular stratification of otherwise identical tumors or those of distinct histogenesis that share a mutation or a mutational signature for purposes of targeted treatment and prognostication.
- Proteins released by tumors into the serum, such as PSA, can be used to monitor for recurrence after treatment but are problematic as screening tests because of low sensitivity and specificity.
- Assays of circulating tumor cells and tumor DNA are under development.

CHAPTER 8

Infectious Diseases

Karen M. Frank • Alexander J. McAdam

CHAPTER CONTENTS

GENERAL PRINCIPLES OF MICROBIAL PATHOGENESIS

Despite the availability of effective vaccines and antibiotics, infectious diseases remain a major health problem throughout the world. In the United States and other high-income countries, infectious diseases are particularly important causes of death among older adults and in people who are immunosuppressed or who suffer from debilitating chronic diseases. In lower-income nations inadequate access to medical care and malnutrition contribute to a heavy burden of infectious diseases. In these regions of the world, five of the ten leading causes of death are infectious diseases. Tragically, most of these deaths occur in children, with respiratory infections, infectious diarrhea, and malaria taking the greatest toll.

How Microorganisms Cause Disease

Most infectious diseases are caused by pathogenic organisms that exhibit a wide range of virulence. These organisms are acquired from a variety of sources, including people, animals, insect vectors, and the environment, but they are not found in the normal microbiota of healthy people. Thus, their presence is diagnostic of an infection. Over the past few years, it has become evident that humans and other animals harbor a complex ecosystem of microbes (the *microbiome*) that has important roles in health and disease. Most of these commensal organisms coexist peacefully with their human hosts, occupying microenvironmental niches that might otherwise be filled by potential pathogens, and in doing so help prevent infectious disease. However, under conditions in which normal host defenses are breached or attenuated (described later), even commensal microbiota may cause symptomatic infections and can even be fatal.

We will start our review of infectious disease at the beginning of the process, the establishment of a beachhead in the host, and then discuss dissemination and transmission of infection, before turning to specific infections.

Routes of Entry of Microbes

Microbes can enter the host by breaching epithelial surfaces, inhalation, ingestion, or sexual transmission (Table 8.1). In general, respiratory, gastrointestinal, and genitourinary tract infections in otherwise healthy persons are caused by virulent microorganisms with the ability to damage or penetrate the epidermis or mucosal epithelium. By contrast, skin infections in healthy persons are mainly caused by organisms that enter the skin through superficial injuries.

Skin

The intact keratinized epidermis protects against infection by serving as a mechanical barrier, having a low pH, and by producing antimicrobial fatty acids and defensins, small peptides that are toxic to bacteria. **Most skin infections are initiated by mechanical injury of the epidermis.** The injury may range from minor trauma to large wounds, burns, and pressure-related ulcers. In the hospital setting, infections may stem from intravenous catheters in patients or needle sticks in health care workers. Some pathogens penetrate the skin via an insect *(vector)* or animal bite; vectors include fleas, ticks, mosquitoes, and lice. The larvae of *Schistosoma* can traverse unbroken skin by releasing enzymes that dissolve the adhesive proteins that hold keratinocytes together. Certain fungi *(dermatophytes)* can cause superficial infections of the intact stratum corneum, hair, and nails.

Gastrointestinal Tract

Gastrointestinal tract infections may occur when local defenses are circumvented by a pathogen, or when they are so weakened that even normal flora produce disease. Most gastrointestinal pathogens are transmitted by food or drink contaminated with fecal material; when hygiene fails, diarrheal disease becomes rampant. The gastrointestinal tract has several local defenses. Of these, acidic gastric secretions are particularly important because they are highly effective at killing certain organisms. Neutralizing the stomach acid of healthy volunteers increased the infectivity of *Vibrio cholerae* by 10,000-fold. A layer of mucus covers the gut throughout its length, preventing access of luminal pathogens to the surface epithelium. Pancreatic enzymes and bile detergents can destroy organisms with lipid

Table 8.1 Routes of Microbial Infection

Site	Major Local Defense(s)	Basis for Failure of Local Defense	Pathogens (Examples)
Skin	Epidermal barrier	Mechanical defects (punctures, burns, ulcers)	*Staphylococcus aureus*, *Candida albicans*, *Pseudomonas aeruginosa*
		Needle sticks	Human immunodeficiency virus, hepatitis viruses
		Arthropod and animal bites	Yellow fever, plague, Lyme disease, malaria, rabies
		Direct penetration	*Schistosoma* spp.
Gastrointestinal tract	Epithelial barrier	Attachment and local proliferation of microbes	*Vibrio cholerae*, *Giardia duodenalis*
		Attachment and local invasion of microbes	*Shigella* spp., *Salmonella* spp., *Campylobacter* spp.
		Uptake through M cells	Poliovirus, *Shigella* spp., *Salmonella* spp.
	Acidic secretions	Acid-resistant cysts and eggs	Many protozoa and helminths
	Peristalsis	Obstruction, ileus, postsurgical adhesions	Mixed aerobic and anaerobic bacteria (*Escherichia coli*, *Bacteroides* spp.)
	Bile and pancreatic enzymes	Resistant microbial external coats	Hepatitis A, rotavirus, norovirus
	Normal protective microbiota	Broad-spectrum antibiotic use	*Clostridioides difficile*
Respiratory tract	Mucociliary clearance	Attachment and local proliferation of microbes	Influenza viruses
		Ciliary paralysis by toxins	*Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Bordetella pertussis*
	Resident alveolar macrophages	Resistance to killing by phagocytes	*Mycobacterium tuberculosis*
Urogenital tract	Urination	Obstruction, microbial attachment, and local proliferation	*Escherichia coli*
	Normal vaginal microbiota	Antibiotic use	*Candida albicans*
	Intact epidermal/epithelial barrier	Microbial attachment and local proliferation	*Neisseria gonorrhoeae*
		Direct infection/local invasion	Herpes viruses, syphilis
		Local trauma	Various sexually transmitted infections (e.g., human papillomavirus)

envelopes. Antimicrobial defensins are produced by gut epithelial cells. IgA antibodies, produced in mucosal lymphoid tissues such as Peyer patches and secreted into the gut lumen (Chapter 17), can neutralize potential pathogens. Peristalsis can clear organisms, preventing their local overgrowth. Finally, the normal gut microbiota competitively inhibits colonization and overgrowth by potential pathogens, such as *Clostridioides difficile*. Many common gastrointestinal pathogens are resistant to local defenses. Norovirus (the scourge of the cruise ship industry) is a nonenveloped virus that is resistant to inactivation by acid, bile, and pancreatic enzymes and hence easily spreads in places where people are crowded together. Intestinal protozoa and helminths transmitted as cysts or eggs, respectively, have acid-resistant outer coats.

Pathogens may establish symptomatic gastrointestinal disease through several distinct mechanisms:

- *Toxin production.* Some organisms contaminating food can produce gastrointestinal disease without necessarily establishing an infection in the host. An example is *Staphylococcus aureus,* which elaborates a powerful exotoxin during its growth in contaminated food that is responsible for acute food poisoning.
- *Bacterial colonoization and toxin production.* Other bacteria establish an infection and produce damaging toxins. Examples include *V. cholerae* and enterotoxigenic *Escherichia coli,* which bind to the intestinal epithelium and multiply in the overlying mucous layer. These organisms elaborate potent exotoxins that are responsible for symptomatic disease.
- *Adhesion and mucosal invasion. Shigella spp., Salmonella enterica, Campylobacter jejuni,* and *Entamoeba histolytica* invade the intestinal mucosa and lamina propria and cause ulceration, inflammation, and hemorrhage that manifest clinically as dysentery. *Candida albicans* invades superficially into oral and esophageal squamous mucosa in immunocompromised patients to cause thrush.

Respiratory Tract

A plethora of microorganisms, including viruses, bacteria, and fungi, are inhaled daily, mainly in dust or aerosol particles. Microorganisms in large particles are trapped in the mucociliary blanket that lines the nose and the upper respiratory tract and transported by ciliary action to the back of the throat, where they are swallowed and cleared. Particles smaller than 5 microns are carried into the alveoli, where they are phagocytosed by leukocytes.

The microorganisms that infect the healthy respiratory tract evade local defenses through several different mechanisms. Some respiratory viruses attach to and enter epithelial cells in the lower respiratory tract and pharynx. For example, influenza viruses have envelope proteins called *hemagglutinins* that bind to sialic acid on the surface of epithelial cells. Attachment induces the host cell to endocytose the virus, leading to viral entry and replication. Certain bacterial respiratory pathogens, including *Mycoplasma pneumoniae* and *Bordetella pertussis,* release toxins that enhance their ability to establish an infection by impairing ciliary activity. Another important mechanism of establishing respiratory infection is resistance to killing following phagocytosis. *Mycobacterium tuberculosis* gains a foothold in alveoli by surviving within the phagolysosomes of macrophages.

Other organisms establish disease when local or systemic defenses are impaired. The damage to respiratory mucociliary clearance by influenza, mechanical ventilation, smoking or cystic fibrosis sets the stage for superinfection by bacteria. Many other infectious agents cause respiratory infections primarily in the setting of systemic immunodeficiency. Examples include fungal infections by *Pneumocystis jirovecii* in acquired immunodeficiency syndrome (AIDS) patients and by *Aspergillus* spp. in patients with neutropenia.

Urogenital Tract

Urine contains small numbers of low-virulence bacteria. The urinary tract is protected from infection by regular emptying during micturition. Urinary tract pathogens (e.g., *E. coli*) almost always gain access via the urethra and must be able to adhere to urothelium to avoid being washed away. Women have more than 10 times as many urinary tract infections as men because the length of the urethra is 5 cm in women versus 20 cm in men, making women more susceptible to entry of bacteria from the rectum. Expulsion of urine from the bladder eliminates microbes. Predictably, **obstruction of urinary flow or reflux of urine is a major factor in susceptibility to urinary tract infections.**

From puberty until menopause the vagina is protected from pathogens by lactobacilli, which ferment glucose to lactic acid, producing a low pH environment that suppresses the growth of pathogens. Antibiotics can kill the lactobacilli and allow overgrowth of yeast, causing vaginal candidiasis.

Vertical Transmission

Vertical transmission of infectious agents from mother to fetus or newborn child is a common mode of transmission of certain pathogens and may occur through several different routes.

- *Placental-fetal transmission* is most likely to occur when the mother becomes infected with a pathogen during pregnancy. Some resulting infections interfere with fetal development, and the degree and type of damage depend on the age of the fetus at the time of infection. Rubella virus infection during the first trimester can lead to heart malformations, intellectual disability, cataracts, or deafness, but rubella virus infection during the third trimester has little effect.
- *Transmission during birth* is caused by contact with infectious agents during passage through the birth canal. Examples include gonococcal and chlamydial conjunctivitis.
- *Postnatal transmission in maternal milk* can transmit cytomegalovirus (CMV), human immunodeficiency virus (HIV), and hepatitis B virus (HBV).

Spread and Dissemination of Microbes Within the Body

Although some disease-causing microorganisms remain localized to the initial site of infection, others have the capacity to invade tissues and spread to distant sites via the lymphatics, the blood, or the nerves (Fig. 8.1). Pathogens can spread within the body in several ways. Some pathogens secrete enzymes that break down tissues, allowing the organisms to spread contiguously in tissue. Organisms that disseminate often travel through the lymphatics to regional

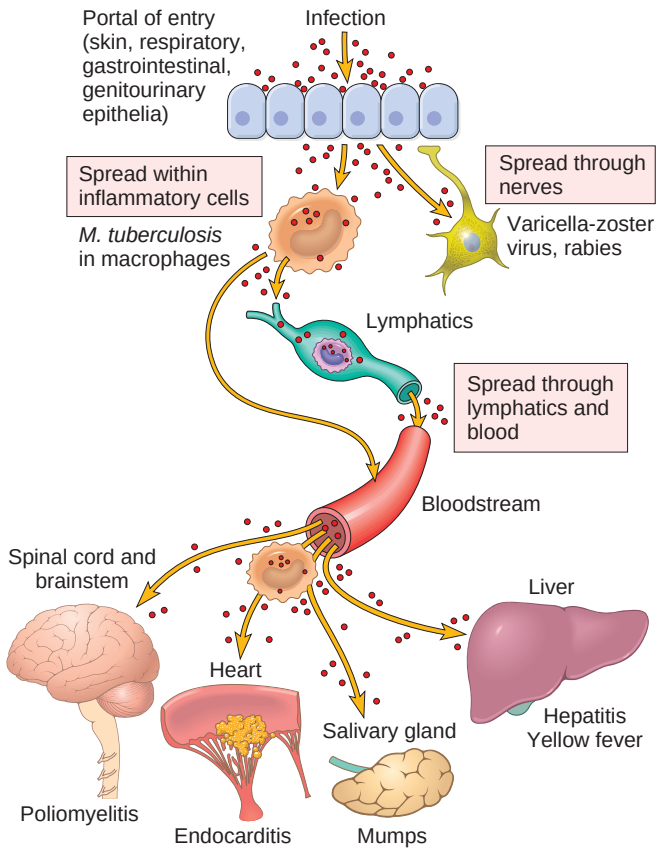

Figure 8.1 Routes of entry and dissemination of microbes. To enter the body, microbes penetrate the epithelial or mucosal barriers. Infection may remain localized at the site of entry or spread to other sites in the body. Most common microbes *(selected examples are shown)* spread through the lymphatics or bloodstream (either freely or within inflammatory cells). However, certain viruses and bacterial toxins may also travel through nerves. (Modified from Mims CA: *The Pathogenesis of Infectious Disease*, ed 4, San Diego, 1996, Academic Press.)

lymph nodes, from which they may reach the bloodstream. Certain viruses, such as rabies virus, poliovirus, and varicella-zoster virus, spread to the central nervous system (CNS) by infecting peripheral nerves and then traveling along axons. However, the most common and efficient mode of microbial dissemination is through the bloodstream, by which the organism can reach all organs. The consequences of blood-borne spread of pathogens vary widely depending on the virulence of the organism, the magnitude of the infection, the pattern of seeding, and host factors such as immune status. As discussed in Chapter 4, disseminated pathogens may produce a systemic inflammatory response syndrome called *sepsis* that manifests as fever, low blood pressure, and coagulopathies that may progress to organ failure and death if unchecked, even in previously healthy individuals. In other instances, the major signs of spread of the infection are related to seeding of tissues by pathogens. These may take the form of a single infectious nidus (an abscess or tuberculoma), multiple small sites of infection (e.g., miliary tuberculosis or *Candida* microabscesses), or infection of the heart and vessels (infectious endocarditis and mycotic aneurysm).

Release From the Body and Transmission of Microbes

Microbes use a variety of exit strategies to ensure their transmission from one host to the next. Release may be accomplished by skin shedding, coughing, sneezing, voiding of urine or feces, during sexual contact, or through insect vectors. Some pathogens are released for only brief periods of time or periodically during disease flares, but others may be shed for long periods by asymptomatic carrier hosts. Pathogens vary in hardiness in the environment. Fragile pathogens persist outside of the body for only short periods of time and must be passed quickly from person to person, often by direct contact.

Most pathogens are transmitted from person to person by respiratory, fecal-oral, or sexual routes.

- Viruses and bacteria spread by the respiratory route are aerosolized in droplets and released into the air. Some respiratory pathogens, including influenza viruses, are spread in large droplets that travel no more than 3 feet from the source, but others, including *M. tuberculosis* and varicella-zoster virus, spread in small particles that can travel longer distances.
- Most enteric pathogens are spread by the fecal-oral route, that is, by ingestion of stool-contaminated water or food. Water-borne pathogens involved in epidemic outbreaks that are spread in this fashion include hepatitis A and E viruses (HAV and HEV), poliovirus, rotavirus, *V. cholera, Shigella* spp., *C. jejuni,* and *S. enterica*. Some parasitic helminths (e.g., hookworms, schistosomes) shed eggs in stool that hatch as larvae that are capable of penetrating the skin of the next host.
- Sexual transmission often entails prolonged intimate or mucosal contact and is responsible for spread of a wide variety of pathogens, including viruses (e.g., herpes simplex virus [HSV], HIV, human papillomavirus [HPV]); bacteria (*Treponema pallidum, Neisseria gonorrhoeae*); protozoa *(Trichomonas vaginalis);* and arthropods (*Phthiris pubis,* lice).

There are several additional routes of transmission. Saliva is responsible for transmitting viruses that replicate in the salivary glands or the oropharynx, including Epstein-Barr virus (EBV). Some important human pathogens are protozoa that are spread through blood meals taken by arthropod vectors (mosquitoes, ticks, mites). Finally, *zoonotic infections* are those transmitted from animals to humans, either by direct contact (including animal bites), use of animal products, or via an invertebrate vector.

KEY CONCEPTS

HOW MICROORGANISMS CAUSE DISEASE

- Transmission of infections can occur by contact (direct and indirect), the respiratory route, the fecal-oral route, sexual transmission, vertical transmission, or insect/arthropod vectors.
- A pathogen can establish infection if it possesses virulence factors that overcome normal host defenses or if the host defenses are compromised.
- Host defenses against infection include the following:
  - Skin: tough keratinized barrier, low pH, fatty acids
  - Respiratory system: alveolar macrophages, mucociliary clearance by bronchial epithelium, IgA

- GI system: acidic gastric pH, viscous mucus, pancreatic enzymes and bile, defensins, IgA, and normal microbiota
- Urogenital tract: repeated flushing and acidic environment created by commensal microbiota

• Pathogens can proliferate locally, at the site of initial infection, or spread to other sites by direct extension (invasion) or by transport in the lymphatics, the blood, or nerves.

Host-Pathogen Interactions

The outcome of infection is determined by the virulence of the microbe and the nature of the host immune response, which may eliminate the infection or, in some cases, exacerbate or cause tissue damage. The host has a large and complex armamentarium of defenses against pathogens, including physical barriers and components of the innate and adaptive immune systems, which were discussed in Chapter 6. Microbes undergo continuous evolution to combat host defenses. Here we discuss some specific features of microbes and the host response that are important determinants of the outcome of infections.

Immune Evasion by Microbes

Most pathogenic microbes have developed one or more strategies to evade host defenses (Fig. 8.2).

- *Antigenic variation.* Antibodies against microbial antigens block microbial adhesion and uptake into cells, act as opsonins to facilitate phagocytosis, and fix complement. To escape recognition, microbes have strategies that allow them to "change their coats" by expressing different surface antigens (*Borrelia* spp. and trypanosomes). Influenza viruses have a segmented RNA genome that allows for frequent recombination events, permitting antigenic drift (changes in antibody-binding sites of major viral envelope glycoproteins) and antigenic shift (reassortment of genomes between two viral strains creating a new strain). Other microbes generate numerous genetic variants through mutation (over 95 capsular polysaccharides in different strains of *Streptococcus pneumoniae*) (Table 8.2).
- *Resistance to antimicrobial peptides.* Pathogens, such as *Shigella* spp., *S. aureus,* and *Candida* spp., use strategies to avoid killing by cationic antimicrobial peptides that include changes in net surface charge and membrane hydrophobicity, which prevent antimicrobial peptide insertion and pore formation, secretion of proteins that inactivate or degrade the peptides, and pumps that export the peptides.
- *Resistance to killing by phagocytes.* The carbohydrate capsule on the surface of many bacteria *(S. pneumoniae, Neisseria meningitidis, Haemophilus influenzae)* prevents phagocytosis of the organisms by neutrophils. *S. aureus* expresses protein A, which binds the Fc portion of antibodies and inhibits phagocytosis by competitively reducing binding of the antibodies to phagocyte Fc receptors. Some pathogens are resistant to intracellular killing in phagocytes, including mycobacteria (which inhibit phagosome-lysosome fusion), *Listeria monocytogenes* (which disrupts the phagosome membrane and escapes onto the cytosol), *Cryptococcus neoformans,* and certain protozoa (e.g., *Leishmania* spp., *Trypanosoma* spp., *Toxoplasma gondii*).
- *Evasion of apoptosis and manipulation of host cell metabolism.* Some viruses produce proteins that interfere with apoptosis of the host cell, buying time to replicate, enter latency, or even transform infected cells. Microbes that replicate intracellularly (viruses, some bacteria, fungi, and protozoa) also express factors that modulate autophagy, thus evading degradation.
- *Resistance to cytokine-, chemokine- and complement-mediated host defense.* Some viruses interfere with interferon (IFN) function by producing soluble homologues of IFN-α/β or IFN-γ receptors that function as "decoys" that inhibit the actions of secreted IFNs; by producing proteins that

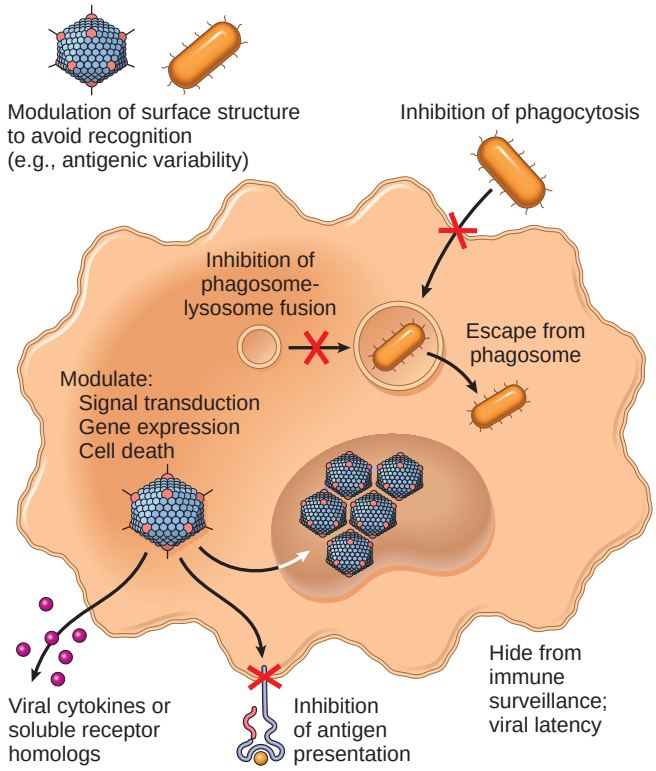

Figure 8.2 An overview of mechanisms used by viral and bacterial pathogens to evade innate and adaptive immunity. (Modified with permission from Finlay B, McFadden G: Anti-immunology: evasion of the host immune system by bacterial and viral pathogens, *Cell* 2006;124:767–782.)

Table 8.2 Mechanisms of Antigenic Variation

Type	Example	Disease
High mutation rate	Human immunodeficiency virus	AIDS
	Influenza virus	Influenza
Genetic reassortment	Influenza virus	Influenza
	Rotavirus	Diarrhea
Genetic rearrangement (e.g., gene recombination, gene conversion, site-specific inversion)	*Borrelia burgdorferi*	Lyme disease
	Neisseria gonorrhoeae	Gonorrhea
	Trypanosoma brucei	African sleeping sickness
	Plasmodium falciparum	Malaria
Large diversity of serotypes	Rhinoviruses	Colds
	Streptococcus pneumoniae	Pneumonia and meningitis

inhibit the JAK/STAT cytokine receptor signaling pathway; or by producing proteins that inactivate or inhibit double-stranded RNA–dependent protein kinase (protein kinase R [PKR]), through which IFNs inhibit viral replication.

- *Evasion of recognition by CD8+ cytotoxic T lymphocytes (CTLs) and CD4+ helper T cells.* T cells recognize microbial antigens presented by MHC molecules, class I for CTLs and class II for CD4+ cells (see Chapter 6). Several DNA viruses (e.g., HSV, CMV, EBV) bind to or alter localization of MHC class I proteins, impairing peptide presentation to CD8+ T cells. Herpesviruses also can target MHC class II molecules for degradation, impairing antigen presentation to CD4+ T-helper cells.
- Another strategy exploits *immunoregulatory mechanisms to downregulate antimicrobial T cell responses*. Loss of T cell potency over time, termed *T-cell exhaustion,* is a feature of chronic infections by HIV, hepatitis C virus (HCV), and HBV. Programmed cell death protein 1 (PD-1) is an immune checkpoint cell surface receptor, and the PD-1 pathway, which normally functions to maintain T-cell tolerance to self antigens, is an important mediator of T-cell exhaustion during chronic viral infection. Tumors exploit the same mechanisms to suppress destructive immune responses (Chapter 7). Anti–PD-1 immunotherapy is approved for the treatment of cancers and is being explored as a possible adjunctive therapy for chronic infections that are resistant to antimicrobial therapy.
- Another way of avoiding the immune system is to "lie low" by establishing a state of *latent infection* in which few, if any, viral genes are expressed, until later reactivation. Examples include latent infections of neurons by HSV and varicella-zoster virus, and of B lymphocytes by EBV.
- Pathogens can infect immune cells and interfere with their function (e.g., HIV, which infects and destroys CD4+ T cells).

KEY CONCEPTS

IMMUNE EVASION BY MICROBES

After bypassing host tissue barriers, infectious microorganisms must also evade host innate and adaptive immunity to successfully proliferate and be transmitted to the next host. Strategies include the following:

- Antigenic variation
- Inactivating antibodies or complement
- Resisting phagocytosis (e.g., by producing a capsule)
- Suppressing the host adaptive immune response (e.g., by interfering with cytokines or inhibiting MHC expression and antigen presentation)
- Establishing latency, during which viruses survive in a silent state in infected cells
- Infecting and disabling or killing immune cells

Injurious Effects of Host Immunity

The host immune response to microbes can be a major cause of tissue injury. The granulomatous inflammatory reaction to *M. tuberculosis* sequesters the bacilli and prevents their spread, but it also can produce tissue damage and fibrosis. Similarly, damage to hepatocytes following HBV and HCV infection is mainly due to the effects of the immune response on infected liver cells: in an attempt to clear the virus, host T cells and, possibly, natural killer (NK) cells kill the hepatocytes. Antibodies produced against the streptococcal M protein can cross-react with cardiac proteins and damage the heart, leading to rheumatic heart disease. Poststreptococcal glomerulonephritis is caused by immune complexes formed between antistreptococcal antibodies and streptococcal antigens that deposit in the renal glomeruli, producing inflammation. A cycle of inflammation and epithelial injury contributes to the pathogenesis of inflammatory bowel disease, with microbes playing a role (Chapter 17). Viruses (HBV, HCV) and bacteria *(Helicobacter pylori)* that are not known to carry or activate oncogenes are associated with cancers, presumably because these microbes trigger chronic inflammation, which provides fertile ground for the development of cancer (Chapter 7).

Infections in People With Immunodeficiencies

Inherited or acquired defects in innate and adaptive immunity often impair the immune system, rendering the affected individual susceptible to infections (Chapter 6). Organisms that cause disease in immunodeficient individuals but not in people with intact immune systems are called *opportunistic*. Worldwide, the most devastating immunodeficiency is that caused by infection with HIV, the cause of AIDS. Other causes of acquired immunodeficiencies include infiltrative processes that suppress bone marrow function (such as leukemia), immunosuppressive drugs used to treat patients with autoimmune diseases and organ transplant recipients, as well as drugs used to treat cancer, and hematopoietic stem cell transplantation. Opportunistic organisms (e.g., *Aspergillus* spp. and *Pseudomonas* spp.) cause significant disease in these patients. Decline of immune responses can result in reactivation of latent infection (e.g., herpesviruses and *M. tuberculosis*). Age-related decline in immune function may increase infections in the elderly. Nonimmune diseases or injuries also increase susceptibility to infection: *Pseudomonas aeruginosa* and *Burkholderia cepacia* in cystic fibrosis due to a defective transmembrane conductance regulator, *S. pneumoniae* in people with sickle cell disease due to loss of splenic macrophages, and *P. aeruginosa* in burns due to barrier disruption. Finally, malnutrition can impair immune defenses.

In addition to common immunodeficiencies, rare inherited (primary) immunodeficiency diseases illuminate important aspects of specific components of host defense, as well as the unique vulnerabilities of certain pathogens.

- *Antibody deficiencies,* as seen in patients with X-linked agammaglobulinemia, lead to increased susceptibility to infections by extracellular bacteria, including *S. pneumoniae, H. influenzae,* and *S. aureus,* as well as a few viruses (rotavirus and enteroviruses).
- *Complement defects* involving the early components of the complement cascade lead to susceptibility to infections by encapsulated bacteria, such as *S. pneumoniae,* whereas deficiencies of the late membrane attack complex components (C5 to C9) are associated with infections due to *Neisseria* spp.
- *Defects in neutrophil function,* as in chronic granulomatous disease, lead to increased susceptibility to infections with *S. aureus,* some gram-negative bacteria, and fungi.

- *Defects in Toll-like receptor (TLR) signaling pathways* have varied effects. Mutations in MyD88 or IRAK4, which are signaling proteins downstream of several TLRs, predispose to pyogenic bacterial infections *(S. pneumoniae)*, and impaired TLR3 responses are associated with childhood HSV encephalitis.
- *T-cell defects* lead to susceptibility to intracellular pathogens, particularly viruses and some parasites. Inherited mutations that impair the generation of T-helper 1 (Th1) cells (such as mutations in IL-12 or IFN-γ receptors, or the transcription factor STAT1) are associated with atypical mycobacterial infections, discussed later. By contrast, defects that impair the generation of Th17 cells (mutations in STAT3) are associated with chronic mucocutaneous candidiasis.

Host Damage by Microbes

Infectious agents establish infection and damage tissues by a few mechanisms:

- They can contact or enter host cells and cause *cell death* directly, or cause changes in cellular metabolism and proliferation that can eventually lead to *transformation*.
- They may release *toxins* that kill cells at a distance, release *enzymes* that degrade tissue components, or damage blood vessels and cause *ischemic necrosis*.
- They can induce host *immune responses* that, though directed against the invader, cause additional tissue damage.

Mechanisms of Viral Injury

Viruses can directly damage host cells by entering them and replicating at the cell's expense. The predilection for viruses to infect certain cells and not others is called *tropism*. **A major determinant of tissue tropism is the presence of viral receptors on host cells.** Viruses bind to proteins found on the surface of host cells that normally function as receptors for host factors. This is presumably one way in which viruses evolve to infect, survive within cells, and spread. For example, HIV glycoprotein gp120 binds to CD4 on T cells and to the chemokine receptors CXCR4 (mainly on T cells) and CCR5 (mainly on macrophages) (Chapter 6), and EBV binds to complement receptor 2 (also known as CR2 or CD21) on B cells. Other tropisms are explained by cell-lineage–specific factors. JC virus infection, which causes leukoencephalopathy (Chapter 28), is restricted to oligodendroglial cells in the CNS because JC viral genes require glial-specific host transcription factors for their expression.

Physical barriers can contribute to tissue tropism. For example, enteroviruses replicate in the intestine in part because they can resist inactivation by acids, bile, and digestive enzymes. Rhinoviruses infect host cells within the upper respiratory tract because they replicate optimally at the lower temperatures found in sites exposed to the ambient atmosphere.

Once viruses are inside host cells, they can damage or kill the cells by a number of mechanisms (Fig. 8.3):

- *Direct cytopathic effects.* Some viruses kill cells by preventing synthesis of critical host macromolecules (e.g., host cell DNA, RNA, or proteins), or by producing degradative enzymes and toxic proteins. Poliovirus inactivates cap-binding protein, which is essential for translation of host cell mRNAs but leaves translation of poliovirus mRNAs unaffected. Viruses can induce cell death by activating so-called *death receptors* (in the tumor necrosis factor [TNF] receptor family) on the plasma membrane and by triggering the intracellular apoptotic machinery. Large amounts of viral proteins are synthesized in infected cells, including unfolded or misfolded proteins that activate the ER stress response; this, too, activates pro-apoptotic pathways. Finally, some viruses encode proteins that are pro-apoptotic, such as the HIV viral protein R (Vpr).
- *Antiviral immune responses.* Host lymphocytes can recognize and destroy virus-infected cells, but, as mentioned earlier, CTLs also can be responsible for tissue injury.
- *Transformation of infected cells.* Oncogenic viruses can stimulate cell growth and survival by a variety of mechanisms, including expression of virus-encoded oncogenes, expression of viral proteins that inactivate key tumor suppressors, and insertional mutagenesis, in which expression of host genes is altered by the insertion of viral genes into host genes or flanking sequences (see Chapter 7).

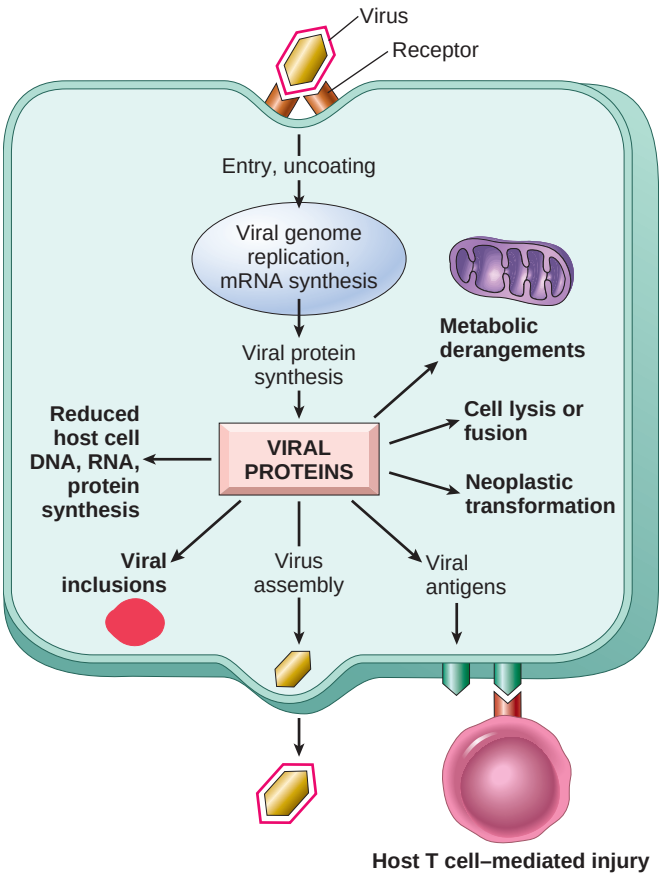

Figure 8.3 Mechanisms by which viruses cause injury to cells.

Mechanisms of Bacterial Injury

Bacterial Virulence. **Bacterial damage to host tissues depends on the ability of the bacteria to adhere to host cells, to invade cells and tissues, and to deliver toxins.** Pathogenic bacteria have *virulence genes* that encode proteins responsible for these properties. An example of the importance of such genes can be found in the various strains of *S. enterica*. All *S. enterica* strains that infect humans are so

closely related that they form a single species, meaning that they share many housekeeping genes. Differences in a relatively small number of virulence genes determine whether an isolate of *S. enterica* causes life-threatening typhoid fever or self-limited enteritis. Virulence genes are frequently found grouped together in clusters called *pathogenicity islands*.

Mobile genetic elements such as plasmids and bacteriophages can transmit functionally important genes to bacteria, including genes that influence pathogenicity and drug resistance. Genes for toxins are sometimes found in plasmids but are more often found in the genomes of bacteriophages, including the genes that encode the toxins responsible for the pathogenesis of the infections cholera, diphtheria, and botulism. Genes for acquired antibiotic resistance traits are more frequently found on plasmids, which can spread not only within bacterial species but also among more distantly related organisms. For example, a plasmid with genes for vancomycin resistance can spread not only among *Enterococcus* spp., but also to more distantly related (and virulent) *S. aureus*.

Many bacteria coordinately regulate gene expression within a large population by a process called *quorum sensing*. Quorum sensing allows bacteria to turn on gene expression and express specific traits only when the organism grows to reach a high concentration. To do this, bacteria secrete small autoinducer molecules which, when present at high levels, induce expression of genes for toxin production *(S. aureus),* competence for genetic transformation *(S. pneumoniae),* or generation of biofilms *(P. aeruginosa).* Autoinducers can be N-acyl-homoserine lactones in gram-negative bacteria, or peptides in gram-positive bacteria. Coordinated expression of virulence factors within bacterial populations may allow bacteria growing in discrete host sites, such as an abscess or consolidated pneumonia, to overcome host defenses. Interestingly, with quorum sensing, different bacterial colonies within the same population may express different genes. Thus, unicellular bacteria acquire some of the more complex properties of multicellular organisms, in which different cells perform different functions.

Communities of bacteria form *biofilms* in which the organisms live within a viscous layer of extracellular polysaccharides that adhere to host tissues or devices such as intravascular catheters and artificial joints. In addition to enhancing adherence to host tissues, biofilms increase the virulence of bacteria by protecting the microbes from immune effector mechanisms and increasing their resistance to antimicrobial drugs. Biofilm formation seems to be particularly important in the persistence and relapse of bacterial endocarditis, artificial joint infections, and respiratory infections in people with cystic fibrosis.

Bacterial Adherence to Host Cells. Bacteria use various surface structures to attach to host cells and tissues.

- *Adhesins* are bacterial surface proteins that bind the organisms to host cells or extracellular matrix. Adhesins have a broad range of host cell specificity. For example, *Streptococcus pyogenes* adheres to host tissues using the adhesins protein F and teichoic acid, which project from the bacterial cell wall and bind to fibronectin on the surface of host cells and in the extracellular matrix.
- *Pili* are filamentous structures on the surface of bacteria that act as adhesins. The stalks of pili are composed of conserved repeating protein subunits, and the variable tip fibrillum determines the tissue-binding specificity of the bacteria. The precise tissue-tropism of *E. coli* that cause urinary tract infections is determined by the tip fibrillum expressed by the bacteria. Adhesion to bladder epithelium is mediated by tip fibrillum that binds d-mannosylated receptors, and adhesion to the renal epithelium depends on binding of tip fibrillum to galabiose-containing glycosphingolipids. Pili can be targets of the host antibody response and, in turn, some bacteria such as *N. gonorrhoeae* vary their pili to escape from the host immune system.

Intracellular Bacteria. Bacteria have evolved a variety of mechanisms for entering host cells. Some bacteria use receptors that are important in the host immune response to gain entry into macrophages. *M. tuberculosis* uses host receptors for opsonins (antibodies and C3b) as well as poorly defined nonopsonic receptors on macrophages. Some gram-negative bacteria use a type III secretion system to enter epithelial cells. This consists of needlelike structures projecting from the bacterial surface that bind to host cells. These proteins then form pores in the host cell membrane and inject bacterial proteins that mediate the rearrangement of the host cell cytoskeleton in a fashion that facilitates bacterial entry.

After bacteria enter the host cell, their fate (and that of the infected cell) varies greatly depending on the organism. *Shigella* spp. and *E. coli* inhibit host protein synthesis, replicate rapidly, and lyse the host cell within hours. Most bacteria are killed within macrophages when the phagosome fuses with an acidic lysosome to form a phagolysosome, where ingested microbes are destroyed, but certain bacteria elude this host defense. *M. tuberculosis* blocks fusion of the lysosome with the phagosome, allowing it to proliferate unchecked within the macrophage. Other bacteria avoid destruction in macrophages by leaving the phagosome and entering the cytoplasm. *L. monocytogenes* produces a pore-forming protein called listeriolysin O and two phospholipases that degrade the phagosome membrane, allowing the bacterium to escape into the cytoplasm, protected from the killing mechanisms of macrophages. In the cytoplasm, *L. monocytogenes* modifies the host cell actin cytoskeleton to promote direct spreading of the organism to neighboring cells. The growth of bacteria inside cells can allow them to escape from certain effector mechanisms of the immune response (e.g., antibodies and complement), and can also facilitate the spread of the bacteria. An example of the latter is the migration of infected macrophages carrying *M. tuberculosis* from the lung to draining lymph nodes and other more distant sites.

Bacterial Toxins. Any bacterial substance that contributes to illness can be considered a toxin. Toxins are classified as endotoxin, which is a component of the gram-negative bacterial cell, and exotoxins, which are proteins that are secreted by many kinds of bacteria.

Bacterial endotoxin is a lipopolysaccharide (LPS) in the outer membrane of gram-negative bacteria that both stimulates host immune responses and injures the host. Lipid A, the part of LPS that anchors the molecule in the host cell membrane, has the endotoxin activity of LPS. LPS

binds to the cell-surface receptor CD14, and the complex of LPS/CD14 then binds to TLR4. Other molecules in the outer structures of gram-positive bacteria can have effects similar to LPS, including lipoteichoic acid, which binds to TLR2. The response to lipid A or lipotechoic acid is beneficial to the host in that it activates protective immunity in several ways. It induces the production of important cytokines and chemoattractants (chemokines) by immune cells and increases the expression of costimulatory molecules, which enhance T-lymphocyte activation. However, high levels of endotoxin play a pathogenic role in septic shock, disseminated intravascular coagulation (DIC), and adult respiratory distress syndrome, mainly through induction of excessive levels of cytokines such as TNF, IL-6, and IL-12.

Exotoxins are secreted bacterial proteins that cause cellular injury and disease. They can be classified into broad categories by their mechanism of action. These are briefly described next and discussed in more detail in the specific sections about each type of bacteria.

- *Enzymes.* Bacteria secrete a variety of enzymes (proteases, hyaluronidases, coagulases, fibrinolysins) that act on substrates in host tissues or on host cells. These enzymes have roles in tissue destruction and abscess formation. For example, exfoliative toxins produced by *S. aureus* cause staphylococcal scalded skin syndrome by degrading proteins that hold keratinocytes together, causing the epidermis to detach from the deeper skin.
- *Toxins that alter intracellular signaling or regulatory pathways.* Most of these toxins have an active (A) subunit with enzymatic activity and a binding (B) subunit that binds to receptors on the cell surface and delivers the A subunit into the cell cytoplasm. The effects of these toxins are diverse and depend on the binding specificity of the B domain and the cellular pathways affected by the A domain. A-B toxins are made by many bacteria including *Bacillus anthracis, V. cholerae,* and some strains of *E. coli*. *Neurotoxins* are A-B toxins produced by *Clostridium botulinum* and *Clostridium tetani* that inhibit release of neurotransmitters, resulting in paralysis. These toxins do not kill neurons; instead, the A domains interact specifically with proteins involved in secretion of neurotransmitters at the synaptic junction. Both tetanus and botulism can result in death from respiratory failure due to paralysis of the chest and diaphragm muscles.
- *Superantigens* are bacterial toxins that stimulate a large number of T lymphocytes by binding to conserved portions of the T-cell receptor, leading to massive T-lymphocyte proliferation and cytokine release. The high levels of cytokines can lead to systemic inflammatory response syndrome.

KEY CONCEPTS

HOST DAMAGE

- Diseases caused by microbes involve interplay between microbial virulence factors and host responses.
- Infectious agents cause death or dysfunction by directly interacting with the host cells.
- Injury may be due to local or systemic release of microbial products including endotoxin (LPS), exotoxins, or superantigens.
- Pathogens can induce immune responses that cause tissue damage. Absence of an immune response may reduce damage induced by some infections; conversely, immune compromise can allow uncontrolled expansion of microorganisms that can directly cause injury.

Spectrum of Inflammatory Responses to Infection

In contrast to the vast molecular diversity of microbes, the morphologic patterns of tissue responses to microbes are limited, as are the mechanisms directing these responses. Therefore, many pathogens produce similar reaction patterns, and few features are unique or pathognomonic for a particular microorganism. Moreover, sometimes the immune status of the host determines the histologic features of the inflammatory response to microbes. Thus, pyogenic bacteria, which normally evoke vigorous leukocyte responses, may cause rapid tissue necrosis with little leukocyte exudation in a profoundly neutropenic host. Similarly, in a patient who is not immunocompromised, *M. tuberculosis* causes well-formed granulomas with few mycobacteria present, whereas in an AIDS patient the same mycobacteria multiply profusely in macrophages, which fail to coalesce into granulomas.

There are five major histologic patterns of tissue reaction in infections (Table 8.3).

Suppurative (Purulent) Inflammation

This pattern is characterized by increased vascular permeability and leukocytic infiltration, predominantly of neutrophils (see Fig. 3.15). The neutrophils are attracted to the site of infection by release of chemoattractants from the "pyogenic" (pus-forming) bacteria that evoke this response, mostly extracellular gram-positive cocci and gram-negative rods. Masses of dying and dead neutrophils and liquefactive necrosis of the tissue form pus. The sizes of purulent lesions range from tiny microabscesses formed in multiple organs during bacterial sepsis secondary to a colonized heart valve, to diffuse involvement of entire lobes of the lung in pneumonia. How destructive the lesions are depends on their location and the organism involved. For example, *S. pneumoniae* usually spare alveolar walls and cause lobar pneumonia that resolves completely, whereas *S. aureus* and *Klebsiella pneumoniae* destroy alveolar walls and form abscesses that heal with scar formation. Bacterial pharyngitis *(S. pyogenes)* can resolve without sequelae, whereas untreated acute bacterial inflammation of a joint can destroy the joint in a few days.

Mononuclear and Granulomatous Inflammation

Diffuse, predominantly mononuclear, interstitial infiltrates are a common feature of all chronic inflammatory processes, but when they develop acutely, they often are a response to viruses, intracellular bacteria, or intracellular parasites. In addition, spirochetes and helminths provoke chronic inflammatory responses. Which mononuclear cell predominates within the inflammatory lesion depends on the host immune response to the organism. For example, plasma cells are abundant in the primary and secondary lesions of syphilis (Fig. 8.4), whereas lymphocytes predominate in HBV infection or viral infections of the brain. The presence

Table 8.3 Spectrum of Inflammatory Responses to Infection

Type of Response	Pathogenesis	Examples
Suppurative (Purulent) Infection	Increased vascular permeability Leukocyte infiltration (neutrophils) Chemoattractants from bacteria Formation of "pus"	Pneumonia *(Staphylococcus aureus)* Abscesses (*Staphylococcus* spp., anaerobic and other bacteria)
Mononuclear and granulomatous inflammation	Mononuclear cell infiltrates (monocytes, macrophages, plasma cells, lymphocytes) Cell-mediated immune response to pathogens ("persistent antigen") Formation of granulomata	Syphilis Tuberculosis
Cytopathic-cytoproliferative reactions	Viral transformation of cells Necrosis or proliferation (including multinucleation) Linked to neoplasia	Cervical cancer (human papillomavirus) Chicken pox, shingles Herpes
Tissue necrosis	Toxin- or lysis-mediated destruction Lack of inflammatory cells Rapidly progressive processes	Gangrene *(Clostridium perfringens)* Hepatitis (hepatitis B virus)
Chronic inflammation/ scarring	Repetitive injury leads to fibrosis Loss of normal parenchyma	Chronic hepatitis with cirrhosis (hepatitis B and C viruses)
No reaction	Severe immune compromise	*Mycobacterium avium* in untreated AIDS (T-cell deficiency) Mucormycosis in bone marrow transplant patients (neutropenia)

of these lymphocytes reflects cell-mediated immune responses against the pathogen or pathogen-infected cells. At the other extreme, macrophages may become filled with organisms, as occurs in *M. avium complex* infections in AIDS patients, who cannot mount an effective immune response to the organisms.

Granulomatous inflammation is a distinctive form of mononuclear inflammation usually evoked by infectious agents that resist eradication and are capable of stimulating strong T cell–mediated immunity (e.g., *M. tuberculosis, Histoplasma capsulatum*, schistosome eggs). Granulomatous inflammation is characterized by accumulation and aggregation of activated macrophages called "epithelioid" cells, some of which may fuse to form giant cells. Granulomas may contain a central area of caseous necrosis (see Chapter 3 and discussion of tuberculosis later in this chapter).

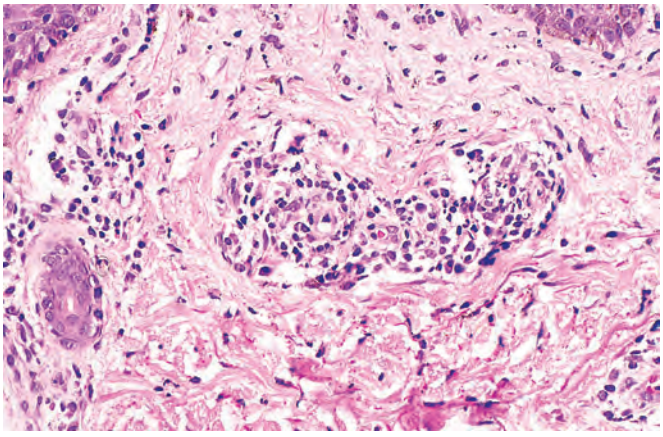

Figure 8.4 Secondary syphilis in the dermis with perivascular lymphoplasmacytic infiltrate and endothelial proliferation.

Cytopathic-Cytoproliferative Reaction

These reactions are usually produced by viruses. The lesions are characterized by cell necrosis or cellular proliferation, usually with sparse inflammatory cells. Some viruses replicate within cells and make viral aggregates that are visible as inclusion bodies (e.g., herpesviruses or adenovirus) or induce cells to fuse and form multinucleated cells called *polykaryons* (e.g., measles virus or herpesviruses). Focal cell damage in the skin may cause epithelial cells to become detached, forming blisters (Fig. 8.5). Some viruses can cause epithelial cells to proliferate (e.g., venereal warts caused by HPV or the umbilicated papules of molluscum contagiosum caused by poxviruses). Finally, viruses can contribute to the development of malignant neoplasms (Chapter 7).

Tissue Necrosis

Clostridium perfringens and other organisms such as *Corynebacterium diphtheriae* that secrete powerful toxins cause such rapid and severe necrosis (gangrenous necrosis) that tissue

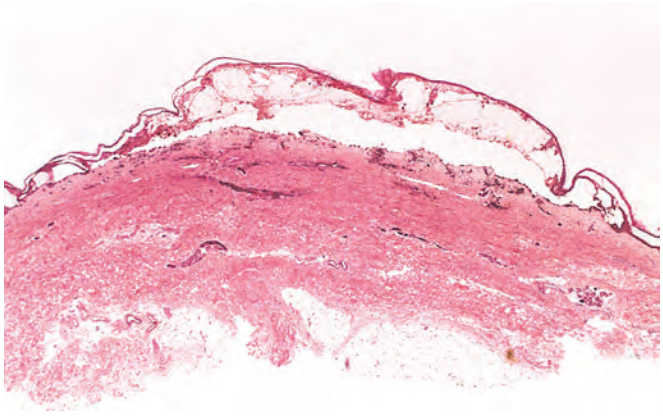

Figure 8.5 Herpesvirus blister in mucosa. See Fig. 8.9 for viral inclusions.

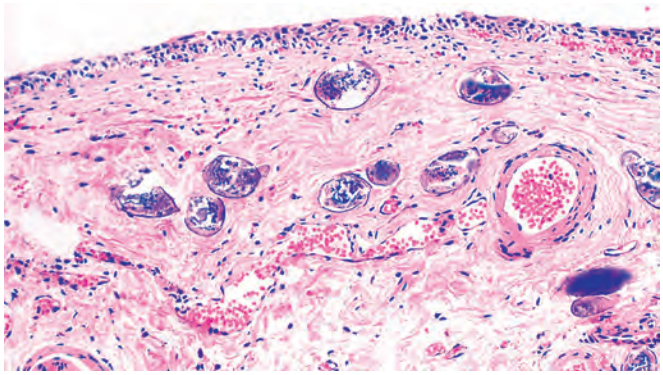

Figure 8.6 *Schistosoma haematobium* infection of the bladder with numerous calcified eggs and extensive scarring.

damage is the dominant feature. The parasite *E. histolytica* causes colonic ulcers and liver abscesses characterized by extensive tissue destruction with liquefactive necrosis and little inflammatory infiltrate. Some viruses can cause widespread and severe necrosis of host cells associated with inflammation, as exemplified by total destruction of the temporal lobes of the brain by HSV or the liver by HBV.

Chronic Inflammation and Scarring

Many infections elicit chronic inflammation, which can lead either to complete healing or to extensive scarring. For example, chronic HBV infection may cause cirrhosis of the liver, in which dense fibrous septae surround nodules of regenerating hepatocytes with complete loss of normal liver architecture and consequent changes in blood flow. Sometimes the exuberant scarring response is the major cause of dysfunction (e.g., the "pipestem" fibrosis of the liver or fibrosis of the bladder wall caused by schistosomal eggs [Fig. 8.6] or the constrictive fibrous pericarditis in tuberculosis).

These patterns of tissue reaction are useful guidelines for analyzing microscopic features of infectious processes, but they rarely appear in pure form because different types of host reactions often occur at the same time. For example, the lung of an AIDS patient may be infected with CMV, which causes cytolytic changes, and at the same time by *Pneumocystis* spp., which causes interstitial inflammation. Similar patterns of inflammation also can be seen in tissue responses to physical or chemical agents and in inflammatory diseases of unknown cause (Chapter 3).

This concludes our discussion of the general principles of the pathogenesis and pathology of infectious disease. We now turn to specific infections caused by viruses, bacteria, fungi, and parasites, and focus on their pathogenic mechanisms and pathologic effects rather than details of clinical features, which are available in clinical textbooks. Infections that typically involve a specific organ are discussed in other chapters.

VIRAL INFECTIONS

Viruses are the cause of many clinically important acute and chronic infections, which may affect virtually every organ system (Table 8.4).

Acute (Transient) Infections

The viruses that cause transient infections are structurally heterogeneous, but all elicit effective immune responses that eliminate the pathogens, limiting the durations of these infections. However, specific viruses exhibit widely differing degrees of genetic diversity, a variable that has an important impact on the susceptibility of the host to reinfection by viruses of the same type. The mumps virus, for example, has only one genetic subtype and infects people only once, whereas other viruses, such as influenza viruses, can repeatedly infect the same individual because new genetic variants arise periodically in nature. Immunity to some viruses,

Table 8.4 Selected Human Viruses and Viral Diseases

Organ System	Species	Disease
Respiratory	Adenovirus	Upper and lower respiratory tract infections, conjunctivitis, diarrhea
	Rhinovirus	Upper respiratory tract infection
	Influenza viruses A, B	Influenza
	Respiratory syncytial virus	Bronchiolitis, pneumonia
Digestive	Mumps virus	Mumps, pancreatitis, orchitis
	Rotavirus	Childhood gastroenteritis
	Norovirus	Gastroenteritis
	Hepatitis A virus	Acute viral hepatitis
	Hepatitis B virus	Acute or chronic hepatitis
	Hepatitis D virus	With hepatitis B virus, acute or chronic hepatitis
	Hepatitis C virus	Acute or chronic hepatitis
	Hepatitis E virus	Acute viral hepatitis
Systemic with skin eruptions	Measles virus	Measles (rubeola)
	Rubella virus	German measles (rubella)
	Varicella-zoster virus	Chickenpox, shingles
	Herpes simplex virus 1	Oral herpes ("cold sore")
	Herpes simplex virus 2	Genital herpes
Systemic with hematologic disorders	Cytomegalovirus	Cytomegalic inclusion disease
	Epstein-Barr virus	Infectious mononucleosis
	Human immunodeficiency viruses 1 and 2	Acquired immunodeficiency syndrome
Arboviral and hemorrhagic fevers	Dengue viruses 1 to 4	Dengue hemorrhagic fever
	Yellow fever virus	Yellow fever
Skin/genital warts	Human papillomavirus	Condyloma; cervical carcinoma
Central nervous system	Poliovirus	Poliomyelitis
	JC virus	Progressive multifocal leukoencephalopathy (opportunistic)

particularly respiratory and gastrointestinal viruses, wanes with time, and this too allows the same virus to infect the host repeatedly.

Measles

Measles is an acute viral infection that affects multiple organs and causes a wide range of disease, from mild, self-limited infections to severe systemic manifestations. A major initiative by several governments and international bodies, including the World Health Organization (WHO), to increase vaccination for measles reduced the number of measles-related deaths by 84% from 2000 to 2016, however there were still almost 90,000 deaths worldwide. Because of poor nutrition and lack of access to medical care, children in lower-income countries are 10 to 1000 times more likely to die of measles than are children in higher-income countries. Measles can produce severe disease in people with defects in cellular immunity (e.g., people infected with HIV or people with a hematologic malignancy). In higher-income nations, epidemics of measles occur when the virus is introduced by individual(s) traveling from an area of endemic disease, and then spreads, primarily to unvaccinated individuals. In recent years, such outbreaks have occurred several times each year in the United States. The diagnosis may be made clinically, by serology, or by detection of viral RNA in respiratory secretions or urine.

Pathogenesis

Measles virus is a single-stranded RNA virus of the Paramyxoviridae family, which includes mumps, respiratory syncytial virus, parainfluenza virus (a cause of croup), and human metapneumovirus. There is only one serotype of measles virus. Measles virus is very efficiently transmitted by the airborne route via aerosolized respiratory secretions. Three cell-surface receptors have been identified for measles hemagglutinin protein. Signaling lymphocytic activation molecule family member 1 (SLAMF1) is expressed on activated lymphocytes, dendritic cells, and monocytes, and it serves as the initial receptor for viral infection. Nectin-4 is found on the basal surface of epithelial cells and is thought to be important for replication of the virus within the respiratory tract, before spread of the virus in respiratory secretions. CD46 was the first cell-surface receptor identified for measles virus, but it has been found to be used only by culture-adapted virus (including the vaccine strain), and not wild-type virus.

Measles can replicate in a variety of cell types, including epithelial cells and leukocytes. The virus initially multiplies within the respiratory tract and then spreads to local lymphoid tissues. Replication of the virus in lymphatic tissue is followed by viremia and dissemination to many tissues, including the conjunctiva, skin, respiratory tract, urinary tract, small blood vessels, lymphatic system, and CNS. Most children develop T cell–mediated immunity to measles virus that helps control the viral infection and produces the measles rash. Hence, the rash is less frequent in people with deficiencies in cell-mediated immunity. In addition, in malnourished children with poor medical care, measles virus may cause croup, pneumonia, diarrhea and protein-losing enteropathy, keratitis leading to scarring and blindness, encephalitis, and hemorrhagic rashes. Subacute sclerosing panencephalitis (Chapter 28) and measles inclusion body encephalitis (in immunocompromised individuals) are rare late complications of measles. The pathogenesis of subacute sclerosing panencephalitis is not well understood, but a replication-defective variant of measles may be involved in this persistent viral infection.

Antibody-mediated immunity to measles virus protects against reinfection. Measles also can cause transient but profound immunosuppression, resulting in secondary bacterial and viral infections, which are responsible for much of measles-related morbidity and mortality. Delayed-type hypersensitivity responses are reduced following measles infection, indicating a reduction in lymphocyte responses. This may be associated with an inhibition of the ability of infected dendritic cells to stimulate lymphocytes.

MORPHOLOGY

The blotchy, reddish brown rash of measles virus infection on the face, trunk, and proximal extremities is produced by dilated skin vessels, edema, and a mononuclear perivascular infiltrate. Ulcerated mucosal lesions in the oral cavity near the opening of the Stensen ducts (the pathognomonic *Koplik spots*) are marked by necrosis, neutrophilic exudate, and neovascularization. The lymphoid organs typically have marked follicular hyperplasia, large germinal centers, and randomly distributed multinucleate giant cells, called *Warthin-Finkeldey cells*, which have eosinophilic nuclear and cytoplasmic inclusion bodies (Fig. 8.7). These are pathognomonic of measles and are also found in the lung and sputum. The milder forms of measles pneumonia show the same peribronchial and interstitial mononuclear cell infiltration that is seen in other nonlethal viral infections.

Mumps

Mumps is an acute systemic viral infection usually associated with pain and swelling of the salivary glands. Like measles virus, mumps virus is a member of the Paramyxoviridae family. Mumps virus has two types of surface glycoproteins, one with hemagglutinin and neuraminidase activities and the other with cell fusion and cytolytic activities. Mumps viruses enter the upper respiratory tract through inhalation of or contact with respiratory droplets, spread to draining lymph nodes where they replicate in lymphocytes

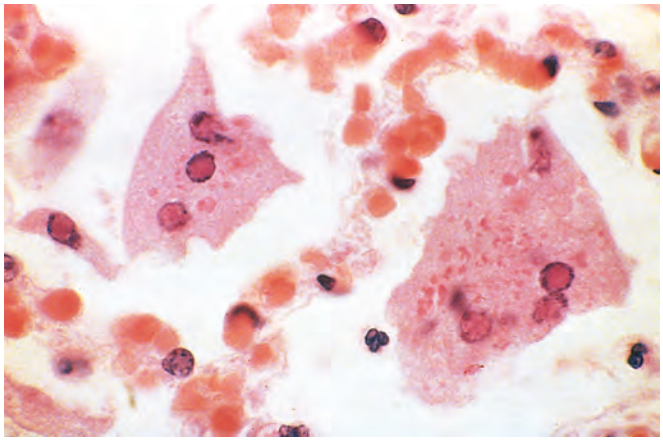

Figure 8.7 Measles giant cells in the lung. Note the glassy eosinophilic intranuclear inclusions.

(preferentially in activated T cells), and then spread through the blood to the salivary and other glands. Mumps virus infects salivary gland ductal epithelial cells, resulting in desquamation of involved cells, edema, and inflammation that leads to the classic salivary gland pain and swelling. Mumps virus also can spread to other sites, including the CNS, testis, ovary, and pancreas. Aseptic meningitis is the most common extrasalivary gland complication of mumps, occurring in up to 15% of cases. In the United States, outbreaks of mumps have occurred in populations with close contact (e.g., university or high-school settings) in recent years, resulting in approximately 6000 cases per year. It is important to note that this is still more than 99% fewer cases than occurred annually in the United States before use of the mumps vaccine. The diagnosis is usually made clinically, but serology or detection of viral RNA in saliva can be used for definitive diagnosis.

MORPHOLOGY

Mumps parotitis is bilateral in 70% of cases. The affected glands are enlarged, have a doughy consistency, and are moist, glistening, and reddish-brown on cross-section. On microscopic examination, the gland interstitium is edematous and diffusely infiltrated by macrophages, lymphocytes, and plasma cells, which compress acini and ducts. Neutrophils and necrotic debris may fill the duct lumen and cause focal damage to the lining epithelium.

In **mumps orchitis,** testicular swelling may be marked, caused by edema, mononuclear cell infiltration, and focal hemorrhages. Because the testis is tightly contained within the tunica albuginea, parenchymal swelling may compromise the blood supply and cause areas of infarction. The testicular damage can lead to scarring, atrophy, and, if severe, sterility.

Infection and damage of acinar cells in the pancreas may release digestive enzymes, causing parenchymal and fat necrosis and neutrophil-rich inflammation. **Mumps encephalitis** is associated with perivenous demyelination and perivascular mononuclear cuffing.

Poliomyelitis

Poliovirus causes an acute systemic viral infection, leading to a wide range of manifestations, from mild, self-limited infections to paralysis of limb muscles and respiratory muscles. Poliovirus is a spherical, unencapsulated RNA virus of the enterovirus genus. Other enteroviruses cause childhood diarrhea as well as rashes (coxsackievirus A), conjunctivitis (enterovirus 70), viral meningitis (coxsackieviruses and echovirus), and myopericarditis (coxsackievirus B). There are three serotypes of poliovirus, but it is likely that most infections are caused by type 1. The inactivated (injected) poliovirus vaccine protects against all three serotypes, and the attenuated (oral) poliovirus vaccine is available in various combinations of one, two, or all three serotypes, although only formulations containing one or two serotypes are currently in use. Use of these vaccines has nearly eradicated polio, because poliovirus infects only humans, shows limited genetic variation, and is effectively neutralized by antibodies generated by immunization. According to global polio surveillance data, in 2017, a total of only 22 polio cases were reported; however, additional cases were reported in 2018 and 2019 caused by the natural infection and the vaccine strain.

Poliovirus, like other enteroviruses, is transmitted by the fecal-oral route. The virus infects human cells by binding to CD155, a molecule expressed on a variety of cell types, including epithelial cells, lymphocytes, and neurons. The virus is ingested and replicates in the mucosa of the pharynx and gut, including tonsils and Peyer patches in the ileum. Poliovirus then spreads through lymphatics to lymph nodes and eventually the blood, producing transient viremia and fever. Although most poliovirus infections are asymptomatic, in about 1 in 100 infected persons poliovirus invades the CNS and replicates in motor neurons of the spinal cord (spinal poliomyelitis) or brainstem (bulbar poliomyelitis). Antiviral antibodies control the disease in most cases; it is not known why they fail to contain the virus in some individuals. Viral spread to the nervous system may be through the blood or by retrograde transport of the virus along axons of motor neurons. Rare cases of poliomyelitis that occur after vaccination are caused by mutations in the attenuated viruses to revert to wild-type, virulent, forms. The diagnosis can be made by viral culture or detection of viral RNA in throat secretions or, more often, stool, or by serology. The neurologic features and neuropathology of poliovirus infection are described in Chapter 28.

West Nile Virus Infections

West Nile Virus causes an acute systemic infection that has two very different presentations: a mild, self-limited infection or neuroinvasive disease associated with long-term neurologic sequelae. West Nile virus is an arthropod-borne virus (arbovirus) of the flavivirus group, which also includes viruses that cause dengue fever and yellow fever. West Nile virus has a broad geographic distribution in the Old World, including Africa, the Middle East, Europe, Southeast Asia, and Australia. It was first detected in the United States in 1999 during an outbreak in New York City and has since spread across the United States; in 2017, a least one case was reported in 47 states. West Nile virus is transmitted by mosquitoes to birds and to mammals. Infected birds develop prolonged viremia and are the major reservoir for the virus. Humans are incidental hosts. Most affected patients acquire the infection from a mosquito bite; less commonly, human-to-human transmission occurs by blood transfusion, organ transplantation, breastfeeding, or transplacental spread.

After inoculation by a mosquito, West Nile virus replicates in skin dendritic cells, which then migrate to lymph nodes. Here, the virus replicates further, enters the bloodstream, and, in some individuals, crosses the blood-brain barrier and infects neurons in the CNS.

West Nile virus infection is usually asymptomatic, but in 20% of infected individuals it gives rise to a fever, headache, myalgia, fatigue, anorexia, and nausea. A maculopapular rash is seen in approximately one-half of cases. CNS complications (meningitis, encephalitis, meningoencephalitis) occur in about 1 in 150 clinically apparent infections. Meningoencephalitis has a mortality rate of about 10% and results in long-term cognitive and neurologic impairment in many survivors. Immunosuppressed persons and older adults appear to be at the greatest risk for severe disease. Rare complications include hepatitis, myocarditis, and pancreatitis. The diagnosis is usually made by serology, but viral culture and polymerase chain reaction (PCR)-based tests are also used.

MORPHOLOGY

Perivascular and leptomeningeal chronic inflammation, microglial nodules (Chapter 28), and neuronophagia predominantly involving the temporal lobes and brainstem have been observed in patients who died of West Nile virus infection.

Viral Hemorrhagic Fever

Viral hemorrhagic fever is a severe life-threatening multisystem syndrome in which there is vascular damage, leading to widespread hemorrhage and shock. Viral hemorrhagic fever is caused by enveloped RNA viruses belonging to four different genera: *Arenaviridae, Filoviridae, Bunyaviridae,* and *Flaviviridae*. These viruses can produce a spectrum of illnesses, ranging from a mild acute disease characterized by fever, headache, myalgia, rash, neutropenia, and thrombocytopenia to severe, life-threatening disease in which there is sudden hemodynamic deterioration and shock. These viruses pass through an animal or insect host during their life cycles, and therefore their ranges are restricted to areas in which their hosts reside. Humans are incidental hosts who are infected when they come into contact with infected hosts (typically rodents) or insect vectors (mosquitoes and ticks). Some viruses that cause hemorrhagic fever (Ebola, Marburg, Lassa) also can spread from person to person.

The pathogenesis of the infection and its complications vary among the different viruses, but there are some common features. Damage to blood vessels is often prominent. It may be caused by direct infection of and damage to endothelial cells, or infection of macrophages and dendritic cells leading to production of inflammatory cytokines.

There was a major outbreak of Ebola virus in Sierra Leone, Liberia and Guinea in 2014 to 2016, with over 28,000 cases and 11,000 deaths reported to the WHO. A second outbreak in the Democratic Republic of Congo occurred in 2019. The outbreaks were characterized by explosive spread of the virus by person-to-person transmission through exposure to mucosal secretions. Ebola carries a very high mortality rate, about 40% during the 2019 outbreak. Effective vaccines for Ebola have been developed, and use of these will reduce the burden of disease. Ebola virus has specific mechanisms by which it can evade the immune response, allowing the virus to rapidly replicate to reach high levels. Two viral proteins, VP24 and VP35, inhibit the action of type I IFN. VP24 blocks type I IFN signaling by preventing tyrosine-kinase dimerization and nuclear translocation of STAT-1. VP35 binds to double-stranded viral RNA in infected host cells, preventing detection of the RNA by cytoplasmic receptors that stimulate type I IFN production. In addition, the viral surface protein, GP, is found in non–virus-associated soluble form, which might act as a decoy for binding of host antibodies, blocking the antibodies from neutralizing intact virus.

MORPHOLOGY

With viral hemorrhagic fever, there may be hemorrhagic manifestations, including petechiae, caused by a combination of thrombocytopenia or platelet dysfunction, endothelial injury, cytokine-induced DIC, and deficiency of clotting factors because of hepatic injury. Hemorrhages may be prominent in some infections (e.g., Congo-Crimean fever) but are rarely life-threatening. Necrosis of tissues secondary to the vascular lesions and hemorrhages may be seen and varies from mild and focal to massive, but the attendant inflammatory response is usually minimal. In Ebola virus infection, there are widespread hemorrhage and viral replication in many organs including the liver with hepatocellular necrosis and scant inflammation, and the spleen with lymphocyte apoptosis and viral replication in dendritic cells, fibroblasts, and monocytes.

Zika Virus Infections

Zika virus is a Flavivirus that was discovered in 1947 and was subsequently found to be widespread in Africa, Asia, and the Middle East. Large outbreaks occurred in the State of Yap in 2007 and French Polynesia in 2013 to 2014. In 2015, an outbreak of Zika virus from March until June in Brazil caused up to 1.3 million suspected cases. Subsequently, a marked increase in the occurrence of microcephaly in infants born in Brazil was noted with 4300 cases reported, and Zika virus has now been clearly linked to this unfortunate outcome. This Zika virus outbreak spread to at least 33 countries and territories in the Americas, with one of the largest outbreaks occurring in Colombia, which had over 50,000 suspected cases. In the United States, most of the approximately 5600 cases occurred in travelers returning from affected areas, however over 200 cases were acquired by local transmission. Zika virus is transmitted by *Aedes* mosquitos, primarily *Aedes aegypti*. It is likely that there is an animal reservoir for the virus, although none has been demonstrated to be a source of human infection. In addition to mosquito-borne and perinatal transmission, the virus can also infect through blood transfusion and sexual contact. The virus is detectable in semen, vaginal secretions, breast milk, and urine for up to several months after infection, although the duration of infectivity from these secretions is not yet clear.

The manifestations of Zika virus infection in adults are usually mild and nonspecific, with fever, myalgia, arthralgia, conjunctivitis, and maculopapular rash lasting a few days to 1 week. The infection is associated with a small number of cases of neurologic complications in adults, primarily Guillain-Barré syndrome. Perinatal transmission of the virus can result in fetal death or moderate to severe brain defects in the fetus and newborn child. In Brazil, the rate of adverse effects on newborns following maternal Zika virus infection was 46%, with the highest rates occurring following infection during the first and second trimesters. The rate of adverse effects on newborns has been higher in Brazil than in other nations. In the US territories, the rates of Zika virus–associated birth defects for infections during the first, second, and third trimesters of pregnancy were 8%, 5%, and 4%, respectively. The reasons for the differences in these rates are not known but might include differences in data-collection methods or effects of genetics, co-infections, immunity from past infections, or as-yet undefined environmental factors.

Our developing understanding of the pathogenesis of Zika virus is from autopsies of infected newborns, in-vitro studies of infected human tissues, and limited animal studies. Viral proteins are present in degenerating neurons and glial cells, as well as in chorionic villi of the placenta in some cases, indicating replication of virus with associated necrosis

in these cells. Viral RNA can be detected in brain tissues in all cases, but virus is absent or present only variably in other tissues. Studies in mice with immune defects suggest that Zika virus replicates initially in the placenta followed by infection of the fetus, and that viral replication occurs in neural precursor cells, leading to reduced brain size and thinning of the cortex. In vitro studies using cell lines and brain organoids, composed of differentiated pluripotent stem cells in a tissue-like structure, confirm that Zika virus replicates in and kills human neurons.

MORPHOLOGY

Cerebral calcifications, cerebral atrophy, ventricular enlargements, and hypoplastic cerebral structures were the most common adverse outcomes associated with Zika virus infection (Fig. 8.8). Microcephaly occurred in a small number of infants, 3.4% of those born to infected women, with one-half of cases being proportionate microcephaly in children who were small for gestational age, and the other half being disproportionate microcephaly, meaning that the head size was small relative to the size of the child. Ocular abnormalities, including pigment mottling, chorioretinal atrophy, and optic nerve abnormalities, are also common.

In small autopsy series, common findings in newborn children include microcephaly, ventriculomegaly, and congenital joint contractures (arthrogryposis) and pulmonary hypoplasia. Severe neuronal depletion and associated thinning of the brain parenchyma occurred, with microcalcifications and microglial nodules.

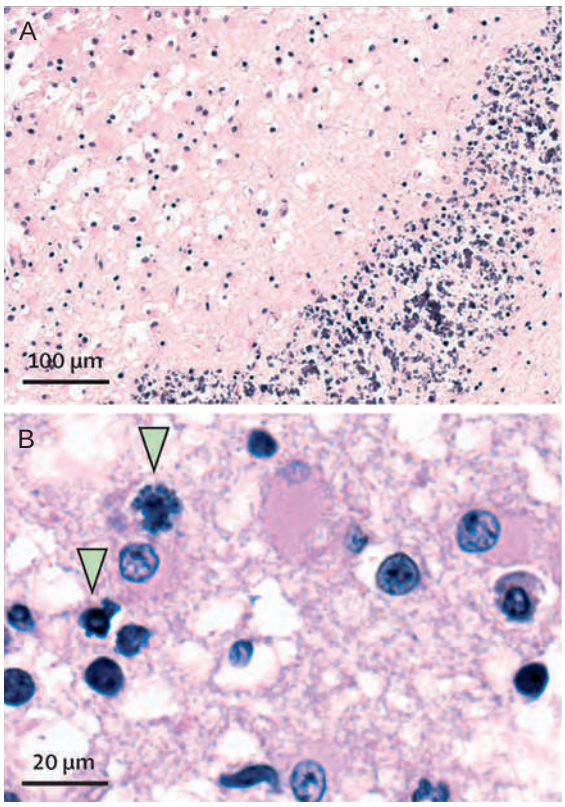

Figure 8.8 The morphology of brain from a two month old child with congenital Zika virus infection. (A) Subcortical band of degenerating cells with prominent calcifications. (B) Cortex with degenerating neurons *(arrows)*. (From Martinez, Pathology of congenital Zika syndrome in Brazil: a case series, *Lancet* 388(10047):898–904, 2016.)

Dengue

Dengue virus is a flavivirus transmitted by *Aedes* mosquitoes in tropical and subtropical regions. It is estimated to infect 390 million people each year, 960,000 of whom have severe infection that requires hospital admission. Clinical manifestations of dengue vary from fever with headache, macular rash and severe myalgias (breakbone fever) to severe dengue *(dengue hemorrhagic fever)* with bleeding, liver failure, reduced consciousness, organ failure, and plasma leakage leading to shock and respiratory distress. In severe dengue, there are widespread hemorrhages throughout the body with hepatic necrosis and mononuclear infiltrates, septal thickening, and hyaline membrane formation in the lung.

The immune response against dengue virus is thought to determine, in part, the severity of the infection. There are four serotypes of dengue virus. Infection with each serotype stimulates protective immunity against that serotype, but also stimulates a cross-reactive antibody response that is weak and nonprotective for other serotypes of the virus. Severe dengue usually occurs in people who have had previous infection with a different serotype than the one associated with their severe illness. Antibody-dependent enhancement, in which the cross-reactive antibodies enhance uptake of virus into macrophages via Fc receptors, is thought to increase infectivity of the virus and contribute to severe dengue. Severe dengue also occurs in infants who have maternal antibodies against dengue virus, consistent with this model.

Novel Coronavirus SARS-CoV-2 (COVID-19)

A novel coronavirus SARS-CoV-2-mediated disease called COVID-19 was first detected in Wuhan, China, and was reported to the WHO in December 2019. By the end of March 2020, the infection had become a worldwide pandemic, with more than 800,000 cases and about 40,000 deaths. This devastating pandemic has caused major social and economic disruptions, in addition to its severe health consequences. Epidemiologic studies suggest that the origin was a seafood and animal market in Wuhan, consistent with initial animal-to-human transmission followed by person-to-person spread soon thereafter. Sequencing of the full viral genome led to development of a rapid molecular diagnostic assay during the evolving outbreak. The clinical manifestations ranged from mild to severe respiratory illness. The vast majority of individuals who contract the virus recover after a flu-like disease. Severe and sometimes fatal illness with respiratory compromise, often associated with bilateral ground-glass opacities on chest imaging, occurs mainly in older individuals and those with comorbidities such as diabetes, COPD, and heart failure. The genomic sequence shows COVID-19 is related to bat coronaviruses and the SARS coronavirus. Histologic analysis of lung tissue done in a few patients revealed diffuse alveolar damage and inflammation with mainly mononuclear cells.

Latent Infections (Herpesvirus Infections)

Latency is defined as the persistence of viral genomes in cells that do not produce infectious virus. Dissemination of the infection and tissue injury stem from reactivation of the latent virus. The viruses that most frequently establish latent infections in humans are herpesviruses. These are large encapsulated viruses with double-stranded DNA

genomes that encode approximately 70 proteins. Herpesviruses cause acute infection followed by latent infection in which the viruses persist in a noninfectious form with periodic reactivation and shedding of infectious virus.

There are eight types of human herpesviruses, belonging to three subgroups that are defined by the type of cell most frequently infected and the site of latency.

- The *α-group viruses,* including HSV-1, HSV-2, and VZV, infect epithelial cells and produce latent infection in postmitotic neurons.
- The *β-group viruses* include CMV and human herpesviruses 6 and 7 (HHV-6 and HHV-7), which infect and produce latent infection in a variety of cell types. HHV-6 and HHV-7 cause exanthem subitum, also known as *roseola infantum,* and sixth disease, a benign rash of infants, and also have been associated with encephalitis, pneumonitis, hepatitis, and myelitis on reactivation.
- The *γ-group viruses,* including EBV and Kaposi sarcoma–associated virus (KSHV/HHV-8), produce latent infection mainly in lymphoid cells.
- *Herpesvirus simiae* (monkey B virus) is an Old World monkey virus that resembles HSV-1 and can cause fatal neurologic disease in animal handlers, usually resulting from an animal bite.

Herpes Simplex Virus (HSV) Infections

HSV-1 and HSV-2 differ serologically but are closely related genetically and cause a similar set of primary and recurrent infections. Herpes simplex viruses are common throughout the world, with an estimated 4 billion infections globally. Both viruses replicate in the skin and the mucous membranes at the site of entry of the virus (usually oropharynx or genitals), where they produce infectious virions and cause vesicular lesions of the epidermis. The viruses spread to sensory neurons that innervate these primary sites of viral replication and release. Viral nucleocapsids are transported along axons to the neuronal cell bodies, where the viruses establish latent infection. In immunocompetent hosts, primary HSV infection resolves in a few weeks, although the virus remains latent in nerve cells. During latency the viral DNA remains within the nucleus of the neuron, and only latency-associated viral RNA transcripts (LATs) are synthesized. No viral proteins appear to be produced during latency. LATs may contribute to latency by conferring resistance to apoptosis, silencing lytic gene expression through heterochromatin formation, and serving as precursors for micro-RNAs that downregulate expression of critical HSV lytic genes. Reactivation of HSV-1 and HSV-2 may occur repeatedly with or without symptoms, and results in the spread of virus from the neurons to the skin or to mucous membranes. It is proposed that during reactivation, release from epigenetic silencing occurs through a methylation/phosphorylation process that is linked to the cellular stress response pathways in neurons. Reactivation can occur in the presence of host immunity, because HSVs have developed ways to avoid immune recognition. For example, HSVs can evade antiviral CTLs by inhibiting the class I MHC recognition pathway, and elude humoral immune defenses by producing "decoy" receptors that bind the Fc domain of immunoglobulin and inhibitors of complement. HSVs can infect multiple cell types, including dendritic cells that are important for the antiviral immune response.

In addition to causing cutaneous and genital lesions, HSV-1 is the major infectious cause of corneal blindness in the United States. Corneal epithelial disease is thought to be due to direct viral damage, and corneal stromal disease appears to be immune-mediated. HSV-1 is also the major cause of fatal sporadic encephalitis in the United States. When the infection spreads to the brain, it usually involves the temporal lobes and orbital gyri of the frontal lobes. Inherited mutations in TLR3 or components of its signaling pathway increase the risk of HSV encephalitis. In addition, neonates and individuals with compromised cellular immunity (e.g., secondary to HIV infection or chemotherapy) may suffer disseminated herpesvirus infections. Due to ulceration and dampening of the immune response, HSV-2 infection increases the risk of HIV transmission fourfold and increases the risk of HIV acquisition twofold to threefold.

MORPHOLOGY

HSV-infected cells contain large, pink to purple *intranuclear inclusions* (Cowdry type A) that consist of viral replication proteins and virions at various stages of assembly that push the host cell chromatin out to the edges of the nucleus (Fig. 8.9). Due to cell fusion, HSV also produces inclusion-bearing multinucleated syncytia.

HSV-1 and HSV-2 cause lesions ranging from self-limited cold sores and gingivostomatitis to life-threatening disseminated visceral infections and encephalitis. **Fever blisters or cold sores** favor the facial skin around mucosal orifices (lips, nose), where their distribution is frequently bilateral and independent of skin dermatomes. Intraepithelial vesicles (blisters), which are formed by intracellular edema and ballooning degeneration of epidermal cells, frequently burst and crust over, but some may result in superficial ulcerations.

Gingivostomatitis, which is usually encountered in children, is caused primarily by HSV-1. It is a vesicular eruption extending from the tongue to the retropharynx and causing cervical lymphadenopathy. Swollen, painful, erythematous HSV lesions of the fingers or palm (herpetic whitlow) occur in infants and, occasionally, in health care workers due to occupational exposure.

Genital herpes is more often caused by HSV-2 than by HSV-1. It is characterized by vesicles on the genital mucous membranes as well as on the external genitalia that are rapidly converted into superficial ulcerations that are rimmed by an

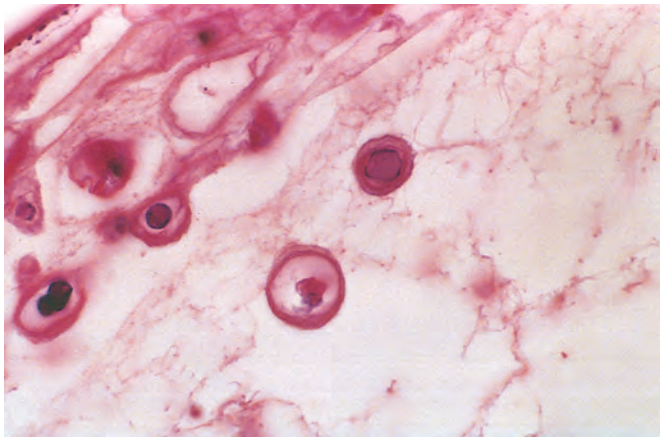

Figure 8.9 A herpesvirus blister showing glassy intranuclear viral inclusion bodies.

inflammatory infiltrate (Chapter 22). Herpesvirus (usually HSV-2) can be transmitted to neonates during passage through the birth canal of infected mothers. Although HSV-2 infection in the neonate may be mild, more commonly it is fulminating with generalized lymphadenopathy, splenomegaly, and necrotic foci throughout the lungs, liver, adrenals, and CNS.

Two forms of corneal lesions are caused by HSV (Chapter 29). **Herpes epithelial keratitis** shows typical virus-induced cytolysis of the superficial epithelium. In contrast, **herpes stromal keratitis** is characterized by infiltrates of mononuclear cells around keratinocytes and endothelial cells, leading to neovascularization, scarring, opacification of the cornea, and eventual blindness. Here, the damage is caused by an immunologic reaction to the HSV infection, rather than the cytopathic effects of the virus itself.

Herpes simplex encephalitis is described in Chapter 28.

Disseminated skin and visceral herpes infections are usually encountered in hospitalized patients with underlying cancer or immunosuppression. **Herpes esophagitis** is frequently complicated by superinfection with bacteria or fungi. **Herpes bronchopneumonia,** sometimes stemming from intubation of a patient with active oral lesions, is often necrotizing, and **herpes hepatitis** may cause liver failure.

Varicella-Zoster Virus (VZV) Infections

Acute infection with VZV causes chickenpox, and reactivation of latent VZV causes shingles (also called herpes zoster). Chickenpox is mild in children but more severe in adults and in immunocompromised people. Shingles is a source of morbidity in older and immunosuppressed persons. Like HSV, VZV infects mucous membranes, skin, and neurons and causes a self-limited primary infection in immunocompetent individuals. Also like HSV, VZV evades immune responses and establishes a latent infection in sensory ganglia. In contrast to HSV, VZV is transmitted in epidemic fashion by respiratory aerosols, disseminates hematogenously, and causes widespread vesicular skin lesions. Latent VZV infection is seen in neurons and/or satellite cells around neurons in the dorsal root ganglia. Reactivation and clinical recurrences causing shingles are uncommon but may occur many years after the primary infection. Localized recurrence of VZV is most frequent and painful in dermatomes innervated by the trigeminal ganglia, where the virus is most likely to be latent. Shingles rarely recurs in immunocompetent individuals (in only 1% to 4% of infected individuals), but immunosuppressed or older persons can have multiple recurrences. For this reason, vaccination to prevent shingles is now recommended in all patients older than 50 years of age, and in younger adults with chronic disorders that may impair immunity. VZV infection is diagnosed by viral culture, PCR, or detection of viral antigens in cells scraped from superficial lesions.

MORPHOLOGY

The **chickenpox** rash occurs approximately 2 weeks after respiratory infection. Lesions appear in multiple waves centrifugally from the torso to the head and extremities. Each lesion progresses rapidly from a macule to a vesicle, which resembles a dewdrop on a rose petal. On histologic examination, chickenpox lesions show intraepithelial vesicles (Fig. 8.10) with intranuclear inclusions in epithelial cells at the base of the vesicles. After a few days, most chickenpox vesicles rupture, crust over, and heal by regeneration, leaving no scars. However, bacterial superinfection of vesicles that are ruptured by trauma may lead to destruction of the basal epidermal layer and residual scarring.

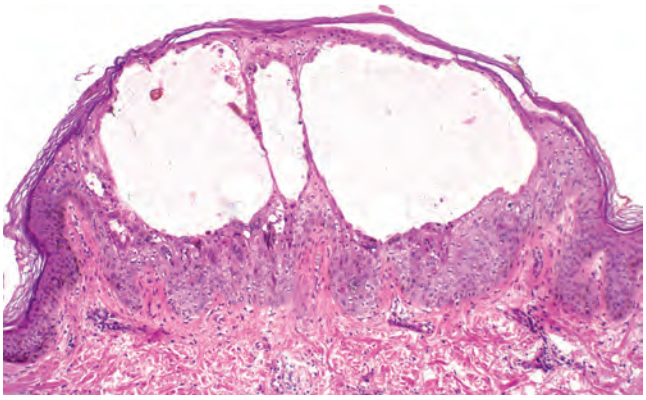

Figure 8.10 Skin lesion of chickenpox (varicella-zoster virus) with intraepithelial vesicle.

Shingles occurs when VZV that has long remained latent in the dorsal root ganglia after a previous chickenpox infection is reactivated and infects sensory nerves that carry it to one or more dermatomes. There, the virus infects keratinocytes and causes vesicular lesions, which, unlike chickenpox, are often associated with intense itching, burning, or sharp pain because of concomitant radiculoneuritis. This pain is especially severe when the trigeminal nerves are involved; rarely, the geniculate nucleus is involved, causing facial paralysis (Ramsay Hunt syndrome). The sensory ganglia contain a dense, predominantly mononuclear infiltrate, with herpetic intranuclear inclusions within neurons and their supporting cells (Fig. 8.11). VZV can also cause interstitial pneumonia, encephalitis, transverse myelitis, vasculopathy, and necrotizing visceral lesions, particularly in immunosuppressed people. Similar to HSV, patients with mutations in TLR3 have an increased risk of VZV encephalitis.

Cytomegalovirus (CMV) Infections

CMV, a β-group herpesvirus, can produce a variety of disease manifestations, depending on the age of the host, and, more importantly, on the host's immune status. CMV latently infects monocytes and their bone marrow progenitors and can be reactivated when cellular immunity is depressed. CMV causes an asymptomatic or mononucleosis-like infection in healthy individuals but devastating systemic infections in neonates and in immunocompromised people, in whom the virus may infect many different cell types and tissues. As its name implies, CMV-infected cells exhibit gigantism of both the entire cell and its nucleus, which typically contains a large inclusion surrounded by a clear halo ("owl's eye").

Transmission of CMV can occur by several routes, depending on the age group affected. These include the following:

- *Transplacental transmission,* from a newly acquired or primary infection in a mother who does not have protective antibodies (congenital CMV)
- *Neonatal transmission,* through cervical or vaginal secretions at birth, or later through breast milk from a mother who has active infection (perinatal CMV)
- *Transmission through saliva* may occur during preschool years, especially in day care centers. Toddlers so infected readily transmit the virus to their parents
- *Transmission by the genital route* is the dominant mode after about 15 years of age. Spread may also occur via respiratory secretions and the fecal-oral route
- *Iatrogenic transmission* can occur at any age through organ transplant or blood transfusion

Acute CMV infection induces transient but severe immunosuppression. CMV can infect dendritic cells and impair antigen processing and the ability of dendritic cells to stimulate T lymphocytes. Similar to other herpesviruses, CMV can evade immune defenses by down-modulating class I and II MHC molecules and by producing homologues of TNF receptor superfamily members, IL-10, and class I MHC molecules. Interestingly, CMV can evade NK cells by producing ligands that block activating receptors and class I–like proteins that engage inhibitory receptors. Adoptive transfer of CMV-specific T cells has been successfully used to prevent CMV disease after bone marrow transplantation, and the CD8+ T cell response has been thought to be the most important effector response. CD4+ T cells, γδ T cells, and NK cells are known to play a role in immune control of the infection. CMV encodes several Fcγ-binding glycoproteins that effectively operate as adversaries of host Fcγ receptors, inhibiting IgG-mediated immunity. Thus, CMV both hides from and actively suppresses immune responses.

MORPHOLOGY

Infected cells are strikingly enlarged, often to a diameter of 40 μm, and show cellular and nuclear pleomorphism. Prominent *intranuclear basophilic inclusions* spanning one-half of the nuclear diameter are usually set off from the nuclear membrane by a clear halo (Fig. 8.12). Within the cytoplasm of infected cells, smaller basophilic inclusions can also be seen. Parenchymal epithelial cells are infected in glandular organs, as well as neurons in the brain, alveolar macrophages, epithelial cells, and endothelial cells in the lungs, and tubular epithelial and glomerular endothelial cells in the kidneys. CMV causes focal necrosis with minimal inflammation in virtually any organ.

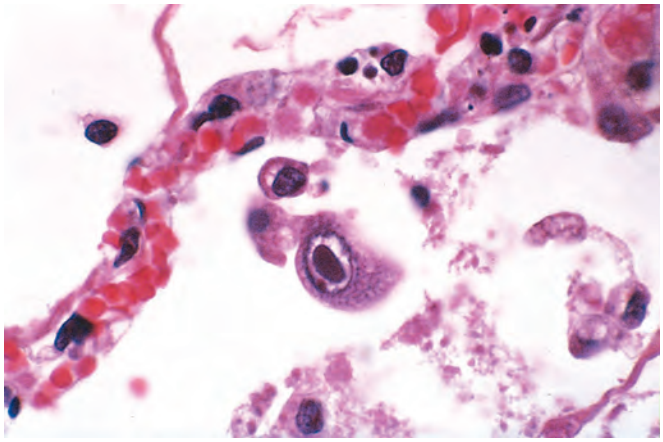

Figure 8.12 Cytomegalovirus: distinct nuclear and ill-defined cytoplasmic inclusions in the lung.

Congenital Infections. Infection acquired in utero may take many forms. In approximately 95% of cases, it is asymptomatic. However, sometimes when the virus is acquired from a mother with primary infection (who does not have protective antibodies), classic cytomegalic inclusion disease develops. Cytomegalic inclusion disease resembles erythroblastosis fetalis. Affected infants may suffer intrauterine growth restriction and present with jaundice, hepatosplenomegaly, anemia, bleeding due to thrombocytopenia, and encephalitis. In fatal cases, the brain is often smaller than normal (microcephaly) and may show foci of calcification. Diagnosis of neonatal CMV is made by viral culture or PCR amplification of viral DNA in urine or saliva.

Infants who survive usually have permanent deficits, including intellectual disability, hearing loss, and other neurologic impairments. The congenital infection is not always devastating, however, and may take the form of interstitial pneumonitis, hepatitis, or a hematologic disorder. Most infants with this milder form of cytomegalic inclusion disease recover, although a few develop intellectual disability later. Uncommonly, a totally asymptomatic infection may be followed months to years later by neurologic sequelae, including delayed-onset intellectual disability and deafness.

Perinatal Infections. Infection acquired during passage through the birth canal or from breast milk is usually asymptomatic due to protective maternal anti-CMV antibodies, which are transmitted to the fetus. Despite the lack of symptoms, many of these infants continue to excrete CMV in their urine or saliva for months to years. Subtle effects on hearing and intelligence later in life have been reported in some studies. Much less commonly, infected infants develop interstitial pneumonitis, failure to thrive, rash, or hepatitis.

CMV Mononucleosis. In healthy young children and adults, the disease is nearly always asymptomatic. In surveys

around the world, 50% to 100% of adults have antibodies to CMV, indicating previous exposure. The most common clinical manifestation of CMV infection in immunocompetent hosts beyond the neonatal period is an infectious mononucleosis-like illness, with fever, atypical lymphocytosis, lymphadenopathy, and hepatitis, marked by hepatomegaly and abnormal liver function tests. The diagnosis is made by serology. Most people recover without any sequelae, but the virus may continue to be excreted in body fluids for months to years. Irrespective of the presence or absence of symptoms, infected individuals remain seropositive for life, and the virus is never cleared, persisting in latently infected leukocytes.

CMV in Immunosuppressed Individuals. Immunocompromised individuals (e.g., transplant recipients and HIV-infected individuals) are susceptible to severe CMV infection, which may be either new infections or reactivation of latent CMV. In the past, CMV was the most common opportunistic viral pathogen in AIDS. Although CMV is still a significant cofactor in HIV disease, especially in Africa, the frequency of serious CMV infection in HIV-positive people has been greatly reduced by antiretroviral treatment. Recipients of solid-organ transplants (heart, liver, kidney) also may contract CMV from the donor organ.

In all of these settings, serious, even life-threatening, disseminated CMV infections in immunosuppressed people primarily affect the lungs (pneumonitis) and gastrointestinal tract (colitis). With pulmonary infection, an interstitial mononuclear infiltrate with foci of necrosis develops, accompanied by the typical enlarged cells with inclusions. The pneumonitis can progress to full-blown acute respiratory distress syndrome. Intestinal necrosis and ulceration can develop and be extensive, leading to the formation of pseudomembranes and debilitating diarrhea. CMV has been associated with vasculopathy and neurocognitive impairment with associated immune markers including the accumulation of multifunctional terminally differentiated αβ T cells, γδ T cells, and NK cells. Diagnosis of CMV infection is made by demonstration of characteristic morphologic alterations in tissue sections, viral culture, rising antiviral antibody titer, and PCR-based detection of CMV DNA. Quantitative PCR-based assays have revolutionized the approach to monitoring CMV infection in people after transplantation.

Chronic Productive Infections

In some infections the immune system is unable to eliminate the virus, and continued viral replication leads to persistent viremia. The high mutation rate of viruses such as HIV and HBV may contribute to their escape from control by the immune system. HIV and HBV infection are described in Chapters 6 and 18, respectively.

Transforming Viral Infections

Some viruses can transform infected cells into benign or malignant tumor cells. Oncogenic viruses can stimulate cell growth and survival by a variety of mechanisms. Several viruses have been implicated in the causation of human cancer, including EBV, HPV, HBV, and HTLV-1 (discussed in Chapters 7, 13, 18, and 22).

Epstein-Barr Virus (EBV) Infections

EBV causes infectious mononucleosis, a benign, self-limited lymphoproliferative disorder, and is associated with the pathogenesis of several human tumors, most commonly certain lymphomas and nasopharyngeal carcinoma. Only infectious mononucleosis is discussed here.

Infectious mononucleosis is characterized by fever, sore throat, generalized lymphadenopathy, splenomegaly, and the appearance in the blood of atypical activated T lymphocytes (mononucleosis cells). Some people develop hepatitis, meningoencephalitis, and pneumonitis. Infectious mononucleosis occurs principally in late adolescents or young adults among upper socioeconomic classes in higher-income nations. In the rest of the world, primary infection with EBV occurs in childhood and is usually asymptomatic.

Pathogenesis

EBV is transmitted by close human contact, frequently through the saliva during kissing. It is not known whether the source of the virus is B cells, oropharyngeal epithelial cells, or both. EBV infects B cells and possibly epithelial cells of the oropharynx. It has been hypothesized that EBV initially infects oropharyngeal epithelial cells and then spreads to underlying lymphoid tissue (tonsils and adenoids), where mature B cells are infected. Of note, people with X-linked agammaglobulinemia, who lack B cells, do not become latently infected with EBV or shed virus, suggesting that B cells are the main reservoir of infection. An EBV envelope glycoprotein binds CD21 (CR2), the receptor for the C3d component of complement, which is present on B cells. Infection of B cells may take one of two forms. In a minority of B cells, infection is lytic, leading to viral replication and eventual cell lysis accompanied by release of virions, which may infect other B cells. In most B cells, however, EBV establishes latent infection, during which the virus persists as an extrachromosomal episome.

B cells that are latently infected with EBV are activated and begin to proliferate and to disseminate. This uncontrolled, expanding polyclonal population of EBV-infected B cells secretes antibodies with many specificities, including antibodies that recognize sheep or horse red cells. These so-called *heterophile antibodies* are detected in diagnostic tests for mononucleosis. EBV-infected B cells may also produce autoantibodies, for example against platelets, leading to transient immune-mediated thrombocytopenia in a small subset of patients with mononucleosis.

The symptoms of infectious mononucleosis appear on initiation of the host immune response. Cellular immunity mediated by CD8+ CTLs and NK cells is the most important component of this response. The *atypical lymphocytes* seen in the blood, characteristic of this disease, are mainly EBV-specific CD8+ CTLs, but also include NK cells. The reactive proliferation of T cells is largely centered in lymphoid tissues, which accounts for the lymphadenopathy and splenomegaly. Early in the course of the infection, IgM antibodies are formed against viral capsid antigens; later, IgG antibodies are formed that persist for life. In otherwise healthy persons, the fully developed humoral and cellular responses to EBV act as brakes on viral shedding, resulting in the elimination of B cells expressing the full complement of EBV latency-associated genes. In hosts with acquired defects

in cellular immunity (e.g., AIDS, organ transplantation), reactivation of EBV can lead to B-cell proliferation, which can progress through a multistep process to EBV-associated B-cell lymphomas. EBV also contributes to the development of some cases of Burkitt lymphoma (Chapters 7 and 13), in which a chromosomal translocation (most commonly an 8:14 translocation) involving the *MYC* oncogene is the critical oncogenic event.

MORPHOLOGY

The major alterations involve the blood, lymph nodes, spleen, liver, CNS, and, occasionally, other organs. The **peripheral blood** shows absolute lymphocytosis; more than 60% of white blood cells are lymphocytes. Between 5% and 80% of these are large, **atypical lymphocytes,** 12 to 16 μm in diameter, characterized by an abundant cytoplasm containing multiple clear vacuolations; an oval, indented, or folded nucleus; and scattered cytoplasmic azurophilic granules (Fig. 8.13). These atypical lymphocytes, most of which express CD8, are sufficiently distinctive to strongly suggest the diagnosis.

The **lymph nodes** are typically discrete and enlarged throughout the body, particularly in the posterior cervical, axillary, and inguinal regions. On histologic examination, the most striking feature is the expansion of paracortical areas due to activation of T cells (immunoblasts). A minor population of EBV-infected B cells expressing Epstein-Barr nuclear antigen 2 *(EBNA2)*, latent membrane protein 1 *(LMP1)*, and other latency-specific genes can also be detected in the paracortex using specific antibodies. EBV-infected B cells resembling Reed-Sternberg cells (the malignant cells of Hodgkin lymphoma, Chapter 13) may be found. B-cell areas (follicles) may also show mild hyperplasia. The T-cell proliferation is sometimes so exuberant that it is difficult to distinguish the nodal morphology from that seen in malignant lymphomas. Similar changes commonly occur in the tonsils and lymphoid tissue of the oropharynx.

The **spleen** is enlarged in most cases, weighing between 300 and 500 g. It is usually soft and fleshy, with a hyperemic cut surface. The histologic changes are analogous to those of the lymph nodes, showing an expansion of white pulp follicles and red pulp sinusoids due to the presence of numerous activated T cells. These spleens are especially vulnerable to rupture, possibly in part because the rapid increase in size produces a tense, fragile splenic capsule.

The **liver** is usually involved to some degree, although hepatomegaly is at most moderate. On histologic examination, atypical lymphocytes are seen in the portal areas and sinusoids, and scattered, isolated cells or foci of parenchymal necrosis may be present. This histologic picture is similar to that of other forms of viral hepatitis.

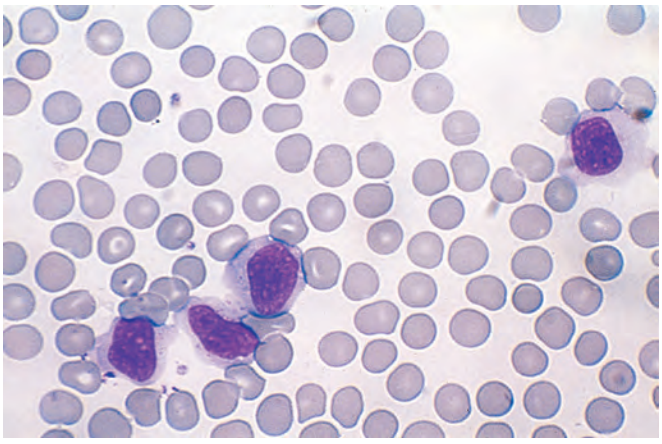

Figure 8.13 Atypical lymphocytes in infectious mononucleosis.

Clinical Features

EBV infection in young children classically presents with fever, sore throat, lymphadenitis, and the other features mentioned earlier. However, malaise, fatigue, and lymphadenopathy are the common presentation in young adults with infectious mononucleosis and can raise the specter of leukemia or lymphoma; EBV also can cause fever of unknown origin without significant lymphadenopathy or other localized findings, hepatitis resembling one of the hepatotropic viral syndromes, or a febrile rash resembling rubella. The diagnosis depends on the following findings (in increasing order of specificity): (1) lymphocytosis with the characteristic atypical lymphocytes in the peripheral blood, (2) a positive heterophile antibody reaction (Monospot test), and (3) a rising titer of specific antibodies for EBV antigens (viral capsid antigens, early antigens, or EBNA). In most patients, infectious mononucleosis resolves within 4 to 6 weeks, but sometimes the fatigue lasts longer. One or more complications occasionally supervene. Perhaps most common is marked hepatic dysfunction with jaundice, elevated hepatic enzyme levels, disturbed appetite, and, rarely, even liver failure. Other complications involve the nervous system, kidneys, bone marrow, lungs, eyes, heart, and spleen. Splenic rupture can occur even with minor trauma, leading to hemorrhage that may be fatal. Recent studies have found a correlation between the severity of infectious mononucleosis and the T-cell receptor repertoire of the host, leading to a hypothesis that heterologous immunity might explain variability in disease outcome.

A more serious complication in those lacking T-cell immunity, such as HIV-infected individuals and individuals receiving immunosuppressive therapy (e.g., bone marrow or solid-organ transplant recipients), is unimpeded B-cell proliferation. This process can be initiated by an acute infection or reactivation of latent B-cell infection and usually begins as polyclonal B-cell proliferation that transforms to monoclonal B-cell lymphoma.

Serious consequences of EBV infection occur in individuals suffering from the X-linked lymphoproliferation disease (also known as *Duncan disease*), a disorder caused by mutations in the *SH2D1A* gene, which encodes a signaling protein that participates in T-cell and NK-cell activation and antibody production. This rare inherited immunodeficiency is characterized by an ineffective immune response to EBV. Patients are usually normal until they are acutely infected with EBV, often during adolescence. In more than half the cases, EBV causes an acute overwhelming infection that may be fatal. Others succumb to EBV-positive B-cell lymphoma or infections related to hypogammaglobulinemia.

BACTERIAL INFECTIONS

Different classes of bacteria are responsible for diverse infections (Table 8.5). Selected examples of the most common or clinically significant infections are discussed next.

Gram-Positive Bacterial Infections

Common gram-positive cocci include *Staphylococcus* spp., *Streptococcus* spp., and *Enterococcus* spp., each of which causes many types of infections. Diphtheria, listeriosis, anthrax, and nocardiosis are less common infections caused by gram-positive rods.

Table 8.5 Selected Human Bacterial Pathogens and Associated Diseases

Organ System	Species	Frequent Disease Presentations
Respiratory	*Streptococcus pyogenes*	Pharyngitis
	Corynebacterium diphtheriae	Diphtheria
	Bordetella pertussis	Pertussis
	Streptococcus pneumonia	Lobar pneumonia
	Mycobacterium tuberculosis	Tuberculosis
	Legionella pneumophila	Legionnaires' disease
Gastrointestinal	*Helicobacter pylori*	Peptic ulcers
	Vibrio cholerae, enterotoxigenic *Escherichia coli*	Noninflammatory gastroenteritis
	Shigella spp., *Salmonella* sp. *Campylobacter jejuni*, enterohemorrhagic *Escherichia coli*	Inflammatory gastroenteritis
	Salmonella serotype *typhi*	Enteric (typhoid) fever
	Clostridioides difficile	Pseudomembranous colitis
Nervous system	*Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Listeria monocytogenes*	Acute meningitis
	Clostridium tetani, *Clostridium botulinum*	Paralytic intoxications, tetanus, and botulism
Urogenital	*Escherichia coli*, *Pseudomonas aeruginosa*, *Enterococcus* spp.	Urinary tract infections
	Neisseria gonorrhoeae	Gonorrhea
	Chlamydia trachomatis	Chlamydia
	Treponema pallidum	Syphilis
Skin and adjacent soft tissue	*Staphylococcus aureus*	Abscess, cellulitis
	Streptococcus pyogenes	Impetigo, erysipelas, necrotizing fasciitis
	Clostridium perfringens	Gas gangrene
	Bacillus anthracis	Cutaneous anthrax
	Pseudomonas aeruginosa	Burn infections
	Mycobacterium leprae	Leprosy
Disseminated infections	*Yersinia pestis*	Plague
	Borrelia burgdorferi	Lyme disease
	Brucella spp.	Brucellosis (undulant fever)
Disseminated neonatal infection	*Streptococcus agalactiae*, *Listeria monocytogenes*	Neonatal bacteremia, meningitis
	Treponema pallidum	Congenital syphilis

Staphylococcal Infections

***S. aureus* causes a myriad of skin lesions (boils, carbuncles, impetigo, and scalded-skin syndrome) as well as abscesses, sepsis, osteomyelitis, pneumonia, endocarditis, food poisoning, and toxic shock syndrome** (Fig. 8.14). There are more than 1 million infections in the United States alone, with 20,000 attributable deaths per year. *S. aureus* is a pyogenic gram-positive coccus that forms clusters resembling bunches of grapes. The general characteristics of *S. aureus* infection are reviewed in the following sections. Infections of specific organs are described in other chapters. Coagulase-negative staphylococci, such as *S. epidermidis*, characteristically cause opportunistic infections in catheterized patients, patients with prosthetic cardiac valves, and intravenous drug users. *S. saprophyticus* is a common cause of urinary tract infection in young women.

Pathogenesis

S. aureus produces a multitude of virulence factors, which include surface proteins involved in adherence and evasion of the host immune response, secreted enzymes that degrade host structures, secreted toxins that damage host cells, and proteins that cause antibiotic resistance. *S. aureus* expresses surface receptors for fibrinogen (called clumping factor), fibronectin, and vitronectin and uses these molecules to bind to host endothelial cells. *S. aureus* produces a polysaccharide capsule, enabling attachment to artificial materials and resulting in significant prosthetic valve and catheter-associated infection and a resistance to host cell phagocytosis.

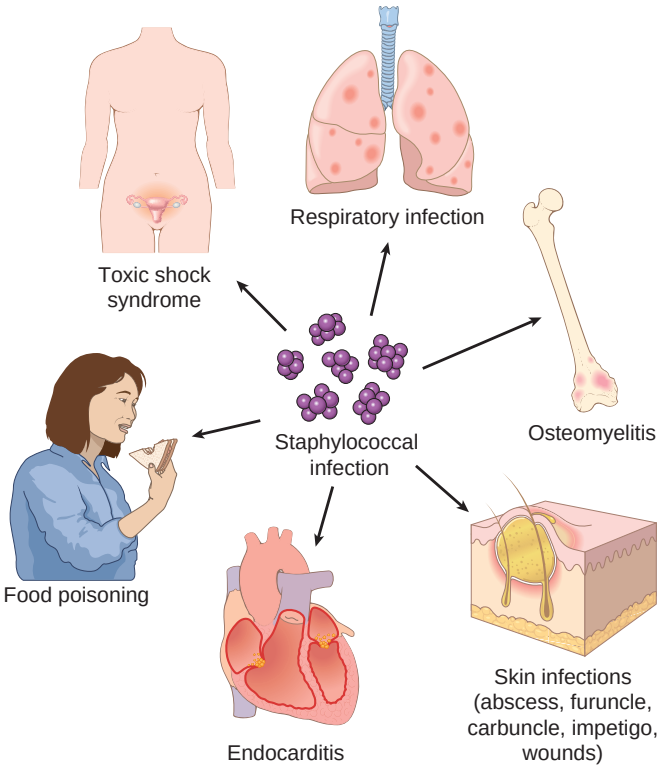

Figure 8.14 The many consequences of staphylococcal infection.

S. aureus also expresses surface protein A, which binds the Fc portion of immunoglobulins, allowing the organism to escape antibody-mediated killing.

***S. aureus* Toxins.** *S. aureus* produces multiple *membrane-damaging (hemolytic) toxins*. These include α-toxin, a protein that intercalates into the plasma membrane of host cells, forming pores that allow toxic levels of calcium to leak into cells; β-toxin, a sphingomyelinase; and δ-toxin, which is a detergent-like peptide. *S. aureus* γ-toxin and leukocidin lyse red cells and phagocytes, respectively.

The *exfoliative A and B toxins* produced by *S. aureus* are serine proteases that cleave the desmosomal protein desmoglein 1, which holds epidermal cells tightly together. This causes keratinocytes to detach from one another and from the underlying basement membrane, resulting in a loss of barrier function that often leads to secondary skin infections. Exfoliation may occur locally at the site of infection (bullous impetigo) or may result in widespread loss of the superficial epidermis (staphylococcal scalded-skin syndrome).

Superantigens produced by *S. aureus* cause food poisoning and toxic shock syndrome (TSS). TSS came to public attention because of its association with the use of hyperabsorbent tampons, which became colonized with *S. aureus* during use. It is now clear that TSS can be caused by growth of *S. aureus* at many sites, most commonly the vagina and infected surgical sites. This syndrome is characterized by hypotension (shock), renal failure, coagulopathy, liver disease, respiratory distress, a generalized erythematous rash, and soft-tissue necrosis at the site of infection. If not promptly treated, it can be fatal. TSS can also be caused by *S. pyogenes*. Bacterial superantigens cause polyclonal T-cell proliferation by binding to conserved portions of MHC molecules and to relatively conserved portions of T-cell receptor β chains. In this manner, superantigens may stimulate up to 20% of T lymphocytes, leading to release of cytokines such as TNF and IL-1, in such large amounts that they may trigger the systemic inflammatory response syndrome (Chapter 4). Superantigens produced by *S. aureus* also cause vomiting when ingested in food, presumably by affecting the CNS or the enteric nervous system.

Antibiotic resistance is a growing problem in treatment of *S. aureus* infections. Methicillin-resistant *S. aureus* (MRSA) are resistant to nearly all penicillin and cephalosporin antibiotics. Previously, MRSA was mainly found in health care facilities, but community-acquired MRSA infections are now common. As a result, empirical treatment of *S. aureus* infections with cephalosporin antibiotics is not recommended.

MORPHOLOGY

Whether the lesion is located in the skin, lungs, bones, or heart valves, ***S. aureus* causes pyogenic inflammation that is distinctive for its local destruction of host tissue.**

Excluding impetigo, which is restricted to the superficial epidermis, staphylococcal skin infections are centered around the hair follicles where they begin. A **furuncle,** or **boil,** is a focal suppurative inflammation of the skin and subcutaneous tissue. They may be solitary, or multiple, or recur in successive crops. Furuncles are most frequent in moist, hairy areas, such as the face, axillae, groin, legs, and submammary folds. Beginning in a single hair follicle, a boil develops into a growing and deepening abscess that eventually "comes to a head" by thinning and rupturing the overlying skin. A **carbuncle** is a deeper suppurative infection that spreads laterally beneath the deep subcutaneous fascia and then burrows superficially to erupt in multiple adjacent skin sinuses. Carbuncles typically appear beneath the skin of the upper back and posterior neck, where fascial planes favor their spread. **Hidradenitis** is chronic suppurative infection of apocrine glands, most often in the axilla. Infections of the nail bed **(paronychia)** or on the palmar side of the fingertips **(felons)** are exquisitely painful. They may follow trauma or embedded splinters and, if deep enough, destroy the bone of the terminal phalanx or detach the fingernail.

S. aureus lung infections (Fig. 8.15) have a polymorphonuclear infiltrate similar to that of *S. pneumoniae* infections (see Fig. 3.18B), but they cause much more tissue destruction. Lung infections usually arise from a hematogenous source, such as an infected thrombus, or in the setting of a predisposing condition such as influenza.

Staphylococcal scalded-skin syndrome, also called Ritter disease, most frequently occurs in children with *S. aureus* infection of the nasopharynx or skin. There is a sunburn-like rash that spreads over the entire body and evolves into fragile bullae that lead to partial or total skin loss. The desquamation of the epidermis in staphylococcal scalded-skin syndrome occurs at the level of the granulosa layer, distinguishing it from toxic epidermal necrolysis, or Lyell disease, which is secondary to drug hypersensitivity and causes desquamation at the level of the epidermal-dermal junction (Chapter 25).

Streptococcal and Enterococcal Infections

Streptococci cause suppurative infections of the skin, oropharynx, lungs, and heart valves. They are also responsible for a number of postinfectious syndromes, including rheumatic fever (Chapter 12), poststreptococcal glomerulonephritis (Chapter 20), and erythema nodosum (Chapter 25). These bacteria are gram-positive cocci that grow in pairs or chains. β-hemolytic streptococci are typed according to their

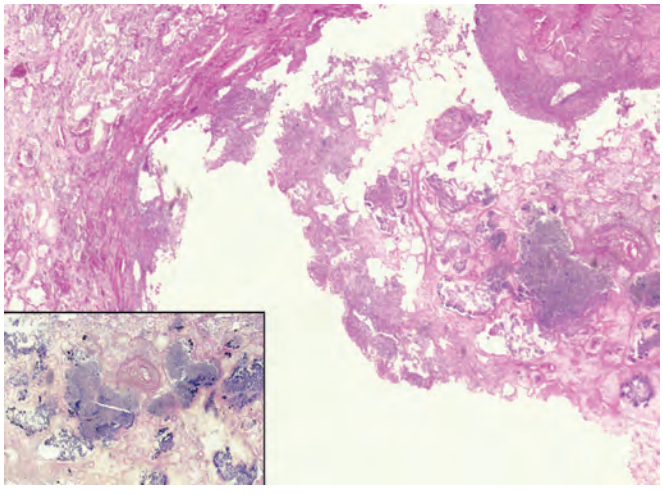

Figure 8.15 Staphylococcal abscess of the lung with extensive neutrophilic infiltrate and destruction of the alveoli (contrast with Fig. 3.18B). The *inset* shows the same area on Gram stain highlighting clusters of bacteria.

surface carbohydrate antigens. *S. pyogenes* (group A) causes pharyngitis, scarlet fever, erysipelas, impetigo, rheumatic fever, TSS, and glomerulonephritis. *Streptococcus agalactiae* (group B) colonizes the female genital tract and causes sepsis and meningitis in neonates and chorioamnionitis in pregnancy. *S. pneumoniae,* the most important α-hemolytic streptococcus, is a common cause of community-acquired pneumonia in older adults and meningitis in children and adults. The viridans-group streptococci include α-hemolytic and nonhemolytic streptococci found in normal oral microbiota that are a common cause of endocarditis. *Streptococcus mutans* is the major cause of dental caries. Streptococcal infections are diagnosed by culture, and, in those with pharyngitis, by the rapid streptococcal antigen test.

Enterococci are gram-positive cocci that also grow in pairs and chains and are hence difficult to distinguish from streptococci by morphology alone. They are often resistant to commonly used antibiotics and are a significant cause of endocarditis and urinary tract infection.

Pathogenesis

The different species of streptococci produce many virulence factors and toxins. *S. pyogenes, S. agalactiae,* and *S. pneumoniae* have capsules that resist phagocytosis. *S. pyogenes* also expresses M protein, a surface protein that prevents bacteria from being phagocytosed, and a complement C5a peptidase that degrades this chemotactic peptide. *S. pyogenes* secretes a phage-encoded pyrogenic exotoxin that causes fever and rash in scarlet fever. Rheumatic fever is probably caused by antistreptococcal M protein antibodies and T cells that cross-react with cardiac proteins. Virulent *S. pyogenes* have been called flesh-eating bacteria because they cause a rapidly progressive necrotizing fasciitis. Although the antiphagocytic capsule is the most important virulence factor of *S. pneumoniae,* this organism also produces pneumolysin, a toxin that inserts into host cell membranes and lyses cells, greatly increasing tissue damage. *S. mutans* produces caries by metabolizing sucrose to lactic acid (which causes demineralization of tooth enamel) and by secreting high-molecular-weight glucans that promote aggregation of bacteria and plaque formation.

Enterococci are low-virulence bacteria, although they do have an antiphagocytic capsule and produce enzymes that injure host tissues. The emergence of enterococci as pathogens is primarily due to their resistance to antibiotics, and incidence is higher in immunosuppressed patient populations, such as those undergoing organ or stem cell transplantation, who receive frequent antimicrobial agents and can have altered commensal microbiota.

MORPHOLOGY

Streptococcal infections are characterized by diffuse interstitial neutrophilic infiltrates with minimal destruction of host tissues. The skin lesions caused by streptococci (furuncles, carbuncles, and impetigo) resemble those of staphylococci.

Erysipelas is caused by exotoxins from superficial infection with *S. pyogenes*. It is characterized by rapidly spreading erythematous cutaneous swelling that may begin on the face or, less frequently, on the body or an extremity. The rash has a sharp, well-demarcated, serpiginous border and may form a "butterfly" distribution on the face (Fig. 8.16). On histologic examination, there is a diffuse, edematous, neutrophilic inflammatory reaction in the dermis and epidermis extending into the subcutaneous tissues. Microabscesses may be formed, but tissue necrosis is usually minor.

Figure 8.16 Streptococcal erysipelas.

Streptococcal pharyngitis, which is the major antecedent of poststreptococcal glomerulonephritis (Chapter 20), is marked by edema, epiglottic swelling, and punctate abscesses of the tonsillar crypts, sometimes accompanied by cervical lymphadenopathy. Swelling associated with severe pharyngeal infection may encroach on the airways, especially if there is peritonsillar or retropharyngeal abscess formation.

Scarlet fever, associated with pharyngitis caused by *S. pyogenes,* is most common between 3 and 15 years of age. It is manifested by a punctate erythematous rash that is most prominent over the trunk and inner aspects of the arms and legs. The face is also involved, but usually a small area about the mouth remains relatively unaffected, producing circumoral pallor. The skin usually becomes hyperkeratotic and scaly during defervescence.

S. pneumoniae is an important cause of lobar pneumonia (Chapter 15).

Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae,* a slender gram-positive rod with clubbed ends that spreads from person to person in respiratory droplets or skin exudate. Fewer than five cases of diphtheria were reported to the Centers for Disease Control and Prevention (CDC) in the United States in the past decade, but annually more than 7000 cases worldwide have been reported to the WHO. Respiratory diphtheria causes pharyngeal or, less often, nasal or laryngeal infection. Damage to the heart, nerves, and other organs may be present. Cutaneous diphtheria causes chronic ulcers with a dirty gray membrane, but does not cause systemic damage. *C. diphtheriae* produces a phage-encoded A-B toxin that blocks host cell protein synthesis. The A fragment does this by catalyzing the covalent transfer of adenosine diphosphate (ADP)-ribose to elongation factor-2 (EF-2). This inhibits EF-2 function, which is required for the translation of mRNA into protein. A single molecule of

diphtheria toxin can kill a cell by ADP-ribosylating, and thereby inactivating, more than a million EF-2 molecules. Immunization with diphtheria toxoid (formalin-fixed toxin) stimulates production of toxin-neutralizing antibodies that protect people from the lethal effects of the toxin.

MORPHOLOGY

Inhaled *C. diphtheriae* carried in respiratory droplets proliferate at the site of attachment on the mucosa of the nasopharynx, oropharynx, larynx, or trachea. The bacteria also form satellite lesions in the esophagus or lower airways. Release of exotoxin causes necrosis of the epithelium, accompanied by an outpouring of a dense fibrinosuppurative exudate. The coagulation of this exudate on the ulcerated necrotic surface creates a tough, dirty, gray to black superficial membrane, sometimes called **pseudomembrane** because it is not formed by viable tissue (Fig. 8.17). There is an intense neutrophilic infiltrate in the underlying tissues with marked vascular congestion, interstitial edema, and fibrin exudation. When the membrane sloughs off its inflamed and vascularized bed, bleeding and asphyxiation may occur. With control of the infection, the membrane is coughed up or removed by enzymatic digestion, and the inflammatory reaction subsides.

Although the bacterial invasion remains localized, with entry of exotoxin into the blood and its systemic distribution, there may be fatty change in the myocardium with isolated myofiber necrosis, polyneuritis with degeneration of the myelin sheaths and axis cylinders, and (less commonly) fatty change and focal necroses of parenchymal cells in the liver, kidneys, and adrenals.

Listeriosis

***Listeria monocytogenes* is a gram-positive bacillus that causes gastroenteritis in most individuals who ingest it in sufficient quantity, and severe food-borne infections in vulnerable hosts.** Outbreaks of *L. monocytogenes* infection have been linked to many foods, but most are associated with contaminated dairy products or processed fruits and vegetables. In the United States, all clinical isolates of *L. monocytogenes* have been typed for epidemiologic surveillance since 1998, resulting in a fivefold increase in the number of outbreaks detected. Pregnant women, neonates, older adults, and immunosuppressed persons are particularly susceptible to severe *L. monocytogenes* infection. In pregnant women, *L. monocytogenes* causes an amnionitis that may result in abortion, stillbirth, or neonatal sepsis. In neonates and immunosuppressed adults, it can cause disseminated disease (granulomatosis infantiseptica of the newborn) and an exudative meningitis.

L. monocytogenes is a facultative intracellular pathogen. The bacteria bind to receptors on host epithelial cells and macrophages and are phagocytosed. The bacteria escape from the phagolysosome using a pore-forming protein, listeriolysin O, and two phospholipases. Listeriolysin O also affects membrane bound organelles, including rounding and shrinking of mitochondria, inhibition of the endoplasmic reticulum, and damage to the lysosomal membrane. In the host cell cytoplasm, Act A, a bacterial surface protein, binds to the Arp2/3 complex, an actin nucleating complex, which induces actin polymerization. This generates force to propel the bacteria into adjacent, uninfected host cells. Resting macrophages fail to kill the intracellular bacteria, whereas macrophages that are activated by IFN-γ can. Accordingly, an effective host response to *L. monocytogenes* depends on IFN-γ produced by NK cells early in the course of the infection and Th1 and CD8+ T cells in chronic infection. Patients with defects in cell-mediated immunity, such as those with reduced levels of CD4+ lymphocytes, are at increased risk for listeriosis.

Figure 8.17 Membrane of diphtheria *(arrow)* lying within a transverse bronchus. (Courtesy Dr. Robin A. Cooke, Department of Anatomical Pathology, Princess Alexandria Hospital, Brisbane, Australia.)

MORPHOLOGY

In acute infections, *L. monocytogenes* evokes an exudative pattern of inflammation with numerous neutrophils. The meningitis due to *L. monocytogenes* is macroscopically and microscopically indistinguishable from meningitis due to other pyogenic bacteria (Chapter 28). **The finding of gram-positive bacilli in the CSF is virtually diagnostic.** More varied lesions may be encountered in neonates and immunosuppressed adults. Focal abscesses alternating with grayish or yellow nodules representing necrotic amorphous tissue debris can occur in any organ, including the lung, liver, spleen, and lymph nodes. In infections of longer duration, macrophages appear in large numbers, but granulomas are rare. Infants born with *L. monocytogenes* sepsis often have a papular red rash over the extremities, and listerial abscesses can be seen in the placenta. A smear of the meconium will disclose the gram-positive bacilli.

Anthrax

Anthrax is characterized by necrotizing inflammatory lesions in the skin or gastrointestinal tract or systemically. It is caused by *Bacillus anthracis,* a large, spore-forming gram-positive rod-shaped bacterium found in environmental sources. Livestock become infected by spores in their environment or feed. Humans usually become infected by eating or handling meat or products from infected animals (e.g., wool or hides). There are a small number of cases of anthrax each year, most of which occur in lower-income nations. Anthrax spores can be made into a fine powder, creating a potent biologic weapon that is a potential bioterrorism threat. In 1979, accidental release of *B. anthracis* spores

at a military research institute in Russia killed 66 people. In 2001, 22 people in the United States were infected with *B. anthracis*, mostly through domestic bioterrorism with spores delivered in the mail.

There are three major forms of anthrax:

- *Cutaneous anthrax,* which makes up 95% of naturally occurring infections, begins as a painless, pruritic papule that develops into a vesicle within 2 days. As the vesicle enlarges, striking edema may occur around it, with development of regional lymphadenopathy. After the vesicle ruptures, the remaining ulcer becomes covered with a characteristic black eschar, which dries and falls off as the person recovers. Bacteremia is rare.
- *Inhalational anthrax* occurs when airborne spores are inhaled. The spores are carried by phagocytes to lymph nodes where they germinate, producing bacilli that release toxins that cause hemorrhagic mediastinitis. After a prodromal illness of 1 to 6 days characterized by fever, cough, and chest or abdominal pain, there is abrupt onset of increased fever, hypoxia, and sweating. Frequently, meningitis develops from bacteremia. Inhalational anthrax rapidly leads to shock and frequently death within 1 to 2 days.
- *Gastrointestinal anthrax* is usually contracted by eating undercooked meat contaminated with *B. anthracis*. Initially, the person has nausea, abdominal pain, and vomiting, followed by severe bloody diarrhea and, sometimes, bacteremia. Mortality is approximately 40%.

Pathogenesis

B. anthracis produces potent toxins and an antiphagocytic polyglutamyl capsule. The mechanisms of action of anthrax toxins are well understood (Fig. 8.18). There are two A subunits and one B subunit. The two A subunits, *edema factor* (EF) and *lethal factor* (LF), are named for their effects in experimental animals. The B subunit is called the *protective antigen* (PA) because antibodies against it protect against the effects of the toxins. PA is not toxic, but it serves to deliver the toxic EF and LF into cells. The bacterium releases each subunit as a separate protein. PA binds to a cell surface receptor that is highly expressed on endothelial cells. Then a host protease removes a fragment of the PA, and the remaining fragment self-associates to form a heptamer. One to three molecules of the EF or LF bind to a PA heptamer, and this complex is endocytosed into the host cell. The low pH of the endosome causes a conformational change in the PA heptamer, which then forms a channel in the endosome membrane through which the EF or LF moves into the cytoplasm. In the cytoplasm, EF binds to calcium and calmodulin to form an adenylate cyclase. The active enzyme converts ATP to intracellular cyclic adenosine monophosphate (cAMP), altering cell function. LF has a different mechanism of action. LF is a protease that destroys mitogen-activated protein kinase kinases (MAPKKs). These kinases regulate the activity of MAPKs, which are important regulators of cell growth and differentiation (Chapter 1). The mechanism of cell death caused by dysregulation of MAPKs is not understood.

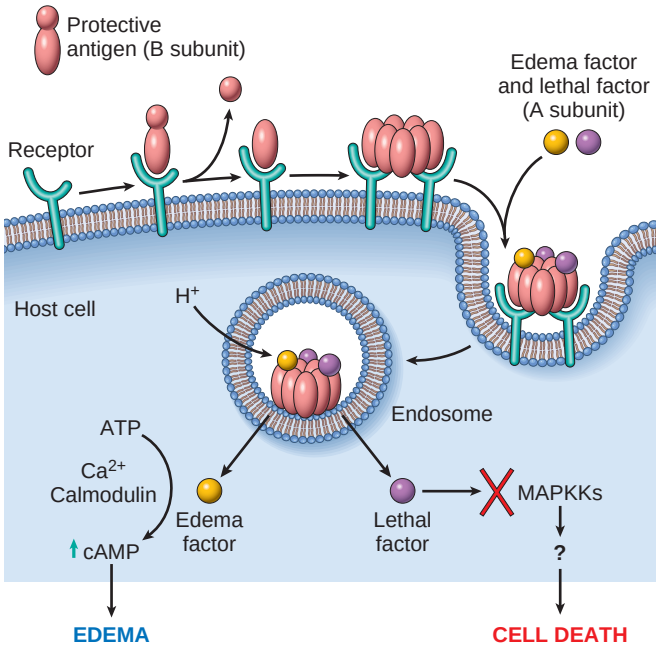

Figure 8.18 Mechanism of action of anthrax toxins. Note that each cluster of B subunits binds either the edema factor or the lethal factor, but not both (as shown for simplicity). (Modified from Mourez M, Lacy DB, Cunningham K, et al: 2001: A year of major advances in anthrax toxin research, *Trends Microbiol* 10:287–293, 2002.)

MORPHOLOGY

Anthrax lesions at any site are typified by necrosis and exudative inflammation rich in neutrophils and macrophages. The presence of large, boxcar-shaped gram-positive extracellular bacteria in chains, seen histopathologically using the Brown and Brenn stain or grown in culture, suggests the diagnosis.

Inhalational anthrax causes numerous foci of hemorrhage in the mediastinum and hemorrhagic lymphadenitis of hilar and peribronchial lymph nodes. The lungs typically show a perihilar interstitial pneumonia with infiltration of macrophages and neutrophils and pulmonary vasculitis. Hemorrhagic lung lesions associated with vasculitis are also present in about one-half of cases. Mediastinal lymph nodes are expanded by edema and by macrophages containing phagocytosed apoptotic lymphocytes. *B. anthracis* is most likely to be seen in the alveolar capillaries and venules and, to a lesser degree, within the alveolar space and draining hilar lymph nodes (Fig. 8.19). In fatal cases, however, the organism may be found in multiple organs (spleen, liver, intestines, kidneys, adrenal glands, and meninges).

Nocardial Infections

***Nocardia* spp. are aerobic gram-positive bacteria found in soil that cause opportunistic infections.** The organism grows in distinctive branched chains. In culture, *Nocardia* form thin aerial filaments resembling hyphae. Despite this morphologic similarity to molds, *Nocardia* are true bacteria.

Nocardia spp. cause respiratory infections, most often in patients with defects in immunity due to prolonged steroid use, HIV infection, or diabetes. Respiratory infection with *Nocardia* spp. manifests as an indolent illness with fever, weight loss, and cough, which may be mistaken for tuberculosis or malignancy. In some cases, *Nocardia* spp. infections disseminate from the lungs to the CNS. Infections of the

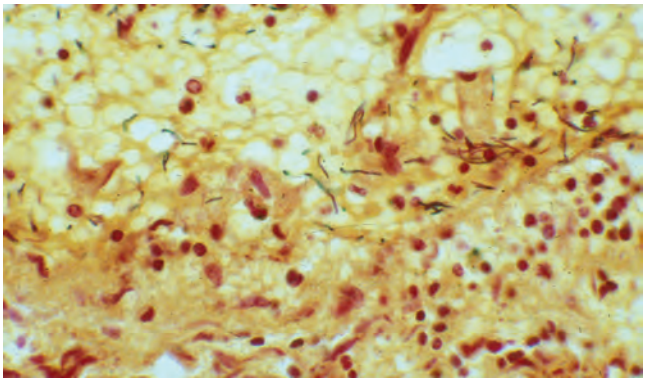

Figure 8.19 Bacillus anthracis in the subcapsular sinus of a hilar lymph node of a patient who died of inhalational anthrax. (Courtesy Dr. Lev Grinberg, Department of Pathology, Hospital 40, Ekaterinburg, Russia, and Dr. David Walker, UTMB Center for Biodefense and Emerging Infectious Diseases, Galveston, Tex.)

CNS are also indolent and cause varying neurologic deficits depending on the site of the lesions. *N. brasiliensis* causes skin infections following injuries contaminated with soil. Manifestations include cellulitis, lymphocutaneous disease, and actinomycetoma with formation of nodules that progress to form chronic draining fistulae.

MORPHOLOGY

Nocardia spp. appear in tissue as slender gram-positive organisms arranged in branching filaments (Fig. 8.20). Irregular staining gives the filaments a beaded appearance. *Nocardia* spp. stain with modified acid-fast stains (Fite-Faraco stain), unlike *Actinomyces* spp., which may appear similar on Gram stain of tissue. *Nocardia* spp. elicit a suppurative response with central liquefaction and surrounding granulation and fibrosis. Granulomas do not form.

Gram-Negative Bacterial Infections

There are a large number of gram-negative bacterial pathogens. Many gram-negative bacteria are increasingly resistant to antibiotics, including carbapenem-resistant *K. pneumoniae* and cephalosporin-resistant *N. gonorrhoeae*. Only a few gram-negative bacteria are discussed in this section. A number of important gram-negative pathogens are discussed in the appropriate chapters of organ systems, including bacterial causes of gastrointestinal infections and urinary tract infections. Anaerobic gram-negative organisms are considered later in this chapter. Gram-negative bacterial infections are usually diagnosed by culture.

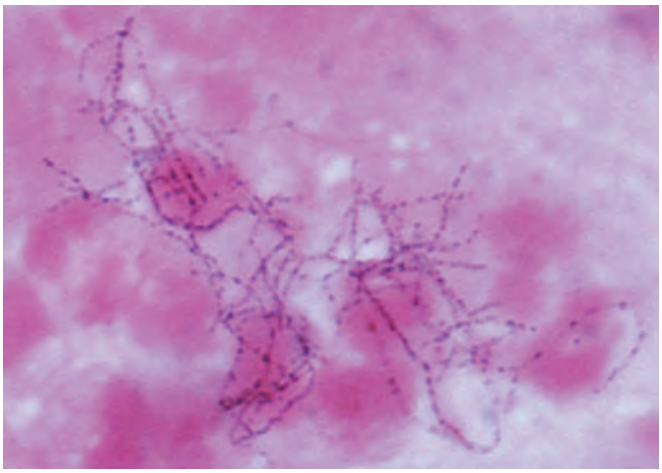

Figure 8.20 *Nocardia asteroides* in a Gram-stained sputum sample. Note the beaded, branched gram-positive organisms and leukocytes. (Courtesy Dr. Ellen Jo Baron, Stanford University Medical Center, Stanford, Calif.)

Neisserial Infections

Neisseria spp. are gram-negative diplococci that are flattened on the adjoining sides, giving the pair the shape of a coffee bean. These aerobic bacteria have stringent nutritional requirements and grow best on enriched media such as lysed sheep's blood (chocolate) agar. Pathogenic *Neisseria* spp. often have the ability to secrete single-stranded DNA for transformation of other *Neisseria* spp., but commensal *Neisseria* spp. usually lack this ability. The two clinically significant *Neisseria* spp. are *N. meningitidis* and *N. gonorrhoeae*.

***N. meningitidis* is a significant cause of bacterial meningitis, particularly among adolescents and young adults.** The organism is a common colonizer of the oropharynx and is spread by the respiratory route. An immune response leads to elimination of the colonizing organism in most people, and this response is protective against subsequent infection with the same serotype of bacteria. There are several capsular serotypes of *N. meningitidis,* however five of them cause most cases of meningitis. Invasive disease mainly occurs when people encounter new strains to which they are not immune, as may happen to young children or to young adults living in crowded quarters such as military barracks or college dormitories. *N. meningitidis* is endemic in the United States, but epidemics occur periodically in sub-Saharan Africa and cause thousands of deaths. Highly effective conjugate vaccines for *N. meningitidis* composed of capsular polysaccharides conjugated to antigenic proteins are available for four serogroups of *N. meningitidis* (A, C, W, and Y), and recombinant protein vaccines are available for serogroup B.

Even in the absence of preexisting immunity, only a small fraction of people infected with *N. meningitidis* develop meningitis. The bacteria must invade respiratory epithelial cells and enter the blood. In the blood, the bacterial capsule inhibits opsonization and destruction of the bacteria by complement proteins. The importance of complement as a first-line defense against *N. meningitidis* is shown by the increased rates of serious infection among people who have inherited defects in the complement proteins (C5 to C9) that form the membrane attack complex, or patients with paroxysmal nocturnal hemoglobinuria (Chapter 14) who are being treated with an antibody inhibitor of the membrane attack complex. If *N. meningitidis* escapes the host response, the consequences can be severe. Although antibiotic treatment greatly reduces the mortality of *N. meningitidis* infection, about 10% of infected patients still die. The pathology of pyogenic meningitis is discussed in Chapter 28.

***N. gonorrhoeae* is an important cause of sexually transmitted infection (STI),** with more than 450,000 cases reported each year in the United States. It is second only to *C. trachomatis* among bacterial STIs. Infection in men causes urethritis. In women, *N. gonorrhoeae* infection is often

asymptomatic and so may go unnoticed. Untreated gonorrhea may lead to pelvic inflammatory disease, which can cause infertility or ectopic pregnancy (Chapter 22). Infection is diagnosed by culture and PCR tests. Increased resistance to oral cephalosporins has led to the recommendation that gonorrhea be treated with intramuscular ceftriaxone and oral azithromycin. Ceftriaxone-resistant *N. gonorrhoeae* is rare but has been detected in Canada and Japan.

Although *N. gonorrhoeae* infection usually manifests locally in the genital or cervical mucosa, pharynx, or anorectum, disseminated infections may occur. Like *N. meningitidis, N. gonorrhoeae* is much more likely to become disseminated in people who lack the complement proteins that form the membrane attack complex. Disseminated infection of adults and adolescents usually causes septic arthritis accompanied by a rash of hemorrhagic papules and pustules. Neonatal *N. gonorrhoeae* infection causes conjunctivitis that may lead to blindness and, rarely, sepsis. The eye infection, which is preventable by instillation of silver nitrate or antibiotics in the newborn's eyes, remains an important cause of blindness in some lower-income nations.

Pathogenesis

Neisseria spp. adhere to and invade nonciliated epithelial cells at the site of entry (nasopharynx, urethra, or cervix). Adherence of *N. gonorrhoeae* to epithelial cells is initially mediated by long pili, which bind to CD46, a protein expressed on all human nucleated cells. OPA proteins (so named because they make bacterial colonies opaque), located in the outer membrane of the bacteria, increase binding of *Neisseria* spp. to epithelial cells and promote entry of bacteria into cells.

***Neisseria* spp. use antigenic variation as a strategy to escape the immune response.** The existence of multiple capsular serotypes of *N. meningitidis* results in meningitis in some people on exposure to a new strain, as discussed earlier. In addition, *Neisseria* spp. also can generate new antigens by genetic mechanisms, which permit a single bacterial clone to change its expressed antigens and escape immune defenses. Such mechanisms involve both pili and OPA proteins:

- *Recombination of genes encoding pili proteins.* The pili are composed of polypeptides encoded by the pilin gene, which consists of a promoter and coding sequences for 10 to 15 pili protein variants. At any point in time, only one of these coding sequences is adjacent to the promoter, allowing it to be expressed. Homologous recombination periodically shuttles one of the other pilin coding sequences next to the promoter, resulting in expression of a different pilin variant.
- *Expression of different OPA proteins.* Each *OPA* gene has several repeats of a five-nucleotide sequence, which are frequently deleted or duplicated. These changes shift the reading frame of the gene so that it encodes new sequences. Stop codons are also introduced by the additions and deletions, which determine whether each *OPA* gene is expressed or silent. Thus, *Neisseria* spp. can express one, none, or multiple OPA proteins at any time.

Pertussis

Pertussis, or whooping cough, caused by the gram-negative coccobacillus *Bordetella pertussis*, is an acute, highly communicable illness characterized by paroxysms of violent coughing followed by a loud inspiratory "whoop" as the patient gasps for air. Infants younger than 1 year of age are at highest risk of death. Children with pertussis can have coughing spells for up to 10 weeks. Worldwide, it is estimated that there are more than 160,000 deaths in children younger than 5 years of age due to pertussis. For diagnosis, PCR is more sensitive than culture, but specificity of the assays can vary, so some level of culture confirmation is critical in an outbreak setting. Widespread use of a vaccine resulted in a dramatic decrease in cases; however, concern about side effects of the whole-cell vaccine increased after the 1980s and led to a decrease in use. An acellular vaccine became available in the 1990s, but protection wanes over time, so there has been an increased incidence in recent years, even in areas where vaccination rates appear satisfactory. Outbreaks observed every 3 to 5 years affect primarily not the infants, but instead older children, adolescents, and adults. It is hypothesized that modifications of *B. pertussis* may also be playing a role, but this is unproven.

Pathogenesis

B. pertussis colonizes the brush border of the bronchial epithelium and also invades macrophages. It contains a filamentous hemagglutinin that binds to carbohydrates on the surface of respiratory epithelial cells, as well as to CR3 (Mac-1) integrins on macrophages. Virulence factors of *B. pertussis* include pertussis toxin, adenylate cyclase toxin, dermonecrotic toxin, and tracheal cytotoxin. Pertussis toxin is a typical A-B toxin that is composed of five subunits. The A unit, like cholera toxin, ADP-ribosylates and inactivates guanine nucleotide-binding proteins, so these G proteins can no longer transduce signals, interrupting the effect of chemokines that use G protein-coupled receptors. The B component contains four subunits that bind to extracellular molecules and allow the A subunit to enter cells. The B subunit can also bind to cell surface molecules such as TLR4, and through these it can initiate signaling events in cells. Collectively, pertussis toxin subunits impair host defenses by inhibiting neutrophil and macrophage recruitment and activation and paralyzing cilia, among other effects.

B. pertussis also produces adenylate cyclase toxin that enters host cells and converts ATP to supraphysiologic levels of cAMP. The rise in cAMP inhibits phagocytosis, the oxidative burst, and nitric oxide–mediated killing in neutrophils and macrophages, and the formation of neutrophil extracellular traps. The interactions of the multiple toxins and virulence factors that determine the course of disease require further study.

MORPHOLOGY

Bordetella spp. cause a laryngotracheobronchitis that in severe cases features bronchial mucosal erosion, hyperemia, and copious mucopurulent exudate (Fig. 8.21). Unless superinfected, the lung alveoli remain open and intact. In parallel with a striking peripheral lymphocytosis (up to 90%), there is hypercellularity and enlargement of the mucosal lymph follicles and peribronchial lymph nodes.

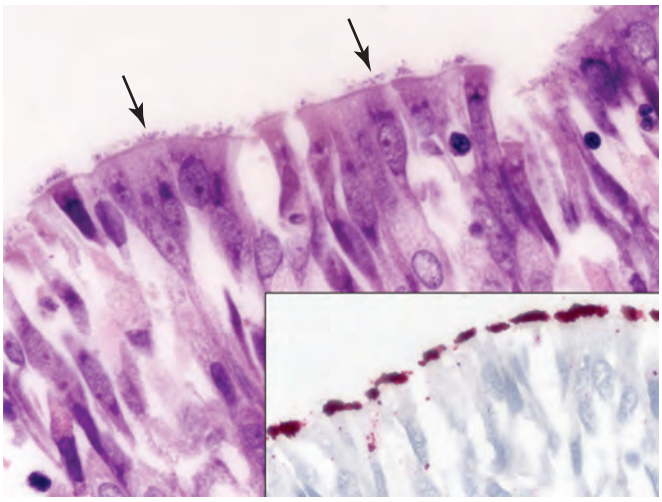

Figure 8.21 Whooping cough showing a haze of bacilli *(arrows)* entangled with the cilia of bronchial epithelial cells. The *inset* highlights the haze of bacilli by immunohistochemistry using a monoclonal antibody reactive to the lipo-oligosaccharide A of *Bordetella* pertussis. (Images courtesy Dr. Christopher Paddock of the Centers for Disease Control, Atlanta, Ga.)

Pseudomonal Infections

***Pseudomonas aeruginosa* is an opportunistic aerobic gram-negative bacillus that is a frequent, deadly pathogen in people with cystic fibrosis, severe burns, or neutropenia.** Many people with cystic fibrosis die of pulmonary failure secondary to chronic infection with *P. aeruginosa*. This bacterium can be very resistant to antibiotics, making these infections difficult to treat. It often infects extensive skin burns, which can lead to sepsis. *P. aeruginosa* is a common cause of hospital-acquired infections; it has been cultured from washbasins, respirator tubing, nursery cribs, and even antiseptic-containing bottles. It also causes corneal keratitis in wearers of contact lenses, endocarditis and osteomyelitis in intravenous drug abusers, external otitis (swimmer's ear) in healthy individuals, and severe external otitis in people with diabetes.

Pathogenesis

P. aeruginosa produces several toxins that contribute to local tissue damage. Early during infection of the lungs of people with cystic fibrosis, the organism secretes an A-B exotoxin called exotoxin A that, like diphtheria toxin, inhibits protein synthesis by ADP-ribosylating the ribosomal protein EF-2, leading to the death of host cells. At this early stage, the organism uses a type III secretion system to transport effector proteins into host cells; these reduce the ability of host cells to make antibacterial reactive oxygen species and also induce apoptosis of the cells. Later in chronic infection in the lungs of people with cystic fibrosis, the bacteria become organized into biofilms composed, in part, of alginate they secrete. Within the biofilm, the bacteria are protected from antibodies, complement, phagocytes, and antibiotics. In addition, the release of exotoxin A is reduced, as is the expression of the type III secretion system, and the organism evolves to become somewhat lower in virulence, although it does continue to damage the host by stimulating inflammation and by releasing enzymes (proteases and elastases) that damage tissue. During chronic infection, the organism develops antibiotic resistance both through biofilm production and genetic changes, making treatment difficult.

MORPHOLOGY

Pseudomonas spp. cause **necrotizing pneumonia** that is distributed through the terminal airways in a fleur-de-lis pattern, with striking pale necrotic centers and red, hemorrhagic peripheral areas. On microscopic examination, masses of organisms are seen, often concentrated in the walls of blood vessels, where host cells undergo coagulative necrosis (Fig. 8.22). This picture of gram-negative **bacterial vasculitis** accompanied by thrombosis and hemorrhage, although not pathognomonic, is highly suggestive of *P. aeruginosa* infection.

Bronchial obstruction caused by mucus plugging and subsequent *P. aeruginosa* infection are frequent complications of cystic fibrosis. Despite antibiotic treatment and the host immune response, chronic *P. aeruginosa* infection may result in bronchiectasis and pulmonary fibrosis (Chapter 15).

In skin burns, *P. aeruginosa* proliferates widely, penetrating deeply into the veins and spreading hematogenously. Well-demarcated necrotic and hemorrhagic oval skin lesions, called **ecthyma gangrenosum,** often appear. DIC is a frequent complication of *P. aeruginosa* bacteremia.

Plague

***Yersinia pestis* is a gram-negative facultative intracellular bacterium that causes an invasive, frequently fatal, infection called plague.** It is transmitted from rodents to humans by flea bites or, less often, from one human to another by aerosols. Plague caused three great pandemics that killed many millions of people; the devastation wreaked by the epidemic in Europe in the 1300s gave the infection the dramatic name *Black Death*. Most cases now occur in Africa, but the organism is endemic in many parts of the world, including nations in the former Soviet Union, the Americas, and Asia. Wild rodents in the rural western United States are infected with *Y. pestis* and are the source of about 10 to 15 human cases every year. In 2017, an outbreak in Madagascar resulted in over 2400 cases and more than 200 deaths. *Y. enterocolitica* and *Y. pseudotuberculosis* are genetically similar to *Y. pestis*; these bacteria cause fecal-orally transmitted ileitis and mesenteric lymphadenitis.

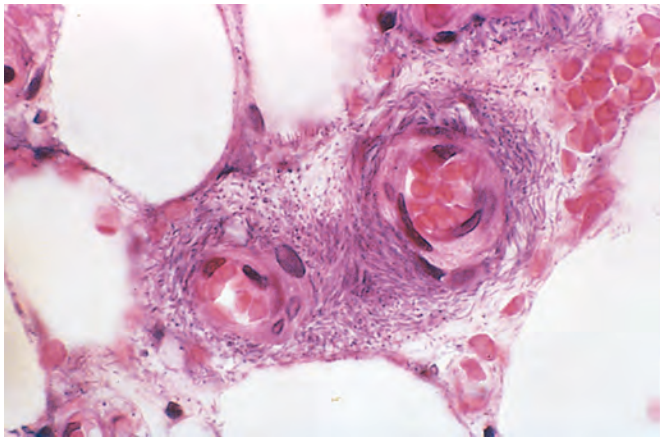

Figure 8.22 *Pseudomonas* vasculitis in which masses of organisms form a perivascular purple-blue haze.

Y. pestis has two growth phases in the flea: an early phase during which bacteria aggregate in the proventriculus but do not block blood flow completely, and a late phase during which a biofilm is formed that obstructs the gut of the infected flea. The starving flea bites and regurgitates before it feeds, and thus infects the rodent or human that it is biting. The bacterial gene regulation shifts on sensing relocation from the insect gut to the human host. The bacteria spread from the site of inoculation to lymphoid tissues, where they proliferate and inhibit the host from mounting an effective response. *Y. pestis* has a plasmid-borne complex of genes, the Yop virulon, which encodes a type III secretion system, a hollow syringe-like structure that projects from the bacterial surface, binds to host cells, and injects bacterial proteins called *Yops* (*Yersinia* outercoat proteins) into the cell. YopE, YopH, and YopT block phagocytosis by inactivating molecules that regulate actin polymerization. YopJ inhibits the signaling pathways that are activated by LPS, blocking the production of inflammatory cytokines.

MORPHOLOGY

Y. pestis causes lymph node enlargement (buboes), pneumonia, or sepsis with a striking neutrophilia. The distinctive histologic features include (1) massive proliferation of the organisms, (2) early appearance of protein-rich and polysaccharide-rich effusions with few inflammatory cells, (3) necrosis of tissues and blood vessels with hemorrhage, thrombosis, and marked tissue swelling, and (4) neutrophilic infiltrates that accumulate adjacent to necrotic areas as healing begins.

In **bubonic plague,** the infected flea bite is usually on the legs, where it forms a small pustule or ulcer. The draining lymph nodes enlarge dramatically within a few days and become soft, pulpy, and plum colored, and may infarct or rupture through the skin. These lymph nodes were called *buboes*, from the Greek word for "groin," giving rise to the name for this form of plague. In **pneumonic plague,** there is a severe, confluent, hemorrhagic, and necrotizing bronchopneumonia, often with fibrinous pleuritis. In **septicemic plague,** lymph nodes throughout the body as well as organs rich in mononuclear phagocytes develop foci of necrosis. Fulminant bacteremia also induces DIC with widespread hemorrhages and thrombi.

Chancroid (Soft Chancre)

Chancroid is an acute, ulcerative STI caused by *Haemophilus ducreyi*. The disease is most common in tropical and subtropical areas among lower socioeconomic groups and men who have frequent sex with prostitutes. Chancroid is one of the most common causes of genital ulcers in Africa, Southeast Asia, and the Caribbean, where it serves as an important cofactor in the transmission of HIV infection. Chancroid is uncommon in the United States, with fewer than 20 cases per year reported to the CDC in the past several years. The organism grows poorly in culture, requiring uncommon and highly-enriched media, and PCR-based tests are not widely available, so chancroid may be underdiagnosed.

MORPHOLOGY

Four to seven days after inoculation, a tender erythematous papule involving the external genitalia develops. In males, the primary lesion is usually on the penis; in females, most lesions occur in the vagina or the periurethral area. Over several days, the surface of the primary lesion erodes to produce an irregular, painful ulcer. In contrast to the primary chancre of syphilis, the ulcer of chancroid is not indurated, and multiple lesions may be present. The base of the ulcer is covered by shaggy, yellow-gray exudate. The regional lymph nodes become enlarged and tender in about 50% of cases within 1 to 2 weeks after primary infection. If the infection is not treated, the enlarged nodes (buboes) may erode the overlying skin to produce chronic, draining ulcers.

Microscopically, the ulcer of chancroid contains a superficial zone of neutrophilic debris and fibrin, and an underlying zone of granulation tissue containing areas of necrosis and thrombosed vessels. A dense, lymphoplasmacytic inflammatory infiltrate is present beneath the layer of granulation tissue. Coccobacilli are sometimes demonstrable in Gram or silver stains, but they are often obscured by other bacteria that colonize the ulcer base.

Granuloma Inguinale

Granuloma inguinale, or donovanosis, is a chronic inflammatory STI caused by *Klebsiella granulomatis* (formerly called *Calymmatobacterium donovani*), a minute, encapsulated, coccobacillus. Granuloma inguinale is an STI that is uncommon in the United States and Western Europe but is endemic in some rural tropical areas and some lower-income countries. Untreated cases are characterized by the development of extensive scarring, often associated with lymphatic obstruction and lymphedema (elephantiasis) of the external genitalia. Culture of the organism is difficult, and PCR assays are not widely available, so the diagnosis is made by microscopic examination of smears or biopsy samples of the ulcer.

MORPHOLOGY

Granuloma inguinale begins as a raised papular lesion on the moist stratified squamous epithelium of the genitalia or, rarely, the oral mucosa or pharynx. The lesion eventually ulcerates and develops abundant granulation tissue, which manifests grossly as a protuberant, soft, painless mass. As the lesion enlarges, its borders become raised and indurated. Disfiguring scars may develop in untreated cases and are sometimes associated with urethral, vulvar, or anal **strictures.** Regional lymph nodes typically are spared or show only nonspecific reactive changes, in contrast to chancroid.

Microscopic examination of active lesions reveals marked epithelial hyperplasia at the borders of the ulcer, sometimes mimicking carcinoma (pseudoepitheliomatous hyperplasia). A mixture of neutrophils and mononuclear inflammatory cells is present at the base of the ulcer and beneath the surrounding epithelium. The organisms are demonstrable in Giemsa-stained smears of the exudate as minute, encapsulated coccobacilli (Donovan bodies) in macrophages. Silver stains (e.g., the Warthin-Starry stain) may also demonstrate the organism.

Mycobacterial Infections

Bacteria in the genus *Mycobacterium* are slender, aerobic rods that grow in straight or branching chains. Mycobacteria have a unique waxy cell wall composed of unusual glycolipids and lipids including mycolic acid, which makes them acid-fast, meaning they will retain stains, even on treatment with a mixture of acid and alcohol. They are weakly gram-positive.

Tuberculosis

Tuberculosis is a chronic pulmonary and systemic disease caused most often by *M. tuberculosis*, and the leading infectious cause of death worldwide. The source of transmission is humans with active tuberculosis who release mycobacteria into the sputum. Oropharyngeal and intestinal tuberculosis contracted by drinking milk contaminated with *Mycobacterium bovis* is rare in countries where milk is routinely pasteurized, but it is still seen in countries that have tuberculous dairy cows and unpasteurized milk.

Epidemiology

According to the WHO, about 10 million people developed tuberculosis worldwide in 2018, with an estimated 1.3 million deaths in people without HIV infection and 300,000 in people with HIV infection. The mortality due to tuberculosis is falling by 3% per year. In 2018 there were about 9,000 cases of tuberculosis reported in the United States, 70% of which occurred in foreign-born people.

Tuberculosis flourishes wherever there is poverty, crowding, and chronic debilitating illness. In the United States, tuberculosis is mainly a disease of older adults, immigrants from high-burden countries, those living in crowded settings (prisons, homeless shelters, long-term care), and people with AIDS. Certain disease states also increase the risk: diabetes, Hodgkin lymphoma, chronic lung disease (particularly silicosis), chronic renal failure, malnutrition, alcoholism, and immunosuppression.

It is important that infection with *M. tuberculosis* be differentiated from active disease. Infection refers to the presence of bacteria in the body, which may be symptomatic (active disease) or not (latent infection). Most infections are acquired by person-to-person transmission of airborne organisms from an active case to a susceptible host. In most healthy people primary tuberculosis is asymptomatic, although it may cause fever and pleural effusion. Generally, the only evidence of infection, if any remains, is a tiny, fibrocalcific pulmonary nodule at the site of the infection. Viable organisms may remain dormant in such lesions for decades. If immune defenses are lowered, the infection may be reactivated, producing communicable and potentially life-threatening disease.

Pathogenesis

The outcome of infection in a previously unexposed, immunocompetent person depends on the development of antimycobacterial T cell–mediated immunity. These T cells control the host response to the bacteria and also result in development of pathologic lesions, such as caseating granulomas and cavitation.

Infection by *M. tuberculosis* proceeds in steps, from initial infection of macrophages to a subsequent Th1 response that both contains the bacteria and causes tissue damage (Fig. 8.23). Early in infection, *M. tuberculosis* replicates essentially unchecked within macrophages, and later in infection, the cell response stimulates macrophages to contain the proliferation of the bacteria. The steps in infection are as follows:

- *Entry into macrophages. M. tuberculosis* enters macrophages by phagocytosis mediated by several receptors expressed on the phagocyte, including mannose-binding lectin and the type 3 complement receptor (CR3).
- *Replication in macrophages. M. tuberculosis* inhibits maturation of the phagosome and blocks formation of the phagolysosome, allowing the bacterium to replicate unchecked within the vesicle, protected from the microbicidal mechanisms of lysosomes. The bacterium blocks phagolysosome formation by recruiting a host protein called coronin to the membrane of the phagosome. Coronin activates the phosphatase calcineurin, leading to inhibition of phagosome-lysosome fusion. Thus, during the earliest stage of primary tuberculosis (<3 weeks) in the nonsensitized individual, bacteria proliferate in the pulmonary alveolar macrophages and air spaces, resulting in bacteremia and seeding of multiple sites. Despite the bacteremia, most people at this stage are asymptomatic or have a mild flulike illness.
- *Innate immunity.* Multiple pathogen associated molecular patterns (Chapter 6) made by *M. tuberculosis* are recognized by innate immune receptors. Mycobacterial lipoarabinomannan binds TLR2, and unmethylated CpG nucleotides bind TLR9. These interactions initiate and enhance the innate and adaptive immune responses to *M. tuberculosis*, as described below.
- *The Th1 response.* About 3 weeks after infection, a Th1 response is mounted that activates macrophages, enabling them to become bactericidal. The response is initiated by mycobacterial antigens that enter draining lymph nodes and are displayed to T cells. Differentiation of Th1 cells depends on IL-12 and IL-18, which are produced by antigen-presenting cells that have encountered the mycobacteria. Stimulation of TLR2 by mycobacterial ligands promotes production of IL-12 by dendritic cells.
- *Th1-mediated macrophage activation and killing of bacteria.* Th1 cells, both in lymph nodes and in the lung, produce IFN-γ. IFN-γ is the critical mediator that activates macrophages and enables them to contain the *M. tuberculosis* infection. First, IFN-γ stimulates maturation of the phagolysosome in infected macrophages, exposing the bacteria to a lethal acidic, oxidizing environment. Second, IFN-γ stimulates expression of inducible nitric oxide (NO) synthase, which produces NO. NO combines with other oxidants to create reactive nitrogen intermediates, which are important for killing of mycobacteria. Third, IFN-γ mobilizes antimicrobial peptides (defensins) against the bacteria. Finally, IFN-γ stimulates autophagy, a process that sequesters and then destroys damaged organelles and intracellular bacteria such as *M. tuberculosis*.
- *Granulomatous inflammation and tissue damage.* In addition to stimulating macrophages to kill mycobacteria, the Th1 response orchestrates the formation of granulomas and caseous necrosis. Macrophages activated by IFN-γ differentiate into the "epithelioid histiocytes" that aggregate to form granulomas; some epithelioid cells may fuse to form giant cells. In many people this response halts the infection before significant tissue destruction or illness occur. In other people the infection progresses due to advanced age or immunosuppression, and the ongoing immune response results in caseous necrosis. Activated macrophages also secrete TNF and chemokines, which promote recruitment of more monocytes. The importance of TNF is underscored by the fact that

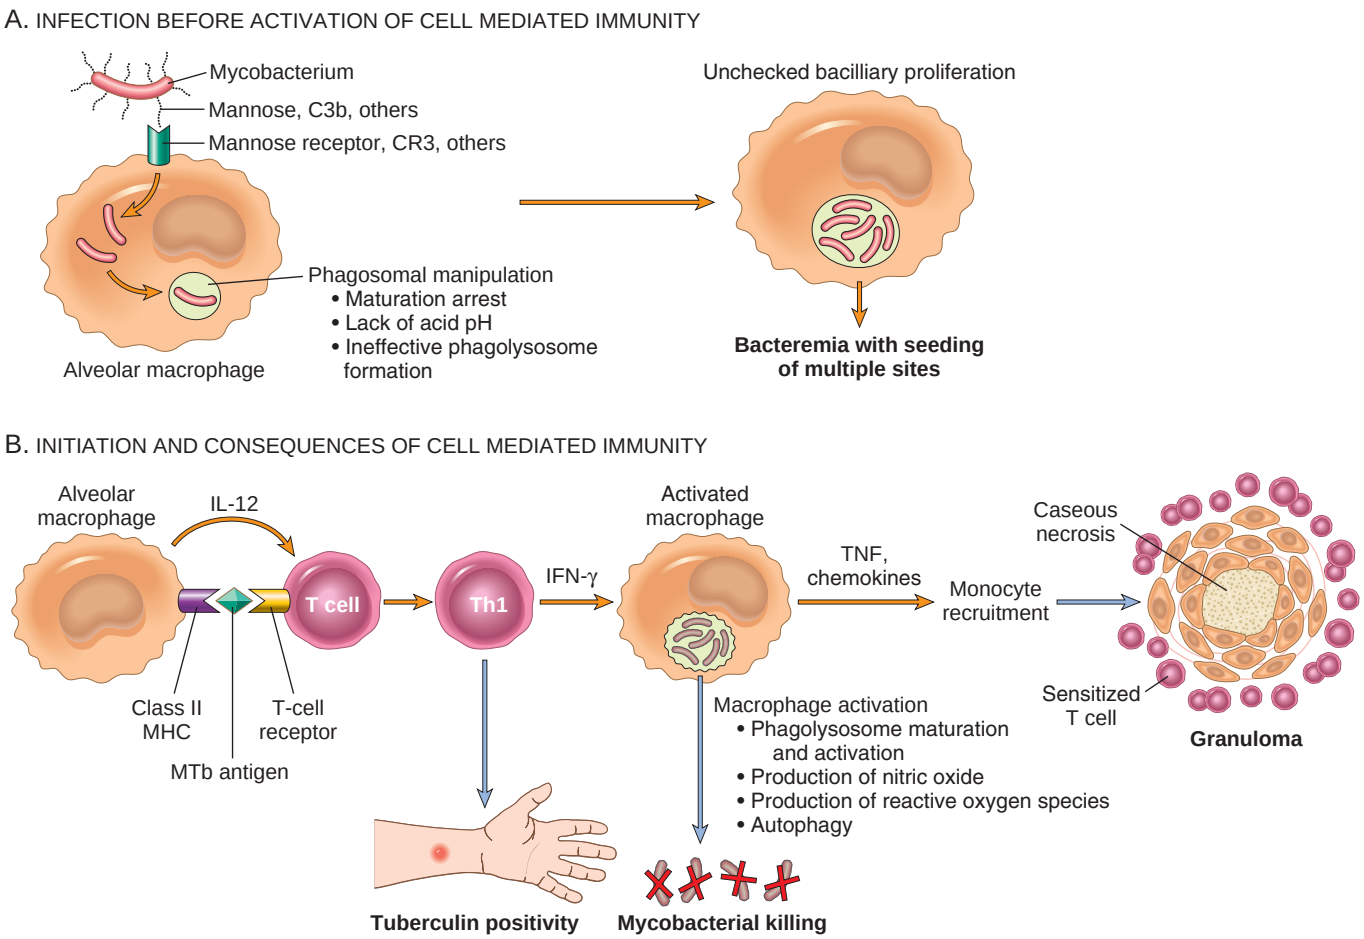

Figure 8.23 The sequence of events in primary pulmonary tuberculosis, commencing with inhalation of virulent *Mycobacterium* tuberculosis organisms and culminating with the development of cell-mediated immunity to the organism. (A) Events occurring during early infection, before activation of T-cell–mediated immunity. (B) The initiation and consequences of T-cell–mediated immunity. The development of resistance to the organism is accompanied by the appearance of a positive tuberculin test. *IFN-γ,* interferon-gamma; *MHC,* major histocompatibility complex; *MTb, M. tuberculosis; TNF,* tumor necrosis factor.

patients with rheumatoid arthritis who are treated with a TNF antagonist have an increased risk of tuberculosis reactivation.

- *Host susceptibility to disease.* AIDS is the greatest risk factor for progression to active disease, due to the loss of immunologic control of the organism. Other forms of immunosuppression, including glucocorticoids, TNF inhibitors, and transplants (solid organ and stem cell) also carry increased risk, as do renal failure and malnutrition. Rare inherited mutations that interfere with the Th1 response, such as loss of the IL-12 receptor β1 protein, result in increased susceptibility to severe tuberculosis and even symptomatic infection with normally avirulent (so-called "atypical") mycobacteria, such as the *Mycobacterium avium complex* (MAC), discussed later, or with the attenuated BCG vaccine strain. As previously mentioned, this group of genetic disorders is called *Mendelian susceptibility to mycobacterial disease.*

In summary, immunity to *M. tuberculosis* is primarily mediated by Th1 cells, which stimulate macrophages to kill the bacteria. This immune response, although largely effective, comes at the cost of accompanying tissue destruction. Reactivation of the infection or re-exposure to the bacilli in a previously sensitized host results in rapid mobilization of a defensive reaction but also increased tissue necrosis. Just as T-cell immunity and resistance are correlated, so, too, the loss of T-cell immunity (indicated by tuberculin negativity in a previously tuberculin-positive individual) may be an ominous sign that resistance to the organism has faded.

Clinical Features

Clinical tuberculosis is separated into two important types that differ in pathophysiology: primary tuberculosis, which occurs with the first infection, and secondary tuberculosis, which occurs in an individual who has been previously infected by *M. tuberculosis* (Fig. 8.24).

Primary tuberculosis is the form of disease that develops in a previously unexposed and therefore unsensitized person. Clinically significant disease develops in about 5% of newly infected people. With primary tuberculosis, the source of the organism is exogenous. In most people, the primary infection is contained, but in others, primary tuberculosis is progressive. The diagnosis of progressive primary tuberculosis in adults can be difficult. In contrast to secondary tuberculosis (apical disease with cavitation; see later), progressive primary tuberculosis more often

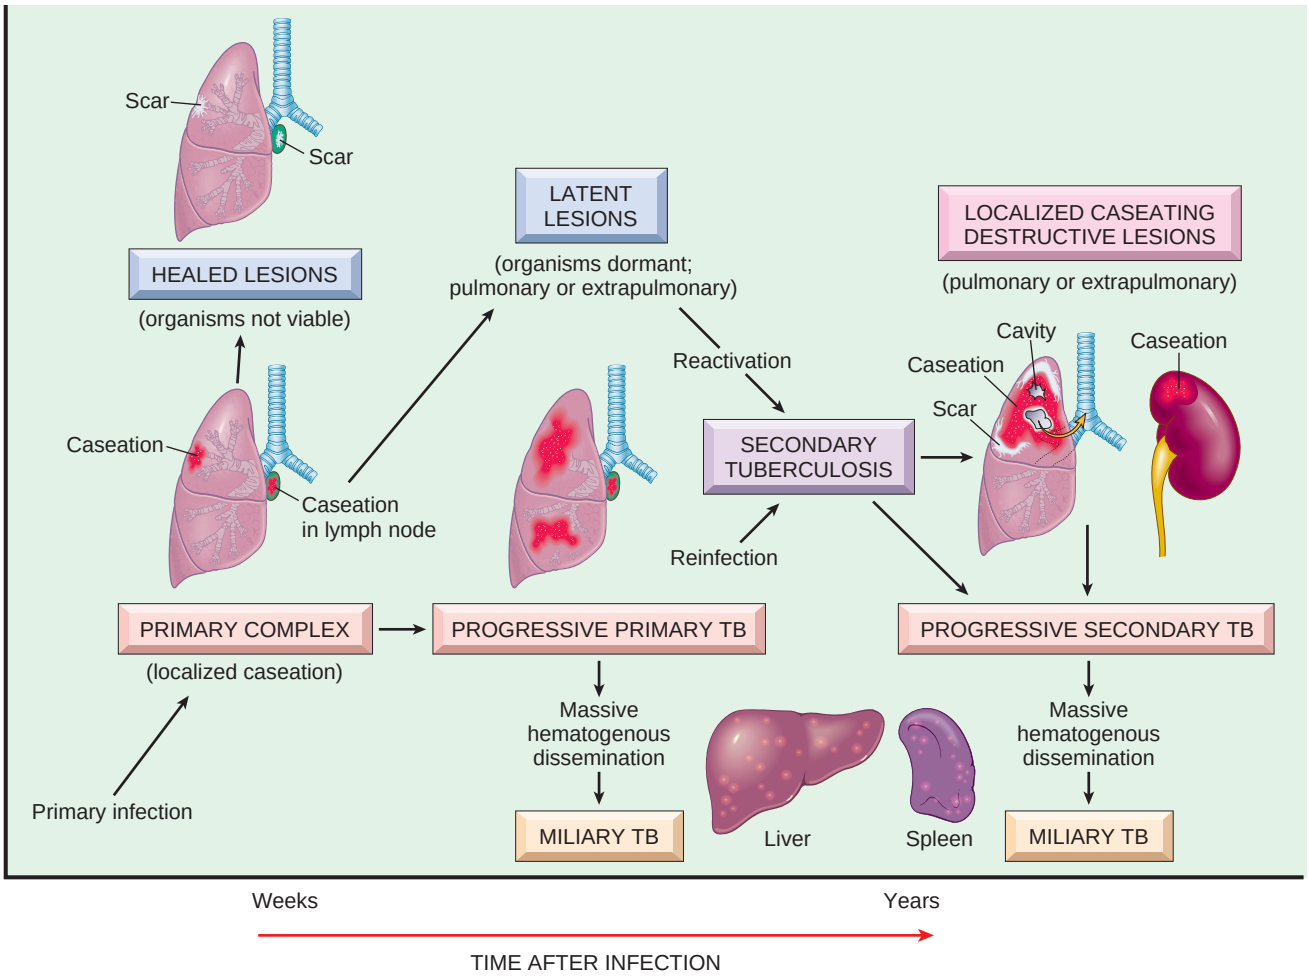

Figure 8.24 The natural history and spectrum of tuberculosis. (Modified from a sketch provided by Professor R. K. Kumar, The University of New South Wales, School of Pathology, Sydney, Australia.)

resembles an acute bacterial pneumonia with consolidation of the lobe, hilar adenopathy, and pleural effusion. Lymphatic and hematogenous dissemination following primary infection may result in the development of tuberculous meningitis and miliary tuberculosis (discussed later).

Secondary tuberculosis is the pattern of disease that arises in a previously sensitized host. It may follow shortly after primary tuberculosis, but more commonly it appears months to years after the initial infection, usually when host resistance is weakened. It most commonly stems from reactivation of a latent infection, but may also result from exogenous reinfection in the face of waning host immunity or when a large inoculum of virulent bacilli overwhelms the host immune system. Reactivation is more common in low-prevalence areas, and reinfection plays an important role in regions of high contagion.

Secondary pulmonary tuberculosis classically involves the apex of the upper lobes of one or both lungs. Because of the preexistence of hypersensitivity, the bacilli elicit a prompt and marked tissue response that tends to wall off the focus of infection. As a result, the regional lymph nodes are less prominently involved early in secondary disease than they are in primary tuberculosis. On the other hand, cavitation occurs readily in the secondary form. Indeed, cavitation is almost inevitable in neglected secondary tuberculosis, and erosion of the cavities into an airway is an important source of infection because the person now coughs sputum that contains bacteria.

Localized secondary tuberculosis may be asymptomatic. When manifestations appear, they are usually insidious in onset. Systemic symptoms, probably related to cytokines released by activated macrophages (e.g., TNF), often appear early in the course and include malaise, anorexia, weight loss, and fever. Commonly, the fever is low grade and remittent (appearing late each afternoon and then subsiding), and night sweats occur. With progressive pulmonary involvement, increasing amounts of sputum, at first mucoid and later purulent, appear. Some degree of hemoptysis is present in about one-half of all cases of pulmonary tuberculosis. Pleuritic pain may result from extension of the infection to the pleural surfaces. Extrapulmonary manifestations of tuberculosis are legion and depend on the organ system involved.

Multidrug resistance is now seen more commonly than it was in past years; hence, all newly diagnosed cases in the United States are treated with at least four drugs, unless the susceptibility of the bacterium from the source case is known. The prognosis is generally good if infections are localized to the lungs, except when they are caused by drug-resistant strains or occur in debilitated individuals.

Tests for tuberculosis detect either the bacteria or the T lymphocyte–mediated host response to the bacteria. There are several tests available for detection of *M. tuberculosis* in patients with active disease. Acid-fast smears and cultures of the sputum of patients suspected of having tuberculosis should be performed. Culture on solid agar media shows growth at 3 to 6 weeks, but culture in liquid media can provide an answer within 2 weeks. Comprehensive antibiotic susceptibility testing can only be performed by culture. PCR amplification of *M. tuberculosis* DNA allows for even more rapid diagnosis. An FDA-approved PCR test is available that identifies both the presence of *M. tuberculosis* and, if the organism is detected, whether it is resistant to rifampin. PCR assays are as sensitive as culture in acid-fast smear-positive samples, but slightly less sensitive in smear-negative tuberculosis, and substantially less sensitive in children. Although culture remains the gold standard, PCR should also be performed if active tuberculosis is suspected because results are available quickly.

Testing for latent tuberculosis is done by detecting T-cells specific for or delayed hypersensitivity to *M. tuberculosis* antigens. This can be detected by either IFN-γ release assays (IGRAs) or the tuberculin (purified protein derivative [PPD], or Mantoux) skin test. IGRAs are in vitro tests in which lymphocytes from the patient are stimulated with protein antigens from *M. tuberculosis*. Production of IFN-γ by the T cells is measured to assess the level of T-cell immunity to the organism. The tuberculin skin test is performed by intracutaneous injection of purified protein derivative of *M. tuberculosis,* which induces a visible and palpable induration that peaks in 48 to 72 hours. A positive IGRA or tuberculin test signifies T cell–mediated immunity to mycobacterial antigens but does not differentiate between infection and active disease. False-negative reactions may occur in the setting of certain viral infections, sarcoidosis, malnutrition, Hodgkin lymphoma, immunosuppression, and (notably) active tuberculous disease. A false-positive tuberculin skin test may result from infection by atypical mycobacteria or prior vaccination with BCG *(Bacillus Calmette-Guerin),* an attenuated strain of *M. bovis* that is used as a vaccine in some countries. False-positive results are uncommon with IGRAs.

Tuberculosis is a leading cause of death in people with AIDS. **All stages of HIV infection are associated with an increased risk of tuberculosis**. The use of antiretroviral therapy (ART) reduces the risk of tuberculosis in people with HIV infection, but even with ART, people infected with HIV are more likely to develop symptomatic tuberculosis. A low CD4 count before starting ART is an important risk factor for development of tuberculosis, which underscores the role of the immune response in keeping reactivation of *M. tuberculosis* in check. Pulmonary manifestations of tuberculosis in HIV-infected individuals are variable, ranging from focal lesions to multifocal infiltrates to localized apical disease with cavitation. The extent of immunodeficiency also determines the frequency of extrapulmonary involvement, rising from 10% to 15% in mildly immunosuppressed people to greater than 50% in those with severe immunodeficiency. Other atypical features of tuberculosis in HIV-positive people include an increased frequency of false-negative sputum smears and tuberculin tests (the latter sometimes referred to as "anergy"), and the absence of characteristic granulomas in tissues, particularly in the late stages of HIV. The increased frequency of sputum smear-negativity is paradoxical because these immunosuppressed patients typically have higher bacterial loads. The likely explanation is that cavitation and bronchial damage are more severe in immunocompetent individuals, resulting in more bacilli in expelled sputum. In contrast, the absence of bronchial wall destruction due to reduced T cell–mediated hypersensitivity results in the excretion of fewer bacilli in the sputum.

MORPHOLOGY

Primary Tuberculosis. In countries where consumption of infected milk has been eliminated, primary tuberculosis almost always begins in the lungs. Typically, the inhaled bacilli implant in the distal airspaces of the lower part of the upper lobe or the upper part of the lower lobe, usually close to the pleura. As sensitization develops, a 1- to 1.5-cm area of gray-white inflammation with consolidation emerges, known as the *Ghon focus*. In most cases, the center of this focus undergoes caseous necrosis. Tubercle bacilli, either free or within phagocytes, drain to the regional nodes, which also often caseate. **This combination of parenchymal lung lesion and nodal involvement is referred to as the *Ghon complex*** (Fig. 8.25). During the first few weeks, there is also lymphatic and hematogenous dissemination to other parts of the body. In approximately 95% of cases, development of cell-mediated immunity controls the infection. Hence, the Ghon complex undergoes progressive fibrosis, often followed by radiologically detectable calcification, and despite seeding of other organs, no lesions develop.

Histologically, sites of active involvement are marked by a characteristic granulomatous inflammatory reaction that forms both caseating and noncaseating tubercles (Fig. 8.26A to C). Individual tubercles are microscopic; it is only when multiple

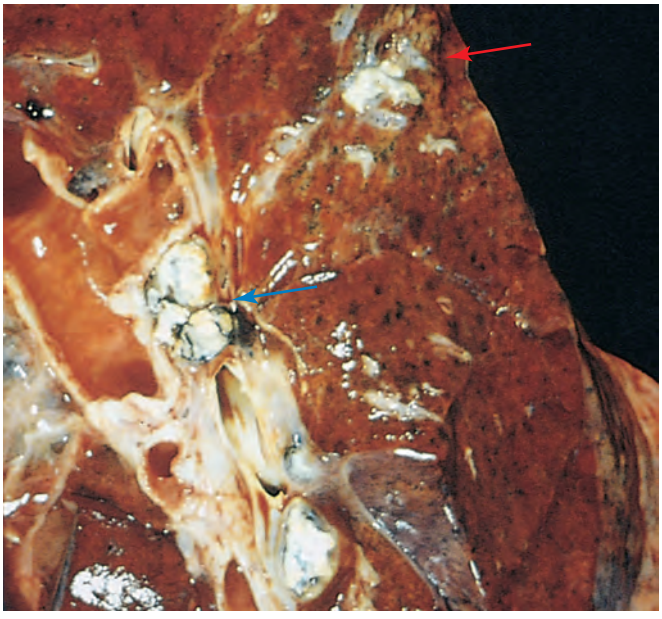

Figure 8.25 Primary pulmonary tuberculosis, Ghon complex. The gray-white parenchymal focus is under the pleura in the lower part of the upper lobe *(red arrow)*. Hilar lymph nodes with caseation are seen on the left *(blue arrow)*.

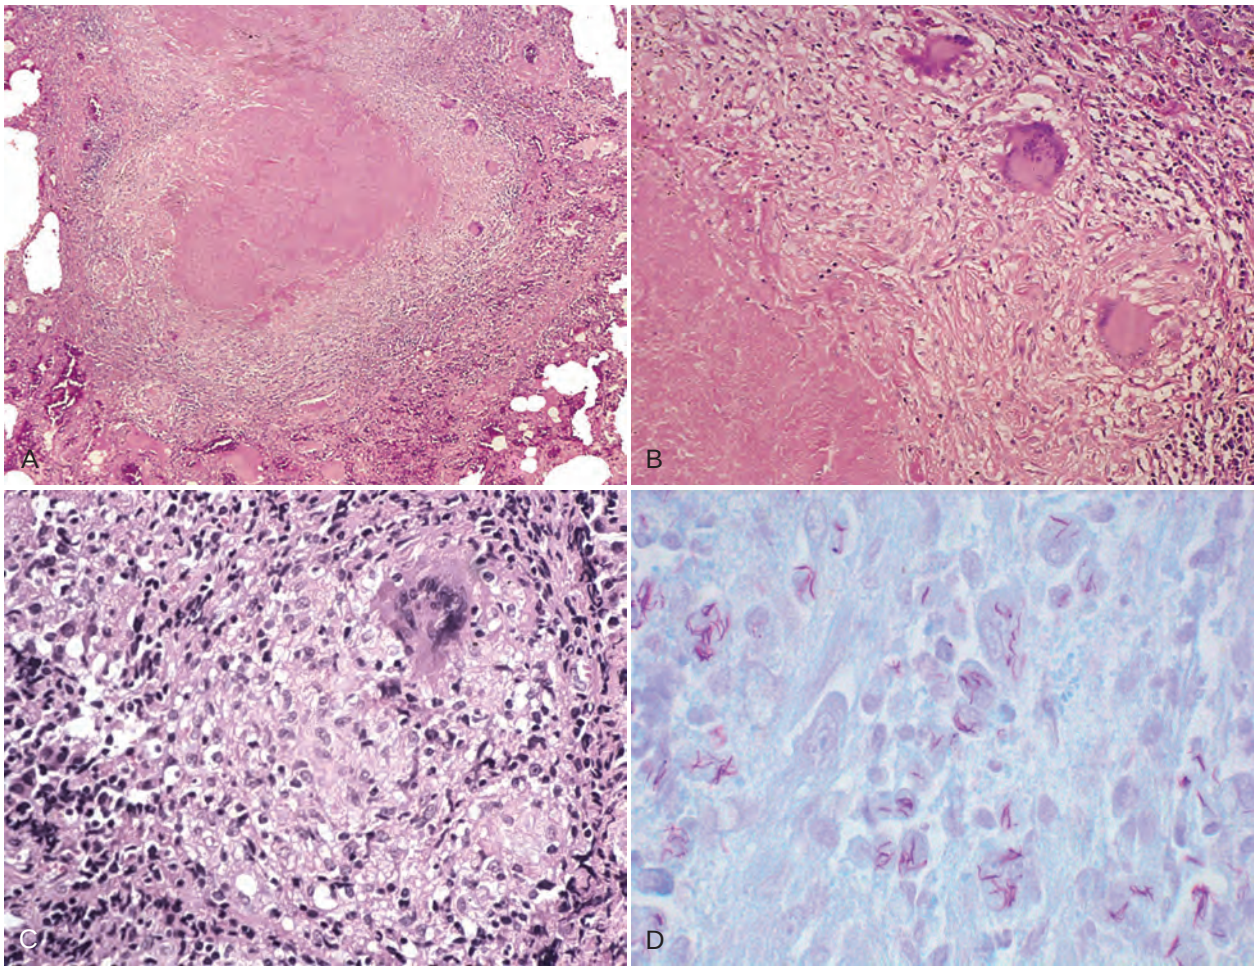

Figure 8.26 The morphologic spectrum of tuberculosis. Characteristic tubercle at low magnification (A) and high magnification (B) shows central granular caseation surrounded by epithelioid and multinucleate giant cells. This is the usual response in people who have developed cell-mediated immunity to the organism. (C) Occasionally, even in immunocompetent patients, tubercular granulomas may not show central caseation; hence regardless of the presence or absence of caseous necrosis, use of special stain for acid-fast organisms is indicated when granulomas are present. (D) In this specimen from an immunocompromised patient, macrophages with large numbers of mycobacteria are seen (acid-fast stain).

granulomas coalesce that they become macroscopically visible. The granulomas are usually enclosed within a fibroblastic rim punctuated by lymphocytes. Multinucleated giant cells are present in the granulomas. Immunocompromised people do not form the characteristic granulomas, and their macrophages contain many bacilli (Fig. 8.26D).

Secondary Tuberculosis. The initial lesion is usually a small focus of consolidation, less than 2 cm in diameter, within 1 to 2 cm of the apical pleura. Such foci are sharply circumscribed, firm and gray-white to yellow in color, and have variable degrees of central caseation and peripheral fibrosis (Fig. 8.27). In immunocompetent individuals, the initial parenchymal focus undergoes progressive fibrous encapsulation, leaving only fibrocalcific scars. Histologically, the active lesions show characteristic coalescent tubercles with central caseation. Tubercle bacilli can often be identified with acid-fast stains in early exudative and caseous phases of granuloma formation but are usually too few to be found in the late, fibrocalcific stages. Localized, apical, secondary pulmonary tuberculosis may heal with fibrosis either spontaneously or after therapy, or the disease may progress and extend along several different pathways.

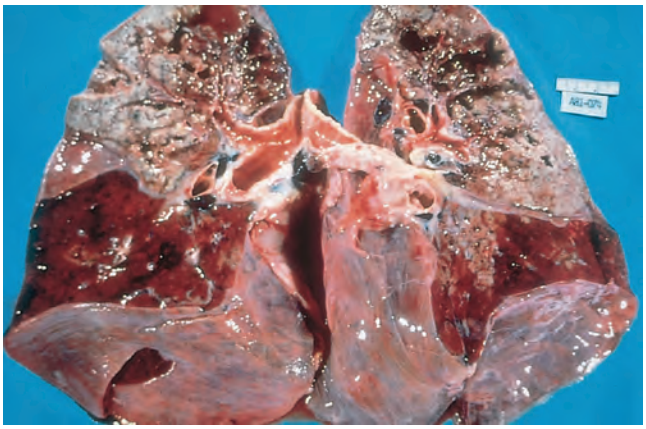

Figure 8.27 Secondary pulmonary tuberculosis. The upper parts of both lungs are riddled with gray-white areas of caseation and multiple areas of softening and cavitation.

Progressive pulmonary tuberculosis may ensue in older adults and immunosuppressed people. The apical lesion expands into adjacent lung and eventually erodes into bronchi and vessels. This evacuates the caseous center, creating a ragged, irregular cavity that is poorly walled off by fibrous tissue. Erosion of blood vessels results in hemoptysis. With adequate treatment the process may be arrested, although healing by fibrosis often distorts the pulmonary architecture. The cavities, now free of inflammation, may persist or become fibrotic. If the treatment is inadequate or if host defenses are impaired, the infection may spread via airways, lymphatic channels, or the vascular system. **Miliary pulmonary disease** occurs when organisms draining through lymphatics enter the venous blood and circulate back to the lung. Individual lesions are either microscopic or small, visible (2-mm) foci of yellow-white consolidation scattered through the lung parenchyma (the adjective "miliary" is derived from the resemblance of these foci to millet seeds). Miliary lesions may expand and coalesce, resulting in consolidation of large regions or even whole lobes of the lung. With progressive pulmonary tuberculosis, the pleural cavity is invariably involved, and serous **pleural effusions**, **tuberculous empyema**, or **obliterative fibrous pleuritis** may develop. Progressive primary tuberculosis that occurs in immunosuppressed individuals spreads in a similar manner.

Endobronchial, **endotracheal**, and **laryngeal tuberculosis** may develop by spread through lymphatic channels or from expectorated infectious material. The mucosal lining may be studded with minute granulomatous lesions that may only be apparent microscopically.

Systemic miliary tuberculosis occurs when bacteria disseminate through the systemic arterial system. Miliary tuberculosis is most prominent in the liver, bone marrow, spleen, adrenals, meninges, kidneys, fallopian tubes, and epididymis, but can involve any organ (Fig. 8.28).

Isolated tuberculosis may appear in any of the organs or tissues seeded hematogenously and may be the presenting manifestation. Organs that are commonly involved include the meninges (tuberculous meningitis), kidneys (renal tuberculosis), adrenals (formerly an important cause of Addison disease), bones (osteomyelitis), and fallopian tubes (salpingitis). When the vertebrae are affected, the disease is referred to as **Pott disease.** Paraspinal "cold" abscesses in these patients may track along tissue planes and present as an abdominal or pelvic mass.

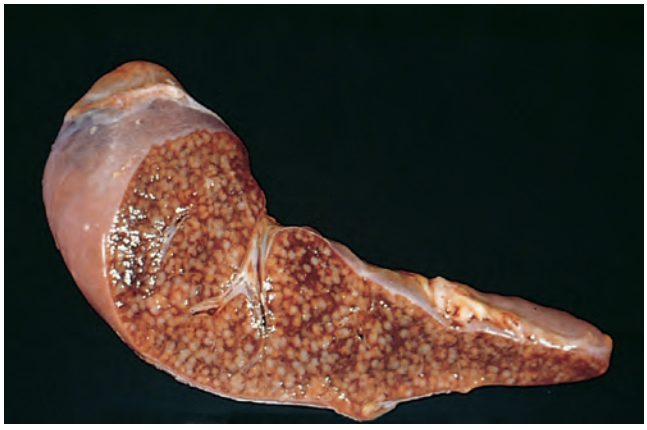

Figure 8.28 Miliary tuberculosis of the spleen. The cut surface shows numerous gray-white tubercles.

Lymphadenitis is the most frequent presentation of extrapulmonary tuberculosis, usually occurring in the cervical region ("scrofula"). In HIV-negative individuals, lymphadenitis tends to be unifocal and localized. HIV-positive people, on the other hand, almost always have multifocal disease, systemic symptoms, and either pulmonary or other organ involvement by active tuberculosis.

As previously mentioned, **intestinal tuberculosis** contracted by the drinking of contaminated milk is common in countries where bovine tuberculosis is present and milk is not pasteurized. In countries where milk is pasteurized, intestinal tuberculosis is more often caused by the swallowing of coughed-up infective material in patients with advanced pulmonary disease. Typically the organisms are seeded to mucosal lymphoid aggregates of the small and large bowel, which then undergo granulomatous inflammation that can lead to ulceration of the overlying mucosa, particularly in the ileum. Healing creates strictures.

Nontuberculous Mycobacterial Infections

Nontuberculous mycobacteria (NTM) refer to mycobacteria other than *M. tuberculosis* and very fastidious *M. leprae*. The prevalence of NTM disease has increased worldwide. Of the 150 NTM species, the most frequent human pathogens are *Mycobacterium avium* complex (MAC), *M. abscessus* complex, and *M. kansasii*. The prevalence of specific species of NTM varies in different geographic regions of the world. Treatment differs for these pathogens, so identifying the specific organism is important. It has been difficult to distinguish *M. avium* and *M. intracellulare* using traditional physical and biochemical tests, and the clinical features of these infections are similar, so they are grouped into a complex. Newer molecular methods are better able to distinguish these two species, as well as *M. chimaera* in the same complex. NTM are ubiquitous in the environment, water, and soil, and there is little human-to-human transmission, except for a small number of cases in cystic fibrosis patients.

Clinical presentations of NTM infections include chronic pulmonary disease (most common), lymphadenitis, cutaneous disease, and disseminated disease. Normal host defense mechanisms usually prevent infection, so vulnerable individuals include those with structural lung damage, cystic fibrosis, bronchiectasis, primary ciliary dyskinesia, chronic obstructive pulmonary disease, or pneumoconiosis. Additional predisposing factors include immunosuppression from HIV, transplantation, treatment with TNF inhibitors, and rare cases of anti-IFN-γ autoantibodies or inherited defects in the IL-12/IFN-γ pathways. Rapidly growing mycobacterial infections are often associated with postsurgical or posttraumatic infections. In patients with marked T-cell immunodeficiency, MAC causes widely disseminated infections, and organisms proliferate abundantly in many organs, including the lungs and gastrointestinal system. Patients are feverish, with drenching night sweats and weight loss. In cases of MAC infection in a person without HIV or another severe immunodeficiency, the organisms primarily infect the lung, causing a productive cough and sometimes fever and weight loss. Radiographic characteristics of disease may be fibrocavitary lesions primarily in the upper lobes or nodular bronchiectasis with multifocal clusters of small nodules. NTM biofilm development on medical devices is a well-documented source of a number of recent cases.

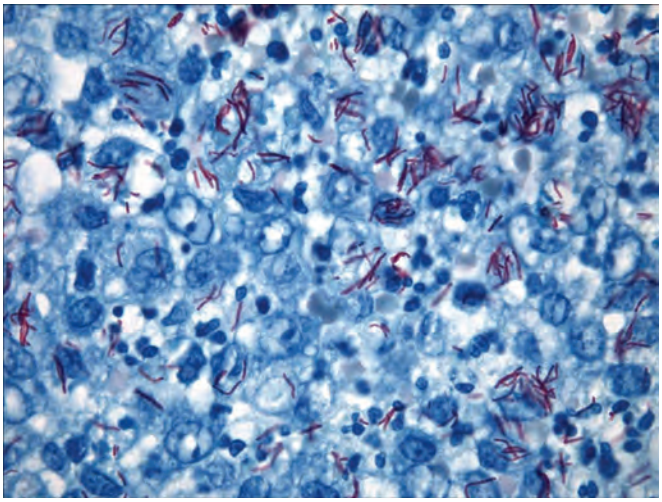

Figure 8.29 *Mycobacterium avium* infection in a patient with AIDS, showing massive infection with acid-fast organisms. This pattern is more common in patients with acquired immunodeficiencies.

MORPHOLOGY

The hallmark of MAC infections in patients with HIV is abundant acid-fast bacilli within macrophages (Fig. 8.29). Depending on the severity of immunodeficiency, MAC infections can be widely disseminated throughout the mononuclear phagocyte system, causing enlargement of involved lymph nodes, liver, and spleen, or localized to the lungs. There may be a yellowish pigmentation to these organs secondary to the large number of organisms present in swollen macrophages. Granulomas, lymphocytes, and tissue destruction are rare.

Leprosy

Leprosy, or *Hansen disease*, is a slowly progressive infection caused by *M. leprae* that mainly affects the skin and peripheral nerves. Despite its low communicability, leprosy remains endemic among people living in several lower-income tropical nations.

Pathogenesis

The source of infection and route of transmission are not known, however human respiratory secretions or soil are likely origins. *M. leprae* is taken up by macrophages and disseminates in the blood, but it replicates primarily in relatively cool tissues of the skin and extremities. It proliferates best at 32° to 34°C, the temperature of the human skin. Like *M. tuberculosis*, *M. leprae* secretes no toxins, and its virulence is based on properties of its cell wall, which is similar enough to that of *M. tuberculosis* that immunization with BCG confers some protection against *M. leprae* infection. Cell-mediated immunity is manifested by delayed-type hypersensitivity reactions to dermal injections of a bacterial extract called *lepromin*.

***M. leprae* causes two strikingly different patterns of disease, called tuberculoid and lepromatous, that are determined by the helper T-lymphocyte response to *M. leprae*.** People with the less severe tuberculoid leprosy have dry, scaly skin lesions that lack sensation. They often have asymmetric involvement of large peripheral nerves. The more severe form, lepromatous leprosy, includes symmetric skin thickening and nodules. In lepromatous leprosy, widespread invasion of the mycobacteria into Schwann cells and into endoneural and perineural macrophages damages the peripheral nervous system. In advanced cases of lepromatous leprosy, *M. leprae* is present in sputum and blood. People can also have intermediate forms of disease, called *borderline leprosy*.

As mentioned earlier, tuberculoid and lepromatous leprosy are associated with different T-cell responses. People with tuberculoid leprosy have a Th1 response associated with production of IL-2 and IFN-γ as well as a Th17 response. As with *M. tuberculosis*, IFN-γ functions to mobilize an effective host macrophage response, and hence the microbial burden is low. Also, antibody production is low. Lepromatous leprosy is associated with a weak Th1 response and, in some cases, a relative increase in the Th2 response. The net result is weak cell-mediated immunity and an inability to control the bacteria, which can be readily visualized in tissue sections. Occasionally, most often in the lepromatous form, antibodies are produced against *M. leprae* antigens. Paradoxically, these antibodies are usually not protective, but they may form immune complexes with free antigens that can lead to erythema nodosum, vasculitis, and glomerulonephritis. Some leprosy patients have a mixed Th1/Th2 cytokine pattern.

MORPHOLOGY

Tuberculoid leprosy begins with localized flat, red skin lesions that enlarge and develop irregular shapes with indurated, elevated, hyperpigmented margins and depressed pale centers (central healing). Neuronal involvement dominates tuberculoid leprosy. Nerves become enclosed within granulomatous inflammatory reactions and, if small (e.g., the peripheral twigs), are destroyed (Fig. 8.30). Nerve degeneration causes skin anesthesias and skin and muscle atrophy that render the person liable to trauma of the affected parts, leading to the development of chronic skin ulcers. Contractures, paralyses, and autoamputation of fingers or toes may ensue. Facial nerve involvement can lead to paralysis of the eyelids, with keratitis and corneal ulcerations. On microscopic examination, all sites of involvement have granulomatous lesions closely resembling those found in tuberculosis. Because of the strong host defense, bacilli are almost never found, hence the name **paucibacillary** leprosy. The presence of granulomas and absence of bacteria reflect strong T-cell immunity. Because leprosy pursues an extremely slow course, spanning decades, most patients die with leprosy rather than of it.

Lepromatous leprosy involves the skin, peripheral nerves, anterior eye chamber, upper airways (down to the larynx), testes, hands, and feet. The vital organs and CNS are rarely affected, presumably because the core temperature is too high for growth of *M. leprae*. Lepromatous lesions contain large aggregates of lipid-laden macrophages (lepra cells), often filled with masses ("globi") of acid-fast bacilli (Fig. 8.31). Because of the abundant bacteria, lepromatous leprosy is referred to as **multibacillary.** Macular, papular, or nodular lesions form on the face, ears, wrists, elbows, and knees. With progression, the nodular lesions coalesce to yield a distinctive leonine facies. Most skin lesions are hypoesthetic or anesthetic. Lesions in the nose may cause persistent inflammation and bacilli-laden discharge. The peripheral nerves,

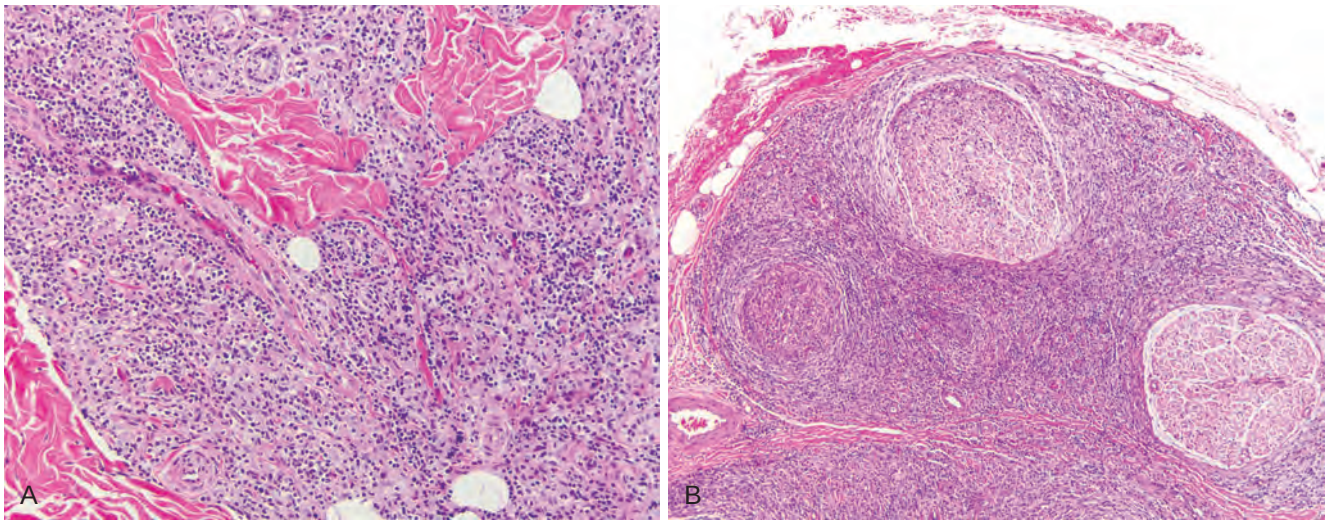

Figure 8.30 Two types of inflammatory infiltrates common in leprosy are: (A) dense dermal macrophage infiltration surrounding adnexa, vessels, and nerves (resulting in subcutaneous nodules) and (B) dense chronic lymphocytic and histiocytic infiltration into large nerve bundles (resulting in mononeuropathy).

particularly the ulnar and peroneal nerves where they approach the skin surface, are symmetrically invaded with mycobacteria, with minimal inflammation. Loss of sensation and trophic changes in the hands and feet follow the nerve lesions. Lymph nodes contain aggregates of bacteria-filled foamy macrophages in the paracortical (T-cell) areas and reactive germinal centers. In advanced disease, aggregates of macrophages are also present in the splenic red pulp and the liver. The testes are usually extensively involved, leading to destruction of the seminiferous tubules and consequent sterility.

Spirochete Infections

Spirochetes are gram-negative, slender, corkscrew-shaped bacteria with axial periplasmic flagella wound around a helical protoplasm. The bacteria are covered in a membrane called an outer sheath, which is thought to mask bacterial antigens from the host immune response. *Treponema pallidum* subsp. *pallidum* is the microaerophilic spirochete that causes syphilis, a chronic STI with multiple clinical presentations. Other closely related treponemes cause yaws *(T. pallidum* subsp. *pertenue)* and pinta *(T. pallidum* subsp. *carateum)*.

Syphilis

Syphilis is a chronic sexually transmitted infection (STI) with varied clinical and pathologic manifestations. The causative spirochete, *T. pallidum* subsp. *pallidum,* hereafter referred to simply as *T. pallidum,* is too slender to be seen in Gram stain, but it can be visualized by silver stains and immunofluorescence techniques (Fig. 8.32). Transplacental transmission of *T. pallidum* occurs readily, and active disease during pregnancy results in congenital syphilis. *T. pallidum* cannot be easily grown in culture. Public health programs and penicillin treatment reduced the number of cases of syphilis in the United States from the late 1940s until the late 1970s. In North America and western Europe, the incidence of syphilis has fluctuated since the 1970s and increased dramatically in the past decade among men who have sex with men, particularly those with HIV infection. Worldwide more than 5 million new cases of syphilis are diagnosed every year, and congenital infections are not uncommon.

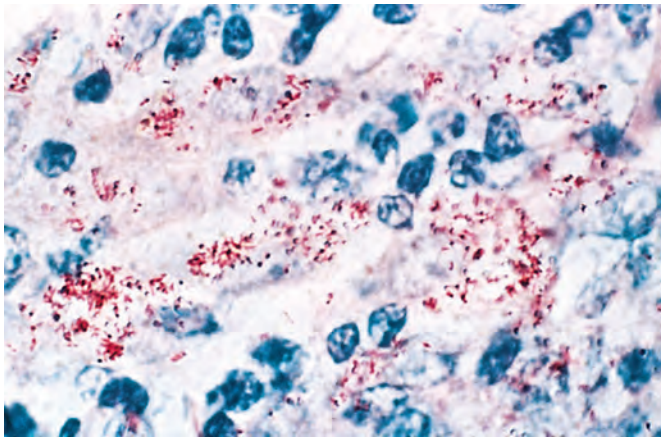

Figure 8.31 Lepromatous leprosy. Acid-fast bacilli ("red snappers") within macrophages.

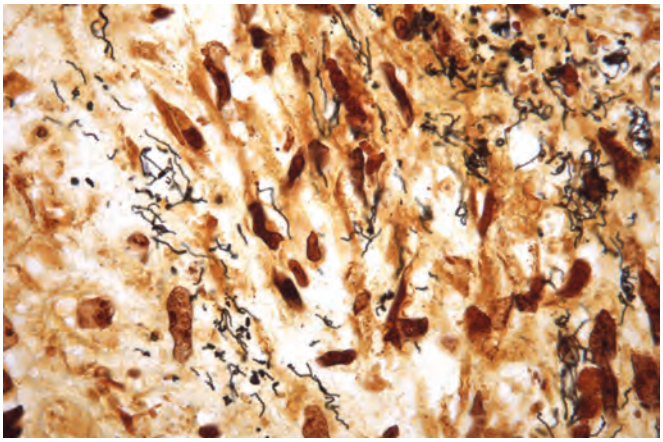

Figure 8.32 *Treponema pallidum* (Steiner silver stain) showing several spirochetes in histologic sections of placental syphilis.

Pathogenesis

Proliferative endarteritis affecting small vessels with a surrounding plasma cell–rich infiltrate is characteristic of all stages of syphilis. Much of the pathology of syphilis can be ascribed to the ischemia produced by the vascular lesions. The pathogenesis of endarteritis is unknown.

The immune response to *T. pallidum* reduces the burden of bacteria and can lead to resolution of local lesions but does not reliably eliminate the systemic infection. Superficial sites of infection (chancres and rashes) have an intense inflammatory infiltrate that includes T cells, plasma cells, and macrophages that surround the bacteria. The infiltrating CD4+ T cells are Th1 cells that may activate macrophages to kill the bacteria. Treponeme-specific antibodies are detectable, and these activate complement in the lesion and opsonize the bacteria for phagocytosis by macrophages. In many patients, the organism persists despite these host responses. A protein in the outer membrane of *T. pallidum*, TprK, accumulates structural diversity during the course of infection through gene conversion (recombination) between silent donor sites and the *tprK* gene, and this might contribute to antigenic diversity that allows the organism to persist. The difficulty of developing a continuous *in vitro* culture system for this organism has limited investigation of pathogenesis.

Syphilis is divided into three stages, with distinct clinical and pathologic manifestations (Fig. 8.33).

Primary Syphilis. This stage, occurring approximately 3 weeks after infection, features a single firm, nontender, raised, red lesion (chancre) located at the site of treponemal invasion on the penis, cervix, vaginal wall, or anus. The chancre heals with or without therapy. Spirochetes are plentiful within the chancre and spread from there throughout the body by hematologic and lymphatic dissemination.

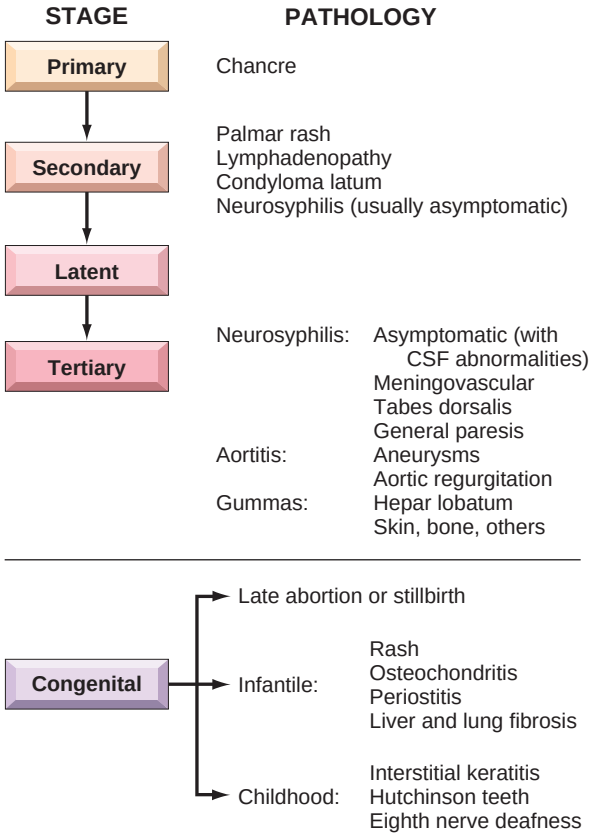

Figure 8.33 Protean manifestations of syphilis.

Secondary Syphilis. This stage is marked by painless, superficial lesions of the skin and mucosal surfaces. It occurs 2 to 10 weeks after the primary chancre in approximately 75% of untreated people. Skin lesions frequently occur on the palms or soles of the feet and may be maculopapular, scaly, or pustular. Moist areas of the skin, such as the anogenital region, inner thighs, and axillae, may have broad-based elevated plaques called *condylomata lata*. Silvery-gray superficial erosions may form on the oral, pharyngeal, and genital mucous membranes. Lymphadenopathy, mild fever, malaise, and weight loss are also common in secondary syphilis. Asymptomatic neurosyphilis (discussed later) occurs in 8% to 40% of patients, and symptomatic neurosyphilis with meningitis, visual changes, or hearing changes occurs in 1% to 2%. Secondary syphilis lasts several weeks, and then the person enters the latent stage of the disease.

Tertiary Syphilis. Tertiary syphilis has three main manifestations: cardiovascular syphilis, neurosyphilis, and so-called benign tertiary syphilis. These may occur alone or in combination. Tertiary syphilis occurs in one-third of untreated patients, usually after a latent period of 5 years or more.

- *Cardiovascular syphilis,* in the form of syphilitic aortitis, accounts for more than 80% of cases of tertiary disease. The pathogenesis of this vascular lesion is not known, but the scarcity of treponemes and the intense inflammatory infiltrate suggest that the immune response plays a role. The aortitis leads to slowly progressive dilation of the aortic root and arch, which causes aortic valve insufficiency and aneurysms of the proximal aorta (Chapter 11).
- *Neurosyphilis* may be symptomatic or asymptomatic. Symptomatic neurosyphilis is discussed in Chapter 28. Asymptomatic neurosyphilis, which accounts for about one-third of neurosyphilis cases, is initially suspected on detection of CSF abnormalities such as pleocytosis (increased numbers of inflammatory cells), elevated protein levels, or decreased glucose, and is confirmed by detection of antibodies stimulated by the spirochetes (discussed later) in the CSF. Antibiotics are given for a longer time if the spirochetes have spread to the CNS, so patients with tertiary syphilis should be tested for neurosyphilis even if they do not have neurologic symptoms.
- *Benign tertiary syphilis* is characterized by the formation of *gummas* in bone, skin, and the mucous membranes of the upper airway and mouth. Gummas are nodular lesions probably related to the development of delayed hypersensitivity to the bacteria. Skeletal involvement characteristically causes pain, tenderness, swelling, and pathologic fractures. Gummas in the skin and mucous membranes may produce nodular lesions or, rarely, destructive, ulcerative lesions. Gummas are rare because of the use of effective antibiotics.

Congenital Syphilis. Congenital syphilis occurs most frequently during maternal primary or secondary syphilis, when the spirochetes are most numerous. Intrauterine death

and perinatal death each occurs in approximately 25% of cases of untreated congenital syphilis.

Manifestations of congenital syphilis are divided into those that occur in the first 2 years of life (infantile syphilis) and those that occur later (tardive syphilis). Infantile syphilis is often manifested by nasal discharge and congestion (snuffles) in the first few months of life. A desquamating or bullous rash can lead to sloughing of the skin, particularly of the hands and feet and around the mouth and anus. Hepatomegaly and skeletal abnormalities are common. Late manifestations develop in nearly one-half of untreated children with neonatal syphilis.

Serologic Tests for Syphilis. Serology remains the mainstay of diagnosis of syphilis. Serologic tests include nontreponemal antibody tests and antitreponemal antibody tests. Nontreponemal tests measure antibody to a cardiolipin-cholesterol-lecithin antigen, present in both host tissues and *T. pallidum*. These antibodies are detected in the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. The nontreponemal assays are nonspecific but have been widely used due to low cost, ease of testing, and quantifiable results that can be used to follow response to treatment. Treponemal antibody tests measure antibodies that specifically react with *T. pallidum*. These include the fluorescent treponemal antibody absorption test and the *T. pallidum* enzyme immunoassay test. Automation of these more complex tests has led to their use as an initial screening test in some centers. A third option, rapid point-of-care tests, are designed for use with fingerstick blood (although serum shows higher sensitivity), are inexpensive, and are simple so that highly trained technologists are not required. There is only one FDA-approved point-of-care test in the United States. Rapid tests and PCR assays that have been developed are not commonly used at this time due to lower sensitivities and specificities.

The interpretation of these tests is complex because of differences in the antibody responses they measure and imperfections in the tests.

- Both treponemal and nontreponemal antibody tests are only moderately sensitive (~70% to 85%) for primary syphilis.
- Both types of test are very sensitive (>95%) for secondary syphilis.
- Treponemal tests are very sensitive for tertiary and latent syphilis. In contrast, nontreponemal antibody titers fall with time, and so nontreponemal tests are somewhat less sensitive for tertiary or latent syphilis.
- Nontreponemal antibody levels fall with successful treatment of syphilis, and so changes in the titers detected in these tests can be used to monitor therapy.
- Treponemal tests, which are nonquantitative, remain positive, even after successful therapy.
- Either nontreponemal or treponemal tests can be used for initial screening for syphilis, but positive results should be confirmed using a test of the other type (e.g., confirm nontreponemal positive test results with a treponemal test and *vice versa*). Confirmatory testing is needed because false-positive results can occur in both nontreponemal and treponemal tests. Causes of false-positive results in these tests include pregnancy, autoimmune diseases, and infections other than syphilis.

MORPHOLOGY

In primary syphilis, a chancre occurs on the penis or scrotum of 70% of men and on the vulva or cervix of 50% of women. The chancre is a slightly elevated, firm, reddened papule, up to several centimeters in diameter, that erodes to create a clean-based shallow ulcer. The contiguous induration creates a buttonlike mass directly adjacent to the eroded skin, providing the basis for the designation hard chancre (Fig. 8.34). On histologic examination, the chancre contains an intense infiltrate of plasma cells, with scattered macrophages and lymphocytes and a proliferative endarteritis. The endarteritis starts with endothelial cell activation and proliferation and progresses to intimal fibrosis (see Fig. 8.4). The regional nodes are usually enlarged due to nonspecific acute or chronic lymphadenitis, plasma cell–rich infiltrates, or granulomas.

In secondary syphilis, widespread mucocutaneous lesions involve the oral cavity, palms of the hands, and soles of the feet. The rash frequently consists of discrete red-brown macules less than 5 mm in diameter, but it may be follicular, pustular, annular, or scaling. Red lesions in the mouth or vagina contain the most organisms and are the most infectious. Histologically, the mucocutaneous lesions of secondary syphilis show the same plasma cell infiltrate and obliterative endarteritis as the primary chancre, although the inflammation is often less intense.

Tertiary syphilis most frequently involves the aorta, the CNS, and the liver, bones, and testes. The aortitis is caused by endarteritis of the vasa vasorum of the proximal aorta. Occlusion of the vasa vasorum results in scarring of the media of the proximal aortic wall, causing a loss of elasticity. There may be narrowing of the coronary artery ostia caused by subintimal scarring with resulting myocardial ischemia. The morphologic and

Figure 8.34 Syphilitic chancre in the scrotum (see Fig. 8.35 for the histopathology of syphilis). (Courtesy Dr. Richard Johnson, Beth Israel-Deaconess Hospital, Boston, Mass.)

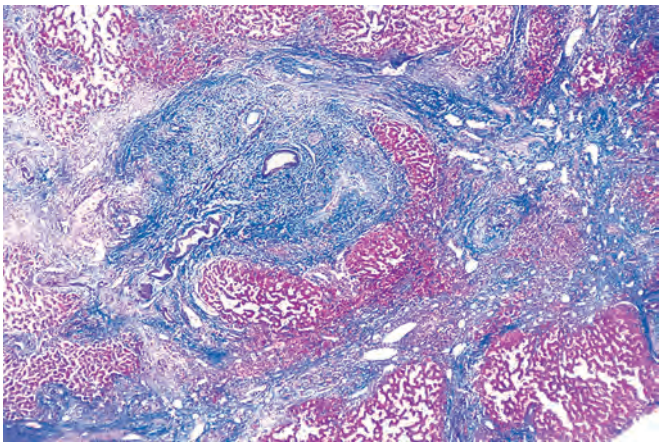

Figure 8.35 Trichrome stain of liver shows a gumma (scar), stained blue, caused by tertiary syphilis (the hepatic lesion is also known as *hepar lobatum*).

clinical features of syphilitic aortitis are discussed in greater detail with diseases of the blood vessels (Chapter 11).

Neurosyphilis takes one of several forms, designated meningovascular syphilis, tabes dorsalis, and general paresis (Chapter 28).

Syphilitic gummas are white-gray and rubbery, occur singly or multiply, and vary in size from microscopic lesions resembling tubercles to large tumorlike masses. They occur in most organs but particularly in skin, subcutaneous tissue, bone, and joints. In the liver, scarring as a result of gummas may cause a distinctive hepatic lesion known as *hepar lobatum* (Fig. 8.35). On histologic examination, the gummas have centers of coagulated, necrotic material and margins composed of plump, palisading macrophages and fibroblasts surrounded by large numbers of mononuclear leukocytes, chiefly plasma cells. Treponemes are scant in gummas and are difficult to demonstrate.

The rash of **congenital syphilis** is more severe than that of adult secondary syphilis. It is a bullous eruption of the palms and soles of the feet associated with epidermal sloughing. **Syphilitic osteochondritis and periostitis** affect all bones, but lesions of the nose and lower legs are most distinctive. Destruction of the vomer causes collapse of the bridge of the nose and, later on, the characteristic saddle nose deformity. Periostitis of the tibia leads to excessive new bone growth on the anterior surfaces and anterior bowing, or saber shin. There is also widespread disturbance in endochondral bone formation. The epiphyses become widened as the cartilage overgrows, and cartilage is found in displaced islands within the metaphysis.

The **liver** is often severely affected in congenital syphilis. Diffuse fibrosis permeates lobules to isolate hepatic cells into small nests, accompanied by the characteristic lymphoplasmacytic infiltrate and vascular changes. Gummas are occasionally found in the liver, even in early cases. The **lungs** may be affected by a diffuse interstitial fibrosis. In the syphilitic stillborn, the lungs appear pale and airless (pneumonia alba). The generalized spirochetemia may lead to diffuse interstitial inflammatory reactions in virtually any other organ (e.g., the pancreas, kidneys, heart, spleen, thymus, endocrine organs, and CNS).

The late manifestations of congenital syphilis include a distinctive **triad of interstitial keratitis, Hutchinson teeth, and eighth-nerve deafness**. In addition to interstitial keratitis, the ocular changes include choroiditis and abnormal retinal pigmentation. Hutchinson teeth are small incisors shaped like a screwdriver or a peg, often with notches in the enamel. Eighth-nerve deafness and optic nerve atrophy develop secondary to meningovascular syphilis.

Lyme Disease

Lyme disease is a common arthropod-borne illness caused by spirochetes in the genus *Borrelia* that can be localized or disseminated with a tendency to cause persistent chronic arthritis. It is named for the Connecticut town, Lyme, where there was an epidemic of arthritis associated with skin erythema in the mid-1970s. The common species of *Borrelia* that cause Lyme diseases are *Borrelia burgdorferi* in the United States, and additionally *B. afzelii* and *B. garinii* in Europe and Asia. These are each transmitted from rodents or, for *B. garinii* from birds, to people by *Ixodes* deer ticks. Lyme disease is endemic in the United States, Europe, and Asia. In the United States, there were between 30,000 and 40,000 cases reported each year for several years. Most cases occur in the northeastern states and the upper Midwest. In endemic areas, *B. burgdorferi* infects up to 50% of ticks, which may also be infected with *Ehrlichia* spp. and *Babesia* spp. Serology is the main method of diagnosis, but PCR can be done on infected tissue.

Lyme disease involves multiple organ systems and is divided into three stages (Fig. 8.36).

- In *early localized disease,* spirochetes multiply and spread in the dermis at the site of a tick bite, causing an expanding area of redness, often with a pale center. This lesion, called *erythema migrans,* may be accompanied by fever and lymphadenopathy. The rash spontaneously disappears in 4 to 12 weeks.
- In *early disseminated disease,* spirochetes spread hematogenously throughout the body and cause secondary skin lesions, lymphadenopathy, migratory joint and muscle pain, cardiac arrhythmias, and meningitis often associated with cranial nerve involvement. In Europe, *B. alfzelii* is associated with borrelial lymphocytoma, in which there is blue to red swelling of the earlobe or nipple, with lymphocytic infiltration.
- The third stage, *late disseminated disease,* manifests many months after the tick bite. *B. burgdorferi* usually causes a chronic arthritis sometimes with severe damage to large joints. Less often, patients will have polyneuropathy and encephalitis that vary from mild to debilitating. Lyme encephalopathy is less common in Europe than in the United States.

Pathogenesis

B. burgdorferi does not produce endotoxin or exotoxins that damage the host. Much of the pathology associated with the infection is thought to be secondary to the immune response against the bacteria and the inflammation that accompanies it. The initial immune response is stimulated by binding of bacterial lipoproteins to TLR2 on macrophages. In response, these cells release pro-inflammatory cytokines (IL-6 and TNF) and generate bactericidal reactive nitrogen intermediates, reducing but usually not eliminating the infection.

The inflammatory lesions are likely triggered by T cells and cytokines. *Borrelia*-specific antibodies, made 2 to 4 weeks

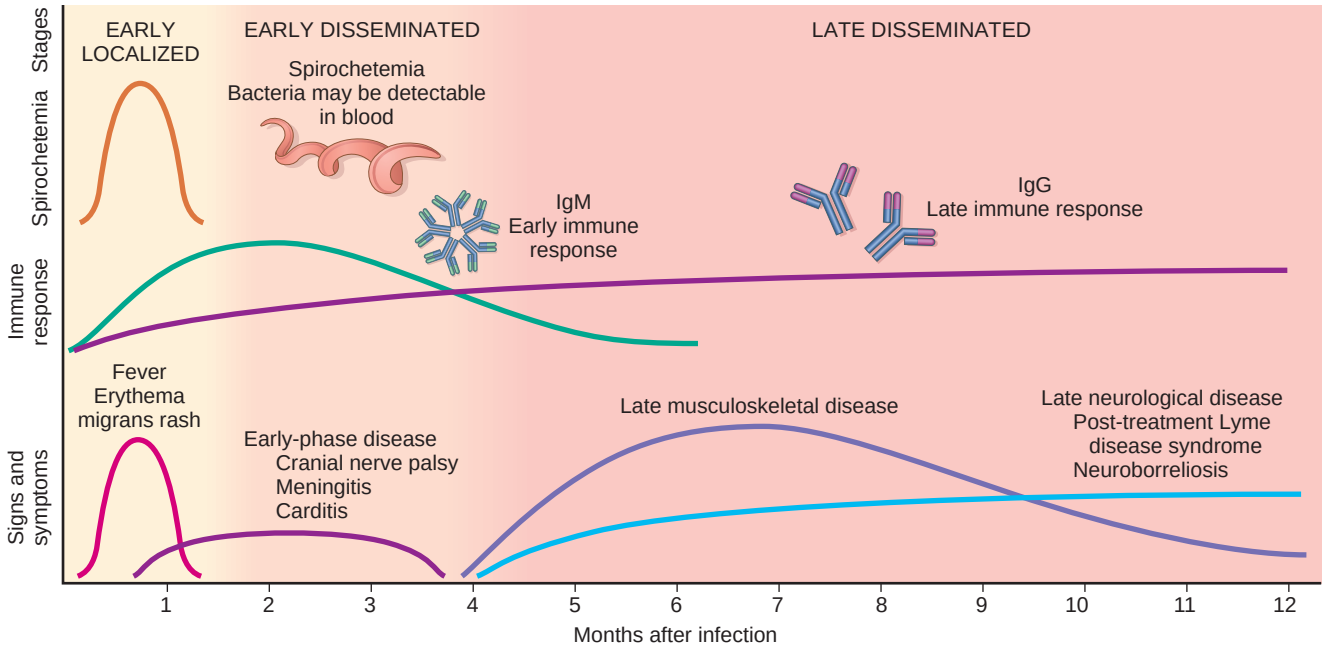

Figure 8.36 Lyme disease progresses through three clinically recognizable phases: early localized, early disseminated, and late disseminated. Although initial manifestations result directly from spirochete infection, later signs and symptoms are likely immune-mediated. (Figure modified from Dr. Charles Chiu, University of California, San Francisco, Calif. Used with permission.)

after infection, direct complement-mediated phagocytosis and killing of the bacteria; however, *B. burgdorferi* escapes the antibody response through antigenic variation. *B. burgdorferi* has a plasmid with a single promoter sequence and multiple coding sequences for an antigenic surface protein, VlsE, each of which can shuttle into position next to the promoter and be expressed. Thus, as the antibody response to one VlsE protein is mounted, bacteria expressing an alternate VlsE protein emerge and can escape immune recognition. Chronic manifestations of Lyme disease, such as late arthritis, may be caused by the immune response against some, as yet unknown, bacterial antigen that cross-reacts with a self antigen.

MORPHOLOGY

Skin lesions caused by *B. burgdorferi* are characterized by edema and a lymphocytic-plasma cell infiltrate. In early Lyme arthritis, the synovium resembles early rheumatoid arthritis, with villous hypertrophy, lining-cell hyperplasia, and abundant lymphocytes and plasma cells in the subsynovium. A distinctive feature of Lyme arthritis is an arteritis, which produces onionskin-like lesions resembling those seen in lupus (Chapter 6). In late Lyme disease, there may be extensive erosion of the cartilage in large joints. In Lyme meningitis, the CSF is hypercellular due to a marked lymphoplasmacytic infiltrate, and it contains antispirochete IgGs.

Anaerobic Bacterial Infections

Many anaerobic bacteria are normal microbiota in sites of the body that have low oxygen levels. The anaerobic microbiota cause disease (such as abscesses or peritonitis) when they are introduced into normally sterile sites or when the balance of organisms is upset and pathogenic anaerobes overgrow (e.g., *C. difficile* colitis with antibiotic treatment). Environmental anaerobes also cause disease (tetanus, botulism, and gas gangrene).

Abscesses

Commensal bacteria from adjacent sites (oropharynx, intestine, and female genital tract) are the usual cause of abscesses, so the species found in an abscess often reflect the normal microbiota in that site. Abscesses are usually caused by mixed anaerobic and facultative aerobic bacterial infections. Because most anaerobes that cause abscesses are part of the normal microbiota it is not surprising that these organisms do not produce significant toxins.

The bacteria found in head and neck abscesses reflect oral and pharyngeal microbiota. Common anaerobes at this site include the gram-negative bacilli *Prevotella* spp. and *Porphyromonas* spp., often mixed with the facultative *S. aureus* and *S. pyogenes*. *Fusobacterium necrophorum,* an oral commensal, causes Lemierre syndrome, characterized by infection of the lateral pharyngeal space and septic jugular vein thrombosis. Abdominal abscesses are caused by the anaerobes of the gastrointestinal tract, including gram-positive *Peptostreptococcus* spp. and *Clostridium* spp., as well as gram-negative *Bacteroides fragilis* and *E. coli*. Genital tract infections in women (e.g., Bartholin cyst abscesses and tubo-ovarian abscesses) are caused by anaerobic gram-negative bacilli, such as *Prevotella* spp., often mixed with *E. coli* or *S. agalactiae*.

MORPHOLOGY

Abscesses caused by anaerobes contain discolored and foul-smelling pus that is often poorly walled off. Otherwise, these lesions pathologically resemble those of the common pyogenic infections. Gram stain reveals mixed infection with gram-positive and gram-negative rods and gram-positive cocci mixed with neutrophils.

Clostridial Infections

Clostridium spp. are gram-positive bacilli that grow under anaerobic conditions and produce spores that are present in the soil. Four types of disease are caused by *Clostridium* spp.:

- *C. perfringens, C. septicum,* and other species cause cellulitis and myonecrosis of traumatic and surgical wounds *(gas gangrene),* uterine myonecrosis often associated with illegal abortions, mild food poisoning, and infection of the small bowel associated with ischemia or neutropenia that often leads to severe sepsis. Spontaneous gas gangrene due to *C. septicum* is highly associated with an underlying malignancy.
- *C. tetani,* the cause of *tetanus,* proliferates in puncture wounds and in the umbilical stump of newborn infants and releases a potent neurotoxin that causes increased muscle tone and generalized spasms of skeletal muscles (lockjaw). Tetanus toxoid (formalin-fixed tetanus toxin) is part of the DPT (diphtheria, pertussis, and tetanus) immunization, and this has greatly decreased the incidence of tetanus worldwide.
- *C. botulinum*, the cause of *botulism,* grows in inadequately cooked foods and releases a potent neurotoxin that blocks synaptic release of acetylcholine and causes flaccid paralysis of respiratory and skeletal muscles.
- *C. difficile* proliferates in the intestines when competition by normal commensal microbiota is reduced by antibiotic treatment. The bacteria release toxin and cause *pseudomembranous colitis* (Chapter 17).

Clostridial infections can be diagnosed by culture (cellulitis, myonecrosis), PCR assays that detect the toxin (pseudomembranous colitis), or both (botulism).

Pathogenesis

C. perfringens does not grow in the presence of oxygen, so tissue death is essential for growth of the bacteria in the host. These bacteria release collagenase and hyaluronidase that degrade extracellular matrix proteins and contribute to bacterial invasiveness, but their most powerful virulence factors are the many toxins they produce. *C. perfringens* secretes 14 toxins, the most important of which is α-toxin. This toxin has multiple actions. It is a phospholipase that degrades lecithin, a major component of cell membranes, and so destroys red cells, platelets, and muscle cells, causing myonecrosis. It also has a sphingomyelinase activity that contributes to nerve sheath damage.

Ingestion of food contaminated with *C. perfringens* causes a brief diarrhea. Spores, usually in contaminated meat, survive cooking, and the organism proliferates in cooling food. *C. perfringens* enterotoxin forms pores in the epithelial cell membranes, lysing the cells and disrupting tight junctions between epithelial cells.

The neurotoxins produced by *C. botulinum* and *C. tetani* both inhibit release of neurotransmitters, resulting in paralysis. Botulism toxin, eaten in contaminated foods or absorbed from wounds infected with *C. botulinum,* binds gangliosides on motor neurons and is transported into the cell. In the cytoplasm, the A fragment of botulism toxin cleaves a protein called synaptobrevin that mediates fusion of neurotransmitter-containing vesicles with the neuron membrane. By blocking vesicle fusion, botulism toxin prevents the release of acetylcholine at the neuromuscular junction, resulting in flaccid paralysis. If the respiratory muscles are affected, botulism can lead to death. The widespread use of botulism toxin (Botox) in cosmetic surgery is based on its ability to cause paralysis of strategically chosen muscles on the face. Tetanus toxin causes a violent spastic paralysis by blocking release of γ-aminobutyric acid, a neurotransmitter that inhibits motor neurons.

C. difficile produces toxin A, an enterotoxin that stimulates chemokine production and thus attracts leukocytes, and toxin B, a cytotoxin that causes distinctive cytopathic effects in cultured cells. Both toxins are glucosyl transferases and are part of a pathogenicity island that is absent from the chromosomes of nonpathogenic strains of *C. difficile*. There has been significant success in treatment of *C. difficile* with fecal transplantation, emphasizing the role of normal commensal microbiota in defense against pathogens.

MORPHOLOGY

The most significant lesions are caused by *C. perfringens;* these are described next. **Clostridial cellulitis,** which originates in wounds, can be differentiated from infection caused by pyogenic cocci by its foul odor, its thin, discolored exudate, and the relatively quick and wide tissue destruction. On microscopic examination, the amount of tissue necrosis is disproportionate to the number of neutrophils and gram-positive bacteria present (Fig. 8.37). Clostridial cellulitis, which often has granulation tissue at its borders, is treatable by debridement and antibiotics.

In contrast, **clostridial gas gangrene** is life-threatening and is characterized by marked edema and enzymatic necrosis of involved muscle cells 1 to 3 days after injury. An extensive fluid exudate, which is lacking in inflammatory cells, causes swelling of the affected region and the overlying skin, which develops large bullous vesicles that rupture. Gas bubbles caused by bacterial fermentation appear within the gangrenous tissues. As the infection progresses, the inflamed muscles become soft, blue-black, friable, and semifluid as a result of the massive proteolytic action of the released bacterial enzymes. On microscopic examination, there is severe **myonecrosis,** extensive hemolysis, and marked vascular injury with thrombosis. *C. perfringens* is also associated with

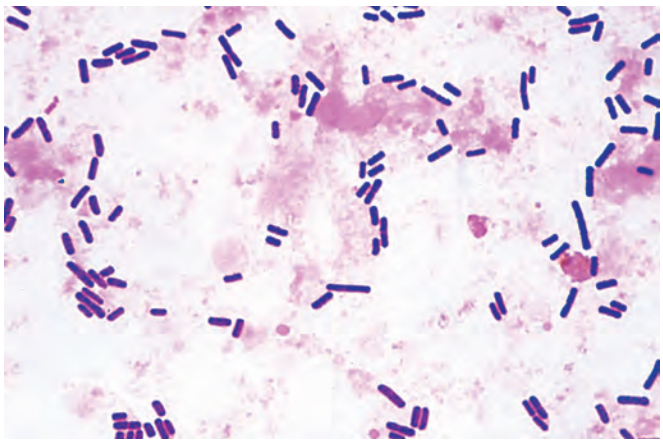

Figure 8.37 Boxcar-shaped gram-positive *Clostridium perfringens* intermingled with necrotic debris in gangrenous tissue.

dusk-colored, wedge-shaped infarcts in the small bowel, particularly in neutropenic people. Regardless of the site of entry, when *C. perfringens* disseminates hematogenously, there is widespread formation of gas bubbles.

Despite the severe neurologic damage caused by botulinum and tetanus toxins, the neuropathologic changes are subtle and nonspecific.

Obligate Intracellular Bacterial Infections

Obligate intracellular bacteria proliferate only within host cells, although some may survive outside of cells. These organisms are well adapted to the intracellular environment, with membrane pumps to capture amino acids and ATP for energy. Some are unable to synthesize ATP at all (e.g., *Chlamydia* spp.), and others synthesize at least some of their own ATP (e.g., the rickettsiae).

Chlamydial Infections

C. trachomatis is a small gram-negative bacterium that is an obligate intracellular pathogen. *C. trachomatis* exists in two forms during its unique life cycle. The infectious form, called the elementary body, is metabolically inactive. Elementary bodies use a type III secretion system to inject a protein, TARP, into host cells, leading to actin remodeling at the site of bacterial entry into the host cell by phagocytosis. The elementary body differentiates into a metabolically active form, called the reticulate body, within a membrane-bound inclusion derived from the endosome. The bacteria modify the inclusion to prevent it from trafficking as an endosome and maturing into an inhospitable phagolysosome. Host lipids, typically found in the Golgi apparatus, and GTPases typical of recycling endosomes and the Golgi apparatus are recruited to the inclusion, marking the inclusion as a nonphagocytic compartment. The reticulate body uses ATP and amino acids from the host cell to replicate and forms new infectious elementary bodies that lyse or are extruded from the infected cell.

The diseases caused by *C. trachomatis* infection are associated with different serotypes of the bacteria: urogenital infections and inclusion conjunctivitis are caused by serotypes D to K, lymphogranuloma venereum by serotypes L1, L2, and L3, and an ocular infection of children, trachoma, by serotypes A, B, and C. The venereal infections caused by *C. trachomatis* are discussed here.

Genital infection by *C. trachomatis* is the most common bacterial STI in the world. In 2016, approximately 1.6 million cases of genital chlamydia were reported to the CDC. The rate of genital chlamydia in the United States has risen fairly steadily over the past 10 years. Genital *C. trachomatis* infections (other than lymphogranuloma venereum, discussed later) are associated with clinical features that are similar to those caused by *N. gonorrhoeae*. Patients may develop epididymitis, prostatitis, pelvic inflammatory disease, pharyngitis, conjunctivitis, perihepatic inflammation, and proctitis. Unlike *N. gonorrhoeae* urethritis, *C. trachomatis* urethritis in men may be asymptomatic and so may go untreated. Both *N. gonorrhoeae* and *C. trachomatis* frequently cause asymptomatic infections in women. *C. trachomatis* urethritis can be diagnosed using amplified nucleic acid tests performed on genital swabs or urine specimens.

Genital infection with the L serotypes of *C. trachomatis* causes *lymphogranuloma venereum*, a chronic, ulcerative disease. Lymphogranuloma venereum is a sporadic disease in the United States and Western Europe, but it is endemic in parts of Asia, Africa, the Caribbean region, and South America. The infection initially manifests as a small, often unnoticed, papule on the genital mucosa or nearby skin. Two to 6 weeks later, growth of the organism and the host response in draining lymph nodes produce swollen, tender lymph nodes, which may coalesce and rupture. If not treated, the infection can subsequently cause fibrosis and strictures in the anogenital tract. Rectal strictures are particularly common in women.

MORPHOLOGY

The features of *C. trachomatis* **urethritis** are virtually identical to those of gonorrhea. The primary infection is characterized by a mucopurulent discharge containing a predominance of neutrophils. Organisms are not visible in Gram-stained smears or sections.

The lesions of **lymphogranuloma venereum** contain a mixed granulomatous and neutrophilic inflammatory response. Variable numbers of chlamydial inclusions are seen in the cytoplasm of epithelial cells or inflammatory cells. Regional lymphadenopathy is common, usually occurring within 30 days of infection. Lymph node involvement is characterized by a granulomatous inflammatory reaction associated with irregularly shaped foci of necrosis containing neutrophils (stellate abscesses). With time, the inflammatory reaction is dominated by nonspecific chronic inflammatory infiltrates and extensive fibrosis. The latter, in turn, may cause local lymphatic obstruction, lymphedema, and strictures. In active lesions, the diagnosis of lymphogranuloma venereum may be made by demonstration of the organism in biopsy sections or smears of exudate. In more chronic cases, the diagnosis rests with the demonstration of antibodies to the appropriate chlamydial serotypes in the patient's serum.

Infections Caused by Other Intracellular Bacteria

Rickettsia spp., *Orientia* spp., *Ehrlichia* spp., and *Anaplasma* spp. are vector-borne obligate intracellular bacteria that cause epidemic and scrub typhus, spotted fevers (*Rickettsia rickettsii* and others), ehrlichiosis, and anaplasmosis. These organisms have the structure of gram-negative, rod-shaped bacteria, although they stain poorly with Gram stain.

- *Epidemic typhus* (caused by *Rickettsia prowazekii*) is transmitted from person to person by body lice. It is associated with wars and poverty, when individuals live in close contact with poor hygiene. Manifestations include a rash that is initially macular, progressing to a petechial, maculopapular rash on the entire body except the face, palms, and soles.
- *Scrub typhus* (caused by *Orientia tsutsugamushi*) is transmitted by chiggers (mites). It is endemic in areas of Asia and Australia, and it has recently emerged in South Korea, Chile, and areas of China. Fever, headache, myalgia, and cough are usual symptoms, sometimes accompanied by a characteristic eschar and associated lymphadenopathy from the chigger bite.
- *Rocky Mountain spotted fever* (caused by *Rickettsia rickettsii*) is transmitted to humans by dog ticks. It is most common

in the southeastern and south-central United States. It begins as a nonspecific severe illness with fever, myalgias, and gastrointestinal distress, and then progresses to a widespread macular then petechial rash that can involve the palms and soles.

- *Ehrlichiosis* (caused mainly by *Ehrlichia chaffeensis*) and *anaplasmosis* (*Anaplasma phagocytophilum*) are transmitted by the lone star tick and deer tick, respectively. These bacteria predominantly infect monocytes *(E. chaffeensis)* or neutrophils *(A. phagocytophilum)*. Ehrlichiosis and anaplasmosis are characterized by abrupt onset of fever, headache, and malaise, and may progress to respiratory insufficiency, renal failure, and shock. Rash occurs in approximately 40% of people with *E. chaffeensis* infections.

Rickettsial diseases are usually diagnosed clinically and confirmed by serology or immunostaining of the organisms.

Pathogenesis

The severe manifestations of rickettsial infections are primarily due to infection of endothelial cells and the consequent endothelial dysfunction and injury. The rickettsiae that cause typhus and spotted fevers predominantly infect vascular endothelial cells, especially those in the lungs and brain. The bacteria enter cells by endocytosis, but escape from the endosome into the cytoplasm using hemolysins to disrupt phagosomal membranes. The organisms proliferate in the endothelial cell cytoplasm and then either lyse the cell (typhus group) or spread from cell to cell using actin-based motility (spotted fever group). The widespread endothelial dysfunction can cause shock, peripheral and pulmonary edema, and DIC, as well as renal failure and a variety of CNS manifestations that can include coma.

The innate immune response to rickettsial infection is complex, but includes NK cells, which produce IFN-γ. Subsequent CTL responses are critical for elimination of rickettsial infections. IFN-γ and TNF produced by activated NK cells and T cells stimulate the production of bactericidal nitric oxide derivatives. CTLs lyse infected cells, reducing bacterial proliferation.

MORPHOLOGY

Typhus Fever. In mild cases, the gross changes are limited to a rash and small hemorrhages due to the vascular lesions. In more severe cases, there may be areas of necrosis of the skin and gangrene of the tips of the fingers, nose, earlobes, scrotum, penis, and vulva. In such cases, irregular ecchymotic hemorrhages may be found internally, principally in the brain, heart muscle, testes, serosal membrane, lungs, and kidneys.

The most prominent microscopic changes are small vessel lesions and focal areas of hemorrhage and inflammation in various organs and tissues. Endothelial swelling in the capillaries, arterioles, and venules may narrow the lumens of these vessels. A cuff of mononuclear inflammatory cells usually surrounds the affected vessel. The vascular lumens are sometimes thrombosed. Necrosis of the vessel wall is unusual in typhus (compared with Rocky Mountain spotted fever). Vascular thromboses lead to gangrenous necrosis of the skin and other structures in a minority of cases. In the brain, characteristic typhus nodules are composed of focal microglial proliferations with an infiltrate of mixed T lymphocytes and macrophages (Fig. 8.38).

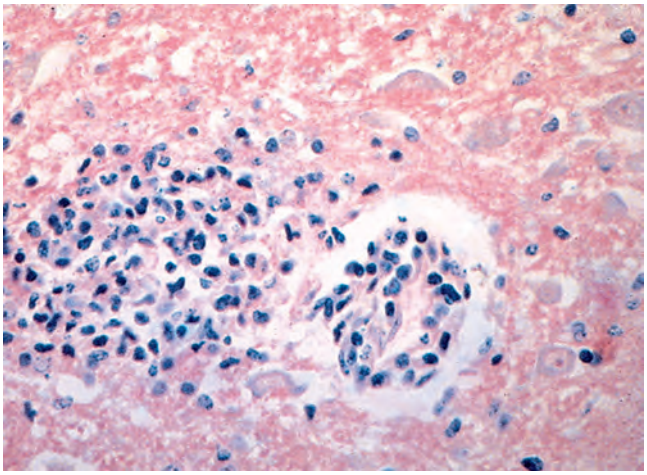

Figure 8.38 Typhus nodule in the brain.

Scrub typhus, or mite-borne infection, is usually a milder version of typhus fever. The rash is usually transitory or might not appear. Vascular necrosis or thrombosis is rare, but there may be a prominent inflammatory lymphadenopathy.

Rocky Mountain Spotted Fever. A hemorrhagic rash that extends over the entire body, including the palms of the hands and soles of the feet, is the hallmark of Rocky Mountain spotted fever. An eschar at the site of the tick bite is uncommon with Rocky Mountain spotted fever but is often seen with *R. akari, R. africae,* and *R. conorii* infection. The vascular lesions that underlie the rash often lead to acute necrosis, fibrin extravasation, and occasionally thrombosis of the small blood vessels, including arterioles (Fig. 8.39). In severe Rocky Mountain spotted fever, foci of necrotic skin appear, particularly on the fingers, toes, elbows, ears, and scrotum. The perivascular inflammatory response, similar to that of typhus, is seen in the brain, skeletal muscle, lungs, kidneys, testes, and heart muscle. The vascular lesions in the brain may involve larger vessels and produce microinfarcts. A noncardiogenic pulmonary edema causing adult respiratory distress

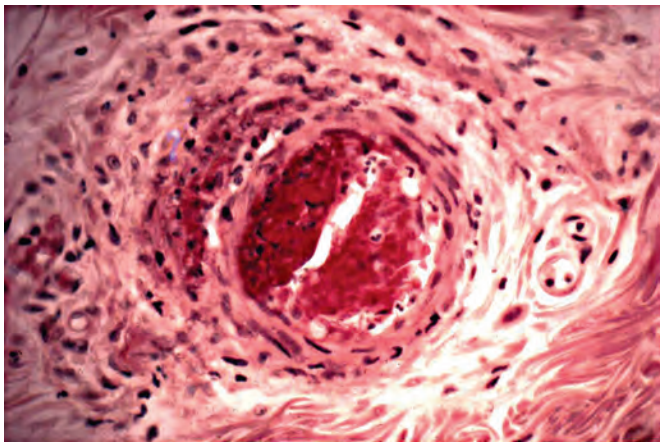

Figure 8.39 Rocky Mountain spotted fever with a thrombosed vessel and vasculitis.

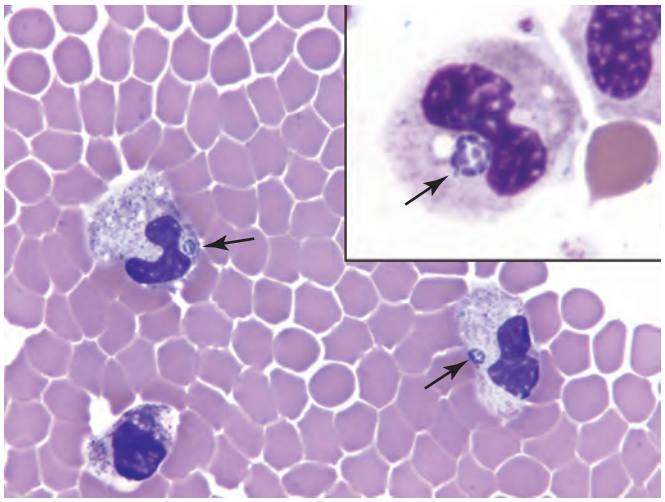

Figure 8.40 Peripheral blood granulocytes (band neutrophils) containing *Anaplasma* inclusions *(arrows).* (Courtesy Dr. Tad Weiczorek, Faulkner Hospital, Boston, Mass.)

syndrome is the major cause of death in patients with Rocky Mountain spotted fever.

Ehrlichiosis and **anaplasmosis** have similar presentations. The rash is nonspecific and can be macular, maculopapular, or petechial. Characteristic cytoplasmic inclusions (morulae), composed of masses of bacteria that occasionally take the shape of a mulberry, are present in leukocytes (Fig. 8.40).

FUNGAL INFECTIONS

Fungi are eukaryotes that grow as multicellular filaments (mold) or individual cells alone or in chains (yeast). Cell walls give fungi their shape. Yeasts are round to oval and mainly reproduce by budding. Some yeasts, such as *C. albicans,* can produce buds that fail to detach and become elongated, producing a chain of elongated yeast cells called *pseudohyphae*. Molds consist of threadlike filaments (hyphae) that grow and divide at their tips. They can produce round cells called *conidia* that easily become airborne, disseminating the fungus. Many medically important fungi are *dimorphic,* existing as yeast or molds, depending on environmental conditions (yeast forms at human body temperature and mold forms at room temperature). Fungal infections can be diagnosed by histologic examination, although definitive identification of some species requires culture.

Fungal infections, also called *mycoses,* are of four major types:

- *Superficial and cutaneous mycoses* are common and limited to the very superficial or keratinized layers of skin, hair, and nails.
- *Subcutaneous mycoses* involve the skin, subcutaneous tissues, and lymphatics and rarely disseminate systemically.
- *Endemic mycoses* are caused by dimorphic fungi that can produce serious systemic illness in healthy individuals.
- *Opportunistic mycoses* can cause life-threatening systemic diseases in individuals who are immunosuppressed or who carry implanted prosthetic devices or vascular catheters. Some of the fungi that cause opportunistic mycoses are discussed in the following sections; those involving specific organs are discussed in other chapters.

Yeast Infections

Candidiasis

***C. albicans* is the most prevalent fungal pathogen of humans.** Although there are more than 200 species of *Candida,* there are about 15 to 20 species that are frequently seen in human infections, with *C. glabrata, C. tropicalis, C. parapsilosis,* and *C. krusei* being more frequent. This section will focus on *C. albicans.*

Most *C. albicans* infections originate when these normal commensal microbiota breach the skin or mucosal barriers. Residing normally in the skin, mouth, gastrointestinal tract, and vagina, *Candida* spp. usually live as benign commensals and seldom produce disease in healthy people. These infections may be confined to the skin or mucous membranes or may disseminate widely. In otherwise healthy people, *C. albicans* causes vaginitis and diaper rash. Individuals with diabetes and burn patients are particularly susceptible to superficial candidiasis. In individuals with indwelling intravenous lines or catheters, or undergoing peritoneal dialysis, *C. albicans* can spread to the bloodstream. Severe disseminated candidiasis most commonly occurs in patients who are neutropenic due to leukemia, chemotherapy, or hematopoietic stem cell transplantation, and may cause shock and DIC.

Pathogenesis

A single strain of *C. albicans* can be successful as a commensal or a pathogen. There is no known environmental reservoir for *C. albicans,* unlike other *Candida* spp., and *C. albicans* has developed multiple adaptive mechanisms to complete its life cycle fully within the human host. *C. albicans* can shift between nine distinct cell shapes. Phenotypic switching involves coordinated transcriptional regulation of phase-specific genes and provides a way for *C. albicans* to adapt to changes in the environment such as temperature, nutrient availability, antibiotic therapy, or the immune response. These variants can exhibit altered colony morphology, cell shape, antigenicity, and virulence.

C. albicans produces a large number of functionally distinct adhesins involved in binding to fibrinogen, fibronectin, laminin, epithelial cells, and endothelial cells. *C. albicans* also produces a number of enzymes that contribute to invasiveness, including at least nine secreted aspartyl proteinases, which may promote tissue invasion by degrading extracellular matrix proteins, and catalases, which may enable the organism to resist oxidative killing by phagocytic cells.

The ability of *C. albicans* to grow as biofilms also contributes to its capacity to cause disease, with at least 30 factors identified to play a role in adhesion, maturation, and dispersion that affect biofilm formation. The biofilms are microbial communities consisting of mixtures of yeast, filamentous forms, and fungal-derived extracellular matrix. *C. albicans* can form biofilms on implanted medical devices that reduce the organism's susceptibility to immune responses and antifungal drug therapy.

Neutrophils, macrophages, and Th17 cells are important for protection against *Candida* infection.

- Neutrophils and macrophages phagocytose *C. albicans*, and oxidative killing by these phagocytes is a first line of host defense. The important role of neutrophils and macrophages is illustrated by the increased risk of *C. albicans* infection in individuals with neutropenia or defects in NADPH oxidase or myeloperoxidase. Filamentous forms, but not yeast, can escape from phagosomes and enter the cytoplasm and proliferate.
- *C. albicans* yeast forms activate dendritic cells through multiple pathways, more so than do the filamentous forms of the fungi. For example, β-1,3-glucan expressed by the yeast engages dectin on dendritic cells and induces IL-6 and IL-23 production, which promotes Th17 responses. The Th17 responses elicited by *C. albicans* promote the recruitment of neutrophils and monocytes (Chapter 6). These responses are critical for protection against *C. albicans* infection, as shown by recurrent mucocutaneous candidiasis in individuals with either low T-cell counts due to HIV infection or inherited defects in Th17 cell development.

MORPHOLOGY

In tissue sections, *C. albicans* can appear as yeast, pseudohyphae, and, less commonly, true hyphae, defined by the presence of septae, such as under reduced oxygen tension (Fig. 8.41). Pseudohyphae, an important diagnostic clue, are a chain of budding yeast cells joined end to end at constrictions. All forms may be present together in the same tissue. The organisms may be seen in routine hematoxylin and eosin stains, but a variety of special fungal stains (Gomori methenamine-silver, periodic acid-Schiff) are commonly used to better visualize them.

Most commonly, candidiasis takes the form of a superficial infection on mucosal surfaces of the oral cavity **(thrush).** Florid proliferation of the fungi creates gray-white, dirty-looking pseudomembranes composed of matted organisms and inflammatory debris. Deep under the surface, there is mucosal hyperemia and inflammation. This form of candidiasis is seen in newborns, debilitated people, children receiving oral steroids for asthma, and following a course of broad-spectrum antibiotics that destroys competing normal bacterial microbiota. The other major risk group includes HIV-positive patients; people with oral thrush for no obvious reason should be evaluated for HIV infection.

C. albicans **esophagitis** is commonly seen in AIDS patients and in those with hematologic malignancies. These patients present with dysphagia (painful swallowing) and retrosternal pain; endoscopy demonstrates white plaques and pseudomembranes resembling oral thrush on the esophageal mucosa (see Fig. 8.41).

C. albicans **vaginitis** is common, especially in women who are diabetic, pregnant, or on oral contraceptive pills. It is usually associated with intense itching and a thick, curdlike discharge.

Cutaneous candidiasis can present in many different forms, including infection of the nail proper (onychomycosis); nail folds (paronychia); hair follicles (folliculitis); moist, intertriginous skin,

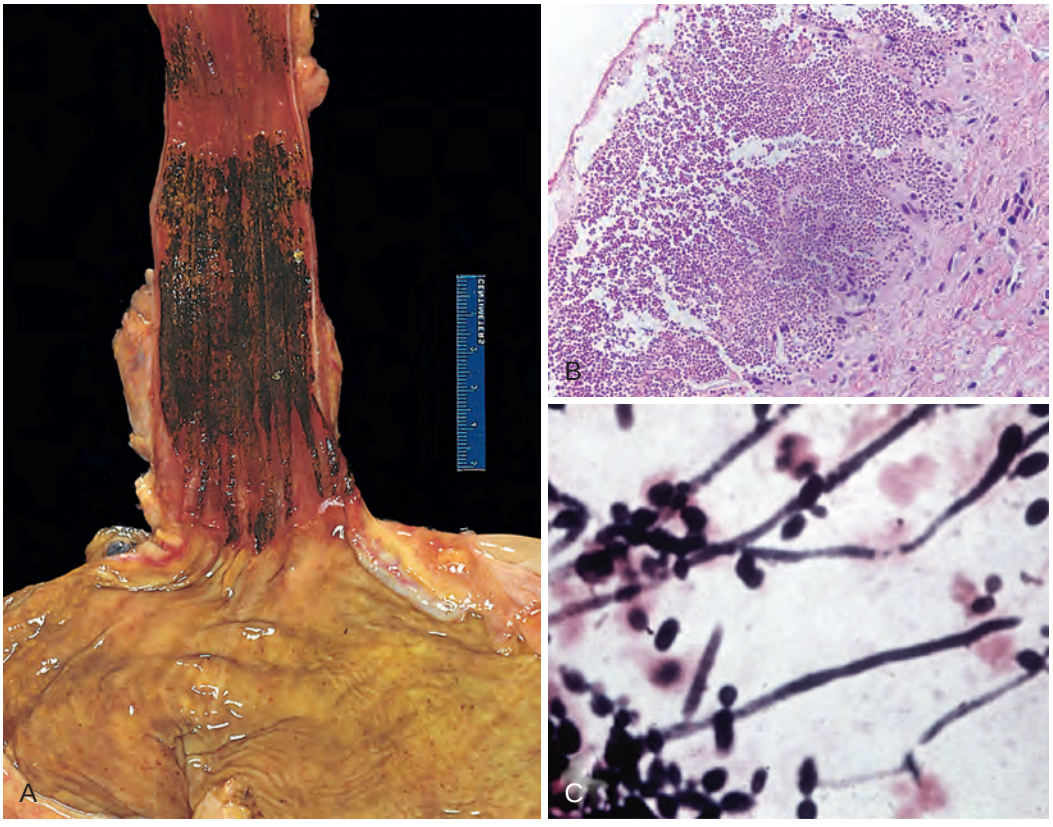

Figure 8.41 The morphology of Candida infections. (A) Severe candidiasis of the distal esophagus. (B) Hematoxylin and eosin stain of esophageal candidiasis reveals the dense mat of *Candida* spp. (C) Characteristic pseudohyphae and budding yeast of *Candida* spp. (C, Courtesy Dr. Dominick Cuvuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

such as armpits or webs of the fingers and toes (intertrigo); and penile skin (balanitis). Diaper rash is a cutaneous candidal infection seen in the perineum of infants, the region in contact with wet diapers.

Invasive candidiasis is caused by blood-borne dissemination of organisms to various tissues or organs. Common patterns include (1) renal abscesses, (2) myocardial abscesses and endocarditis, (3) brain microabscesses and meningitis, (4) endophthalmitis (virtually any eye structure can be involved), and (5) hepatic abscesses. In any of these locations, depending on the immune status of the infected person, the fungus may evoke little inflammation, cause the usual suppurative response, or occasionally produce granulomas. People with acute leukemias who are profoundly neutropenic after chemotherapy are particularly prone to developing systemic disease. *Candida* spp. endocarditis is the most common fungal endocarditis, usually occurring in the setting of prosthetic heart valves or in intravenous drug abusers. In the latter group, the tricuspid valve is involved.

Candida auris Infections

C. auris is an emerging pathogen associated with multiple nosocomial infections on five continents. Genomic analysis indicates that separate clades of this organism have emerged simultaneously in different geographic regions. Antifungal resistance of this organism and difficulty in identification of the species with traditional laboratory diagnostics have heightened concern. Increased colonization and infection with non-*albicans Candida* spp. are attributed in part to increased use of prophylactic antifungal agents. There is an association of *C. auris* with intensive care units and central venous or urinary catheters, so biofilm formation is a suggested virulence mechanism of this organism. There has been variable resistance reported, but resistance to triazole antifungals and variable susceptibility to amphotericin B has been demonstrated in a number of studies. Colonization with *C. auris* has been reported in nares, groin, axilla, and rectum. Mortality in patients with invasive *C. auris* infection varies, but with some rates reported as high as 50%; attributable mortality has been difficult to determine in a vulnerable patient population with complex comorbidities. *C. auris* has been demonstrated to survive on dry and moist surfaces up to 14 days, so environmental cleaning to eliminate a source of nosocomial infections is a challenge.

Cryptococcosis

Two species of cryptococcus are known to cause disease in humans, *C. neoformans* and *C. gattii,* both of which grow as encapsulated yeasts. It has long been recognized that although *C. neoformans* may cause meningoencephalitis in otherwise healthy individuals, it more frequently presents as an opportunistic infection in people with AIDS, leukemia, lymphoma, systemic lupus erythematosus, or sarcoidosis, as well as in immunosuppressed transplant recipients. Many of these patients receive high-dose corticosteroids, a major risk factor for *C. neoformans* infection. It is estimated that there are more than 220,000 cases of cryptococcal meningitis occurring worldwide each year, with more than 180,000 associated deaths. *C. neoformans* is present in the soil and in bird (particularly pigeon) droppings and infects people when it is inhaled.

C. gattii is an obscure infectious agent that was classically viewed as a tropical or subtropical fungus until 1999, when it was identified as the cause of an outbreak of cryptococcal disease in the American Pacific Northwest and contiguous areas of British Columbia. It has subsequently been linked to cryptococcal infections in other regions of the world. Because most current tests used to diagnose cryptococcal infections do not distinguish between *C. gatti* and *C. neoformans,* the true incidence of infections caused by these two agents is currently uncertain. Based on findings from areas where *C. gattii* is now specifically monitored, it appears that *C. gattii* is more likely than *C. neoformans* to cause disease in immunologically normal individuals and to present with large lesions that produce mass effects or that mimic the radiologic appearance of a neoplasm. *C. gattii* is associated with certain species of trees, is found in soil, and, like *C. neoformans,* is acquired by inhalation.

Pathogenesis

Cryptococcus spp. have several virulence factors that enable it to evade host defenses, as follows:

- *Polysaccharide capsule.* Glucuronoxylomannan inhibits phagocytosis by alveolar macrophages, leukocyte migration, and recruitment of inflammatory cells. *Cryptococcus* spp. can block dendritic cell maturation by reducing MHC class II–dependent antigen presentation and inhibiting the production of IL-12 and IL-23. *Cryptococcus* spp. can make large cells, called *Titan cells,* that are greater than 12 µm and have a thickened cell wall. *Cryptococcus* spp. also produce small (micro) cells of 2 to 4 µm that may be adapted for growth in macrophages.
- *Melanin production.* Laccase in the yeast catalyzes the formation of melanin which (1) has antioxidant properties, (2) decreases antibody-mediated phagocytosis, (3) counteracts the effects of antifungal agents, (4) binds iron, (5) and provides cell wall integrity.
- *Enzymes.* Phospholipases degrade cell wall components and may aid tissue invasion. Urease helps neutralize the reactive oxygen species and pH of the phagocytic cell.
- *Differential cellular response to phagocytes.* A mechanism has been hypothesized to explain the success of the *C. gattii* strain in the Northwestern U.S. outbreak: In response to reactive oxygen species in the phagocyte, some cells stop growing and acquire an unusual morphology with tubularization of mitochondria, and other cells rapidly divide. Further investigation of these pathogenic pathways is needed for complete understanding.

MORPHOLOGY

Cryptococcus spp. have yeast forms, but not pseudohyphal or hyphal forms, in human hosts. **The typically 5- to 10-µm cryptococcal yeast form has a highly characteristic thick gelatinous capsule containing a polysaccharide that stains intense red with periodic acid-Schiff and mucicarmine in tissues** (Fig. 8.42) and can be detected in blood or CSF with various immunoassays. Although the lung is the primary site of infection, pulmonary involvement is usually mild and asymptomatic, even while the fungus is spreading to the CNS. *C. gattii* appears to be particularly likely to form a solitary pulmonary granuloma similar to the circumscribed (coin) lesions caused by *Histoplasma* spp.

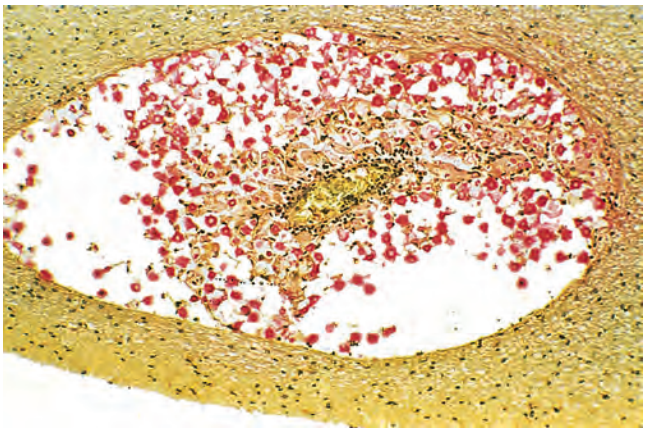

Figure 8.42 Mucicarmine stain of cryptococci *(staining red)* in a Virchow-Robin perivascular space of the brain (soap-bubble lesion).

The major lesions caused by *Cryptococcus* spp. are in the CNS, involving the meninges, cortical gray matter, and basal nuclei. The host response to cryptococci is extremely variable. In immunosuppressed people, organisms may evoke virtually no inflammatory reaction, so gelatinous masses of fungi grow in the meninges or expand the perivascular Virchow-Robin spaces within the gray matter, producing the so-called soap-bubble lesions (see Fig. 8.42). In severely immunosuppressed persons, *C. neoformans* may disseminate widely to the skin, liver, spleen, adrenals, and bones. In immunocompetent people or in those with protracted disease, the fungi induce a chronic granulomatous reaction composed of macrophages, lymphocytes, and foreign body-type giant cells. Suppuration also may occur, as well as a rare granulomatous arteritis of the circle of Willis.

Pneumocystis Infections

***P. jirovecii* is a yeastlike fungus that primarily causes lung infections and is a significant opportunistic infection in AIDS patients, despite the overall improvements seen with antiretroviral therapy.** The organism can cause a rapidly progressive, bilateral pneumonia. The organism was originally classified as a protozoal parasite, and descriptions of developmental forms reflect this historical classification. Three forms of the organism include trophozoites of 1 to 4 µm, sporocytes of 5 to 6 µm, and cysts of 5 to 8 µm. The cysts have a characteristic cup-shaped appearance, or they are oval with a central dot. Clusters of organisms in bronchoalveolar lavage fluid may be 200 µm in diameter. The nucleus and mitochondria are visible by Wright-Giemsa stain. The trophic forms are not visible with a cell wall stain such as methenamine silver, however, the sporocyst and ascus forms will be visible (Fig. 8.43). Histopathologic findings include alveolar interstitial thickening and eosinophilic honeycombed exudate in the lumen of the lung. Fluorescein-conjugated antibody stains are commonly used to diagnose these infections. Beta-D-glucan will be elevated with infection, although it is not specific for *Pneumocystis* spp., and sensitive and specific PCR tests are available for diagnosis.

Many *Pneumocystis* spp. exist, and each species is host-specific. No environmental source or external reservoir outside of humans has been identified for *P. jirovecii,* and the lack of a continuous in vitro culture method has hindered research of the pathogenesis. Transmission is believed to be via an airborne route, and there is evidence that healthy individuals might contribute to the reservoir. Most people are infected transiently early in life, with subsequent effective clearance. The average mortality rate of symptomatic infection is 10% to 14%, but it is higher in lower-income countries and urban communities. Extrapulmonary findings with *P. jirovecii* infection are not common, but can include involvement of lymph nodes, spleen, bone marrow, and liver, as well as other sites. Infection with *P. jirovecii* induces both a humoral and cellular immune response.

Mold Infections

The medically important dimorphic fungi are discussed in Chapter 15 and include *Blastomyces dermatitidis, H. capsulatum,* and *Coccidioides immitis*. This section discusses some important hyaline (transparent) molds.

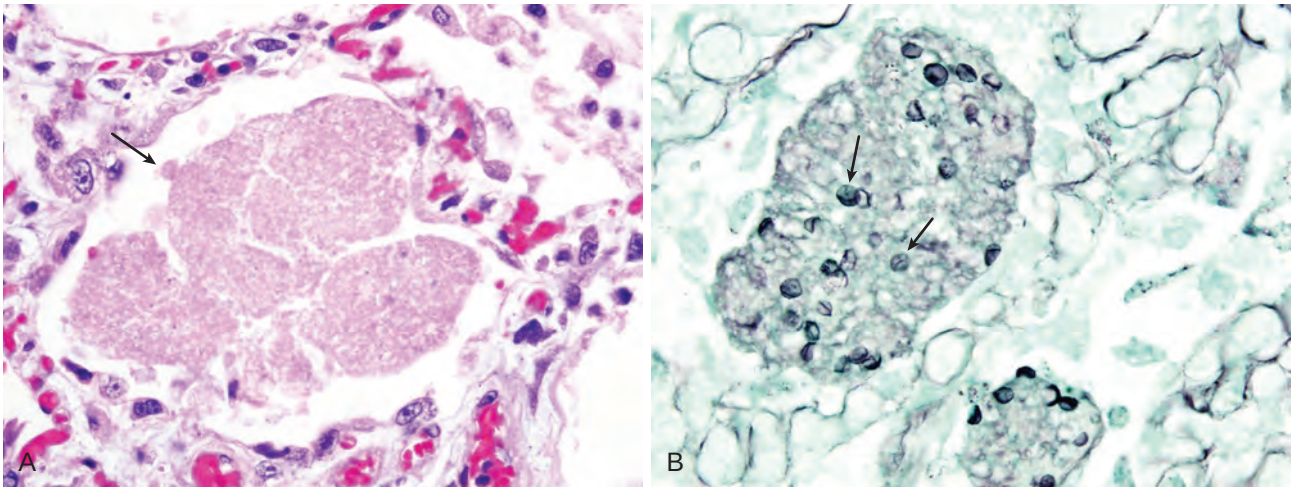

Figure 8.43 Pneumonia caused by *Pneumocystis jirovecii.* (A) Alveoli of lung filled with foamy exudate *(arrow)* and interstitial inflammation. (B) Silver stain of alveoli, showing cysts of *Pneumocystis jirovecii* stained black *(arrows).* (From Procop GW, Pritt BS: *Pathology of Infectious Diseases,* Philadelphia, 2015, Elsevier; Courtesy Dr. Ann M. Nelson, Joint Pathology Center, Silver Spring, Md.)

Aspergillosis

***Aspergillus* is a ubiquitous mold that causes allergies (allergic bronchopulmonary aspergillosis) in otherwise healthy people and serious sinusitis, pneumonia, and invasive disease in immunocompromised individuals.** The major conditions that predispose to *Aspergillus* infection are neutropenia and use of corticosteroids. *Aspergillus fumigatus* is the most common pathogenic species of the fungus.

Pathogenesis

Aspergillus spp. are transmitted as airborne conidia, and the lung is the major portal of entry. The small size of *A. fumigatus* spores, approximately 2 to 3 μm, enables them to reach alveoli. Conidia are coated in hydrophobic proteins that mask the microbial molecules from innate immune recognition. As conidia grow and form hyphae, these molecules are exposed. Alveolar macrophages recognize *Aspergillus* through TLR2 and the lectin dectin-1, which recognizes β-1,3-glucan in the fungal cell wall. Both receptors activate phagocytes to ingest and kill the conidia. In immunosuppressed states, conidia can germinate into hyphae, which then invade tissues. TLRs can recognize products of the fungal hyphae and trigger the release of pro-inflammatory mediators, including TNF, IL-1, and chemokines. Neutrophils produce reactive oxygen intermediates that kill hyphae. Invasive aspergillosis is highly associated with neutropenia and impaired neutrophil defenses.

***Aspergillus* produces several virulence factors, including adhesins, antioxidants, enzymes, and toxins.** The antioxidant defenses include melanin pigment, mannitol, catalases, and superoxide dismutases. This fungus also produces phospholipases, proteases, and toxins, but their roles in pathogenicity are not clear. *Aflatoxin* is made by *Aspergillus* spp. that grow on the surface of some crops, including corn and peanuts, particularly in warm regions if the crops are not stored or inspected appropriately. Aflatoxin causes acute and chronic hepatotoxicity and is associated with increased risk of liver cancer. Sensitization to *Aspergillus* spores produces an allergic alveolitis (Chapter 15). Allergic bronchopulmonary aspergillosis, associated with hypersensitivity arising from superficial colonization of the bronchial mucosa, often occurs in asthmatic people.

MORPHOLOGY

Colonizing aspergillosis (aspergilloma) refers to growth of the fungus in the respiratory tract with minimal or no invasion of the tissues. Colonized lung cavities are usually the result of prior tuberculosis, bronchiectasis, old infarcts, or abscesses. Proliferating masses of hyphae within proteinaceous debris form brownish "fungus balls" within the cavities. The surrounding inflammatory reaction may be sparse, or there may be chronic inflammation and fibrosis. People with aspergillomas usually have recurrent hemoptysis.

Invasive aspergillosis is an opportunistic infection that is confined to immunosuppressed hosts. The primary lesions are usually in the lung, but widespread hematogenous dissemination with involvement of the heart valves and brain is common. The pulmonary lesions take the form of necrotizing pneumonia with sharply delineated, rounded, gray foci and hemorrhagic borders; they are often referred to as target lesions (Fig. 8.44A). ***Aspergillus* forms fruiting bodies (usually in lung cavities) and septate filaments, 5 to 10 μm thick, branching at acute angles (40 degrees)** (see Fig. 8.44B). *Aspergillus* hyphae without the distinct fruiting body cannot be distinguished from *Pseudallescheria boydii* and *Fusarium* spp. by morphology alone. *Aspergillus* has a tendency to invade blood vessels, therefore areas of hemorrhage and infarction are usually superimposed on the necrotizing, inflammatory tissue reactions. Rhinocerebral *Aspergillus* infection in immunosuppressed individuals resembles that caused by Mucormycoses (e.g., *Mucor* spp., *Rhizopus* spp.).

Mucormycosis (Zygomycosis)

Mucormycotina are widely distributed in nature and cause no harm to immunocompetent individuals, but they infect immunosuppressed people, causing mucormycosis. Mucormycosis (formerly *zygomycosis*) is an opportunistic infection caused by environmental fungi, including *Mucor* spp., *Rhizopus* spp., and *Cunninghamella* spp., which belong to the subphylum *Mucormycotina*. Major predisposing factors are neutropenia, corticosteroid use, diabetes mellitus, iron overload, and breakdown of the cutaneous barrier (e.g., as a result of burns, surgical wounds, or trauma).

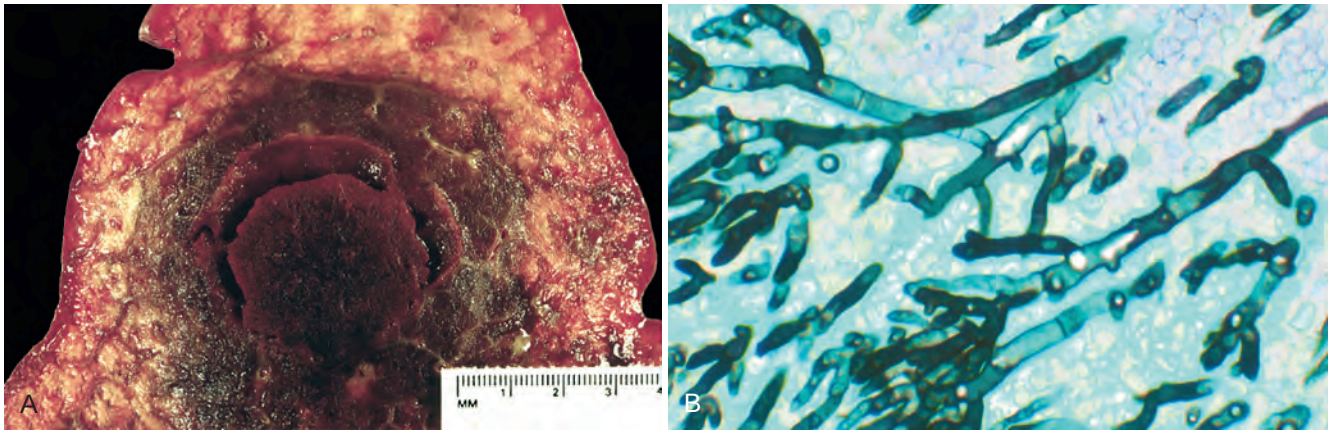

Figure 8.44 *Aspergillus* infection. (A) Invasive aspergillosis of the lung in a bone marrow transplant patient. (B) Gomori methenamine-silver stain shows septate hyphae with acute-angle branching, consistent with *Aspergillus*.

Pathogenesis

Mucormycotina are transmitted by airborne asexual spores. Inhalation of spores is the most common route of entry into the body, but percutaneous exposure or ingestion can also lead to infection. Macrophages provide the initial defense by phagocytosis and nonoxidative killing of germinating sporangiospores. *Mucormycotina* hyphal components are recognized by TLR2, which results in a pro-inflammatory cascade of cytokines including IL-6 and TNF. Neutrophils have a key role in killing hyphae after germination by directly damaging hyphae walls. If the macrophages or neutrophils are compromised in number or function, the probability of an established and then invasive infection is greatly increased. For unknown reasons, different *Mucor* species vary in resistance to phagocytosis of spores and in neutrophil damage to hyphae; thus, some infections can appear more aggressive than others despite a similar host milieu. The availability of free iron (a promoter of *Mucormycotina* growth) increases the probability of infection, as seen in people with diabetes (increased free iron due to ketoacidosis and/or glycosylation-induced poor iron affinity) and patients on chronic iron chelation treatment (where deferoxamine acts as a siderophore for the fungi).

MORPHOLOGY

Mucormycetes form nonseptate hyphae of variable width (6 to 50 μm) with frequent right-angle branching, distinct from *Aspergillus* hyphae, which are readily demonstrated by hematoxylin and eosin or special fungal stains (Fig. 8.45). The three primary sites of invasion are the nasal sinuses, lungs, and gastrointestinal tract, depending on whether the spores (which are widespread in dust and air) are inhaled or ingested. Most commonly in individuals with diabetes, the fungus may spread from nasal sinuses to the orbit and brain, giving rise to **rhinocerebral mucormycosis.** The *Mucormycotina* cause local tissue necrosis, invade arterial walls, and penetrate the periorbital tissues and cranial vault. Meningoencephalitis follows, sometimes complicated by cerebral infarctions when fungi invade arteries and induce thrombosis.

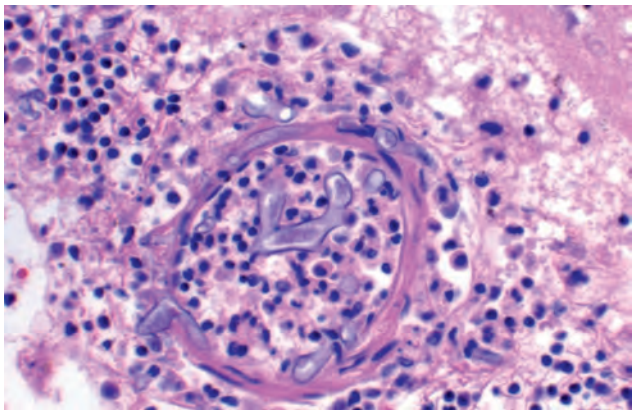

Figure 8.45 Meningeal blood vessels with angioinvasive *Mucor* spp. Note the irregular width and near right-angle branching of the hyphae. Compare with *Aspergillus*, Fig. 8.44.

Lung involvement with *Mucormycotina* may be secondary to rhinocerebral disease, or it may be primary in people with severe immunodeficiency. The lung lesions combine areas of hemorrhagic pneumonia with vascular thrombi and distal infarctions.

PARASITIC INFECTIONS

Protozoal Infections

Protozoa are unicellular eukaryotic organisms. The parasitic protozoa are transmitted by insects or by the fecal-oral route and, in humans, mainly reside in the blood or intestine (Table 8.6). Most protozoal infections are diagnosed by microscopic examination of blood smears or lesions.

Malaria

Malaria, caused by the intracellular parasite *Plasmodium,* affected an estimated 219 million people worldwide in 2017 and killed more than 435,000 people. According to the WHO, 90% of deaths from malaria occur in sub-Saharan Africa, where malaria is a leading cause of death in children younger than 5 years of age. *Plasmodium falciparum* (the cause of severe cerebral malaria) and the four other malarial parasites that infect humans (*P. vivax, P. ovale, P. knowlesi,* and *P. malariae*) are all transmitted by female *Anopheles* mosquitoes, which are widely distributed throughout Africa, Asia, and Latin America. Nearly all of the approximately 1700 new cases of malaria each year in the United States occur in travelers or immigrants. Mass spraying to eliminate the mosquito vectors was successful initially but ultimately failed when DDT was removed from the market due to environmental concerns. Worldwide public health efforts to control malaria today face the challenges of insecticide-resistant mosquitoes and drug-resistant *Plasmodium* spp. Currently, a combination of mosquito control and antimalarial drugs is viewed as the means to decrease the incidence.

Table 8.6 Selected Human Protozoal Diseases

Location	Species	Disease
Luminal or epithelial	*Entamoeba histolytica*	Amebic dysentery; liver abscess
	Balantidium coli	Colitis
	Giardia duodenalis	Diarrheal disease, malabsorption
	Cystoisospora belli	Chronic enterocolitis or malabsorption or both
	Cryptosporidium spp.	
	Trichomonas vaginalis	Urethritis, vaginitis
Central nervous system	*Naegleria fowleri*	Meningoencephalitis
	Acanthamoeba spp.	Meningoencephalitis or ophthalmitis
Bloodstream	*Plasmodium* spp.	Malaria
	Babesia spp.	Babesiosis
	Trypanosoma spp.	African sleeping sickness
Intracellular	*Trypanosoma cruzi*	Chagas disease
	Leishmania donovani	Kala-azar
	Leishmania spp.	Cutaneous and mucocutaneous leishmaniasis
	Toxoplasma gondii	Toxoplasmosis

Pathogenesis

The life cycles of the *Plasmodium* spp. are similar, although *P. falciparum* differs in ways that contribute to its greater virulence. *P. vivax*, *P. ovale*, *P. knowlesi,* and *P. malariae* cause low levels of parasitemia, mild anemia, and, in very rare instances, splenic rupture and nephrotic syndrome. ***P. falciparum* infection is associated with high levels of parasitemia that may lead to severe anemia, cerebral symptoms, renal failure, pulmonary edema, and death, depending on the susceptibility of the host.**

The life cycle of *Plasmodium* spp. involves only humans and mosquitoes, but the development of the parasite is complex, as it passes through several morphologically distinct forms. The infectious stage of *Plasmodium,* the *sporozoite,* is found in the salivary glands of female mosquitoes. When the mosquito takes a blood meal, sporozoites are released into the human's blood and, within minutes, attach to and invade liver cells by binding to the hepatocyte receptor for the serum proteins thrombospondin and properdin (Fig. 8.46). Within liver cells, malarial parasites multiply, releasing as many as 30,000 *merozoites* (asexual, haploid forms) when each infected hepatocyte ruptures. During *P. falciparum* infection, rupture usually occurs within 8 to 12 weeks. In contrast, *P. vivax* and *P. ovale* form latent *hypnozoites* in hepatocytes, which cause relapses of malaria weeks to months after initial infection. The infection of the liver and development of merozoites is called the *exoerythrocytic stage*. This stage is asymptomatic. Once released from the liver, *Plasmodium* merozoites use a lectin-like molecule to bind to sialic acid residues on glycophorin molecules on the surface of red cells and invade by active membrane penetration. Within the red cells (*erythrocytic stage*), the parasites grow in a membrane-bound digestive vacuole, hydrolyzing hemoglobin through secreted enzymes. The *trophozoite* is the first stage of the parasite in the red cell and is defined by the presence of a single chromatin mass. The next stage, the *schizont,* has multiple chromatin masses, each of which develops into a merozoite. Upon lysis of the red cell, the new merozoites infect additional red cells. Paroxysmal fever, chills, and rigors characteristic of malaria occur when the merozoites are released into the blood. As discussed later, release of merozoites induces the host cells to produce cytokines such as TNF that cause fever. The periodicity of such paroxysms (every 24-72 hours) varies with the species of the malaria parasite. Although most malaria parasites within the red cells develop into merozoites, some parasites develop, under specific conditions, into sexual forms called *gametocytes* that infect the mosquito when it takes its blood meal.

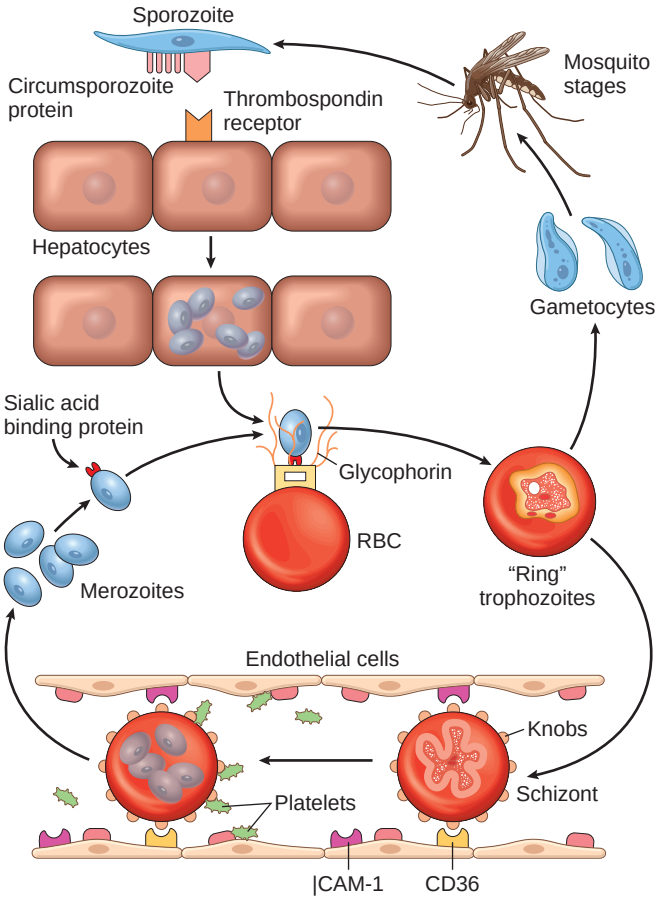

Figure 8.46 Life cycle of *Plasmodium falciparum.* Both exoerythrocytic and erythrocytic stages are depicted. *ICAM-1*, Intercellular adhesion molecule 1; *RBC*, red blood cell. (Drawn by Dr. Jeffrey Joseph, Beth Israel-Deaconess Hospital, Boston, Mass.)

Several features of *P. falciparum* account for its greater pathogenicity:

- *P. falciparum* is able to infect red blood cells of any age, whereas other species infect only young or old red cells, which are a smaller fraction of the red cell pool.
- *P. falciparum* causes infected red cells to clump together (rosette) and to stick to endothelial cells lining small blood vessels (sequestration), which blocks blood flow. Adhesive polypeptides, including *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), associate and form knobs on the surface of red cells (see Fig. 8.46). PfEMP1 binds to ligands on endothelial cells, including CD36, thrombospondin, VCAM-1, ICAM-1, and E-selectin. Red cell sequestration decreases tissue perfusion and leads to ischemia, which is responsible for the manifestations of cerebral malaria, the major cause of death in children with malaria.
- In *P. falciparum* infection, GPI-linked proteins, including merozoite surface antigens, are released from infected red cells and induce cytokine production by host cells. These cytokines increase fever, stimulate the production of reactive nitrogen species (leading to tissue damage), and induce expression of endothelial receptors for PfEMP1 (increasing sequestration).

Host resistance to *Plasmodium* can be intrinsic or acquired. Intrinsic resistance stems from inherited alterations that reduce the susceptibility of red cells to productive *Plasmodium* infections. Resistance may also be acquired following repeated or prolonged exposure to *Plasmodium* spp., which stimulates a partially protective immune response.

Several types of mutations affecting red cells are highly prevalent in parts of the world where malaria is endemic and are absent in other parts of the world. Most of these mutations are pathogenic in homozygous form, suggesting that they are maintained in populations due to a selective advantage for heterozygous carriers against malaria. The mutations fall into four broad classes.

- Point mutations in globin genes—sickle cell disease (HbS), HbC disease (hemoglobinopathies)
- Mutations leading to globin deficiencies—α- and β-thalassemia
- Mutations affecting red cell enzymes—glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Mutations causing red cell membrane defects—absence of DARC (Duffy surface blood group), band 3, spectrin

P. vivax enters red cells by binding to the Duffy blood group antigen, and most of the population of West Africa is not susceptible to infection by *P. vivax* because they do not have the Duffy antigen. The mechanisms of the protective effects of the other three types of mutations are less well understood.

Individuals living where *Plasmodium* is endemic often gain partial immune-mediated resistance to malaria, evidenced by reduced illness despite infection. Antibodies and T lymphocytes specific for *Plasmodium* reduce disease manifestations, although the parasite has developed strategies to evade the host immune response. *P. falciparum* uses antigenic variation to escape from antibody responses to PfEMP1 and other surface proteins. Each haploid *P. falciparum* genome has multiple genes encoding variants of these parasite proteins. At least a percentage of the parasites switch genes each generation, producing antigenically new surface proteins. CTLs may also be important in resistance to *P. falciparum*. Multiple approaches to potential vaccines are in development; current vaccine trials have demonstrated decreases in severe disease but only modest efficacy against clinical infection.

MORPHOLOGY

The diagnostic test for malaria infection is examination of a Giemsa-stained peripheral blood smear, which permits the asexual stages of the parasite to be identified within infected red cells. PCR assays are more sensitive than the smear, but are not yet accepted as the gold standard; given the potential severity of disease, it is likely that both assays should be required to rule out infection. Insertion of parasite proteins into the red cell membrane leads to recognition by macrophages, particularly in the spleen. *Plasmodium falciparum* infection leads to splenomegaly, due to both congestion and hyperplasia of the red pulp, and the spleen may eventually exceed 1000 g in weight. In chronic infections, the spleen becomes increasingly fibrotic and brittle, with a thick capsule and fibrous trabeculae. The parenchyma is gray or black because the phagocytes contain granular, brown-black, faintly birefringent hemozoin pigment. Macrophages with engulfed parasitized red cells are also numerous.

With progression of malaria, the liver becomes enlarged and pigmented. Kupffer cells are heavily laden with malarial pigment, parasites, and cellular debris, and some pigment is also present in the parenchymal cells. Pigmented phagocytic cells may be found dispersed throughout the bone marrow, lymph nodes, subcutaneous tissues, and lungs. The kidneys are often enlarged and congested with a dusting of pigment in the glomeruli and hemoglobin casts in the tubules.

In **cerebral malaria** caused by *P. falciparum,* brain vessels are plugged with parasitized red cells (Fig. 8.47). Around the vessels, there are ring hemorrhages that are probably related to local hypoxia incident to the vascular stasis and small focal inflammatory reactions (called *malarial* or *Dürck granulomata*). With more severe hypoxia, there is degeneration of neurons, focal ischemic softening, and occasionally scant inflammatory infiltrates in the meninges.

Nonspecific focal hypoxic lesions in the heart may be induced by the progressive anemia and circulatory stasis in chronically infected people. In some, the myocardium shows focal interstitial infiltrates. Finally, in the nonimmune patient, pulmonary edema or shock with DIC may cause death, sometimes in the absence of other characteristic lesions.

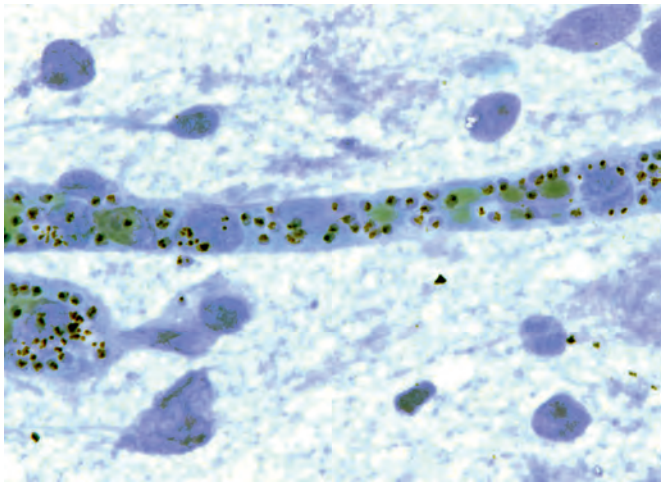

Figure 8.47 Field stain of *Plasmodium falciparum*–infected red cells marginating within a capillary in cerebral malaria.

Babesiosis

Babesia microti and *Babesia divergens,* the primary causes of babesiosis, are malaria-like protozoans transmitted in a manner similar to Lyme disease and granulocytic ehrlichiosis, by ticks, *Ixodes scapularis* (deer tick) and *Ixodes ricinus* (sheep tick), with additional cases due to *B. duncani* and *B. venatorum.* The white-footed mouse is the reservoir for *B. microti,* and in some areas, nearly all mice have a persistent low-level parasitemia. *B. microti* survives well in refrigerated blood, and a number of transfusion-acquired babesiosis cases have been reported. *Babesia* spp. parasitize red cells and cause fever and hemolytic anemia. Although most infections are asymptomatic, infection in debilitated or splenectomized individuals can cause severe, potentially fatal parasitemias.

MORPHOLOGY

In blood smears, *Babesia* spp. superficially resemble *P. falciparum* ring stages, but lack hemozoin pigment, exhibit greater pleomorphism, and form characteristic tetrads (Maltese cross), which are diagnostic, if found (Fig. 8.48). The level of *B. microti* parasitemia is a good indication of the severity of infection (about 1% in mild cases and up to 30% in splenectomized persons). In fatal cases, the anatomic findings are related to shock and hypoxia, and include jaundice, hepatic necrosis, acute renal tubular necrosis, adult respiratory distress syndrome, erythrophagocytosis, and visceral hemorrhage.

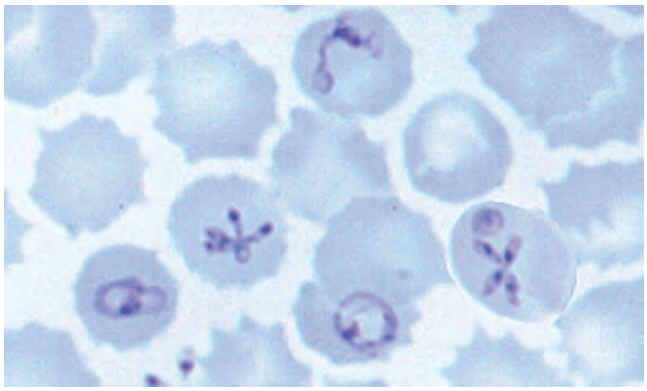

Figure 8.48 Erythrocytes with *Babesia*, including the distinctive Maltese cross form. (Courtesy Lynne Garcia, LSG and Associates, Santa Monica, Calif.)

Leishmaniasis

Leishmaniasis is a chronic inflammatory disease of the skin, mucous membranes, or viscera caused by obligate intracellular, kinetoplast-containing (kinetoplastid) protozoan parasites transmitted through the bite of infected sandflies. Leishmaniasis is endemic throughout the Middle East, South Asia, Africa, and Latin America. It may also be epidemic, as is tragically the case in Sudan, India, Bangladesh, and Brazil. There are an estimated 0.7 million to 1.2 million cases per year of cutaneous leishmaniasis, and 200,000 to 400,000 cases of visceral leishmaniasis with more than 20,000 deaths. Leishmanial infection, like infections by other intracellular organisms (mycobacteria, *Histoplasma* spp., *Toxoplasma* spp., and trypanosomes), is exacerbated by conditions that interfere with T-cell function, such as AIDS. Culture, PCR, or histologic examination is used to diagnose the infection.

Pathogenesis

The life cycle of *Leishmania* spp. involves two forms: the promastigote, which develops and lives extracellularly in the sandfly vector, and the amastigote, which multiplies intracellularly in host macrophages. There are about 21 species of *Leishmania* that infect humans and about 30 species of sandflies that serve as vectors. Mammals, including rodents, dogs, and foxes, are reservoirs of *Leishmania* spp. When sandflies bite infected humans or animals, macrophages harboring amastigotes are ingested. The amastigotes differentiate into promastigotes, multiply within the digestive tract of the sandfly, and migrate to the salivary gland, where they are poised for transmission by the fly bite. When the infected fly bites a person, the slender, flagellated infectious promastigotes are released into the host dermis along with the sandfly saliva, which potentiates parasite infectivity. The promastigotes are phagocytosed by macrophages, and the acidity within the phagolysosome induces them to transform into round amastigotes that lack flagella but contain a single mitochondrion with its DNA massed into a unique suborganelle, the kinetoplast. Amastigotes proliferate within macrophages, and dying macrophages release progeny amastigotes that can infect additional macrophages.

How far the amastigotes spread throughout the body depends on the specific *Leishmania* spp. and host, and determines the extent of disease. There are several forms of disease that are caused by different *Leishmania* spp. Old World (*L. major, L. tropica, L. donovani,* and *L. infantum*) refers to the Eastern Hemisphere (parts of Asia, the Middle East, Africa (particularly the tropical region and North Africa), and southern Europe. New World (*L. mexicana, L. braziliensis,* and *L. chagasi*) refers to the Western Hemisphere (parts of Mexico, Central America, and South America). A few cases have been acquired in Texas and Oklahoma.

***Leishmania* spp. manipulate innate host defenses to facilitate their entry and survival in phagocytes.** Promastigotes produce two abundant surface glycoconjugates that contribute to their virulence.

- Lipophosphoglycan forms a dense glycocalyx that both activates complement (leading to C3b deposition on the parasite surface) and inhibits complement action (by preventing membrane attack complex insertion into the parasite membrane). Thus, the parasite becomes coated with C3b but avoids destruction by the membrane attack complex. Instead, the C3b on the surface of the parasite binds to Mac-1 and CR1 on macrophages, targeting the promastigote for phagocytosis.
- Gp63 is a zinc-dependent proteinase that cleaves complement and some lysosomal antimicrobial enzymes. Gp63 also binds to fibronectin receptors on macrophages and promotes promastigote adhesion to macrophages.

To escape killing by neutrophils, *Leishmania* spp. use the following mechanisms: (1) interfere with the formation of phagolysosomes and fusion with granules, (2) localize to nonlytic compartments, (3) resist toxicity by reactive oxygen species, and (4) resist neutrophil extracellular trap (NET) formation by producing endonucleases that digest the NETs and expressing protease-resistant molecules.

Leishmania spp. amastigotes also produce molecules that facilitate their survival and replication within macrophages. Amastigotes reproduce in macrophage phagolysosomes, which normally have a pH of 4.5. However, the amastigotes protect themselves from this hostile environment by expressing a proton-transporting ATPase, which maintains the phagolysosome pH at 6.5.

Leishmania spp. require iron for survival, and they have an iron transporter from the ZRT-, IRT-like (ZIP) family of membrane proteins that is expressed on amastigotes and stimulates iron entry into the normally low iron environment of macrophage phagolysosomes. The host combats this iron acquisition by using pro-inflammatory cytokines to repress iron absorption (in part by increasing production of hepcidin, the principal iron exporter, and by activating synthesis of ferritin, which binds free iron. In addition, macrophages downregulate the transferrin receptor and remove iron from the phagosome.

The primary mechanisms of resistance and susceptibility to *Leishmania* spp. are determined by Th1 and Th2 responses. Parasite-specific CD4+ Th1 cells are needed to control *Leishmania* spp. in mice and humans. *Leishmania* spp. evade host immunity by impairing the development of the Th1 response. In animal models, mice that are resistant to *Leishmania* infection produce high levels of Th1-derived IFN-γ, which activates macrophages to kill the parasites. By contrast, mouse strains that are susceptible to leishmaniasis mount a dominant Th2 response. Th2 cytokines such as IL-4, IL-13,

and IL-10 prevent effective killing of *Leishmania* spp. by inhibiting the microbicidal activity of macrophages.

MORPHOLOGY

Leishmania spp. produce four different types of lesions in humans: visceral, cutaneous, mucocutaneous, and diffuse cutaneous. In **visceral leishmaniasis,** parasites invade and activate macrophages throughout the mononuclear phagocyte system (Fig. 8.49) and cause a systemic inflammatory disease marked by hepatosplenomegaly, lymphadenopathy, pancytopenia, fever, and weight loss. The spleen may weigh as much as 3 kg. Phagocytic cells are enlarged and filled with *Leishmania* spp., many plasma cells are present, and the normal architecture of the spleen is obscured. In the late stages, the liver becomes increasingly fibrotic. Phagocytic cells crowd the bone marrow and also may be found in the lungs, gastrointestinal tract, kidneys, pancreas, and testes. Often there is hyperpigmentation of the skin in individuals of South Asian ancestry, which is why the disease is called *kala-azar* (*black fever* in Hindi). In the kidneys there may be an immune complex–mediated mesangioproliferative glomerulonephritis, and in advanced cases there may be amyloid deposition. People with advanced leishmaniasis can develop life-threatening secondary bacterial infections, such as pneumonia, sepsis, or tuberculosis. Hemorrhages related to thrombocytopenia may also be fatal.

Cutaneous leishmaniasis is a relatively mild, localized disease consisting of ulcers on exposed skin. The lesion begins as a papule surrounded by induration, changes into a shallow and slowly expanding ulcer, often with heaped-up borders, and usually heals by involution within 6 to 18 months without treatment. On microscopic examination, the lesion shows granulomatous inflammation, usually with many giant cells and few parasites.

Mucocutaneous leishmaniasis is found only in the New World. Moist, ulcerating, or nonulcerating lesions develop in the nasopharyngeal areas and, with progression, may be highly destructive and disfiguring. Microscopic examination reveals a mixed inflammatory infiltrate composed of parasite-containing macrophages with lymphocytes and plasma cells. Later, the tissue inflammatory response becomes granulomatous, and the number of parasites declines. Eventually, the lesions remit and scar, although reactivation may occur after long intervals by mechanisms that are not currently understood.

Diffuse cutaneous leishmaniasis is a rare form of dermal infection found in Ethiopia and adjacent East Africa and in Central and South America. Diffuse cutaneous leishmaniasis begins as a single skin nodule, which continues spreading until the entire body is covered by nodular lesions. Microscopically, they contain aggregates of foamy macrophages stuffed with *Leishmania* organisms.

African Trypanosomiasis

African trypanosomes are kinetoplastid parasites (containing a large mass of DNA called a *kinetoplast*) that proliferate as extracellular forms in the blood and cause sustained or intermittent fevers, lymphadenopathy, splenomegaly, progressive brain dysfunction (sleeping sickness), cachexia, and death. *Trypanosoma brucei rhodesiense* infection, which occurs in East Africa and is often acute and virulent, is a zoonotic infection that is best combated by reducing infected fly (vector) populations. A few hundred cases are reported per year. *Trypanosoma brucei gambiense* infection occurring in West Africa spreads from human to human via fly bites and requires active case detection and treatment, with about 3000 cases reported annually. Tsetse flies (genus *Glossina*) transmit African *Trypanosoma* to humans either from wild and domestic animals *(T. brucei rhodesiense)* or from other humans *(T. brucei gambiense)*. Within the fly, the parasites multiply in the stomach and then in the salivary glands before developing into nondividing trypomastigotes, which are transmitted to humans and animals with the next blood meal. Diagnosis is made by microscopic examination of blood smears, lymph node, or chancre. Cerebrospinal fluid must be examined to determine whether there is infection of the CNS, as this determines the course of treatment.

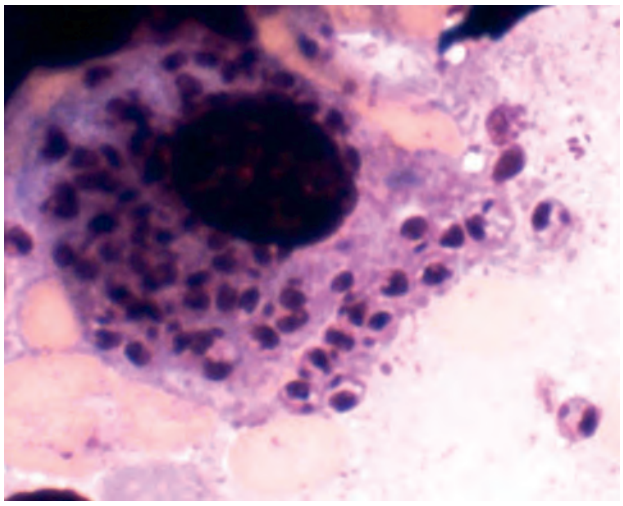

Figure 8.49 Giemsa stain of a tissue macrophage with *Leishmania donovani* parasites.

Pathogenesis

African trypanosomes are covered by a single, abundant, glycolipid-anchored protein called the *variant surface glycoprotein* (VSG). As parasites proliferate in the bloodstream, the host produces antibodies to the VSG, which, in association with phagocytes, kill most of the organisms, causing a spike of fever. A small number of parasites, however, undergo a genetic rearrangement and produce a different VSG on their surface and so escape the host immune response. These successor trypanosomes multiply until the host mounts a new anti-VSG response and kills most of them, but then another clone with a distinct VSG takes over. In this way, African trypanosomes cause waves of fever before they finally invade the CNS. Trypanosomes have many VSG genes, only one of which is expressed at a time. The parasite uses an elegant mechanism to turn VSG genes on and off. Although VSG genes are scattered throughout the trypanosome genome, only VSG genes found within bloodstream expression sites near the ends of chromosomes are transcribed. New VSG genes are periodically moved into these sites, mainly by homologous recombination, generating a new VSG. A specialized RNA polymerase that transcribes VSG genes associates with only a single bloodstream expression site, limiting expression to one VSG at a time.

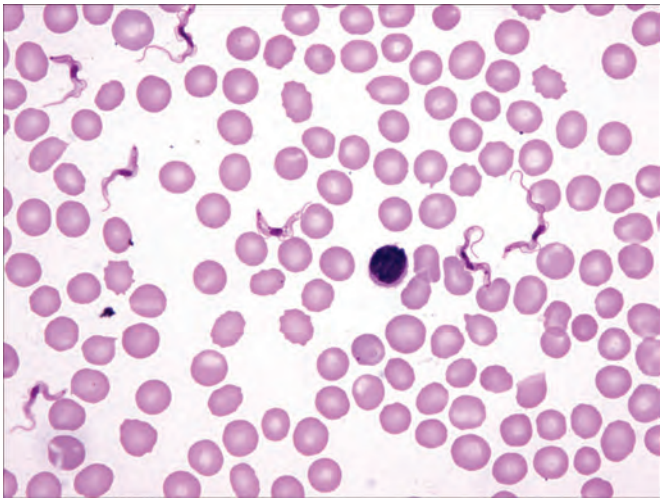

Figure 8.50 Slender bloodstream parasites of African trypanosomiasis.

MORPHOLOGY

A large, red, rubbery chancre forms at the site of the insect bite and contains numerous parasites surrounded by a dense, predominantly mononuclear, inflammatory infiltrate. With chronicity, the lymph nodes and spleen enlarge due to infiltration by lymphocytes, plasma cells, and macrophages, which are filled with dead parasites. Trypanosomes (Fig. 8.50) concentrate in capillary loops, such as the choroid plexus and glomeruli. When parasites breach the blood-brain barrier and invade the CNS, a leptomeningitis develops that extends into the perivascular Virchow-Robin spaces, and eventually a demyelinating panencephalitis occurs. Plasma cells containing cytoplasmic globules filled with immunoglobulins are frequent and are referred to as **Mott cells.** Chronic disease leads to progressive cachexia; patients, devoid of energy and normal mentation, literally waste away.

Chagas Disease

***Trypanosoma cruzi* is a kinetoplastid, intracellular protozoan parasite that causes American trypanosomiasis (Chagas disease).** Chagas disease occurs rarely in the United States and Mexico but is more common in South America, particularly Brazil, with an estimated 8 million people infected globally. *T. cruzi* parasites infect many animals, including cats, dogs, and rodents. The parasites are transmitted between animals and to humans by triatomine bugs (also known as kissing bugs or reduviids), which hide in the cracks of loosely constructed houses, feed on the sleeping inhabitants, and pass the parasites in feces; the infectious parasites enter the host through damaged skin or through mucous membranes. At the site of skin entry, there may be a transient, erythematous nodule. Another important route of infection is oral ingestion of the parasites due to contamination of food products with triatomine bugs and/or their feces. Other modes of infection include receipt of infected blood products, organ transplantation, or congenital transmission. Diagnosis can be made by a blood smear in the acute case, but is made more commonly by serology.

Pathogenesis

T. cruzi has a superfamily of glycosylphosphatidylinositol-anchored surface glycoproteins that interact with multiple ligands, such as laminin, fibronectin, collagen, cytokeratin, and other extracellular proteins, and are involved in cell adhesion and invasion. Although most intracellular pathogens avoid the toxic contents of lysosomes, after ingestion into macrophages, *T. cruzi* actually requires brief exposure to the acidic phagolysosome for development of amastigotes, the intracellular stage of the parasite. To ensure exposure to lysosomes, *T. cruzi* trypomastigotes elevate the concentration of cytoplasmic calcium in host cells, which promotes fusion of the phagosome and lysosome. In addition to enhancing amastigote development, the low pH of the lysosome activates pore-forming proteins that disrupt the lysosomal membrane, releasing the parasite into the cell cytoplasm. Parasites reproduce as rounded amastigotes in the cytoplasm of host cells and then develop flagella, lyse host cells, enter the bloodstream, and penetrate smooth, skeletal, and heart muscles. *T. cruzii* evades the complement system activation by expressing complement regulatory proteins.

Chagas disease primarily affects the heart, and in endemic areas it is a major cause of sudden death due to cardiac arrhythmia. In acute Chagas disease, which is mild in most individuals, cardiac damage results from direct invasion of myocardial cells by the organisms and the subsequent inflammation. Rarely, acute Chagas disease presents with high parasitemia, fever, or progressive cardiac dilation and failure, often with generalized lymphadenopathy or splenomegaly. In chronic Chagas disease, which occurs in 20% of people 5 to 15 years after initial infection, the mechanism of cardiac damage has two components.

- The presence of persistent *T. cruzi* parasites leads to a continued immune response with inflammatory infiltration of the myocardium, even though only scant organisms may be present.
- The parasite also may induce autoimmune responses, such that antibodies and T cells that recognize parasite proteins cross-react with host myocardial cells, nerve cells, and extracellular proteins such as laminin. For example, cross-reactive antibodies may induce electrophysiologic dysfunction of the heart.

Damage to myocardial cells and to conductance pathways causes a dilated cardiomyopathy and cardiac arrhythmias. In addition, damage to the myenteric plexus causes dilation of the colon (megacolon) and esophagus. This is particularly common in Brazilian endemic areas, where as many as 50% of the patients with lethal carditis have colonic and esophageal disease.

MORPHOLOGY

In lethal **acute myocarditis,** the changes are diffusely distributed throughout the heart. Clusters of amastigotes cause swelling of individual myocardial fibers and create intracellular pseudocysts. There is focal myocardial cell necrosis accompanied by extensive, dense, acute interstitial inflammatory infiltration throughout the

myocardium, often associated with four-chamber cardiac dilation (Chapter 12).

In **chronic Chagas disease,** the heart is typically dilated, rounded, and increased in size and weight. Often, there are mural thrombi that, in about one-half of autopsy cases, have given rise to pulmonary or systemic emboli or infarctions. On histologic examination, there are interstitial and perivascular inflammatory infiltrates composed of lymphocytes, plasma cells, and monocytes. There are scattered foci of myocardial cell necrosis and interstitial fibrosis, especially toward the apex of the left ventricle, which may undergo aneurysmal dilation and thinning. Even with dilation of the esophagus and colon, parasites cannot be found within ganglia of the myenteric plexus. Chronic Chagas cardiomyopathy often has to be treated by cardiac transplantation.

Toxoplasmosis

Although millions of people carry the ubiquitous parasitic protozoa *T. gondii* without symptoms due to control by their immune systems, *T. gondii* causes significant disease in the immunocompromised and in pregnant women and their offspring. It is estimated that 11% of the US population 6 years of age and older has been infected. In some regions of the world, 95% of the population has been infected. *T. gondii* infection occurs by eating undercooked meat (pork, lamb, venison) contaminated with the tissue cysts or by acquiring oocysts through drinking contaminated water, or by accidental ingestion following cleaning of a cat's litter box or handling contaminated soil. Another route of infection is vertical transmission during pregnancy. Rarely, infection occurs via blood transfusion or organ transplantation. Some infected individuals (10% to 20%) may experience swollen lymph nodes and muscle aches, with a benign, self-limited course of weeks to months, followed by a latent infection. The organism can be reactivated following immunosuppression, such as after organ transplantation or in HIV infection. Congenital toxoplasmosis symptoms may not become evident for months or many years after birth, and prompt treatment at birth may reduce the ultimate sequelae. Although congenital chorioretinitis is bilateral, ocular toxoplasmosis may be acquired and then is often unilateral. *Toxoplasma* encephalitis, due to reactivation, is the most common opportunistic pathogen of the CNS in AIDS patients. Myocarditis and pneumonitis are two other common manifestations in AIDS patients. Investigators have hypothesized a connection between toxoplasmosis and schizophrenia and other neurologic conditions, but studies are inconclusive.

Pathogenesis

The cat is the only definitive host, and humans are a dead-end host. Unsporulated oocysts are shed in cat feces, which sporulate in the environment. Intermediate hosts (birds, rodents) become infected from ingestion of contaminated soil, water, or plants. Ingested oocysts release sporozoites that invade the human intestinal epithelium, disseminating throughout the body. The sporozoites transform into tachyzoites that localize to tissues and develop into bradyzoites. Cats become infected after ingestion of intermediate hosts. *T. gondii* is an intracellular pathogen that can invade any nucleated cell by a unique form of actin-myosin moving junction and forms a parasitophorous vacuole (PV) protected from lysosomal fusion. To avoid clearance of the tachyzoites, *T. gondii* also inhibits autophagy of the parasite-containing vacuole.

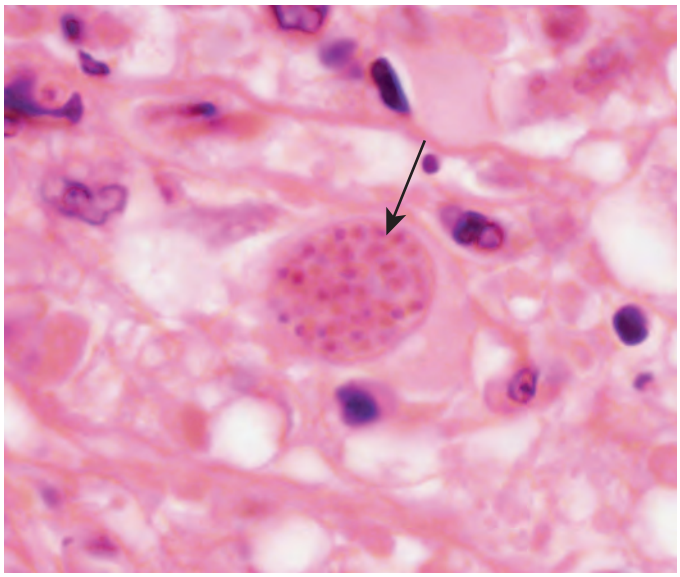

Figure 8.51 A brain biopsy showing a cyst of *Toxoplasma gondii (arrow).* (From Procop GW, Pritt BS: *Pathology of Infectious Diseases,* Philadelphia, Elsevier, 2015; Courtesy Dr. Bobbi S. Pritt, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minn.)

MORPHOLOGY

In humans, the parasites form cysts in skeletal muscle, myocardium, visceral organs, brain, and eyes. Although diagnosis is usually through serologic testing, cysts may be observed in biopsies (Fig. 8.51), or **tachyzoites** may be observed in stained fluid specimens, such as a bronchoalveolar lavage fluid from an immunocompromised host. Tachyzoites may be observed with periodic acid-Schiff, Giemsa, or hematoxylin and eosin stains. Tissue cysts can vary in size from 5 to 100 μm. Intact cysts can remain for the life of the host without causing inflammation. The cyst wall is thin and contains crescent-shaped bradyzoites of approximately 1.5 by 7 μm. PCR of blood or cerebrospinal fluid is a sensitive assay and permits less invasive testing in many cases. **Congenital toxoplasmosis** can result in fetal death and abortion, or hydrocephalus, microcephaly, cerebral calcifications, neurocognitive deficits, and chorioretinitis.

Metazoal Infections

Metazoa are multicellular, eukaryotic organisms with organ systems. Parasitic metazoal infections are contracted by consuming the parasite, often in undercooked meat, or by direct invasion of the host through the skin or via insect bites. Metazoa dwell in many sites of the body, including the intestine, skin, lung, liver, muscle, blood vessels, and lymphatics. The infections are diagnosed by microscopic identification of larvae or ova in excretions or tissues, and by serology.

Strongyloidiasis

Strongyloides stercoralis infects tens of millions of people worldwide and is endemic in tropical and subtropical regions of South America, sub-Saharan Africa, and Southeast Asia. It occurs sporadically in the United States, including in Appalachia. **The worms live in the soil and infect humans when larvae penetrate the skin, travel in the circulation to the lungs, and then travel up the trachea to be swallowed.** Female worms reside in the mucosa of the small intestine, where they produce eggs by asexual reproduction (parthenogenesis). Most of the larvae are passed in the stool and then may contaminate soil to continue the cycle of infection, however some develop and become infectious within the host, leading to autoinfection.

In immunocompetent hosts, *S. stercoralis* is often asymptomatic, but may cause diarrhea, bloating, and occasionally malabsorption. Immunocompromised hosts, particularly people on prolonged corticosteroid therapy, can have very high worm burdens (hyperinfection) due to uncontrolled autoinfection, leading to fatal disease. Corticosteroids inhibit the functions of eosinophils and other host immune cells that accumulate in tissues in response to infection, and stimulate female *Strongyloides* spp. to increase infective larvae production. In addition, other disease states that perturb immune control mechanisms (e.g., organ transplantation, lymphoma, HTLV-1) are associated with increased risk. Hyperinfection can be complicated by sepsis caused by intestinal bacteria, which enter the blood following damage to the intestinal wall by the invading larvae.

MORPHOLOGY

In mild strongyloidiasis, worms, mainly larvae, are present in the duodenal crypts but are not seen in the underlying tissue. There is an eosinophil-rich infiltrate in the lamina propria with mucosal edema. Hyperinfection with *S. stercoralis* results in invasion of larvae into the colonic submucosa, lymphatics, and blood vessels, with an associated mononuclear infiltrate. There are many adult worms, larvae, and eggs in the crypts of the duodenum and ileum (Fig. 8.52). Worms of all stages may be found in other organs, including skin and lungs, and may even be found in large numbers in sputum.

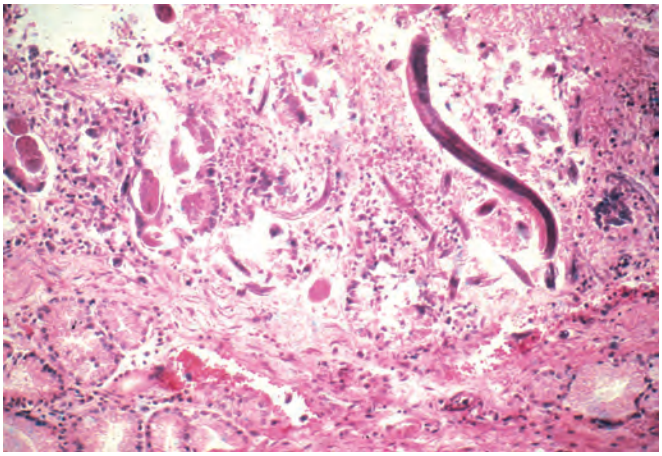

Figure 8.52 *Strongyloides* hyperinfection in a patient treated with high-dose cortisone. A female, her eggs, and rhabditoid larvae are in the duodenal crypts; filariform larvae are entering the blood vessels and muscularis mucosa. (Courtesy Dr. Franz C. Von Lichtenberg, Brigham and Women's Hospital, Boston, Mass.)

Cysticercosis and Hydatid Disease (Tapeworm Infections)

Taenia solium and *Echinococcus granulosus* are cestode parasites (tapeworms) that cause cysticercosis and hydatid infections, respectively. Both diseases are caused by larvae that develop after ingestion of tapeworm eggs. These tapeworms have a complex life cycle requiring two mammalian hosts: a definitive host, in which the worm reaches sexual maturity, and an intermediate host, in which the worm does not reach sexual maturity.

***T. solium* causes disease because of deposition of cysts (cysticerci) in organs and the resulting inflammatory response.** These tapeworms consist of a head (scolex) that has suckers and hooklets that attach to the intestinal wall, a neck, and many flat segments called proglottids that contain both male and female reproductive organs. New proglottids develop behind the scolex. The most distal proglottids are mature and contain many eggs, and they can detach and be shed in feces. *T. solium* can be transmitted to humans in two ways, ingestion of larval cysts or eggs, with distinct outcomes.

- Larval cysts, called *cysticerci,* are ingested in undercooked pork and attach to the intestinal wall, where they develop into mature adult tapeworms. These can grow to many meters in length and produce mild abdominal symptoms. The parasite life cycle is completed with this mode of infection, and disseminated cysticercosis does not develop.
- When intermediate hosts (pigs or humans) ingest eggs in food or water contaminated with human feces, the egg becomes an oncosphere that hatches and penetrates the gut wall, disseminating hematogenously, followed by transition to a cysticercus that can encyst in many organs, giving rise to clinical symptoms of cysticercosis. The most serious manifestations result from encystment in the brain (neurocysticercosis). Convulsions, increased intracranial pressure, and other neurologic disturbances may occur. Adult tapeworms are not produced with this mode of infection because larval cysts lodged in various tissues other than the intestine cannot develop into mature worms. Viable *T. solium* cysts often do not produce symptoms and can evade host immune defenses by producing taeniaestatin and paramyosin, which seem to inhibit complement activation. When the cysticerci die and degenerate, an inflammatory response develops.

Taenia saginata, the beef tapeworm, and *Diphyllobothrium latum,* the fish tapeworm, are acquired by eating undercooked meat or fish. In humans, these parasites live only in the gut and do not form cysticerci.

Hydatid disease is caused by ingestion of eggs of *Echinococcus* spp and formation of cysts in organs where the parasite larvae are deposited. For *E. granulosus* the definitive host is the dog, and the usual intermediate hosts are sheep. For *E. multilocularis* the fox is the most important definitive host, and rodents are intermediate hosts. Humans are accidental intermediate hosts, infected by ingestion of food contaminated with eggs shed by dogs or foxes. Eggs hatch in the duodenum and larvae invade the liver, lungs, or bones. Infection in humans is usually asymptomatic, but

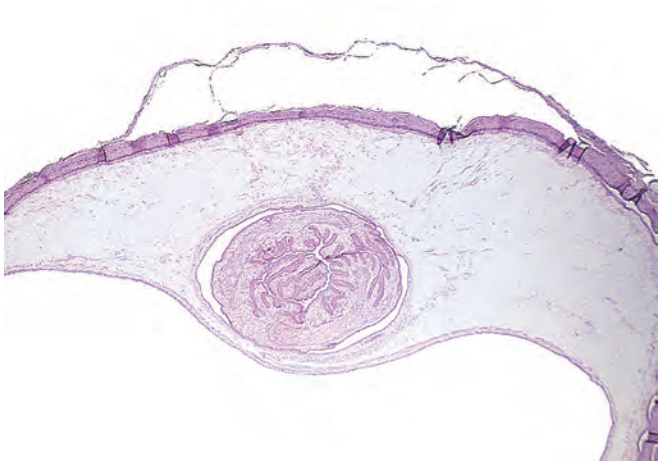

Figure 8.53 Portion of a cysticercus cyst in the skin.

large cysts in the liver can cause abdominal pain or obstruction, and pulmonary cysts can cause pain, cough, and hemoptysis. Caution is warranted if surgical removal of the cyst is considered, as anaphylaxis and/or dissemination of organisms can result from spillage of the cyst contents.

MORPHOLOGY

Cysticerci may be found in any organ, but the more common locations include the brain, muscles, skin, and heart. Cerebral symptoms depend on the precise location of the cysts, which may be intraparenchymal, attached to the arachnoid, or freely floating in the ventricular system. The cysts are ovoid and white to opalescent, often grape-sized, and contain an invaginated scolex with hooklets that are bathed in clear cyst fluid (Fig. 8.53). The cyst wall is more than 100 μm thick, is rich in glycoproteins, and evokes little host inflammatory response when it is intact. When cysts degenerate, however, there is inflammation, followed by focal scarring, and calcifications, which may be visible by radiography.

***E. granulosus* cysts** are found in the liver in about two thirds of cases, with 5% to 15% in the lung, and the rest in bones and brain, or other organs. In the various organs, the larvae lodge within the capillaries and first incite an inflammatory reaction composed principally of mononuclear leukocytes and eosinophils. Many such larvae are destroyed, but others encyst. The cysts begin at microscopic levels and progressively increase in size, so that in 5 years or more they may have achieved dimensions of more than 10 cm in diameter. Enclosing an opalescent fluid is an inner, nucleated, germinative layer and an outer, opaque, non-nucleated layer. The outer non-nucleated layer is distinctive and has innumerable delicate laminations. Outside this opaque layer, there is a host inflammatory reaction that produces a zone of fibroblasts, giant cells, and mononuclear and eosinophilic cells. In time a dense fibrous capsule forms. Daughter cysts often develop within the large mother cyst. These appear first as minute projections of the germinative layer that develop central vesicles and thus form tiny brood capsules. Degenerating scolices of the worm produce a fine, sandlike sediment within the hydatid fluid (hydatid sand).

Trichinosis

***Trichinella* spp. are nematode parasites that are acquired by ingestion of larvae in undercooked meat from infected animals (usually pigs, boars, or horses) that have themselves been infected by eating rats or meat products containing *T. spiralis*, *T. nativa*, or *T. britovi*.** There are an estimated 10,000 cases in the world each year. In the United States the number of *T. spiralis*–infected pigs has been greatly reduced by laws requiring proper cooking of food fed to hogs; the number of reported human infections in the United States is usually about 20 cases each year. Still, trichinosis remains widespread in other parts of the world, where undercooked meat, including noncommercial livestock and game (e.g., bear), is commonly eaten.

Pathogenesis

The life cycle of *T. spiralis* begins in the human intestine but ends within muscle as humans are dead-end hosts. In the human gut, *T. spiralis* larvae develop into adults that mate and release new larvae, which penetrate into the tissues. Larvae disseminate hematogenously and penetrate muscle cells, causing fever, myalgias, marked eosinophilia, and periorbital edema. Less commonly, the larvae lodge in the heart, lungs, and brain, and patients can develop dyspnea, encephalitis, and cardiac failure. In striated skeletal muscle, *T. spiralis* larvae become intracellular parasites, increase dramatically in size, and modify the host muscle cell so that it loses its striations, gains a collagenous capsule, and develops a plexus of new blood vessels around itself. The cell-parasite complex is largely asymptomatic, and the worm may persist for years before it dies and calcifies. Antibodies to larval antigens, which include an immunodominant carbohydrate epitope called **tyvelose,** may reduce reinfection and are useful for serodiagnosis of the disease.

T. spiralis and other invasive nematodes stimulate a Th2 response, with production of IL-4, IL-5, IL-10, and IL-13. The cytokines produced by Th2 cells activate eosinophils and mast cells, both of which are associated with the inflammatory response to these parasites. In animal models of *T. spiralis* infection, the Th2 response is associated with increased contractility of the intestine, which expels adult worms from the gut and subsequently reduces the number of larvae in the muscles. Although the Th2 response indirectly reduces the number of larvae in muscle by eliminating adults from the intestine, it is not clear whether the intramuscular inflammatory response, which is composed of mononuclear cells and eosinophils, is effective against the larvae.

MORPHOLOGY

During the invasive phase of trichinosis, cell destruction can be widespread with heavy infections and may be lethal. In the heart, there is a patchy interstitial myocarditis characterized by many eosinophils and scattered giant cells. The myocarditis can lead to scarring. Larvae in the heart do not encyst and are difficult to identify, because they die and disappear. In the lungs, trapped larvae cause focal edema and hemorrhages, sometimes with an allergic eosinophilic infiltrate. In the CNS, larvae cause a diffuse lymphocytic and eosinophilic infiltrate, with focal gliosis in and about small capillaries of the brain.

T. spiralis preferentially encysts in striated skeletal muscles with the richest blood supply, including the diaphragm and the extraocular, laryngeal, deltoid, gastrocnemius, and intercostal muscles (Fig. 8.54). Coiled larvae are approximately 1 mm long and are

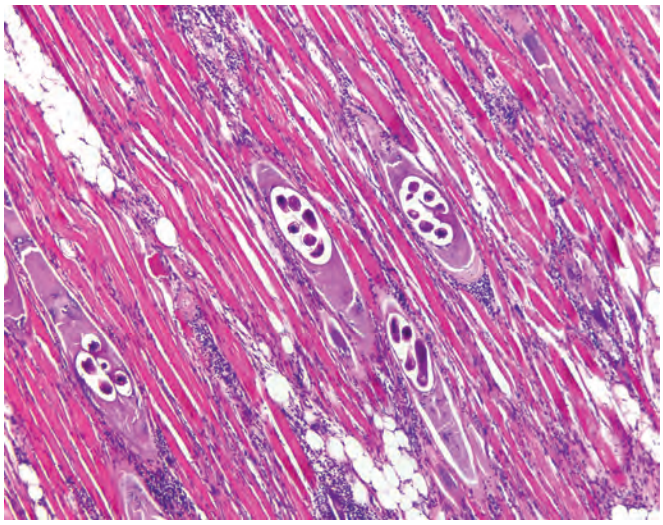

Figure 8.54 Multiple coiled *Trichinella spiralis* larvae within skeletal muscle cells.

surrounded by intracellular membrane-bound vacuoles, which in turn are surrounded by new blood vessels and an eosinophil-rich mononuclear cell infiltrate. This infiltrate is greatest around dying parasites, which eventually calcify and leave behind scars that are sufficiently characteristic to suggest the diagnosis of trichinosis.

Schistosomiasis

Schistosomiasis is estimated to infect approximately 230 million persons and kill more than 200,000 individuals annually. The affected organs and hence the site of major disease vary with the species. *Shistosoma mansoni* and *S. japonicum* affect the liver and the gut predominantly. Most deaths are due to hepatic cirrhosis, which is caused by *S. mansoni* in Latin America, Africa, and the Middle East and by *S. japonicum* and *S. mekongi* in East Asia. By contrast, *S. haematobium,* found in Africa, causes chronic granulomatous bladder inflammation that may lead to hematuria, obstructive uropathy, and carcinoma. *Schistosoma* flukes require passage through freshwater snails that live in the slow-moving water of tropical rivers, lakes, and irrigation ditches, ironically linking agricultural development with spread of the disease. Acute schistosomiasis in humans can be a severe febrile illness that peaks about 2 months after infection. Severe hepatic fibrosis is a serious manifestation of chronic schistosomiasis.

Pathogenesis

Much of the pathology of schistosomiasis is caused by host inflammatory reactions to different stages of the parasite. The life cycle of *Schistosoma* spp. involves stepwise infection of several human tissues, each associated with host inflammatory responses. After release from snails, ciliated miracidium larvae mature into infectious larvae (cercariae) that swim through fresh water and penetrate human skin with the aid of powerful proteolytic enzymes that degrade the keratinized layer. There is minimal skin reaction. Schistosomes migrate through the skin into the peripheral vasculature and lymphatics, travel to the lungs and heart, from where they are disseminated widely, including the mesenteric, splanchnic, and portal circulation, ultimately reaching the hepatic vessels, where they mature (*S. mansoni* and *S. japonicum*). Mature male-female worm pairs then migrate once again and settle in the venous system (commonly the portal or pelvic veins). Females produce hundreds to thousands of eggs per day that secrete proteases and elicit localized inflammatory reactions. This inflammatory response to egg migration is necessary for passive transfer across the intestine and, in the case of *S. haematobium,* bladder walls, allowing the eggs to be shed in stool or urine, respectively. Infection of freshwater snails completes the life cycle.

Eggs that are carried by the portal circulation into the hepatic parenchyma can cause severe chronic inflammation in the liver. This immune response to *S. mansoni* and *S. japonicum* eggs is responsible for the most serious complication of schistosomiasis, liver fibrosis. The helper T-cell response in the early stage is dominated by Th1 cells that produce IFN-γ, which stimulates macrophages to secrete high levels of the cytokines TNF-α, IL-1, and IL-6 that cause fever. Chronic schistosomiasis is associated with a dominant Th2 response, associated with the presence of activated macrophages. Both types of helper T cells contribute to the formation of granulomas surrounding eggs in the liver. Hepatic fibrosis is a serious manifestation of chronic schistosomiasis in which Th2 cells and activated macrophages may play the major role.

MORPHOLOGY

In early *S. mansoni* or *S. japonicum* infections, white, pinhead-sized granulomas are scattered throughout the gut and liver. At the center of the granuloma is the schistosome egg, which contains a miracidium; this degenerates over time and calcifies. The granulomas are composed of macrophages, lymphocytes, neutrophils, and eosinophils, which are distinctive for helminth infections (Fig. 8.55). The liver is darkened by regurgitated heme-derived

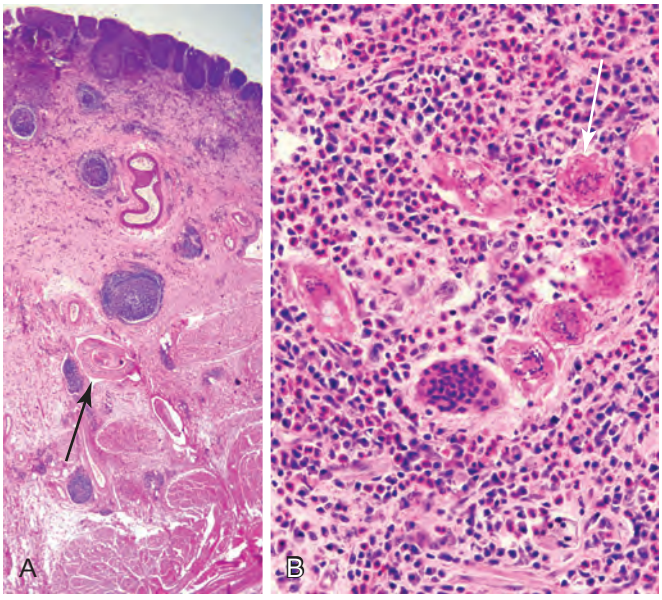

Figure 8.55 *Schistosoma haematobium* infection of the bladder (A) showing dense fibrosis, scattered granulomas, and a cross-section of adult worms in a vessel *(arrow)*. High magnification (B) demonstrates miracidium-containing eggs *(arrow)*, prominent eosinophils, histiocytes, and giant cells.

pigments from the schistosome gut, which, like malaria pigments, are iron-free and accumulate in Kupffer cells and splenic macrophages.

In late *S. mansoni* or *S. japonicum* infections, inflammatory patches or pseudopolyps may form in the colon. The surface of the liver is bumpy, and cut surfaces reveal granulomas and widespread fibrosis and portal enlargement without intervening regenerative nodules. Because these fibrous tracts resemble the stem of a clay pipe, the lesion is named **pipe-stem fibrosis** (Fig. 8.56). The fibrosis often obliterates the portal veins, leading to portal hypertension, severe congestive splenomegaly, esophageal varices, and ascites. Schistosome eggs, diverted to the lung through portal collaterals, may produce granulomatous pulmonary arteritis with intimal hyperplasia, progressive arterial obstruction, and ultimately heart failure (cor pulmonale). On histologic examination, arteries in the lungs show disruption of the elastic layer by granulomas and scars, luminal organizing thrombi, and angiomatoid lesions similar to those of idiopathic pulmonary hypertension (Chapter 15). Patients with hepatosplenic schistosomiasis also have an increased frequency of mesangioproliferative or membranous glomerulopathy (Chapter 20) in which glomeruli contain deposits of immunoglobulin and complement but rarely schistosome antigen.

In *S. haematobium* infection, inflammatory cystitis due to massive egg deposition and granulomas appears early, leading to mucosal erosions and hematuria. Later, the granulomas calcify and develop a sandy appearance, which, if severe, may line the wall of the bladder and cause a dense concentric rim (calcified bladder) on radiographic films. The most frequent complication of *S. haematobium* infection is inflammation and fibrosis of the ureteral walls, leading to obstruction, hydronephrosis, and chronic pyelonephritis. There is also an association between urinary schistosomiasis and squamous cell carcinoma of the bladder (Chapter 21).

Lymphatic Filariasis

Lymphatic filariasis is transmitted by mosquitoes and is caused by closely related nematodes, *Wuchereria bancrofti* and *Brugia* spp. (*B. malayi* [90%] or *B. timori* [10%]), which are responsible for 120 million infections worldwide. In endemic areas, which include parts of Latin America, sub-Saharan Africa, and Southeast Asia, filariasis causes a spectrum of diseases:

- Asymptomatic microfilaremia
- Recurrent lymphadenitis
- Chronic lymphadenitis with swelling of the dependent limb or scrotum (elephantiasis)
- Tropical pulmonary eosinophilia

Pathogenesis

Infective larvae released by mosquitoes into the tissues during a blood meal develop within lymphatic channels into adult males and females, which mate and release microfilariae that enter into the bloodstream. Mosquitoes that bite infected individuals take up the microfilariae and can transmit the disease. The genomes of *W. bancrofi* and *B. malayi* have been sequenced, leading to the discovery of filarial molecules that may contribute to host invasion and enable these organisms to evade or inhibit immune defenses:

- *Elastases and trypsin-like proteases,* which facilitate invasion of host tissues
- *Several surface glycoproteins* with antioxidant function, which may protect the parasite from reactive oxygen species
- *Homologs of cystatins* (cysteine protease inhibitors), which can impair the MHC class II antigen-processing pathway
- *Serpins* (serine protease inhibitors), which can inhibit neutrophil proteases, critical inflammatory mediators
- *Homologs of host molecules,* such as TGF-β and macrophage migration inhibition factor, which could dampen the immune response.

In addition, symbiotic *Wolbachia* bacteria infect filarial nematodes and contribute to pathogenesis of disease. *Wolbachia* spp. are required for nematode development and reproduction, and antibiotics that eradicate *Wolbachia* spp. impair nematode survival and fertility.

Immune responses to the filarial worms produce damage to the human host. As is the case with leprosy and leishmanial infections, some of the different disease manifestations caused by lymphatic filariae are likely related to variations in host T-cell responses to the parasites. In chronic lymphatic filariasis, damage to the lymphatics is caused directly by the adult parasites and by a Th1-mediated immune response, which stimulates the formation of granulomas around the adult parasites. Hypersensitivity to microfilaria in the lungs is thought to be associated with tropical pulmonary eosinophilia. IgE and eosinophils may be stimulated by IL-4 and IL-5, respectively, which are secreted by filaria-specific Th2 helper T cells.

MORPHOLOGY

Chronic filariasis is characterized by **persistent lymphedema** of the extremities, scrotum, penis, or vulva (Fig. 8.57). Frequently there is hydrocele and lymph node enlargement. In severe and long-lasting infections, chylous weeping of the enlarged scrotum may ensue, or a chronically swollen leg may develop tough subcutaneous fibrosis and epithelial hyperkeratosis, termed **elephantiasis.** Elephantoid skin shows dilation of the dermal lymphatics, widespread lymphocytic infiltrates, and focal cholesterol

Figure 8.57 Massive edema and elephantiasis caused by filariasis of the leg. (Courtesy Dr. Willy Piessens, Harvard School of Public Health, Boston, Mass.)

deposits; the epidermis is thickened and hyperkeratotic. Adult filarial worms—live, dead, or calcified—are present in the draining lymphatics or nodes, surrounded by (1) mild or no inflammation, (2) an intense eosinophilia with hemorrhage and fibrin (recurrent filarial funiculoepididymitis), or (3) granulomas. Over time, the dilated lymphatics develop polypoid infoldings. In the testis, hydrocele fluid, which often contains cholesterol crystals, red cells, and hemosiderin, induces thickening and calcification of the tunica vaginalis.

Lung involvement by microfilariae is marked by eosinophilia caused by Th2 responses and cytokine production (tropical eosinophilia) or by dead microfilariae surrounded by stellate, hyaline, eosinophilic precipitates embedded in small epithelioid granulomas (Meyers-Kouwenaar bodies). Typically, these patients lack other manifestations of filarial disease.

Onchocerciasis

***Onchocerca volvulus* is a filarial nematode that is the leading cause of preventable blindness in sub-Saharan Africa**. It is transmitted by black flies and affects 17 million people in Africa, South America, and Yemen. An aggressive campaign of ivermectin treatment has dramatically reduced the incidence of *Onchocerca* spp. infections in Africa and South America. The WHO has declared that onchocerciasis has been eliminated in Colombia, Ecuador, Mexico, and Guatemala. Because the vector's habitat is near fast-moving water, there is higher incidence of human disease near rivers, accounting for the name *river blindness* given to this disease.

The disease attributable to onchocerciasis is primarily due to inflammation induced by microfilaria. Adult *O. volvulus* parasites mate in the dermis, where they are surrounded by a mixed infiltrate of host cells that produces a characteristic subcutaneous nodule *(onchocercoma)*. Inseminated females produce microfilariae, which accumulate in the skin and disseminate to the eye chambers. Ivermectin kills only immature worms, not adult worms, so parasites can repopulate the host, requiring retreatment every 3 to 6 months until symptoms are gone.

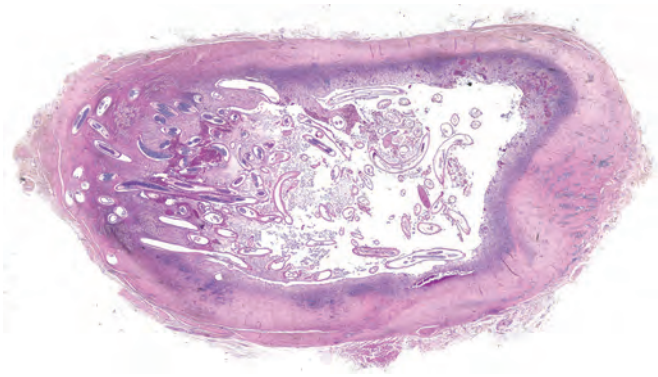

Figure 8.58 Microfilaria-laden gravid female of *Onchocerca volvulus* in a subcutaneous fibrous nodule.

MORPHOLOGY

O. volvulus causes chronic, itchy dermatitis with focal darkening or loss of pigment and scaling, referred to as leopard, lizard, or elephant skin. Foci of epidermal atrophy and elastic fiber breakdown may alternate with areas of hyperkeratosis, hyperpigmentation with pigment incontinence, dermal atrophy, and fibrosis. The subcutaneous onchocercoma is composed of a fibrous capsule surrounding adult worms and a mixed chronic inflammatory infiltrate that includes fibrin, neutrophils, eosinophils, lymphocytes, and giant cells (Fig. 8.58). The progressive eye lesions begin with punctate keratitis along with small, fluffy opacities of the cornea caused by degenerating microfilariae, which evoke an eosinophilic infiltrate. This is followed by a sclerosing keratitis that opacifies the cornea, beginning at the scleral limbus. Keratitis is sometimes accentuated by treatment with antifilarial drugs (Mazzotti reaction). Microfilariae in the anterior chamber cause inflammation of the anterior chamber of the eye and ciliary body (iridocyclitis) and glaucoma, whereas involvement of the choroid and retina results in atrophy and loss of vision.

SEXUALLY TRANSMITTED INFECTIONS

A variety of organisms can be transmitted through sexual contact (Table 8.7). Groups at greater risk for STIs include adolescents, men who have sex with men, and people who use illegal drugs parenterally. Although the increased risk among these groups is partially due to unsafe sexual practices, limited access to health care is often a contributing factor. The presence of an STI in a child, unless acquired during birth, strongly suggests sexual abuse.

Some pathogens, such as *Chlamydia trachomatis* and *N. gonorrhoeae,* are almost always spread by sexual intercourse, whereas others, such as *Shigella* spp. and *E. histolytica,* are typically spread by other means, but are also occasionally spread by oral-anal sex. To reduce the spread of STIs, these

Table 8.7 Classification of Important Sexually Transmitted Infections

Pathogens	Disease or Syndrome and Population Principally Affected		
	Males	**Females**	**Both**
Viruses			
Herpes simplex virus			Primary and recurrent herpes, neonatal herpes
Hepatitis B virus			Hepatitis
Human papillomavirus	Cancer of penis	Cervical dysplasia and cancer, vulvar cancer	Condyloma acuminatum
Human immunodeficiency virus			Acquired immunodeficiency syndrome
Chlamydiae			
Chlamydia trachomatis	Urethritis, epididymitis, proctitis	Urethral syndrome, cervicitis, bartholinitis, salpingitis, and sequelae	Lymphogranuloma venereum
Mycoplasmas			
Ureaplasma urealyticum	Urethritis		
Bacteria			
Neisseria gonorrhoeae	Epididymitis, prostatitis, urethral stricture	Cervicitis, endometritis, bartholinitis, salpingitis, and sequelae (infertility, ectopic pregnancy, recurrent salpingitis)	Urethritis, proctitis, pharyngitis, disseminated gonococcal infection
Treponema pallidum			Syphilis
Haemophilus ducreyi			Chancroid
Klebsiella granulomatis			Granuloma inguinale (donovanosis)
Protozoa			
Trichomonas vaginalis	Urethritis, balanitis	Vaginitis	

infections are often reported to public health authorities so that people who have had intimate contact with the person may be tested and treated.

Although the various pathogens that cause STIs differ in many ways, some general features should be noted.

- *STIs may become established locally and then spread from the urethra, vagina, cervix, rectum, or oral pharynx*. Organisms that cause STIs depend on direct contact for person-to-person spread because these pathogens do not survive in the environment. Transmission of STIs often occurs from asymptomatic people who do not realize that they have an infection.
- *Infection with one STI-associated organism increases the risk for additional STIs*. This is mainly because the risk factors are the same for all STIs. In addition, the epithelial injury caused by *N. gonorrhoeae* or *C. trachomatis* can increase the chance of co-infection with the other, as well as the risk of HIV infection if there is concomitant exposure.
- *The microbes that cause STIs can be spread from a pregnant woman to the fetus and cause severe damage to the fetus or child*. Perinatally acquired *C. trachomatis* causes conjunctivitis, and neonatal HSV infection is much more likely to cause visceral and CNS disease than is infection acquired later in life. Syphilis frequently causes miscarriage. Untreated HIV infection may be fatal to children infected with the virus prenatally or perinatally. Diagnosis of STIs in pregnant women is critical, because intrauterine or neonatal transmission of STIs can often be prevented by treatment of the mother or newborn. Antiretroviral treatment of pregnant women with HIV infection and their newborn infants can reduce the transmission of HIV to offspring from 25% to less than 1%.

Syphilis is discussed earlier in this chapter, and other STIs are described in Chapters 21 and 22.

EMERGING INFECTIOUS DISEASES

The rapidly expanding human population juxtaposed with environmental infractions allow the emergence of new pathogens and the re-emergence of old infectious agents. Table 8.8 lists the history of diseases that have emerged over the past half century. The infectious causes of some diseases were not new, but previously unrecognized because some of the infectious agents are difficult to culture; examples include *H. pylori* gastritis, HBV and HCV, and *Legionella pneumophila*. Some infectious agents are new to humans, such as HIV causing AIDS, and *B. burgdorferi* causing Lyme disease. Other infections have become much more common because of immunosuppression caused by AIDS or immunosuppressive therapy (e.g., CMV, KSHV, *M. avium-intracellulare, P. jirovecii*, and *Cryptosporidium parvum*). Finally, infectious diseases that are common in one area may be introduced into a new area. For example, West Nile virus was common in Europe, Asia, and Africa for years before it was described in the United States.

Human demographics and behavior are important contributors to the pattern of emergence of infectious diseases, such as AIDS in Africa versus AIDS in the United States. Annual outbreaks of Nipah virus infection have occurred in Bangladesh due to consumption of date palm sap. Bats, which shed the virus in their saliva and urine, are thought to contaminate the sap by feeding on it while it is being collected from the tree. Nipah virus can also

Table 8.8 Diseases That Have Emerged or Reemerged Over the Past 45 Years

Date Recognized	Infectious Agent	Manifestations
1977	Ebola virus	Epidemic Ebola hemorrhagic fever
	Hantaan virus	Hemorrhagic fever with renal syndrome
	Legionella pneumophila	Legionnaire disease
	Campylobacter jejuni	Enteritis
1980	Human T-lymphotropic virus I (HTLV-I)	T-cell lymphoma or leukemia, HTLV-associated myelopathy
1981	*Staphylococcus aureus*	Toxic shock syndrome
1982	*Escherichia coli* O157:H7	Hemorrhagic colitis, hemolytic-uremic syndrome
	Borrelia burgdorferi	Lyme disease
1983	Human immunodeficiency virus (HIV)	AIDS
	Helicobacter pylori	Gastric ulcers
1988	Hepatitis E	Enterically transmitted hepatitis
1989	Hepatitis C	Hepatitis C
1992	*Vibrio cholerae* O139	New epidemic cholera strain
	Bartonella henselae	Cat-scratch disease
1995	Kaposi sarcoma–associated virus (HHV-8)	Kaposi sarcoma in AIDS
1999	West Nile virus	West Nile fever, neuroinvasive disease
2003	Severe acute respiratory syndrome (SARS) coronavirus	SARS
2007	Zika virus	Fever, rash, Guillain-Barré syndrome Fetal loss, microcephaly, neurologic complications in newborns
2014	Ebola virus	Fever, rash, hemorrhage, multisystem organ failure
2016	*Candida auris*	Candidemia, wound and ear infections resistant to multiple antifungal agents
2019	COVID-19	Fever, cough, dyspnea, pneumonia

spread by person-to-person contact, and by transmission from pigs to people. Changes in the environment occasionally drive rates of infectious diseases. Reforestation of the eastern United States has led to massive increases in the populations of deer and mice, which carry the ticks that transmit Lyme disease, babesiosis, and ehrlichiosis. Failure of DDT to control the mosquitoes that transmit malaria and the development of drug-resistant parasites have dramatically increased the morbidity and mortality of *Plasmodium falciparum* infection in Asia, Africa, and Latin America. Microbial adaptation to widespread antibiotic use contributed to the emergence of drug resistance in many species of bacteria, including *M. tuberculosis, N. gonorrhoeae, S. aureus,* and *K. pneumoniae*. Human commercial use of dense populations of domestic animals (e.g., pigs, chickens) juxtaposed to habitat destruction of other disease reservoirs (e.g., bats and wild birds) can lead to acquisition of either unique traits in common pathogens such as influenza or emergence of unique viruses such as severe acute respiratory syndrome (SARS) virus, West Nile Virus, and Ebola virus. Because these pathogens are novel, humans lack immunity and so these infections can quickly spread through the population as pandemics, as was seen with influenza A H1N1 in 2009. Causes of more recent emerging infectious diseases discussed in this chapter include Ebola virus, Zika virus, COVID-19, *C. auris*, and some of the *Babesia* spp.

Agents of Bioterrorism. Bioterrorism is the use of biologic or chemical agents as weapons, and microorganisms are classified based on an assessment of which pose the greatest danger. The CDC classifies potential agents of bioterrorism based on the risk they present and whether they can be easily disseminated.

- Category A agents pose the highest risk and can be readily disseminated or transmitted from person to person, can cause high mortality, might cause public panic, and might require public health preparedness. For example, smallpox is a category A agent because of its high transmissibility, case mortality rate of 30% or greater, and lack of effective antiviral therapy. Because vaccination ended in the United States in 1972 and immunity has waned, the population is highly susceptible to smallpox. Concern that smallpox could be used for bioterrorism has led to a return of vaccination for selected groups. Other category A agents include *B. anthracis, Yersinia pestis,* and Ebola virus.
- Category B agents are relatively easy to disseminate, produce moderate morbidity but low mortality, and require specific diagnostic and disease surveillance. Many of these agents are food-borne or water-borne. Examples include *Brucella* spp. and *V. cholerae*.
- Category C agents include emerging pathogens that could be engineered for mass dissemination because of availability, ease of production and dissemination, potential for high morbidity and mortality, and great impact on health. Examples include Hantavirus and Nipah virus.

SPECIAL TECHNIQUES FOR DIAGNOSING INFECTIOUS AGENTS
