Adenomas are epithelial neoplasms that range from small, often pedunculated, polyps to large sessile lesions. Adenomas develop in approximately 30% of adults living in the Western world by age 60. Because these polyps are precursors to colorectal adenocarcinoma, surveillance is recommended beginning at age 45 to 50. Individuals at increased risk, including those with a family history of colorectal adenocarcinoma, are typically screened colonoscopically at least 10 years before the youngest age at which a relative was diagnosed. The preferred approach to surveillance varies, but colonoscopy is the most frequent mode. Adenomas are less common in Asia, but their incidence has risen (in parallel with increasing incidence of colorectal adenocarcinoma) as Western diets and lifestyles become more prevalent.

Consistent with their being precursor lesions, the prevalence of colorectal adenomas within populations correlates with that of colorectal adenocarcinoma, and the distributions of adenomas and adenocarcinoma within the colon are similar. Regular surveillance colonoscopy and polyp removal reduce the incidence of colorectal adenocarcinoma. Despite this strong relationship, it must be emphasized that majority of adenomas do not progress to become adenocarcinomas. There are no tools presently available to identify adenomas that are destined to undergo malignant transformation. Most adenomas are clinically silent, with the exception of large polyps that can produce occult bleeding and anemia.

MORPHOLOGY

Colorectal adenomas are characterized by the presence of epithelial dysplasia. Typical adenomas range from 0.3 to 10 cm in diameter and can be pedunculated (Fig. 17.45A) or sessile, with the surface of both types having a texture resembling velvet or a raspberry (Fig. 17.45B). Histologically, **the hallmarks of epithelial dysplasia are nuclear hyperchromasia, elongation, and stratification** (Fig. 17.46C). These changes are most easily appreciated at the surface of the adenoma and are often accompanied by prominent nucleoli, eosinophilic cytoplasm, and a reduction in the number of goblet cells. Pedunculated adenomas have slender fibromuscular stalks (Fig. 17.45C) containing prominent blood vessels derived from the submucosa. The stalk is usually covered by nonneoplastic epithelium, but dysplasia can be present.

Adenomas can be classified as **tubular, tubulovillous,** or **villous** based on their architecture. These categories, however, have little clinical significance in isolation. Tubular adenomas tend to be small, pedunculated polyps composed of rounded, or tubular, glands (Fig. 17.46A). In contrast, villous adenomas, which are often larger and sessile, are covered by slender villi (Fig. 17.46B). Villous adenomas harbor cancers more frequently than tubular adenomas, but this also correlates with the larger size of villous adenomas. As the name implies, tubulovillous adenomas have a mixed architecture.

Sessile serrated lesions, also referred to as sessile serrated adenomas, overlap histologically with hyperplastic polyps but are more commonly found in the right colon. Despite their malignant potential, these polyps **lack typical cytologic features of dysplasia** that are present in other adenomas. Histologically, these lesions can be differentiated from hyperplastic polyps by the presence of serrated architecture throughout the full length of the glands including the crypt base, crypt dilation, and lateral crypt growth (Fig. 17.46D).

Intramucosal carcinoma occurs when dysplastic epithelial cells breach the basement membrane to invade the lamina propria. These may extend into, but not through, the muscularis mucosae. Because functional lymphatic channels are absent in the colonic mucosa, intramucosal carcinomas have little or no metastatic potential and complete polypectomy is generally curative (Fig. 17.47A). Invasion beyond the muscularis mucosae, including into the submucosal stalk of a pedunculated polyp (Fig. 17.47B), constitutes invasive adenocarcinoma and carries a risk of spread to other sites. In such cases, several factors, such as the histologic grade of the invasive component, the presence of vascular or lymphatic invasion, and the distance from the invasive component to the margin of resection are considered in planning further therapy.

Although most colorectal adenomas are benign lesions, a small proportion harbor invasive cancer at the time of detection. **Size is the most important characteristic that correlates with risk of malignancy.** For example, while cancer is extremely rare in adenomas less than 1 cm in diameter, nearly 40% of lesions larger than 4 cm in diameter contain foci of invasive cancer. High-grade dysplasia is also a risk factor for cancer in an individual polyp, but does not confer an increased risk of cancer in other polyps within the same patient.

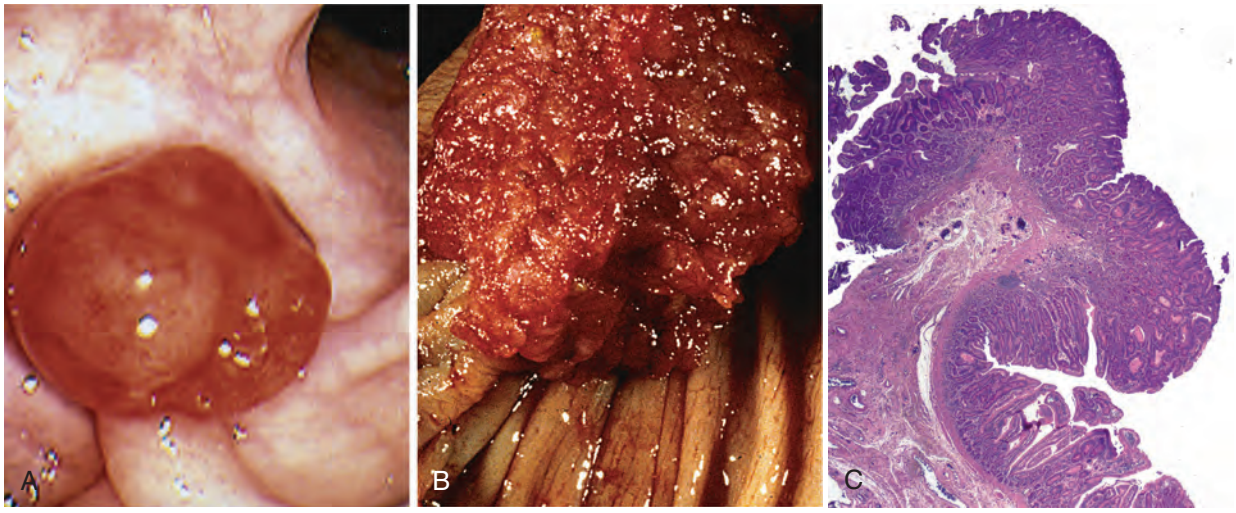

Figure 17.45 Colonic adenomas. (A) Pedunculated adenoma (endoscopic view). (B) Adenoma with a velvety surface. (C) Low-magnification photomicrograph of a pedunculated tubular adenoma.

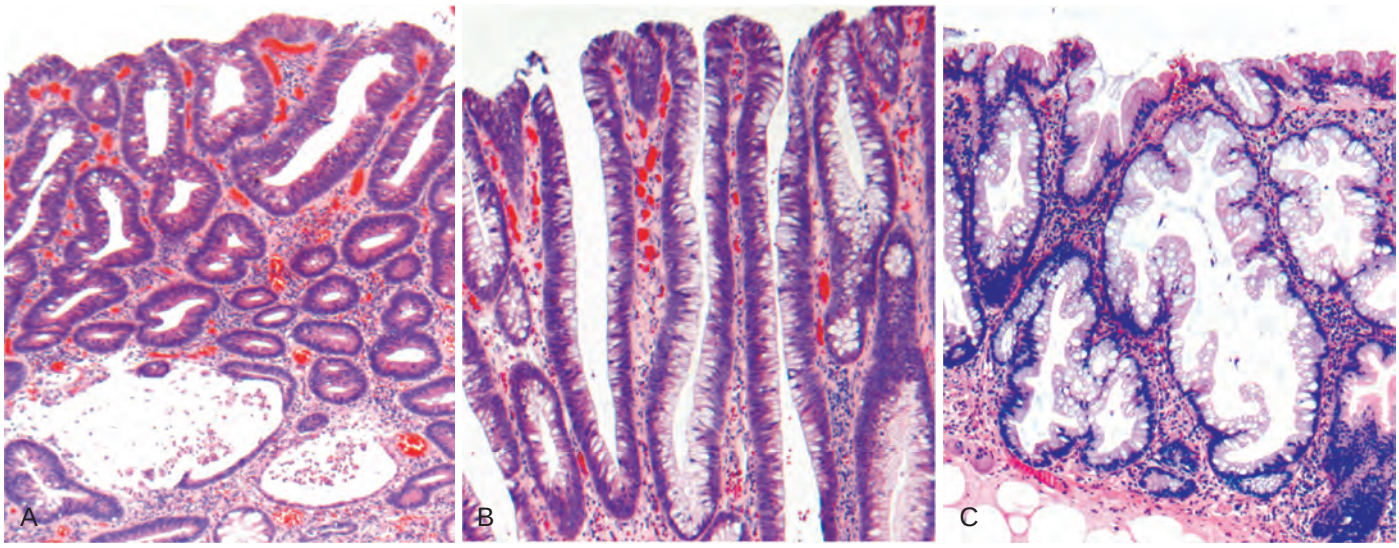

Figure 17.46 Histologic appearance of colonic adenomas. (A) Tubular adenoma with a smooth surface and rounded glands. Active inflammation is occasionally present in adenomas; in this case, crypt dilation and rupture can be seen at the bottom of the field. (B) Villous adenoma with long, slender projections that are reminiscent of small intestinal villi. (C) Sessile serrated adenoma lined by goblet cells without cytologic features of dysplasia. This lesion is distinguished from a hyperplastic polyp by extension of the neoplastic process to the crypts, resulting in lateral growth. Compare to the hyperplastic polyp in Fig. 17.41.

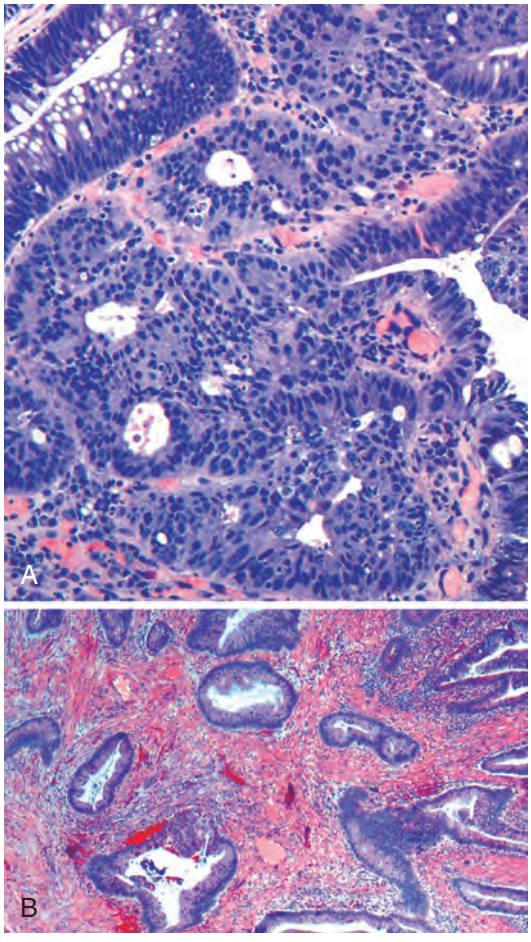

Figure 17.47 Adenoma with carcinoma. (A) Cribriform glands interface directly with the lamina propria without an intervening basement membrane in this intramucosal carcinoma. (B) Invasive adenocarcinoma (left) beneath a villous adenoma (right). Note the desmoplastic response to the invasive components.

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder in which patients develop numerous colorectal adenomas as teenagers. It is caused by somatic mutations of the adenomatous polyposis coli, or *APC*, gene, which is a key negative regulator of the Wnt signaling pathway (Chapter 7). Approximately 75% of cases are inherited, while the remainder appear to be caused by de novo mutations.

At least 100 polyps are necessary for a diagnosis of classic FAP, but thousands may be present (Fig. 17.48). Except for their numbers, FAP-associated polyps are morphologically indistinguishable from sporadic adenomas. However, flat or depressed adenomas are also prevalent in FAP, and microscopic adenomas, consisting of only one or two dysplastic crypts, are common in otherwise normal-appearing mucosa.

Colorectal adenocarcinoma develops in 100% of untreated FAP patients, often before age 30 and nearly always by age 50. As a result, prophylactic colectomy is the standard of care. Colectomy prevents colorectal cancer, but patients remain at risk for neoplasia at other sites. The ampulla of Vater and the stomach are common extracolonic sites of adenomas in FAP patients.

FAP is associated with a variety of extraintestinal manifestations including congenital hypertrophy of the retinal pigment epithelium, which can be detected at birth and may be an adjunct to early screening. Specific *APC* mutations have been associated with other manifestations of FAP and partly explain variants such as Gardner syndrome and Turcot syndrome (Table 17.10).

Table 17.10 Common Patterns of Sporadic and Familial Colorectal Neoplasia

Etiology	Molecular Defect	Target Genes	Transmission	Predominant Site	Histology
Familial adenomatous polyposis	APC/WNT pathway	*APC*	Autosomal dominant	None	Tubular, villous; typical adenocarcinoma
MYH-associated polyposis	DNA mismatch repair	*MYH*	Autosomal recessive	None	Sessile serrated adenoma; mucinous adenocarcinoma
Hereditary non-polyposis colorectal cancer	DNA mismatch repair	*MSH2, MLH1*	Autosomal dominant	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (70%–80%)	APC/WNT pathway	*APC*	None	Left side	Tubular, villous; typical adenocarcinoma
Sporadic colon cancer (10%–15%)	DNA mismatch repair	*MSH2, MLH1*	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (5%–10%)	Hypermethylation	*MLH1, BRAF*	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma

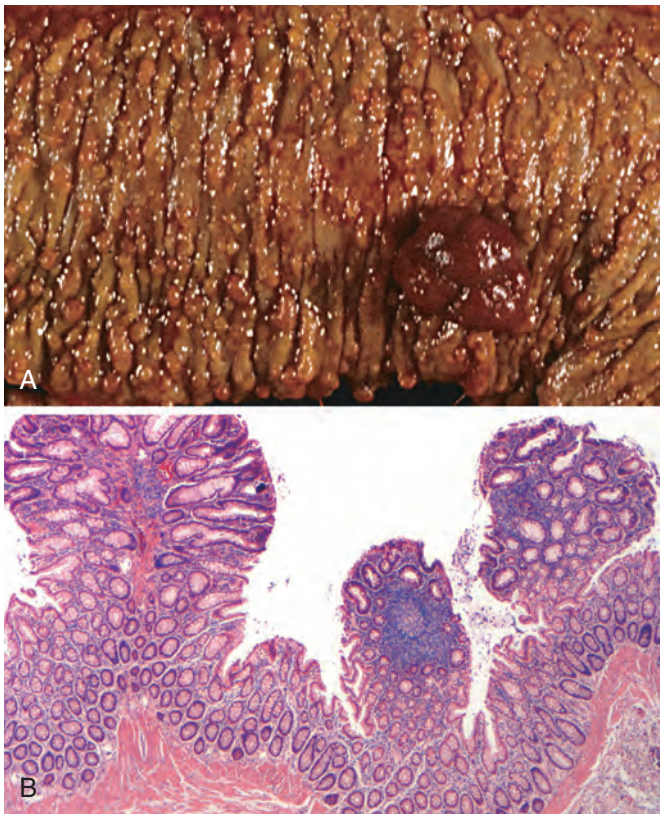

Figure 17.48 Familial adenomatous polyposis. (A) Hundreds of small polyps are present throughout this colon with a dominant polyp (right). (B) Three tubular adenomas are present in this single microscopic field.

Some polyposis patients without *APC* loss have bi-allelic mutations of the base-excision repair gene *MUTYH* (also referred to as *MYH*). This autosomal recessive disorder is termed *MUTYH-associated polyposis, or MAP.* In contrast to FAP, MAP is characterized by fewer than 100 polyps, which appear at later ages. Colon cancer development is also delayed. In addition, sessile serrated adenomas and hyperplastic polyps, often with *KRAS* mutations, are frequently present in those with MAP.

HEREDITARY NON-POLYPOSIS COLORECTAL CANCER (HNPCC)

HNPCC is caused by inherited mutations in mismatch repair genes that encode proteins responsible for the detection, excision, and repair of errors that occur during DNA replication (Chapter 7). HNPCC, also known as Lynch syndrome, was originally described based on familial clustering of cancers at several sites, including the colorectum, endometrium, stomach, ovary, ureters, brain, small bowel, hepatobiliary tract, pancreas, and skin. HNPCC is thought to account for 2% to 4% of all colorectal cancers, making it the most common syndromic form of colon cancer. Colon cancers in HNPCC patients tend to occur at younger ages than sporadic colon cancers and are often located in the right colon (see Table 17.10).

Just as identification of *APC* mutations in FAP provided molecular insight into the pathogenesis of the majority of sporadic colon cancers, unraveling the defects in HNPCC has shed light on the mechanisms responsible for most of the remaining sporadic cases. There are at least five mismatch repair genes, but the majority of patients with HNPCC have mutations in *MSH2* or *MLH1*. Patients with HNPCC inherit one mutant gene and one normal allele. When the second copy is lost through mutation or epigenetic silencing, defects in mismatch repair lead to the accumulation of mutations at rates up to 1000 times higher than normal, mostly in regions containing short repeating sequences referred to as microsatellites. The human genome contains approximately 50,000 to 100,000 microsatellites, which are prone to undergo expansion during DNA replication and represent the most frequent sites of mutations in HNPCC. The consequences of mismatch repair deficiency and the resulting microsatellite instability (MSI) are discussed next in the context of colonic adenocarcinoma.

ADENOCARCINOMA

Adenocarcinoma of the colon is the most common malignancy of the GI tract and is a major cause of morbidity and mortality worldwide. In contrast, the small intestine,

which accounts for 75% of the overall length of the GI tract, is an uncommon site for benign and malignant tumors. Among malignant small intestinal tumors, adenocarcinomas and well-differentiated neuroendocrine tumors have roughly equal incidence, followed by lymphomas and sarcomas.

Epidemiology. **Colorectal adenocarcinoma is responsible for nearly 10% of all cancer deaths worldwide.** Approximately 1.2 million new cases of colorectal adenocarcinoma and 600,000 associated deaths occur each year worldwide. The incidence of these tumors is highest in North America, with the United States accounting for approximately 10% of worldwide cases and cancer deaths. This represents nearly 15% of all cancer-related deaths in the United States, second only to lung cancer. Australia, New Zealand, Europe, and (with changes in lifestyle and diet) Japan also have high incidences of colorectal adenocarcinoma. In contrast, rates are lower in South America, India, Africa, and South Central Asia. Colorectal cancer incidence peaks at 60 to 70 years of age. Fewer than 20% of cases occur before age 50, but recent data suggest that incidence of disease before age 40 is increasing.

The dietary factors most closely associated with increased risk of colorectal cancer are low intake of unabsorbable vegetable fiber and high intake of refined carbohydrates and fat. Although these associations are clear, the mechanistic relationship between diet and risk is poorly understood. It is theorized that reduced fiber content leads to decreased stool bulk and altered composition of the intestinal microbiota. This change may increase synthesis of potentially toxic oxidative by-products of bacterial metabolism, which would be expected to remain in contact with the colonic mucosa for longer periods of time as a result of reduced stool bulk. High fat intake also enhances hepatic synthesis of cholesterol and bile acids, which can be converted into carcinogens by intestinal bacteria.

In addition to dietary modification, pharmacologic chemoprevention is possible. Aspirin and other NSAIDs have a protective effect. This is consistent with studies showing that some NSAIDs cause polyp regression in FAP patients in whom the rectum was left in place after colectomy. It is suspected that this effect is mediated by inhibition of the enzyme COX-2, which is highly expressed in 90% of colorectal carcinomas and 40% to 90% of adenomas. COX-2 is necessary for production of prostaglandin E_2, which promotes epithelial proliferation, particularly after injury. TLR4, which recognizes lipopolysaccharide and is also overexpressed in adenomas and carcinomas, upregulates COX-2 expression.

Pathogenesis

Studies of colorectal carcinogenesis have provided fundamental insight into the general mechanisms of cancer evolution. These were discussed in Chapter 7; concepts that pertain specifically to colorectal carcinogenesis will be reviewed here.

The combination of molecular events that lead to colonic adenocarcinoma is heterogeneous and includes genetic and epigenetic abnormalities. **At least two genetic pathways have been described: the APC/β-catenin pathway, which is activated in the classic adenoma-carcinoma sequence, and the MSI pathway, which is associated with defects in DNA mismatch repair and accumulation of mutations in microsatellite repeat regions of the genome** (Table 17.10). Both pathways involve the stepwise accumulation of multiple mutations, but differ in the genes involved and the mechanisms by which mutations occur. Epigenetic events, the most common of which is methylation-induced gene silencing, may enhance progression along either pathway.

- *The classic adenoma-carcinoma sequence accounts for up to 80% of sporadic cancers and typically includes mutation of APC early in the neoplastic process* (Fig. 17.49). Both copies of the *APC* gene must be functionally inactivated, either by mutation or by epigenetic events, for adenomas to develop. The APC protein normally binds to and promotes degradation of β-catenin, a component of the Wnt signaling pathway (Chapter 7). With loss of APC function, β-catenin accumulates and translocates to the nucleus, where it forms a complex with the DNA-binding factor TCF and activates the transcription of genes, including *MYC* and cyclin D1, that promote proliferation. The critical role of β-catenin in this pathway is demonstrated by the fact that many colon cancers without *APC* mutations harbor β-catenin mutations that prevent APC-dependent degradation, thereby allowing β-catenin to accumulate and activate Wnt signaling. Additional mutations accumulate including activating mutations in *KRAS* that promote growth and prevent apoptosis. *KRAS* mutations are present in fewer than 10% of adenomas less than 1 cm in diameter but are found in 50% of adenomas greater than 1 cm in diameter and in 50% of invasive adenocarcinomas, indicating that this is a late event in neoplastic progression. Carcinogenesis is also associated with mutations in tumor suppressor genes such as those encoding SMAD2 and SMAD4, which are effectors of TGF-β signaling. Because TGF-β signaling normally inhibits the cell cycle, loss of these genes may allow unrestrained cell growth. The tumor suppressor gene *TP53* is mutated in 70% to 80% of colon cancers but is uncommonly affected in adenomas, suggesting that *TP53* mutations also occur at later stages of tumor progression. Loss of function of *TP53* and other tumor suppressor genes is often caused by chromosomal deletions, demonstrating the chromosomal instability that is a hallmark of the APC/β-catenin pathway. Alternatively, tumor suppressor genes may be silenced by methylation of CpG-rich zones, or CpG islands, within the 5′ region that frequently includes the promoter and transcriptional start site of some genes. Telomerase expression also increases as lesions become more advanced.
- *In patients with DNA mismatch repair deficiency, mutations accumulate in microsatellite repeats, a condition referred to as microsatellite instability (MSI).* These are referred to as MSI high, or MSI-H, tumors. Some microsatellite sequences are located in the coding or promoter regions of genes involved in regulation of cell growth, such as the type II TGF-β receptor and the pro-apoptotic protein BAX (Fig. 17.50). Because TGF-β inhibits colonic epithelial cell proliferation, mutation of *TGFBR2,* which encodes the type II TGF-β receptor, can contribute to uncontrolled cell growth, while loss of BAX may enhance the survival of genetically abnormal clones.

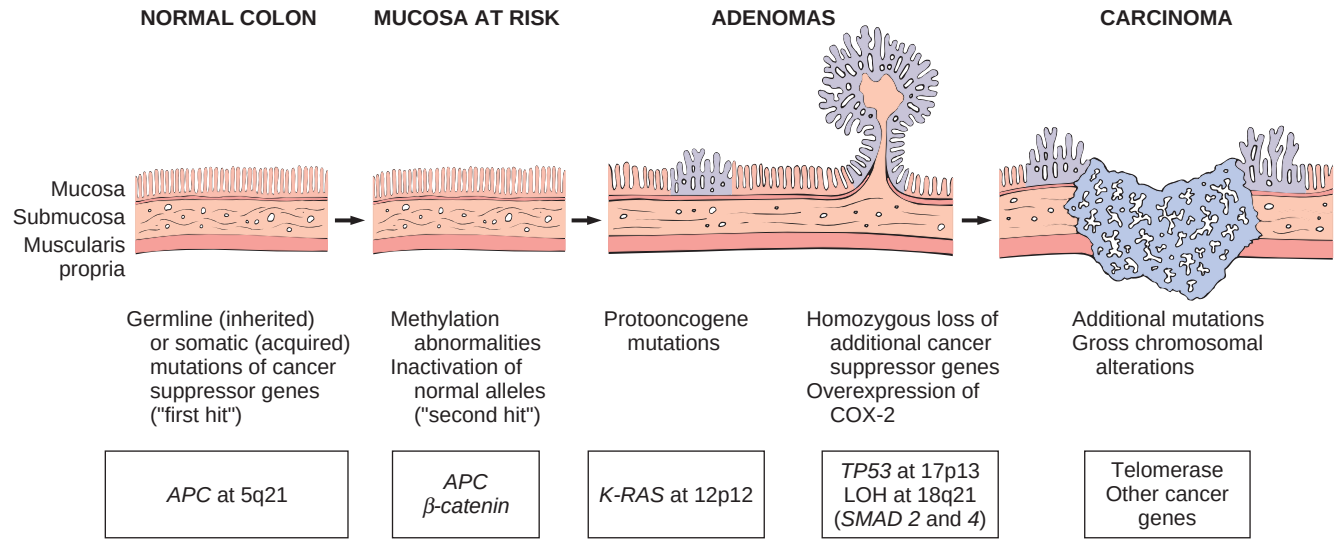

Figure 17.49 Morphologic and molecular changes in the adenoma-carcinoma sequence. Loss of one normal copy of the tumor suppressor gene *APC* occurs early. Individuals born with one mutant allele are therefore at increased risk of developing colon cancer. Alternatively, inactivation of *APC* in colonic epithelium may occur later in life. This is the "first hit" according to the Knudson hypothesis (Chapter 7). The loss of the intact second copy of *APC* follows ("second hit"). Other changes, including mutation of *KRAS*, losses at 18q21 involving *SMAD2* and *SMAD4*, and inactivation of the tumor suppressor gene *TP53*, lead to the emergence of carcinoma. Although there seems to be a temporal sequence of changes, the accumulation of mutations, rather than their occurrence in a specific order, is most critical.

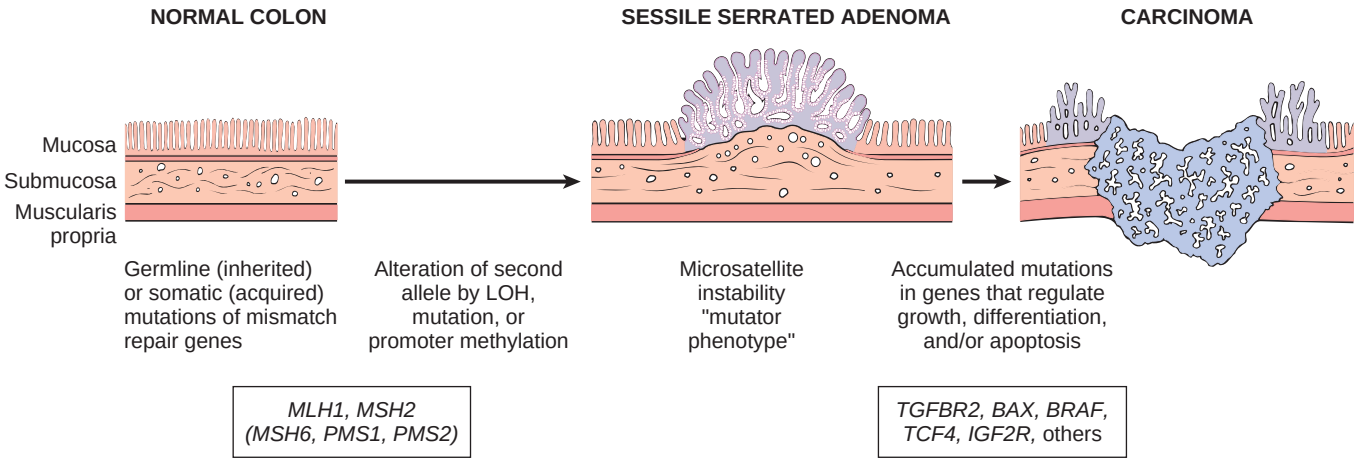

Figure 17.50 Morphologic and molecular changes in the mismatch repair pathway of colon carcinogenesis. Defects in mismatch repair genes result in microsatellite instability and permit accumulation of mutations in numerous genes. If these mutations affect genes involved in cell survival and proliferation, cancer may develop.

- *A subset of microsatellite unstable colon cancers without mutations in DNA mismatch repair enzymes demonstrate the CpG island hypermethylation phenotype (CIMP).* In these tumors, the *MLH1* promoter region is typically hypermethylated, thereby reducing MLH1 expression and repair function. Activating mutations in the oncogene *BRAF* are common in these cancers. In contrast, *KRAS* and *TP53* are not typically mutated. The combination of MSI, *BRAF* mutation, and methylation of specific targets, such as *MLH1,* is the signature of this pathway of carcinogenesis.
- *A small group of colon cancers display increased CpG island methylation in the absence of MSI.* Many of these tumors harbor *KRAS* mutations, but *TP53* and *BRAF* mutations are uncommon. In contrast, *TP53* mutations are common in colon cancers that do not display a CpG island methylator phenotype.

While morphology cannot reliably define the underlying molecular events that lead to carcinogenesis, certain correlations have been associated with mismatch repair deficiency and MSI. These molecular alterations are common in sessile serrated lesions and cancers that arise from them. In addition, invasive carcinomas with MSI often have prominent mucinous differentiation and peritumoral lymphocytic infiltrates. These tumors as well as those with a CpG island hypermethylation phenotype are frequently located in the right colon. MSI can be identified by the absence of immunohistochemical staining for mismatch repair proteins or by molecular genetic analysis of microsatellite sequences. It is important to identify patients

with HNPCC because of the implications for genetic counseling, the elevated risk of a second malignancy of the colon or other organs, and, in some settings, differences in prognosis and therapy.

MORPHOLOGY

Overall, adenocarcinomas are distributed approximately equally over the entire length of the colon. Tumors in the **proximal colon often grow as polypoid, exophytic masses** that extend along one wall of the large-caliber cecum and ascending colon; these tumors rarely cause obstruction. In contrast, **carcinomas in the distal colon tend to be annular lesions that produce "napkin-ring" constrictions and luminal narrowing** (Fig. 17.51), sometimes to the point of obstruction. Both forms grow into the bowel wall over time. The general microscopic characteristics of right- and left-sided colonic adenocarcinomas are similar. Most tumors are composed of tall columnar cells that resemble dysplastic epithelium found in adenomas (Fig. 17.52A). The invasive component of these tumors elicits a strong stromal desmoplastic response, which is responsible for their characteristic firm consistency. Some poorly differentiated tumors form few glands (Fig. 17.52B). Others may produce abundant mucin that accumulates within the intestinal wall; these are associated with poor prognosis. Uncommonly, tumors may be composed of signet-ring cells similar to those in gastric cancer (Fig. 17.52C).

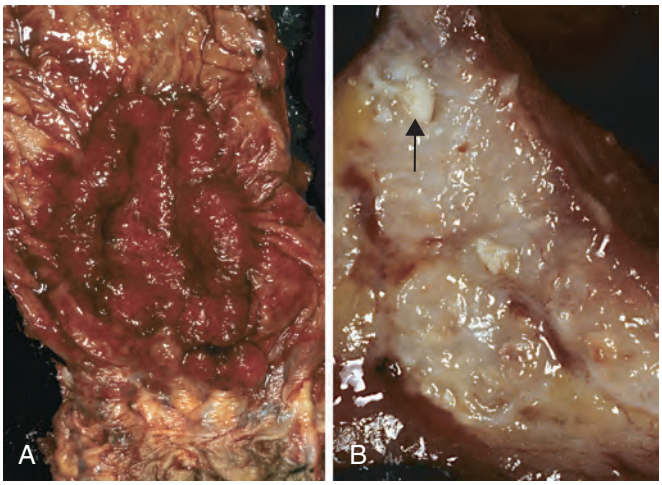

Figure 17.51 Colorectal carcinoma. (A) Circumferential, ulcerated rectal cancer. Note the anal mucosa at the bottom of the image. (B) Cancer of the sigmoid colon that has invaded through the muscularis propria and is present within subserosal adipose tissue (left). Areas of chalky necrosis are present within the colon wall *(arrow)*.

Clinical Features

The availability of endoscopic screening combined with the knowledge that most carcinomas arise within adenomas presents a unique opportunity for cancer prevention. Unfortunately, colorectal cancers develop insidiously and may go undetected for long periods. Cecal and other right-sided colon cancers are most often called to clinical attention by the appearance of fatigue and weakness due to iron deficiency anemia. Thus, it is a clinical maxim that the underlying cause of iron deficiency anemia in an older man or postmenopausal woman is GI cancer until proven otherwise. Left-sided colorectal adenocarcinomas may produce occult bleeding, changes in bowel habits, or cramping and left lower quadrant discomfort.

Although poorly differentiated and mucinous histologies are associated with worse prognosis, **the two most important prognostic factors are depth of invasion and the presence of lymph node metastases.** Invasion into the muscularis propria significantly reduces the probability of survival, which is decreased further by the presence of lymph node metastases (Fig. 17.53A). Metastases may involve regional lymph nodes, lungs (Fig. 17.53B), and bones, but as a result of portal drainage of the colon, the liver is the most common site of distant metastatic lesions (Fig. 17.53C). The rectum does not drain via the portal circulation; hence anal carcinomas that metastasize often circumvent the liver.

These prognostic factors were originally recognized by Dukes and Kirklin and form the core of the TNM (tumor-nodes-metastasis) system (Table 17.11). The TNM classification is used to define tumor stage (Table 17.12). Regardless of stage, it must be remembered that some patients with small numbers of metastases do well for years following resection of distant tumor nodules.

Five-year survival rates vary widely worldwide. The overall 5-year survival rate in the United States is 65% and

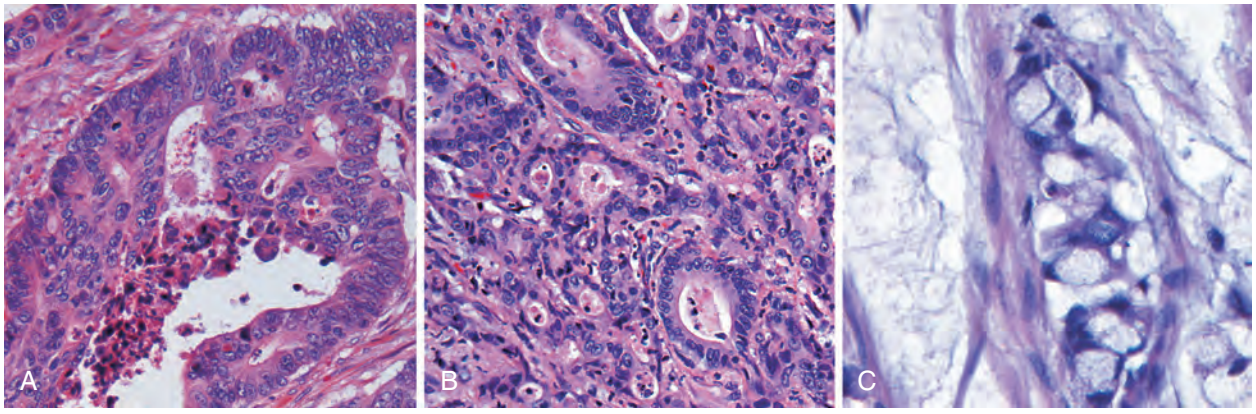

Figure 17.52 Histologic appearance of colorectal carcinoma. (A) Well-differentiated adenocarcinoma. Note the elongated, hyperchromatic nuclei. Necrotic debris, present in the gland lumen, is typical. (B) Poorly differentiated adenocarcinoma forms a few glands but is largely composed of infiltrating nests of tumor cells. (C) Mucinous adenocarcinoma with signet-ring cells and extracellular mucin pools.

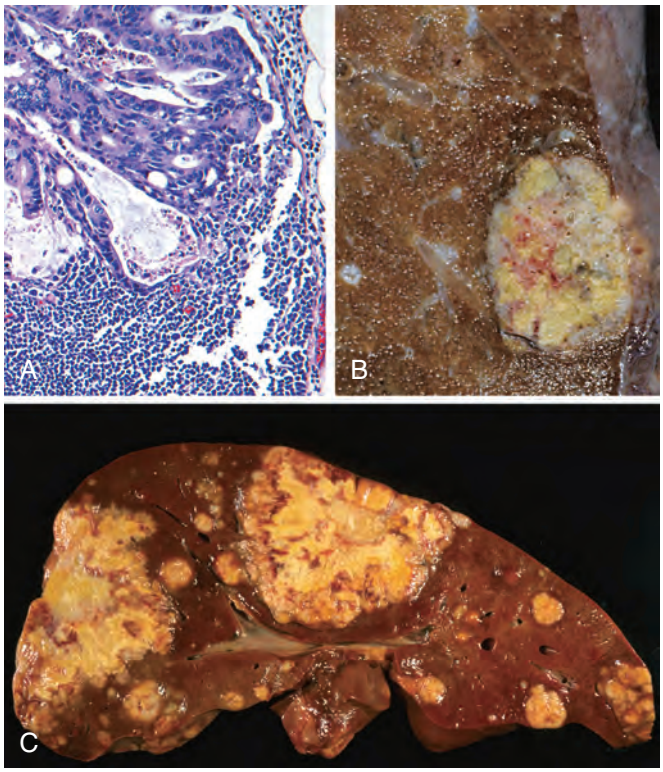

Figure 17.53 Metastatic colorectal carcinoma. (A) Lymph node metastasis. Note the glandular structures within the subcapsular sinus. (B) Solitary subpleural nodule of colorectal carcinoma metastatic to the lung. (C) Liver containing two large and many smaller metastases. Note the central necrosis within metastases.

ranges from 90% to 40% depending on stage. Survival rates in Europe, Japan, and Australia are similar, ranging from 60% (Switzerland, Japan) to 40% (Poland). Overall survival rates are somewhat lower in other countries, such as China, India, the Philippines, and Thailand (30% to 42%). In contrast, the 5-year survival rate in Gambia is only 4%, a measure of the challenges of delivering healthcare to under-resourced parts of the world.

Table 17.11 American Joint Committee on Cancer (AJCC) TNM Classification of Colorectal Carcinoma

TNM	
Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ, intramucosal carcinoma
T1	Tumor invades the submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4	Tumor invades visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades visceral peritoneum
T4b	Tumor directly invades or adheres to adjacent organs or structures
Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in two to three regional lymph nodes
N1c	Tumor deposit(s) in subserosa or in non-peritonealized pericolic or perirectal soft tissue without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis to one or more distant sites or organs or peritoneal metastasis
M1a	Metastasis to one site or organ without peritoneal metastasis
M1b	Metastases to two or more sites or organs without peritoneal metastasis
M1c	Metastasis to the peritoneal surface, alone or with other site or organ metastases

KEY CONCEPTS

BENIGN AND MALIGNANT PROLIFERATIVE LESIONS OF THE COLON

- Intestinal polyps can be classified as nonneoplastic or neoplastic. The nonneoplastic polyps can be further subclassified as hyperplastic, inflammatory, or hamartomatous.
- Hyperplastic polyps are benign epithelial proliferations most commonly found in the left colon and rectum. They have no malignant potential and must be distinguished from sessile serrated polyps.
- Inflammatory polyps form as a result of chronic cycles of injury and healing.
- Hamartomatous polyps occur sporadically or as a part of genetic diseases. The latter include juvenile polyposis and Peutz-Jeghers syndrome, which are associated with increased risk of malignancy.
- Benign epithelial neoplastic polyps of the intestines are termed adenomas. The hallmark of these lesions, which are the precursors of colonic adenocarcinomas, is cytologic dysplasia.
- In contrast to traditional adenomas, sessile serrated polyps lack cytologic dysplasia and share morphologic features with hyperplastic polyps.
- Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) are the most common forms of familial colon cancer.
- FAP is caused by *APC* mutations. Patients typically have more than 100 adenomas, and all patients develop colon cancer before 30 years of age.
- HNPCC is caused by mutations in DNA mismatch repair enzymes. HNPCC patients have far fewer polyps and develop cancer at older ages than FAP patients but younger ages than those with sporadic colon cancer.
- FAP and HNPCC typify distinct pathways of neoplastic transformation and progression that are also involved in the majority of sporadic colon cancers. A third pathway characterized by

CpG island hypermethylation underlies most remaining colon cancers.

- Nearly all colonic cancers are adenocarcinomas. The two most important prognostic factors are depth of invasion and the presence or absence of lymph node metastases.

TUMORS OF THE ANAL CANAL

The anal canal can be divided into thirds. The upper zone is lined by columnar rectal epithelium; the middle third by transitional epithelium; and the lower third by stratified squamous epithelium. Carcinomas of the anal canal may have typical glandular or squamous patterns of differentiation, recapitulating the normal epithelium of the upper and lower thirds, respectively (Fig. 17.54A). An additional differentiation pattern of squamous cell carcinomas, termed basaloid, is present in tumors populated by immature cells derived from the basal layer of transitional epithelium (Fig. 17.54B). These tumors are classified as squamous, but the archaic term cloacogenic carcinoma is often applied when the entire tumor displays a basaloid pattern. Alternatively, basaloid differentiation may be mixed with mucinous differentiation. Squamous cell carcinoma of the anal canal is frequently associated with infection by high-risk strains of human papilloma virus (HPV), whereas infections with low-risk HPV strains are associated with condyloma acuminatum (Fig. 17.54C). The major risk factor for these HPV associated lesions is anal sex.

Table 17.12 Colorectal Cancer Staging System

Stage	T	N	M
0	Tis	N0	M0
I	T1–T2	N0	M0

HEMORRHOIDS

Hemorrhoids affect about 5% of the general population and develop secondary to persistently elevated venous pressure within the hemorrhoidal plexus. The most frequent predisposing influences are straining at defecation, e.g., in constipation, and venous stasis of pregnancy. Hemorrhoids may also develop secondary to portal hypertension. The pathogenesis of hemorrhoids (anal varices) in portal hypertension is similar to that of esophageal varices; anal varices are both more common and much less serious. Anal and perianal varices connect portal and caval venous systems, thereby relieving the venous hypertension.

Hemorrhoids often present with pain and rectal bleeding, particularly bright red blood seen on toilet tissue. Except for pregnant women, hemorrhoids are rarely encountered in persons younger than age 30. Hemorrhoidal bleeding is not generally a medical emergency and can be treated by sclerotherapy, rubber band ligation, or infrared coagulation. Extensive or severe internal or external hemorrhoids may be removed surgically by hemorrhoidectomy.

ACUTE APPENDICITIS

The appendix is a normal true diverticulum of the cecum that is prone to acute and chronic inflammation. Acute

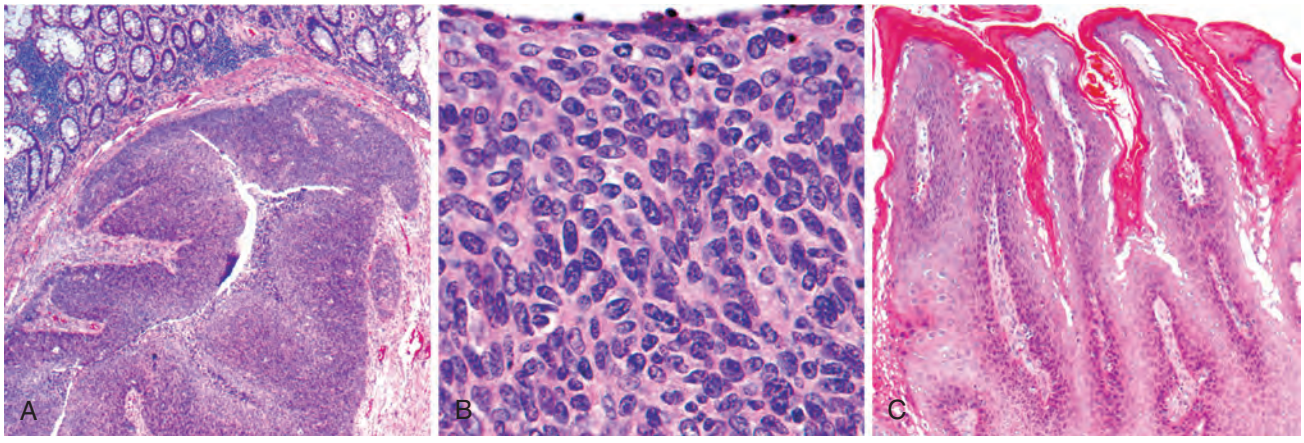

Figure 17.54 Anal tumors. (A) This anal squamous cell carcinoma demonstrates a multilayered organization reminiscent of squamous mucosa. The adjacent rectal mucosa is normal. (B) This anal squamous cell carcinoma with basaloid features is composed of hyperchromatic cells that resemble the basal layer of normal squamous mucosa. (C) Condyloma acuminatum with verrucous architecture.

appendicitis is most common in adolescents and young adults, with a lifetime risk of 7%; males are affected slightly more often than females. Despite the prevalence of acute appendicitis, the diagnosis can be difficult to confirm preoperatively and may be confused with mesenteric lymphadenitis (often secondary to unrecognized *Yersinia* infection or viral enterocolitis), acute salpingitis, ectopic pregnancy, mittelschmerz pain (caused by minor pelvic bleeding at the time of ovulation), and Meckel diverticulitis.

Pathogenesis

Acute appendicitis is thought to be initiated by progressive increases in intraluminal pressure that compromise venous outflow. In 50% to 80% of cases, acute appendicitis is associated with overt luminal obstruction, usually caused by a small stone-like mass of stool, or fecalith, or, less commonly, a gallstone, tumor, or mass of worms (oxyuriasis vermicularis). Peri-appendiceal lymphoid hyperplasia, e.g., after viral infection, and the resulting appendiceal compression has also been proposed as a mechanism of venous and luminal obstruction. Stasis of luminal contents allows bacterial proliferation that leads to ischemia and inflammation.

MORPHOLOGY

In early acute appendicitis, subserosal vessels are congested, and there is a modest perivascular neutrophilic infiltrate within all layers of the wall. The inflammatory reaction transforms the normal glistening serosa into a dull, granular, erythematous surface. Although mucosal neutrophils and focal superficial ulceration are often present, these are not specific markers of acute appendicitis. Diagnosis of acute appendicitis requires **neutrophilic infiltration of the muscularis propria.** In more severe cases a prominent neutrophilic exudate generates a serosal fibrinopurulent reaction. As the process continues, focal abscesses may form within the wall (acute suppurative appendicitis). Further compromise of appendiceal vessels can result in ischemia, hemorrhagic ulceration, and gangrenous necrosis that extends to the serosa, creating acute gangrenous appendicitis, which can be followed by rupture and suppurative peritonitis.

Clinical Features

Typically, early acute appendicitis produces periumbilical pain that ultimately localizes to the right lower quadrant, followed by nausea, vomiting, low-grade fever, and a mildly elevated peripheral white cell count. A classic physical finding is the *McBurney sign,* deep tenderness located two-thirds of the distance from the umbilicus to the right anterior superior iliac spine (McBurney point).

Regrettably, classic signs and symptoms of acute appendicitis are often absent. In some cases, a retrocecal appendix may generate right flank or pelvic pain, while a malrotated colon may give rise to appendiceal pain in the left upper quadrant. As with other causes of acute inflammation, there is neutrophilic leukocytosis. In some cases the peripheral leukocytosis may be minimal or, alternatively, so great that other causes are considered. The diagnosis of acute appendicitis in young children and the very old is particularly problematic, since other causes of abdominal emergencies are prevalent in these populations, and the very young and old are also more likely to have atypical clinical presentations.

Given these diagnostic challenges, it should be no surprise that even highly skilled surgeons remove normal appendices. This is preferred to delayed resection of a diseased appendix, given the significant morbidity and mortality associated with appendiceal perforation. Other complications of appendicitis include pyelophlebitis, portal venous thrombosis, liver abscess, and bacteremia.

TUMORS OF THE APPENDIX

Several tumors occur in the appendix. The most common is the well-differentiated neuroendocrine (carcinoid) tumor. It is usually discovered incidentally at the time of surgery or pathologic examination of a resected appendix. This neoplasm, which is almost always benign, most frequently forms a solid bulbous swelling at the distal tip of the appendix, where it can reach 2 to 3 cm in diameter. Although intramural and transmural extension may be evident, nodal metastases are very infrequent, and distant spread is exceptionally rare.

Conventional adenomas, mucin-producing and non–mucin-producing adenocarcinomas, and the uncommon adenocarcinoid tumor also occur in the appendix and may cause obstruction and enlargement that mimics acute appendicitis.

Mucinous neoplasms of the appendix occur in adults, most often in the sixth decade of life. They are characterized by mucinous epithelial proliferation, extracellular mucin, and pushing tumor margins; an infiltrating invasive pattern classifies the tumor as a mucin-producing adenocarcinoma.

Mucin can dissect through the wall to the peritoneal surface, causing appendiceal rupture. Tumors are classified as low-grade or high-grade appendiceal mucinous neoplasms (LAMN, HAMN) on the basis of histological features. *GNAS,* which encodes Gαs, is frequently mutated and thought to contribute to excessive mucin production. *KRAS* mutations are also common. Genes involved in colon cancer, such as *APC, TP53,* and *SMAD4,* are typically intact in LAMN but may be mutated in HAMN. When confined to the appendix, prognosis of LAMN is excellent. Outcomes are more variable in HAMN. Peritoneal spread of LAMN, HAMN, or mucin-producing adenocarcinomas (of the appendix or colon) can lead to pseudomyxoma peritonei, in which tenacious, semisolid mucin fills the abdomen. This disseminated intraperitoneal disease may be held in check for years by repeated surgical debulking but, in most instances, follows an inexorably fatal course.

KEY CONCEPTS

HEMORRHOIDS AND APPENDICEAL DISEASE

- Hemorrhoids are collateral vessels that develop secondary to persistently elevated venous pressure within the hemorrhoidal plexus. They also occur in portal hypertension.
- Acute appendicitis is most common in children and adolescents. It is thought to be initiated by increased intraluminal pressure and compromised venous outflow.
- The most common tumor of the appendix is the well-differentiated neuroendocrine (carcinoid) tumor, which is almost always benign.
- Peritoneal dissemination of mucinous neoplasms can cause pseudomyxoma peritonei.

Peritoneal Cavity

The peritoneal cavity houses the abdominal viscera and is lined by a single layer of mesothelial cells; these cover the visceral and parietal surfaces and are supported by a thin layer of connective tissue to form the peritoneum. Here we discuss inflammatory, infectious, and neoplastic disorders of the peritoneal cavity and retroperitoneal space.

INFLAMMATORY DISEASE

Peritonitis may result from bacterial invasion or chemical irritation and is most often due to:

- Leakage of bile or pancreatic enzymes, which produces *sterile peritonitis.*
- *Perforation or rupture of the biliary system* that evokes a highly irritating peritonitis, usually complicated by bacterial superinfection
- *Acute hemorrhagic pancreatitis* (Chapter 19), which is associated with leakage of pancreatic enzymes and fat necrosis. Damage to the bowel wall may allow bacteria to spread to the peritoneal cavity.
- *Foreign material,* including that introduced surgically (e.g., talc and sutures), may induce foreign body–type granulomas and fibrous scarring.
- *Endometriosis,* which causes hemorrhage into the peritoneal cavity, that acts as an irritant.
- *Ruptured dermoid cysts,* which release keratins and induce an intense granulomatous reaction.
- *Perforation* of abdominal viscera, which results in leakage of luminal materials that can lead to infection and immune activation.

Peritoneal Infection

Bacterial peritonitis occurs when bacteria from the GI lumen are released into the abdominal cavity, most commonly following intestinal perforation. *E. coli*, streptococci, *S. aureus,* enterococci, and *C. perfringens* are implicated most often.

Spontaneous bacterial peritonitis develops in the absence of an obvious source of contamination. It is seen most often in patients with cirrhosis and ascites and less frequently in children with nephrotic syndrome. Diagnosis is based on the presence of neutrophils in ascitic fluid and positive bacterial cultures; *E. coli,* streptococci, and *Klebsiella* species are the most frequently involved organisms.

MORPHOLOGY

The cellular inflammatory response is composed primarily of dense collections of neutrophils and fibrinopurulent debris that coat the viscera and abdominal wall. Serous or slightly turbid fluid begins to accumulate and becomes suppurative as infection progresses. Subhepatic and subdiaphragmatic abscesses may be formed. With the exception of tuberculous peritonitis, the reaction usually remains superficial.

Sclerosing Retroperitonitis

Sclerosing retroperitonitis, also known as idiopathic retroperitoneal fibrosis or Ormond disease, is characterized by dense fibrosis that may extend to involve the mesentery. Although the cause of sclerosing retroperitonitis is unknown, many cases are now thought to fall within the spectrum of IgG4-related sclerosing disease, an immunoinflammatory disorder that can lead to fibrosis in a wide variety of tissues. Because the process frequently compresses the ureters, this entity is described in more detail in Chapters 6 and 21.

TUMORS

Primary malignant tumors arising from the peritoneal lining, mesotheliomas, are similar to tumors of the pleura and pericardium. Peritoneal mesotheliomas are almost always associated with high levels of asbestos exposure. Rarely, primary benign and malignant soft tissue tumors may also develop within the peritoneum and retroperitoneum. The most common of these is desmoplastic small round cell tumor. This is an aggressive tumor that occurs in children and young adults. It bears a strong morphologic resemblance to Ewing sarcoma (Chapter 26) and like Ewing sarcoma is also characterized by a reciprocal translocation, t(11;22) (p13;q12), that produces a *EWS* and *WT1* fusion gene.

Secondary tumors may involve the peritoneum by direct spread or metastatic seeding, resulting in peritoneal carcinomatosis. As discussed earlier, mucinous carcinomas, particularly those of the appendix, may cause pseudomyxoma peritonei.

CHAPTER 18

Liver and Gallbladder

Ryan M. Gill • Sanjay Kakar[a]

CHAPTER CONTENTS

The Liver and Bile Ducts

The normal adult liver weighs 1400 to 1600 g. It has a dual blood supply, with the portal vein providing 60% to 70% of hepatic blood flow and the hepatic artery supplying the remaining 30% to 40%. The portal vein and the hepatic artery enter the inferior aspect of the liver through the hilum, or *porta hepatis*. Within the liver, the branches of the portal veins, hepatic arteries, and bile ducts travel in parallel within portal tracts.

The lobule model provides one useful way to consider the anatomic organization of the liver (Fig. 18.1). In this model, the liver is divided into 1- to 2-mm hexagonal lobules

[a]The contributions of Drs. James Crawford and Neil Theise to this chapter in the last several editions of this book are gratefully acknowledged.

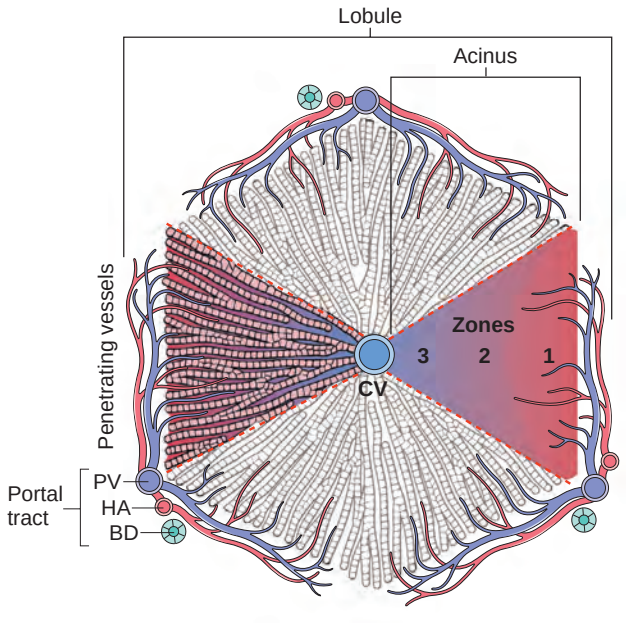

Figure 18.1 Model of liver anatomy. In the hexagonal lobular model, the terminal hepatic vein *(CV)* is at the center of a "lobule," while the portal tracts are at the periphery; these landmarks serve to identify "periportal" and "pericentral" parenchyma. In the acinar model, on the basis of blood flow, three zones can be defined, zone 1 being the closest to the blood supply and zone 3 being the farthest. *BD,* Bile duct; *HA,* hepatic artery; *PV,* portal vein.

that are oriented around the terminal tributaries of the hepatic vein. The veins lie at the center of the lobules and hence are termed central veins, and portal tracts are located at the periphery. Each lobule can be further subdivided into six triangular acini. The hepatocytes in the vicinity of the central vein are called "pericentral" and are said to be in "zone 3," while those near the portal tract are periportal and belong to "zone 1." Notably, certain types of hepatic injury preferentially affect hepatocytes in particular zones (see Fig. 18.1). These differing sensitivities result from variation in hepatocyte oxygenation (highest in zone 1, lowest in zone 3) and metabolic activities from the periphery to the center of the lobule.

Within the lobule, hepatocytes are organized into anastomosing sheets or "plates" extending from portal tracts to the terminal hepatic veins. Between the trabecular plates of hepatocytes are vascular sinusoids. Blood traverses the sinusoids and exits into the terminal hepatic veins through numerous orifices in the vein wall. Hepatocytes are thus bathed on two sides by a mixture of portal venous and hepatic arterial blood. The sinusoids are lined by fenestrated endothelium. Beneath the endothelial cells lies the *space of Disse,* into which protrude abundant hepatocyte microvilli. Scattered *Kupffer cells* of the mononuclear phagocyte system are attached to the luminal face of endothelial cells, and fat-containing *hepatic stellate cells* are found in the space of Disse. Between abutting hepatocytes are bile canaliculi, which are channels 1 to 2 μm in diameter, formed by grooves in the plasma membranes of facing hepatocytes and separated from the vascular space by tight junctions. These channels drain into the *canals of Hering* that, in turn, connect to bile ductules. The ductules empty into the interlobular bile ducts within portal tracts. Large numbers of lymphocytes (mostly gamma delta T cells, but also natural killer [NK] cells) are also present in normal liver, comprising as many as 22% of cells other than hepatocytes.

GENERAL FEATURES OF LIVER DISEASE

The liver is vulnerable to a wide variety of metabolic, toxic, microbial, circulatory, and neoplastic insults. Hepatic damage also occurs secondary to other diseases, such as heart failure, disseminated cancer, and extrahepatic infections. The enormous functional reserve of the liver masks the clinical impact of mild liver damage, but with progression of diffuse disease or disruption of bile flow, the consequences of deranged liver function may become life threatening.

With the exception of acute liver failure, liver disease is an insidious process in which clinical detection and symptoms of hepatic decompensation may occur weeks, months, or many years after the onset of injury. The ebb and flow of hepatic injury may be imperceptible to the patient and detectable only by abnormal laboratory tests (Table 18.1).

Mechanisms of Injury and Repair

Hepatocyte and Parenchymal Responses

Injured or dysfunctional hepatocytes in a variety of disorders may demonstrate several potentially reversible morphologic changes. These include accumulation of fat (steatosis) and bilirubin (cholestasis), as well as ballooning, a change marked by cell swelling, cytoplasmic clearing, and clumping of intermediate filaments, which when prominent, may form *Mallory hyaline.* Ballooned hepatocytes are a hallmark of

Table 18.1 Laboratory Evaluation of Liver Disease

Test Category	Serum Measurement
Hepatocyte integrity	Cytosolic hepatocellular enzymes[a] Serum aspartate aminotransferase (AST) Serum alanine aminotransferase (ALT) Serum lactate dehydrogenase (LDH)
Biliary excretory function	Substances normally secreted in bile[a] Serum bilirubin Total: unconjugated plus conjugated Direct: conjugated only Urine bilirubin Serum bile acids Plasma membrane enzymes (from damage to bile canaliculus)[a] Serum alkaline phosphatase Serum γ-glutamyl transpeptidase (GGT)
Hepatocyte synthetic function	Proteins secreted into the blood Serum albumin[b] Coagulation factors[b] Prothrombin time (PT) and partial thromboplastin time (PTT): fibrinogen, prothrombin, factors V, VII, IX, and X Hepatocyte metabolism Serum ammonia[a] Aminopyrine breath test (hepatic demethylation)[b]

[a]Increased in liver disease.

[b]Decreased in liver disease.

alcohol-induced or nonalcoholic steatohepatitis (see later discussion), but may also occur with ischemic or toxic injury, or with cholestasis.

When injury is irreversible, hepatocytes may die by necrosis or apoptosis. In hepatocyte necrosis, ion imbalances due to defective plasma membrane transporter function cause water to flow into the cell, which swells and ruptures. Membrane abnormalities also lead to accumulation of intracellular calcium and several events that trigger mitochondrial dysfunction. Even before membrane ruptures, loss of membrane integrity leads to the release of cytoplasmic constituents into the extracellular compartment, including substances that alert innate immune cells to an ongoing threat (danger signals). The remnants of the necrotic cells are rapidly phagocytosed by macrophages, which tend to cluster and mark sites of hepatocyte necrosis (Fig. 18.2). This form of injury is the predominant mode of death in ischemic/hypoxic injury and a significant part of hepatic injury in the setting of oxidative stress.

Hepatocyte apoptosis is an active form of "programmed" cell death resulting in hepatocyte shrinkage, nuclear chromatin condensation *(pyknosis),* fragmentation *(karyorrhexis),* and cellular fragmentation into acidophilic *apoptotic bodies*. These changes are a result of caspase cascades described in detail in Chapter 2. Apoptotic hepatocytes were first clearly described in yellow fever by William Thomas Councilman and therefore have often been referred to as *Councilman bodies;* while apoptosis occurs in many forms of liver disease, by convention this eponym is restricted to that disease. In the more frequent settings in which apoptotic hepatocytes are seen (e.g., acute and chronic hepatitis), the term *acidophil bodies* is used, due to their deeply eosinophilic staining characteristics (Fig. 18.3).

If parenchymal injury is widespread, it may lead to confluent necrosis, a zonal loss of contiguous hepatocytes. This may be seen in acute toxic or ischemic injuries or in severe viral or autoimmune hepatitis. Confluent necrosis may begin with hepatocyte dropout in zone 3 near the central vein. The resulting space is filled by cellular debris, macrophages, and remnants of the reticulin meshwork. In *bridging necrosis,* the area of necrosis may extend from the central veins to the portal tracts, or across adjacent portal tracts (often with an inapparent central vein within the area of injury). In pan-acinar necrosis, the entire lobule is obliterated. Even in diseases such as viral hepatitis, in which hepatocytes are the principal targets of attack, secondary vascular insults—due to inflammation or thrombosis—may produce large areas of confluent hepatocyte necrosis. This process occurs in many types of liver diseases in which there is extensive hepatocyte loss and collapse of the supporting reticulin framework. The resultant scarring (known in the liver as *cirrhosis*) in which hepatocytes are surrounded by fibrosis (with or without a regenerative response) represents a common end point for chronic liver disease. In some cases, there is scar regression (described in the next section).

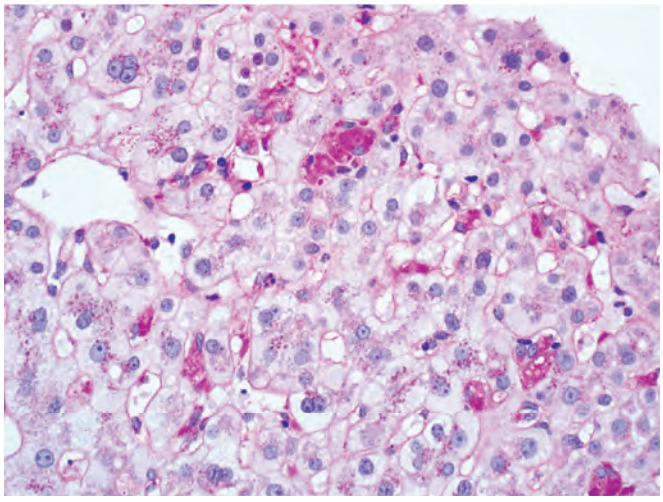

Figure 18.2 Acute hepatitis B. Clusters of macrophages with PAS-positive intracellular material derived from necrotic hepatocytes.

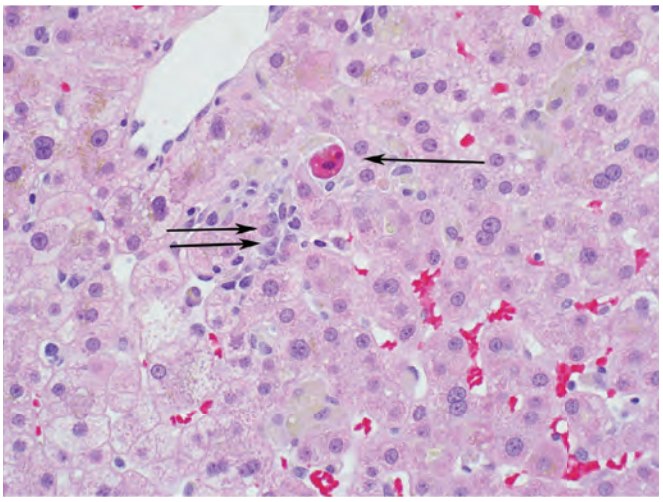

Figure 18.3 Foci of lobular hepatitis in chronic hepatitis C show an apoptotic hepatocyte ("acidophil body"; *arrow*) and a focus of mononuclear infiltration surrounding a more darkly stained, injured hepatocyte *(double arrows).*

Replacement of lost hepatocytes occurs primarily by replication of mature hepatocytes adjacent to those that have died, even when there is significant confluent necrosis. Hepatocytes are almost stem cell–like in their ability to continually replicate, even after years of chronic injury, and thus replenishment of parenchyma from tissue stem cells is usually not a significant part of the repair process. Eventually, however, in individuals with chronic disease, the hepatocytes enter into replicative senescence; once this occurs, stem cell populations may begin to expand and differentiate, an event marked by *ductular reactions*. These ductlike structures, sometimes without lumens, contain multipotent cells that may contribute significantly to parenchymal restoration.

Scar Formation and Regression

The principal cell type involved in scar deposition in the liver is the hepatic stellate cell. When quiescent, the main function of stellate cells is lipid storage, including vitamin A. However, in several forms of acute and chronic injury, stellate cells become activated and differentiate into highly fibrogenic myofibroblasts. The stimuli for stellate cell activation are varied and include: (1) inflammatory cytokines, such as tumor necrosis factor alpha (TNF-α), produced by Kupffer cells, macrophages, and other cell types; (2) altered

interactions with extracellular matrix (ECM); and (3) toxins and reactive oxygen species (ROS). Following activation, the conversion of stellate cells into myofibroblasts is stimulated by signals transmitted by platelet-derived growth factor receptor β and by cytokines, such as transforming growth factor β (TGF-β) and interleukin-17 (IL-17), as well as chemokines, which may be released from resident Kupffer cells or recruited macrophages and lymphocytes. The activated stellate cells in turn also release cytokines, growth factors or and chemotactic and vasoactive factors. If the injury and inflammatory stimuli persist, extracellular matrix deposition and scarring commence, often in the space of Disse; there is concurrent loss of sinusoidal endothelial cell fenestration, a change termed *sinusoidal capillarization* that is a particularly prominent feature in nonalcoholic steatohepatitis and also is a feature of the abnormal sinusoids seen in hepatocellular carcinoma (both described later).

Areas of hepatocyte loss in chronic liver disease, perhaps related to vascular compromise, are transformed into dense fibrous septa through collapse of the underlying reticulin framework and deposition of collagen by myofibroblasts. Portal fibroblasts may also play a role in the scarring that accompanies chronic liver injury in some disorders. Eventually, the fibrous septa encircle surviving hepatocytes and give rise to diffuse scarring (cirrhosis). In chronic liver disease, surviving hepatocytes replicate in an effort to restore the parenchyma, forming regenerative nodules that are a predominant feature in most cirrhotic livers.

If the chronic injury leading to scar formation is interrupted (e.g., clearance of hepatitis virus infection or cessation of alcohol use), then stellate cell activation and scarring ceases and fibrous septae may begin to be broken down by metalloproteinases produced by hepatocytes, leading to partial resolution and an appearance termed *incomplete septal cirrhosis*. Unfortunately, vascular remodeling and other architectural changes that occur in cirrhosis may not revert to normal, even with extensive scar resorption, which may explain why vascular abnormalities such as portal hypertension fail to improve in some patients.

Liver Failure

The most severe form of liver disease is liver failure, which may be acute (due to sudden and massive hepatic destruction) or (more commonly) chronic, following years of insidious, progressive liver injury. In some cases, individuals with chronic liver disease develop *acute-on-chronic liver failure,* in which an unrelated acute injury is superimposed on late-stage chronic disease or there is a "flare" of the chronic disease that leads to liver decompensation. Whatever the sequence, 80% to 90% of functional capacity must be lost before hepatic failure appears. When the liver can no longer maintain homeostasis, liver transplantation offers the best hope for survival; without transplantation, the mortality rate in persons with hepatic failure is about 80%.

Acute Liver Failure

Acute liver failure is defined as an acute liver illness associated with encephalopathy and coagulopathy that occurs within 26 weeks of the initial liver injury in the absence of preexisting liver disease. Usually the syndrome manifests within 8 weeks of injury, and many patients progress to coma within only a week. Within this 26-week window, it is useful to know the interval between the onset of symptoms and liver failure, since this may provide helpful clues to the etiology. Very rapid onset acute liver failure is most often induced by drugs or toxins and is typically the result of *massive hepatic* necrosis, This form of liver failure has been referred to as "fulminant liver failure" in the past, a term that remains entrenched in the literature and is still used interchangeably. Accidental or deliberate ingestion of acetaminophen (Chapter 9) accounts for almost 50% of adult cases in the United States, while autoimmune hepatitis, other drugs/toxins, and acute hepatitis A and B infections account for most remaining cases. In Asia, acute hepatitis B and E are the predominant causes. With acetaminophen toxicity, the liver failure occurs within 1 week of the onset of symptoms, whereas failure due to hepatitis viruses takes longer to develop. The mechanism of hepatocellular necrosis may be direct toxic damage (as with acetaminophen), but more often is a variable combination of toxicity and immune-mediated hepatocyte destruction (e.g., hepatitis virus infection). Rare causes of acute liver failure include abnormalities of blood flow, metabolic disorders, and malignancies, most commonly leukemia or lymphoma (33%), followed by breast cancer (30%) and colon cancer (7%). An etiology cannot be established in about 15% of adult and 50% of pediatric cases.

MORPHOLOGY

Acute liver failure usually is associated with **massive hepatic necrosis,** with broad regions of parenchymal loss surrounding islands of preserved or regenerating hepatocytes (Fig. 18.4). Affected livers are small and shrunken. The prominence of hepatocellular dropout and of ductular reactions in these livers depends on the nature and duration of the insult. Toxic injuries, such as acetaminophen overdoses, usually take place within hours to days, too brief a period to allow for scar formation or regeneration. Acute viral infections may cause failure over weeks to a few months, so that although hepatocyte injury continues to outpace repair, regeneration is often evident along with scarring.

Rarely, acute liver failure is associated with widespread dysfunction of liver cells without obvious cell death, such as in **diffuse microvesicular steatosis** related to fatty liver of pregnancy or in idiosyncratic reactions to toxins (e.g., valproate, tetracycline). In these settings, hepatocyte metabolism is severely affected, usually due to mitochondrial dysfunction, preventing the liver from carrying out its normal functions. In states of immunodeficiency, such as untreated infection with human immunodeficiency virus (HIV), posttransplant immunosuppression, and certain lymphoid malignancies, nonhepatotropic viruses, particularly cytomegalovirus, herpes simplex viruses, and adenovirus, can cause acute liver failure. With better treatments for HIV infection, these forms of viral hepatitis are declining in incidence.

Clinical Features

Acute liver failure manifests first with nausea, vomiting, and jaundice, followed by life-threatening encephalopathy, and coagulation defects. Typically, serum liver transaminases are markedly elevated. The liver is initially enlarged due to hepatocyte swelling, inflammatory infiltrates, and edema;

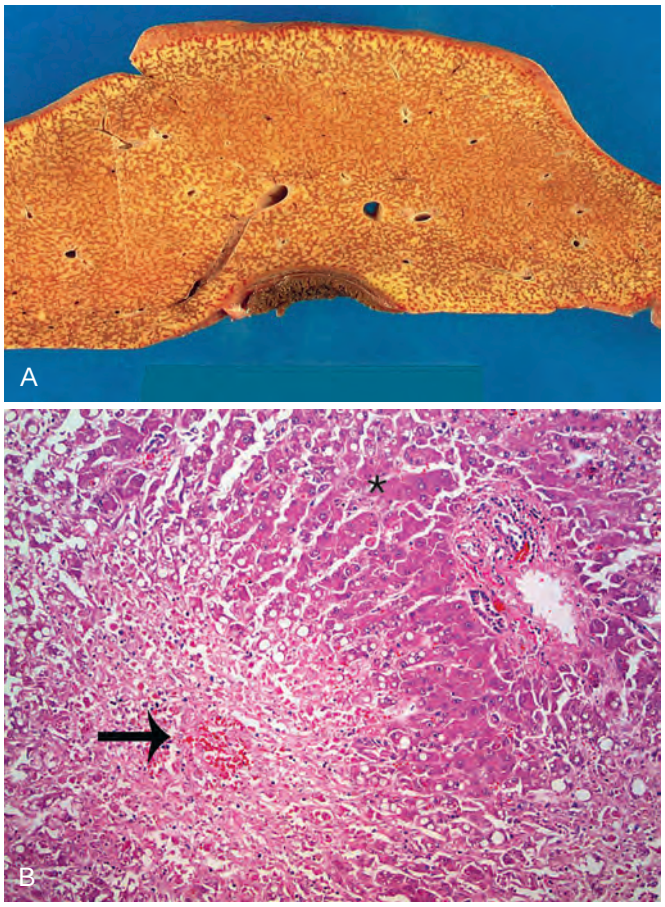

Figure 18.4 (A) Massive necrosis, cut section of liver. The liver is small (700 g), bile-stained, soft, and congested. (B) Hepatocellular necrosis caused by acetaminophen overdose. Confluent necrosis is seen in the perivenular region (zone 3) *(large arrow)*. Residual normal tissue is indicated by an *asterisk*. (Courtesy Dr. Matthew Yeh, University of Washington, Seattle, Wash.)

as parenchyma is destroyed, however, the liver shrinks dramatically. Decline of serum transaminases (as hepatocytes die) often is not, therefore, a sign of improvement, but is rather an indication that there are few viable hepatocytes left; this suspicion is confirmed if there is worsening jaundice, coagulopathy, and encephalopathy. With unabated progression, multiorgan system failure occurs and, if transplantation is not possible, death ensues. Other manifestations of acute liver failure are as follows:

- *Cholestasis* occurs due to alterations of bile formation and flow leading to retention of bilirubin and other solutes normally eliminated in bile. Yellow discoloration of the skin and sclera (*jaundice* and *icterus,* respectively) occur with bilirubin retention, and there is increased risk of potentially life-threatening bacterial infection.
- *Hepatic encephalopathy* is a spectrum of disturbances in consciousness, ranging from subtle behavioral abnormalities, to marked confusion and stupor, to deep coma and death. Encephalopathy may progress over days, weeks, or months following acute liver injury. Associated fluctuating neurologic signs include rigidity and hyperreflexia. *Asterixis,* a particularly characteristic sign, is manifested as nonrhythmic, rapid extension-flexion movements of the head and extremities, best seen when the arms are held in extension with dorsiflexed wrists. Hepatic encephalopathy is believed to be caused by elevated ammonia levels, which correlate with impaired neuronal function and cerebral edema. The principal source of the ammonia is the gastrointestinal tract, where it is produced by microorganisms and also by enterocytes during glutamine metabolism. Normally, ammonia is transported in the portal vein to the liver, where it is metabolized in the urea cycle; in severe liver disease, this detoxification mechanism fails. Several nonexclusive mechanisms of CNS toxicity for ammonia have been proposed, including direct effects on neurons and indirect effects mediated through its metabolism in astocytes to glutamine, which appears to contribute to edema by serving as an osmolyte.
- *Coagulopathy*. Hepatocytes are responsible for synthesis of clotting factors II (prothrombin), V, VII, IX, X, XI, and XII, as well as fibrinogen (Chapter 4). Thus, with liver failure, factor deficiencies and coagulopathy develops. Easy bruisability is an early sign, which can progress to life-threatening or fatal intracranial bleeding. The liver is also responsible for helping to remove activated coagulation factors from the circulation, and loss of this function in some instances leads to disseminated intravascular coagulation (Chapter 14), further exacerbating the bleeding tendency.
- *Portal hypertension* arises when there is diminished flow through the portal venous system, which may occur because of obstruction at the prehepatic, intrahepatic, or post-hepatic level. Although it can occur in acute liver failure, portal hypertension is more commonly seen with chronic liver failure and is described later. In acute liver failure, if portal hypertension develops within days to weeks, obstruction is predominantly intrahepatic and the major clinical consequence is *ascites*. In chronic liver disease, portal hypertension develops over months to years, and its effects are more complex and widespread.
- *Hepatorenal syndrome* is a form of renal failure occurring in individuals with liver failure in whom there is no intrinsic morphologic or functional cause for kidney dysfunction. Its onset is marked by a drop in urine output and increasing levels of urea and creatinine in the blood. Its pathophysiology is incompletely understood, but the triggering event is hypothesized to be portal hypertension and secondary increased production of vasodilators such as nitric oxide by endothelial cells in the splanchnic vasculature. This in turn leads to systemic vasodilation and diminished renal perfusion, which is sensed by the kidney, provoking activation of the renin/angiotensin axis. In the setting of portal hypertension and persistent vasodilator production, the principal effect of renin/angiotensin activation is to further diminish renal perfusion and glomerular filtration rate, leading to renal failure. The decline in renal function is reversible if liver function is restored, for example, by liver transplantation. Patients who develop the hepatorenal syndrome usually have portal hypertension due to cirrhosis, severe alcoholic hepatitis, or (less often) metastatic tumors. However, patients with fulminant hepatic failure from any cause may develop hepatorenal syndrome.

Chronic Liver Failure and Cirrhosis

Liver failure in chronic liver disease is most often associated with advanced fibrosis/cirrhosis, a condition marked by diffuse remodeling of the liver into parenchymal nodules (often regenerative) surrounded by fibrous bands and a variable degree of vascular (often portosystemic) shunting. The leading causes of chronic liver failure worldwide are chronic hepatitis B, chronic hepatitis C, nonalcoholic fatty liver disease, and alcoholic liver disease. In the United States, chronic liver disease is the twelfth most common cause of mortality and accounts for most liver-related deaths.

Although cirrhosis and chronic liver failure are often associated, they are not synonymous; not all cirrhosis leads inexorably to chronic liver failure, and not all end-stage chronic liver disease is cirrhotic. For example, chronic diseases such as primary biliary cholangitis, primary sclerosing cholangitis, nodular regenerative hyperplasia, chronic schistosomiasis, and fibropolycystic liver disease are often not accompanied by fully established cirrhosis, even at end stage. On the other hand, patients with well-treated autoimmune hepatitis or those with suppressed hepatitis B or cured hepatitis C often do not progress to end-stage liver disease, even if cirrhosis is present.

In some diseases that give rise to cirrhosis, such as untreated viral hepatitis, alcoholic liver disease, nonalcoholic fatty liver disease, and metabolic diseases, the morphology and pathophysiology of cirrhosis show some distinctive features (described in subsequent sections of this chapter). Thus, while the term cirrhosis implies the presence of severe chronic disease, it is not a specific diagnosis and has variable prognostic implications. There are also some instances in which cirrhosis arises without any clear cause; the term *cryptogenic cirrhosis* is sometimes applied to such cases.

MORPHOLOGY

Cirrhosis is marked by the presence of parenchymal nodules surrounded by dense bands of fibrosis throughout the liver, converting the normally smooth liver capsule into a bumpy surface with depressed areas of scarring and bulging regenerative nodules (Fig. 18.5). Microscopically the extent of the fibrosis is highlighted by the use of special stains for collagen (Fig. 18.6A). The size of the nodules, the pattern of scarring (linking portal tracts to each other versus linking portal tracts to central veins), the degree of parenchymal collapse, and the extent of vascular thrombosis (particularly of the portal vein) all vary between diseases and, to some degree, between individuals with the same disease. Morphologic features of regression include thin incomplete scars (see Fig. 18.6B) associated with variable ductular reaction and architectural changes. As mentioned earlier, not all end-stage livers are cirrhotic, but all reveal varying degrees of injury, repair, regeneration, and fibrosis. Thus, end-stage liver disease is best viewed as a spectrum of ineffective attempts to repair ongoing, intermittent, or past injury.

Clinical Features

About 40% of individuals with cirrhosis are asymptomatic until the most advanced stages of the disease. When symptomatic, they present with nonspecific manifestations:

Figure 18.5 Cirrhosis resulting from chronic viral hepatitis. Note the depressed areas of dense scar separating bulging regenerative nodules over the liver surface.

anorexia, weight loss, weakness, and, in advanced disease, symptoms and signs of liver failure discussed earlier. The common causes of death are hepatic encephalopathy, bleeding from esophageal varices, bacterial infections (resulting from damage to the gut mucosal barrier and Kupffer cell dysfunction), and hepatocellular carcinoma.

In addition to jaundice, encephalopathy, and coagulopathy (all also seen with acute liver failure), chronic liver failure is associated with several other significant features.

- *Through unclear mechanisms, persistent cholestasis can lead to pruritus* (itching), the intensity of which can be profound. Some patients may scratch their skin raw, risking repeated bouts of potentially life-threatening infection. Relief may only be found in liver transplantation.
- *Impaired estrogen metabolism leads to hyperestrogenemia, which has several effects.* It produces vascular changes that may lead to palmar erythema (a reflection of local vasodilation) and spider angiomas of the skin. Each angioma is a central, pulsating, dilated arteriole from which small vessels radiate. In males, hyperestrogenemia may also produce *hypogonadism* and *gynecomastia*.
- *Hypogonadism can also occur in women due to disruption of hypothalamic-pituitary axis function,* either through nutritional deficiencies associated with the chronic liver disease or primary hormonal alterations.

Portal Hypertension

Increased resistance to portal blood flow may develop in a variety of circumstances, which can be divided into *prehepatic, intrahepatic, and posthepatic* (Table 18.2). The major prehepatic conditions are obstructive thrombosis, narrowing of the portal vein before it ramifies within the liver, or massive splenomegaly with increased splenic vein blood flow. The main posthepatic causes are severe right-sided heart failure, constrictive pericarditis, and hepatic vein outflow obstruction. The dominant intrahepatic cause is cirrhosis, accounting for most cases of portal hypertension. Far less frequent intrahepatic causes are schistosomiasis, massive fatty change, diffuse fibrosing granulomatous disease such as sarcoidosis, and diseases affecting the portal

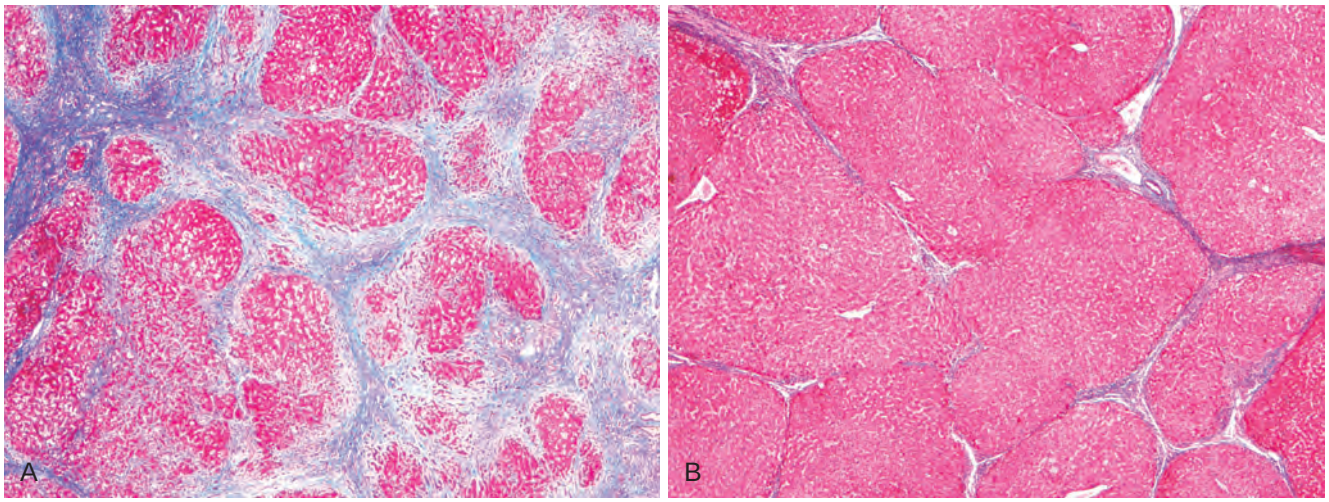

Figure 18.6 Alcoholic cirrhosis in an active drinker (A) and after long-term abstinence (B). (A) Thick bands of collagen separate rounded cirrhotic nodules. (B) After 1 year of abstinence, most scars are gone. (Masson trichrome stain) (Courtesy Drs. Hongfa Zhu and Isabel Fiel, Mount Sinai School of Medicine, NY.)

Table 18.2 Location and Causes of Portal Hypertension

Prehepatic Causes
Obstructive thrombosis of portal vein
Structural abnormalities such as narrowing of the portal vein before it ramifies in the liver
Intrahepatic Causes
Cirrhosis from any cause
Nodular regenerative hyperplasia
Primary biliary cholangitis (even in the absence of cirrhosis)
Schistosomiasis
Massive fatty change
Diffuse, fibrosing granulomatous disease (e.g., sarcoid)
Infiltrative malignancy, primary or metastatic
Focal malignancy with invasion into portal vein (particularly hepatocellular carcinoma)
Amyloidosis
Post-Hepatic Causes
Severe right-sided heart failure
Constrictive pericarditis
Hepatic vein outflow obstruction

microcirculation such as nodular regenerative hyperplasia (discussed later).

The pathophysiology of portal hypertension is complex and involves resistance to portal flow at the level of sinusoids and an increase in portal flow caused by hyperdynamic circulation. The increased resistance to portal flow at the level of the sinusoids is caused by contraction of vascular smooth muscle cells and myofibroblasts, and disruption of blood flow by scarring and the formation of parenchymal nodules. Alterations in sinusoidal endothelial cells that contribute to the intrahepatic vasoconstriction associated with portal hypertension include a decrease in nitric oxide (NO) production and increased release of endothelin-1, angiotensinogen, and eicosanoids. Sinusoidal remodeling and anastomoses between the arterial and portal system in the fibrous septa contribute to portal hypertension by imposing arterial pressures on the low-pressure portal venous system. Sinusoidal remodeling and intrahepatic shunts also interfere with the metabolic exchange between sinusoidal blood and hepatocytes.

Another major factor in the development of portal hypertension is an increase in portal venous blood flow resulting from a hyperdynamic circulation. This is caused by arterial vasodilation, primarily in the splanchnic circulation. The increased splanchnic arterial blood flow in turn leads to increased venous efflux into the portal venous system. While various mediators such as prostacyclin and TNF have been implicated in the causation of the splanchnic arterial vasodilation, NO has emerged as the most significant one.

The four major consequences of portal hypertension are (1) hepatic encephalopathy (described under liver failure), (2) ascites, (3) the formation of portosystemic venous shunts, and (4) congestive splenomegaly. These are illustrated in Fig. 18.7 and are described next.

Ascites

The accumulation of fluid in the peritoneal cavity is called ascites, which in 85% of cases is caused by cirrhosis. Ascites usually becomes clinically detectable when at least 500 mL have accumulated. The fluid is generally serous, having less than 3 g/dL of protein (largely albumin), and a serum-to-ascites albumin gradient of ≥1.1 g/dL. The fluid may contain a scant number of mesothelial cells and mononuclear leukocytes. The presence of neutrophils suggests infection, whereas the presence of red cells points to possible disseminated intra-abdominal cancer. With long-standing ascites, seepage of peritoneal fluid through trans-diaphragmatic lymphatics may produce hydrothorax, usually on the right side. The pathogenesis of ascites is complex, involving sinusoidal hypertension, hypoalbuminemia, increased hepatic lymph flow, and splanchnic vasodilation and hyperdynamic circulation.

Portosystemic Shunts

In the setting of chronic portal hypertension, vascular dilation and remodeling often leads to the development of thin-walled venous shunts between the portal and systemic circulations that bypass the liver. These shunts

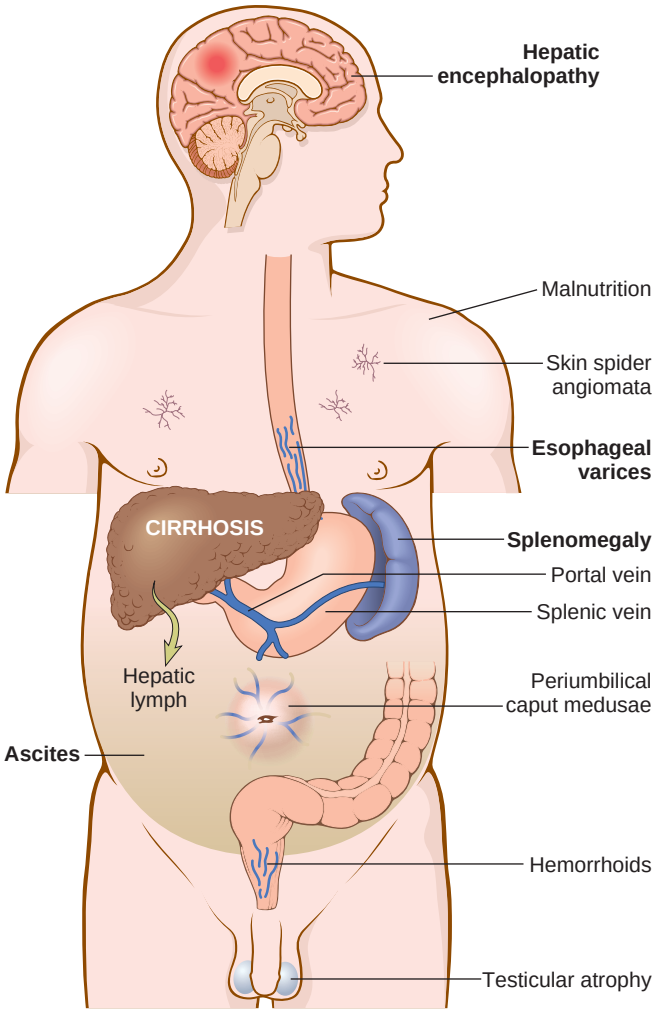

Figure 18.7 Major clinical consequences of portal hypertension in the setting of cirrhosis, shown for the male. In women, oligomenorrhea, amenorrhea, and sterility as a result of hypogonadism are frequent. Clinically significant findings are in boldface.

may appear wherever the systemic and portal circulations share capillary beds (see Fig. 18.7). The principal sites are veins around and within the rectum (manifest as hemorrhoids), the esophagogastric junction (producing varices), the retroperitoneum, and the falciform ligament of the liver (involving periumbilical and abdominal wall collaterals). Abdominal wall collaterals appear as dilated subcutaneous veins extending from the umbilicus toward the rib margins (caput medusae) and constitute a clinical hallmark of portal hypertension. Although hemorrhoidal bleeding may occur, it is rarely massive or life threatening. Much more important are esophagogastric varices, which appear in about 40% of individuals with advanced cirrhosis of the liver and cause massive hematemesis and death in about half of those affected. Each episode of bleeding is associated with ~30% mortality.

Splenomegaly

Long-standing portal hypertension may cause congestive splenomegaly. The degree of splenic enlargement varies widely, and the splenic weight may reach as much as 1000 g (five to six times normal), but it is not necessarily correlated with other features of portal hypertension. Splenomegaly may secondarily induce hematologic abnormalities attributable to "hypersplenism," particularly thrombocytopenia or even pancytopenia, in large part because of sequestration of blood elements in the expanded splenic red pulp.

Pulmonary Complications of Liver Failure and Portal Hypertension. We conclude this discussion with two pulmonary syndromes that occur in the setting of chronic liver failure and portal hypertension:

- *Hepatopulmonary syndrome* is seen in up to ~30% patients with cirrhosis of the liver and portal hypertension. The syndrome is caused by the dilatation of intrapulmonary capillary and precapillary vessels up to 500 μM in size. Right-to-left shunting of blood through the dilated vessels produces ventilation-perfusion mismatch and impairs oxygenation of blood, which manifests as hypoxemia. The resultant dyspnea is worse in the upright position rather than in the recumbent position, as gravity exacerbates the ventilation-perfusion mismatch. Patients with this syndrome have a poorer prognosis than patients without hepatopulmonary syndrome. The pathogenesis is unclear, although it has been postulated that the diseased liver may not clear factors such as endothelin-1 that stimulate endothelial cells to produce vasodilators such as nitric oxide.
- *Portopulmonary hypertension* refers to pulmonary arterial hypertension arising in liver disease. It also is not well understood, but it seems to depend on concomitant portal hypertension and excessive pulmonary vasoconstriction and vascular remodeling. The most common clinical manifestations are dyspnea on exertion and clubbing of the fingers.

Acute-on-Chronic Liver Failure

Some individuals with stable but well-compensated, advanced chronic liver disease suddenly develop signs of acute liver failure. In such patients, there is often established cirrhosis with extensive vascular shunting. Thus, large volumes of functioning liver parenchyma have a borderline vascular supply, leaving them highly vulnerable to superimposed insults. The short-term mortality of patients with this form of liver failure is around 50%.

Patients with chronic hepatitis B infection who become superinfected with hepatitis D may suddenly decompensate, as may patients with medically suppressed hepatitis B infection in whom viral mutants arise that are resistant to therapy, both due to acute flares of disease. Ascending cholangitis in a patient with primary sclerosing cholangitis or fibropolycystic liver disease (described later) may also cause rapid decompensation of liver function. Rare patients with nonalcoholic steatohepatitis may develop severe hepatic dysfunction following rapid weight loss or malnutrition; the mechanism of injury in such cases is unknown.

Other causes of decompensation are systemic rather than intrahepatic insults. For example, sepsis and its attendant hypotension may undermine hepatic parenchyma with borderline vascular supply. Likewise, acute cardiac failure or a superimposed drug or toxic injury might tip a well-compensated cirrhotic patient into failure. Finally, the possibility of malignancy, either a primary liver tumor,

particularly hepatocellular carcinoma or cholangiocarcinoma, or liver metastases from some other site (e.g., colon), should always be kept in mind as a possible cause of acute liver failure in previously well-compensated chronic liver disease.

KEY CONCEPTS

LIVER FAILURE

- Liver failure may follow acute injury or chronic injury, but may also occur as an acute insult superimposed on an otherwise well-compensated chronic liver disease.
- The mnemonic for causes of acute liver failure is as follows:
  - A: Acetaminophen, hepatitis A, autoimmune hepatitis
  - B: Hepatitis B
  - C: Hepatitis C, cryptogenic
  - D: Drugs/toxins, hepatitis D
  - E: Hepatitis E, esoteric causes (e.g., Wilson disease, Budd-Chiari syndrome, lymphoma, carcinoma)
  - F: Fatty change of the microvesicular type (e.g., fatty liver of pregnancy, valproate, tetracycline, Reye syndrome)
- Serious and sometimes fatal sequelae of liver failure include coagulopathy, encephalopathy, portal hypertension, bleeding esophageal varices, hepatorenal syndrome, and portopulmonary hypertension.

INFECTIOUS DISORDERS

Viral Hepatitis

The term "viral hepatitis" is most commonly used in the context of liver involvement by hepatotropic viruses, which include hepatitis A, B, C, D, and E. Nonhepatotropic viruses such as Epstein-Barr virus, cytomegalovirus, herpes simplex virus, adenovirus, and yellow fever virus can also cause hepatitis, often in association with systemic infection. Liver involvement can occur in a wide variety of other systemic viral infections, but it is generally mild and often subclinical.

In the sections that follow, we will first discuss individual hepatotropic viruses, and then review certain clinicopathologic syndromes that are common to all.

Hepatitis A Virus

Hepatitis A virus (HAV) infection is a self-limited disease and does not lead to chronic hepatitis or a carrier state. It accounts for about 25% of clinically evident acute hepatitis worldwide and is responsible for an estimated 2000 new cases of viral hepatitis per year in the United States.

Epidemiology

HAV is spread by ingestion of contaminated water and foods, and is endemic in countries with poor hygiene and sanitation. In high income countries, the prevalence of seropositivity (indicative of previous exposure) increases gradually with age, reaching 50% by 50 years of age in the United States. HAV is shed in the stool for 2 to 3 weeks before and 1 week after the onset of jaundice. Close personal contact with an infected individual or fecal-oral contamination during this period accounts for most cases and can result in outbreaks in institutional settings such as schools and nurseries. Water-borne epidemics can occur in places with overcrowded, unsanitary conditions. In high income countries, sporadic infections may be contracted by the consumption of raw or steamed shellfish (oysters, mussels, clams), which concentrate the virus from seawater contaminated with human sewage. Sexual transmission may occur, but maternal-fetal transmission does not. Since HAV viremia is transient, blood-borne transmission of HAV is rare, and donated blood is not screened for this virus.

Pathogenesis

Discovered in 1973, HAV is a small, nonenveloped, positive-strand RNA picornavirus that occupies its own genus, *Hepatovirus*. Ultrastructurally, HAV is an icosahedral capside that is 27 nm in diameter. The receptor for HAV on hepatocytes is HAVcr-1 (also known as TIM-1), a glycoprotein that is a member of a family of proteins that serve as receptors for several other viruses as well. HAV is not cytopathic, and the hepatocellular injury is inflicted by cytotoxic T-lymphocytes and NK cells that recognize and kill hepatocytes infected by the virus.

Clinical Features

The incubation period for HAV is 2 to 6 weeks. IgM antibody against HAV appears with the onset of symptoms and persists for 3 to 6 months (Fig. 18.8). IgG anti-HAV appear during recovery from the acute infection and persists for years, conferring lifelong immunity against reinfection. Affected individuals have nonspecific symptoms such as fatigue and loss of appetite, and they often develop jaundice. Most patients recover within 3 months, and disease resolution occurs in nearly all patients by 6 months. Acute liver failure occurs in 0.1% to 0.3% of patients, especially those with chronic liver disease due to another etiology. Other

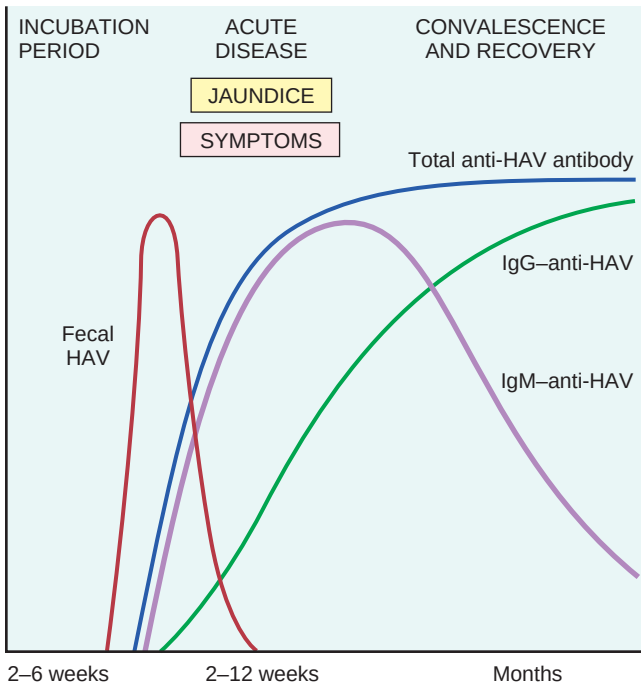

Figure 18.8 Temporal changes in serologic markers in acute hepatitis A infection *(HAV)*. *IgM*, immunoglobulin M.

uncommon complications include prolonged cholestasis and relapse of disease within 6 months of the original onset. Extrahepatic manifestations include rash, arthralgia and immune complex mediated complications like leukocytoclastic vasculitis, glomerulonephritis and cryoglobulinemia. HAV vaccine is effective in preventing infection.

Hepatitis B Virus

Hepatitis B virus (HBV) infection has varied clinical outcomes, which depend on the age of exposure, comorbid conditions (including exposure to other infectious agents), and host immunity. **The major clinical presentations include: (1) acute hepatitis followed by recovery and clearance of the virus, (2) acute hepatic failure with massive liver necrosis, (3) chronic hepatitis with or without progression to cirrhosis, and (4) an asymptomatic, "healthy" carrier state** (Fig. 18.9).

Epidemiology

Chronic HBV infection affects 400 million people worldwide, with the highest prevalence (>8%) in Africa, Asia, and the Western Pacific rim. The prevalence is also relatively high (2% to 7%) in Southern and Eastern Europe, and lower (<2%) in Western Europe, North America, and Australia. It is estimated that there are 60,000 new cases of HBV infection in the United States every year, and that nearly 2 million people have chronic HBV infection. The virus has a parenteral mode of transmission through unprotected sex, blood transfusion, and sharing of needles and syringes for intravenous drug use. Transfusion-related transmission has been sharply curtailed by screening of donated blood for HBsAg and exclusion of paid blood donors. In high-prevalence regions, transmission during childbirth accounts for 90% of cases. Horizontal transmission can also occur in children through minor breaks in the skin or mucous membranes or with close bodily contact.

Pathogenesis

HBV was first linked to hepatitis in the 1960s when Australia antigen (now known as hepatitis B surface antigen) was identified. The virus is a member of the *Hepadnaviridae,* a family of DNA viruses that cause hepatitis in multiple animal species. The mature virion has an outer surface envelope composed of viral proteins and host-derived lipids that surrounds a core consisting of nucleocapsid proteins, viral polymerase, and viral DNA. The HBV genome is a partially double-stranded circular DNA molecule with several open reading frames encoding the following proteins:

- *Hepatitis B surface antigen (HBsAg)*, which refers to three related viral envelope glycoproteins, large, middle, and small HBsAg. Large HBsAg is usually associated with complete virions, while noninfective viral envelope proteins (mainly small HBsAg) are released in large quantities by infected hepatocytes free of viral core elements.
- *Hepatitis B core antigen (HBcAg),* the nucleocapsid protein, which plays a role in assembly of complete virions; and a longer polypeptide transcript with a precore and core region, designated *hepatitis Be antigen (HBeAg)*.
- *HBV polymerase (Pol),* which exhibits both DNA polymerase and reverse transcriptase activities.
- *Hepatitis B X protein (HBx),* which is not necessary for virus replication, but may act as a transcriptional transactivator of both viral genes and a subset of host genes. It has been implicated in the pathogenesis of HBV-related hepatocellular carcinoma.

Entry of HBV into hepatocytes is enabled by binding of large HbsAg to the bile salt transporter known as sodium taurocholate cotransporting polypeptide (NTCP). The viral genome enters the nucleus, where the plus strand is synthesized to form covalently closed circular DNA (ccc DNA). HBV replication occurs through reverse transcription via an RNA intermediate.

The host immune response to the virus is the main determinant of the outcome of the infection. High-level viral replication and high production of viral proteins can produce cytopathic changes in infected cells; however, most hepatocyte injury is caused by an attack of CD8+ cytotoxic T cells on infected cells. A strong response by virus-specific

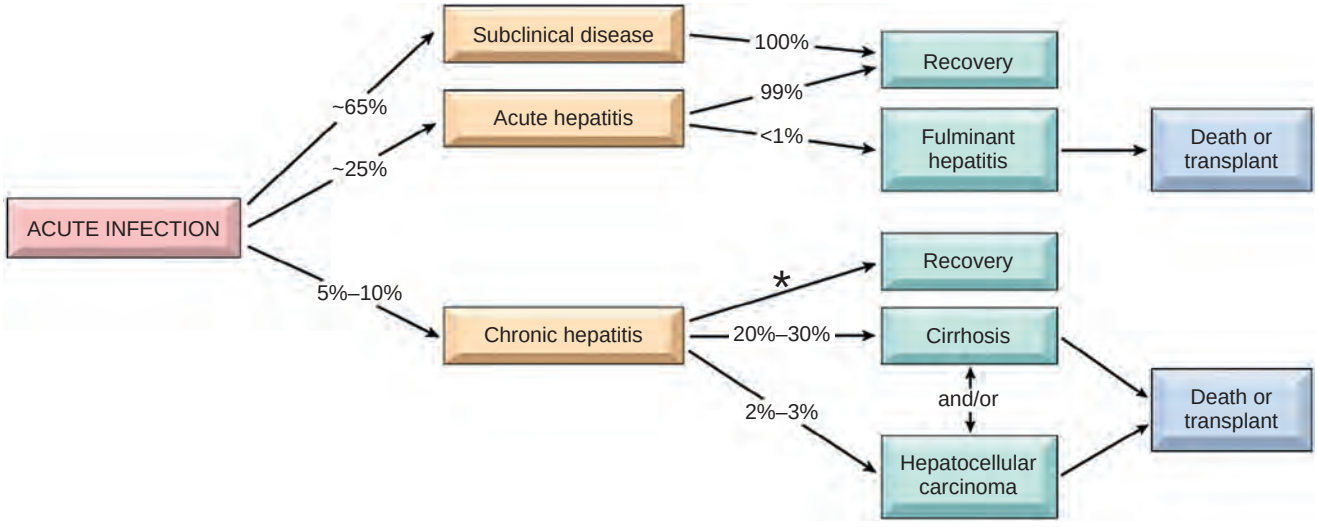

Figure 18.9 Potential outcomes of hepatitis B infection in adults and their approximate frequencies in the United States. *Spontaneous hepatitis B surface antigen clearance occurs during chronic hepatitis B viral infection at an estimated annual incidence of 1% to 2% in Western countries.

CD4+ and CD8+ interferon (IFN)-γ–producing cells is associated with resolution of acute infection.

Clinical Features

HBV has a prolonged incubation period (4 to 26 weeks). The course of the infection is followed by measuring viral antigens and serologic responses in the blood, as shown in Fig. 18.10. A few salient points about these markers is merited:

- *HBsAg* appears before the onset of symptoms and peaks in acute, symptomatic disease. In those who clear the infection, it often declines to undetectable levels in 12 weeks, but can be present for as long as 24 weeks. By contrast, HBsAg persists in cases that progress to chronicity.
- *Anti-HBs antibody* begins to rise following the resolution of acute disease, generally after the disappearance of HBsAg (see Fig. 18.10A). In some cases, the appearance of anti-HBs antibody is delayed until weeks to months after disappearance of HBsAg; in such instances, the serologic diagnosis can be made by detection of IgM anti-HBc antibody. Anti-HBs antibodies tend to persist for life, conferring protection; this is the basis for current vaccination strategies using noninfectious HBsAg. By contrast, anti-HBs antibodies are not produced in cases that progress to chronic liver disease, which is also associated with variable persistent elevations of serum transaminases in most (but not all) cases (see Fig. 18.10B).
- *HBeAg, HBV DNA, and HBV DNA polymerase* are detectable in the serum soon after HBsAg and signify active viral replication. Persistence of HBeAg is an important indicator of continued virus replication, infectivity, and probable progression to chronic hepatitis. One caveat is that mutated strains of HBV can emerge that do not produce HBeAg, but are replication competent and express HBcAg. In such patients, the HBeAg may be low or undetectable despite the presence of serum HBV DNA.
- *Anti-HBe antibody* signifies that acute infection has peaked and is on the wane, whereas in cases that progress to chronic infection, anti-HBe antibody is not produced or appears only late in the disease course.

Acute HBV infection is mild or subclinical in nearly two-thirds of adults, while others have nonspecific constitutional symptoms such as anorexia, fever, jaundice, and upper right quadrant pain. Immune complex–mediated phenomena such as glomerulonephritis may occur, as well as other immunologic disorders, such as *polyarteritis nodosa* (Chapter 11). Acute liver failure is rare, occurring in approximately 0.1% to 0.5% of acutely infected individuals. In most cases, the infection is self-limited and resolves without treatment. The infection persists and becomes chronic in 5% to 10% of infected individuals. The risk of chronic infection is inversely related to age and is greatest (approximately 90%) in infants who are exposed to the virus through transmission from their mothers at the time of birth. Individuals who acquire HBV at birth and who subsequently develop chronic hepatitis are also at greatest risk of developing hepatocellular carcinoma (Fig. 18.9), which is one of the most common and deadliest cancers in parts of the world such as China where perinatal transmission occurs frequently.

Vaccination is highly effective, as it induces a protective anti-HBs antibody response in 95% of infants, children, and adolescents. Although vaccine-induced escape mutants that replicate in the presence of vaccine-induced immunity have been described, these do not appear to be increasing in prevalence. In those with chronic HBV, treatment with interferon and antiviral agents such as reverse transcriptase inhibitors (entecavir, tenofovir) can slow disease progression, reduce liver damage, and lower the risk of cirrhosis and hepatocellular carcinoma, but complete cure is difficult.

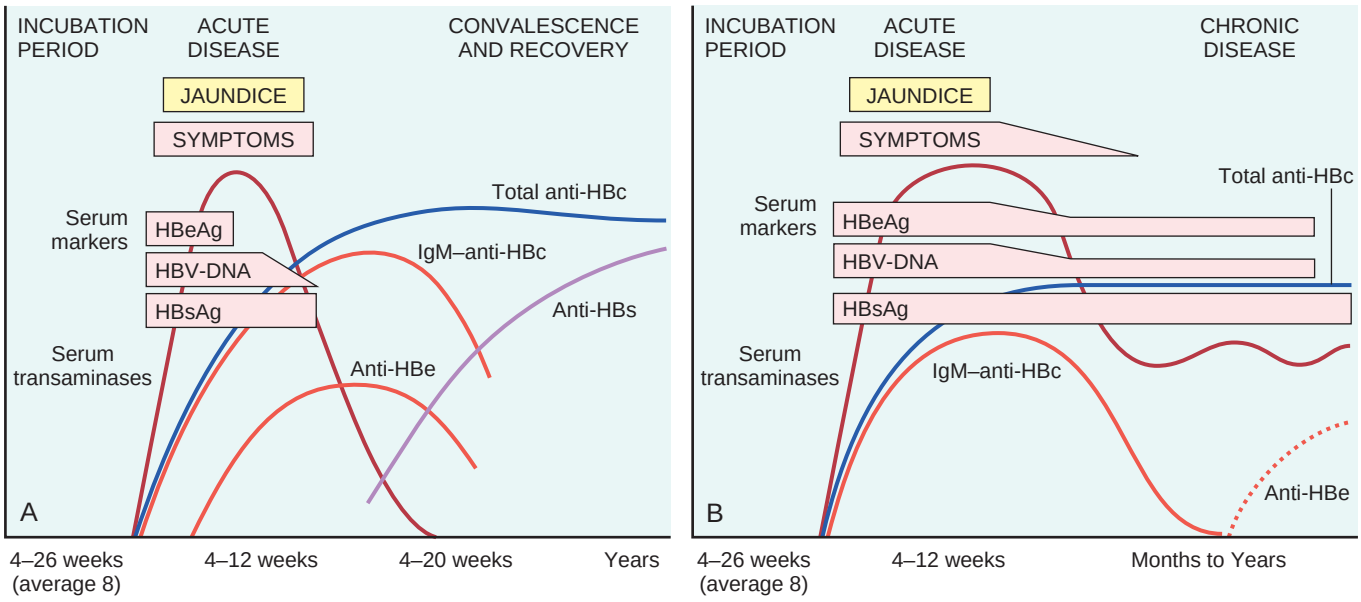

Figure 18.10 Temporal changes in serologic markers in hepatitis B viral infection. (A) Acute infection with resolution. (B) Progression to chronic infection. In some cases of chronic hepatitis B virus, serum transaminases may become normal.

Hepatitis C Virus

Hepatitis C Virus (HCV) rarely causes symptomatic acute hepatitis, but it is the most common cause of chronic viral hepatitis.

Epidemiology

HCV affects approximately 170 million people worldwide, and there are 2.7 million chronic HCV cases in the United States. Screening of donor blood has decreased the annual incidence of infection from 230,000 new infections per year in the mid-1980s to 17,000 new infections per year currently. The mode of transmission is parenteral; intravenous drug abuse, multiple sex partners, needle-stick injury, and multiple contacts with an HCV-infected person are the most common risk factors. Transfusion-related transmission has largely disappeared in the United States. Perinatal transmission can occur in children. One-third of infected individuals have no identifiable risk factors, an enduring hepatologic mystery.

Pathogenesis

HCV, discovered in 1989, is a member of the *Flaviviridae* family. It is a small, enveloped, single-stranded RNA virus with one open reading frame that codes for a single polyprotein, which is subsequently processed into several functional proteins. These include two envelope proteins, E1 and E2, and five core proteins: p7, NS2, NS3/4a (protease), NS5A (replication complex), and NS5B (RNA polymerase). The role of these proteins in the life cycle of HCV is summarized in Fig. 18.11.

The inability of the host immune response to eliminate HCV is related to rapid emergence of genetic variants, both within the population and within infected individuals. HCV RNA polymerase has low fidelity, giving rise to variants that fall into seven genotypes and many subtypes. As the disease progresses, multiple "personal" genetic variants, known as *quasispecies,* emerge in infected individuals. Anti-HCV antibodies directed against E2 envelope protein are common and have neutralizing activity, but emergent variants with altered E2 epitopes escape from this host defense. NS3/NS4A protease also impairs the interferon-mediated cellular antiviral response, defeating another potential means of host defense.

Clinical Features

The incubation period for HCV hepatitis ranges from 4 to 26 weeks, with a mean of 9 weeks. HCV RNA is detectable in blood for 1 to 3 weeks in acute infection and coincides with increase in transaminases. Anti-HCV antibodies emerge 3 to 6 weeks after infection. Spontaneous clearance of the virus after 4 to 6 months is rare, hence persistent detection of HCV RNA after this period is an indicator of chronic HCV infection (Fig. 18.12). Assay for anti-HCV antibodies is used as a screening test for HCV, but it can be negative in early infection and in immunosuppressed individuals. After successful treatment, or in cases with spontaneous viral clearance, anti-HCV antibodies may be detected in the absence of HCV RNA, but can disappear with time.

Acute HCV infection is asymptomatic in about 85% of individuals, and severe acute hepatitis is rare. Although a few fortunate people clear the acute infection (for unclear reason), persistent infection and chronic hepatitis are the usual outcome. In contrast with HBV, chronic disease occurs in 80% to 90% of HCV-infected individuals, and approximately 20% of these individuals progress to cirrhosis over 20 to 30 years. Fluctuating elevations of serum aminotransferases are typically present during the chronic phase of the disease. Even those with normal transaminases are at a risk for

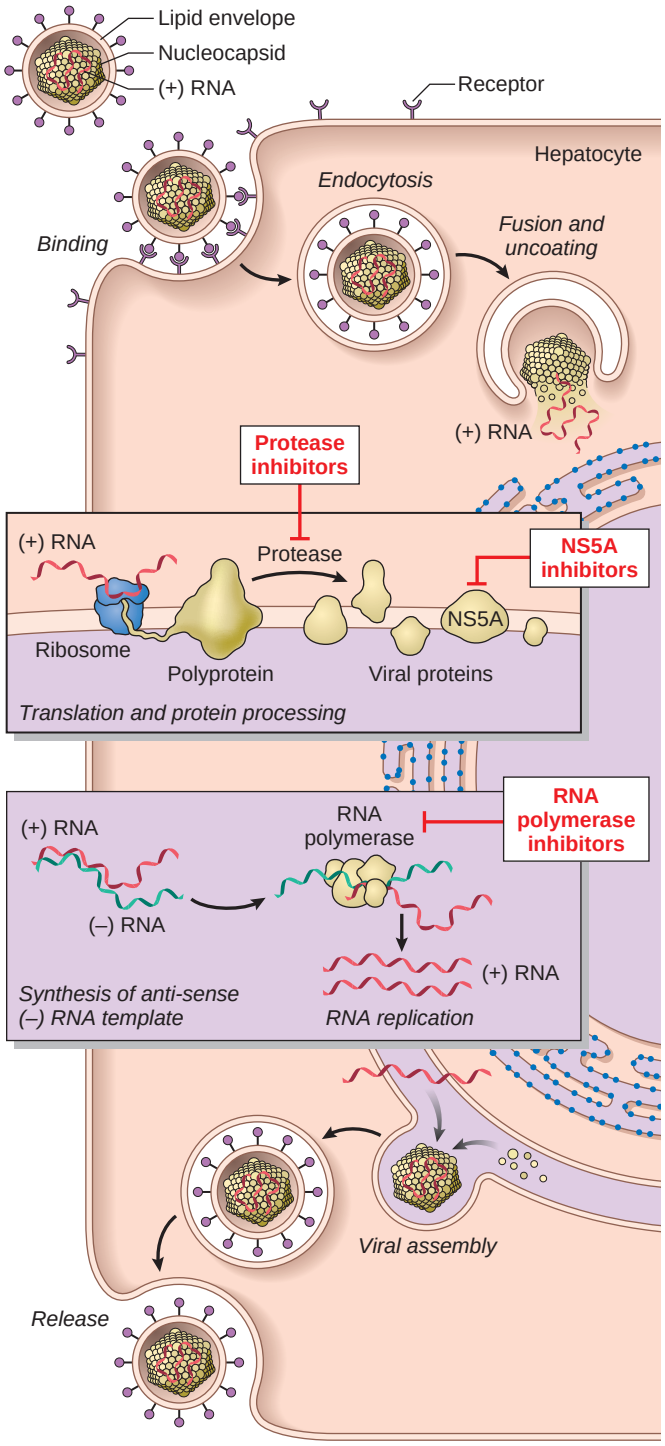

Figure 18.11 Life cycle of hepatitis C. Viral entry, replication, assembly, and budding are shown, emphasizing steps that can be effectively targeted with antiviral drugs.

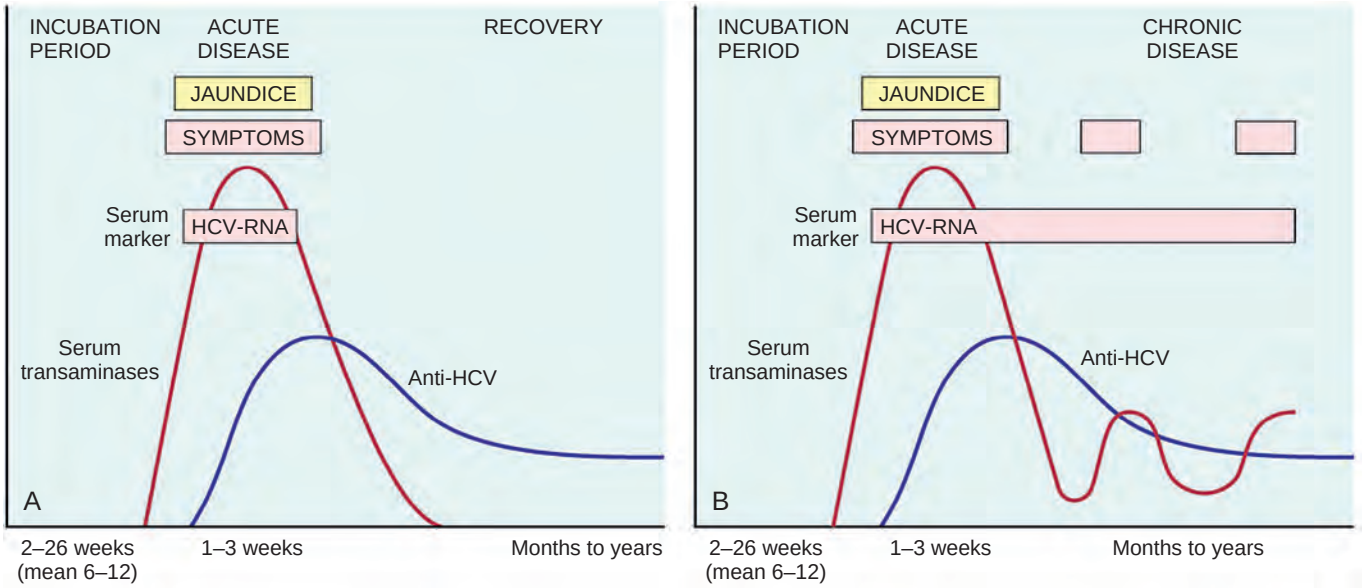

Figure 18.12 Temporal changes in serologic markers in hepatitis C viral infection. (A) Acute infection with resolution. (B) Progression to chronic infection.

developing permanent liver damage, and hence all those with detectable serum HCV RNA levels need treatment and long-term follow-up. Older age, male gender, alcohol use, immunosuppressive drugs, hepatitis B/HIV co-infection, and diseases associated with insulin resistance, including obesity, type 2 diabetes, and metabolic syndrome have been associated with progression. Those who develop cirrhosis are at risk for development of hepatocellular carcinoma. Although the overall risk is small, in the United States, HCV is responsible for about one-third of the cases of liver cancer.

Fortunately, the treatment of hepatitis C has been revolutionized in the past few years by the availability of highly effective antiviral agents. This remarkable advance has been made possible by understanding the role of viral proteins in the virus' life cycle, which in turn has enabled the development of specific drug antagonists (see Fig. 18.11). As in HIV infection, these drugs are used in combination to overcome resistance, and include agents that target the NS3/4a protease, the NS5A replication complex, and the NS5B polymerase. Unlike HIV, HCV does not integrate into the genome where it can lie latent, and as a result true cures are often achieved. Sustained therapeutic response is defined as undetectable HCV RNA after 12 to 24 weeks of drug therapy; overall, such sustained responses are obtained in 80% to 90% of cases, with lower response rates in patients infected with genotype 3 HCV. HCV appears to be cured in >99% of patients who achieve a sustained viral response. The major downside of these advances is their very high cost; a curative course of drug therapy costs over $100,000, and it is estimated that treatment of HCV infections in the United States alone may generate expenses of greater than $50 billion over the next 5 years.

Hepatitis D Virus

Hepatitis D virus (HDV) or "the delta agent," is a unique RNA virus that is dependent for its life cycle on HBV.

Epidemiology

It is estimated that 5% of HBV-infected individuals are co-infected with HDV, which amounts to approximately 15 million people worldwide. The highest prevalence is in the Amazon basin, central Africa, the Middle East, and the Mediterranean basin. HDV is uncommon in Southeast Asia and China. Disease transmission occurs through a parenteral route, often in association with intravenous drug use and multiple blood transfusions.

Pathogenesis

HDV, discovered in 1977, is a 35-nm, double-shelled particle. The external coat antigen of HDV surrounds an internal polypeptide assembly, designated delta antigen (HDAg), the only protein produced by the virus. Associated with the virus particle is a small circular molecule of single-stranded RNA, whose length is the shortest of any known animal virus. Replication of the virus is through RNA-directed RNA synthesis by host RNA polymerase. The basis for disease flares associated with HDV superinfection is not well understood; both cytopathic effects and enhanced cytotoxic host responses have been proposed.

Clinical Features

Infection with HDV arises in two settings, each with somewhat different clinical courses.

- *Co-infection* occurs following exposure to serum containing both HDV and HBV. Co-infection can result in acute hepatitis that is indistinguishable from acute hepatitis B. It is self -limited and is usually followed by clearance of both viruses. However, there is a higher rate of acute hepatic failure in intravenous drug users.
- *Superinfection* occurs when a chronic carrier of HBV is exposed to a new inoculum of HDV. This results in disease 30 to 50 days later, presenting either as severe acute hepatitis in an asymptomatic HBV carrier, or as

an exacerbation of preexisting chronic hepatitis B infection. Chronic HDV infection occurs in more than 80% of superinfections and may have two phases, an acute phase with active HDV replication and suppression of HBV associated with high transaminase levels, and a chronic phase in which HDV replication decreases, HBV replication increases, and transaminase levels fluctuate.

HDV RNA is detectable in the blood and liver just before and in the early days of acute symptomatic disease. IgM anti-HDV antibody is the most reliable indicator of recent HDV exposure, although its appearance is late and frequently short-lived. With chronic delta hepatitis arising from HDV superinfection, HBsAg is present in serum, and anti-HDV antibodies persist for months or longer.

Co-infection with HDV and HBV increases the risk of progression to cirrhosis and HCC. Chronic HDV infection is treated with interferon-γ, but clearance of the virus occurs in only a minority of cases. Newer agents targeting viral entry and replication are in clinical trials. Vaccination for HBV also prevents HDV infection.

Hepatitis E Virus

Hepatitis E virus (HEV) is an enterically transmitted, waterborne infection that occurs primarily in young to middle-aged adults.

Epidemiology

HEV is a zoonotic disease with animal reservoirs, such as monkeys, cats, pigs, and dogs. Epidemics have been reported in Asia and the Indian subcontinent, sub-Saharan Africa, the Middle East, China, and Mexico. HEV infection accounts for more than 30% of cases of sporadic acute hepatitis in India, exceeding the frequency of HAV. Sporadic cases can occur in travelers to these regions, and are also seen in high income nations in association with pig farming or consumption of organ meat.

Pathogenesis

Discovered in 1983, HEV is an unenveloped, positive-stranded RNA virus in the *Hepevirus* genus. The RNA genome is 7.3 kb in length and contains four open reading frames that encode multiple proteins, including a viral protease and viral RNA polymerase. HEV is not cytopathic, and hepatic damage is thought to stem from the host response to cells infected with virus.

Clinical Features

Virions are shed in stool during the acute illness, and infection is typically by the fecal-oral route. The average incubation period following exposure is 4 to 5 weeks, followed by a self-limited acute hepatitis in most cases, with resolution in 2 to 4 weeks. Before the onset of clinical illness, HEV RNA and HEV virions can be detected by PCR in stool and serum. The onset of clinical symptoms, rise of serum aminotransferases, and appearance of IgM anti-HEV are virtually simultaneous. IgM is replaced with persistent IgG anti-HEV antibodies during recovery.

Chronic liver disease or persistent viremia in immunocompetent patients is not observed. However, acute HEV infection is associated with a mortality rate approaching 20% among pregnant women. Chronic HEV infection can occur in the setting of immunosuppression, such as in those with AIDS and in transplant recipients.

Clinicopathologic Syndromes of Viral Hepatitis

Viral hepatitis may pursue several clinical courses: (1) acute asymptomatic infection with recovery; (2) acute symptomatic hepatitis, anicteric or icteric, with recovery; (3) acute liver failure with massive to submassive hepatic necrosis; and (4) chronic hepatitis, with or without progression to cirrhosis. Table 18.3 provides a summary of the salient features of infection by various hepatitis viruses. Acute infections by all of the hepatotropic viruses can either be asymptomatic or symptomatic. HAV and HEV (in immunocompetent

Table 18.3 Hepatitis Viruses

Virus	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Type of virus	ssRNA	Partially dsDNA	ssRNA	Circular defective ssRNA	ssRNA
Route of transmission	Fecal-oral (contaminated food or water)	Parenteral, sexual contact, perinatal	Parenteral; intranasal cocaine use	Parenteral	Fecal-oral
Mean incubation period	2–6 weeks	2–26 weeks	4–26 weeks	Same as HBV	4–5 weeks
Frequency of chronic liver disease	Never	5%–10%	>80%	10% (co-infection); 90%-100% for superinfection	In immunocompromised hosts only
Diagnosis	Serum IgM antibodies	HBsAg or HBcAg antibodies; PCR for HBV DNA	ELISA for HCV antibodies; PCR for HCV RNA	Serum IgM and IgG antibodies; PCR for HDV RNA	Serum IgM and IgG antibodies; PCR for HEV RNA

From Washington K: Inflammatory and infectious diseases of the liver. In Iacobuzio-Donahue CA, Montgomery EA, editors: *Gastrointestinal and Liver Pathology,* Philadelphia, 2005, Churchill Livingstone.

hosts) do not cause chronic hepatitis, and only a small number of HBV-infected adult patients develop chronic hepatitis. In contrast, HCV is notorious for progressing to chronic infection. Acute liver failure is unusual and is seen primarily with HAV, HBV, or HDV infection, depending on region. HEV can cause acute liver failure in pregnant women. Although HBV and HCV are responsible for most cases of chronic hepatitis, many other disorders have similar clinicopathologic features, especially autoimmune and drug/toxin-induced hepatitis, described later. Therefore, serologic and molecular studies are essential for the diagnosis of viral hepatitis and for distinguishing among the various types.

Major features of the main clinicopathologic syndromes associated with hepatropic virus infections are as follows.

- *Acute asymptomatic infection with recovery*. Here, infection is identified due to minimally elevated serum transaminases or, after recovery, by the presence of antiviral antibodies. HAV and HBV infection can be subclinical events, verified only by the presence of anti-HAV or anti-HBV antibodies.
- *Acute symptomatic infection with recovery*. Symptomatic disease can be divided into four phases: (1) incubation period, (2) symptomatic preicteric phase, (3) symptomatic icteric phase, and (4) convalescence. The incubation period for the different viruses is given in Table 18.3. Peak infectivity occurs during the last asymptomatic days of the incubation period and the early days of acute symptoms.
- *Acute liver failure*. Viral hepatitis accounts for approximately 10% of cases of acute hepatic failure. Hepatitis A and E are the most common causes worldwide, while HBV is more common in Asia and the Mediterranean. The treatment is to provide supportive care and allow for replication of residual hepatocytes to lead to restitution of the liver. Liver transplantation is the only option if the disease does not resolve before secondary infection and failure of other organs develops.
- *Chronic hepatitis*. **This is defined as symptomatic, biochemical, or serologic evidence of continuing or relapsing hepatic disease for more than 6 months.** In some patients, persistent elevation of serum transaminases may be the only clinical evidence of chronicity. Prolongation of the prothrombin time, hyperglobulinemia, hyperbilirubinemia, and mild elevations in alkaline phosphatase level can occur. In symptomatic individuals, the most common finding is fatigue; less common symptoms are malaise, loss of appetite, and occasional bouts of mild jaundice. Immune complex disease can develop due to circulating antibody-antigen complexes in chronic HBV and HCV infection, and can manifest as vasculitis, glomerulonephritis, and cryoglobulinemia.
- *Carrier state*. A "carrier" is an individual who harbors and can transmit an organism, but has no symptoms. For hepatotropic viruses, carrier state has been used to described two separate scenarios: (1) individuals who harbor the virus but have no liver disease; and (2) individuals who harbor the virus and have asymptomatic nonprogressive liver damage. In both cases, particularly the latter, affected individuals constitute reservoirs of infection. For HBV infection, the term "healthy carrier" has been used for an individual with HBsAg and anti-HBe, but without HBeAg. These patients have normal aminotransferases, low or undetectable serum HBV DNA, and lack of significant inflammation or liver injury on biopsy (see Fig. 18.11). For HCV, a state equivalent to the HBV "healthy carrier" is not recognized.

HIV is an important comorbid factor in hepatotropic viral infections. Co-infection of HIV and hepatitis viruses is common in the United States, as between 10% and 25% of HIV-infected individuals are also infected with HBV and HCV, respectively. Chronic HBV and HCV infection are leading causes of morbidity and mortality in HIV-infected individuals, although the severity and progression in immunocompetent HIV patients is similar to those who are HIV negative. Untreated HIV infection significantly exacerbates the severity of liver disease caused by HBV or HCV.

MORPHOLOGY

The general morphologic features of viral hepatitis are depicted schematically in Fig. 18.13. The morphologic changes in acute and chronic viral hepatitis due to hepatotropic viruses are largely similar and overlap with those associated with autoimmune hepatitis, adverse drug reactions, and Wilson disease.

In acute viral hepatitis, the liver may be normal in size, enlarged (due to inflammation), or shrunken in those cases that are associated with acute liver failure and massive liver necrosis (see Fig. 18.4). Microscopically, there is a portal and lobular inflammatory infiltrate comprised predominantly of lymphocytes and variably admixed with plasma cells and eosinophils. The hepatocyte injury may result in necrosis or apoptosis (see Figs. 18.2 and 18.3), often with pigmented macrophages scavenging the dead cell debris. Necrosis of groups of hepatocytes (i.e., confluent necrosis) may be seen in severe cases and can progress to necrosis of the entire lobule (i.e., panlobular or panacinar necrosis) or connect vascular structures (i.e., bridging necrosis). Liver failure can develop with massive hepatic necrosis.

The defining histologic feature of chronic viral hepatitis is portal lymphocytic, or lymphoplasmacytic, inflammation with fibrosis. The inflammatory cells often cross the limiting plate and lead to injury of periportal hepatocytes **(interface activity).** This may be accompanied by a variable degree of lobular inflammation. Fibrosis develops with increasing liver damage manifesting initially as portal and periportal fibrosis. Fibrous septa develop and lead to portoportal bridging fibrosis, and eventually cirrhosis.

There are some morphologic features that are distinctive for particular subtypes of chronic viral hepatitis. In chronic hepatitis B, the swollen endoplasmic reticulum of hepatocytes are swollen and filled with HBsAg, leading to a **"ground-glass" appearance**. Immunostaining for hepatitis B surface and core antigens can confirm the HBV infection (Fig. 18.14). Chronic hepatitis C typically shows prominent lymphoid aggregates or fully formed lymphoid follicles in the portal tracts (Fig. 18.15). Steatosis is common in chronic hepatitis C, and can be marked with genotype 3 infection. Bile duct injury can be seen in hepatitis C, mimicking biliary disease, but it is typically a focal finding.

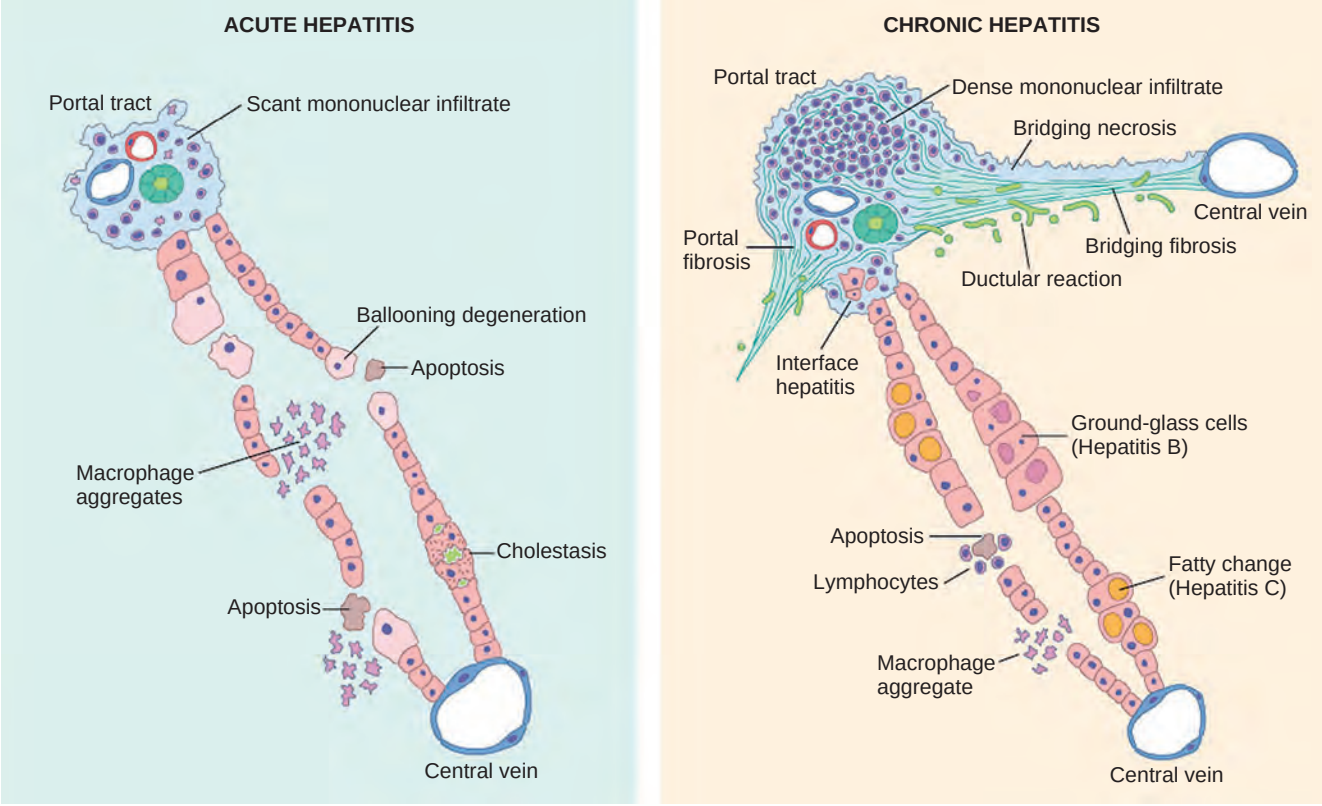

Figure 18.13 Diagrammatic representation of the morphologic features of acute and chronic hepatitis. Acute hepatitis is characterized by lobular inflammation and hepatocellular injury, and chronic hepatitis shows dense portal inflammation. Bridging necrosis can occur in severe acute hepatitis, and fibrosis is seen in chronic hepatitis. Ductular reaction is often present in areas of fibrosis in chronic hepatitis.

Liver biopsy is often performed to confirm the diagnosis of chronic hepatitis and to assess inflammatory activity (grade) and fibrosis (stage). Stage of the disease is used along with other clinical parameters to determine the therapeutic approach.

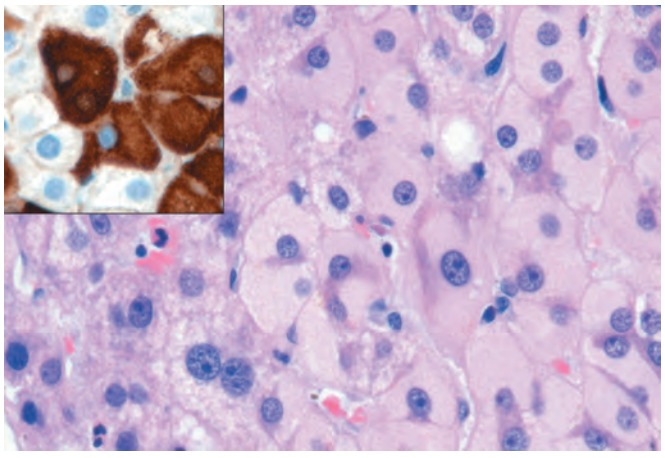

Figure 18.14 Ground-glass hepatocytes in chronic hepatitis B caused by accumulation of hepatitis B surface antigen in the endoplasmic reticulum. The cytoplasmic inclusions are light pink and finely granular on hematoxylin and eosin staining; immunostaining *(inset)* confirms that they contain hepatitis B surface antigen *(brown)*.

KEY CONCEPTS

VIRAL HEPATITIS

- Hepatitis A is transmitted through the fecal-oral route, causes acute hepatitis, and does not lead to chronic liver disease.
- Hepatitis B is transmitted parenterally with most infections being subclinical, but can cause acute hepatitis, chronic hepatitis, and cirrhosis.
- Hepatitis C is most often associated with progression to chronic liver disease (80% or more), while acute infections are almost always subclinical.
- Hepatitis D is a defective virus, requiring hepatitis B co-infection for replication and infection.
- Hepatitis E is endemic in equatorial regions and frequently epidemic; it causes acute disease, which can be severe in pregnancy and can lead to chronic hepatitis in immunocompromised individuals.
- The inflammatory cells in both acute and chronic viral hepatitis are mainly T cells; the morphologic findings overlap with other hepatitic disorders such as autoimmune hepatitis, drug-induced liver injury, and Wilson disease.
- Biopsy assessment in chronic viral hepatitis provides the extent of fibrosis (stage), which can determine the therapeutic course of action.
- Patients with HBV or HCV are at increased risk for development of HCC, especially in the setting of cirrhosis.

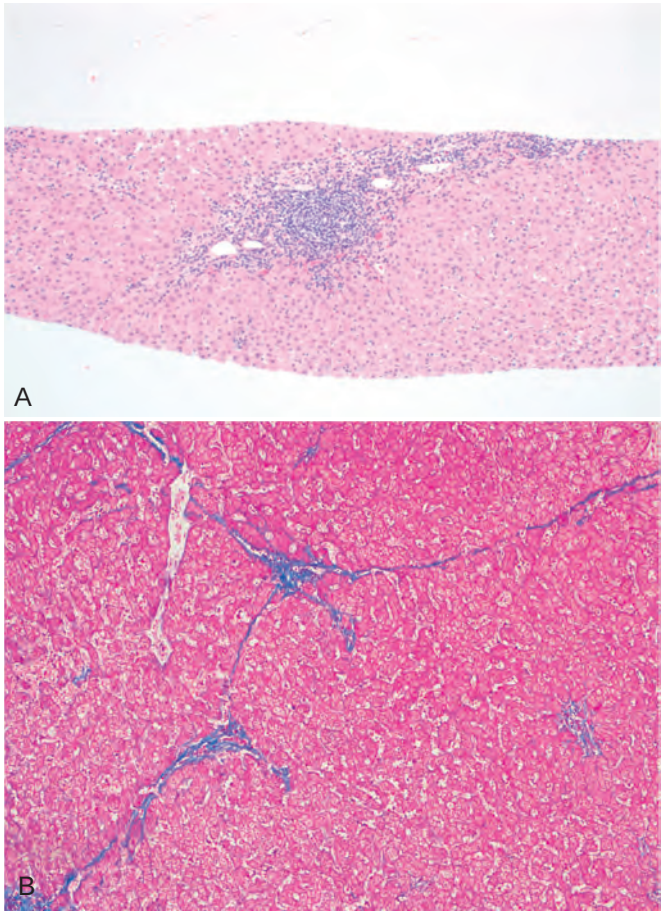

Figure 18.15 Chronic viral hepatitis due to hepatitis C virus. (A) Characteristic portal tract expansion by a lymphoid aggregate. (B) Delicate bridging fibrosis, seen later in the disease course.

Bacterial, Fungal, and Parasitic Infections

Bacteria, fungi, helminths, and other parasites/protozoa can involve the liver and biliary tree as localized infections or as part of a systemic disease. Examples of bacterial infections include *Staphylococcus aureus* in toxic shock syndrome, *Salmonella typhi* in typhoid fever, *Treponema pallidum* in secondary or tertiary syphilis, and *Bartonella henselae* in cat scratch disease. Biliary obstruction creates a milieu for bacterial proliferation leading to infection of the biliary tree, often called ascending cholangitis. When severe, this may extend to the liver and produce intrahepatic abscesses. Spread of bacteria through the hematogenous route or direct spread from adjacent infected tissues can also lead to abscess formation. Liver abscesses are associated with fever, right upper quadrant pain, and tender hepatomegaly. Jaundice may result from extrahepatic biliary obstruction. Antibiotic therapy is generally effective, but surgical drainage may be necessary for large lesions. Extrahepatic bacterial infections, particularly intraabdominal infections, may lead to nonspecific inflammatory changes in the liver. Sepsis can be associated with ductular reaction and cholestasis presenting as bile plugs in ductules (ductular or *cholangiolar cholestasis*), a typical feature of sepsis.

The liver can be involved in disseminated fungal (e.g., histoplasmosis) and mycobacterial infections. The liver histology shows epithelioid granulomas, with or without necrosis, at sites of involvement. The diagnosis rests on serologic findings, blood cultures, or demonstrating the organisms in liver biopsies.

Parasitic and helminthic infections that can involve the liver include malaria, schistosomiasis, strongyloidiasis, cryptosporidiosis, leishmaniasis, echinococcosis, amebiasis, and infections by the liver flukes *Fasciola hepatica, Opisthorchis* species, and *Clonorchis sinensis* (Chapter 8). Schistosomiasis is most commonly found in Asia, Africa, and South America in areas where the water contains numerous freshwater snails as a vector, and it is particularly likely to cause chronic liver disease. Liver fluke infections, most common in Southeast Asia, are notorious for increasing the risk of cholangiocarcinoma (discussed later). Hydatid cysts are usually caused by echinococcal infections (Chapter 8). They often have characteristic calcifications in the cyst walls, which may enable radiologic diagnosis. Hydatid cysts are uncommon in high income countries. Cystic liver degeneration or abscesses can be caused by amebic and other protozoal and helminthic infections. The incidence of amebic infections is low in high income countries and is usually found in immigrants from endemic regions.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic, progressive hepatitis associated with genetic predisposition, autoantibodies, and therapeutic response to immunosuppression. There is a female predominance (78%).

Pathogenesis

Autoimmune hepatitis has a strong association with specific HLA alleles in Caucasians (DR3), Japanese (DR4), and in South Americans (DRB1). Proposed triggers for the immune reaction include viral infections, drugs/toxins, and vaccination, but the antigens that are the target of autoimmunity are unknown, and as with other autoimmune disorders, that basis for the immune attack on hepatocytes remains obscure. The lymphocytic infiltrate in the liver is composed predominantly of CD4+ helper T cells with CD8+ cytotoxic T cells at the interface. CD4+ cells play an important role in activating B lymphocytes and their differentiation into plasma cells, which are responsible for production of autoantibodies. The mechanism by which the interplay of lymphocytes, autoantibodies, and HLA types lead to liver injury is unclear. A small number of drugs such as minocycline, nitrofurantoin, and α-methyl dopa can trigger the formation of autoantibodies and hepatocellular injury that mimics autoimmune hepatitis.

MORPHOLOGY

The features of autoimmune hepatitis overlap with acute and chronic hepatitis of other etiologies. Extensive inflammation and hepatocellular injury at the interface, as well as in the hepatic parenchyma, is characteristic of autoimmune hepatitis. Numerous plasma cells in clusters are typical (Fig. 18.16). Lymphocytes and plasma cells may be seen within the cytoplasm of hepatocytes,

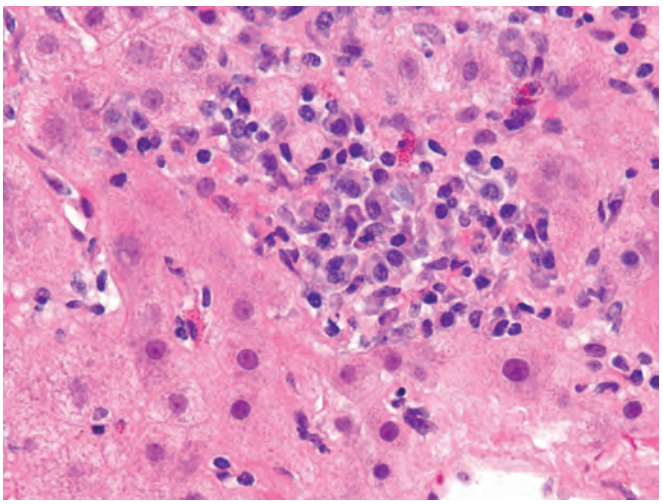

Figure 18.16 Autoimmune hepatitis. A focus of lobular hepatitis with prominent plasma cells typical for this disease is shown.

often at the interface, a curious phenomenon called emperipolesis. Necrosis of groups of hepatocytes (confluent necrosis) can involve the perivenular areas, the entire acinus (panacinar necrosis), or connect vascular structures (bridging necrosis). The resultant regenerative features can manifest as "rosettes," a circular arrangement of hepatocytes around a dilated canaliculus. Most cases have some degree of fibrosis at initial presentation, which increases with disease progression. Cirrhosis with limited inflammatory activity (i.e., "burnt out cirrhosis") is seen at initial presentation in some cases, the end result of subclinical disease.

Clinical Features

Untreated autoimmune hepatitis leads to death or progresses to cirrhosis in a majority of cases. It has a wide range of presentations ranging from asymptomatic disease detected by elevated transaminases during screening, to acute and chronic presentations. Acute presentations may be indistinguishable from acute viral or drug-induced hepatitis and may lead to acute liver failure. More commonly, the presentation is insidious with nonspecific symptoms such as fatigue, anorexia, nausea, and abdominal pain. Patients without symptoms or apparently acute presentations often prove to have fibrosis and even cirrhosis on biopsy, indicating the existence of subclinical disease that went unrecognized.

In a small subset of patients, there may be overlapping features with primary biliary cholangitis or primary sclerosing cholangitis, the latter occurring most often in the pediatric setting. The diagnosis of overlap syndromes requires the unequivocal presence of serologic, biochemical, and/or histologic evidence of both diseases. In some instances, the second component of the overlap syndrome becomes evident months or years after treatment of the first component. Autoimmune hepatitis may also be associated with other autoimmune diseases like type 1 diabetes mellitus, thyroiditis, and celiac sprue. Autoimmune hepatits-like injury induced by drugs is important to recognize because discontinuation of the drug typically leads to clinical recovery.

The diagnosis of autoimmune hepatitis is based on the combination of four features: autoantibodies, elevation of serum IgG, exclusion of other etiologies (e.g., viral hepatitis, drugs), and supportive histologic findings on liver biopsy. These features have been combined to create a scoring scheme, which enables categorization of cases into definite and probable autoimmune hepatitis (Table 18.4). Based on the types of autoantibodies present, autoimmune hepatitis is subclassified as types 1 and 2. *Type 1* is more common and is typically characterized by the presence of antinuclear antibodies (ANAs) and anti–smooth muscle actin (SMA) antibodies. Antibodies against soluble liver antigen/liver-pancreas antigen (SLA/LPA) and, less commonly, anti-mitochondrial antibodies (AMA, more typical of primary biliary cholangitis) also may be seen. *Type 2* disease is more common in children and is characterized by anti–liver kidney microsome-1 (LKM-1) antibodies, which are directed against CYP2D6, and anti–liver cytosol-1 (ACL-1) antibodies. The other clinical features, natural history, and pathologic findings are similar in the two types. Serum IgG is often elevated in autoimmune hepatitis and may provide another clue to the diagnosis.

Autoantibody titers do not correlate well with disease severity or outcome, and may not be present in a small subset of cases (i.e., seronegative autoimmune hepatitis). Autoantibodies also may be present in other disease processes such as steatohepatitis and chronic viral hepatitis (e.g., with HBV and HCV); hence, it is important to make the diagnosis based on overall clinical, serologic, and histologic features.

The treatment of choice is immunosuppression with prednisone, with or without azathioprine, leading to remission in 80% to 90% of patients, generally within 12 months of treatment. Other immunosuppressants are used if the side effects of steroids cannot be tolerated. Patients with incomplete responses or with multiple relapses are at higher risk of progression to cirrhosis and also at risk for developing

Table 18.4 Simplified Diagnostic Criteria (2008) of the International Autoimmune Hepatitis Group

		Points[a]
Autoantibodies	ANA or ASMA or LKM > 1:80	2
	ANA or ASMA or LKM > 1:40	1
	SLA/LP Positive (>20 units)	0
IgG (or gamma-globulins)	>1.10 times normal limit	2
	Upper normal limit	1
Liver histology[b]	Typical for autoimmune hepatitis	2
	Compatible with autoimmune hepatitis	1
	Atypical for autoimmune hepatitis	0
Absence of viral hepatitis	Yes	2
	No	0

[a]Definite autoimmune hepatitis (AIH): N = 7; probable AIH: N = 6.

[b]Typical: (1) Interface hepatitis, lymphocytic/lymphoplasmacytic infiltrates in portal tracts and extending in the lobule; (2) emperipolesis (active penetration by one cell into and through larger cell); (3) hepatic rosette formation.

Compatible: Chronic hepatitis with lymphocytic infiltration without features considered typical.

Atypical: Showing signs of another diagnosis like nonalcoholic fatty liver disease.

AIH, Autoimmune hepatitis; *ANA*, antinuclear antibody; *ASMA*, anti–smooth muscle actin; *IgG*, immunoglobulin G; *LKM*, anti–liver kidney microsomal antibodies; *LP*, liver pancreas; *SLA*, soluble liver antigen.

hepatocellular carcinoma. Liver transplantation may be necessary for cirrhotic patients. The 10-year survival rate after liver transplant is 75%, with disease recurrence in 20% of patients.

KEY CONCEPTS

AUTOIMMUNE HEPATITIS

- The diagnosis of autoimmune hepatitis is based on a combination of four features: autoantibodies, elevated serum IgG, pathologic findings, and exclusion of viral/drug etiologies.
- The most common autoantibodies in type 1 autoimmune hepatitis are ANAs and anti–smooth muscle antibodies (ASMAs), while type 2 autoimmune hepatitis is characterized by anti-LKM1 autoantibodies.
- Autoimmune hepatitis can have varied presentations: asymptomatic liver enzyme elevation, acute liver failure, chronic hepatitis, and cirrhosis.
- Typical histologic features of autoimmune hepatitis include a high degree of necroinflammatory activity and numerous plasma cells.

DRUG- AND TOXIN-INDUCED LIVER INJURY

Drug or toxin-induced liver injury is a major cause of acute liver failure in the United States. Due to its central role in metabolism, the liver is susceptible to injury by a wide array of compounds found in medicines (Table 18.5), herbal products, dietary supplements, poisonous plants and fungi (e.g., *Amanita phylloides* mushrooms), and household and industrial products (e.g., ointments, perfumes, shampoo, cleaning solvents, pesticides). Based on U.S. Drug Induced Liver Injury Network data, 10% of the patients with drug-induced liver injury die or require liver transplantation, and 17% go on to develop chronic liver disease.

Pathogenesis

Principles of drug and toxic injury are discussed in Chapter 9. Liver injury may develop immediately after exposure to the responsible agent or manifest after weeks or even months. In most instances, the injury is mediated by reactive metabolites generated in the liver. The cytochrome family of enzymes, particularly cytochrome P-450, is involved in most of these metabolic reactions. Since these enzymes are more active in the central zone of the lobule, necrosis of perivenular hepatocytes is a typical feature of drug-induced liver injury. Agents that induce the cytochrome system, such as rifampicin, phenytoin, isoniazid, tobacco smoke, and ethanol, may exacerbate the toxicity of other drugs.

Drug-induced liver injury can be idiosyncratic (unpredictable) or dose-dependent (predictable). Idiosyncratic reactions are the most common form of drug-induced liver injury and usually occur after 1 to 3 months of exposure (see Table 18.5). In some instances, they appear to stem from a hypersensitivity response to the drug or its metabolite(s). It is thought that there is genetic susceptibility in those who have idiosyncratic reactions. For example, the metabolism of isoniazid (an antituberculous agent) is slow in individuals who have a variant of N-acetyltransferase (NAT2) with decreased enzymatic activity, raising drug levels in the liver and leading to susceptibility to isoniazid hepatotoxicity. Antimicrobial drugs are the most common culprits in idiosyncratic reactions, accounting for nearly one-half of cases. Other commonly implicated agents include cardiovascular drugs, central nervous system agents, antineoplastic drugs, and analgesics like nonsteroidal anti-inflammatory

Table 18.5 Patterns of Drug- and Toxin-Induced Hepatic Injury

Pattern of Injury	Morphologic Findings	Examples of Associated Agents
Cholestatic	Bland hepatocellular cholestasis, without inflammation	Contraceptive and anabolic steroids, antibiotics, ART
Cholestatic hepatitis	Cholestasis with lobular necroinflammatory activity; may show bile duct destruction	Antibiotics, phenothiazines, statins
Hepatocellular necrosis	Spotty hepatocyte necrosis	Methyldopa, phenytoin
	Massive necrosis	Acetaminophen, halothane
	Chronic hepatitis	Isoniazid
Fatty liver disease	Large and small droplet fat	Ethanol, corticosteroids, methotrexate, total parenteral nutrition
	"Microvesicular steatosis" (diffuse small droplet fat)	Valproate, tetracycline, aspirin (Reye syndrome), ART
	Steatohepatitis with Mallory hyaline	Ethanol, amiodarone, irinotecan
Fibrosis and cirrhosis	Periportal and pericellular fibrosis	Alcohol, methotrexate, enalapril, vitamin A and other retinoids
Granulomas	Noncaseating epithelioid granulomas	Sulfonamides, amiodarone, isoniazid
	Fibrin ring granulomas	Allopurinol
Vascular lesions	Sinusoidal obstruction syndrome (veno-occlusive disease): obliteration of central veins	High-dose chemotherapy, bush teas
	Budd-Chiari syndrome	Oral contraceptives
	Peliosis hepatis: blood-filled cavities, not lined by endothelial cells	Anabolic steroids, tamoxifen
Neoplasms	Hepatocellular adenoma	Oral contraceptives, anabolic steroids
	Hepatocellular carcinoma	Alcohol, thorotrast
	Cholangiocarcinoma	Thorotrast
	Angiosarcoma	Thorotrast, vinyl chloride

ART, Antiretroviral therapy.

Modified from Washington K: Metabolic and toxic conditions of the liver. In Iacobuzio-Donahue CA, Montgomery EA, editors: *Gastrointestinal and Liver Pathology*, Philadelphia, 2005, Churchill Livingstone.

drugs. A wide variety of herbal and nutritional agents also have been implicated in idiosyncratic reactions.

A classic, dose-dependent, predictable hepatotoxin is acetaminophen, now the most common cause of acute liver failure necessitating transplantation in the United States. The toxic agent is not acetaminophen itself but rather a metabolite, N-acetyl_P-benzquinone immine (NAPQI), produced by the cytochrome P-450 system. Pericentral zone 3 hepatocytes are most sensitive to NAPQI, but in severe overdoses the injury affects all parts of the lobules, resulting in acute hepatic failure. While suicide attempts with acetaminophen are common, so are accidental overdoses. This is because the activity of the cytochrome P-450 system may be up-regulated by other agents taken in combination with acetaminophen, such as alcohol (beware acetaminophen as a hangover prophylactic) or codeine in acetaminophen compound tablets. Other examples of direct-acting hepatotoxins that may produce severe liver injury include organic solvents and toxins in mushrooms.

MORPHOLOGY

Drugs can lead to one or more patterns of injury. Hepatocellular injury accounts for almost one-half of cases, and the remaining are divided approximately equally between cholestatic and mixed hepatocellular/cholestatic patterns. Idiosyncratic reactions with a hepatocellular pattern of injury show typical features of acute hepatitis dominated by inflammation and varying degrees of necrosis. The picture is similar to viral and autoimmune hepatitis, and centrizonal necrosis is a common feature. Progression to chronic hepatitis, and even cirrhosis, can be seen in a small minority of cases. Injury caused by intrinsic hepatotoxins is dominated by necrosis with minimal inflammation. Injury centered on bile ducts is characterized by varying combinations of cholestasis and ductular reactions, which can progress to chronic cholestasis and duct "dropout" in a minority of cases.

Some agents produce other patterns of injury. Drugs like amiodarone (antiarrhythmic), tamoxifen (anti-estrogen), irinotecan (antineoplastic), and methotrexate (immunosuppressive) can cause a **steatohepatitis-like** pattern of injury. Mitochondrial dysfunction caused by drugs such as tetracycline (antibiotic), valproic acid (anticonvulsant), and zidovudine (antiretroviral) can result in **microvesicular steatosis.** Endothelial injury to sinusoids and central veins can be caused by cytotoxic agents (azathioprine, oxaliplatin), leading to **sinusoidal obstruction syndrome** (formerly called veno-occlusive disease).

Clinical Features

Drug-induced liver injury can have a wide variety of presentations and should always be included in the differential diagnosis of liver disease. Since there are no specific clinical or pathologic features, the diagnosis is established based on temporal association of drug or toxin exposure with onset of liver injury. Liver enzyme tests can be used to gauge whether the injury is primarily (1) hepatocellular (alanine aminotransferase [ALT] ≥5 times the upper limit of normal, or ALT/alkaline phosphatase [ALP] ratio >5), (2) cholestatic (ALP ≥2 times the upper limit of normal, or ALT/ALP ratio <2), or (3) mixed (increased ALT and ALP with ALT/ALP ratio between 2 and 5). Exclusion of other etiologies and disease recovery (in most cases) on withdrawal of the offending agent support the presumptive diagnosis. Recurrence with rechallenge with the drug can be confirmatory but is rarely done in practice for obvious reasons.

KEY CONCEPTS

DRUG-INDUCED LIVER INJURY

- There are two mechanisms of liver injury:
  - Direct hepatotoxicity, a dose-dependent phenomenon of the drug, or its metabolite, which predictably affects exposed individuals, a typical example being acetaminophen, which is the most common cause of acute liver failure in the United States.
  - Idiosyncratic (hypersensitivity) response, which is not dose-dependent, accounts for the majority of drug-induced liver injury, but typically occurs in a minority of individuals.
- Drugs can mimic any clinical or histologic pattern of injury and should be included in the differential diagnosis of liver diseases in diverse clinical settings.
- Correlation of temporal profile of drug intake and onset of disease is necessary for diagnosis.

FATTY LIVER DISEASE

Alcoholic liver disease and nonalcoholic fatty liver disease share many similarities and are considered together in this section.

Alcoholic Liver Disease

Excessive alcohol (ethanol) consumption is a major cause of liver disease in most Western countries; it accounts for 5.9% of deaths globally and more often leads to death and disability earlier in life than other forms of chronic liver injury. There are three distinctive, albeit overlapping, forms of alcohol-induced liver injury: (1) steatosis, or fatty change, (2) alchoholic steato-hepatitis, and (3) fibrosis, which leads to cirrhosis.

Pathogenesis

The pharmacokinetics and metabolism of alcohol are described in Chapter 9. Pertinent to this discussion are the detrimental effects of alcohol and its byproducts on hepatocellular function. Short-term ingestion of as little as 80 g of alcohol (six beers or 8 ounces of 80-proof liquor) over one to several days generally produces mild, reversible, hepatic steatosis. The risk of severe hepatic injury becomes significant with intake of 80 g or more of ethanol per day, and daily ingestion of 160 g or more for 10 to 20 years is frequently associated with severe liver injury. However, only 10% to 15% of alcoholics develop cirrhosis. Thus, other factors also influence the development and severity of alcoholic liver disease. These include:

- *Gender.* Although the majority of patients with alcoholic liver disease are men, on a dose-for-dose basis, women are more susceptible to alcohol-induced hepatic injury.

Gender differences in alcohol pharmacokinetics and metabolism may contribute, as well as estrogen-dependent responses of the liver to gut-derived endotoxin (lipopolysaccharide [LPS]). Although exact mechanisms are not known, it appears that estrogen increases gut permeability to endotoxins. These are transported in the portal system to the liver, where they bind the LPS receptor CD14 expressed on Kupffer cells, an event that stimulates Toll-like receptor 4. Toll-like receptor signaling triggers the release of cytokines and chemokines, which may contribute to the inflammation that accompanies alcoholic liver disease.

- *Ethnic and genetic differences.* In the United States, cirrhosis rates are higher for African Americans than for Caucasian Americans despite similar levels of alcohol consumption. Studies with twins suggest that there is a genetic component in alcohol-induced liver disease, although it remains difficult to separate genetic from environmental influences. Genetic variation in alcohol detoxifying enzymes and cytokine promoters may play significant roles and contribute to differences across populations. *ALDH**2, a variant of aldehyde dehydrogenase *(ALDH)* found in 50% of Asians, has a very low enzyme activity. Individuals homozygous for *ALDH**2 are unable to oxidize acetaldehyde and are intolerant of alcohol, which produces upper body flushing and variable levels of nausea and lethargy.
- *Comorbid conditions.* Iron overload, nonalcoholic steatohepatitis, and infection with HCV and HBV synergize with alcohol to increase the severity of liver disease.

Excessive alcohol intake causes steatosis, dysfunction of mitochondria, microtubules and cellular membranes, and oxidative stress, and the resulting injury leads to varying degrees of inflammation and hepatocyte death. Several factors appear to contribute to steatosis. Alcohol metabolism by alcohol dehydrogenase and acetaldehyde dehydrogenase generate large amounts of reduced nicotinamide adenine dinucleotide (NADH). This alters the redox balance in hepatocytes and has a plethora of effects that favor lipogenesis, including suppression of fatty acid oxidation and increased expression of enzymes that carry out fatty acid synthesis. The accumulation of intrahepatic lipids may be further exacerbated by impaired lipoprotein assembly and secretion. Alcohol also enhances peripheral catabolism of fat, increasing the circulating pool of lipids that are available for uptake by hepatocytes.

The exact mechanisms underlying hepatocyte injury and alcoholic hepatitis are uncertain, but several likely contributory factors have been identified.

- *Acetaldehyde* (the product of alcohol dehydrogenase) induces lipid peroxidation and acetaldehyde-protein adduct formation, disrupting cytoskeleton and membrane function and possibly producing neoantigens.
- *CYP2E1 induction.* High levels of alcohol consumption induce liver microsomes that contain CYP2E1, a component of the cytochrome P-450 system. CYP2E1 metabolism of alcohol produces ROS that damage cellular protein, membranes, and mitochondria, effects that may promote apoptosis.
- *Methoinine metabolism.* Alcohol impairs hepatic metabolism of methionine, which decreases glutathione levels, thereby sensitizing the liver to oxidative injury, and contributes to homocysteine production, which may induce the endoplasmic reticulum stress response.

The induction of cytochrome P-450 enzymes in the liver by alcohol also enhances the conversion of other drugs (e.g., acetaminophen) to toxic metabolites. Furthermore, as already mentioned, alcohol has been linked to increased uptake of bacterial endotoxin from the gut, which induces inflammatory responses in the liver.

Damage caused by these and other factors lead to inflammation and, with chronicity, liver fibrosis and deranged vascular perfusion (summarized in Fig. 18.17). In essence, alcoholic liver disease can be a regarded as a maladaptive state in which cells in the liver respond in an increasingly pathologic manner to a stimulus (alcohol) that originally was only marginally harmful.

MORPHOLOGY

Characteristic changes in alcoholic liver disease begin in centrilobular zone 3 and extend outward toward the portal tracts as the injury increases in severity. **Hepatic steatosis (fatty liver)** is an early, predictable effect of alcohol consumption. After even moderate intake of alcohol, lipid droplets accumulate in hepatocytes. Lipid accumulation begins as small droplets that coalesce into large droplets, which distend the hepatocyte and push the nucleus aside (Fig. 18.18). Macroscopically, the fatty liver of chronic alcoholism is enlarged (as heavy as 4 to 6 kg), soft, yellow, and greasy. Steatosis may be separated into microvesicular and macrovesicular forms. **Macrovesicular steatosis** is the predominant form in alcoholic liver disease. An unusual exception is **alcoholic foamy degeneration,** a form of microvesicular steatosis sometimes seen with chronic heavy alcohol use that is associated with endoplasmic reticulum and mitochondrial damage. In general, fatty change is completely reversible if there is abstention from further intake of alcohol.

In a subset of patients with alcoholic liver disease, liver inflammation **(alcoholic hepatitis)** and fibrosis (see Fig. 18.18) are prominent features. The morphologic findings in alcoholic hepatitis include the following:

- *Ballooned hepatocytes* (Fig. 18.19). These are injured, swollen hepatocytes with cleared-out cytoplasm and cytoskeletal damage, which when extensive, results in formation of **Mallory hyaline,** tangled skeins of intermediate filaments such as keratin 8 and keratin 18 that are partially degraded and ubiquitinated (see Fig. 18.19B). Mallory hyaline may reflect a failed attempt to sequester and degrade damaged cytoplasmic proteins. Other ballooned hepatocytes lack Mallory hyaline and contain fat droplets instead. While ballooned hepatocytes are not entirely specific for alcoholic steatohepatitis, they are essential for this diagnosis. Other conditions with ballooned hepatocytes include nonalcoholic steatohepatitis (NASH), Wilson disease, and chronic biliary tract diseases.
- *Inflammation and necrosis.* Neutrophils are generally more prominent in alcoholic hepatitis than in NASH and can satellite around ballooned hepatocytes, particularly when Mallory hyaline is present. Lobular lymphocytic infiltrates are common, and portal lymphocytic infiltrates also may occur, along with increases in macrophages in both portal tracts and lobular parenchyma.

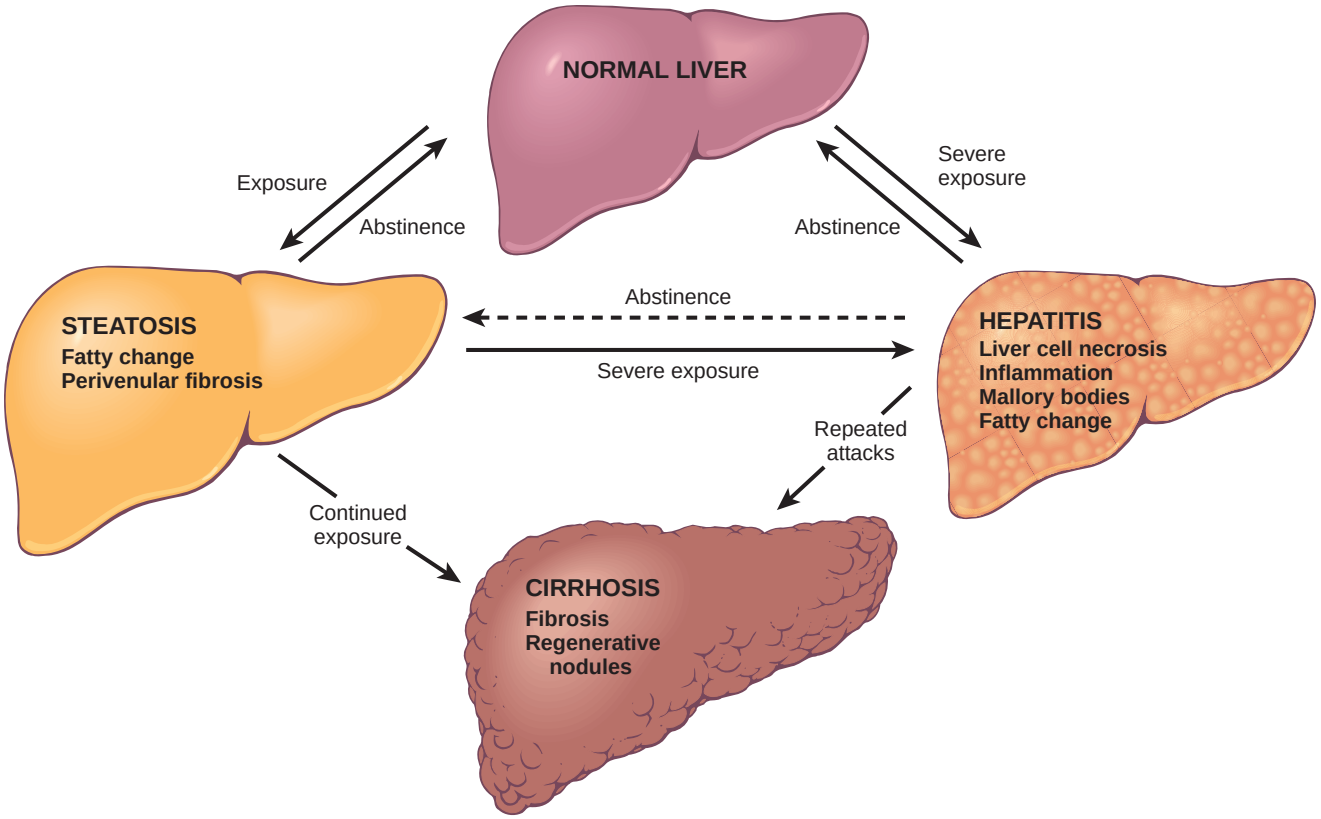

Figure 18.17 Alcoholic liver disease. The interrelationships among hepatic steatosis, alcoholic hepatitis, and alcoholic cirrhosis are shown, along with depictions of key morphologic features. It should be noted that some patients present initially with cirrhosis without any of the other forms of alcoholic liver disease.

Necrosis/apoptosis is usually spotty, but more prominent hepatocellular injury and confluent necrosis can occur in some cases.

- *Perivenular/pericellular fibrosis.* Steatohepatitis is often accompanied by fibrosis. This usually starts in acinar Zone 3 as pericellular, or perisinusoidal, fibrosis with a "chicken wire" appearance (see Fig. 18.18). With continued damage, this progresses to portal/periportal fibrosis, and then to bridging fibrosis and cirrhosis, which in many cases is micronodular ("Laennec cirrhosis") (Fig. 18.20). Early stages of scarring can regress with cessation of alcohol use, but with the development of cirrhosis and its vascular derangements (related to perivenular fibrosis and fibrous obliteration, termed phlebosclerosis, and veno-occlusive lesions), the chances of full restoration of normal function diminish. Complete regression of alcoholic cirrhosis, although reported, is rare.

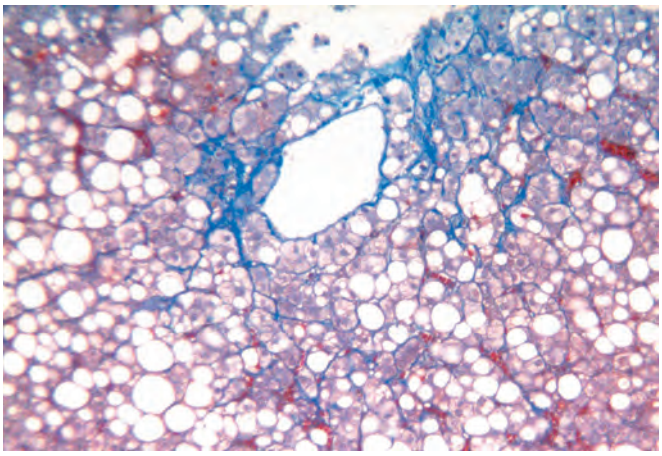

Figure 18.18 Alcoholic steatosis and fibrosis. A mix of small and large fat droplets (seen as clear vacuoles) is most prominent around the central vein and extends outward to the portal tracts. Some fibrosis *(stained blue)* is present in a characteristic perisinusoidal chicken wire pattern. (Masson trichrome stain). (Courtesy Dr. Elizabeth Brunt, Washington University, St. Louis, Mo.)

Clinical Features

Hepatic steatosis may cause hepatomegaly, with mild elevation of serum bilirubin and alkaline phosphatase levels. Severe hepatic dysfunction is unusual. Alcohol withdrawal and consumption of an adequate diet are sufficient treatment. In contrast, alcoholic hepatitis tends to appear acutely, usually following a bout of heavy drinking. Typically, there is malaise, anorexia, weight loss, upper abdominal discomfort, and tender hepatomegaly, accompanied by the laboratory findings of hyperbilirubinemia, elevated serum aminotransferases and alkaline phosphatase, and often a neutrophilic leukocytosis. In contrast to other chronic liver diseases, in which serum ALT tends to be higher than serum AST, in alcoholic liver disease serum AST tend to be higher

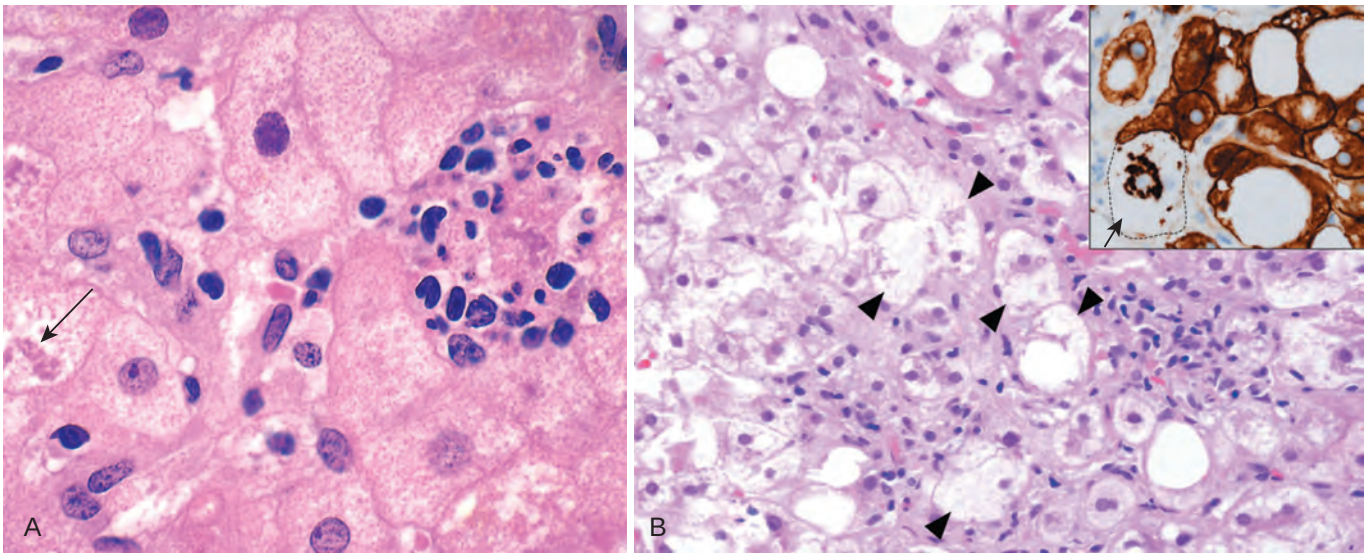

Figure 18.19 (A) Alcoholic hepatitis with clustered inflammatory cells marking the site of a necrotic hepatocyte. Mallory hyaline is present in another hepatocyte *(arrow).* (B) Alcoholic hepatitis with many ballooned hepatocytes *(arrowheads).* Clusters of inflammatory cells are also present; *inset* shows immunostaining for keratins 8 and 18 *(brown),* with most hepatocytes, including those with fat vacuoles, showing normal cytoplasmic staining, but in the ballooned cell *(arrow)* the ubiquinated keratins are collapsed into Mallory hyaline, leaving the cytoplasm "empty." (Courtesy Dr. Elizabeth Brunt, Washington University, St. Louis, Mo.)

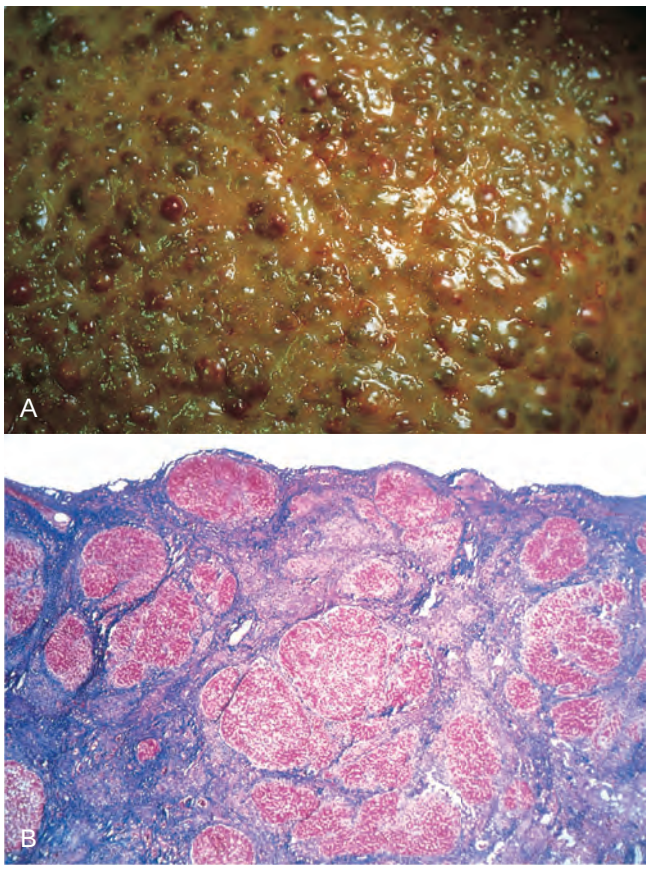

Figure 18.20 Alcoholic cirrhosis. (A) The characteristic diffuse nodularity of the surface is induced by the underlying fibrous scarring. The average nodule size is 3 mm in this close-up view, typical of the "micronodular" cirrhosis of alcoholic liver disease. The greenish tint is caused by cholestasis. (B) Microscopically, this cirrhosis is marked by small nodules entrapped in blue-staining fibrous tissue; fatty accumulation is no longer seen in this "burned-out" stage (Masson trichrome stain).

than serum ALT levels by a ratio of 2:1 or greater. This finding can be particularly helpful in the setting of occult alcoholism. On the other end of the spectrum, in severe cases symptoms and laboratory findings may mimic those of acute liver failure. In other instances, an acute cholestatic syndrome picture is seen that resembles large bile duct obstruction.

The outlook is unpredictable; each episode of hepatitis incurs about a 10% to 20% risk of death. With repeated bouts, cirrhosis develops in about one-third of patients within a few years. Alcoholic hepatitis also may be superimposed on established cirrhosis. With proper nutrition and total cessation of alcohol consumption, alcoholic hepatitis may clear. However, in some patients, the hepatitis persists despite abstinence, and progression to cirrhosis is seen.

The manifestations of alcoholic cirrhosis are similar to those of other forms of cirrhosis. Laboratory findings reflect hepatic dysfunction and include elevated serum aminotransferases, hyperbilirubinemia, variable elevation of serum alkaline phosphatase, hypoproteinemia (globulins, albumin, and clotting factors), and anemia. In some instances, liver biopsy may be indicated, since in about 10% to 20% of cases of presumed alcoholic cirrhosis, another disease process is found. Finally, cirrhosis may be clinically silent, discovered only at autopsy or when a stress such as infection or trauma tips the balance toward hepatic insufficiency.

The long-term outlook for alcoholics with liver disease is variable. The 5-year survival rate approaches 90% in abstainers who are free of jaundice, ascites, or hematemesis; it drops to 50% to 60% in those who continue to imbibe. In advanced disease, common proximate causes of death include (1) hepatic coma, (2) massive gastrointestinal hemorrhage, (3) intercurrent infection (to which these patients are predisposed), (4) hepatorenal syndrome (often following a bout of alcoholic hepatitis), and (5) hepatocellular carcinoma (the risk of developing this tumor in alcoholic cirrhosis is 1% to 6% annually).

KEY CONCEPTS

ALCOHOLIC LIVER DISEASE

- Alcoholic liver disease is a chronic disorder that can give rise to steatosis, alcoholic hepatitis, progressive fibrosis, and marked derangement of vascular perfusion leading eventually to cirrhosis.
- Consumption of 80 g/day of alcohol is considered to be the threshold for development of alcoholic liver disease, but may be lower in women.
- It may take 10 to 15 years of drinking for development of cirrhosis, which occurs only in a small proportion of chronic alcoholics.
- The pathologic effects of alcohol on hepatocytes include changes in lipid metabolism related to altered redox potential, injury caused by ROS generated by metabolism of alcohol by the P450 system, and protein adducts formed by acetaldehyde, a major metabolite of alcohol.

Table 18.6 World Health Organization Criteria for the Metabolic Syndrome

One of:	Diabetes mellitus or impaired glucose tolerance or impaired fasting glucose or insulin resistance
and two of:	Blood pressure: ≥140/90 mm Hg Dyslipidemia: triglycerides (TG): ≥1.695 mmol/L and high-density lipoprotein cholesterol (HDL-C) ≤0.9 mmol/L (male), ≤1 mmol/L (female) Central obesity: waist-hip ratio >0.90 (male); >0.85 (female), or body mass index >30 kg/m^2 Microalbuminuria: urinary albumin excretion rate of ≥20 μg/min or albumin-to-creatinine ratio ≥30 mg/g

Nonalcoholic Fatty Liver Disease (NAFLD)

NAFLD is defined as the presence of hepatic steatosis (fatty liver) in individuals who do not consume alcohol or do so in small quantities and who do not have another cause of secondary hepatic fat accumulation (e.g., HCV, Wilson disease, medications). NAFLD is associated with obesity, diabetes mellitus type 2, and hyperlipidemia, all components of the metabolic syndrome (Table 18.6). It has become the most common cause of chronic liver disease in the United States and is projected to exceed 30% prevalence in the adult population by 2030. The term *nonalcoholic steatohepatitis* (or its common acronym *NASH*) is reserved for NAFLD patients who demonstrate steatohepatitic injury with histologic features similar to those seen with alcoholic hepatitis. The diagnosis of NASH confers an increased risk of developing advanced fibrotic liver disease, and the rise in NAFLD prevalence is expected to produce a concomitant increase in the incidence of NASH and its serious complications (e.g., decompensated cirrhosis, hepatocellular carcinoma).

Pathogenesis

The precise mechanisms underlying NAFLD are unknown. The strong association with insulin resistance suggests that this factor is particularly important in disease development. However, even among those with insulin resistance, there is significant variability in the severity of NAFLD, and complex associations with genetic variants, diet, and the intestinal microbiome have also been suggested. As in alcoholic liver disease, there is an established association between increased gut-derived endotoxin production and liver inflammation and injury. High-fructose diets have also been associated with increased risk of NAFLD-related fibrosis, and dietary fat, particularly trans-fat, may have a role in producing liver injury. Obstructive sleep apnea, usually occurring in the setting of obesity, has been associated with disease progression, possibly related to intermittent hypoxia. Fibrosis may be accelerated when injury from another liver disease (e.g., hemochromatosis) is superimposed on NAFLD.

In individuals with established insulin resistance and metabolic syndrome, visceral adipose tissue not only increases in mass but also becomes dysfunctional. Resistance to insulin leads to increased release of free fatty acids from adipocytes due to overactivity of lipoprotein lipase (Chapter 24). This is associated with reduced production of the hormone adiponectin from adipocytes, which decreases oxidation of free fatty acids by skeletal muscle and increases free fatty acid uptake into hepatocytes (Chapter 9), where the fatty acids are stored as triglycerides. The dysfunctional adipocytes also synthesize pro-inflammatory cytokines such as TNF-α. At the same time, there is evidence that hepatocytes in NAFLD down-regulate lipolysis, an alteration that may further contribute to the accumulation of lipids. Lipolysis occurs through a mechanism called lipophagy that closely resembles macroautophagy, which you will recall is the process by which cells remove excessive or dysfunctional cellular components and (in times of starvation) generate metabolites for energy production.

The net effect of these changes is to cause lipid to accumulate in hepatocytes. Fat-laden cells are highly sensitive to lipid peroxidation products generated by oxidative stress, which can damage mitochondrial and plasma membranes, potentially leading to apoptosis or necrosis. These tendencies may be exacerbated by the pro-inflammatory state that accompanies insulin resistance. Once cell injury becomes established, release of cytokines such as TNF-α and TGF-β locally from Kupffer cells leads to the activation of stellate cells, collagen deposition, and scarring.

MORPHOLOGY

NASH shares many morphologic features with alcoholic hepatitis; steatosis (≥5% of hepatocytes), lobular inflammation, and ballooned hepatocytes are required for its diagnosis. It is not possible to reliably distinguish alcoholic hepatitis from NASH based on histologic findings, though alcoholic hepatitis has on average less steatosis and more ballooned hepatocytes, lobular inflammation, Mallory hyaline, neutrophilic infiltrates, cholestasis, and obliterated central veins (Fig. 18.21).

Determination of the extent of fibrosis is important for clinical management. Fibrosis typically develops around the central vein as a fine "spider web" of pericellular collagen deposition (also

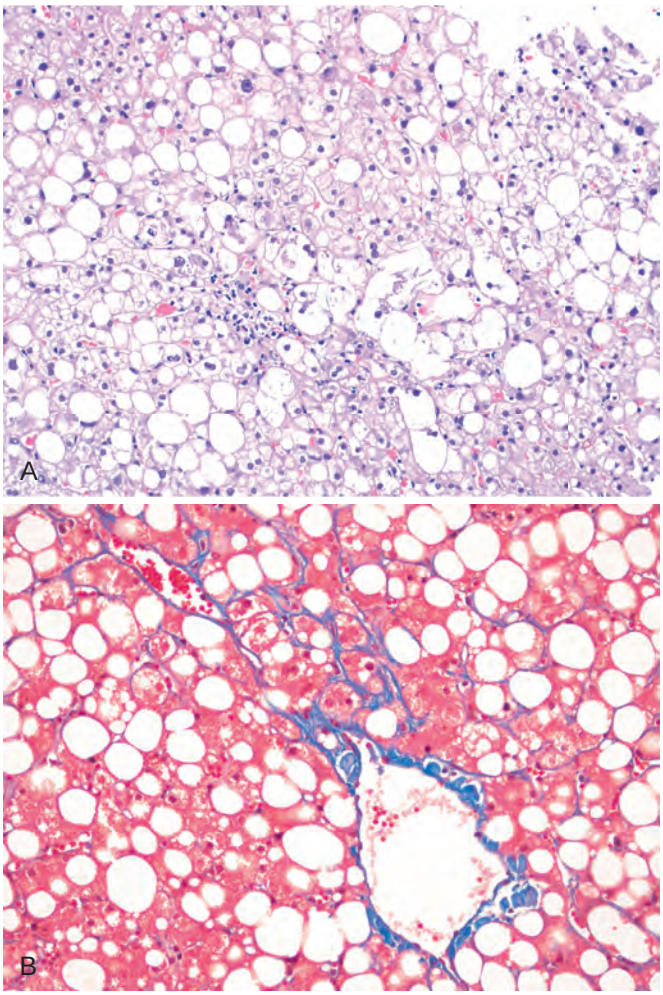

Figure 18.21 Nonalcoholic fatty liver disease. (A) Liver with mixed small and large fat droplets as well as ballooned hepatocytes. (B) Steatosis and fibrosis extending along sinusoids in a chicken wire pattern in which individual and clustered hepatocytes are surrounded by thin scars *(blue fibers)*. Note the resemblance to alcoholic hepatitis depicted in Fig. 18.18. (Masson trichrome stain.)

referred to as a chicken wire pattern), which may only be appreciated with a trichrome stain. Progression of fibrosis usually manifests as periportal fibrosis, followed by bridging fibrosis and cirrhosis. Cirrhosis is often subclinical for years, and, when established, the steatosis or ballooned hepatocytes may be reduced or absent. More than 90% of cases labeled as "cryptogenic cirrhosis" (i.e., cirrhosis of unknown cause) are thought to be due to NASH (i.e., "burned out NASH").

Pediatric NAFLD differs significantly from adult NAFLD. Typically, children show more diffuse steatosis and portal (rather than central) fibrosis, and ballooned hepatocytes may not be present.

Clinical Features

The varied clinical course of individuals with NAFLD is summarized in Fig. 18.22. Individuals with only steatosis are generally asymptomatic. Clinical presentation is often related to other signs and symptoms of the metabolic syndrome, in particular insulin resistance or diabetes mellitus. Imaging studies may reveal fat accumulation in the liver. Liver biopsy is required for diagnosis of NASH and aids in assessment of fibrosis. Viral, autoimmune, and other metabolic diseases of the liver must be excluded, and biopsy may be helpful when there is more than one potential etiology for liver injury. Serum AST and ALT are elevated in most patients with NASH. Despite the enzyme elevations, patients may be asymptomatic. Others have nonspecific symptoms such as fatigue, or complain of right-sided abdominal discomfort caused by hepatomegaly. Because of the association with metabolic syndrome, cardiovascular disease is a frequent cause of death in patients with NASH. NASH also increases the risk of hepatocellular carcinoma, as do other metabolic diseases (discussed later).

The goal of treating individuals with NASH is to reverse the histologic features of disease and prevent or reverse fibrosis by correcting underlying risk factors, such as obesity and hyperlipidemia, and to treat insulin resistance. Weight loss, diet, and exercise can potentially reverse the histologic

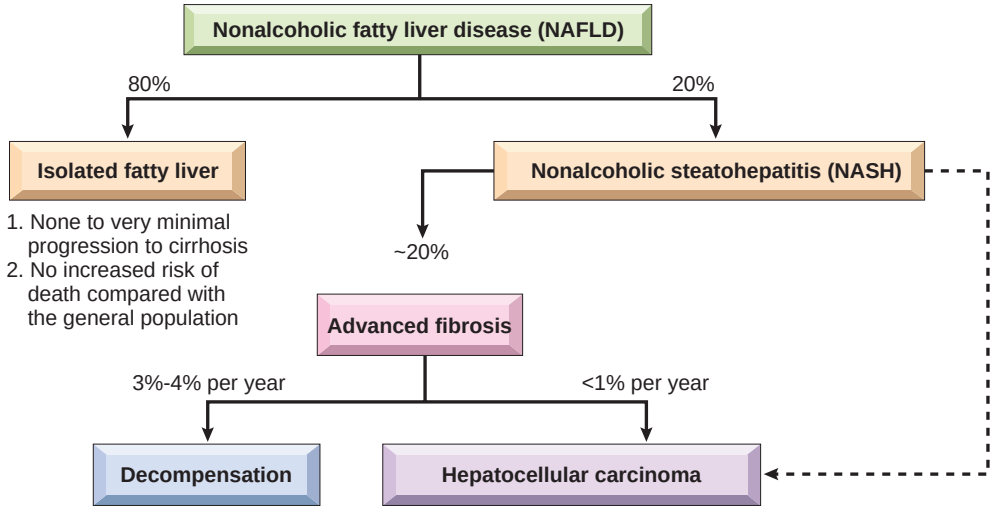

Figure 18.22 Natural history of nonalcoholic fatty liver disease phenotypes. Isolated fatty liver, shows minimal risk for progression to cirrhosis or increased mortality, and nonalcoholic steatohepatitis shows increased overall mortality as well as increased risk for cirrhosis and hepatocellular carcinoma.

abnormalities in NASH. There are numerous ongoing clinical trials aimed at developing pharmacologic approaches for treating NASH and its complications.

KEY CONCEPTS

NONALCOHOLIC FATTY LIVER DISEASE

- The most common metabolic liver disorder is NAFLD, which is associated with metabolic syndrome, obesity, type 2 diabetes mellitus, and hyperlipidemia.
- NAFLD may show all the histologic changes associated with alcoholic liver disease (e.g., steatosis, steatohepatitis, and steatofibrosis). The diagnosis of NASH requires biopsy, and NASH cannot be reliably distinguished from alcoholic hepatitis without clinical history.
- Pediatric NAFLD is being increasingly recognized as the obesity epidemic involves pediatric age groups. Its histologic features differ somewhat from those seen in adults.

INHERITED LIVER DISEASE

Among inherited metabolic diseases, hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency are most prominent and are discussed in the following sections.

Hemochromatosis

Hemochromatosis is caused by excessive iron absorption, most of which is deposited in the liver and pancreas, followed by the heart, joints, and endocrine organs. When hemochromatosis results from an inherited disorder, it is referred to as *hereditary hemochromatosis*. When accumulation occurs as a consequence of parenteral administration of iron, usually in the form of transfusions, or other causes, it is called *secondary hemochromatosis*. The classification of the various causes of iron overload is shown in Table 18.7.

Table 18.7 Classification of Iron Overload

I. Hereditary Hemochromatosis
Mutations of genes encoding HFE, transferrin receptor 2 (TfR2), or hepcidin
Mutations of genes encoding HJV (hemojuvelin: juvenile hemochromatosis)
II. Hemosiderosis (Secondary Hemochromatosis)
Parenteral iron overload due to red cell transfusions
Severe chronic hemolytic anemias (e.g., sickle cell disease)
Severe forms of thalassemia
Bone marrow failure (e.g., aplastic anemia)
Conditions associated with increased iron uptake
β-Thalassemia
Myelodysplastic syndrome
Increased oral intake of iron
African iron overload (Bantu siderosis)
Congenital atransferrinemia
Chronic liver disease
Alcoholic liver disease
Porphyria cutanea tarda
Neonatal hemochromatosis[a]

[a]Neonatal hemochromatosis develops in utero but does not appear to be a hereditary condition.

As discussed in Chapter 14, the total body iron pool ranges from 2 to 6 g in normal adults; about 0.5 g is stored in the liver, 98% of which is in hepatocytes. In severe hemochromatosis, the total body iron pool may exceed 50 g, more than one-third of which accumulates in the liver. The following features characterize severe iron overload:

- Fully developed cases exhibit (1) micronodular cirrhosis (all patients); (2) diabetes mellitus (75% to 80% of patients); and (3) abnormal skin pigmentation (75% to 80% of patients).
- Iron accumulation in hereditary forms is lifelong, but the injury caused by excessive iron is slow and progressive; hence symptoms usually first appear in the fourth to fifth decades of life in men and later in women since menstrual bleeding counterbalances the accumulation until menopause.
- Because many women do not accumulate clinically relevant amounts of iron within their lifetime, hereditary hemochromatosis affects more males than females (ratio of 5 to 7:1).

Pathogenesis

Because there is no regulated iron excretion from the body, the total body content of iron is tightly regulated by intestinal absorption. In hereditary hemochromatosis, regulation of intestinal absorption of dietary iron is abnormal, leading to net iron accumulation of 0.5 to 1 g/year. The disease typically manifests after 20 g of stored iron has accumulated. Mechanisms of liver injury include (1) lipid peroxidation via iron-catalyzed free radical reactions, (2) stimulation of collagen formation by activation of hepatic stellate cells, and (3) interaction of ROS and iron itself with DNA, leading to lethal cell injury and predisposition to hepatocellular carcinoma.

The main regulator of iron absorption is the protein hepcidin, encoded by the *HAMP* gene and produced and secreted by the liver (Fig. 18.23). Transcription of *HAMP* is increased by inflammatory cytokines and iron, and decreased by iron deficiency, hypoxia, and erythroferrone, a hormone produced by marrow erythroblasts. These inputs are integrated to regulate the synthesis and plasma levels of hepcidin (see Chapter 14). Hepcidin binds to the cellular iron efflux channel ferroportin, causing its internalization and proteolysis, thereby inhibiting the release of iron from intestinal cells and macrophages. Due to these activities, an increase in hepcidin lowers plasma iron levels. Conversely, an abnormal deficiency of hepcidin causes iron overload. Other proteins involved in iron metabolism do so by regulating hepcidin levels. Decreased hepcidin synthesis or activity may be caused by loss-of-function mutations in the genes *HAMP*, *HJV*, *TFR2*, and *HFE*, all of which are associated with hereditary forms of hemochromatosis. Deficiencies of hepcidin also occur when erythroferrone levels are chronically elevated, as occurs in disorders marked by ineffective hematopoiesis, such as β-thalassemia and myelodysplastic syndrome.

The adult form of hereditary hemochromatosis is usually caused by mutations of *HFE;* mutation of *TFR2* is a rare cause. Mutations in *HAMP* and *HJV* genes are much less common and give rise to juvenile forms of hereditary hemochromatosis. *HFE* encodes an HLA class I–like molecule that governs intestinal absorption of dietary iron by regulating

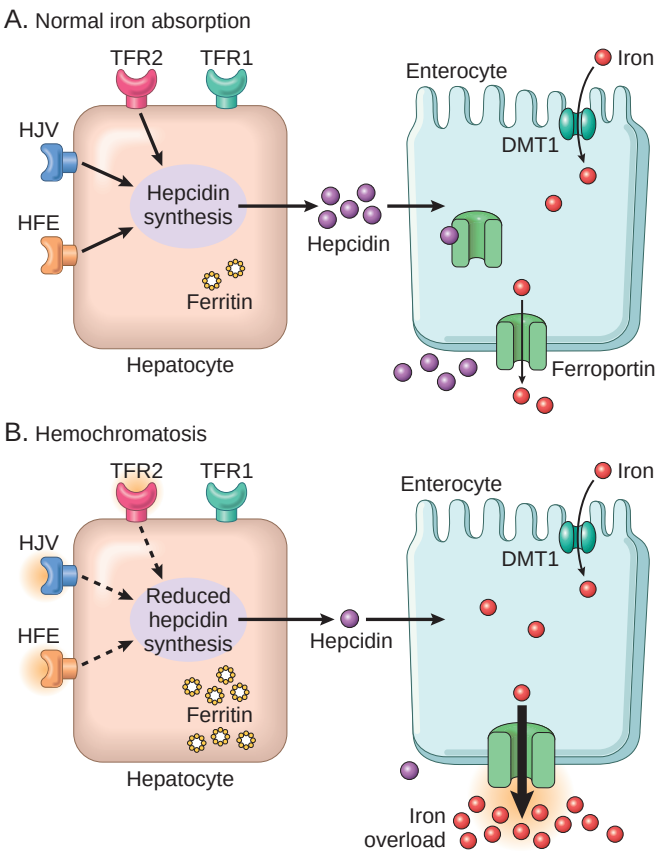

Figure 18.23 Normal iron metabolism and altered iron metabolism in hereditary hemochromatosis. (A) In normal state, HFE, HJV, and TFR2 regulate hepcidin synthesis by hepatocytes maintaining normal circulating hepcidin levels. Hepcidin binds to ferroportin on enterocytes leading to internalization of the complex and ferroportin degradation. This in turn reduces efflux of iron from enterocytes. Through these regulatory interactions, normal iron absorption is maintained. (B) In hereditary hemochromatosis, *HFE, HJV,* or *TFR2* gene mutations reduce hepcidin synthesis, diminishing circulating hepcidin levels. Due to decreased hepcidin-ferroportin interaction, ferroportin activity and iron efflux from enterocytes increases, giving rise to systemic iron overload.

hepcidin synthesis. The most common *HFE* mutation produces an inactivating cysteine-to-tyrosine substitution at amino acid 282 (C282Y) and is present in 70% or more of patients diagnosed with hereditary hemochromatosis. The other common disease-associated *HFE* mutation results in a H63D (histidine at position 63 to aspartate) substitution.

The C282Y mutation of *HFE* is largely confined to Caucasian populations of European origin, while the H63D mutation has a worldwide distribution. The frequency of C282Y homozygosity is 0.45% (1 in 220 persons), and the heterozygous frequency is 11%, making hereditary hemochromatosis one of the most common genetic disorders in humans. The penetrance of the disorder is low in patients with the homozygous C282Y mutation, and is even lower in homozygous H63D and C282Y/H63D compound heterozygous individuals.

MORPHOLOGY

Severe hemochromatosis (hereditary or secondary) is characterized by (1) **deposition of hemosiderin** in the following organs (in decreasing order of severity): liver, pancreas, myocardium, pituitary gland, adrenal gland, thyroid and parathyroid glands, joints, and skin; (2) cirrhosis; and (3) pancreatic fibrosis. In the **liver,** iron becomes evident first as golden-yellow hemosiderin granules in the cytoplasm of periportal hepatocytes that stain with Prussian blue (Fig. 18.24). With increasing iron load, there is progressive deposition in the rest of the lobule, along with bile duct epithelium and Kupffer cells. Iron is a direct hepatotoxin, and inflammation is characteristically absent. In early stages of disease, the liver is typically slightly larger than normal, dense, and chocolate brown. Fibrous septa develop slowly, leading ultimately to a small, shrunken liver with a micronodular pattern of cirrhosis. The liver parenchyma in later stages is often dark brown to nearly black due to extensive iron accumulation.

Other organs that are particularly susceptible to the toxic effects of iron also show morphologic changes. The **pancreas** becomes intensely pigmented and may undergo parenchymal atrophy associated with interstitial fibrosis. The **heart** is often enlarged and exhibits hemosiderosis, producing a striking brown coloration. Both organs may develop fibrosis. Skin pigmentation predominantly results from increased epidermal melanin production, the mechanism of which is unknown. The combination of these pigments imparts a characteristic slate-gray color to the skin. With hemosiderin deposition in joint linings, an **acute synovitis** may develop. Excessive deposition of calcium pyrophosphate damages the articular cartilage, producing a disabling polyarthritis referred to as **pseudogout.** The **testes may be small and atrophic,** secondary to pituitary involvement and reduced gonadotropin and testosterone levels.

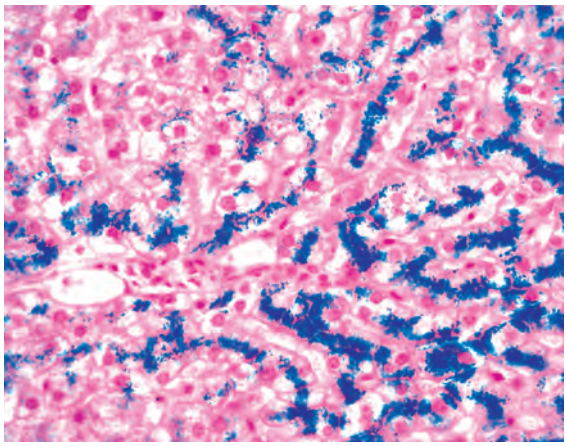

Figure 18.24 Hereditary hemochromatosis. In this Prussian blue–stained section, hepatocellular iron appears blue. The parenchymal architecture is normal.

Clinical Features

The principal manifestations of hemochromatosis include hepatomegaly, abdominal pain, abnormal skin pigmentation (particularly in sun-exposed areas), deranged glucose homeostasis or diabetes mellitus (due to destruction of pancreatic islets), cardiac dysfunction (arrhythmias, cardiomyopathy), and atypical arthritis. In some patients, the presenting complaint is hypogonadism (e.g., amenorrhea in the female, impotence and loss of libido in the male). It is more often a disease of males, for reasons described earlier,

and rarely becomes evident before 40 years of age. The classic tetrad of cirrhosis with hepatomegaly, abnormal skin pigmentation, diabetes mellitus, and cardiac dysfunction may not develop until late in the course. Death may result from cirrhosis or cardiac disease.

Another significant cause of death is hepatocellular carcinoma; the risk is 200-fold greater than in the general population. Treatment that reduces iron overload does not fully remove the cancer risk, presumably because DNA damage occurs prior to diagnosis and treatment initiation.

Fortunately, hemochromatosis is often diagnosed before irreversible tissue damage has occurred. Currently most patients with hemochromatosis are identified in the subclinical, precirrhotic stage due to routine serum iron measurements (as part of other diagnostic workups), and the diagnosis is confirmed by DNA sequencing and detection of causative mutations, usually in *HFE*. Further evaluation includes exclusion of secondary causes of iron overload. A liver biopsy may also provide useful information (e.g., about the presence of fibrosis), but is not done routinely, as genetic testing and imaging have negated the need for quantitative assessment of tissue iron content. Screening of the family members of probands is important, as identification of asymptomatic carriers can prevent disease development.

Prevention of the development or progression of disease in patients with adult onset hereditary is remarkably simple, as regular phlebotomy steadily depletes tissue iron stores. With treatment, life expectancy is normal.

The most common causes of secondary (or acquired) hemochromatosis are disorders associated with ineffective erythropoiesis, such as thalassemia (Chapter 14) and myelodysplastic syndrome (Chapter 13). In these disorders, the excess iron results not only from transfusions, but also from increased absorption. Erythroferrone released from an expanded population of erythroid progenitors in the bone marrow suppress hepcidin production by the liver, leading to increased iron absorption. Transfusions alone, when given repeatedly over a period of years (e.g., in patients with chronic hemolytic anemias), can also lead to systemic hemosiderosis and parenchymal injury, independent of ineffective hematopoiesis. Finally, other forms of cirrhosis may also diminish hepcidin production due to loss of hepatocyte mass, leading again to increased iron uptake from the gut and increased tissue levels of iron.

Wilson Disease

Wilson disease is an autosomal recessive disorder caused by mutation of the *ATP7B* gene, resulting in impaired copper excretion into bile and a failure to incorporate copper into ceruloplasmin. This disorder is marked by the accumulation of toxic levels of copper in many tissues and organs, principally the liver, brain, and eye. Free copper is taken up by hepatocytes and incorporated into apoceruloplasmin to form *ceruloplasmin,* which is secreted into the blood. Ceruloplasmin accounts for 90% to 95% of plasma copper. Excess copper within hepatocytes that is not incorporated into ceruloplasmin is sequestered in lysosomes and transported into the bile, from which it is eventually excreted in the feces.

Pathogenesis

Wilson disease results from loss-of-function mutations in the *ATP7B* gene, which encodes a transmembrane copper-transporting ATPase, expressed on the hepatocyte canalicular membrane. More than 300 sequence variants in the *ATP7B* gene have been identified, but not all cause the disease. The overwhelming majority of patients are compound heterozygotes containing different mutations on each *ATP7B* allele. The overall frequency of mutated alleles is 1:100, and the prevalence of the disease is approximately 1:30,000 to 1:50,000 (approximately 9000 patients in the United States). Deficiency of ATP7B decreases copper transport into bile, impairs its incorporation into ceruloplasmin, and inhibits ceruloplasmin secretion into the blood. These defects lead to a decrease in circulating ceruloplasmin accompanied by the accumulation of copper in hepatocytes. Total serum copper may be lower than normal due to the deficiency in ceruloplasmin, particularly early in the disease course.

The excess hepatic copper causes toxic injury by three mechanisms: (1) promoting the formation of free radicals by the Fenton reaction (Chapter 2); (2) binding to sulfhydryl groups of cellular proteins; and (3) displacing other metals from hepatic metalloenzymes. Hepatocyte injury causes nonceruloplasmin-bound copper to be spilled into the blood and accumulate in certain tissues, particularly the basal ganglia of the brain and the cornea. Concomitantly, urinary excretion of copper markedly increases, but not to levels sufficient to prevent deposition of copper in tissues.

MORPHOLOGY

The liver often bears the brunt of injury, but the disease may also present as a neurologic disorder. The hepatic changes are variable, ranging from relatively minor to massive damage, and mimic many other disease processes. **Fatty change (steatosis)** may be present with focal hepatocyte necrosis. Acute liver failure can mimic acute viral hepatitis. Chronic hepatitis in Wilson disease typically exhibits moderate to severe portal inflammation and hepatocyte necrosis, admixed with fatty change and features of steatohepatitis (i.e., ballooned hepatocytes, prominent Mallory hyaline, and perisinusoidal fibrosis). Eventually cirrhosis supervenes. Histochemical copper staining is not sensitive or specific for diagnosis of Wilson disease. Toxic brain injury primarily involves the basal ganglia, and nearly all patients with neurologic involvement develop eye lesions called **Kayser-Fleischer rings,** green to brown deposits of copper in Descemet membrane in the limbus of the cornea.

Clinical Features

The age at onset of Wilson disease ranges from 6 to 40 years of age (average age is 11.4 years). Its clinical presentation is extremely variable. Some patients present with acute or chronic liver disease. Neurologic involvement may lead to movement disorders (tremor, poor coordination, chorea or choreoathetosis) or rigid dystonia (spastic dystonia, masklike facies, rigidity, and gait disturbances). Patients may also have psychiatric symptoms. Hemolytic anemia may occur due to red cell membrane damage caused by oxidants

produced by free copper. The biochemical diagnosis of Wilson disease is usually based on the presence of decreased serum ceruloplasmin, increased hepatic copper content (the most sensitive and accurate test), and increased urinary excretion of copper (the most specific test). Sequencing of the *ATP7B* gene is now available for cases in which results of biochemical tests are indeterminate. Such problems may arise in the setting of liver injury, which may cause serum ceruloplasmin levels to rise into the normal range. Demonstration of Kayser-Fleischer rings by slit examination also is diagnostically helpful. Early recognition and long-term copper chelation therapy (with D-penicillamine or trientine) or zinc-based therapy (which blocks uptake of dietary copper in the gut) is effective. Individuals with hepatitis or unmanageable cirrhosis require liver transplantation, which can be curative.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin deficiency is an autosomal recessive disorder of protein folding marked by very low levels of circulating α_1-antitrypsin (α_1AT). The major function of this protein is the inhibition of proteases, particularly neutrophil elastase, cathepsin G, and proteinase 3, which are normally released from neutrophils at sites of inflammation. α_1AT deficiency leads to the development of pulmonary emphysema, because the activity of neutrophil elastases is not inhibited (Chapter 15). It also causes liver disease as a consequence of hepatocellular accumulation of the misfolded protein, an example of a "toxic gain-of-function" mutation.

α_1AT is a small 394–amino acid plasma glycoprotein synthesized predominantly by hepatocytes. It is a member of the serine protease inhibitor (serpin) family. The gene is very polymorphic, and at least 75 forms of α_1AT have been identified, denoted alphabetically by their relative migration in an isoelectric gel. The general notation is "Pi" for "protease inhibitor" and an alphabetic letter for the position in the gel; two letters denote the genotype of an individual's two alleles. The most common genotype is PiMM, occurring in 90% of individuals (the "wild type").

The most common clinically significant mutation is PiZ; homozygotes for the PiZZ protein have circulating α_1AT levels that are only 10% of normal. These individuals are at high risk for developing clinical disease. Expression of alleles is autosomal codominant, and, consequently, PiMZ heterozygotes have intermediate plasma levels of α_1AT. Among people of northern European descent, the PiZZ state affects 1 in 1800 live births. Because of its early presentation with liver disease, α_1AT deficiency is the most commonly diagnosed inherited hepatic disorder in infants and children.

Pathogenesis

Disease-associated variants show a selective defect in transport of the protein from the endoplasmic reticulum to the Golgi apparatus; this is particularly characteristic of the PiZ polypeptide, resulting from the substitution of lysine for glutamine at amino acid position 342. The mutant polypeptide (α_1AT-Z) misfolds and aggregates, creating endoplasmic reticulum stress and triggering the unfolded protein response, a signaling cascade that may lead to apoptosis (Chapter 2). All individuals with the PiZZ genotype accumulate α_1AT-Z in the endoplasmic reticulum of hepatocytes, but only a small subset develops overt liver disease. Other genetic factors or environmental factors are thus posited to play a role in the development of liver disease.

MORPHOLOGY

α_1AT deficiency is characterized by the presence of round-to-oval **cytoplasmic globular inclusions in hepatocytes,** which are strongly periodic acid–Schiff (PAS)-positive and diastase-resistant (Fig. 18.25). The inclusions appear first in periportal hepatocytes in early and mild forms of the disease and with progression appear in central hepatocytes in more severe disease, such as that associated with the PiZZ variant. However, the number of globule-containing hepatocytes is not tightly correlated with disease severity, and patients may present with neonatal hepatitis prior to the appearance of the globules (generally 12 weeks of age or older for PiZZ-associated disease).

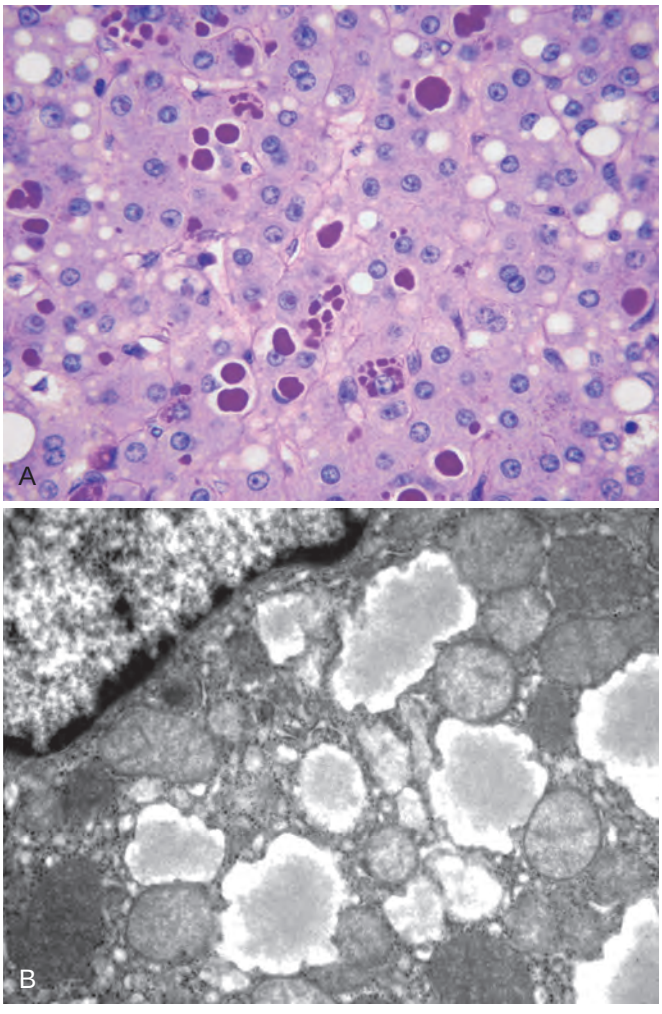

Figure 18.25 α_1-Antitrypsin deficiency. (A) Periodic acid–Schiff stain after diastase digestion of the liver, highlighting the characteristic magenta cytoplasmic granules. (B) Electron micrograph showing endoplasmic reticulum dilated by aggregates of misfolded protein.

Clinical Features

The clinical findings and course are quite variable. Unusual neonatal presentations tend to be associated with severe disease and rapid progression to cirrhosis. Other patients present in adulthood with chronic hepatitis, cirrhosis, or hepatocelllar carcinoma, which develops in 2% to 3% of PiZZ adults, usually (but not always) in the setting of cirrhosis. Liver transplantation is curative of hepatic disease, but it has no effect on the development and course of pulmonary disease (Chapter 15).

KEY CONCEPTS

INHERITED LIVER DISEASE

- Hereditary hemochromatosis is most commonly caused by loss-of-function mutations in the *HFE* gene, whose product regulates intestinal iron uptake by increasing hepcidin synthesis by the liver. It is characterized by increased absorption of dietary iron, and accumulation of iron in the liver and pancreas; injury to these organs results in cirrhosis and diabetes.
- Wilson disease is caused by mutations that abolish the function of the metal ion transporter ATP7B, which results in accumulation of copper in the liver, brain (particularly basal ganglia), and eyes ("Kayser-Fleisher rings").
- α_1-Antitrypsin deficiency is a disease of protein misfolding that results in impaired secretion of α_1-antitrypsin into the serum and creates endoplasmic reticulum stress, leading to hepatocyte injury through the unfolded protein response pathway. The main consequence of α_1-antitrypsin deficiency is pulmonary emphysema because of unchecked elastase activity.

CHOLESTATIC DISEASE

Bile Formation and Secretion

Bile plays a critical role in elimination of bilirubin, excess cholesterol, xenobiotics, and trace metals such as copper, arsenic, selenium, and zinc, and its detergent action emulsifies dietary fat in the intestinal lumen, enabling its absorption by the gut. The major components of bile are bilirubin, bile salts, cholesterol, and phospholipids (mainly phosphatidylcholine).

Bilirubin is a toxic end product of heme degradation that is processed by the liver and excreted in the bile (Fig. 18.26). Hepatic handling of bilirubin involves uptake from the circulation, intracellular storage, conjugation with glucuronic acid, and excretion into bile. The majority of the bilirubin produced daily (0.2 to 0.3 g, 85%) is derived from breakdown of senescent red cells by macrophages in the spleen, liver, and bone marrow. The remaining bilirubin is produced by the turnover of hepatic proteins containing heme groups (e.g., P-450 cytochromes). Heme is converted to bilirubin by the action of several phagocyte enzymes and released into the blood, where it binds albumin, a necessary step for transport, as bilirubin is insoluble at physiologic pH. Uptake by hepatocytes at the sinusoidal membrane is followed by conjugation of bilirubin with one or two molecules of glucuronic acid in the endoplasmic reticulum, and excretion of the water-soluble, nontoxic bilirubin glucuronides into bile. Most bilirubin glucuronides are deconjugated in the gut lumen by bacterial β-glucuronidases and degraded to colorless urobilinogens. The urobilinogens and the residue of intact pigment are largely excreted in feces. Approximately 20% of the urobilinogens formed are reabsorbed in the ileum and colon, returned to the liver, and re-excreted into bile. A small amount of reabsorbed urobilinogen is excreted in the urine.

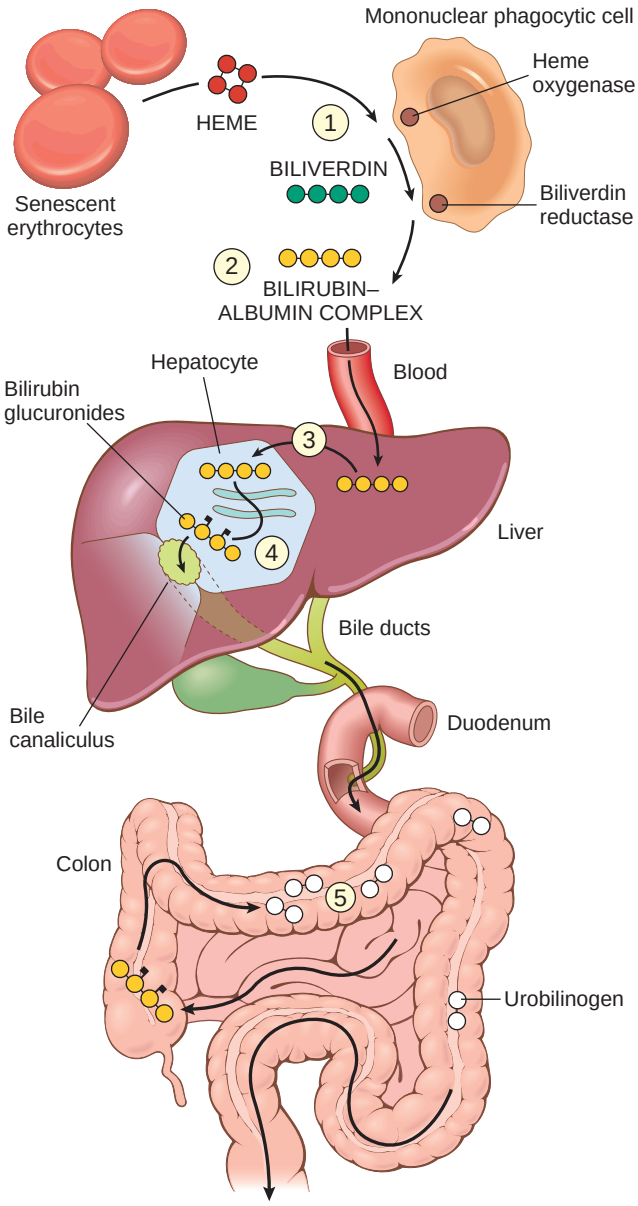

Figure 18.26 Bilirubin metabolism and elimination. (1) Normal bilirubin production from heme (0.2 to 0.3 g/day) is derived primarily from the breakdown of senescent circulating erythrocytes. (2) Extrahepatic bilirubin is bound to serum albumin and delivered to the liver. (3) Hepatocellular uptake and (4) glucuronidation in the endoplasmic reticulum generates bilirubin monoglucuronides and diglucuronides, which are water soluble and readily excreted into bile. (5) Gut bacteria deconjugate the bilirubin and degrade it to colorless urobilinogens. The urobilinogens and the residue of intact pigments are excreted in the feces, with some reabsorption and excretion into urine.

Bile salts are formed by the conjugation of bile acids with taurine or glycine. The predominant bile acids in humans are cholic acid and chenodeoxycholic acid, both of which are highly effective detergents. Bile acids combine with cholesterol and phospholipids to form micelles that solubilize cholesterol and reduce the toxic effect of bile acids on biliary epithelium. Most of the secreted bile acids, conjugated or unconjugated, are reabsorbed from the intestine and recirculate to the liver (enterohepatic circulation), where they are taken up by hepatocytes, thus helping to maintain the endogenous pool of bile acids.

The constituents of bile are ferried across the canalicular membrane of hepatocytes by a variety of transporter proteins. Some of the important ones are MRP2 (multidrug-resistant protein-2) for conjugated bilirubin, bile salt export pump (BSEP) for bile salts, MDR3 (multi-drug resistance-3) for phosphatidylcholine, and sterolins 1 and 2 for cholesterol.

Pathophysiology of Hyperbilirubinemia

Serum bilirubin levels in the normal adult vary between 0.3 and 1.2 mg/dL, and the rate of bilirubin production is equal to the rate of hepatic uptake, conjugation, and biliary excretion. Jaundice becomes evident when the serum bilirubin levels rise above 2 to 2.5 mg/dL. Depending on the underlying etiology (summarized in Table 18.8), the elevation can predominantly involve unconjugated (indirect) or conjugated (direct) bilirubin. Testing for conjugated and unconjugated plasma bilirubin helps determine the cause of hyperbilirubinemia. Excess bilirubin production (e.g., due to hemolytic anemia or ineffective erythropoiesis) or defective conjugation (due to immaturity or hereditary causes) leads to the accumulation of unconjugated bilirubin. This form is largely insoluble and cannot be excreted in the urine. Although most unconjugated bilirubin is tightly bound to albumin in the blood, at excessive levels the unbound fraction rises and may diffuse into tissues, particularly the brain in infants, and produce neurologic damage (kernicterus). Conjugated hyperbilirubinemia most often results from hepatocellular disease, bile duct injury, and biliary obstruction. Since this form is water-soluble and loosely bound to serum albumin, it can be excreted in the urine.

With this as an overview, we next discuss hepatobiliary disorders that lead to hyperbilirubinemia. Many of these are characterized by cholestasis, which refers to the retention of bilirubin and other solutes eliminated in bile due to impaired bile formation or obstruction of flow. Before delving into specific entities, we will briefly review the morphologic and clinical features of cholestasis that are common to all.

MORPHOLOGY

The hallmark of cholestasis is accumulation of green-brown plugs of bile pigment in hepatocytes and dilated canaliculi (Fig. 18.27). Rupture of canaliculi can lead to extravasation of bile, which is phagocytosed by Kupffer cells. Accumulation of bile salts in hepatocytes results in a swollen, foamy appearance of the cytoplasm ("feathery degeneration").

Table 18.8 Causes of Jaundice

Predominantly Unconjugated Hyperbilirubinemia
Excess production of bilirubin
Hemolytic anemias
Resorption of blood from internal hemorrhage (e.g., alimentary tract bleeding, hematoma)
Ineffective erythropoiesis (e.g., pernicious anemia, thalassemia)
Reduced hepatic uptake
Drug interference with membrane carrier systems
Some cases of Gilbert syndrome
Impaired bilirubin conjugation
Physiologic jaundice of the newborn (decreased UGT1A1 activity, decreased excretion)
Breast milk jaundice (β-glucuronidases in milk)
Genetic deficiency of UGT1A1 activity (Crigler-Najjar syndrome types I and II, some cases of Gilbert syndrome)
Predominantly Conjugated Hyperbilirubinemia
Deficiency of canalicular membrane transporters (Dubin-Johnson syndrome, Rotor syndrome)
Hepatocellular disease (e.g., viral or drug-induced hepatitis, cirrhosis)
Impaired bile flow from duct obstruction or autoimmune cholangiopathies

UGT1A1, Uridine diphosphate-glucuronyltransferase family, peptide A1.

Clinical Features

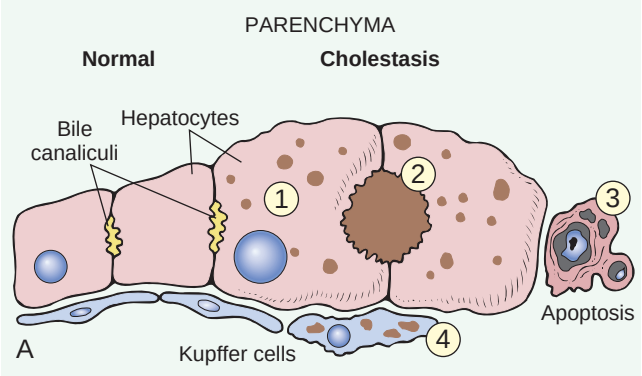
Elevated bilirubin becomes clinically evident as yellow discoloration of the skin (jaundice) and sclera (icterus). Other manifestations include pruritus, skin xanthomas (focal accumulation of cholesterol), or symptoms related to intestinal malabsorption, including deficiencies of fat-soluble vitamins (vitamins A, D, and K). Elevated serum alkaline phosphatase and γ-glutamyl transpeptidase (GGT), enzymes present on the apical (canalicular) membranes of hepatocytes and bile duct epithelial cells, are characteristic laboratory findings of cholestatic disease.

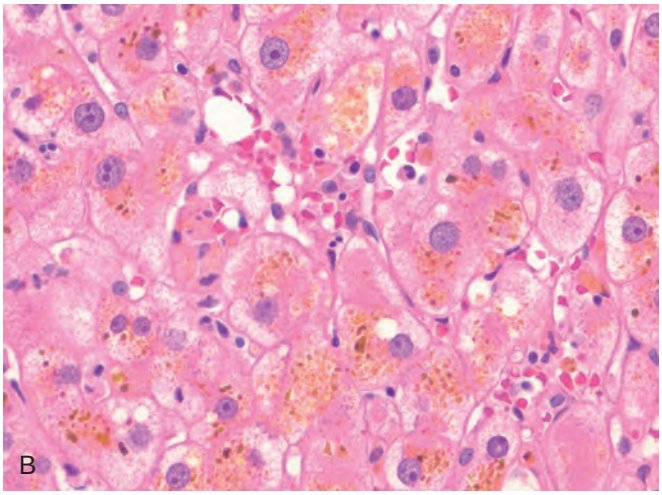
Physiologic Jaundice of the Newborn

In physiologic jaundice of the newborn, levels of UGT1A1 (uridine diphosphate-glucuronyltransferase family, peptide A1), the enzyme that is responsible for bilirubin glucuronidation, are low at birth and do not reach adult levels until 3 to 4 months of age. Hence, transient and mild unconjugated hyperbilirubinemia is nearly universal in the first week. Breastfeeding may exacerbate unconjugated hyperbilirubinemia, possibly because of the presence of bilirubin-deconjugating enzymes in breast milk. In most infants, phototherapy with blue light (which converts bilirubin to a soluble isomer that is readily excreted in the urine) is sufficient to keep the levels of unconjugated bilirubin within a safe range until the hepatic machinery for conjugation matures sufficiently.

Hereditary Hyperbilirubinemia

Genetic mutations can result in impaired uptake, conjugation, or secretion of bilirubin. *Crigler-Najjar syndrome type 1* is caused by severe UGT1A1 deficiency and is fatal around birth; in *Crigler-Najjar type 2* and Gilbert syndrome, there is some UGT1A1 activity, leading to a milder phenotype. In contrast, *Dubin-Johnson syndrome* and *Rotor syndrome* lead





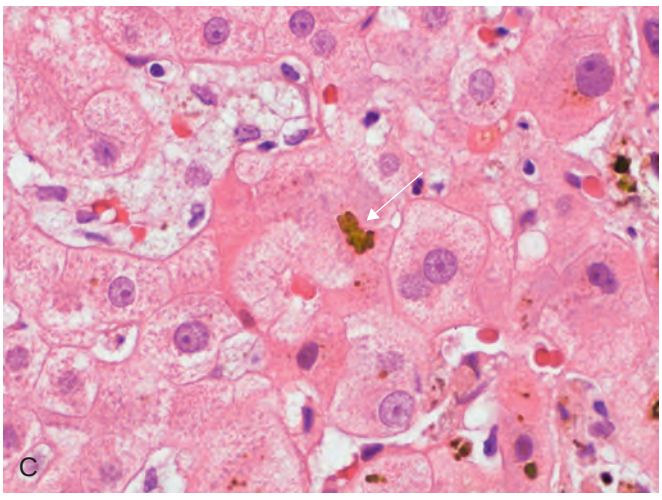


Figure 18.27 Cholestasis. (A) Morphologic features of cholestasis (right) and comparison with normal liver (left). Cholestatic hepatocytes (1) are enlarged with dilated canalicular spaces (2). Apoptotic cells (3) may be seen, and Kupffer cells (4) frequently contain regurgitated bile pigments. (B) Intracellular cholestasis showing the bile pigments in the cytoplasm. (C) Bile plug *(arrow)* showing the expansion of bile canaliculus by bile.

to conjugated hyperbilirubinemia. Both are autosomal recessive disorders and clinically innocuous. Dubin-Johnson syndrome is caused by mutation in the *MRP2* gene (multidrug resistant protein 2), which is required for transport of non–bile salt organic anions at the canalicular membranes. Deposition of brown-black melanin-like pigment in the hepatocytes is a striking feature in this disease and can lead to blackening of the liver.

Large Bile Duct Obstruction

Obstruction of the large bile ducts has diverse causes. In adults, the common causes are stones (choledocholithiasis), malignant neoplasms of the biliary tree or head of pancreas (usually adenocarcinoma), and strictures resulting from previous surgical procedures or ischemic injury. Primary sclerosing cholangitis (described later) may lead to an obstructive picture due to inflammatory injury to the large intrahepatic or extrahepatic bile ducts. In the pediatric setting, the common culprits are biliary atresia, cystic fibrosis, and choledochal cysts. The resulting cholestatic changes are reversible if the obstruction is corrected early in the disease course, but persistent obstruction can lead to fibrosis and so-called biliary cirrhosis. Biliary obstruction also predisposes to ascending cholangitis, a bacterial infection of the biliary tree most commonly caused by enteric organisms such as coliforms and enterococci. Cholangitis usually presents with fever, chills, abdominal pain, and jaundice. Severe cases can result in abscess formation, sepsis, and death.

MORPHOLOGY

Obstruction of extrahepatic or large intrahepatic bile ducts leads to proximal duct dilation. The hallmark on liver biopsies is portal expansion due to edema, prominent ductular reaction at the portal-parenchymal interface, and infiltrating neutrophils associated with ductules **("pericholangitis")** (Fig. 18.28). In ascending cholangitis, the neutrophils also involve the bile duct epithelium and lumens (Fig. 18.29). Persistent obstruction leads to fibrosis, which can eventually proceed to biliary cirrhosis (Fig. 18.30). Swelling of periportal hepatocytes **("feathery degeneration"),** bile pigment, and Mallory hyaline is seen in periportal hepatocytes in advanced disease. Superimposed ascending cholangitis in advanced disease can precipitate acute-on-chronic liver failure.

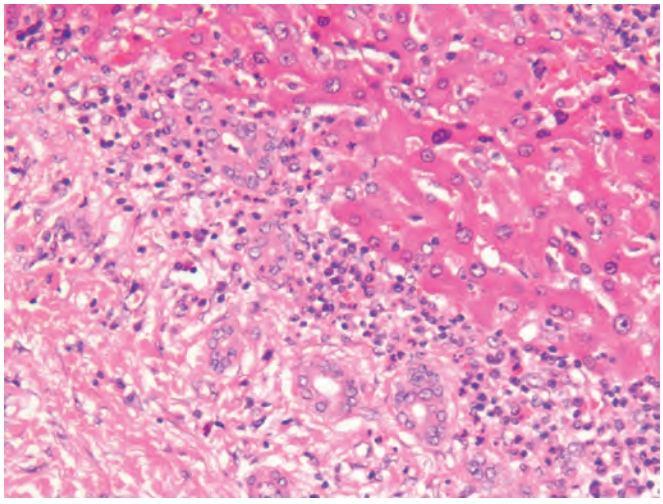

Figure 18.28 Acute large duct obstruction. There is marked edema of the portal tract stroma *(white spaces)* and a ductular reaction with admixed neutrophils at the interface between portal tract and hepatocellular parenchyma.

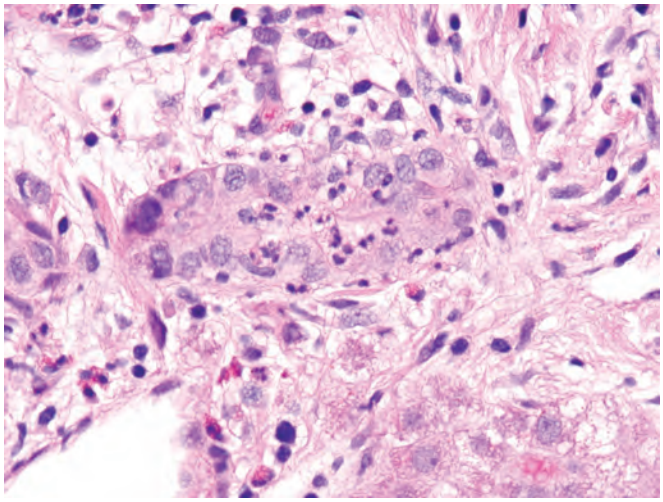

Figure 18.29 Ascending cholangitis. Individuals with large bile duct obstruction are at risk for bacterial infections within the biliary tree. Neutrophils are seen within the bile duct epithelial lining and within the lumen.

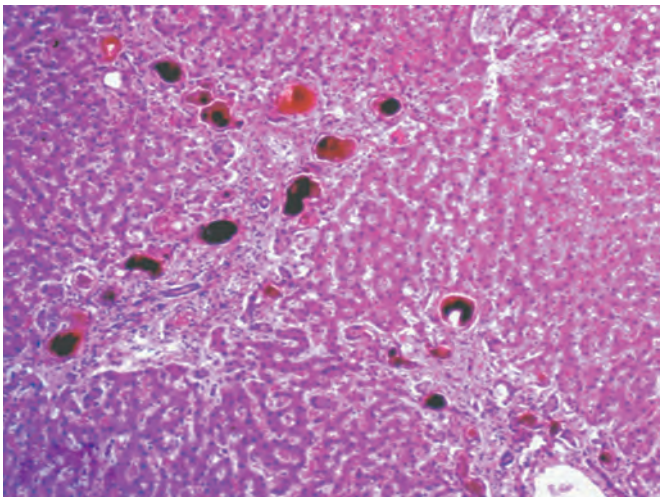

Figure 18.31 Ductular cholestasis of sepsis. Large, dark bile concretions within markedly dilated canals of Hering and ductules at the portal-parenchymal interface. (Courtesy Dr. Jay Lefkowitch, Columbia University College of Physicians and Surgeons, NY.)

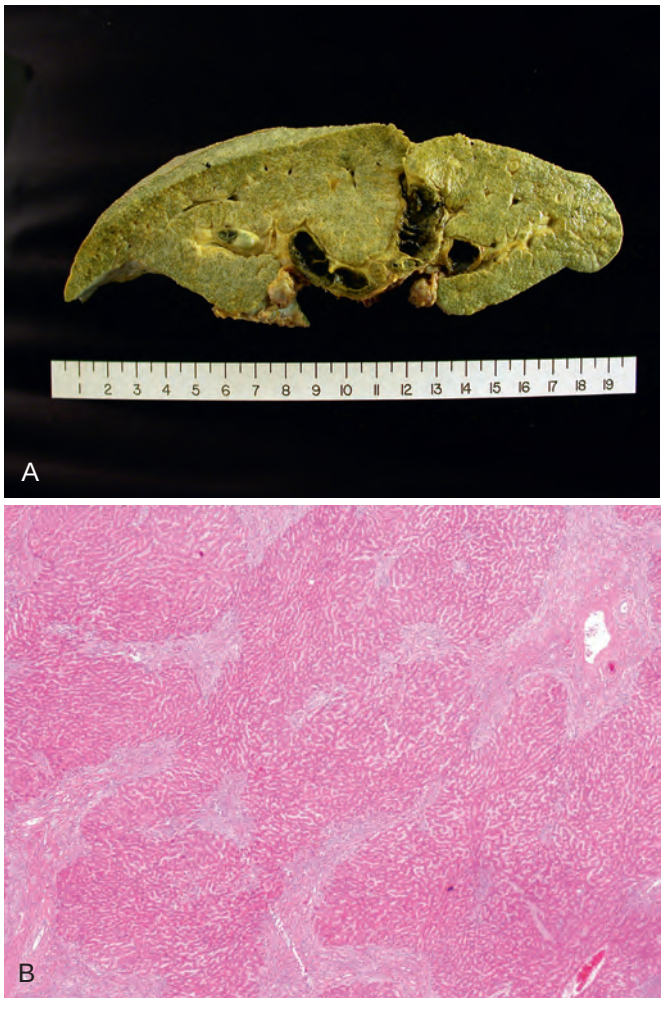

Figure 18.30 Biliary cirrhosis. (A) Sagittal section through the liver demonstrates the nodularity (most prominent at the right) and bile staining of end-stage biliary cirrhosis. (B) Unlike other forms of cirrhosis, nodules of liver cells in biliary cirrhosis are often not round but irregular, like jigsaw puzzle shapes.

Cholestasis of Sepsis

Sepsis may affect the liver by several mechanisms: (1) through direct effects of intrahepatic bacterial infection (e.g., abscess formation or bacterial cholangitis); (2) ischemia relating to hypotension caused by sepsis (particularly when the liver is cirrhotic); or (3) in response to circulating microbial products. The latter effect is most likely to lead to the cholestasis of sepsis, particularly when the systemic infection is caused by gram-negative organisms. Characteristic morphologic findings in the setting of severe sepsis include canalicular cholestasis and bile plugs within dilated canals of Hering and bile ductules at the portal-parenchymal interface ("ductular" or "cholangiolar cholestasis") (Fig. 18.31). Inflammation and hepatocellular injury is typically mild.

Primary Hepatolithiasis

At one time called "recurrent pyogenic cholangitis," hepatolithiasis refers to stones in the intrahepatic bile ducts that can lead to repeated bouts of ascending cholangitis and progressive inflammatory destruction of hepatic parenchyma. The disease is highly prevalent in East Asia, but is rare in other parts of the world. Its cause is uncertain; congenital duct abnormalities, diet, and chronic infection with bacteria or parasites have all been suggested as possible etiologies. Chronic inflammatory injury associated with hepatolithiasis is a risk factor for cholangiocarcinoma, particularly in Taiwan and to a lesser extent in Japan.

MORPHOLOGY

Pigmented calcium bilirubinate stones are present in distended intrahepatic bile ducts (Fig. 18.32). The ducts show chronic inflammation, mural fibrosis, and peribiliary gland hyperplasia. Obstruction of extrahepatic ducts is not present. Repeated bouts of inflammation, parenchymal collapse, and fibrosis can lead to a mass-like lesion, which can mimic a tumor on imaging.

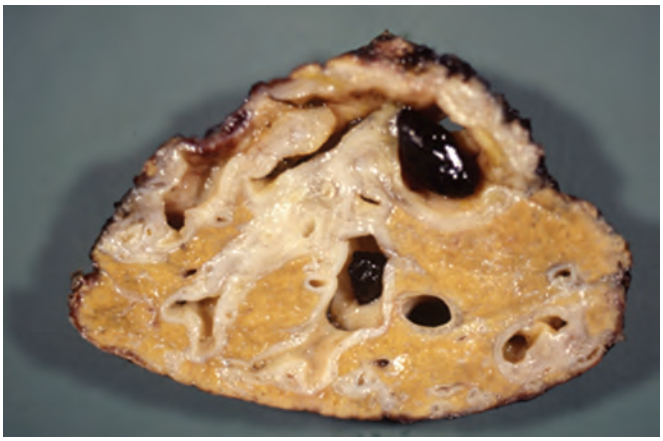

Figure 18.32 Hepatolithiasis. A resected, atrophic right hepatic lobe with characteristic findings including markedly dilated and distorted bile ducts containing large pigment stones and broad areas of collapsed liver parenchyma. (Courtesy Dr. Wilson M.S. Tsui, Caritas Medical Centre, Hong Kong.)

Neonatal Cholestasis

Physiologic jaundice of the newborn (discussed earlier) resolves by 2 weeks, and infants who have jaundice beyond 14 to 21 days after birth must be evaluated for neonatal cholestasis. The major causes can be grouped under the two broad categories: (1) obstructive biliary disease such as biliary atresia; and (2) nonobstructive etiologies that include paucity of bile ducts, infectious/metabolic diseases, bile transporter defects, and idiopathic neonatal hepatitis.

Extrahepatic Biliary Atresia

Extrahepatic biliary atresia is characterized by complete or partial obstruction of the extrahepatic biliary tree within the first 3 months of life. It accounts for one-third of neonatal cholestasis cases and for 50% to 60% of children referred for liver transplantation. In its most common perinatal form (80% of cases), the biliary tree is normally formed and the disease onset is after birth. Infections, toxic agents, and autoimmune injury have been invoked, but the cause is unknown. The less common fetal form likely results from aberrant development of the extrahepatic biliary tree. Infants with extrahepatic biliary atresia present with jaundice, dark urine, light or acholic stools, and hepatomegaly.

MORPHOLOGY

Inflammation and fibrosis of the hepatic or common bile ducts is the hallmark of the disease and can extend to involve the intrahepatic ducts. Typical features of biliary obstruction are seen on liver biopsy, including portal edema, ductular reaction, and neutrophil infiltrates. If left uncorrected, cirrhosis can develop by 3 to 6 months of age.

Clinical Features

Since extrahepatic biliary atresia requires surgical intervention (portoenterostomy or Kasai procedure), its differentiation from nonobstructive neonatal cholestasis is critical. Other etiologies of obstructive biliary diseases like cystic fibrosis also must be excluded. The combination of clinical presentation, imaging (ultrasound and hepatospecific iminodiacetic-acid [HIDA] scans), and biopsy can confirm the diagnosis in a vast majority of cases. Ultrasound findings of a small or absent gallbladder and fibrosis at the porta hepatis support the diagnosis of extrahepatic biliary atresia, as do HIDA scans with technetium-99m (^{99m}Tc), which is excreted in bile. In extrahepatic biliary atresia, there is total lack of secretion of ^{99m}Tc into the bile, and the biliary tree is not visualized. Involvement of ducts proximal to the porta hepatis, intrahepatic progression of disease, and ascending cholangitis are impediments to successful surgical therapy. Liver transplantation is the only option when surgical intervention is not feasible.

Nonobstructive Neonatal Cholestasis

A diverse group of disorders are associated with nonobstructive neonatal cholestasis. These can be divided into those in which cholestasis appears as part of a syndrome or as an isolated liver abnormality.

- *Alagille syndrome* is an autosomal dominant disorder that is associated with cholestasis and paucity of bile ducts as well as other abnormalities such as dysmorphic facies, butterfly-shaped vertebra, eye defects, and cardiac defects. It is caused by loss-of-function mutations in the Notch pathway involving either the genes encoding the ligand JAG1 or the receptor NOTCH2, both of which are required for normal development of the biliary tree.
- *Certain inborn errors of metabolism,* particularly galactosemia (Chapter 10) and Niemann-Pick disease (Chapter 5), can present with nonobstructive cholestasis.
- *Nonsyndromic causes* of nonobstructive cholestasis include α_1-antitrypsin deficiency (discussed earlier) and diverse disorders of bile acid synthesis and bile transport.

With recent advances, the underlying etiology can be determined in 85% to 90% of cases (summarized in Table 18.9).

Table 18.9 Major Causes of Neonatal Cholestasis

Obstructive Biliary Disease
Extrahepatic biliary atresia
Neonatal Infection
Cytomegalovirus Bacterial sepsis Urinary tract infection Syphilis
Genetic Disorders
Metabolic diseases: Tyrosinemia, galactosemia Lipid storage diseases: Niemann-Pick disease Bile synthesis defects: Bile transport abnormalities (progressive intrahepatic cholestasis), bile acid synthesis defects Cystic fibrosis α_1-Antitrypsin deficiency Alagille syndrome (syndromic paucity of bile ducts)
Miscellaneous
Shock/hypoperfusion, drugs, total parenteral nutrition, hypopituitarism Idiopathic neonatal hepatitis

MORPHOLOGY

Decreased numbers of bile ducts within portal regions profiles is the most characteristic and constant feature. The biliary insufficiency often is associated with hepatitis, characterized by inflammation and hepatocellular apoptosis/necrosis. The most striking features are hepatocanalicular cholestasis and giant-cell or syncytial cell change with multinucleated hepatocytes (Fig. 18.33). Reactive Kupffer cells and extramedullary hematopoiesis are usually present.

Autoimmune Cholangiopathies

This section discusses the two main autoimmune disorders of bile ducts: primary biliary cholangitis and primary sclerosing cholangitis. The features of these two conditions are contrasted in Table 18.10.

Primary Biliary Cholangitis (PBC)

PBC is an autoimmune disease characterized by inflammatory destruction of small- and medium-sized intrahepatic bile ducts. Large intrahepatic ducts and the extrahepatic biliary tree are not involved. Most patients are diagnosed in the early stages of disease, and hence the former name "primary biliary cirrhosis" is no longer used. PBC has a striking female predilection of 9:1, with a peak incidence between 40 and 50 years of age. The disease is most common in the United States and Northern Europe, and the incidence is low in Africa and the Indian subcontinent. Family members of PBC patients have an increased risk for development of the disease.

Pathogenesis

PBC is thought to be an autoimmune disorder resulting from a T lymphocyte–mediated attack on small interlobular bile ducts. The trigger for the attack is not known, but may involve exposure to environmental factors like infections and toxic chemicals in genetically susceptible individuals. This may lead to expression of "auto-antigens" on bile duct epithelial cells and the resultant destruction by T lymphocytes. The retention of bile salts due to bile duct injury leads to secondary hepatocellular injury in PBC, which can eventually produce a cirrhotic picture.

Antimitochondrial antibodies directed against the E2 component of the pyruvate dehydrogenase complex (PDC-E2) are the most characteristic finding in PBC. PDC-E2–specific T cells are present in PBC, further supporting the notion of an immune-mediated process. The role of antimitochondrial antibodies in the pathogenesis of PBC is unclear, as 5% of patients with otherwise typical PBC are antimitochondrial antibody (AMA)-negative. Moreover, antibody titers do not correlate with disease severity or disease progression, and they are not predictive of response to therapy (discussed later). Other autoantibodies against nuclear pore proteins and centromeric proteins may also be present.

Table 18.10 Main Features of Primary Biliary Cholangitis and Primary Sclerosing Cholangitis

Parameter	Primary Biliary Cholangitis	Primary Sclerosing Cholangitis
Age	Median age 50 years	Median age 30 years
Gender	90% female	70% male
Associated conditions	Sjögren syndrome (70%), thyroid disease, scleroderma	Inflammatory bowel disease (70%)
Serology	95% AMA-positive, 40%–50% ANA positive	65% ANCA-positive; ANA variable, AMA typically negative 6% ANA-positive
Radiology	Normal	Strictures and beading of large bile ducts; pruning of smaller ducts
Duct lesion	Florid duct lesions; loss of small ducts	Inflammatory destruction of extrahepatic and large intrahepatic ducts; fibrotic obliteration of medium and small intrahepatic ducts; ductular reaction in smaller portal tracts

AMA, Antimitochondrial antibody; *ANA*, antinuclear antibody; *ANCA*, antineutrophil cytoplasmic antibody.

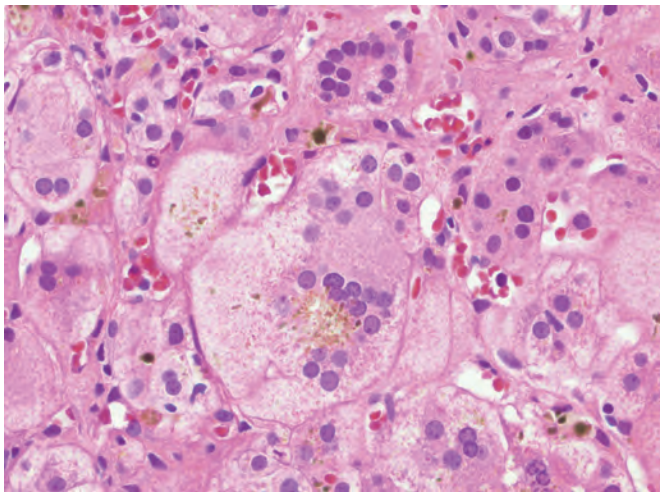

Figure 18.33 Neonatal hepatitis. Note the multinucleated giant hepatocytes.

MORPHOLOGY

The hallmark of PBC is lymphocytic infiltration and epithelial injury involving the small interlobular bile ducts. Poorly formed epithelioid granulomas are often present in the portal tracts and can be centered on bile ducts. **The histologic picture of lymphocytic and/or granulomatous bile duct destruction (florid duct lesion) is highly characteristic of PBC** (Fig. 18.34). Portal lymphoplasmacytic inflammation and ductular reaction are often present. The bile duct involvement has a patchy distribution, with involvement of a minority of portal tracts being a common feature in early disease. Disease progression leads to loss of small intrahepatic bile ducts ("ductopenia"). Unlike obstructive, drug-induced, or sepsis-associated cholestasis, the bile

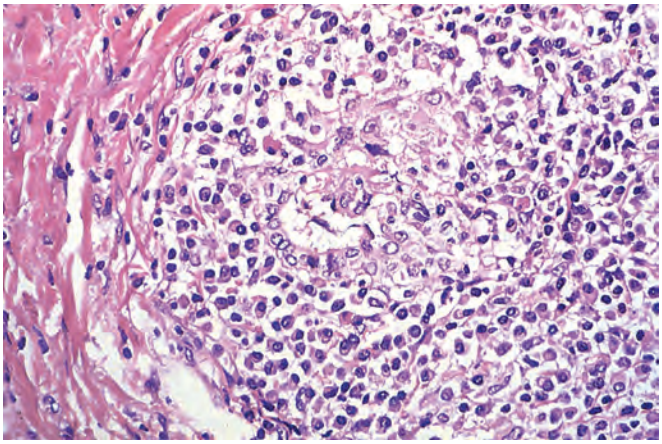

Figure 18.34 Primary biliary cholangitis. A portal tract is markedly expanded by an infiltrate of lymphocytes and plasma cells surrounding a destructive granulomatous reaction centered on a bile duct ("florid duct lesion").

accumulation in PBC is not centrizonal, but is seen in periportal/periseptal regions. Stasis of bile salts leads to swelling of periportal hepatocytes, which have clear cytoplasm with granular strands **(feathery degeneration)** and may develop Mallory hyaline. These periportal changes are referred to as cholate stasis and can be seen in any chronic biliary disease. End-stage disease culminates in cirrhosis. Like other biliary diseases, cirrhotic nodules in PBC tend to be elongated ("garland-shaped"), in contrast to the round nodules in hepatitic diseases. Some patients develop portal hypertension due to regenerative nodules without fibrosis, a feature called nodular regenerative hyperplasia. The basis of this phenomenon in PBC is not known.

Clinical Features

Symptomatic PBC usually presents with fatigue and pruritus, which increase slowly over time. Hypercholesterolemia is common. Splenomegaly and jaundice are seen in advanced disease. Other features that may be seen include skin hyperpigmentation, xanthelasmas, steatorrhea, and vitamin D malabsorption–related osteomalacia and/or osteoporosis. Other autoimmune diseases, such as Sjögren syndrome, systemic sclerosis, thyroiditis, rheumatoid arthritis, Raynaud phenomenon, and celiac disease, may also be present in affected patients.

An increasing number of cases are being detected in asymptomatic patients with elevated serum alkaline phosphatase levels. Antimitochondrial antibodies are present in 90% to 95% of patients at all stages of the disease process and are highly characteristic. For uncertain reasons, many patients also have elevated serum levels of IgM antibody. Antimitochondrial antibodies can be detected by indirect immunofluorescence or enzyme-linked immunosorbent assay (ELISA); the latter has higher sensitivity and specificity as it selectively detects antibodies directed against the E2 subunit of the pyruvate dehydrogenase complex. The diagnosis can be established if two of the following are present: elevated alkaline phosphatase for more than 6 months; positive test for antimitochondrial antibodies; and characteristic histologic findings. The AMA-negative form of the disease has only two of these findings and is sometimes termed "autoimmune cholangiopathy" or "autoimmune cholangitis." Its clinical presentation, pathology, and natural history are otherwise similar.

PBC is a slowly progressive disease, and progression to end-stage liver disease occurs in 20% to 25% of patients over 15 to 20 years. Treatment with oral ursodeoxycholic acid, a naturally occurring bile acid, slows disease progression in most patients, but the response is inadequate in up to 40% of those affected; other medical therapies, such as with obeticholic acid (a synthetic bile acid) are being evaluated in such patients. In those in whom medical treatment fails, liver transplantation yields excellent results, with survival of more than 70% at 7 years. Like many chronic forms of hepatic injury, PBC is associated with an increased risk of hepatocellular carcinoma.

Primary Sclerosing Cholangitis (PSC)

PSC is characterized by inflammation and obliterative fibrosis of extrahepatic and large intrahepatic ducts and dilation of preserved segments. PSC tends to occur in the third through fifth decades and has a 2:1 male predominance.

Pathogenesis

The presence of circulating autoantibodies and T lymphocytes in the periductal stroma, and associations with HLA-B8 and other MHC antigens and ulcerative colitis, all support the idea that PSC is an immunologically mediated process. A combination of environmental and genetic factors is thought to trigger the inflammatory injury of bile ducts. First-degree relatives of patients with PSC have an increased risk of developing the disease, suggesting a genetic component. It has been proposed that T cells, activated in the damaged mucosa of patients with ulcerative colitis, migrate to the liver, where they recognize a cross-reacting bile duct antigen. Infections or changes in the intestinal microbiome have also been postulated to lead to alterations in cholangiocytes that incite inflammatory injury. Unlike PBC, the autoantibody profile in PSC is not characteristic, but atypical perinuclear antineutrophil cytoplasmic antibodies (pANCA) targeting a nuclear envelope protein are found in approximately 65% of patients.

MORPHOLOGY

The large intrahepatic bile ducts and extrahepatic ducts show epithelial injury and neutrophilic infiltrates superimposed on chronic inflammation. The edema and inflammation cause narrowing of the lumen, leading to fibrosis and strictures. Lithiasis can develop in the dilated ducts. The inflammatory injury can result in circumferential "onion skin" fibrosis (periductal fibrosis/sclerosis) around an increasingly atrophic duct lumen (Fig. 18.35), eventually leading to obliteration by a "tombstone" scar. The smaller intrahepatic bile ducts, which are more commonly sampled on biopsy, are not directly involved by inflammation, but may exhibit mild injury and prominent ductular reaction due to cholestasis. Progression of cholestasis and fibrosis culminates in biliary cirrhosis. Biliary intraepithelial neoplasia can develop and eventually lead to cholangiocarcinoma, a dreaded complication of PSC.

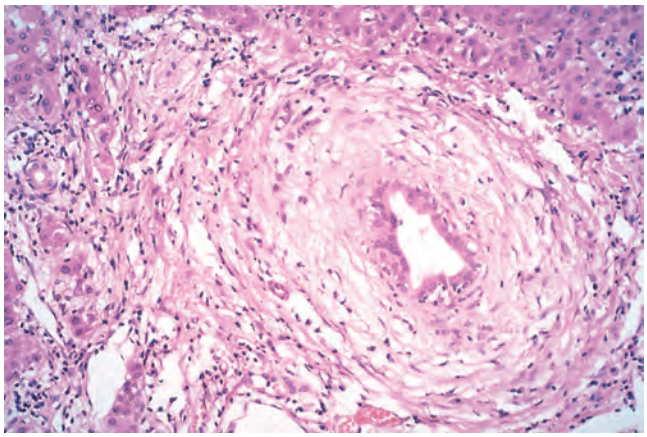

Figure 18.35 Primary sclerosing cholangitis. A degenerating bile duct is entrapped in a dense, "onion-skin" concentric scar.

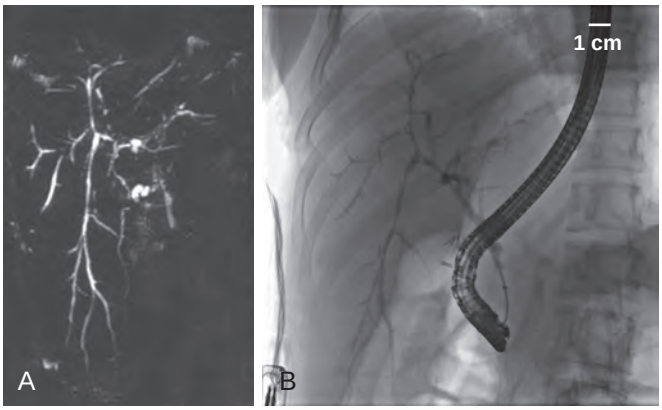

Figure 18.36 Imaging studies of a patient with primary sclerosing cholangitis. (A) Magnetic resonance cholangiography shows focal dilation in some bile ducts *(bright, broad areas)* and strictures in others *(thinning or absence)*. (B) Endoscopic retrograde cholangiography of the same patient shows nearly identical features as in A. The endoscope is visible, giving a sense of scale. (Courtesy Dr. M. Edwyn Harrison, MD, Mayo Clinic, Scottsdale, Ariz.)

Clinical Features

The most common presenting symptoms are fatigue, pruritus, and jaundice. Nearly one-half of the patients are asymptomatic at presentation and come to attention because of persistent elevation of serum alkaline phosphatase, particularly in ulcerative colitis patients who are routinely screened. Ascending cholangitis can also be the initial presentation. Chronic pancreatitis and chronic cholecystitis, from involvement of pancreatic ducts and gallbladder, are also seen. Fibrosis and eventually cirrhosis can occur.

The gold standard for diagnosis of PSC is the characteristic "beading" seen in the large intrahepatic and extrahepatic biliary tree by endoscopic/magnetic retrograde cholangiopancreaticography (ERCP/MRCP), involving attributable to irregular biliary strictures and dilations (Fig. 18.36). Inflammatory bowel disease, particularly ulcerative colitis, affects approximately 70% of individuals with PSC, whereas 8% of inflammatory bowel disease patients develop PSC. In a small subset of cases, mostly in association with inflammatory bowel disease, there is involvement of smaller bile ducts only and the ERCP/MRCP examination is normal. This is referred to as small-duct PSC and can progress to typical large-duct PSC. Classic PSC needs to be distinguished from cholangitis that occurs in IgG_4 sclerosing disease (Chapter 6), which is steroid-responsive and often associated with pancreatitis. In 5% to 10% of cases, autoimmune hepatitis is present along with PSC.

The disease typically follows a protracted course leading to cirrhosis over 10 to 15 years. The lifetime risk of developing cholangiocarcinoma is 20%. There is no established medical therapy for PSC; clinical trials of ursodeoxycholic acid are ongoing. Cholestyramine, a bile acid–binding resin, is used to alleviate pruritus, and endoscopic dilation or stenting is used to relieve biliary obstruction. Liver transplantation is the treatment of choice for end-stage liver disease.

KEY CONCEPTS

CHOLESTATIC DISEASES

- Cholestasis occurs with impaired bile flow, leading to accumulation of bile pigment in the hepatic parenchyma. Hepatic etiologies include metabolic defects in bile formation or secretion and inflammatory injury to bile ducts, while posthepatic etiologies include mechanical obstruction or inflammatory destruction of the extrahepatic bile ducts.
- Large bile duct obstruction is most commonly associated with gallstones and carcinomas involving the head of the pancreas. Ascending cholangitis may develop. Chronic obstruction can lead to cirrhosis.
- Cholestasis in sepsis may result from direct effects of intrahepatic bacterial infection, circulating microbial products, or ischemia relating to hypotension.
- Primary hepatolithiasis is a disorder of intrahepatic gallstone formation that is most common in East Asia and leads to repeated bouts of ascending cholangitis and inflammatory parenchymal destruction. It predisposes to cholangiocarcinoma.
- PBC is an autoimmune disease with inflammatory and often granulomatous destruction of small- to medium-sized intrahepatic bile ducts. It occurs most often in middle-aged women and is typically associated with antimitochondrial antibodies and with other autoimmune diseases (e.g., Sjögren syndrome and Hashimoto thyroiditis).
- PSC is an autoimmune disease that is more common in males and is strongly associated with inflammatory bowel disease, particularly ulcerative colitis. The diagnosis is established by visualization of the biliary tree. Histologically, the typical features are inflammation, fibrosis, and strictures involving large intrahepatic and extrahepatic bile ducts. Patients are at risk for developing cholangiocarcinoma.

STRUCTURAL ANOMALIES OF THE BILIARY TREE

Choledochal Cyst

Choledochal cysts are congenital dilations of the common bile duct. They present most often in children before age 10 as jaundice and/or recurrent abdominal pain, symptoms

that are typical of biliary colic. Approximately 20% of cases become symptomatic only in adulthood. In some cases, choledochal cysts occur in conjunction with cystic dilation of the intrahepatic biliary tree (*Caroli disease*, described later). The female-to-male ratio is 3:1 to 4:1. These uncommon cysts may take the form of segmental or cylindric dilation of the common bile duct, diverticula of the extrahepatic ducts, or choledochoceles, which are cystic lesions that protrude into the duodenal lumen. Choledochal cysts predispose to stone formation, stenosis and stricture, pancreatitis, and obstructive biliary complications within the liver. There also is an increased risk of developing bile duct carcinoma.

Fibropolycystic Disease

Fibropolycystic disease of the liver is a heterogeneous group of lesions in which the primary abnormality is congenital malformation of the biliary tree. Lesions may be found incidentally during radiographic studies, surgery, or autopsy. The most severe forms may manifest as hepatosplenomegaly or portal hypertension in the absence of hepatic dysfunction, starting in late childhood or adolescence. These lesions are part of the spectrum of developmental ductal plate malformations, which result from persistence of the fetal periportal ductal plates. The caliber of involved portal tracts determines the size, morphology, and distributions of the lesions. Fibropolycystic liver disease often occurs in association with autosomal recessive polycystic renal disease (Chapter 20). Persons with fibropolycystic liver disease are at increased risk for cholangiocarcinoma.

Three sets of pathologic findings may be seen with polyfibrocystic disease, sometimes overlapping with each other:

- *Von Meyenburg complexes* are small bile duct hamartomas (Fig. 18.37). Occasional von Meyenburg complexes are common in otherwise normal individuals. When they are diffuse, they signal the presence of underlying, clinically important fibropolycystic disease.
- *Single or multiple intrahepatic or extrahepatic biliary cysts*. When present in isolation, these may be symptomatic due to ascending cholangitis. Multifocal cystic dilation of the large intrahepatic bile ducts is referred to as *Caroli disease*. When the cystic dilation of the biliary tree occurs along with congenital hepatic fibrosis, the term *Caroli syndrome* is applied (Fig. 18.38). Ducts may be cystically dilated, but true cysts are also present. These may be intrahepatic cysts or choledochal cysts, as described earlier.
- *Congenital hepatic fibrosis* is characterized by portal tracts enlarged by broad bands of collagenous tissue forming septa that divide the liver into irregular islands (Fig. 18.39). Variable numbers of abnormally shaped bile ducts are embedded in the fibrous tissue, although they remain in continuity with the biliary tree. As with cirrhosis, individuals with congenital hepatic fibrosis are at risk for developing portal hypertension and its complications, particularly bleeding varices.

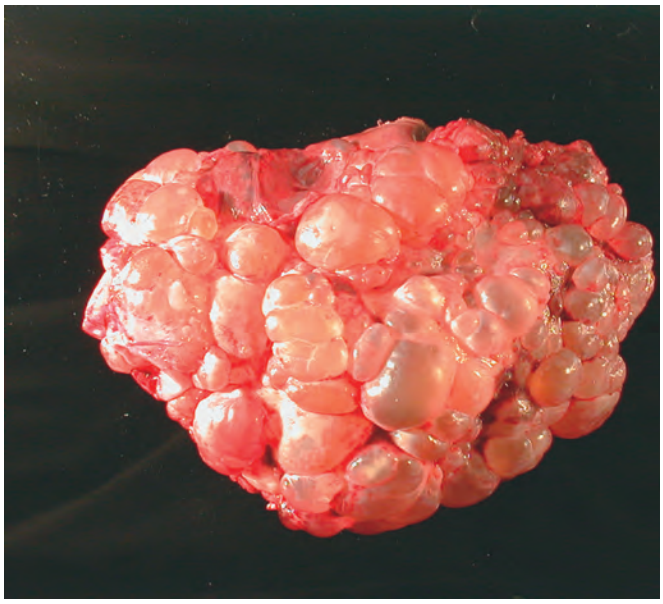

Figure 18.38 Congenital hepatic fibrosis with multiple biliary cysts.

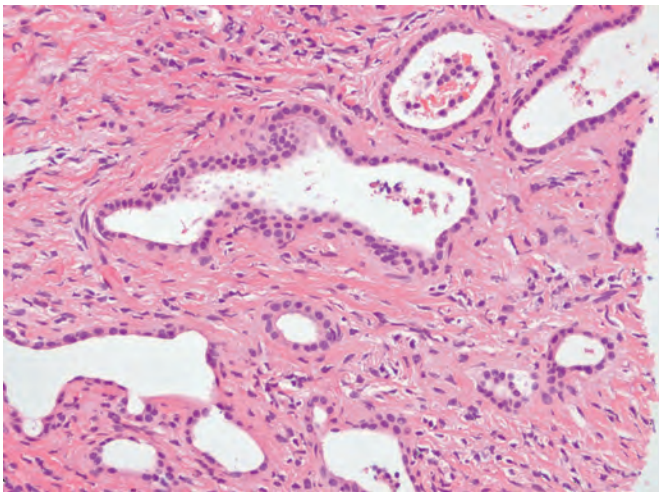

Figure 18.37 Von Meyenburg complex (bile duct hamartoma). Dilated irregular bile ducts with curvilinear outlines thought to represent ductal plate formation.

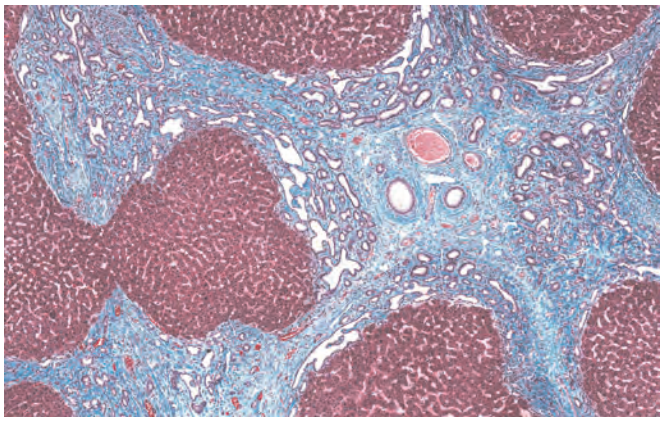

Figure 18.39 Congenital hepatic fibrosis. Broad bands of fibrosis with dilated remnants of ductal plates. The intervening parenchyma is relatively normal (Masson Trichrome stain).

CIRCULATORY DISORDERS

Given the large volume of blood that flows through the liver, it is not surprising that circulatory disturbances have considerable impact on the organ. In most instances, however, clinically significant liver function abnormalities do not develop, but hepatic morphology may be strikingly affected. These disorders can be grouped according to whether blood flow into, through, or from the liver is impaired (Fig. 18.40).

Impaired Blood Flow Into the Liver

Hepatic Artery Compromise

The liver's dual blood supply mitigates against infarction; however, obstruction of an intrahepatic branch of the hepatic artery by emboli, thrombi, or compression may result in a localized infarct that is either pale and anemic, or hemorrhagic if there is suffusion with portal blood (Fig. 18.41). Underlying causes may include neoplasia, polyarteritis nodosa (Chapter 11), or sepsis. Interruption of blood flow through the main hepatic artery does not always produce ischemic necrosis of the organ, particularly if the liver is otherwise normal, as retrograde arterial flow through accessory vessels, when coupled with the portal venous supply, is usually sufficient to sustain the liver parenchyma.

Several conditions increase the vulnerability of the liver to infarction in the setting of hepatic artery obstruction. Hepatic artery thrombosis in a transplanted liver generally leads to infarction of the major ducts of the biliary tree, since their blood supply is entirely arterial, and may also lead to hepatic injury and regenerative changes. Large infarcts may occur with combined portal vein and hepatic artery thrombosis, which eventually result in subcapsular scarring.

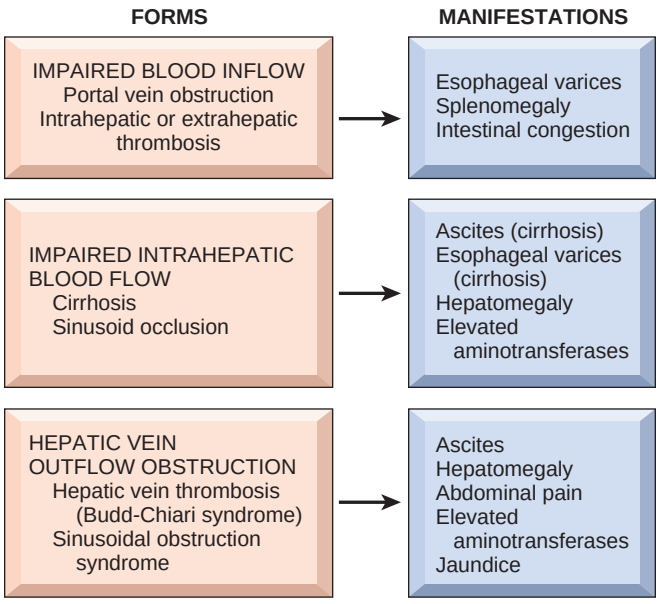

Figure 18.40 Forms and clinical manifestations of hepatic circulatory disorders.

Figure 18.41 Liver infarct. A thrombus is lodged in a peripheral branch of the hepatic artery *(arrow)* and compresses the adjacent portal vein; the distal necrotic infarcted tissue has pale margins and multifocal areas of hemorrhage.

Portal Vein Obstruction and Thrombosis

Blockage of the portal vein and its tributaries may be insidious and well tolerated, or may be a catastrophic, potentially lethal event; most cases fall somewhere in between. Occlusive disease of the portal vein or its major branches typically produces abdominal pain and, in most instances, manifestations of portal hypertension, principally esophageal varices that are prone to rupture.

The obstruction may occur at the level of the extrahepatic portal vein, intrahepatic portal vein radicles, or small portal vein branches. Extrahepatic portal vein obstruction may be idiopathic (approximately one-third of cases) or may arise from the following conditions:

- *Neonatal umbilical sepsis or umbilical vein catheterization,* often producing subclinical occlusion of the portal vein that presents as variceal bleeding and ascites years later
- *Intraabdominal infection* caused by acute diverticulitis or appendicitis, leading to pyelophlebitis in the splanchnic circulation
- *Inherited or acquired hypercoagulable states,* including myeloproliferative neoplasms such as polycythemia vera (Chapter 13), in which platelet abnormalities predispose to portal vein thrombosis
- *Trauma,* surgical or otherwise
- *Pancreatitis- and pancreatic cancer–associated splenic vein thrombosis,* which propagates into the portal vein
- *Invasion of the portal vein by hepatocellular carcinoma*
- *Cirrhosis,* which is associated with portal vein thrombosis in about 25% of patients. Many such patients have an underlying thrombophilic genotype (e.g., Factor V Leiden, Chapter 4).

Intrahepatic portal vein radicles are most likely to be obstructed by acute thrombosis, often in the setting of a malignancy or some other hypercoagulable state. By contrast, small portal vein branch obstruction may be seen in a variety of pathogenically distinct conditions characterized by noncirrhotic portal hypertension, as follows:

- *The most common cause of small portal vein branch obstruction is schistosomiasis;* the eggs of the parasites and the associated granulomatous inflammatory response obstruct the smallest portal vein branches.
- *Other diseases associated with obstruction of small portal vein branches are collectively referred to as idiopathic noncirrhotic portal hypertension.* The pathogenesis is unknown; associations with prothrombotic states, infections (e.g., HIV), drugs, toxins, immune deficiencies, chronic biliary obstruction, and autoimmune diseases have been noted. Geographic variation in the incidence of noncirrhotic portal fibrosis and hypertension has been reported. It is particularly common in India, although the incidence appears to be declining. Patients often present with upper gastrointestinal bleeding. In East Asia, particularly Japan, there is a female predominance and patients present with splenomegaly, often in association with rheumatologic diseases. The disease is seen in untreated HIV disease and in those being treated with antiretroviral therapy, in whom it may represent a complication of treatment. Liver transplantation may be necessary to avoid fatal sequelae of portal hypertension in all these settings.

Impaired Blood Flow Through the Liver

The most common intrahepatic cause of blood flow impairment is cirrhosis, as described earlier. In addition, physical occlusion of sinusoidal blood flow occurs in a small group of diseases, including the following:

- *Sickle cell disease* (Fig. 18.42), due to obstruction by sickled red cells
- *Disseminated intravascular coagulation*, due to myriad small thrombi
- *Eclampsia* (discussed later)
- *Diffuse intrasinusoidal metastatic tumor,* due to physical obstruction by plugs of tumor, sometimes with superimposed thrombosis

In all of these scenarios, obstruction of blood flow may lead to massive necrosis of hepatocytes and acute liver failure.

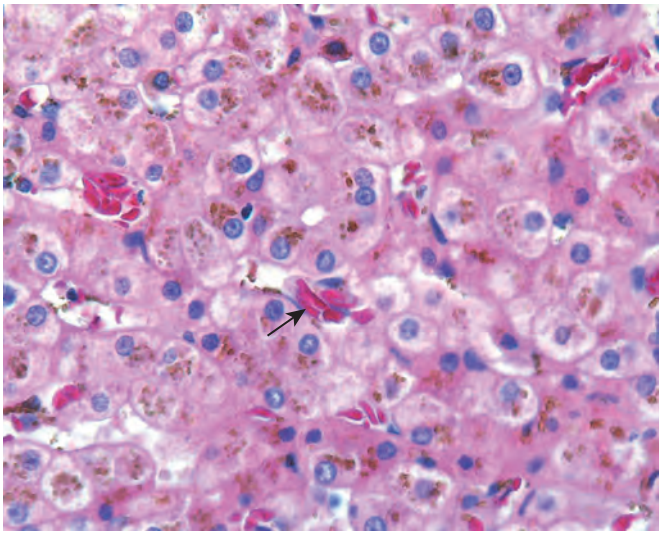

Figure 18.42 Sickle cell crisis in liver. The photomicrograph shows several sinusoids containing "sickled" red cells *(arrow).*

Peliosis hepatis is a peculiar form of sinusoidal dilation that occurs in any condition in which efflux of hepatic blood is impeded. The liver contains blood-filled cystic spaces, either unlined or lined with sinusoidal endothelial cells. The pathogenesis is unknown. *Bartonella* species have been seen in the sinusoidal endothelial cells in AIDS-associated peliosis, but peliosis is also seen in cancer and with other infections, such as tuberculosis. Sex hormone administration (e.g., anabolic steroids, oral contraceptives, danazol) sometimes causes peliosis as well. While clinical signs are generally absent, potentially fatal intraabdominal hemorrhage or hepatic failure may occur. Lesions usually disappear after correction of the underlying cause.

Hepatic Venous Outflow Obstruction

Hepatic Vein Thrombosis

The obstruction of major hepatic veins produces liver enlargement, pain, and ascites, a condition known as Budd-Chiari syndrome. Obstruction of a single main hepatic vein by thrombosis is clinically silent. Hepatic damage is the consequence of increased intrahepatic blood pressure. Hepatic vein thrombosis is associated with myeloproliferative neoplasms such as polycythemia vera (Chapter 13), inherited disorders of coagulation (Chapter 4), antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria (Chapter 14), and intraabdominal cancers, particularly hepatocellular carcinoma. In pregnancy or with oral contraceptive use, it occurs through interaction with an underlying thrombophilic disorder.

MORPHOLOGY

In Budd-Chiari syndrome, the liver is swollen and red-purple and has a tense capsule (Fig. 18.43). There may be areas of hemorrhagic collapse alternating with preserved or regenerating parenchyma, with the patterns being dependent on which small and large hepatic veins are obstructed. Microscopically, the affected hepatic parenchyma reveals severe centrilobular congestion and necrosis. Pericentral/sinusoidal fibrosis develops in instances in which thrombosis develops more slowly. The major veins contain thrombi showing various degrees of organization.

Clinical Features

The mortality of untreated acute hepatic vein thrombosis is high. Prompt surgery to create a portosystemic venous

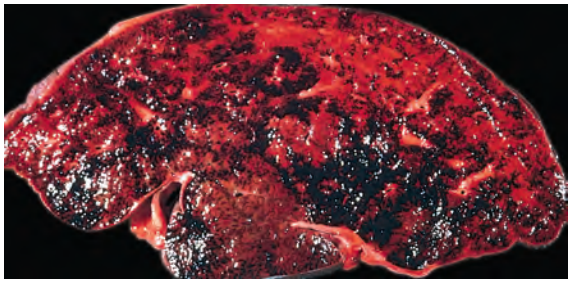

Figure 18.43 Budd-Chiari syndrome. Thrombosis of the major hepatic veins has caused hemorrhagic liver necrosis.

shunt permits reverse flow through the portal vein and improves the prognosis. The chronic form is far less lethal, and more than two-thirds of patients are alive after 5 years.

Sinusoidal Obstruction Syndrome

Originally described in Jamaican drinkers of pyrrolizidine alkaloid–containing bush tea and named *veno-occlusive disease,* sinusoidal obstruction syndrome now occurs primarily in two settings: (1) following allogeneic (or less commonly, autologous) hematopoietic stem cell transplantation, usually within the first 3 weeks (though changes in conditioning regimens have lowered the incidence); and (2) in cancer patients receiving certain forms of chemotherapy. The mortality rate is up to 80% in severe disease.

Pathogenesis

Sinusoidal obstruction syndrome arises from toxic injury to the sinusoidal endothelium. Injured, sloughed endothelium obstructs sinusoidal blood flow, and associated debris accumulates in the terminal hepatic vein. Red cells enter the space of Disse in the disrupted sinusoids, and the cessation of blood flow often leads to necrosis of perivenular hepatocytes.

MORPHOLOGY

Sinusoidal obstruction syndrome is characterized by obliteration of the terminal hepatic venules by swollen or necrotic endothelium, edema, and eventual collagen deposition. In acute disease, there is centrilobular congestion, hepatocellular necrosis, and accumulation of hemosiderin-laden macrophages. In advanced lesions, the obliterated lumens of venules can be highlighted by special stains for connective tissue (Fig. 18.44). In chronic or healed sinusoidal obstruction syndrome, complete fibrous obliteration of the venule may follow.

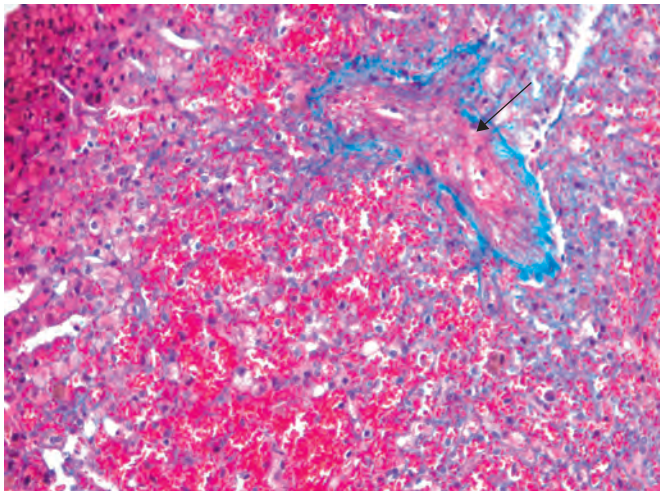

Figure 18.44 Sinusoidal obstruction syndrome. Collagen stain reveals marked sinusoidal congestion, hepatocyte atrophy and loss, and organizing thrombus within the vein lumen *(arrow).* (Masson trichrome stain.)

Clinical Features

Although histology is the gold standard for diagnosis, liver biopsy is often risky in these patients. As a result, the diagnosis is typically made on clinical grounds based on the findings of tender hepatomegaly, ascites, weight gain, and jaundice, as well as reversed or attenuated hepatic venous flow on Doppler ultrasonography. Early results suggest that treatment with anticoagulants and ursodeoxycholate may lower the incidence and severity of sinusoidal obstruction syndrome in patients undergoing hematopoietic stem cell transplantation.

Passive Congestion and Centrilobular Necrosis

These hepatic manifestations of systemic circulatory compromise—passive congestion and centrilobular necrosis—are considered together because they represent a morphologic continuum. Both changes are commonly seen at autopsy because there is an element of preterminal circulatory failure in virtually every nontraumatic death.

MORPHOLOGY

Right-sided cardiac decompensation leads to passive congestion of the liver. The liver is slightly enlarged, tense, and cyanotic, with rounded edges. Microscopically, there is **congestion of dilated centrilobular sinusoids.** With time, centrilobular hepatocytes become atrophic, resulting in markedly attenuated liver cell plates.

Left-sided cardiac failure or shock may lead to hepatic hypoperfusion and hypoxia of hepatocytes around central veins. The combination of hypoperfusion and retrograde congestion acts synergistically to cause **centrilobular hemorrhagic necrosis.** The liver takes on a variegated mottled appearance, reflecting hemorrhage and necrosis in the centrilobular regions (Fig. 18.45*A*). This finding is known as **nutmeg liver** due to its resemblance to the cut surface of a nutmeg. In most instances, the only clinical evidence of centrilobular necrosis or its variants is transient elevation of serum aminotransferases, but the parenchymal damage may be sufficient to induce mild to moderate jaundice.

By microscopy, there is a sharp demarcation of viable periportal and necrotic or atrophic pericentral hepatocytes, with suffusion of blood through the centrilobular region (see Fig. 18.45B). With sustained chronic severe congestive heart failure, **cardiac sclerosis** develops with centrilobular pericellular fibrosis, sometimes with bridging fibrous septa.

KEY CONCEPTS

CIRCULATORY DISORDERS

- Circulatory disorders of the liver can be caused by impaired blood inflow, defects in intrahepatic blood flow, and obstruction of blood outflow.
- Portal vein obstruction by intrahepatic or extrahepatic thrombosis may cause portal hypertension, esophageal varices, and ascites.
- The most common cause of impaired intrahepatic blood flow is cirrhosis.

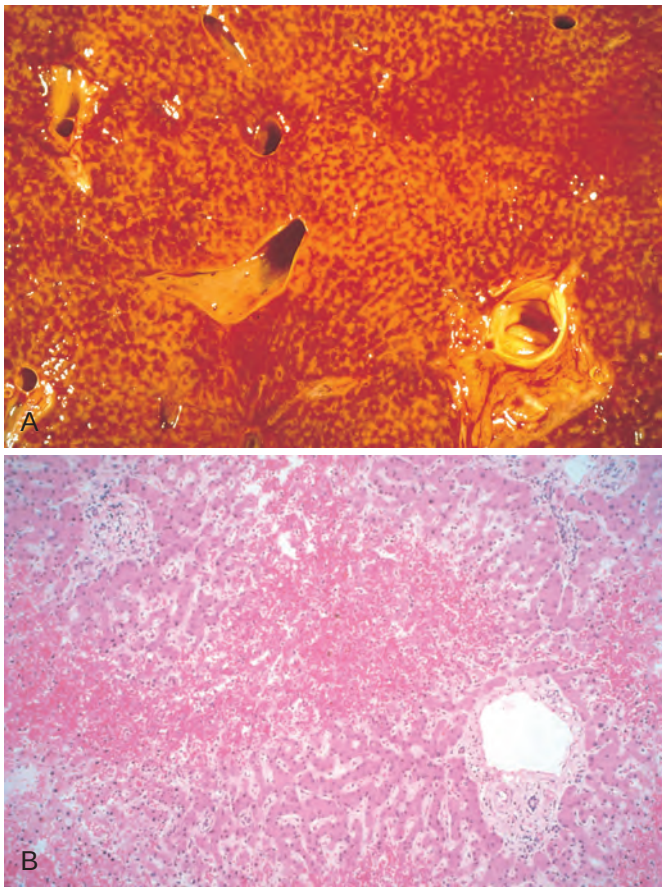

Figure 18.45 Acute passive congestion ("nutmeg liver"). (A) The cut surface of the liver has a variegated mottled red appearance, representing congestion and hemorrhage in the centrilobular regions of the parenchyma. (B) On microscopic examination, the centrilobular region is suffused with red blood cells, and atrophied hepatocytes are not easily seen. Portal tracts and the periportal parenchyma are intact.

- Obstructions of blood outflow include hepatic vein thrombosis (Budd-Chiari syndrome) and sinusoidal obstruction syndrome, previously known as veno-occlusive disease.

HEPATIC DISEASE ASSOCIATED WITH PREGNANCY

Some forms of hepatic disease may be exacerbated by pregnancy. Viral hepatitis (HAV, HBV, HCV, or HBV + HDV) is the most common cause of jaundice in pregnancy. While these women require careful clinical management, pregnancy does not specifically alter the course of viral hepatitis, with exception of HEV infection, which, for unknown reasons, runs a more severe course and has a fatality rate approaching 20% in pregnant patients. The liver may also be secondarily involved by other infections during pregnancy. These include hepatitis caused by herpes simplex virus, a rare cause of acute liver failure in pregnancy, and liver abscess caused by *Listeria monocytogenes,* an organism that thrives in placental tissue, from where it may seed the liver.

Abnormal liver tests occur in 3% to 5% of pregnancies, but in most cases these are of no clinical importance. In a very small subgroup of pregnant women (0.1%), more serious hepatic complications develop. These disorders include preeclampsia and eclampsia, acute fatty liver of pregnancy, and intrahepatic cholestasis of pregnancy. In extreme cases, eclampsia and acute fatty liver of pregnancy may be fatal.

Preeclampsia and Eclampsia

Preeclampsia affects up to 10% of pregnancies and is characterized by maternal hypertension, proteinuria, peripheral edema, and coagulation abnormalities (see Chapter 22 for detailed discussion). When hyperreflexia and convulsions occur, the condition is called *eclampsia* and may be life-threatening. Alternatively, subclinical hepatic disease may be the primary manifestation of preeclampsia, as part of a syndrome of *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets, dubbed the *HELLP syndrome.* Here we focus on the hepatic pathology of these entities.

MORPHOLOGY

In preeclampsia, **periportal sinusoids contain fibrin deposits associated with hemorrhage into the space of Disse,** leading to periportal hepatocellular coagulative necrosis. Blood under pressure may coalesce and expand to form a hepatic hematoma; dissection of blood under Glisson capsule may lead to catastrophic hepatic rupture in eclampsia (Fig. 18.46).

Clinical Features

Patients with hepatic involvement in preeclampsia may show modest to severe elevation of serum aminotransferases and mild elevation of serum bilirubin. Hepatic dysfunction sufficient to cause a coagulopathy signifies advanced and potentially lethal disease. Mild cases may be managed conservatively. Termination of pregnancy is required in severe cases. Women who survive mild or severe preeclampsia recover without sequelae.

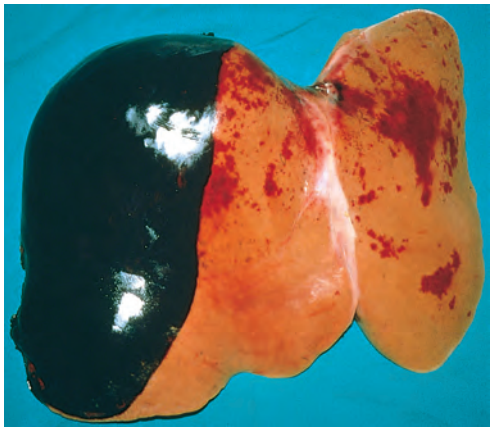

Figure 18.46 Eclampsia. Subcapsular hematoma dissecting under Glisson capsule in a fatal case. (Courtesy Dr. Brian Blackbourne, Office of the Medical Examiner, San Diego, Calif.)

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy presents with a spectrum of disease ranging from subclinical or modest hepatic dysfunction (evidenced by elevated serum aminotransferase levels) to hepatic failure, coma, and death. It is a rare disease affecting approximately 1 in 16,000 pregnant women.

Pathogenesis

The pathogenesis of this disease in some cases may involve an inherited disorder of metabolism. In a subset of patients, both mother and father carry a heterozygous deficiency in mitochondrial long-chain 3-hydroxyacyl coenzyme A (CoA) dehydrogenase. The homozygous-deficient fetuses and placenta fare well during pregnancy but cause hepatic dysfunction in the mother, because long-chain 3-hydroxylacyl metabolites produced by the fetus, or placenta, enter the maternal circulation and cause hepatic toxicity. Thus, this may be a rare instance of the fetus causing metabolic disease in the mother.

MORPHOLOGY

The diagnosis of acute fatty liver of pregnancy rests on biopsy identification of characteristic **diffuse microvesicular steatosis** in hepatocytes. In severe cases, there may be lobular disarray with hepatocyte dropout, reticulin collapse, and portal tract inflammation, making distinction from viral hepatitis difficult. Cholestasis may also be present.

Clinical Features

While this condition most commonly runs a mild course, women with acute fatty liver of pregnancy can progress within days to hepatic failure and death. The primary treatment is termination of pregnancy. Affected women present in the latter half of pregnancy, usually in the third trimester. Symptoms are directly attributable to incipient hepatic failure, including bleeding, nausea and vomiting, jaundice, and coma. In 20% to 40% of cases, the presenting symptoms may be those of coexistent preeclampsia.

Intrahepatic Cholestasis of Pregnancy

The onset of pruritus in the second or third trimester, followed in some cases (10% to 25%) by darkening of the urine, and occasionally light stools and jaundice, heralds the development of this enigmatic syndrome, which resolves within 2 to 3 weeks of delivery. Serum bilirubin (mostly conjugated) rarely exceeds 5 mg/dL; alkaline phosphatase may be slightly elevated. The level of bile salts is increased greatly. The altered hormonal state of pregnancy likely combines with environmental factors and transporter protein defects to engender canalicular cholestasis. There is a modest risk of fetal loss, and the condition may recur in subsequent pregnancies. The pruritus resulting from retention of bile salts can be extremely distressing for the pregnant mother.

NODULES AND TUMORS

Hepatic mass lesions include non-neoplastic processes like focal nodular hyperplasia, regenerative nodules, and abscess or another infectious process. Neoplastic mass lesions include benign hepatocellular nodules such as hepatocellular adenoma; malignant primary liver epithelial neoplasms, such as hepatocellular carcinoma or intrahepatic cholangiocarcinoma; and nonepithelial neoplasms, such as angiosarcoma and metastatic tumors.

Non-Neoplastic Mass Lesions

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is a benign, non-neoplastic lesion that is most common in adult women.

Pathogenesis

FNH is thought to result from altered blood flow that leads to hyperplastic changes in hepatocytes. FNH-like nodules can occur adjacent to other tumors and in vascular conditions such as hemangiomas and Budd-Chiari syndrome. Multifocal FNH can occur in association with hepatic or extrahepatic hemangioma, vascular malformations, or (curiously) brain tumors, such as meningioma and astrocytoma.

MORPHOLOGY

FNH is well circumscribed, typically lacks a capsule, and has a **central stellate scar** in up to 80% of cases (Fig. 18.47A). Most lesions are 5 cm or less in diameter. Microscopically, fibrous septa radiate from the central scar dividing the hepatic parenchyma into nodules. The fibrous septa and central scar contain thick-walled arteries with intimal and fibromuscular hyperplasia and poorly formed elastic lamina (Fig. 18.47B). A prominent ductular reaction is often present, but interlobular bile ducts are absent. The hepatocytes in the nodules are arranged in one- to two-cell-thick plates; cytologic and architectural atypia is not present. Immunohistochemistry for glutamine synthetase (GS), an enzyme normally present in centrizonal hepatocytes, is very useful for diagnosis. In FNH, a highly characteristic "maplike pattern" of strong cytoplasmic GS staining is seen within anastomosing groups of hepatocytes.

Clinical Features

Most cases are asymptomatic and come to clinical attention during imaging or surgery. The presence of a central scar is a highly characteristic finding and helps in establishing the diagnosis on imaging. FNH is a benign lesion and does not need any treatment. Resection is performed for large symptomatic lesions.

Other Non-Neoplastic Mass Lesions

Non-neoplastic mass forming lesions like abscesses, granulomas, and inflammatory pseudotumors can mimic true neoplasms. Large regenerative nodules can occur in non-cirrhotic liver in vascular conditions such as Budd-Chiari

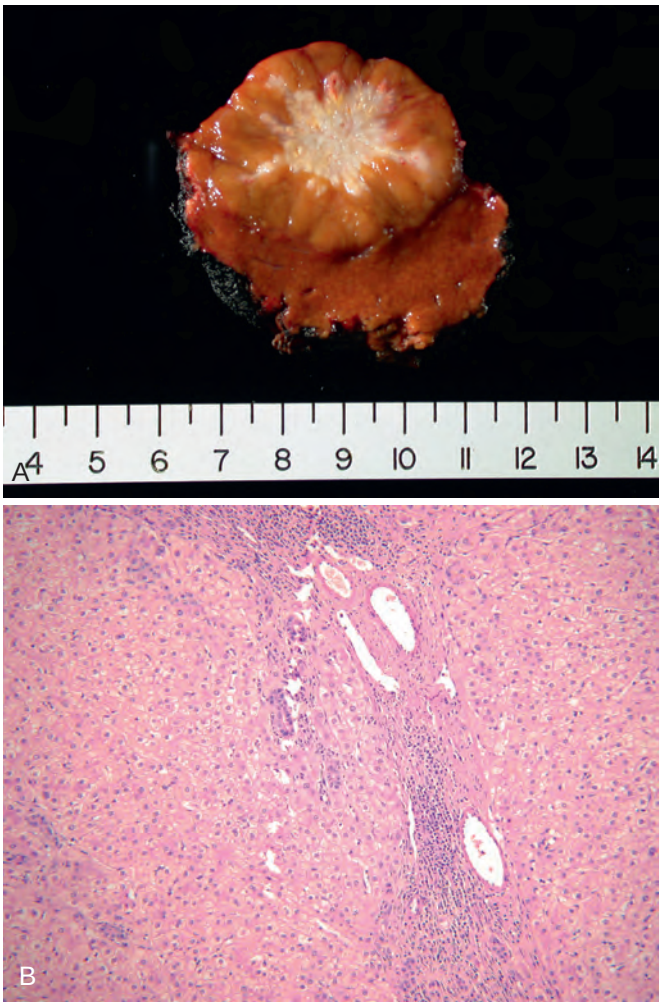

Figure 18.47 Focal nodular hyperplasia. (A) Resected specimen showing lobulated contours and a central stellate scar. (B) Low-power micrograph showing a broad fibrous scar with thick-walled arteries and ductular reaction, but no interlobular bile ducts.

syndrome, hemangioma, and vascular malformations. In some conditions, the entire liver becomes nodular without significant fibrosis, a condition referred to as nodular regenerative hyperplasia (NRH). NRH can lead to portal hypertension and mimic cirrhosis on imaging.

Benign biliary proliferations include bile duct adenoma and biliary hamartoma (von Meyenburg complex, described earlier). Both are asymptomatic and generally less than 2 cm. These lesions come to clinical attention as tiny nodules or cysts on imaging, or as small subcapsular lesions observed during abdominal surgery when they can be mistaken for metastatic disease. Both lesions show haphazard bile ducts in a fibrous stroma, and lack atypical cytologic or architectural features. The ductular profiles in bile duct adenoma tend to be round and nondilated, while those in biliary hamartoma are dilated, curvilinear and often show inspissated bile or secretions. The latter are thought to be a remnant of ductal plate malformation. The recent identification of pathogenic acquired *BRAF* mutations in the majority of bile duct adenomas indicates that this is a benign neoplasm, settling a longstanding debate.

Benign Neoplasms

Cavernous Hemangioma

Cavernous hemangioma is the most common benign liver tumor. It appears as a discrete red-blue, soft nodule, usually less than 2 cm in diameter, generally in a subcapsular location. Histologically, the tumor consists of dilated thin-walled vascular channels (Fig. 18.48). Most are asymptomatic and are detected incidentally by imaging.

Hepatocellular Adenoma

Hepatocellular adenoma is a benign neoplasm that typically occurs in young women and is strongly associated with use of oral contraceptives and anabolic steroids. The incidence has increased in the past decade, presumably related to obesity and metabolic syndrome. Multiple hepatocellular adenomas (termed *hepatic adenomatosis* when 10 or more tumors are present) can occur both in familial and acquired settings.

Pathogenesis

Three molecular subtypes have been defined, each associated with distinct clinicopathologic features and varying risk of transformation into hepatocellular carcinoma.

- *Hepatocyte nuclear factor 1-alpha (HNF1α)-inactivated hepatocellular adenoma*. All of these tumors by definition have loss-of-function mutations in the *HNF1-α* gene, which encodes a transcription factor that regulates many genes in hepatocytes and in pancreatic islets. Heterozygous germline mutations are responsible for autosomal dominant maturity onset diabetes of the young, type 3, and are also associated with 10% of HNF1α-inactivated hepatocellular adenomas. This subtype accounts for 40% to 50% of cases, has a strong female predilection, and is associated with minimal risk of transformation to hepatocellular carcinoma.
- *Inflammatory hepatocellular adenoma* is a subtype that results from acquired activating mutations in gp130, a co-receptor for IL-6, that lead to constitutive activation of JAK-STAT signaling. This subtype accounts for 40% to 50% of cases,

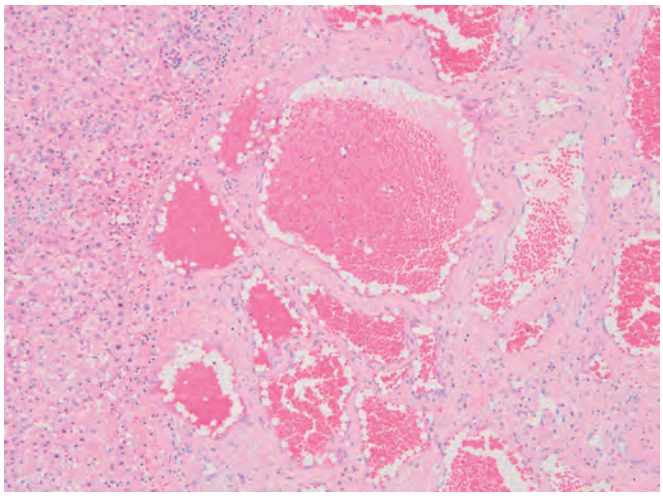

Figure 18.48 Cavernous hemangioma. Blood-filled vascular channels separated by a dense fibrous stroma.

is more common in women, and is associated with obesity and metabolic syndrome. β-catenin–activating mutations also are present in 10% of inflammatory hepatocellular adenomas, and these tumors have a higher risk of malignant transformation.

- *β-Catenin–activated hepatocellular adenoma* is defined by activating mutations in the β-catenin gene *(CTNNB1)* or in other components of the Wnt pathway (such as *APC*). These tumors are at high risk for malignant transformation to hepatocellular carcinoma and are associated with oral contraceptive and anabolic steroid use. Nearly 40% occur in men.

MORPHOLOGY

Hepatocellular adenomas appear as discrete masses, sometimes with associated hemorrhage, composed of hepatocytes arranged in one- to two-cell-thick plates (Fig. 18.49). Large arteries are present within a small amount of fibrous stroma, while interlobular bile ducts and normal portal tracts are absent. *HNF1α*-mutated tumors typically show prominent fat in the lesional hepatocytes and by immunohistochemistry, liver fatty acid binding protein (LFABP), a protein regulated by *HNF1α*, is absent (Fig. 18.50A).

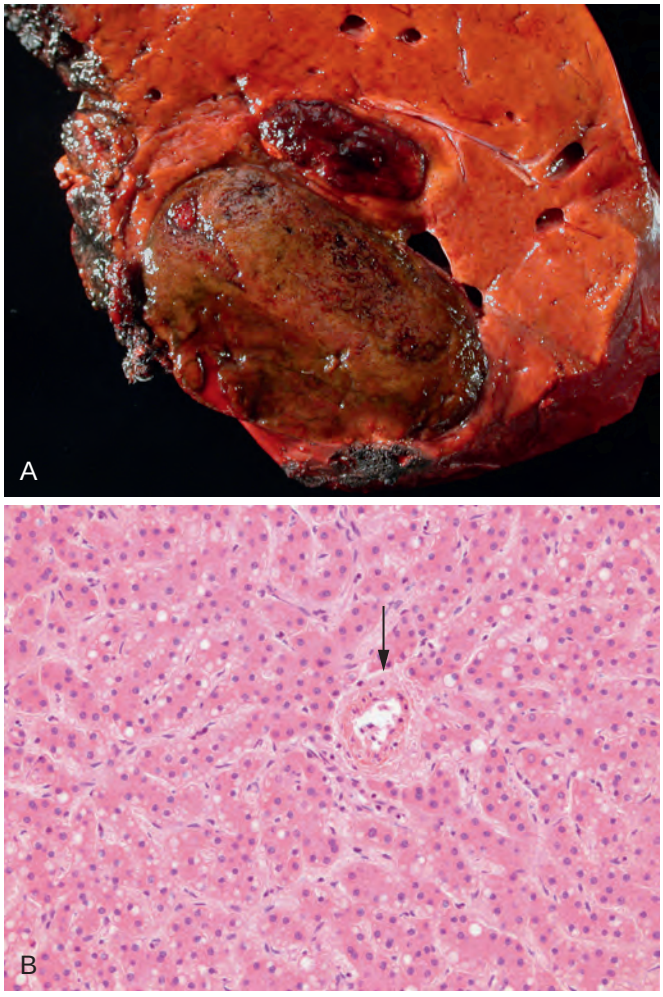

Figure 18.49 Hepatocellular adenoma. (A) Resected specimen showing a well-define tan mass in the liver. (B) Microscopic view showing thin cords of hepatocytes, with an arterial vascular supply *(arrow)* and no portal tracts.

β-catenin–mutated tumors often show atypical cytologic or architectural features, and areas showing overt transformation to hepatocellular carcinoma may be present. Due to β-catenin mutations or other mutations that activate Wnt signaling, strong nuclear localization of β-catenin is seen within at least a subset of the tumor cells (see Fig. 18.50B). Inflammatory tumors typically show sinusoidal dilation and may have features mimicking focal nodular hyperplasia, such as fibrous septa and ductular reaction. Because of hyperactive JAK-STAT signaling, these tumors overexpress acute-phase reactants, such as C-reactive protein and serum amyloid A (see Fig. 18.50C).

Clinical Features

Hepatocellular adenoma may be detected incidentally by imaging or come to attention due to symptoms related abdominal pain or hemorrhagic necrosis. Rupture of hepatocellular adenomas can cause massive abdominal bleeding and represents a surgical emergency. Resection is recommended for β-catenin–activated tumors as well as tumors 5 cm or larger due to the risk of hemorrhage and malignant transformation. For smaller tumors without β-catenin activation, close follow-up and cessation of exposure to oral contraceptive or anabolic steroids may suffice.

Primary Malignant Neoplasms

Malignant tumors in the liver can be primary or metastatic. Among primary epithelial tumors, the most common are hepatocellular carcinoma and intrahepatic cholangiocarcinoma. Hepatoblastoma is a rare hepatocellular tumor that occurs in the pediatric setting. Nonepithelial tumors, such as angiosarcoma, are exceedingly rare.

Hepatoblastoma

Hepatoblastoma is the most common liver tumor of early childhood. It rarely occurs over the age of 3 years, and its incidence is increasing. Activation of the Wnt signaling pathway is characteristic of hepatoblastoma, leading to nuclear β-catenin and increased expression of Wnt target genes such as glutamine synthetase in nearly all cases. These tumors are associated with several syndromes, including *familial adenomatous polyposis* (caused by germline loss-of-function mutations in *APC;* Chapter 17) and *Beckwith-Wiedemann syndrome*. The latter is a disorder associated with congenital growth abnormalities caused by abnormal epigenetic imprinting of a region of chromosome 11 that leads to overexpression of insulin-like growth factor-2 and loss of expression of *CDKN1C,* a tumor suppressor gene that encodes the cyclin-dependent kinase inhibitor p57.

MORPHOLOGY

There are a variety of histologic subtypes of hepatoblastoma, which can be broadly grouped into two categories: (1) **epithelial type,** composed of small polygonal fetal cells or smaller embryonal cells forming trabeculae, acini, tubules, or papillary structures vaguely recapitulating the developing liver (Fig. 18.51); and (2) **mixed epithelial and mesenchymal type,** which contains additional foci of mesenchymal differentiation that may consist of primitive mesenchyme, osteoid, cartilage, or striated muscle.

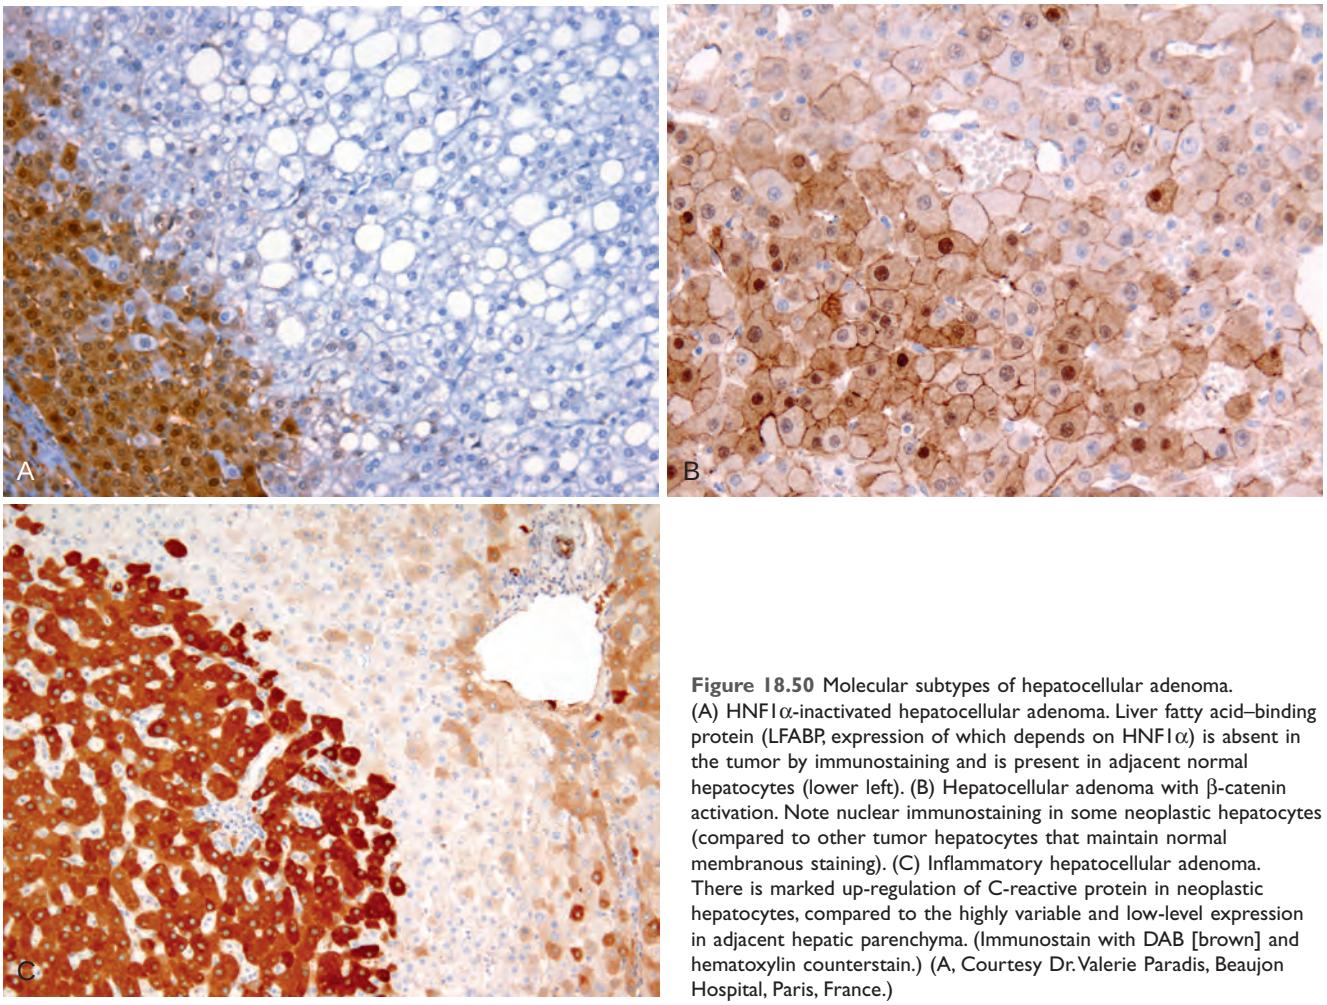

Figure 18.50 Molecular subtypes of hepatocellular adenoma. (A) HNF1α-inactivated hepatocellular adenoma. Liver fatty acid–binding protein (LFABP, expression of which depends on HNF1α) is absent in the tumor by immunostaining and is present in adjacent normal hepatocytes (lower left). (B) Hepatocellular adenoma with β-catenin activation. Note nuclear immunostaining in some neoplastic hepatocytes (compared to other tumor hepatocytes that maintain normal membranous staining). (C) Inflammatory hepatocellular adenoma. There is marked up-regulation of C-reactive protein in neoplastic hepatocytes, compared to the highly variable and low-level expression in adjacent hepatic parenchyma. (Immunostain with DAB [brown] and hematoxylin counterstain.) (A, Courtesy Dr. Valerie Paradis, Beaujon Hospital, Paris, France.)

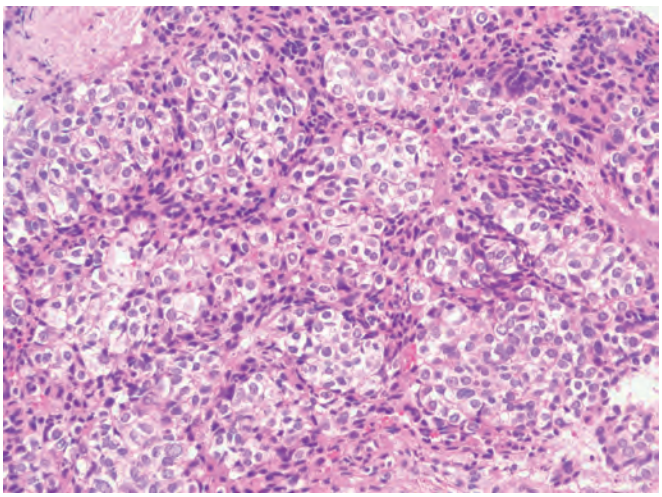

Figure 18.51 Hepatoblastoma. The tumor cells are arranged in sheets and resemble embryonal and fetal hepatocytes.

Clinical Features

Hepatoblastoma usually comes to clinical attention due to abdominal swelling in an asymptomatic infant or child. Symptoms related to liver dysfunction (jaundice, pruritis) are seen in a subset of patients, and about 20% of tumors will have metastasized to the lungs by the time of diagnosis. The tumor is treated with surgical resection and chemotherapy, which has improved outcomes. The overall 5-year survival rate is approximately 80%.

Hepatocellular Carcinoma (HCC)

HCC accounts for approximately 5.4% of all cancers worldwide and is one of the most common cancers in geographic regions with high rates of hepatitis B infection. More than 85% of cases occur in countries in Asia (southeast China, Korea, Taiwan) and sub-Saharan Africa, where chronic HBV infection is common. The peak incidence of HCC in these areas is in young adults between 20 and 40 years of age who acquired hepatitis B virus by maternal-fetal transmission. Encouragingly, the incidence of HCC is decreasing in Asia due to hepatitis B vaccination, but at the same time the incidence is increasing in the Western countries owing to rising rates of hepatitis C infection and metabolic syndrome. For unclear reasons, there is a pronounced male predominance, as high as 8:1, in high-incidence areas.

Pathogenesis

Most HCCs occur in the setting of chronic liver disease with cirrhosis, while 15% to 20% arise in noncirrhotic livers (Fig. 18.52). The most common underlying diseases are chronic viral hepatitis (B and C), metabolic diseases

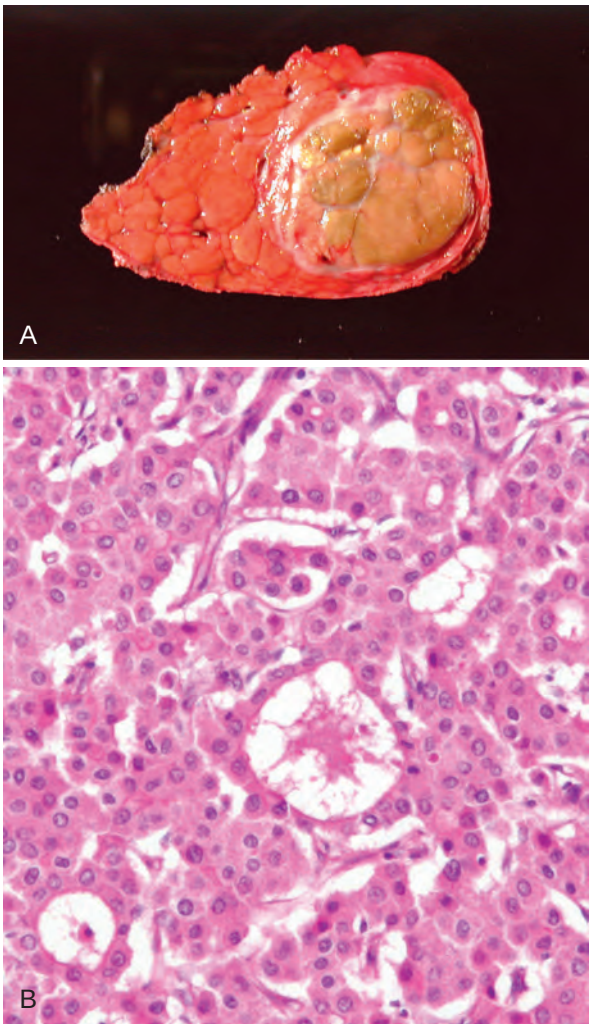

Figure 18.52 Hepatocellular carcinoma. (A) Liver removed at autopsy showing a unifocal neoplasm replacing most of the right hepatic lobe. (B) Malignant hepatocytes growing in distorted versions of normal architecture, including large pseudoacinar spaces (malformed, dilated bile canaliculi) and thickened hepatocyte trabeculae.

such as hereditary hemochromatosis and α_1-antitrypsin deficiency, and alcoholic liver disease. Nonalcoholic fatty liver disease also increases the risk of HCC, even in the absence of cirrhosis. Although details are not clearly worked out, it is believed that the chronic injury, inflammation, and hepatocyte regeneration that are seen in these disorders contribute to the acquisition of driver mutations that lead to HCC development (described later). Part of the risk in Africa and Asia appears to be related to contamination of crops by aflatoxin, a mycotoxin produced by *Aspergillus* species that acts synergistically with alcohol and hepatitis B. The risk for HCC in cirrhosis related to other etiologies, like Wilson disease and chronic biliary diseases, is somewhat lower but still elevated above the population average.

As with other cancers, HCC is associated with complementary sets of driver mutations that lead to the acquisition of cancer hallmarks (Chapter 7). Among the most common are activating mutations in the β-catenin gene (40% of tumors), mutations in the *TERT* (telomerase transcriptase) gene promoter that up-regulate telomerase activity (50% to 60% of tumors), and inactivating mutations in *TP53* (up to 60% of tumors). One unusual histologic subtype that often occurs in adolescents and young adults in the absence of preexisting liver disease, *fibrolamellar HCC,* is strongly associated with a fusion gene that leads to aberrant activity of protein kinase A, an enzyme that participates in a signaling pathway regulated by cAMP.

MORPHOLOGY

Several precursor lesions for HCC have been described. As discussed earlier, in noncirrhotic liver, HCC can arise in hepatocellular adenoma, especially those with β-catenin–activating mutations. In chronic liver disease, the earliest morphologic alterations that appear to correlate with the presence of "at-risk" hepatocytes are called "large cell change" and "small cell change" (Fig. 18.53). **Large cell change** refers to hepatocytes that are larger than normal and often have enlarged, multiple, pleomorphic nuclei, without an increase in nuclear-to-cytoplasmic ratio (see Fig. 18.53A). In **small cell change,** the hepatocytes have a high nuclear-to-cytoplasmic ratio and mild nuclear hyperchromasia and/or pleomorphism (see Fig. 18.53B). More ominous are nodular lesions

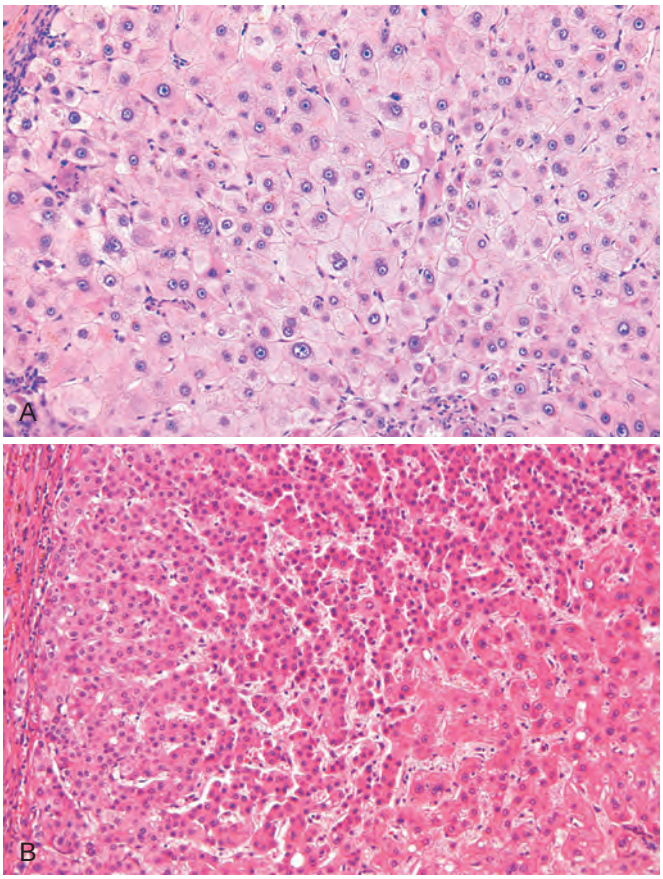

Figure 18.53 Premalignant changes in hepatocytes. (A) Large cell change. Large hepatocytes with large, often atypical nuclei are scattered among normal-size hepatocytes with round, typical nuclei. (B) Small cell change. The abnormal cells have a high nuclear-to-cytoplasmic ratio and are separated by thickened plates. Normal-appearing hepatocytes are in the lower-right corner. (Courtesy Dr. Young Nyun Park, Yonsei Medical College, Seoul, South Korea.)

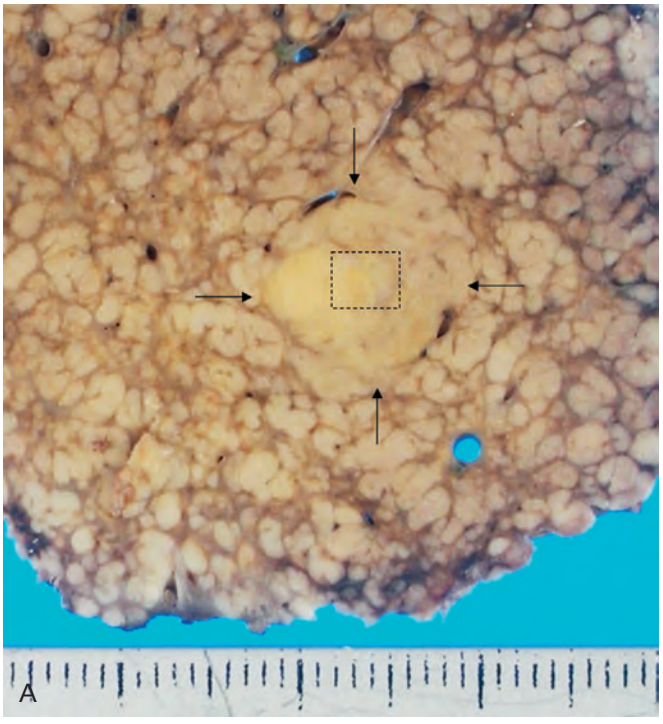
in cirrhotic liver referred to as **dysplastic nodules** (Fig. 18.54), which are often associated with small cell change. Dysplastic nodules differ from adjacent cirrhotic nodules in size, color, and vascularization, show varying degrees of dysplasia, and have clonal aberrations associated with full-blown HCC. Small areas of HCC may sometimes be seen in high-grade dysplastic nodules ("nodule in nodule appearance") (see Fig. 18.54B).

HCC may form a single mass or multiple discrete masses, or it may diffusely infiltrate the liver. They may be pale and yellow due to fatty change or green due to cholestasis. Tumors larger than 2 cm are more likely to be associated with vascular invasion and intrahepatic metastases. Invasion of veins with extension into the portal vein, inferior vena cava, and even the right side of the heart may occur.



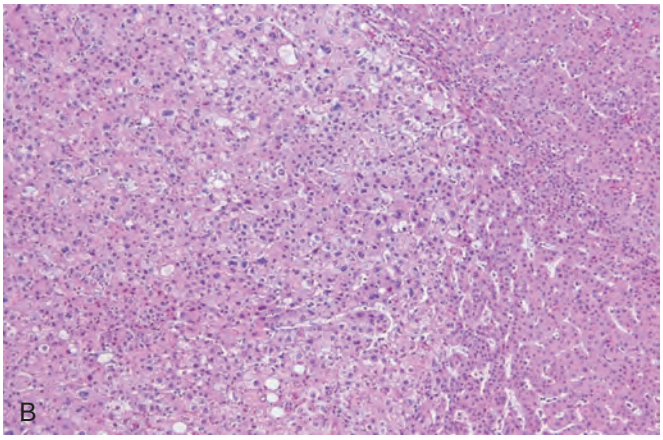


Figure 18.54 (A) Hepatitis C–related cirrhosis with a distinctively large nodule *(arrows)*. Nodule-in-nodule growth suggests an evolving cancer. (B) Histologically, the region with in the box in A shows a well-differentiated hepatocellular carcinoma (HCC) (right side) and a subnodule of moderately differentiated HCC within it (center, left). (Courtesy Dr. Masamichi Kojiro, Kurume University, Kurume, Japan.)

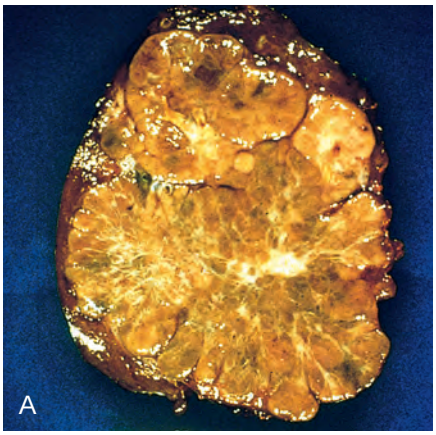

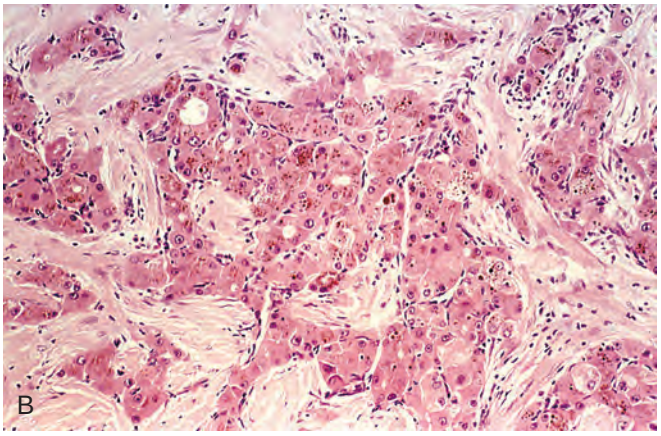

Figure 18.55 Fibrolamellar carcinoma. (A) Resected specimen showing a well-demarcated nodule. (B) Microscopic view showing nests and cords of malignant-appearing, oncocytic hepatocytes separated by dense bundles of collagen.

Microscopically, well and moderately differentiated HCC are composed of cells that resemble normal hepatocytes, while poorly differentiated tumors show marked cytologic atypia. The tumor cells grow in thick plates or trabeculae, pseudoglandular structures with bile plugs, or sheets (see Fig. 18.52B). The distinctive fibrolamellar variant shows a characteristic triad of features: large polygonal cells with granular (oncocytic) cytoplasm due to abundant mitochondria; vesicular nuclei with a prominent nucleolus; and parallel lamellae of dense collagen bundles (Fig. 18.55).

Clinical Features

The clinical manifestations of HCC are nonspecific and include abdominal pain, malaise, fatigue, weight loss, and hepatomegaly. Features of underlying chronic liver disease can be present. Elevated levels of serum α-fetoprotein is a frequent finding in advanced disease, but it is not sensitive as a screening test for early tumors and is not associated with the fibrolamellar variant. Ultrasonography is used for screening high-risk patients such as those with cirrhosis. Computed tomography and magnetic resonance imaging with contrast studies yield highly characteristic findings. Early enhancement of the tumor due to contrast uptake in the arterial phase, followed by rapid venous washout, is considered diagnostic of HCC.

Surgical resection when possible is the treatment of choice for tumors in noncirrhotic livers and in cirrhotic livers with

adequate function. Liver transplantation is considered for HCC in the setting of advanced cirrhosis. Image-guided tumor ablation with alcohol or radiofrequency waves can be done for unresectable tumors or those that do not meet criteria for transplantation. Hematogenous metastases, especially to the lung, tend to occur late in the disease. Lymph node metastases occur in <5% of cases.

Overall outcomes in HCC are poor due to underlying liver disease and the intrinsic resistance of HCC to conventional chemotherapy. The overall 5-year survival rate is 30% for tumor confined to the liver and only 5% to 10% for cases with extrahepatic spread. Outcomes are better for the unusual fibrolamellar variant, with up to 40% of patients surviving 10 years or longer. This is in large part because, in the absence of underlying liver disease, extensive surgical resection is possible thanks to the regenerative capacity of the remaining liver.

Malignant Biliary Tumors

Adenocarcinomas arising from the intrahepatic biliary tree are referred to as *intrahepatic cholangiocarcinoma,* while similar tumor arising from the extrahepatic bile ducts are referred to as *biliary adenocarcinoma*. Intrahepatic cholangiocarcinoma is the most common primary malignant tumor of the liver after HCC. Its incidence is rising in the United States. It accounts for 7.6% of cancer deaths worldwide and 3% of cancer deaths in the United States. It is very common in Southeast Asian countries such as Thailand, Laos, and Cambodia, where liver fluke infestation is endemic.

Pathogenesis

Developmental disorders, like fibropolycystic liver disease, and chronic inflammatory conditions involving the bile ducts, including primary sclerosing cholangitis, infestation by liver flukes (particularly *Opisthorchis* and *Clonorchis* species), and hepatolithiasis are risk factors for biliary tract neoplasms. Chronic liver diseases that predispose to HCC, such as hepatitis B, hepatitis C, and nonalcoholic fatty liver disease, also increase the risk for intrahepatic cholangiocarcinoma. As with HCC, chronic injury, inflammation, and regeneration of biliary epithelium in these conditions may set the stage for acquisition of driver mutations leading to cancer.

Driver mutations in intrahepatic cholangiocarcinoma and extrahepatic biliary adenocarcinoma only partially overlap. *KRAS* mutations are common in both tumors. In addition, subsets of intrahepatic cholangiocarcinoma have distinctive driver mutations in *IDH1* and *IDH2* (isocitrate dehydrogenase) that generate "oncometabolites" (Chapter 7), and in chromatin modifier genes like *BAP1* and *PBRM1*. Fusion genes involving *FGFR2* (fibroblast growth factor receptor 2) are also common. By contrast, in addition to *KRAS* mutations, extrahepatic biliary adenocarcinomas are most likely to have mutations in *TP53* and *SMAD4,* genetic features that are similar to those of pancreatic adenocarcinoma.

(B) Invasive malignant glands in a reactive, sclerotic stroma. (C) Perineural invasion by malignant glands, forming a wreathlike pattern around the central, trapped nerve. (A, Courtesy Dr. Wilson M.S. Tsui, Caritas Medical Centre, Hong Kong.)

MORPHOLOGY

Intrahepatic cholangiocarcinoma usually occurs in the noncirrhotic liver (Fig. 18.56) and typically forms a firm gray-white mass. Extrahepatic biliary adenocarcinomas include perihilar tumors known as **Klatskin tumors,** which are located at the junction of the right and left hepatic ducts. These tumors comprise 60% to 70% of extrahepatic biliary adenocarcinomas, while the remaining 30% to 40% involve the common bile duct. Extrahepatic biliary adenocarcinomas are generally small at diagnosis, as they are detected early due to obstructive features. These tumors may

form a firm nodule in the bile duct wall, may be diffusely infiltrative, or may form papillary lesions.

Microscopically, both intrahepatic and extrahepatic tumors show features of adenocarcinomas. Most are well to moderately differentiated and are arranged in clearly defined glandular/tubular structures lined by malignant epithelial cells embedded in an abundant fibrous stroma (see Fig. 18.56B). Lymphovascular and perineural invasion (see Fig. 18.56C) are common. These tumors are thought to usually arise from premalignant lesions termed biliary intraepithelial neoplasia. Other less common precursor lesions are mucinous cystic neoplasms and intraductal papillary neoplasms.

Clinical Features

Intrahepatic cholangiocarcinoma may be detected incidentally on imaging or may present with a cholestatic picture or symptomatic liver mass, whereas extrahepatic adenocarcinoma typically presents with symptoms related to biliary obstruction. Tumor resection with negative margins and absence of lymph node involvement are favorable factors. Lymph node metastasis is present in 50% to 60% of patients at presentation. Adjuvant chemotherapy is commonly given after resection, but tumor responses are usually transient. The overall prognosis is poor, as recurrences are common, and the 5-year survival rate is 20% to 40% after surgical resection.

Other Primary Hepatic Malignant Tumors

A number of other cancers may arise within the liver. Among the most common or pathogenically interesting are the following:

- *Combined hepatocellular-cholangiocarcinoma* is composed of cells resembling both HCC and intrahepatic cholangiocarcinoma. These tumors have the same risk factors as HCC.
- *Angiosarcoma* is a malignant vascular tumor that is historically associated with exposure to vinyl chloride, arsenic, or the imaging agent Thorotrast (Chapters 9 and 11). This tumor has become rare with reduced exposures to these agents.
- *Epithelioid hemangioendothelioma* is another vascular tumor with intermediate malignant potential and a somewhat better prognosis than angiosarcoma, which is almost uniformly fatal.
- *Primary hepatic lymphoma* is a rare type of liver malignancy. The most common subtype is *diffuse large B-cell lymphoma,* a form of non-Hodgkin lymphoma that frequently occurs at extranodal sites (Chapter 13). Another rare subtype is *hepatosplenic T-cell lymphoma,* most common in young adult males, which has a predilection for growth within the sinusoids of the liver, spleen, and bone marrow.

Metastasis

Involvement of the liver by metastatic malignancy is far more common than primary hepatic neoplasia. Although the most common primary sources are the colon, breast, lung, and pancreas, virtually any may spread to the liver. Typically, multiple nodular metastases are found that often cause striking hepatomegaly and replace much of the normal liver parenchyma. The liver weight can exceed several kilograms. Metastasis may also appear as a single nodule, in which case it may be resected surgically. Always surprising is the extent of metastatic involvement that may be present in the absence of clinical or laboratory evidence of hepatic insufficiency; often the only telltale sign is hepatomegaly. However, with massive destruction of hepatocytes or direct obstruction of major bile ducts, jaundice and other evidence of liver dysfunction inevitably appears.

KEY CONCEPTS

LIVER TUMORS

- The liver is the most common site of metastatic cancers from primary tumors of the colon, lung, and breast.
- Hepatocellular adenomas are benign tumors of neoplastic hepatocytes, which can be subclassified on the basis of different sets of driver mutations.
- HCC is the most common primary hepatic malignant neoplasm, often occurring in the setting of cirrhosis related to chronic liver disease such as chronic hepatitis B and C, autoimmune hepatitis, alcoholic/nonalcoholic fatty liver disease, and hemochromatosis.
- Intrahepatic cholangiocarcinoma and extrahepatic biliary adenocarcinoma show similar histologic features and share risk factors like primary sclerosing cholangitis and infestation by liver flukes such as *Opisthorchis* and *Clonorchis*. These tumors have a poor prognosis.

Gallbladder

As much as 1 L of bile is secreted by the liver per day. Between meals, bile is stored in the gallbladder, where it is concentrated. The adult gallbladder has a capacity of about 50 mL. The organ is not essential for biliary function, since humans do not suffer from indigestion or malabsorption of fat after cholecystectomy.

CONGENITAL ANOMALIES

The gallbladder may be congenitally absent, or there may be gallbladder duplication with conjoined or independent cystic ducts. A longitudinal or transverse septum may create a bilobed gallbladder. Aberrant locations of the gallbladder occur in 5% to 10% of the population, most commonly with partial or complete embedding in the liver substance. A folded fundus is the most common anomaly, creating a *phrygian cap* (Fig. 18.57). *Agenesis* of all or any portion of the hepatic or common bile ducts and hypoplastic narrowing of biliary channels (true "biliary atresia") may also occur. *Choledochal cysts,* described earlier, may be isolated findings in the gallbladder or associated with other cysts in the extrahepatic biliary tree or with fibropolycystic disease.

Figure 18.57 Phrygian cap of the gallbladder; the fundus is folded inward.

CHOLELITHIASIS (GALLSTONES)

More than 95% of biliary tract disease is attributable to gallstones. Gallstones afflict 10% to 20% of adult populations in high income countries. It is estimated that more than 20 million persons in the United States have gallstones, totaling some 25 to 50 tons in weight, leading to more than 700,000 cholecystectomies performed annually at a cost of approximately $6 billion.

Epidemiology

There are two general classes of gallstones: cholesterol stones, containing more than 50% of crystalline cholesterol monohydrate, and pigment stones composed predominantly of bilirubin calcium salts, each with different risk factors. Cholesterol gallstones are more prevalent in the United States and Western Europe (90%) and uncommon in low income countries. The prevalence rates of cholesterol gallstones approach 75% in Native Americans of the Pima, Hopi, and Navajo groups, while pigment stones are rare in these populations. Pigment gallstones, the predominant type of gallstone in non-Western populations, arise primarily in the setting of bacterial infections or parasitic infestations of the biliary tree, and as well as in individuals with diseases that lead to chronic red cell hemolysis.

The major risk factors associated with the development of gallstones are listed in Table 18.11 and are briefly described here:

- *Age and sex.* The prevalence of cholesterol gallstones increases throughout life, but they predominantly affect individuals of middle to older age. Prevalence is higher in females in any region or ethnicity; in Caucasian women, it is about twice as high as in men. Hypersecretion of biliary cholesterol seems to play the major role in both age and gender differences. Significant associations are also seen with metabolic syndrome and obesity.
- *Environmental factors.* Estrogen exposure, including through oral contraceptive use and during pregnancy, increases expression of hepatic lipoprotein receptors and stimulates hepatic HMG-CoA reductase activity, enhancing both cholesterol uptake and biosynthesis, respectively. The net result is excess biliary secretion of cholesterol. Obesity and rapid weight loss are also strongly associated with increased biliary cholesterol secretion.
- *Acquired disorders.* Gallbladder stasis, either neurogenic or hormonal, fosters a local environment that is favorable for both cholesterol and pigment gallstone formation.
- *Hereditary factors.* Genes encoding hepatocyte proteins that transport biliary lipids, known as ATP-binding cassette (ABC) transporters, have associations with gallstone formation. In particular, a common variant of the sterol transporter encoded by the *ABCG8* gene is associated with an increased risk of cholesterol gallstones.

Pathogenesis of Cholesterol Stones

Cholesterol is rendered soluble in bile by forming micelles with bile salts and lecithins, both of which act as detergents. When cholesterol concentrations exceed the solubilizing capacity of bile (supersaturation), cholesterol can no longer remain dispersed and nucleates into solid cholesterol monohydrate crystals. Four conditions appear to contribute to formation of cholesterol gallstones: (1) supersaturation of bile with cholesterol; (2) hypomotility of the gallbladder; (3) accelerated cholesterol crystal nucleation; and (4) hypersecretion of mucus in the gallbladder, which traps the nucleated crystals, leading to accretion of more cholesterol and the appearance of macroscopic stones.

Pathogenesis of Pigment Stones

Pigment gallstones are complex mixtures of insoluble calcium salts of unconjugated bilirubin and inorganic calcium salts. Disorders that are associated with elevated levels of unconjugated bilirubin in bile increase the risk of developing pigment stones. These include chronic hemolytic anemia, severe ileal dysfunction or bypass, and bacterial contamination of the biliary tree, Unconjugated bilirubin is normally a minor component of bile, but it increases when infection of the biliary tract leads to release of microbial β-glucuronidases, which hydrolyze bilirubin glucuronides. Thus, infection of the biliary tract with *Escherichia coli, Ascaris lumbricoides,* or the liver fluke *C. sinensis* increases the

Table 18.11 Risk Factors for Gallstones

Gastrointestinal disorders: ileal disease (e.g., Crohn disease), ileal resection or bypass, cystic fibrosis with pancreatic insufficiency

Figure 18.58 Cholesterol gallstones. The wall of the gallbladder is thickened and fibrotic due to chronic cholecystitis.

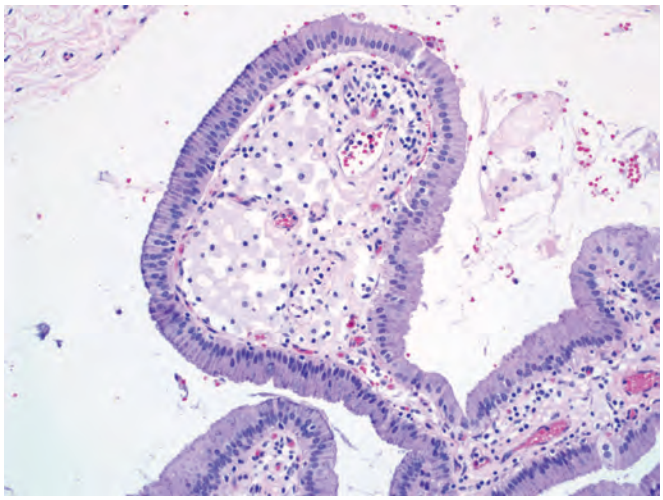

Figure 18.59 Cholesterolosis. Gallbladder mucosa demonstrates lamina propria distended by foamy macrophages.

likelihood of pigment stone formation. In hemolytic anemias, the secretion of conjugated bilirubin into bile increases. About 1% of bilirubin glucuronides are deconjugated in the biliary tree, and in the setting of chronically increased secretion of conjugated bilirubin, a sufficiently large amount of deconjugated bilirubin is generated to allow pigment stones to form.

MORPHOLOGY

Cholesterol stones arise exclusively in the gallbladder and range from 100% pure (which is rare) down to around 50% cholesterol. Pure cholesterol stones are pale yellow, round to ovoid, and have a finely granular, hard external surface (Fig. 18.58), which on transection reveals a glistening radiating crystalline palisade. With increasing proportions of calcium carbonate, phosphates, and bilirubin, the stones take on a gray-white to black color and may be lamellated. Multiple stones are usually present that range up to several centimeters in diameter. Rarely, a very large stone may virtually fill the fundus. Surfaces of stones may be rounded or faceted because of tight apposition to adjacent stones. Stones composed largely of cholesterol are radiolucent; sufficient calcium carbonate is found in 10% to 20% of cholesterol stones to render them radiopaque. The supersaturated cholesterol in bile that forms cholesterol stones may also diffuse into the mucosa and manifest as *cholesterolosis* (Fig. 18.59).

Pigment gallstones are brown to black. In general, black pigment stones are found in sterile gallbladder bile, and brown stones are found in infected large bile ducts. Black stones contain oxidized polymers of calcium salts of unconjugated bilirubin, small amounts of calcium carbonate, calcium phosphate, mucin glycoprotein, and some cholesterol monohydrate crystals. Brown stones contain similar compounds along with some cholesterol and calcium salts of palmitate and stearate. Black stones are rarely greater than 1.5 cm in diameter, are almost invariably present in great number (with an inverse relationship between size and number; Fig. 18.60), and are quite friable. Their contours are usually spiculated and molded. Brown stones tend to be laminated and soft and may have a soaplike or greasy consistency. Approximately 50% to 75% of black stones are radiopaque due to calcium salts, while brown stones, which contain calcium soaps, are radiolucent. Mucin glycoproteins constitute the scaffolding and interparticle cement of all types of stones.

Clinical Features

Gallstones may be present for decades before symptoms develop, and 70% to 80% of patients remain asymptomatic throughout their lives. Asymptomatic individuals convert to being symptomatic at an average rate of up to 4% per year, although the risk diminishes with time. Symptomatic patients with biliary "colic" experience excruciating pain, although this name is a misnomer, as the pain is usually constant, not colicky. Pain often follows a fatty meal that induces gallbladder contraction, which presses a stone against the gall bladder outlet, leading to increased pressure and eventually pain. The pain is localized to right upper quadrant

Figure 18.60 Pigment gallstones. Several faceted black gallstones are present in this otherwise unremarkable gallbladder from a patient with a mechanical mitral valve prosthesis, leading to chronic intravascular hemolysis.

or epigastrium and may radiate to the right shoulder or the back. Inflammation of the gallbladder (cholecystitis, discussed later) in association with stones also generates pain. More severe complications include empyema, perforation, fistula, inflammation of the biliary tree (cholangitis), obstructive cholestasis, and pancreatitis. The larger the calculi, the less likely they are to enter the cystic or common ducts to produce obstruction; it is very small stones, or "gravel," that are most dangerous. Occasionally a large stone may erode directly into an adjacent loop of small bowel, generating intestinal obstruction ("gallstone ileus" or Bouveret syndrome). Gallstones also are associated with an increased risk of gallbladder carcinoma (discussed later).

CHOLECYSTITIS

Inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic. It almost always occurs in association with gallstones. In the United States, cholecystitis is one of the most common indications for abdominal surgery. Its epidemiology closely parallels that of gallstones.

Acute Cholecystitis

Acute cholecystitis is precipitated in 90% of cases by obstruction of the neck of the gallbladder or the cystic duct by a stone. Acute calculous cholecystitis is the primary complication of gallstones and the most common reason for emergency cholecystectomy. Cholecystitis without gallstones *(acalculous cholecystitis)* may also occur in severely ill patients and accounts for the remaining 10% of cases.

Pathogenesis

Acute calculous cholecystitis results from chemical irritation and inflammation of a gallbladder obstructed by stones. The action of mucosal phospholipases hydrolyzes luminal lecithins to toxic lysolecithins. The normally protective glycoprotein mucus layer is disrupted, exposing the mucosal epithelium to the direct detergent action of bile salts. Prostaglandins released within the wall of the distended gallbladder contribute to mucosal and mural inflammation; distention and increased intraluminal pressure compromise blood flow to the mucosa. These events initially occur in the absence of bacterial infection, but later in the course bacterial infection may be superimposed and exacerbate the inflammatory process. Acute calculous cholecystitis is particularly common in diabetic patients who have symptomatic gallstones.

Acute acalculous cholecystitis is thought to result from ischemia. The cystic artery is an end artery without a collateral circulation. Contributing factors may include inflammation and edema of the wall (compromising blood flow) and gallbladder stasis due to accumulation of microcrystals of cholesterol (biliary sludge), viscous bile, and mucus, causing cystic duct obstruction in the absence of stones. It usually occurs in acutely ill patients who are hospitalized for unrelated conditions. Risk factors for acute acalculous cholecystitis include: (1) sepsis with hypotension and multisystem organ failure; (2) immunosuppression; (3) major trauma and burns; (4) diabetes mellitus; and (5) infections.

MORPHOLOGY

In **acute cholecystitis** the gallbladder is usually enlarged and tense, and it may assume a bright red or blotchy, violaceous to green-black discoloration, imparted by subserosal hemorrhages. The serosa is frequently covered by a fibrinous exudate that may be fibrinopurulent in severe cases. There are no specific morphologic differences between acute acalculous and calculous cholecystitis, save the absence of stones in the acalculous form. In **calculous cholecystitis,** an obstructing stone is usually present in the neck of the gallbladder or the cystic duct. The gallbladder lumen contains one or more stones and is filled with cloudy or turbid bile mixed with fibrin, pus, and hemorrhage. When the exudate is virtually pure pus, the condition is referred to as **gallbladder empyema.** In mild cases, the gallbladder wall is thickened, edematous, and hyperemic. In more severe cases, it is transformed into a green-black necrotic organ, termed **gangrenous cholecystitis,** with small-to-large perforations. The invasion of gas-forming organisms, notably clostridia and coliforms, may cause an **acute "emphysematous" cholecystitis.** Histologically, early changes of acute cholecystitis include edema, congestion, and mucosal erosion. Neutrophils are typically sparse, unless there is superimposed infection.

Clinical Features

Individuals with acute calculous cholecystitis usually (but not always) have experienced previous episodes of pain related to the gallbladder. An attack begins with progressive right upper quadrant or epigastric pain that lasts for more than 6 hours. It is frequently associated with mild fever, anorexia, tachycardia, sweating, nausea, and vomiting. Most patients are free of jaundice; the presence of hyperbilirubinemia suggests obstruction of the common bile duct. Mild to moderate leukocytosis may be accompanied by modestly elevated serum alkaline phosphatase. Acute calculous cholecystitis may appear with remarkable suddenness and constitute an acute surgical emergency, or it may present with mild symptoms that resolve without medical intervention. In the absence of medical attention, the attack usually subsides in 7 to 10 days and frequently within 24 hours. However, as many as 25% of patients develop progressively more severe symptoms and require immediate surgical intervention. Recurrence is common in patients who recover without surgery.

Clinical symptoms of acute acalculous cholecystitis tend to be more insidious, since they are obscured by the underlying conditions precipitating the attack. A higher proportion of patients have no symptoms referable to the gallbladder; diagnosis therefore rests on a high index of suspicion. In the severely ill patient, early recognition of the condition is crucial, since failure to do so almost ensures a fatal outcome. As a result of either delay in diagnosis or the disease itself, the incidence of gangrene and perforation is much higher in acalculous cholecystitis than in calculous cholecystitis. In rare instances, primary bacterial infection by agents such as *S. typhi* and staphylococci can give rise to acute acalculous cholecystitis. A more indolent form of acute acalculous cholecystitis may occur in the setting of systemic vasculitis, severe atherosclerotic ischemic disease in the elderly, AIDS (usually related to *Cryptosporidium* infection), or ascending biliary tract infection.

Chronic Cholecystitis

Chronic cholecystitis may be a sequel to repeated bouts of mild to severe acute cholecystitis, but in many instances it develops in the apparent absence of antecedent attacks. Since it is associated with cholelithiasis in more than 90% of cases, the at-risk patient population is the same as that for gallstones. The evolution of chronic cholecystitis is obscure; it is not clear that gallstones play a direct role in the initiation of inflammation or the development of pain, particularly since chronic acalculous cholecystitis shows symptoms and histology similar to those of the calculous form. Rather, supersaturation of bile predisposes to both chronic inflammation and, in most instances, stone formation. Microorganisms, usually *E. coli* and enterococci, are cultured from the bile in about one-third of cases. Unlike acute calculous cholecystitis, obstruction of gallbladder outflow is not a prerequisite.

MORPHOLOGY

The morphologic changes in chronic cholecystitis are extremely variable and sometimes minimal. The serosa is usually smooth and glistening but may be dulled by **subserosal fibrosis.** Dense fibrous adhesions may be present that represent the sequelae of prior acute inflammation. On sectioning, the wall is variably thickened and has an opaque gray-white appearance. In uncomplicated cases, the lumen contains green-yellow, mucoid bile and usually stones. The mucosa itself is generally preserved.

On histologic examination, the degree of inflammation is variable. In the mildest cases, only scattered lymphocytes, plasma cells, and macrophages are found in the mucosa and in the subserosal fibrous tissue (Fig. 18.61A). In more advanced cases, there is marked subepithelial and subserosal fibrosis, accompanied by mononuclear cell infiltration. Reactive proliferation of the mucosa and fusion of the mucosal folds may give rise to buried crypts of epithelium within the gallbladder wall. Outpouchings of the mucosal epithelium through the wall **(Rokitansky-Aschoff sinuses)** may be quite prominent (see Fig. 18.61B).

In rare instances, there is extensive dystrophic calcification of the gallbladder wall **(porcelain gallbladder).** More often, there is complete replacement of the gallbladder wall and mucosa by dense fibrosis **(hyalinizing cholecystitis),** with or without calcification. This change is notable for being associated with an increased incidence of gallbladder carcinoma (discussed later). In **xanthogranulomatous cholecystitis,** the gallbladder has a massively thickened wall and is shrunken, nodular, and chronically inflamed with foci of necrosis and hemorrhage. It is triggered by rupture of Rokitansky-Aschoff sinuses into the wall of the gallbladder followed by an accumulation of macrophages that have ingested biliary phospholipids. Such lipid-containing cells with foamy cytoplasm are called xanthoma cells, hence the name of this condition. Finally, an atrophic, chronically obstructed, often dilated gallbladder may contain only clear secretions, a condition known as **hydrops of the gallbladder.** Other rare forms of chronic cholecystitis include IgG_4-related sclerosing cholecystitis, another manifestation of IgG_4-related fibrosing disease.

Clinical Features

Chronic cholecystitis does not have the striking manifestations of the acute forms and is usually characterized by recurrent attacks of either steady epigastric or right upper quadrant pain. Nausea, vomiting, and intolerance for fatty foods are frequent accompaniments.

Diagnosis of both acute and chronic cholecystitis is important because of the following complications:

- *Bacterial superinfection* with cholangitis or sepsis
- *Gallbladder perforation* and local abscess formation
- *Gallbladder rupture* with diffuse peritonitis
- *Biliary enteric (cholecystenteric) fistula,* with drainage of bile into adjacent organs, entry of air and bacteria into the biliary tree, and potentially, gallstone-induced intestinal obstruction (ileus)
- *Aggravation of preexisting medical illness,* with cardiac, pulmonary, renal, or liver decompensation

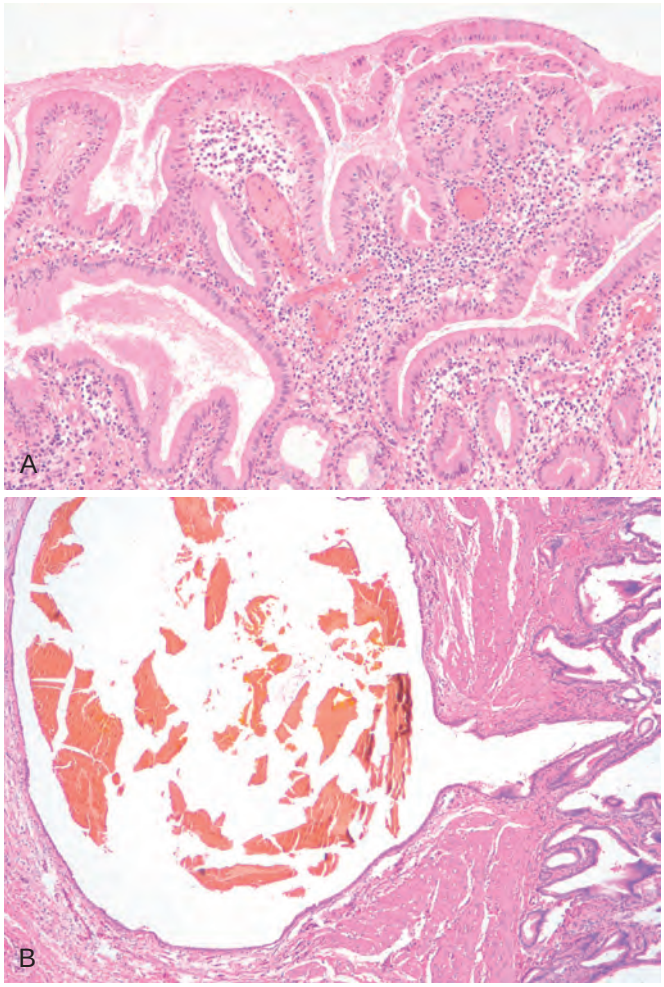

Figure 18.61 Chronic cholecystitis. (A) The gallbladder mucosa is infiltrated by inflammatory cells. (B) Outpouching of the mucosa through the wall forms Rokitansky-Aschoff sinus (contains bile).

GALLBLADDER CARCINOMA

Carcinoma of the gallbladder is the most common malignancy of the extrahepatic biliary tract. Approximately 6000 new cases of gallbladder cancer are diagnosed each year in the United States. There are wide variations in the incidence of gallbladder cancer worldwide, with regions

such as Chile, Bolivia, and Northern India harboring the highest numbers of cases. Even within the United States, areas with large Native American or Hispanic populations, such as the southwest, have a higher incidence of gallbladder cancer than the rest of the country. Gallbladder cancer is at least twice as common in women as in men; this gender disparity can be several-fold greater in regions of highest incidence. The overwhelming majority of patients are diagnosed at an advanced, surgically unresectable, stage, and the mean 5-year survival rate for affected patients is less than 10%.

Pathogenesis

The most important risk factor for gallbladder cancer (besides gender and ethnicity) is gallstones, which are present in 95% of cases. However, it should be noted that only 1% to 2% of patients with gallstones develop gallbladder cancer. In Asia, chronic bacterial or parasitic infections have been implicated as risk factors, and the coexistence of gallstones with gallbladder cancer is much lower. Nonetheless, the common thread that ties gallstones or chronic infections together with gallbladder cancer is chronic inflammation. Relatively common driver mutations include gain-of-function aberrations affecting members of the EGF receptor gene family (including *HER2*) and genes enocding downstream signaling components such as RAS, and loss-of-function mutations in the *TP53* tumor suppressor gene, which are present in up to one-half of tumors. As is typical of *TP53*-mutated cancers, most gallbladder carcinomas exhibit aneuploidy.

MORPHOLOGY

Several precursor lesions of gallbladder carcinoma have been described, indicating that (as is typical of carcinoma generally) full-blown cancer likely arises from a lengthy stepwise process. These precursors include flat in situ lesions with varying degrees of dysplasia, mass-forming adenoma-like lesions termed intracholecystic papillary tubular neoplasm, and intestinal metaplasia. Gallbladder cancers are mainly adenocarcinomas and are most often detected in the fundus (Fig. 18.62). They may produce a firm, poorly circumscribed mass or may diffusely infiltrate the wall of gallbladder, simulating the gross appearance of chronic cholecystitis. Microscopically, they are usually characterized by the presence of glands embedded in desmoplastic stroma, but in some cases cytologic atypia and stromal response are minimal; in these instances, identification of perineural and vascular invasion help establish the diagnosis. With progression, direct extension into other organs, fistula formation, peritoneal and biliary spread, and metastasis to the liver and portahepatic lymph nodes occur. Rarely, other types of malignant tumors arise primarily within the gallbladder, including neuroendocrine tumors, squamous cell carcinoma, and sarcomas.

Clinical Features

Preoperative diagnosis of carcinoma of the gallbladder is the exception rather than the rule, occurring in fewer than 20% of patients. Presenting symptoms are insidious and typically indistinguishable from those associated with cholelithiasis, including abdominal pain, jaundice, anorexia, and nausea and vomiting. If the tumor is detected prior to invasion and spread, such as when carcinoma is an incidental finding during surgery for symptomatic gallstones or acute cholecystitis, cure by surgical resection is possible. However, most patients have advanced disease at diagnosis, and the overall prognosis for such patients is poor, even with apparently complete resection of evident tumor. Adjuvant chemotherapy is often offered to such patients but is not curative, and most patients eventually succumb to their disease.

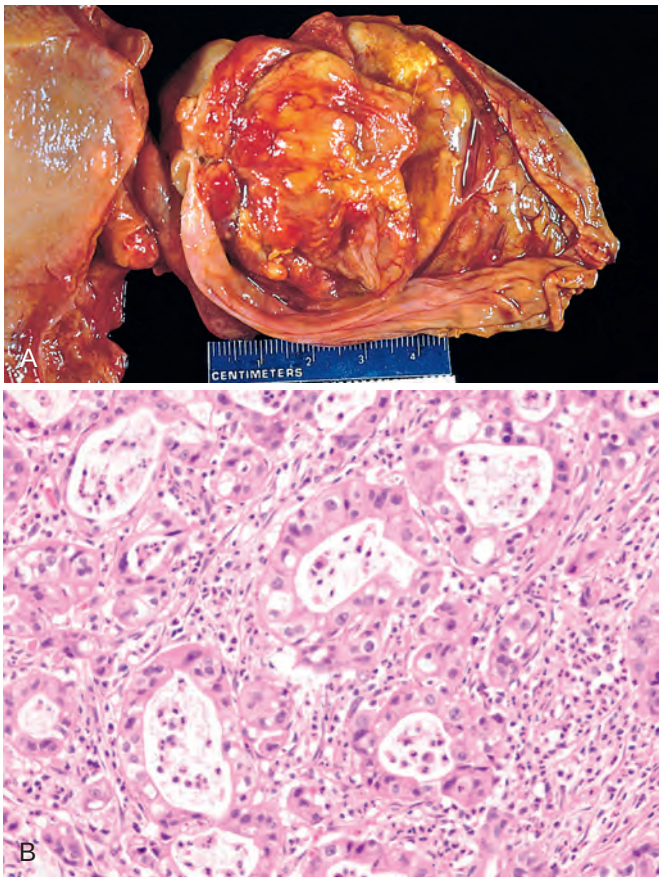

Figure 18.62 Gallbladder adenocarcinoma. (A) The opened gallbladder contains a large, exophytic tumor that virtually fills the lumen. (B) Malignant glands are seen infiltrating a densely fibrotic gallbladder wall.

KEY CONCEPTS

DISEASES OF THE GALLBLADDER

- Gallbladder diseases include cholelithiasis, acute and chronic cholecystitis, and gallbladder cancer.
- Gallstones are common in Western countries. The great majority are cholesterol stones. Pigmented stones containing bilirubin and calcium are most common in Asian countries.
- Risk factors for the development of cholesterol stones are advancing age, female gender, estrogen use, obesity, and heredity.
- Cholecystitis almost always occurs in association with cholelithiasis, although in about 10% of cases it occurs in the absence of gallstones. Gallstones are also a risk factor for gallbladder cancer.

- Acute calculous cholecystitis is the most common reason for emergency cholecystectomy.
- Gallbladder cancers are associated with gallstones in the vast majority of cases. Typically, they are detected late because of nonspecific symptoms and hence carry a poor prognosis.

CHAPTER 19

The Pancreas

Anirban Maitra[a]

CHAPTER CONTENTS

The adult pancreas is a transversely oriented retroperitoneal organ extending from the C-loop of the duodenum to the hilum of the spleen (Fig. 19.1A). Although the organ gets its name from the Greek *pankreas* ("all flesh"), it is in fact a complex lobulated organ with distinct exocrine and endocrine components.

The *exocrine pancreas* constitutes 80% to 85% of the organ and is composed of acinar cells. These pyramidally shaped epithelial cells contain membrane-bound granules rich in proenzymes (zymogens), including trypsinogen, chymotrypsinogen, procarboxypeptidase, proelastase, kallikreinogen, and prophospholipase A and B, all of which contribute to digestion. Upon secretion, these proenzymes and enzymes are carried by a series of ductules and ducts to the duodenum, where they are activated by proteolytic cleavage (described later).

The *endocrine pancreas* is composed of about 1 million endocrine cell clusters, the islets of Langerhans, that are scattered throughout the gland. Islet cells secrete insulin, glucagon, somatostatin, and pancreatic polypeptide. Although they constitute only 1% to 2% of the organ mass, the hormones released by the islet cells are essential regulators of systemic metabolism. Diseases of the endocrine pancreas are described in detail in Chapter 24.

CONGENITAL ANOMALIES

The complex process by which the dorsal and ventral pancreatic primordia fuse during pancreatic development is imperfect, giving rise to variation in pancreatic anatomy. The pancreas normally arises from the fusion of dorsal and ventral outpouchings of the foregut. The body, the tail, and the superior/anterior aspect of the head of the pancreas, as well as the accessory duct of Santorini, are derived from the dorsal primordium. Typically, the ventral primordium gives rise to the posterior/inferior part of the head of the pancreas and drains through the main pancreatic duct into the papilla of Vater.

Pancreas Divisum. **Pancreas divisum is the most common congenital anomaly of the pancreas** with an incidence of 3% to 10%. In most individuals, the main pancreatic duct (the duct of Wirsung) joins the common bile duct just proximal to the papilla of Vater, and the accessory pancreatic duct (the duct of Santorini) drains into the duodenum through a separate minor papilla (see Fig. 19.1A). Pancreas divisum is caused by a failure of fusion of the fetal duct systems of the dorsal and ventral pancreatic primordia. As a result, in this anatomic variant the bulk of the pancreas (formed by the dorsal pancreatic primordium) drains into the duodenum through the small-caliber minor papilla (Fig. 19.1B), while the duct of Wirsung drains only a small portion of the head of the gland through the papilla of Vater. Although controversial, it has been suggested that inadequate drainage of the pancreatic secretions through the minor papilla, especially when combined with genetic defects that also increase susceptibility to pancreatitis (described later), predisposes individuals with pancreatic divisum to chronic pancreatitis.

Annular Pancreas. Annular pancreas is a band-like ring of normal pancreatic tissue that completely encircles the second portion of the duodenum. Annular pancreas can produce duodenal obstruction.

Ectopic Pancreas. Pancreatic tissue that is aberrantly situated, or ectopic, is found in about 2% of careful routine postmortem examinations. The favored sites for ectopia are

[a]I am grateful for the immense contributions of Ralph H. Hruban and Christine A. Iacobuzio-Donahue, who authored this chapter in the prior edition of this book. Many of the photomicrographs used in this chapter are contributed by Dr. Hruban.

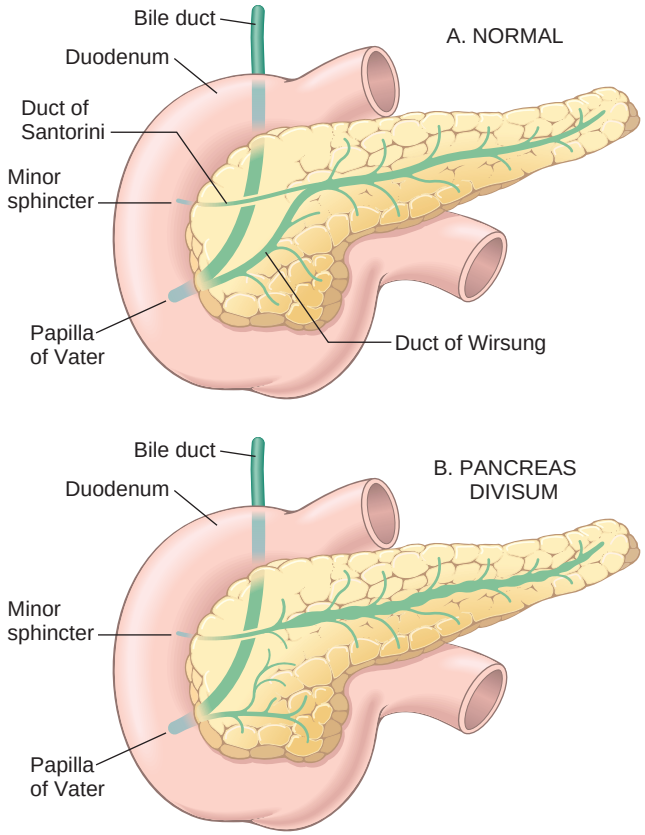

Figure 19.1 Pancreatic ductal anatomy. (A) Normal ductal anatomy. (B) Ductal anatomy in pancreatic divisum. (Modified from Gregg JA, et al: Pancreas divisum: results of surgical intervention, *Am J Surg* 145:488–492, 1983.)

the stomach and duodenum, followed by the jejunum, Meckel diverticula, and ileum. Although usually incidental findings, these embryologic rests, composed of normal-appearing pancreatic acini, glands, and sometimes islets of Langerhans, may cause pain from localized inflammation or may incite mucosal bleeding.

Agenesis. Very rarely the pancreas fails to develop (agenesis). Some cases of agenesis are caused by homozygous germline mutations involving *PDX1,* a gene encoding a homeobox transcription factor that is critical for pancreatic development.

PANCREATITIS

Pancreatitis is divided into two forms, acute and chronic, each with its own characteristic pathologic and clinical features; both are initiated by injuries that lead to autodigestion of the pancreas by its own enzymes. Under normal circumstances, several factors protect the pancreas from autodigestion.

- *Most digestive enzymes are synthesized as inactive proenzymes* (zymogens) and packaged within secretory granules.
- *Proenzymes are typically activated by trypsin,* which itself is activated by duodenal enteropeptidase (enterokinase) in the small bowel; as a result, intrapancreatic activation of proenzymes is normally minimal.
- *Acinar and ductal cells secrete trypsin inhibitors,* including serine protease inhibitor Kazal type 1 (SPINK1), which further limit intrapancreatic trypsin activity.

Pancreatitis occurs when these protective mechanisms are disrupted or overwhelmed. Acute attacks may range from mild and self-limited to life-threatening events. Recurrent or persistent pancreatitis may lead to permanent loss of pancreatic function.

Acute Pancreatitis

Acute pancreatitis is characterized by reversible pancreatic parenchymal injury and inflammation and has many causes, including toxic exposures (e.g., alcohol), pancreatic duct obstruction (e.g., biliary calculi), inherited genetic defects, vascular injury, and infections. Acute pancreatitis is relatively common with an annual incidence in Western countries of 10 to 20 cases per 100,000 people. Biliary tract disease and alcoholism account for approximately 80% of these cases (Table 19.1). The proportion of cases caused by excessive alcohol intake varies from 65% in the United States to 20% in Sweden to 5% or less in southern France and the United Kingdom. The male-to-female ratio is 6:1 in those with alcoholism and 1:3 in patients with biliary tract disease. Gallstones are present in 35% to 60% of acute pancreatitis cases and cause "gallstone pancreatitis" in about 5% of patients with gallstones.

Pathogenesis

Acute pancreatitis results from inappropriate release and activation of pancreatic enzymes that, in turn, destroy

Table 19.1 Etiologic Factors in Acute Pancreatitis

Metabolic

pancreatic tissue and elicit an acute inflammatory reaction. Inappropriate trypsin activation within the pancreas can activate other proenzymes such as prophospholipase and proelastase, which degrade fat cells and damage the elastic fibers of blood vessels, respectively. Once tissue damage commences, trypsin can also directly or indirectly activate factors found in the blood, including components of the coagulation, complement, kallikrein, and fibrinolytic pathways (Chapters 3 and 4). The resulting inflammation and small-vessel thrombosis causes further damage to acinar cells, amplifying intrapancreatic enzyme activation.

The triggers that cause intrapancreatic enzyme activation in sporadic acute pancreatitis remain a topic of investigation, but there is evidence for at least three major initiating events (Fig. 19.2):

- *Pancreatic duct obstruction* is most commonly caused by gallstones and biliary sludge but can also stem from periampullary neoplasms (e.g., pancreatic cancer), choledochoceles (congenital cystic dilation of the common bile duct), parasites (particularly *Ascaris lumbricoides* and *Clonorchis sinensis*), and possibly pancreas divisum. Obstruction raises intrapancreatic ductal pressure and leads to accumulation of enzyme-rich fluid within the interstitium. Unlike other pancreatic enzymes, lipase is secreted in an active form and has the potential to cause local fat necrosis. The death of adipocytes is hypothesized to produce "danger" signals locally that are sensed by pancreatic stellate cells and leukocytes, which release proinflammatory mediators that promote microvascular leak and development of interstitial edema. Edema may further compromise local blood flow, causing vascular insufficiency and ischemic injury to acinar cells.
- *Primary acinar cell injury* leads to release of digestive enzymes, inflammation, and tissue autodigestion. Acinar cells can be damaged by a variety of endogenous, exogenous, and iatrogenic insults. Many of these result in oxidative stress and generation of intracellular free radicals that lead to membrane lipid oxidation and transcription factor activation. The latter include AP1 and NF-κB, which induce expression of chemokines that attract mononuclear cells. Increased calcium flux is another important trigger for inappropriate enzyme activation. Calcium has a key role in trypsin regulation. When calcium levels are low, trypsin tends to cleave and inactivate itself, but this autoinhibition is abrogated and trypsin autoactivation is favored when calcium levels are increased. Any factor causing increased calcium within acinar cells may therefore trigger excessive trypsin activation. Examples include inherited abnormalities that affect calcium levels (Table 19.2).

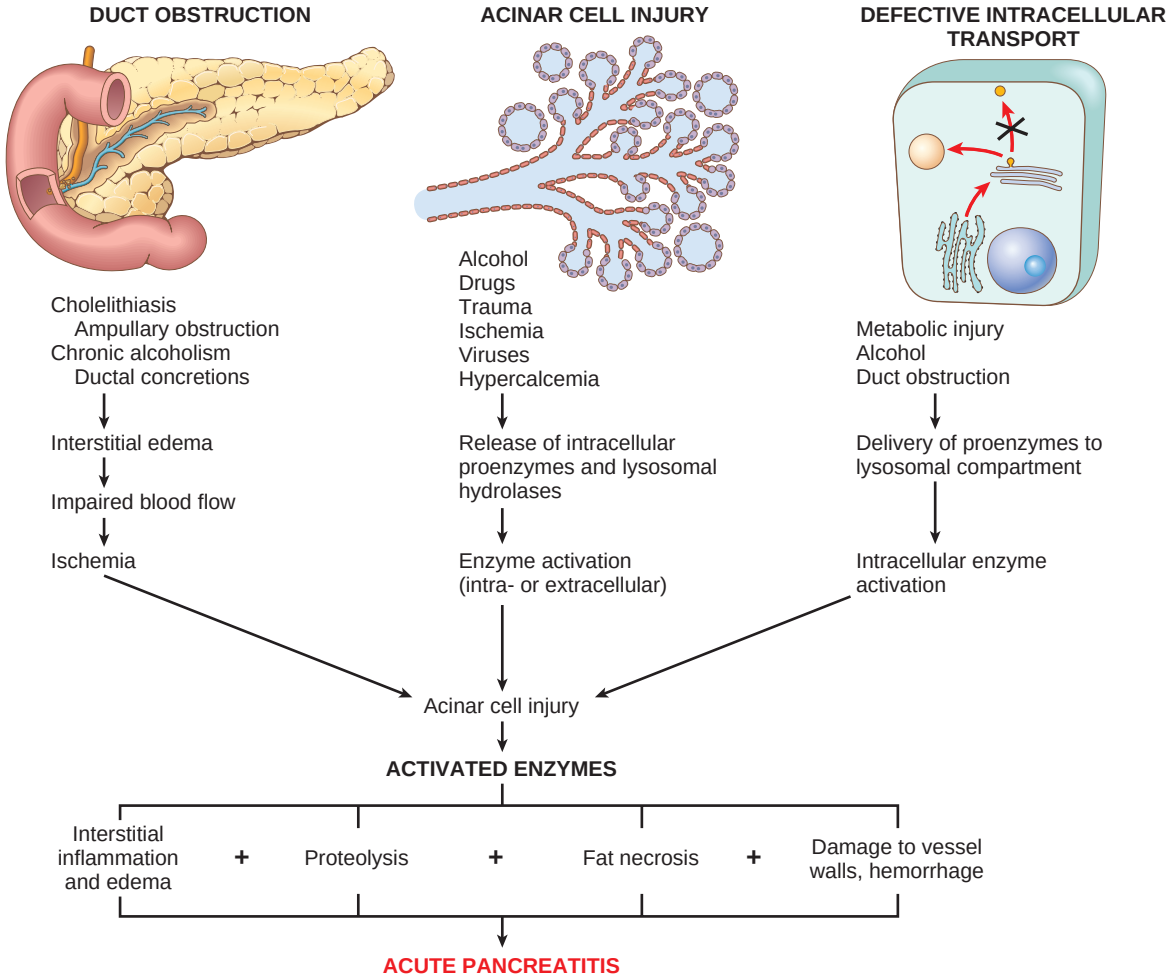

Figure 19.2 Three proposed pathways in the pathogenesis of acute pancreatitis.

Table 19.2 Inherited Predisposition to Pancreatitis

Gene (Chromosome Location)	Protein Product	Function
CFTR (7q31)	Cystic fibrosis transmembrane conductance regulator	Epithelial anion channel. Loss-of-function mutations alter fluid pressure and limit bicarbonate secretion, leading to inspissation of secreted fluids and duct obstruction
PRSS1 (7q34)	Serine protease 1 (trypsinogen 1)	Cationic trypsin. Gain-of-function mutations prevent self-inactivation of trypsin
SPINK1 (5q32)	Serine peptidase inhibitor, Kazal type 1	Inhibitor of trypsin. Mutations cause loss-of-function, increasing trypsin activity
CASR (3q13)	Calcium-sensing receptor	Membrane-bound receptor that senses extracellular calcium levels and controls luminal calcium levels. Mutations may alter calcium concentrations and activate trypsin
CTRC (1p36)	Chymotrypsin C (caldecrin)	Degrades trypsin, protects the pancreas from trypsin-related injury
CPA1 (7q32)	Carboxypeptidase A1	Exopeptidase involved in regulating zymogen activation

- *Defective intracellular transport of proenzymes within acinar cells.* In normal acinar cells, digestive enzymes and lysosomal hydrolases are transported via separate pathways. In animal models of acinar injury, pancreatic proenzymes, of which the *cathepsin* family of hydrolases is most important, are aberrantly delivered to lysosomes. The hydrolases then activate pancreatic proenzymes that disrupt lysosomal membranes, ultimately leading to release of activated enzymes. It is not clear if this mechanism is relevant to human acute pancreatitis.

Two factors have been proposed to contribute to alcohol-indcuced pancreatitis: duct obstruction and acinar cell damage. Alcohol consumption transiently increases contraction of the sphincter of Oddi (the muscle at the papilla of Vater), and chronic alcohol ingestion results in the secretion of protein-rich pancreatic fluid that is prone to form inspissated protein plugs that obstruct small pancreatic ducts. Within acinar cells, alcohol-induced oxidative stress may generate free radicals, leading to membrane lipid oxidation and activation of the proinflammatory transcription factors AP1 and NF-κB. Oxidative stress also may promote fusion of lysosomes and zymogen granules and increase intracellular calcium levels, possibly through mitochondrial damage, thereby promoting the intracellular activation of trypsin and other digestive enzymes. Nevertheless, it should be noted that most alcoholics never develop pancreatitis and those who do usually do so after many years of alcohol abuse. Thus, key aspects of the pathophysiology of alcohol-induced pancreatitis remain obscure.

Other proven or suspected triggers of acute pancreatitis in sporadic cases include (see Table 19.1):

- *Metabolic disorders* such as hypertriglyceridemia and hypercalcemic states, as in hyperparathyroidism.
- *Genetic lesions,* as described below.
- *Medications.* Hundreds of drugs have been anecdotally linked to acute pancreatitis, but only about 50 have a definite association. The latter include azathioprine, angiotensin-converting enzyme (ACE) inhibitors, statins, and antidiabetic drugs such as glucagon-like peptide-1 (GLP-1) agonists and dipeptidyl peptidase-4 (DPP-4) inhibitors.
- *Traumatic acinar cell injury,* by either blunt abdominal trauma or iatrogenic injury during surgery or endoscopic retrograde cholangiopancreatography.
- *Ischemic acinar cell injury* due to shock, vascular thrombosis, embolism, or vasculitis.
- *Infections,* including mumps, can lead to acute pancreatitis through direct acinar cell injury,

Hereditary factors are increasingly recognized as causes of pancreatitis. Affected individuals have recurrent attacks of severe acute pancreatitis, which often begin in childhood, and can ultimately lead to chronic pancreatitis. **The feature shared by most forms of hereditary pancreatitis is a defect that increases or sustains the activity of trypsin** (see Table 19.2). Three genes implicated in hereditary pancreatitis deserve special note: *PRSS1, SPINK1,* and *CFTR*. Most hereditary cases are due to gain-of-function mutations in the trypsinogen gene (known as *PRSS1*). Some of these *PRSS1* gene mutations make trypsin resistant to self-inactivation, abrogating an important negative feedback mechanism; other mutations make trypsinogen more prone to proteolytic activation. Hereditary pancreatitis associated with trypsinogen mutation has an autosomal dominant mode of inheritance, as is typically true of disorders associated with gain-of-function mutations.

Hereditary pancreatitis can also be caused by loss-of-function mutations in *SPINK1,* a gene encoding a trypsin inhibitor. Because one functional copy of *SPINK1* produces sufficient inhibitor to maintain adequate trypsin control, this form of hereditary pancreatitis has an autosomal recessive mode of inheritance.

As discussed in detail in Chapter 10, cystic fibrosis is caused by mutations in the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene that encodes an apical chloride channel. Loss of *CFTR* leads to abnormal secretions that promote protein plugging, duct obstruction, and the development of pancreatitis. Disease can occur in those with homozygous and even heterozygous *CFTR* gene mutations, particularly in patients who also have *SPINK1* mutations.

Of note, patients with *PRSS1*-associated hereditary pancreatitis have a 40% lifetime risk of developing pancreatic cancer, yet another example of the nefarious association between neoplasia and chronic tissue injury and inflammation.

MORPHOLOGY

The morphology of acute pancreatitis ranges from limited inflammation and edema to extensive necrosis and hemorrhage. The basic alterations are **(1) microvascular leak and edema, (2) fat necrosis, (3) acute inflammation, (4) damage, including autodigestion, of pancreatic parenchyma, and (5) blood vessel destruction with interstitial hemorrhage.** The extent of each of these depends on the duration and severity of disease.

In more limited forms of **acute interstitial pancreatitis,** histologic alterations are limited to mild inflammation, interstitial edema, and focal fat necrosis within the pancreas and the peripancreatic fat (Fig. 19.3). Fat necrosis, triggered by lipase activity, leads to **saponification,** a process in which fatty acids combine with calcium to form insoluble calcium soaps that impart a granular blue microscopic appearance to surviving fat cells (Chapter 2).

In **acute necrotizing pancreatitis,** acini, ducts, and even islets undergo necrosis. In the most severe form, **hemorrhagic pancreatitis,** extensive parenchymal necrosis is accompanied by intraparenchymal hemorrhage due to vascular injury. This imparts a red-black color with interspersed foci of yellow-white, chalky fat necrosis (Fig. 19.4). Fat necrosis may also occur in the omentum and the mesentery of the bowel adjacent to the pancreas and beyond the abdominal cavity, such as in the subcutaneous fat, as a result of systemic lipase release. The peritoneal cavity typically contains a serous, slightly turbid, brown-tinged fluid with fat globules that reflect digestion of adipose tissue.

Clinical Features

Abdominal pain is the cardinal manifestation of acute pancreatitis. Characteristically the pain is constant, intense, and referred to the upper or mid back and, occasionally, the left shoulder. The severity ranges from mild discomfort to incapacitating pain. Anorexia, nausea, and vomiting are common. Elevated plasma levels of amylase and lipase support the diagnosis of acute pancreatitis, as does the exclusion of other causes of abdominal pain.

Severe acute pancreatitis is a medical emergency. Patients usually present with an acute abdomen and systemic findings caused by the release of toxic enzymes, cytokines, and other mediators into the circulation. These activate a systemic inflammatory response, resulting in leukocytosis, disseminated intravascular coagulation, edema, and acute respiratory distress syndrome. Shock, due to the systemic inflammatory response syndrome (Chapter 4), and acute renal tubular necrosis may occur.

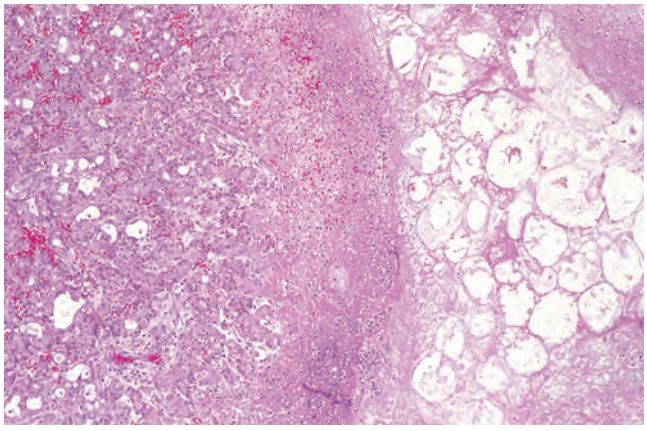

Figure 19.3 The microscopic field shows a region of fat necrosis on the right and focal pancreatic parenchymal necrosis (center).

Figure 19.4 The pancreas has been sectioned longitudinally to reveal dark areas of hemorrhage in the head of the pancreas and a focal area of pale fat necrosis in the peripancreatic fat (upper left).

Laboratory findings include elevation of serum amylase and lipase levels during the first 4 to 12 hours following the onset of pain. Serum lipase is the most specific and sensitive marker of acute pancreatitis, as serum amylase has a short half-life and may return to normal in 3 to 5 days, whereas lipase levels remain elevated for 8 to 14 days. Glycosuria occurs in 10% of cases, and hypocalcemia may result from saponification of necrotic fat. Direct visualization of the enlarged inflamed pancreas by computed tomography (CT) scanning is useful in the diagnosis of pancreatitis.

Treatment centers on "resting" the pancreas by total elimination of oral intake and supportive therapy with intravenous fluids and analgesia. Most individuals with acute pancreatitis recover fully but about 5% with severe acute pancreatitis die in the first week of illness. Acute respiratory distress syndrome and acute renal failure are ominous complications. Possible sequelae include sterile pancreatic abscesses and pancreatic pseudocysts. In 40% to 60% of patients with acute necrotizing pancreatitis the acellular debris becomes infected, usually by gram-negative organisms from the gut, further complicating the clinical course. Systemic organ failure and pancreatic necrosis are both adverse prognostic indicators.

KEY CONCEPTS

ACUTE PANCREATITIS

- Acute pancreatitis is a form of reversible pancreatic parenchymal injury associated with inflammation.
- Acute pancreatitis may be caused by:
  - Excessive alcohol intake
  - Pancreatic duct obstruction (e.g., gallstones)
  - Genetic factors (e.g., *PRSS1*, *SPINK1*, *CFTR*)
  - Traumatic injuries
  - Medications
  - Infections (e.g., mumps or coxsackievirus)
  - Metabolic disorders leading to hypercalcemia
  - Ischemia

- The key feature common to all these causes is that they promote inappropriate activation of digestive enzymes within the pancreas.
- Clinical features include acute abdominal pain, systemic inflammatory response syndrome, and elevated serum lipase and amylase levels.

Chronic Pancreatitis

Chronic pancreatitis is defined as prolonged inflammation of the pancreas associated with irreversible destruction of exocrine parenchyma, fibrosis, and, in the late stages, loss of endocrine parenchyma. The prevalence of chronic pancreatitis is between 0.04% and 5%; most affected patients are middle-aged males. **The most common cause of chronic pancreatitis is long-term alcohol use.** In addition to alcohol, chronic pancreatitis has been associated with the following conditions:

- Long-standing *obstruction* of the pancreatic duct by calculi or neoplasms
- *Autoimmune injury*
- *Hereditary factors,* as discussed above; up to 25% of chronic pancreatitis has a genetic basis

Pathogenesis

Chronic pancreatitis often follows repeated episodes of acute pancreatitis. It has been proposed that acute pancreatitis initiates a sequence of perilobular fibrosis, duct distortion, and altered secretions that, as a result of recurrent injury, leads to loss of exocrine parenchyma and fibrosis.

Chronic pancreatic injury of any cause leads to local production of inflammatory mediators that promote fibrosis and acinar cell loss. While there is overlap between the cytokines released during chronic and acute pancreatitis, fibrogenic factors tend to predominate in chronic pancreatitis. These fibrogenic cytokines, including transforming growth factor β (TGFβ) and platelet-derived growth factor (PDGF), induce activation and proliferation of pancreatic stellate cells (periacinar myofibroblasts), collagen deposition, and fibrosis (Fig. 19.5).

Autoimmune pancreatitis is a pathogenically distinct form of chronic pancreatitis that comes in two distinct forms, each with its own characteristic histopathology. Autoimmune pancreatitis type 1 is associated with the presence of immunoglobulin G4 (IgG4)–secreting plasma cells in the pancreas and is one manifestation of a systemic IgG-related disease (Chapter 6). In contrast, autoimmune pancreatitis type 2 is restricted to the pancreas with the exception of a subset of patients with ulcerative colitis. Both variants of autoimmune pancreatitis may mimic pancreatic carcinoma, including presentation as a "mass lesion" in the pancreatic head on imaging. Autoimmune pancreatitis, which responds to steroid therapy, is therefore important to distinguish from neoplasia.

MORPHOLOGY

Chronic pancreatitis is characterized by parenchymal fibrosis, acinar atrophy and dropout, and variable ductal dilation (Fig. 19.6A). Grossly, the gland is hard, sometimes with visibly dilated ducts containing calcified concretions. These changes are typically accompanied by a histologically evident chronic inflammatory infiltrate that surrounds lobules and ducts. Acinar loss is a constant feature, but there is usually relative sparing of the islets of Langerhans, which become embedded in the sclerotic tissue and may fuse and appear enlarged. Ductal epithelium may

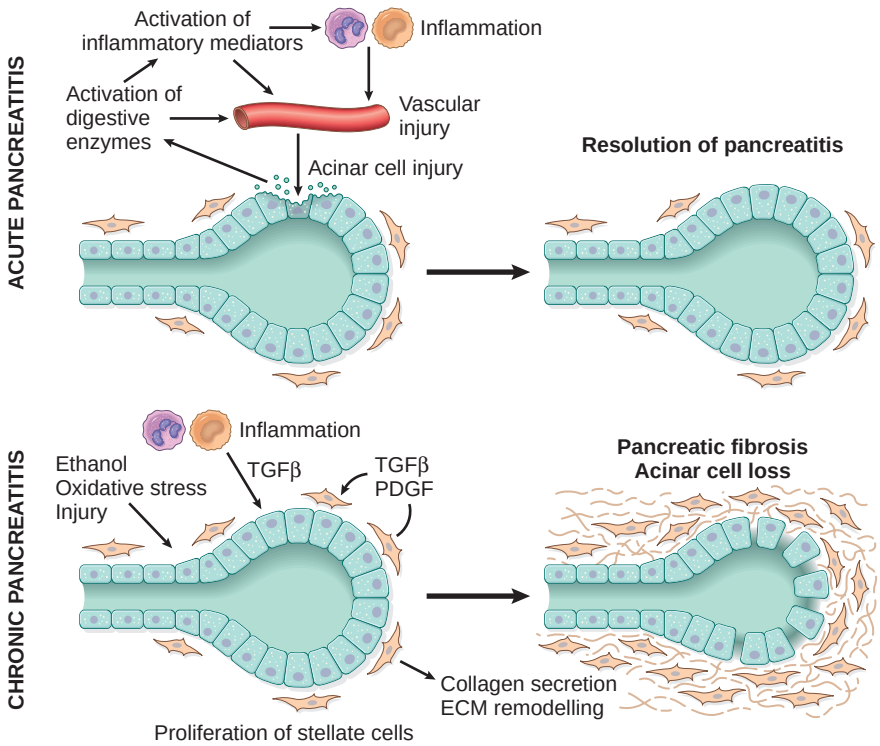

Figure 19.5 Comparison of the mediators in acute and chronic pancreatitis. In acute pancreatitis, acinar injury results in release of digestive enzymes, leading to a cascade of events including activation of the clotting cascade, acute and chronic inflammation, vascular injury, and edema. In most patients, complete resolution of the acute injury occurs with restoration of acinar cell mass. In chronic pancreatitis, repeated episodes of acinar cell injury lead to the production of profibrogenic cytokines such as transforming growth factor β (TGFβ) and platelet-derived growth factor (PDGF), resulting in myofibroblast proliferation, collagen synthesis, and extracellular matrix (ECM) remodeling. Repeated injury leads to irreversible loss of acinar cell mass, fibrosis, and (exocrine) pancreatic insufficiency.

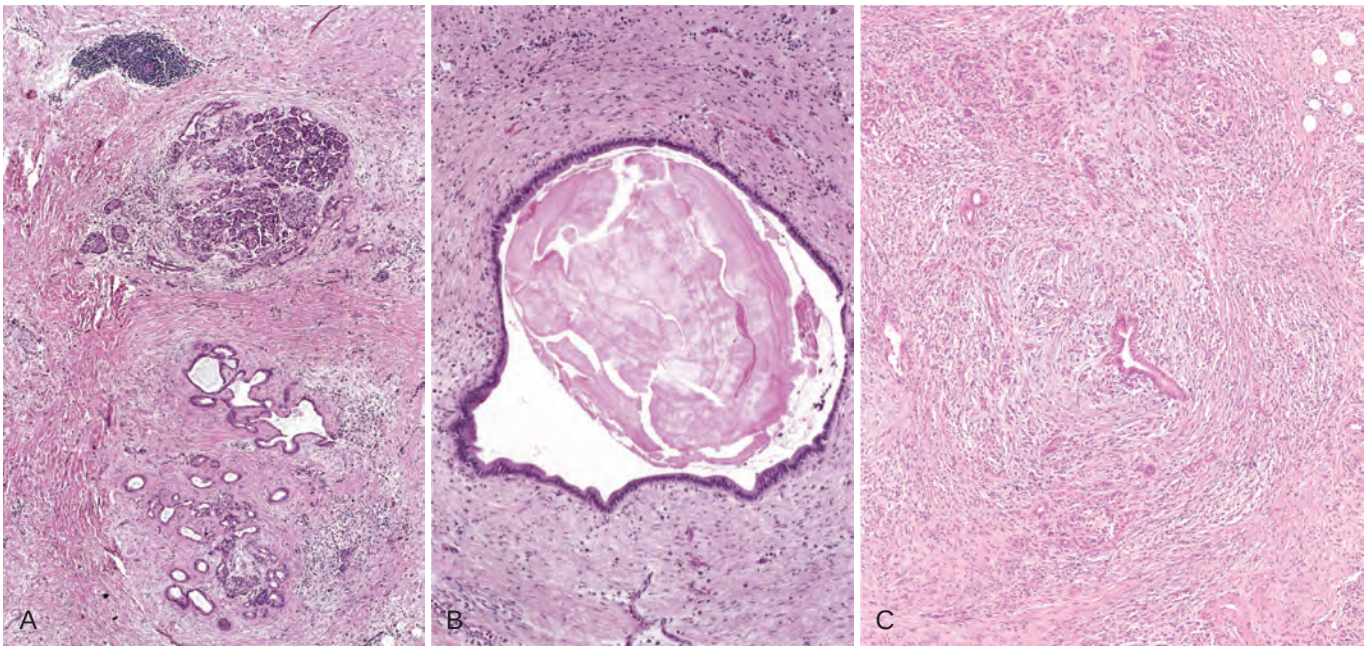

Figure 19.6 Chronic pancreatitis. (A) Extensive fibrosis and atrophy has left only residual islets (top) and ducts (bottom), with a sprinkling of chronic inflammatory cells and a few islands of acinar tissue. (B) Higher power view demonstrating dilated ducts with inspissated eosinophilic ductal concretions in a person with alcoholic chronic pancreatitis. (C) Example of autoimmune pancreatitis with extensive lymphoplasmacytic infiltrates and storiform fibrotic stroma. In this case, an IgG4 stain confirmed abundant IgG4-expressing plasma cells. (C, Photomicrograph courtesy Aatur D. Singhi, University of Pittsburgh Medical Center, Pittsburgh, Pa.)

be atrophic, hyperplastic, or metaplastic (squamous). Chronic pancreatitis caused by alcohol abuse is characterized by ductal dilation and intraluminal protein plugs and calcifications (Fig. 19.6B). **Autoimmune pancreatitis** type 1 typically displays swirling or storiform fibrosis, obliterative inflammation of the veins (phlebitis), and a dense lymphoplasmacytic inflammation that is enriched in IgG4-secreting plasma cells (Fig. 19.6C). The last-mentioned may also be seen in other organs. In contrast, autoimmune pancreatitis type 2 is characterized by neutrophilic infiltrates within the epithelium and lumen of medium-sized pancreatic ducts (granulocytic epithelial lesions). While lymphoplasmacytic infiltrates are seen in both variants, type 2 autoimmune pancreatitis lacks the abundant IgG4-secreting plasma cells that characterize type 1.

Clinical Features

Chronic pancreatitis may follow multiple bouts of acute pancreatitis with repeated attacks of mild to moderately severe abdominal pain or persistent abdominal and back pain. Attacks may be precipitated by excessive alcohol consumption, overeating (which increases demand on the pancreas), or use of opiates and other drugs that increase sphincter of Oddi tone. In other patients the disease may be entirely silent until pancreatic insufficiency and diabetes mellitus develop due to destruction of the exocrine and endocrine pancreas.

Diagnosis of chronic pancreatitis requires a high degree of suspicion. During an attack there may be mild fever and mild-to-moderate elevations of serum amylase. In chronic disease, however, acinar cell dropout may be so great that this diagnostic clue is absent. Gallstone-induced obstruction may present with jaundice or elevated serum alkaline phosphatase. Visualization of calcifications within the pancreas by CT and ultrasonography can be very helpful. Weight loss (due to pancreatic exocrine insufficiency and malabsorption) and edema (secondary to hypoalbuminemia) may also support the diagnosis.

Chronic pancreatitis is usually not an immediately life-threatening condition, but the long-term outlook is poor, with a 20- to 25-year mortality rate of 50%. Pancreatic exocrine insufficiency, chronic malabsorption, and diabetes mellitus all can lead to significant morbidity and contribute to mortality. In other patients, severe, chronic pain is a dominant problem. Pancreatic pseudocysts (described later) develop in about 10% of patients. Patients with hereditary pancreatitis associated with *PRSS1*-mutations have a 40% lifetime risk of developing pancreatic cancer; the risk of pancreatic cancer is only modestly elevated with other forms of chronic pancreatitis.

KEY CONCEPTS

CHRONIC PANCREATITIS

- Chronic pancreatitis is characterized by irreversible injury of the pancreas leading to fibrosis, loss of pancreatic parenchyma, loss of exocrine and endocrine function, and pseudocyst development.
- Chronic pancreatitis is most often caused by:
  - Repeated bouts of acute pancreatitis
  - Chronic alcohol use
  - Germline mutations in genes such as *CFTR* (the gene encoding the transporter that is defective in cystic fibrosis), particularly when combined with environmental stressors

- Chronic pancreatitis may be the manifestation of a systemic or localized autoimmune etiology.
- Clinical features include intermittent or persistent abdominal pain, intestinal malabsorption, and diabetes.

NONNEOPLASTIC CYSTS

A variety of cysts can arise in the pancreas. Most are nonneoplastic pseudocysts, but congenital cysts and neoplastic cysts also occur.

Congenital Cysts

Congenital cysts are unilocular, thin-walled cysts that likely result from anomalous pancreatic duct development. They range in size from microscopic to 5 cm in diameter and are lined by a uniform cuboidal epithelium or, if intracystic pressure is high, flattened and attenuated epithelial cells. A thin, fibrous capsule filled by clear serous fluid typifies congenital cysts that may be sporadic or part of inherited conditions such as *autosomal-dominant polycystic kidney disease* (Chapter 20) and *von Hippel–Lindau disease* (Chapter 28). Cysts in the kidney, liver, and pancreas frequently coexist in polycystic kidney disease. In von Hippel–Lindau disease vascular neoplasms are found in the retina and cerebellum or brain stem in association with congenital cysts (and also neoplasms) in the pancreas, liver, and kidney.

Pseudocysts

Pseudocysts are formed when areas of intrapancreatic or peripancreatic hemorrhagic fat necrosis are walled off by fibrosis and granulation tissue. These lesions, which account for 75% of all pancreatic cysts, are referred to as pseudocysts because they lack an epithelial lining. Pseudocysts typically arise following a bout of acute pancreatitis, particularly one superimposed on chronic alcoholic pancreatitis. Traumatic injury to the pancreas can also give rise to pseudocysts. While many pseudocysts resolve spontaneously, they may also become secondarily infected, and larger pseudocysts may compress or even perforate into adjacent structures.

MORPHOLOGY

Pseudocysts are usually solitary and may be situated within the pancreas or, more commonly, in the lesser omental sac or in the retroperitoneum between the stomach and transverse colon or between the stomach and liver. They can even be subdiaphragmatic (Fig. 19.7A). Pseudocysts are lined by fibrous tissue and granulation tissue (Fig. 19.7B) and range in size from 2 to 30 cm in diameter.

NEOPLASMS

A broad spectrum of exocrine neoplasms arises in the pancreas. These neoplasms may be cystic or solid; some are benign, while others are among the most lethal of all malignancies. Endocrine tumors also occur in the pancreas and are discussed in Chapter 24.

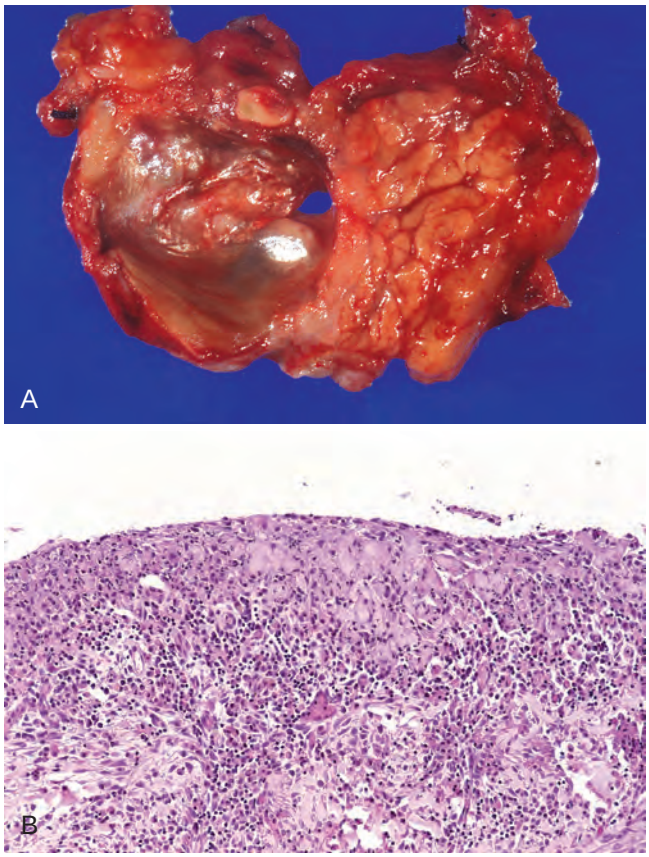

Figure 19.7 Pancreatic pseudocyst. (A) Cross-section revealing a poorly defined cyst with a necrotic brown-black wall. (B) The cyst lacks a true epithelial lining and instead is lined by fibrin and granulation tissue.

Cystic Neoplasms

Cystic neoplasms are diverse tumors that range from harmless benign cysts to lesions that are precursors to invasive, potentially lethal, cancers. Only 5% to 15% of all pancreatic cysts are neoplastic; conversely, fewer than 5% of all pancreatic neoplasms are cystic. Serous cystic neoplasms are almost always benign, whereas others, such as intraductal papillary mucinous neoplasms and mucinous cystic neoplasms, are precancerous. The genomic landscape of each type of cystic neoplasm is distinct, underscoring differences in pathogenesis and natural history.

Serous cystic neoplasms usually occur in the tail of the pancreas. The cysts are small (1 to 3 mm) and can be solitary, multiple, or present as a honeycomb of microcystic lesions. Serous cysts are lined by glycogen-rich cuboidal cells, and contain clear, thin, straw-colored fluid (Fig. 19.8). They account for 15% to 25% of all cystic neoplasms of the pancreas and are twice as common in women. Serous cystic neoplasms typically present in the sixth to seventh decade of life with nonspecific symptoms such as abdominal pain, but many are detected incidentally during imaging for another indication. Surgical resection is curative in the vast majority of patients. Inactivation of the *VHL* tumor suppressor gene

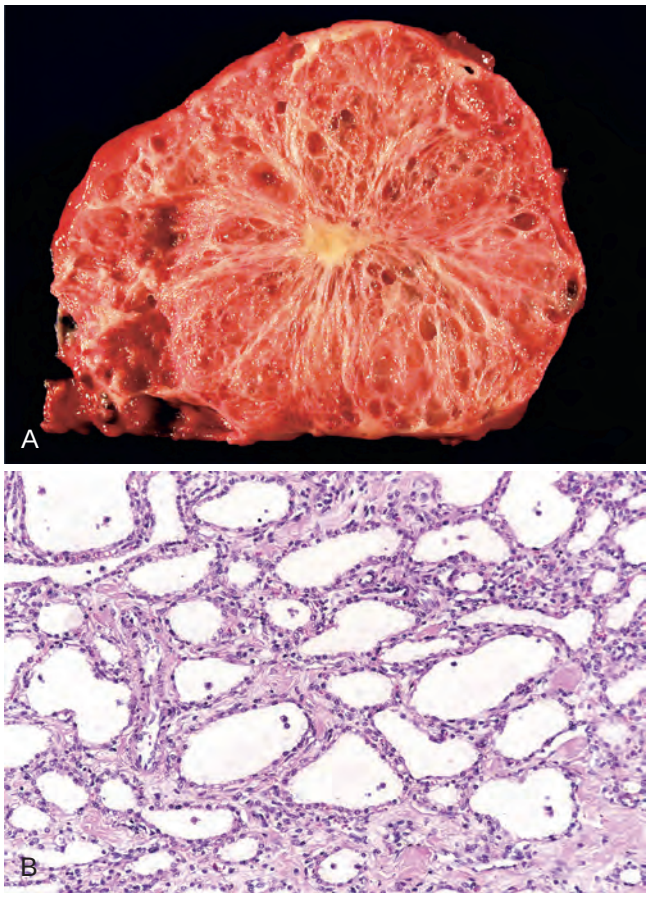

Figure 19.8 Serous cystic neoplasm (serous cystadenoma). (A) Cross-section through a microcystic serous cystic neoplasm. Only a thin rim of normal pancreatic parenchyma remains. The cysts are relatively small and contain clear, straw-colored fluid. (B) The cysts are lined by cuboidal epithelium without atypia.

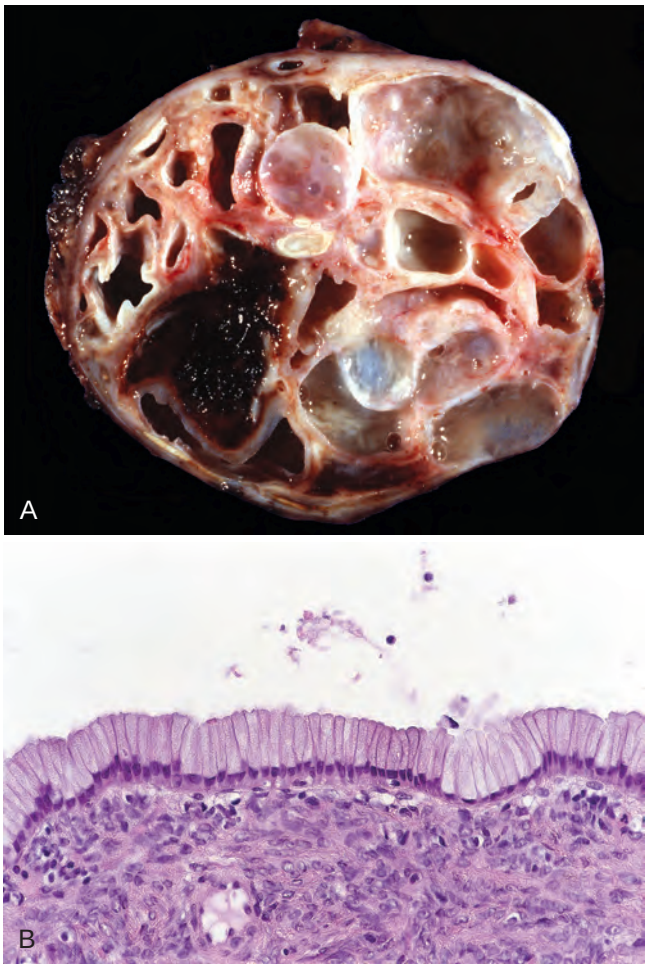

Figure 19.9 Pancreatic mucinous cystic neoplasm with low-grade dysplasia. (A) Cross-section through a mucinous multiloculated cyst in the tail of the pancreas. The cysts are large and filled with tenacious mucin. (B) The cysts are lined by columnar mucinous epithelium with a dense "ovarian" stroma.

on chromosome 3p is the most common genetic abnormality in serous cystic neoplasms.

Close to 95% of *mucinous cystic neoplasms* arise in women and, in contrast to serous cystic neoplasms, they are precursors to invasive carcinomas. These neoplasms usually arise in the tail of the pancreas and present as painless, slow-growing masses. The cystic cavities are larger than those in serous cystic neoplasms and are filled with thick, tenacious mucin. The columnar mucin-producing epithelium that lines the cysts is associated with a dense stroma similar to ovarian stroma (Fig. 19.9). The latter frequently expresses estrogen and progesterone receptors as well as other markers of the ovarian stroma, such as inhibin. Surgical resection is curative for noninvasive mucinous cystic neoplasms, but up to one-third harbor an invasive adenocarcinoma. Up to 50% of patients with an invasive adenocarcinoma arising in a mucinous cystic neoplasm will succumb to their disease within 5 years; therefore, early detection and treatment, before invasive cancer develops, is critical. Mucinous cystic neoplasms harbor oncogenic *KRAS* mutations in approximately half of cases, while mutations of *TP53* and *SMAD4* are typically observed in invasive neoplasms arising from these cysts. Recently, loss-of-function mutations of *RNF43,* which encodes an E3 ubiquitin ligase that normally downregulates Wnt signaling, have been described in up to one-third of mucinous cystic neoplasms. Similar *RNF43* mutations also occur in colorectal cancers.

Intraductal papillary mucinous neoplasms (IPMNs) are mucin-producing neoplasms that involve the larger ducts of the pancreas. In contrast to mucinous cystic neoplasms, IPMNs arise more frequently in men and tend to involve the head of the pancreas. Up to 20% are multifocal. Two features are useful in distinguishing IPMNs from mucinous cystic neoplasms: (1) absence of the dense "ovarian" stroma seen in mucinous cystic neoplasms and (2) involvement of a pancreatic duct (Fig. 19.10). Just as with mucinous cystic neoplasms, IPMNs can progress to an invasive cancer; early detection and treatment before progression to invasive cancer is thus critical. Similar to mucinous cystic neoplasms, intraductal mucinous papillary neoplasms harbor oncogenic *KRAS* mutations in approximately 80% of tumors and loss-of-function *RNF43* mutations in up to 50%. *TP53* and *SMAD4* mutations typically occur only with transition to invasive cancer. Notably, oncogenic mutations of *GNAS,* which encodes the alpha subunit of the stimulatory G protein,

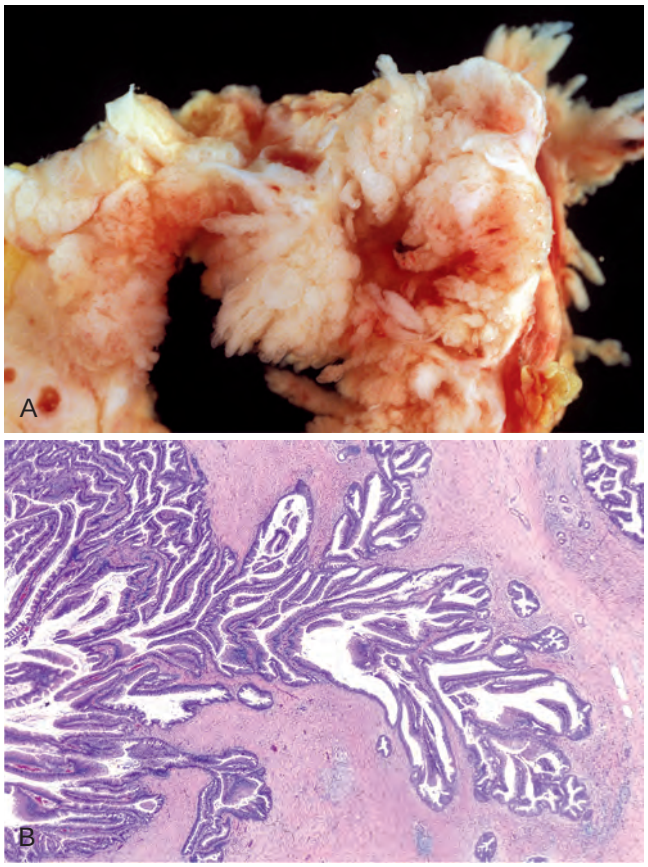

Figure 19.10 Intraductal papillary mucinous neoplasm. (A) Cross-section through the head of the pancreas showing a prominent papillary neoplasm distending the main pancreatic duct. (B) The neoplasm involves the main pancreatic duct (left) and extends down into the smaller ducts and ductules (right).

Gsα, are present in approximately two-thirds of IPMNs but are not found in other pancreatic cysts.

The uncommon *solid-pseudopapillary neoplasm* occurs mainly in young women and due to its large size often presents with abdominal discomfort. As implied by the name, these well-circumscribed neoplasms have solid and cystic components, with the latter filled with hemorrhagic debris. The neoplastic cells grow in solid sheets or, as the name suggests, as pseudopapillary projections and often appear to be poorly cohesive. Activating mutations of *CTNNB1* (β-catenin) are present in nearly all of these tumors, while mutations of *KRAS, RNF43, GNAS,* or *VHL* (characteristic of other pancreatic cystic neoplasms) are not observed. Surgical resection is the treatment of choice and proves curative in most patients.

KEY CONCEPTS

CYSTIC NEOPLASMS

- Virtually all serous cystic neoplasms are benign.
- Noninvasive intraductal papillary mucinous neoplasms and mucinous cystic neoplasms are almost always curable, but both may progress to invasive, potentially lethal carcinomas.
- Each of the major cystic neoplasms has a relatively specific mutational profile.

Pancreatic Carcinoma

Infiltrating ductal adenocarcinoma of the pancreas, more commonly known as pancreatic cancer, is the third leading cause of cancer deaths in the United States, trailing only lung and colon cancers, and has one of the highest mortality rates of any cancer. It was estimated that in 2020 pancreatic cancer would strike approximately 57,600 Americans, virtually all of whom would die of their disease. The 5-year survival rate is a dismal 10%.

Precursors to Pancreatic Cancer

Invasive pancreatic cancers arise from noninvasive precursor lesions referred to as pancreatic intraepithelial neoplasia (PanIN) (Fig. 19.11). These lesions develop in small ducts and are often microscopic, although some, such as the two variants of cystic mucinous neoplasms described above, can be detected macroscopically. Overall, it is thought that greater than 90% of pancreatic cancers arise from PanIN (with the remainder arising from cystic lesions). This conclusion is supported by the following observations:

- The genetic and epigenetic alterations identified in PanIN are similar to those found in invasive cancers (described later).
- PanIN is often found in pancreatic parenchyma adjacent to infiltrating carcinoma. A corollary of this observation is that while isolated low-grade PanIN lesions can be observed in the pancreata of elderly individuals, high-grade PanIN (also known as carcinoma in situ) is almost never observed in the absence of an invasive cancer.
- PanIN precedes the development of invasive cancer in genetically engineered mouse models of pancreatic cancer.
- Isolated case reports have documented individuals with PanIN who later developed an invasive pancreatic cancer.

The epithelial cells in PanIN show dramatic telomere shortening, which may predispose these lesions to accumulate chromosomal abnormalities and progress to invasive carcinoma (Chapter 7). As previously mentioned, PanIN is separated into low-grade and high-grade based on

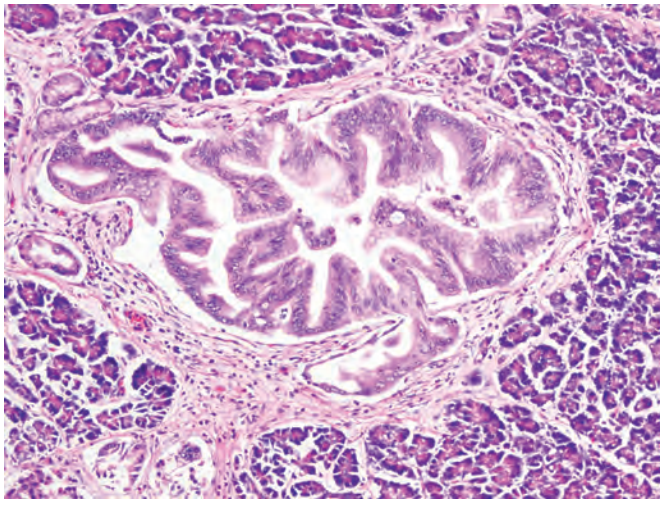

Figure 19.11 High-grade pancreatic intraepithelial neoplasia involving a small pancreatic duct.

morphologic features, which also tend to correlate with the stepwise accumulation of genetic abnormalities (Fig. 19.12).

Pathogenesis

As with other carcinomas, pancreatic cancer is the product of complementary mutations and epigenetic alterations that alter the expression of oncogenes and tumor suppressor genes. The most common molecular alterations in pancreatic carcinogenesis are summarized in Table 19.3 and include the following.

- ***KRAS* (chromosome 12p) is the most frequently altered oncogene in pancreatic cancer, with activating point mutations present in greater than 90% of cases.** These result in constitutive activation of Ras, a small, guanosine triphosphate (GTP)–binding protein enzyme that normally participates in signaling events downstream of growth factor receptors with intrinsic tyrosine kinase activity (Chapters 1 and 7). Ras signaling activates several downstream pathways that augment cell growth and survival, most notably the mitogen-activated protein kinase (MAPK) and PI3K/AKT pathways (Chapter 7).
- *CDKN2A* (chromosome 9p) is inactivated in 30% of pancreatic cancers through point mutations or homozygous deletions. This complex locus encodes two tumor suppressor proteins (Chapter 7): p16/INK4a, a cyclin-dependent kinase inhibitor that antagonizes cell cycle progression, and ARF, a protein that augments the function of the p53 tumor suppressor protein.
- *SMAD4* (chromosome 18q) is inactivated in 55% of pancreatic cancers. *SMAD4* encodes a tumor suppressor that plays an important role in signal transduction from the TGFβ family of cell surface receptors. *SMAD4* is only rarely inactivated in other cancer types.
- *TP53* (chromosome 17p) is inactivated in 70% to 75% of pancreatic cancers. This gene encodes the tumor suppressor p53, a nuclear DNA-binding protein that can respond to DNA damage by arresting cell growth, inducing cell death (apoptosis), or causing cellular senescence (Chapter 7).

Also seen are less common mutations that affect genes involved in DNA repair or regulation of chromatin structure (Table 19.3). In addition, other work has identified pathogenic epigenetic changes, which together with the aforementioned genetic changes produce several distinct molecular subtypes of pancreatic cancer.

- *DNA methylation (epigenetic) abnormalities.* DNA methylation abnormalities are widespread in pancreatic cancer. For example, promoter hypermethylation causes transcriptional silencing of tumor suppressor genes including *CDKN2A*. Conversely, promoter hypomethylation leads to overexpression of oncogenes such as *GATA6* and *BRD4*.
- *Transcriptomic profiles and pancreatic cancer subtypes.* Global analyses of gene expression have identified two distinct pancreatic cancer subtypes, termed basal-like and classical. Basal-like pancreatic cancers are highly aggressive, whereas the classical subtype has a somewhat more favorable prognosis. How these subtypes respond differentially to specific therapies is an area of active investigation.

Epidemiology and Inheritance. Pancreatic cancer is primarily a disease of older adults, with 80% of cases occurring after age 60. The incidence is increased in African Americans, Japanese Americans, Native Hawaiian Islanders, and Ashkenazi Jews.

The strongest environmental influence is cigarette smoking, which doubles the risk of pancreatic cancer. Chronic pancreatitis is an additional risk factor that may reflect the association between chronic inflammation, tissue repair, and neoplasia. Pancreatic cancer risk is also greater in those with visceral obesity and high body mass index. Diabetes mellitus is also a modest risk factor. Conversely, new-onset diabetes mellitus may be the first indication of an occult pancreatic cancer in older patients; abnormal glucose tolerance or frank diabetes is present in as many as half of pancreatic cancer patients up to 3 years before clinical signs of cancer appear. Thus, the appearance of diabetes may present an opportunity for early diagnosis of pancreatic cancer.

Approximately 10% of patients with pancreatic cancer have a deleterious germline mutation in a cancer predisposition gene (Table 19.4) or report one or more first-degree relatives with pancreatic cancer. *BRCA2* mutations are the

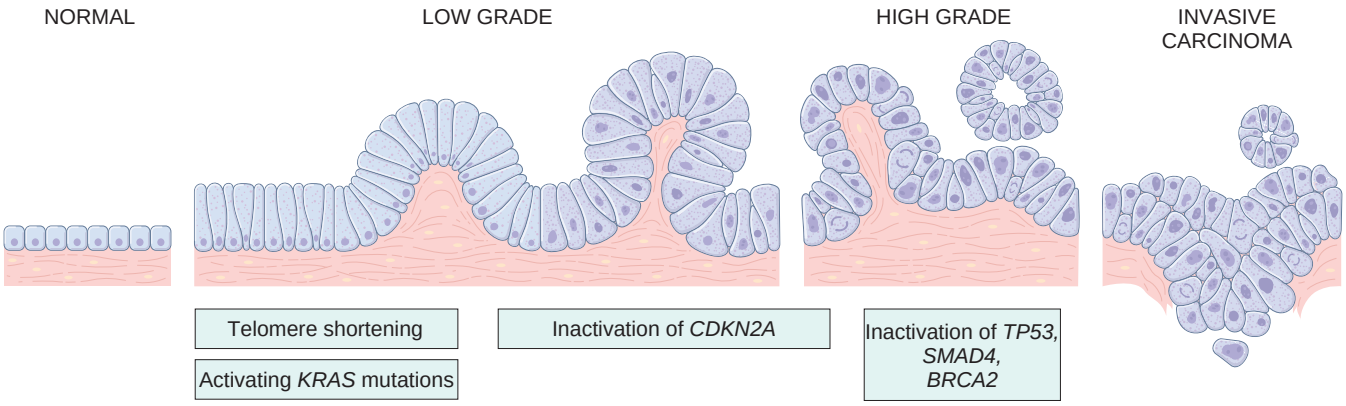

Figure 19.12 Model for the progression from normal ducts (far left) through low- and high-grade pancreatic intraepithelial neoplasia (center) to invasive carcinoma (far right). Telomere shortening and mutations of the oncogene *KRAS* are the earliest discernible alterations in multistep progression, followed by inactivation of the *CDKN2A* tumor suppressor gene that encodes the cell cycle regulator p16. Inactivation of the *TP53*, *SMAD4*, and *BRCA2* tumor suppressor genes occurs in high-grade pancreatic intraepithelial neoplasia that precedes invasive cancer. It is important to note that while there is a general temporal sequence of changes, the accumulation of multiple mutations is more important than their occurrence in a specific order.

Table 19.3 Somatic Molecular Alterations in Pancreatic Ductal Adenocarcinoma

Gene	Chromosomal Region	Percentage of Cases With Genetic Alteration[a]	Gene Function
Oncogenes (Frequency Includes Point Mutations and Amplifications)			
KRAS	12p	>90%	GTP binding enzyme and growth factor signal transducer
AKT2	19q	6%	Growth factor signal transducer
MYC	8q	5%	Transcription factor
GATA6	18q	9%	Transcription factor
FGFR1	8p	5%	Growth factor receptor
BRAF	7q	3%	Serine threonine kinase, regulates MAPK signaling
Tumor Suppressor Genes (Frequency Includes Point Mutations and Homozygous Deletions)			
p16/CDKN2A	9p	30%	Negative cell-cycle regulator
TP53	17p	75%	Response to DNA damage
SMAD4	18q	55%	TGFβ pathway
BRCA2	13q	4%	DNA damage response
ATM	11q	5%	DNA damage response
ARID1A	1p	6%	Chromatin regulator
MLL3/KMT2C	7q	4%	Chromatin regulator
KDM6A	Xp	3%	Chromatin regulator

[a]Frequency of alterations abstracted from The Cancer Genome Atlas Research Network: Integrated Molecular Characterization of Pancreatic Ductal Adenocarcinoma, *Cancer Cell* 32(2):185–203.e13, 2017.

GTP, Guanosine triphosphate; *MAPK*, mitogen-activated protein kinase; *TGFβ*, transforming growth factor β.

most common known cause of familial pancreatic cancer; germline mutations in other genes that are linked to hereditary breast and ovarian cancer (*BRCA1, PALB2, ATM*) are also associated with a 4- to 10-fold elevated risk. With the availability of therapeutic agents that specifically target cancers with DNA repair defects, most commonly *BRCA1* or *BRCA2* mutations, germline testing is now recommended for all patients with pancreatic cancer. Patients with defects in DNA mismatch repair genes who have hereditary nonpolyposis colorectal cancer are also at increased risk for pancreatic cancer. Identification of microsatellite instability, the molecular signature of DNA mismatch repair in pancreatic cancer, is also therapeutically important, as such cancers are more likely to respond to immune checkpoint therapy.

Table 19.4 Inherited Predisposition to Pancreatic Cancer

Disorder	Gene	Increased Risk of Pancreatic Cancer (Fold)	Risk of Pancreatic Cancer by Age 70 (%)
Peutz-Jeghers syndrome	*STK11*	130	30–60
Hereditary pancreatitis	*PRSS1*, *SPINK1*	50–80	25–40
Familial atypical multiple-mole melanoma syndrome	*CDKN2A*	20–35	10–17
Strong family history (3 or more relatives with pancreatic cancer)	Unknown	14–32	8–16
Hereditary breast and ovarian cancer	Multiple, including *BRCA1*, *BRCA2*, *PALB2*, *ATM*	4–10	5
Hereditary non-polyposis colorectal cancer	Multiple, including *MLH1*, *MSH2*, *PMS2*	8–10	4

MORPHOLOGY

Approximately 60% of pancreatic cancers arise in the head, 15% in the body, and 5% in the tail; in 20% of cases the entire pancreas is involved.

The vast majority of pancreatic neoplasms are adenocarcinomas that recapitulate normal ductal epithelium by forming glands and secreting mucin. Two features are characteristic: (1) these cancers are highly invasive, often extending into peripancreatic tissues; and (2) they elicit an intense desmoplastic response that results in the deposition of dense collagen. As a result of these characteristics, most pancreatic cancers are hard, stellate, gray-white, poorly defined masses (Fig. 19.13A).

Most carcinomas of the head of the pancreas obstruct the distal common bile duct resulting in distention of the biliary tree in about 50% of patients. In contrast, carcinomas of the pancreatic body and tail do not impinge on the biliary tract and may be large and widely disseminated at diagnosis.

Pancreatic cancers tend to grow along nerves and invade into blood vessels and the retroperitoneum. The spleen, adrenals, transverse colon, and stomach are often involved by direct invasion, and peripancreatic, gastric, mesenteric, omental, and portohepatic lymph nodes are frequently involved. Perineural, lymphatic, and large vessel invasion are common. Distant metastases are principally to the liver and lungs.

Microscopically, carcinomas of the head, body, and tail of the pancreas are indistinguishable. They form abortive tubular structures or cell clusters with an aggressive, deeply infiltrative growth pattern

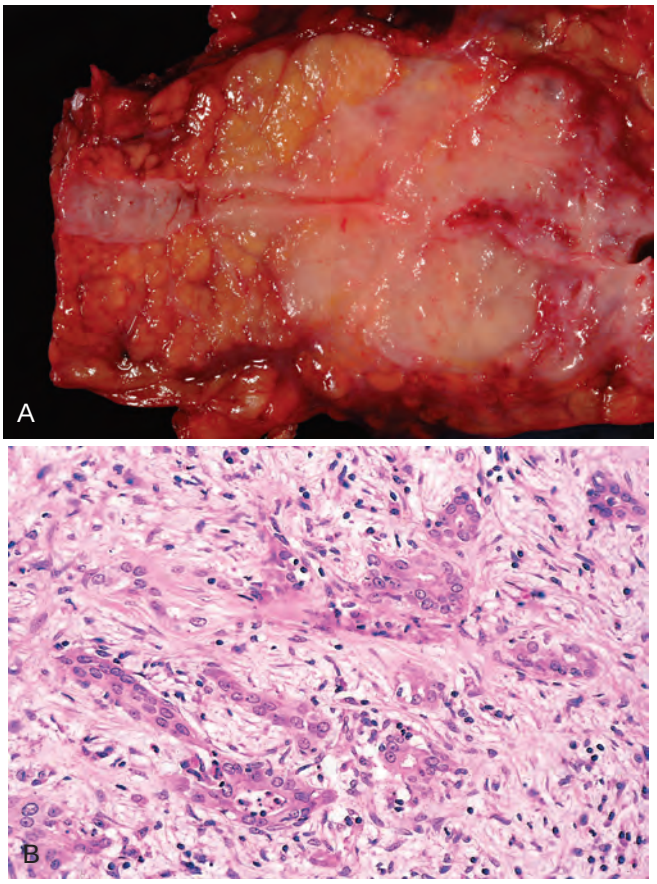

Figure 19.13 Carcinoma of the pancreas. (A) Cross-section through the tail of the pancreas showing normal pancreatic parenchyma and a normal pancreatic duct (*left*) and a pale mass centered on the duct (*right*). (B) Poorly formed glands composed of malignant epithelial cells are dispersed within densely fibrotic stroma; some inflammatory cells are also present.

(Fig. 19.13B). The poorly formed malignant glands are lined by pleomorphic cuboidal-to-columnar epithelial cells. It can, however, occasionally be difficult to discriminate between well-differentiated carcinomas and benign glands with epithelial atypia and stromal fibrosis that are common in chronic pancreatitis. The intense desmoplasia elicited by pancreatic cancers can also interfere with diagnostic interpretation of needle biopsies, regardless of tumor differentiation, as much of the tumor mass is nonneoplastic.

Less common morphologic variants of pancreatic cancer include adenosquamous carcinomas, colloid carcinoma, hepatoid carcinoma, medullary carcinoma, signet-ring cell carcinoma, undifferentiated carcinoma, and undifferentiated carcinoma with osteoclast-like giant cells.

Clinical Features

Carcinomas of the pancreas typically remain silent until they cause obstruction or invade into adjacent structures. Pain is usually the first symptom, but by the time pain appears these cancers are usually beyond cure. Obstructive jaundice is associated with most cases involving the pancreatic head, as these tend to block the common bile duct; this is exemplified by the *Courvoisier sign,* a palpably enlarged, nontender gallbladder with mild painless jaundice. Weight loss, anorexia, and generalized malaise and weakness are often signs of advanced disease. Migratory thrombophlebitis, known as the *Trousseau sign,* occurs in about 10% of patients and is attributable to the elaboration of platelet-activating factors and procoagulants from the carcinoma or its necrotic products (Chapter 4). Sadly, Armand Trousseau (1801–1867, physician at Hotel Dieu, Paris), for whom this sign is named, correctly suspected that he had carcinoma when he developed spontaneously appearing and disappearing (migratory) thromboses.

Survival after diagnosis of advanced pancreatic carcinoma is typically short. Greater than 80% of pancreatic cancers are unresectable at the time of diagnosis due to invasion of vessels and other structures or distant metastases. In contrast, patients who undergo successful resection are increasingly surviving longer (some greater than 5 years), underscoring the critical importance of early detection. To facilitate diagnosis when pancreatic cancers are resectable, many have sought tests that could be used for early detection. Although serum levels of several antigens (e.g., carcinoembryonic antigen and CA19-9 antigen) are often elevated in individuals with pancreatic cancer and can be useful in following individual patient's response to treatment, these markers lack the specificity and sensitivity needed for tests applied to larger populations. Although imaging techniques such as endoscopic ultrasonography and CT can be used to establish the diagnosis, they are not useful as screening tests. Thus, the US Screening and Prevention Task Force (USPSTF) does not currently recommend screening the general population for pancreatic cancer due to the overarching concern for false positives and potential harm. Screening is however recommended for individuals who harbor deleterious germline mutations (Table 19.4) that place them at increased risk for pancreatic cancer.

KEY CONCEPTS

PANCREATIC CARCINOMA

- Pancreatic cancer is one of the most aggressive of the solid cancers.
- Cigarette smoking is a significant cause of pancreatic cancer.
- Cancer-causing germline mutations are present in 10% of patients.
- Invasive pancreatic cancer arises from histologically well-defined precursor lesions, the most common of which is pancreatic intraepithelial neoplasia (PanIN).
- Ductal adenocarcinomas are highly invasive and elicit an intense desmoplastic response.
- The genes most frequently mutated or otherwise altered in pancreatic cancer include *KRAS, p16/CDKN2A, TP53,* and *SMAD4;* transcriptional profiles can be used to define the highly aggressive basal-like and somewhat less aggressive classical subtypes.
- Patients often present with abdominal pain and weight loss, sometimes accompanied by jaundice and deep vein thrombosis. New-onset diabetes is detected in up to half of cases.

Acinar Cell Carcinoma

Like normal acinar cells, acinar cell carcinomas form zymogen granules and produce exocrine enzymes such as trypsin and lipase. Up to 15% of those with acinar cell carcinoma develop metastatic fat necrosis syndrome due to lipase release

into the circulation. Acinar cell carcinomas demonstrate aberrant Wnt pathway activation, due to either loss-of-function mutations of the *APC* tumor suppressor gene or activating point mutations of *CTNNB1*, which encodes beta-catenin.

Pancreatoblastoma

Pancreatoblastomas are rare neoplasms that occur primarily in children 1 to 15 years of age. They have a distinct microscopic appearance consisting of squamous islands admixed with acinar cells. They are malignant, but survival is better than with pancreatic ductal adenocarcinomas. Like acinar cell carcinoma, pancreatoblastomas frequently harbor mutations that activate the Wnt signaling pathway.

CHAPTER 20

The Kidney

Anthony Chang • Zoltan G. Laszik

CHAPTER CONTENTS

What is a human but an ingenious machine designed to turn, with "infinite artfulness, the red wine of Shiraz into urine?" So said the storyteller in Isak Dinesen's *Seven Gothic Tales*. More accurately but less poetically, human kidneys serve to convert more than 1700 L of blood per day into about 1 L of a highly concentrated fluid called *urine*. In so doing, the kidney excretes the waste products of metabolism; precisely regulates the body's concentration of water, salt, calcium, phosphorus, and other anions and cations; and maintains the appropriate acid-base balance of plasma. The kidney also serves as an endocrine organ, secreting such hormones as erythropoietin, renin, and prostaglandins, and regulating vitamin D metabolism. The physiologic mechanisms that the kidney has developed to carry out these functions require a high degree of structural complexity.

Renal diseases are responsible for a great deal of morbidity and mortality. According to the 2015 U.S. Renal Data System Annual Data Report, more than 660,000 Americans had end-stage renal disease (ESRD), of whom two-thirds are maintained on dialysis, at a cost of approximately $72,000 per person annually. The 1-year mortality rate of ESRD, when the enhanced risk for cardiovascular disease conferred by ESRD is considered, exceeds that of most newly diagnosed cancers. Acute kidney injury occurs in more than 2 million people worldwide, and it is a major risk factor for the development of chronic kidney disease and ESRD. In addition, millions of people are affected annually by nonfatal kidney diseases, most notably infections of the kidney or lower urinary tract, kidney stones, and urinary obstruction. The availability of dialysis and the success of renal transplantation have improved the outlook for patients.

The study of kidney diseases is facilitated by dividing them into those that affect the four basic morphologic components: glomeruli, tubules, interstitium, and blood vessels. This approach is useful because the early manifestations of disease affecting each of these components tend to be distinct. Further, some components seem to be more vulnerable to specific forms of renal injury; for example, **most glomerular diseases are immunologically mediated, whereas tubular and interstitial disorders are frequently caused by toxic or infectious agents.** However, some disorders affect more than one structure, and the anatomic and functional interdependence of the components of the kidney means that damage to one usually secondarily affects the others. Primary disorders of the blood vessels, for example, inevitably affect all structures supplied by these vessels. Severe glomerular damage impairs the flow through the peritubular vascular system; conversely, tubular destruction, by increasing intraglomerular pressure, induces glomerular injury. Thus, whatever the origin, all forms of chronic kidney disease ultimately damage all four components of the kidney, culminating in what are called *end-stage kidneys*. The functional reserve of the kidney is large, and much damage may occur before there is evident functional impairment. For these reasons, recognizing the early signs and symptoms is of particular clinical importance.

CLINICAL MANIFESTATIONS OF RENAL DISEASES

The clinical manifestations of renal disease can be grouped into reasonably well-defined syndromes. Some are unique to glomerular diseases, and others are present in diseases that affect any one of the components.

- *Azotemia* is a biochemical abnormality that refers to an elevation of blood urea nitrogen (BUN) and creatinine levels, and is related largely to a decreased glomerular filtration rate (GFR). Azotemia is a consequence of many renal disorders, but it also arises from extrarenal disorders. It is a typical feature of both acute and chronic kidney injury. *Prerenal azotemia* is encountered when there is hypoperfusion of the kidneys that impairs renal function in the absence of parenchymal damage. It may be caused by hypotension, excessive fluid losses from any cause, or if the effective intravascular volume is decreased due to shock, volume depletion, congestive heart failure, or cirrhosis of the liver. *Postrenal azotemia* is seen whenever urine flow is obstructed distal to the kidney. Relief of the obstruction is followed by correction of the azotemia.
- When azotemia leads to clinical signs and symptoms associated with biochemical abnormalities, it is termed *uremia*. Uremia is characterized not only by failure of renal excretory function but also by a host of metabolic and endocrine alterations resulting from renal damage. Uremic patients frequently manifest secondary involvement of the gastrointestinal system (e.g., uremic gastroenteritis), peripheral nerves (e.g., peripheral neuropathy), and heart (e.g., uremic fibrinous pericarditis).
- *Nephritic syndrome* is a clinical entity caused by inflammatory glomerular disease and is dominated by the acute onset of either grossly visible hematuria (red blood cells in urine) or microscopic hematuria with dysmorphic red cells and red cell casts on urinalysis, diminished GFR, mild to moderate proteinuria, and hypertension. It is the classic presentation of acute poststreptococcal glomerulonephritis. *Rapidly progressive glomerulonephritis* (RPGN) is a form of nephritic syndrome in which there is rapid decline in GFR (within hours to days).
- *Nephrotic syndrome,* also due to glomerular disease, is characterized by heavy proteinuria (more than 3.5 g/day), hypoalbuminemia, severe edema, hyperlipidemia, and lipiduria (lipid in the urine). The clinical features of nephritis and the nephrotic syndrome are discussed in more detail later.
- *Asymptomatic hematuria or proteinuria,* or a combination of these two, is usually a manifestation of subtle or mild glomerular abnormalities.
- *Acute kidney injury* (previously called acute renal failure) is characterized by rapid decline in GFR (within hours to days) with concurrent dysregulation of fluid and electrolyte balance, and retention of metabolic waste products normally excreted by the kidney including urea and creatinine. In its most severe forms, it is manifested by *oliguria* or *anuria* (reduced or no urine flow). It can result from glomerular, interstitial, vascular, or acute tubular injury (ATI).
- *Chronic kidney disease* (previously called chronic renal failure) is defined as the presence of a diminished GFR that is persistently less than 60 mL/min/1.73 m^2 for at least 3 months, from any cause, and/or persistent albuminuria. It may present with a clinically silent decline in renal excretory function in milder forms or with prolonged symptoms and signs of uremia in more severe

cases. It is the end result of all chronic renal parenchymal diseases.

- *In end-stage renal disease,* the GFR is less than 5% of normal; this is the terminal stage of uremia.
- *Renal tubular defects* are dominated by polyuria (excessive urine formation), nocturia, and electrolyte disorders (e.g., metabolic acidosis). They are the result of diseases that either directly affect tubular structures (e.g., the nephronophthisis) or cause defects in specific tubular functions. The latter can be inherited (e.g., familial nephrogenic diabetes, cystinuria, renal tubular acidosis) or acquired (e.g., lead nephropathy).
- *Urinary tract obstruction* and *renal tumors* have varied clinical manifestations based on the specific anatomic location and nature of the lesion. *Urinary tract infection* is characterized by bacteriuria and pyuria (bacteria and leukocytes in the urine). The infection may be symptomatic or asymptomatic, and it may affect the kidney *(pyelonephritis)* or the bladder *(cystitis)*.
- *Nephrolithiasis (renal stones)* is manifested by spasms of severe pain (renal colic) and hematuria, often with recurrent stone formation.

Chronic kidney disease is estimated to affect 11% of all adults in the United States, with a particular predominance among older adults. It is the end result of a variety of renal diseases, but most commonly diabetes and hypertension, and the major cause of death from renal disease. The evolution from normal renal function to symptomatic chronic kidney injury progresses through a series of stages that are defined by measures of serum creatinine from which estimates of reduction in GFR are derived. Chronic kidney disease causes significant systemic abnormalities, which are listed in Table 20.1.

KEY CONCEPTS

CLINICAL MANIFESTATIONS OF RENAL DISEASES

- Azotemia is the biochemical manifestation of acute or chronic kidney injury and is characterized by elevated BUN or alternately by an elevated serum creatinine. It reflects a reduction in GFR.
- Kidney injury that results in azotemia can be either acute or chronic. Acute kidney injury can be reversible or progress to chronic kidney disease, which is generally irreversible.
- One major manifestation of kidney injury is the nephrotic syndrome, in which injury to the glomerulus results in abnormal filtration, leading to heavy proteinuria, edema, and metabolic disturbances.
- Nephritic syndromes are those in which hematuria, azotemia, hypertension, and sub-nephrotic proteinuria are the major manifestations.
- Diseases involving the tubules and interstitium may have clinical manifestations of the nephritic syndrome, or of specific defects in tubular function, or of acute or chronic kidney disease without more specific defining features.

GLOMERULAR DISEASES

Glomerular diseases constitute some of the major problems in nephrology. Glomeruli may be injured by a variety of factors and in the course of several systemic diseases. Systemic immunologic diseases such as systemic lupus erythematosus (SLE), vascular disorders such as hypertension, metabolic diseases such as diabetes mellitus, and some hereditary conditions such as Fabry disease often affect the glomerulus. These are termed *secondary glomerular diseases*. Disorders in which the kidney is the only or predominant organ involved constitute the various types of *primary glomerulonephritis* or, because some do not have a cellular inflammatory component, *primary glomerulopathy*. However, both the clinical manifestations and glomerular histologic changes in primary and secondary forms can be similar.

In the following sections, we discuss the normal glomerulus and mechanisms of glomerular injury, and then the various types of primary glomerulopathies. We briefly review the secondary forms covered in other parts of this book. Table 20.2 lists the most common forms of glomerulonephritis that have reasonably well-defined morphologic and clinical characteristics. The clinical manifestations of glomerular disease are clustered into the five major glomerular syndromes summarized in Table 20.3. Both the primary glomerulopathies and the systemic diseases affecting the glomerulus can result in these syndromes. Because glomerular diseases are often associated with systemic disorders, mainly diabetes mellitus, SLE, vasculitis, and amyloidosis, in any

Table 20.2 Glomerular Diseases

Primary Glomerulopathies

Hereditary Disorders
Alport syndrome
Thin basement membrane nephropathy
Fabry disease

patient with manifestations of glomerular disease it is essential to consider these systemic conditions.

Structure of the Glomerulus

Many clinical manifestations of glomerular diseases result from perturbations of specific components of the glomerular tuft, so before discussing these diseases we describe the key anatomic structures of glomeruli. The glomerulus consists of an anastomosing network of capillaries lined by fenestrated endothelium invested by two layers of epithelial cells (Fig. 20.1). The visceral epithelial cells (commonly referred to as *podocytes*) are incorporated into and become an intrinsic part of the capillary wall, separated from endothelial cells by a basement membrane. The parietal epithelium, situated on the Bowman capsule, lines the urinary space, the cavity in which plasma filtrate first collects.

The glomerular capillary wall is the filtering membrane and consists of the following structures (Fig. 20.2):

- There is a thin layer of fenestrated *endothelial cells,* with each fenestra being about 70 to 100 nm in diameter.

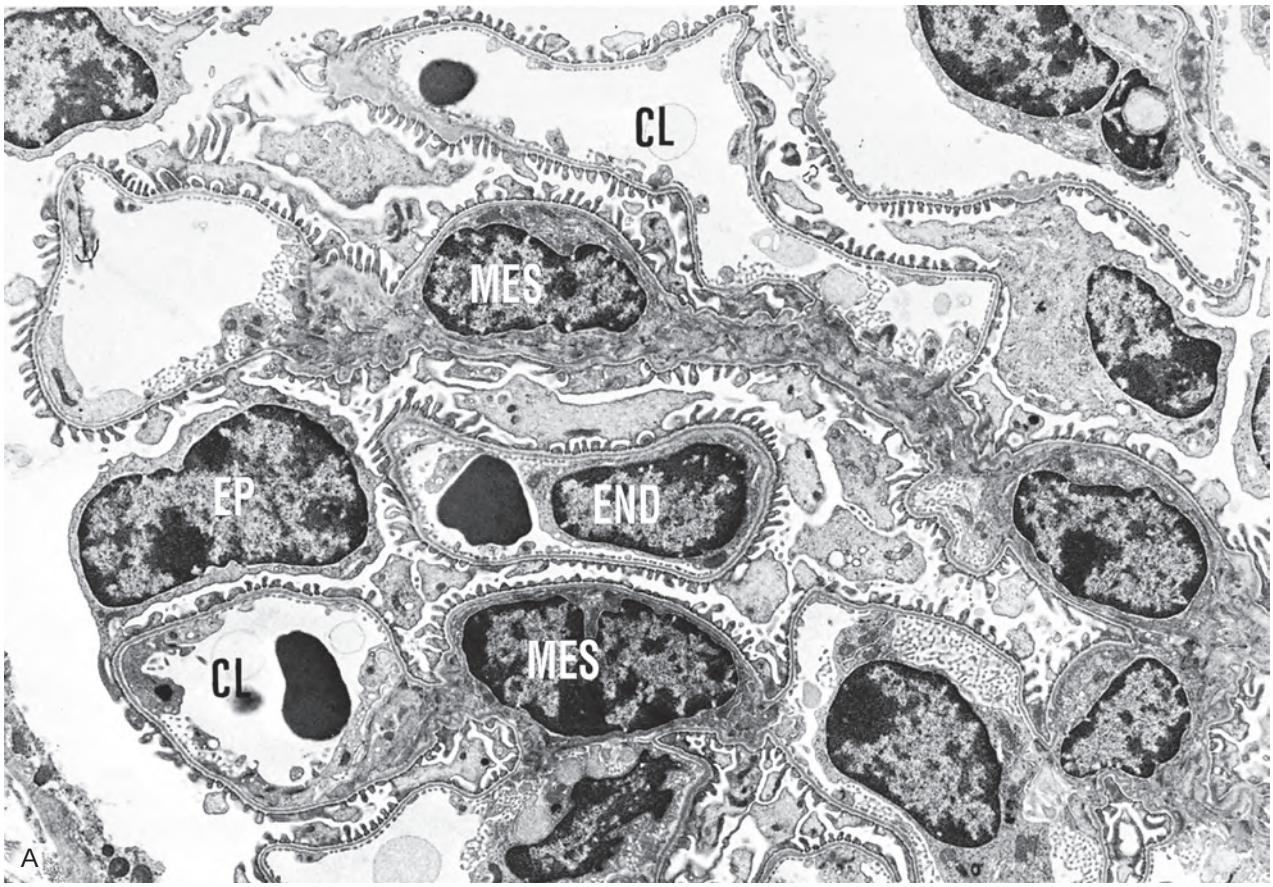
Table 20.3 Clinical Manifestations of Glomerular Diseases

Syndrome	Manifestations
Nephritic syndrome	Hematuria, azotemia, variable proteinuria, oliguria, edema, and hypertension
Rapidly progressive glomerulonephritis	Acute nephritis, proteinuria, and acute renal failure
Nephrotic syndrome	>3.5 g/day proteinuria, hypoalbuminemia, hyperlipidemia, lipiduria
Chronic kidney disease	Azotemia → uremia progressing for months to years
Isolated urinary abnormalities	Glomerular hematuria and/or subnephrotic proteinuria

- A *glomerular basement membrane* (GBM) with a thick electron-dense central layer, the *lamina densa,* and thinner electron-lucent peripheral layers, the *lamina rara interna* and *lamina rara externa*. The GBM consists of collagen (mostly type IV), laminin, polyanionic proteoglycans (mostly heparan sulfate), fibronectin, entactin, and several other glycoproteins. Type IV collagen forms a network suprastructure to which other glycoproteins attach. The building block (monomer) of this network is a triple-helical molecule composed of one or more of six types of α chains (α_1 to α_6 or COL4A1 to COL4A6). Each molecule consists of a 7S domain at the N terminus, a triple-helical domain in the middle, and a globular noncollagenous (NC1) domain at the C terminus. The NC1 domain is important for helix formation and for assembly of collagen monomers into the basement membrane suprastructure. Glycoproteins (laminin, entactin) and proteoglycans (heparan sulfate, perlecan) attach to the collagenous suprastructure. The biochemical properties of these structural components are critical to understanding glomerular diseases. For example, antigens in the NC1 domain are the targets of antibodies in anti-GBM nephritis; genetic defects in the α-chains underlie some forms of hereditary nephritis; and the proteoglycan content of the GBM may contribute to its permeability characteristics.
- The *visceral epithelial cells* (podocytes) possess interdigitating processes embedded in and adherent to the lamina rara externa of the basement membrane (see Fig. 20.1). Adjacent *foot processes* are separated by 20- to 30-nm–wide *filtration slits,* which are bridged by a thin diaphragm (see Fig. 20.2).
- The entire glomerular tuft is supported by the mesangium, the tissue that lies between the capillaries and is composed of basement membrane–like *mesangial matrix* that forms a meshwork in which the *mesangial cells* are embedded (see Fig. 20.1). These cells, of mesenchymal origin, are contractile, phagocytic, and capable of proliferation, of laying down both matrix and collagen, and of secreting several biologically active mediators. Biologically, they are most akin to vascular smooth muscle cells and pericytes. They are important in many forms of glomerulonephritis.

The normal glomerulus is highly permeable to water and small solutes because of the fenestrated nature of the endothelium, and it is impermeable to proteins of the size of albumin (~3.6-nm radius; 70 kilodaltons [kD] molecular weight) or larger. The permeability characteristics of the *glomerular filtration barrier* allow discrimination among various protein molecules, depending on their size (the larger, the less permeable) and charge (the more cationic, the more permeable). This size- and charge-dependent barrier function is accounted for by the structure of the capillary wall. The charge-dependent restriction is important in the virtually complete exclusion of albumin from the filtrate, because albumin is an anionic molecule.

The visceral epithelial cell is important for the maintenance of glomerular barrier function; its slit diaphragm presents a size-selective distal diffusion barrier to the filtration of proteins, and this cell type is largely responsible, under normal circumstances, for synthesis of GBM components. Proteins located in the slit diaphragm or present in assemblies of molecules within visceral epithelial cells



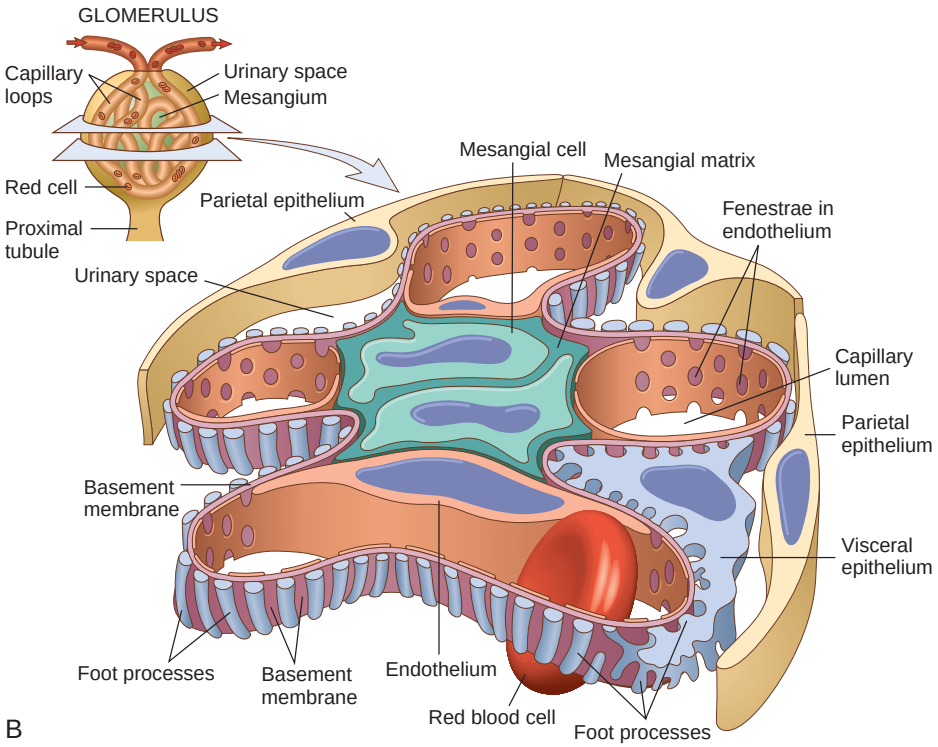


Figure 20.1 (A) Low-power electron micrograph of renal glomerulus. *CL,* Capillary lumen; *EP,* visceral epithelial cells with foot processes; *END,* endothelium; *MES,* mesangium. Figure 20.2 Glomerular filter consisting *(from bottom to top)* of fenestrated endothelium, basement membrane, and foot processes of epithelial cells. Note the filtration slits *(arrows)* and diaphragm between the foot processes. Note also that the basement membrane consists of a central lamina densa, sandwiched between two looser layers, the lamina rara interna and lamina rara externa. (Courtesy Dr. Helmut Rennke, Brigham and Women's Hospital, Boston, Mass.)

that are attached to the slit diaphragm are illustrated in Fig. 20.3. Nephrin is a transmembrane protein with a large extracellular portion made up of immunoglobulin (Ig)-like domains. Nephrin molecules extend toward each other from neighboring foot processes and dimerize across the slit diaphragm. Within the cytoplasm of the foot processes, nephrin forms molecular connections with podocin, CD2-associated protein, and ultimately the actin cytoskeleton of the visceral epithelial cells. More slit diaphragm proteins continue to be identified, and comprehensive descriptions of their structure and interactions have been published. The importance of the slit diaphragm proteins in maintaining glomerular permeability is demonstrated by the observation that mutations in the genes encoding them give rise to defects in permeability and the nephrotic syndrome (discussed later).

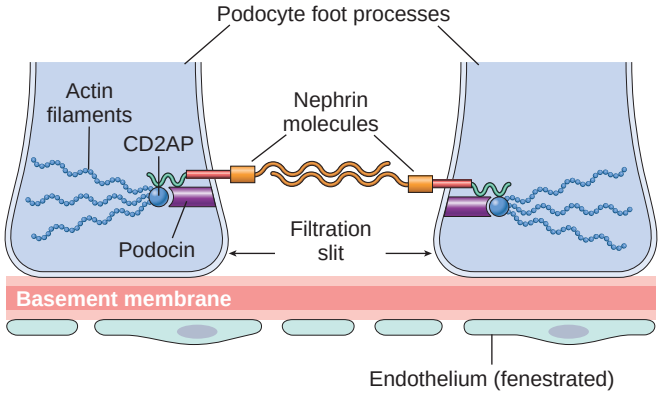

Figure 20.3 A simplified schematic diagram of some of the best-studied proteins of the glomerular slit diaphragm. *CD2AP,* CD2-associated protein.

Pathologic Responses of the Glomerulus to Injury

Various types of glomerulopathies are characterized by one or more of four basic tissue reactions.

Hypercellularity

Some *inflammatory diseases* of the glomerulus are characterized by an increase in the number of cells in the glomerular tufts. This hypercellularity results from one or more of the following:

- *Proliferation* of mesangial or endothelial cells.
- *Infiltration of leukocytes,* including neutrophils, monocytes, and, in some diseases, lymphocytes. The combination of infiltration of leukocytes and swelling and proliferation of mesangial and/or endothelial cells is often referred to as *endocapillary proliferation*.
- *Formation of crescents.* These are accumulations of cells composed of proliferating glomerular epithelial cells and infiltrating leukocytes. The epithelial cell proliferation that characterizes crescent formation occurs following an immune/inflammatory injury involving the capillary walls. Plasma proteins leak into the urinary space, where it is believed that exposure to procoagulants such as tissue factor leads to fibrin deposition. Activation of coagulation factors such as thrombin is suspected of being a trigger for crescent formation, but the actual mechanisms are still poorly understood. Molecules that have been implicated in recruitment of leukocytes into crescents include multiple proinflammatory cytokines.

Basement Membrane Thickening

By light microscopy, this change appears as thickening of the capillary walls, best seen in sections stained with periodic acid–Schiff (PAS). By electron microscopy, such thickening takes one of three forms:

- Deposition of amorphous electron-dense material, most often immune complexes, on the endothelial or epithelial side of the basement membrane or within the GBM itself. Fibrin, amyloid, cryoglobulins, and abnormal fibrillary proteins may also deposit in the GBM.
- Increased synthesis of the protein components of the basement membrane, as occurs in diabetic glomerulosclerosis.
- Formation of additional layers of basement membrane matrices, which most often occupy subendothelial locations and may range from poorly organized matrix to fully duplicated lamina densa, as occurs in membranoproliferative glomerulonephritis (MPGN).

Hyalinosis and Sclerosis

Hyalinosis, as applied to the glomerulus, denotes the accumulation of material that is homogeneous and eosinophilic by light microscopy. *Hyalin* is an extracellular, amorphous material composed of plasma proteins that have insudated from the circulation into glomerular structures. When extensive, these deposits may obliterate the capillary lumens of the glomerular tuft. Hyalinosis is usually a consequence of endothelial or capillary wall injury and typically the end result of various forms of glomerular damage.

Sclerosis is characterized by deposition of extracellular collagenous matrix. It may be confined to mesangial areas, as is often the case in diabetic glomerulosclerosis, involve

the capillary loops, or both. The sclerosing process may also result in obliteration of some or all of the capillary lumens in affected glomeruli.

Many primary glomerulopathies are classified by their histology, as seen in Table 20.2. The histologic changes can be further subdivided by their distribution into the following categories: *diffuse,* involving all of the glomeruli in the kidney; *global,* involving the entirety of individual glomeruli; *focal,* involving only a fraction of the glomeruli in the kidney; *segmental,* affecting a part of each glomerulus; and *capillary loop* or *mesangial,* affecting predominantly capillary or mesangial regions.

KEY CONCEPTS

INJURY OF GLOMERULAR STRUCTURES

- The GBM is composed of type IV collagen molecules and other matrix proteins. These proteins can be the target of antibodies in some types of glomerulonephritis; genetic abnormalities in their composition are the basis for some forms of hereditary nephritis.
- Visceral epithelial cells (podocytes) are a critical component of the glomerular filtration barrier, and their injury leads to protein leakage into the urinary space (proteinuria).
- The acute glomerular response to injury includes hypercellularity with proliferation of mesangial and/or endothelial cells, influx of leukocytes, and, when severe, formation of crescents.
- Chronic glomerular responses to injury include basement membrane thickening, hyalinosis, and sclerosis.

Pathogenesis of Glomerular Injury

Although much remains unknown about etiologic agents and triggering events, it is clear that **immune mechanisms underlie most forms of primary glomerulopathy and many secondary glomerular disorders** (Table 20.4). Glomerulonephritis can be induced experimentally by antigen-antibody reactions. Furthermore, glomerular deposits of immunoglobulins, often with components of complement, are found in the majority of individuals with glomerulonephritis.

Activation of Alternative Complement Pathway

GBM, Glomerular basement membrane.

Cell-mediated immune reactions also may play a role, usually in concert with antibody-mediated events. We begin this discussion with a review of antibody-instigated injury.

Two forms of antibody-associated injury have been established: (1) injury by *antibodies reacting in situ within the glomerulus,* either binding to insoluble fixed (intrinsic) glomerular antigens or extrinsic molecules planted within the glomerulus, and (2) injury resulting from *deposition of circulating antigen-antibody complexes in the glomerulus.* It is clear that the major cause of glomerulonephritis resulting from formation of antigen-antibody complexes is the consequence of in situ immune complex formation, and not deposition of circulating complexes as was once thought.

Diseases Caused by In Situ Formation of Immune Complexes

In this form of injury, immune complexes are formed locally by antibodies that react with intrinsic tissue antigens or with extrinsic antigens "planted" in the glomerulus from the circulation. Membranous nephropathy is the classic example of glomerular injury resulting from local formation of immune complexes by antibodies reactive with endogenous antigens.

The pattern of immune deposition by immunofluorescence microscopy is granular, reflecting the very localized antigen-antibody interaction. On electron microscopy, the glomerulopathy is characterized by the presence of numerous discrete subepithelial electron-dense deposits (made up of immune reactants). These subepithelial complexes, with resultant host responses, can result in a thickened basement membrane appearance by light microscopy; hence the term *membranous nephropathy*.

Antibodies can react in situ with antigens that are not normally present in the glomerulus but are "planted" there. Such antigens may localize in the kidney by interacting with various intrinsic components of the glomerulus. Planted antigens include cationic molecules that bind to anionic components of the glomerulus; DNA, nucleosomes, and other nuclear proteins, which have an affinity for GBM components; bacterial products; large aggregated proteins (e.g., aggregated immunoglobulins), which deposit in the mesangium because of their size; and immune complexes themselves, because they continue to have reactive sites for further interactions with free antibody, free antigen, or complement. There is no dearth of other possible planted antigens, including viral, bacterial, and parasitic products and drugs.

Disease Caused by Antibodies Directed Against Normal Components of the Glomerular Basement Membrane

In anti-GBM antibody–induced glomerulonephritis, antibodies bind to intrinsic antigens homogeneously distributed along the entire length of the GBM, resulting in a diffuse linear pattern of staining for the antibodies by immunofluorescence techniques (Fig. 20.4B and E). This contrasts with the granular pattern of immunofluorescence staining corresponding to the discrete immune complexes seen in membranous nephropathy, or other glomerular diseases in which large complexes of antigens and antibodies form in situ. Although anti-GBM antibody–induced glomerulonephritis accounts for less than 5% of cases of human glomerulonephritis, it causes severe necrotizing and crescentic glomerular damage and the clinical syndrome of RPGN.

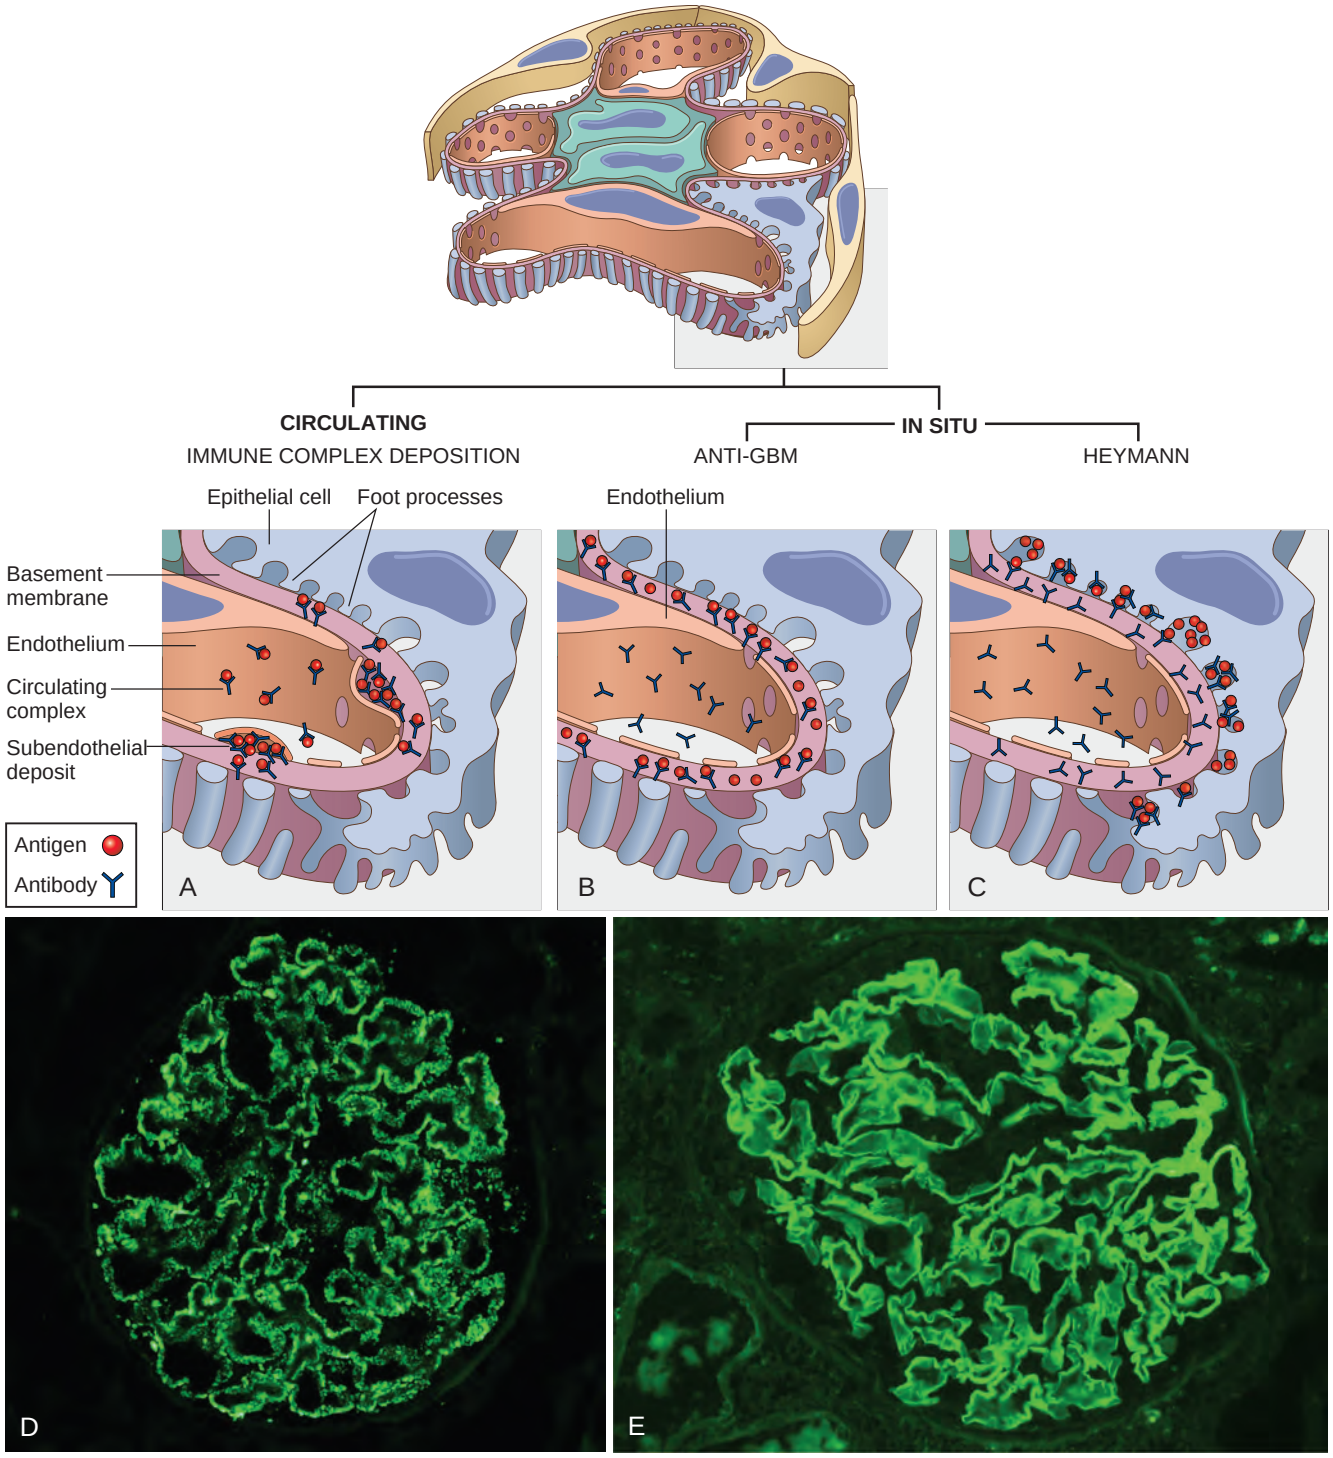

Figure 20.4 Antibody-mediated glomerular injury can result either from the deposition of circulating immune complexes (A) or, more commonly, from in situ formation of complexes exemplified by anti–glomerular basement membrane (anti-GBM) disease (B) or Heymann nephritis (C). (D and E) Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy: granular, characteristic of circulating and in situ immune complex nephritis (D), and linear, characteristic of classic anti-GBM disease (E). (D, Courtesy Dr. J. Kowalewska, Department of Pathology, University of Washington, Seattle, Washington. E, From Kumar V, Abbas AK, Aster JC: *Robbins Basic Pathology,* ed 10, Philadelphia, 2018, Elsevier.)

Glomerulonephritis Resulting From Deposition of Circulating Immune Complexes

In this type of nephritis, glomerular injury is caused by the trapping of circulating antigen-antibody complexes within glomeruli. The antibodies have no immunologic specificity for glomerular constituents, and the complexes localize within the glomeruli because of their physicochemical properties and the hemodynamic factors peculiar to the glomerulus (see Fig. 20.4A).

The antigens that trigger the formation of circulating immune complexes may be of endogenous origin, as in the glomerulonephritis associated with SLE or in IgA nephropathy, **or they may be exogenous,** as may occur in the glomerulonephritis that follows certain infections. Microbial antigens that are implicated include bacterial products (streptococcal proteins), the surface antigen of hepatitis B virus, hepatitis C virus antigens, and antigens of *Treponema pallidum, Plasmodium falciparum,* and several viruses. Some tumor antigens are also thought to cause immune complex–mediated nephritis. In many cases, the inciting antigen is unknown.

Mechanisms of Glomerular Injury Following Immune Complex Formation

The pathogenesis of immune complex diseases is discussed in Chapter 6. Here we briefly review the salient features that relate to glomerular injury. **Whatever the antigen may be, antigen-antibody complexes formed or deposited in the glomeruli may elicit a local inflammatory reaction that produces injury.** The antibodies may activate complement and engage Fc receptors on leukocytes and perhaps glomerular mesangial or other cells, leading to inflammation. The glomerular lesions may exhibit leukocytic infiltration and proliferation of mesangial and endothelial cells.

Electron microscopy reveals electron-dense deposits, presumably containing immune complexes, that may lie in the mesangium, between the endothelial cells and the GBM (subendothelial deposits), or between the outer surface of the GBM and the podocytes (subepithelial deposits). Deposits may be located at more than one site in a given case. By immunofluorescence microscopy, the immune complexes are seen as granular deposits along the basement membrane (see Fig. 20.4D), in the mesangium, or in both locations. Once deposited in the kidney, immune complexes may eventually be degraded, mostly by infiltrating neutrophils and monocytes/macrophages, mesangial cells, and endogenous proteases, and the inflammatory reaction may then subside. Such a course occurs when the exposure to the inciting antigen is short-lived and limited, as in most cases of poststreptococcal glomerulonephritis. However, if immune complexes are deposited repeatedly for prolonged periods, as may be seen in SLE or viral hepatitis, many cycles of injury may occur, leading to a more chronic membranous or membranoproliferative type of glomerulonephritis.

Several factors affect glomerular localization of antigen, antibody, or immune complexes. The molecular charge and size of these reactants are clearly important. Highly cationic antigens tend to cross the GBM, and the resultant complexes eventually reside in a subepithelial location. Highly anionic macromolecules are excluded from the GBM and are trapped subendothelially or are not nephritogenic at all. Molecules of neutral charge and immune complexes containing these molecules tend to accumulate in the mesangium. Large circulating complexes are not usually nephritogenic, because they are cleared by the mononuclear phagocyte system and do not enter the GBM in significant quantities. The pattern of localization is also affected by changes in glomerular hemodynamics, mesangial function, and integrity of the charge-selective barrier in the glomerulus. These influences may underlie the variable pattern of immune-reactant deposition in various forms of glomerulonephritis (Fig. 20.5). In turn, the distinct patterns of localization of immune complexes is a key determinant of the injury response and the histologic features that subsequently develop. Immune complexes located in subendothelial portions of capillaries and in mesangial regions are accessible to the circulation and more likely to be involved in inflammatory processes that require interaction and activation of circulating leukocytes. Diseases in which immune complexes are confined to the subepithelial locations and for which the capillary basement membranes may be a barrier to interaction with circulating leukocytes, as in the case of membranous nephropathy, typically have a noninflammatory pathology.

In summary, **most cases of immune complex–mediated glomerulonephritis are a consequence of deposition of discrete immune complexes, which give rise to granular immunofluorescence staining along the basement membranes or in the mesangium.** However, it may be difficult to determine whether the deposition has occurred in situ, by circulating complexes, or by both mechanisms

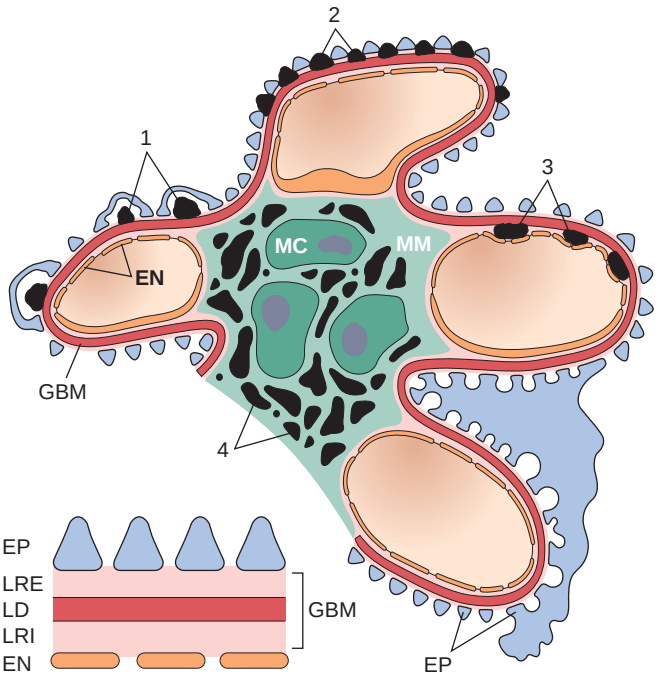

Figure 20.5 Localization of immune complexes in the glomerulus: (1) subepithelial humps, as in acute glomerulonephritis; (2) membranous deposits, as in membranous nephropathy and Heymann nephritis; (3) subendothelial deposits, as in lupus nephritis and membranoproliferative glomerulonephritis; (4) mesangial deposits, as in IgA nephropathy. *EN,* Endothelium; *EP,* epithelium; *GBM,* glomerular basement membrane; *LD,* lamina densa; *LRE,* lamina rara externa; *LRI,* lamina rara interna; *MC,* mesangial cell; *MM,* mesangial matrix. (Modified from Couser WG: Mediation of immune glomerular injury, *J Am Soc Nephrol* 1[1]: 13–29, 1990.)

because, as discussed earlier, trapping of circulating immune complexes can initiate further in situ complex formation. Single etiologic agents, such as hepatitis B and C viruses, can cause either a membranous pattern of glomerulonephritis, with subepithelial in situ deposition of antigens, or a membranoproliferative pattern, more indicative of subendothelial deposition of antigens or deposition of circulating complexes. It is best then to consider that **antigen-antibody deposition in the glomerulus is a major pathway of glomerular injury and that in situ immune reactions, trapping of circulating complexes, interactions between these two events, and local hemodynamic and structural determinants in the glomerulus all contribute to the diverse morphologic and functional alterations in glomerulonephritis.**

Cell-Mediated Immunity in Glomerulonephritis

Although antibody-mediated mechanisms may initiate most forms of glomerulonephritis, there is evidence that sensitized T cells cause glomerular injury and are involved in the progression of some glomerulonephritides. Clues to the role of cellular immunity include the presence of activated macrophages and T cells and their products in the glomerulus in some forms of human and experimental glomerulonephritis; in vitro and in vivo evidence of lymphocyte activation on exposure to antigen in human and experimental glomerulonephritis; abrogation of glomerular injury by lymphocyte depletion; and experiments in which glomerular injury may be induced by transfer of T cells from nephritic animals to normal recipients. The evidence is most compelling for certain types of experimental crescentic glomerulonephritis in which antibodies to GBM initiate glomerular injury and activated T lymphocytes propagate the inflammation. Despite this body of suggestive evidence, proof of glomerulonephritis in humans resulting primarily from T-cell activation remains lacking.

Activation of Alternative Complement Pathway

Alternative complement pathway activation occurs in the clinicopathologic entity called *dense-deposit disease,* until recently referred to as *membranoproliferative glomerulonephritis (MPGN type II),* and in *C3 glomerulopathies.* This is discussed later in the sections describing these diseases.

Mediators of Glomerular Injury

Once immune reactants or sensitized T cells have localized in the glomerulus, how does the glomerular damage ensue? The mediators—both cells and molecules—are the usual suspects involved in acute and chronic inflammation, described in Chapter 3, and only a few are highlighted here (Fig. 20.6).

Cells

- *Neutrophils* and *monocytes* infiltrate glomeruli in certain types of glomerulonephritis, largely as a result of activation of complement, resulting in generation of chemotactic agents (mainly C5a), but also by Fc receptor–mediated activation. Neutrophils release proteases, which cause GBM degradation; oxygen-derived free radicals, which cause cell damage; and arachidonic acid metabolites, which contribute to the reductions in GFR.
- *Macrophages and T lymphocytes,* which infiltrate glomeruli in antibody- and cell-mediated reactions, when activated, release a vast number of biologically active molecules.
- *Platelets* may aggregate in glomeruli during immune-mediated injury. Their release of eicosanoids, growth factors, and other mediators may contribute to vascular injury and proliferation of glomerular cells. Antiplatelet agents have beneficial effects in both human and experimental glomerulonephritis.
- *Resident glomerular cells,* particularly mesangial cells, can be stimulated to produce inflammatory mediators, including reactive oxygen species (ROS), cytokines, chemokines,

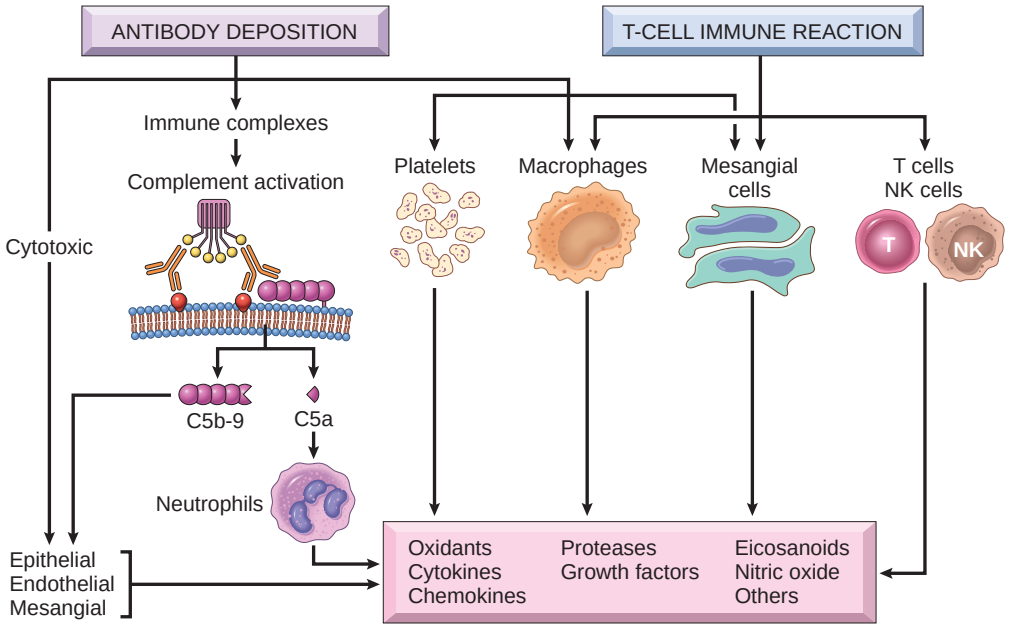

Figure 20.6 Mediators of immune glomerular injury.

growth factors, eicosanoids, nitric oxide, and endothelin. They may initiate inflammatory responses in glomeruli, even in the absence of leukocytic infiltration.

Soluble Mediators

Virtually all the known inflammatory chemical mediators (Chapter 3) have been implicated in glomerular injury.

- *Complement activation* leads to the generation of chemotactic products that induce leukocyte influx (complement-neutrophil–dependent injury) and the formation of C5b–C9, the membrane attack complex. C5b–C9 causes cell lysis but, in addition, it may stimulate mesangial cells to produce oxidants, proteases, and other mediators. Thus, even in the absence of neutrophils, C5b–C9 can cause proteinuria, as has been demonstrated in experimental membranous glomerulopathy. In some diseases, collectively called *C3 glomerulopathies,* there is evidence of complement activation resulting not from antibody or immune complex deposition but from defective regulation of the complement system. As expected, because antibodies are not involved, in these disorders complement activation is by the alternative pathway. The end result is the same as in classical pathway activation.
- *Eicosanoids, nitric oxide, angiotensin,* and *endothelin* are involved in the hemodynamic changes.
- *Cytokines,* particularly IL-1 and TNF, which may be produced by infiltrating leukocytes and resident glomerular cells, induce leukocyte adhesion and a variety of other effects.
- *Chemokines* such as monocyte chemoattractant protein 1 promote monocyte and lymphocyte influx. *Growth factors* such as platelet-derived growth factor (PDGF) are involved in mesangial cell proliferation. TGF-β, connective tissue growth factor, and fibroblast growth factor seem to be critical in the ECM deposition and hyalinization leading to glomerulosclerosis in chronic injury. Vascular endothelial growth factor (VEGF) seems to maintain endothelial integrity and may help regulate capillary permeability.
- The *coagulation system* is also a mediator of glomerular damage. Fibrin is frequently present in the glomeruli and Bowman space in glomerulonephritis, indicative of coagulation cascade activation, and activated coagulation factors, particularly thrombin, may be a stimulus for crescent formation.

Epithelial Cell Injury

Podocyte injury is common to many forms of both primary and secondary glomerular diseases, of both immune and nonimmune etiologies. The term *podocytopathy* has been applied to diseases with disparate etiologies whose principal manifestation is injury to podocytes. This can be induced by antibodies to podocyte antigens; by toxins, as in an experimental model of proteinuria induced by puromycin aminonucleoside; conceivably by certain cytokines; by certain viral infections such as human immunodeficiency virus (HIV); or by incompletely characterized circulating factors, postulated in minimal change disease and focal segmental glomerulosclerosis (FSGS). Such injury is reflected by morphologic changes in podocytes, which include effacement of foot processes, vacuolization, and retraction and detachment of cells from the GBM, and functionally by proteinuria (Fig. 20.7).

Loss of podocytes, which have only a very limited capacity for replication and repair, may be a feature of multiple types of glomerular injury, including FSGS and diabetic nephropathy. Such loss typically cannot be recognized in pathologic specimens unless morphometric techniques are applied. In most forms of glomerular injury, loss of normal slit diaphragms is a key event in the development of proteinuria (see Fig. 20.7). Functional abnormalities of the slit diaphragm may also result from mutations in its components, such as nephrin and podocin, without actual inflammatory damage to the glomerulus. Such mutations are the cause of rare hereditary forms of the nephrotic syndrome.

Mechanisms of Progression in Glomerular Diseases

Thus far, the immunologic mechanisms and mediators that *initiate* glomerular injury have been discussed. The outcome of such injury depends on several factors, including the severity of renal damage, the nature and persistence of the antigens, and the immune status, age, and genetic predisposition of the host.

It has long been known that **once any renal disease, glomerular or otherwise, destroys functioning nephrons**

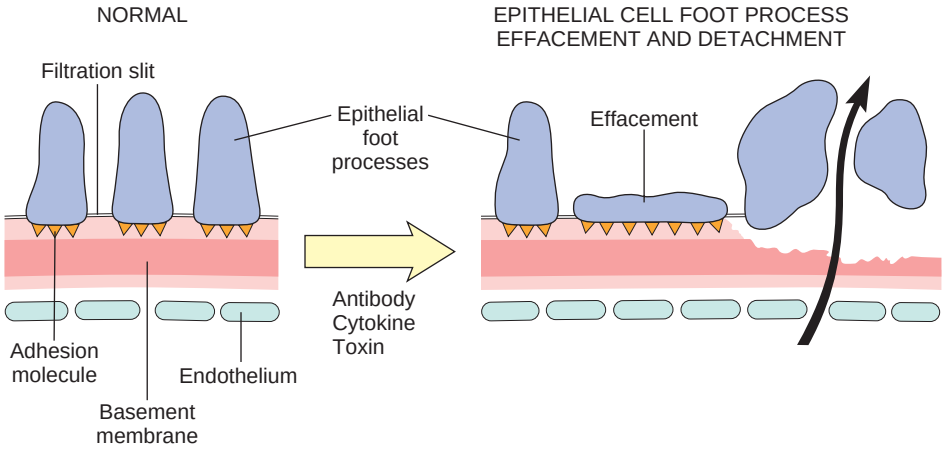

Figure 20.7 Epithelial cell injury. The postulated sequence is a consequence of antibodies specific to epithelial cell antigens, toxins, cytokines, or other factors causing injury; this results in foot process effacement and sometimes detachment of epithelial cells and protein leakage through defective glomerular basement membrane and filtration slits.

and reduces the GFR to about 30% to 50% of normal, progression to end-stage renal failure proceeds at a steady rate, independent of the original insult or activity of the underlying disease. The secondary factors that lead to progression are of great clinical interest because they can be targets of therapy that delays or even prevents the inexorable journey to dialysis or transplantation.

The two major histologic characteristics of such progressive renal damage are *glomerulosclerosis* and *tubulointerstitial fibrosis*.

Glomerulosclerosis

Sclerosis involving portions of some glomeruli (also referred to as secondary FSGS develops after many types of renal injury and can lead to proteinuria and increasing functional impairment. Glomerular sclerosis may be seen even in cases in which the primary disease was nonglomerular. The mechanisms of glomerulosclerosis in this setting are described in the discussion of FSGS later in this chapter.

Tubular Injury and Interstitial Fibrosis

Tubulointerstitial injury, manifested by tubular damage and interstitial inflammation, is a component of many acute and chronic glomerulonephritides. Tubulointerstitial fibrosis contributes to progression in both immune and nonimmune glomerular diseases, for example, diabetic nephropathy. Indeed, **there is often a much better correlation of decline in renal function with the extent of tubulointerstitial damage than with the severity of glomerular injury.** Many factors may lead to such tubulointerstitial injury, including ischemia of tubular segments downstream from sclerotic glomeruli, acute and chronic inflammation in the adjacent interstitium, and damage or loss of the peritubular capillary blood supply. It appears that proteinuria also can cause *direct injury to and activation of tubular cells*. Activated tubular cells in turn express adhesion molecules and elaborate proinflammatory cytokines, chemokines, and growth factors that contribute to interstitial fibrosis. Filtered proteins that may produce these tubular effects include cytokines, complement products, the iron in hemoglobin, immunoglobulins, lipid moieties, and oxidatively modified plasma proteins.

KEY CONCEPTS

PATHOGENESIS OF GLOMERULAR INJURY AND PROGRESSION OF GLOMERULAR DISEASE

- Antibody-mediated injury is an important mechanism of glomerular damage, mainly via complement- and leukocyte-mediated pathways. Antibodies may also be directly cytotoxic to glomerular cells.
- The most common forms of antibody-mediated glomerulonephritis are caused by the formation of immune complexes, which may involve either endogenous antigens (e.g., PLA_2R in membranous nephropathy) or exogenous antigens (e.g., microbial). Immune complexes show a granular pattern of deposition by immunofluorescence.
- Autoantibodies against components of the GBM are the cause of anti–GBM antibody–mediated disease, often associated with severe injury. The immunofluorescence pattern of antibody deposition is linear.
- Activation of the alternative complement pathway is an important mechanism of injury in C3 glomerulopathies that include dense deposit disease and C3 glomerulonephritis.
- Soluble inflammatory mediators, such as cytokines, chemokines, growth factors, eicosanoids, nitric oxide, and activated coagulation factors, also contribute to the glomerular injury.
- Epithelial cell (podocyte) injury induced by antibodies, toxins, cytokines, infections, and poorly characterized circulating factors is a common manifestation of various forms of glomerular diseases.
- Progressive glomerular injury can be the result of either primary or secondary glomerular injuries, of diseases that are either renal limited or systemic, and of diseases that initially involve renal structures other than glomeruli.
- Progressive injury ensues from a cycle of glomerular and nephron loss, compensatory changes that lead to further glomerular injury and glomerulosclerosis, and eventually ESRD.
- Progressive glomerular injury is accompanied by chronic injuries to other renal structures, typically manifest as tubulointerstitial fibrosis.

Having discussed the factors involved in the initiation and progression of glomerular injury, we now turn to a discussion of individual glomerular diseases. Table 20.5 summarizes the main clinical and pathologic features of the major forms of primary glomerulopathies.

Nephritic Syndrome

Glomerular diseases presenting with a nephritic syndrome are characterized by inflammation in the glomeruli. The main clinical features of nephritic syndrome include the following:

- *Hematuria* (red blood cells and red cell casts in urine)
- *Proteinuria* (usually subnephrotic range) with or without edema
- *Azotemia*
- *Hypertension*

Nephritic syndrome is the typical clinical presentation of most proliferative types of GN such as postinfectious GN, crescentic GN, and proliferative lupus GN. The lesions that cause the nephritic syndrome have in common proliferation of the cells within the glomeruli, often accompanied by an inflammatory leukocytic infiltrate. This inflammatory reaction severely injures the capillary walls, permitting blood to pass into the urine and inducing hemodynamic changes that lead to a reduction in GFR. The reduced GFR is manifested clinically by oliguria, fluid retention, and azotemia. Hypertension probably is a result of both the fluid retention and renin release from the ischemic kidneys.

Acute Proliferative (Postinfectious and Infection-Associated) Glomerulonephritis

As the name implies, **this cluster of diseases is characterized histologically by diffuse proliferation of glomerular cells associated with influx (exudation) of leukocytes, typically caused by immune complexes.** The inciting antigen may be exogenous or endogenous. The prototypic exogenous antigen-induced disease pattern is postinfectious

Table 20.5 Summary of Major Primary Glomerulonephritides

Disease	Most Frequent Clinical Presentation	Pathogenesis	Glomerular Pathology		
			Light Microscopy	Fluorescence Microscopy	Electron Microscopy
Postinfectious glomerulonephritis	Nephritic syndrome	Immune complex mediated; circulating or planted antigen	Diffuse endocapillary proliferation; leukocytic infiltration	Granular IgG and C3 in GBM and mesangium; Granular IgA in some cases	Primarily subepithelial humps; subendothelial deposits in early disease stages
Crescentic (rapidly progressive) glomerulonephritis	Nephritic syndrome; rapid progression	Anti-GBM antibody mediated; immune complex mediated; ANCA mediated and unknown	Extracapillary proliferation with crescents; necrosis	Linear IgG and C3 in anti-GBM antibody mediated GN; granular IgG, other Igs, and/or complement in immune complex mediated GN; or no deposits in ANCA mediated GN	No deposits in anti-GBM and ANCA mediated GN; immune complexes at various locations in immune complex mediated GN
Membranous nephropathy	Nephrotic syndrome	In situ immune complex PLA_2R antigen in most cases of primary disease	Diffuse capillary wall thickening	Granular IgG and C3; diffuse	Subepithelial deposits
Minimal change disease	Nephrotic syndrome	Unknown; loss of glomerular polyanion; podocyte injury	Normal; lipid in tubules	Negative	Effacement of foot processes; no deposits
Focal segmental glomerulosclerosis	Nephrotic syndrome; non-nephrotic proteinuria	Unknown Ablation nephropathy Plasma factor (?); podocyte injury	Focal and segmental sclerosis and hyalinosis	Focal; IgM + C3 in many cases	Effacement of foot processes; epithelial denudation
Membranoproliferative glomerulonephritis (MPGN) type I	Nephritic/ nephrotic syndrome	Immune complex	Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening; splitting	IgG ++ C3; C1q ++ C4	Subendothelial deposits
Dense-deposit disease (MPGN type II)	Hematuria Chronic renal failure	Acquired or genetic dysregulation of the alternative complement pathway	Mesangial proliferative or membranoproliferative patterns of proliferation; GBM thickening; splitting	C3; no C1q or C4	Dense deposits
IgA nephropathy	Recurrent hematuria or proteinuria	Unknown	Focal mesangial proliferative glomerulonephritis; mesangial widening	IgA ± IgG, IgM, and C3 in mesangium	Mesangial and paramesangial dense deposits

ANCA, Antineutrophil cytoplasmic antibodies; *GBM*, glomerular basement membrane.

glomerulonephritis, whereas an example of an endogenous antigen-induced disease is the nephritis of SLE, described in Chapter 6. The most common underlying infections are streptococcal, but the disorder may also be associated with other infections. Poststreptococcal GN is decreasing in frequency in the United States but continues to be a fairly common disorder worldwide. It usually appears 1 to 4 weeks after a streptococcal infection of the pharynx or skin (impetigo). Skin infections are commonly associated with overcrowding and poor hygiene. Poststreptococcal glomerulonephritis occurs most frequently in children 6 to 10 years of age, but children and adults of any age can also be affected.

Pathogenesis

Poststreptococcal GN is caused by immune complexes containing streptococcal antigens and specific antibodies. Only certain strains of group A β-hemolytic streptococci are nephritogenic, more than 90% of cases being traced to types 12, 4, and 1, which can be identified by typing of the M protein of the bacterial cell walls.

Many lines of evidence support an immunologic basis for poststreptococcal glomerulonephritis. The latent period between infection and onset of nephritis is compatible with the time required for the production of antibodies and the formation of immune complexes. Elevated titers of antibodies

against one or more streptococcal antigens are present in a great majority of patients. Serum complement levels are low, compatible with activation of the complement system and consumption of complement components. There are granular immune deposits in the glomeruli, indicative of an immune complex–mediated mechanism.

The streptococcal antigenic component responsible for the immune reaction had long eluded identification, but the preponderance of evidence identifies streptococcal pyogenic exotoxin B (SpeB) as the principal antigenic determinant in most but not all cases of poststreptococcal glomerulonephritis. This protein can directly activate complement, is commonly secreted by nephritogenic strains of streptococci, and has been localized to the "humplike" deposits characteristic of this disease (described later). At the outset, the inciting antigens are exogenously planted from the circulation in subendothelial locations in glomerular capillary walls, leading to in situ formation of immune complexes, where they elicit an inflammatory response. Subsequently, through mechanisms that are not well understood, the antigen-antibody complexes dissociate, migrate across the GBM, and reform on the subepithelial side of the GBM. Deposition of circulating immune complexes also may contribute to the lesions. A similar form of glomerulonephritis occurs sporadically in association with other infections, including those of bacterial (e.g., staphylococcal endocarditis, pneumococcal pneumonia, and meningococcemia), viral (e.g., hepatitis B, hepatitis C, mumps, HIV infection, varicella, and infectious mononucleosis), and parasitic (malaria, toxoplasmosis) origin. In these settings, granular immunofluorescent deposits and subepithelial humps characteristic of immune complex nephritis are also present.

MORPHOLOGY

The classic histologic picture is one of **enlarged, hypercellular glomeruli** (Fig. 20.8B). The hypercellularity is caused by (1) infiltration by leukocytes, both neutrophils and monocytes; (2) proliferation of endothelial and mesangial cells; and (3) in severe cases by crescent formation. The proliferation and leukocyte infiltration are typically global and diffuse, that is, involving all lobules of all glomeruli. There is also swelling of endothelial cells, and the combination of proliferation, swelling, and leukocyte

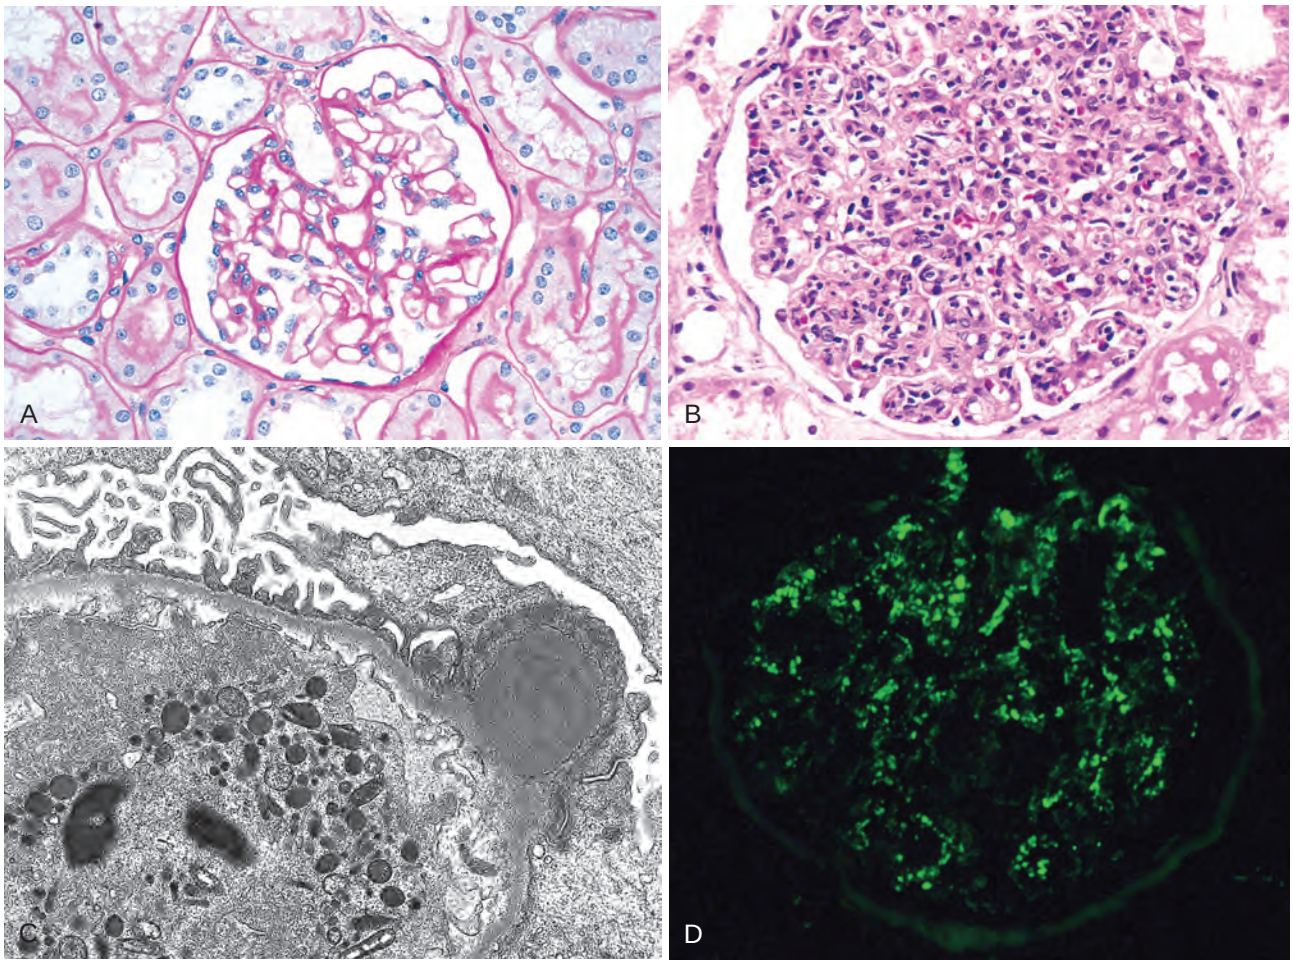

Figure 20.8 Acute proliferative glomerulonephritis. (A) Normal glomerulus. (B) Glomerular hypercellularity is due to intracapillary leukocytes and proliferation of intrinsic glomerular cells. (C) Typical electron-dense subepithelial "hump" and a neutrophil in the lumen. (D) Immunofluorescent stain demonstrates discrete, coarsely granular deposits of complement protein C3 (stain for IgG was similar), corresponding to "humps" illustrated in part C. (*A–C,* Courtesy Dr. H. Rennke, Brigham and Women's Hospital, Boston, Mass. *D,* Courtesy D. J. Kowalewska, Cedars-Sinai Medical Center, Los Angeles, Calif.)

infiltration obliterates the capillary lumens. There may be interstitial edema and inflammation, and the tubules often contain red cell casts.

By **immunofluorescence microscopy,** there are granular deposits of IgG and C3, and sometimes IgM in the mesangium and along the GBM (Fig. 20.8D). Although immune complex deposits are almost universally present, they are often focal and sparse. The characteristic **electron microscopic findings** are discrete, amorphous, electron-dense deposits on the epithelial side of the membrane, often having the appearance of "humps" (Fig. 20.8C), presumably representing the antigen-antibody complexes at the subepithelial cell surface. Subendothelial deposits are also commonly seen, typically early in the disease course, and mesangial and intramembranous deposits may be present.

Clinical Features

In the typical case, a young child abruptly develops malaise, fever, nausea, oliguria, and hematuria (smoky or cola-colored urine) 1 to 2 weeks after recovery from a sore throat. The patients have dysmorphic red cells or red cell casts in the urine, mild proteinuria (usually less than 1 g/day), periorbital edema, and mild to moderate hypertension. In adults the onset is more likely to be atypical, such as the sudden appearance of hypertension or edema, frequently with elevation of BUN. The glomerulonephritis is subclinical in some infected individual, and is discovered only on screening for microscopic hematuria carried out during epidemic outbreaks. Important laboratory findings include elevations of antistreptococcal antibody titers and a decline in the serum concentration of C3 and other components of the complement cascade.

More than 95% of affected children eventually recover renal function with conservative therapy aimed at maintaining sodium and water balance. A small minority of children (perhaps less than 1%) do not improve, become severely oliguric, and develop a rapidly progressive form of glomerulonephritis (described later). Some of the remaining patients may undergo slow progression to chronic glomerulonephritis with or without recurrence of an active nephritic picture. Prolonged and persistent heavy proteinuria and abnormal GFR mark patients with an unfavorable prognosis.

In adults the disease is less benign. Although the overall prognosis in epidemics is good, in only about 60% of sporadic cases do the patients recover promptly. In the remainder, the glomerular lesions fail to resolve quickly, as manifested by persistent proteinuria, hematuria, and hypertension. In some of these patients, the lesions eventually clear, but others develop chronic glomerulonephritis or even RPGN.

Crescentic (Rapidly Progressive) Glomerulonephritis

RPGN is a clinical syndrome associated with severe glomerular injury, but it does not denote a specific etiology. It is characterized by relatively rapid and progressive loss of renal function associated with severe oliguria and signs of nephritic syndrome; if untreated, death from renal failure may occur within weeks to months. *The most common histologic picture is the presence of crescents in most of the glomeruli, hence the name crescentic glomerulonephritis.* As discussed earlier, these are produced predominantly by the proliferation of the epithelial cells lining the Bowman capsule and by the infiltration of monocytes and macrophages.

Pathogenesis

Crescentic GN may be a manifestation of a number of different diseases, some restricted to the kidney and others systemic. Although no single mechanism can explain all cases, there is little doubt that **in most cases the glomerular injury is immunologically mediated.** A practical classification divides crescentic GN into three groups on the basis of immunologic findings (Table 20.6), which have been described as follows:

- *Anti-GBM antibody–mediated disease, characterized by linear deposits of IgG and, in many cases, C3 in the GBM.* In some of these patients, the anti-GBM antibodies cross-react with pulmonary alveolar basement membranes to produce the clinical picture of pulmonary hemorrhage associated with renal failure *(Goodpasture syndrome)*. Plasmapheresis to remove the pathogenic circulating antibodies is usually part of the treatment, which also includes therapy to suppress the underlying immune response.

  The antigen common to the alveoli and GBM is a peptide within the noncollagenous portion of the α_3 chain of collagen type IV. What triggers the formation of these autoantibodies is unclear in most patients. Exposure to viruses or hydrocarbon solvents (found in paints and dyes) has been implicated in some patients, as have various drugs and cancers. There is a high prevalence of certain HLA alleles (e.g., HLA-DRB1) in affected patients, a finding consistent with the genetic predisposition to autoimmunity.
- *Diseases caused by immune complex deposition, with granular deposits of antibodies and complement by immunofluorescence.* Crescentic GN can be a complication of any of the immune complex nephritides, including postinfectious glomerulonephritis, lupus nephritis, IgA nephropathy, and Henoch-Schönlein purpura. These patients usually cannot be helped by plasmapheresis, and they require treatment for the underlying disease.
- *Pauci-immune crescentic GN, defined by the lack of detectable anti-GBM antibodies or immune complexes by immunofluorescence and electron microscopy.* Most patients with this type of RPGN have circulating antineutrophil cytoplasmic

Table 20.6 Crescentic (Rapidly Progressive) Glomerulonephritides

Type I (Anti-GBM Antibody)
Renal limited
Goodpasture syndrome
Type II (Immune Complex)
Idiopathic
Postinfectious glomerulonephritis

Henoch-Schönlein purpura
IgA nephropathy
Others
Type III (Pauci-Immune)
ANCA-associated
Idiopathic
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
Microscopic polyangiitis

ANCA, Antineutrophil cytoplasmic antibodies; *GBM*, glomerular basement membrane.

antibodies (ANCAs) that produce a cytoplasmic (c-ANCA) or perinuclear (p-ANCA) staining pattern and are known to play a role in some vasculitides (Chapter 11). This type of RPGN may be a component of a systemic vasculitis such as granulomatosis with polyangiitis (formerly called Wegener granulomatosis) or microscopic polyangiitis. In many cases, however, pauci-immune crescentic glomerulonephritis is limited to the kidneys and hence idiopathic. More than 90% of such idiopathic cases have c-ANCAs (now called PR3-ANCA because the antibodies are specific for the neutrophil granule protein proteinase-3) or p-ANCAs (now called MPO-ANCA indicating reactivity with neutrophil myeloperoxidase) in the serum. The presence of circulating ANCAs in both idiopathic crescentic glomerulonephritis and cases of crescentic glomerulonephritis that occur as a component of systemic vasculitis, and the similar pathologic features in both settings, have led to the idea that these disorders are pathogenetically related. According to this concept, all cases of crescentic glomerulonephritis of the pauci-immune type are manifestations of small-vessel vasculitis or polyangiitis, which is limited to glomerular and perhaps peritubular capillaries in cases of idiopathic crescentic glomerulonephritis. ANCAs have proved to be invaluable as a highly sensitive diagnostic marker for pauci-immune crescentic glomerulonephritis, but proof of their role as a direct cause of this glomerulonephritis has been elusive. Recent evidence of their pathogenic potential has been obtained by studies in mice showing that transferring antibodies against myeloperoxidase (the target antigen of most p-ANCAs) induces a form of RPGN.

To summarize, about one-fifth of patients with RPGN have anti-GBM antibody–mediated glomerulonephritis without lung involvement; another one-fourth have immune complex–mediated crescentic glomerulonephritis; and the remainder are of the pauci-immune type.

MORPHOLOGY

The kidneys are enlarged and pale, often with petechial hemorrhages on the cortical surfaces. Depending on the underlying cause, the glomeruli often show focal and segmental necrosis, and variably show diffuse or focal endothelial proliferation, and mesangial proliferation. Segmental glomerular necrosis and distinctive **crescents** (Fig. 20.9) adjacent to glomerular segments uninvolved by inflammatory or proliferative changes is the feature most typical of pauci-immune RPGN. Crescents are formed by proliferation of glomerular epithelial cells and by migration of monocytes and macrophages into the urinary space. Neutrophils and lymphocytes may be present. The crescents may obliterate the urinary space and compress the glomerular tuft. **Fibrin strands are frequently prominent between the cellular layers in the crescents;** indeed, as discussed earlier, the escape of procoagulant factors, fibrin, and cytokines into Bowman space may contribute to crescent formation. By immunofluorescence microscopy, immune complex–mediated cases show granular immune deposits; Goodpasture syndrome cases show linear GBM fluorescence for Ig and complement, and pauci-immune cases have little or no deposition of immune reactants. Electron microscopy discloses deposits in those cases due to immune complex deposition. Regardless of type, electron microscopy may show **ruptures in the GBM,** a severe injury that allows leukocytes, plasma proteins such as coagulation factors and complement, and inflammatory mediators to reach the urinary space, where they trigger crescent formation (Fig. 20.10). In time, most crescents undergo organization and foci of segmental necrosis resolve as segmental scars (a type of segmental sclerosis), but restoration of normal glomerular architecture may be achieved with early aggressive therapy.

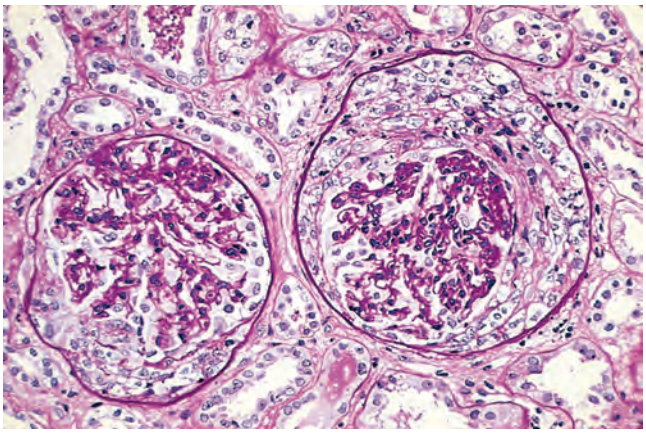

Figure 20.9 Crescentic glomerulonephritis (periodic acid–Schiff stain). Note the compressed glomerular tufts and the crescent-shaped mass of proliferating epithelial cells and leukocytes within the Bowman capsule. (Courtesy Dr. M. A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, Tex.)

Clinical Features

The renal manifestations of all forms of crescentic glomerulonephritis include hematuria with red blood cell casts in the urine, moderate proteinuria occasionally reaching the

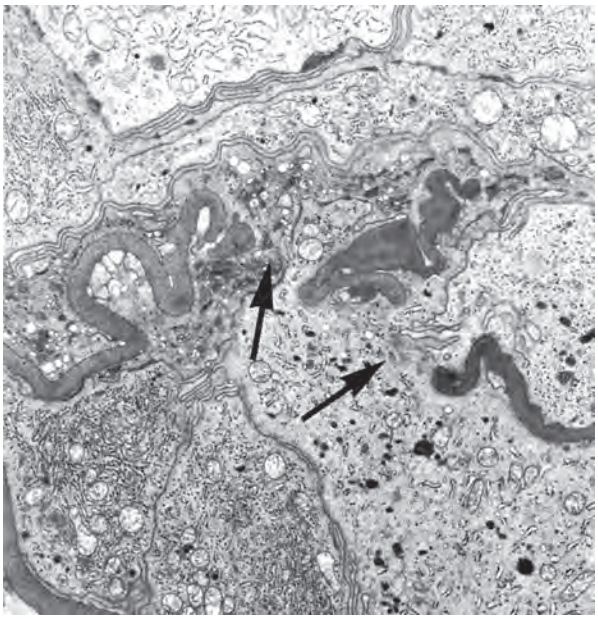

Figure 20.10 Crescentic glomerulonephritis. Electron micrograph showing characteristic wrinkling of glomerular basement membrane with focal disruptions *(arrows)*.

nephrotic range, and variable hypertension and edema. In Goodpasture syndrome, the course may be dominated by recurrent hemoptysis or even life-threatening pulmonary hemorrhage. Serum analyses for anti-GBM antibodies, antinuclear antibodies, and ANCAs are helpful in the diagnosis of specific subtypes. Although milder forms of glomerular injury may subside, the renal involvement is usually progressive over a matter of weeks and culminates in severe oliguria. Recovery of renal function may follow early intensive plasmapheresis (plasma exchange) combined with steroids and cytotoxic agents in Goodpasture syndrome. This therapy can reverse both pulmonary hemorrhage and renal failure. Other forms of RPGN also respond well to steroids and cytotoxic agents. However, despite therapy, many patients eventually require chronic dialysis or transplantation, particularly if the disease is discovered at a late stage.

KEY CONCEPTS

THE NEPHRITIC SYNDROME

- The nephritic syndrome is characterized by hematuria, oliguria with azotemia, proteinuria, and hypertension.
- The most common causes are immunologically mediated glomerular injury; lesions are characterized by proliferative changes and leukocyte infiltration.
- Acute postinfectious glomerulonephritis typically occurs after streptococcal infection in children and young adults but may occur following infection with many other organisms; it is caused by deposition of immune complexes, mainly in the subepithelial spaces, with abundant neutrophils and proliferation of glomerular cells. Most affected children recover; the prognosis is worse in adults.
- RPGN is a clinical entity with features of the nephritic syndrome and rapid loss of renal function.
- RPGN is commonly associated with severe glomerular injury with necrosis and GBM breaks and subsequent proliferation of parietal epithelial cells forming crescents, also called crescentic GN.
- Crescentic GN may be antibody mediated, caused by autoantibodies to the GBM, or as a result of immune complex deposition. It can also occur in the absence of significant antibody deposition; most patients with this type of RPGN have circulating ANCAs.

Nephrotic Syndrome

Certain glomerular diseases virtually always produce the nephrotic syndrome. In addition, many other forms of primary and secondary glomerulopathies discussed in this chapter may underlie the syndrome. Before the major diseases associated with nephrotic syndrome are presented, the causes and pathophysiology of this clinical complex are briefly discussed.

Pathophysiology

Nephrotic syndrome is caused by a derangement in glomerular capillary walls resulting in increased permeability to plasma proteins. The manifestations of the syndrome include the following:

- *Massive proteinuria,* with the daily loss of 3.5 g or more of protein (less in children)
- *Hypoalbuminemia,* with plasma albumin levels less than 3 g/dL
- *Generalized edema*
- *Hyperlipidemia and lipiduria*

The various components of nephrotic syndrome bear a logical relationship to one another. The glomerular capillary wall, with its endothelium, GBM, and visceral epithelial cells, acts as a size and charge barrier through which the plasma filtrate passes. Increased permeability resulting from either structural or physicochemical alterations in this barrier allows proteins to escape from the plasma into the urinary space, resulting in proteinuria.

Heavy proteinuria depletes serum albumin levels at a rate beyond the compensatory synthetic capacity of the liver, resulting in hypoalbuminemia. Increased renal catabolism of filtered albumin also contributes to the hypoalbuminemia. The generalized edema is a direct consequence of *decreased intravascular colloid osmotic pressure*. There is also *sodium and water retention,* which aggravates the edema (Chapter 4). This seems to be due to several factors, including compensatory secretion of aldosterone, mediated by the hypovolemia-enhanced renin secretion; stimulation of the sympathetic system; and a reduction in the secretion of natriuretic factors such as atrial peptides. Edema is characteristically soft and pitting, and it is most marked in the periorbital regions and dependent portions of the body. If severe, it may also lead to pleural effusions and ascites.

The largest proportion of protein lost in the urine is albumin, but globulins are also excreted in some diseases. The ratio of low- to high-molecular-weight proteins in the urine in various cases of nephrotic syndrome is a manifestation of the selectivity of proteinuria. A highly selective proteinuria consists mostly of low-molecular-weight proteins (albumin, 70 kD; transferrin, 76 kD molecular weight), whereas a poorly selective proteinuria consists of higher-molecular-weight globulins in addition to albumin.

The genesis of the hyperlipidemia is complex. Most patients with nephrotic syndrome have increased blood levels of cholesterol, triglyceride, very-low-density lipoprotein, low-density lipoprotein, lipoprotein(a), and apoprotein, and there is a decrease in high-density lipoprotein concentration in some patients. These defects seem to be due to a combination of increased synthesis of lipoproteins in the liver, abnormal transport of circulating lipid particles, and decreased lipid catabolism. Lipiduria follows the hyperlipidemia, because lipoproteins also leak across the glomerular capillary wall. The lipid appears in the urine either as free fat or as *oval fat bodies,* representing lipoprotein resorbed by tubular epithelial cells and then shed along with injured tubular cells that have detached from the basement membrane.

Nephrotic patients are particularly vulnerable to *infection,* especially staphylococcal and pneumococcal infections, probably due to loss of immunoglobulins in the urine. *Thrombotic and thromboembolic complications* are also common in nephrotic syndrome, due in part to loss of endogenous anticoagulants (e.g., antithrombin III) in the urine. *Renal vein thrombosis,* once thought to be a cause of nephrotic syndrome, is most often a consequence of this hypercoagulable state, particularly in patients with membranous nephropathy (see later).

Pathogenesis

The incidences of the several causes of the nephrotic syndrome vary according to age and geography. In children younger than 17 years of age in North America, for example, nephrotic syndrome is almost always caused by a lesion primary to the kidney; among adults, in contrast, it is often associated with a systemic disease. Table 20.7 represents a composite derived from several studies of the causes of the nephrotic syndrome and is therefore only approximate. The most frequent *systemic causes* of the nephrotic syndrome are diabetes, amyloidosis, and SLE. The most important of the *primary glomerular lesions* are minimal change disease, membranous nephropathy, and FSGS. The first is most common in children in North America, the second is most common in older adults, and FSGS occurs at all ages. These three lesions are discussed individually in the following sections. Other less common causes of nephrotic syndrome include the various proliferative glomerulonephritides such as MPGN and IgA nephropathy.

Membranous Nephropathy

Membranous nephropathy is characterized by diffuse thickening of the glomerular capillary wall due to the accumulation of deposits containing Ig along the subepithelial side of the basement membrane. Approximately 75% of cases of membranous nephropathy are primary. The remaining cases occur in association with other systemic diseases and have identifiable etiologic agents, and hence are referred to as secondary membranous nephropathy. The most notable of these associations are as ollows:

- *Drugs* (penicillamine, captopril, gold, nonsteroidal antiinflammatory drugs [NSAIDs]). From 1% to 7% of patients with rheumatoid arthritis treated with penicillamine or gold (drugs now used infrequently for this disease) develop membranous nephropathy.
- *Underlying malignant tumors,* particularly carcinomas of the lung and colon, and melanoma. According to some studies, these are present in as many as 5% to 10% of adults with membranous nephropathy.
- *SLE.* About 10% to 15% of glomerulonephritis in SLE is of the membranous type.
- *Infections* (chronic hepatitis B, hepatitis C, syphilis, schistosomiasis, malaria)
- *Other autoimmune disorders* such as thyroiditis can be associated with secondary membranous nephropathy.

Table 20.7 Cause of Nephrotic Syndrome

Causes	Approximate Prevalence (%)[a]	
	Children	Adults
Primary Glomerular Disease		
Membranous nephropathy	3	30
Minimal change disease	75	8
Focal segmental glomerulosclerosis	10	35
Membranoproliferative glomerulonephritis and dense deposit disease[b]	10	10
Other proliferative glomerulonephritides (focal, "pure mesangial," IgA nephropathy)[b]	2	17
Systemic Diseases		
Diabetes mellitus		
Amyloidosis		
Systemic lupus erythematosus		
Drugs (nonsteroidal antiinflammatory, penicillamine, heroin)		
Infections (malaria, syphilis, hepatitis B and C, HIV)		
Malignant disease (carcinoma, lymphoma)		
Miscellaneous (bee-sting allergy, hereditary nephritis)		

[a]Approximate prevalence of primary disease = 95% of nephrotic syndrome in children, 60% in adults. Approximate prevalence of systemic disease = 5% in children, 40% in adults.

[b]Membranoproliferative and other proliferative glomerulonephritides may result in mixed nephrotic/nephritic syndromes.

Pathogenesis

Membranous nephropathy is a form of chronic immune complex–mediated disease. In secondary membranous nephropathy, the inciting antigens can sometimes be identified in the immune complexes. The antigens may be endogenous or exogenous. The endogenous antigens may be renal or nonrenal (described later). Membranous nephropathy in SLE is associated with deposition of complexes of self nuclear proteins and autoantibodies. Exogenous antigens include those derived from hepatitis B virus and *Treponema pallidum* in patients infected with these microbes.

Primary (formerly idiopathic) membranous nephropathy is an *autoimmune disease caused in most cases by antibodies to a renal autoantigen.* A major recent advance came from the identification of the M-type phospholipase A_2 receptor (PLA_2R) as the antigen that underlies 60% to 70% of human membranous nephropathy. Autoantibody binding to PLA_2R, a membrane protein at the basal surface of the glomerular epithelial cell, is followed by complement activation and then shedding of the immune aggregates from the cell surface to form characteristic deposits of immune complexes along the *subepithelial aspect* of the basement membrane (see Fig. 20.4C). Less often, the target antigen is thrombospondin type-1 domain–containing 7A (THSD7A) or neutral endopeptidase (CD10), a membrane protein recognized by placentally transferred maternal antibodies in cases of neonatal membranous nephropathy. The lesions bear a striking resemblance to those of experimental Heymann nephritis, which is induced by antibodies to the megalin antigenic complex present in the rat podocyte, the antigenic counterpart of the human PLA_2R.

How does the glomerular capillary wall become leaky in membranous nephropathy? There is a paucity of neutrophils, monocytes, or platelets in glomeruli. The virtually uniform presence of complement and corroborating experimental work suggest that the complement C5b–C9 membrane attack complex has an important role. It is postulated that C5b–C9 activates glomerular epithelial and mesangial cells, inducing them to liberate proteases and oxidants, which cause capillary wall injury and increased protein leakage. A subclass of IgG, IgG4, which differs from other IgG subclasses in being a poor activator of the classical complement pathway, is the principal immunoglobulin deposited in most cases of membranous nephropathy. How IgG4 may activate the complement system is not clear.

MORPHOLOGY

By light microscopy, the glomeruli either appear normal in the early stages of the disease or exhibit **uniform, diffuse thickening of the glomerular capillary wall** (Fig. 20.11A). By electron microscopy, the thickening is seen to be caused by irregular electron-dense deposits containing immune complexes between the basement membrane and the overlying epithelial cells, with effacement of podocyte foot processes (Fig. 20.11B and D). Basement membrane material is laid down between these deposits, appearing as irregular spikes protruding from the GBM. These spikes are best seen by silver stains, which color the basement membrane, but not the deposits, black. In time, these spikes thicken to produce domelike protrusions and eventually close over the immune deposits, burying them within a markedly thickened, irregular membrane. Immunofluorescence microscopy demonstrates that the granular deposits contain both immunoglobulins and complement (Fig. 20.11C). Immunostains also reveal PLA_2R or THSD7A glomerular positivity in the majority of patients; however, a significant proportion of patients with secondary membranous nephropathy can also be positive. As the disease advances, segmental sclerosis may occur; in the course of time, glomeruli may become totally sclerosed. The epithelial cells of the proximal tubules contain protein reabsorption droplets, and there may be considerable interstitial mononuclear cell inflammation.

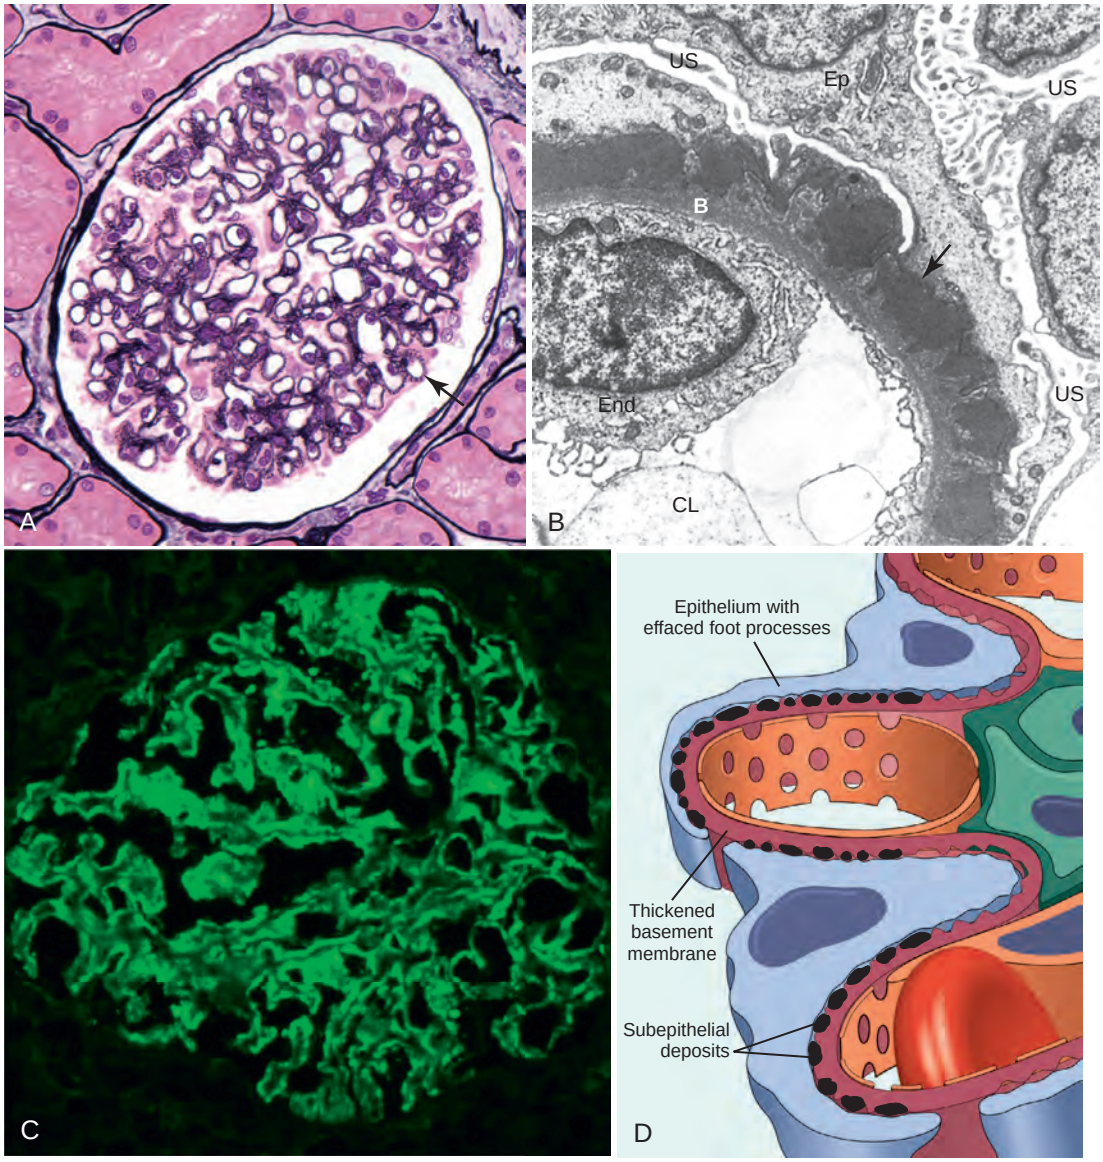

Figure 20.11 Membranous nephropathy. (A) Silver methenamine stain. Note the marked diffuse thickening of the capillary walls without an increase in the number of cells. There are prominent "spikes" of silver-staining matrix *(arrow)* projecting from the basement membrane lamina densa toward the urinary space, which separate and surround deposited immune complexes that lack affinity for the silver stain. (B) Electron micrograph showing electron-dense deposits *(arrow)* along the epithelial side of the basement membrane (B). Note the effacement of foot processes overlying deposits. (C) Characteristic granular immunofluorescent deposits of IgG along the glomerular basement membrane. (D) Diagrammatic representation of membranous nephropathy. *CL,* Capillary lumen; *End,* endothelium; *Ep,* epithelium; *US,* urinary space. Clinical Features

This disorder usually presents with the insidious onset of the nephrotic syndrome or, in 15% of patients, with non-nephrotic proteinuria. Hematuria and mild hypertension are present in 15% to 35% of cases. It is necessary in any patient to first rule out the secondary causes described earlier, because treatment of the underlying condition (malignant neoplasm, infection, or SLE) or discontinuance of the offending drug can reverse or ameliorate the injury.

The course of the disease is variable but generally indolent. In contrast to minimal change disease, described later, the proteinuria is nonselective and usually does not respond well to corticosteroid therapy. Complete or partial remissions may occur in up to 40% of patients, even in some patients without therapy. Progression is associated with increasing sclerosis of glomeruli, rising serum creatinine reflecting renal insufficiency, and development of hypertension. Although proteinuria persists in more than 60% of patients, only about 10% die or progress to renal failure within 10 years, and no more than 40% eventually develop severe chronic kidney disease or ESRD. The disease recurs in up to 40% of patients who undergo transplantation for ESRD. Spontaneous remissions and a relatively benign outcome occur more commonly in women and in those with proteinuria in the non-nephrotic range.

Because of the variable course of the disease, it has been difficult to evaluate the overall effectiveness of corticosteroids or other immunosuppressive therapy in controlling the proteinuria or progression. It is thought that circulating antibodies to PLA_2R and THSD7A may be useful biomarkers of disease activity and thereby aid in the diagnosis and management of membranous nephropathy.

Minimal Change Disease

This relatively benign disorder is characterized by diffuse effacement of foot processes of visceral epithelial cells (podocytes), detectable only by electron microscopy, in glomeruli that appear normal by light microscopy. It is the most frequent cause of nephrotic syndrome in children, but it is less common in adults (see Table 20.7). The peak incidence is between 2 and 6 years of age. The disease sometimes follows a respiratory infection or routine prophylactic immunization.

Pathogenesis

Although the absence of immune deposits in the glomerulus excludes immune complex–mediated injury, several features of the disease point to an immunologic basis, including (1) the clinical association with respiratory infections and prophylactic immunization; (2) the response to corticosteroids and/or other immunosuppressive therapy; (3) the association with other atopic disorders (e.g., eczema, rhinitis); (4) the increased prevalence of certain HLA haplotypes in cases associated with atopy (suggesting a genetic predisposition); and (5) the increased incidence of minimal change disease in patients with Hodgkin lymphoma, in whom defects in T cell–mediated immunity are well recognized.

The current leading hypothesis is that minimal change disease involves some immune dysfunction that results in the elaboration of factors that damage visceral epithelial cells and cause proteinuria. Candidate pathogenic factors such as angiopoietin-like-4 have been identified in animal models, but none of these factors have been proven to cause the human disease. The ultrastructural changes point to a primary *visceral epithelial cell injury* (podocytopathy), and studies in animal models suggest the loss of glomerular polyanions. Thus, defects in the charge barrier may contribute to the proteinuria. The actual route by which protein traverses the epithelial cell portion of the capillary wall remains an enigma. Possibilities include transcellular passage through epithelial cells, passage through residual spaces between remaining but damaged foot processes or through abnormal spaces developing underneath the portion of the foot process that directly abuts the basement membrane, or leakage through foci in which the epithelial cells have become detached from the basement.

MORPHOLOGY

The glomeruli are normal by light microscopy (Fig. 20.12A). By electron microscopy the GBM appears normal, and no electron-dense material is deposited. **The principal lesion is in the visceral epithelial cells, which show a uniform and diffuse effacement of foot processes,** these being reduced to a rim of cytoplasm with loss of recognizable intervening slit diaphragms (Fig. 20.12B). This change, often incorrectly termed "fusion" of foot processes, actually represents simplification of the epithelial cell architecture with flattening, retraction, and swelling of foot processes. Foot process effacement is also present in other proteinuric states (e.g., membranous glomerulopathy, diabetic nephropathy); it is only when effacement is associated with normal glomeruli by light microscopy that the diagnosis of minimal change disease can be made. The visceral epithelial changes are completely reversible after corticosteroid therapy, concomitant with remission of the proteinuria. The cells of the proximal tubules are often laden with lipid and protein, reflecting tubular reabsorption of lipoproteins passing through diseased glomeruli (thus, the historical name **lipoid nephrosis** for this disease). Immunofluorescence studies show no Ig or complement deposits.

Clinical Features

Despite massive proteinuria, renal function remains good, and there is commonly no hypertension or hematuria. The proteinuria usually is highly selective, most of the protein being albumin. **A characteristic feature is its usually dramatic response to corticosteroid therapy.** Most children (>90%) with minimal change disease respond rapidly to this treatment. However, proteinuria may recur in a significant proportion of patients, and some patients may become steroid-dependent or resistant. Nevertheless, the long-term prognosis for patients is excellent, and even steroid-dependent disease usually resolves when children reach puberty. Although adults are slower to respond, their long-term prognosis is also excellent.

As has been noted, minimal change disease in adults can be associated with Hodgkin lymphoma and, less frequently, other lymphomas and leukemias. In addition, secondary minimal change disease may follow NSAID therapy, usually in association with acute interstitial nephritis, to be described later in this chapter.

Focal Segmental Glomerulosclerosis

Primary FSGS is the most common cause of nephrotic syndrome in adults in the United States. It is sometimes

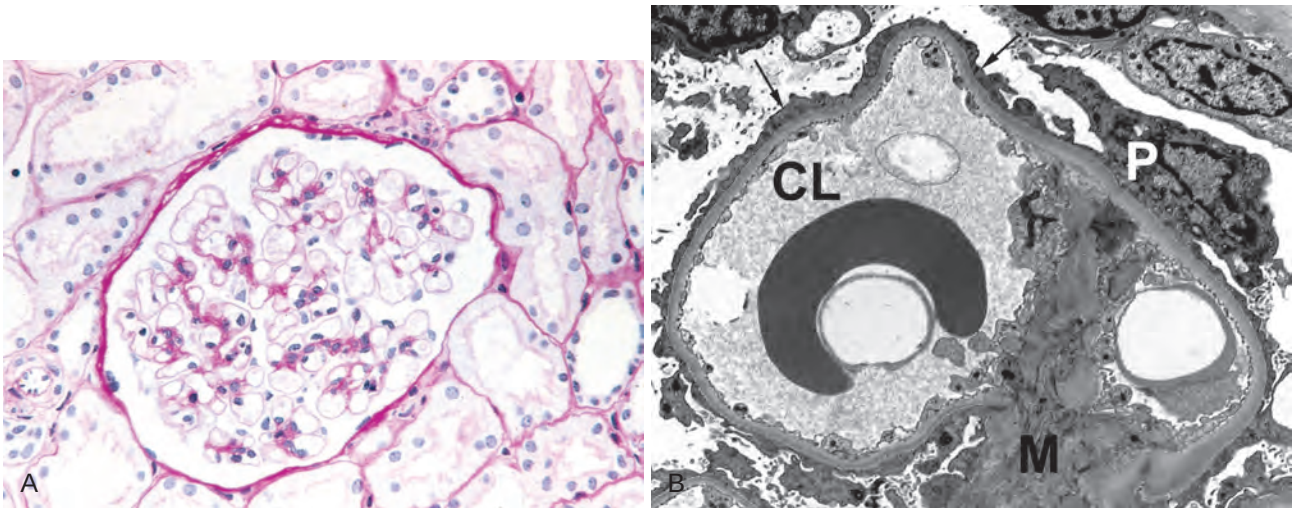

Figure 20.12 Minimal change disease. (A) Glomerulus stained with periodic acid–Schiff. Note normal basement membranes and absence of proliferation. (B) Ultrastructural characteristics of minimal change disease include effacement of foot processes *(arrows)* and absence of deposits. *CL,* Capillary lumen; *M,* mesangium; *P,* podocyte cell body.

considered to be a primary disorder of podocytes, like minimal change disease. As the name implies, this lesion is characterized by sclerosis of some, but not all, glomeruli (thus, it is focal); and in the affected glomeruli, only a portion of the capillary tuft is involved (thus, it is segmental). FSGS is frequently manifest clinically by the acute or subacute onset of nephrotic syndrome or non-nephrotic proteinuria. Hypertension, microscopic hematuria, and some degree of azotemia are commonly present when the disease is first clinically recognized.

Classification and Types

FSGS occurs in the following settings:

- As a primary disease (idiopathic FSGS)
- In association with other known conditions, such as HIV infection (HIV-associated nephropathy), heroin addiction (heroin nephropathy), sickle cell disease, and morbid obesity
- As a secondary event, reflecting scarring of previously active necrotizing lesions, in cases of focal glomerulonephritis (e.g., IgA nephropathy)
- As a component of the adaptive response to loss of renal tissue (renal ablation, described earlier), whether from congenital anomalies (e.g., unilateral renal agenesis or renal dysplasia) or acquired causes (e.g., reflux nephropathy), or in advanced stages of other renal disorders, such as hypertensive nephropathy.
- In uncommon inherited forms of nephrotic syndrome where the disease may be caused by mutations in genes that encode proteins localized to the slit diaphragm, e.g., podocin, α-actinin 4, and TRPC6 (transient receptor potential calcium channel-6)

Idiopathic FSGS accounts for 10% and 35% of cases of nephrotic syndrome in children and adults, respectively. FSGS (both primary and secondary forms) has increased in incidence and is now the most common cause of nephrotic syndrome in adults in the United States, particularly in Hispanic and African-American patients. The clinical signs differ from those of minimal change disease in the following respects: (1) there is a higher incidence of hematuria, reduced GFR, and hypertension; (2) proteinuria is more often nonselective; (3) there is poor response to corticosteroid therapy; and (4) there is progression to chronic kidney disease, with at least 50% developing ESRD within 10 years.

Pathogenesis

The characteristic degeneration and focal disruption of visceral epithelial cells with effacement of foot processes resemble the diffuse epithelial cell change typical of minimal change disease and other podocytopathies. *This epithelial damage is the ultrastructural hallmark of FSGS.* Multiple different mechanisms can cause such epithelial damage, including circulating factors and genetically determined defects affecting components of the slit diaphragm complex. The hyalinosis and sclerosis stem from entrapment of plasma proteins in extremely hyperpermeable foci and increased ECM deposition. The recurrence of proteinuria after transplantation, sometimes within 24 hours, with subsequent progression to overt lesions of FSGS, suggests that an unknown circulating factor is the cause of the epithelial damage in some patients.

The discovery of a genetic basis for some cases of FSGS and other causes of the nephrotic syndrome has improved the understanding of the pathogenesis of proteinuria in the nephrotic syndrome and has provided new methods for diagnosis and prognosis. Inherited forms of FSGS may be associated with the following:

- The first relevant gene to be identified, *NPHS1,* maps to chromosome 19q13 and encodes the protein *nephrin*. Nephrin is a key component of the slit diaphragm (see Fig. 20.3), the structure that controls glomerular permeability. Several mutations of the *NPHS* gene have been identified that give rise to *congenital nephrotic syndrome* of the Finnish type, producing a minimal change disease–like glomerulopathy with extensive foot process effacement.
- A distinctive pattern of autosomal recessive FSGS results from mutations in the *NPHS2* gene, which maps to chromosome 1q25–q31 and encodes the protein product

podocin. Podocin has also been localized to the slit diaphragm. Mutations in *NPHS2* result in a syndrome of steroid-resistant nephrotic syndrome of childhood onset.

- Mutations in the gene encoding the podocyte actin-binding protein α-actinin 4 underlie some cases of autosomal dominant FSGS, which can be insidious in onset but has a high rate of progression to renal insufficiency.
- Mutations in the gene encoding TRPC6 have been found in some kindreds with adult-onset FSGS. This protein is widely expressed, including in podocytes, and the pathogenic mutations may perturb podocyte function by increasing calcium flux in these cells.

What these proteins have in common is their localization to the slit diaphragm and to adjacent podocyte cytoskeletal structures. Their specific functions and interactions are incompletely understood, but it is clear that the integrity of each is necessary to maintain the normal glomerular filtration barrier. Recently, two sequence variants (G1/G2 risk alleles) in the apolipoprotein L1 gene *(APOL1)* on chromosome 22 have been strongly associated with an increased risk of FSGS and renal failure in individuals of African descent, although the mechanisms underlying this association are not yet known. These sequence variants are particularly remarkable because the selective pressures for their conservation in people of African descent is a result of resistance to trypanosome infection conferred by these polymorphisms.

Renal ablation FSGS, a secondary form of FSGS, occurs as a complication of glomerular and nonglomerular diseases causing reduction in functioning renal tissue. Particularly striking examples in which this occurs are reflux nephropathy and unilateral agenesis. These may lead to progressive glomerulosclerosis and renal failure. The glomerulosclerosis seems to be initiated by the adaptive change that occurs in the relatively unaffected glomeruli of diseased kidneys. Such a mechanism is suggested by experiments in rats subjected to subtotal nephrectomy. *Compensatory hypertrophy* of the remaining glomeruli initially maintains renal function in these animals, but proteinuria and segmental glomerulosclerosis soon develop, leading eventually to total glomerular sclerosis and uremia. The glomerular hypertrophy is associated with *hemodynamic changes,* including increases in glomerular blood flow, filtration, and transcapillary pressure (glomerular hypertension), and often with systemic hypertension.

The sequence of events (Fig. 20.13) that is thought to lead to sclerosis in this setting entails endothelial and visceral epithelial cell injury; visceral epithelial cell loss leading to segments of GBM denuded of overlying foot processes and consequent increased glomerular permeability to proteins; and accumulation of proteins in the mesangial matrix. This is followed by proliferation of mesangial cells, infiltration by macrophages, increased accumulation of extracellular matrix (ECM), and segmental and eventually global sclerosis of glomeruli. With increasing reductions in nephron mass and ongoing compensatory changes, a vicious cycle of continuing glomerulosclerosis sets in. Most of the mediators of chronic inflammation and fibrosis, particularly TGF-β, play a role in the development of sclerosis. Currently, the most successful interventions to interrupt these mechanisms of progressive glomerulosclerosis involve treatment with inhibitors of the renin-angiotensin system, which not only reduce intraglomerular hypertension, but also have direct effects on each of the mechanisms identified earlier. Importantly, these agents have been shown to ameliorate progression of sclerosis in both animal and human studies.

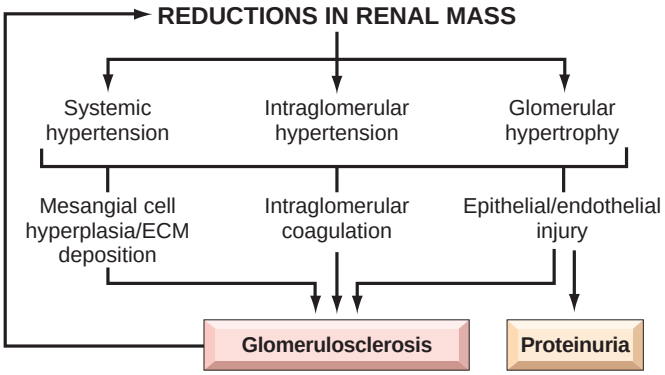

Figure 20.13 Focal segmental glomerulosclerosis associated with loss of renal mass. The adaptive changes in glomeruli (hypertrophy and glomerular capillary hypertension), as well as systemic hypertension, cause epithelial and endothelial injury and resultant proteinuria. The mesangial response, involving mesangial cell proliferation and extracellular matrix production, together with intraglomerular coagulation, causes glomerulosclerosis. This results in further loss of functioning nephrons and a vicious circle of progressive glomerulosclerosis.

MORPHOLOGY

By light microscopy, the **focal and segmental lesions may involve only a minority of the glomeruli** and may be missed if the biopsy specimen contains an insufficient number of glomeruli (Fig. 20.14A). In the sclerotic segments, there is collapse of capillary loops, increase in matrix, and segmental deposition of plasma proteins along the capillary wall (hyalinosis), which may become so pronounced as to occlude capillary lumens. Lipid droplets and foam cells are often present (Fig. 20.14B). Glomeruli that do not show segmental lesions usually appear normal on light microscopy but may show increased mesangial matrix. On electron microscopy, both sclerotic and nonsclerotic areas show **diffuse effacement of foot processes,** and there may also be focal detachment of the epithelial cells and denudation of the underlying GBM. By immunofluorescence microscopy, IgM and C3 may be present in the sclerotic areas and/or in the mesangium. In addition to the focal sclerosis, there may be pronounced hyalinosis and thickening of afferent arterioles. With progression of the disease, increased numbers of glomeruli become involved, and sclerosis spreads within each glomerulus. In time, this leads to total (i.e., global) sclerosis of glomeruli, with pronounced tubular atrophy and interstitial fibrosis.

A morphologic variant of FSGS, called **collapsing glomerulopathy,** is characterized by retraction and/or collapse of the entire glomerular tuft, with or without additional FSGS lesions of the type described earlier (Fig. 20.15). A characteristic feature is proliferation and hypertrophy of glomerular visceral epithelial cells. Collapsing glomerulopathy may be idiopathic, but it also has been associated with some drug toxicities (e.g., pamidronate), and it is the most characteristic lesion of HIV-associated nephropathy. Collapsing glomerulopathy is typically associated with prominent tubular injury with formation of microcysts and prominent interstitial inflammation. It has a particularly poor prognosis.

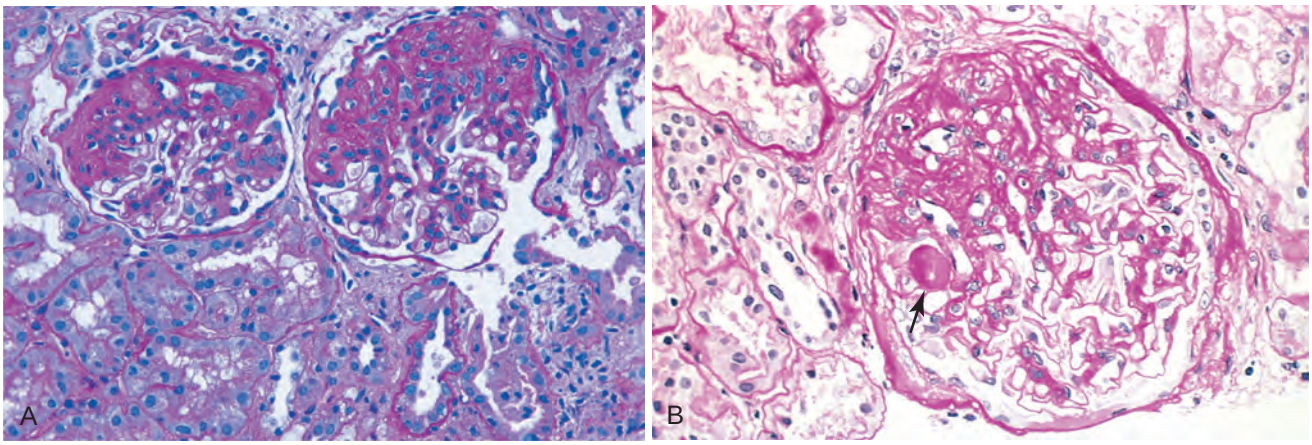

Figure 20.14 Focal segmental glomerulosclerosis, periodic acid–Schiff stain. (A) Segmental sclerosis involves the upper half of both glomeruli. (B) High-power view showing hyaline insudation *(arrow)* and lipid (small vacuoles) in sclerotic area.

Clinical Features

There is little tendency for spontaneous remission in idiopathic FSGS, and responses to corticosteroid therapy are variable. In general, children have a better prognosis than adults do. Progression to renal failure occurs at variable rates. About 20% of patients follow an unusually rapid course, with intractable massive proteinuria ending in renal failure within 2 years. Factors associated with rapid progression include the degree of proteinuria, the degree of renal insufficiency at diagnosis, and histologic subtype (the collapsing variant has an unfavorable course; the tip variant has a relatively good prognosis). Recurrences are seen in 25% to 50% of patients receiving allografts.

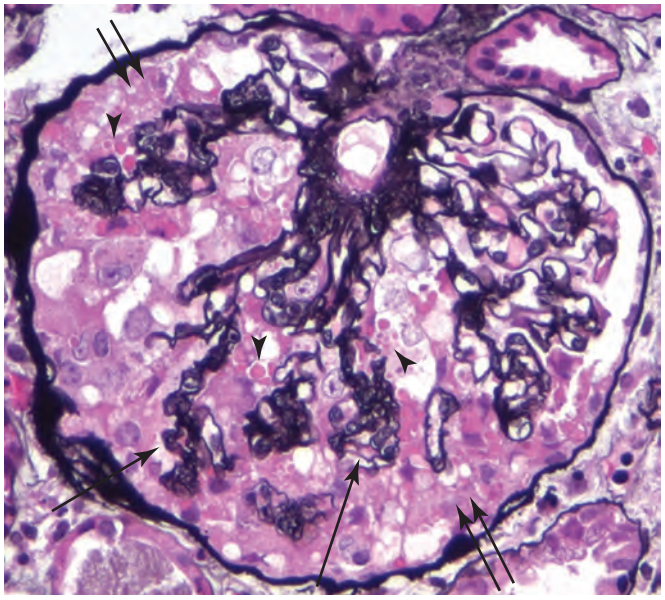

Figure 20.15 Collapsing glomerulopathy. Visible are retraction of the glomerular tuft *(arrows)*, narrowing of capillary lumens, proliferation and swelling of visceral epithelial cells *(double arrows)*, and prominent accumulation of intracellular protein absorption droplets in the visceral epithelial cells *(arrowheads)*. HIV-Associated Nephropathy

HIV infection can directly or indirectly cause several renal complications, including acute renal failure or acute interstitial nephritis induced by drugs or infection, thrombotic microangiopathies, postinfectious glomerulonephritis, and, most commonly, a severe form of the collapsing variant of FSGS, termed *HIV-associated nephropathy*. The latter has been reported in 5% to 10% of HIV-infected individuals in some older series, more frequently in blacks than in whites. With the advent of antiretroviral therapy for HIV infection, the incidence of this lesion has been much reduced. The morphologic features of HIV-associated nephropathy are:

- A high frequency of the collapsing variant of FSGS (see Fig. 20.15)
- A striking focal cystic dilation of tubule segments, which are filled with proteinaceous material, and inflammation and fibrosis
- The presence of large numbers of tubuloreticular inclusions within endothelial cells, detected by electron microscopy. Such inclusions, also present in SLE, have been shown to be modifications of endoplasmic reticulum induced by circulating interferon-α. They are not usually present in idiopathic FSGS and therefore may have diagnostic value in a biopsy specimen.

The pathogenesis of HIV-associated FSGS is unclear, but may be primarily due to the presence of the G1/G2 risk alleles for *APOL1*. There is some data to suggest that HIV can infect tubular epithelial cells and podocytes, but much remains to be known.

Membranoproliferative Glomerulonephritis

MPGN is best considered a pattern of immune-mediated injury rather than a specific disease. An emerging consensus on classification separates MPGN into two groups, one (type I) characterized by deposition of immune complexes containing IgG and complement, and a second (type II, now called *dense deposit disease*) in which activation of complement appears to be the most important factor. The latter belong to a group of disorders called *C3 glomerulopathies*. The criteria that define this group are still evolving.

MPGN is characterized histologically by alterations in the GBM, accumulation of mesangial matrix, proliferation of glomerular cells, leukocyte infiltration, and the presence of deposits in mesangial regions and glomerular capillary walls. As we will describe later, these deposits are made up of immune complexes in type I MPGN and some unknown material in type II MPGN. In type II, C3 is present on the GBM but not in the dense deposits. This difference is important and suggests that although morphologically similar, types I and II MPGN are pathogenically distinct. In both types, because the proliferation is predominantly in the mesangium but also may involve the capillary loops, an older synonym is *mesangiocapillary glomerulonephritis*.

MPGN accounts for up to 10% of cases of nephrotic syndrome in children and young adults. Some patients present only with hematuria or proteinuria in the non-nephrotic range, but many others have a combined nephrotic-nephritic picture. MPGN is increasingly recognized to be associated with other systemic disorders and known etiologic agents (secondary MPGN), but there is still a residue of cases of unknown etiology (primary MPGN).

Pathogenesis

In most cases of type I MPGN, there is evidence of immune complexes in the glomerulus and activation of both classical and alternative complement pathways. The antigens involved in idiopathic MPGN are unknown. In many cases, they are believed to be proteins derived from infectious agents such as hepatitis C and B viruses, which presumably behave either as "planted" antigens after first binding to or becoming trapped within glomerular structures or are contained in preformed immune complexes deposited from the circulation.

MORPHOLOGY

The **glomeruli are large and hypercellular.** The hypercellularity is produced both by proliferation of cells in the mesangium and so-called endocapillary proliferation involving capillary endothelium and infiltrating leukocytes. The glomeruli have an accentuated "lobular" appearance due to the **proliferating mesangial cells and increased mesangial matrix** (Fig. 20.16). The GBM is thickened, and often shows a **"double-contour" or "tram-track" appearance**, especially evident in silver or PAS stains. This is caused by **"duplication" of the basement membrane** (also commonly referred to as splitting), usually as the result of new basement membrane synthesis in response to subendothelial deposits of immune complexes. Between the duplicated basement membranes, there is inclusion or interposition of cellular elements, which can be of mesangial, endothelial, or leukocytic origin. Such interposition also gives rise to the appearance of "split" basement membranes (Fig. 20.17A). Crescents are present in many cases.

Type I MPGN is characterized by the presence of discrete **subendothelial electron-dense deposits.** Mesangial and occasional subepithelial deposits may also be present (see Fig. 20.17A). By immunofluorescence, IgG and C3 are deposited in a granular pattern, and early complement components (C1q and C4) are often also present, indicative of an immune complex pathogenesis.

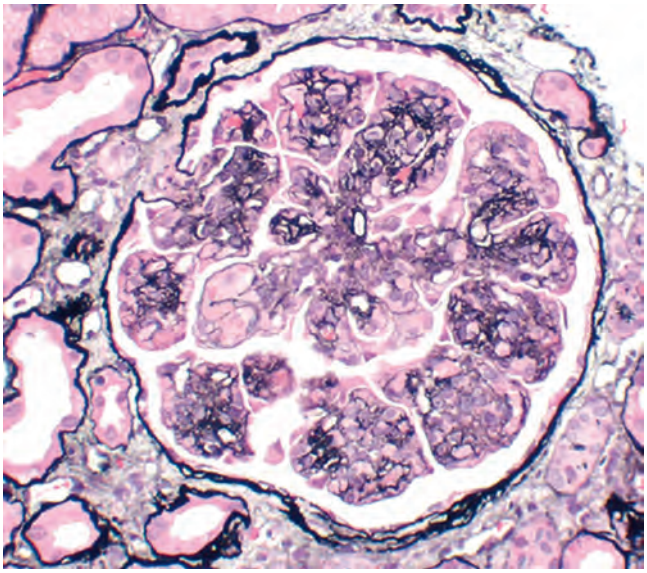

Figure 20.16 Membranoproliferative glomerulonephritis, showing mesangial cell proliferation, increased mesangial matrix (staining black with silver stain), basement membrane thickening with segmental splitting, accentuation of lobular architecture, swelling of cells lining peripheral capillaries, and influx of leukocytes (endocapillary proliferation).

Clinical Features

Most patients with primary MPGN present in adolescence or as young adults with nephrotic syndrome and a nephritic component manifested by hematuria or, more insidiously, as mild proteinuria. Few remissions occur spontaneously in either type, and the disease follows a slowly progressive but unremitting course. Some patients develop numerous crescents and a clinical picture of RPGN. About 50% develop chronic renal failure within 10 years. Treatments with steroids, immunosuppressive agents, and antiplatelet drugs have not proven to be of any benefit.

Secondary Membranoproliferative Glomerulonephritis

Secondary MPGN (invariably type I) is more common in adults and arises in the following settings:

- Chronic immune complex disorders, such as SLE; hepatitis B infection; hepatitis C infection, usually with cryoglobulinemia; endocarditis; infected ventriculoatrial shunts; chronic visceral abscesses; HIV infection; and schistosomiasis
- α_1-Antitrypsin deficiency
- Malignant diseases, particularly lymphoid tumors such as chronic lymphocytic leukemia, which are commonly complicated by development of autoantibodies

Dense Deposit Disease

Most patients with dense-deposit disease (formerly called type II MPGN) have abnormalities resulting in excessive activation of the alternative complement pathway. These patients have a consistently decreased serum C3 but normal C1 and C4, the early components of complement. They also have diminished serum levels of Factor B and properdin, components of the alternative complement pathway. The glomeruli contain deposits of C3 and properdin but not IgG. Recall that in the alternative complement pathway, C3 is directly cleaved to C3b (Fig. 20.18; see also Chapter 3,

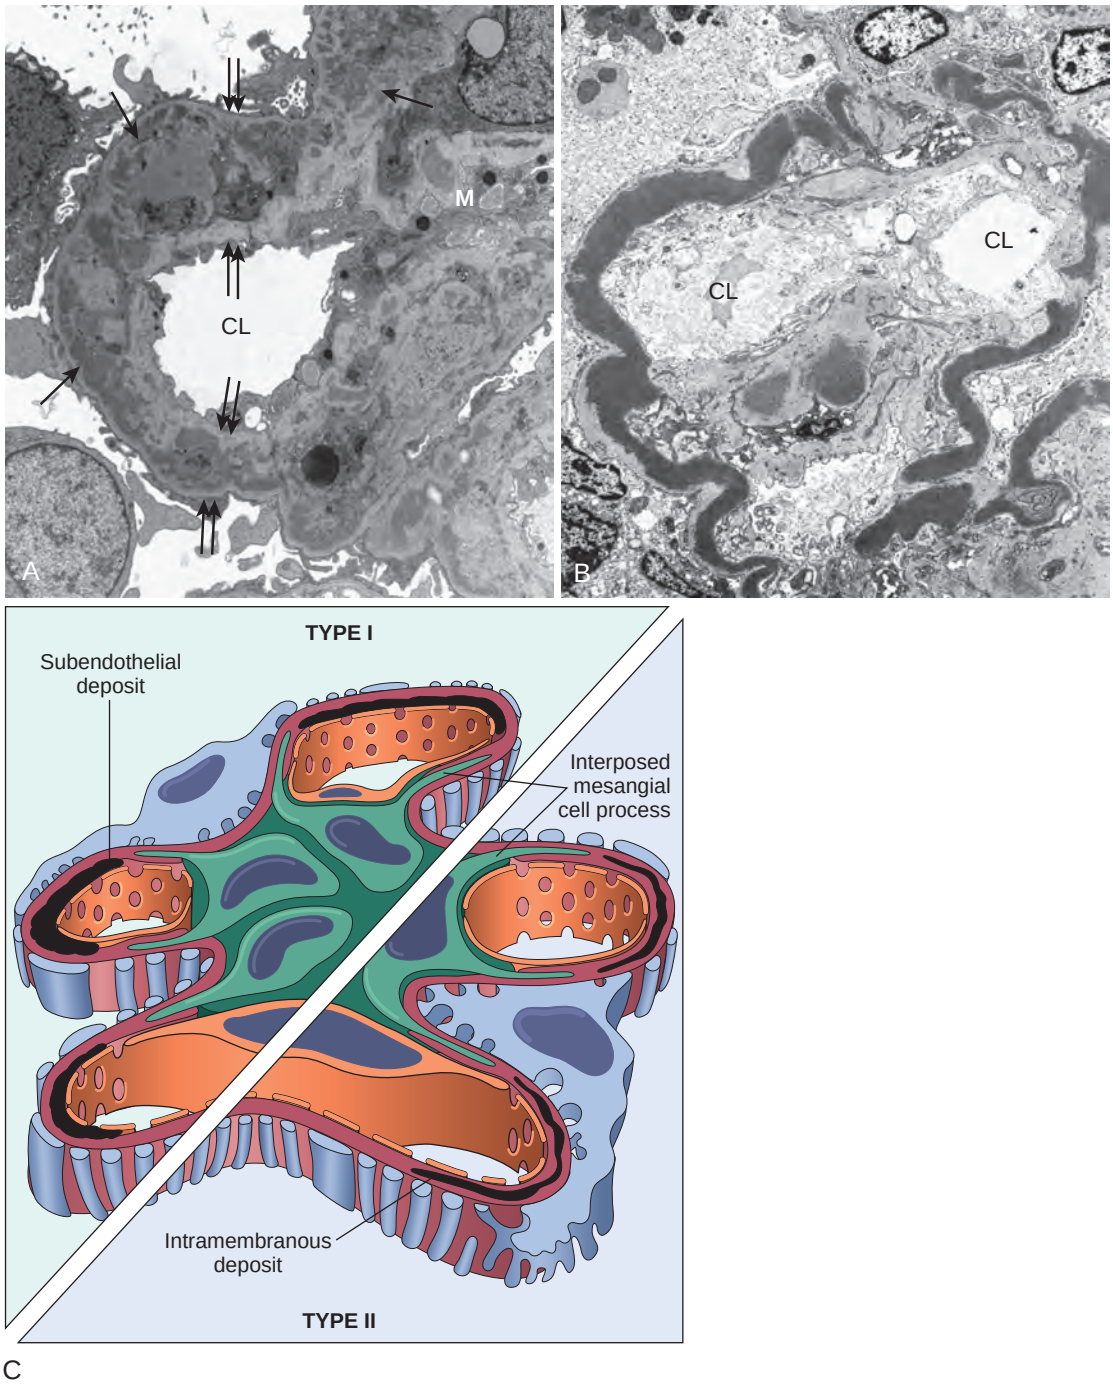

Figure 20.17 (A) Membranoproliferative glomerulonephritis, type I. Note discrete electron-dense deposits *(arrows)* incorporated into the glomerular capillary wall between duplicated (split) basement membranes *(double arrows)*, and in mesangial regions *(M);* (B) Dense-deposit disease (type II membranoproliferative glomerulonephritis). There are dense homogeneous deposits within the basement membrane. In both, mesangial interposition gives the appearance of split basement membranes when viewed in the light microscope. (C) Schematic representation of patterns in the two types of membranoproliferative glomerulonephritis. In type I, there are subendothelial deposits; type II is characterized by intramembranous dense deposits (dense-deposit disease). In both, the basement membranes appear split when viewed in the light microscope. *CL,* Capillary lumen. (A, Courtesy Dr. Jolanta Kowalewska, Cedars-Sinai Medical Center, Los Angeles, Calif.)

Fig. 3.12). The reaction depends on the initial activation of C3 by such substances as bacterial polysaccharides, endotoxin, and aggregates of IgA via a pathway involving Factors B and D. This leads to the generation of C3bBb, the alternative pathway C3 convertase. Normally, this C3 convertase is labile, but more than 70% of patients with dense-deposit disease have a circulating autoantibody termed *C3 nephritic factor (C3NeF)* that binds the alternative pathway C3 convertase and protects it from inactivation (see Fig. 20.18). This favors persistent C3 activation and hypocomplementemia. There is also decreased C3 synthesis by the liver, further contributing to the profound hypocomplementemia.

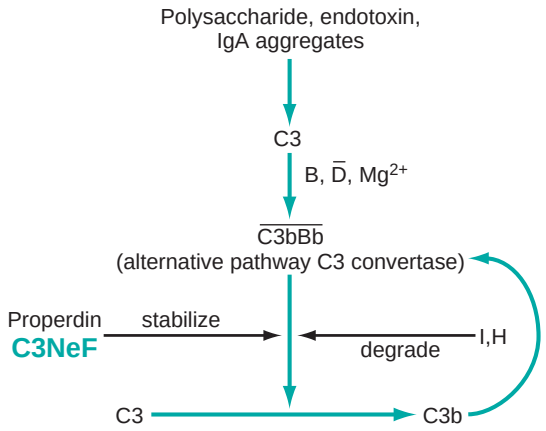

Figure 20.18 The alternative complement pathway in C3 glomerulopathy and atypical hemolytic uremic syndrome. Note that C3NeF, an antibody present in the serum of individuals with membranoproliferative glomerulonephritis, acts at the same step as properdin, serving to stabilize the alternative pathway C3 convertase, thus enhancing C3 activation and consumption, causing hypocomplementemia.

The precise nature of the dense deposits is unknown. Mutations in components of the alternate pathway such as Factor H have also been associated with dense deposit disease.

MORPHOLOGY

While some cases of dense deposit disease share histologic features with MPGN, there is a wider spectrum of histologic alterations in dense deposit disease. Many cases have a predominately mesangial proliferative pattern of injury, while others have an inflammatory and focally crescentic appearance. In some cases, dense deposits of a cellular material can be seen permeating the GBMs in histologic sections. The defining feature is revealed by election microscopy, which demonstrates permeation of the lamina densa of the GBM by a ribbonlike, homogeneous, extremely electron-dense material of unknown composition (see Fig. 20.17B). By immunofluorescence, C3 is present in irregular granular or linear foci in the basement membranes on either side but not within the dense deposits. C3 is also present in the mesangium in characteristic circular aggregates (mesangial rings). IgG is usually absent, as are components of the classical pathway of complement activation (such as C1q and C4). C3 glomerulopathies other than dense deposit disease can have a similar distribution, with mesangial and capillary wall involvement, but lack the extremely electron dense deposits that define dense deposit disease.

Clinical Features

Dense deposit disease affects primarily children and young adults. The clinical presentation of nephritic syndrome with hematuria and/or nephrotic syndrome with proteinuria overlaps with that of MPGN. The prognosis is poor, with over one-half of patients progressing to ESRD. There is a high incidence of recurrence in transplant recipients; dense deposits recur in 90% of such patients.

Fibrillary Glomerulonephritis

Fibrillary glomerulonephritis is a rare disease characterized by fibrillary deposits in the mesangium and glomerular capillary walls that resemble amyloid fibrils superficially but differ ultrastructurally and do not stain with Congo red. The glomerular lesions usually show mesangioproliferative or membranoproliferative patterns by light microscopy. By immunofluorescence microscopy, there is selective deposition of polyclonal IgG, often of the IgG4 subclass, complement C3, and Igκ and Igλ light chains. Clinically, patients develop nephrotic syndrome, hematuria, and progressive renal insufficiency. The disease recurs in kidney transplants. The pathogenesis is unknown, but DNAJB9, a co-chaperone for heat shock protein 70s, recently has been identified as a highly sensitive and specific marker for fibrillary GN.

KEY CONCEPTS

THE NEPHROTIC SYNDROME

- Membranous nephropathy is caused by an autoimmune response, most often directed against the PLA_2R on podocytes; it is characterized by granular subepithelial deposits of antibodies with GBM thickening and loss of foot processes but little or no inflammation; the disease is often resistant to steroid therapy.
- The nephrotic syndrome is characterized by proteinuria, which results in hypoalbuminemia and edema.
- Podocyte injury is an underlying mechanism of proteinuria, and may be the result of nonimmune causes (as in minimal change disease and FSGS) or immune mechanisms (as in membranous nephropathy).
- Minimal change disease is the most frequent cause of nephrotic syndrome in children; it is manifested by proteinuria and effacement of glomerular foot processes without antibody deposits; the pathogenesis is unknown; secondary forms can be triggered by infections, immunization, drugs, and certain neoplastic lesions; the disease responds well to steroid therapy.
- FSGS may be primary (podocyte injury by unknown mechanisms) or secondary (e.g., as a consequence of prior glomerulonephritis, hypertension, or infection such as HIV); glomeruli show focal and segmental obliteration of capillary lumens, and loss of foot processes; the disease is often resistant to therapy and may progress to ESRD.
- MPGN in most cases is the result of immune complex deposition in both mesangial regions and capillary walls. It may be associated with systemic infections.
- Dense deposit disease (formerly type II MPGN), defined by a unique permeation of GBMs by electron dense material, primarily affects children and young adults. It is associated with acquired or genetic dysregulation of the alternate pathway of complement.
- Fibrillary glomerulonephritis is a rare disease characterized by Congo-red negative fibrillary glomerular deposits of unknown etiology.

Other Glomerular Diseases

IgA Nephropathy (Berger Disease)

IgA nephropathy, characterized by the presence of prominent IgA deposits in the mesangial regions and recurrent hematuria, is the most common type of glomerulonephritis worldwide. The disease can be suspected by light microscopic examination, but the diagnosis is made only by the detection of glomerular IgA deposition (Fig. 20.19). Mild proteinuria is usually present, and the nephrotic syndrome

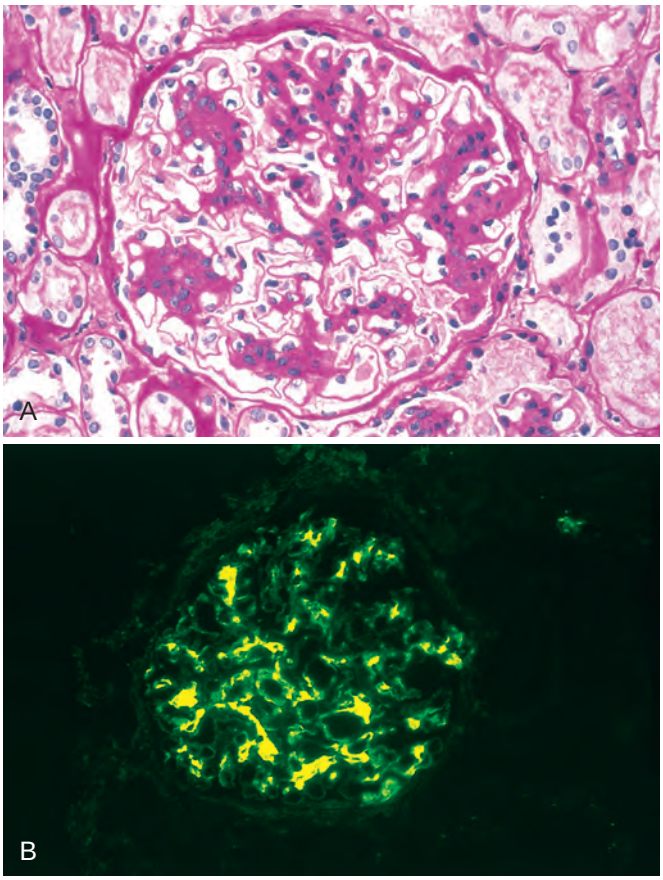

Figure 20.19 IgA nephropathy. (A) Light microscopy showing mesangial proliferation and matrix increase. (B) Characteristic deposition of IgA, principally in mesangial regions, detected by immunofluorescence.

may occasionally develop. Rarely, patients may present with crescentic GN.

Whereas IgA nephropathy is typically an isolated renal disease, similar IgA deposits are present in a systemic disorder of children, *Henoch-Schönlein purpura,* to be discussed later, which has many overlapping features with IgA nephropathy. In addition, *secondary IgA nephropathy* occurs in patients with liver and intestinal diseases, as discussed later.

Pathogenesis

Current evidence favors a "multi-hit" etiology for this disorder involving several steps. IgA, the main Ig in mucosal secretions, is present in plasma at low concentrations, mostly in monomeric form, the polymeric forms being catabolized in the liver. In patients with IgA nephropathy, levels of plasma polymeric IgA are increased, but increased production is not sufficient to cause this disease. A clue comes from the observation that in IgA nephropathy, the glomerular deposits consist predominantly of polymeric IgA molecules with aberrant glycosylation. It is believed that a key facet of IgA nephropathy is a hereditary or acquired defect in the normal formation or attachment of galactose-containing sugar chains called O-linked glycans to the hinge region of the IgA molecule (particularly to those of the IgA1 subclass) prior to their secretion by B cells. This aberrantly glycosylated IgA is either deposited by itself in glomeruli, or it elicits an autoimmune response and forms immune complexes in the circulation with IgG autoantibodies directed against the abnormal IgA molecules. The immune complexes are deposited in the mesangium; alternatively, the abnormal IgA1 is deposited in the mesangium with subsequent formation of immune complexes in situ. The mesangial immune deposits then activate mesangial cells to proliferate, produce increased amounts of ECM, and secrete numerous cytokines and growth factors. These secreted mediators may not only participate in further mesangial cell activation but may also recruit inflammatory cells into the glomeruli. The recruited leukocytes contribute to glomerular injury and also to a reparative response, which can include opsonization and removal of the immune complexes. The deposited IgA and IgA-containing immune complexes activate the complement system via the alternate pathway, and hence the presence of C3 and the absence of C1q and C4 in glomeruli are typical of this disorder. A genetic influence is suggested by the occurrence of this condition in families and in HLA-identical siblings, the increased frequency of certain HLA and complement genotypes in some populations, and the findings of genomewide association studies linking specific MHC Class II loci to disease susceptibility.

Epidemiologic features of this disorder indicate that the increased synthesis of abnormal IgA may occur in response to respiratory or gastrointestinal exposure to environmental agents (e.g., viruses, bacteria, food proteins). The specific initiating antigens are unknown, and several infectious agents and food products have been implicated. IgA nephropathy occurs with increased frequency in individuals with *gluten enteropathy* (celiac disease), in whom intestinal mucosal defects are well defined, and in *liver disease,* in which there is defective hepatobiliary clearance of IgA complexes *(secondary IgA nephropathy)*.

MORPHOLOGY

On histologic examination, the lesions vary considerably. The glomeruli may be normal or may show mesangial widening and endocapillary proliferation (mesangioproliferative glomerulonephritis) (Fig. 20.19A), segmental proliferation confined to some glomeruli (focal proliferative glomerulonephritis), or rarely, overt crescentic glomerulonephritis. The presence of leukocytes within glomerular capillaries is a variable feature. The mesangial widening may be the result of cell proliferation, accumulation of matrix, immune deposits, or some combination of these abnormalities. Healing of the focal proliferative lesion may lead to secondary focal segmental sclerosis. The characteristic immunofluorescent picture is of **mesangial deposition of IgA** (Fig. 20.19B), often with C3 and properdin and lesser amounts of IgG or IgM. Early complement components are usually absent. Electron microscopy confirms the presence of electron-dense deposits predominantly in the mesangium; capillary wall deposits, if present, are usually sparse.

Clinical Features

The disease affects people of any age, most commonly older children and young adults. Many patients present with gross hematuria after an infection of the respiratory or, less commonly, gastrointestinal or urinary tract; 30% to 40% have only microscopic hematuria, with or without proteinuria;

and 5% to 10% develop acute nephritic syndrome, including some with RPGN. The hematuria typically lasts for several days and then subsides, only to return every few months. The subsequent course is highly variable. Many patients maintain normal renal function for decades. Slow progression to chronic renal failure occurs in 15% to 40% of cases over a period of 20 years. Onset in old age, heavy proteinuria, hypertension, and the extent of glomerulosclerosis on biopsy are clues to an increased risk of progression. Recurrence of IgA deposits in transplanted kidneys is frequent, and in approximately 15% of those with recurrent IgA deposits, the disease runs the same slowly progressive course as that of primary IgA nephropathy.

Hereditary Nephritis

Hereditary nephritis refers to a group of heterogeneous familial renal diseases associated with mutations in collagen genes that manifest primarily with glomerular injury. Two deserve discussion: *Alport syndrome,* because the lesions and genetic defects have been well studied, and *thin basement membrane nephropathy,* the most common cause of *benign familial hematuria*.

Alport Syndrome

Alport syndrome is caused by mutations affecting type IV collagen that result in hematuria with progression to chronic renal failure, accompanied by nerve deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy. The disease is inherited as an X-linked trait in approximately 85% of cases. In the X-linked form, males express the full syndrome, while female heterozygotes typically present with hematuria. Approximately 90% of affected males progress to ESRD before 40 years of age. Autosomal recessive and autosomal dominant pedigrees also exist, in which males and females are equally susceptible to the full syndrome.

Pathogenesis

The disease manifestations are due to mutations in one of several genes coding for subunits of the collagen IV molecule. More than 500 mutations resulting in disease have been identified, all of which interfere with assembly of type IV collagen, which is crucial for function of the GBM, the lens of the eye, and the cochlea. Because the GBM consists of networks of trimeric collagen IV molecules composed of α_3, α_4, and α_5 chains, mutations affecting any one chain result in defective assembly of the collagen network. Because type IV collagen chains are encoded on autosomes (chromosomes 2 and 13) and the X-chromosome, the inheritance pattern can be autosomal or X-linked. Missense and splice site mutations, insertions, and deletions have all been identified. Genetic analysis has shown that in patients with X-linked disease, large deletions in the collagen IV α_5 chain (COL4A5) are associated with ESRD at an earlier age.

MORPHOLOGY

Fully developed Alport syndrome has characteristic electron microscopic findings. The GBM shows irregular foci of thickening alternating with attenuation (thinning), and pronounced splitting and lamination of the lamina densa, often producing a distinctive basket-weave appearance (Fig. 20.20). Similar alterations can be found in the tubular basement membranes.

Immunohistochemistry can be helpful in cases with absent or borderline basement membrane lesions, because antibodies to α_3, α_4, and α_5 collagen fail to stain both glomerular and tubular basement membranes in the classic X-linked form. There is also absence of α_5 staining in skin biopsy specimens from these patients. As the disease progresses, there is development of focal segmental and global glomerulosclerosis and other changes of progressive renal injury, including vascular sclerosis, tubular atrophy, and interstitial fibrosis.

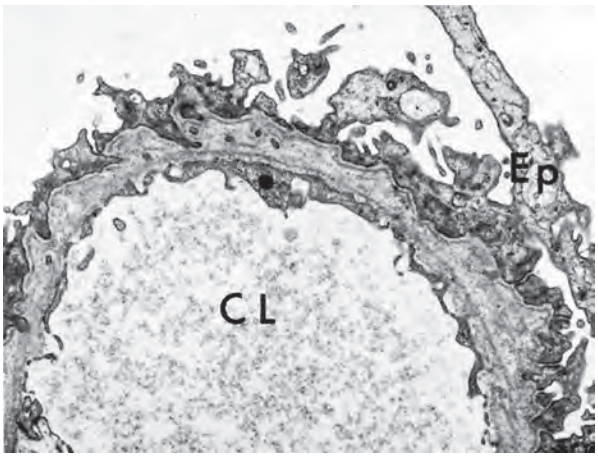

Figure 20.20 Hereditary nephritis (Alport syndrome). Electron micrograph of a glomerular capillary with irregular thickening of the basement membrane, lamellation of the lamina densa, and foci of rarefaction. Such changes may be present in other diseases but are most pronounced and widespread in hereditary nephritis. *CL,* Capillary lumen; *Ep,* epithelium.

Clinical Features

The most common presenting sign is gross or microscopic hematuria, frequently accompanied by red cell casts. Proteinuria may develop later, and rarely, the nephrotic syndrome develops. Symptoms appear at 5 to 20 years of age, and the onset of overt renal failure is between 20 and 50 years of age in men. The auditory defects may be subtle, requiring sensitive testing.

Thin Basement Membrane Nephropathy (Benign Familial Hematuria)

This is a fairly common hereditary entity manifested *clinically by familial asymptomatic hematuria* – usually uncovered on routine urinalysis – *and morphologically by diffuse thinning of the GBM* to widths between 150 and 225 nm (compared with 300 to 400 nm in healthy adults). Although mild or moderate proteinuria may also be present, renal function is normal and prognosis is excellent. The abnormality is estimated to affect 1% of the general population.

The disorder should be distinguished from IgA nephropathy, another common cause of hematuria, and X-linked Alport syndrome. In contrast to Alport syndrome, hearing loss, ocular abnormalities, and a family history of renal failure are absent.

The anomaly in thin basement membrane nephropathy has also been traced to mutations in genes encoding α_3 or

α_4 chains of type IV collagen. The disease most often has an autosomal inheritance, and most patients are heterozygous for the defective gene. The disorder in homozygotes resembles autosomal recessive Alport syndrome. Homozygotes or compound heterozygotes may progress to renal failure. Thus, these diseases illustrate a continuum of changes resulting from mutations in collagen type IV genes.

KEY CONCEPTS

GLOMERULAR DISEASES WITH ISOLATED HEMATURIA

- IgA nephropathy, characterized by mesangial deposits of IgA-containing immune complexes, is the most common cause of glomerulonephritis worldwide. It is a common cause of both isolated and frequently recurrent hematuria and of various degrees of proteinuria and sometimes of nephritic syndrome; it commonly affects children and young adults and has a variable course.
- Alport syndrome, a form of hereditary nephritis, is caused by mutations in genes encoding GBM type IV collagen. It manifests as hematuria and slowly progressing proteinuria and declining renal function; glomeruli appear normal by light microscopy until late in the disease course.
- Thin basement membrane nephropathy has a benign clinical course and is also the result of mutations in genes coding for GBM type IV collagen and hence may be considered as part of a spectrum of diseases that includes hereditary nephritis.

Glomerular Lesions Associated With Systemic Diseases

Many immunologically mediated, metabolic, or hereditary systemic disorders are associated with glomerular injury; in some (e.g., SLE and diabetes), the glomerular involvement is a major clinical manifestation. Most of these diseases are discussed elsewhere in this book. Here we briefly recall some of the lesions and discuss only those not considered in other sections.

Lupus Nephritis

The various types of lupus nephritis are described in Chapter 6. As discussed, SLE gives rise to a wide variety of renal lesions and clinical presentations. Clinical manifestations can include recurrent microscopic or gross hematuria, nephritic syndrome, RPGN, nephrotic syndrome, acute and chronic renal failure, and hypertension.

Henoch-Schönlein Purpura

This childhood syndrome consists of purpuric skin lesions, abdominal pain and intestinal bleeding, and arthralgias along with renal abnormalities. Skin lesions characteristically involve the extensor surfaces of arms and legs as well as buttocks; abdominal manifestations include pain, vomiting, and intestinal bleeding. Renal manifestations occur in one-third of patients and include gross or microscopic hematuria, nephritic syndrome, nephrotic syndrome, or some combination of these. A small number of patients, mostly adults, develop a rapidly progressive form of glomerulonephritis with many crescents. Not all components of the syndrome need to be present for the diagnosis, and individual patients may have purpura, abdominal pain, or urinary abnormalities as the dominant feature. The disease is most common in children 3 to 8 years of age, but it also occurs in adults, in whom the renal manifestations are usually more severe. There is a strong background of atopy in about one-third of patients, and onset often follows an upper respiratory infection. IgA is deposited in the glomerular mesangium in a distribution similar to that of IgA nephropathy. This has led to the concept that *IgA nephropathy and Henoch-Schönlein purpura are manifestations of the same disease.* The finding of Ig and C3 deposits in glomeruli suggests that immune complexes are involved in the disease.

MORPHOLOGY

On histologic examination, the renal lesions vary from mild focal mesangial proliferation to diffuse mesangial proliferation and/or endocapillary proliferation to crescentic glomerulonephritis. Whatever the histologic lesions, the pathognomonic feature by fluorescence microscopy is the **deposition of IgA, sometimes with IgG and C3, in the mesangial region**, sometimes with deposits extending to the capillary loops. The skin lesions consist of subepidermal hemorrhages and a necrotizing vasculitis involving the small vessels of the dermis. Deposits of IgA, along with IgG and C3, are also present in such vessels. Vasculitis also occurs in other organs, such as the gastrointestinal tract, but is rare in the kidney.

The course of the disease is variable, but recurrences of hematuria may persist for many years after onset. Most children have an excellent prognosis. Patients with the more diffuse lesions, crescents, or the nephrotic syndrome have a somewhat poorer prognosis.

Diabetic Nephropathy

Diabetes is a major cause of renal morbidity and mortality, and diabetic nephropathy is the leading cause of chronic kidney failure in the United States. Advanced or end-stage kidney disease occurs in as many as 40% of both type 1 diabetics and type 2 diabetics. The pathology and pathogenesis of this disorder are discussed in Chapter 24.

Other Systemic Disorders

Goodpasture syndrome (Chapter 15), *microscopic polyangiitis,* and *granulomatosis with polyangiitis* (formerly called *Wegener granulomatosis)* (Chapter 11) are commonly associated with glomerular lesions, as described in the discussion of these diseases. Suffice it to say here that the glomerular lesions in these three conditions can be histologically similar and are principally characterized by foci of glomerular necrosis and crescent formation. In the early or mild forms of renal involvement, there is focal and segmental, sometimes necrotizing, glomerulonephritis, and most of these patients will have hematuria with a mild decline in GFR. In the more severe cases, which may be associated with RPGN, there is more extensive necrosis, fibrin deposition, and extensive formation of epithelial (cellular) crescents, which can become organized to form fibrocellular and fibrous crescents if the glomerular injury evolves into segmental or global scarring (sclerosis).

Essential mixed cryoglobulinemia is another systemic condition in which deposits of cryoglobulins composed principally of IgG-IgM complexes induce cutaneous vasculitis, synovitis, and a proliferative glomerulonephritis, typically MPGN. Most cases of essential mixed cryoglobulinemia have been associated with infection with hepatitis C virus, and this condition in particular is associated with glomerulonephritis, usually MPGN type I.

Immunoglobulins secreted by plasma cell neoplasms may also induce glomerular lesions, including amyloidosis.

TUBULAR AND INTERSTITIAL DISEASES

Most forms of tubular injury involve the interstitium as well; therefore, diseases affecting these two components are discussed together. Under this heading, we consider two major processes: (1) ischemic or toxic tubular injury, and (2) inflammation of the tubules and interstitium *(tubulointerstitial nephritis)*.

Acute Tubular Injury/Necrosis

ATI is characterized by acute renal failure and often, but not invariably, morphologic evidence of tubular injury, in the form of necrosis of tubular epithelial cells. Because necrosis is often not present, the term ATI is preferred by pathologists over the older name *acute tubular necrosis* (ATN). It is the most common cause of acute kidney injury. ATI can be caused by a variety of conditions, including the following:

- *Ischemia, due to decreased or interrupted blood flow*. Examples include diffuse involvement of the intrarenal blood vessels such as in microscopic polyangiitis, microangiopathies (e.g., hemolytic uremic syndrome [HUS] or thrombotic thrombocytopenic purpura [TTP]), or decreased effective circulating blood volume, as occurs in hypovolemic shock (Chapter 4).
- *Direct toxic injury to the tubules*. This may be caused by *endogenous* agents, e.g., myoglobin, hemoglobin, monoclonal light chains, bile/bilirubin, *or exogenous agents,* e.g., drugs, radiocontrast dyes, heavy metals, organic solvents.

ATI accounts for some 50% of cases of acute kidney injury in hospitalized patients. Other causes of acute renal failure are discussed elsewhere in this chapter.

ATI is a reversible process that arises in a variety of clinical settings. Most of these, ranging from severe trauma to acute pancreatitis, have in common a period of inadequate blood flow to the peripheral organs, usually accompanied by marked hypotension and shock. This pattern is called *ischemic ATI*. The second pattern, called *nephrotoxic ATI,* is caused by a multitude of drugs, such as gentamicin, radiographic contrast agents, poisons, including heavy metals (e.g., mercury), and organic solvents (e.g., carbon tetrachloride). Combinations of ischemic and nephrotoxic ATI also can occur, exemplified by mismatched blood transfusions and other hemolytic crises causing *hemoglobinuria* and skeletal muscle injuries causing *myoglobinuria*. Such injuries result in characteristic intratubular hemoglobin or myoglobin casts, respectively; the toxic iron content of these globin molecules contributes to the ATI. In addition to its frequency, the potential reversibility of ATI adds to its clinical importance. Proper management can make the difference between recovery and death.

Pathogenesis

The critical events in both ischemic and nephrotoxic ATI are (1) tubular injury and (2) persistent and severe disturbances in blood flow (Fig. 20.21).

- *Tubular cell injury:* Tubular epithelial cells, especially those of proximal tubules, are particularly sensitive to ischemia and are also vulnerable to toxins. Several factors predispose the tubules to toxic injury, including an increased surface area for tubular reabsorption, active transport systems for ions and organic acids, a high rate of metabolism and oxygen consumption that is required to perform these transport and reabsorption functions, and the capability for resorption and concentration of toxins. Ischemia causes numerous structural and functional

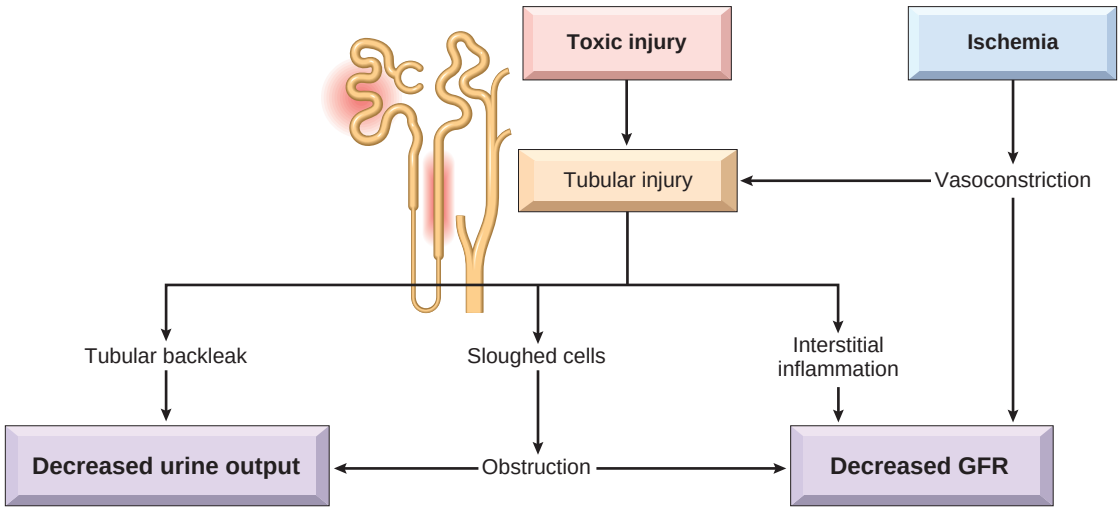

Figure 20.21 Postulated sequence in ischemic or toxic acute tubular injury. *GFR,* Glomerular filtration rate.

alterations in epithelial cells, as discussed in Chapter 2. One early reversible result of ischemia is loss of cell polarity due to redistribution of membrane proteins (e.g., the enzyme Na,K^+-ATPase) from the basolateral to the luminal surface of the tubular cells, resulting in abnormal ion transport across the cells and increased sodium delivery to distal tubules, which incites vasoconstriction via *tubuloglomerular feedback*. Initially, this response to the increased sodium lowers the GFR to maintain distal blood flow. In addition, ischemic tubular cells express cytokines and adhesion molecules, thus recruiting leukocytes that appear to participate in the subsequent injury. In time, injured cells detach from the basement membranes and cause *luminal obstruction,* increased intratubular pressure, and further decrease in GFR. In addition, glomerular filtrate in the lumen of the damaged tubules can leak back into the interstitium, resulting in interstitial edema, increased interstitial pressure, and further damage to the tubule. All of these effects, as shown in Fig. 20.21, contribute to the decreased GFR.

- *Disturbances in blood flow:* Ischemic renal injury is also characterized by *hemodynamic alterations* that cause reduced GFR. The major one is *intrarenal vasoconstriction,* which results in both reduced glomerular blood flow and reduced oxygen delivery to the functionally important tubules in the outer medulla (thick ascending limb and straight segment of the proximal tubule). Several vasoconstrictor pathways have been implicated, including the renin-angiotensin system, stimulated by decreased sodium in the tubules as a result of decreased blood pressure, and *sublethal endothelial injury,* leading to increased release of the vasoconstrictor *endothelin* and decreased production of the vasodilators *nitric oxide* and *prostacyclin (prostaglandin I_2)*. There is also some evidence of a direct effect of ischemia or toxins on the glomerulus, causing a reduced glomerular ultrafiltration coefficient.

The patchiness of tubular necrosis and maintenance of the integrity of the basement membrane along many segments allow repair of the injured foci and recovery of function if the precipitating cause is removed. This repair is dependent on the capacity of reversibly injured epithelial cells to proliferate and differentiate. Re-epithelialization is mediated by a variety of growth factors and cytokines produced locally by the tubular cells themselves or by inflammatory cells in the vicinity of necrotic foci.

MORPHOLOGY

ATI is characterized by **tubular epithelial injury** at multiple points along the nephron, with large skip areas in between, often accompanied by rupture of basement membranes (tubulorrhexis) and **occlusion of tubular lumens by casts** (Figs. 20.22 and 20.23). The distinct patterns of tubular injury in ischemic and toxic ATI are shown in Fig. 20.22. The straight portion of the proximal tubule and the ascending thick limb in the renal medulla are especially vulnerable, but focal lesions may also occur in the distal tubule, often in conjunction with casts. It should be noted that the severity of the morphologic findings often does not correlate with the severity of clinical manifestations.

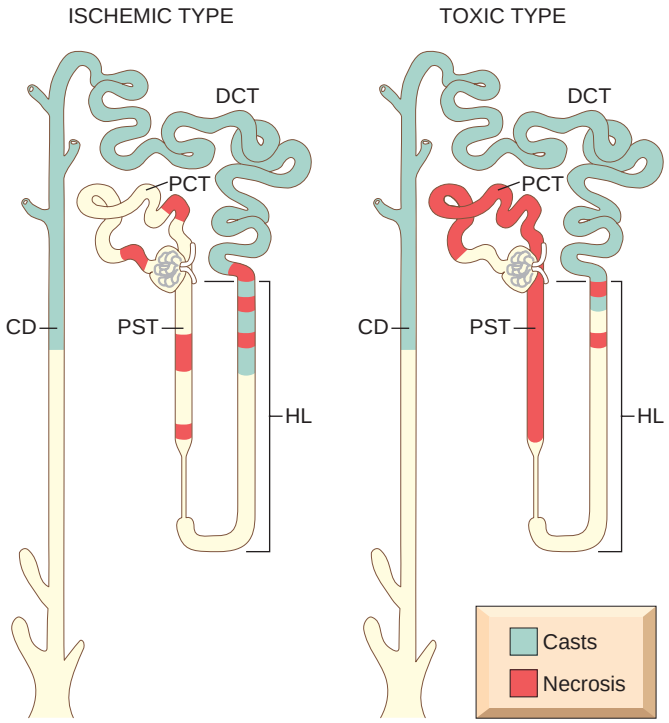

Figure 20.22 Patterns of tubular damage in ischemic and toxic acute tubular injury. In the ischemic type, tubular necrosis is patchy, relatively short lengths of tubules are affected, and proximal straight tubule *(PST)* segments and ascending limbs of Henle's loop *(HL)* are most vulnerable. In toxic acute tubular injury, extensive necrosis is present along the proximal convoluted tubule *(PCT)* segments with many toxins (e.g., mercury), but necrosis of the distal tubule, particularly ascending HL, also occurs. In both types, lumens of the distal convoluted tubules *(DCT)* and collecting ducts *(CD)* contain casts.

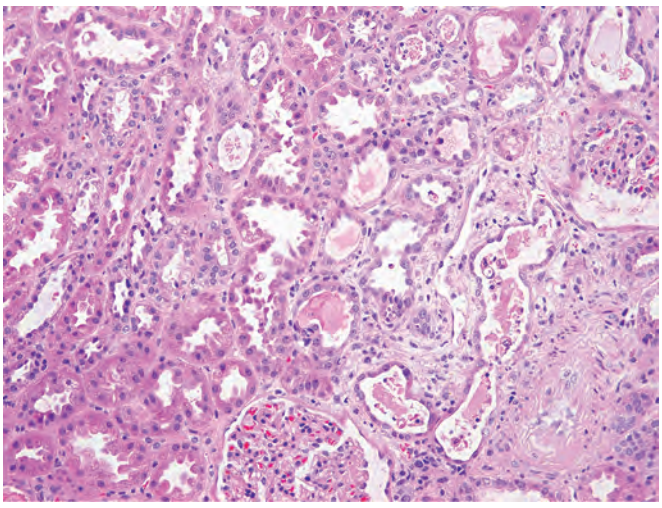

Figure 20.23 Acute tubular injury. Some tubular epithelial cells in the tubules are necrotic, and many have detached (from their basement membranes) and been sloughed into the tubular lumens.

Other findings in ischemic ATI are interstitial edema and accumulations of leukocytes within dilated vasa recta. There is also evidence of epithelial regeneration in the form of flattened epithelial cells with hyperchromatic nuclei and mitotic figures. In time, this regeneration repopulates the tubules so that no residual evidence of damage is seen.

Toxic ATI is manifested by ATI, most obvious in the proximal convoluted tubules. On histologic examination, the tubular injury can be distinctive in poisoning with certain agents. With mercuric chloride, for example, severely injured cells may contain large acidophilic inclusions. Later, these cells become necrotic, are desquamated into the lumen, and may undergo calcification. Ethylene glycol poisoning produces marked ballooning and hydropic or vacuolar degeneration of proximal convoluted tubules, and calcium oxalate crystals are often also found in the tubular lumens.

Clinical Features

The clinical course of ATI is highly variable, but the classic case may be divided into *three* stages.

- *Initiation phase,* lasting about 36 hours, is dominated by the inciting medical, surgical, or obstetric event. The only indication of renal involvement is a slight decline in urine output with a rise in BUN. At this point, oliguria could be explained by a transient decrease in blood flow and declining GFR.
- *Maintenance phase* is characterized by sustained decreases in urine output to between 40 and 400 mL/day (oliguria), salt and water overload, rising BUN concentrations, hyperkalemia, metabolic acidosis, and other manifestations of uremia. With appropriate management, the patient can overcome this oliguric crisis.
- *Recovery phase* is ushered in by a steady increase in urine volume that may reach up to 3 L/day. The tubules are still damaged, so large amounts of water, sodium, and potassium are lost in the flood of urine. *Hypokalemia, rather than hyperkalemia, becomes a clinical problem.* There is a peculiar increased vulnerability to infection at this stage. Eventually, renal tubular function is restored and concentrating ability improves. At the same time, BUN and creatinine levels begin to return to normal. Subtle tubular functional impairment may persist for months, but most patients who reach this phase eventually recover completely.

The prognosis of ATI depends on the magnitude and duration of injury. Recovery is expected with nephrotoxic ATI when the toxin has not caused serious damage to other organs, such as the liver or heart. With supportive care, 95% of those who do not succumb to the precipitating cause recover. Conversely, in shock related to sepsis, extensive burns, or other causes of multiorgan failure, the mortality rate can exceed 50%.

KEY CONCEPTS

ACUTE TUBULAR INJURY

- ATI is the most common cause of acute kidney injury and attributed to ischemia and/or toxicity from an endogenous or exogenous substance.
- Tubular epithelial cell injury and altered intrarenal hemodynamics are the primary contributors to ATI.
- The clinical outcome is determined by the magnitude and duration of ATI.

Tubulointerstitial Nephritis

This group of renal diseases involves inflammatory injuries of the tubules and interstitium that are often insidious in onset and are principally manifest by azotemia. Tubulointerstitial nephritis can be acute or chronic. *Acute tubulointerstitial nephritis* has a rapid clinical onset and is characterized histologically by interstitial edema, often accompanied by leukocytic infiltration of the interstitium and tubules, and tubular injury. In *chronic interstitial nephritis,* there is infiltration with predominantly mononuclear leukocytes, prominent interstitial fibrosis, and widespread tubular atrophy. *Secondary tubulointerstitial nephritis* is also present in a variety of vascular, cystic (polycystic kidney disease), and metabolic (diabetes) renal disorders, in which it may also contribute to progressive damage. Here we discuss primary causes of tubulointerstitial injury (Table 20.8). Glomerular and vascular abnormalities may also be present in advanced stages of these diseases. Conversely, chronic tubulointerstitial damage is an important consequence of progression in diseases that primarily affect the glomerulus.

Tubulointerstitial disorders are distinguished clinically from the glomerular diseases by the following hallmarks:

- Absence of nephritic or nephrotic syndrome
- Presence of defects in tubular function. The latter may be subtle and include impaired ability to concentrate urine, evidenced clinically by polyuria or nocturia; salt wasting; diminished ability to excrete acids (metabolic acidosis); and isolated defects in tubular reabsorption or secretion. Advanced forms, however, may be difficult to distinguish clinically from other causes of renal insufficiency.

Table 20.8 Causes of Tubulointerstitial Nephritis

Infections
Acute bacterial pyelonephritis
Chronic pyelonephritis (including reflux nephropathy)
Other infections (e.g., viruses, parasites)
Toxins
Drugs
Acute-hypersensitivity interstitial nephritis
Analgesics
Heavy metals
Lead, cadmium
Metabolic Diseases
Urate nephropathy
Nephrocalcinosis (hypercalcemic nephropathy)
Oxalate nephropathy
Physical Factors
Chronic urinary tract obstruction
Neoplasms
Multiple myeloma (light-chain cast nephropathy)
Immunologic Reactions
Transplant rejection
Sjögren syndrome
Sarcoidosis
Vascular Diseases
Miscellaneous
Nephronophthisis
"Idiopathic" interstitial nephritis

Specific conditions are listed in Table 20.8 and are discussed elsewhere in this book. This section deals principally with pyelonephritis and drug-induced tubulointerstitial nephritis.

Pyelonephritis and Urinary Tract Infection

Pyelonephritis is one of the most common diseases of the kidney and is defined as inflammation affecting the tubules, interstitium, and renal pelvis. It occurs in two forms. *Acute pyelonephritis* is generally caused by bacterial infection and is associated with urinary tract infection. *Chronic pyelonephritis* is a more complex disorder; bacterial infection plays a dominant role, but other factors (vesicoureteral reflux, obstruction) predispose to repeat episodes of acute pyelonephritis.

Pyelonephritis is a serious complication of *urinary tract infections* that affect the bladder (cystitis), the kidneys and their collecting systems (pyelonephritis), or both. Bacterial infections of the lower urinary tract may be asymptomatic (asymptomatic bacteriuria) and remain localized to the bladder, but lower urinary tract infection can potentially spread to the kidney.

Pathogenesis

More than 85% of urinary tract infections are caused by the gram-negative bacilli that are normal inhabitants of the intestinal tract. By far the most common is *Escherichia coli,* followed by *Proteus, Klebsiella,* and *Enterobacter. Streptococcus faecalis,* also of enteric origin, staphylococci, and virtually every other bacterial and fungal agent can also cause lower urinary tract and renal infection. Mycobacterial and fungal organisms induce caseating and non-caseating granulomatous inflammation, respectively. In immunocompromised persons, particularly those with transplanted organs, viruses such as polyomavirus, cytomegalovirus, and adenovirus can also cause renal infection.

There are two routes by which bacteria can reach the kidneys: (1) through the bloodstream (hematogenous infection) and (2) from the lower urinary tract (ascending infection) (Fig. 20.24). The hematogenous route is less common and results from seeding of the kidneys by bacteria from distant foci in the course of septicemia or localized infections such as infective endocarditis. Hematogenous infection is more likely to occur in the presence of ureteral obstruction, and in debilitated patients. Typically, in patients receiving immunosuppressive therapy, nonenteric organisms, such as staphylococci and certain fungi and viruses, are involved.

Ascending infection is the most common cause of clinical pyelonephritis. Normal human bladder and bladder urine are sterile; therefore, a number of steps must occur for renal infection to occur:

- The first step is *colonization of the distal urethra and introitus* (in the female) by coliform bacteria. This colonization is influenced by the degree of bacterial adherence to urethral mucosal epithelia, as discussed in Chapter 8, which involves adhesive molecules (adhesins) on the P-fimbriae (pili) of bacteria that interact with receptors on the surface of urothelial cells.
- *From the urethra to the bladder*, organisms gain entrance during urethral catheterization or other instrumentation. Long-term catheterization, in particular, carries a risk of infection. In the absence of instrumentation, *urinary infections are much more common in females,* and this has been ascribed to the shorter urethra in females, the absence of antibacterial properties in prostatic fluid, hormonal changes affecting bacterial adherence to the mucosa, and urethral trauma during sexual intercourse, or any combination of these factors.

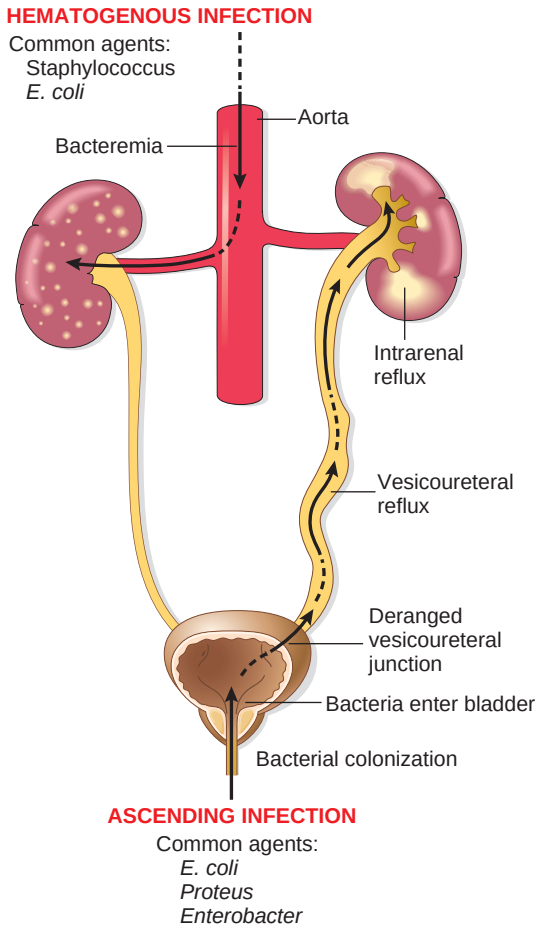

Figure 20.24 Schematic representation of pathways of renal infection. Hematogenous infection results from bacteremic spread. More common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux.

Several conditions predispose to the movement of microbes from the bladder to the kidneys:

- *Urinary tract obstruction and stasis of urine.* Ordinarily, organisms introduced into the bladder are cleared by continual voiding and by antibacterial mechanisms. However, outflow obstruction or bladder dysfunction results in incomplete emptying and residual urine. In the presence of stasis, bacteria introduced into the bladder can multiply unhindered. Accordingly, urinary tract infection is frequent among patients with lower urinary tract obstruction, such as may occur with benign prostatic hypertrophy, tumors, calculi, or neurogenic bladder dysfunction caused by diabetes or spinal cord injury.
- *Vesicoureteral reflux.* Although obstruction is an important predisposing factor in ascending infection, *incompetence of the vesicoureteral valve* allows bacteria to ascend the ureter into the renal pelvis. The normal ureteral insertion

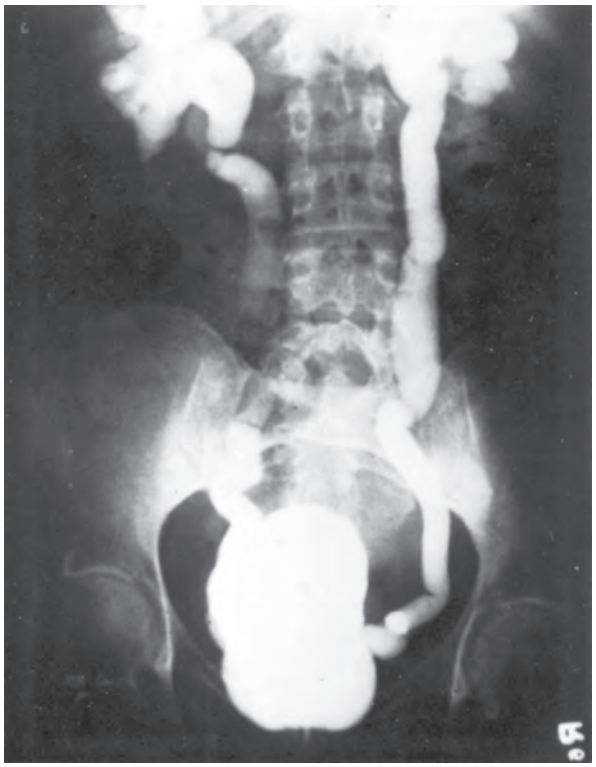

Figure 20.25 Vesicoureteral reflux demonstrated by a voiding cystourethrogram. Dye injected into the bladder refluxes into both dilated ureters, filling the pelvis and calyces.

into the bladder is a one-way valve that prevents retrograde flow of urine when the intravesical pressure rises, as in micturition. An incompetent vesicoureteral orifice allows the reflux of bladder urine into the ureters *(vesicoureteral reflux)* (Fig. 20.25). Reflux is most often due to a congenital absence or shortening of the intravesical portion of the ureter, such that the ureter is not compressed during micturition. In addition, it may be acquired by bladder infection itself. It is postulated that bacteria themselves or the associated inflammation can promote reflux by affecting ureteral contractility, particularly in children. Vesicoureteral reflux is estimated to affect 1% to 2% of otherwise normal children. *Acquired vesicoureteral reflux* in adults can result from persistent bladder atony caused by spinal cord injury. Similar to that of an obstruction, the residual urine in the urinary tract after voiding favors bacterial growth.

- *Intrarenal reflux.* Vesicoureteral reflux also affords a mechanism to propel infected bladder urine up to the renal pelvis and deep into the renal parenchyma through open ducts at the tips of the papillae (intrarenal reflux). Intrarenal reflux is most common in the upper and lower poles of the kidney, where papillae tend to have flattened or concave tips rather than the convex pointed type present in the midzones of the kidney (and depicted in most textbooks). Reflux can be demonstrated by voiding cystourethrography, in which the bladder is filled with a radiopaque dye and images are taken during micturition. Vesicoureteral reflux can be demonstrated in about 30% of infants and children with urinary tract infection (see Fig. 20.25).

In the absence of vesicoureteral reflux, infection usually remains localized in the bladder. Thus, the majority of individuals with repeated or persistent bacterial colonization of the urinary tract suffer from cystitis and urethritis *(lower urinary tract infection)* rather than pyelonephritis.

Acute Pyelonephritis

Acute pyelonephritis is a suppurative inflammation of the kidney caused by bacterial and sometimes viral (e.g., polyomavirus) infection, which can reach the kidney by hematogenous spread or, more commonly, through the ureters in association with vesicoureteral reflux.

MORPHOLOGY

The hallmarks of acute pyelonephritis are **patchy interstitial suppurative inflammation, intratubular aggregates of neutrophils, neutrophilic tubulitis, and tubular injury.** The suppuration may occur as discrete focal abscesses or large wedgelike areas and can involve one or both kidneys (Fig. 20.26).

In the early stages, the neutrophilic infiltration is limited to the tubules. The tubular lumens are a conduit for the extension of the infection, and the infection can extend to the interstitium and produces abscesses that destroy the involved tubules (Fig. 20.27). Characteristically, glomeruli are relatively resistant to the infection. Extensive disease, however, eventually also destroys the glomeruli, and fungal pyelonephritis (e.g., *Candida*) often results in granulomatous interstitial inflammation.

Three complications may be superimposed on acute pyelonephritis.

- *Papillary necrosis* is seen mainly in diabetics, sickle cell disease, and in those with urinary tract obstruction. Papillary necrosis is usually bilateral but may be unilateral. One or all of the pyramids of the affected kidney may be involved. On cut section, the tips or distal two thirds of the pyramids have areas of gray-white to yellow necrosis (Fig. 20.28). On microscopic examination, the necrotic tissue shows characteristic ischemic

Figure 20.26 Acute pyelonephritis. Cortical surface shows grayish white areas of inflammation and abscess formation.

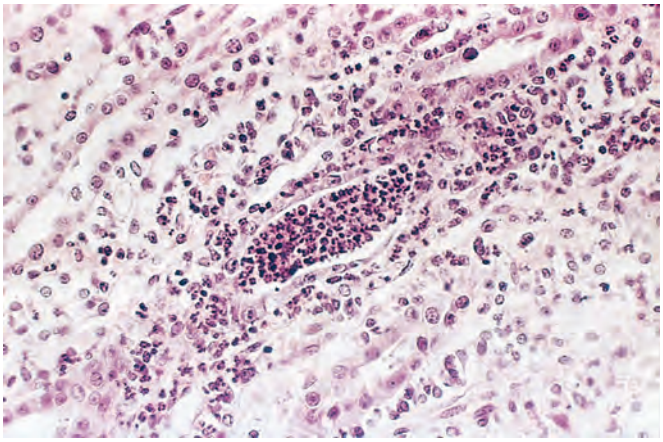

Figure 20.27 Acute pyelonephritis marked by a neutrophilic exudate within tubules and interstitial inflammation.

coagulative necrosis, with preservation of outlines of tubules. The leukocytic response is limited to the junctions between preserved and destroyed tissue.

- *Pyonephrosis* is seen when there is total or almost complete obstruction, particularly when it is high in the urinary tract. The suppurative exudate is unable to drain and fills the renal pelvis, calyces, and ureter with pus.
- *Perinephric abscess* is an extension of suppurative inflammation through the renal capsule into the perinephric tissue.

After the acute phase of pyelonephritis, healing occurs. The neutrophilic infiltrate is replaced by one that is predominantly composed of macrophages, plasma cells, and lymphocytes. The inflammatory foci are eventually replaced by irregular scars that can be seen on the cortical surface as fibrous depressions. Such scars are characterized microscopically by tubular atrophy, interstitial fibrosis, and a lymphocytic infiltrate in a characteristic patchy, jigsaw pattern with intervening preserved parenchyma. **The pyelonephritic scar is almost always associated with inflammation, fibrosis, and deformation of the underlying calyx and pelvis,** reflecting the role of ascending infection and vesicoureteral reflux in the pathogenesis of the disease.

Clinical Features

Acute pyelonephritis is often associated with the following:

- *Urinary tract obstruction,* either congenital or acquired
- *Instrumentation* of the urinary tract, most commonly catheterization
- *Vesicoureteral reflux*
- *Pregnancy.* Between 4% and 6% of pregnant women develop bacteriuria sometime during pregnancy, and 20% to 40% of these eventually develop symptomatic urinary infection if not treated.
- *Gender and age.* After the first year of life (when congenital anomalies in males commonly become evident) and up to around 40 years of age, infections are much more frequent in females. With increasing age, the incidence in males rises as a result of prostatic hypertrophy and instrumentation.
- *Preexisting renal lesions,* causing intrarenal scarring and obstruction
- *Diabetes,* in which increased susceptibility to infection, neurogenic bladder dysfunction, and more frequent instrumentation are predisposing factors
- *Immunosuppression and immunodeficiency*

Acute pyelonephritis usually presents with a sudden onset of pain at the costovertebral angle and systemic evidence of infection, such as fever and malaise. There are often indications of bladder and urethral irritation, such as dysuria, frequency, and urgency. The urine contains many leukocytes (pyuria) derived from the inflammatory infiltrate, but pyuria does not differentiate upper from lower urinary tract infection. The finding of leukocyte *casts,* typically rich in neutrophils (pus casts), indicates renal involvement, because casts are formed only in tubules. The diagnosis of infection is established by quantitative urine culture.

Uncomplicated acute pyelonephritis follows a benign course, and symptoms disappear within a few days after the institution of appropriate antibiotic therapy. Bacteria, however, may persist in the urine, or there may be recurrence of infection with new serologic types of *E. coli* or other

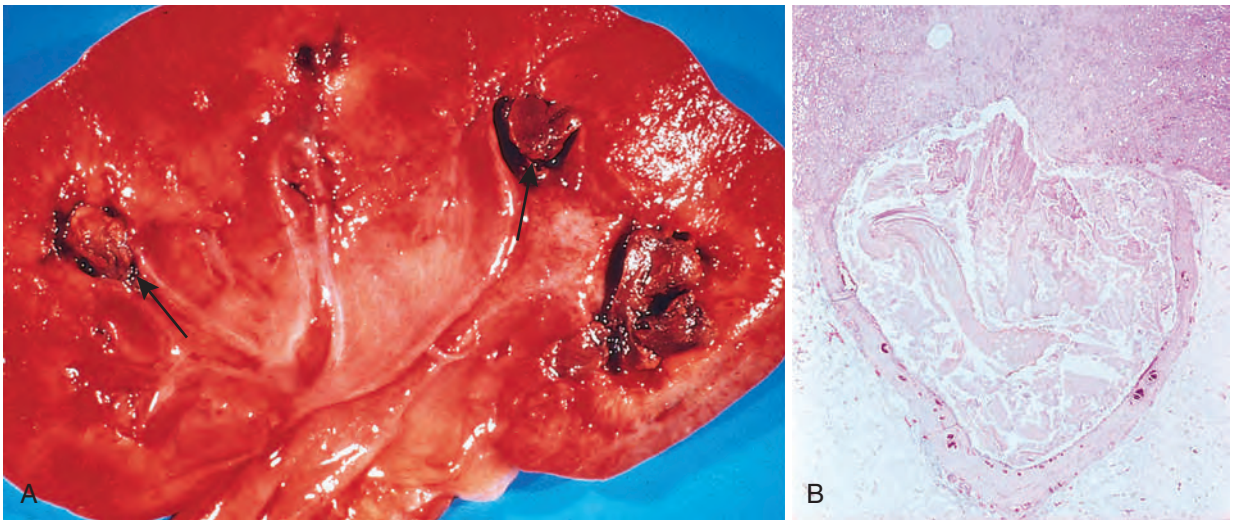

Figure 20.28 Papillary necrosis. Areas of pale-gray hemorrhage and necrosis involve the papillae *(arrows)*.

organisms. Such bacteriuria then either disappears or may persist, sometimes for years. In the presence of unrelieved urinary obstruction, diabetes mellitus, or immunodeficiency, acute pyelonephritis may be more serious, leading to repeated septicemic episodes. The superimposition of *papillary necrosis* may lead to acute renal failure.

A viral pathogen causing pyelonephritis in kidney allografts is *polyomavirus*. Latent infection with polyomavirus is widespread in the general population, and immunosuppression of the allograft recipient can lead to reactivation of latent infection and the development of nephropathy resulting in allograft failure in up to 5% of kidney transplant recipients. This form of pyelonephritis, now referred to as polyomavirus nephropathy, is characterized by infection of tubular epithelial cell nuclei, leading to nuclear enlargement and intranuclear inclusions visible by light microscopy (viral cytopathic effect). The inclusions are composed of virions arrayed in distinctive crystalline-like lattices when visualized by electron microscopy (Fig. 20.29). An interstitial inflammatory response is invariably present. Treatment consists of a reduction in immunosuppression.

Chronic Pyelonephritis and Reflux Nephropathy

Chronic pyelonephritis is a disorder in which chronic tubulointerstitial inflammation and scarring involve the calyces and pelvis (Fig. 20.30). Although several diseases produce chronic tubulointerstitial alterations (see Table 20.8), only chronic pyelonephritis and analgesic nephropathy affect the calyces, making pelvocalyceal damage an important diagnostic clue. Chronic pyelonephritis at one time accounted for 10% to 20% of patients in renal transplant or dialysis units, until predisposing conditions such as reflux became better recognized. This condition remains an important cause of kidney destruction in children with severe lower urinary tract abnormalities.

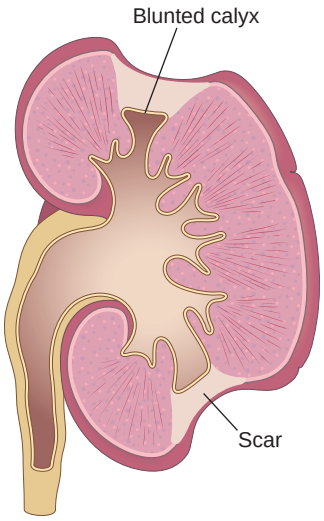

Figure 20.30 Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually polar and are associated with underlying blunted calyces.

MORPHOLOGY

The characteristic changes of chronic pyelonephritis are seen on gross examination (Figs. 20.30 and 20.31A). The kidneys usually are irregularly scarred; if bilateral, the involvement is asymmetric. In contrast, both kidneys in chronic glomerulonephritis are diffusely and symmetrically scarred. The hallmarks of chronic pyelonephritis are **coarse, discrete, corticomedullary scars overlying dilated, blunted, or deformed calyces, and flattening of the papillae.** The scars vary from one to several, and most are in the upper and lower poles, consistent with the frequency of reflux in these sites.

(B) Intranuclear viral inclusions visualized by electron microscopy. (Courtesy Dr. Jean Olson, Department of Pathology, University of California San Francisco, San Francisco, Calif.)

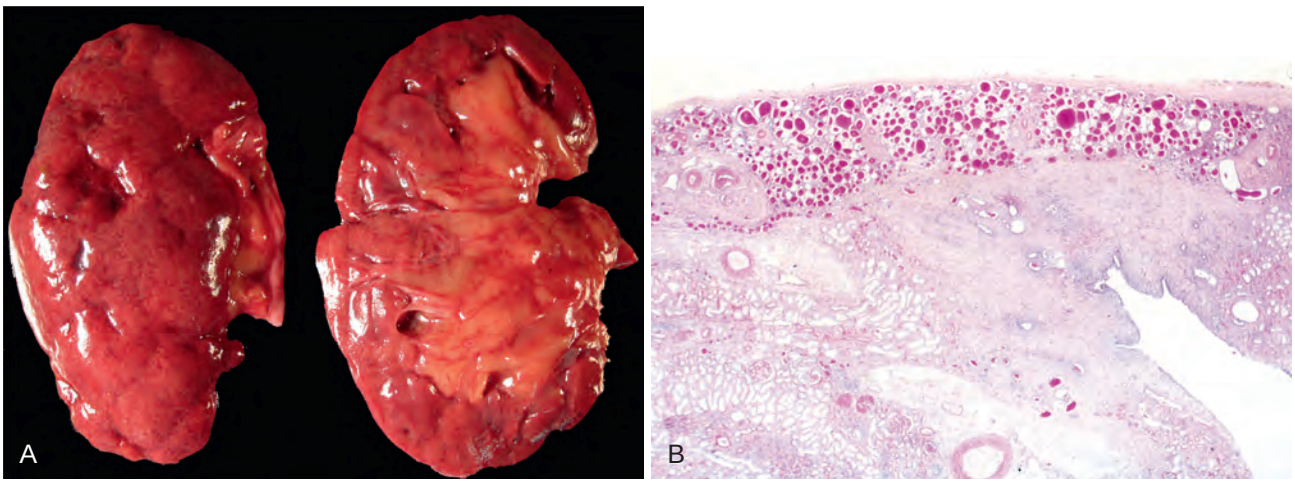

Figure 20.31 (A) Chronic pyelonephritis. The surface *(left)* is irregularly scarred. The cut section *(right)* reveals blunting and loss of several papillae. (B) Low-power view shows a corticomedullary renal scar with an underlying dilated deformed calyx. Note the thyroidization of tubules in the cortex.

The microscopic changes involve predominantly tubules and interstitium. The tubules show atrophy in some areas and hypertrophy or dilation in others. Dilated tubules with flattened epithelium may be filled with casts resembling thyroid colloid (thyroidization). There are varying degrees of chronic interstitial inflammation and fibrosis in the cortex and medulla. There is often fibrosis around the calyceal epithelium as well as a marked chronic inflammatory infiltrate. Glomeruli may appear normal except for a variety of ischemic changes, including periglomerular fibrosis, fibrous obliteration, and secondary changes related to hypertension. Individuals with chronic pyelonephritis and reflux nephropathy who develop proteinuria in advanced stages show secondary FSGS, as described later.

Xanthogranulomatous pyelonephritis is a rare form of chronic pyelonephritis characterized by accumulation of foamy macrophages intermingled with plasma cells, lymphocytes, polymorphonuclear leukocytes, and occasional giant cells. Often associated with *Proteus* infections and obstruction, the lesions sometimes produce large, yellowish orange nodules that may be grossly confused with renal cell carcinoma.

Clinical Features

Chronic obstructive pyelonephritis may have a silent onset or present with manifestations of acute recurrent pyelonephritis, such as back pain, fever, pyuria, and bacteriuria. These patients receive medical attention relatively late in their disease course because of the gradual onset of renal insufficiency and hypertension. Reflux nephropathy is often discovered in children when the cause of hypertension is investigated. Loss of tubular function—in particular of concentrating ability—gives rise to polyuria and nocturia. Radiographic studies show asymmetrically contracted kidneys with characteristic coarse scars and blunting and deformity of the calyceal system. Significant bacteriuria may be present, but it is often absent in the late stages.

Although proteinuria is usually mild, some individuals with pyelonephritic scars develop secondary *FSGS* with significant proteinuria, even in the nephrotic range, usually several years after the scarring has occurred and often in the absence of continued infection or persistent vesicoureteral reflux. The onset of proteinuria is a poor prognostic sign since it increases the likelihood of progression to ESRD. The glomerulosclerosis, as discussed, is attributable to the adaptive glomerular alterations secondary to loss of renal mass caused by pyelonephritic scarring.

KEY CONCEPTS

PYELONEPHRITIS

- Both acute and chronic pyelonephritis may be caused by infection via the ascending (more common) or hematogenous route. Obstructive lesions of the urinary tract are important predisposing factors.
- Bacteria are the most common infectious agent in acute pyelonephritis and induce a prominent neutrophilic inflammatory response; granulomatous interstitial inflammation is characteristic of fungal or mycobacterial infections.
- Chronic pyelonephritis ensues when anatomic anomalies result in urine reflux or urine outflow obstruction; multiple episodes of this injury leads to irregular scarring of the kidney that is typically more prominent at the upper or lower poles where reflux is more common.

Tubulointerstitial Nephritis Induced by Drugs and Toxins

Drug- and toxin-induced tubulointerstitial nephritis is the second most common cause of acute kidney injury (after pyelonephritis). Toxins and drugs can injure kidneys in at least three ways: (1) trigger an interstitial immunologic reaction, exemplified by the acute hypersensitivity nephritis induced by drugs such as methicillin; (2) cause ATI, as described earlier; and (3) cause subclinical but cumulative injury to tubules that takes years to result in chronic kidney disease. The last type of damage is especially worrisome, because it may be unrecognized until the renal damage is irreversible.

Acute Drug-Induced Interstitial Nephritis

First reported after the use of sulfonamides, acute tubulointerstitial nephritis most frequently occurs with synthetic penicillins (methicillin, ampicillin), other synthetic antibiotics (rifampin), diuretics (thiazides), nonsteroidal antiinflammatory drugs (NSAIDs), and miscellaneous other drugs (allopurinol, cimetidine, checkpoint inhibitors). The chronic tubulointerstitial nephritis caused by phenacetin-containing analgesics, termed *analgesic nephropathy,* is of historical importance as its incidence has substantially diminished due to the withdrawal or restriction of phenacetin in most countries.

Drug-induced acute interstitial nephritis begins 2 to 40 days after drug exposure and is characterized by *fever, eosinophilia* (which may be transient), *rash* in about 25% of patients, and *renal abnormalities*. The latter takes the form of hematuria, mild proteinuria, and leukocyturia (often including eosinophils). A rising serum creatinine or acute kidney injury with oliguria develops in about 50% of cases.

Pathogenesis

Many features of the disease suggest an idiosyncratic immune mechanism. Clinical evidence of hypersensitivity includes the latent period, eosinophilia and rash, the fact that the onset of nephropathy is not dose-related, and recurrence of clinical and pathologic manifestations after re-exposure to the same or a chemically related drug. In some patients, serum IgE levels are increased, and IgE-containing plasma cells and basophils are present in the lesions, suggesting that the *late-phase reaction of an IgE-mediated (type I) hypersensitivity* may be involved in the pathogenesis (Chapter 6). In other cases, a mononuclear or granulomatous reaction, together with positive results of skin tests to drugs, suggest a T cell–mediated (type IV) delayed-hypersensitivity reaction.

The most likely sequence of events is that the drugs function as haptens and covalently bind to some plasma membrane or extracellular component of tubular cells. These modified self antigens then become immunogenic. The resultant injury is due to IgE or cell-mediated immune reactions directed against the tubular cells or their basement membranes.

MORPHOLOGY

The interstitium shows variable but frequently pronounced **edema and infiltration by mononuclear cells,** principally lymphocytes and macrophages. Eosinophils and neutrophils may be present (Fig. 20.32), often in clusters and large numbers, and smaller numbers of plasma cells and mast cells are sometimes also present. Inflammation may be more prominent in the medulla where the inciting agent is concentrated. With some drugs (e.g., methicillin, thiazides), interstitial non-necrotizing granulomas may be seen when tubules rupture. Tubulitis, the infiltration of tubules by lymphocytes, is common. Variable degrees of tubular injury and regeneration are present. The glomeruli are normal except in some cases caused by NSAIDs, when minimal change disease and the nephrotic syndrome develop concurrently (see below).

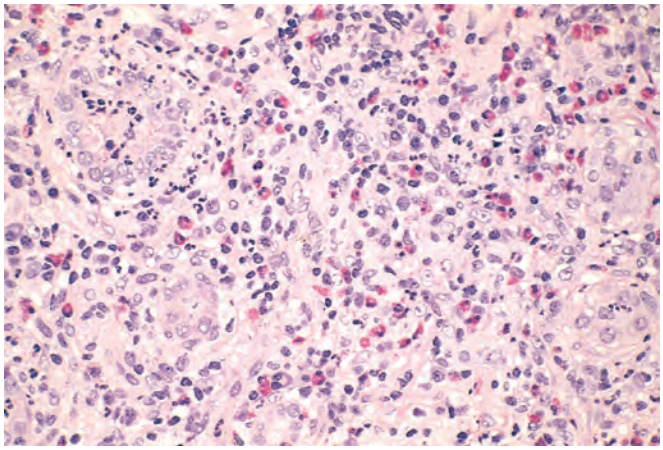

Figure 20.32 Drug-induced interstitial nephritis, with prominent eosinophilic and mononuclear cell infiltrate. (Courtesy Dr. H. Rennke, Brigham and Women's Hospital, Boston, Mass.)

Clinical Features

It is important to recognize drug-induced acute interstitial nephritis because withdrawal of the offending drug is followed by recovery, although it may take several months, and irreversible damage can occur. While drugs are the leading cause of acute interstitial nephritis, in many affected patients (approximately 30% to 40%) an offending drug or mechanism cannot be identified.

On occasion, necrotic papillae are excreted and may cause gross hematuria or renal colic due to ureteric obstruction. Papillary necrosis is not specific for analgesic nephropathy and is also seen in diabetes, as well as in urinary tract obstruction, sickle cell disease or trait (described later), and focally in renal tuberculosis. In all cases, it is caused by ischemia resulting from compression or obstruction of small blood vessels in the medulla. Such compression may be caused by interstitial edema (as in inflammatory reactions and urinary tract obstruction) or microvascular disease (as in diabetes). Table 20.9 lists the main features of papillary necrosis in these conditions.

Nephropathy Associated With NSAIDs

NSAIDs, one of the most commonly used classes of drugs, produce several forms of renal injury. Although these complications are uncommon, they should be kept in mind because NSAIDs are frequently administered to patients with other potential causes of renal disease. Many NSAIDs are nonselective cyclo-oxygenase inhibitors, and their adverse renal effects are related to their ability to inhibit cyclo-oxygenase–dependent prostaglandin synthesis. The selective COX-2 inhibitors, while sparing the gastrointestinal tract, do affect the kidneys because COX-2 is expressed in human kidneys. NSAID-associated renal syndromes include the following:

- *Acute kidney injury,* due to the decreased synthesis of vasodilatory prostaglandins and resultant ischemia. This is particularly likely to occur in the setting of other renal diseases or conditions causing volume depletion.
- *Acute hypersensitivity interstitial nephritis,* resulting in renal failure, as described earlier.
- *Acute interstitial nephritis and minimal change disease.* This curious association of two diverse renal conditions, one

Table 20.9 Causes of Papillary Necrosis

	Diabetes	Analgesic Nephropathy[a]	Sickle Cell Disease	Obstruction
Male-to-female ratio	1:3	1:5	1:1	9:1
Time course	10 years	>5 years of abuse	Variable	Variable
Infection	80%	25%	±	90%
Calcification	Rare	Frequent	Rare	Frequent
Number of papillae affected	Several; all of same stage	Almost all; different stages of necrosis	Few	Variable

[a]The incidence of this disease has greatly decreased since the 1990s because its main cause, phenacetin, has been withdrawn from the market in most countries, and combination analgesics are no longer available without prescription.

Data from Seshan S, et al, editors: *Classification and Atlas of Tubulointerstitial and Vascular Diseases,* Baltimore, 1999, Williams & Wilkins.

leading to renal failure and the other to nephrotic syndrome, suggests a hypersensitivity reaction affecting the interstitium and possibly the glomeruli, but also is consistent with injury to podocytes mediated by cytokines released as part of the inflammatory process.

- *Membranous nephropathy,* with the nephrotic syndrome, is a recently appreciated association, also of unclear pathogenesis.

KEY CONCEPTS

TUBULOINTERSTITIAL NEPHRITIS INDUCED BY DRUGS AND TOXINS

- Drug-induced tubulointerstitial nephritis is the second most common cause of acute kidney injury.
- Prominent interstitial inflammation with associated tubular injury, which may or may not be accompanied by eosinophils or granulomatous inflammation, can be induced by almost any pharmacologic agent.
- NSAIDs can cause tubulointerstitial nephritis and/or glomerular injury, such as minimal change disease or membranous nephropathy.

Other Tubulointerstitial Diseases

Urate Nephropathy

Three types of nephropathy can occur in persons with hyperuricemic disorders:

- *Acute uric acid nephropathy* is caused by the precipitation of uric acid crystals in the renal tubules, principally in collecting ducts, leading to obstruction of nephrons and the development of acute renal failure. This is particularly likely to occur in individuals with leukemias or lymphomas who are undergoing chemotherapy (tumor lysis syndrome); the drugs kill tumor cells, and uric acid is produced as released nucleic acids are broken down. Precipitation of uric acid is favored by the acidic pH in collecting tubules.
- *Chronic urate nephropathy,* or gouty nephropathy, occurs rarely in protracted forms of hyperuricemia. The monosodium urate crystals deposit in the acidic milieu of the distal tubules and collecting ducts, and form distinct birefringent needlelike crystals either in the tubular lumens or in the interstitium (Fig. 20.33). The urate deposits evoke a mononuclear response that contains foreign-body giant cells. This lesion is called a *tophus* (Chapter 26). Tubular obstruction by the urates causes cortical atrophy and scarring. Clinically, urate nephropathy is a subtle disease associated with tubular defects that may progress slowly. Some individuals with gout who develop a chronic nephropathy have evidence of increased exposure to lead.
- *Nephrolithiasis:* uric acid stones are present in 22% of individuals with gout and 42% of those with secondary hyperuricemia (see later discussion of renal stones).

Hypercalcemia and Nephrocalcinosis

Disorders associated with hypercalcemia, such as hyperparathyroidism, multiple myeloma, vitamin D intoxication, metastatic cancer, or excess calcium intake (milk-alkali syndrome), may induce the formation of calcium stones and deposition of calcium in the kidney (nephrocalcinosis). Extensive degrees of calcinosis, under certain conditions, may lead to chronic tubulointerstitial disease and renal insufficiency.

The earliest functional defect is an inability to concentrate the urine. Other tubular defects, such as tubular acidosis and salt-losing nephritis, may also occur. With further damage, a slowly progressive chronic kidney disease develops. This is usually due to nephrocalcinosis, but many of these patients also have calcium stones and secondary pyelonephritis.

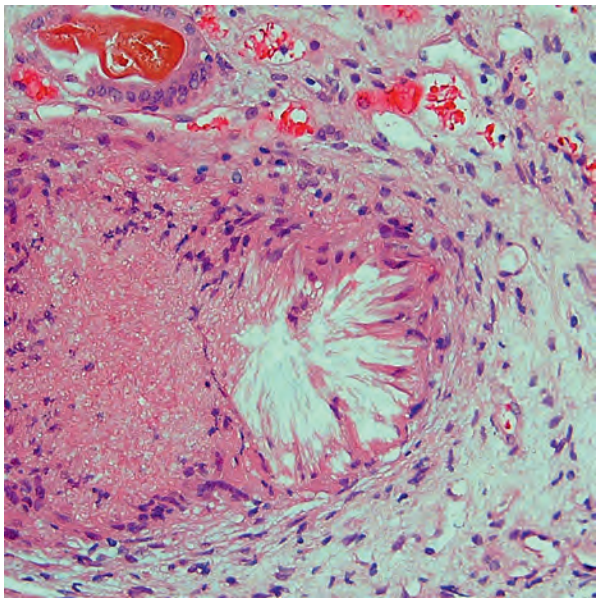

Figure 20.33 Granulomatous inflammation outlines the slender urate crystals in the renal medulla.

Autosomal Dominant Tubulointerstitial Kidney Disease

Autosomal dominant tubulointerstitial kidney disease (ADTKD) was previously known as medullary cystic kidney disease. Given the variable presence of cysts, which often are not located in the medulla, and the distinctive genetics, it is now recognized as ADTKD due to following genetic mutations:

- *MUC1* encodes mucin-1 (expressed in distal nephrons)
- *UMOD* encodes uromodulin (expressed in thick ascending limb of loop of Henle)
- *REN* encodes preprorenin (expressed by juxtaglomerular apparatus)
- *HNF1β* encodes hepatocyte nuclear factor 1β, a transcription factor that regulates multiple genes, including *UMOD*.

ADTKD is associated with nonspecific clinical and pathologic findings and causes progressive renal failure in adult life with an autosomal dominant pattern of transmission. The pathogenic mechanisms are unknown.

Light-Chain Cast Nephropathy ("Myeloma Kidney")

Nonrenal malignant tumors, particularly those of hematopoietic origin, affect the kidneys in several ways (Table 20.10). The most common involvements are tubulointerstitial, caused by complications of the tumor (hypercalcemia, ureteral obstruction) or therapy (irradiation, hyperuricemia, chemotherapy, hematopoietic cell transplantation, infections in immunosuppressed patients). We limit the discussion here to the tubulointerstitial lesions in *multiple myeloma* patients.

Overt renal insufficiency occurs in half of those with multiple myeloma and related lymphoplasmacytic disorders. Several factors contribute to renal damage:

- *Bence-Jones proteinuria and cast nephropathy*. The main cause of renal dysfunction is related to Bence-Jones (light-chain) proteinuria and correlates with the degree of proteinuria. Two mechanisms seem to account for the renal toxicity of Bence-Jones proteins. First, some Ig light chains are directly toxic to epithelial cells, because of their intrinsic physicochemical properties. Second, Bence-Jones proteins combine with urinary glycoprotein (Tamm-Horsfall protein) under acidic conditions to form large, histologically distinct tubular casts that obstruct the tubular lumens and induce a characteristic inflammatory reaction (light-chain cast nephropathy).
- *Amyloidosis* of AL type, formed from free light chains (usually of λ type), occurs in 6% to 24% of individuals with myeloma.
- *Light-chain deposition disease*. In some patients, light chains (usually of κ type) deposit in GBMs and mesangium in nonfibrillar forms, causing a glomerulopathy (described earlier), and in tubular basement membranes, which may cause tubulointerstitial nephritis.
- *Hypercalcemia* and *hyperuricemia* are often present in these patients.

Effects of Radiation Therapy, Chemotherapy, Hematopoietic Cell Transplantation, Secondary Infection

MORPHOLOGY

The tubulointerstitial changes in light-chain cast nephropathy are characteristic. The Bence-Jones tubular casts appear as pink to blue amorphous masses, sometimes concentrically laminated and often fractured, which fill and distend the tubular lumens. Some casts are surrounded by multinucleated giant cells that are derived from activated macrophages (Fig. 20.34). The adjacent interstitial tissue usually shows an inflammatory response and fibrosis. On occasion, the casts rupture the tubules, evoking a granulomatous inflammatory reaction. Amyloidosis, light-chain deposition disease, nephrocalcinosis, and infection may also be present.

Clinical Features

Clinically, the renal manifestations are of several types. In the most common form, *chronic kidney disease* develops insidiously and progresses slowly during a period of several months to years. Another form occurs suddenly and is manifested by *acute kidney injury* with oliguria. Precipitating factors include dehydration, hypercalcemia, acute infection, and treatment with nephrotoxic antibiotics. *Bence-Jones proteinuria* occurs in 70% of individuals with multiple myeloma; the presence of significant non–light-chain proteinuria (e.g., albuminuria) suggests AL amyloidosis or light-chain deposition disease.

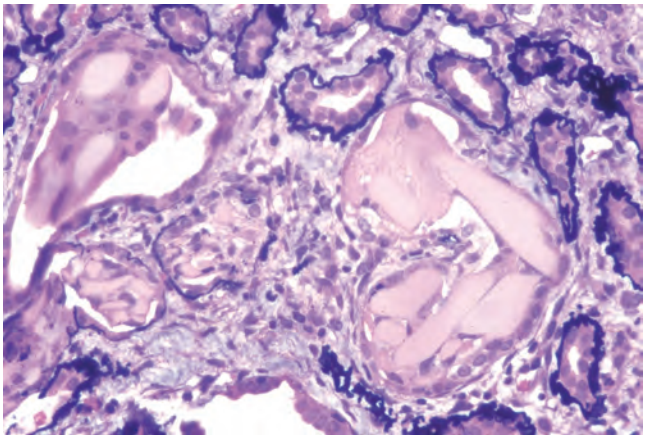

Figure 20.34 Light-chain cast nephropathy. Note the angulated and tubular casts, surrounded by macrophages, including multinucleated cells.

Bile Cast Nephropathy

Impairment of renal function often occurs in patients with severe acute or advanced chronic liver disease. In this setting, serum bilirubin levels can be markedly elevated, particularly in jaundiced patients, with bile cast formation (also known as cholemic nephrosis) in distal nephron segments. The casts can extend to proximal tubules, resulting in both direct toxic effects on tubular epithelial cells and obstruction of the involved nephron. This mechanism of injury is analogous to that with monoclonal immunoglobulin and myoglobin casts. The tubular bile casts can range from yellowish-green to red-pink and contain variable degrees of sloughed cells or cellular debris. The reversibility of the renal injury depends on the severity and duration of the liver dysfunction.

VASCULAR DISEASES

Nearly all diseases of the kidney involve the renal blood vessels secondarily. Systemic vascular diseases, such as various forms of vasculitis, also affect renal vessels, and their effects on the kidney are clinically important. Hypertension, as discussed in Chapter 11, is intimately linked with the kidney, because kidney disease can be both a cause and consequence of increased blood pressure. In this chapter, we discuss nephrosclerosis and renal artery stenosis, lesions associated with hypertension, and sundry lesions involving mostly smaller vessels of the kidney.

Nephrosclerosis

***Nephrosclerosis* is the term used for the renal pathology associated with sclerosis of renal arterioles and small arteries; it is strongly associated with hypertension, which can be both a cause and a consequence of nephrosclerosis.** Nephrosclerosis at autopsy is associated with advanced age, is more frequent in blacks than in whites, and may be seen in the absence of hypertension. Hypertension and diabetes, however, increase the incidence and severity of the lesions.

Pathogenesis

Two processes participate in the arterial lesions:

- Medial and intimal thickening, a response to hemodynamic changes, aging, genetic defects, or some combination of these
- Hyalinization of arteriolar walls, caused by extravasation of plasma proteins through injured endothelium and by increased deposition of basement membrane matrix

Because of thickened walls, the affected vessels have narrowed lumens, which results in focal parenchymal ischemia. Ischemia leads to glomerulosclerosis and chronic tubulointerstitial injury, and it produces a reduction in functional renal mass.

MORPHOLOGY

The kidneys are either normal or moderately reduced in size, with average weights between 110 and 130 g. The cortical surfaces have a fine, even granularity that resembles grain leather (Fig. 20.35). The loss of mass is due mainly to **cortical scarring and shrinking.**

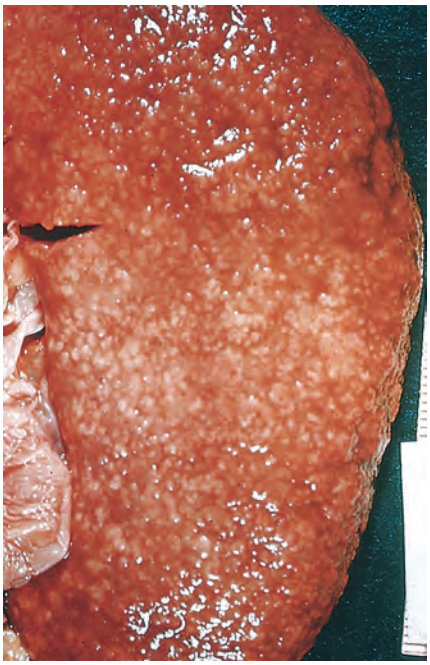

Figure 20.35 Close-up of the gross appearance of the cortical surface in benign nephrosclerosis illustrating the fine, leathery granularity of the surface.

On histologic examination, there is narrowing of the lumens of arterioles and small arteries, caused by thickening and hyalinization of the walls **(hyaline arteriolosclerosis)** (Fig. 20.36). Corresponding to the finely granular surface are microscopic subcapsular scars with sclerotic glomeruli and tubular dropout, alternating with better preserved parenchyma. In addition, the interlobular and arcuate arteries show medial hypertrophy, replication of the internal elastic lamina, and increased myofibroblastic tissue in the intima, all of which narrow the lumen. This change, called fibroelastic hyperplasia, often accompanies hyaline arteriolosclerosis and increases in severity with age and in the presence of hypertension.

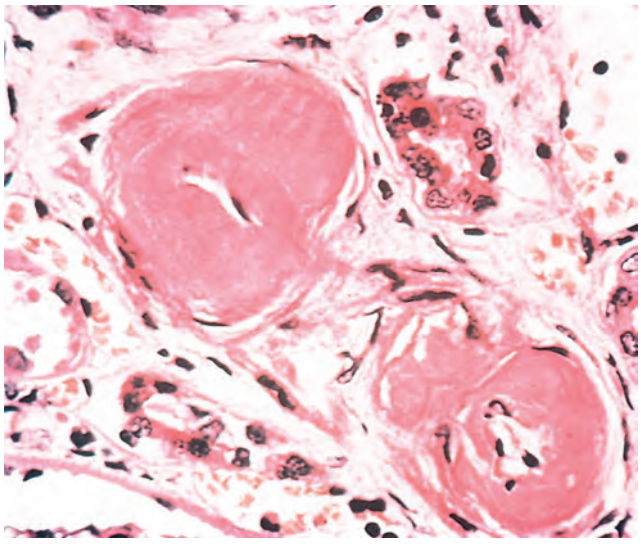

Figure 20.36 Hyaline arteriolosclerosis. High-power view of two arterioles with hyaline deposition, marked thickening of the walls, and a narrowed lumen. (Courtesy Dr. M. A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, Tex.)

Consequent to the vascular narrowing, there is patchy ischemic atrophy, which consists of (1) foci of **tubular atrophy and interstitial fibrosis** and (2) a variety of **glomerular alterations.** The latter include collapse of the GBM, deposition of collagen within the Bowman space, periglomerular fibrosis, and total sclerosis of glomeruli. When the ischemic changes are pronounced and affect large areas of parenchyma, they can produce wedge-shaped infarcts or regional scars with histologic alterations that may resemble those in renal ablation injury, mentioned earlier.

Clinical Features

It is unusual for uncomplicated nephrosclerosis to cause renal insufficiency or uremia. However, three groups of hypertensive patients with nephrosclerosis are at increased risk of developing renal failure: people of African descent, people with severe blood pressure elevations, and persons with a second underlying disease, especially diabetes. In these groups, renal insufficiency may supervene after prolonged hypertension, but rapid renal failure may result from the development of the malignant or accelerated phase of hypertension.

A small percentage of hypertensive persons (as many as 5%) show a rapidly rising blood pressure that, if untreated, leads to death within 1 to 2 years. This form of hypertension, called *malignant hypertension,* is characterized by severe pressure elevations (i.e., systolic pressure more than 200 mm Hg, diastolic pressure more than 120 mm Hg), renal failure, and retinal hemorrhages and exudates, with or without papilledema (swelling of the optic nerve that reflects increased intracranial pressures). Renal lesions associated with malignant hypertension have been referred to as malignant nephrosclerosis. It should be noted, however, that there is considerable clinical and morphologic overlap between the renal pathology of malignant hypertension and thrombotic microangiopathies. About 30% of cases of malignant hypertension have microangiopathic hemolytic anemia (discussed below) and conversely, severe hypertension can occur in primary forms of hemolytic uremic syndrome. Endothelial injury is a common pathogenic factor in these disorders.

KEY CONCEPTS

NEPHROSCLEROSIS

- Nephrosclerosis, which is commonly associated with hypertension, is defined by the presence of varying degrees of glomerulosclerosis, interstitial fibrosis and tubular atrophy, arteriosclerosis, and arteriolosclerosis.
- Luminal reduction of the renal vasculature (arteries and arterioles) contributes to glomerulosclerosis (both global and segmental), which can subsequently cause interstitial fibrosis and tubular atrophy.

Renal Artery Stenosis

Unilateral renal artery stenosis is responsible for 2% to 5% of hypertension cases, and it is important to recognize because it is potentially curable by surgery. Furthermore, important insights into renal mechanisms of hypertension came from studies of experimental and human renal artery stenosis.

Pathogenesis

Hypertension secondary to renal artery stenosis is caused by increased production of renin from the ischemic kidney. The classic experiments of Goldblatt and colleagues showed that constriction of one renal artery in dogs results in hypertension and that the magnitude of the effect is proportional to the amount of narrowing. Elevation in blood pressure, at least initially, is due to stimulation of renin secretion by the juxtaglomerular apparatus and the subsequent production of the vasoconstrictor angiotensin II. A large proportion of individuals with renovascular hypertension have elevated renin levels, and almost all show a reduction of blood pressure when given drugs that block angiotensin II activity. Other factors, however, may contribute to the maintenance of renovascular hypertension after the renin-angiotensin system has initiated it, including *sodium retention*.

MORPHOLOGY

The most common cause of renal artery stenosis (70% of cases) is narrowing at the origin of the renal artery by an **atheromatous plaque.** This occurs more frequently in men, and the incidence increases with advancing age and diabetes. The plaque is usually concentrically placed, and superimposed thrombosis often occurs.

The second most frequent cause of stenosis is **fibromuscular dysplasia** of the renal artery. This heterogeneous entity is characterized by fibrous or fibromuscular thickening that may involve the intima, the media, or the adventitia of the artery (Fig. 20.37). The stenoses, as a whole, are more common in women and tend to occur in younger age groups (i.e., in the third and fourth decades).

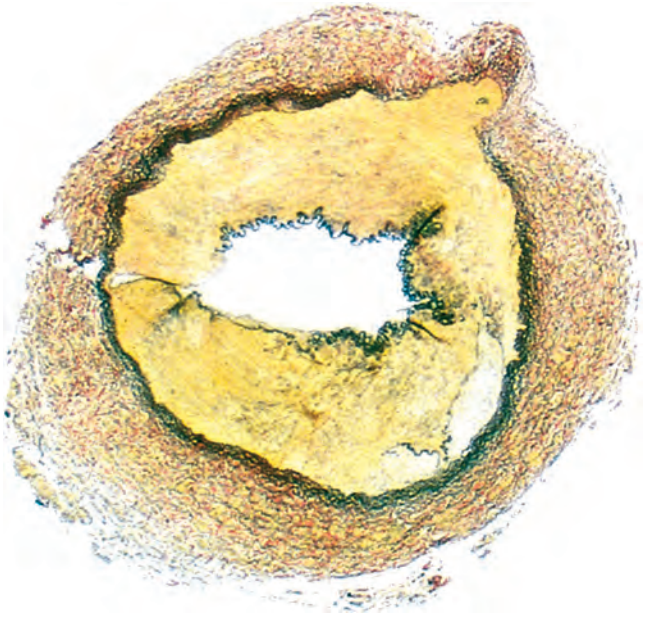

Figure 20.37 Fibromuscular dysplasia of the renal artery, medial type (elastic tissue stain). The media shows marked fibrous thickening, and the lumen is stenotic. (Courtesy Dr. Seymour Rosen, Beth Israel Hospital, Boston, Mass.)

The ischemic kidney is reduced in size and shows signs of **diffuse ischemic atrophy,** with crowded glomeruli, atrophic tubules, interstitial fibrosis, and focal inflammatory infiltrates. The arterioles in the ischemic kidney are usually protected from the effects of high pressure, thus showing only mild arteriolosclerosis. In contrast, the contralateral nonischemic kidney may show more severe arteriolosclerosis, depending on the severity of the hypertension.

Clinical Features

Few distinctive features suggest the presence of renal artery stenosis, and in general, these patients resemble those with essential hypertension. On occasion, a bruit can be heard on auscultation of the affected kidneys. Elevated plasma or renal vein renin, response to angiotensin-converting enzyme inhibitor, renal scans, and intravenous pyelography may aid with diagnosis, but arteriography is required to localize the stenotic lesion. The cure rate after surgery is 70% to 80% in well-selected cases.

Thrombotic Microangiopathies

The term *thrombotic microangiopathy* encompasses a spectrum of clinical syndromes that includes thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS). As discussed in Chapter 14, **HUS and TTP are caused by diverse insults that lead to thrombi in capillaries and/or arterioles in various tissue beds, including those of the kidney** (Fig. 20.38). The thrombi create flow abnormalities that shear red cells, producing a microangiopathic hemolytic anemia. Of greater importance, the thrombi produce microvascular occlusions that cause tissue ischemia and organ dysfunction. Widespread "consumption" of platelets leads to thrombocytopenia.

This group of disorders is classified according to the current understanding of their causes or associations (Table 20.11):

- *Typical HUS (synonyms: epidemic, classic, diarrhea-positive)* is most frequently associated with consumption of food contaminated by bacteria producing Shiga-like toxins.

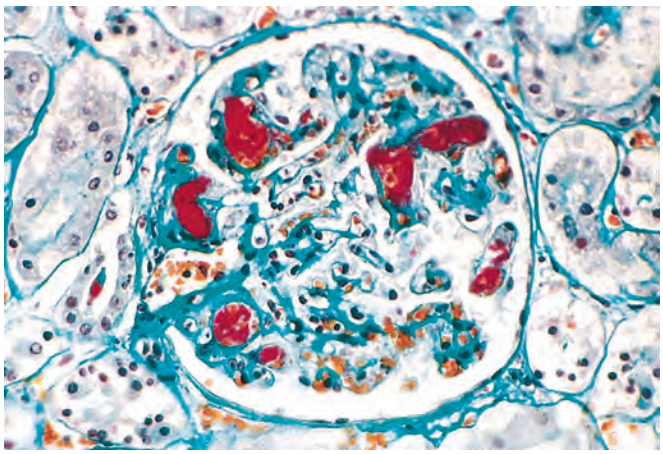

Figure 20.38 Fibrin stain showing thrombi *(red)* in the glomerular capillaries, characteristic of thrombotic microangiopathic disorders.

Table 20.11 Etiologic Classification of the Major Forms of Primary Thrombotic Microangiopathy

	Forms	Etiology
Shiga toxin–mediated HUS	Acquired	Shiga toxin–producing *E. coli*, *Shigella dysenteriae* serotype 1
Atypical HUS (complement-mediated TMA)	Inherited	Complement dysregulation due to genetic abnormalities (relatively common)
	Acquired	Acquired complement dysregulation due to autoantibodies
TTP	Inherited	Genetic ADAMTS13 deficiency (rare)
	Acquired	ADAMTS13 deficiency due to autoantibodies (relatively common)

ADAMTS13, von Willebrand factor cleaving protease; *HUS*, hemolytic uremic syndrome; *TMA*, thrombotic microangiopathy; *TTP*, thrombotic thrombocytopenic purpura.

- *Atypical HUS (synonyms: non-epidemic, diarrhea-negative)* is associated with the following:
  - Inherited mutations of or autoantibodies targeting complement-regulatory proteins
  - Diverse acquired causes of endothelial injury, including: antiphospholipid antibodies; complications of pregnancy and oral contraceptives; vascular renal diseases such as scleroderma and malignant hypertension; chemotherapeutic and immunosuppressive drugs; and radiation
- *TTP* is characterized by inherited or acquired deficiencies of ADAMTS13, a plasma metalloprotease that regulates the function of von Willebrand factor (vWF).

Pathogenesis

Within the thrombotic microangiopathies, two pathogenetic triggers dominate: (1) *endothelial injury* and (2) *excessive platelet activation and aggregation*. As we will discuss, endothelial injury appears to be the primary cause of HUS, whereas platelet activation may be the inciting event in TTP.

Endothelial Injury. In typical (epidemic, classic, diarrhea-positive) HUS, the trigger for endothelial injury and activation is usually a Shiga-like toxin, while for inherited forms of atypical HUS the cause of the endothelial injury appears to be excessive, inappropriate activation of complement. Many other exposures and conditions can occasionally precipitate a HUS-like picture, presumably also by injuring the endothelium. The endothelial injury in HUS appears to cause platelet activation and thrombosis within microvascular beds. There is evidence that reduced endothelial production of prostaglandin I_2 and nitric oxide (both inhibitors of platelet aggregation) contributes to thrombosis. The reduction in these two factors and increased production of endothelium-derived endothelin may also promote vasoconstriction, exacerbating the hypoperfusion of tissues.

Platelet Aggregation. In contrast to HUS, in TTP the initiating event appears to be platelet aggregation induced by very large multimers of vWF, which accumulate due to a deficiency of ADAMTS13, a plasma protease that cleaves vWF multimers into smaller sizes. The deficiency of ADAMTS13 is

most often caused by autoantibodies that inhibit ADAMTS13 function. Less commonly, a chronic relapsing and remitting form of TTP is associated with inherited deficiencies of ADAMTS13. Very large vWF multimers can bind platelet surface glycoproteins and activate platelets spontaneously, providing a pathophysiologic explanation for the microthrombi that are observed in vascular beds.

With this as an introduction, we will now briefly delve into the various subtypes of HUS/TTP and then return to the morphologic features that are common to all.

Typical (Epidemic, Classic, Diarrhea-Positive) Hemolytic Uremic Syndrome

This is the best-characterized form of HUS. Most cases occur after intestinal infection with strains of *E. coli* (the most common being O157:H7) that produce Shiga-like toxins, so-called because they resemble those made by *Shigella dysenteriae* (Chapter 17). Epidemics have been traced to various sources, most commonly the ingestion of contaminated ground meat (as in hamburgers), but also drinking water, raw milk, and person-to-person transmission. However, most cases of typical HUS caused by *E. coli* are sporadic. Less commonly, infections by other agents, including *S. dysenteriae*, can give rise to a similar clinical picture.

Typical HUS can occur at any age, but children and older adults are at highest risk. Following a prodrome of influenza-like or diarrheal symptoms, there is a sudden onset of bleeding manifestations (especially hematemesis and melena), severe oliguria, and hematuria, associated with microangiopathic hemolytic anemia, thrombocytopenia, and (in some patients) prominent neurologic changes. Hypertension is present in about half of patients.

Precisely how Shiga-like toxin exposure causes HUS is not well understood. According to one model, the toxin "activates" endothelial cells, which respond by increasing their expression of leukocyte adhesion molecules and endothelin and decreasing nitric oxide production. In the presence of cytokines such as TNF, Shiga-like toxin may cause endothelial apoptosis. These alterations lead to platelet activation and induce vasoconstriction, resulting in the characteristic microangiopathy. But other possibilities remain. For example, there is some evidence that Shiga-like toxins may bind and activate platelets directly; or alternatively, may bind the regulatory complement protein Factor H and inhibit its activity, causing hyperactivation of complement, an intriguing idea given the clear role of complement activation in some forms of atypical HUS (described in the next section).

In typical HUS, if the renal failure is managed properly with dialysis, most patients recover normal renal function in a matter of weeks. However, due to underlying renal damage, the long-term (15- to 25-year) outlook is more guarded. In one study, only 10 of 25 patients with prior typical HUS had normal renal function, and 7 had chronic kidney disease.

Atypical (Non-Epidemic, Diarrhea-Negative) Hemolytic Uremic Syndrome

Atypical HUS occurs in a number of different settings. More than one-half of those affected have an inherited deficiency of complement-regulatory proteins, most commonly Factor H, which breaks down the alternative pathway C3 convertase and protects cells from damage by uncontrolled complement activation (Chapter 3). A number of patients have mutations in other proteins that regulate complement, complement Factor I and CD46 (membrane cofactor protein). Having multiple genetic mutations in complement-regulatory proteins may cause atypical HUS to manifest at a younger age. Autoantibodies against complement regulatory proteins also result in atypical HUS.

The remaining cases of atypical HUS arise in association with a variety of miscellaneous conditions or exposures. These include the following:

- The *antiphospholipid syndrome,* either primary or secondary to SLE (lupus anticoagulant). The syndrome is described in detail in Chapter 4. In this setting, the microangiopathy tends to follow a chronic course.
- Complications of pregnancy or the postpartum period. So-called *postpartum renal failure* is a form of HUS that usually occurs after an uneventful pregnancy, 1 day to several months after delivery. The condition has a grave prognosis, although recovery can occur in milder cases.
- *Vascular diseases affecting the kidney,* such as systemic sclerosis and malignant hypertension (Fig. 20.39).

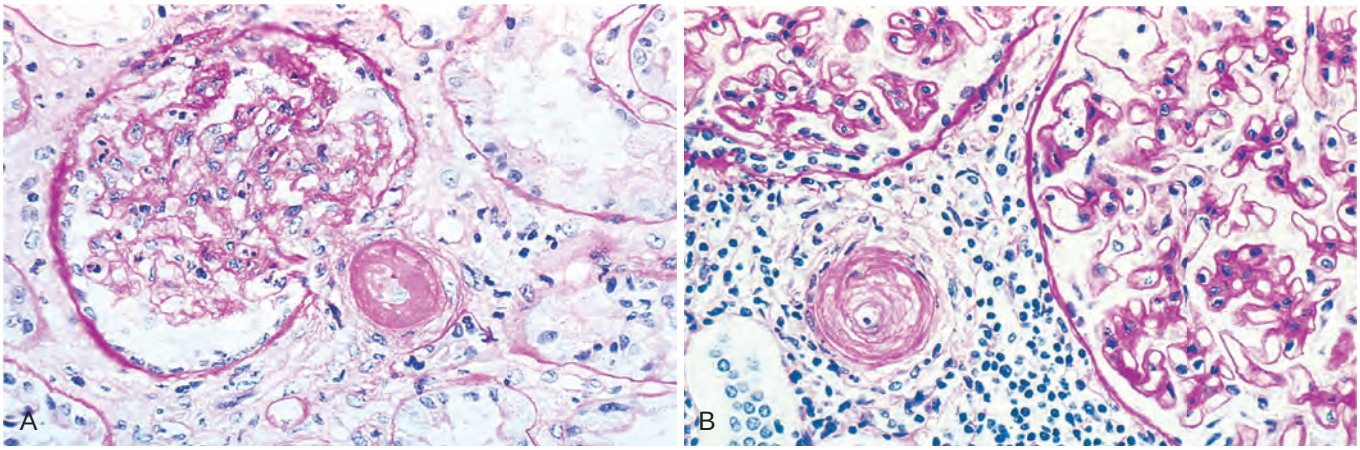

Figure 20.39 Thrombotic microangiopathy associated with malignant hypertension. (A) Fibrinoid necrosis of afferent arteriole (periodic acid–Schiff stain). (B) Hyperplastic arteriolitis (onion-skin lesion). (Courtesy Dr. H. Rennke, Brigham and Women's Hospital, Boston, Mass.)

- Chemotherapeutic and immunosuppressive drugs, such as mitomycin, cyclosporine, cisplatin, gemcitabine, and antagonists of VEGF.
- Irradiation of the kidney.

Patients with atypical HUS do not fare as well as those with typical HUS, in large part because the underlying conditions may be chronic and difficult to treat. As in typical HUS, some patients have neurologic symptoms; the disease in these patients can be distinguished from TTP by the presence of ADAMTS13 levels in the plasma of greater than 10% (see later).

Thrombotic Thrombocytopenic Purpura

TTP is classically manifested by the pentad of fever, neurologic symptoms, microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. The most common cause of deficient ADAMTS13 activity is inhibitory autoantibodies, and the majority of individuals with such antibodies are women. Regardless of the cause, most patients present as adults younger than 40 years of age. Less commonly, patients inherit an inactivating mutation in *ADAMTS13*. In those with hereditary ADAMTS13 deficiency, the onset is often delayed until adolescence, and the symptoms are episodic. Thus, factors other than ADAMTS13 (e.g., some superimposed vascular injury or prothrombotic state) must be involved in triggering full-blown TTP.

For unknown reasons, in TTP, central nervous system involvement is the dominant feature, whereas renal involvement is seen in about 50% of patients. The clinical findings are dictated by the distribution of the microthrombi, which are found in arterioles throughout the body. With plasma exchange, which removes autoantibodies and provides functional ADAMTS13, TTP (which once was uniformly fatal) can be treated successfully in more than 80% of patients.

MORPHOLOGY

The morphologic findings in the various forms of HUS/TTP are indistinguishable and vary mainly in chronicity rather than cause. In acute, active disease, the kidney may show patchy or diffuse cortical necrosis and subcapsular petechiae. The glomerular capillaries are distended and occluded by thrombi. Disruption of the mesangial matrix and damage to the mesangial cells often results in mesangiolysis. Interlobular arteries and arterioles often show occlusive thrombi. Chronic disease is common in patients with atypical HUS, and has features that stem from continued injury and attempts at healing. The renal cortex reveals various degrees of scarring. By light microscopy, the glomeruli are mildly hypercellular and have marked thickening of the capillary walls associated with splitting or reduplication of the basement membrane (so called double contours or tram tracks). The walls of arteries and arterioles often exhibit increased layers of cells and connective tissue ("onion-skinning") that narrow the vessel lumens. The morphologic lesions are similar to those seen in malignant hypertension (Fig. 20.39). These changes lead to persistent hypoperfusion and potentially diffuse cortical necrosis, which manifests clinically as renal failure and hypertension. The gross alterations of massive ischemic necrosis are sharply limited to the cortex (Fig. 20.40). The histologic appearance is that of acute ischemic infarction. The lesions may be patchy, with areas of coagulative necrosis and apparently better preserved cortex.

Figure 20.40 Diffuse cortical necrosis. The pale ischemic necrotic areas are confined to the cortex and columns of Bertin.

KEY CONCEPTS

THROMBOTIC MICROANGIOPATHY

- Thrombotic microangiopathy encompasses a diverse set of conditions that all lead to deposition of thrombi in the microvasculature, accompanied by red cell hemolysis, tissue ischemia and organ dysfunction, and a consumptive thrombocytopenia.
- In typical HUS, Shiga-like toxin produced by bacteria, most commonly *E. coli* strain O157:H7, is responsible for producing platelet activation and thrombosis.
- In most cases of atypical HUS, aberration activation of complement due to inherited mutations or acquired autoantibodies is the key pathogenic abnormality.
- In TTP, deficiencies of ADAMTS13, a negative regulator of vWF, permits the formation of abnormally large multimers of vWF that are capable of activating platelets.

Other Vascular Disorders

Atherosclerotic Ischemic Renal Disease

We have seen that atherosclerotic unilateral renal artery stenosis can lead to hypertension. *Bilateral renal artery disease,* usually diagnosed definitively by arteriography, is a fairly common cause of chronic ischemia with renal insufficiency in older individuals, sometimes in the absence of hypertension. The importance of recognizing this condition is that surgical revascularization can prevent further decline in renal function.

Atheroembolic Renal Disease

Embolization of fragments of atheromatous plaques from the aorta or renal artery into intrarenal vessels occurs in older adults with severe atherosclerosis, especially after surgery on the abdominal aorta, aortography, or intra-aortic cannulization. These emboli can be recognized in the lumens of arcuate and interlobular arteries by their content of cholesterol crystals, which appear as rhomboid clefts (Fig. 20.41). The clinical consequences of atheroemboli vary according to the number of emboli and the preexisting state of renal function. Frequently they are of no significance. However, acute renal injury or failure may develop in older adults in whom renal function is already compromised.

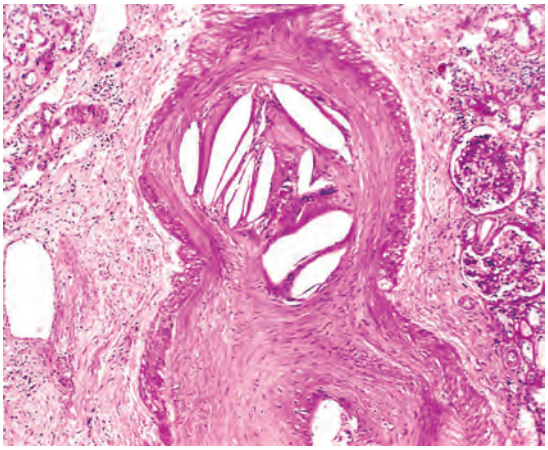

Figure 20.41 Atheroembolus with typical cholesterol clefts in an interlobar artery.

Sickle Cell Nephropathy

Sickle cell disease (homozygous) or trait (heterozygous) may lead to a variety of alterations in renal morphology and function, some of which produce clinically significant abnormalities. The various manifestations are grouped under *sickle cell nephropathy*.

The most common abnormalities are *hematuria* and a *diminished concentrating ability* (hyposthenuria). These are thought to be due to accelerated sickling in the hypertonic hypoxic milieu of the renal medulla; the hyperosmolarity dehydrates red cells and increases intracellular sickle hemoglobin (HbS) concentrations, which likely explains why even those with sickle cell trait are affected. Patchy *papillary necrosis* may occur in both homozygotes and heterozygotes; this is sometimes associated with cortical scarring. *Proteinuria* is also common in sickle cell disease, occurring in about 30% of patients. It is usually mild to moderate, but on occasion the overt nephrotic syndrome arises, associated with sclerosing glomerular lesions.

Renal Infarcts

The kidneys are common sites for the development of infarcts. Contributing to this predisposition is the extensive blood flow to the kidneys (one-fourth of the cardiac output), but probably more important is the limited collateral circulation from extrarenal sites (small blood vessels penetrating from the renal capsule supply only the very outer rim of the cortex). Although thrombosis in advanced atherosclerosis and the acute vasculitis of polyarteritis nodosa may occlude arteries, most infarcts are due to embolism. A major source of such emboli is mural thrombosis in the left atrium and ventricle as a result of myocardial infarction. Vegetative endocarditis, aortic aneurysms, and aortic atherosclerosis are less frequent sources of emboli.

MORPHOLOGY

Because of the lack of a collateral blood supply, most renal infarcts are of the "white" anemic variety. Within 24 hours, infarcts become sharply demarcated, pale, yellow-white areas that may contain small irregular foci of hemorrhagic discoloration. They are usually ringed by a zone of intense hyperemia.

The infarcts are wedge-shaped, with the base against the cortical surface and the apex pointing toward the medulla. In time, these acute areas of ischemic necrosis undergo progressive fibrous scarring, giving rise to depressed, pale, gray-white scars that assume a *V*-shape on section. The histologic changes in renal infarcts are those of ischemic coagulative necrosis, described in Chapter 2.

Many renal infarcts are clinically silent. Sometimes, pain with tenderness localized to the costovertebral angle occurs, associated with showers of red cells in the urine. Large infarcts of one kidney are probably associated with narrowing of the renal artery or one of its major branches, which, in turn, may cause hypertension.

CONGENITAL AND DEVELOPMENTAL ANOMALIES

About 10% of people are born with significant malformations of the urinary system. Renal dysplasias and hypoplasias account for 20% of chronic kidney disease in children.

Congenital renal disease can be hereditary but most often results from an acquired developmental defect during gestation. As discussed in Chapter 10, defects in genes involved in normal renal development, including the Wilms tumor–associated genes, understandably cause urogenital anomalies. As a rule, the resulting developmental abnormalities involve structural components of both the kidney and urinary tract. Other genetic defects primarily produce functional abnormalities in tubular transport, such as cystinuria and renal tubular acidosis. Here, we restrict the discussion to structural anomalies involving primarily the kidney. All except horseshoe kidney are uncommon. Anomalies of the lower urinary tract are discussed in Chapter 21.

Agenesis of the Kidney. Bilateral agenesis is incompatible with life and usually encountered in stillborn infants. It is often associated with other congenital disorders (e.g., limb defects, hypoplastic lungs). Unilateral agenesis is uncommon and compatible with normal life if no other abnormalities exist. The solitary kidney enlarges as a result of compensatory hypertrophy. Some patients eventually develop progressive glomerular sclerosis in the remaining kidney as a result of the adaptive changes in hypertrophied nephrons, discussed earlier in the chapter, and, in time, chronic kidney disease ensues.

Hypoplasia. *Hypoplasia* refers to failure of the kidneys to develop to a normal size. This anomaly may occur bilaterally, resulting in renal failure in early childhood, but it is more commonly encountered as a unilateral defect. True renal hypoplasia is observed in low-birth-weight infants and may contribute to their increased lifetime risk for chronic kidney disease. Differentiation between congenital and acquired atrophic kidneys may be impossible, but a truly hypoplastic kidney shows no scars and has a reduced number of renal lobes and pyramids, usually six or fewer.

Ectopic Kidneys. The development of the metanephros into the kidneys may occur in ectopic foci. These kidneys lie either just above the pelvic brim or sometimes within the pelvis.

They are usually normal or slightly small in size but otherwise are not remarkable. Because of their abnormal position, kinking or tortuosity of the ureters may cause obstruction to urinary flow, which predisposes to bacterial infections.

Horseshoe Kidneys. Fusion of the upper (10%) or lower poles (90%) of the kidneys produces a horseshoe-shaped structure that is continuous across the midline anterior to the great vessels. This anomaly is found in 1 in 500 to 1000 autopsies.

CYSTIC DISEASES OF THE KIDNEY

Cystic diseases of the kidney are heterogeneous, comprising hereditary, developmental, and acquired disorders. They are important for several reasons: (1) They are reasonably common and often represent diagnostic problems for clinicians, radiologists, and pathologists; (2) some forms, such as adult polycystic kidney disease, are major causes of chronic kidney disease; and (3) they can occasionally be confused with malignant tumors. A useful classification of renal cysts is summarized in Table 20.12.

Autosomal Dominant (Adult) Polycystic Kidney Disease

Autosomal dominant (adult) polycystic kidney disease is a hereditary disorder characterized by multiple expanding cysts of both kidneys that ultimately destroy the renal parenchyma and cause renal failure. It is a common condition affecting roughly 1 in 400 to 1000 live births and accounting for about 5% to 10% of cases of ESRD requiring transplantation or dialysis. The inheritance pattern is autosomal dominant with high penetrance. Although the susceptibility to develop this disease is inherited as an autosomal dominant trait, as with tumor suppressor genes, both alleles of the involved genes have to be nonfunctional for development of the disease. Thus, individuals prone to autosomal dominant polycystic kidney disease inherit one copy of a mutated *APKD* gene, and mutation of the other allele is acquired in the somatic cells of the kidney. The disease is bilateral; reported unilateral cases probably represent multicystic dysplasia. The cysts initially involve a minority of the nephrons, so renal function is retained until about the fourth or fifth decade of life.

Genetics and Pathogenesis

A wide range of different mutations in *PKD1* and *PKD2* has been described, and this allelic heterogeneity has complicated genetic diagnosis of this disorder.

- The *PKD1* gene is located on chromosome 16p13.3. It encodes a large (460-kD) integral membrane protein named *polycystin-1,* which has a large extracellular region, multiple transmembrane domains, and a short cytoplasmic tail. Polycystin-1 is expressed in tubular epithelial cells, particularly those of the distal nephron. At present, its precise function is not known, but it contains domains that are usually involved in cell-cell and cell-matrix interactions. Mutations in *PKD1* account for about 85% of cases. In individuals with these mutations, the likelihood of developing renal failure is less than 5% by 40 years of age, rising to more than 35% by 50 years of age, more than 70% at 60 years of age, and more than 95% by 70 years of age.

Table 20.12 Summary of Renal Cystic Diseases

Disease	Inheritance	Pathologic Features	Clinical Features or Complications	Typical Outcome	Diagrammatic Representation
Adult polycystic kidney disease	Autosomal dominant	Large multicystic kidneys, liver cysts, berry aneurysms	Hematuria, flank pain, urinary tract infection, renal stones, hypertension	Chronic renal failure beginning at 40–60 years of age	
Childhood polycystic kidney disease	Autosomal recessive	Enlarged, cystic kidneys at birth	Hepatic fibrosis	Variable, death in infancy or childhood	
Medullary sponge kidney	None	Medullary cysts on excretory urography	Hematuria, urinary tract infection, recurrent renal stones	Benign	
Familial juvenile nephronophthisis	Autosomal recessive	Corticomedullary cysts, shrunken kidneys	Salt wasting, polyuria, growth retardation, anemia	Progressive renal failure beginning in childhood	
Multicystic renal dysplasia	None	Irregular kidneys with cysts of variable size	Association with other renal anomalies	Renal failure if bilateral, surgically curable if unilateral	
Acquired renal cystic disease	None	Cystic degeneration in end-stage kidney disease	Hemorrhage, erythrocytosis, neoplasia	Dependence on dialysis	
Simple cysts	None	Single or multiple cysts in normal-sized kidneys	Microscopic hematuria	Benign	

- The *PKD2* gene, located on chromosome 4q21, accounts for most of the remaining cases of polycystic disease. Its product, *polycystin-2,* is an integral membrane protein that is expressed in all segments of the renal tubules and in many extrarenal tissues. Polycystin-2 functions as a Ca^{2+}-permeable cation channel. Overall, the disease is less severe than that associated with *PKD1* mutations. Renal failure occurs in less than 5% of patients with *PKD2* mutations at 50 years of age, but this rises to 15% at 60 years of age, and 45% at 70 years of age.

The pathogenesis of polycystic disease is not established, but the currently favored hypothesis places the cilia-centrosome complex of tubular epithelial cells at the center of the disorder (Fig. 20.42). The tubular epithelial cells of the kidney contain a single nonmotile primary cilium, a 2- to 3-μm-long hairlike organelle that projects into the tubular lumen from the apical surface of the cells. The cilium is made up of microtubules, and it arises from and is attached to a basal body derived from the centriole. The cilia are part of a system of organelles and cellular structures that sense mechanical signals. The apical cilia function in the kidney tubule as a mechanosensor to monitor changes in fluid flow and shear stress, while intercellular junctional complexes monitor forces between cells, and focal adhesions sense attachment to extracellular matrices. In response to external signals, these sensors regulate ion flux (cilia can induce Ca^{2+} flux in cultured kidney epithelial cells) and cellular behavior, including cell polarity and proliferation. The idea that defects in mechanosensing, Ca^{2+} flux, and signal transduction underlie cyst formation is supported by several observations.

- Both polycystin-1 and polycystin-2 are localized to the primary cilium.
- Other genes that are mutated in cystic diseases (e.g., the nephrocystin genes, described later) encode proteins that are also localized to cilia and/or basal bodies.

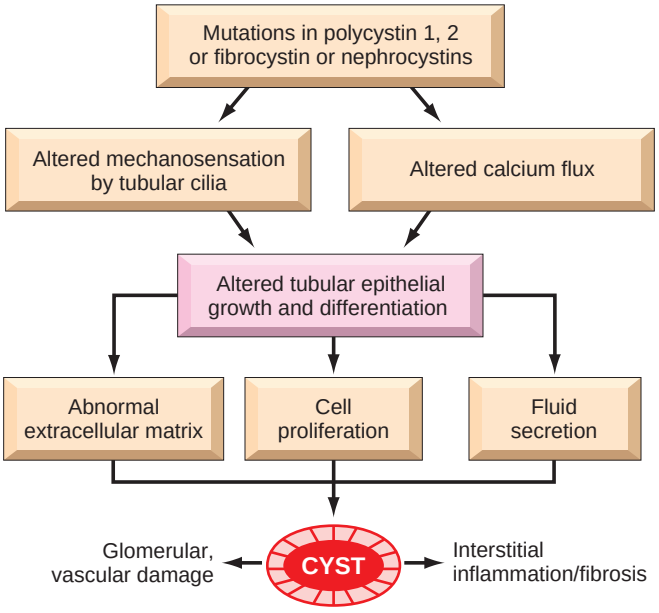

Figure 20.42 Possible mechanisms of cyst formation in cystic kidney diseases *(see text).*

- Knockout of the *PKD1* gene in one model organism (the worm *Caenorhabditis elegans*) results in ciliary abnormalities and cyst formation.
- Tubular cells obtained from mice with a deletion of the *PKD1* gene (which causes embryonic lethality in this species) retain normal architecture of cilia but lack the flow-induced Ca^{2+} flux that occurs in normal tubular cells.

Polycystin-1 and polycystin-2 appear to form a protein complex that regulates intracellular Ca^{2+} in response to fluid flow, perhaps because fluid moving through the kidney tubules causes ciliary bending that opens Ca^{2+} channels. Mutation of either of the *PKD* genes leads to loss of the polycystin complex or formation of an aberrant complex. The consequent disruption of normal polycystin activity results in alterations of intracellular Ca^{2+}, which (you will recall) regulates many downstream signaling events, including pathways that directly or indirectly impact cellular proliferation, apoptosis, and secretory functions. The increase in calcium is thought to stimulate proliferation and secretion from epithelial cells lining the cysts, which together result in progressive cyst formation and enlargement. In addition, cyst fluids have been shown to harbor mediators derived from epithelial cells that enhance fluid secretion and induce inflammation. Finally, the calcium-induced signals also alter the interaction of epithelial cells with ECM, and this too is thought to contribute to the cyst formation and interstitial fibrosis that are characteristic of progressive polycystic kidney disease.

MORPHOLOGY

In gross appearance, the kidneys are bilaterally enlarged and may achieve enormous sizes; weights as much as 4 kg for each kidney have been reported. The external surface appears to be composed solely of a mass of cysts, up to 3 to 4 cm in diameter, with no intervening parenchyma (Fig. 20.43A and B). However, microscopic examination reveals functioning nephrons dispersed between the cysts. The cysts may be filled with a clear, serous fluid or with turbid, red to brown, sometimes hemorrhagic fluid. As these cysts enlarge, they may encroach on the calyces and pelvis to produce pressure defects. The cysts arise from the tubules throughout the nephron and therefore have variable lining epithelia. On occasion, papillary epithelial formations and polyps project into the lumen.

Clinical Features

Many patients remain asymptomatic until renal insufficiency announces the presence of the disease. In others, hemorrhage or progressive dilation of cysts may produce pain. Excretion of blood clots causes renal colic. The enlarged kidneys, usually apparent on abdominal palpation, may induce a dragging sensation. The disease occasionally begins with the insidious onset of hematuria, followed by other features of progressive chronic kidney disease, such as proteinuria (rarely more than 2 g/day), polyuria, and hypertension. Patients with *PKD2* mutations tend to have an older age at onset and later development of renal failure. Both genetic and environmental factors influence disease severity. Progression is accelerated in blacks (particularly in those with sickle cell trait), in males, and in the presence of hypertension.

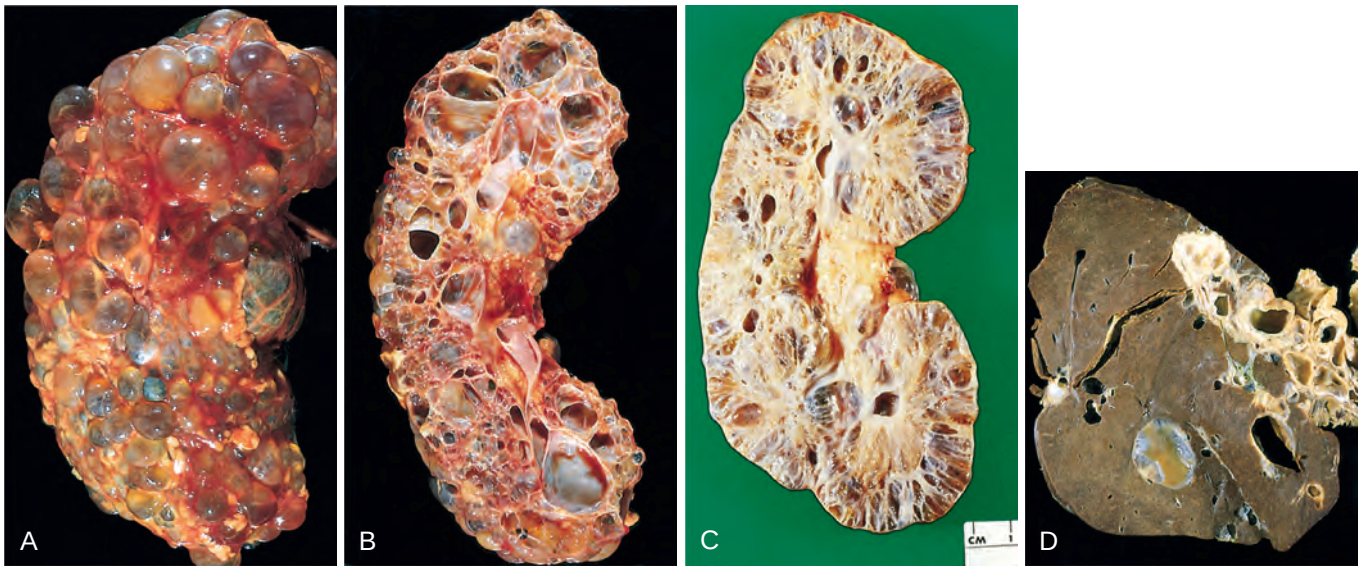

Figure 20.43 (A and B) Autosomal dominant adult polycystic kidney disease (ADPKD) viewed from the external surface and bisected. The kidney is markedly enlarged and contains numerous dilated cysts. (C) Autosomal recessive childhood PKD, showing smaller cysts and dilated channels at right angles to the cortical surface. (D) Liver cysts in adult PKD.

Individuals with polycystic kidney disease also tend to have extrarenal congenital anomalies. About 40% have one to several cysts in the liver (polycystic liver disease) that are usually asymptomatic. The cysts are derived from biliary epithelium. Cysts occur much less frequently in the spleen, pancreas, and lungs. Intracranial berry aneurysms, presumably from altered expression of polycystin in vascular smooth muscle, arise in the circle of Willis, and subarachnoid hemorrhages from these account for death in 4% to 10% of individuals. *Mitral valve prolapse* and other cardiac valvular anomalies occur in 20% to 25% of patients, but most are asymptomatic. The diagnosis is made by radiologic imaging techniques.

This form of chronic kidney disease is remarkable in that patients may survive for many years with azotemia slowly progressing to uremia. Ultimately, about 40% of adult patients die of coronary or hypertensive heart disease, 25% of infection, 15% of a ruptured berry aneurysm or hypertensive intracerebral hemorrhage, and the rest of other causes.

Autosomal Recessive (Childhood) Polycystic Kidney Disease

Autosomal recessive (childhood) polycystic kidney disease is genetically distinct from adult polycystic kidney disease. *Perinatal, neonatal, infantile,* and *juvenile* subcategories have been defined, depending on the time of presentation and presence of associated hepatic lesions. The first two are the most common; serious manifestations are usually present at birth, and the young infant might succumb rapidly to renal failure.

Genetics and Pathogenesis

In most cases, the disease is caused by mutations in the *PKHD1* gene, which maps to chromosome region 6p21–p23. The gene is highly expressed in adult and fetal kidney and also in liver and pancreas. The *PKHD1* gene encodes *fibrocystin*, a 447-kD integral membrane protein with a large extracellular region, a single transmembrane component, and a short cytoplasmic tail. The extracellular region contains multiple copies of a domain forming an Ig-like fold. Like polycystins 1 and 2, fibrocystin also has been localized to the primary cilium of tubular cells. The function of fibrocystin is unknown, but its putative conformational structure indicates it may be a cell surface receptor with a role in collecting duct and biliary differentiation.

Analysis of autosomal recessive polycystic disease patients has revealed a wide range of different mutations. The vast majority of cases are compound heterozygotes (i.e., inherit a different mutant allele from each of the two parents). This complicates molecular diagnosis of the disorder.

MORPHOLOGY

The kidneys are enlarged and have a smooth external appearance. On cut section, numerous small cysts in the cortex and medulla give the kidney a spongelike appearance. Dilated elongated channels are present at right angles to the cortical surface, completely replacing the medulla and cortex (Fig. 20.43C). On microscopic examination, there is cylindrical or, less commonly, saccular dilation of all collecting tubules. The cysts have a uniform lining of cuboidal cells, reflecting their origin from the collecting ducts. In almost all cases, the liver has cysts (Fig. 20.43D) associated with portal fibrosis and proliferation of portal bile ducts.

Patients who survive infancy (infantile and juvenile forms) may develop a peculiar hepatic injury characterized by bland periportal fibrosis and proliferation of well-differentiated biliary ductules, now termed *congenital hepatic fibrosis*. In older children, hepatic disease is the predominant clinical concern. Such patients may develop portal hypertension with splenomegaly. Curiously, congenital hepatic fibrosis

sometimes occurs in the absence of polycystic kidneys or has been reported in the presence of adult polycystic kidney disease.

Cystic Diseases of the Renal Medulla

The two major types of medullary cystic disease are *medullary sponge kidney,* a relatively common and usually innocuous structural change, and *nephronophthisis,* which is almost always associated with renal dysfunction.

Medullary Sponge Kidney

The term *medullary sponge kidney* is restricted to multiple cystic dilations of the collecting ducts in the medulla. The condition occurs in adults and is usually discovered radiographically. Renal function is usually normal. On gross inspection, the papillary ducts in the medulla are dilated, and small cysts may be present. The cysts are lined by cuboidal epithelium or occasionally by transitional epithelium. Unless there is superimposed pyelonephritis, cortical scarring is absent. The pathogenesis is unknown.

Nephronophthisis

This group of progressive renal disorders is characterized by variable number of cysts in the medulla, usually concentrated at the corticomedullary junction. Initial injury probably involves the distal tubules with tubular basement membrane disruption, followed by chronic and progressive tubular atrophy involving both medulla and cortex and interstitial fibrosis. Although the medullary cysts are important, the **cortical tubulointerstitial damage is the cause of the eventual renal insufficiency.**

Three variants of the nephronophthisis disease complex are recognized: (1) sporadic, nonfamilial; (2) familial juvenile nephronophthisis (most common); and (3) renal-retinal dysplasia (15%) in which the kidney disease is accompanied by ocular lesions. The familial forms are inherited as autosomal recessive traits and usually become manifest in childhood or adolescence. As a group, the nephronophthisis complex is now the most common genetic cause of ESRD in children and young adults.

Children affected with nephronophthisis present first with polyuria and polydipsia, which reflect a marked defect in the concentrating ability of renal tubules. Sodium wasting and tubular acidosis are also prominent. Some syndromic variants of nephronophthisis (e.g., Senior-Loken syndrome, Joubert syndrome, Bardet Biedl syndrome, Jeune syndrome, Meckel Gruber syndrome, Mainzer-Saldino syndrome, Sensenbrenner syndrome) can have extrarenal associations, including ocular motor abnormalities, retinal dystrophy, liver fibrosis, and cerebellar abnormalities. The expected course is progression to ESRD in 5 to 10 years.

Genetics and Pathogenesis

Sixteen responsible gene loci, *NPHP1* to *NPHP11* (that encode proteins called nephrocystins, *JBTS2, JBTS3, JBTS9,* and *JBTS11,* are mutated in the juvenile forms of nephronophthisis, and the list continually expands as additional loci that contribute to this ciliopathy are identified. These proteins are present in the primary cilia, basal bodies attached to these cilia, or the centrosome organelle from which the basal bodies originate. The *NPHP2* gene product has been identified as *inversin,* which mediates left-right patterning during embryogenesis.

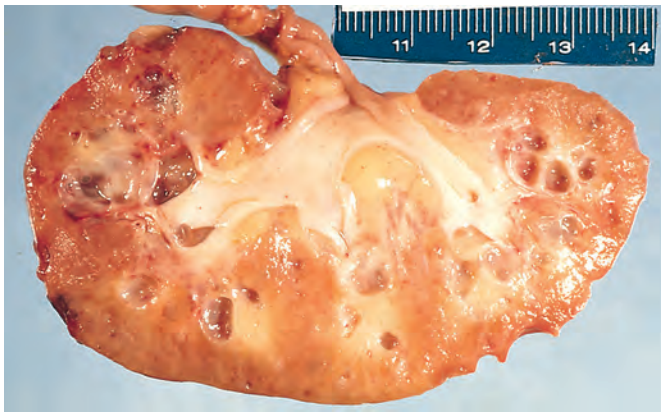

Figure 20.44 Medullary cystic disease. Cut section of kidney showing cysts at the corticomedullary junction and in the medulla.

MORPHOLOGY

In nephronophthisis, the kidneys are small, have contracted granular surfaces, and show cysts in the medulla, most prominently at the corticomedullary junction. The cysts are similar to those in medullary cystic disease, a rare, usually autosomal dominant, disease (Fig. 20.44). Small cysts are also seen in the cortex. The cysts are lined by flattened or cuboidal epithelium and are usually surrounded by either inflammatory cells or fibrous tissue. In the cortex, there is widespread atrophy and thickening of the tubular basement membranes, together with interstitial fibrosis. In general, glomerular structure is preserved.

There are few specific clues to diagnosis, because the medullary cysts might be too small to be visualized radiographically. The disease should be strongly considered in children or adolescents with otherwise unexplained chronic renal failure, a positive family history, and chronic tubulointerstitial nephritis on biopsy.

Multicystic Renal Dysplasia

Dysplasia is a sporadic disorder that can be unilateral or bilateral and is often cystic. The kidney is usually enlarged, extremely irregular, and multicystic (Fig. 20.45A). The cysts vary in size from several millimeters to centimeters in diameter. On histologic examination, they are lined by flattened epithelium. Although normal nephrons are present, the characteristic histologic feature is the presence of islands of undifferentiated mesenchyme, often with cartilage, and immature collecting ducts (Fig. 20.45B). Most cases are associated with ureteropelvic obstruction, ureteral agenesis or atresia, and other anomalies of the lower urinary tract.

When unilateral, the dysplasia may mimic a neoplasm and lead to surgical exploration and nephrectomy. The opposite kidney functions normally, and such patients have an excellent prognosis after surgical removal of the affected kidney. In bilateral multicystic renal dysplasia, renal failure may ultimately result.

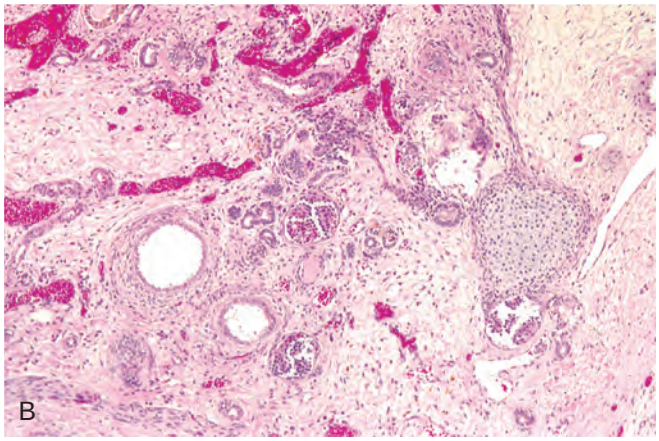

Figure 20.45 Multicystic renal dysplasia. (A) Gross appearance. (B) Histologic section showing disorganized architecture, dilated tubules with cuffs of primitive stroma, and an island of cartilage (hematoxylin and eosin stain). (A, Courtesy Dr. D. Schofield, Children's Hospital, Los Angeles, Calif.; B, courtesy Dr. Laura Finn, Children's Hospital, Seattle, Wash.)

Acquired Cystic Disease

Patients with ESRD who have undergone prolonged dialysis sometimes show numerous cortical and medullary renal cysts. The cysts measure 0.1 to 4 cm in diameter, contain clear fluid, are lined by either hyperplastic or flattened tubular epithelium, and often contain calcium oxalate crystals. They probably form as a result of obstruction of tubules by interstitial fibrosis or by oxalate crystals. Most are asymptomatic, but sometimes the cysts bleed, causing hematuria. There is up to 100-fold increased risk of renal cell carcinoma, which develops in 7% of patients observed for 10 years.

Simple Cysts

Simple cysts may be single or multiple and usually involve the cortex. They are commonly 1 to 5 cm but may reach 10 cm or more in size. They are translucent, lined by a gray, glistening, smooth membrane, and filled with clear fluid. On microscopic examination, these membranes are composed of a single layer of cuboidal or flattened cuboidal epithelium, which in many instances may be completely atrophic.

Simple cysts are common postmortem findings without clinical significance. On occasion, hemorrhage into them may cause sudden distention and pain, and calcification of the hemorrhage may give rise to bizarre radiographic shadows. The main importance of cysts lies in their differentiation from kidney tumors. Radiologic studies show that in contrast to renal tumors, renal cysts have smooth contours, are almost always avascular, and give fluid rather than solid signals on ultrasonography.

KEY CONCEPTS

CYSTIC DISEASES

- Autosomal dominant polycystic kidney disease accounts for a small yet significant subset of ESRD.
- Ciliopathies or abnormalities of the cilium-centrosome complex underlie the major cystic kidney diseases, including polycystic kidney disease (both autosomal dominant and autosomal recessive forms) and nephronophthisis.
- Dysfunction of the primary cilium of tubular epithelial cells results in alterations in ion flux and changes in cell proliferation and function, culminating in renal cyst formation.

URINARY TRACT OBSTRUCTION (OBSTRUCTIVE UROPATHY)

Obstructive lesions of the urinary tract increase susceptibility to infection and to stone formation, and unrelieved obstruction almost always leads to permanent renal atrophy, termed *hydronephrosis* or *obstructive uropathy*. Fortunately, many causes of obstruction are surgically correctable or medically treatable.

Obstruction may be sudden or insidious, partial or complete, unilateral or bilateral; it may occur at any level of the urinary tract from the urethra to the renal pelvis. It can be caused by *intrinsic* lesions of the urinary tract or *extrinsic* lesions that compress the ureter. The common causes are as follows (Fig. 20.46):

- *Congenital anomalies:* posterior urethral valves and urethral strictures, meatal stenosis, bladder neck obstruction; ureteropelvic junction narrowing or obstruction; severe vesicoureteral reflux
- *Urinary calculi*
- *Benign prostatic hypertrophy*
- *Tumors:* carcinoma of the prostate, bladder tumors, contiguous malignant disease (retroperitoneal lymphoma), carcinoma of the cervix or uterus
- *Inflammation:* prostatitis, ureteritis, urethritis, retroperitoneal fibrosis
- *Sloughed papillae or blood clots*
- *Pregnancy*
- *Uterine prolapse and cystocele*
- *Functional disorders:* neurogenic (spinal cord damage or diabetic nephropathy) and other functional abnormalities of the ureter or bladder (often termed *dysfunctional obstruction*)

***Hydronephrosis* is the term used to describe dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney due to obstruction to the outflow of urine.** Even with complete obstruction, glomerular filtration

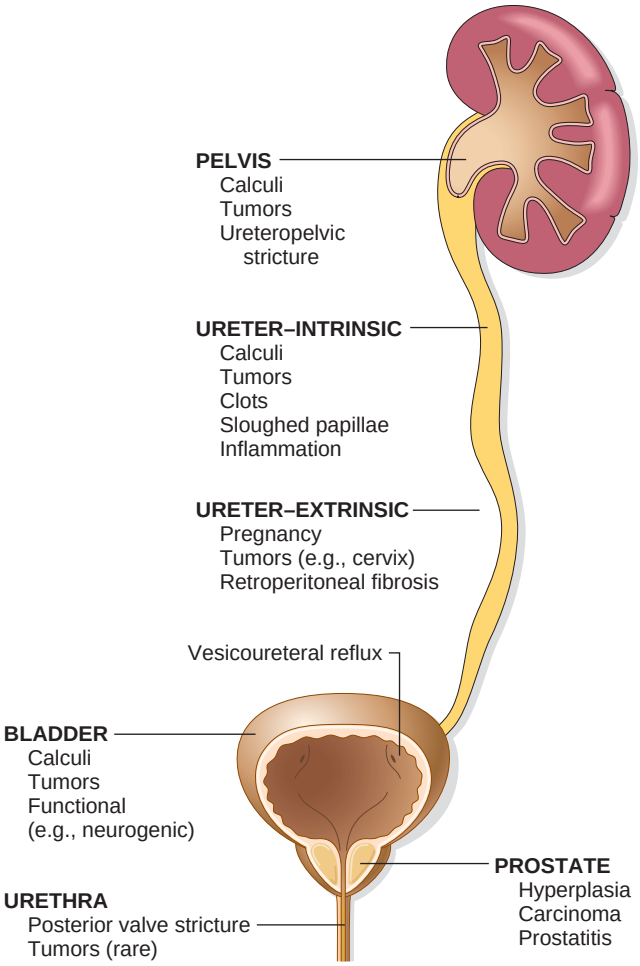

Figure 20.46 Obstructive lesions of the urinary tract.

persists for some time because the filtrate subsequently diffuses back into the renal interstitium and perirenal spaces, from where it ultimately returns to the lymphatic and venous systems. Because of this continued filtration, the affected calyces and pelvis become dilated, often markedly so. The high pressure in the pelvis is transmitted back through the collecting ducts into the cortex, causing renal atrophy, but it also compresses the renal vasculature of the medulla, causing a diminution in inner medullary blood flow. The medullary vascular defects are initially reversible, but lead to medullary functional disturbances. Accordingly, the initial functional alterations caused by obstruction are largely tubular, manifested primarily by impaired concentrating ability. Only later does the GFR begin to fall. Obstruction also triggers an interstitial inflammatory reaction, leading eventually to interstitial fibrosis, by mechanisms similar to those discussed earlier (see Fig. 20.8).

MORPHOLOGY

When the obstruction is sudden and complete, it leads to mild dilation of the pelvis and calyces and sometimes to atrophy of the renal parenchyma. When the obstruction is subtotal or intermittent, progressive dilation ensues, giving rise to hydronephrosis (Fig. 20.47). Depending on the level of urinary block, the dilation may affect the bladder first, or the ureter and then the kidney.

The kidney may be slightly to massively enlarged, depending on the degree and the duration of the obstruction. The earlier features are those of simple dilation of the pelvis and calyces, but in addition there is often significant interstitial inflammation, even in the absence of infection. In chronic cases, the picture is one of cortical tubular atrophy with marked diffuse interstitial fibrosis. Progressive blunting of the apices of the pyramids occurs, and these eventually become cupped. In far-advanced cases, the kidney may become transformed into a thin-walled cystic structure having a diameter of up to 15 to 20 cm (see Fig. 20.47) with striking parenchymal atrophy, total obliteration of the pyramids, and thinning of the cortex.

Figure 20.47 Hydronephrosis of the kidney, with marked dilation of the pelvis and calyces and thinning of the renal parenchyma.

Clinical Features

Acute obstruction may provoke pain attributed to distention of the collecting system or renal capsule. Most of the early symptoms are produced by the underlying cause of the hydronephrosis. Thus, calculi lodged in the ureters may give rise to renal colic, and prostatic enlargements may give rise to bladder symptoms.

Unilateral complete or partial hydronephrosis may remain silent for long periods because the unaffected kidney can maintain adequate renal function. Sometimes its existence first becomes apparent in the course of imaging studies. In its early stages, perhaps the first few weeks, relief of obstruction leads to reversion to normal function. *Ultrasonography* is a useful noninvasive technique in the diagnosis of obstructive uropathy.

In *bilateral partial obstruction,* the earliest manifestation is inability to concentrate urine, reflected by polyuria and nocturia. Some patients develop distal tubular acidosis, renal salt wasting, secondary renal calculi, and chronic tubulointerstitial nephritis with scarring and atrophy of the papilla and medulla. Hypertension is common.

Complete bilateral obstruction of rapid onset results in oliguria or anuria and is incompatible with survival unless the obstruction is relieved. Curiously, after relief of complete urinary tract obstruction, postobstructive *diuresis* occurs. This can often be massive, with the kidney excreting large amounts of urine that is rich in sodium chloride.

UROLITHIASIS (RENAL CALCULI, STONES)

Urolithiasis affects 5% to 10% of people in the United States in their lifetime, and the stones may form anywhere in the urinary tract, but most arise in the kidney. Men are affected more often than women, and the peak age at onset is between 20 and 30 years. Familial and hereditary predisposition to stone formation has long been known. Many inborn errors of metabolism, such as cystinuria and primary hyperoxaluria, provide examples of hereditary disease characterized by excessive production and excretion of stone-forming substances.

Etiology and Pathogenesis

There are four main types of calculi (Table 20.13): (1) *calcium stones* (about 70%), composed largely of calcium oxalate or calcium oxalate mixed with calcium phosphate; (2) another 15% are so-called *triple stones* or *struvite stones,* composed of magnesium ammonium phosphate; (3) 5% to 10% are *uric acid stones;* and (4) 1% to 2% are made up of *cystine*. An organic mucoprotein matrix, making up 1% to 5% of the stone by weight, is present in all calculi. **Although there are many causes for the initiation and propagation of stones, the most important determinant is an increased urinary concentration of the stones' constituents, such that it exceeds their solubility (supersaturation).** A low urine volume in some metabolically normal patients may also favor supersaturation.

Table 20.13 Prevalence of Various Types of Renal Stones

Stone Type	Percentage of All Stones
Calcium Oxalate and Phosphate	**70**
Idiopathic hypercalciuria (50%)	
Hypercalciuria and hypercalcemia (10%)	
Hyperoxaluria (5%)	
Enteric (4.5%)	
Primary (0.5%)	
Hyperuricosuria (20%)	
Hypocitraturia	
No known metabolic abnormality (15% to 20%)	
Magnesium Ammonium Phosphate (Struvite)	**5–10**
Uric Acid	**5–10**
Associated with hyperuricemia	
Associated with hyperuricosuria	
Idiopathic (50% of uric stones)	
Cystine	**1–2**
Others or Unknown	**±5**

- *Calcium oxalate stones* are associated in about 5% of patients with hypercalcemia and hypercalciuria, such as occurs with hyperparathyroidism, diffuse bone disease, sarcoidosis, and other hypercalcemic states. About 55% have hypercalciuria without hypercalcemia, which is caused by several factors, including hyperabsorption of calcium from the intestine (absorptive hypercalciuria), an intrinsic impairment in renal tubular reabsorption of calcium (renal hypercalciuria), or idiopathic fasting hypercalciuria with normal parathyroid function. As many as 20% of calcium oxalate stones are associated with increased uric acid secretion *(hyperuricosuric calcium nephrolithiasis),* with or without hypercalciuria. The mechanism of stone formation in this setting involves "nucleation" of calcium oxalate by uric acid crystals in the collecting ducts. Five percent are associated with *hyperoxaluria,* either hereditary (primary oxaluria) or, more commonly, acquired by intestinal overabsorption in patients with enteric diseases. *Hypocitraturia,* which can be idiopathic or associated with acidosis and chronic diarrhea of unknown cause, may produce calcium stones. In a variable proportion of individuals with calcium stones, no cause can be found (idiopathic calcium stone disease).
- *Magnesium ammonium phosphate stones* are formed largely after infections by urea-splitting bacteria (e.g., *Proteus* and some staphylococci) that convert urea to ammonia. The resultant alkaline urine causes the precipitation of magnesium ammonium phosphate salts. These form some of the largest stones, as the amount of urea excreted normally is very large. Indeed, so-called *staghorn calculi* occupying large portions of the renal pelvis are frequently a consequence of infection.
- *Uric acid stones* are common in individuals with hyperuricemia, such as patients with gout, and diseases involving rapid cell turnover, such as the leukemias. However, **more than half of all patients with uric acid calculi have neither hyperuricemia nor increased urinary excretion of uric acid.** In this group, it is thought that a tendency to excrete urine of pH below 5.5 may predispose to uric acid stones, because uric acid is insoluble in acidic urine. In contrast to the radiopaque calcium stones, uric acid stones are radiolucent.
- *Cystine stones* are caused by genetic defects in the renal reabsorption of amino acids, including cystine, leading to cystinuria. These stones also form at low urinary pH.

It can therefore be appreciated that **increased concentration of stone constituents, changes in urinary pH, decreased urine volume, and the presence of bacteria influence the formation of calculi.** However, many calculi occur in the absence of these factors; conversely, individuals with hypercalciuria, hyperoxaluria, and hyperuricosuria often do not form stones. It has been postulated that stone formation is enhanced by a deficiency in inhibitors of crystal formation in urine. The list of such inhibitors is long, including pyrophosphate, diphosphonate, citrate, glycosaminoglycans, osteopontin, and a glycoprotein called nephrocalcin.

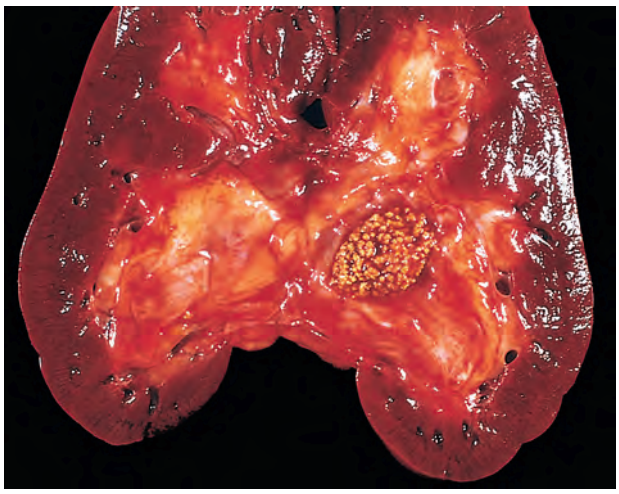

Figure 20.48 Nephrolithiasis. A large stone impacted in the renal pelvis. (Courtesy Dr. E. Mosher, Brigham and Women's Hospital, Boston, Mass.)

MORPHOLOGY

Stones are unilateral in about 80% of patients. The favored sites for their formation are within the renal calyces and pelves (Fig. 20.48) and in the bladder. If formed in the renal pelvis, they tend to remain small, having an average diameter of 2 to 3 mm. These may have smooth contours or may take the form of an irregular, jagged mass of spicules. Often many stones are found within one kidney. On occasion, progressive accretion of salts leads to the development of branching structures known as staghorn calculi, which create a cast of the pelvic and calyceal system.

Clinical Features

Urolithiasis may be asymptomatic, produce severe renal colic and abdominal pain, or may cause significant renal damage. Larger stones often manifest themselves by hematuria. Stones also predispose to superimposed infection, both by their obstructive nature and by the trauma they produce.

NEOPLASMS OF THE KIDNEY

Both benign and malignant neoplasms occur in the kidney. Malignant neoplasms are of great importance clinically. By far the most common malignant tumor is renal cell carcinoma, followed by Wilms tumor, which is found in children and described in Chapter 10, and finally urothelial carcinoma of the calyces and pelves.

Benign Neoplasms

Renal Papillary Adenoma

Small, discrete adenomas arising from the renal tubular epithelium are found commonly (7% to 22%) at autopsy. They are most frequently papillary and therefore called *papillary adenomas*.

MORPHOLOGY

These small tumors are less than 1.5 cm in diameter. They are present invariably within the cortex and appear grossly as pale yellow-gray, discrete, well-circumscribed nodules. On microscopic examination, they are composed of complex, branching, papillomatous structures with numerous complex fronds. Cells may also grow as tubules, glands, cords, and sheets of cells. The cells are cuboidal to polygonal in shape and have regular, small central nuclei, scanty cytoplasm, and no atypia.

By histologic criteria, these tumors do not differ from low-grade papillary renal cell carcinoma and share some immunohistochemical and cytogenetic features (trisomies 7 and 17) with papillary cancers, to be discussed later. The tumor size is used as a prognostic feature, with a cutoff of 3 cm separating those that metastasize from those that rarely do. However, because of occasional reports of small tumors that have metastasized, some regard all adenomas, regardless of size, as potentially malignant.

Angiomyolipoma

This benign neoplasm consists of vessels, smooth muscle, and fat originating from perivascular epithelioid cells. **Angiomyolipomas are present in 25% to 50% of patients with tuberous sclerosis,** a disease caused by loss-of-function mutations in the *TSC1* or *TSC2* tumor suppressor genes. Tuberous sclerosis is characterized by lesions of the cerebral cortex that produce epilepsy and intellectual disability, a variety of skin abnormalities, and unusual benign tumors at other sites, such as the heart (Chapters 12 and 28). The clinical importance of angiomyolipoma is due largely to their susceptibility to spontaneous hemorrhage.

Oncocytoma

This is an epithelial neoplasm composed of large eosinophilic cells having small, round, benign-appearing nuclei that have large nucleoli. It is thought to arise from the intercalated cells of collecting ducts, and accounts for approximately 5% to 15% of renal neoplasms. Ultrastructurally the eosinophilic cells have numerous mitochondria. In gross appearance, the tumors are tan or mahogany brown, relatively homogeneous, and usually well encapsulated with a central scar in one-third of cases. However, they may achieve a large size (up to 12 cm in diameter). There are some familial cases in which these tumors are multicentric rather than solitary.

Malignant Neoplasms

Renal Cell Carcinoma

Renal cell carcinomas represent about 3% of all newly diagnosed cancers in the United States and account for 85% of renal cancers in adults. There are approximately 65,000 new cases per year and 13,000 deaths from the disease. The tumors occur most often in older individuals, usually in the sixth and seventh decades of life, and show a 2:1 male preponderance.

Epidemiology

Tobacco is the most significant risk factor. Cigarette smokers have double the incidence of renal cell carcinoma, and pipe and cigar smokers are also more susceptible. An international

study has identified additional risk factors, including obesity (particularly in women); hypertension; unopposed estrogen therapy; and exposure to asbestos, petroleum products, and heavy metals. There is also an increased risk in patients with ESRD, chronic kidney disease, acquired cystic disease (see earlier), and tuberous sclerosis.

Most renal cancer is sporadic, but unusual forms of autosomal dominant familial cancers occur, usually in younger individuals. Although they account for only 4% of renal cancers, familial variants have been instructive in understanding renal carcinogenesis.

- *Von Hippel-Lindau (VHL) syndrome.* One-half to two-thirds of individuals with VHL (nearly all, if they live long enough) (Chapter 28) develop renal cysts and bilateral, often multiple, renal cell carcinomas. *Current studies implicate the* VHL *gene in the development of both familial and sporadic clear cell carcinomas.*
- *Hereditary leiomyomatosis and renal cell cancer syndrome.* This autosomal dominant disease is caused by mutations of the *FH* gene, which expresses fumarate hydratase, and is characterized by cutaneous and uterine leiomyomata and an aggressive type of papillary carcinoma with increased propensity for metastatic spread.
- *Hereditary papillary carcinoma.* This autosomal dominant form is manifested by multiple bilateral tumors with papillary histology. These tumors show a series of cytogenetic abnormalities and, as we will describe, mutations in the *MET* proto-oncogene.
- *Birt-Hogg-Dubé syndrome.* The autosomal dominant inheritance pattern of this disease is due to mutations involving the *BHD* gene, which expresses folliculin. The syndrome features a constellation of skin (fibrofolliculomas, trichodiscomas, and acrochordons), pulmonary (cysts or blebs), and renal tumors with a wide range of histologic subtypes.

Classification of Renal Cell Carcinoma: Histology, Cytogenetics, and Genetics

The classification of renal cell carcinoma is based on correlative cytogenetic, genetic, and histologic studies of both familial and sporadic tumors. The major types of tumor are as follows (Fig. 20.49):

- *Clear cell carcinoma.* This is the most common type, accounting for 70% to 80% of renal cell cancers. The tumors are made up of cells with clear or granular cytoplasm and are *nonpapillary*. They can be familial, but in most cases (95%) are sporadic. In 98% of these tumors, whether familial, sporadic, or associated with VHL syndrome, there is loss of sequences on the short arm of chromosome 3. The deleted region harbors the *VHL* gene (3p25.3). A second nondeleted allele of the *VHL* gene shows somatic mutations or hypermethylation-induced inactivation in up to 80% of clear cell cancers, indicating that the *VHL* gene acts as a tumor suppressor gene in both sporadic and familial cancers (Chapter 7). The *VHL* gene encodes a protein that is part of a ubiquitin ligase complex involved in targeting other proteins for degradation. Important among the targets of the VHL protein is the transcription factor hypoxia-inducible factor-1 (HIF-1). When *VHL* is inactive, HIF-1 levels remain high, even under normoxic conditions, causing inappropriate expression of a number of genes that are turned on by HIF. These include genes that promote angiogenesis, such as VEGF, and genes that stimulate cell growth, such as insulin-like growth factor-1 (IGF-1). In addition, HIF collaborates in complex ways with the oncogenic factor MYC to "reprogram" cellular metabolism in a way that favors growth. Deep sequencing of renal carcinoma genomes has revealed frequent mutations in a number of genes that regulate histone modifications, indicating that dysregulation of

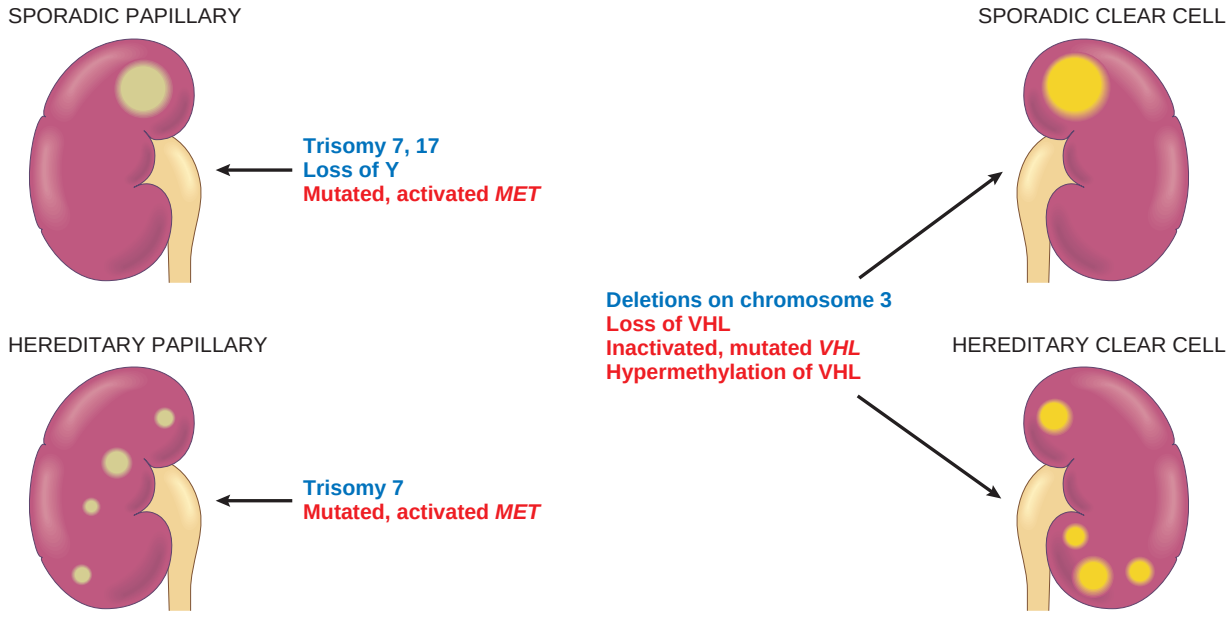

Figure 20.49 Cytogenetics *(blue)* and genetics *(red)* of clear cell versus papillary renal cell carcinoma. (Courtesy Dr. Keith Ligon, Brigham and Women's Hospital, Boston, Mass.)

the epigenome also has an important role in clear cell carcinoma.

- *Papillary carcinoma* accounts for 10% to 15% of renal cancers. It is characterized by a papillary growth pattern and also occurs in both familial and sporadic forms. These tumors are not associated with 3p deletions. The most common cytogenetic abnormalities are trisomies 7 and 17 and loss of Y in male patients in the sporadic form, and trisomy 7 in the familial form. The gene on chromosome 7 for the familial form has been mapped to *MET,* a proto-oncogene that encodes the tyrosine kinase receptor for *hepatocyte growth factor*. *MET* is also mutated in a small proportion of sporadic papillary carcinomas. Hepatocyte growth factor (also called *scatter factor*) mediates growth, cell mobility, invasion, and morphogenetic differentiation. Unlike clear cell carcinomas, papillary carcinomas are frequently multifocal in origin.
- *Chromophobe carcinoma* represents 5% of renal cell cancers and is composed of cells with prominent cell membranes and pale eosinophilic cytoplasm, usually with a halo around the nucleus. On cytogenetic examination, these tumors show multiple chromosome losses and extreme hypodiploidy. Like the benign oncocytoma, they are thought to grow from intercalated cells of collecting ducts and have an excellent prognosis compared with that of the clear cell and papillary cancers. Histologic distinction from oncocytoma can be difficult.
- *Xp11 translocation carcinoma* is a genetically distinct subtype of renal cell carcinoma. It often occurs in young patients and is defined by translocations of the *TFE3* gene located at Xp11.2 with a number of partner genes, all of which result in overexpression of the TFE3 transcription factor. The neoplastic cells consist of clear cytoplasm with a papillary architecture.
- *Collecting duct (Bellini duct) carcinoma* represents approximately 1% or less of renal epithelial neoplasms. They arise from collecting duct cells in the medulla. Several chromosomal losses and deletions have been described, but a distinct pattern has not been identified. Histologically these tumors are characterized by malignant cells forming glands enmeshed within a prominent fibrotic stroma, typically in a medullary location. *Medullary carcinoma* is a morphologically similar neoplasm that is seen in patients with sickle cell trait.

MORPHOLOGY

Renal cell carcinomas may arise in any portion of the kidney, but more commonly affects the poles. **Clear cell carcinomas** most likely arise from proximal tubular epithelium, and usually occur as solitary unilateral lesions. They are bright yellow-gray-white spherical masses of variable size that distort the renal outline. The yellow color is a consequence of the prominent lipid accumulations in tumor cells. There are commonly large areas of gray-white necrosis and foci of hemorrhagic discoloration. The margins are usually sharply defined and confined within the renal capsule (Fig. 20.50). In clear cell carcinoma, the growth pattern varies from solid to trabecular (cordlike) or tubular (resembling tubules). The tumor cells have a rounded or polygonal shape and abundant clear or granular cytoplasm, which contains glycogen and lipids (Fig. 20.51A). The tumors have delicate branching vasculature and may show cystic as well as solid areas. Most tumors are well differentiated, but some show nuclear atypia with bizarre nuclei and giant cells.

Figure 20.50 Renal cell carcinoma. Typical cross-section of yellowish, spherical neoplasm in one pole of the kidney. Note the tumor in the dilated thrombosed renal vein.

As tumors enlarge, they may bulge into the calyces and pelvis and eventually fungate through the walls of the collecting system to extend into the ureter. **One of the striking characteristics of renal cell carcinoma is its tendency to invade the renal vein** (see Fig. 20.50), in which it may grow as a solid column of cells that extends up the inferior vena cava, sometimes as far as the right side of the heart.

Papillary carcinomas, thought to arise from distal convoluted tubules, can be multifocal and bilateral. They are typically hemorrhagic and cystic, especially when large. The tumor is composed of cuboidal or low columnar cells arranged in papillary formations. Interstitial foam cells are common in the papillary cores (see Fig. 20.51B). Psammoma bodies may be present. The stroma is usually scanty but highly vascularized. **Chromophobe renal carcinoma** is made up of pale eosinophilic cells, often with a perinuclear halo, arranged in solid sheets with a concentration of the largest cells around blood vessels (see Fig. 20.51C). **Collecting duct carcinoma** is a rare variant showing irregular channels lined by highly atypical epithelium with a hobnail pattern. Sarcomatoid changes arise infrequently in all types of renal cell carcinoma and are a decidedly ominous feature.

Clinical Features

The classic clinical features of renal cell carcinoma are *costovertebral pain, palpable mass,* and *hematuria,* but all three are seen in only 10% of cases. The most reliable clue is hematuria, but it is usually intermittent and may be microscopic; thus, the tumor may remain silent until it attains a large size, often greater than 10 cm. At this time, it is often associated with generalized constitutional symptoms, such as fever, malaise, weakness, and weight loss. This pattern of asymptomatic growth occurs in many patients, so the

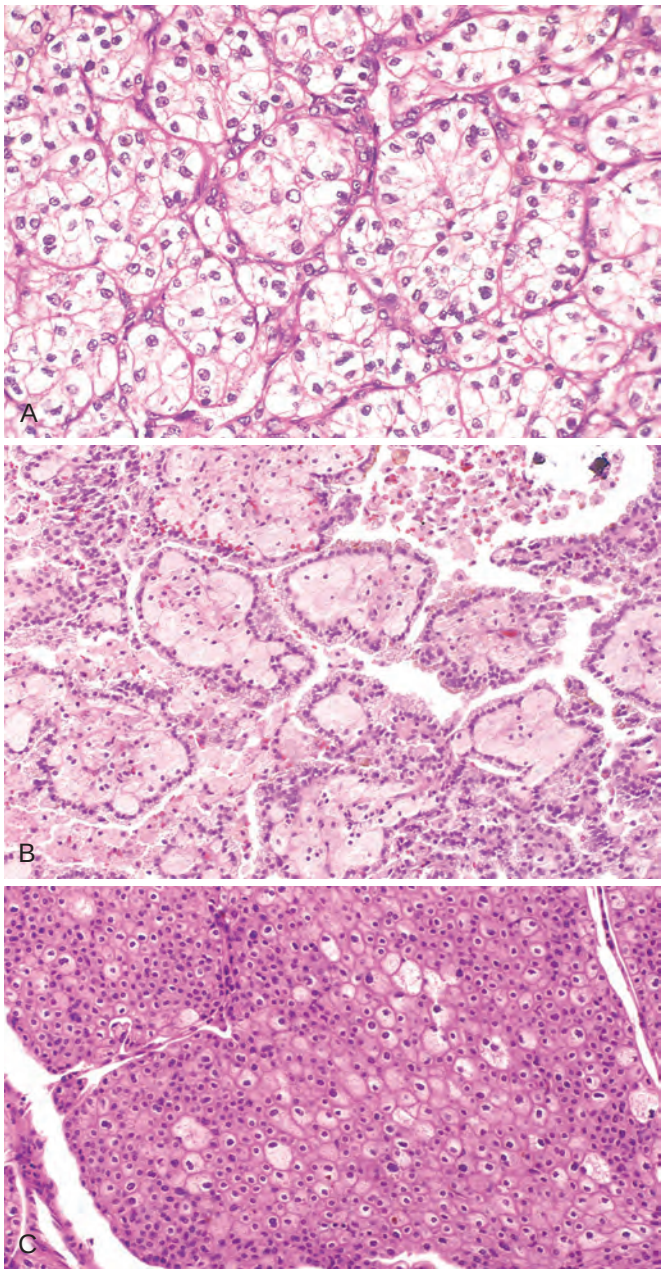

Figure 20.51 Renal cell carcinoma. (A) Clear cell type. (B) Papillary type. Note the papillae and foamy macrophages in the stalk. (C) Chromophobe type. (Courtesy Dr. A. Renshaw, Baptist Hospital, Miami, Fla.)

tumor may have reached a diameter of more than 10 cm when it is discovered. Currently, an increasing number of tumors are being discovered in the asymptomatic state by incidental radiologic studies (e.g., computed tomography or magnetic resonance imaging) performed for other indications.

Renal cell carcinoma is considered one of the great mimics in medicine, because it tends to produce a diversity of systemic symptoms not related to the kidney. In addition to fever and constitutional symptoms mentioned earlier, renal cell carcinomas produce a number of syndromes ascribed to abnormal hormone production, including polycythemia, hypercalcemia, hypertension, hepatic dysfunction, feminization or masculinization, Cushing syndrome, eosinophilia, leukemoid reactions, and amyloidosis.

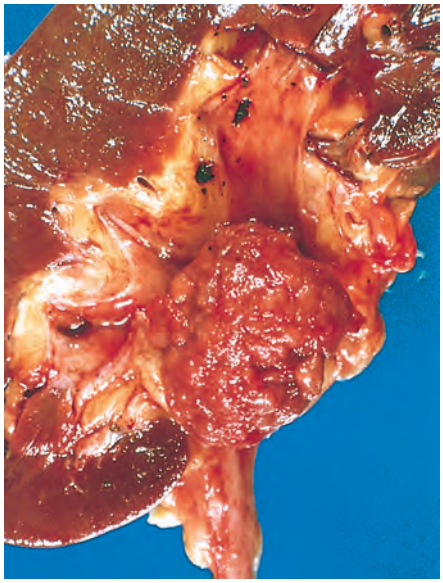

Figure 20.52 Urothelial carcinoma of the renal pelvis. The pelvis has been opened to expose the nodular irregular neoplasm, just proximal to the ureter.

A particularly troublesome feature of renal cell carcinoma is its tendency to metastasize widely before giving rise to any local symptoms or signs. In 15% of new patients with renal cell carcinoma, there is radiologic evidence of metastases at the time of presentation. The most common locations of metastasis are the lungs (more than 50%) and bones (33%), followed in frequency by the regional lymph nodes, liver, adrenal glands, and brain.

The average 5-year survival rate of persons with renal cell carcinoma is about 70% and as high as 100% in the absence of distant metastases. With renal vein invasion or extension into the perinephric fat, the figure is reduced to approximately 60%. Radical nephrectomy has been the treatment of choice, but nephron-sparing surgery to preserve renal function is recommended for T1a tumors (<4 cm) as well as larger tumors when technically feasible. Drugs that inhibit VEGF and various tyrosine kinases are used as an adjunct to therapy for metastatic disease.

Urothelial Carcinoma of the Renal Pelvis

Approximately 5% to 10% of primary renal tumors originate from the urothelium of the renal pelvis (Fig. 20.52). These tumors range from apparently benign papillomas to invasive urothelial (transitional cell) carcinomas.

Renal pelvic tumors usually become clinically apparent within a relatively short time, because they lie within the pelvis and, by fragmentation, produce noticeable hematuria. They are almost invariably small when discovered. These tumors may block urinary outflow and lead to palpable hydronephrosis and flank pain. On histologic examination, pelvic tumors are the exact counterpart of those found in the urinary bladder; further details are in Chapter 21.

Urothelial tumors may occasionally be multiple, involving the pelvis, ureters, and bladder. In 50% of renal pelvic tumors, there is a preexisting or concomitant bladder urothelial

tumor. On histologic examination, there are also foci of atypia or carcinoma in situ in grossly normal urothelium remote from the pelvic tumor. There is an increased incidence of urothelial carcinomas of the renal pelvis in individuals with Lynch syndrome.

Infiltration of the wall of the pelvis and calyces is common. For this reason, despite their apparently small, deceptively benign appearance, the prognosis for these tumors is not good. Reported 5-year survival rates vary from 50% to 100% for low-grade noninvasive lesions to 10% with high-grade infiltrating tumors.

KEY CONCEPTS

KIDNEY NEOPLASMS

- Clear cell renal cell carcinoma is the most common subtype of malignant renal neoplasms, which often involves *VHL*, a tumor suppressor gene.
- Papillary renal cell carcinoma is the second most common subtype of malignant renal neoplasms, which may involve the *MET* proto-oncogene.
- Hereditary forms of renal cell carcinoma have led to the discovery of important genes (e.g., *VHL*, *BHD*) in renal carcinogenesis.
- Urothelial tumors resembling similar tumors in the urinary bladder can also originate in the renal pelvis. These tumors have a poor prognosis.

CHAPTER 21

The Lower Urinary Tract and Male Genital System

George Jabboure Netto • Mahul B. Amin

CHAPTER CONTENTS

The Lower Urinary Tract

The renal pelves, ureters, urinary bladder, and urethra (except the terminal portion) are lined by a special form of transitional epithelium called *urothelium*. Urothelium is composed of five to six layers of cells with oval nuclei, often with linear nuclear grooves, and a surface layer consisting of large, flattened "umbrella cells" with abundant cytoplasm. This epithelium rests on a well-developed basement membrane, beneath which is a lamina propria. The lamina propria in the bladder contains wisps of smooth muscle that form a discontinuous muscularis mucosa. It is important to differentiate the muscularis mucosa from the deeper well-defined larger muscle bundles of the detrusor muscle (muscularis propria), since bladder cancers are staged on the basis of invasion of the latter. If urine flow is obstructed and intravesical pressures rise, the bladder musculature undergoes hypertrophy.

The ureters lie throughout their course in a retroperitoneal position. Retroperitoneal tumors or fibrosis may entrap and obstruct the ureters. In middle-aged and older women, relaxation of pelvic support leads to prolapse (descent) of the uterus, pulling with it the floor of the bladder. In this fashion the bladder is protruded into the vagina, creating a pouch *(cystocele)* that fails to empty readily with micturition. In males, the seminal vesicles and prostate have similar close relationships, being situated just posterior and inferior to the neck of the bladder. Thus, enlargement of the prostate, so common in middle to later life, constitutes an important cause of urinary tract obstruction. Subsequent sections discuss the major pathologic lesions of the ureters, urinary bladder, and urethra.

URETERS

Congenital Anomalies

Congenital anomalies of the ureters are found in about 2% to 3% of all autopsies (Table 21.1). Although most have little clinical significance, certain anomalies may lead to obstruction of the flow of urine and thus cause clinical disease.

Ureteropelvic junction (UPJ) obstruction is the most common cause of hydronephrosis in infants and children. Cases that present early in life preferentially affect males, are bilateral in 20% of cases, and are often associated with other anomalies. There is agenesis of the contralateral kidney in a minority of cases. In adults, UPJ obstruction is more common in women and is most often unilateral. The condition is most commonly ascribed to abnormal organization of smooth muscle bundles or excess stromal deposition of collagen between smooth muscle bundles at the UPJ, or in rare cases to extrinsic compression of the UPJ by abnormal renal vessels.

Tumors and Tumor-Like Lesions

Primary tumors of the ureter are rare. Benign tumors are generally of mesenchymal origin. *Fibroepithelial polyp,* a tumor-like lesion often occurring in children, is composed of loose, vascularized connective tissue overlaid by urothelium. Primary malignant tumors of the ureter resemble those arising in the renal pelvis, calyces, and bladder. The majority are *urothelial carcinomas* (Fig. 21.1). They occur most frequently during the sixth and seventh decades of life and cause obstruction of the ureteral lumen. They commonly occur concurrently with urothelial carcinomas of bladder or renal pelvis.

Obstructive Lesions

Intrinsic and extrinsic lesions may obstruct the ureters and may give rise to *hydroureter, hydronephrosis,* and *pyelonephritis* (Chapter 20). Unilateral obstruction typically results from proximal intrinsic or extrinsic causes (e.g., stones, neoplasms etc.), whereas bilateral obstruction arises from distal causes, such as nodular hyperplasia of the prostate (Table 21.2).

Sclerosing Retroperitoneal Fibrosis

This rare lesion is characterized by a fibrotic proliferative inflammatory process that encases retroperitoneal structures and causes hydronephrosis. The disorder occurs in middle to late age and is more common in males than females. At least a subset of these cases is related to *IgG4-related disease,* a recently described entity associated with elevated levels of serum immunoglobulin G4 (IgG4) and fibroinflammatory lesions rich in IgG4-secreting plasma cells, that also affects other organs (Chapter 6). Other etiologies for retroperitoneal fibrosis include drug exposures (ergot derivatives, β-adrenergic blockers), inflammatory conditions (vasculitis, diverticulitis, Crohn disease), or malignancies (lymphomas, urinary tract carcinomas). Most, however, have no obvious cause and are considered primary or idiopathic *(Ormond disease).*

Microscopic examination typically reveals fibrous tissue containing a prominent infiltrate of lymphocytes, often with germinal centers, plasma cells (frequently IgG4-positive), and eosinophils. Treatment initially involves corticosteroids, although many patients eventually become resistant and require ureteral stents or surgical extrication of the ureters from the surrounding fibrous tissue (ureterolysis).

Table 21.1 Congenital Anomalies of Ureter

- Vesicoureteral reflux
- Double and bifid ureters
- Ureteropelvic junction obstruction
- Diverticula

Table 21.2 Major Causes of Ureteral Obstruction

Cause of Obstruction	Characteristics/Mechanisms
Intrinsic	
Calculi	Typically of renal origin Usually small (5 mm in diameter or less) Impact at loci of ureteral narrowing—ureteropelvic junction, where ureters cross iliac vessels and where they enter bladder—and cause excruciating "renal colic"
Strictures	May be congenital or acquired
Tumors	Urothelial carcinomas arising in ureters Rarely, benign tumors or fibroepithelial polyps
Blood clots	Massive hematuria from renal calculi, tumors, or papillary necrosis
Neurogenic	Interruption of the neural pathways to the bladder
Extrinsic	
Pregnancy	Physiologic relaxation of smooth muscle or pressure on ureters at pelvic brim from enlarging fundus
Periureteral inflammation	Salpingitis, diverticulitis, peritonitis, sclerosing retroperitoneal fibrosis
Endometriosis	With pelvic lesions associated with scarring
Tumors	Cancers of the rectum, bladder, prostate, ovaries, uterus, cervix; lymphomas, sarcomas

KEY CONCEPTS

DISORDERS OF THE URETERS

- Ureteral obstruction is clinically significant because it can lead to hydroureter, hydronephrosis, or pyelonephritis, thus compromising renal function.
- In children, congenital UPJ obstruction is the most common obstructive lesion.
- In adults, ureteral obstruction may be acute (e.g., due to obstructing calculi) or chronic (e.g., due to intrinsic or extrinsic tumors or rarely idiopathic conditions such as sclerosing retroperitoneal fibrosis).

URINARY BLADDER

Congenital Anomalies

Several different types of congenital abnormalities of the bladder are recognized; these are variously associated with increased risk of infection or neoplasia.

- *Vesicoureteral reflux* is the most common and serious congenital anomaly. As discussed in Chapter 20, vesicoureteral reflux predisposes to ascending pyelonephritis and loss of renal function. Abnormal connections between the bladder and the vagina, rectum, or uterus may create *congenital vesicouterine fistulae.*
- *Diverticula* are pouch-like invaginations of the bladder wall that vary from less than 1 cm to 10 cm in diameter and may be congenital or acquired. *Congenital diverticula* may be due to a focal failure of development of the normal musculature or to a urinary tract obstruction during fetal development. *Acquired diverticula* are most often associated with prostatic hyperplasia, producing urinary outflow obstruction. The resulting increase in intravesical pressure causes outpouching of the bladder wall and the formation of diverticula. Although most diverticula are small and asymptomatic, they may come to clinical attention since they constitute sites of urinary stasis and predispose to infection and the formation of bladder calculi. Rarely, carcinoma may arise in bladder diverticula; such tumors are on average more advanced in stage due to the thin or absent muscularis propria layer of diverticula.
- *Exstrophy of the bladder* is a developmental failure in the anterior wall of the abdomen and the bladder. As a result, the bladder communicates directly with the abdominal surface (Fig. 21.2). The exposed bladder mucosa may undergo colonic glandular metaplasia and is subject to chronic infection that often spreads to the upper urinary tract. Exstrophy is associated with an increased risk of adenocarcinoma in the bladder remnant.
- *Urachal anomalies.* The urachal canal connects the fetal bladder with the allantois and normally is obliterated at birth. Rarely, it remains fully or partially patent. The former creates a fistulous urinary tract connection between the bladder and umbilicus. When only a central region of patent urachus persists, a *urachal cyst* lined by urothelial or metaplastic glandular epithelium is formed. Urachal cysts are at increased risk for neoplastic transformation, mostly presenting as adenocarcinomas (see Neoplasms). These account for only a small minority of bladder cancers overall (0.1% to 0.3%), but constitute 20% to 40% of bladder adenocarcinomas.

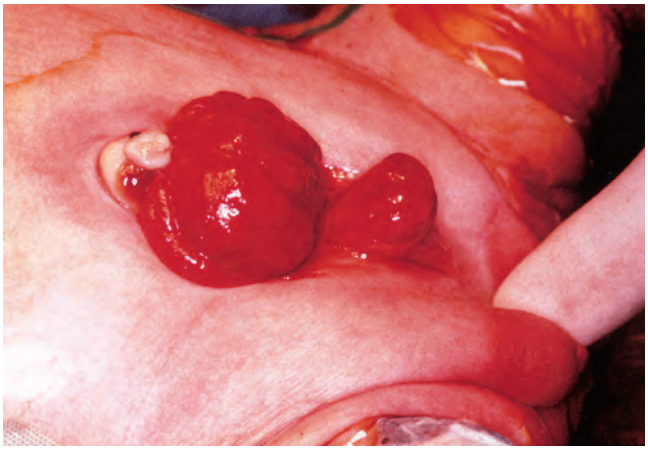

Figure 21.2 Exstrophy of the bladder in a newborn boy. The tied umbilical cord is seen above the hyperemic mucosa of the everted bladder. Below is an incompletely formed penis with marked epispadias. (Courtesy Dr. John Gearhart, The Johns Hopkins Hospital, Baltimore, Md.)

Inflammation

Acute and Chronic Cystitis

Bacterial pyelonephritis is frequently preceded by infection of the urinary bladder, with retrograde spread of microorganisms into the kidneys and their collecting systems (discussed in Chapter 20). Predisposing factors for cystitis include bladder calculi, urinary obstruction, diabetes mellitus, instrumentation, and immune deficiency. The most common etiologic agents of cystitis are the coliforms: *Escherichia coli,* followed by *Proteus, Klebsiella,* and *Enterobacter.* Women are more likely to develop cystitis as a result of their shorter urethras. *Tuberculous cystitis* is almost always a sequel to renal tuberculosis. *Candida albicans* and, much less often, cryptococcal agents may cause cystitis, particularly in immunosuppressed patients or those receiving long-term antibiotics. Schistosomiasis *(Schistosoma haematobium)* remains an important cause of cystitis in certain African and Middle Eastern countries. Viruses (e.g., adenovirus), *Chlamydia,* and *Mycoplasma* may also cause cystitis. Adenovirus and BK virus infections may result in hemorrhagic cystitis. Gas-forming bacteria (such as *Clostridium perfringens*) result in *emphysematous cystitis* (gas-filled vesicles in the bladder wall).

MORPHOLOGY

Most cases of cystitis produce nonspecific acute or chronic inflammation of the bladder. In **acute cystitis,** there is hyperemia of the mucosa and neutrophilic infiltrate, sometimes associated with exudate. Persistence of the bacterial infection leads to **chronic cystitis** associated with mononuclear inflammatory infiltrates.

Other types of non-infectious cystitis include iatrogenic, follicular, and eosinophilic cystitis. Patients receiving systemic chemotherapy or pelvic irradiation may develop **iatrogenic** cystitis.

Cytotoxic agents, such as cyclophosphamide, may cause **hemorrhagic cystitis.** Acute and chronic **radiation cystitis** may occur following the irradiation of the bladder region. **Follicular cystitis** is characterized by the presence of lymphoid follicles within the bladder mucosa and underlying wall. **Eosinophilic cystitis,** manifested by infiltration of the submucosa by eosinophils, typically is a nonspecific subacute inflammation but may also be a manifestation of a systemic allergic disorder.

Clinical Features

All forms of cystitis are characterized by a triad of symptoms: (1) frequency, which in acute cases may necessitate urination every 15 to 20 minutes; (2) lower abdominal pain localized over the bladder region or in the suprapubic region; and (3) dysuria (pain or burning on urination). The local symptoms of cystitis may be merely disturbing, but these infections may be antecedents to pyelonephritis, a more serious disorder (Chapter 20). Cystitis is sometimes a secondary complication of an underlying disorder associated with urinary stasis, such as prostatic hypertrophy, cystocele, calculi, or bladder neoplasms. These primary lesions must be corrected before the cystitis can be relieved.

Special Forms of Cystitis

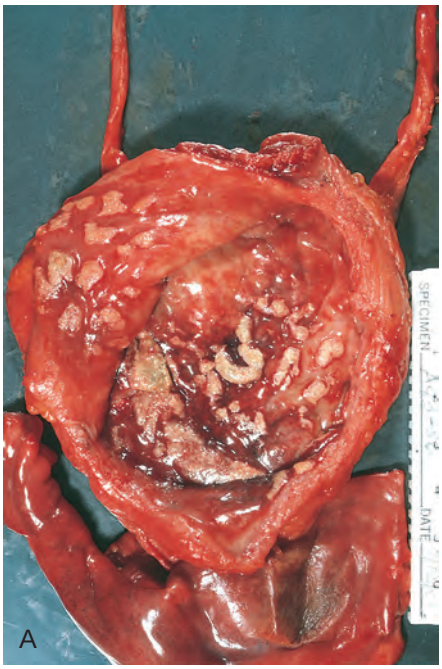
Several variants of cystitis have distinctive causes or morphologic appearances.

Interstitial Cystitis (Chronic Pelvic Pain Syndrome). Interstitial cystitis is a disorder of unknown etiology that occurs most frequently in women. The associated pain syndrome is defined by the American Urological Association as "an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with urinary tract symptoms of more than six weeks duration, in the absence of infection or other identifiable causes." It is characterized by intermittent, often severe, suprapubic pain; urinary frequency; urgency; hematuria; and dysuria. Typical cystoscopic findings include mucosal fissures and punctate hemorrhages (glomerulations). Microscopically, the pathologic findings are nonspecific; mast cells are often increased in the submucosa, but the pathogenic significance of this finding is uncertain. The main role of biopsy is to rule out carcinoma in situ (CIS), which clinically mimics interstitial cystitis. Treatment is largely empiric. Some cases are associated with chronic mucosal ulcers (Hunner ulcers); this is termed the late (classic, ulcerative) phase. Late in the course, transmural fibrosis may lead to a contracted bladder.

Malakoplakia. Malakoplakia is a distinctive chronic inflammatory reaction that appears to stem from acquired defects in phagocyte function. It arises in the setting of chronic bacterial infection, mostly by *E. coli* or occasionally *Proteus* species, and occurs with increased frequency in the setting of immunosuppression, such as in renal transplant recipients.

MORPHOLOGY

Cystoscopically, malakoplakia takes the form of soft yellow, slightly raised mucosal plaques, 3 to 4 cm in diameter (Fig. 21.3A). Histologically, the lesion is composed of aggregates of large foamy macrophages with occasional multinucleate giant cells and lymphocytes. The **macrophages have abundant granular cytoplasm** due to phagosomes stuffed with particulate and membranous debris of bacterial origin, which are believed to accumulate due to defective phagolysosome function. In addition, laminated mineralized concretions resulting from deposition of calcium in enlarged lysosomes, known as **Michaelis-Gutmann bodies,** are typically present within the macrophages (Fig. 21.3B). Similar lesions have been described in other organs including the colon and other parts of the gastrointestinal tract, brain, lungs, bones, endometrium, kidneys, prostate, and epididymis.



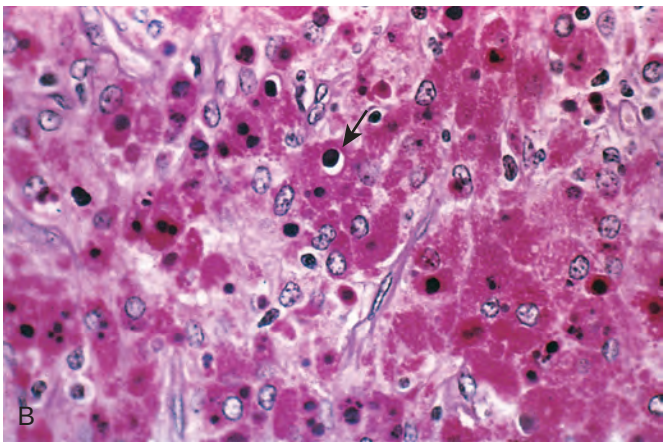


Figure 21.3 Malakoplakia. (A) Bladder involved by malakoplakia showing the characteristic yellow-orange mucosal lesions. (B) Periodic acid–Schiff (PAS) stain. Note the large macrophages with granular PAS-positive cytoplasm and several dense, round Michaelis-Gutmann bodies surrounded by artifactual cleared holes in the upper middle field *(arrow)*.

Polypoid Cystitis. Polypoid cystitis is an inflammatory lesion resulting from irritation of the bladder mucosa, most commonly as a result of instrumentation, including

indwelling catheters. The urothelium is thrown into broad bulbous polypoid projections as a result of marked submucosal edema. Polypoid cystitis may be mistaken for papillary urothelial carcinoma, both clinically and histologically.

Metaplastic Lesions

Several lesions that stem from true metaplasia or conditions that mimic metaplasia affect the bladder.

- *Cystitis glandularis and cystitis cystica.* These are common lesions of the urinary bladder in which nests of urothelium (von Brunn nests) grow downward into the lamina propria. Here, epithelial cells in the center of the nest undergo metaplasia and take on a cuboidal or columnar appearance *(cystitis glandularis)* or retract to produce cystic spaces lined by flattened urothelium *(cystitis cystica)*. Because the two processes often coexist, the condition is typically referred to as *cystitis cystica et glandularis*. In a variant of cystitis, glandularis goblet cells are present, and the epithelium resembles intestinal mucosa *(intestinal or colonic metaplasia)*. Both variants can arise in the setting of inflammation and metaplasia. Extensive and multifocal intestinal metaplasia is a precursor to adenocarcinoma.
- *Squamous metaplasia.* As a response to chronic injury, the urothelium is often replaced by nonkeratinizing or keratinizing squamous epithelium, which is a more durable lining. This should be distinguished from glycogenated squamous epithelium that is normally found in women at the trigone region of bladder. Extensive multifocal keratinizing squamous metaplasia is a precursor to dysplastic lesions and in situ and invasive squamous cell carcinoma. A classic example of this sequence is seen with bladder schistosomiasis, which commonly produces squamous metaplasia and is associated with squamous cell carcinoma in areas in which it is endemic.
- *Nephrogenic adenoma.* Nephrogenic adenoma is an unusual lesion that may not be a form of true metaplasia. There is convincing evidence from renal transplant recipients showing that at least some of these lesions are caused by implantation and growth of renal tubular cells at sites of bladder mucosa erosion. The overlying urothelium is focally replaced by cuboidal epithelium, which can assume a papillary growth pattern. Although the lesions are typically less than 1 cm in size, larger lesions have been reported that can produce signs and symptoms that raise a suspicion of cancer. In addition, the tubular proliferation can infiltrate the underlying lamina propria and superficial detrusor muscle, microscopically mimicking a malignant process.

KEY CONCEPTS

INFLAMMATORY DISORDERS AND METAPLASIAS OF THE BLADDER

- The bladder can be involved by a number of inflammatory lesions, many of which manifest with frequency and dysuria.
- Acute or chronic bacterial cystitis is extremely common, particularly in women, and results from retrograde spread of colonic bacteria in most cases.
- Other forms of cystitis have iatrogenic causes, such as radiation cystitis and hemorrhagic cystitis due to chemotherapy.
- Some inflammatory or metaplastic bladder lesions are significant in that they may clinically and/or histologically mimic bladder cancer, including malakoplakia, polypoid cystitis, cystitis cystica et glandularis, and nephrogenic adenoma.

Neoplasms

Bladder cancer is the ninth most common cancer type worldwide and is responsible for significant morbidity and mortality. It is the fourth most common cancer in American men (7% of all new cases). The overwhelming majority (>95%) of bladder tumors are of epithelial origin (Table 21.3), with urothelial neoplasms being by far the most common type followed by squamous and glandular neoplasms.

Urothelial Neoplasms

Urothelial neoplasms represent about 90% of all bladder tumors and run the gamut from small benign lesions that do not recur to aggressive cancers that are often fatal. Many of these tumors are multifocal at presentation. Though most common in the bladder, all of the urothelial lesions described here may be seen at any site where there is urothelium, from the renal pelvis to the distal urethra.

There are two distinct precursor lesions to invasive urothelial carcinoma: noninvasive papillary tumors and flat noninvasive urothelial carcinoma in situ (CIS) (Fig. 21.4). The most common precursor lesions are the noninvasive

Table 21.3 Tumors of the Urinary Bladder

papillary tumors, which originate from papillary urothelial hyperplasia. These tumors have a range of atypical changes and are graded according to their biologic behavior. The other precursor lesion to invasive carcinoma, flat noninvasive urothelial carcinoma, is referred to as CIS. As discussed in Chapter 7, CIS is a term used to describe epithelial lesions that have the cytologic features of malignancy but are confined to the epithelium, showing no evidence of basement membrane invasion. Such lesions are considered to be high grade. In about one-half of individuals with invasive bladder cancer, the tumor has already invaded the bladder wall at the time of presentation, and precursor lesions are not detected. It is presumed in such cases that the precursor lesion was destroyed by the high-grade invasive component, which typically appears as a large, ulcerated mass. Although invasion into the lamina propria worsens the prognosis, the major decrease in survival is associated with invasion of the muscularis propria (detrusor muscle). Once muscularis propria invasion occurs, there is a 30% 5-year mortality rate.

Epidemiology. The incidence of bladder cancer is higher in men (male-to-female ratio of 3:1), in higher income nations, and in urban dwellers. About 80% of patients are between 50 and 80 years of age. Bladder cancer, with rare exceptions, is not familial.

Several factors have been implicated in the causation of urothelial carcinoma, including the following:

- *Cigarette smoking* is clearly the most important influence, increasing the risk threefold to sevenfold, depending on the duration and type of tobacco use. Between 50% and 80% of all bladder cancers among men are associated with the use of cigarettes. Cigars, pipes, and smokeless tobacco are associated with a smaller risk.
- *Industrial exposure to aryl amines,* particularly 2-naphthylamine and related compounds, as pointed out in our earlier discussion of chemical carcinogenesis (Chapter 7). Cancer appears 15 to 40 years after the first exposure.
- *Schistosoma haematobium* infections in endemic areas (Egypt, Sudan) are an established risk. The ova are deposited in the bladder wall and incite a brisk chronic inflammatory response that induces progressive mucosal squamous metaplasia, dysplasia, and, in some instances, neoplasia. Seventy percent of the cancers are squamous, the remainder being urothelial or glandular (the least common type).
- *Long-term use of analgesics* is implicated, as it is in analgesic nephropathy (Chapter 20).
- *Heavy long-term exposure to cyclophosphamide,* an immunosuppressive agent, induces, as noted, hemorrhagic cystitis and increases the risk of bladder cancer.
- *Irradiation,* often administered for other pelvic malignancies, increases the risk of urothelial carcinoma occurring several years following exposure.

Pathogenesis

Analysis of the genomes of precursor lesions and invasive bladder carcinomas has identified two relatively distinct molecular pathways of tumor progression (Fig. 21.5). Non–muscle-invasive papillary cancers often have gain-of-function alterations that increase signaling through growth factor receptor pathways, such as amplifications of the *FGFR3* tyrosine kinase receptor gene and activating mutations in the genes encoding RAS and PI 3-kinase. These tumors frequently recur but progress to muscle-invasive bladder cancer in only about 20% of cases. The majority of muscle-invasive bladder cancers develop by progression from "flat" CIS. Mutations that disrupt the function of p53 and RB are prevalent in all muscle-invasive cancers, but occur early in the development of CIS and later in the progression of papillary cancers.

Additional work is ongoing to further characterize the genetic and molecular landscape of bladder cancer. Consistent with epidemiologic data suggesting that environmental carcinogens have an important role, bladder cancers have a high burden of somatic mutations, comparable to other carcinogen-induced cancers, such as lung cancer and melanoma. As in other cancers, recurrently mutated

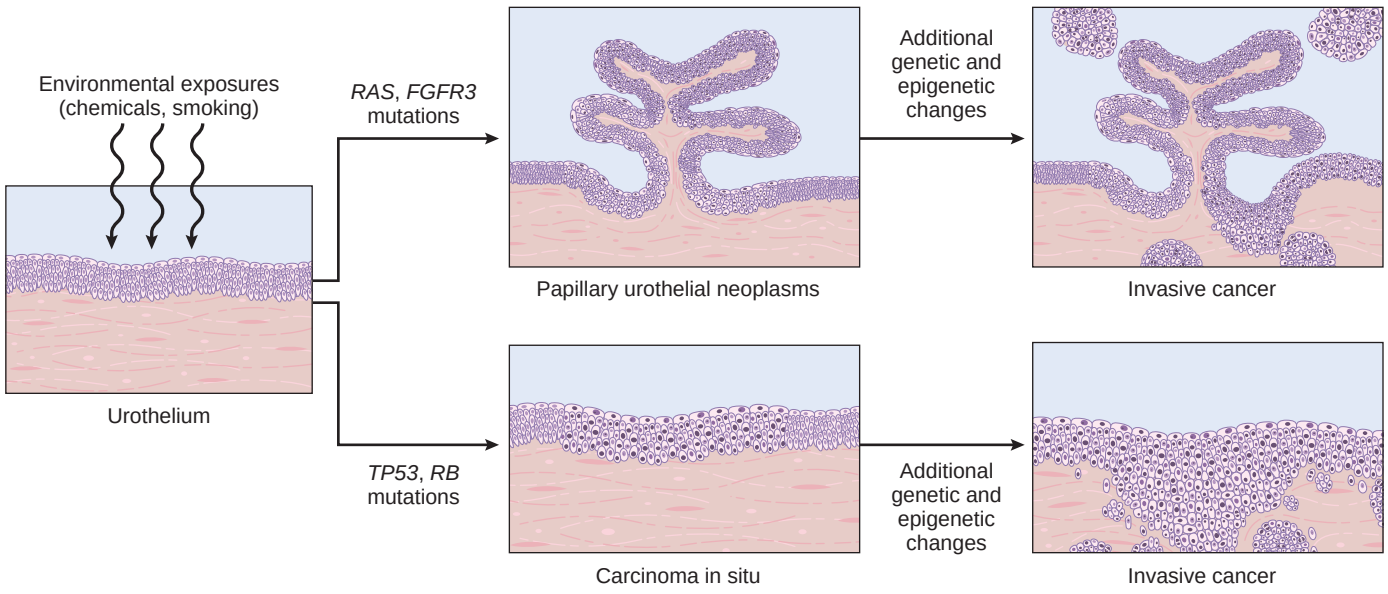

Figure 21.5 Salient environmental risk factors and major molecular pathways of bladder cancer development from carcinoma in situ and papillary bladder neoplasms. See text for details.

oncogenes and tumor suppressor genes include genes involved in cell cycle regulation, chromatin regulation, DNA repair, and growth factor signaling pathways. Analyses of RNA expression suggest the existence of several relatively distinct molecular subtypes; further work is needed to fully understand their biologic and clinical significance.

MORPHOLOGY

The appearance of urothelial tumors varies from purely papillary to nodular or flat. Papillary lesions are red, elevated excrescences ranging in size from less than 1 cm in diameter to large masses up to 5 cm in diameter (Fig. 21.6). Multiple discrete tumors are often present.

Table 21.3 lists the grading system of urothelial tumors. **Papillomas** represent 1% or less of bladder tumors and are often seen in younger patients. These tumors typically arise singly as small (0.5 to 2 cm), delicate structures superficially attached to the mucosa by a stalk and are referred to as **exophytic papillomas.** The individual finger-like papillae have a central core of loose fibrovascular tissue covered by epithelium that is histologically identical to normal urothelium (Fig. 21.7A). Recurrences and progression are rare but

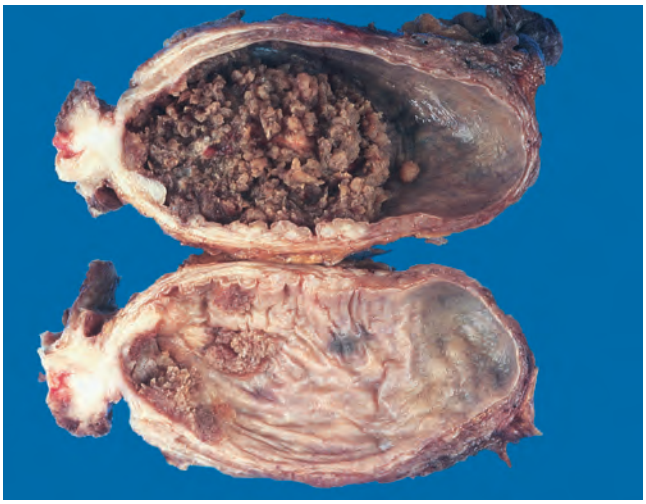

Figure 21.6 Cross-section of bladder with the upper section showing a large papillary tumor. The lower section demonstrates multifocal smaller papillary neoplasms. (Courtesy Dr. Fred Gilkey, Sinai Hospital, Baltimore, Md.)

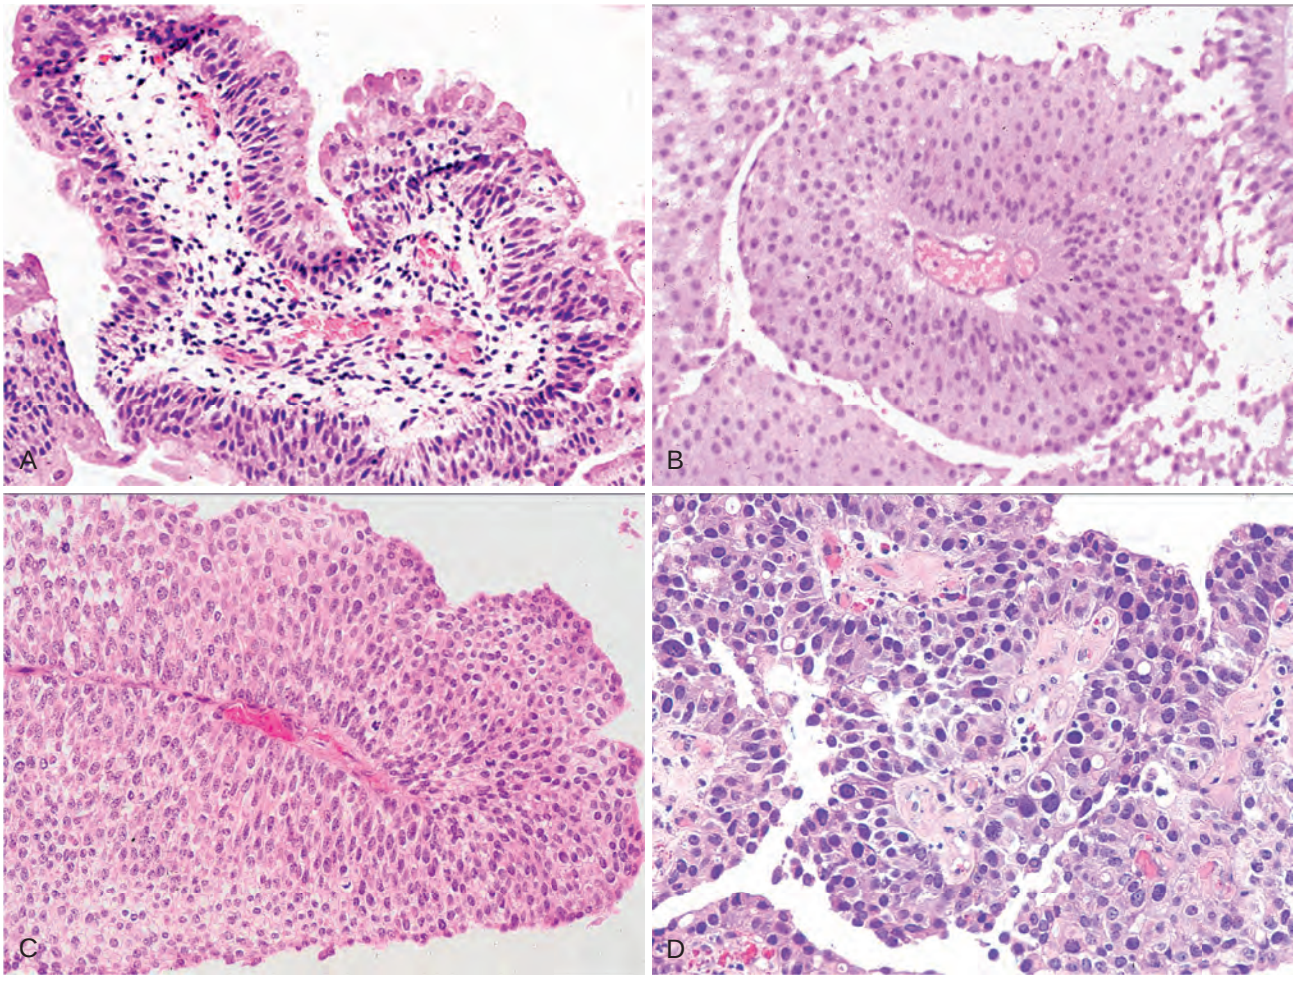

Figure 21.7 Papillary urothelial neoplasms. (A) Papilloma consisting of small papillary fronds lined by normal-appearing urothelium. (B) Papillary urothelial neoplasms of low malignant potential (PUNLMP) showing thicker urothelium with greater density of cells. (C) Low-grade papillary urothelial carcinoma with an overall orderly appearance, with scattered hyperchromatic nuclei and mitotic figures *(upper left)*. (D) High-grade papillary urothelial carcinoma with marked cytologic atypia.

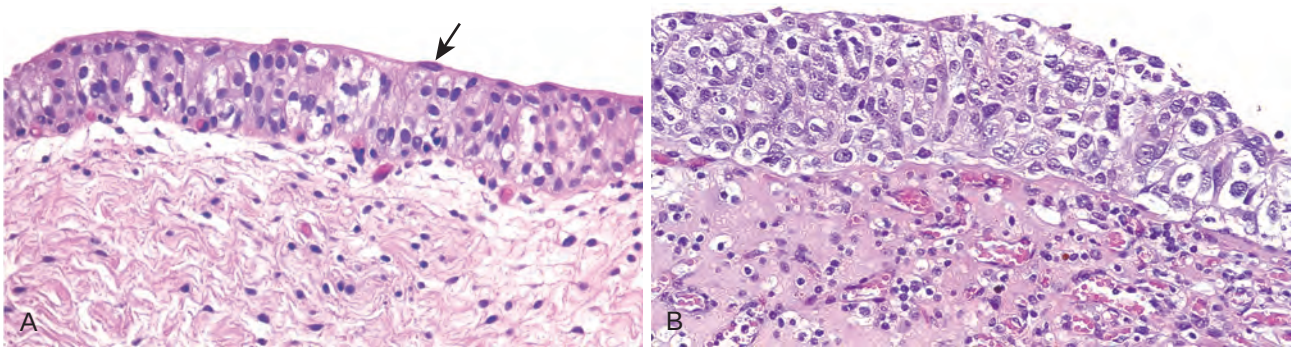

Figure 21.8 Bladder carcinoma in situ. (A) Normal urothelium with uniform nuclei and well-developed umbrella cell layer. (B) Carcinoma in situ showing a disorganized urothelium containing numerous cells having markedly enlarged and pleomorphic nuclei.

may occur. In contrast to exophytic papillomas, **inverted papillomas** are completely benign lesions consisting of inter-anastomosing cords of cytologically bland urothelium that extend down into the lamina propria; they simulate an invasive process.

Papillary urothelial neoplasms of low malignant potential (PUNLMP) share many histologic features with papillomas, differing only in having thicker urothelium with greater density of cells (Fig. 21.7B) At cystoscopy, these tumors tend to be larger than papillomas and may be indistinguishable from papillary cancers. Recurrent tumors usually show the same morphology; progression to tumors of higher grade may occur but is rare.

Low-grade papillary urothelial carcinomas have an orderly architectural appearance and low-grade cytologic atypia. The cells are evenly spaced (i.e., maintain polarity) and cohesive. There are scattered hyperchromatic nuclei, infrequent mitotic figures predominantly toward the base, and slight variation in nuclear size and shape (Fig. 21.7C). These low-grade cancers may recur and, infrequently, may also invade. Only rarely do these tumors pose a threat to life.

High-grade papillary urothelial carcinomas contain dyscohesive cells with large hyperchromatic nuclei, irregular nuclear chromatin, and prominent nucleoli. Some of the tumor cells are highly anaplastic (Fig. 21.7D). Mitotic figures, including atypical ones, are frequent. Architecturally, there is disarray and loss of polarity. As compared to low-grade lesions, these tumors have a much higher incidence of progression to muscle-invasive bladder cancer and have a significant potential for metastasis to regional lymph nodes and systemic spread (e.g., to liver and lung).

CIS (or flat urothelial carcinoma) is defined by the presence of cytologically malignant cells within a flat urothelium (Fig. 21.8). CIS may range from full-thickness cytologic atypia to scattered malignant cells in an otherwise normal urothelium, the latter termed **pagetoid spread.** A common feature shared with high-grade papillary urothelial carcinoma is a lack of cohesiveness, which leads to shedding of malignant cells into the urine. When shedding is extensive, only a few CIS cells may be left clinging to a largely denuded basement membrane. On cystoscopy CIS usually appears as an area of mucosal reddening, granularity, or thickening without an evident intraluminal mass. It is commonly multifocal and may involve most of the bladder surface and extend into the ureters and urethra. **If untreated, 50% to 75% of CIS progresses to invasive cancer.**

Invasive urothelial carcinoma (Fig. 21.9) may be associated with papillary urothelial cancer, usually high grade, or adjacent CIS. The extent of spread (stage), based primarily on depth of invasion in the bladder wall, at the time of initial diagnosis is the most important prognostic factor. Stage also determines treatment modality, with invasion of the muscularis propria layer being an indication for radical cystectomy or radiation therapy with neoadjuvant or adjuvant chemotherapy (Table 21.4).

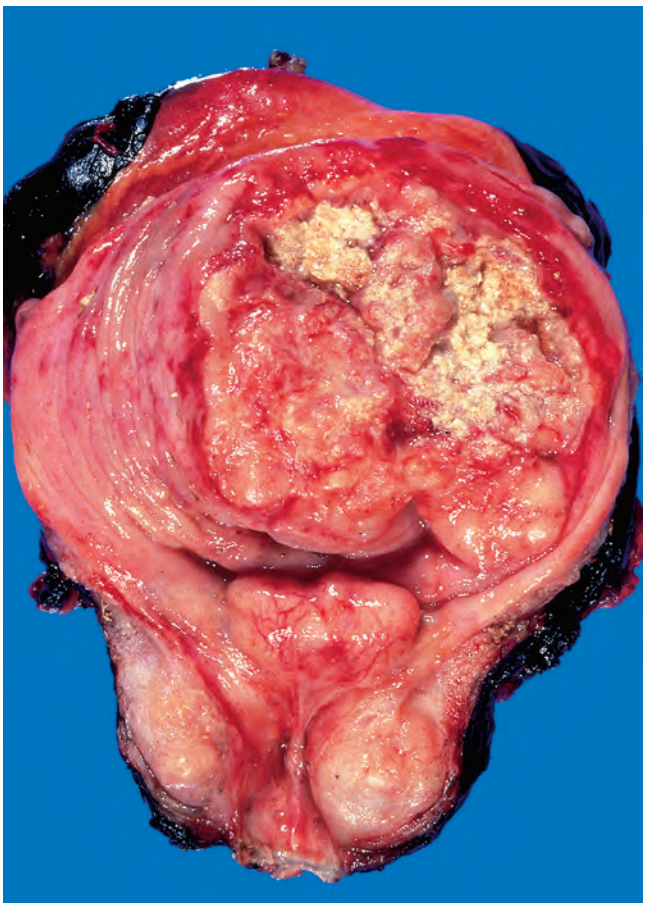

Figure 21.9 Opened bladder showing a high-grade invasive transitional cell carcinoma at an advanced stage. The aggressive multinodular neoplasm has fungated into the bladder lumen and spread over a wide area. The yellow regions represent areas of ulceration and necrosis.

Table 21.4 Grading of Noninvasive Urothelial (Transitional Cell) Tumors

WHO/ISUP Grades (2016)
Flat Lesions
• Urothelial proliferation of uncertain malignant potential (flat hyperplasia) • Urothelial dysplasia • Urothelial carcinoma in situ
Exophytic Papillary Lesions
• Papilloma • Urothelial proliferation of uncertain malignant potential (papillary hyperplasia) • Papillary urothelial neoplasms of low malignant potential • Papillary urothelial carcinoma, low grade • Papillary urothelial carcinoma, high grade

ISUP, International Society of Urological Pathology; *WHO*, World Health Organization.

Unusual variants of urothelial cancer include a nested variant with deceptively bland cytology, lymphoepithelioma-like carcinoma, micropapillary carcinoma, and sarcomatoid carcinoma (see Table 21.3).

Clinical Features

Painless hematuria is the most common symptom of bladder cancer. Frequency, urgency, and dysuria may accompany hematuria. Occasionally, obstruction of the ureteral orifice may lead to pyelonephritis or hydronephrosis.

The subsequent treatment and course of bladder carcinoma depend on tumor grade and stage (Table 21.5), with the key variable being whether the tumor is muscle-invasive or not. Noninvasive papillary urothelial tumors and those that solely invade the lamina propria (together referred to as non–muscle-invasive) constitute the majority (70% to 80%) of urothelial neoplasms. Twenty percent to 30% of bladder cancers are muscle-invasive with only a minority of these originating in patients with a prior history of non–muscle-invasive disease.

Initial treatment of non–muscle-invasive tumors is guided by the pathologic findings. For small, localized low-grade papillary tumors, diagnostic transurethral resection is the only procedure needed. CIS and papillary tumors that are large, high grade, multifocal, have a history of recurrence, or are associated with lamina propria invasion are treated with intravesical instillation of an attenuated strain of *Mycobacterium bovis* called bacillus Calmette-Guérin (BCG), which elicits a local inflammatory reaction that destroys the tumor.

Unfortunately, non–muscle-invasive bladder cancers have a high tendency to recur (up to 70%) and are at risk for progression to a higher grade or stage. The risk of recurrence and progression is related to several variables, including tumor size, stage, grade, multifocality, prior recurrence, and the presence of CIS in the surrounding mucosa. Most recurrences appear at sites other than that of the original lesion, yet are clonally related, apparently arising from shedding and implantation of cells from the original tumor at a distant site. Other recurrences are clonally distinct and represent a second primary tumor. Papillomas, PUNLMP, and low-grade papillary urothelial cancer have a 98% 10-year survival rate regardless of the number of recurrences, and only a few tumors (<10%) progress to higher-grade lesions. In contrast, high-grade papillary urothelial carcinomas invade and lead to death in about 25% of cases. Patients with CIS only, as opposed to CIS associated with infiltrating urothelial carcinoma, are less likely to progress to muscle-invasive cancer (28% versus 59%) or die of disease (7% versus 45%).

Because of the risk of recurrence and progression, patients with non–muscle-invasive urothelial neoplasms need lifelong surveillance and follow-up. Surveillance cystoscopy, biopsies, and urine cytologic examinations contribute mightily to the huge burden on health care resources (over 3 billion dollars annually in the United States alone) imposed by bladder cancer. Several noninvasive assays to screen for recurrence have been developed, but none have been proven to have sufficient sensitivity and specificity to replace cystoscopy.

Muscle-invasive bladder carcinoma is treated with radical cystectomy or cystoprostatectomy, or radiation therapy with neoadjuvant and/or adjuvant chemotherapy. In addition

Table 21.5 Pathologic Stage Classification of Urinary Bladder Carcinoma (Primary Tumor)

pTNM, AJCC 8th Edition	
Tumor	
pTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Urothelial carcinoma in situ: "flat tumor"
T1	Tumor invades lamina propria (subepithelial connective tissue)
T2	Tumor invades muscularis propria
T2a	Tumor invades superficial muscularis propria (inner half)
T2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical soft tissue
T3a	Tumor invades perivesical soft tissue microscopically
T3b	Tumor invades perivesical soft tissue macroscopically (extravesical mass)
T4	Extravesical tumor directly invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Extravesical tumor invades directly into prostatic stroma, seminal vesicles, uterus, or vagina
T4b	Extravesical tumor invades pelvic wall or abdominal wall
Regional Lymph Nodes (pN)	
NX	Lymph nodes cannot be assessed
N0	No lymph node metastasis
N1	Single regional lymph node metastasis in the true pelvis (perivesical, obturator, internal and external iliac, or sacral lymph node)
N2	Multiple regional lymph node metastasis in the true pelvis (perivesical, obturator, internal and external iliac, or sacral lymph node metastasis)
N3	Lymph node metastasis to the common iliac lymph nodes
Metastasis	
M1	Distant metastasis
M1a	Distant metastasis limited to lymph nodes beyond the common iliac arteries
M1b	Non–lymph node distant metastases

AJCC, American Joint Commission on Cancer.

to muscle-invasive cancers, radical cystectomy is also indicated in cases of (1) CIS or high-grade papillary cancer refractory to BCG and other intravesical therapies; (2) CIS extending into the prostatic urethra and ducts, sites where instilled BCG does not come into contact with the neoplastic cells; and (3) occasional cases of non–muscle-invasive papillary urothelial high-grade carcinoma, such as multifocal lesions that are too large and extenisive to completely eradicate by transurethral resection.

Once bladder carcinoma metastasizes, treatment options are limited. Most metastatic tumors respond poorly to chemotherapy, which produces 5-year survival rates of only 15%. As with other cancers linked to environmental carcinogens with high mutational loads, a subset (roughly 30%) of metastatic bladder carcinomas respond to immune checkpoint inhibitors, sometimes dramatically, providing some hope for this group of patients.

Other Epithelial Bladder Tumors

Squamous cell carcinomas resembling squamous cell cancers occurring at other sites make up 3% to 7% of bladder cancers in the United States but are much more frequent in countries where urinary schistosomiasis is endemic. Pure squamous cell carcinomas arise from atypical keratinizing mucosa (squamous dysplasia and CIS) and are nearly always associated with chronic bladder irritation and infection. *Mixed urothelial carcinoma with areas of squamous carcinoma* is more frequent than pure squamous cell carcinoma. Most are invasive, fungating tumors or are infiltrative and ulcerative. The level of cellular differentiation varies widely, from well-differentiated lesions producing abundant keratin to anaplastic tumors with only focal evidence of squamous differentiation. *Adenocarcinoma* of the bladder is rare and histologically identical to adenocarcinomas seen in the gastrointestinal tract. Some arise from urachal remnants or in association with extensive intestinal metaplasia (discussed earlier).

Small-cell carcinoma, indistinguishable from small-cell carcinomas of the lung, occasionally arise in the bladder, often in association with urothelial, squamous, or adenocarcinoma (see Table 21.3). As with small-cell carcinomas in other anatomic sites, these very aggressive tumors are strongly associated with loss-of-function mutations in the *TP53* and *RB* tumor suppressor genes.

Mesenchymal Tumors

Benign Tumors. A great variety of benign mesenchymal tumors may arise in the bladder, having the histologic features of their counterparts elsewhere. Even collectively, they are rare. The most common is *leiomyoma.* They tend to grow as isolated, intramural (submucosal), encapsulated, oval-to-spherical masses up to several centimeters in diameter.

Sarcomas. True sarcomas are distinctly uncommon in the bladder. Inflammatory myofibroblastic tumors and various carcinomas that assume sarcomatoid growth patterns are more common than true sarcomas. As a group, sarcomas tend to produce large masses (up to 15 cm in diameter) that protrude into the vesicle lumen. Their soft, fleshy, gray-white gross appearance suggests their mesenchymal nature. The most common bladder sarcoma in infancy or childhood is *embryonal rhabdomyosarcoma.* In some of these cases they manifest as a polypoid grape-like mass *(sarcoma botryoides).* The most common bladder sarcoma in adults is *leiomyosarcoma* (Chapter 26).

Secondary Tumors

Secondary malignant involvement of the bladder is most often due to direct extension of cancers arising in adjacent organs, mainly the cervix, uterus, prostate, and rectum. Lymphoma may involve the bladder as a component of systemic disease. Metastatic spread of solid tumors to the bladder may occur but is very rare.

KEY CONCEPTS

BLADDER NEOPLASMS

- Bladder cancer is most common in older males, and cigarette smoking constitutes one of the most important risk factors.
- Painless hematuria is a common presenting symptom of bladder cancer and requires clinical investigation by cystoscopy and/or urine cytology analysis to rule out urothelial neoplasia.
- Non–muscle-invasive bladder cancer is associated with gain-of-function mutations in growth factor signaling pathways and frequently recur but rarely progress in stage or grade.
- Muscle-invasive bladder cancers are associated with inactivation of *TP53* and *RB* tumor suppressor genes and often develop from "flat" carcinoma in situ, with or without a high-grade papillary component.
- Molecular subtyping of bladder cancer has identified several molecular subtypes that are being evaluated for prognostic and potential therapeutic significance.
- Other epithelial bladder tumor variants may occur, either alone or mixed with urothelial carcinoma, including squamous cell carcinoma, adenocarcinoma, and small cell carcinoma.

Obstruction

Obstruction of the bladder outlet is of major clinical importance because of its eventual effect on the kidney. In males, the most common cause is enlargement of the prostate gland due to benign prostatic hyperplasia (BPH). Bladder obstruction is less common in females and is most often caused by cystocele of the bladder. Infrequent causes are (1) congenital urethral strictures; (2) inflammatory urethral strictures; (3) inflammatory fibrosis and contraction of the bladder; (4) bladder tumors, either benign or malignant; (5) invasion of the bladder neck by tumors arising in contiguous organs; (6) mechanical obstructions caused by foreign bodies and calculi; and (7) injury of nerves controlling bladder contraction (neurogenic bladder).

MORPHOLOGY

In the early stages there is only thickening of the bladder wall due to smooth muscle hypertrophy. With progressive hypertrophy the individual muscle bundles greatly enlarge and produce trabeculation of the bladder wall (see Fig. 21.9). In the course of time, crypts form and may be converted into diverticula.

In some cases of acute obstruction or in terminal disease when the patient's normal reflex mechanisms are depressed, the bladder may become extremely dilated. The enlarged bladder may reach the brim of the pelvis or even the level of the umbilicus. In such cases, the bladder wall is markedly thinned and lacks trabeculations.

URETHRA

Inflammation

Urethritis is classically divided into gonococcal and nongonococcal causes. *Gonococcal urethritis* is one of the earliest manifestations of this venereal infection. *Nongonococcal urethritis* is common and can be caused by several different organisms. Various strains of *Chlamydia* (e.g., *Chlamydia trachomatis*) are the cause of 25% to 60% of nongonococcal urethritis in men and about 20% in women. *Mycoplasma (Ureaplasma urealyticum)* also accounts for symptoms of urethritis in many cases. Urethritis is often accompanied by cystitis in women and by prostatitis in men. In many instances of suspected bacterial urethritis, no organism can be isolated. Some urethritis is truly noninfectious in origin. An example of such an inflammatory urethritis is a disorder known as *reactive arthritis* (formerly Reiter syndrome), which is associated with the clinical triad of arthritis, conjunctivitis, and urethritis (Chapter 26).

The morphologic changes are entirely typical of inflammation in other sites within the urinary tract. The urethral involvement is not itself a serious clinical problem but may cause considerable local pain, itching, and frequency and may warn of more serious disease at higher levels of the urogenital tract.

Tumors and Tumor-Like Lesions

Urethral caruncle is an inflammatory lesion that presents as a small, red, painful mass about the external urethral meatus, typically in older females. It consists of inflamed granulation tissue covered by an intact but friable mucosa, which may ulcerate and bleed with the slightest trauma. Surgical excision affords prompt relief and cure.

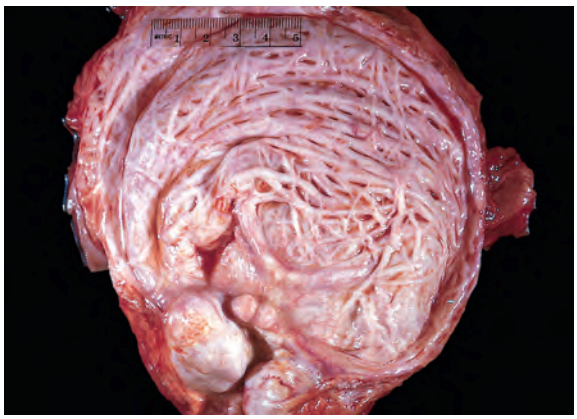

Figure 21.10 Hypertrophy and trabeculation of bladder wall secondary to benign prostatic hyperplasia.

Benign epithelial tumors of the urethra include squamous and urothelial papillomas, inverted urothelial papillomas, and condylomas. *Primary carcinoma of the urethra* is an uncommon lesion (Fig. 21.10). Cancers arising within the proximal urethra tend to show urothelial differentiation and are analogous to those occurring within the bladder, whereas lesions originating within the distal urethra are more often squamous cell carcinomas and HPV-related. Adenocarcinomas are infrequent in the urethra and generally occur in women. Neoplasms of the prostatic urethra are addressed later in the section on the prostate.

The Male Genital Tract

PENIS

Congenital Anomalies

The penis is involved by many congenital anomalies; only those that are clinically significant are discussed here.

Hypospadias and Epispadias

Malformation of the urethral groove and canal may create an abnormal opening either on the ventral surface of the penis *(hypospadias)* or on the dorsal surface *(epispadias)*. Either of these anomalies can be associated with failure of normal descent of the testes and with malformations of the urinary tract. Hypospadias, the more common of the two, occurs in approximately 1 in 300 live male births. Even when isolated, these urethral defects may have clinical significance because the abnormal opening is often constricted, resulting in urinary tract obstruction and an increased risk of ascending infections. When the orifices are situated near the base of the penis, normal ejaculation and insemination are hampered and may be a cause of sterility.

Phimosis

When the orifice of the prepuce is too small to permit its normal retraction, the condition is designated *phimosis*. An abnormally small orifice may result from anomalous development but is more frequently the result of repeated bouts of infection that cause scarring of the preputial ring. Phimosis is important because it interferes with cleanliness and permits the accumulation of secretions and detritus under the prepuce, favoring the development of secondary infections and increasing the risk for penile carcinoma.

Inflammation

Inflammations of the penis almost invariably involve the glans and prepuce and include a wide variety of specific and nonspecific infections. The specific infections—syphilis, gonorrhea, chancroid, granuloma inguinale, lymphopathia venerea, genital herpes—are sexually transmitted and are discussed in Chapter 8. Only the nonspecific infections causing so-called balanoposthitis are described here.

Balanoposthitis refers to infection of the glans and prepuce caused by a wide variety of organisms. Among the more

common agents are *C. albicans,* anaerobic bacteria, *Gardnerella,* and pyogenic bacteria. Most cases occur as a consequence of poor local hygiene in uncircumcised males, in whom the accumulation of desquamated epithelial cells, sweat, and debris, termed *smegma,* acts as a local irritant. Persistence of such infections leads to inflammatory scarring and, as mentioned earlier, is a common cause of phimosis.

Tumors

Tumors of the penis are uncommon. The most frequent neoplasms are squamous cell carcinoma and benign genital warts (condyloma acuminatum).

Benign Tumors and Tumor-Like Conditions

Condyloma Acuminatum

Condyloma acuminatum is a benign sexually transmitted wart caused by human papillomavirus (HPV). It is related to the common wart and may occur on any moist mucocutaneous surface of the external genitals in either sex. "Low-risk" HPV serotypes (HPV 6 and, less frequently, HPV 11) are the most frequent cause of condylomata acuminata.

MORPHOLOGY

Condylomata acuminata may arise in the external genitalia or perineal areas. Penile lesions usually occur in the coronal sulcus and inner surface of the prepuce. They consist of **single or multiple sessile or pedunculated, red papillary excrescences** that are several millimeters in diameter (Fig. 21.11). Histologically, a branching, villous, papillary connective tissue stroma is covered by epithelium that may have considerable superficial hyperkeratosis and thickening of the underlying epidermis **(acanthosis)** (Fig. 21.12A). The normal orderly maturation of the epithelial cells is preserved. The lining cells frequently display perinuclear cytoplasmic vacuolization (koilocytosis), characteristic of HPV infection (Fig. 21.12B).

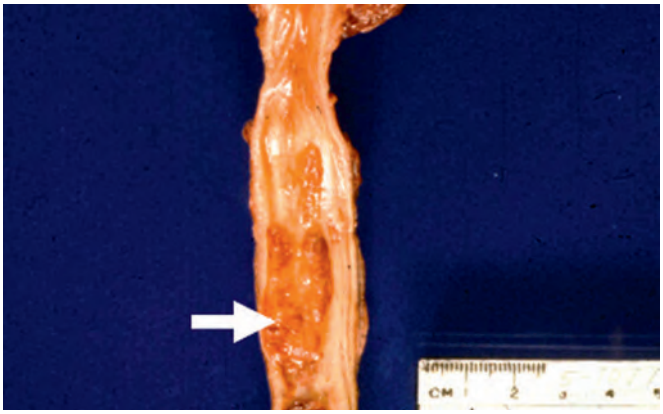

Figure 21.11 Carcinoma of urethra with typical fungating growth pattern *(arrow).*

Peyronie Disease

This disorder, which appears to be reactive rather than neoplastic, is characterized by hard penile plaques that result from the deposition of collagen in the connective tissue between the corpora cavernosa and the tunica albuginea. The fibrosis is believed to be the product of microvascular trauma and subsequent organizing sclerosing chronic inflammation. Clinically, the lesion results in penile curvature toward the side of the lesion and pain during intercourse. Treatments include surgery and injection of collagenase to lyse the fibrous plaques.

Malignant Tumors

Squamous Carcinoma in situ/Penile Intraepithelial Neoplasia

As at other sites, such as uterine cervix, in situ squamous lesions span a range of morphologies from CIS to less severe derangements. These lesions are encompassed by the umbrella term *penile intraepithelial neoplasia (PeIN).* All are squamous lesions confined to the epidermis by an intact basement membrane. PeIN may be HPV-related (undifferentiated PeIN) or non–HPV-related (differentiated). The latter is associated with balanitis xerotica obliterans, occurs on

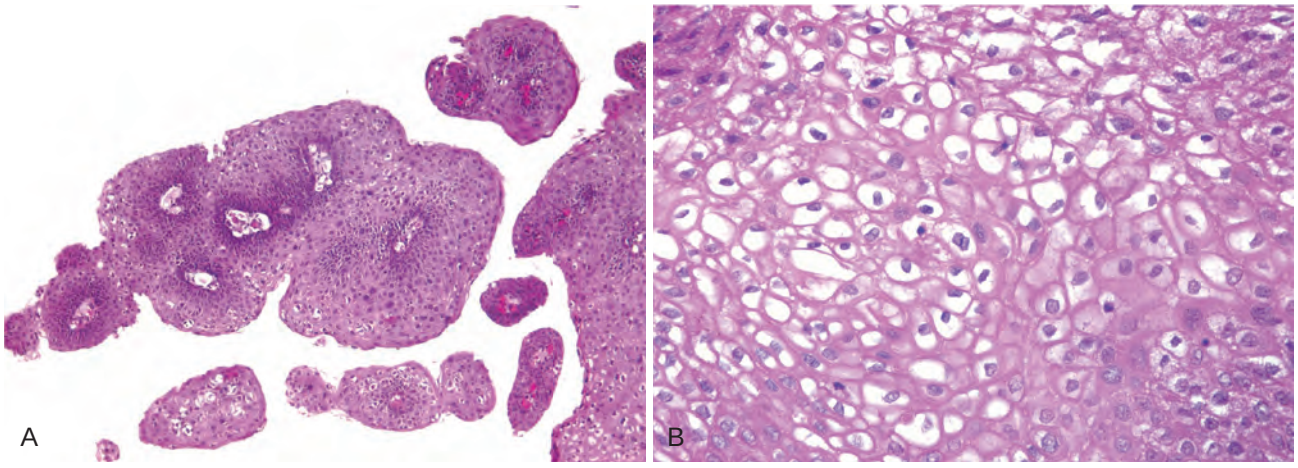

Figure 21.12 Condyloma acuminatum of the penis. (A) Low magnification reveals the papillary architecture and thickening of the epidermis. (B) On high magnification the epithelium shows perinuclear vacuolization (koilocytosis) characteristic of human papillomavirus infection.

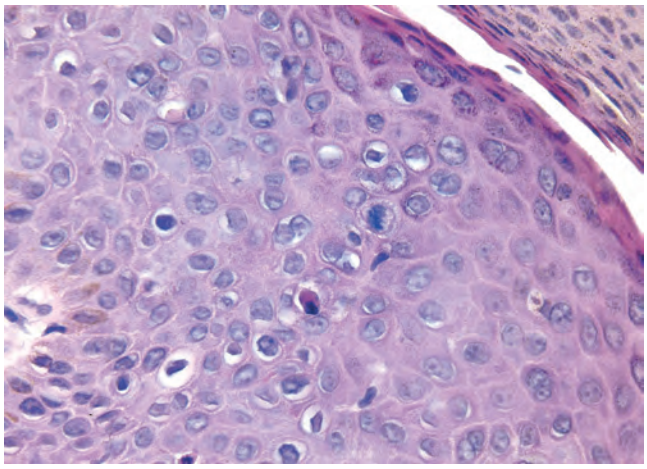

Figure 21.13 Bowen disease (carcinoma in situ) of the penis. Note the hyperchromatic, dysplastic dyskeratotic epithelial cells and scattered mitoses *(mid-right)* well above the basal layer.

the foreskin of older patients, and as the name implies retains a degree of squamous maturation. Undifferentiated PeIN is composed of more overtly malignant cells and may manifest clinically as two distinct lesions: Bowen disease and bowenoid papulosis. Both are associated with high-risk HPV, most commonly HPV 16.

- *Bowen disease* most commonly affects the penile shaft and scrotum of older men. At these sites, it appears as a solitary, thickened, gray-white, opaque plaque. In less common cases when it affects the glans, the lesion acquires a velvety red appearance. Histologically, the lesion consists of dysplastic squamous cells containing large hyperchromatic irregular nuclei and lacking orderly maturation (Fig. 21.13). Mitoses, some atypical, are numerous. In 10% of patients, Bowen disease gives rise to infiltrating squamous cell carcinoma.
- *Bowenoid papulosis* occurs in sexually active adults. It is distinguished from Bowen disease by the younger age of affected patients and its presentation as multiple (rather than solitary) reddish brown papular lesions. Although etiologically related to HPV 16 and histologically indistinguishable from Bowen disease, Bowenoid papulosis virtually never develops into invasive carcinoma and usually regresses spontaneously.

Invasive Squamous Cell Carcinoma

Squamous cell carcinoma of the penis is associated with poor genital hygiene and high-risk HPV infection. Penile carcinoma affects middle-aged and older patients (40 to 70 years of age). In the United States, it accounts for less than 1% of cancers in males. In contrast, in some parts of Asia, Africa, and South America, penile cancer accounts for 10% to 20% of male malignancies. Low income status and poor hygiene habits are salient risk factors. Circumcision confers protection, and hence penile cancer is extremely rare among Jews and Muslims and is correspondingly more common in populations in which circumcision is not practiced routinely. It is postulated that circumcision reduces exposure to carcinogens that may be concentrated in smegma and decreases the likelihood of infections with potentially oncogenic types of HPV. Only a minority of penile cancer is HPV-related; other factors such as poor hygiene and chronic inflammation presumably contribute to those that are not HPV-related. The availability of vaccines to both low-risk and high-risk subtypes of HPV may help reduce the incidence of penile cancer and condyloma acuminatum. Other risk factors include cigarette smoking and chronic inflammatory conditions such as *lichen sclerosis et atrophicus (balanitis xerotica obliterans).*

Pathogenesis

The contribution of high-risk HPV to penile carcinoma is identical to its role in cervical cancer (Chapters 7 and 22). These forms of HPV encode E6 and E7 proteins that inactivate the p53 and RB tumor suppressor proteins, leading to genomic instability and increased proliferation, respectively. E6 protein also stimulates telomerase expression, leading to cellular immortalization. E7 protein induces feedback loops that increase levels of the cyclin-dependent kinase inhibitor p16, a feature that can be used as a surrogate for the presence of high-risk HPV in tumor cells.

MORPHOLOGY

Squamous cell carcinoma of the penis usually originates in glans or inner surface of the prepuce near the coronal sulcus. Macroscopically the tumors may be irregular, fungating cauliflower-like masses; flat, indurated lesions; or large verruciform/papillary tumors (Fig. 21.14). The World Health Organization (WHO) 2016 classification of penile squamous cell carcinoma recognizes HPV-related and non–HPV-related categories, each with a number of different histologies (Table 21.6). Conventional (usual) squamous cell carcinoma is the most common HPV-negative type, encompassing almost half of all penile cancers. Pathologic prognostic factors in penile carcinoma include stage, grade, histologic subtype, vascular invasion, and perineural invasion. Many of the histologic subtypes are associated with distinct grades (e.g., verrucous and papillary carcinomas are well differentiated/grade 1 tumors, while sarcomatoid and basaloid carcinomas are poorly differentiated/grade 3 tumors. Among the special subtypes of penile carcinoma, several merit brief description. **Verrucous carcinoma** is an exophytic, warty well-differentiated, non–HPV-related variant that invades

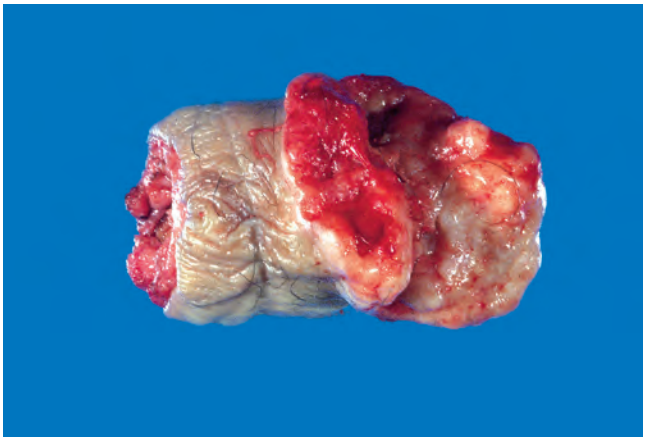

Figure 21.14 Carcinoma of the penis. The glans penis is deformed by a firm, ulcerated, infiltrative mass.

From Cubilla A, Velazquez EF, Amin MB, et al: The World Health Organisation 2016 classification of penile carcinomas: a review and update from the International Society of Urological Pathology expert-driven recommendations, *Histopathology* 72(6):893–904, 2018.

locally along a broad pushing border, but rarely metastasizes. In contrast, **basaloid carcinoma** is an HPV-related tumor comprised of relatively small hyperchromatic cells that has a destructive pattern of invasion and usually pursues an aggressive course.

Clinical Features

Invasive squamous cell carcinoma of the penis is a slowly growing, locally invasive lesion that often has been present for a year or more before it is brought to medical attention. The lesions are nonpainful until they undergo secondary ulceration and infection. Metastases to inguinal lymph nodes may occur early in its course, but widespread dissemination is rare until the lesion is far advanced. Clinical assessment of regional lymph node involvement is notoriously inaccurate; only 50% of enlarged inguinal nodes detected in men with penile squamous cell carcinoma contain cancer, with the remainder showing only reactive lymphoid hyperplasia when examined histologically. As mentioned above, prognosis is strongly correlated with tumor stage at diagnosis. Patients with penile cancer metastasis to multiple, bilateral lymph or pelvic lymph nodes have a guarded prognosis with reported 5-year disease-specific survival rates ranging from 7% to 60%.

KEY CONCEPTS

CARCINOMA OF THE PENIS

- Most common in lower income parts of the world, such as Africa, Asia, and South America, due in part to a lower incidence of circumcision.
- Two pathogenic pathways, one related to HPV and the other unrelated to HPV.
- Squamous cell carcinoma occurs on the glans or shaft of the penis as an ulcerated infiltrative lesion that may spread to inguinal nodes and infrequently to distant sites.
- Other important lesions of the penis include congenital abnormalities involving the position of the urethra (epispadias, hypospadias) and inflammatory disorders (balanitis, phimosis).

TESTIS AND EPIDIDYMIS

Distinct pathologic conditions affect the testis and epididymis. In the epididymis, the most frequent conditions are inflammatory diseases, whereas tumors dominate in the testis.

Congenital Anomalies

With the exception of undescended testes (cryptorchidism), congenital anomalies are extremely rare and include absence of one or both testes and fusion of the testes (so-called *synorchism*).

Cryptorchidism

Cryptorchidism is a complete or partial failure of the intra-abdominal testes to descend into the scrotal sac and is associated with testicular dysfunction and an increased risk of testicular cancer. It is found in approximately 1% of 1-year-old boys. It usually occurs as an isolated anomaly but may be accompanied by other malformations of the genitourinary tract, such as hypospadias.

Testicular descent occurs in two phases. During the first transabdominal phase, the testis comes to lie within the lower abdomen or brim of the pelvis. This phase is controlled by the hormone müllerian-inhibiting substance. In the second inguinoscrotal phase, the testes descend through the inguinal canal into the scrotal sac. This phase is androgen-dependent and is thought to be mediated by androgen-induced release of calcitonin gene–related peptide from the genitofemoral nerve. The testes may arrest anywhere along their pathway of descent; the most common site is in the inguinal canal, while arrest within the abdomen is uncommon, accounting for approximately 5% to 10% of cases. Even though testicular descent is controlled by hormonal factors, cryptorchidism is only rarely associated with a well-defined hormonal disorder.

MORPHOLOGY

Cryptorchidism is usually unilateral, being bilateral in 25% of patients. Cryptorchid testes are small and firm. The histologic changes in the malpositioned testis begin as early as 2 years of age. Early on, **thickening of the basement membrane** of the spermatic tubules is seen (Fig. 21.15). Subsequent loss of spermatogonia leaves the tubules with only Sertoli cells. The scarred tubules may appear as dense cords of hyaline connective tissue associated with a concomitant increase in interstitial stroma. Leydig cells are spared and therefore appear relatively prominent. Similar histologic changes may also be seen in the contralateral (descended) testis in males with unilateral cryptorchidism, suggesting that cryptorchidism is a marker of an intrinsic defect in gonadal development.

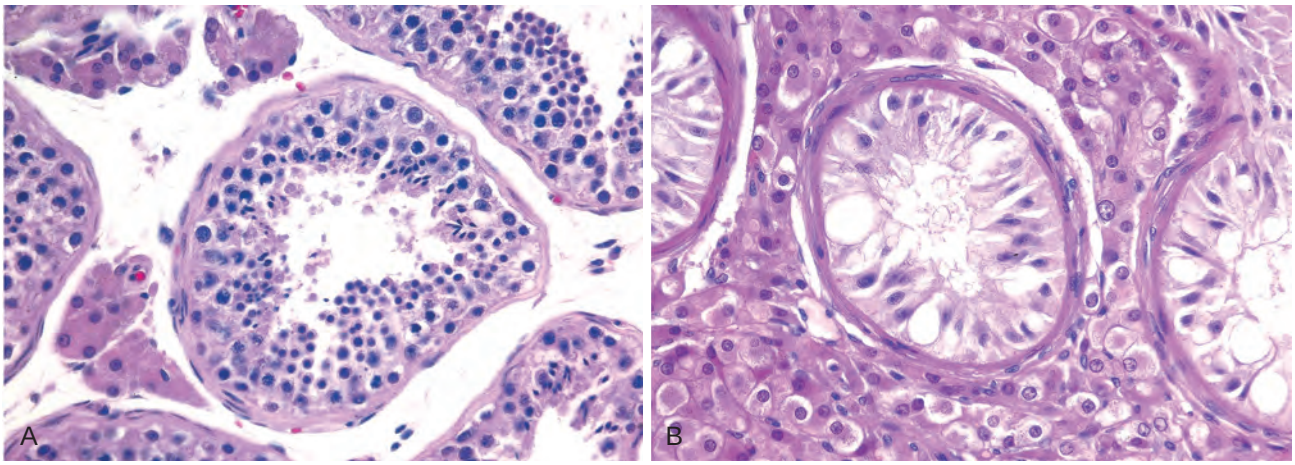

Figure 21.15 Cryptorchidism. (A) Normal testis shows tubules with active spermatogenesis. (B) Testicular atrophy in cryptorchidism. The tubules show Sertoli cells but no spermatogenesis. There is thickening of basement membranes and an apparent increase in interstitial Leydig cells.

Clinical Features

Cryptorchidism is asymptomatic and comes to attention when the scrotal sac is discovered to be empty by the patient, a parent, or a physician. In addition to sterility, cryptorchidism may be associated with other morbidity such as crushing injuries due to trauma to the inguinal region and inguinal hernia (10% to 20% of cases).

During the first year of life the majority of inguinal cryptorchid testes descend spontaneously into the scrotum. If it remains undescended, surgical correction by orchiopexy (placement in the scrotal sac) is required, preferably prior to development of histologic changes. Current recommendations are for orchiopexy to be performed at 6 to 12 months of age. Even with this corrective procedure, deficient spermatogenesis has been reported in 10% to 60% of patients, and repositioning has not been proven to completely eliminate the risk of cancer. Since the contralateral normally descended testis is also at higher risk for malignancy, it is believed that cryptorchidism and the associated risk for germ cell neoplasm is linked to an in utero defect in gonadal cell development (see discussion of testicular dysgenesis syndrome later), rather than the abnormal anatomic position.

KEY CONCEPTS

CRYPTORCHIDISM

- Cryptorchidism refers to incomplete descent of the testis from the abdomen to the scrotum and is present in about 1% of 1-year-old male infants.
- Bilateral or, in some cases, even unilateral cryptorchidism is associated with tubular atrophy and sterility.
- The cryptorchid testis carries a three- to fivefold higher risk for testicular cancer.
- Orchiopexy reduces but does not completely eliminate the risk of sterility and cancer.

Regressive Changes

Atrophy and Decreased Fertility

Testicular atrophy may be caused by one of several conditions, including (1) progressive atherosclerotic narrowing of the blood supply in old age; (2) end-stage inflammatory orchitis; (3) cryptorchidism; (4) hypopituitarism; (5) generalized malnutrition or cachexia; (6) irradiation; (7) prolonged administration of antiandrogens (e.g., for treatment of carcinoma of the prostate); (8) cirrhosis; (9) primary failure of genetic origin, such as in Klinefelter syndrome; and (10) exhaustion atrophy, which may follow persistent stimulation by high levels of follicle-stimulating pituitary hormone. The gross and microscopic alterations follow the pattern already described for cryptorchidism. In extreme cases there is complete regression ("vanishing testis").

Inflammation and Infections

Inflammatory disorders are distinctly more common in the epididymis. Several, including tuberculosis and gonorrhea, arise first in the epididymis and only involve the testis secondarily, while others, such as syphilis, involve the testis first.

Nonspecific Epididymitis and Orchitis

Epididymitis and possible subsequent orchitis are commonly related to infections in the urinary tract (cystitis, urethritis, prostatitis), which reach the epididymis and the testis through the vas deferens or the lymphatics of the spermatic cord. The cause of epididymitis varies with the age of the patient. Though uncommon in children, epididymitis in childhood is usually associated with a congenital genitourinary abnormality and infection with gram-negative rods. In sexually active men younger than age 35 years, the sexually transmitted pathogens *C. trachomatis* and *Neisseria gonorrhoeae* are most frequent. In men older than age 35, common urinary tract pathogens, such as *E. coli* and *Pseudomonas,* are responsible for most infections.

MORPHOLOGY

As elsewhere in the body, bacterial infection induces acute inflammation characterized by congestion, edema, and infiltration by neutrophils. The infection usually starts in the interstitial connective tissue, but then rapidly extends to involve the tubules, sometimes culminating in abscess formation or suppurative necrosis of the entire epididymis (Fig. 21.16). From here infection often extends

Figure 21.16 Acute epididymitis caused by gonococcal infection. The epididymis is replaced by an abscess. Normal testis is seen on the right.

to the testis, where it evokes a similar inflammatory reaction. Inflammation of the epididymis and testis is often followed by fibrous scarring, which may produce sterility. Usually the Leydig cells are not destroyed, and as a result androgen production by the testis is relatively unaffected.

Granulomatous (Autoimmune) Orchitis

Idiopathic granulomatous orchitis usually presents in middle age as a moderately tender testicular mass of sudden onset, sometimes associated with fever. It may sometimes appear insidiously, however, as a painless testicular mass mimicking a testicular tumor—hence its importance. Histologically, the orchitis is distinguished by granulomas restricted to spermatic tubules. The process must be distinguished from mycobacterial infection (see below), which often involves the epididymus and produces caseous necrosis. Although an autoimmune basis is suspected, the cause of these lesions remains unknown.

Infections

Gonorrhea

Extension of infection from the posterior urethra to the prostate, seminal vesicles, and then to the epididymis is a frequent complication of neglected gonococcal infection. In severe cases epididymal abscesses may develop, leading to extensive destruction and scarring. The infection may also spread to the testis and produce suppurative orchitis.

Mumps

Mumps is a systemic viral disease that most commonly affects school-aged children. Testicular involvement is extremely uncommon in this age group. In postpubertal males, however, orchitis occurs in 20% to 30% of cases. Most often, acute interstitial orchitis develops 1 week after the onset of swelling of the parotid glands.

Tuberculosis

When it involves the male genital tract, tuberculosis almost invariably begins in the epididymis, from where it may spread to the testis. The infection invokes the classic morphologic reactions of caseating granulomatous inflammation characteristic of tuberculosis elsewhere.

Syphilis

The testis and epididymis may be affected in both acquired and congenital syphilis, but almost invariably the testis is involved first. The morphologic pattern of the reaction takes two forms: (1) *obliterative endarteritis* associated with perivascular cuffs of lymphocytes and plasma cells, the histologic hallmark of syphilis, or (2) granulomatous inflammation, a lesion known as a *gumma*.

Other Infections

Leprosy, sarcoidosis, Crohn disease, malakoplakia, toxoplasmosis, fungi, parasites and brucellosis are other rare causes of orchitis.

Vascular Disorders

Torsion

Twisting of the spermatic cord typically cuts off the venous drainage of the testis. If untreated, it frequently leads to testicular infarction and thus represents one of the few true urologic emergencies. The thick-walled arteries remain patent, producing intense vascular engorgement followed by hemorrhagic infarction.

There are two settings in which testicular torsion occurs. Neonatal torsion occurs either in utero or shortly after birth. It lacks any associated anatomic defect to account for its occurrence. "Adult" torsion is typically seen in adolescence and presents with the sudden onset of testicular pain. It often occurs without any inciting injury. If the testis is manually untwisted within approximately 6 hours of the onset of torsion, the affected testis may be spared an orchiectomy. In adults, torsion results from a bilateral anatomic defect that leads to increased mobility of the testes *(bell-clapper abnormality)*. Contralateral *orchiopexy* is performed to prevent recurrence in the unaffected testis.

MORPHOLOGY

Depending on the duration of torsion, the morphologic changes range from intense congestion to widespread hemorrhage and testicular infarction (Fig. 21.17). In advanced stages, the swollen testis consists entirely of soft, necrotic, hemorrhagic tissue.

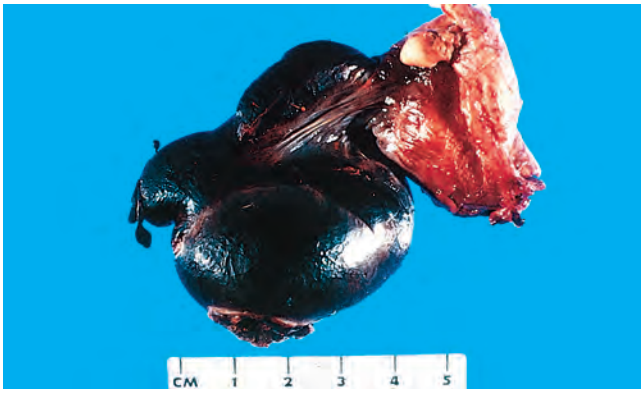

Figure 21.17 Torsion of testis. The dark discoloration is the result of hemorrhage and infarction.

Spermatic Cord and Paratesticular Tumors

Lipomas are common lesions involving the proximal spermatic cord, identified at the time of inguinal hernia repair. Although diagnosed as "lipomas," many of these lesions probably represent retroperitoneal adipose tissue that has been pulled into the inguinal canal along with the hernia sac, rather than a true neoplasm.

The most common benign paratesticular tumor is *adenomatoid tumor*. Although these lesions are mesothelial in nature, they are not referred to as mesotheliomas to distinguish them from other mesothelial lesions that may occur at this site. Adenomatoid tumors are usually small nodules, typically occurring near the upper pole of the epididymis. The importance of this lesion is that it is one of the few benign tumors that occur near the testis. If the pathologist can identify the nature of this lesion in intraoperative frozen sections, local excision of the adenomatoid tumor can spare the patient from an orchiectomy.

The most common malignant paratesticular tumors are rhabdomyosarcomas in children and liposarcomas in adults.

Testicular Tumors

Testicular neoplasms span an amazing gamut of histologic types. The 2016 WHO classification (Table 21.7) lists numerous categories, two of which are responsible for the overwhelming majority of lesions: germ cell tumors (GCTs) (95%) and sex cord–stromal tumors, both of which are discussed here.

Table 21.7 Pathologic Classification of Common Testicular Tumors

Germ Cell Tumors Derived From Germ Cell Neoplasia in Situ
Noninvasive germ cell neoplasia Germ cell neoplasia in situ
Tumors of a single histologic type (pure forms) Seminoma
Nonseminomatous germ cell tumors Embryonal carcinoma Yolk sac tumor, postpubertal type Choriocarcinoma Teratoma, postpubertal type Teratoma with somatic-type malignancy
Nonseminomatous germ cell tumors of more than one histologic type Mixed germ cell tumor
Germ Cell Tumors Unrelated to Germ Cell Neoplasia in Situ
Spermatocytic tumor
Teratoma, prepubertal type
Yolk sac tumor, prepubertal type
Mixed teratoma and yolk sac tumor, prepubertal type
Sex Cord–Stromal Tumors
Pure tumors
Leydig cell tumor
Sertoli cell tumor
Other
Tumor Containing Both Germ Cell and Sex Cord–Stromal Elements
Gonadoblastoma

Germ Cell Tumors

GCTs predominantly affect Caucasian males between 15 and 45 years of age and are the most common cancer in this age group. GCTs are increasing in incidence and occur at variable rates across populations, both for unclear reasons. The lifetime risk is highest in Northern Europe and New Zealand and is lowest in Africa and Asia. In the United States in 2019, it was predicted that there would be 9560 new cases diagnosed and 410 deaths from GCTs.

Pathogenesis

Both environmental exposures and inherited and acquired genetic abnormalities contribute to the development of germ cell neoplasia. Below we touch on important environmental and genetic factors and how their interplay appears to lead to the stepwise development of GCTs (Fig. 21.18).

Environmental Factors. The role of environmental factors is inferred in part from population migration studies. For example, the incidence of testicular GCTs in Finland is about two times lower than in Sweden, but second-generation Finnish immigrants to Sweden have a tumor incidence that approaches that of the Swedish population. Testicular GCTs

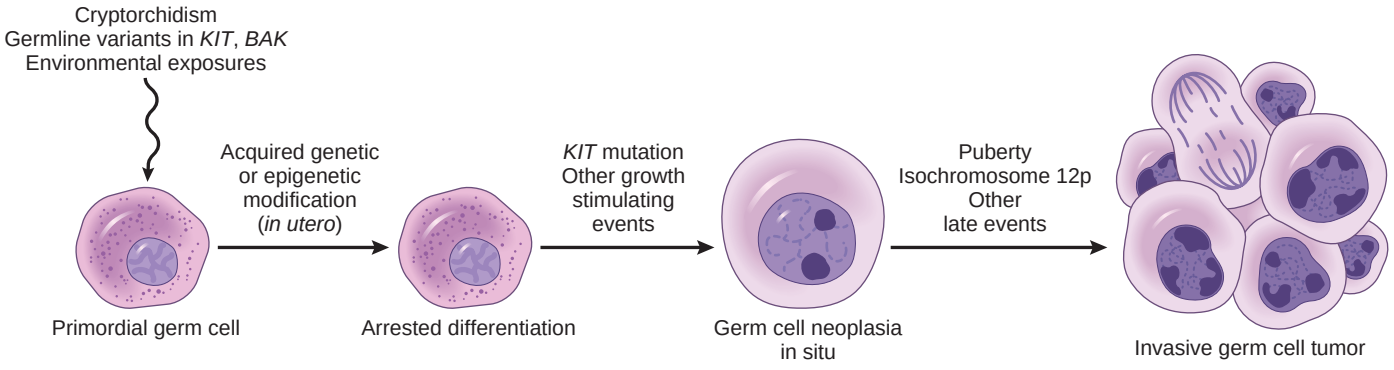

Figure 21.18 Salient environmental and genetic risk factors and acquired genetic and epigenetic alterations leading to germ cell tumor development and progression. See text for details.

also are associated with a spectrum of disorders collectively known as *testicular dysgenesis syndrome*. Components of this syndrome include cryptorchidism, hypospadias, and poor sperm quality. It has been proposed that these conditions are increased by in utero exposures to pesticides and nonsteroidal estrogens. The most important association is with cryptorchidism, which is seen with approximately 10% of testicular GCTs. Curiously, Klinefelter syndrome is associated with a greatly increased risk (50 times normal) for development of mediastinal GCTs, but these patients do not develop testicular tumors.

Genetic Factors. The relative risk of GCTs is four times higher than normal in fathers and sons of affected patients and is 8 to 10 times higher in brothers. Several genetic loci have been linked to familial GCT risk, including variants in genes encoding the ligand for the receptor tyrosine kinase KIT and BAK, which you will recall is an important inducer of apoptotic cell death (Chapter 1). Interestingly, these genes are also thought to play a role in gonadal development. Associations with variants in genes involved in sex hormone metabolism have also been found.

Steps in the Development of Germ Cell Tumors. A preponderance of evidence points to a primordial germ cell with an acquired defect in differentiation as the cell of origin of GCTs. The next step down the road to transformation consists of activation of growth factor receptor signaling, often by activating mutations in the KIT receptor tyrosine kinase, which stimulate proliferation and appear to be involved in the genesis of a precursor lesion termed *germ cell neoplasia in situ*. This precursor lesion is found in about 90% of testes involved by germ cell neoplasms and is associated with all types of GCTs except spermatocytic tumor and unusual types that arise in infancy. Germ cell neoplasia in situ also is frequently found in testes at high risk for developing GCTs, such as cryptorchid testes. Germ cell neoplasia in situ is believed to arise in utero and stay dormant until puberty, when hormonal influences may stimulate germ cell growth. The lesional cells retain the expression of the transcription factors OCT3/4 and NANOG, which are important in maintenance of pluripotent stem cells. Progression to full-blown GCTs is strongly associated with reduplication of the short arm of chromosome 12 (isochromosome 12p), a cytogenetic alteration that is invariably found in invasive GCTs regardless of histologic type. Progression is very likely, if not inevitable, as about 70% of individuals with germ cell neoplasia in situ (e.g., in cryptorchid testes) develop invasive GCTs within 7 years of diagnosis.

Classification. A simple classification of the most common types of testicular tumors is presented in Table 21.7. Two broad groups are recognized. *Seminomatous tumors* are composed of cells that resemble primordial germ cells or early gonocytes. *Nonseminomatous tumors* may be composed of undifferentiated cells that resemble embryonic stem cells, as in the case of embryonal carcinoma, but the malignant cells may also differentiate along other lineages, generating yolk sac tumors, choriocarcinomas, and teratomas. GCTs may be composed of a single cell type or mixtures of seminomatous and/or nonseminomatous components.

Seminoma

Seminoma is the most common type of GCT, making up about 50% of these tumors overall. The peak incidence is in the fourth decade. An identical tumor arises in the ovary, where it is called *dysgerminoma* (Chapter 22), and in the central nervous system, usually in midline structures such as the pineal gland, where it is referred to as *germinoma*.

MORPHOLOGY

Seminomas produce bulky masses, sometimes ten times the size of the normal testis. The typical seminoma has a homogeneous, gray-white, lobulated cut surface, usually devoid of hemorrhage or necrosis (Fig. 21.19). Generally the tunica albuginea is not penetrated, but occasionally extension to the epididymis, spermatic cord, or scrotal sac occurs.

The lesion is composed of sheets of uniform cells divided into poorly demarcated lobules by delicate fibrous septa containing a lymphocytic infiltrate (Fig. 21.20A); in some tumors, ill-defined granulomas also are present, presumably as part of a host response to the neoplasm. **The classic seminoma cell is round to polyhedral and has a distinct cell membrane; clear or watery-appearing cytoplasm; and a large, central nucleus with one or two prominent nucleoli** (Fig. 21.20B). The cytoplasm contains varying amounts of glycogen. By immunohistochemistry, the tumor cells are typically positive for KIT, OCT3/4, and podoplanin and negative for cytokeratin. Approximately 15% of seminomas contain syncytiotrophoblasts. In this subset of patients, serum human chorionic gonadotropin (hCG) levels are elevated, though not to the extent seen in patients with choriocarcinoma.

Spermatocytic Tumor

Spermatocytic tumors are uncommon, representing 1% to 2% of all testicular germ cell neoplasms. In contrast to other GCTs, affected individuals are generally older (usual more than 65 years old). This slow-growing tumor does not metastasize, and when treated by surgical resection it has an excellent prognosis. Although it bears some morphologic resemblance to seminoma, the origin and pathogenesis of spermatocytic tumor are quite distinct, as the tumor is not

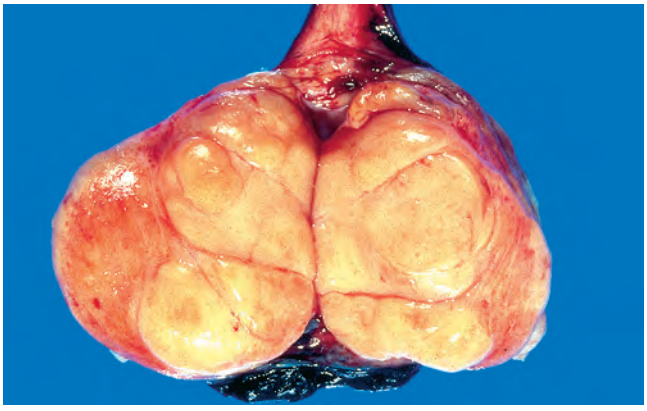

Figure 21.19 Seminoma of the testis, appearing as a well-circumscribed, pale, fleshy, homogeneous mass on cut surface.

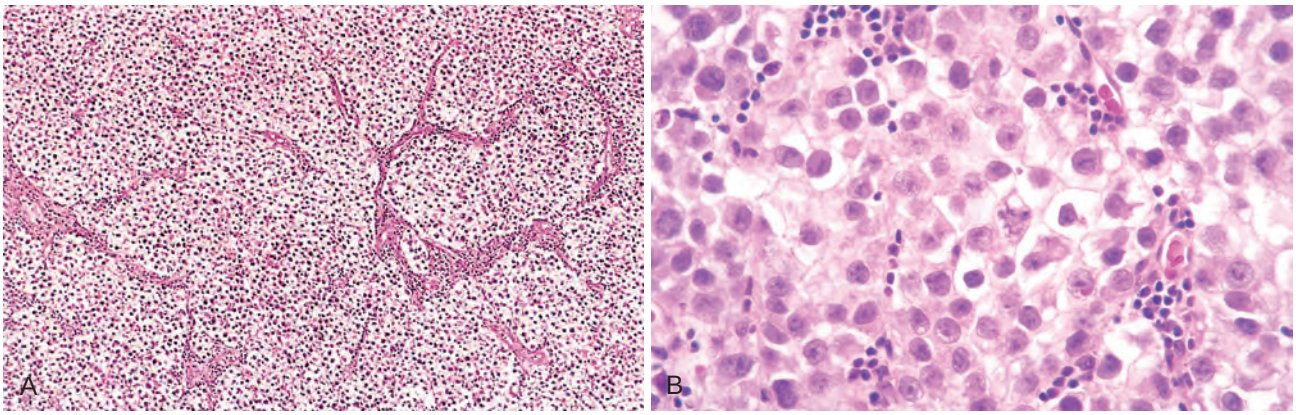

Figure 21.20 Seminoma. (A) Low magnification shows sheets of pale tumor cells divided into poorly demarcated lobules by delicate septa containing reactive lymphocytes. (B) High magnification reveals large cells with distinct cell borders, pale nuclei, prominent nucleoli, and abundant cytoplasm.

associated with germ cell neoplasia in situ, lacks isochromosome 12p, and instead is characteristically associated with gain of chromosome 9q.

MORPHOLOGY

Grossly, spermatocytic tumor tends to be circumscribed and fleshy and is occasionally myxoid, sometimes with cystic regions. The tumor characteristically contains three intermixed cell populations: (1) medium-sized cells containing a round nucleus, spireme-type chromatin (similar to that seen in the meiotic phase of normal spermatocytes) with occasional nucleoli, and eosinophilic cytoplasm; (2) smaller cells with dense chromatin and with a narrow rim of eosinophilic cytoplasm resembling secondary spermatocytes; and (3) scattered giant cells, either uninucleate or multinucleate. In contrast to seminoma, spermatocytic tumor uniformly lacks inflammatory infiltrates and syncytiotrophoblasts, does not occur at extratesticular sites, and is never admixed with other GCTs.

Embryonal Carcinoma

The peak incidence for embryonal carcinoma is in the 20- to 30-year-old age group, about a decade earlier than that of seminoma. Embryonal carcinoma is more aggressive than seminoma and may occur as a pure tumor or mixed with other germ cell components.

MORPHOLOGY

Embryonal carcinomas tend to be locally aggressive, frequently extending through the tunica albuginea into the epididymis or spermatic cord. On cut surface, the tumor often has a variegated appearance due to the presence of foci of hemorrhage or necrosis (Fig. 21.21). Histologically, the cells grow in alveolar or tubular patterns, sometimes with papillary folds. More undifferentiated lesions may display sheets of cells with cleft-like spaces (Fig. 21.22). The neoplastic cells have an epithelial appearance, are large and anaplastic, and have hyperchromatic nuclei with prominent nucleoli. The cell borders are usually indistinct, and there is considerable variation in cell and nuclear size and shape (pleomorphism). Mitotic figures and tumor giant cells are frequently seen. Vascular-lymphatic invasion is common. Like seminoma, embryonal carcinoma stains positively for OCT3/4, but differs in that it is typically also positive for cytokeratin and negative for KIT and podoplanin.

Yolk Sac Tumor

Also known as *endodermal sinus tumor,* prepubertal yolk sac tumors are the most common testicular tumor in infants and children up to 3 years of age. In this age group it has a very good prognosis. By contrast, postpubertal yolk sac tumor is rarely "pure" and more frequently occurs in combination with embryonal carcinoma or other germ cell components.

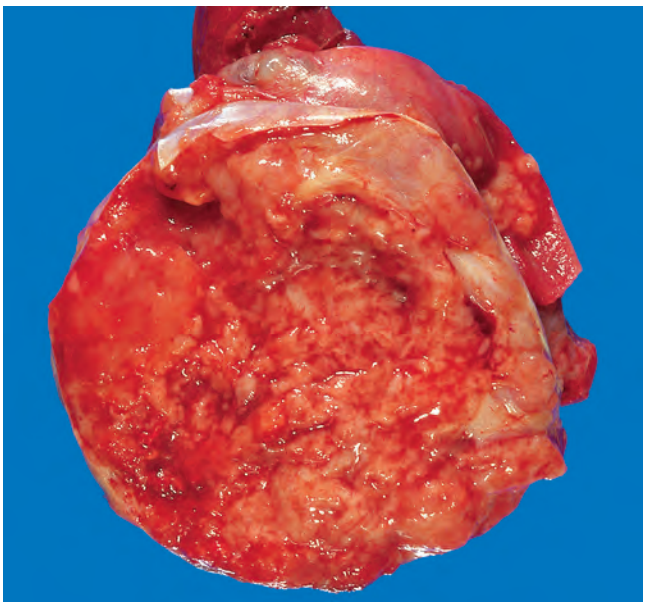

Figure 21.21 Embryonal carcinoma. In contrast to the seminoma illustrated in Fig. 21.19, as shown here, embryonal carcinoma often produces a hemorrhagic mass.

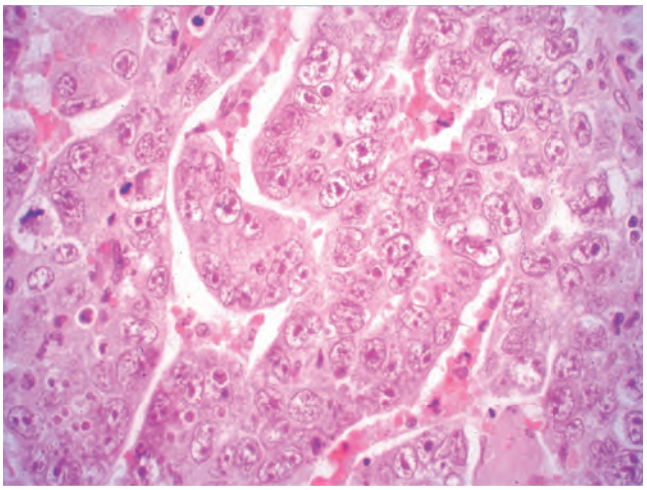

Figure 21.22 Embryonal carcinoma composed of cells with large, hyperchromatic nuclei arranged in sheets and poorly formed glands.

MORPHOLOGY

Pre- and postpubertal yolk sac tumors have similar histology; the chief difference is that prepubertal tumors are not known to be associated with germ cell neoplasia in situ and lack other germ cell elements. Yolk sac tumors are typically composed of a lace-like (reticular) network of medium-sized cuboidal, flattened, or spindled cells, which generally show less cytologic atypia than embryonal carcinoma. In addition, papillary structures, solid cords of cells, and a multitude of other, less common growth patterns may be found. In approximately 50% of tumors, structures resembling endodermal sinuses **(Schiller-Duval bodies)** may be seen; these consist of a mesodermal core with a central capillary and a visceral and parietal layer of cells resembling primitive glomeruli. Eosinophilic, hyaline-like globules containing α-fetoprotein (AFP) and α_1-antitrypsin are typically seen in yolk sac tumor cells. The expression of AFP is characteristic of yolk sac tumor cells and underscores their resemblance to yolk sac; stains for cytokeratin are also positive.

Choriocarcinoma

Choriocarcinoma is a highly malignant type of GCT. In its pure form, choriocarcinoma is rare, constituting less than 1% of all GCTs. Serum hCG is invariably elevated, often markedly so. Widespread metastasis, often associated with hemorrhage at sites of involvement, may be seen.

MORPHOLOGY

Typically, choriocarcinoma primary tumors are small, rarely larger than 5 cm in diameter. Hemorrhage and necrosis are extremely common. The tumor is composed of two intimately juxtaposed cell types, **syncytiotrophoblasts** and **cytotrophoblasts** (Fig. 21.23). Syncytiotrophoblasts are large multinucleated cells with abundant eosinophilic vacuolated cytoplasm containing hCG, which is readily detected by immunohistochemistry. Cytotrophoblasts are more regular and tend to be polygonal, with distinct borders and clear cytoplasm; they grow in cords or sheets and have a single, fairly uniform nucleus. This neoplasm can also arise in the female genital tract (Chapter 22).

Teratoma

The designation *teratoma* refers to GCTs having various cellular or organoid components reminiscent of the normal derivatives of more than one germ layer. They may occur at any age from infancy to adulthood. Pure teratoma is fairly common in infants and children and is referred to as the "prepubertal type." Among GCTs, teratomas are second in frequency in infants and children only to yolk sac tumors. In adults, pure teratomas are rare, constituting 2% to 3% of GCTs, and most often teratomas are found mixed with other histologies (a phenomenon that is discussed later). Teratomas that occur early in life also differ biologically and clinically from those that occur in adults. Prepubertal teratomas are not associated with germ cell neoplasia in situ or isochromosome 12p and pursue a benign course. Only a minor fraction of teratomas occurring in adults share these features, and postpubertal adult teratomas are generally taken to be malignant.

MORPHOLOGY

Teratomas presenting in adult males are usually large, ranging from 5 to 10 cm in diameter. The presence of a variety of tissues imparts a heterogeneous appearance, with solid, sometimes cartilaginous, and cystic areas (Fig. 21.24). Microscopically, collections of differentiated cells or organoid structures, such as neural tissue, muscle bundles, islands of cartilage, squamous epithelium lining epidermal-like surfaces with or without skin adnexal structures, structures reminiscent of thyroid gland, bronchial epithelium, and bits of intestinal wall or brain substance, are seen embedded in a fibrous or myxoid stroma (Fig. 21.25). Elements may be mature (resembling various adult tissues) or immature (sharing histologic features with fetal or embryonic tissue).

Rarely, malignant non–germ cell (somatic) tumors arise in postpubertal teratomas, a phenomenon referred to as *teratoma with somatic-type malignant transformation*. Transformation may take the form of a squamous cell carcinoma, mucin-secreting

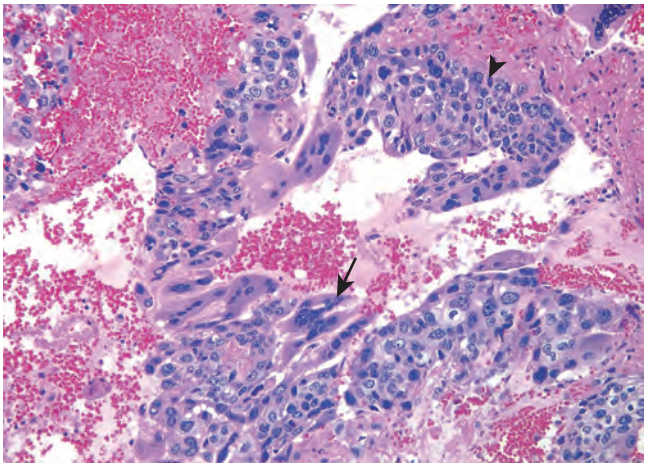

Figure 21.23 Choriocarcinoma. Both cytotrophoblastic cells *(arrowhead)* with central nuclei and syncytiotrophoblastic cells *(arrow)* with multiple dark nuclei embedded in eosinophilic cytoplasm are present. Hemorrhage and necrosis are seen in the upper right field.

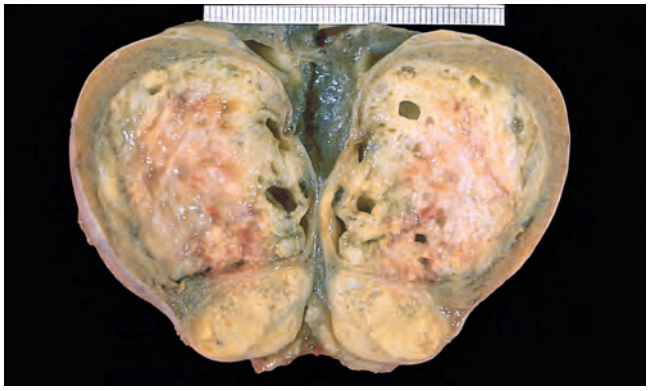

Figure 21.24 Teratoma of testis. The variegated cut surface with cysts reflects the presence of multiple tissue types.

adenocarcinoma, sarcoma, or other cancers. The importance of recognizing a somatic-type malignancy arising in a teratoma is that these secondary tumors are chemoresistant; thus, the only hope for cure resides in resection of the tumor. These non–germ cell malignancies retain isochromosome 12p, proving a clonal relationship to the preceding teratoma.

In contrast to their postpubertal counterparts, prepubertal teratomas produce distinct elements that are arranged into structures that more closely resemble normal tissue. Special types include dermoid cysts, which typically contain hair, teeth, and skin. On rare occasions, prepubertal teratoma may be admixed with yolk sac tumor.

Mixed Tumors

About 60% of GCTs are composed of more than one of the above types. Common mixtures include teratoma, embryonal carcinoma, and yolk sac tumor; seminoma with embryonal carcinoma; and embryonal carcinoma with teratoma.

Clinical Features of Testicular Germ Cell Tumors. Although painless enlargement of the testis is a characteristic feature of GCTs, any solid testicular mass should be considered neoplastic until proven otherwise. Biopsy of a testicular neoplasm is associated with a risk of tumor spillage, which would necessitate excision of the scrotal skin in addition to orchiectomy. Consequently, the standard management of a solid testicular mass is radical orchiectomy based on the presumption of malignancy. Occasionally, when a benign lesion is suspected and the lesion can be excised by partial orchiectomy, an intraoperative frozen section examination may be performed in an effort to avoid an unnecessary radical orchiectomy.

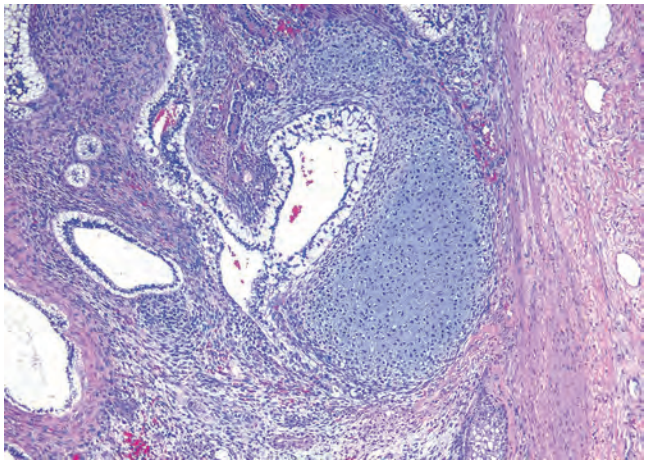

Figure 21.25 Teratoma of the testis, consisting of a disorganized collection of glands, cartilage, smooth muscle, and immature stroma.

Testicular tumors have a characteristic mode of spread. *Lymphatic spread* is common to all forms. In general, retroperitoneal para-aortic nodes are the first to be involved. Subsequent spread may occur to mediastinal and supraclavicular nodes. *Hematogenous spread* is primarily to the lungs, but liver, brain, and bones may also be involved. Metastases from seminomas typically involve lymph nodes. Hematogenous spread occurs later in the course of dissemination. Nonseminomatous GCTs tend to metastasize earlier and more frequently via a hematogenous route. The histology of metastases and distant recurrences may differ from that of the testicular lesion. This is a reflection of the fact that GCTs are derived from pluripotent germ cells. Furthermore, a minor component in the primary tumor that is unresponsive to chemotherapy may survive and subsequently become the dominant histologic type in the metastatic site.

Serum Biomarkers in Germ Cell Tumors. GCTs secrete polypeptide hormones and enzymes that can be detected in the patient's peripheral blood. These include hCG, AFP, and lactate dehydrogenase, all of which can serve as valuable biomarkers in the diagnosis and management of testicular cancer. The elevation of lactate dehydrogenase correlates with the mass of tumor cells and provides a tool to assess tumor burden. Marked elevation of serum AFP or hCG levels is produced by yolk sac tumor and syncytiotrophoblastic elements, respectively. Both of these markers are elevated in more than 80% of individuals with nonseminomatous GCTs at the time of diagnosis. As stated earlier, approximately 15% of seminomas have syncytiotrophoblastic giant cells and minimal elevation of hCG levels. In the context of testicular tumors, serum markers are valuable in several different ways:

- In the initial evaluation of testicular masses
- In the staging of testicular GCTs; for example, after orchiectomy, persistent elevation of hCG or AFP concentrations indicates metastatic spread
- In assessing tumor burden
- In monitoring the response to therapy

The therapy and prognosis of testicular tumors depend largely on the clinical and pathologic stage and the histologic type. Seminoma, which is radiosensitive and chemosensitive, has the best prognosis. More than 95% of patients with stage I and II seminoma are cured by orchiectomy with or without chemotherapy or radiotherapy. In nonseminomatous GCT patients, approximately 90% achieve complete remission with aggressive chemotherapy, and most can be cured. Pure embryonal carcinoma behaves more aggressively than mixed GCTs. Pure choriocarcinoma and mixed GCT with predominantly choriocarcinoma have a poor prognosis.

Tumors of Sex Cord–Gonadal Stroma

As indicated in Table 21.7, sex cord–gonadal stromal tumors are subclassified based on their presumed histogenesis and differentiation. The two most important members of this group—Leydig cell tumors and Sertoli cell tumors—are described here. Pathologic features correlated with malignancy in sex cord–stromal tumors of the testis include large size (greater than 5 cm), necrosis, infiltrative borders, anaplasia, mitotic activity, vascular-lymphatic invasion, and extratesticular extension.

Leydig Cell Tumors

Tumors of Leydig cells often elaborate androgens and in some cases estrogens and corticosteroids as well. They may arise in children or adults. As with other testicular tumors, the most common presenting feature is testicular swelling, but in some patients gynecomastia brings them to clinical attention. In children, hormonal effects, manifested primarily as sexual precocity, may be the dominant feature. Leydig cell tumor is associated with Klinefelter syndrome, cryptorchidism, and hereditary leiomyomatosis and renal cell carcinoma syndrome (caused by germline mutations in the metabolic enzyme fumarate hydratase). Approximately 10% of Leydig cell tumors in adults are malignant and can produce metastases.

MORPHOLOGY

Leydig cell tumors form circumscribed nodules, usually less than 5 cm in diameter, that have a distinctive golden brown, homogeneous appearance on cut surfaces. Histologically, the tumor cells resemble their normal counterparts. They are large in size and have round or polygonal cell outlines, abundant granular eosinophilic cytoplasm, and a round central nucleus. The cytoplasm frequently contains lipid droplets, vacuoles, or lipofuscin pigment and, most characteristically, rod-shaped **crystalloids of Reinke,** which are seen in about 25% of the tumors.

Sertoli Cell Tumors

Most Sertoli cell tumors are hormonally silent and present as a testicular mass. They are associated with Carney complex (caused by germline mutations in the gene *PRKAR1A,* which encodes a cyclic adenosine monophosphate–dependent protein kinase), Peutz-Jeghers syndrome (Chapter 17), and familial adenomatosis polyposis syndrome (Chapter 17). These neoplasms appear as firm, small nodules with a homogeneous gray-white to yellow cut surface. Histologically, the tumor cells are arranged in distinctive trabeculae that tend to form cord-like structures and tubules. Most Sertoli cell tumors are benign, but approximately 10% pursue a malignant course.

Gonadoblastoma

Gonadoblastomas are rare neoplasms comprised of a mixture of germ cells and gonadal stromal elements that almost always arise in gonads with some form of testicular dysgenesis (discussed earlier). In some cases, the germ cell component becomes malignant, giving rise to seminoma.

Testicular Lymphoma

Primary testicular lymphomas are rare, accounting for 5% of testicular neoplasms, but are the most common form of testicular neoplasm in men older than 60 years of age. In most cases, these are aggressive tumors that are disseminated at the time of detection. In contrast to GCTs, tumors are frequently bilateral and involve the spermatic cord. The most common testicular lymphomas, in decreasing order of frequency, are diffuse large B-cell lymphoma, Burkitt lymphoma, and Epstein-Barr virus–positive extranodal NK/T-cell lymphoma (Chapter 13). Testicular lymphomas have a high propensity for central nervous system involvement, which is a frequent site of recurrence.

KEY CONCEPTS

TESTICULAR TUMORS

- GCTs are by far the most common tumor types and account for 95% of testicular neoplasms.
- Cryptorchidism, infertility, and prior history of GCT in contralateral testis are risk factors.
- Germ cell neoplasia in situ is a precursor lesion associated with most GCTs. Seventy percent of patients with documented germ cell neoplasia in situ will develop invasive GCTs.
- Seminoma, embryonal carcinoma, yolk sac tumors, choriocarcinoma, and teratoma are the most common types of GCTs. Mixed tumors that contain more than one histologic type account for 40% of GCTs.
- Clinically, testicular GCTs are divided into two groups: seminomas and nonseminomatous tumors. Seminomas spread mainly to para-aortic nodes and are radiosensitive. Nonseminomatous tumors tend to spread earlier via lymphatic and hematogenous routes.
- hCG, AFP, and lactate dehydrogenase can serve as valuable blood biomarkers in the diagnosis and management of GCTs.
- Non-GCTs include sex cord–gonadal stromal tumors and non-Hodgkin lymphoma, which is the most common testicular tumor in men older than 60 years.

Lesions of Tunica Vaginalis

The tunica vaginalis is a mesothelial-lined surface exterior to the testis that may accumulate serous fluid *(hydrocele)* causing considerable enlargement of the scrotal sac. By transillumination it is usually possible to define the clear, translucent character of the contained fluid. Rarely, malignant mesotheliomas and ovarian epithelial-type tumors can arise from the tunica vaginalis.

Hematocele is a collection of blood in the tunica vaginalis. It is an uncommon condition usually encountered following testicular trauma or torsion, or in individuals with systemic bleeding disorders. *Chylocele* refers to the accumulation of lymph in the tunica and is almost always found in patients with elephantiasis who have widespread, severe lymphatic obstruction caused, for example, by filariasis (Chapter 8). *Spermatocele* refers to a small cystic accumulation of semen in dilated efferent ducts or ducts of the rete testis. *Varicocele* is a dilated vein in the spermatic cord. Varicoceles may be asymptomatic but have also been implicated in some men as a contributing factor to infertility. They can be corrected by surgical repair.

PROSTATE

The prostate is a retroperitoneal organ encircling the neck of the bladder and urethra that lacks a distinct capsule. In a normal adult, the prostate weighs approximately 20 g and can be divided into four biologically and anatomically distinct regions, the peripheral, central, transition, and periurethral zones (Fig. 21.26). These zones are at risk for different types of proliferative lesions. For example, most hyperplasias arise in the transition zone, whereas most carcinomas originate in the peripheral zone.

Histologically, the prostate consists of glands separated by abundant fibromuscular stroma. The glands are lined by two layers of cells: a basal layer of low cuboidal basal epithelium covered by a layer of columnar secretory cells (Fig. 21.27), which often contain small papillary infoldings. Testicular androgens control the growth and survival of prostatic cells, and castration leads to widespread apoptosis of prostatic epithelium and atrophy of the prostate.

Only three pathologic processes affect the prostate gland with sufficient frequency to merit discussion: inflammation, benign prostatic hypertrophy (BPH), and tumors. Of these, BPH is the most common and occurs so often in older males that it can almost be viewed as a "normal" part of aging. Prostatic carcinoma is also extremely common in older men and is an important cause of morbidity and mortality. We begin our discussion with consideration of inflammatory processes.

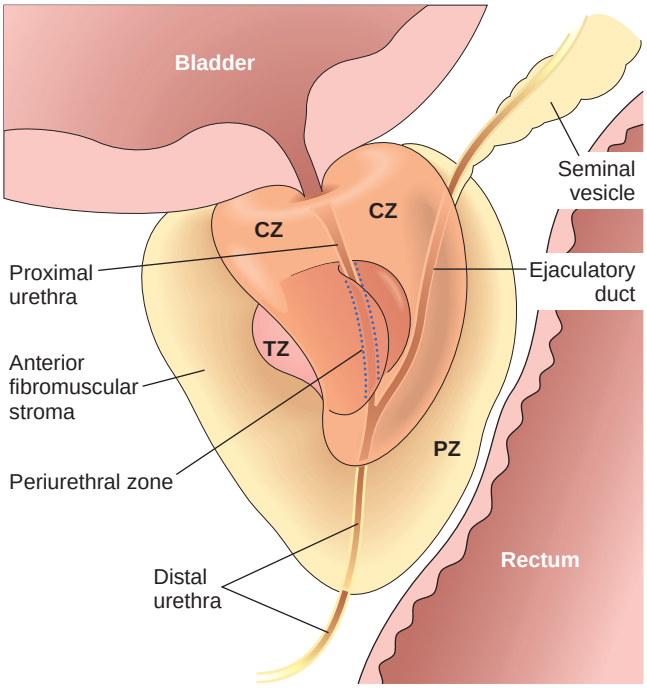

Figure 21.26 Adult prostate. The normal prostate contains several distinct regions, including a central zone *(CZ)*, a peripheral zone *(PZ)*, a transitional zone *(TZ)*, and a periurethral zone. Most carcinomas arise from the peripheral zone and may be palpable during digital examination of the rectum. Benign prostatic hyperplasia, in contrast, arises from the more centrally situated transitional zone and often produces urinary obstruction.

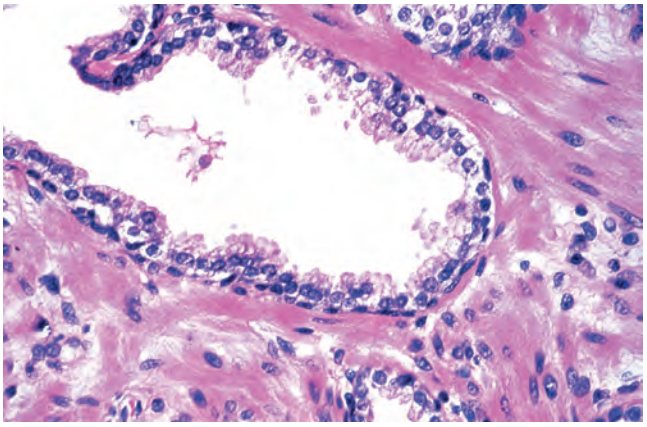

Figure 21.27 Normal prostate gland, with basal cell and secretory cell layers.

Inflammation

Prostatitis may be divided into several categories, depending on cause, patterns of tissue reaction, and clinical course.

- *Acute bacterial prostatitis* typically results from bacteria similar to those that cause urinary tract infections. Thus, most cases are caused by various strains of *E. coli,* other gram-negative rods, enterococci, and staphylococci. The organisms usually reach the prostate through the reflux of contaminated urine from the posterior urethra or the urinary bladder, but occasionally distant foci of infection seed the prostate through lymphohematogenous routes. Prostatitis sometimes follows surgical manipulation of the urethra or prostate gland itself (e.g., catheterization, cystoscopy, or urethral dilation). Clinically, acute bacterial prostatitis is associated with fever, chills, and dysuria. On rectal examination the prostate is exquisitely tender and boggy. The diagnosis can be established by urine culture and clinical features. Biopsy of a gland in which acute prostatitis is suspected is contraindicated, as this may lead to sepsis.
- *Chronic bacterial prostatitis* usually presents with low back pain, dysuria, and perineal and suprapubic discomfort, though it also may be asymptomatic. Patients often have a history of recurrent urinary tract infections (cystitis, urethritis) caused by the same organism. Because most antibiotics penetrate the prostate poorly, bacteria find haven in the parenchyma and constantly seed the urinary tract. Diagnosis of chronic bacterial prostatitis depends on the demonstration of leukocytosis in expressed prostatic secretions and positive bacterial cultures. The implicated organisms are the same as those that cause acute prostatitis.
- *Chronic abacterial prostatitis,* the most common form of prostatitis, is often referred to clinically as *chronic pelvic pain syndrome.* It is indistinguishable from chronic bacterial prostatitis in terms of signs and symptoms, but there is no history of recurrent urinary tract infection. Expressed prostatic secretions contain more than 10 leukocytes per high-power field, but bacterial cultures are uniformly negative.
- *Granulomatous prostatitis* may be caused by a specific infectious agent or may refer to a pattern of tissue reaction to noninfectious stimuli. In the United States, the most common cause is instillation of BCG for treatment of

bladder cancer. In this setting, the finding of granulomas in the prostate is of no clinical significance and requires no treatment. Fungal granulomatous prostatitis is typically seen in immunocompromised hosts. Nonspecific granulomatous prostatitis is relatively common and represents a reaction to secretions from ruptured prostatic ducts and acini.

- *Other forms of prostatitis.* Adenoviral and IGg4-associated (Chapter 6) autoimmune prostatitis have also been described.

Benign Enlargement

Benign Prostatic Hyperplasia

BPH (also referred to as nodular hyperplasia) is the most common benign prostatic disease in men older than age 50 years. Approximately 30% of white American men in that age group have moderate to severe symptoms of BPH, and histologic evidence of BPH is found in up to 90% of men by age 80. It is not a premalignant lesion.

Etiology and Pathogenesis

Dihydrotestosterone (DHT) is the main androgen in the prostate, where it is formed from testosterone through the action of type 2 5α-reductase (Fig. 21.28A). This enzyme is expressed primarily in stromal cells and is not expressed in prostatic epithelial cells. Type 1 5α-reductase is another enzyme that mediates DHT production from testosterone in extraprostatic locations (e.g., liver and skin) and provides an additional source of DHT that reaches the prostate through the blood.

DHT binds to and activates androgen receptors (ARs) found in both stromal and epithelial prostate cells. It is more potent than testosterone because it has a higher affinity for ARs and forms a more stable complex with them. Binding of DHT stimulates ARs to translocate from the cytoplasm to the nucleus and activate the transcription of androgen-dependent genes, which encode several growth factors and their receptors. Most important among the upregulated factors are members of the fibroblast growth factor (FGF) family and transforming growth factor (TGF) β (Chapter 3). FGFs, produced by stromal cells, are paracrine regulators of androgen-stimulated epithelial growth during embryonic prostatic development, and some of these pathways may be "reawakened" in adulthood to produce prostatic growth in BPH. TGFβ serves as a mitogen for fibroblasts and other mesenchymal cells but inhibits epithelial proliferation. Although the ultimate cause of BPH is unknown, it is believed that DHT-induced growth factors act by increasing the proliferation of stromal cells and decreasing the death of epithelial cells.

While it is recognized that androgens play a permissive role in BPH pathogenesis, multiple lines of evidence support a role for estrogens as well. Two different forms of estrogen receptor (ER), ERα and ERβ, have opposing proliferative and antiproliferative effects on prostate cells, respectively. Effects of estrogens on the prostate are associated with multiple mechanisms including apoptosis, aromatase expression, and paracrine regulation via prostaglandin E_2. Estrogens thus contribute to BPH pathogenesis by tipping the balance toward proliferation (Fig. 21.28B).

MORPHOLOGY

In BPH, the weight of the enlarged prostate often increases three- to fivefold (60 to 100 g), and even greater enlargement

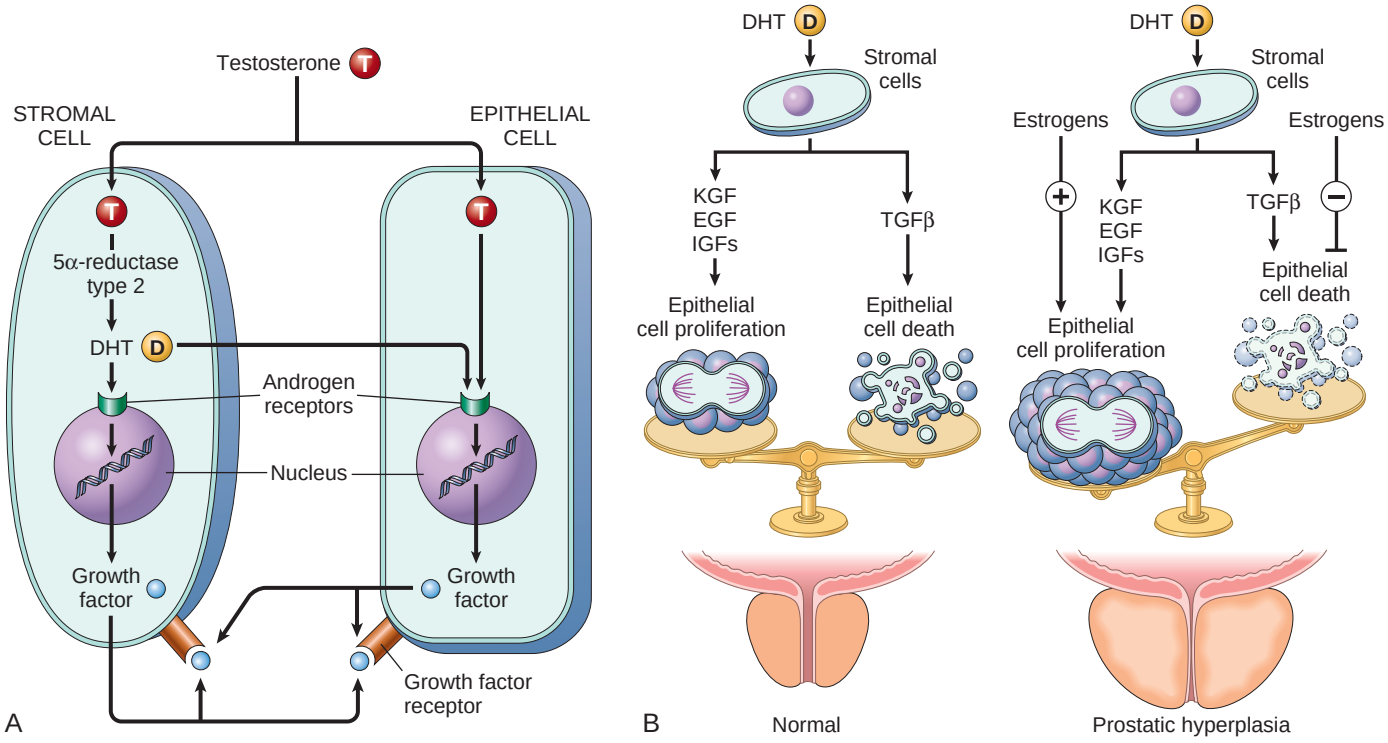

Figure 21.28 Simplified scheme of the pathogenesis of prostatic hyperplasia. (A) The central role of the stromal cells in generating dihydrotestosterone *(DHT)* is depicted. DHT may also be produced in skin and liver by both type 1 and type 2 5α-reductase. (B) The contribution of estrogen in tipping the balance of cell proliferation and cell death toward the former is illustrated. *EGF,* Epidermal growth factor; *IGFs,* insulin-like growth factors; *KGF,* keratinocyte growth factor; *TGFβ,* transforming growth factor β.

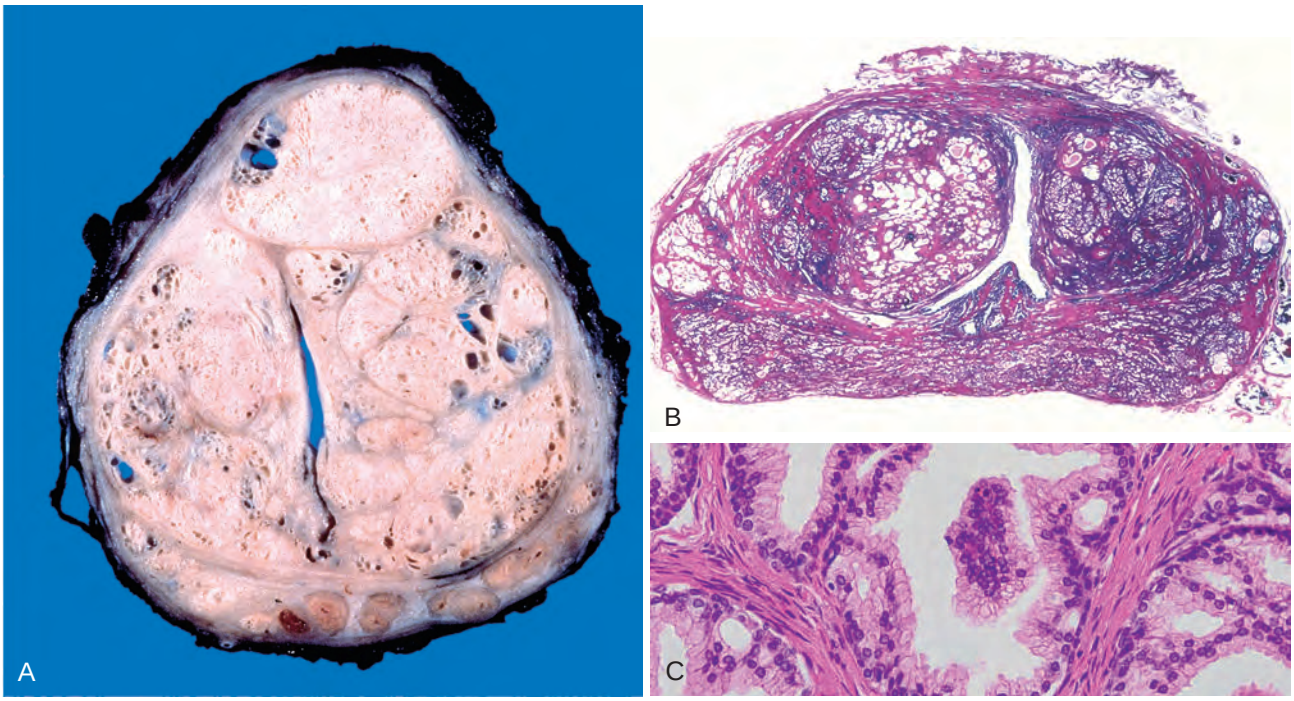

Figure 21.29 Benign prostatic hyperplasia (BPH). (A) Well-defined nodules of BPH compress the urethra into a slit-like lumen. (B) Microscopic view of a whole mount of the prostate shows nodules of hyperplastic glands on both sides of the urethra. (C) Under high power a nodule composed of hyperplastic glands with papillary epithelial infoldings is seen.

may be seen. BPH affects the transition zone and thus may encroach on the urethra, compressing it to a slit-like orifice (Fig. 21.29A). On cross-section, hyperplastic nodules are seen that vary in color and consistency depending on their cellular content (Fig. 21.29B). Nodules that contain mostly glands are yellow-pink and soft and exude a milky white prostatic fluid. Nodules composed primarily of fibromuscular stroma are pale gray and firm.

Microscopically, individual nodules contain small to large to cystically dilated glands that are separated by bland spindle-shaped stromal cells. The glands are lined by two layers of cells, an inner columnar secretory cell layer and an outer layer of cuboidal or flattened basal epithelium (Fig. 21.29C), and infolding of the glands may produce a papillary architecture. In markedly enlarged glands, compromise of the vascular supply may produce prostatic infarcts, which may have adjacent areas of squamous metaplasia.

Clinical Features

The main symptoms of BPH are due to urinary obstruction caused by prostatic enlargement and stromal smooth muscle–mediated contraction. The increased resistance to urinary outflow leads to bladder hypertrophy and distention, accompanied by urine retention. The inability to empty the bladder completely creates a reservoir of residual urine that is a common source of infection. Patients experience increased urinary frequency, nocturia, difficulty in starting and stopping the stream of urine, overflow dribbling, and dysuria (painful micturition) and have an increased risk of developing bacterial infections of the bladder and kidney. In many cases, sudden, acute urinary retention occurs that requires emergency catheterization for relief.

Symptomatic BPH is usually managed medically with α-adrenergic blockers and 5α-reductase inhibitors. The former decrease prostate smooth muscle tone via inhibition of α_1-adrenergic receptors, while the latter physically shrink the prostate by decreasing DHT synthesis. For moderate to severe cases recalcitrant to medical therapy, a wide range of invasive procedures exist. Transurethral resection of the prostate (TURP) was for long the gold standard, but alternative procedures to destroy excessive prostatic tissue have been developed with lower morbidity and lower costs. These procedures include high-intensity focused ultrasound (HIFU), laser therapy, hyperthermia, transurethral electrovaporization, and radiofrequency ablation.

KEY CONCEPTS

BENIGN PROSTATIC HYPERPLASIA

- BPH is characterized by proliferation of benign stromal and glandular elements. DHT, an androgen derived from testosterone, is the major hormonal stimulus for proliferation.
- BPH most commonly affects the inner periurethral zone and transition zone of the prostate, producing nodules that compress the prostatic urethra.
- Clinical symptoms and signs are related to urinary obstruction that also predisposes to recurrent urinary tract infections.
- Medical management is based on α-adrenergic blockers and 5α-reductase inhibitors, which decrease prostatic smooth muscle tone and inhibit DHT production, respectively.

Neoplasms

Adenocarcinoma

In the United States, adenocarcinoma of the prostate is the most common form of cancer in men, with an expected 174,650 new cases in 2019, accounting for 20% of all male cancers. Prostate cancer is the second cause of cancer-related

death in men, surpassed only by lung cancer. The biologic behavior of prostate cancer spans the gamut from clinically insignificant "histologic" cancers to aggressive tumors that are rapidly fatal. It is largely a disease of aging. Based on autopsy studies, the incidence of prostate cancer increases from 20% in men in their 50s to approximately 70% in men between the ages of 70 and 80 years.

Epidemiology and Pathogenesis. An interplay of both environmental exposures and inherited genetic factors contributes to striking differences in the incidence of prostate cancer across geographic locales (Chapter 7). For example, the incidence of prostate cancer in individuals of Japanese descent living in the United States is substantially higher than in Japanese living in Japan, but also is only about 50% of the reported incidence in African Americans. As explained below, some genetic factors appear to increase risk due to intrinsic effects on prostatic epithelium, while others may act by modifying the risk associated with environmental exposures. Furthermore, as might be expected of an androgen-sensitive organ, androgens and AR function have central roles in the development, progression, and treatment of prostate cancer.

Environmental Factors. It is hypothesized that exposure to carcinogens, estrogens, and oxidants damage prostatic epithelium, setting the stage for acquisition of genetic and epigenetic changes that lead to cancer development (Fig. 21.30). Broadly speaking, the "Western diet" is a suspect, given the relatively high incidence of prostate cancer in the United States, South America, Western Europe, and Australia. One dietary component that epidemiologic and animal model studies suggest contributes to risk is consumption of charred red meats and animal fats, which leads to formation of carcinogenic heterocyclic aromatic amines and polycyclic aromatic hydrocarbons. These and other dietary exposures may create oxidant stress in prostatic epithelium, leading to cell injury and inflammation. One piece of evidence linking these exposures to prostate cancer development is the observation that polymorphisms in glutathione-*S*-transferase *(GSTP1),* an enzyme involved in detoxification of polycyclic aromatic hydrocarbons, are linked to prostate cancer risk.

Inherited Genetic Factors. Studies of twins and families support the existence of important genetic predisposing factors. Men with first-degree relatives affected by the disease have a twofold increased risk, and numerous germline variants have been identified that are associated with risk. Among the relatively common variants conveying a modest increase in risk are variants in regulatory regions that influence the expression of *MYC,* an important oncogene in prostate cancer. Other rare variants have been identified that are linked to a high risk of early-onset, aggressive disease. Among these are mutations that disrupt the function of several DNA repair genes, including loss-of-function mutations in *BRCA2* (required for repair by homologous recombination) and in DNA mismatch repair genes (as part of Lynch syndrome; see Chapter 17). A variant in the gene encoding the transcription factor HOXB13, which plays a role in prostatic development during embryogenesis, also has been described that is associated with a severalfold increase in risk.

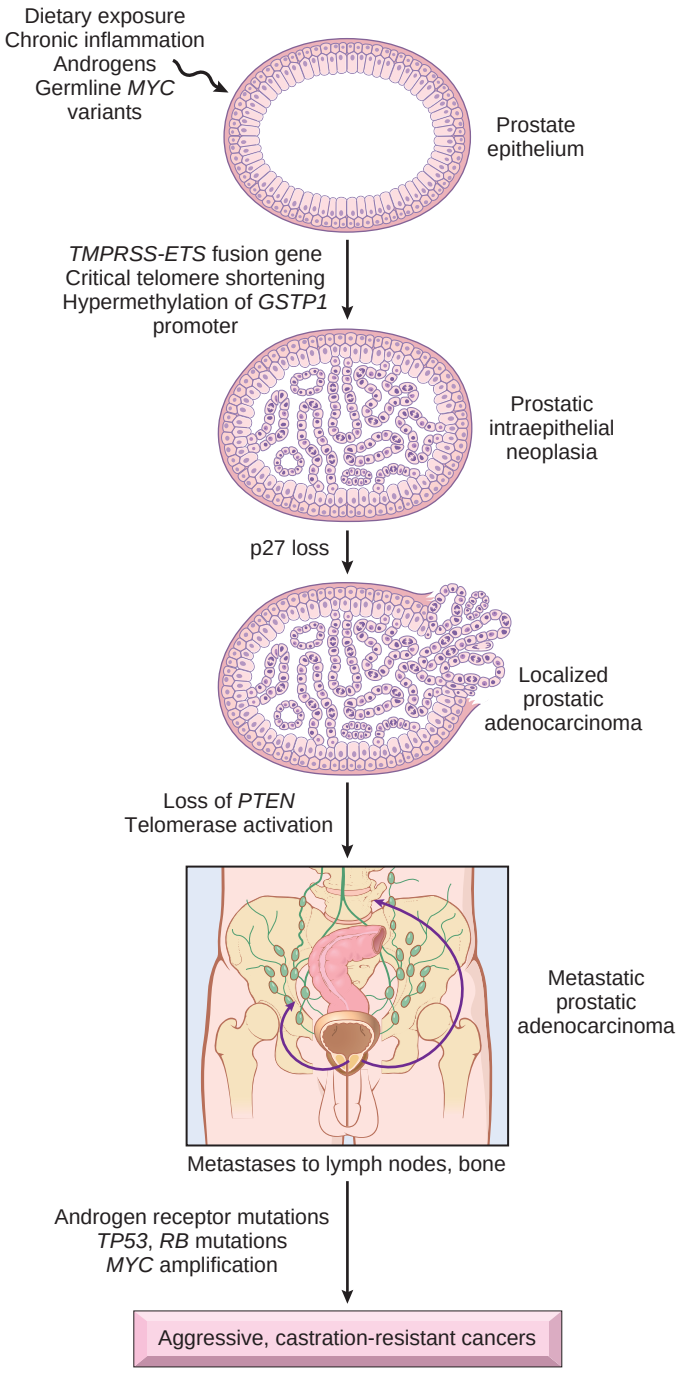

Figure 21.30 Salient environmental and genetic risk factors and acquired genetic and epigenetic alterations leading to prostate cancer development and progression. See text for details.

Androgens. **Like their normal counterparts, the growth and survival of prostate cancer cells depend on androgens, which bind to the AR and induce the expression of pro-growth and pro-survival genes.** The importance of androgens in maintaining the growth and survival of prostate cancer cells can be seen in the therapeutic effect of castration or treatment with antiandrogens, which usually induce disease regression. Unfortunately, most tumors eventually become resistant to androgen blockade. Tumors escape through a variety of mechanisms, including acquisition of hypersensitivity to low levels of androgen (e.g., through AR gene amplification);

ligand-independent AR activation (e.g., via splice variants that lack the ligand binding domain); mutations in AR that allow it to be activated by non-androgen ligands; and other mutations or epigenetic changes that activate alternative signaling pathways and bypass the need for AR altogether.

Acquired Genetic and Epigenetic Alterations. As with other cancers, prostate cancer is caused by genetic and epigenetic alterations that altered the expression of tumor suppressor genes and oncogenes, ultimately leading to acquisition of the hallmarks of cancer (Chapter 7). **The most common genetic alteration in the prostate is a chromosomal rearrangement that juxtaposes the coding sequence of an ETS family transcription factor gene (most commonly *ERG* or *ETV1*) next to the androgen-regulated *TMPRSS2* promoter.** The rearrangements, which occur in approximately half of prostate cancers, place the involved ETS oncogene under the control of the androgen-regulated *TMPRSS2* promoter and lead to its overexpression in an androgen-dependent fashion. Silencing of the gene encoding p27, an inhibitor of cyclin-dependent kinases, is another common event. DNA sequencing has demonstrated many other recurrent genomic rearrangements, primarily deletions and amplifications, that involve other cancer genes in prostate carcinoma. Among these are amplification of *MYC* and deletion of *PTEN,* both of which accelerate cell growth and may contribute to resistance to antiandrogen therapy. In late-stage disease, loss of *TP53* (by deletion or mutation), and deletions of *RB* are common, as are amplifications of the AR gene.

Epigenetic events that modify gene expression are also common in prostate cancer. Work carried out as part of The Cancer Genome Atlas project has identified several distinct subsets of prostate cancers that are defined by differences in DNA methylation. One particularly frequent early event is epigenetic silencing by DNA methylation of the *GSTP1* gene, which downregulates *GSTP1* expression, possibly enhancing the genotoxic effects of environmental carcinogens. Other genes silenced by epigenetic modifications in a subset of prostate cancers include genes involved in cell cycle regulation *(RB, CDKN2A),* maintenance of genomic stability *(MLH1, MSH2),* and Wnt signaling *(APC).* The cumulative salient genetic and epigenetic alterations during prostate cancer development and progression are illustrated in Fig. 21.30.

Precursor Lesions. Evidence in favor of stepwise development of prostate cancer (as outlined in Fig. 21.30) includes the existence of a putative precursor lesion, *prostatic intraepithelial neoplasia (PIN)*. A precursor role for PIN in at least some cases of prostate cancer is supported by several observations. Both PIN and cancer typically predominate in the peripheral zone and are relatively uncommon in other zones, and prostates containing cancer have a higher frequency and a greater extent of PIN, which is often seen in proximity to cancer. More directly, many of the molecular changes seen in invasive cancers are also present in PIN, strongly supporting the argument that PIN is a precursor.

MORPHOLOGY

When the term *prostate cancer* is used without qualification, it refers to the common or acinar variant of prostatic adenocarcinoma. In approximately 70% of cases, carcinoma of the prostate arises in the peripheral zone of the gland, classically in a posterior location, where it may be palpable on rectal examination. Characteristically, on cross-section the neoplastic tissue is gritty and firm to palpation, but it is sometimes extremely difficult to visualize by eye (Fig. 21.31). Histologically, most adenocarcinomas consist of glands arranged in well-defined, easily recognized patterns, which are used to grade these tumors (discussed later). The glands are typically smaller than benign glands and are lined by a single uniform layer of cuboidal or low columnar epithelium. In contrast to benign glands, malignant glands have tightly packed cells and characteristically lack branching and papillary infoldings. **The outer basal cell layer typical of benign glands is absent.** The cytoplasm of the tumor cells ranges from pale-clear to a distinctive amphophilic appearance. Nuclei are enlarged and often contain one or more large nucleoli. There is some variation in nuclear size and shape, but in general pleomorphism is not marked. Mitotic figures are uncommon.

Figure 21.31 Adenocarcinoma of the prostate. An area of cancer is present in the posterior aspect *(lower left)* that has solid gray-white appearance, in contrast to the spongy appearance of benign peripheral zone on the contralateral side.

When prostate cancer invades locally, it most commonly involves periprostatic tissue, seminal vesicles, and the base of the urinary bladder, which in advanced disease may produce ureteral obstruction. Metastases spread via lymphatics to the obturator nodes and eventually to the para-aortic nodes. **Hematogenous spread occurs chiefly to the bones,** particularly the axial skeleton. Bony metastases are typically osteoblastic, a feature that in men points strongly to a prostatic origin (Fig. 21.32). The bones that are most commonly involved, in descending order of frequency, are lumbar spine, proximal femur, pelvis, thoracic spine, and ribs. Tumors may also spread to viscera, but extensive visceral dissemination is the exception rather than the rule.

The diagnosis of prostate cancer on biopsy specimens can be challenging due to several factors. There is often only a scant amount of tissue available for histologic examination in needle biopsies, and malignant glands may be admixed with numerous benign glands (Fig. 21.33). Moreover, the histologic findings may be subtle (leading to underdiagnosis), and there are benign mimickers of cancer that can lead to a misdiagnosis. A few findings are specific, such as perineural invasion (Fig. 21.34), but in general the diagnosis is made based on a constellation of architectural, cytologic, and ancillary findings. As discussed earlier, one distinguishing feature

Figure 21.32 Metastatic osteoblastic prostatic carcinoma within vertebral bodies.

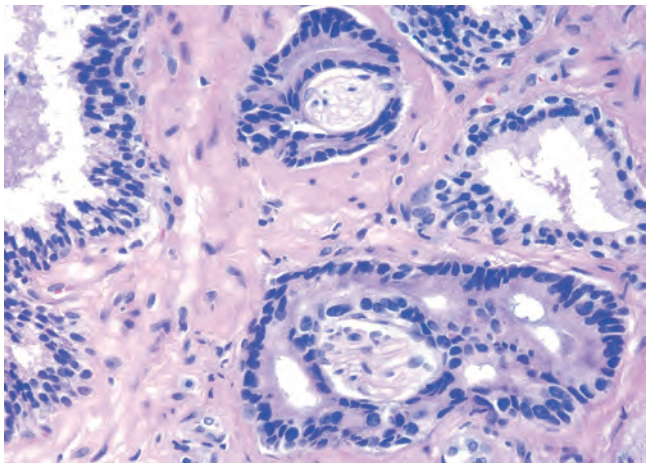

Figure 21.34 Carcinoma of prostate, showing perineural invasion by malignant glands. Compare to benign gland *(left)*.

is that benign glands contain basal cells, which are absent in cancer (compare benign normal glands in Fig. 21.33A and benign hyperplastic glands in Fig. 21.29C with cancerous glands in Fig. 21.33B). This distinction can be brought out by using various immunohistologic markers that stain basal cells. Another useful marker is α-methylacyl coenzyme A racemase (AMACR), which is upregulated in prostate cancer. Most prostate cancers are positive for AMACR, the sensitivity varying among studies from 82% to 100%. Such markers, while improving diagnostic accuracy, are still prone to false-positive and false-negative results and must be used in conjunction with the routine hematoxylin and eosin–stained sections.

As already discussed, in approximately 80% of cases prostatic tissue removed for carcinoma also harbors **prostatic intraepithelial neoplasia (PIN)**. PIN consists of architecturally benign large, branching prostatic acini lined by atypical cells with prominent nucleoli that may be cytologically identical to carcinoma. Unlike malignant glands, glands involved by PIN retain, at least partially, a layer of basal cells and have an intact basement membrane.

Grading and Staging. **Grade and stage are the most important prognostic factors in prostate cancer.** Grading is performed using the Gleason system, which stratifies prostate cancer into five grades on the basis of glandular patterns of growth. Grade 1 corresponds to well-differentiated tumors in which the neoplastic glands are uniform and round in appearance and are packed into well-circumscribed nodules (Fig. 21.35A). In contrast, grade 5 tumors do not form glands, with tumor cells infiltrating the stroma in cords, sheets, and solid nests (Fig. 21.35C). Other grades fall between

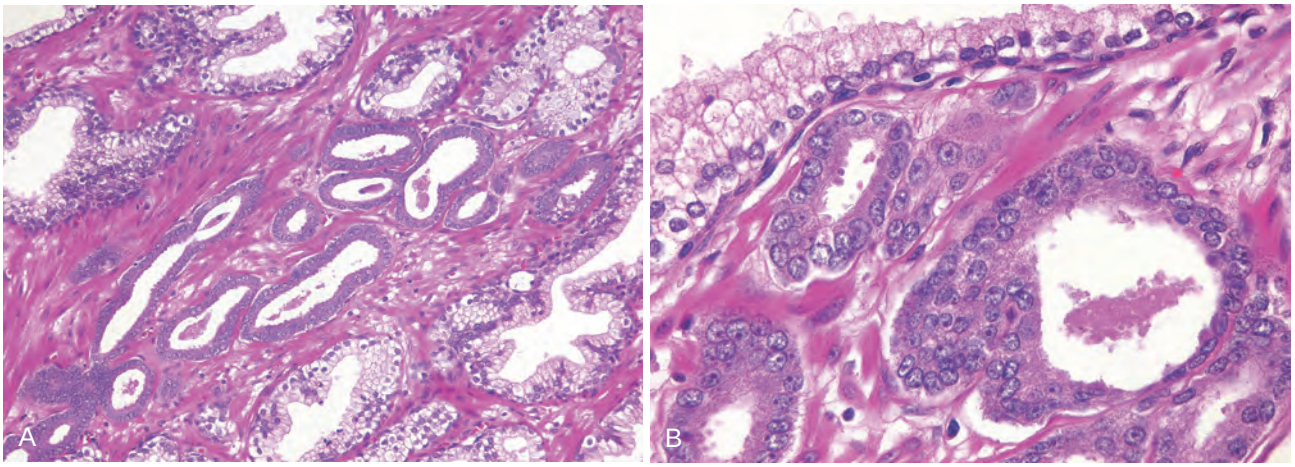

Figure 21.33 Prostatic adenocarcinoma. (A) Photomicrograph of small focus of adenocarcinoma of the prostate demonstrating small glands crowded in between larger benign glands. (B) Higher magnification shows several small malignant glands with enlarged nuclei, prominent nucleoli, and dark cytoplasm compared with larger benign gland *(top)*.

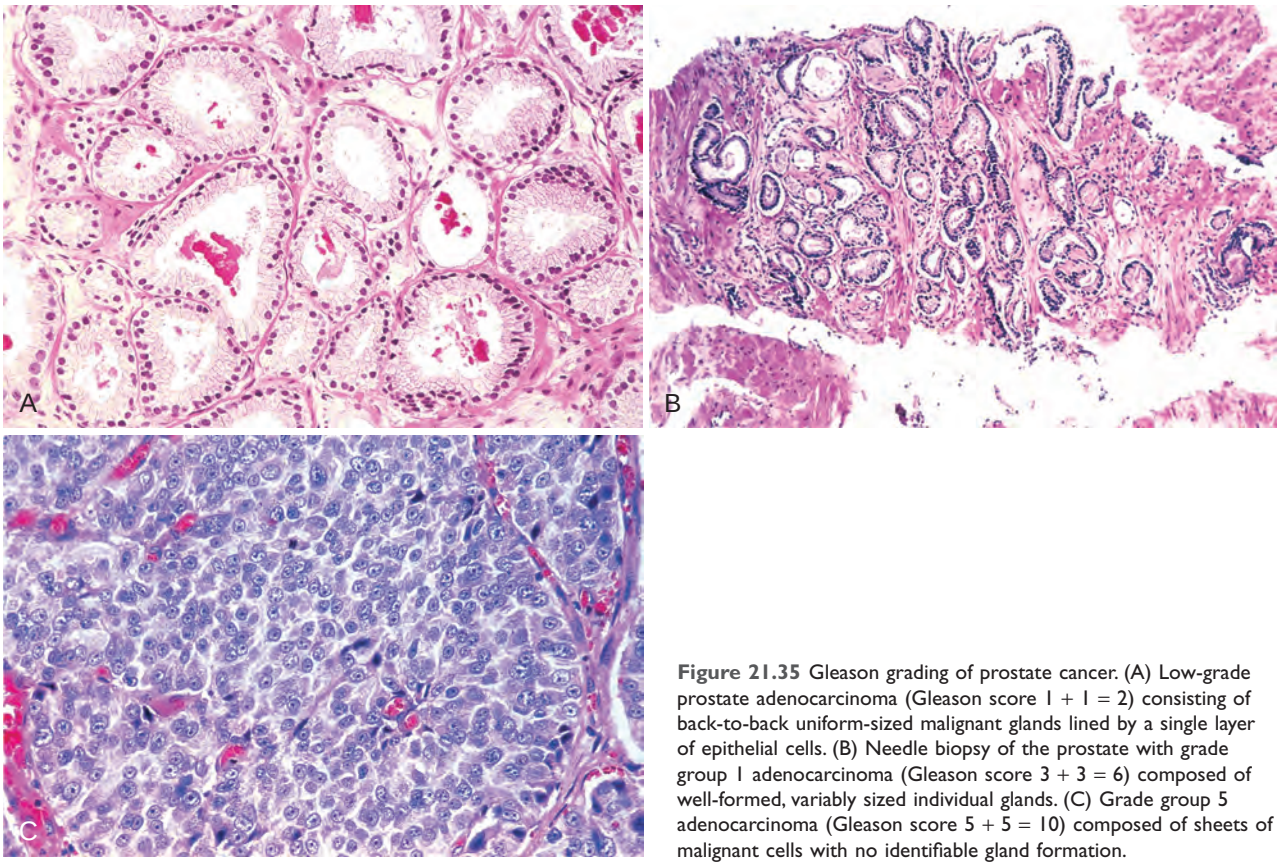

Figure 21.35 Gleason grading of prostate cancer. (A) Low-grade prostate adenocarcinoma (Gleason score 1 + 1 = 2) consisting of back-to-back uniform-sized malignant glands lined by a single layer of epithelial cells. (B) Needle biopsy of the prostate with grade group 1 adenocarcinoma (Gleason score 3 + 3 = 6) composed of well-formed, variably sized individual glands. (C) Grade group 5 adenocarcinoma (Gleason score 5 + 5 = 10) composed of sheets of malignant cells with no identifiable gland formation.

these extremes (Fig. 21.35B). Most tumors contain more than one pattern; in such instances, a primary grade is assigned to the dominant pattern, and a secondary grade is assigned to the second most frequent pattern. The two numeric grades are then added to obtain a combined Gleason score. Tumors with only one pattern are treated as if their primary and secondary grades are the same, and hence the number is doubled for the score. The majority of potentially treatable cancers detected on needle biopsy as a result of screening have Gleason scores of 6 or 7. Tumors with Gleason scores of 8 through 10 tend to be advanced cancers that are less likely to be cured. Although there is some evidence that prostate cancers can become more aggressive with time, most commonly, the Gleason score remains stable over a period of several years. Presently, Gleason scores are combined into five Grade Groups (Table 21.8), each with a different prognosis.

Pathologic staging of prostatic cancer is used in combination with the grade to stratify management of prostate cancer. As shown in Table 21.9, pTNM staging is based on tumor extent (T) and presence of nodal or distant metastasis (N and M). Grade is now integrated with TNM pathologic stage data to derive combined prognostic groups that result in "upstaging" of some tumors.

Clinical Features

Localized prostate cancer is asymptomatic and is usually discovered by the detection of a suspicious nodule on rectal examination or elevated serum prostate-specific antigen (PSA) level (discussed later). Digital rectal examination may detect some early prostatic carcinomas because of their posterior location, but suffers from both low sensitivity and specificity. Patients with clinically advanced prostatic cancer may present with symptoms of urinary obstruction. Typically, a transrectal needle biopsy is required to confirm the diagnosis.

Measurement of serum PSA levels is widely used to assist with the diagnosis and management of prostate cancer but is controversial. PSA is a product of prostatic epithelium and is normally secreted in the semen. It is an androgen-regulated serine protease whose function is to cleave and liquefy the seminal coagulum formed after ejaculation. In normal men, only minute amounts of PSA circulate in the serum. Elevated blood levels of PSA occur in association with localized as well as advanced cancer. However, as a screening test for prostate cancer, PSA measurement has suboptimal sensitivity and specificity.

Table 21.8 Prostate Cancer Gleason Grade Groups

- Grade Group 1 (≤6)
  Only individual discrete well-formed glands
- Grade Group 2 (3 + 4)
  Predominantly well-formed glands with a lesser component of poorly formed, fused or cribriform glands
- Grade Group 3 (4 + 3)
  Predominantly poorly formed/fused/cribriform glands with a lesser component of well-formed glands
- Grade Group 4 (4 + 4/3 + 5/5 + 3)
  Only poorly formed/fused/cribriform glands or predominantly mix of well-formed glands and lack of glands
- Grade Group 5 (4 + 5/5 + 4/5 + 5)
  Lack gland formation (or with necrosis) with or without poorly formed/fused/cribriform glands

Table 21.9 Pathologic Staging of Prostatic Adenocarcinoma Using the pTNM System

pTNM, AJCC 8th Edition	
pTNM Designation	**Anatomic Findings**
Extent of Primary Tumor (T)	
pT2	Organ confined
pT3	Extraprostatic extension
pT3a	Extraprostatic extension (unilateral or bilateral) or microscopic invasion of bladder neck
pT3b	Tumor invades seminal vesicles
pT4	Tumor is fixed or invades adjacent structures other than seminal vesicles, such as external sphincter, rectum, bladder, levator muscles, or pelvic wall
Definition of Regional Lymph Nodes (N)	
Nx	Regional nodes not accessed
N0	No regional nodal metastases
N1	Metastasis in regional lymph nodes
Definition of Distant Metastases (M)	
M0	No distant metastases
M1	Distant metastases present
M1a	Metastases to distant lymph nodes
M1b	Bone metastases
M1c	Other distant sites

AJCC, American Joint Commission on Cancer.

PSA is organ specific, but not cancer specific. Although serum levels of PSA are elevated on average to a lesser extent in patients with BPH than in those with prostate cancer, there is considerable overlap in these two groups of patients. Other factors such as prostatitis, prostate gland infarction (e.g., in the setting of BPH), instrumentation of the prostate, and ejaculation also increase serum PSA levels. Of even greater concern, many prostate cancers are so indolent that they are clinically insignificant, and detection of such cancers may lead to overtreatment, with its associated morbidity and economic costs. As a result of these concerns, some countries with national health care systems (e.g., the United Kingdom) have recommended against using PSA as a screening test. By contrast, once the diagnosis of prostate cancer has been established, serial measurements of PSA after treatment has clear-cut value in monitoring recurrence and disease progression.

Following the diagnosis of prostate cancer, the next challenge is to determine whether the cancer is biologically significant, that is, one that is likely to progress locally or metastasize. In addition to tumor grade, a number of genomic tests using gene panels have recently been developed that may enhance the ability to predict which cancers (e.g., low-volume Grade Group 1) can be followed by active surveillance alone. Patients with localized prostate cancer that is considered to be at high risk for local and systemic spread are treated with surgery or radiation, with or without hormonal manipulation. More than 90% of patients who receive such therapy can expect to live for 15 years. Currently, the most common treatment is radical prostatectomy. The prognosis following radical prostatectomy is based on the pathologic stage, margin status, and Gleason grade. For patients who are not candidates for surgery because of age or other medical conditions, radiotherapy with either external-beam radiation or placement of radioactive seeds in the prostate (brachytherapy) often provides excellent local control of disease.

Metastatic carcinoma is treated with androgen deprivation therapy. Androgen deprivation is usually achieved by orchiectomy or by administration of synthetic analogs of luteinizing hormone–releasing hormone (LHRH); chronic administration of LHRH agonists desensitizes pituitary cells expressing LHRH receptors, suppressing the release of luteinizing hormone (LH), which is required for testosterone production by Leydig cells. Although androgen deprivation therapy induces remissions, most tumors eventually become resistant to testosterone withdrawal, an event that is a harbinger of disease progression and death.

KEY CONCEPTS

CARCINOMA OF THE PROSTATE

- Carcinoma of the prostate is very common in older men. In the United States, it is the most common malignancy in men.
- Prostate carcinomas range from very indolent lesions, which are being increasingly managed by active surveillance, to lethal disease that requires definitive therapy.
- Carcinomas of the prostate arise most commonly in the outer, peripheral gland and may be palpable by rectal examination.
- The most common driver mutations in prostate cancer are gene rearrangements that result in androgen dependent overexpression of Ets family transcription factors, most commonly ERG or ETV1.
- Grading of prostate cancer by the Gleason system strongly correlates with pathologic stage and is a strong prognosticator. The system is compressed into Grade Groups that also influence the combined prognostic stage of the tumor.
- Most localized cancers are clinically silent and are detected by routine monitoring of PSA concentrations in older men. Bone metastases, often osteoblastic, typify advanced prostate cancer.
- Serum PSA measurement is a useful but imperfect cancer-screening test, with significant rates of false-negative and false-positive results. Evaluation of PSA concentrations after treatment has great value in monitoring progressive or recurrent disease.

Miscellaneous Tumors

Prostate adenocarcinomas may also arise from prostatic ducts. *Ductal adenocarcinoma* arising in peripheral ducts may present in a fashion similar to ordinary prostate cancer, whereas those arising in the larger periurethral ducts may show signs and symptoms similar to urothelial cancer, causing hematuria and urinary obstructive symptoms. Ductal adenocarcinomas are associated with a relatively poor prognosis. Prostate cancers may show squamous differentiation, either following hormone therapy or de novo, resulting in either adenosquamous or pure squamous cancer. Prostate cancers that reveal abundant mucinous secretions in greater than 25% of the tumor are termed *colloid carcinoma of the prostate.*

The most aggressive variant of prostate cancer is *small-cell carcinoma* (also known as neuroendocrine carcinoma). Almost all cases of small-cell carcinoma are rapidly fatal. This cancer is increasing in frequency and is most often seen as a form of recurrent disease in patients with typical prostate cancer undergoing treatment with antiandrogen therapies. While these therapies control conventional prostate cancers, in some cases they provoke the emergence of an androgen-independent sub-clone with a neuroendocrine phenotype.

The most common tumor to secondarily involve the prostate is urothelial cancer. Two distinct patterns of involvement exist. Large invasive urothelial cancers can directly invade from the bladder into the prostate. Alternatively, CIS of the bladder can extend into the prostatic urethra and down into the prostatic ducts and acini.

The same mesenchymal tumors described earlier that involve the bladder may also manifest in the prostate. In addition, there exist unique mesenchymal tumors of the prostate derived from the prostatic stroma.

CHAPTER 22

The Female Genital Tract

Lora Hedrick Ellenson • Edyta C. Pirog

CHAPTER CONTENTS

A brief review of the development and anatomy of the female genital tract is fundamental to understanding the diseases that affect this complex organ system. Normal development of the female genital tract proceeds through a series of tightly choreographed events involving the primordial germ cells, the müllerian (paramesonephric) ducts, the wolffian (mesonephric) ducts, and the urogenital sinus (Fig. 22.1).

- *Germ cells* arise in the wall of the yolk sac by the fourth week of gestation. By the fifth or sixth week, they migrate into the urogenital ridge and induce proliferation of the mesodermal epithelium, which gives rise to the epithelium and stroma of the ovary.
- The lateral *müllerian ducts* form at about the sixth week of development through invagination and fusion of the coelomic lining epithelium. The ducts progressively grow caudally into the pelvis, where they swing medially to fuse with the urogenital sinus at the müllerian tubercle (see Fig. 22.1A). Further caudal growth brings these fused ducts into contact with the urogenital sinus. The unfused upper portions of the müllerian ducts mature into the fallopian tubes, while the fused lower portion develops into the uterus, cervix, and upper vagina.
- The *urogenital sinus* develops when the cloaca is subdivided by the urorectal septum; it eventually forms the lower part of the vagina and the vestibule of the external genitalia (see Fig. 22.1B).
- The *mesonephric ducts* normally regress in the female, but remnants may persist into adult life as epithelial inclusions adjacent to the ovaries, tubes, and uterus. In the cervix and vagina, these rests may be cystic and are termed *Gartner duct cysts*.

The epithelial lining of the female genital tract as well as the ovarian surface share a common origin from coelomic epithelium (mesothelium), which may explain why morphologically similar benign and malignant lesions arise in various sites within the female genital tract and the adjacent peritoneal surfaces.

Diseases of the female genital tract are extremely common and include complications of pregnancy, infections, tumors, and hormonally induced abnormalities. The following discussion presents the pathology of the major diseases that result in clinical problems. Additional details can be found in current textbooks of gynecologic pathology and clinical obstetrics and gynecology. We will discuss the pathologic conditions peculiar to each segment of the female genital tract separately, but before doing so we will briefly review infections and pelvic inflammatory disease because they can affect many of the various anatomic structures concomitantly.

INFECTIONS

A large variety of organisms can infect the female genital tract. Some infections with microorganisms such as *Candida, Trichomonas,* and *Gardnerella* are very common and may cause significant discomfort, but are without serious sequelae. Others, such as *Neisseria gonorrhoeae* and *Chlamydia* infections, are major causes of infertility, while organisms such as *Group B Streptococcus* infections are implicated in preterm deliveries, stillbirths, and neonatal infections. Viruses, especially herpes simplex viruses (HSVs) and human papillomaviruses (HPVs), also account for considerable morbidity; HSVs cause painful genital ulcerations, whereas HPVs are involved in the pathogenesis of cervical, vaginal, and vulvar cancers (described later).

Many of these infections are sexually transmitted, including trichomoniasis, gonorrhea, *Mycoplasma, Chlamydia,* HSV, and HPV as well as less common infections such as syphilis, chancroid, granuloma inguinale, and lymphogranuloma venereum. Most of these conditions are considered in Chapter 8; HPV is also discussed in Chapter 7 due to its important

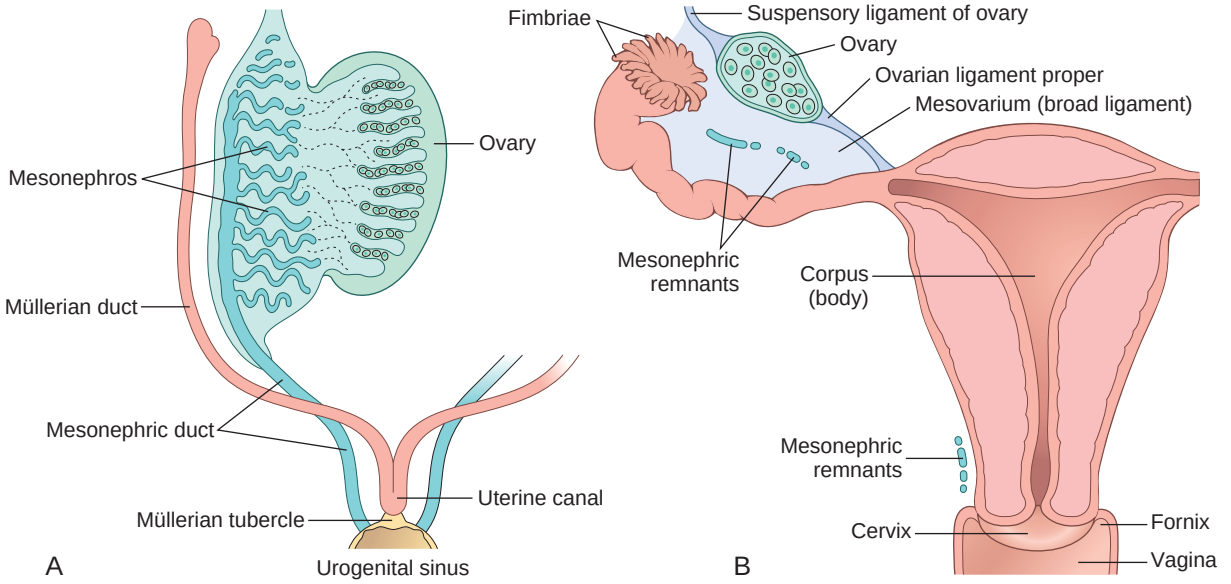

Figure 22.1 Embryology and anatomy of the female genital tract. (A) Early in development, the mesonephric *(blue)* and müllerian *(red)* ducts merge at the urogenital sinus to form the müllerian tubercle. (B) By birth, the müllerian ducts have fused to form the fallopian tubes, uterus, and endocervix *(red)*, merging with the vaginal squamous mucosa. The mesonephric ducts regress, but may be found as a remnant in the ovary, adnexa, and cervix (Gartner duct cysts). (Modified from Langman J: *Medical Embryology*, Baltimore, 1981, Williams and Wilkins.)

role as a transforming virus. Here we touch only on aspects relevant to the female genital tract, including pathogens confined to the lower genital tract (vulva, vagina, and cervix) and those that involve the entire genital tract and are implicated in pelvic inflammatory disease.

Infections of the Lower Genital Tract

Herpes Simplex Virus

Genital herpes simplex virus (HSV) infection is common and may involve the vulva, vagina, or cervix. HSVs are DNA viruses that include two serotypes, HSV-1 and HSV-2. HSV-1 typically results in perioral infection, whereas HSV-2 usually involves genital mucosa and skin; however, depending on sexual practices, HSV-1 may be detected in the genital region and HSV-2 may cause oral infections as well (Chapter 8). By 40 years of age, approximately 30% of women are seropositive for antibodies against HSV-2.

About one-third of newly infected individuals are symptomatic. Lesions typically develop 3 to 7 days after transmission and are often associated with systemic symptoms such as fever, malaise, and tender inguinal lymph nodes. The earliest lesions usually consist of red papules that progress to vesicles and then to painful coalescent ulcers. The lesions are easily visible on vulvar skin and mucosa, while cervical and vaginal lesions present with purulent discharge and pelvic pain. Lesions around the urethra may cause painful urination and urine retention. The vesicles and ulcers contain numerous viral particles, accounting for the high transmission rate during active infection. The mucosal and cutaneous lesions heal spontaneously in 1 to 3 weeks, but during the acute infection the virus migrates to the regional lumbosacral nerve ganglia and establishes a latent infection. Because of viral latency, HSV infections persist indefinitely, and any decrease in immune function due to stress, trauma, concurrent viral infection, or hormonal changes can trigger reactivation of the virus and recurrence of the skin and mucosal lesions. As expected, recurrences are much more common in immunosuppressed individuals.

MORPHOLOGY

By the time an HSV lesion is biopsied, it typically has ulcerated. The epithelium is desquamated, and marked acute inflammation is present in the ulcer bed. Smears of the inflammatory exudate from active lesions show characteristic cytopathic changes consisting of multinucleated squamous cells containing eosinophilic to basophilic viral inclusions with a "ground-glass" appearance (Fig. 22.2).

Transmission of HSV takes place mainly during the active phase but occasionally may occur during the latent phase due to subclinical virus shedding. Condoms and antiviral therapies reduce the risk of transmission, but do not prevent it completely. As with other sexually transmitted diseases, the virus is more readily transmitted to women than to men. Previous infection with HSV-1 seems to reduce susceptibility to HSV-2 infection. The gravest consequence of HSV infection is transmission to the neonate during birth. This risk is highest if the infection is active during delivery and particularly if it is a primary (initial) infection in the mother. Cesarean delivery is warranted in such cases to prevent transmission to the neonate. Another important consequence of active genital HSV infection is that it increases the risk of HIV-1 acquisition and transmission.

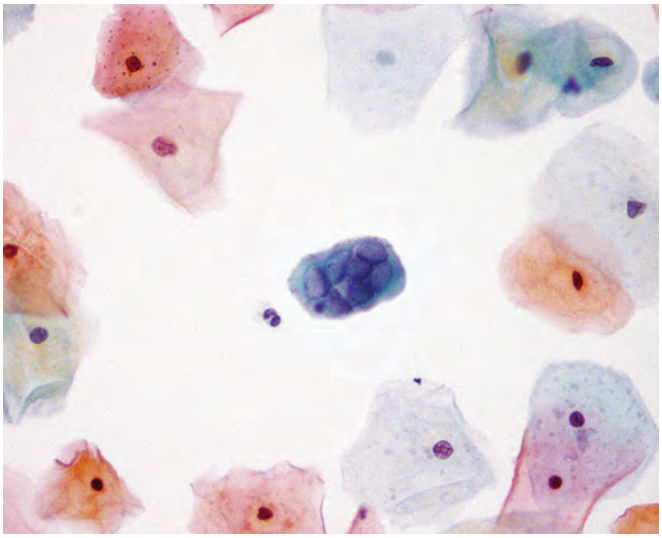

Figure 22.2 Herpes simplex virus (HSV) infection (cervical smear). The cell in the center shows HSV cytopathic effect. Infected cells become multinucleated and contain intranuclear viral inclusions with a characteristic "ground-glass" appearance.

The diagnosis is based on typical clinical findings and HSV detection. The purulent exudate is aspirated from the lesions and inoculated into a tissue culture. The viral cytopathic effect can be seen after 48 to 72 hours, and the virus can then be serotyped. In addition, some laboratories offer more sensitive polymerase chain reaction tests, enzyme-linked immunosorbent assays, and direct immunofluorescent antibody tests for detection of HSV in the lesional secretions. Individuals with primary, acute HSV infection do not have serum anti-HSV antibodies. Detection of anti-HSV antibodies in the serum is indicative of recurrent/latent infection.

There is no effective treatment for latent HSV; however, antiviral agents like acyclovir or famciclovir shorten the length of the initial and recurrent symptomatic phases. The ultimate solution is an effective vaccine, a tantalizing goal yet to be realized.

Other Lower Female Genital Tract Infections

As mentioned earlier, a variety of other viruses, fungi, and bacteria can also cause symptomatic infections of the lower genital tract. Those that are most common include the following:

- *Molluscum contagiosum* is a cutaneous or mucosal lesion caused by poxvirus (Fig. 22.3A). There are four types of molluscum contagiosum viruses (MCVs), MCV-1 to MCV-4, with MCV-1 being the most prevalent and MCV-2 being most often sexually transmitted. The infections are common in young children between 2 and 12 years of age, in whom they are transmitted through direct contact or shared articles (e.g., towels). Molluscum may affect any area of the skin but is most common on the trunk, arms, and legs. In adults, molluscum infections are typically sexually transmitted and affect the genitals, lower abdomen, buttocks, and inner thighs. The average

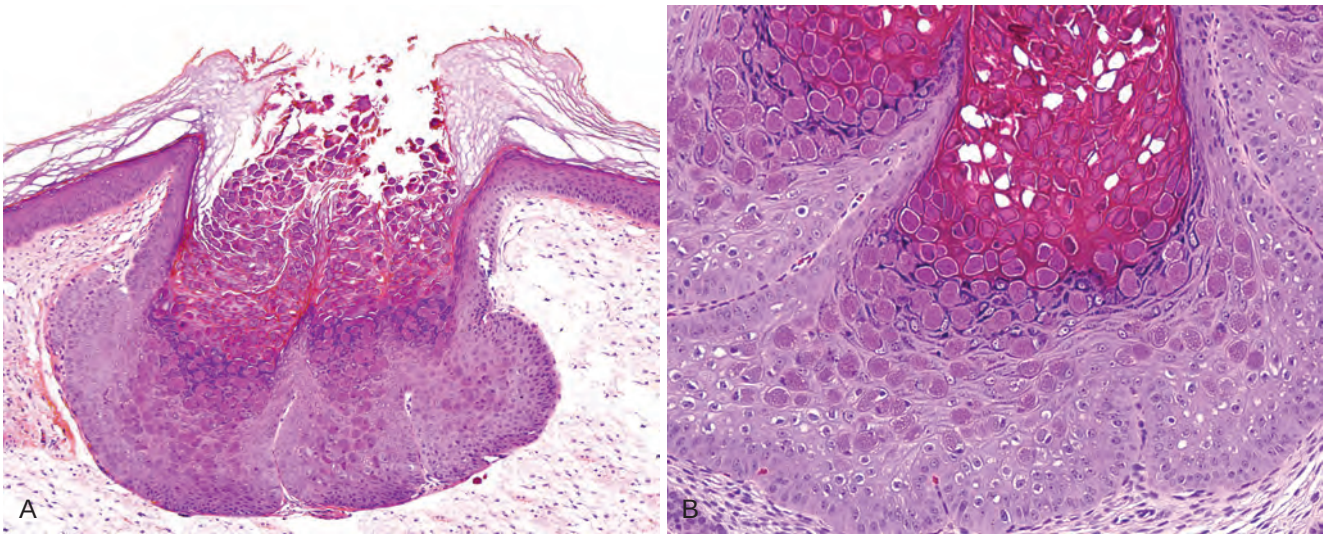

Figure 22.3 Molluscum contagiosum infection. (A) Low-power appearance of a dome-shaped papule with dimpled center. (B) High-power magnification reveals intracytoplasmic viral inclusions.

incubation period is 6 weeks. Diagnosis is based on the characteristic clinical appearance of pearly, dome-shaped papules with a dimpled center. The papules measure 1 to 5 mm in diameter, and their central waxy core contains cells with *cytoplasmic viral inclusions* (see Fig. 22.3B).

- *Fungal infections,* especially those caused by yeast *(Candida),* are extremely common; in fact, yeast are part of many women's normal vaginal microflora, and the development of symptomatic candidiasis is typically a result of a disturbance in the patient's vaginal microbial ecosystem. Diabetes mellitus, antibiotics, pregnancy, and conditions that compromise neutrophil or Th17 T-cell function increase the risk of symptomatic candidal infection, which manifests itself by marked vulvovaginal pruritus, erythema, swelling, and curdlike vaginal discharge. Severe infection may result in mucosal ulcerations. The diagnosis is made by finding the pseudospores or filamentous fungal hyphae in wet KOH mounts of the discharge or on Papanicolaou (Pap) smear. Even though sexual transmission of yeast infection has been documented, candidiasis is not considered a sexually transmitted disease.
- *Trichomonas vaginalis* is a large, flagellated ovoid protozoan that is usually transmitted by sexual contact. Infected patients may be asymptomatic or may complain of yellow, frothy vaginal discharge, vulvovaginal discomfort, dysuria (painful urination), and dyspareunia (painful intercourse). The vaginal and cervical mucosa typically has a fiery-red appearance, with marked dilation of cervical mucosal vessels resulting in characteristic colposcopic appearance of "strawberry cervix."
- *Gardnerella vaginalis* is a gram-negative coccobacillus that is implicated as the main cause of *bacterial vaginosis* (vaginitis). Patients typically present with thin, green-gray, malodorous (fishy) vaginal discharge. Pap smears reveal superficial and intermediate squamous cells covered with a shaggy coat of coccobacilli. Bacterial cultures in such cases reveal *G. vaginalis* and other bacteria, including anaerobic peptostreptococci and aerobic α-hemolytic streptococci. In pregnant patients, bacterial vaginosis has been implicated in premature labor.
- *Ureaplasma urealyticum* and *Mycoplasma hominis* species account for some cases of vaginitis and cervicitis and have been implicated in chorioamnionitis and premature delivery in pregnant patients.
- *Chlamydia trachomatis* infections mainly take the form of cervicitis. However, in some patients the infection may ascend to the uterus and fallopian tubes, resulting in endometritis and salpingitis; thus Chlamydia is one of the causes of pelvic inflammatory disease, as discussed next.

Infections Involving the Lower and Upper Genital Tract

Pelvic Inflammatory Disease (PID)

PID is an infection that begins in the vulva or vagina and spreads upward to involve most of the structures in the female genital system, resulting in pelvic pain, adnexal tenderness, fever, and vaginal discharge. *Neisseria gonorrhoeae* continues to be a common cause of PID, the most serious complication of gonorrhea in women. *Chlamydia* infection is another well-recognized cause of PID. Infections after spontaneous or induced abortions and normal or abnormal deliveries (called *puerperal infections*) are also important causes of PID. In these situations, the infections are typically polymicrobial and may be caused by staphylococci, streptococci, coliforms, and *Clostridium perfringens*.

With gonococcus, inflammatory changes start to appear approximately 2 to 7 days after inoculation. The initial infection most commonly involves the endocervical mucosa, but it may also begin in the Bartholin gland and other vestibular, or periurethral, glands. From these sites, the organisms may spread upward to involve the fallopian tubes and tuboovarian region. The non-gonococcal bacterial infections that follow induced abortion, dilation and curettage of the uterus, and other surgical procedures are thought to spread upward from the uterus through the lymphatics or venous

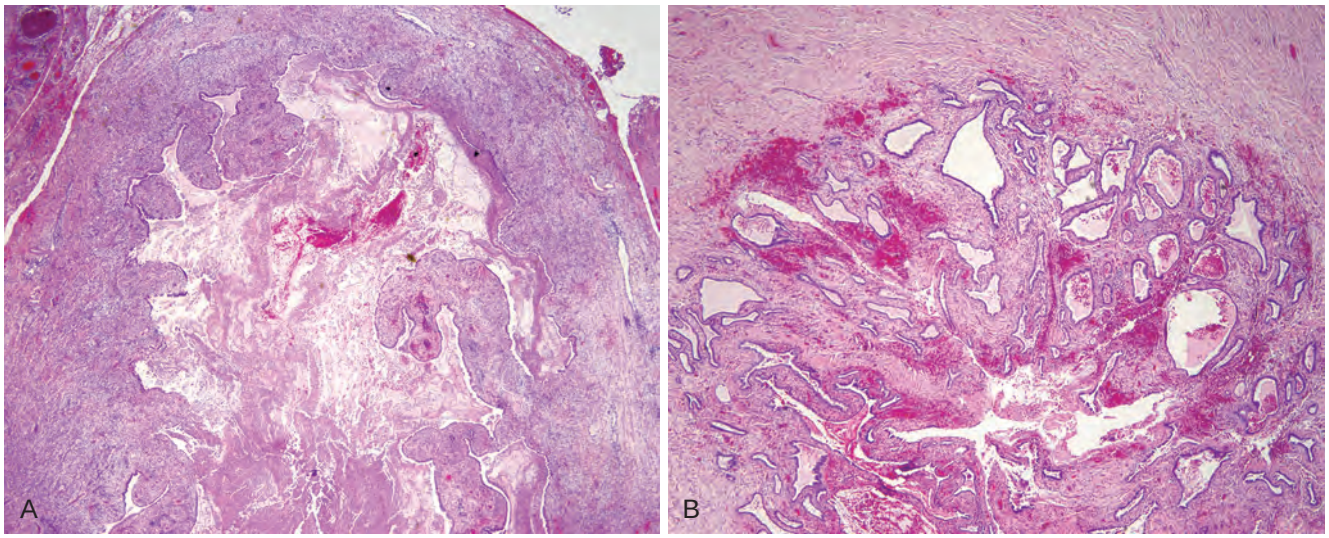

Figure 22.4 Salpingitis. (A) Acute salpingitis; note the dilated tube lumen and edematous tubal plicae expanded by inflammatory cell infiltrates. Pus fills the center of the fallopian tube. (B) Chronic salpingitis showing scarring and fusion of the plicae with formation of glandlike spaces. Such scarring may cause infertility or ectopic tubal pregnancy.

channels rather than on the mucosal surfaces. Therefore, these infections tend to produce more inflammation within the deeper layers of the organs than gonococcal infections.

MORPHOLOGY

Gonococcal infection is characterized by marked acute inflammation of involved mucosal surfaces. Smears of the inflammatory exudate disclose phagocytosed gram-negative diplococci within neutrophils; however, definitive diagnosis requires culture or detection of gonococcal RNA or DNA. If infection spreads, the endometrium is usually spared (for unclear reasons), but within the fallopian tubes, an **acute suppurative salpingitis** ensues (Fig. 22.4A). The tubal mucosa becomes congested and diffusely infiltrated by neutrophils, plasma cells, and lymphocytes, resulting in epithelial injury and sloughing of the plicae. The tubal lumen fills with purulent exudate that may leak out of the fimbriated end. The infection may then spread to the ovary to create a **salpingo-oophoritis.** Collections of pus may accumulate within the ovary and tube **(tubo-ovarian abscess)** or tubal lumen **(pyosalpinx)** (see Fig. 22.4A). With time, the infecting organisms may disappear, but the tubal plicae, denuded of epithelium, adhere to one another and slowly fuse in a reparative, scarring process that forms glandlike spaces and blind pouches, referred to as **chronic salpingitis** (see Fig. 22.4B). The scarring of the tubal lumen and fimbriae may prevent the uptake and passage of oocytes, leading to infertility or ectopic pregnancy. **Hydrosalpinx** may also develop as a consequence of the fusion of the fimbriae and the subsequent accumulation of the tubal secretions and tubal distention.

As compared to gonococcal infections, PID caused by staphylococci, streptococci, and the other puerperal invaders tends to show less involvement of the mucosa and the tube lumen, and more inflammation within the deeper tissue layers. These infections often spread throughout the wall to involve the serosa and the broad ligaments, pelvic structures, and peritoneum. Bacteremia is a more frequent complication of streptococcal or staphylococcal PID than of gonococcal infections.

The acute complications of PID include peritonitis and bacteremia, which in turn may result in endocarditis, meningitis, and suppurative arthritis. The chronic sequelae of PID include infertility and tubal obstruction, ectopic pregnancy, pelvic pain, and intestinal obstruction due to adhesions between the bowel and pelvic organs. In the early stages, gonococcal infections are usually readily controlled with antibiotics, although penicillin-resistant strains have emerged. Infections that become walled off in tubo-ovarian abscesses are difficult to eradicate with antibiotics, and it sometimes becomes necessary to remove the organs surgically. Postabortion and postpartum PIDs may also be amenable to treatment with antibiotics, but are far more difficult to control because of the broad spectrum of pathogens that may be involved.

Vulva

Diseases of the vulva in the aggregate constitute only a small fraction of gynecologic practice. Many inflammatory diseases that affect skin elsewhere on the body also occur on the vulva, such as psoriasis, eczema, and allergic dermatitis. Because it is constantly exposed to secretions and moisture, the vulva is more prone to superficial infections than skin elsewhere on the body. Nonspecific vulvitis is particularly likely to occur in the setting of immunosuppression. Most skin cysts (epidermal inclusion cysts) and skin tumors such as squamous cell carcinoma, basal cell carcinoma, and melanoma can also occur in the vulva. Here we discuss vulvar disorders that are relatively specific and

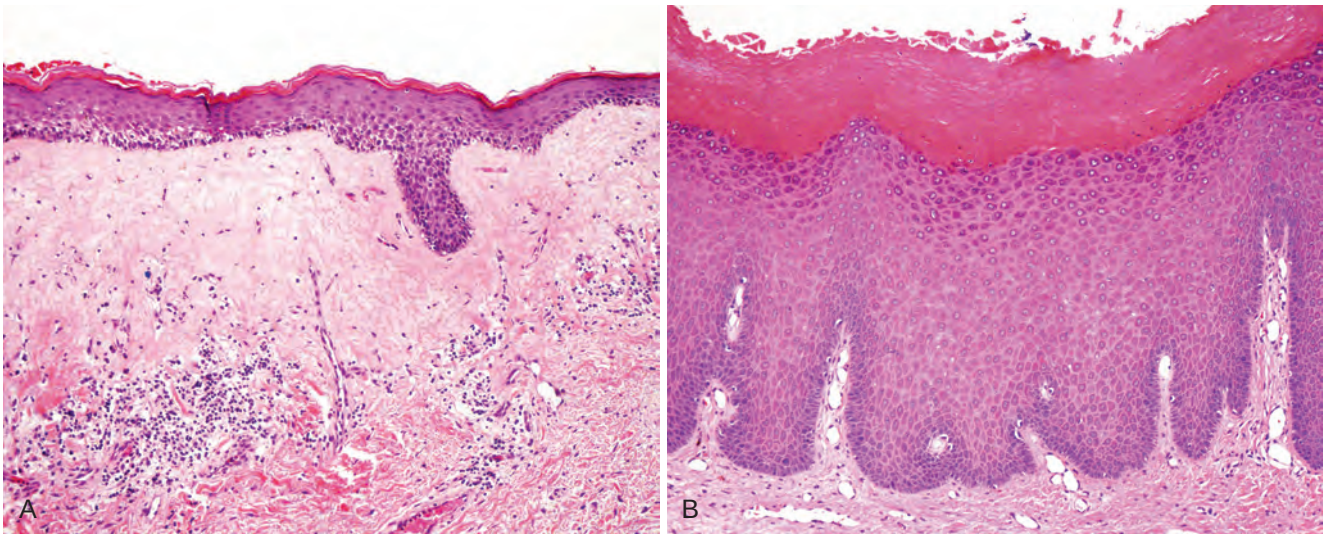

Figure 22.5 Non-neoplastic epithelial vulvar disorders. (A) Lichen sclerosus. There is marked thinning of the epidermis, sclerosis of the superficial dermis, and chronic inflammatory cells in deeper dermis. (B) Squamous cell hyperplasia, displaying thickened epidermis and hyperkeratosis.

common, including Bartholin cyst, non-neoplastic epithelial disorders, benign exophytic lesions, and tumors of the vulva.

BARTHOLIN CYST

Infection of the Bartholin gland produces an acute inflammation (adenitis) and may result in an abscess. Bartholin duct cysts are relatively common, occur at all ages, and result from obstruction of the duct by an inflammatory process. These cysts are usually lined by transitional or squamous epithelium. They may become large, up to 3 to 5 cm in diameter, and produce pain and local discomfort. Bartholin duct cysts are either excised or opened permanently (marsupialization).

NON-NEOPLASTIC EPITHELIAL DISORDERS

Leukoplakia is a descriptive clinical term for opaque, white, plaquelike epithelial thickening that may produce pruritus and scaling. Leukoplakia (literally, *white plaques*) may be caused by a variety of benign, premalignant, or malignant disorders, including the following:

- Inflammatory dermatoses (e.g., psoriasis, chronic dermatitis)
- Lichen sclerosus and squamous cell hyperplasia
- Neoplasias, such as vulvar intraepithelial neoplasia (VIN), Paget disease, and invasive carcinoma

Inflammatory dermatoses associated with leukoplakia are described in Chapter 25, while neoplastic disorders are discussed later in this chapter. Here the major non-neoplastic causes of leukoplakia—lichen sclerosis and squamous cell hyperplasia—are briefly discussed.

Lichen Sclerosus

Lichen sclerosis presents as smooth, white plaques or macules that in time may enlarge and coalesce, producing a surface that resembles porcelain or parchment. When the entire vulva is affected, the labia become atrophic and agglutinated, and the vaginal orifice constricts. Histologically, the lesion is characterized by marked thinning of the epidermis (Fig. 22.5A), degeneration of the basal epithelial cells, excessive keratinization (hyperkeratosis), sclerotic changes of the superficial dermis, and a bandlike lymphocytic infiltrate in the underlying dermis. The disease occurs in all age groups but is most common in postmenopausal women. It may also be encountered elsewhere on the skin. Its pathogenesis is uncertain, but the presence of activated T cells in the subepithelial inflammatory infiltrate and the increased frequency of autoimmune disorders in affected women suggest that an autoimmune reaction is involved. Although lichen sclerosus is not itself a premalignant lesion, women with symptomatic lichen sclerosus have a slightly increased chance of developing squamous cell carcinoma of the vulva.

Squamous Cell Hyperplasia

Previously called hyperplastic dystrophy or *lichen simplex chronicus,* squamous cell hyperplasia is a nonspecific condition resulting from rubbing or scratching of the skin to relieve pruritus. Clinically it presents as leukoplakia, and histologic examination reveals thickening of the epidermis (acanthosis) and hyperkeratosis (see Fig. 22.5B). Lymphocytic infiltration of the dermis is sometimes present. The hyperplastic epithelium may show mitotic activity but lacks cellular atypia. While squamous cell hyperplasia is not considered premalignant, it is sometimes present at the margins of vulvar cancers.

BENIGN EXOPHYTIC LESIONS

Benign raised (exophytic) or wartlike lesions of the vulva may be caused by infection or may be reactive conditions of unknown etiology. *Condyloma acuminatum,* a papillomavirus-induced lesion, also called a *genital wart,* and syphilitic *condyloma latum* (described in Chapter 21) are consequences

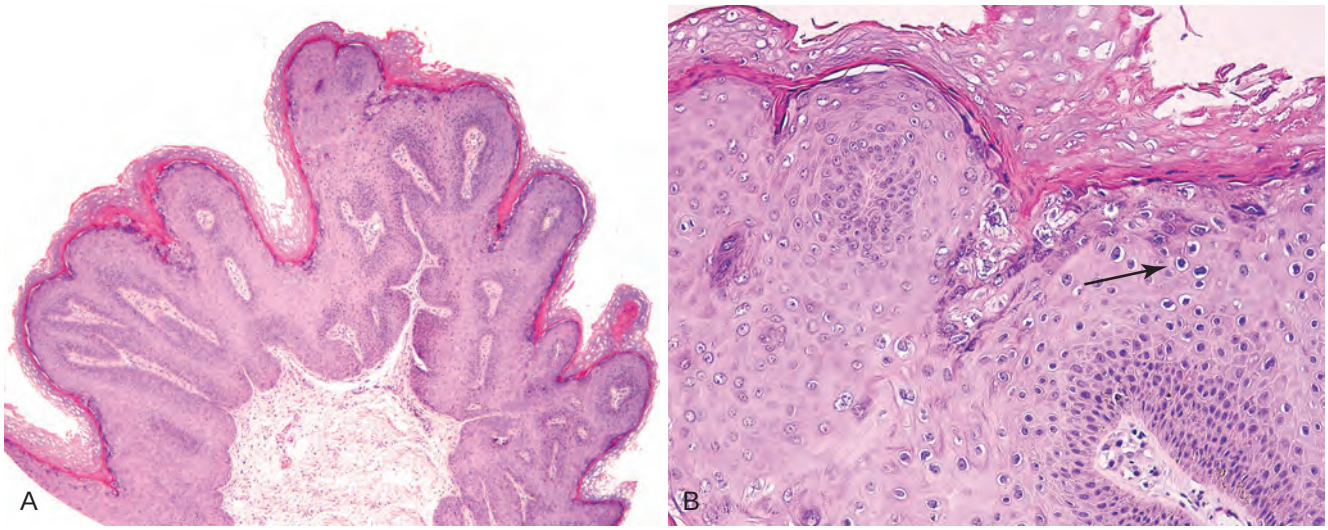

Figure 22.6 Condyloma acuminatum. (A) Low-power view showing exophytic, papillary architecture. (B) High-power view reveals human papillomavirus cytopathic effect (koilocytic atypia) characterized by atypical, enlarged, hyperchromatic nuclei with perinuclear halos *(arrow)*.

of sexually transmitted infections. Vulvar *fibroepithelial polyps,* or skin tags, are similar to skin tags occurring elsewhere on the skin. Vulvar *squamous papillomas* are benign exophytic proliferations covered by nonkeratinized squamous epithelium that develop on vulvar surfaces; they may be single or numerous (vulvar papillomatosis). The etiology of fibroepithelial polyps and squamous papillomas is unknown.

Condyloma Acuminatum

Condylomata acuminata are benign genital warts caused by low-risk HPV, mainly types 6 and 11. They may be solitary, but are more frequently multifocal, and they may involve vulvar, perineal, and perianal regions as well as the vagina and, less commonly, the cervix. The lesions are identical to those found on the penis and around the anus in males (Chapter 21). On histologic examination, they consist of papillary, exophytic, treelike cores of stroma covered by thickened squamous epithelium (Fig. 22.6A). The surface epithelium shows characteristic viral cytopathic changes referred to as *koilocytic atypia* (see Fig. 22.6B), which manifest as nuclear enlargement, hyperchromasia, and a cytoplasmic perinuclear halo (see the Cervix section later in this chapter). Condylomata acuminata are not precancerous lesions. HPV vaccines (described later) provide excellent protection against infection by low-risk HPV and genital warts.

SQUAMOUS NEOPLASTIC LESIONS

Vulvar Intraepithelial Neoplasia and Vulvar Carcinoma

Carcinoma of the vulva is an uncommon malignant neoplasm (approximately one-eighth as frequent as cervical cancer) representing about 3% of all genital cancers in the female; approximately two-thirds occur in women older than 60 years of age. Squamous cell carcinoma is the most common histologic type of vulvar cancer. In terms of etiology, pathogenesis, and histologic features, vulvar squamous cell carcinomas are divided into two groups:

- *Basaloid and warty carcinomas* are related to infection with high-risk HPVs, most commonly HPV-16. These are less common (30% of cases) and occur in younger women (average 60 years of age).
- *Keratinizing squamous cell carcinomas* are unrelated to HPV infection. These are more common (70% of cases) and occur in older women (average 75 years of age).

Basaloid and *warty carcinomas* develop from an in situ precursor lesion called *classic vulvar intraepithelial neoplasia* (VIN). This form of VIN occurs mainly in reproductive age women and includes lesions formerly designated as *carcinoma in situ* or *Bowen disease.* The risk factors for VIN are the same as those associated with cervical squamous intraepithelial lesions (e.g., young age at first intercourse, multiple sexual partners, male partner with multiple sexual partners), as both are related to HPV infection. VIN is frequently multicentric, and 10% to 30% of patients with VIN also have vaginal or cervical HPV-related lesions. Spontaneous regression of classic VIN has been reported, usually in younger women. The risk of progression to invasive carcinoma is higher in women who are older than 45 years of age or who are immunosuppressed.

Keratinizing squamous cell carcinoma occurs most often in individuals with long-standing lichen sclerosus or squamous cell hyperplasia and is not related to HPV. It arises from a precursor lesion referred to as *differentiated vulvar intraepithelial neoplasia* (differentiated VIN). It is postulated that chronic epithelial irritation in lichen sclerosus or squamous cell hyperplasia may contribute to a gradual evolution to the malignant phenotype, presumably through acquisition of driver mutations in oncogenes and tumor suppressor genes. In line with this idea, some investigators have reported a high frequency of *TP53* mutations in differentiated VIN.

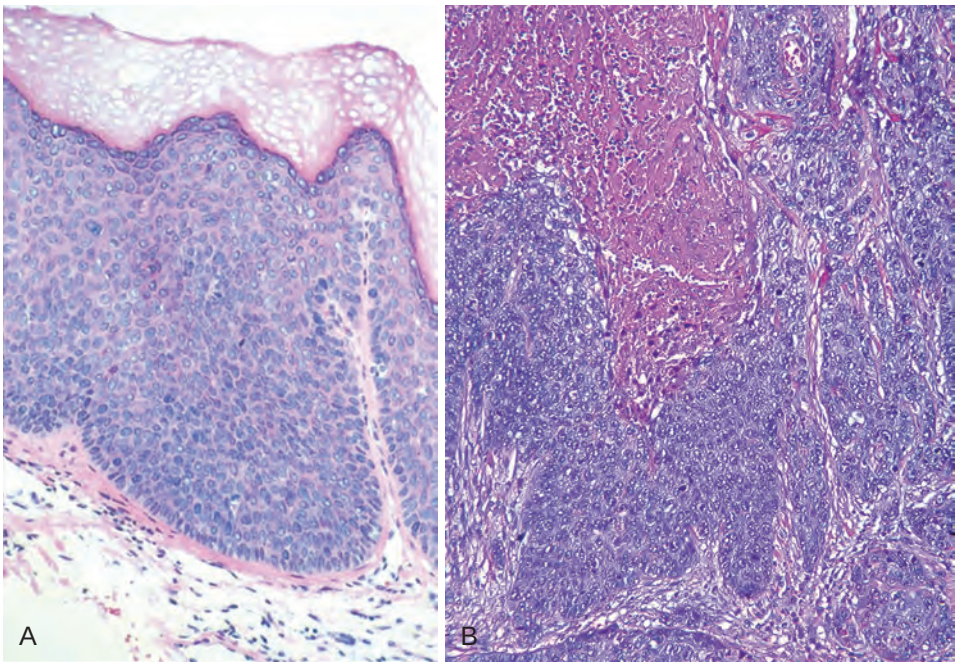

Figure 22.7 Human papillomavirus (HPV)-related vulvar pre-neoplastic and malignant lesions. (A) Classic vulvar intraepithelial neoplasia (HPV positive), showing small, immature basaloid cells encompassing full thickness of the epithelium. No invasion is present. (B) Basaloid vulvar carcinoma (HPV positive), composed of invasive small, immature (basaloid) cells. There is a focus of necrosis *(red area)*.

MORPHOLOGY

The lesions of **classic VIN** may be discrete and white (hyperkeratotic) or slightly raised and pigmented. Microscopically, it is characterized by epidermal thickening, nuclear atypia, increased mitoses, and lack of cellular maturation (Fig. 22.7A), features analogous to those seen in cervical squamous intraepithelial lesions (SIL, see the Cervix section later in this chapter). Invasive carcinomas that arise from classic VIN may be exophytic or indurated with central ulceration. On histologic examination, basaloid carcinoma (see Fig. 22.7B) consists of nests and cords of small, tightly packed cells that lack maturation and resemble the basal layer of the normal epithelium. The tumor may have foci of central necrosis. By contrast, warty carcinoma is characterized by exophytic, papillary architecture and prominent koilocytic atypia.

Differentiated VIN is characterized by marked atypia of the basal layer of the squamous epithelium and normal-appearing differentiation of the more superficial layers (Fig. 22.8A). Invasive keratinizing squamous cell carcinomas that arise in differentiated VIN contain nests and tongues of malignant squamous epithelium with prominent central keratin pearls (see Fig. 22.8B).

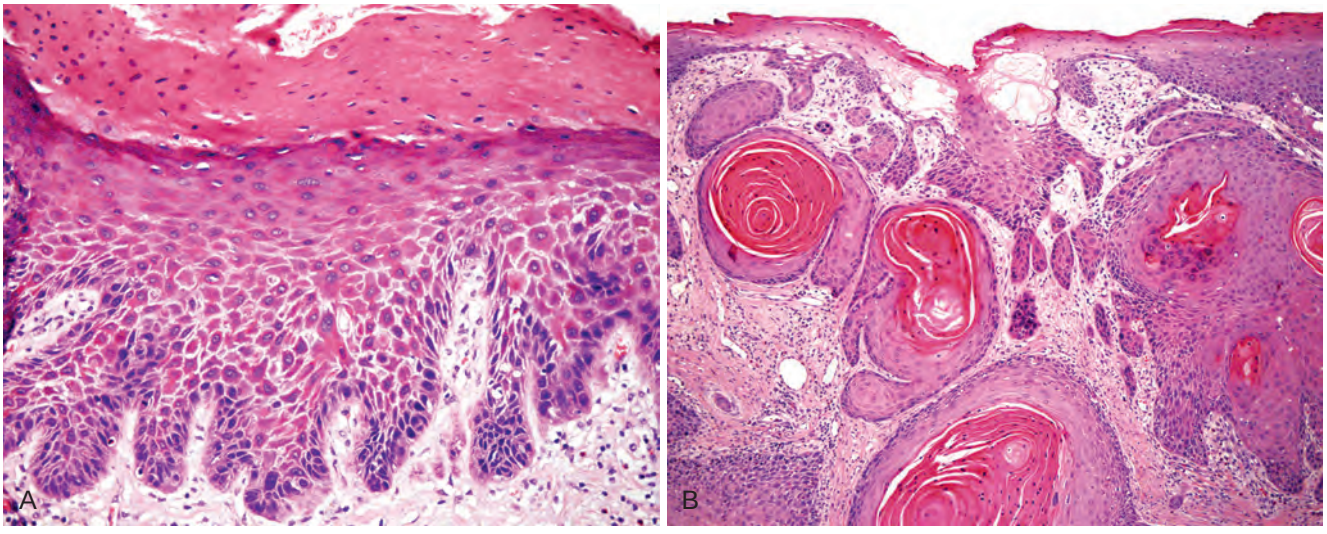

Figure 22.8 Non–human papillomavirus (HPV) vulvar pre-neoplastic and malignant lesions. (A) Differentiated vulvar intraepithelial neoplasia (HPV negative), showing maturation of the superficial layers, hyperkeratosis, and atypia of basal epithelial cells. No invasion is present. (B) Well-differentiated, keratinizing squamous cell carcinoma of the vulva (HPV negative) composed of invasive tumor nests with central keratin pearls.

The risk of cancer development in VIN depends on duration and extent of disease, and the immune status of the patient. Invasive carcinomas associated with lichen sclerosus, squamous cell hyperplasia, and differentiated VIN may develop in an insidious fashion and may be misinterpreted as dermatitis or leukoplakia for long periods. Once invasive cancer develops, the risk of metastatic spread is determined by the size of tumor, the depth of invasion, and whether there is lymphatic invasion. The initial spread is to inguinal, pelvic, iliac, and periaortic lymph nodes. Ultimately, hematogenous dissemination to the lungs, liver, and other internal organs may occur. Patients with lesions less than 2 cm in diameter have a 90% 5-year survival rate after treatment with vulvectomy and lymphadenectomy; however, larger lesions with lymph node involvement have a poor prognosis.

GLANDULAR NEOPLASTIC LESIONS

Like the breast, the vulva contains modified apocrine sweat glands. Presumably because of these "breastlike" features, the vulva may be involved by two tumors with counterparts in the breast, papillary hidradenoma and extramammary Paget disease.

Papillary Hidradenoma

Papillary hidradenoma presents as a sharply circumscribed nodule, most commonly on the labia majora or interlabial folds, and may be confused clinically with carcinoma because of its tendency to ulcerate. Its histologic appearance is identical to that of intraductal papilloma of the breast and consists of papillary projections covered by two cell layers, an upper layer of columnar secretory cells and a deeper layer of flattened myoepithelial cells. These myoepithelial elements are characteristic of sweat glands and sweat gland tumors (Fig. 22.9).

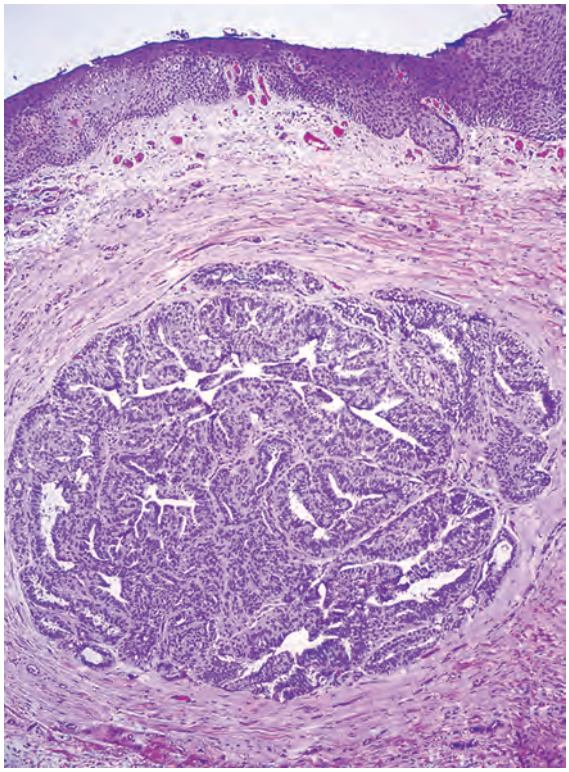

Figure 22.9 Papillary hidradenoma of the vulva, a well-circumscribed tumor composed of benign papillary projections covered with columnar secretory epithelium and underlying myoepithelial cells.

Extramammary Paget Disease

This curious and rare lesion of the vulva is similar in its manifestations to Paget disease of the breast (Chapter 23). In the vulva, it presents as a pruritic, red, crusted, maplike area, usually on the labia majora.

In contrast to Paget disease of the nipple, in which 100% of patients have an underlying ductal breast carcinoma, vulvar Paget is typically not associated with underlying cancer and is confined to the vulvar epidermis. Treatment consists of wide local excision, which is necessary because Paget cells spread laterally within the epidermis and may be present beyond the confines of the grossly visible lesion. Intra-epidermal Paget disease may persist for many years or even decades without invasion or metastases. In the rare instances when invasion develops, the prognosis is poor.

MORPHOLOGY

Paget disease is a distinctive intraepithelial proliferation of malignant cells. Paget cells are larger than surrounding keratinocytes and are seen singly or in small clusters within the epidermis (Fig. 22.10A). The cells have pale cytoplasm containing mucopolysaccharide that stains with periodic acid–Schiff (PAS), Alcian blue, or mucicarmine stains. In addition, unlike squamous epithelium, the cells express cytokeratin 7 (see Fig. 22.10B). Ultrastructurally, Paget cells display apocrine, eccrine, and keratinocyte differentiation and presumably arise from multipotent cells found within the mammary gland–like ducts of the vulvar skin.

KEY CONCEPTS

- Approximately 30% of vulvar cancers are caused by infection with high-risk HPVs, principally HPV-16. These cancers develop from an in situ lesion termed classic vulvar intraepithelial neoplasia (classic VIN).
- Most vulvar cancers (70%) are not related to HPV and develop in a background of lichen sclerosus or squamous cell hyperplasia from the premalignant lesion called differentiated vulvar intraepithelial neoplasia (differentiated VIN).

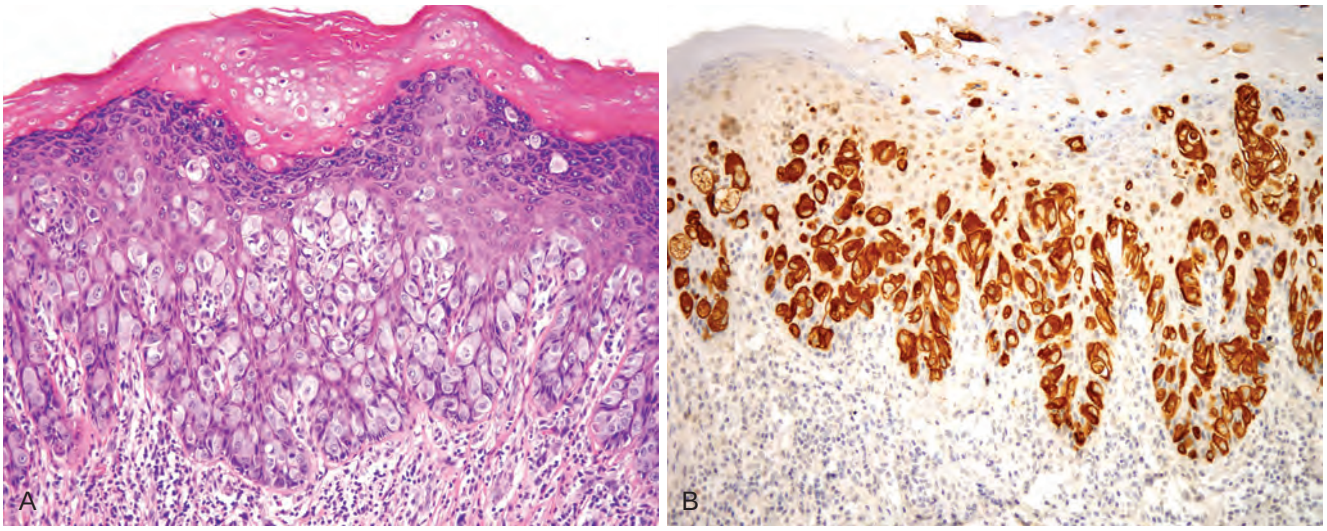

Figure 22.10 Paget disease of the vulva. (A) The epidermis is infiltrated by large cells with pale-pink cytoplasm that are spreading along the basal portion of the squamous epithelium. There is inflammation in the underlying dermis. (B) Immunostaining for cytokeratin 7 highlights the intraepidermal Paget cells.

Vagina

The vagina is a portion of the female genital tract that is remarkably resistant to diseases that affect nearby structures. For example, in the adult, inflammation that begins in the vulva and perivulvar structures often spreads to the cervix without significant involvement of the vagina. Primary lesions of the vagina are rare, the most serious being vaginal squamous cell carcinoma; they are discussed only briefly here.

DEVELOPMENTAL ANOMALIES

Septate, or double, vagina is an uncommon anomaly that arises from a failure of müllerian duct fusion and is accompanied by a double uterus *(uterus didelphys)*. These and other anomalies of the external genitalia may be the manifestations of genetic syndromes, in utero exposure to diethylstilbestrol (DES, used to prevent threatened abortions in the 1940s to 1960s), or other unknown factors that perturb reciprocal epithelial-stromal signaling during fetal development.

During embryonal development, the vagina is initially covered by columnar, endocervical-type epithelium. This is normally replaced by squamous epithelium advancing upward from the urogenital sinus. Small patches of residual glandular epithelium may persist into adult life; such areas are recognized as *vaginal adenosis,* which on examination presents as red, granular areas that stand out from the surrounding normal pale-pink vaginal mucosa. Microscopically, adenosis consists of columnar mucinous epithelium indistinguishable from endocervix. Adenosis is found in only a small percentage of adult women, but has been reported in 35% to 90% of women exposed to DES in utero. Rare cases of clear cell carcinoma arising in DES-related adenosis were recorded in teenagers and young adult women in the 1970s and 1980s, resulting in discontinuation of DES treatment.

Gartner duct cysts are relatively common lesions found along the lateral walls of the vagina that are derived from wolffian (mesonephric) duct rests. They consist of 1- to 2-cm fluid-filled submucosal cysts. Other cysts, including mucus cysts, which occur in the proximal vagina, are derived from müllerian epithelium. Another müllerian-derived lesion, endometriosis (described later), may occur in the vagina and clinically simulate a neoplasm.

PREMALIGNANT AND MALIGNANT NEOPLASMS OF THE VAGINA

Most benign tumors of the vagina occur in reproductive-age women and include stromal tumors (stromal polyps), leiomyomas, and hemangiomas. The most common malignant tumor to involve the vagina is carcinoma spreading from the cervix, followed by primary squamous cell carcinoma of the vagina. Infants may develop a unique, rare malignancy—embryonal rhabdomyosarcoma (sarcoma botryoides).

Vaginal Intraepithelial Neoplasia and Squamous Cell Carcinoma

Virtually all primary carcinomas of the vagina are squamous cell carcinomas associated with high-risk HPV infection. Vaginal carcinoma is extremely uncommon (about 0.6 per 100,000 women yearly) and accounts for about 1% of malignant neoplasms in the female genital tract. The greatest risk factor is a previous carcinoma of the cervix or vulva; 1% to 2% of women with an invasive cervical carcinoma eventually develop a vaginal squamous cell carcinoma. Squamous cell carcinoma of the vagina arises from a premalignant lesion, *vaginal intraepithelial neoplasia,* analogous to cervical squamous intraepithelial lesion (SIL; see the Cervix section later in this chapter). Most often the invasive tumor affects the upper vagina, particularly the posterior wall at the junction with the ectocervix. The lesions in the lower two-thirds of the vagina metastasize to the inguinal nodes, whereas lesions in the upper vagina tend to spread to regional iliac nodes.

Embryonal Rhabdomyosarcoma

Also called *sarcoma botryoides,* this uncommon vaginal tumor composed of malignant embryonal rhabdomyoblasts is most frequently found in infants and children younger than 5 years of age. These tumors tend to grow as polypoid, rounded, bulky masses that have the appearance and consistency of grapelike clusters (hence the designation *botryoides,* or grapelike) (Fig. 22.11). The tumor cells are small and have oval nuclei, with small protrusions of cytoplasm from one end, resembling a tennis racket. Rarely, striations (indicative of muscle differentiation) can be seen within the cytoplasm. Beneath the vaginal epithelium, the tumor cells are crowded in a so-called cambium layer, but in the deep regions they lie within a loose edematous fibromyxomatous stroma that may contain many inflammatory cells. Such lesions can be mistaken for benign inflammatory polyps. The tumors tend to invade locally and cause death by penetration into the peritoneal cavity or by obstruction of the urinary tract. Conservative surgery coupled with chemotherapy offer the best hope, particularly in cases diagnosed sufficiently early.

Cervix

Anatomically the cervix consists of the external vaginal portio (ectocervix) and the endocervical canal. The ectocervix is visible on vaginal examination and is covered by a mature squamous epithelium that is continuous with the vaginal wall. The squamous epithelium converges centrally at a small opening termed the *external os* that leads to the endocervical canal. The endocervix is lined by columnar, mucus-secreting epithelium. The point where the squamous and the columnar epithelium meet is referred to as the *squamocolumnar junction* (Fig. 22.12). The position of the junction is variable and changes with age and hormonal influence, but in general the junction moves upward into the endocervical canal with time. The replacement of the glandular epithelium by advancing squamous epithelium is a process called squamous metaplasia. The area of the cervix where the columnar epithelium coexists with the squamous epithelium is termed the "*transformation zone.*" The unique epithelial environment of the cervix renders it highly susceptible to infection with HPV, the main cause of cervical cancer. Immature squamous cells in the transformation zone are most susceptible to HPV infection, and as a result this is where the majority of cervical precursor lesions and cervical cancers develop.

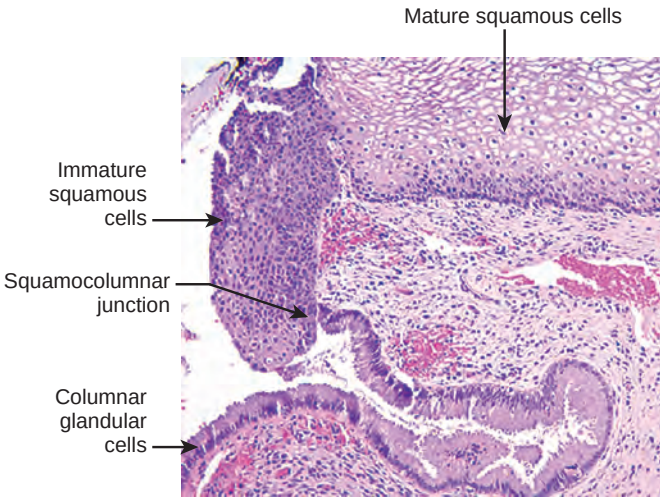

Figure 22.12 Cervical squamocolumnar junction showing a transition from mature, glycogenized squamous epithelium to columnar endocervical glandular epithelium. The superficial, mature squamous epithelial cells are not susceptible to human papillomavirus (HPV) infection. The HPV-susceptible cells include immature basal squamous cells and endocervical glandular cells.

INFLAMMATIONS

Acute and Chronic Cervicitis

At the onset of menarche, the production of estrogens by the ovary stimulates maturation of the cervical and vaginal squamous mucosa and formation of intracellular glycogen vacuoles in the squamous cells. As these cells are shed, the glycogen provides a substrate for various endogenous vaginal aerobes and anaerobes, but particularly lactobacilli, which are the dominant microbial species in the normal vagina. Lactobacilli produce lactic acid, which maintains the vaginal pH below 4.5, suppressing the growth of other saprophytic and pathogenic organisms. In addition, at low pH, lactobacilli produce bacteriotoxic hydrogen peroxide (H_2O_2). If the pH becomes alkaline due to bleeding, sexual intercourse, or vaginal douching, H_2O_2 production by lactobacilli decreases. Antibiotic therapy that suppresses lactobacilli can also cause the pH to rise. In each of these settings, the altered vaginal environment promotes the overgrowth

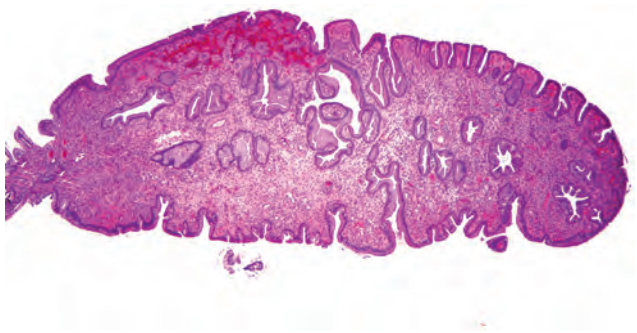

Figure 22.13 Endocervical polyp composed of a dense fibrous stroma covered with endocervical columnar epithelium.

of other microorganisms, which may result in cervicitis or vaginitis. Some degree of cervical inflammation may be found in virtually all women, and it is usually of little clinical consequence. However, infections by gonococci, chlamydiae, mycoplasmas, and HSV may produce significant acute or chronic cervicitis and are important to identify due to their association with upper genital tract disease, complications during pregnancy, and sexual transmission. Marked cervical inflammation produces reparative and reactive changes of the epithelium and shedding of atypical-appearing squamous cells, and therefore may cause an abnormal Pap test result.

ENDOCERVICAL POLYPS

Endocervical polyps are common benign exophytic growths that arise within the endocervical canal. They vary from small, sessile "bumps" to large polypoid masses that may protrude through the cervical os. Histologically, they are composed of a fibrous stroma covered by mucus-secreting endocervical glands, often accompanied by inflammation (Fig. 22.13). Their main significance is that they may be the source of irregular vaginal "spotting" or bleeding that arouses suspicion of some more ominous lesion. Simple curettage or surgical excision is curative.

PREMALIGNANT AND MALIGNANT NEOPLASMS OF THE CERVIX

Worldwide, cervical carcinoma is the fourth most common cancer in women, with an estimated 570,000 new cases in 2018, of which more than one-half will prove fatal. In the United States, it was estimated in 2019 that 13,179 women would be diagnosed with cervical cancer and that 4250 women would die of the disease. Fifty years ago, carcinoma of the cervix was the leading cause of cancer death in women in the United States, but the death rate has declined by 75% to its present rank as the thirteenth cause of cancer mortality. No form of cancer better documents the remarkable benefits of effective screening, early diagnosis, and curative therapy than does cancer of the cervix. Most credit for these dramatic gains belongs to the effectiveness of the Pap test in detecting cervical precursor lesions, some of which would have progressed to cancer if not treated; in addition, the Pap test can also detect low-stage, highly curable cancers. The accessibility of the cervix to Pap testing and visual examination (colposcopy) as well as the slow progression from precursor lesions to invasive carcinoma (typically over the course of decades) provides ample time for screening, detection, and preventive treatment.

Pathogenesis

High-risk HPVs are by far the most important factor in the development of cervical cancer. HPVs are DNA viruses that are grouped into those of high and low oncogenic risk based on their genotypes. There are 15 high-risk HPVs that are currently identified, but HPV-16 alone accounts for almost 60% of cervical cancer cases, and HPV-18 accounts for another 10% of cases; other HPV types contribute to less than 5% of cases, individually. High-risk HPVs are also implicated in squamous cell carcinomas arising at many other sites, including the vagina, vulva, penis, anus, tonsil, and other oropharyngeal locations. As noted earlier, low oncogenic risk HPVs are the cause of sexually transmitted vulvar, perineal, and perianal warts (condyloma acuminatum).

Genital HPV infections are extremely common; most of them are asymptomatic, do not cause any tissue changes, and therefore are not detected on Pap test. The prevalence of HPV in cervical smears in women with normal Pap test results peaks between 20 and 24 years of age, around the onset of sexual activity, and subsequently declines as protective immunity is established and women enter into monogamous relationships. Most HPV infections are transient; overall, 50% of HPV infections are cleared within 8 months, and 90% of infections are cleared within 2 years. The duration of the infection is related to HPV type, as infections with high-risk HPVs take longer to clear on average than infections with low-risk HPVs (13 months vs. 8 months, respectively). Persistent infection increases the risk of the development of cervical precursor lesions and subsequent carcinoma.

Productive, persistent HPV infection requires viral entry into immature basal epithelial cells. As a result, surfaces covered with mature, intact squamous epithelium, such as the ectocervix, vagina, vulva, penis, and oropharynx, are normally resistant to HPV infection. Sites in the female genital tract that are susceptible to infection include areas of squamous epithelial trauma and repair, where the virus may access basal cells, and the immature metaplastic squamous cells that are present at the squamocolumnar junction of the cervix (see Fig. 22.12). The cervix, with its relatively large areas of immature squamous metaplastic epithelium, is particularly vulnerable to HPV infection. Other sites in the body that are vulnerable to HPV infection include the squamocolumnar junction of the anus and the squamous cells of oropharyngeal tonsillar crypts, both relatively common sites of HPV-associated cancers in individuals who practice anal or oral sex, respectively.

The ability of HPV to act as a carcinogen depends on the viral E6 and E7 proteins, which interfere with the activity of the key tumor suppressor proteins, p53 and RB, respectively. Although HPV infects immature squamous cells, viral replication occurs in maturing squamous cells. Normally, these more mature cells are arrested in the G_1 phase of the cell cycle, but they continue to actively progress through the cell cycle when infected with HPV, which uses

the host cell DNA synthesis machinery to replicate its own genome. As you will recall from Chapter 7, viral E7 protein binds the hypophosphorylated (active) form of RB and promotes its degradation via the proteasome pathway, and also binds and inhibits p21 and p27, two important cyclin-dependent kinase inhibitors. Removal of these controls not only enhances cell cycle progression, but also impairs the ability of cells to repair DNA damage. The DNA repair defect in infected cells is exacerbated by E6 proteins encoded by high-risk HPV subtypes, which bind p53 and promote its degradation by the proteasome. In addition, E6 up-regulates the expression of telomerase, which leads to cellular immortalization. The net effect is increased proliferation of cells that are prone to acquire additional mutations that may lead to cancer development. By contrast to high-risk HPVs, the E7 proteins of low-risk HPVs bind RB with lower affinity, while the E6 proteins of low-risk HPVs fail to bind p53 altogether and instead appear to dysregulate growth and survival by interfering with the Notch signaling pathway.

Another factor that contributes to malignant transformation by HPV is the physical state of the virus. The viral DNA is integrated into the host cell genome in most cancers. This configuration increases the expression of *E6* and *E7* genes, and may also dysregulate oncogenes near the sites of viral insertion, such as *MYC*. By contrast, viral DNA is extrachromosomal (episomal) in precursor lesions associated with high-risk HPVs and in condylomata associated with low-risk HPVs.

Even though HPV is firmly established as the major cause of cervical cancer, it is worth remembering that although a high percentage of young women are infected with one or more HPV types during their reproductive years, only a few develop cancer. Thus, other factors, such as exposure to co-carcinogens and host immune status, influence whether an HPV infection regresses or persists and eventually leads to cancer.

Cervical Intraepithelial Neoplasia (Squamous Intraepithelial Lesions)

The classification of cervical precursor lesions has evolved over time, and the terms from the various classification systems are used interchangeably. Hence a brief review of the terminology is warranted. The oldest classification system grouped lesions as having mild dysplasia on one end and severe dysplasia/carcinoma in situ on the other. This was followed by the *cervical intraepithelial neoplasia* (CIN) classification, with mild dysplasia termed *CIN I,* moderate dysplasia termed *CIN II,* and severe dysplasia termed *CIN III*. Because the decision with regard to patient management is two-tiered (observation vs. surgical treatment), the three-tier classification system has been recently simplified to a two-tiered system, with CIN I renamed low-grade squamous intraepithelial lesion (LSIL) and CIN II and CIN III combined into one category referred to as high-grade squamous intraepithelial lesion (HSIL) (Table 22.1).

Table 22.1 Classification Systems for Squamous Cervical Precursor Lesions

Dysplasia/Carcinoma in situ	CIN	SIL, Current Classification
Mild dysplasia	CIN I	Low-grade SIL (LSIL)
Moderate dysplasia	CIN II	High-grade SIL (HSIL)
Severe dysplasia	CIN III	High-grade SIL (HSIL)
Carcinoma in situ	CIN III	High-grade SIL (HSIL)

CIN, Cervical intraepithelial neoplasia; *SIL,* squamous intraepithelial lesion.

LSIL does not progress directly to invasive carcinoma, and, in fact, most cases regress spontaneously; only a small percentage progress to HSIL. LSIL represents a productive HPV infection in which there is a high level of viral replication, but only mild alterations in the growth of host cells. For these reasons, LSIL is not treated like a premalignant lesion. LSIL is approximately ten times more common than HSIL.

By contrast to LSIL, HSIL is considered to be at high risk for progression to carcinoma. In HSIL, there is a progressive deregulation of the cell cycle by HPV, which results in increased cellular proliferation, decreased or arrested epithelial maturation, and a lower rate of viral replication as compared with LSIL. Derangement of the cell cycle in HSIL may become irreversible and lead to a fully transformed malignant phenotype.

MORPHOLOGY

The diagnosis of SIL is based on identification of nuclear atypia characterized by nuclear enlargement, hyperchromasia (dark staining), coarse chromatin granules, and variation in nuclear size and shape (Fig. 22.14). The nuclear changes are often accompanied by cytoplasmic "halos." At an ultrastructural level, these "halos" consist of perinuclear vacuoles, a cytopathic change created in part by an HPV-encoded protein E5 that localizes to the membranes of the endoplasmic reticulum. Nuclear alterations associated with perinuclear halos are termed **koilocytic atypia.** The grading of SIL into low or high grade is based on expansion of the immature cell layer from its normal, basal location. If the immature squamous cells are confined to the lower one-third of the epithelium, the lesion is called LSIL; if they expand to the upper two-thirds of the epithelial thickness, it is called HSIL.

The histologic features of LSIL correlate with HPV replication and changes in host cell growth and gene expression (Fig. 22.15). The highest viral loads (assessed by in situ hybridization for HPV DNA; see Fig. 22.15B) are found in maturing keratinocytes in the upper half of the epithelium. HPV E6 and E7 proteins prevent cell cycle arrest. As a result, cells in the upper portion of the epithelium express markers of actively dividing cells, such as Ki-67 (see Fig. 22.15C), that are normally confined to the basal layer of the epithelium. Disturbed growth regulation also leads to overexpression of p16, a cyclin-dependent kinase inhibitor (see Fig. 22.15D). Both Ki-67 and p16 staining are highly correlated with HPV infection and are useful for confirmation of the diagnosis in equivocal cases of SIL.

More than 80% of LSILs and 100% of HSILs are associated with high-risk HPVs, with HPV-16 being the most

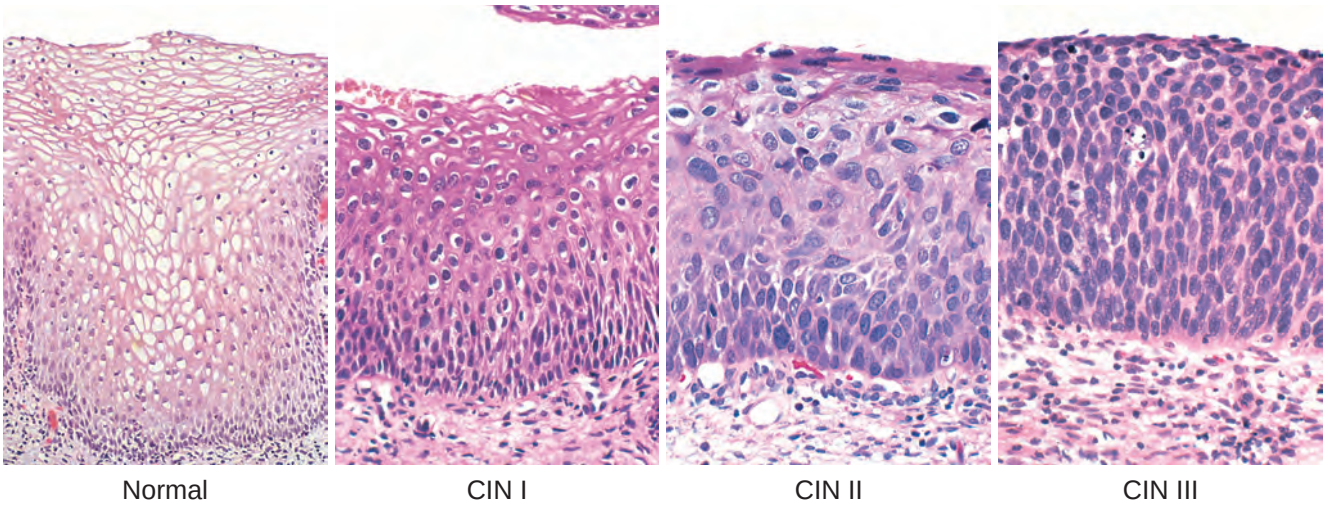

Figure 22.14 Spectrum of cervical intraepithelial neoplasia: normal squamous epithelium for comparison; low-grade squamous intraepithelial lesion (cervical intraepithelial neoplasia *[CIN]* I) with koilocytic atypia; high-grade squamous intraepithelial lesion (HSIL) (CIN II) with progressive atypia and expansion of the immature basal cells above the lower third of the epithelial thickness; HSIL (CIN III) with diffuse atypia, loss of maturation, and expansion of the immature basal cells to the epithelial surface.

common HPV type in both lesions. Table 22.2 shows rates of regression and progression of SILs within a 2-year follow-up. Although the majority of HSILs develop from LSILs, approximately 20% of cases of HSIL develop de novo, independent of any preexisting LSIL. The rates of progression are by no means uniform, and although HPV type—especially HPV 16—is associated with increased risk, it is difficult to predict the outcome in an individual patient. These findings underscore that the risk of precursor lesions and cancer is conferred only in part by HPV type. Progression to invasive carcinoma, when it occurs, on average takes place over several decades.

Cervical Carcinoma

The average age of patients with invasive cervical carcinoma is between 45 and 50 years. Squamous cell carcinoma is the most common histologic subtype, accounting for approximately 80% of cases. The second most common tumor type is adenocarcinoma, which constitutes about 15% of cervical cancer cases and develops from a precursor lesion called *adenocarcinoma in situ*. Adenosquamous and neuroendocrine carcinomas are rare cervical tumors that account for the remaining 5% of cases. All of the aforementioned tumor types are caused by high-risk HPVs. The progression time

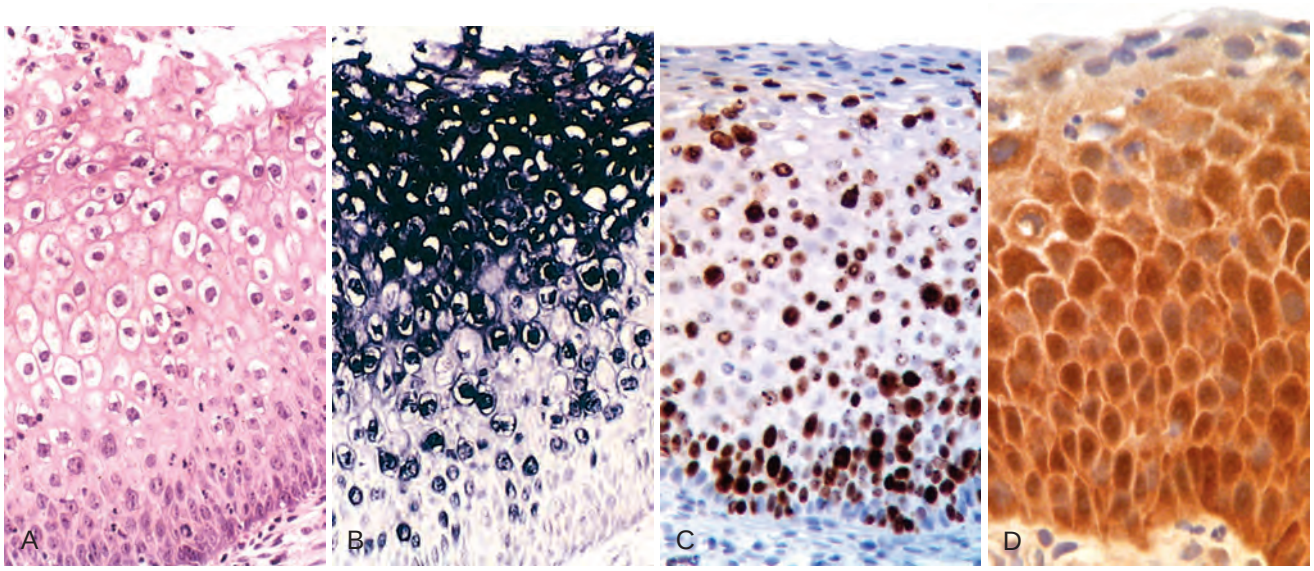

Figure 22.15 (A) Low-grade squamous intraepithelial lesion: routine hematoxylin and eosin staining shows koilocytic change, seen as nuclear enlargement and perinuclear "halos." (B) In situ hybridization test for human papillomavirus deoxyribonucleic acid (HPV DNA). The dark granular staining denotes HPV DNA, which is most abundant in the superficial koilocytes. (C) Diffuse positivity for the proliferation marker Ki-67 (seen as brown nuclear staining), illustrates expansion of the proliferating cells from the normal basal location to the superficial layers of the epithelium. (D) Up-regulation of the cyclin-dependent kinase inhibitor p16 (seen here as brown staining) characterizes high-risk HPV infections.

Table 22.2 Natural History of Squamous Intraepithelial Lesions With Approximate 2-Year Follow-Up

Lesion	Regress	Persist	Progress
LSIL	60%	30%	10% to HSIL
HSIL	30%	60%	10% to carcinoma[a]

HSIL, High-grade squamous intraepithelial lesion; *LSIL*, low-grade squamous intraepithelial lesion.

[a]Progression within 2 to 10 years.

from in situ to invasive adenosquamous and neuroendocrine carcinomas is shorter than in squamous cell carcinoma, and patients with these tumors often present with advanced disease and have a less favorable prognosis.

MORPHOLOGY

Invasive cervical carcinoma may manifest as fungating (exophytic) or infiltrative masses. **Squamous cell carcinoma** is composed of nests and tongues of malignant squamous epithelium, either keratinizing or nonkeratinizing, which invade the underlying cervical stroma (Fig. 22.16A–B). **Adenocarcinoma** is characterized by proliferation of glandular epithelium composed of malignant endocervical cells with large, hyperchromatic nuclei and relatively mucin-depleted cytoplasm, resulting in a dark appearance of the glands, as compared with the normal endocervical epithelium

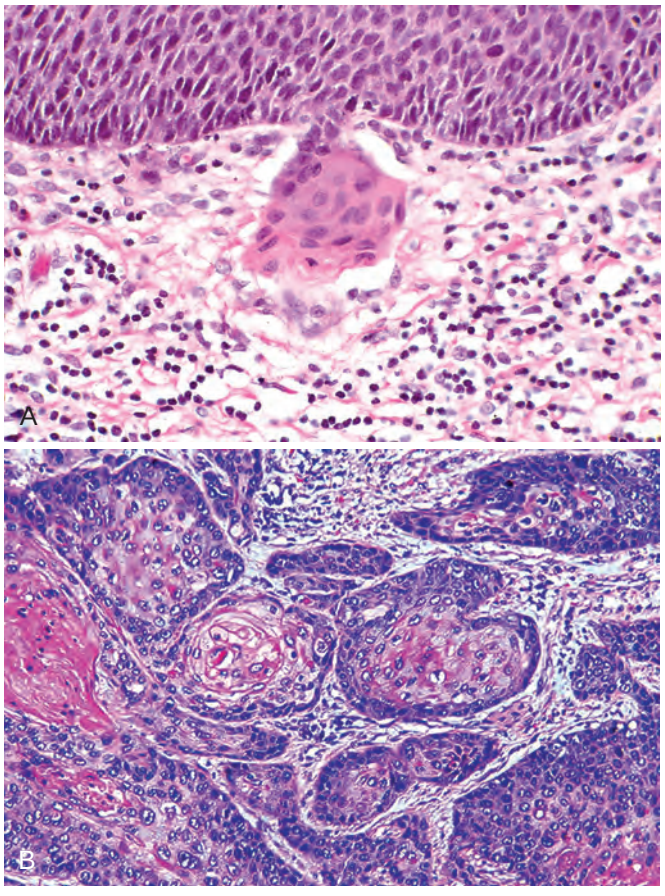

Figure 22.16 Squamous cell carcinoma of the cervix. (A) Early invasion in squamous cell carcinoma showing an invasive nest breaking through the basement membrane of a high-grade squamous intraepithelial lesion. (B) Invasive squamous cell carcinoma.

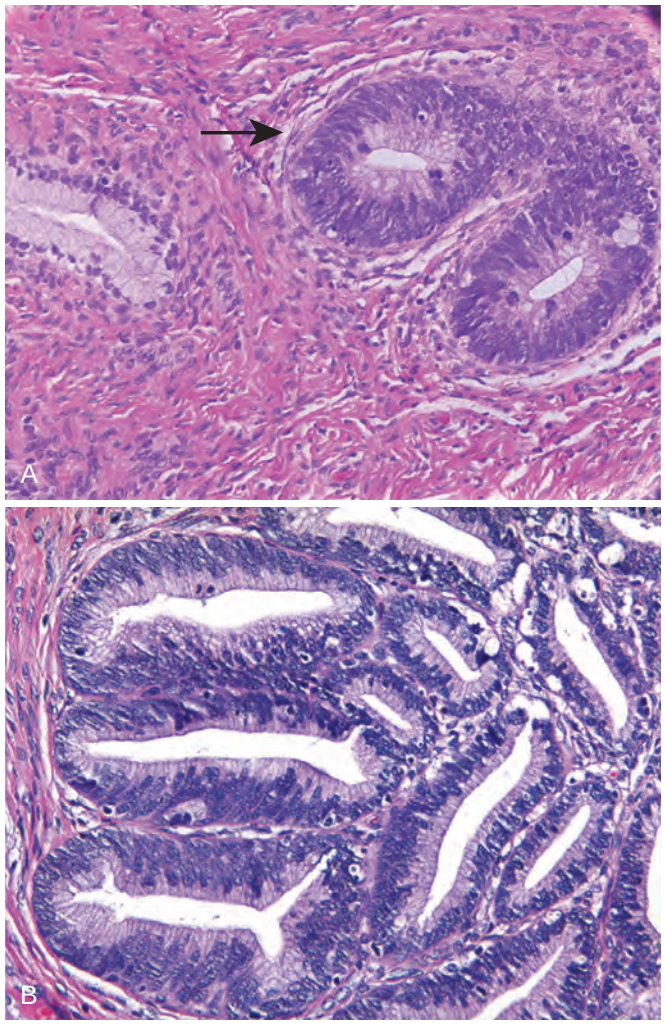

Figure 22.17 Adenocarcinoma of the cervix. (A) Adenocarcinoma in situ *(arrow)* showing dark glands with atypical, enlarged nuclei adjacent to a normal, pale endocervical gland. (B) Invasive adenocarcinoma.

(Fig. 22.17A–B). Adenosquamous carcinoma is composed of intermixed malignant glandular and squamous epithelium. Neuroendocrine cervical carcinoma has an appearance similar to small cell carcinoma of the lung (Chapter 15) but differs in being positive for high-risk HPVs.

Advanced cervical carcinoma spreads by direct extension to contiguous tissues, including paracervical soft tissue, urinary bladder, ureters (resulting in hydronephrosis), rectum, and vagina. Lymphovascular invasion results in local and distant lymph nodes metastases. Distant metastases may also be found in the liver, lungs, bone marrow, and other organs.

Cervical cancer is staged as follows:

Stage 0—Carcinoma in situ (CIN III, HSIL)

Stage I—Carcinoma confined to the cervix

- Ia—Preclinical carcinoma, that is, diagnosed only by microscopy
- Ia1—Stromal invasion no deeper than 3 mm and no wider than 7 mm (so-called superficially invasive squamous cell carcinoma)
- Ia2—Maximum depth of invasion of stroma deeper than 3 mm and no deeper than 5 mm taken from base of epithelium; horizontal invasion no more than 7 mm

Ib—Histologically invasive carcinoma confined to the cervix and greater than stage Ia2

Stage II—Carcinoma extends beyond the cervix but not to the pelvic wall. Carcinoma involves the vagina but not the lower third.

Stage III—Carcinoma has extended to the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina.

Stage IV—Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. This stage also includes cancers with metastatic dissemination.

Clinical Features

More than one-half of invasive cervical cancers are detected in women who did not participate in regular screening. While superficially invasive squamous cell carcinomas may be treated by cervical cone excision alone, most invasive cancers are managed by hysterectomy with lymph node dissection and, for advanced lesions, radiation and chemotherapy. The prognosis for invasive carcinomas depends on the stage of the cancer at diagnosis and to some degree on histologic subtype, with small-cell neuroendocrine tumors having a very poor prognosis. With current treatments, the 5-year survival rate is 100% for superficially invasive squamous cell carcinomas and less than 20% for tumors extending beyond the pelvis. Most patients with advanced cervical cancer die of the consequences of local tumor invasion (e.g., ureteral obstruction, pyelonephritis, and uremia) rather than distant metastases.

CERVICAL CANCER SCREENING AND PREVENTION

As is well known, cytologic cancer screening has significantly reduced mortality from cervical cancer. In countries where such screening is not widely practiced, cervical cancer continues to exact a high toll. The reason that cytologic screening is so effective in preventing cervical cancer is that most cancers arise from precursor lesions over the course of years. These lesions shed abnormal cells that can be detected on cytologic examination. Using a spatula or brush, the transformation zone of the cervix is circumferentially scraped and the cells are smeared or spun down onto a slide. Following fixation and staining with the Papanicolaou method, the smears are screened microscopically by eye or (increasingly) with automated image analysis systems. The cellular changes seen on the Pap test, illustrating the spectrum from LSIL to HSIL, are shown in Fig. 22.18.

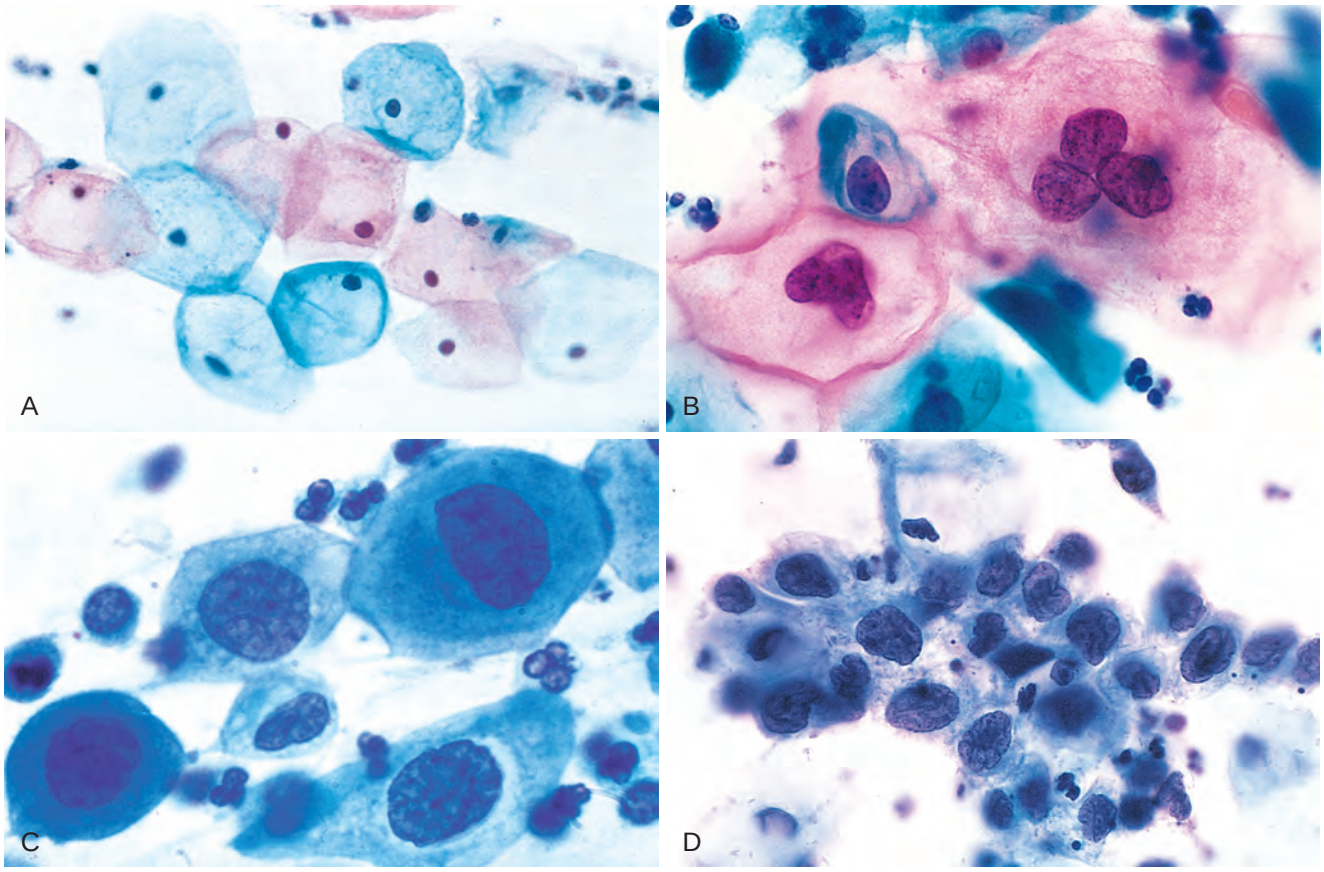

Figure 22.18 The cytology of cervical intraepithelial neoplasia as seen on the Papanicolaou smear. The cytoplasmic staining of desquamated cells may be either red or blue. (A) Normal exfoliated superficial squamous cells. (B) Low-grade squamous intraepithelial lesion—koilocytes. (C) High-grade squamous intraepithelial lesion (HSIL; cervical intraepithelial neoplasia [CIN] II). (D) HSIL (CIN III). Note the reduction in cytoplasm and the increase in the nucleus-to-cytoplasm ratio, which occurs as the grade of the lesion increases. This reflects the progressive loss of cellular differentiation on the surface of the lesions from which these cells are exfoliated. (Courtesy Dr. Edmund S. Cibas, Brigham and Women's Hospital, Boston, Mass.)

Testing for the presence of HPV DNA in the cervical scrape is a molecular method of cervical cancer screening. HPV testing has a higher sensitivity but lower specificity, as compared to the Pap test. HPV DNA testing may be added to cervical cytology for screening in women 30 years of age or older. HPV testing of women younger than 30 years of age is not recommended because of the high incidence of infection, and thus the particularly low specificity of HPV test results in this age group.

Cervical cancer screening and preventive measures are carried out in a stepwise fashion. Recommendations for the frequency of Pap screening vary, but in general the first smear should be at 21 years of age or within 3 years of onset of sexual activity, and thereafter every 3 years. After 30 years of age, women who have had normal cytology results and are negative for HPV may be screened every 5 years. Women who have a normal cytology result but test positive for high-risk HPV DNA should have cervical cytology repeated every 6 to 12 months.

When the result of a Pap test is abnormal, a colposcopic examination of the cervix and vagina is performed to identify the lesion. The mucosa is examined with a magnifying glass following application of acetic acid, which highlights abnormal epithelium as white spots *(aceto-white areas)*. Abnormal appearing areas are biopsied. Women with biopsy-confirmed LSIL can be followed in a conservative fashion. Some gynecologists will perform local ablation (e.g., cryotherapy) of LSIL, particularly if there is concern about the reliability of patient follow-up. HSIL is treated with cervical conization (superficial excision).

An additional important aspect of cervical cancer prevention is vaccination against high-risk oncogenic HPV, which is now recommended for all girls and boys by 11 to 12 years of age, as well as young men and women up to 26 years of age. Two HPV vaccines are now FDA-licensed. Both provide nearly complete protection against high-risk oncogenic HPV types 16 and 18 (together accounting for approximately 70% of cervical cancers), and one also provides protection against additional five high oncogenic risk HPVs as well as two low oncogenic risk HPV types 6 and 11, which are responsible for genital warts. Vaccination is now recommended for boys as well as girls due to the role that males play in the spread of HPV to women and the toll that HPV-related anal and oropharyngeal cancers take in men. The vaccines offer protection for up to 10 years; longer follow-up studies are still pending. Because the HPV vaccines do not protect against all high-risk HPV types, current guidelines recommend that cervical cancer screening be continued as in the past.

KEY CONCEPTS

- Cervical LSIL is a productive HPV infection that usually regresses spontaneously but occasionally progresses to HSIL.
- HSIL is characterized by progressive deregulation of the cell cycle and increasing cellular atypia. HSIL may progress to invasive carcinoma.
- Almost all cervical precursor lesions and cervical carcinomas are caused by high-risk HPV types, most commonly HPV-16.

Body of Uterus and Endometrium

The uterus has two major components: the myometrium and the endometrium. The myometrium is composed of tightly interwoven bundles of smooth muscle that form the wall of the uterus. The internal cavity of the uterus is lined by the endometrium, which is composed of glands embedded in a cellular stroma. The uterus is affected by a variety of disorders, the most common of which results from endocrine imbalances, complications of pregnancy, and neoplastic proliferation.

ENDOMETRIAL HISTOLOGY IN THE MENSTRUAL CYCLE

The endometrium undergoes dynamic physiologic and morphologic changes during the menstrual cycle in response to sex steroid hormones coordinately produced in the ovary. The ovary is influenced by hormones produced by the pituitary gland due to signals from the hypothalamus. Together, hypothalamic, pituitary, and ovarian factors and their interactions regulate maturation of ovarian follicles, ovulation, and menstruation.

The histologic appearance of the endometrium may be used to assess hormonal status, document ovulation, and determine causes of endometrial bleeding and infertility (Fig. 22.19). Progression through a normal menstrual cycle is correlated with the following histologic features:

- The cycle commences with *menses,* during which the superficial portion of the endometrium, referred to as the functionalis, is shed.
- The *proliferative phase* is marked by rapid growth of glands and stroma arising from the deeper portion of the endometrium (basalis). During the proliferative phase, the glands are straight, tubular structures lined by regular, tall, pseudostratified columnar cells. Mitotic figures are numerous, and there is no evidence of mucus secretion or vacuolation. The endometrial stroma is composed of spindle cells with scant cytoplasm that are also actively proliferating (see Fig. 22.19A).
- At *ovulation,* endometrial proliferation ceases and differentiation commences in response to the effects of progesterone made by the corpus luteum in the ovary.
- *Postovulation* is initially marked by the appearance of *secretory vacuoles* beneath the nuclei in the glandular epithelium (see Fig. 22.19B). Secretory activity is most prominent during the third week of the menstrual cycle, when the basal vacuoles progressively move to the apical surface. By the fourth week, the glands are tortuous, producing a serrated appearance. This serrated or "sawtooth" appearance is accentuated by secretory exhaustion and shrinkage of the glands.
- *Stromal changes in the late secretory phase,* due predominantly to progesterone, are the most significant features. Prominent spiral arterioles appear accompanied by an

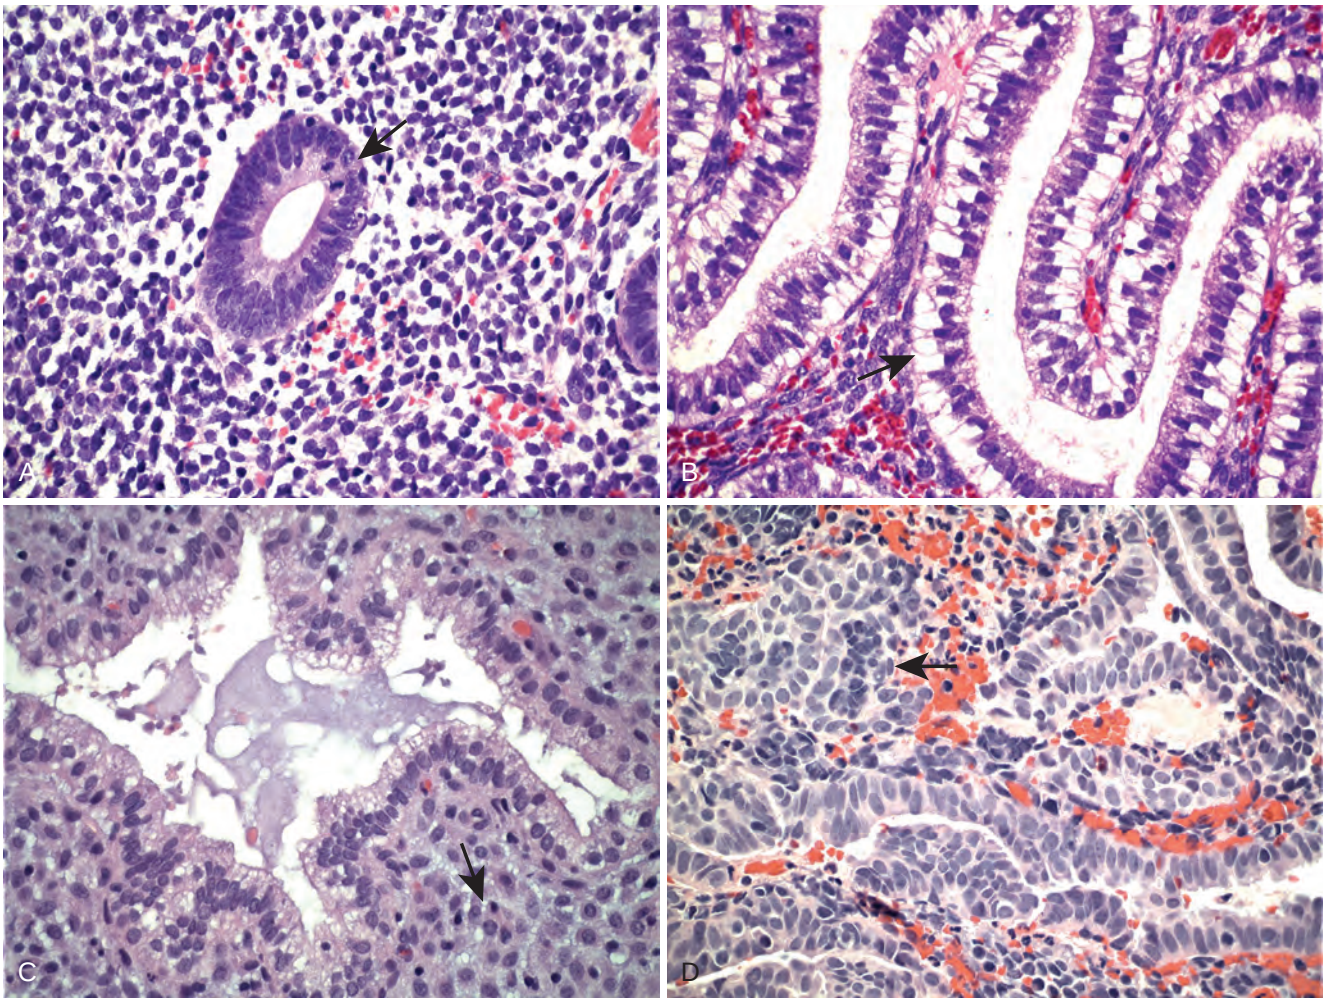

Figure 22.19 Histology of the menstrual cycle. (A) Proliferative phase with mitoses *(arrow)*. (B) Early secretory phase with subnuclear vacuoles *(arrow)*. (C) Late secretory exhaustion and predecidual changes *(arrow)*. (D) Menstrual endometrium with stromal breakdown *(arrow) (see text)*.

increase in ground substance and edema between the stromal cells followed by stromal cell hypertrophy, increased cytoplasmic eosinophilia *(predecidual change)*, and a resurgence of stromal mitoses (see Fig. 22.19C). Predecidual changes spread throughout the functionalis and are accompanied by a sparse infiltrate of neutrophils and lymphocytes, which in this context are considered normal.

- With the dissolution of the corpus luteum and the subsequent drop in progesterone levels, the functionalis degenerates and bleeding into the stroma occurs, followed by stromal breakdown and onset of the next menstrual cycle (see Fig. 22.19D).

The action of the ovarian hormones on the endometrium primarily occurs through their cognate nuclear receptors. During the proliferative phase, estrogen drives the proliferation of both glands and stroma, sometimes by promoting "cross-talk" between these two cell types. For example, much of the effect of estrogen on glandular proliferation occurs via stromal cells, which in response to estrogen produce growth factors (e.g., insulin-like growth factor-1 and epidermal growth factor) that bind receptors expressed on the epithelial cells. During the secretory phase, progesterone down-regulates the expression of estrogen receptor in both the glands and the stroma, and as a result endometrial proliferation is suppressed. Progesterone also promotes the differentiation of the glands and causes functional changes in the stromal cells. Endometrial stem cells have been identified that likely have a central role in the regeneration of the endometrium after menses. They may also contribute to the development of ectopic endometrial tissue and endometrial cancer.

FUNCTIONAL ENDOMETRIAL DISORDERS (DYSFUNCTIONAL UTERINE BLEEDING)

Although abnormal uterine bleeding can be caused by well-defined pathologic conditions, such as chronic endometritis, endometrial polyps (Fig. 22.20C), submucosal leiomyomas (see Fig. 22.20D), or endometrial neoplasms, it most commonly stems from hormonal disturbances that produce *dysfunctional uterine bleeding* (Table 22.3). This is a clinical term for uterine bleeding that lacks an underlying structural abnormality. As discussed earlier, the normal

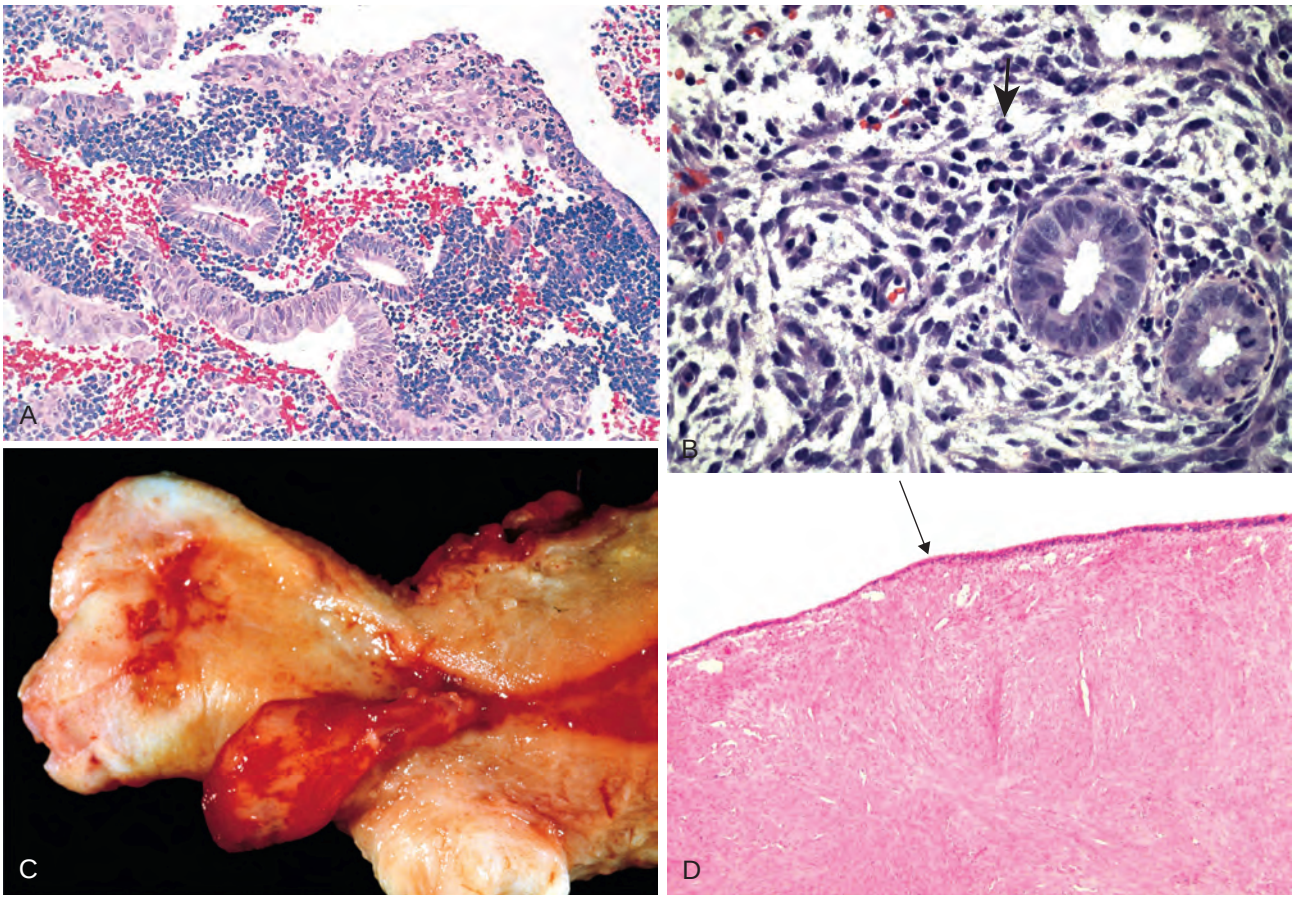

Figure 22.20 Common causes of abnormal uterine bleeding. (A) The most common is dysfunctional uterine bleeding, seen here as anovulatory endometrium with stromal breakdown. Note breakdown associated with proliferative glands. (B) Chronic endometritis with plasma cells *(arrow)*. (C) Endometrial polyp. (D) Submucosal leiomyoma with attenuation of the endometrial lining *(arrow)*.

cyclical proliferation, differentiation, and shedding of the endometrium requires that all the involved pituitary and ovarian hormones be released at the proper time in the right amounts. Any disturbance of this finely tuned system may result in dysfunctional uterine bleeding, the most common causes of which are discussed in the following sections.

Table 22.3 Causes of Abnormal Uterine Bleeding by Age Group

Age Group	Causes
Prepuberty	Precocious puberty (hypothalamic, pituitary, or ovarian origin)
Adolescence	Anovulatory cycle, coagulation disorders
Reproductive age	Complications of pregnancy (abortion, trophoblastic disease, ectopic pregnancy) Anatomic lesions (leiomyoma, adenomyosis, polyps, endometrial hyperplasia, carcinoma) Dysfunctional uterine bleeding Anovulatory cycle Ovulatory dysfunctional bleeding (e.g., inadequate luteal phase)
Perimenopausal	Dysfunctional uterine bleeding Anovulatory cycle Anatomic lesions (carcinoma, hyperplasia, polyps)
Postmenopausal	Endometrial atrophy Anatomic lesions (carcinoma, hyperplasia, polyps)

Anovulatory Cycle

The most frequent cause of dysfunctional bleeding is anovulation (failure to ovulate). Anovulatory cycles result from hormonal imbalances and are most common at menarche and in the perimenopausal period. Less commonly, anovulation is the result of the following:

- *Endocrine disorders,* such as thyroid disease, adrenal disease, or pituitary tumors
- *Ovarian lesions,* such as a functioning ovarian tumor (granulosa cell tumors) or polycystic ovaries (see the Ovaries section later in this chapter)
- *Generalized metabolic disturbances*, such as obesity, malnutrition, or other chronic systemic diseases

Failure of ovulation results in excessive endometrial stimulation by estrogens that is unopposed by progesterone. Under these circumstances, the endometrial glands undergo mild architectural changes, including cystic dilation, that usually resolve due to a subsequent ovulatory cycle. However, repeated anovulation may result in bleeding that, in certain clinical situations, may prompt an endometrial biopsy. In this setting, biopsies reveal stromal condensation and eosinophilic

epithelial metaplasia, features similar to those seen in menstrual endometrium. However, unlike menstrual endometrium, progesterone-dependent morphologic features (e.g., glandular secretory changes and stromal pre-decidualization) are absent because the source of progesterone, the corpus luteum, does not develop without ovulation. Most commonly, the endometrium is composed of pseudostratified glands and contains scattered mitotic figures (see Fig. 22.20A). More severe consequences of repeated anovulation are discussed in the Endometrial Hyperplasia section later in this chapter.

INFLAMMATORY DISORDERS

The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix forms a barrier to ascending infection. Thus, although chronic inflammation in the cervix is common and usually insignificant, it is of concern in the endometrium.

Acute Endometritis

Acute endometritis is uncommon and limited to bacterial infections that arise after delivery or miscarriage. Retained products of conception are the usual predisposing factors; the causative agents include group A hemolytic streptococci, staphylococci, and other bacteria. The inflammatory response is chiefly limited to the stroma and is entirely nonspecific. Removal of the retained gestational products by curettage and antibiotic therapy promptly clears these infections.

Chronic Endometritis

Chronic endometritis occurs in association with the following disorders:

- Chronic pelvic inflammatory disease
- Retained gestational tissue, postpartum or postabortion
- Intrauterine contraceptive devices
- Tuberculosis, either from miliary spread or, more often, from drainage of tuberculous salpingitis. Endometrial tuberculosis is rare in high income countries.

The diagnosis of chronic endometritis rests on the identification of plasma cells in the stroma (see Fig. 22.20B), which are not seen in normal endometrium. In about 15% of cases, no cause is apparent. Some women with this so-called "nonspecific" chronic endometritis have gynecologic complaints such as abnormal bleeding, pain, discharge, and infertility. *Chlamydia* may be involved and is commonly associated with both acute (e.g., neutrophils) and chronic (e.g., lymphocytes, plasma cells) inflammatory infiltrates. The responsible organisms may not be detected by culture. If infection is suspected on clinical grounds, antibiotic therapy is indicated, even in the face of negative cultures, as it may prevent other sequelae (e.g., salpingitis).

ENDOMETRIOSIS AND ADENOMYOSIS

Endometriosis is defined by the presence of "ectopic" endometrial tissue at a site outside of the uterus. The abnormal tissue most commonly includes both endometrial glands and stroma, but may consist only of stroma in some cases. It occurs in the following sites, in descending order of frequency: (1) ovaries, (2) uterine ligaments, (3) rectovaginal septum, (4) cul de sac, (5) pelvic peritoneum, (6) serosa of the large and small bowel and appendix, (7) mucosa of the cervix, vagina, and fallopian tubes, and (8) laparotomy scars.

Endometriosis can have significant clinical consequences; it often causes infertility, dysmenorrhea (painful menstruation), pelvic pain, and other problems. The disorder is principally a disease of women in active reproductive life, most often in the third and fourth decades, and affects approximately 10% of women. There are three types of endometriosis: superficial peritoneal endometriosis, ovarian endometriosis, and deep infiltrating endometriosis (Fig. 22.21). The superficial and ovarian forms of endometriosis are uncommonly associated with the development of malignancy, whereas it is extremely rare for the deep infiltrating form to undergo malignant transformation.

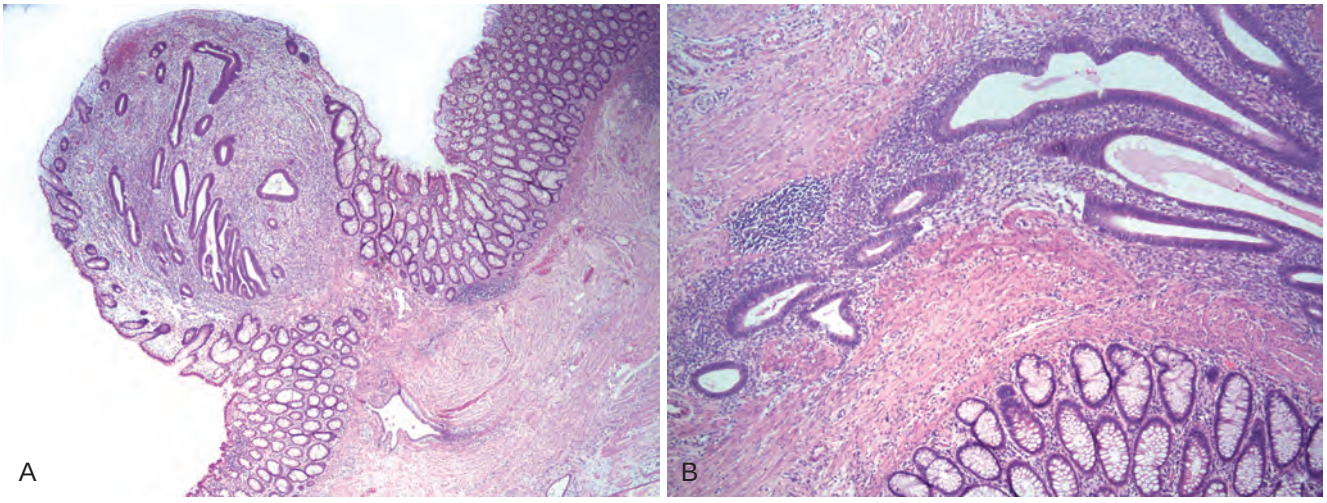

Figure 22.21 Endometriosis. (A) Endometriosis involving the mucosa of the colon. (B) Higher magnification reveals endometrial glands and stroma adjacent to normal colonic mucosa.

Pathogenesis

The pathogenesis of endometriosis remains elusive. Proposed origins of endometriotic lesions fall into two main categories: (1) those that propose an origin from the uterine endometrium and (2) those that propose an origin from cells outside the uterus that have the capacity to give rise to endometrial tissue. The leading theories are as follows:

- *The regurgitation theory* proposes that endometrial tissue implants at ectopic sites via retrograde flow of menstrual endometrium.
- *The benign metastasis theory* holds that endometrial tissue from the uterus can "spread" to distant sites (e.g., bone, lung, and brain) via blood vessels and lymphatic channels.
- *The metaplastic theory* suggests that endometrium arises directly from coelomic epithelium (mesothelium of pelvis or abdomen), from which the müllerian ducts and ultimately the endometrium itself originate during embryonic development. In addition, mesonephric remnants may undergo endometrial differentiation and give rise to ectopic endometrial tissue.
- *The extrauterine stem/progenitor cell theory* proposes that stem/progenitor cells from the bone marrow differentiate into endometrial tissue.

Retrograde menstruation through the fallopian tubes is common, and the regurgitation theory provides a plausible explanation for the origin of ectopic endometrial tissue in the peritoneal cavity, which constitutes the vast majority of cases. However, it cannot explain endometriosis in women who are amenorrheic because of a variety of underlying etiologies (e.g., gonadal dysgenesis); endometriosis in the urogenital tract of men treated with high-dose estrogens for prostate cancer; and endometriosis in distant sites like the brain, lung, and bone. In addition, the relatively low incidence of endometriosis, despite the common occurrence of retrograde menstruation (up to 90% of women), suggests that additional factors are involved in the pathogenesis of the disorder.

Molecular analyses have provided additional insights. The endometriotic implants show certain differences when compared to the endometria of women without endometriosis (Fig. 22.22). These include the following:

- *Release of proinflammatory and angiogenic factors,* including PGE_2, IL-1β, TNFα, IL-6 and IL-8, NGF, VEGF, MCP-1, MMPs, and TIMPs. Some of these factors are released by associated macrophages, which are recruited to endometriotic implants by proinflammatory factors. Like metastatic tumors, the ability of endometriotic implants to survive and grow is dependent on angiogenesis, which is mediated by typical proangiogenic factors such as VEGF. Similarly, the ability to implant requires remodeling of the extracellular matrix, which is carried out by factors such as matrix metalloproteases. These factors may also contribute to avoidance of immune clearance.
- *Increased estrogen and retinoic acid production by endometriotic stromal cells,* due in large part to high levels of the key steroidogenic enzyme aromatase, which is absent in normal endometrial stroma. Estrogen enhances the survival and persistence of endometriotic tissue, and inhibitors of aromatase are beneficial in the treatment of endometriosis. A link between inflammation and estrogen production is made plausible by the ability of prostaglandin E_2 to stimulate local synthesis of estrogen. It also has been shown that retinoic acid produced in the stromal cells promotes epithelial cell survival via paracrine signaling. In addition, epigenetic alterations (DNA methylation) have been described that lead to increased responsiveness to estrogen and decreased responsiveness to progesterone, alterations that promote endometrial proliferation and survival. These abnormalities are present not only in ectopic endometriotic tissue, but also, albeit to a lesser degree, in the uterine endometrium of patients with endometriosis, suggesting that there is a fundamental defect in the endometrium.
- *Mutations in tumor suppressor genes and oncogenes,* such as *KRAS, PIK3CA, PPP2R1A,* and *ARID1A,* have been identified in the epithelial cells of deeply infiltrating endometriosis. The significance of these mutations in cancer driver genes is unknown, but it is possible that they contribute to the locally aggressive behavior of deeply infiltrating endometriosis. An association between endometriosis and ovarian cancer of the endometrioid and clear cell types (discussed later) has been noted in a number of epidemiologic studies with an approximate threefold increase in women with endometriosis. These studies suggest a common origin of abnormal endometriotic tissue and ovarian cancers in some cases. Consistent with this idea, in some instances it has been shown that carcinomas harbor the same mutations as associated endometriosis in the same patient, strongly supporting a pathogenic role for these driver mutations in the development of both the premalignant and malignant lesions.

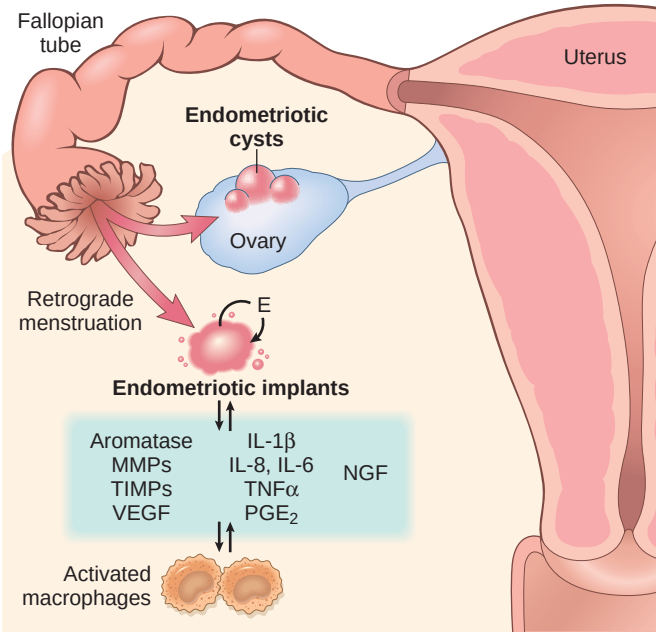

Figure 22.22 Pathogenesis of endometriosis. Depicted is the interplay between factors expressed in endometriotic implants and activated macrophages that are hypothesized to play a role in the establishment and maintenance of endometriotic implants. *E,* Estrogen.

MORPHOLOGY

Endometriotic lesions bleed periodically in response to both extrinsic cyclic (ovarian) and intrinsic hormonal stimulation. This bleeding produces nodules with a red-blue to yellow-brown appearance on or just beneath the mucosal and/or serosal surfaces at sites of involvement. When lesions are widespread, organizing hemorrhage causes extensive fibrous adhesions between tubes, ovaries, and other structures and obliterates the pouch of Douglas. The ovaries may become markedly distorted by large cystic masses (3 to 5 cm in diameter) filled with brown fluid resulting from previous hemorrhage; these are referred to clinically as **chocolate cysts** or **endometriomas.** Deeply infiltrating endometriosis can invade tissues and also cause fibrosis and adhesions.

The histologic diagnosis of endometriosis is usually straightforward but may be difficult in long-standing cases in which the endometrial tissue is obscured by secondary fibrosis. The diagnosis is readily made when both endometrial glands and stroma are present (see Fig. 22.21B), with or without the presence of hemosiderin. In rare cases only stroma is identified. If only glands are present, other diagnoses with different clinical ramifications, such as endosalpingiosis, must be considered.

Atypical endometriosis, the likely precursor to endometriosis-related ovarian carcinoma, has two morphologic appearances. One shows cytologic atypia of the epithelium lining the endometriotic cyst, without major architectural changes. The second is marked by glandular crowding due to excessive epithelial proliferation, often associated with cytologic atypia, producing an appearance that resembles complex atypical endometrial hyperplasia (discussed later).

Clinical Features

Clinical signs and symptoms usually include severe dysmenorrhea, dyspareunia (pain with intercourse), and pelvic pain due to the intrapelvic bleeding and periuterine adhesions. Menstrual irregularities are common, and infertility is the presenting complaint in 30% to 40% of women. In addition, although uncommon, malignancies can develop within endometriomas, suggesting that these lesions contain "at-risk" epithelium.

A related disorder, *adenomyosis,* is defined as the presence of endometrial tissue within the uterine wall (myometrium). Adenomyosis remains in continuity with the endometrium, presumably signifying down-growth of endometrial tissue into and between the smooth muscle fascicles of the myometrium. Adenomyosis occurs in up to 20% of uteri. On microscopic examination, irregular nests of endometrial stroma, with or without glands, are arranged within the myometrium. Like endometriosis, the clinical symptoms of adenomyosis include menometrorrhagia (irregular and heavy menses), colicky dysmenorrhea, dyspareunia, and pelvic pain, particularly during the premenstrual period. It can coexist with endometriosis.

KEY CONCEPTS

ENDOMETRIOSIS

- Endometriosis is defined as endometrial glands and stroma outside of the uterus. The "ectopic" endometrial tissue may bleed cyclically.
- Most common sites of endometriosis are within the abdominal cavity, but occasionally it is found at distant sites.
- Several theories (regurgitation, metaplasia, metastasis, and stem cell origin) are proposed to explain the distribution of endometriosis.
- It commonly results in dysmenorrhea, pelvic pain, and infertility.
- Peritoneal and ovarian endometriosis may be a precursor to carcinoma (endometrioid and clear cell carcinoma).

Endometrial Polyps

Endometrial polyps are exophytic masses of variable size that project into the endometrial cavity. They may be single or multiple and are usually sessile and relatively small, measuring 0.5 to 3 cm in diameter, but are occasionally large and pedunculated. Polyps may be asymptomatic or may cause abnormal bleeding and infertility.

Cytogenetic studies indicate that the stromal cells in endometrial polyps contain acquired chromosomal rearrangements that are similar to those found in other benign mesenchymal tumors, suggesting that these lesions are best considered epithelial neoplasms. Polyps are responsive to estrogen but show little or no response to progesterone (see Fig. 22.20C). Endometrial polyps may occur in association with the administration of tamoxifen, which is often used in the therapy of breast cancer due to its anti-estrogenic activity on the breast. However, tamoxifen has weak pro-estrogenic effects in the endometrium. Atrophic polyps, which mainly occur in postmenopausal women, likely represent the atrophic remnants of polyps that developed prior to menopause. Rarely, adenocarcinoma arises within endometrial polyps.

ENDOMETRIAL HYPERPLASIA

Endometrial hyperplasia is an important cause of abnormal bleeding and a frequent precursor to the most common type of endometrial carcinoma. It is defined as an abnormal proliferation of the endometrial glands relative to the stroma, resulting in an increased gland-to-stroma ratio when compared with normal proliferative endometrium. Clinicopathologic and epidemiologic studies have pointed to the malignant potential of endometrial hyperplasia, and molecular studies have confirmed this relationship, as endometrial hyperplasia and carcinoma share specific acquired driver mutations in cancer genes (described later).

Endometrial hyperplasia is associated with *prolonged estrogenic stimulation of the endometrium,* which can be due to anovulation, increased estrogen production from endogenous sources, or exogenous estrogen. Associated conditions include the following:

- Obesity (peripheral conversion of androgens to estrogens)
- Menopause
- Polycystic ovarian syndrome
- Functioning granulosa cell tumors of the ovary
- Excessive ovarian cortical function (cortical stromal hyperplasia)
- Prolonged administration of estrogenic substances (estrogen replacement therapy)

These are the same influences postulated to be of pathogenic significance in some endometrial carcinomas, discussed later.

Inactivation of the *PTEN* tumor suppressor gene is a common genetic alteration in both endometrial hyperplasias and endometrioid endometrial carcinoma. As discussed in Chapter 7, *PTEN* encodes a lipid phosphatase that is an important negative regulator of phosphatidylinositol 3-kinase (PI3K)/AKT growth-regulatory pathway. When PTEN function is lost, the PI3K/AKT pathway becomes overactive. Mutations in *PTEN* are found in more than 20% of hyperplasias, both with and without atypia, and in 30% to 80% of endometrial carcinomas, suggesting that alterations in *PTEN* occur at an early stage of endometrial tumorigenesis (although they are not predictive of progression of hyperplasia to carcinoma). Of note, patients with *Cowden syndrome,* which is caused by germline mutations in *PTEN,* have a high incidence of endometrial carcinoma and certain other tumors, particularly breast cancer. As with many other tumor suppressors, it is not entirely clear why the loss of *PTEN* (which is expressed in many tissues) is so highly associated with particular tumors. It is interesting to note, however, that PI3K/AKT signaling enhances the ability of the estrogen receptor to turn on the expression of its target genes. Thus, loss of PTEN function may stimulate estrogen-dependent gene expression, leading to overgrowth of cell types that depend on estrogen for trophic signals, such as endometrial and mammary epithelial cells.

MORPHOLOGY

The classification of endometrial hyperplasia according to the World Health Organization (WHO) includes two major categories, hyperplasia and atypical hyperplasia (also referred to as endometrial intraepithelial neoplasia), which differ in appearance and propensity to progress to carcinoma. **Typical hyperplasia** has a wide-range of appearances, but the cardinal feature is an increased gland-to-stroma ratio. The glands show variation in size and shape and may be dilated (Fig. 22.23A). Although there may be back-to-back glands focally, some intervening stroma is usually retained (see Fig. 22.23B). These lesions are caused by persistent estrogen stimulation and rarely progress to adenocarcinoma (approximately 1% to 3%). Hyperplasia may evolve into cystic atrophy when estrogen is withdrawn.

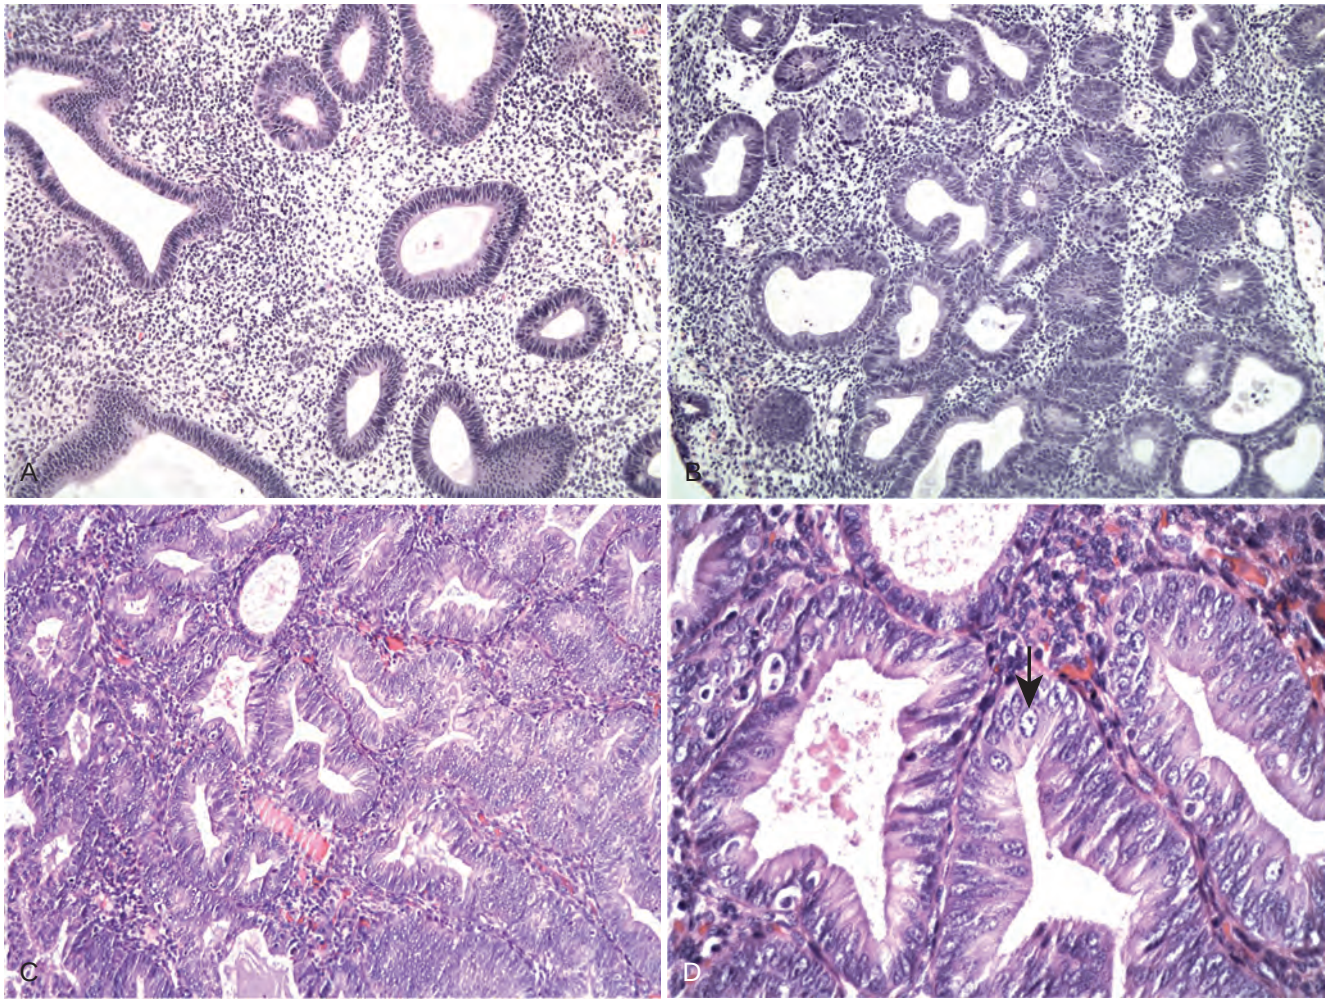

Figure 22.23 Endometrial hyperplasia. (A) Typical hyperplasia. Note the architectural abnormalities including mild glandular crowding and cystic glandular dilation. (B) Typical hyperplasia demonstrating increased glandular crowding with areas of back-to-back glands and cytologic features similar to proliferative endometrium. (C) Atypical hyperplasia with further increase in glandular crowding and abnormal cytologic features. (D) High magnification of atypical hyperplasia showing rounded, vesicular nuclei with prominent nucleoli *(arrow)*.

Atypical hyperplasia (endometrial intraepithelial neoplasia) is composed of complex patterns of proliferating glands displaying nuclear atypia. The glands are commonly back-to-back and often have complex outlines due to branching structures. Individual cells are rounded and lose the normal perpendicular orientation to the basement membrane. In addition, the nuclei have open (vesicular) chromatin and conspicuous nucleoli. The features of atypical hyperplasia have considerable overlap with those of well-differentiated endometrioid adenocarcinoma (discussed later), and accurate distinction from cancer may not be possible without hysterectomy (Fig. 22.23C–D). Indeed, up to 50% of women with a diagnosis of atypical hyperplasia are found to have carcinoma when a hysterectomy is performed.

Currently, atypical hyperplasia is managed by hysterectomy or, in young women who desire fertility, a trial of progestin therapy and close follow-up. Most often, hopefully after a successful pregnancy, lack of regression prompts removal of the uterus.

KEY CONCEPTS

ENDOMETRIAL HYPERPLASIA

- Endometrial hyperplasia is defined as an increase in the number of glands relative to the stroma, appreciated as crowded glands, often with abnormal shapes.
- It is most commonly caused by unopposed estrogen stimulation and is an important cause of abnormal vaginal bleeding.
- It is divided into typical and atypical hyperplasia based on nuclear morphology. Atypical hyperplasia is associated with an increased risk of endometrial carcinoma.
- The *PTEN* tumor suppressor gene is mutated in approximately 20% of endometrial hyperplasias.

MALIGNANT TUMORS OF THE ENDOMETRIUM

Carcinoma of the Endometrium

Endometrial carcinoma is the most common invasive cancer of the female genital tract. It accounts for 7% of all invasive cancer in women, excluding skin cancer. At one time endometrial carcinoma was far less common than cancer of the cervix, but earlier detection and eradication of the precursor lesions of cervical carcinoma, coupled with an increase in endometrial carcinomas in younger women, have reversed this ratio. In 2019 in the United States, 61,880 new endometrial cancers and 12,160 deaths were predicted. Worldwide there were over 380,000 new cases diagnosed in 2018.

Pathogenesis

Clinicopathologic studies and molecular analyses support the existence of two broad categories of endometrial carcinoma referred to as type I and type II, each with distinct risk factors, precursor lesions, molecular genetics, and clinical behaviors (summarized in Table 22.4). More recently, genomic sequencing of endometrial carcinoma has revealed four major molecular subtypes among endometrioid and serous carcinomas, the most common morphologies of type 1 and type 2 tumors, respectively. The salient molecular features of these four subtypes are as follows:

- *Ultramutated/POLE tumors,* which are defined by the presence of mutations in DNA polymerase ε (POLE) that produce an exceptionally high burden of somatic mutations, the large majority of which are passenger mutations.
- *Hypermutated/MSI (microsatellite instability) tumors,* defined by mutations in or epigenetic silencing of mismatch repair genes, also leading to genomic instability and a high burden of somatic mutations.
- *Copy number low/MSS (microsatellite stable) tumors,* a common subtype also associated with endometrioid morphology that is frequently associated with mutations that upregulate signaling through the PI3K/AKT pathway.
- *Copy number high/serous-like tumors,* aggressive tumors with serous or high-grade endometrioid morphology that are often associated with *TP53* mutations and numerous genomic copy number variants.

Table 22.4 Characteristics of Type I and Type II Endometrial Carcinoma

Characteristics	Type I	Type II
Age	55–65 years	65–75 years
Clinical setting	Unopposed estrogen Obesity Hypertension Diabetes	Atrophy Thin physique
Morphology	Endometrioid	Serous Clear cell Mixed müllerian tumor
Precursor	Hyperplasia	Serous endometrial intraepithelial carcinoma
Mutated genes/ genetic abnormalities	*PTEN* *ARID1A* (regulator of chromatin) *PIK3CA* (PI3K) *KRAS* *FGF2* (growth factor) MSI[a] *CTNNB1* (Wnt signaling) *POLE* *TP53* (progressed tumors)	*TP53* Aneuploidy *PIK3CA* (PI3K) *FBXW7* (regulator of MYC, cyclin E) *CCNE1* *PPP2R1A* (PP2A)
Behavior	Indolent Spreads via lymphatics	Aggressive Intraperitoneal and lymphatic spread

[a]Microsatellite instability.

Endometrioid Endometrial Carcinoma

This is the most common type of endometrial carcinoma, accounting for approximately 80% to 85% of cases. The majority of these tumors fall in to the type I category. Most are well differentiated and mimic proliferative endometrial glands, features that are the basis for their name. As discussed earlier, it typically arises in the setting of endometrial hyperplasia, and, like endometrial hyperplasia, is associated with conditions in which unopposed estrogenic stimulation

of the endometrium occurs. Most notable of these is obesity, a rapidly increasing problem in high income countries. The association with obesity underlies other conditions that commonly co-occur with endometrial carcinoma, particularly hypertension and type 2 diabetes.

As with other cancers, development of endometrioid carcinoma stems from the stepwise acquisition of genetic alterations in tumor suppressor genes and oncogenes. In hysterectomy specimens containing both atypical hyperplasia and carcinoma, identical *PTEN* mutations have been identified in each component, supporting the view that atypical hyperplasia is a precursor to carcinoma and that *PTEN* mutations occur before the development of overt carcinoma (Fig. 22.24A).

Sequencing of the genomes of endometrioid carcinomas has shown that the most common mutations act to increase signaling through the PI3K/AKT pathway, which is a hallmark of this particular tumor type. As mentioned earlier, PI3K/AKT signaling augments expression of estrogen receptor–dependent target genes in endometrial cells. Type I endometrial carcinomas are somewhat unique in that individual tumors may harbor multiple mutations that increase PI3K/AKT signaling, suggesting that tumor development and progression is fostered by successive increases in signal strength. Among the mutations that impact the PI3K/AKT pathway in endometrial carcinomas are the following:

- Mutations in the *PTEN* tumor suppressor gene are found in 30% to 80% of endometrioid carcinomas.
- *PIK3CA*, an oncogene that encodes the catalytic subunit of PI3K, harbors activating mutations in approximately 40% of endometrioid carcinomas. *PIK3CA* mutations rarely occur in atypical hyperplasias, suggesting that mutations in *PIK3CA* play a role in malignant transformation.
- Mutations that activate *KRAS*, which also stimulates PI3K/AKT signaling, are found in approximately 25% of cases.
- Loss-of-function mutations in *ARID1A*, a regulator of chromatin structure, occur in approximately one-third of tumors. Of interest, *ARID1A* is also frequently mutated in ovarian endometrioid and clear cell carcinomas, tumors that arise within endometriosis. Through unclear mechanisms, it appears that loss of ARID1A function also enhances pro-oncogenic changes in gene expression that are mediated by PI3K/AKT signaling.

Other commonly observed mutations in endometrioid carcinoma disrupt genes that are required for the maintenance of genomic stability, presumably acting in part to create a mutator phenotype that increases the rate of acquisition of mutations in oncogenes and tumor suppressor genes.

- *Defects involving DNA mismatch repair genes* are found in about 20% of sporadic tumors and are particularly prevalent in endometrial carcinomas arising in women with hereditary nonpolyposis colorectal carcinoma syndrome (HNPCC, also referred to as Lynch syndrome, discussed in Chapter 17). In sporadic endometrioid

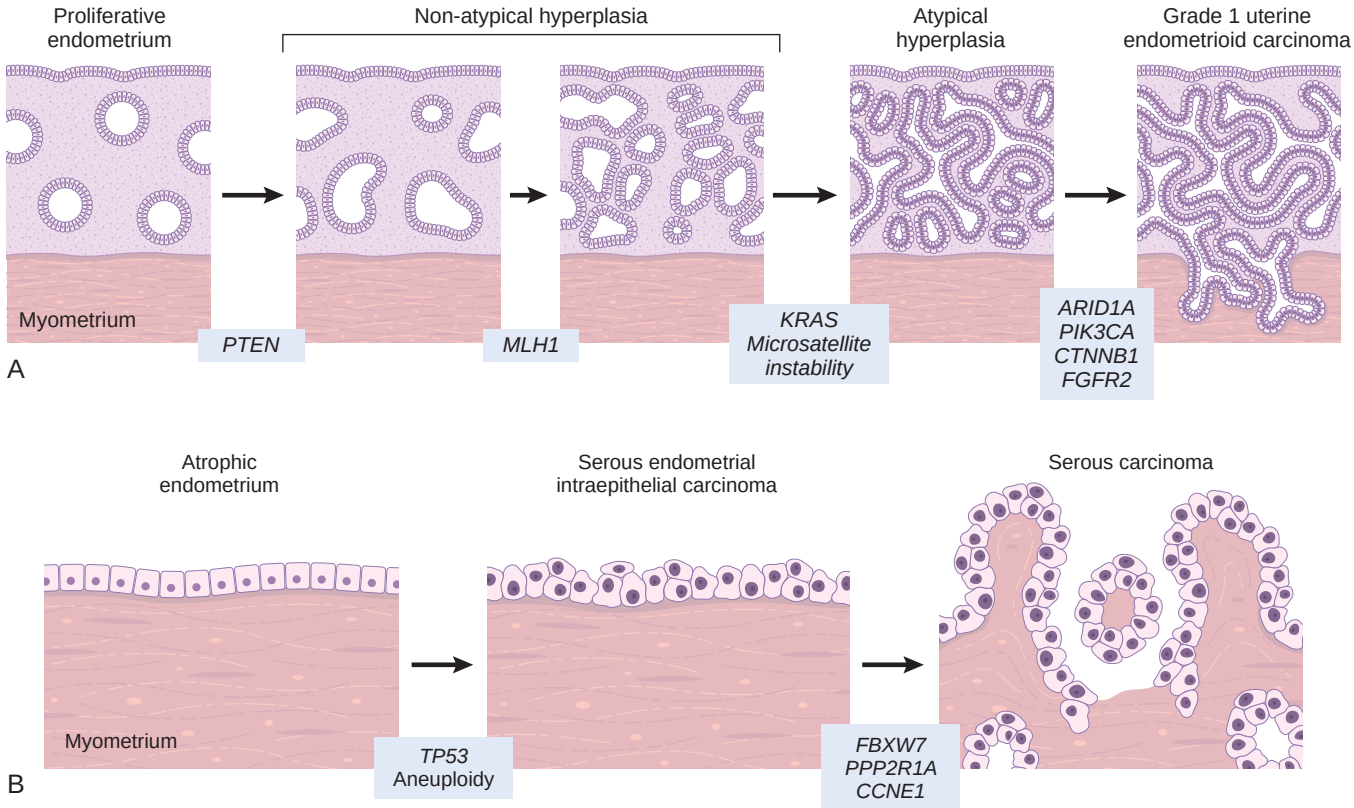

Figure 22.24 Schematic diagram depicting the development of type I endometrial carcinoma (A) and type II endometrial carcinoma (B). The most common molecular genetic alterations are shown at the time they are most likely to occur during the progression of the disease. *MLH1* encodes a component of the mismatch repair complex of proteins, and its loss of function results in microsatellite instability, found in about 20% of endometrioid carcinomas.

carcinoma, loss of expression of DNA mismatch repair genes is commonly caused by epigenetic silencing (via promoter hypermethylation).

- *A small subset (less than 10%) of endometrial carcinomas have mutations that disrupt the proofreading function of DNA polymerase ε, encoded by the POLE gene*. These tumors have a remarkably high burden of somatic point mutations, possibly the highest of any human cancer.
- *In approximately 50% of poorly differentiated carcinomas, loss-of-function mutations in TP53 are present*. Because *TP53* mutations are lacking in the vast majority of well-differentiated endometrioid carcinomas, these mutations are thought to be late events involved in tumor progression.

MORPHOLOGY

Endometrioid carcinoma can take the form of a localized polypoid mass or diffusely involve the endometrial lining (Fig. 22.25A). Spread generally occurs by myometrial invasion followed by direct extension to adjacent structures/organs. Invasion of the broad ligaments may create a palpable mass. Eventually, dissemination to regional lymph nodes occurs, and in the late stages, distant metastatic spread to the lungs, liver, bones, and other organs may be seen.

Endometrioid adenocarcinomas demonstrate glandular growth patterns that fall into three histologic grades: **well differentiated** (grade 1) (Fig. 22.25B), composed almost entirely of well-formed glands; **moderately differentiated** (grade 2) (Fig. 22.25C), showing well-formed glands mixed with areas composed of solid sheets of cells, which by definition make up 50% or less of the tumor; and **poorly differentiated** (grade 3) (Fig. 22.25D), characterized by greater than 50% solid growth pattern. Well-differentiated tumors may be distinguished from hyperplasias by the presence of desmoplastic stroma or complex epithelial growth patterns (e.g., confluent glandular or papillary growth patterns).

Tumors with polymerase ε mutations or defects in DNA mismatch repair are frequently associated with large numbers of infiltrating T cells. It is believed that these cells represent an ineffective host response to neoantigens created by mutations that lead to tumor-specific amino acid substitutions in proteins.

Up to 20% of endometrioid carcinomas contain foci of squamous differentiation. Squamous elements may be histologically benign-appearing when they are associated with well-differentiated

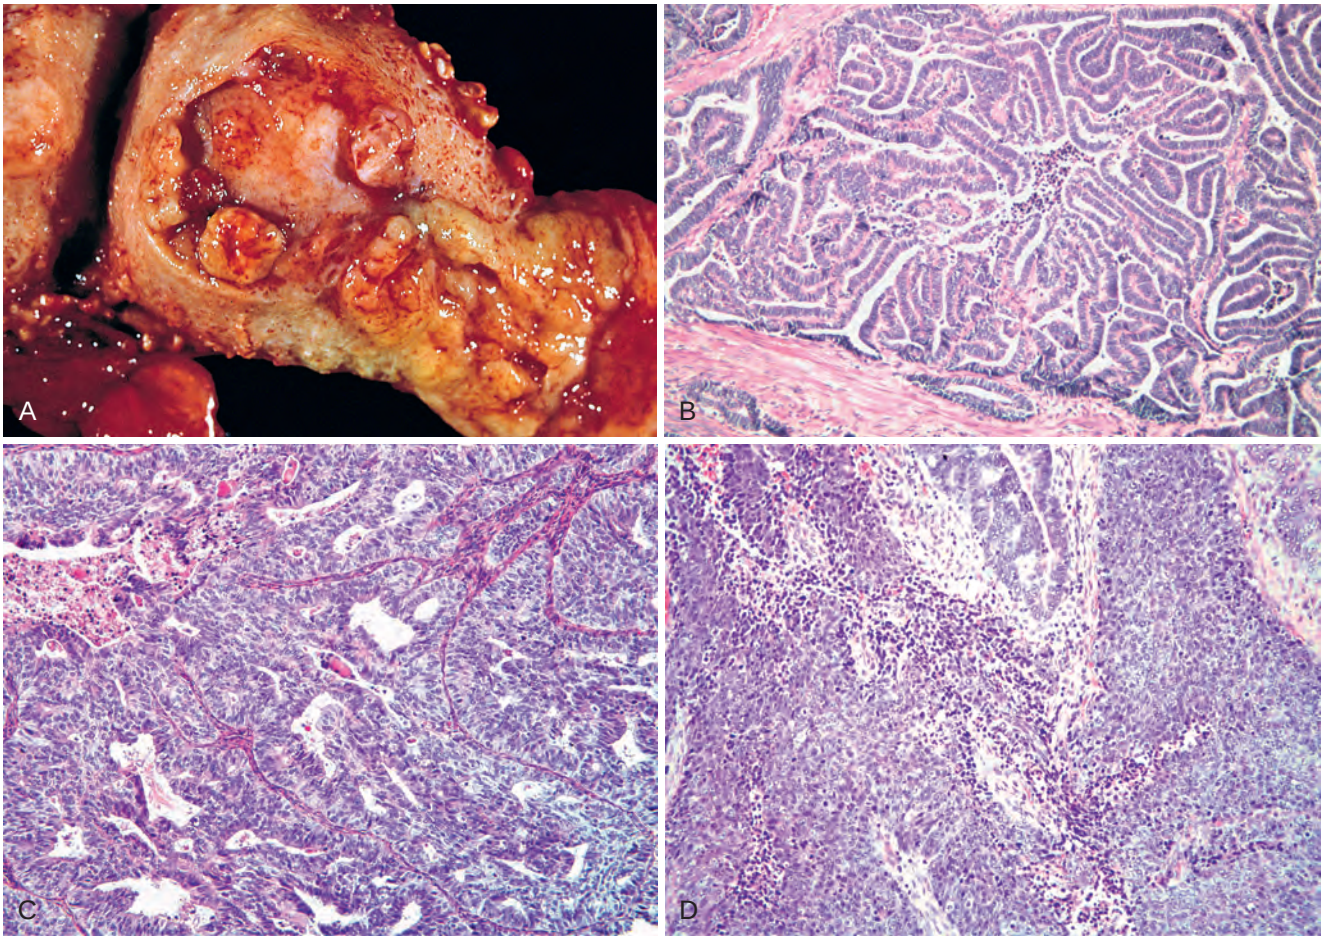

Figure 22.25 Type I endometrial carcinoma. (A) Endometrial adenocarcinoma presenting as a fungating mass in the fundus of the uterus. (B) Well-differentiated (grade 1) endometrioid adenocarcinoma with preserved glandular architecture but lack of intervening stroma. (C) Moderately differentiated (grade 2) endometrioid adenocarcinoma with glandular architecture admixed with solid areas. (D) Poorly differentiated (grade 3) endometrioid adenocarcinoma with a predominantly solid growth pattern.

adenocarcinomas. Less commonly, moderately or poorly differentiated endometrioid carcinomas contain squamous elements that appear frankly malignant. Current classification systems grade the carcinomas based on glandular differentiation alone and ignore areas of squamous differentiation.

Serous Endometrial Carcinoma

Serous endometrial carcinoma generally occurs in women who are about 10 years older than those with endometrioid carcinomas, and in contrast with endometrioid carcinoma, they usually arise in the setting of endometrial atrophy (see Fig. 22.24B). Serous tumors are considered type II tumors and are by definition poorly differentiated (grade 3). They account for approximately 15% of cases of endometrial carcinoma. This subtype shows significant morphologic and biologic overlap with ovarian serous carcinoma.

Pathogenesis

Serous endometrial carcinoma is highly associated with disruptive mutations in the *TP53* tumor suppressor gene.

TP53 mutations are present in greater than 90% of tumors. Most consist of missense mutations that result in the accumulation of the altered p53 protein (Fig. 22.26B and D). Genomic sequencing studies have detected driver mutations in a number of other cancer genes (see Table 22.4). In addition to point mutations, serous carcinomas typically are associated with significant chromosomal instability and numerous copy number alterations, a general feature of *TP53*-mutated cancers. All serous carcinomas belong to the copy number high/serous-like molecular category.

Mutations in *TP53* are also found in approximately 75% of endometrial intraepithelial carcinomas, an in situ precursor lesion, suggesting that mutation of *TP53* is an early event in the evolution of serous endometrial carcinoma. The tumor presumably arises as a surface epithelial neoplasm that then extends into adjacent gland structures and later invades endometrial stroma. Their generally poorer prognosis is thought to be a consequence of a propensity to exfoliate, travel through the fallopian tubes, and implant on peritoneal surfaces like their ovarian counterparts. As a result, they have often spread outside of the uterus at the time of diagnosis.

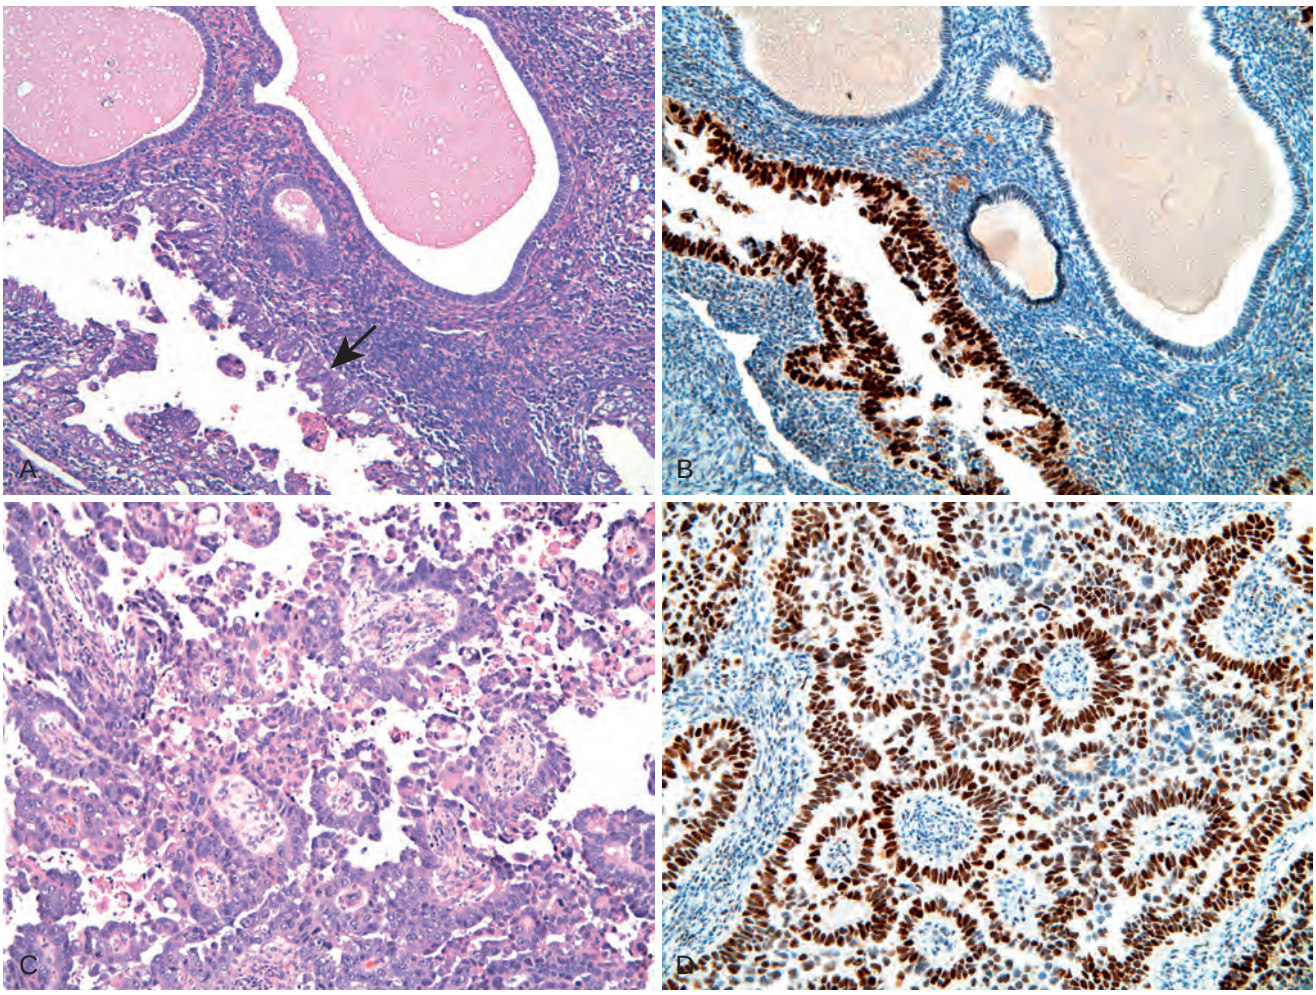

Figure 22.26 Type II endometrial carcinoma. (A) Endometrial intraepithelial carcinoma, the precursor to serous carcinoma showing malignant cells *(arrow)* with morphologic features identical to serous carcinoma lining the surfaces of the endometrial glands without obvious stromal invasion. (B) Strong, diffuse expression of p53 as detected by immunohistochemistry in endometrial intraepithelial carcinoma. (C) Serous carcinoma of the endometrium with papillary growth pattern consisting of malignant cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, and hyperchromasia. (D) As with the previous lesion, there is an accumulation of p53 protein in the nucleus.

MORPHOLOGY

Generally, serous carcinomas arise in small atrophic uteri and are often large bulky tumors or deeply invasive into the myometrium. The precursor lesion, **serous endometrial intraepithelial carcinoma,** consists of malignant cells identical to those of serous carcinoma that are confined to the epithelial surface (see Fig. 22.26A–B).The invasive lesions may have a papillary growth pattern composed of cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, hyperchromasia, and prominent nucleoli (see Fig. 22.26C–D). However, they can also have a predominantly glandular growth pattern; in such cases, they are distinguished from endometrioid carcinoma by the marked cytologic atypia. All of the tumors in this category are classified as grade 3 irrespective of architectural pattern. Serous carcinoma, despite relatively superficial endometrial involvement, may be associated with extensive peritoneal disease, suggesting spread by routes (i.e., tubal regurgitation) other than direct invasion.

Clinical Features

Carcinoma of the endometrium is uncommon in women younger than 40 years of age; the peak incidence is in postmenopausal women 55 to 65 years of age. There is no currently available screening test. Although it may be asymptomatic for a period, it usually produces irregular or postmenopausal vaginal bleeding. Fortunately, postmenopausal bleeding often leads to early detection, and cures are possible in most patients. The diagnosis must be established by histologic examination of tissue obtained by biopsy or curettage. At the time of diagnosis, endometrioid carcinomas are analyzed for evidence of DNA mismatch repair defects because approximately 3% to 5% of women with endometrial cancer have Lynch syndrome and are at high risk for colon carcinoma.

As would be anticipated, the prognosis depends heavily on the stage at diagnosis, as well as histologic grade and subtype. The staging system for endometrial adenocarcinoma is as follows:

Stage I—Carcinoma is confined to the corpus uteri itself.
Stage II—Carcinoma involves the corpus and the cervix.
Stage III—Carcinoma extends outside the uterus but not outside the true pelvis.
Stage IV—Carcinoma extends outside the true pelvis or involves the mucosa of the bladder or the rectum.

In the United States, most tumors (about 80%) are stage I well-differentiated or moderately differentiated endometrioid carcinomas. Surgery, alone or in combination with irradiation, gives about 90% 5-year survival in stage I (grade 1 or 2) disease. This rate drops to approximately 75% for stage I/grade 3 tumors and to 50% or less for stage II and III endometrial carcinomas.

As mentioned, serous carcinoma has a propensity for extrauterine (lymphatic or transtubal) spread. For unknown reasons, it occurs more frequently in women of African-American descent, a difference that accounts for a twofold higher mortality rate in African-American women with endometrial carcinoma compared with Caucasian women. Overall, the 5-year survival for women with serous carcinoma is 18% to 27%, and even when it is confined to the uterus the recurrence rate is as high as 80%.

Treatment varies according to tumor type. Women with endometrioid carcinoma often receive adjuvant radiation to reduce local recurrence and are treated with chemotherapy when the tumor has spread beyond the uterus. By contrast, because of the aggressive nature of serous carcinoma, women may be treated with chemotherapy, even in the absence of detectable extrauterine spread. Inhibitors of the PI3K/AKT pathway are being tested in clinical trials, and the continued identification of biologic targets is likely to expand the roster of rational therapies in the future. In addition, immune checkpoint inhibitors are under investigation for the treatment of women with tumors in the hypermutated MSI and "ultramutated" polymerase ε molecular categories.

Carcinosarcoma (Malignant Mixed Müllerian Tumors)

Carcinosarcomas (also referred to as malignant mixed müllerian tumors) are mixed epithelial and mesenchymal tumors. The epithelial component most often resembles poorly differentiated endometrioid or serous carcinoma, while the mesenchymal component can take a number of forms. Some contain uterine mesenchymal elements (stromal sarcoma, leiomyosarcoma), while others contain heterologous malignant cell types (rhabdomyosarcoma, chondrosarcoma). Based on molecular studies showing the presence of shared driver mutations, the epithelial and mesenchymal elements appear to be derived from a single founding cancer cell. The mutations found in carcinosarcomas involve the same genes that are mutated in endometrial carcinoma, such as *PTEN, TP53,* and *PIK3CA,* whereas alterations typical of sarcomas are absent, suggesting that these tumors are carcinomas that have acquired the capacity for mesenchymal differentiation. At present, the mechanisms underlying the sarcomatous transformation are unknown, but some abnormality of epigenetic regulation seems likely.

MORPHOLOGY

Carcinosarcomas are often bulky and polypoid, and they may protrude through the cervical os. These tumors usually contain areas of adenocarcinoma (endometrioid, serous, or clear cell) mixed with the malignant mesenchymal (sarcomatous) elements (Fig. 22.27A); alternatively, the tumor may contain two distinct and separate epithelial and mesenchymal components. Sarcomatous components may also mimic extrauterine tissues (e.g., striated muscle, cartilage, adipose tissue, and bone). Metastases usually contain only epithelial components (see Fig. 22.27B).

Carcinosarcomas occur in postmenopausal women and present with bleeding. Outcome is determined primarily by depth of invasion and stage. The only other known prognostic factor is the differentiation of the mesenchymal component; patients with tumors that have heterologous mesenchymal components have a poorer prognosis than those whose tumors do not. Overall 5-year survival rates are 25% to 30% for patients with high-stage disease.

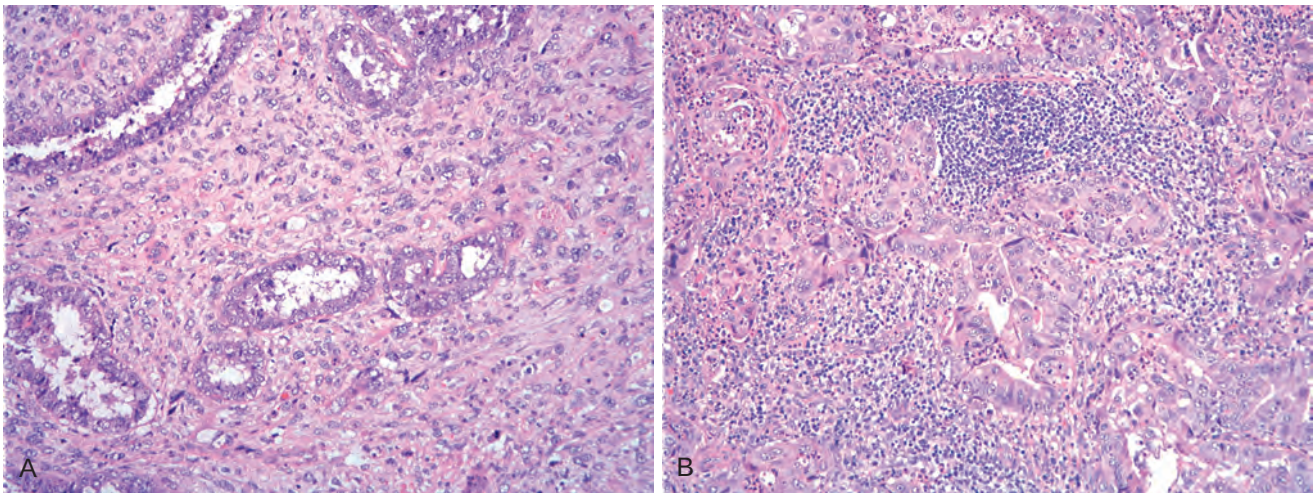

Figure 22.27 Carcinosarcoma. (A) Micrograph showing both malignant epithelial and stromal components. (B) Lymph node metastasis from a carcinosarcoma showing only the epithelial component, as is typically the case.

KEY CONCEPTS

ENDOMETRIAL CARCINOMA

- Endometrial carcinoma is the most common malignancy of the female genital tract.
- There are two major types of endometrial carcinoma: type I and type II. Type I tumors are low-grade and usually indolent; type II tumors are high-grade aggressive tumors and have a poor prognosis.
- Four molecular subtypes of endometrioid and serous carcinoma are currently recognized.
- Endometrioid (type I) carcinoma is often preceded by atypical hyperplasia and commonly has mutations that upregulate PI3K/AKT signaling.
- Serous (type II) carcinoma is associated with serous endometrial intraepithelial carcinoma, and the most common mutations are in *TP53*. *TP53* mutations are also found in precursor lesions.
- Stage remains the most important factor in outcome; serous tumors are much more likely to present at advanced stage and have a decidedly worse prognosis.
- Carcinosarcomas are aggressive tumors that resemble endometrial carcinoma genetically and have poor outcomes with current therapies.

TUMORS OF ENDOMETRIAL STROMA

These relatively uncommon tumors comprise less than 5% of endometrial cancers and include stromal neoplasms admixed with benign glands (adenosarcomas) and pure stromal neoplasms.

Adenosarcoma

Adenosarcoma presents most commonly as large broad-based endometrial polypoid growths that may prolapse through the cervical os. The diagnosis is based on the presence of malignant-appearing stroma, which coexists with benign but abnormally shaped endometrial glands. These tumors predominate in women between the fourth and fifth decades and are generally considered to be a low-grade malignancy; recurrences develop in one-fourth of cases and are nearly always confined to the pelvis. The principal diagnostic dilemma is distinguishing these tumors from large benign polyps.

Stromal Tumors

The endometrium occasionally gives rise to neoplasms that resemble normal stromal cells. Endometrial stromal neoplasms are divided into two categories: (1) benign stromal nodules and (2) endometrial stromal sarcoma. Stromal sarcoma may be further divided into low-grade and high-grade types depending on their differentiation.

Clues to the pathogenesis of stromal sarcoma have come from the identification of several recurrent chromosomal aberrations that are quite specific for these malignancies. As with many sarcomas, stromal sarcoma is associated with chromosomal translocations that create fusion genes. Low-grade endometrial stromal sarcoma usually has a translocation in which a portion of the *JAZF1* gene, which encodes a transcriptional repressor, is fused to a second gene belonging to the polycomb gene family, such as *SUZ12*. Polycomb proteins participate in complexes that introduce repressive histone marks into chromatin, thereby silencing genes, and it is hypothesized that the JAZF1 fusion proteins act by disrupting the function of the polycomb complex, leading to misexpression of oncogenic genes. Recently, high-grade endometrial stromal sarcomas have been observed to contain different chromosomal translocations that also result in the formation of fusion genes, which are presumed to be pathogenically significant but are currently of unknown function.

About one-half of stromal sarcomas recur; relapse rates range from 36% to more than 80% for stage I and stage III/IV tumors, respectively. Unfortunately, relapse is not reliably predicted by either mitotic index or the degree of cytologic atypia. Distant metastases may announce their

presence decades after the initial diagnosis, and death from metastatic tumor occurs in about 15% of cases. The 5-year survival rates average 50% for low-grade tumors and are lower for high-grade tumors.

TUMORS OF THE MYOMETRIUM

Leiomyoma

Uterine leiomyoma (commonly called *fibroid*) is perhaps the most common tumor in women. They are benign smooth muscle neoplasms that may occur singly, but more often are multiple. Most leiomyomas have normal karyotypes, but approximately 40% have a simple chromosomal abnormality. Several cytogenetic subgroups are recognized, including tumors with rearrangements of chromosomes 12q14 and 6p involving the *HMGIC* and *HMGIY* genes, respectively, which are also implicated in a variety of other benign neoplasms. Both genes encode closely related DNA-binding factors that regulate chromatin structure. Additionally, mutations in the gene *MED12* occur in roughly 70% of uterine leiomyomas. *MED12* encodes a component of Mediator, a multiprotein complex that stimulates gene expression by serving as a bridge between transcription factors and RNA polymerase. Mice expressing mutated forms of *MED12* develop uterine leiomyoma, proving that such mutations can be causative, but precisely how they contribute to tumor development remains to be defined.

MORPHOLOGY

Leiomyomas are sharply circumscribed, discrete, round, firm, gray-white tumors varying in size from small, barely visible nodules to massive tumors that fill the pelvis. Except in rare instances, they are found within the myometrium of the corpus. Only infrequently do they involve the uterine ligaments, lower uterine segment, or cervix. They can occur within the myometrium (intramural), just beneath the endometrium (submucosal) or beneath the serosa (subserosal) (Fig. 22.28A). The characteristic whorled pattern of smooth muscle bundles on cut section usually makes these lesions readily identifiable. Large tumors may develop areas of yellow-brown to red softening.

Leiomyomas are composed of bundles of smooth muscle cells that resemble the uninvolved myometrium (Fig. 22.28B). Usually, the individual muscle cells are uniform in size and shape and have a characteristic oval nucleus and long, slender bipolar cytoplasmic processes. Mitotic figures are scarce. Morphologic variants include leiomyoma with bizarre nuclei, which has nuclear atypia and giant cells, and cellular leiomyomas. Both have a low mitotic index, helping to distinguish these benign tumors from leiomyosarcoma. An extremely rare variant, **intravenous leiomyomatosis,** is a uterine leiomyoma that extends into vessels and spreads hematogenously to other sites, most commonly the vena cava and the right atrium. Another variant, **disseminated peritoneal leiomyomatosis,** presents as multiple small peritoneal nodules. Both are considered benign despite their unusual behavior.

Uterine leiomyomas, even when large or numerous, may be asymptomatic. Common signs and symptoms include abnormal bleeding, urinary frequency due to compression of the bladder, sudden pain from infarction of a large or pedunculated tumor, and impaired fertility. In pregnant women, leiomyomas may increase the frequency of spontaneous abortion, fetal malpresentation, uterine inertia (failure to contract with sufficient force), and postpartum hemorrhage. Malignant transformation to leiomyosarcoma is extremely rare.

Leiomyosarcoma

These uncommon malignant neoplasms are thought to arise from the myometrium or endometrial stromal precursor cells, rather than leiomyomas. In contrast to leiomyomas, leiomyosarcomas have complex, highly variable karyotypes that frequently include deletions. Like leiomyomas, a subset contains *MED12* mutations, a genetic aberration that appears to be virtually unique to uterine smooth muscle tumors.

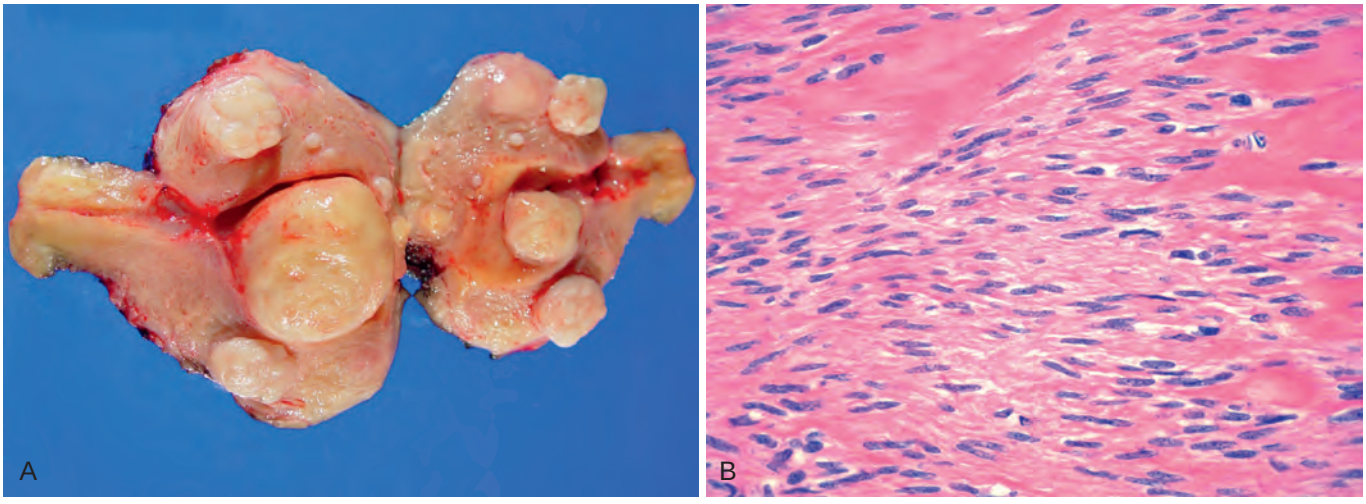

Figure 22.28 Leiomyomas of the uterine myometrium (A) The uterus is opened to reveal multiple tumors in submucosal (bulging into the endometrial cavity), intramural, and subserosal locations that display a firm white appearance on sectioning. (B) Leiomyoma showing well-differentiated, regular, spindle-shaped smooth muscle cells associated with hyalinization.

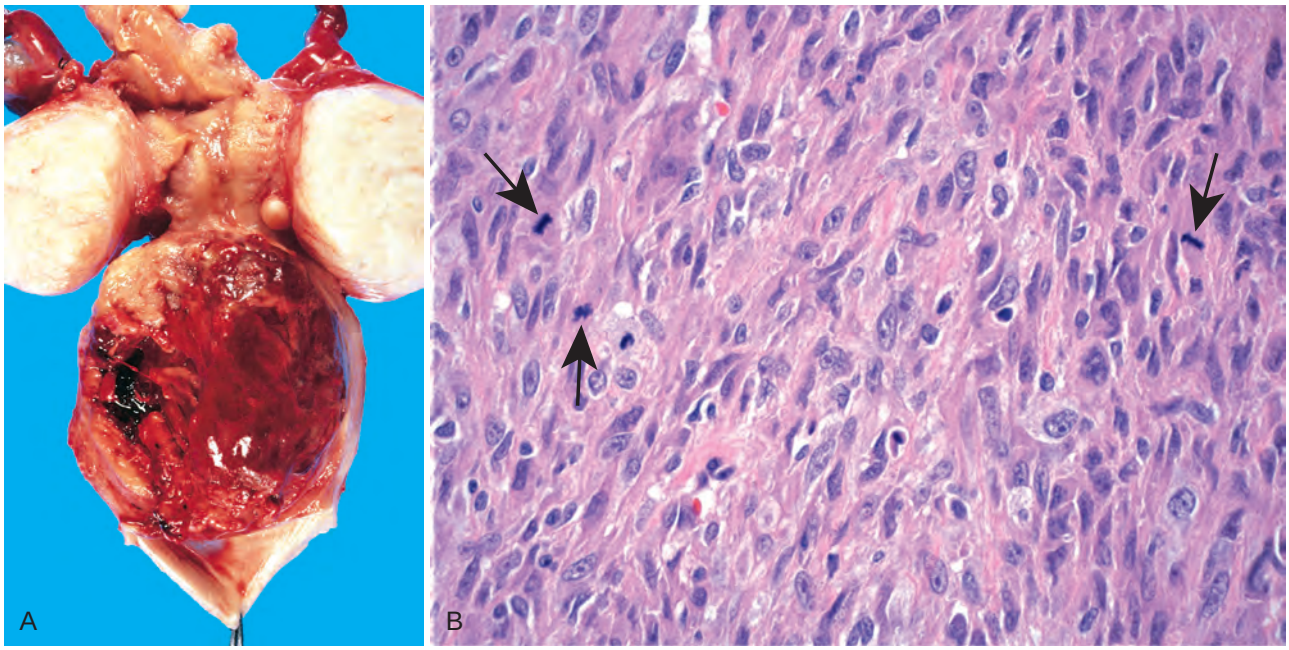

Figure 22.29 Leiomyosarcoma. (A) A large hemorrhagic tumor mass distends the lower corpus and is flanked by two leiomyomas. (B) The tumor cells are irregular in size and have hyperchromatic nuclei. Numerous mitotic figures are present *(arrows)*.

MORPHOLOGY

Leiomyosarcomas grow within the uterus in two somewhat distinctive patterns: (1) bulky, fleshy masses that invade the uterine wall or (2) polypoid masses that project into the uterine lumen (Fig. 22.29A). They exhibit a wide range of cytologic atypia, from extremely well differentiated to highly anaplastic (Fig. 22.29B). The distinction from leiomyoma is based on nuclear atypia, mitotic index, and tumor necrosis. With few exceptions, the presence of 10 or more mitoses per 10 high-power (400×) fields indicates malignancy, particularly if accompanied by cytologic atypia and/or necrosis. If the tumor contains nuclear atypia or large (epithelioid) cells, five mitoses per 10 high-power (400×) fields are sufficient to justify a diagnosis of malignancy. Rare exceptions include mitotically active leiomyomas in young or pregnant women, and caution should be exercised in interpreting such neoplasms as malignant. A proportion of smooth muscle neoplasms may be impossible to classify and are called smooth muscle tumors of "uncertain malignant potential."

Leiomyosarcoma occurs both before and after menopause, with a peak incidence at 40 to 60 years of age. These tumors often recur following surgery, and more than one-half eventually metastasize hematogenously to distant organs, such as lungs, bone, and brain. Dissemination throughout the abdominal cavity is also encountered. The overall 5-year survival rate is about 40%, but the anaplastic lesions have a 5-year survival rate of only 10% to 15%.

KEY CONCEPTS

- Endometrial stromal tumors include stromal nodules, low-grade stromal sarcoma, and high-grade stromal sarcoma.
  - Stromal nodules are benign, well-circumscribed tumors.
  - Low-grade stromal sarcoma resembles stromal nodules but infiltrates into the surrounding myometrium. It is associated with fusion of the *JAZF1* gene and various polycomb factor genes, usually *SUZ12*.
  - High-grade stromal sarcoma shows marked atypia and is associated with other gene fusions.
  - Both low- and high-grade stromal sarcoma are prone to late recurrences.
- Leiomyomas are very common benign smooth muscle tumors that cause significant morbidity, but are not prone to malignant transformation.
- Leiomyosarcoma (a malignant smooth muscle tumor) is an uncommon, highly malignant myometrial tumor that usually arises de novo.

FALLOPIAN TUBES

The most common disorders affecting the fallopian tube are infections and associated inflammatory conditions, followed in frequency by ectopic (tubal) pregnancy and endometriosis.

Inflammations

Suppurative salpingitis may be caused by any pyogenic organism; in some cases more than one organism is involved. *Gonococcus* is the causative organism in more than 60% of cases, with *Chlamydiae* being responsible for many of the remaining cases. These tubal infections are a part of pelvic inflammatory disease, described earlier in this chapter.

Tuberculous salpingitis is rare in the United States, accounting for not more than 1% to 2% of all forms of salpingitis. It is more common, however, in parts of the world where tuberculosis is prevalent and is an important cause of infertility in these areas.

TUMORS AND CYSTS

The most common primary lesions of the fallopian tube (excluding endometriosis) are minute, 0.1- to 2-cm translucent cysts filled with clear serous fluid, called *paratubal cysts*. Larger varieties are found near the fimbriated end of the tube or in the broad ligaments and are referred to as *hydatids of Morgagni*. These cysts, lined by benign serous (tubal type) epithelium, are presumed to arise in remnants of the müllerian duct and are of little significance.

Benign tumors of the fallopian tube are rare and include *adenomatoid tumor* (mesothelioma), which occurs subserosally on the tube or sometimes in the mesosalpinx. These small nodules are counterparts of the adenomatoid tumors that occur in the testes or epididymis (Chapter 21).

Historically, fallopian tube carcinoma was considered to be a rare entity. However, substantial data have accumulated indicating that at least a subset of "serous ovarian cancers" actually arise from the epithelium of the fallopian tube (discussed later). This idea is supported by the frequent identification of serous tubal in situ carcinoma in women at risk for serous carcinoma (e.g., women with germline *BRCA1* mutations) and observations showing that failure to remove the fallopian tubes at the time of oophorectomy is associated with a significant residual risk of "ovarian" cancer. We will return to this issue when discussing ovarian cancer in the next section.

Ovaries

The most common lesions encountered in the ovary are functional or benign cysts and tumors. Neoplastic disorders can be grouped according to their origin from each of the three main ovarian cell types: (1) müllerian epithelium, (2) germ cells, and (3) sex cord–stromal cells. Primary inflammations of the ovary (oophoritis) are uncommon, and on rare occasions may have an autoimmune basis (autoimmune oophoritis); the autoimmune reactions affect the ovarian follicles and may lead to infertility.

NON-NEOPLASTIC AND FUNCTIONAL CYSTS

Follicle and Luteal Cysts

Cystic follicles are very common in the ovary. They originate from unruptured graafian follicles or in follicles that have ruptured and immediately sealed.

MORPHOLOGY

These cysts are usually multiple. They range in size up to 2 cm in diameter, are filled with a clear serous fluid, and are lined by a gray, glistening membrane. On occasion, larger cysts exceeding 2 cm (follicle cysts) may be diagnosed by palpation or ultrasonography; these may cause pelvic pain. Granulosa lining cells are present if the intraluminal pressure has not been so great as to cause their atrophy. The outer theca cells may be conspicuous due to increased amounts of pale cytoplasm (a change referred to as luteinization). As discussed later, when luteinization is pronounced (hyperthecosis), it may be associated with increased estrogen production and endometrial abnormalities.

Luteal cysts (corpora lutea) are present in the normal ovaries of women of reproductive age. They are lined by a rim of bright yellow tissue containing luteinized granulosa cells and are prone to rupture, which may produce a peritoneal reaction. Sometimes the combination of old hemorrhage and fibrosis may make their distinction from endometriotic cysts difficult.

Polycystic Ovaries and Stromal Hyperthecosis

***Polycystic ovarian syndrome* (PCOS) is a complex endocrine disorder characterized by hyperandrogenism, menstrual abnormalities, polycystic ovaries, chronic anovulation, and decreased fertility.** Formerly called Stein Leventhal syndrome, it affects 6% to 10% of reproductive age women worldwide. It is also associated with obesity, type 2 diabetes, and premature atherosclerosis, all of which may be indicative of an underlying metabolic disorder. The etiology of PCOS remains incompletely understood. It is marked by a dysregulation of enzymes involved in androgen biosynthesis and excessive androgen production, which is considered to be a central feature of this disorder. In addition, women with PCOS show insulin resistance and altered adipose tissue metabolism, which contribute to the development of both diabetes and obesity.

The central morphologic abnormality of PCOS is numerous cystic follicles or follicle cysts that enlarge the ovaries. However, polycystic ovaries are detected in 20% to 30% of all women, so this finding is not specific. In addition, due to an increase in free serum estrone levels, women with PCOS are at risk for endometrial hyperplasia and carcinoma.

Stromal hyperthecosis, also called cortical stromal hyperplasia, is a disorder of ovarian stroma most often seen in postmenopausal women, but it may overlap with PCOS in younger women. The disorder is characterized by uniform, usually bilateral, enlargement of the ovary (up to 7 cm), which has a white to tan appearance on sectioning. Microscopic examination shows hypercellular stroma and luteinization of the stromal cells, which are visible as discrete nests of cells with vacuolated cytoplasm. The clinical presentation and effects on the endometrium are similar to those of PCOS, although virilization may be even more striking.

A physiologic condition mimicking the aforementioned syndromes is *theca lutein hyperplasia of pregnancy*. In response to pregnancy hormones (gonadotropins), theca cells proliferate and the perifollicular zone expands. As the follicles regress, the concentric theca-lutein hyperplasia may appear nodular. This change is not to be confused with true luteomas of pregnancy (see later).

OVARIAN TUMORS

There are numerous types of ovarian tumors. About 80% are benign, and these occur mostly in young women between 20 and 45 years of age. So-called borderline tumors (tumors

of indeterminate malignancy) occur at slightly older ages. Malignant tumors are more common in women between 45 and 65 years of age. Ovarian cancer accounts for 3% of all cancers in females and is the fifth most common cause of death due to cancer in women in the United States. **Because most ovarian cancers have spread beyond the ovary and fallopian tube by the time of diagnosis, they account for a disproportionate number of deaths from cancer of the female genital tract.**

Classification

The classification of ovarian tumors given in Table 22.5 is a simplified version of the World Health Organization Histological Classification, which separates ovarian neoplasms according to the most probable tissue of origin. It is now believed that most tumors of the ovary arise ultimately from one of three ovarian components:

Table 22.5 WHO Classification of Ovarian Neoplasms

Surface Epithelial-Stromal Tumors

- Serous tumors
  - Benign (cystadenoma, cystadenofibroma)
  - Borderline (serous borderline tumor)
  - Malignant (low- and high-grade serous adenocarcinoma)
- Mucinous tumors, endocervical-like and intestinal type
  - Benign (cystadenoma, cystadenofibroma)
  - Borderline (mucinous borderline tumor)
  - Malignant (mucinous adenocarcinoma)
- Endometrioid tumors
  - Benign (cystadenoma, cystadenofibroma)
  - Borderline (endometrioid borderline tumor)
  - Malignant (endometrioid adenocarcinoma)
- Clear cell tumors
  - Benign
  - Borderline
  - Malignant (clear cell adenocarcinoma)
- Transitional cell tumors
  - Benign Brenner tumor
  - Brenner tumor of borderline malignancy
  - Malignant Brenner tumor
- Epithelial-stromal
  - Adenosarcoma
  - Malignant mixed müllerian tumor

Sex Cord–Stromal Tumors

- Granulosa tumors
- Fibromas
- Fibrothecomas
- Thecomas
- Sertoli-Leydig cell tumors
- Steroid (lipid) cell tumors

Germ Cell Tumors

- Teratoma
  - Immature
  - Mature
  - Solid
  - Cystic (dermoid cyst)
- Monodermal (e.g., struma ovarii, carcinoid)
- Dysgerminoma
- Yolk sac tumor
- Mixed germ cell tumors

Metastatic Cancer From Non-Ovarian Primary

- Colonic, appendiceal
- Gastric
- Pancreaticobiliary
- Breast

Table 22.6 Frequency of Major Ovarian Tumors

Type	Percentage of Malignant Ovarian Tumors	Percentage That Are Bilateral
Serous		
Benign (60%)	47	25
Borderline (15%)		30
Malignant (25%)		65
Mucinous		
Benign (80%)	3	5
Borderline (10%)		10
Malignant (10%)		<5
Endometrioid carcinoma	20	40
Undifferentiated carcinoma	10	—
Clear cell carcinoma	6	40
Granulosa cell tumor	5	5
Teratoma	1	15
Benign (96%)		Rare
Malignant (4%)		
Metastatic	5	>50
Others	3	—

- Surface/fallopian tube epithelium and endometriosis
- Germ cells, which migrate to the ovary from the yolk sac and are pluripotent
- Stromal cells, including the sex cords, which are forerunners of the endocrine apparatus of the postnatal ovary

There is also a group of miscellaneous tumors, and finally there are secondary or metastatic tumors to the ovary.

Although some of the specific tumors have distinctive features and are hormonally active, most are nonfunctional and produce few symptoms until they reach a large size. Some, principally epithelial tumors, are often bilateral. Table 22.6 lists the tumors and their subtypes. Abdominal pain and distention, urinary and gastrointestinal tract symptoms due to compression by the tumor or cancer invasion, and vaginal bleeding are the most common symptoms. The benign forms may be entirely asymptomatic and occasionally are found unexpectedly on abdominal or pelvic examination or during surgery.

Epithelial Tumors

Most primary ovarian neoplasms arise from müllerian epithelium. The classification of these tumors is based on both differentiation and extent of proliferation of the epithelium. There are three major histologic types based on the differentiation of the neoplastic epithelium: serous, mucinous, and endometrioid tumors. These epithelial proliferations are classified as benign, borderline, and malignant. The benign tumors are often further subclassified based on the components of the tumors, which may include cystic areas (cystadenoma), cystic and fibrous areas (cystadenofibroma), and predominantly fibrous areas (adenofibroma). The borderline tumors and the malignant tumors can also have a cystic component, and when malignant they are sometimes referred to as *cystadenocarcinoma*. The tumors can be relatively small, or they can grow to fill the entire pelvis before they are detected.

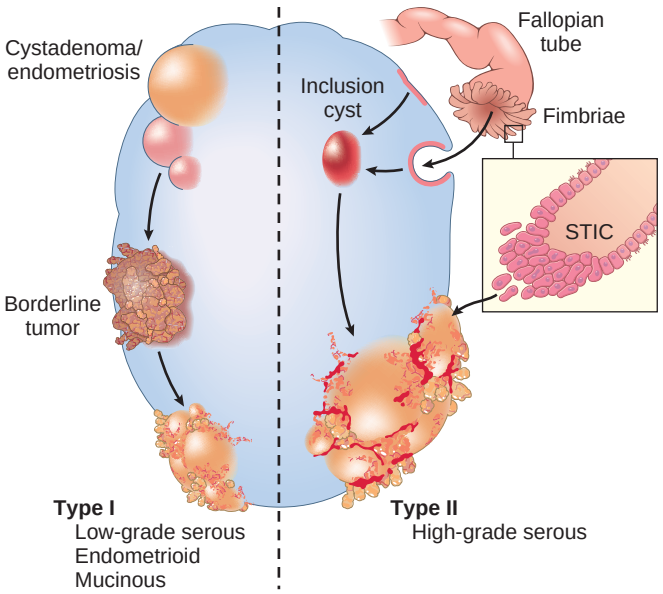

Figure 22.30 Schematic diagram of the pathogenesis of ovarian epithelial tumors. Type I tumors progress from benign tumors through borderline tumors that may give rise to a low-grade carcinoma. These include low-grade serous, endometrioid, and mucinous carcinomas. Type II tumors arise from inclusions cysts/fallopian tube epithelium via intraepithelial precursors that are often not identified. They demonstrate high-grade features and are most commonly of serous histology. *STIC*, Serous tubal intraepithelial carcinoma.

Clinicopathologic and molecular studies have suggested that ovarian carcinoma may be broadly categorized into two different types, referred to as type I and type II (Fig. 22.30). Type I carcinomas are low-grade tumors that often arise in association with borderline tumors or endometriosis. These tumors encompass several histologic subtypes, including low-grade serous, endometrioid, and mucinous tumors, as discussed later. Type II tumors are most often high-grade serous carcinomas that arise from serous intraepithelial carcinoma (see later).

Serous Tumors

These cystic neoplasms include the most common malignant ovarian tumors and account for approximately 40% of all cancers of the ovary. Although the term *serous* appropriately describes the cyst fluid, it has become synonymous with the tubal-like epithelium in these tumors. Together, benign, borderline, and malignant serous tumors account for about 30% of all ovarian tumors and just over 50% of ovarian epithelial tumors. About 70% are benign or borderline, and 30% are malignant. Benign and borderline tumors are most common between 20 and 45 years of age. Serous carcinomas occur later in life on average, but often occur at earlier ages in familial cases.

Pathogenesis

Little is known about the risk factors for benign and borderline tumors. Risk factors for malignant serous tumors (serous carcinomas) are also not completely understood, but nulliparity, family history, and heritable mutations play a role in tumor development. There is a higher frequency of carcinoma in women with low parity. Women 40 to 59 years of age who have taken oral contraceptives or undergone tubal ligation have a reduced risk of developing ovarian cancer. The most intriguing risk factors are genetic. As discussed in Chapters 7 and 23, inherited germline mutations in both *BRCA1* and *BRCA2* increase susceptibility to both ovarian cancer and breast cancer. *BRCA1* mutations are present in about 5% of patients younger than 70 years of age with ovarian cancer. The estimated risk of ovarian cancer in women bearing *BRCA1* or *BRCA2* mutations is 20% to 60% by 70 years of age.

Serous ovarian carcinoma is divided into two major groups: (1) low-grade carcinoma and (2) high-grade carcinoma. This distinction is made based on the degree of nuclear atypia and correlates with patient survival. Low-grade carcinomas may arise in association with serous borderline tumors, while high-grade carcinomas arise from in situ lesions in the fallopian tube fimbriae or from serous inclusion cysts within the ovary.

The concept of a fallopian tube origin for high-grade serous carcinomas was initially sparked by the observation that women with *BRCA1/2* germline mutations were often discovered at the time of prophylactic salpingo-oophorectomy to have areas of marked epithelial atypia in their fallopian tubes. The lesions, called serous tubal intraepithelial carcinoma (STIC), have since been described in association with sporadic high-grade serous ovarian cancers, suggesting that at least some high-grade serous carcinomas arise from the fallopian tube. What then is the origin of high-grade serous carcinomas that involve the ovary, without concomitant involvement of the fallopian tube? Historically, the source of these tumors was hypothesized to be cortical inclusion cysts (Fig. 22.31), which were thought to arise through invagination of the surface epithelium, followed by serous metaplasia. A recent alternative idea is that the cysts arise from implantation of detached fallopian tube epithelium at sites where ovulation has disrupted the surface of the ovary (see Fig. 22.30).

The percentage of sporadic high-grade serous carcinomas that arise in the fallopian tube or from ovarian inclusion cysts is currently uncertain, as is the origin of cortical inclusion cysts. However, this paradigm shift has already altered the management of women at high-risk for ovarian

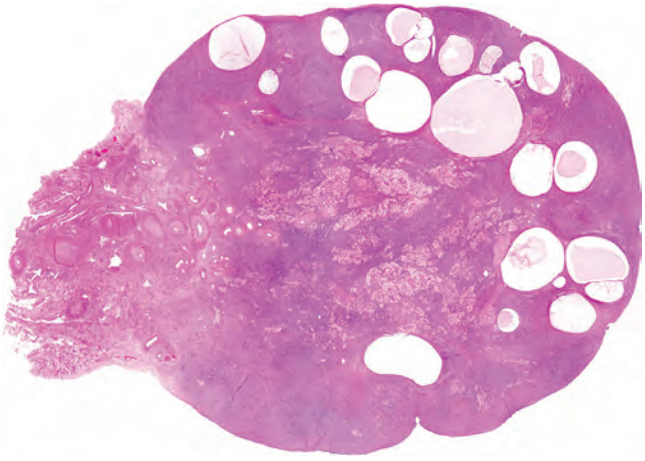

Figure 22.31 Cortical inclusion cysts of the ovary.

carcinoma (*BRCA* mutation carriers and women with a strong family history of breast/ovarian cancer), as these women now undergo salpingo-oophorectomy, instead of simple oophorectomy.

Regardless of their origin, studies have shown that low- and high-grade serous carcinoma have distinct mutational profiles, as follows:

- Low-grade tumors arising in serous borderline tumors have mutations in the *KRAS, BRAF,* or *ERBB2* oncogenes, and usually have wild-type *TP53* genes.
- High-grade tumors have a high frequency of *TP53* mutations and lack mutations in either *KRAS* or *BRAF*. Genomic imbalances are very common and include amplifications of a number of oncogenes (e.g., *PIK3CA,* the gene encoding the catalytic subunit of PI3K) and deletions of tumor suppressor genes (e.g., *RB*). Almost all ovarian carcinomas arising in women with *BRCA1* or *BRCA2* mutations are high-grade serous carcinomas with *TP53* mutations. Curiously, *BRCA1* and *BRCA2* mutations are rare in sporadic high-grade serous carcinoma.

MORPHOLOGY

Serous tumors may present as a multicystic lesion in which papillary epithelium is contained within fibrous walled cysts (intracystic) (Fig. 22.32A) or as a mass projecting from the ovarian surface. Benign tumors typically have a smooth glistening cyst wall with no epithelial thickening or with small papillary projections. Borderline tumors contain an increased number of papillary projections (Fig. 22.32A and C). Larger areas of solid or papillary tumor growth, tumor irregularity, and fixation or nodularity of the capsule are features associated with malignancy (Fig. 22.32B). Bilaterality is common, occurring in 20% of benign serous cystadenomas, 30% of serous borderline tumors, and approximately 66% of serous carcinomas. A significant proportion of borderline and malignant serous tumors involve the surface of the ovary (Fig. 22.32C).

Microscopically, the cysts are lined by columnar epithelium. In benign tumors (Fig. 22.33A), the epithelial cells retain abundant cilia, and microscopic papillae may be found. **Serous borderline tumors** exhibit increased complexity of the stromal papillae, stratification of the epithelium, and mild nuclear atypia, but invasion of the stroma is not seen (Fig. 22.33B). The epithelial cells often grow in a delicate, papillary pattern referred to as "micropapillary carcinoma," which is thought to be the precursor to **low-grade serous carcinoma** (Fig. 22.33C). **High-grade serous carcinoma** is distinguished by having more complex growth patterns and widespread infiltration or frank effacement of the underlying stroma (Fig. 22.33D). The individual tumor cells display marked nuclear atypia, including pleomorphism, atypical mitotic figures, and multinucleation; occasionally, tumors may be so undifferentiated that serous features are no longer recognizable. Serous tubal intraepithelial carcinoma consists of cells morphologically identical to high-grade serous carcinoma that do not invade the underlying stroma. Concentric calcifications (psammoma bodies) are common in all types of serous tumors, but are not specific for neoplasia.

Ovarian serous tumors, both low- and high-grade, have a propensity to spread to the peritoneal surfaces and omentum and are commonly associated with the presence of ascites. As with other tumors, the extent of the spread outside the ovary determines the stage of the disease.

The biologic behavior of serous tumors depends on the degree of differentiation and the extent and distribution of peritoneal disease. Serous tumors may occur on the surface of the ovaries; if unencapsulated, such tumors are likely to spread to the peritoneum. As discussed, at least some of these carcinomas likely originate from the fallopian tube, from which they may exfoliate and spread to the peritoneum. In rare instances, they appear to originate on the peritoneal surface (referred to as primary peritoneal serous carcinoma).

Prognosis is closely related to the histologic appearance of the tumor and the presence and extent of peritoneal disease. Borderline serous tumors may arise from or secondarily involve the peritoneal surfaces as noninvasive implants, remaining localized and causing no symptoms, or slowly spread, producing intestinal obstruction or other complications after many years. Similarly, low-grade carcinomas, even after spread outside the ovary, often progress slowly, and patients may survive for relatively long periods before dying of disease. In contrast, high-grade tumors are often widely metastatic throughout the abdomen at the time

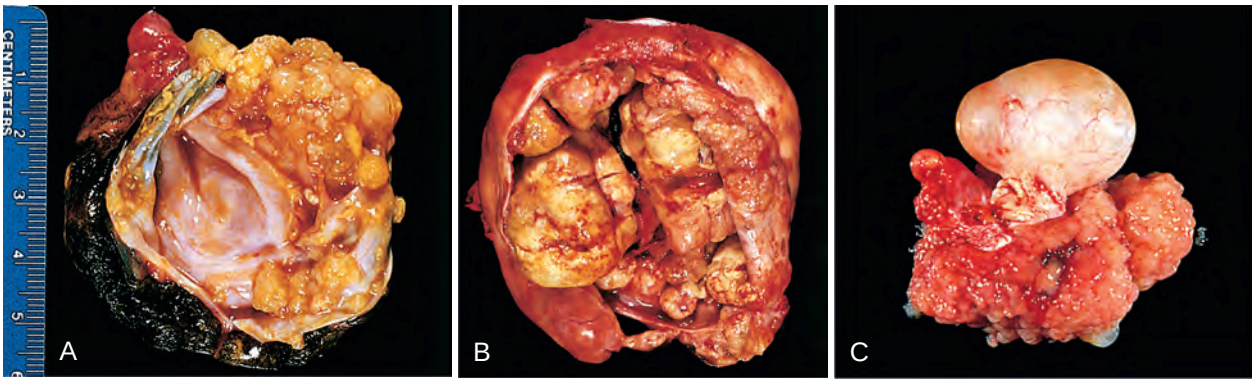

Figure 22.32 Gross appearances of serous tumors of the ovary. (A) Serous borderline tumor opened to display a cyst cavity lined by delicate papillary tumor growths. (B) Carcinoma. The cyst is opened to reveal a large, bulky tumor mass. (C) Another borderline tumor growing on the ovarian surface *(lower).*

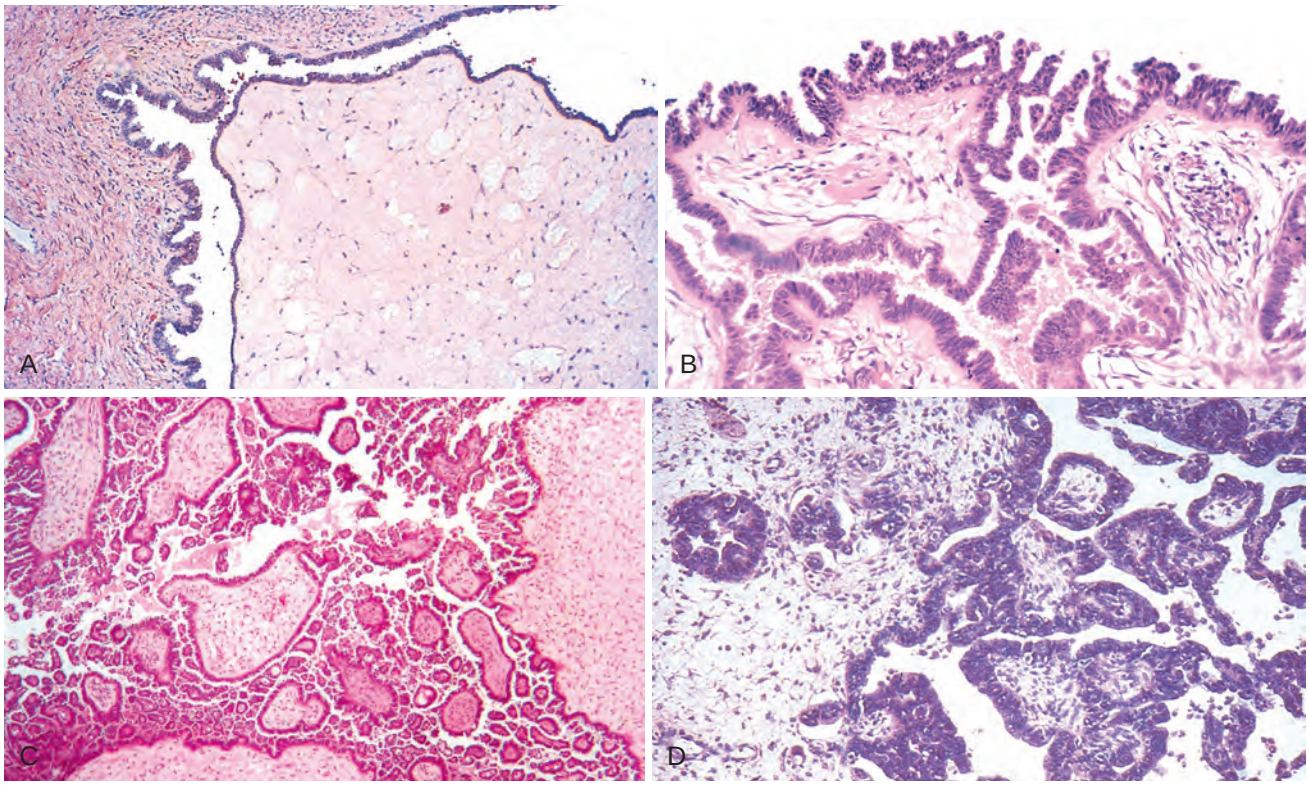

Figure 22.33 Microscopic appearances of serous tumors of the ovary. (A) Serous cystadenoma revealing stromal papillae with a columnar epithelium. (B) Borderline serous tumor showing increased architectural complexity and epithelial cell stratification. (C) Complex micropapillary growth defines a low-grade "micropapillary" serous carcinoma. (D) High-grade serous carcinoma of the ovary with invasion of underlying stroma.

of presentation, a picture associated with rapid clinical deterioration. Consequently, grading of the tumor, even after extension to the peritoneum, impacts both prognosis and selection of therapy. The 5-year survival rate for borderline and malignant tumors confined to the ovary is 100% and 70%, respectively, whereas the 5-year survival rate for the same tumors involving the peritoneum is about 90% and 25%, respectively. Because of their protracted course, borderline tumors may recur after many years, and 5-year survival is not synonymous with cure.

Mucinous Tumors

Mucinous tumors account for about 20% to 25% of all ovarian neoplasms. They occur principally in middle adult life and are rare before puberty and after menopause. The vast majority are benign or borderline tumors. Primary ovarian mucinous carcinomas are uncommon and account for approximately 3% of all ovarian cancers.

Pathogenesis

Mutation of the *KRAS* proto-oncogene is a consistent genetic alteration in mucinous tumors of the ovary, including the majority of benign mucinous cystadenomas (58%), mucinous borderline tumors (75% to 86%), and ovarian mucinous carcinomas (85%). Interestingly, one study showed that several tumors with distinct areas of epithelium showing benign, borderline, and carcinoma had identical *KRAS* mutations in each area. Thus, *KRAS* mutations may initiate the development of these neoplasms.

MORPHOLOGY

Mucinous tumors differ from the serous variety in several ways. The surface of the ovary is rarely involved, and only 5% of primary mucinous cystadenomas and mucinous carcinomas are bilateral. Mucinous tumors also tend to produce larger cystic masses; some have been recorded with weights of more than 25 kg. They are multiloculated tumors filled with sticky, gelatinous fluid rich in glycoproteins (Fig. 22.34A).

Microscopically, benign mucinous tumors are characterized by a lining of tall, columnar epithelial cells with apical mucin that lack cilia. The vast majority demonstrate gastric or intestinal type differentiation; uncommonly, tumors may show endocervical type mucinous differentiation instead (Fig. 22.34B). Mucinous borderline tumors are distinguished from cystadenomas by epithelial stratification, tufting, and/or papillary intraglandular growth, often producing an appearance strikingly similar to tubular adenomas or villous adenomas of the intestine. **Mucinous carcinoma** characteristically demonstrates confluent glandular growth that is now recognized as a form of "expansile" invasion. Some authors use the term intraepithelial carcinomas for tumors with marked epithelial atypia that lack invasive features. Approximate 10-year survival rates for stage I noninvasive "intraepithelial carcinoma" and for frankly invasive malignant tumors are greater than 95% and 90%, respectively. Mucinous carcinomas that have spread beyond the ovary are usually fatal, but as stated earlier, these tumors are uncommon and must be distinguished from metastatic mucinous adenocarcinomas.

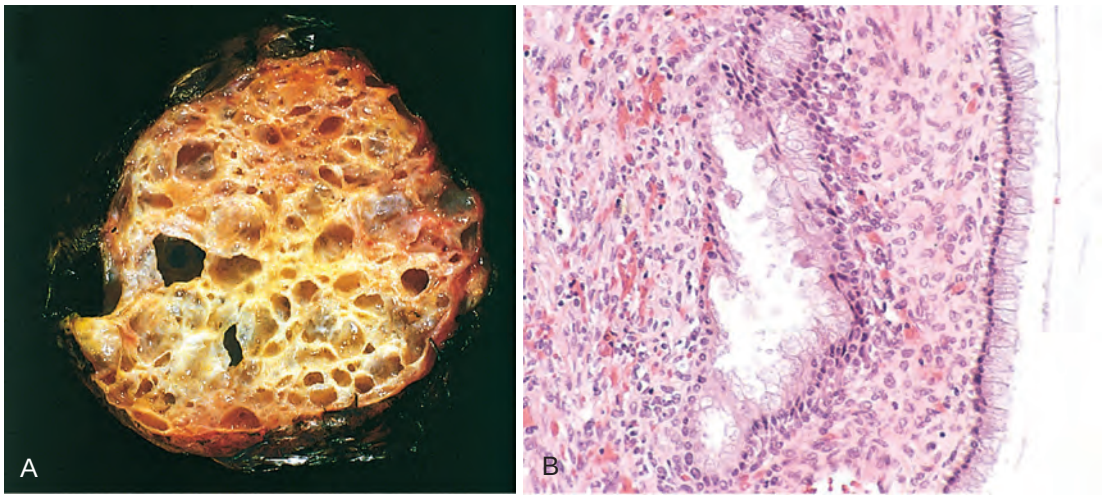

Figure 22.34 Mucinous cystadenoma (A) Note the multicystic appearance, delicate septa, and the presence of glistening mucin within the cysts. (B) Columnar cells lining the cysts.

A clinical condition referred to as *pseudomyxoma peritonei* is marked by mucinous ascites, cystic epithelial implants on the peritoneal surfaces, adhesions, and frequent involvement of the ovaries (Fig. 22.35). Pseudomyxoma peritonei, if extensive, may result in intestinal obstruction and death. Historically, it was thought that many cases in women were due to the spread of primary ovarian mucinous neoplasms. However, recent evidence points in almost all cases to an extra-ovarian source, usually the appendix (Chapter 17). Because the majority of primary mucinous ovarian tumors are unilateral, bilateral presentation of mucinous tumors always requires exclusion of metastasis from a non-ovarian primary tumor.

Endometrioid Ovarian Tumors

Endometrioid carcinoma accounts for approximately 10% to 15% of all ovarian cancers. Benign endometrioid tumors, called *endometrioid adenofibroma,* and borderline endometrioid tumors also occur, but are uncommon. Approximately 15% to 30% of ovarian endometrioid carcinomas are accompanied by carcinoma of the endometrium; although such cases have a relatively good prognosis, molecular data suggest that in most instances of concomitant endometrial and ovarian disease, the ovarian disease arises from metastatic spread of a primary endometrial tumor.

Pathogenesis

In about 15% to 20% of cases, endometrioid carcinoma coexists with endometriosis. The peak incidence of tumors associated with endometriosis is a decade earlier than that of endometrioid carcinomas that are not associated, suggesting that ovarian endometriosis serves as a precursor to ovarian endometrioid carcinoma in some instances. Molecular studies have found striking similarities to endometrial endometrioid carcinoma; shared features include relatively frequent alterations that increase PI3K/AKT pathway signaling (mutations in *PTEN, PIK3CA, ARID1A,* and *KRAS*) and mutations in mismatch DNA repair genes. Also similar to endometrioid carcinomas of the endometrium, *TP53* mutations are common in poorly differentiated tumors.

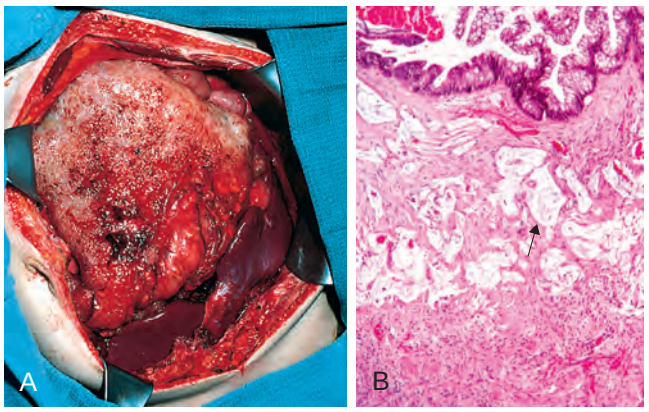

Figure 22.35 Pseudomyxoma peritonei. (A) View at laparotomy revealing massive overgrowth of a gelatinous metastatic tumor. (B) Histology of peritoneal implants from an appendiceal tumor, showing mucin-producing epithelium and free mucin *(arrow)*. (A, Courtesy Dr. Paul H. Sugarbaker, Washington Hospital Cancer Center, Washington, DC.)

MORPHOLOGY

Endometrioid tumors are distinguished from serous and mucinous tumors by the presence of tubular glands resembling benign or malignant endometrium. Endometrioid carcinomas typically present with solid and cystic areas of growth. Forty percent involve both ovaries, and such bilaterality usually implies extension of the neoplasm beyond the genital tract. These are low-grade tumors that reveal glandular patterns bearing a strong resemblance to those of endometrial origin. The 5-year survival rate for patients with stage I tumors is approximately 75%.

Clear Cell Carcinoma

Benign and borderline clear cell tumors are exceedingly rare, and clear cell carcinomas are uncommon. They are composed of large epithelial cells with abundant clear cytoplasm, an appearance that resembles hypersecretory

gestational endometrium. Because these tumors sometimes occur in association with endometriosis or endometrioid carcinoma of the ovary and resemble clear cell carcinoma of the endometrium, they are now thought to be variants of endometrioid adenocarcinoma. In line with this idea, the most common genetic aberrations (*PIK3CA, ARID1A, KRAS, PTEN,* and *TP53*) are shared with endometrioid carcinoma, albeit at somewhat different frequencies. Clear cell tumors of the ovary can be predominantly solid or cystic. In the solid neoplasms, the clear cells are arranged in sheets or tubules, while in the cystic variety, the neoplastic cells line the spaces. Clear cell carcinoma confined to the ovaries has a 90% 5-year survival, but in advanced stage disease it appears that clear cell morphology portends a poor outcome. Clear cell carcinoma is treated like other types of ovarian carcinoma.

Cystadenofibroma

Cystadenofibroma is an uncommon variant in which there is pronounced proliferation of the fibrous stroma that underlies the columnar lining epithelium. These benign tumors are usually small and multilocular and have simple papillary processes that are not as complicated and branching as those found in the ordinary cystadenoma. They may contain mucinous, serous, endometrioid, or transitional (Brenner tumor) epithelium. Borderline lesions with cellular atypia and, rarely, tumors with focal areas of carcinoma occur, but metastatic spread of either is extremely uncommon.

Transitional Cell Tumors

Transitional cell tumors contain neoplastic epithelial cells resembling urothelium and are usually benign. They comprise roughly 10% of ovarian epithelial tumors and are also referred to as *Brenner tumors*. Uncommon transitional cell carcinomas also occur in the ovary.

MORPHOLOGY

Brenner tumors may be solid or cystic, are usually unilateral (approximately 90%), and vary in size from small lesions less than 1 cm in diameter to massive tumors up to 20 to 30 cm in diameter (Fig. 22.36A). The fibrous stroma, resembling that of the normal ovary, is marked by sharply demarcated nests of epithelial cells resembling the epithelium of the urinary tract, often with mucinous glands in their center (Fig. 22.36B). Infrequently, the stroma is composed of plump fibroblasts resembling theca cells; such neoplasms may have hormonal activity. Most Brenner tumors are benign, but borderline and malignant counterparts have been reported. Tumors with benign Brenner nests admixed with malignant tumor cells are referred to as malignant Brenner tumors, while tumors with greater than 50% malignant transitional type epithelium are considered transitional cell carcinomas of the ovary.

Brenner tumors are often detected incidentally and even when large behave in a benign fashion. Malignant Brenner tumors generally present in stage 1 and for prognostic purposes are considered to be equivalent to low-grade (type 1) carcinomas. The uncommon transitional cell carcinomas are considered to be equivalent to high-grade (type II) ovarian carcinomas; these often present at advanced stage and are treated like high-grade serous carcinomas.

Clinical Course, Detection, and Prevention of Ovarian Epithelial Tumors

All ovarian carcinomas produce similar clinical manifestations, most commonly lower abdominal pain and abdominal enlargement. Gastrointestinal complaints, urinary frequency, dysuria, pelvic pressure, and many other symptoms may appear. Benign lesions are easily resected and cured. The malignant tumors tend to cause progressive weakness, weight loss, and cachexia. Once carcinomas extend through the capsule of the tumor and seed the peritoneal cavity, they often cause ascites, which may be massive. Characteristically, the ascitic fluid is filled with exfoliated tumor cells. The peritoneal pattern of spread is distinctive: serosal surfaces are diffusely seeded with 0.1- to 0.5-cm nodules of tumor that only rarely invade deeply into the underlying parenchyma. The regional nodes are often involved, and metastases may be found in the liver, lungs, gastrointestinal tract, and elsewhere. Metastasis across the midline to the opposite ovary is discovered in about one-half the cases at surgery and heralds a progressive downhill course and death within a few months or years.

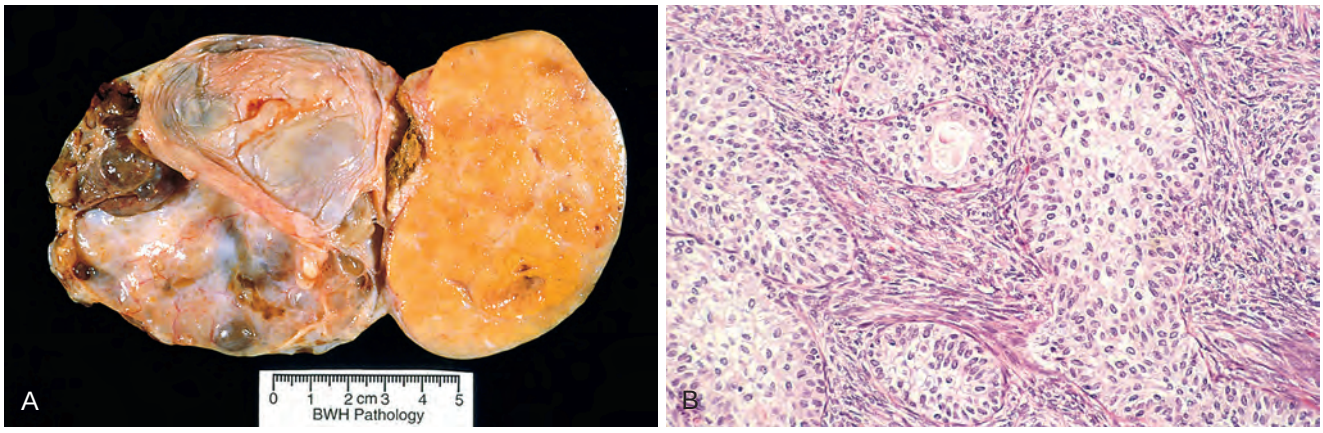

Figure 22.36 Brenner tumor (A) Brenner tumor *(right)* associated with a benign cystic teratoma *(left)*. (B) Histologic detail of characteristic epithelial nests within the ovarian stroma. (Courtesy Dr. M. Nucci, Brigham and Women's Hospital, Boston, Mass.)

Most women with ovarian carcinoma present with high-stage disease. This is the primary reason for the relatively poor 5- and 10-year survival rates of patients with these tumors, as compared with rates for patients with cervical or endometrial carcinoma. For these reasons, development of new assays that permit early diagnosis is a top priority. Biochemical tests for tumor antigens or tumor products in the plasma of these patients are being sought vigorously, but none proposed to date has sufficient sensitivity and specificity to be useful. The serum marker CA-125 is used in patients with known disease to monitor disease recurrence/progression.

Prevention of ovarian cancer also remains an elusive goal. Screening to identify women at risk (positive for *BRCA* mutations or with strong family histories) and treatment with risk-reducing salpingo-oophorectomy are currently standard. The long-term impact of these approaches in women at high risk remains to be determined; recent data suggest that there remains a 3% to 4% risk of developing ovarian cancer after salpingo-oophorectomy.

KEY CONCEPTS

- Epithelial ovarian tumors are classified into benign, borderline, or malignant.
- About 80% of all ovarian epithelial tumors are benign and occur in young women. The malignant tumors occur most commonly in older women and account for approximately 3% of all cancers in women in the United States.
- The majority of the malignant epithelial tumors are high-grade serous carcinomas, which have a poor prognosis in large part because they are usually detected after they have spread beyond the ovary and/or the fallopian tube.
- There are three major histologic types of epithelial ovarian tumors: serous, mucinous, and endometrioid, all of which have a benign, borderline, and malignant category.
- Benign tumors are composed of well-differentiated epithelial cells with minimal proliferation. Borderline tumors show increased cell proliferation, but lack stromal invasion. Malignant tumors show increased epithelial atypia and are defined by the presence of stromal invasion.
- Ovarian carcinomas are currently divided into type I (low-grade) and type II (high-grade) tumors.
- The origin of ovarian tumors is still under investigation, but it appears that *BRCA1*- and *BRCA2*-related tumors as well as the majority of sporadic ovarian serous tumors likely arise from fallopian tube epithelium rather than ovarian epithelium.

Germ Cell Tumors

Germ cell tumors constitute 15% to 20% of all ovarian tumors and include multiple subtypes (Fig. 22.37). Most are *benign cystic teratomas,* but others, found principally in children and young adults, may show malignant behavior and pose problems in histologic diagnosis and in therapy. They bear a high degree of morphologic and molecular similarity to germ cell tumors in the male testis (Chapter 21).

Teratoma

Teratomas are divided into three categories: (1) mature (benign), (2) immature (malignant), and (3) monodermal or highly specialized.

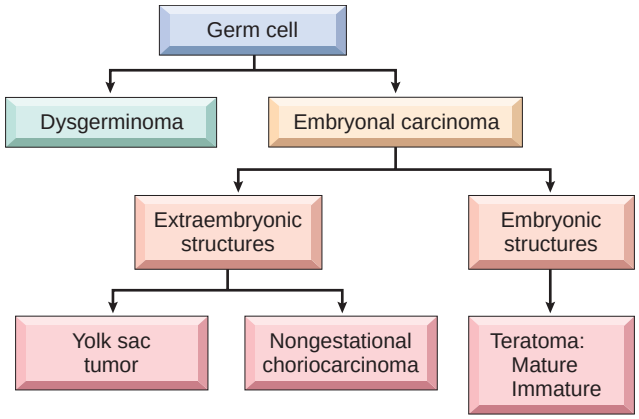

Figure 22.37 Histogenesis and interrelationships of ovarian tumors of germ cell origin.

Mature (Benign) Teratomas

Most benign teratomas are cystic and are often referred to as *dermoid cysts* because they are almost always lined by skinlike structures. Cystic teratomas are usually found in young women. They may be discovered incidentally, but are occasionally associated with clinically important paraneoplastic syndromes, such as *inflammatory limbic encephalitis,* which may remit following removal of the tumor.

MORPHOLOGY

Benign teratoma is bilateral in 10% to 15% of cases. Characteristically it consists of a unilocular cyst containing hair and sebaceous material (Fig. 22.38). Sectioning reveals a thin wall lined by opaque, gray-white, wrinkled epidermis, frequently with protruding hair shafts. Within the wall, it is common to find grossly evident tooth structures and areas of calcification.

Microscopically, the cyst wall is composed of stratified squamous epithelium with underlying sebaceous glands, hair shafts, and other skin adnexal structures (Fig. 22.39). In most cases, tissues from other germ layers can be identified, such as cartilage, bone, thyroid, and neural tissue. Dermoid cysts are sometimes incorporated within the wall of a mucinous cystadenoma. **About 1% of the**

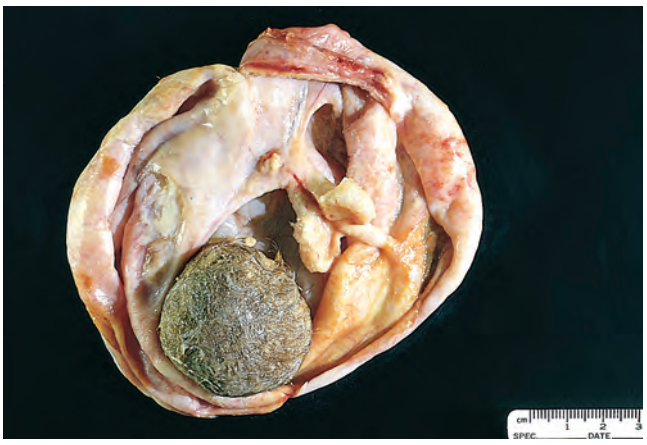

Figure 22.38 Opened mature cystic teratoma (dermoid cyst) of the ovary. Hair *(bottom)* and a mixture of tissues are evident.

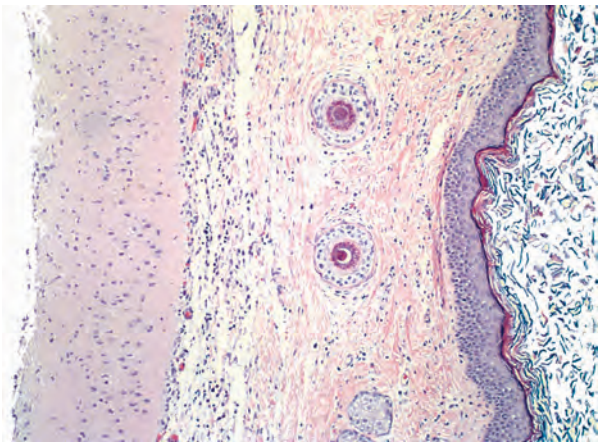

Figure 22.39 Benign cystic teratoma. Low-power view of skin *(right edge)*, beneath which there is brain tissue *(left edge)*.

dermoid cysts undergo malignant transformation, most commonly to squamous cell carcinoma, but also to other cancers (e.g., thyroid carcinoma, melanoma).

In rare instances, a benign teratoma is solid and composed entirely of benign-looking heterogeneous collections of tissues and organized structures derived from all three germ layers. These tumors presumably have the same histogenetic origin as dermoid cysts but lack preponderant differentiation into ectodermal derivatives. Such neoplasms may be difficult to distinguish from malignant immature teratomas on gross inspection.

The origin of teratomas has been a matter of fascination for centuries. Some common beliefs blamed witches, nightmares, or adultery with the devil. The karyotype of almost all benign ovarian teratomas is 46,XX. Genetic analyses indicate that the majority of teratomas arise from an ovum after the first meiotic division, while the remainder arise before the first division.

Monodermal or Specialized Teratomas

Specialized teratomas are a rare but remarkable group of tumors, the most common of which are struma ovarii and carcinoid. They are always unilateral, although a contralateral teratoma may be present. Struma ovarii is composed entirely of mature thyroid tissue, which may be functional and cause hyperthyroidism. Carcinoid tumors, which presumably arise from intestinal tissue found in teratomas, may also be functional; particularly if large (>7 cm), they can produce sufficient 5-hydroxytryptamine to cause the carcinoid syndrome even in the absence of hepatic metastases because ovarian veins connect directly to the systemic circulation. Primary ovarian carcinoid must be distinguished from metastatic intestinal carcinoid, which virtually always involves the ovaries bilaterally. Even rarer is strumal carcinoid, a combination of struma ovarii and carcinoid in the same ovary. Only about 2% of carcinoids in teratomas metastasize.

Immature Malignant Teratomas

These are rare tumors that differ from benign teratomas in that the component tissues resemble embryonal and immature fetal tissue. The tumor is found chiefly in prepubertal adolescents and young women, the mean age being 18 years.

MORPHOLOGY

Immature malignant teratomas are bulky, have a smooth external surface, and tend to be solid on sectioning. Hair, sebaceous material, cartilage, bone, and calcification may be present, along with areas of necrosis and hemorrhage. On microscopic examination, there are varying amounts of immature neuroepithelium, cartilage, bone, muscle, and other elements. An important risk for subsequent extraovarian spread is the histologic grade (I to III) of the tumor. Grading is based on the proportion of the tumor that is comprised of immature neuroepithelium (Fig. 22.40).

Immature teratomas grow rapidly, frequently penetrate the capsule, and spread either locally or distantly. Stage I tumors, particularly those with low-grade (grade 1) histology, have an excellent prognosis. Higher-grade tumors confined to the ovary are generally treated with adjuvant chemotherapy. Most recurrences develop in the first 2 years, and absence of disease beyond this period carries an excellent chance of cure.

Dysgerminoma

Dysgerminoma is the ovarian counterpart of testicular seminoma. Dysgerminoma accounts for about 2% of ovarian cancers and roughly 50% of malignant ovarian germ cell tumors. They may occur in childhood, but 75% occur in the second and third decades of life. Some occur in patients with gonadal dysgenesis, including pseudohermaphroditism. Most of these tumors have no endocrine function. A few produce elevated levels of chorionic gonadotropin, a finding that correlates with the presence of syncytiotrophoblastic giant cells. Like seminoma, dysgerminoma expresses stem cell markers such as OCT3, OCT4, and NANOG, transcription factors implicated in maintenance of pluripotency. They also express the receptor tyrosine kinase KIT, and approximately one-third have activating mutations in the *KIT* gene. These proteins are useful diagnostic markers, and mutated,

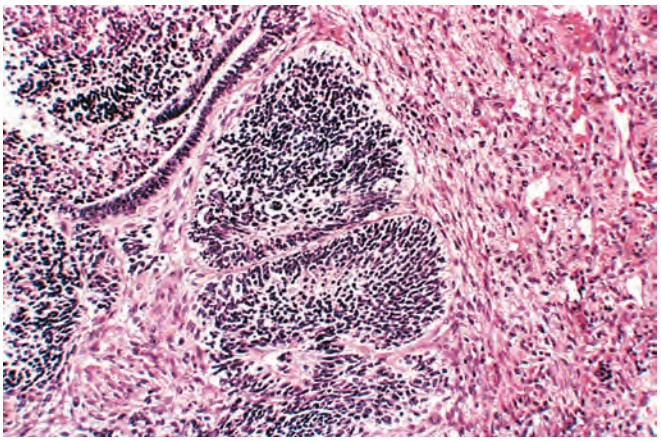

Figure 22.40 Immature teratoma of the ovary illustrating primitive neuroepithelium.

constitutively active KIT also represents a potential therapeutic target.

MORPHOLOGY

Most dysgerminomas (80% to 90%) are unilateral tumors ranging in size from barely visible nodules to masses that virtually fill the abdomen. On cut surface they have a solid yellow-white to gray-pink appearance and are often soft and fleshy. Like seminoma, it is composed of large vesicular cells with clear cytoplasm, well-defined cell boundaries, and centrally placed regular nuclei. The tumor cells grow in sheets or cords separated by scant fibrous stroma (Fig. 22.41), which is infiltrated by lymphocytes and may contain noncaseating granulomas. On occasion, small nodules of dysgerminoma are encountered in the wall of an otherwise benign cystic teratoma; conversely, a predominantly dysgerminomatous tumor may contain a small cystic teratoma.

All dysgerminomas are malignant, but the degree of histologic atypia is variable, and only about one-third are aggressive. A unilateral tumor that has not broken through the capsule or spread outside the ovary has an excellent prognosis (up to 96% cure rate) after simple salpingo-oophorectomy. These neoplasms are responsive to chemotherapy, and even those that have extended beyond the ovary can often be cured. Overall survival exceeds 80%.

Yolk Sac Tumors

Though rare, yolk sac tumor (also known as *endodermal sinus tumor*) still ranks as the second most common malignant ovarian tumor of germ cell origin. It is thought to be derived from malignant germ cells that are differentiating along the extraembryonic yolk sac lineage (see Fig. 22.37). Similar to the normal yolk sac, the tumor cells elaborate *α-fetoprotein*. Its characteristic histologic feature is a glomerulus-like structure composed of a central blood vessel enveloped by tumor cells within a space that is also lined by tumor cells *(Schiller-Duval body)* (Fig. 22.42). Conspicuous intracellular and extracellular hyaline droplets are typically present, some of which stain for α-fetoprotein by immunoperoxidase techniques.

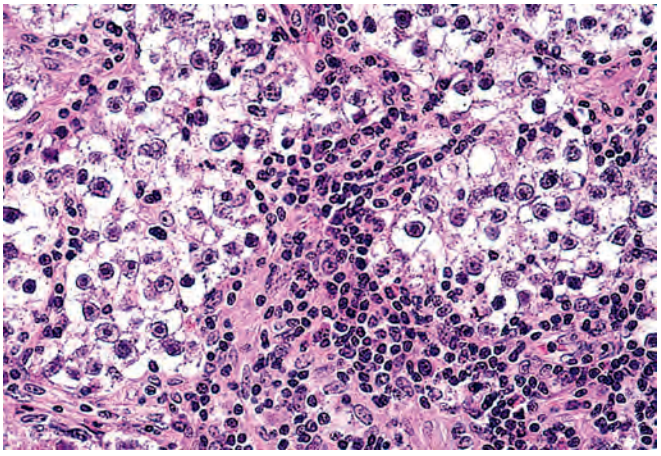

Figure 22.41 Dysgerminoma showing polyhedral tumor cells with round nuclei and adjacent inflammation.

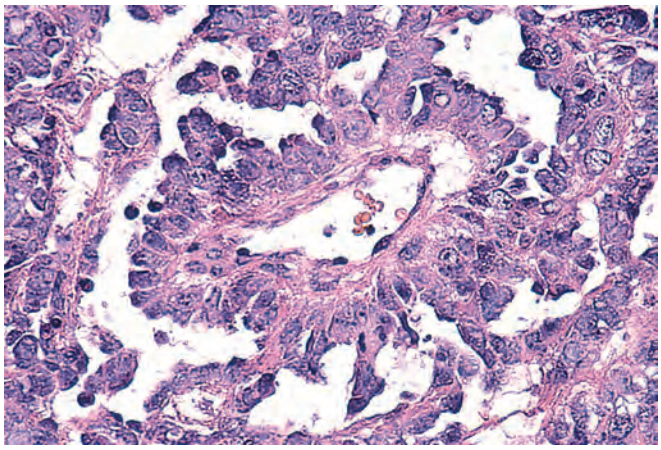

Figure 22.42 A Schiller-Duval body in a yolk sac carcinoma.

Most patients are children or young women presenting with abdominal pain and a rapidly growing pelvic mass that involves a single ovary. With combination chemotherapy, there is greater than 80% survival, independent of disease stage.

Choriocarcinoma

More commonly of placental origin, ovarian choriocarcinoma, like yolk sac tumor, is an example of a malignant germ cell that exhibits extraembryonic differentiation. Most ovarian choriocarcinomas exist in combination with other germ cell tumors, and pure choriocarcinoma is extremely rare. They are histologically identical to the more common placental lesions (described later). The ovarian tumors are aggressive and have usually metastasized hematogenously to the lungs, liver, bone, and other sites by the time of diagnosis. Like all choriocarcinomas, they elaborate high levels of *chorionic gonadotropins,* which may be helpful in establishing the diagnosis or detecting recurrences. In contrast to choriocarcinoma arising in placental tissue, those arising in the ovary are generally unresponsive to chemotherapy and are often fatal.

Other Germ Cell Tumors

These include (1) *embryonal carcinoma,* a highly malignant tumor of primitive embryonal elements that is histologically similar to embryonal carcinoma arising in the testes (Chapter 21); (2) *polyembryoma,* a malignant tumor containing so-called embryoid bodies; and (3) *mixed germ cell tumors* containing various combinations of dysgerminoma, teratoma, yolk sac tumor, and choriocarcinoma.

KEY CONCEPTS

GERM CELL TUMORS

- Germ cell tumors constitute 15% to 20% of ovarian tumors.
- The majority are mature cystic teratomas (dermoid cysts) in women of reproductive age.
- The remainder occur in young women and children; in these age groups, malignant tumors dominate.

- Immature teratomas are distinguished from mature teratomas by the presence of embryonal or fetal elements, most often consisting of primitive neuroepithelium.
- Germ cell tumors show various lines of differentiation toward oogonia (dysgerminoma), extra-embryonic yolk sac (yolk sac tumors), placenta (choriocarcinoma), or multiple germ layers (teratoma).

Sex Cord–Stromal Tumors

These ovarian neoplasms arise from the ovarian stroma, which is derived from the sex cords of the embryonic gonad. The undifferentiated gonadal mesenchyme eventually produces specific types of cells in male (Sertoli and Leydig) and female (granulosa and theca) gonads, and tumors resembling all of these cell types can be identified in the ovary. Moreover, because some of these cells normally secrete estrogens (granulosa and theca cells) or androgens (Leydig cells), their corresponding tumors may be either feminizing (granulosa/theca cell tumors) or masculinizing (Leydig cell tumors).

Granulosa Cell Tumors

Granulosa cell tumors are composed of cells that resemble granulosa cells of a developing ovarian follicle. They are broadly divided into adult and juvenile granulosa cell tumors, based largely on the age of the patient. Collectively, these neoplasms account for about 5% of all ovarian tumors, and 95% of granulosa cell tumors are of the adult type. Although they may be discovered at any age, approximately two-thirds occur in postmenopausal women.

MORPHOLOGY

Granulosa cell tumors are usually unilateral and vary from microscopic foci to large, solid, and cystic encapsulated masses. Tumors that are hormonally active have a yellow coloration to their cut surfaces, due to intracellular lipids.

The granulosa cell component of these tumors has many histologic patterns. The small, cuboidal to polygonal cells may grow in anastomosing cords, sheets, or strands (Fig. 22.43A). In occasional cases, small, distinctive, glandlike structures filled with an acidophilic material recall immature follicles **(Call-Exner bodies)**. When these structures are evident, the diagnosis is straightforward. Occasionally, there is a predominant thecoma component that consists of clusters or sheets of cuboidal to polygonal cells (see later). In some tumors, the granulosa or theca cells may appear plumper and have ample cytoplasm characteristic of luteinization (i.e., luteinized granulosa–theca cell tumors).

Granulosa cell tumors are of clinical importance for two reasons: (1) they sometimes elaborate large amounts of estrogen, and (2) they may behave like low-grade malignancies. Functionally active tumors in prepubertal girls (juvenile granulosa cell tumors) may produce precocious sexual development. In adult women, they may be associated with proliferative breast disease, endometrial hyperplasia, and endometrial carcinoma, which eventually develops in about 10% to 15% of women with steroid-producing tumors. Occasionally, granulosa cell tumors produce androgens, masculinizing the patient.

All granulosa cell tumors are potentially malignant. It is difficult to predict their biologic behavior from histology. The likelihood of malignant behavior (recurrence, extension) ranges from 5% to 25%. In general, malignant tumors pursue an indolent course in which local recurrences may be amenable to surgical therapy. Recurrences within the pelvis and abdomen may appear 10 to 20 years after removal of the original tumor. The 10-year survival rate is approximately 85%. Tumors composed predominantly of theca cells are almost never malignant.

Elevated tissue and serum levels of *inhibin,* a product of granulosa cells, are associated with granulosa cell tumors. Detection and measurement of inhibin is useful in diagnosing granulosa and other sex cord–stromal tumors (see Fig. 22.43B), and for monitoring patients being treated for these neoplasms. The most common driver mutations are found in the *FOXL2* gene, which is mutated in 97% of adult granulosa cell tumors. *FOXL2* encodes a transcription factor that is important in granulosa cell development, which presumably explains its strong association with this tumor type. Interestingly, mutations in *FOXL2* appear to be less

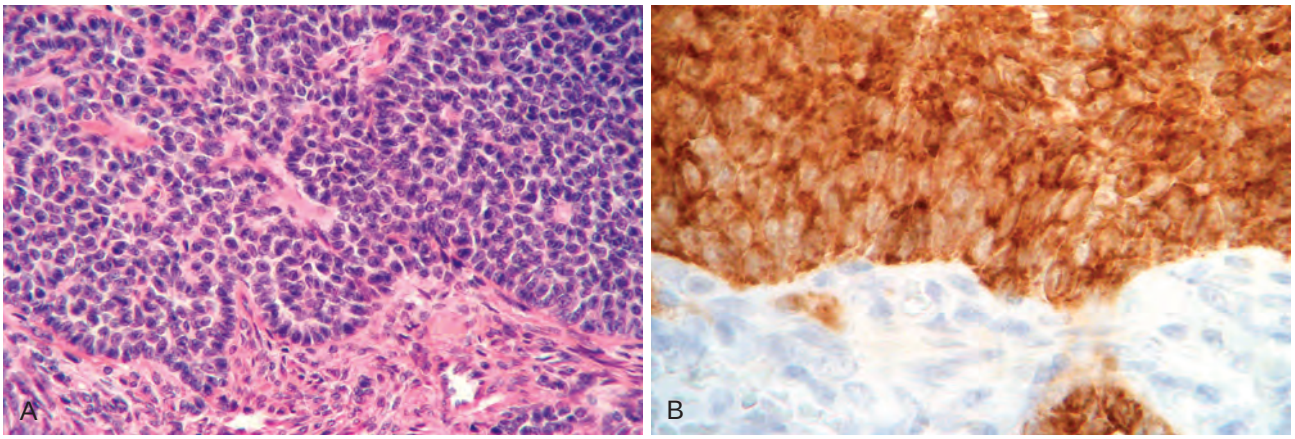

Figure 22.43 Granulosa cell tumor. (A) Tumor cells are arranged in sheets punctuated by small follicle-like structures (Call-Exner bodies). (B) Strong immunohistochemical positivity with an antibody to inhibin characterizes these tumors.

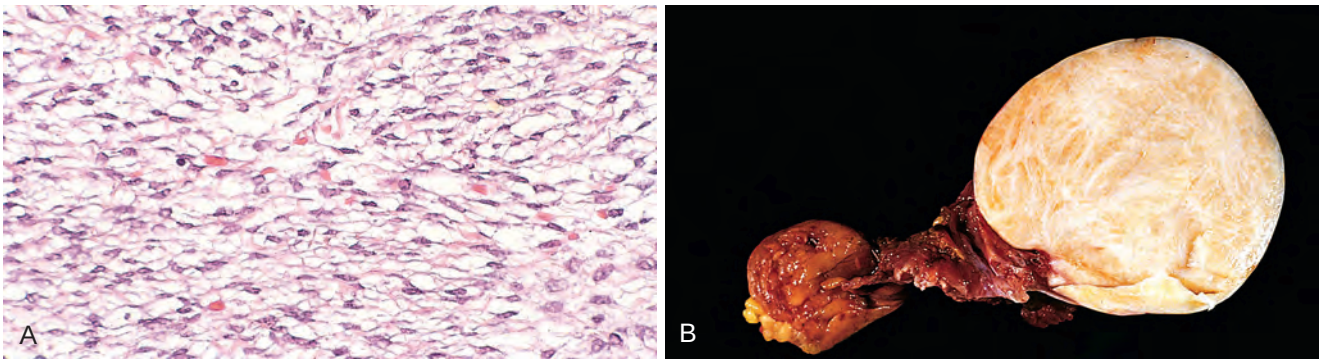

Figure 22.44 Ovarian fibroma. (A) Thecoma-fibroma composed of plump, differentiated stromal cells with thecal appearance. (B) Large bisected fibroma of the ovary apparent as a white, firm mass *(right)*. The fallopian tube is attached.

common in juvenile granulosa tumor, suggesting that it is genetically distinct from the adult type.

Fibromas, Thecomas, and Fibrothecomas

Tumors arising in the ovarian stroma that are composed of either fibroblasts (fibromas) or plump spindle cells with lipid droplets (thecomas) are relatively common, accounting for about 4% of all ovarian tumors (Fig. 22.44A). Many tumors contain a mixture of these cells and are termed *fibrothecomas*. Fibrothecomas and pure thecomas (a rare subtype) may be hormonally active. By contrast, pure fibromas as a rule are hormonally inactive.

Fibromas of the ovary are unilateral in about 90% of cases and are usually solid, spherical or slightly lobulated, encapsulated, hard, gray-white masses covered by glistening, intact ovarian serosa (see Fig. 22.44B). On histologic examination, they are composed of well-differentiated fibroblasts and scant interspersed collagenous stroma. Focal areas of thecal differentiation may be identified.

Most of these tumors come to attention as a pelvic mass, sometimes accompanied by pain and two decidedly curious associations. The first is ascites, found in about 40% of cases in which the tumors measure more than 6 cm in diameter. Uncommonly there is also a hydrothorax, usually only on the right side. This combination of findings (ovarian tumor, hydrothorax, and ascites) is designated *Meigs syndrome*. Its genesis is unknown. The second association is with the basal cell nevus syndrome, described in Chapter 25. The vast majority of fibromas, fibrothecomas, and thecomas are benign. Rarely, cellular fibromas with mitotic activity and increased nuclear-to-cytoplasmic ratio are identified; because they may pursue a malignant course, they are termed *fibrosarcomas*.

Sertoli-Leydig Cell Tumors

These tumors are often functional; they most commonly produce masculinization or defeminization, but a few have estrogenic effects. The tumor cells recapitulate, to a certain extent, testicular Sertoli or Leydig cells at various stages of development. They occur in women of all ages, although the peak incidence is in the second and third decades. In over one-half of cases, the tumor cells have mutations in *DICER1,* a gene that you will recall encodes an endonuclease that is essential for proper processing of micro-RNAs (Chapter 1). The presence of *DICER1* mutations suggests that genesis of these tumors involves abnormalities of gene expression related to dysregulation of micro-RNAs.

MORPHOLOGY

These tumors are unilateral and may resemble granulosa cell tumors grossly. The cut surface is usually solid and varies from gray to golden brown in appearance (Fig. 22.45A). Microscopically,

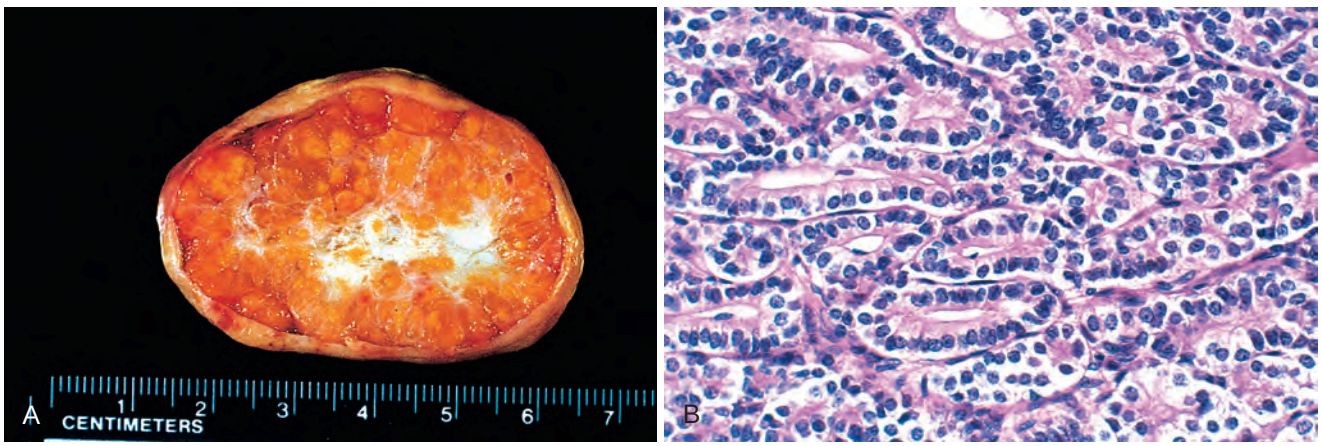

Figure 22.45 Sertoli cell tumor. (A) Gross photograph illustrating characteristic golden-yellow appearance of the tumor. (B) Photomicrograph showing well-differentiated Sertoli cell tubules. (Courtesy Dr. William Welch, Brigham and Women's Hospital, Boston, Mass.)

a range of differentiation is seen. Well-differentiated tumors show tubules composed of Sertoli cells or Leydig cells interspersed with stroma (Fig. 22.45B). The intermediate forms show only immature tubules and large eosinophilic Leydig cells. The poorly differentiated tumors have a sarcomatous pattern with a disorderly disposition of epithelial cell cords. Leydig cells may be absent. Heterologous elements, such as mucinous glands, bone, and cartilage, may be present in some tumors.

The incidence of recurrence or metastasis by Sertoli-Leydig cell tumors is less than 5%. These neoplasms may block normal female sexual development in children and may cause defeminization of women, manifest by atrophy of the breasts, amenorrhea, sterility, and loss of hair. The syndrome may progress to striking virilization (hirsutism) associated with male hair distribution, hypertrophy of the clitoris, and voice changes.

Other Sex Cord–Stromal Tumors

There are several other uncommon but distinctive ovarian tumors of sex cord or stromal origin that often produce steroid hormones.

- *Hilus cell tumors (pure Leydig cell tumors)* are rare, unilateral tumors comprised of large lipid-laden Leydig cells with distinct borders and characteristic cytoplasmic structures called *Reinke crystalloids*. Women with hilus cell tumors usually present with evidence of masculinization (hirsutism, voice changes, and clitoral enlargement), but these changes are milder than those seen in association with Sertoli–Leydig cell tumors. The tumors produce predominantly testosterone. Treatment consists of surgical excision. True hilus cell tumors are almost always benign.
- *Pregnancy luteoma* refers to a rare tumor that closely resembles the corpus luteum of pregnancy. These tumors may produce virilization in pregnant patients and their female infants.
- *Gonadoblastoma* is an uncommon tumor composed of germ cells and sex cord–stroma derivatives resembling immature Sertoli and granulosa cells. It occurs in individuals with abnormal sexual development and in gonads of indeterminate nature. Eighty percent of patients are phenotypic females, and 20% are phenotypic males with undescended testicles and female internal secondary organs. A coexistent dysgerminoma occurs in 50% of the cases. The prognosis is excellent if the tumor is completely excised.

KEY CONCEPTS

SEX CORD–STROMAL TUMORS

- Granulosa cells tumors are the most common malignant tumor in this category. They are indolent tumors, but may recur 10 to 20 years after resection of the primary tumor. They are often hormonally active; such tumors are associated with hyperestrinism, leading to an elevated risk of endometrial carcinoma.
- Fibromas are relatively common benign tumors composed of fibroblasts. They are predominantly unilateral and are generally hormonally inactive.
- Pure thecomas are rare but may be hormonally active.
- Sertoli–Leydig cell tumors commonly present with masculinization; less than 5% recur or metastasize.

Metastatic Tumors

The most common metastatic tumors of the ovary are derived from tumors of müllerian origin: the uterus, fallopian tube, contralateral ovary, or pelvic peritoneum. The most common extra-müllerian tumors metastatic to the ovary are carcinomas of the breast and gastrointestinal tract, including colon, stomach, biliary tract, and pancreas. Also included in this group are rare cases of pseudomyxoma peritonei, derived from appendiceal tumors. A classic metastatic gastrointestinal carcinoma involving the ovaries is termed *Krukenberg tumor,* characterized by bilateral metastases composed of mucin-producing cancer cells with a "signet-ring" appearance, most often of gastric origin.

Gestational and Placental Disorders

Diseases of pregnancy and pathologic conditions of the placenta are important causes of fetal intrauterine or perinatal death, congenital malformations, intrauterine growth restriction, maternal death, and morbidity for both the mother and child. Only those disorders for which recognition of morphologic features contribute to an understanding of the clinical problem are discussed here. These include selected disorders of early pregnancy, late pregnancy, and trophoblastic neoplasia.

Understanding placental disorders requires a working knowledge of normal placental anatomy. The placenta is composed of chorionic villi (Fig. 22.46A and B) that sprout from the chorion to provide a large contact area between the fetal and maternal circulations. In the mature placenta, the maternal blood enters the intervillous space through endometrial arteries (spiral arteries) and circulates around the villi to allow gas and nutrient exchange (Fig. 22.47). The deoxygenated blood flows back from the intervillous space to the decidua and enters the endometrial veins. Deoxygenated fetal blood enters the placenta through two umbilical arteries that branch radially to form chorionic arteries. Chorionic arteries branch further as they enter the villi. In the chorionic villi, they form an extensive capillary system, bringing fetal blood in close proximity to maternal blood. The gas and nutrient diffusion occurs through the villous capillary endothelial cells and thinned-out syncytiotrophoblasts and cytotrophoblasts. Under normal circumstances, there is little or no mixing of fetal and maternal blood, though sufficient free fetal DNA reaches the maternal circulation to permit prenatal genetic testing (Chapter 5). Blood oxygenated in the placenta returns to the fetus through the single umbilical vein.

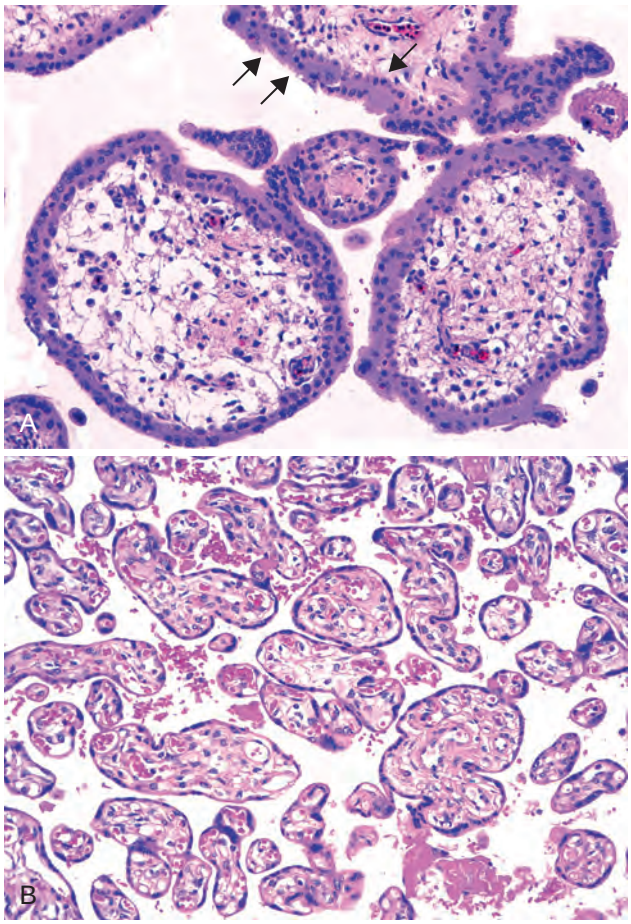

Figure 22.46 Normal placenta. (A) First-trimester chorionic villi composed of delicate mesh of central stroma surrounded by two discrete layers of epithelium—the outer layer consisting of syncytiotrophoblast *(double arrows)* and the inner layer consisting of cytotrophoblast *(arrow)*. (B) Third-trimester chorionic villi composed of stroma with a dense network of dilated capillaries surrounded by markedly thinned-out syncytiotrophoblast and cytotrophoblast (same magnification as A).

DISORDERS OF EARLY PREGNANCY

Spontaneous Abortion

Spontaneous abortion, or "miscarriage," is defined as pregnancy loss before 20 weeks of gestation. Most of these occur before 12 weeks. Ten to fifteen percent of clinically recognized pregnancies terminate in spontaneous abortion. However, using sensitive chorionic gonadotropin assays, it has been determined that an additional 20% of early pregnancies in otherwise healthy women terminate spontaneously, many without notice. In most individual instances, the mechanisms leading to early loss of pregnancy are unknown. However, multiple fetal and maternal causes of spontaneous abortion have been identified. Among the most important are the following:

- *Fetal chromosomal anomalies,* such as aneuploidy, polyploidy, and translocations, are present in approximately 50% of early abortuses. More subtle genetic defects, for which routine genetic testing is not available, account for an additional fraction of abortions.
- *Maternal endocrine factors,* including luteal-phase defect, poorly controlled diabetes, and other endocrine disorders
- *Physical defects of the uterus,* such as submucosal leiomyomas, uterine polyps, or uterine malformations, may prevent or disrupt implantation.
- *Systemic disorders affecting the maternal vasculature,* such as antiphospholipid antibody syndrome, coagulopathies, and hypertension
- *Infections* with protozoa *(Toxoplasma),* bacteria *(Mycoplasma, Listeria),* or a number of viruses. Ascending infection is particularly common in second-trimester losses.

Ectopic Pregnancy

Ectopic pregnancy refers to implantation of the fetus in a site other than the normal intrauterine location; the most common site is the extrauterine fallopian tube (approximately 90% of cases). Other sites include the ovary, the abdominal cavity, and the intrauterine portion of the fallopian tube (cornual pregnancy). Ectopic pregnancies account for 2% of confirmed pregnancies. The most important predisposing condition, present in 35% to 50% of patients, is prior pelvic inflammatory disease resulting in intraluminal fallopian tube scarring (chronic salpingitis). The risk of ectopic pregnancy is also increased with peritubal scarring and adhesions, which may be caused by appendicitis, endometriosis, and previous surgery. In some cases, however, the fallopian tubes are apparently normal. Another risk factor is use of an intrauterine contraceptive device, which is associated with a twofold increase in ectopic pregnancy.

Ovarian pregnancy results from the fertilization and trapping of the ovum within the follicle just at the time of its rupture. Abdominal pregnancies occur when the fertilized ovum fails to enter or drops out of the fimbriated end of the tube. In each abnormal location, the fertilized ovum develops as usual, forming placental tissue, amniotic sac, and fetus. The host implantation site may also develop decidual changes.

MORPHOLOGY

Tubal pregnancy is the most common cause of **hematosalpinx (blood-filled fallopian tube)** and should always be suspected when a tubal hematoma is present. Initially the embryonal sac, surrounded by immature chorionic villi, implants within the lumen of the fallopian tube. Trophoblastic cells and chorionic villi then invade the wall of the fallopian tube, as in the uterus during normal pregnancy. With time, the growth of the gestational sac distends the fallopian tube, causing thinning of the wall and rupture. **Rupture frequently results in massive intraperitoneal hemorrhage,** which sometimes is fatal. Less commonly, the tubal pregnancy may undergo spontaneous regression and resorption, or may be extruded through the fimbriated end of the tube into the abdominal cavity (tubal abortion).

Clinical Features

Rupture of a tubal pregnancy is a medical emergency. The clinical course of ectopic tubal pregnancy is characterized by the onset of moderate to severe abdominal pain and vaginal bleeding 6 to 8 weeks after the last menstrual period,

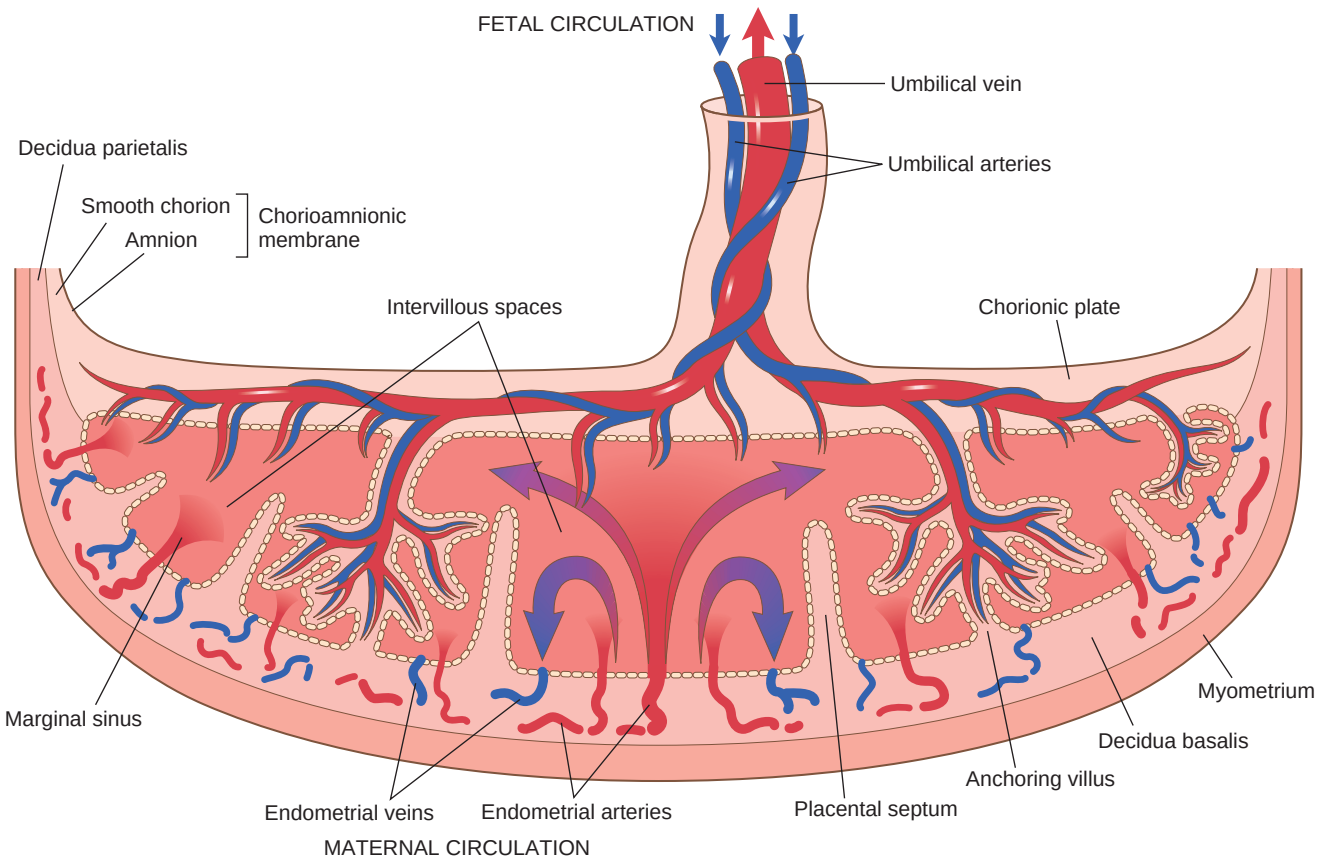

Figure 22.47 Diagram of placental anatomy. Within the outer boundary of myometrium is a layer of decidua, from which the maternal vessels originate and deliver blood to and from the intervillous spaces. Umbilical vessels branch and terminate in placental villi, where nutrient exchange takes place.

correlating with distention and then rupture of the fallopian tube. In such cases, the patient may rapidly develop hemorrhagic shock and signs of an acute abdomen. Rapid diagnosis is critical and is based on determination of chorionic gonadotropin titers, pelvic sonography, endometrial biopsy (which shows decidua without chorionic villi or implantation site), and/or laparoscopy. Despite advances in early diagnosis, ectopic pregnancy still accounts for 4% to 10% of pregnancy-related deaths.

DISORDERS OF LATE PREGNANCY

Disorders that occur in the third trimester of pregnancy are related to the complex anatomy of the maturing placenta. Complete interruption of blood flow through the umbilical cord from any cause (e.g., constricting knots or compression) can be lethal to the fetus. Ascending infections involving the chorioamnionic membranes may lead to premature rupture of amniotic membranes and delivery. Retroplacental hemorrhage at the interface of the placenta and myometrium *(abruptio placentae)* threatens both the mother and fetus. Disruption of the fetal vessels in terminal villi may produce a significant loss of fetal blood, resulting in fetal injury or death. Uteroplacental malperfusion can be precipitated by abnormal placental implantation or development, or maternal vascular disease; the effects may range from mild intrauterine growth restriction to severe uteroplacental ischemia and maternal preeclampsia (described later).

Twin Placentas

Twin pregnancies arise from fertilization of two ova (dizygotic) or from division of one fertilized ovum (monozygotic). There are three types of twin placentas (Fig. 22.48): diamnionic dichorionic (which may be fused); diamnionic monochorionic; and monoamnionic monochorionic.

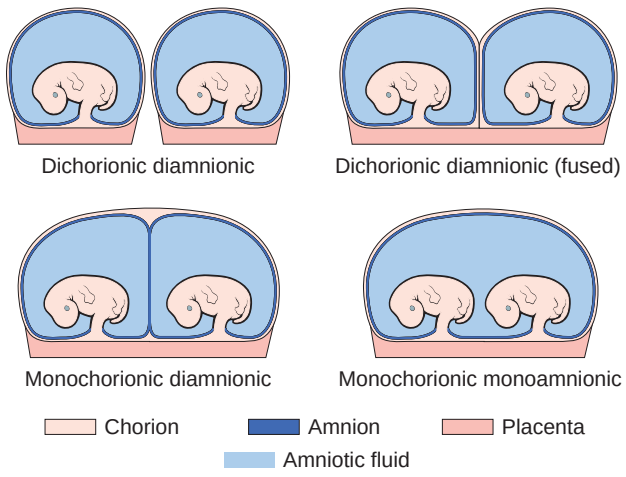

Figure 22.48 Diagrammatic representation of the various types of twin placentation and their membrane relationships. (Modified from Gersell D, et al: Diseases of the placenta. In Kurman R, editor: *Blaustein's Pathology of the Female Genital Tract,* New York, 1994, Springer-Verlag.)

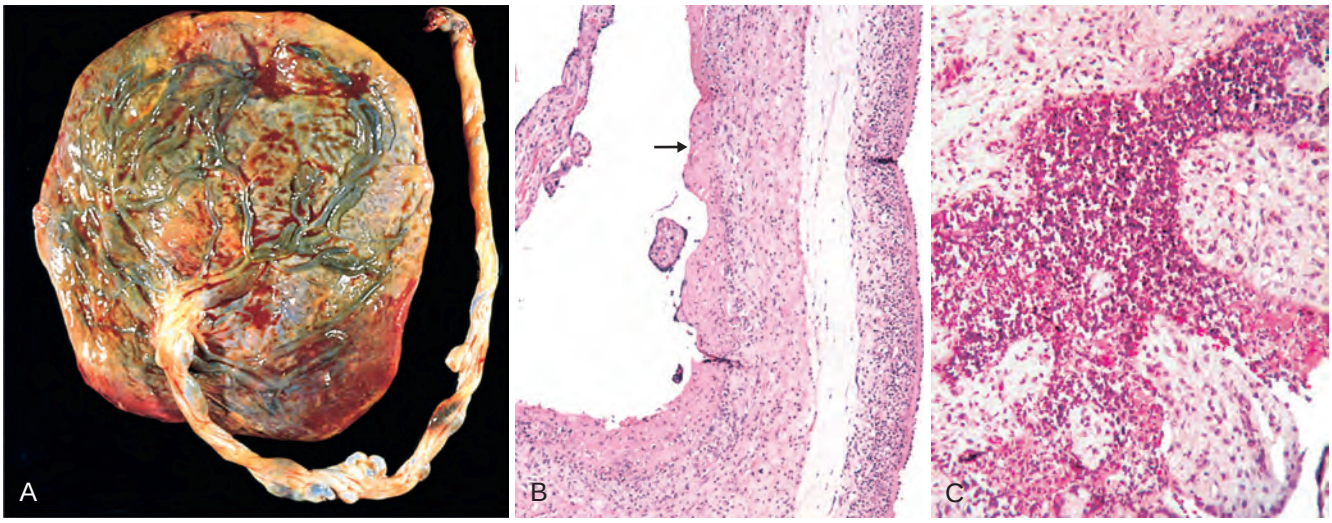

Figure 22.49 Placental infections derived from ascending and blood-borne routes. Acute chorioamnionitis. (A) On gross examination, the placenta contains greenish opaque membranes. (B) A photomicrograph illustrates a dense bandlike inflammatory exudate on the amniotic surface *(arrow)*. (C) Acute necrotizing intervillositis from *Listeria* infection. The space between the villi is filled with blood and acute inflammatory cells (neutrophils). The villi appear necrotic.

Monochorionic placentas imply monozygotic (identical) twins, and the time at which splitting of the developing embryo occurs determines whether one or two amnions are present. Dichorionic placentation may occur with either monozygotic or dizygotic twins and is not specific.

One complication of monochorionic twin pregnancy is *twin-to-twin transfusion syndrome*. Monochorionic twin placentas have vascular anastomoses that connect the circulations of the twins, and in some cases these connections include one or more arteriovenous shunts. Twin-to-twin perfusion syndrome results when these shunts preferentially increase blood flow to one twin at the expense of the second, causing one twin to be underperfused and the second to be fluid overloaded. If severe, it may result in the death of one or both fetuses.

Abnormalities of Placental Implantation

Several types of abnormal placental implantations are associated with significant complications. *Placenta previa* is a condition in which the placenta implants in the lower uterine segment or cervix, often leading to serious third-trimester bleeding. A complete placenta previa covers the internal cervical os and thus requires cesarean delivery to avert placental rupture and fatal maternal hemorrhage during vaginal delivery. *Placenta accreta* is caused by partial or complete absence of the decidua, such that the placental villous tissue adheres directly to the myometrium, which leads to a failure of placental separation at birth. It is an important cause of severe, potentially life-threatening postpartum bleeding. Common predisposing factors are placenta previa (in up to 60% of cases) and history of previous cesarean delivery.

Placental Infections

Infections in the placenta develop by two pathways: (1) ascending infection through the birth canal and (2) hematogenous (transplacental) infection. Ascending infections are by far the most common and are virtually always bacterial; in many such instances, localized infection of the membranes produces premature rupture of membranes and preterm delivery. The amniotic fluid may be cloudy with purulent exudate, and histologically the chorion-amnion contains an infiltrate of neutrophils accompanied by edema and congestion of the vessels (Fig. 22.49A–B). The infection frequently elicits a fetal response consisting of a "vasculitis" of the umbilical and fetal chorionic plate vessels. Uncommonly, bacterial infections may result from hematogenous spread to the placenta, leading to acute villitis (Fig. 22.49C).

Several hematogenous infections, classically components of the TORCH group (*t*oxoplasmosis and *o*thers [syphilis, tuberculosis, listeriosis], *r*ubella, *c*ytomegalovirus, *h*erpes simplex), can affect the placenta. They give rise to chronic inflammatory cell infiltrates in the chorionic villi (chronic villitis) and are described in Chapter 10.

Preeclampsia and Eclampsia

Preeclampsia is a systemic syndrome characterized by widespread maternal endothelial dysfunction that presents during pregnancy with hypertension, edema, and proteinuria. It occurs in about 3% to 5% of pregnant women, usually in the last trimester and more commonly in women pregnant for the first time (primiparas). Some of these women become seriously ill, developing convulsions; this particularly severe form of the disorder is termed *eclampsia*. Other complications stemming from systemic endothelial dysfunction include hypercoagulability, acute renal failure, and pulmonary edema. Approximately 10% of women with preeclampsia develop microangiopathic hemolytic anemia, elevated liver enzymes, and low platelets, referred to as the HELLP syndrome (Chapter 18). Preeclampsia should be distinguished from gestational hypertension that can develop in pregnancy without proteinuria.

Pathogenesis

The placenta plays a central role in the pathogenesis of preeclampsia, as symptoms disappear rapidly after delivery of the placenta. The critical abnormalities in preeclampsia are diffuse endothelial dysfunction, vasoconstriction (leading to hypertension), and increased vascular permeability (resulting in proteinuria and edema). Recent work has demonstrated that these effects are most likely mediated by placenta-derived factor(s) released into the maternal circulation. Although the release of these factors and the clinical syndrome develop late in gestation, the pathogenesis of the disease appears to be closely tied to the earliest events of pregnancy and placentation. The principal pathophysiologic aberrations are proposed to be the following:

- *Abnormal placental vasculature*. The precipitating events in preeclampsia are abnormal trophoblastic implantation and a failure of physiologic remodeling of the maternal vessels, which is required for adequate perfusion of the placenta. At the implantation site of a normal pregnancy, fetal extravillous trophoblasts (cells not associated with chorionic villi) invade the maternal decidua and decidual vessels, destroy the vascular smooth muscle, and replace the maternal endothelial cells with fetal trophoblastic cells, forming hybrid fetomaternal blood vessels. This process converts the decidual spiral arteries from small-caliber resistance vessels to large-capacity uteroplacental vessels lacking a smooth muscle coat (Fig. 22.50). In preeclampsia, this vascular remodeling fails to occur, leaving the placenta ill equipped to meet the increased circulatory demands of late gestation and setting the stage for the development of placental ischemia.
- *Endothelial dysfunction and imbalance of angiogenic and antiangiogenic factors*. It is postulated that in response to hypoxia, the ischemic placenta releases factors into the maternal circulation that cause an imbalance in circulating angiogenic and anti-angiogenic factors; this, in turn, leads to systemic maternal endothelial dysfunction and the clinical symptoms of the disease. In support of this, the blood levels of two placenta-derived antiangiogenic factors, soluble FMS-like tyrosine kinase (sFltl) and endoglin, which antagonize the effects of VEGF and TGFβ, respectively, are several orders of magnitude higher in women with preeclampsia than in healthy controls. In preeclampsia, high levels of sFlt1 and soluble endoglin bring about a decrease in angiogenesis much earlier than in normal pregnancy. The result is defective vascular development in the placenta. Furthermore, TGFβ induces endothelial production of nitric oxide, a potent vasodilator; thus, inhibition of TGFβ by endoglin may directly contribute to systemic vasoconstriction, hypertension, and tissue hypoperfusion.

  Studies in animal models also implicate sFltl and soluble endoglin in the pathogenesis of endothelial dysfunction. When sFlt and endoglin are overexpressed together, rats develop nephrotic-range proteinuria, severe hypertension, and fetal growth restriction, the hallmarks of severe preeclampsia, as well as features of the HELLP syndrome, including elevated liver enzymes, decreased platelet count, and hemolysis. Thus, it seems that sFlt1 and soluble endoglin are key mediators that link the placenta to the characteristic maternal endothelial dysfunction of preeclampsia.

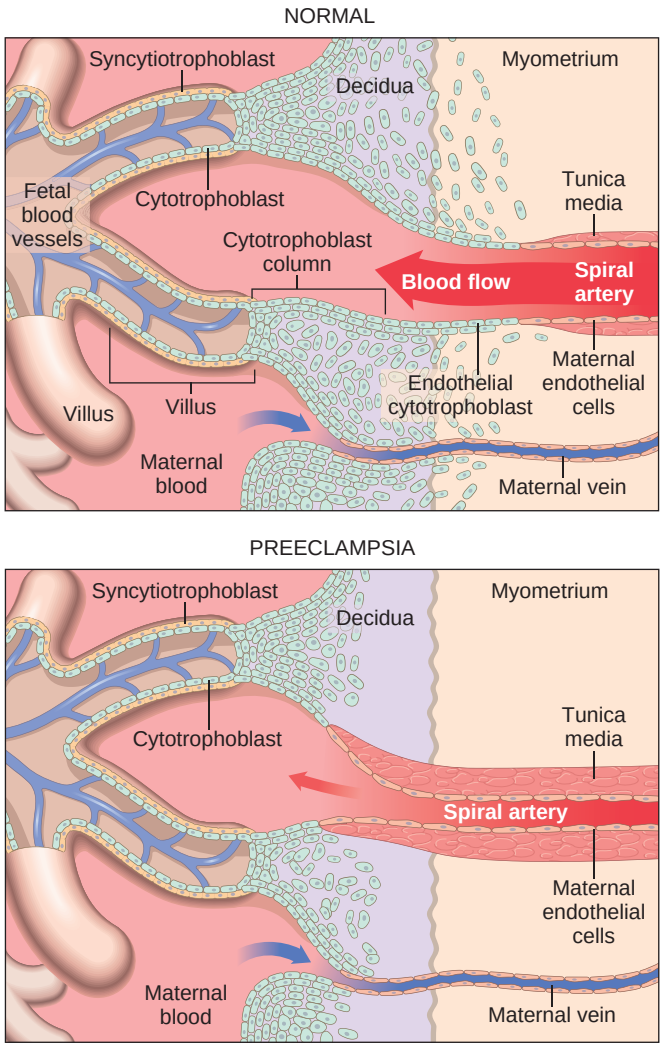

Figure 22.50 The physiologic alterations in the uterine spiral arteries and the failure of their remodeling in preeclampsia. (Modified from Maynard S, Epstein FH, Karumanchi SA: Preeclampsia and angiogenic imbalance, *Annu Rev Med* 59:61–78, 2008.)

- *Coagulation abnormalities*. Preeclampsia is associated with a hypercoagulable state that may lead to the formation of thrombi in arterioles and capillaries throughout the body, but particularly in the liver, kidneys, brain, and pituitary gland. Hypercoagulability is likely related to the reduced endothelial production of PGI_2, a potent antithrombotic factor, and increased release of procoagulant factors. Production of PGI_2 is stimulated by VEGF, and women with preeclampsia have decreased endothelial production of PGI_2, presumably due to antagonism of VEGF by sFlt1.

MORPHOLOGY

The placenta reveals several microscopic changes, most of which reflect malperfusion, ischemia, and vascular injury. These include (1) **infarcts,** which are larger and more numerous than those that may be seen in normal full-term placentas, (2) **exaggerated ischemic changes** in the chorionic villi and trophoblast, consisting of increased syncytial knots, (3) frequent **retroplacental**

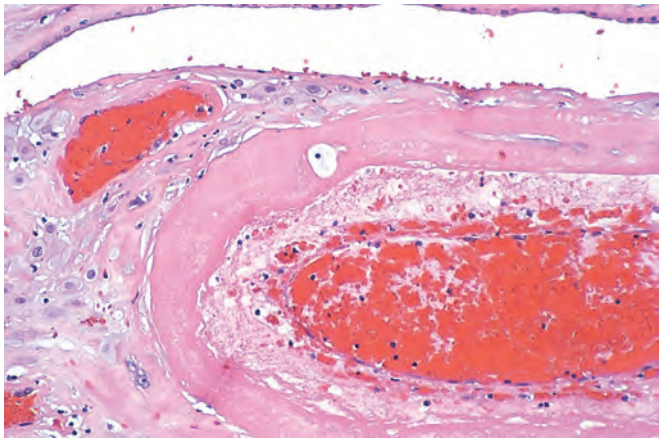

Figure 22.51 Acute atherosis of uterine vessels in eclampsia. Note fibrinoid necrosis of the vessel wall and subendothelial macrophages. (Courtesy Dr. Drucilla J. Roberts, Massachusetts General Hospital, Boston, Mass.)

hematomas due to bleeding and instability of uteroplacental vessels, and (4) **abnormal decidual vessels,** which may show thrombi, lack of normal physiologic conversion (described earlier), fibrinoid necrosis, or intimal lipid deposition (acute atherosis) (Fig. 22.51).

The liver lesions, when present, take the form of irregular, focal, subcapsular, and intraparenchymal hemorrhages. On histologic examination, there are fibrin thrombi in the portal capillaries and foci of hemorrhagic necrosis.

The kidney lesions are variable. The glomeruli show marked swelling of endothelial cells, amorphous dense deposits on the endothelial side of the basement membrane, and mesangial cell hyperplasia. Immunofluorescent studies show abundant fibrin deposition in glomeruli. In advanced cases, fibrin thrombi are present in the glomeruli and capillaries of the cortex. If widespread and severe, these thrombi may produce **bilateral renal cortical necrosis** (Chapter 20), leading to complete destruction of the cortices. The brain may have gross or microscopic foci of hemorrhage along with small-vessel thromboses. Similar changes are often found in the heart and the anterior pituitary gland.

Clinical Features

Preeclampsia most commonly starts after 34 weeks of gestation but begins earlier in women with hydatidiform mole (discussed later) or preexisting kidney disease, hypertension, or coagulopathies. The onset is typically marked by hypertension and edema, with proteinuria appearing several days later. Headaches and visual disturbances may follow and are indicative of severe preeclampsia, often requiring delivery. Eclampsia is heralded by more severe central nervous system involvement, including convulsions and eventual coma.

Management of preeclampsia differs depending on the gestational age and severity of disease. For term pregnancies, delivery is the treatment of choice regardless of disease severity. For preterm pregnancies, in which delivery is not in the best interest of the fetus, patients with mild disease can be managed expectantly by closely monitoring the mother and fetus. However, eclampsia, severe preeclampsia with maternal end-organ dysfunction, fetal compromise, or the HELLP syndrome are indications for delivery regardless of gestational age. Antihypertensive therapy does not affect the disease course or improve outcome. Proteinuria and hypertension usually disappear within 1 to 2 weeks after delivery except when they predate the pregnancy. Although in most instances preeclampsia has no lasting sequelae, about 20% of affected women develop hypertension and microalbuminuria within 7 years of a pregnancy complicated by preeclampsia. There is also a twofold increase in the long-term risk of vascular disease of the heart and the brain.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease encompasses a spectrum of tumors and tumorlike conditions characterized by proliferation of placental tissue, either villous or trophoblastic. The major disorders of this type are hydatidiform mole (complete and partial), invasive mole, choriocarcinoma, and placental site trophoblastic tumor (PSTT).

Hydatidiform Mole

Hydatidiform moles are important to recognize because they are associated with an increased risk of persistent trophoblastic disease (invasive mole) or choriocarcinoma. Moles are characterized histologically by cystic swelling of the chorionic villi and variable trophoblastic proliferation. They are usually diagnosed during early pregnancy (average 9 weeks) by pelvic sonography. Molar pregnancy can develop at any age, but the risk is higher at the two ends of reproductive life, in teenagers and between 40 and 50 years of age. For unknown reasons, the incidence varies considerably in different parts of the world. Hydatidiform mole occurs in about 1 in 1000 to 2000 pregnancies in the United States, but it is twice as common in Southeast Asia. Two types of benign, noninvasive moles—complete and partial—can be identified by cytogenetic and histologic studies.

Complete Mole

Complete mole results from fertilization of an egg that has lost its female chromosomes, and as a result the genetic material is completely paternally derived (Fig. 22.52A–B). Ninety percent have a 46,XX karyotype stemming from the duplication of the genetic material of one sperm (a phenomenon called androgenesis). The remaining 10% result from the fertilization of an empty egg by two sperm; these may have a 46,XX or 46,XY karyotype. In complete moles, the embryo dies very early in development and therefore is usually not identified. Patients have 2.5% risk of subsequent choriocarcinoma and a 15% risk of persistent or invasive mole.

Partial Mole

Partial moles result from fertilization of an egg with two sperm (see Fig. 22.52C). In these moles, the karyotype is triploid (e.g., 69,XXY) or occasionally tetraploid (92,XXXY). Fetal tissues are typically present. Partial moles have an increased risk of persistent molar disease but are not associated with choriocarcinoma.

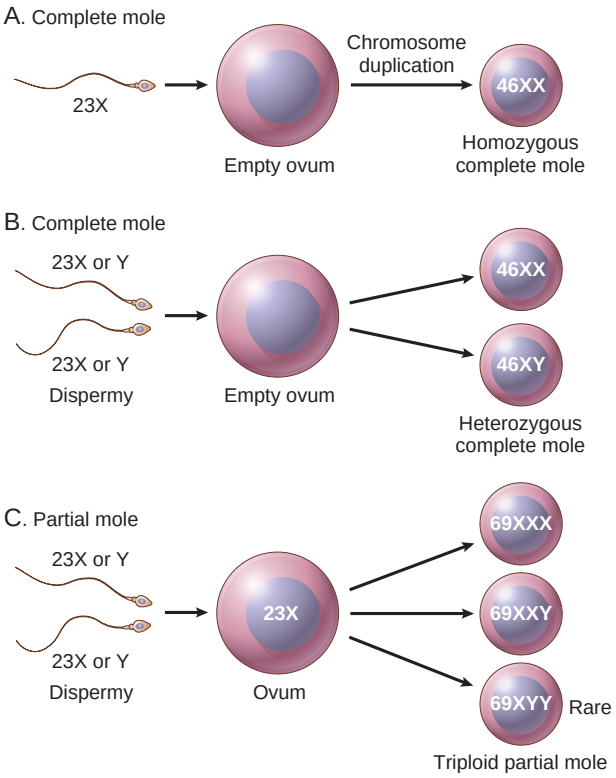

Figure 22.52 Origin of complete and partial hydatidiform moles. (A) Complete moles most commonly arise from fertilization of an empty ovum by a single sperm that undergoes duplication of its chromosomes. (B) Less commonly, complete moles arise from dispermy in which two sperm fertilize an empty ovum. (C) Partial moles arise from two sperm fertilizing a single ovum.

MORPHOLOGY

Grossly, hydatidiform mole appears as a delicate, friable mass of thin-walled, translucent, cystic, grapelike structures consisting of swollen edematous (hydropic) villi (Figs. 22.53 and 22.54). In complete mole, the microscopic abnormalities involve all or most of the villous tissue. The chorionic villi are enlarged, scalloped in shape with central cavitation (cisterns), and covered by extensive trophoblast proliferation that involves the entire circumference of the villi. In contrast, in partial moles, only a fraction of the villi are enlarged and edematous, and the trophoblastic hyperplasia is focal and less marked than in complete moles.

Clinical Features

Most women with partial or early complete mole present with spontaneous miscarriage or undergo curettage because of ultrasound findings of abnormal villous enlargement. In cases of complete mole, human chorionic gonadotropin (hCG) levels greatly exceed those of a normal pregnancy of similar gestational age. In addition, the rate at which hCG levels rise over time in molar pregnancy exceeds what is seen with normal single or even multiple pregnancies. Most moles are successfully removed by curettage. Patients are subsequently monitored for 6 months to 1 year to ensure that hCG levels decrease to nonpregnant levels. Continuous elevation of hCG may be indicative of persistent or invasive mole (described next).

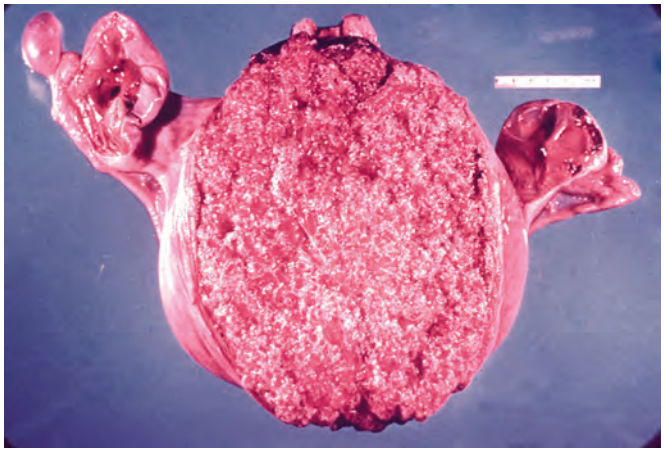

Figure 22.53 Complete hydatidiform mole. Note marked distention of the uterus by enlarged, vesicular chorionic villi. Adnexa (ovaries and fallopian tubes) are visible on the left and right side of the uterus.

Invasive Mole

Invasive mole is an infiltrative lesion that penetrates or even perforates the uterine wall. There is invasion of the myometrium by hydropic chorionic villi, accompanied by proliferation of both cytotrophoblasts and syncytiotrophoblasts. In some instances, the villi invade parametrial tissue and blood vessels and may even embolize to distant sites, such as the lungs and brain. However, these emboli do not grow, as do true metastases, and even without chemotherapy they eventually regress. The tumor manifests clinically with vaginal bleeding and irregular uterine enlargement. It is always associated with a persistently elevated serum hCG. Invasive mole responds well to chemotherapy but may result in uterine rupture, necessitating hysterectomy.

Choriocarcinoma

Gestational choriocarcinoma is a malignant neoplasm of trophoblastic cells derived from a previously normal or abnormal pregnancy, such as an extrauterine ectopic pregnancy. Gestational choriocarcinoma is an uncommon condition that arises in 1 in 20,000 to 30,000 pregnancies in the

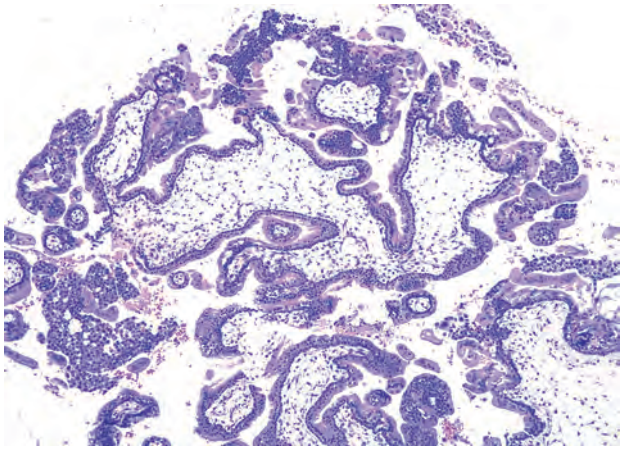

Figure 22.54 Complete hydatidiform mole demonstrating marked villous enlargement, edema, and circumferential trophoblast proliferation.

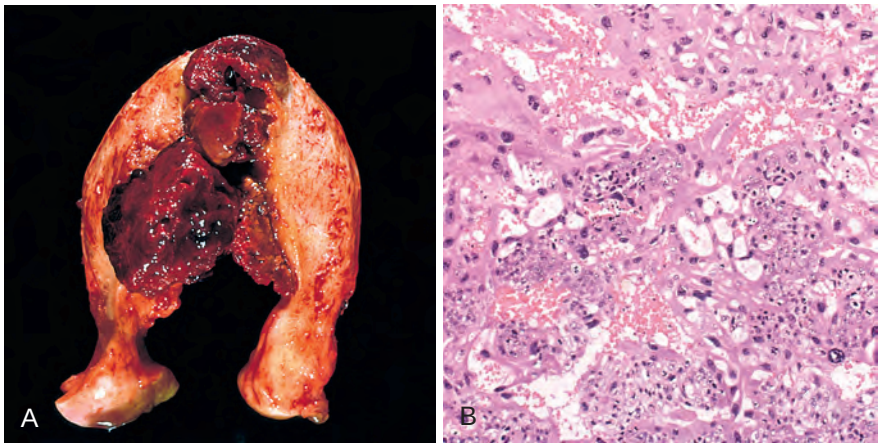

Figure 22.55 Choriocarcinoma. (A) Choriocarcinoma presenting as a bulky hemorrhagic mass invading the uterine wall. (B) Photomicrograph illustrating a tumor composed of neoplastic cytotrophoblasts and syncytiotrophoblasts. (Courtesy Dr. David R. Genest, Brigham and Women's Hospital, Boston, Mass.)

United States. It may be preceded by several conditions; 50% arise in complete hydatidiform moles, 25% in previous abortions, approximately 22% follow normal pregnancies, with the remainder occurring in ectopic pregnancies. Gestational choriocarcinoma is rapidly invasive and metastasizes widely, but once identified responds well to chemotherapy. Rarely, nongestational choriocarcinoma develops from germ cells in the ovaries or the mediastinum. These tumors are morphologically identical to gestational choriocarcinoma but can be distinguished by the absence of paternally derived DNA, which is present in all gestational choriocarcinomas.

MORPHOLOGY

Choriocarcinoma is a soft, fleshy, yellow-white tumor that usually has large pale areas of necrosis and extensive hemorrhage (Fig. 22.55A). Histologically, it consists entirely of proliferating syncytiotrophoblasts and cytotrophoblasts (Fig. 22.55B); chorionic villi are absent. Mitoses are abundant and sometimes abnormal. The tumor invades the underlying myometrium, frequently penetrates blood vessels, and in some cases extends out onto the uterine serosa and into adjacent structures.

Clinical Features

Gestational choriocarcinoma usually manifests as irregular vaginal spotting of a bloody, brown fluid. This discharge may appear in the course of an apparently normal pregnancy, after a miscarriage, or after curettage. Sometimes the tumor does not appear until months after these events. This tumor has high propensity for hematogenous spread, and by the time it is discovered, radiographs of the chest and bones may disclose the presence of metastatic lesions. The hCG levels are typically elevated to levels above those encountered in hydatidiform moles, but occasional tumors produce little hormone, and some tumors are so necrotic that hCG levels are low. Widespread metastases are characteristic; the most common sites are the lungs (50%) and vagina (30% to 40%), followed by, in descending order of frequency, the brain, liver, bone, and kidney.

Treatment of gestational choriocarcinoma depends on the stage of the tumor and usually consists of evacuation of the contents of the uterus and chemotherapy. The results of chemotherapy are spectacular and result in nearly 100% remission and a high rate of cures. Many of the cured patients have had normal subsequent pregnancies and deliveries. By contrast, rare nongestational choriocarcinomas that arise outside of the uterus are more resistant to therapy, although cures are possible with regimens used to treat other forms of germ cell neoplasms.

Placental Site Trophoblastic Tumors

PSTTs comprise less than 2% of gestational trophoblastic neoplasms. They are neoplastic proliferations of extravillous trophoblasts, also called *intermediate trophoblasts*. Normal extravillous trophoblasts are polygonal mononuclear cells that have abundant cytoplasm and produce human placental lactogen. In normal pregnancy, extravillous trophoblasts are found in the implantation site, as clusters of cells within the placental parenchyma, and in the placental membranes. PSTT presents as a uterine mass, accompanied by either abnormal uterine bleeding or amenorrhea and moderately elevated hCG. The malignant trophoblastic cells typically diffusely infiltrate the endomyometrium. PSTT may follow a normal pregnancy (one-half of the cases), spontaneous abortion, or hydatidiform mole. Patients with localized disease have an excellent prognosis, but 10% to 15% of women die of disseminated disease.

CHAPTER 23

The Breast

Susan C. Lester

CHAPTER CONTENTS

The breast is distinguished from other organs by three important characteristics. First, its major function is to provide for the nutritional support and survival of another individual, the infant. Second, it undergoes dynamic structural changes throughout life: expansion of the lobular system after menarche; periodic remodeling during adulthood, especially during and after pregnancy; and ultimately involution and regression. Finally, as symbols of femininity, breasts have social, cultural, and personal importance that is unique from other organs. All of these features impact the origin, presentation, and treatment of breast disease.

Understanding diseases of the breast requires knowledge of its normal anatomy and cellular constituents, which include two major structures (ducts and lobules), two types of epithelial cells (luminal and myoepithelial), and two types of stroma (interlobular and intralobular). Each of these elements is the source of both benign and malignant lesions (Fig. 23.1). Six to 10 major ducts extend down from the nipple and branch into multiple smaller ducts and finally terminate as lobules. Superficial portions of the major ducts are lined by keratinizing squamous epithelium that abruptly transitions to a double-layered epithelium (luminal and myoepithelial cells), which lines the remainder of the duct/lobular system. Following puberty, the duct system expands and proliferates, giving rise to numerous terminal duct lobular units. These units consist of grape-like clusters of small acini surrounded by a specialized intralobular stroma (see Fig. 23.1). In some women, ducts and lobules extend into the subcutaneous tissue of the chest wall and into the axilla. As a result, diseases such as breast cancer sometimes arise outside of the confines of the grossly evident breast tissue.

Changes in the female breast are most dynamic and profound during the reproductive years. Further branching of ducts and lobule formation occur under the influence of hormones such as estrogen, progesterone, and prolactin. Just as the endometrium grows and ebbs with each menstrual cycle, so does the breast. In the first half of the menstrual cycle the lobules are relatively quiescent. After ovulation, under the influence of estrogen and rising progesterone levels, cell proliferation increases, as does the number of acini per lobule. Upon menstruation, the fall in hormone levels induces regression of the lobules.

Only with pregnancy does the breast completely mature and become fully functional. Lobules increase progressively in number and size. By the end of a full-term pregnancy the breast is composed almost entirely of lobules separated by scant stroma. After parturition, the lobules initially produce colostrum (high in protein), changing to milk (higher in fat

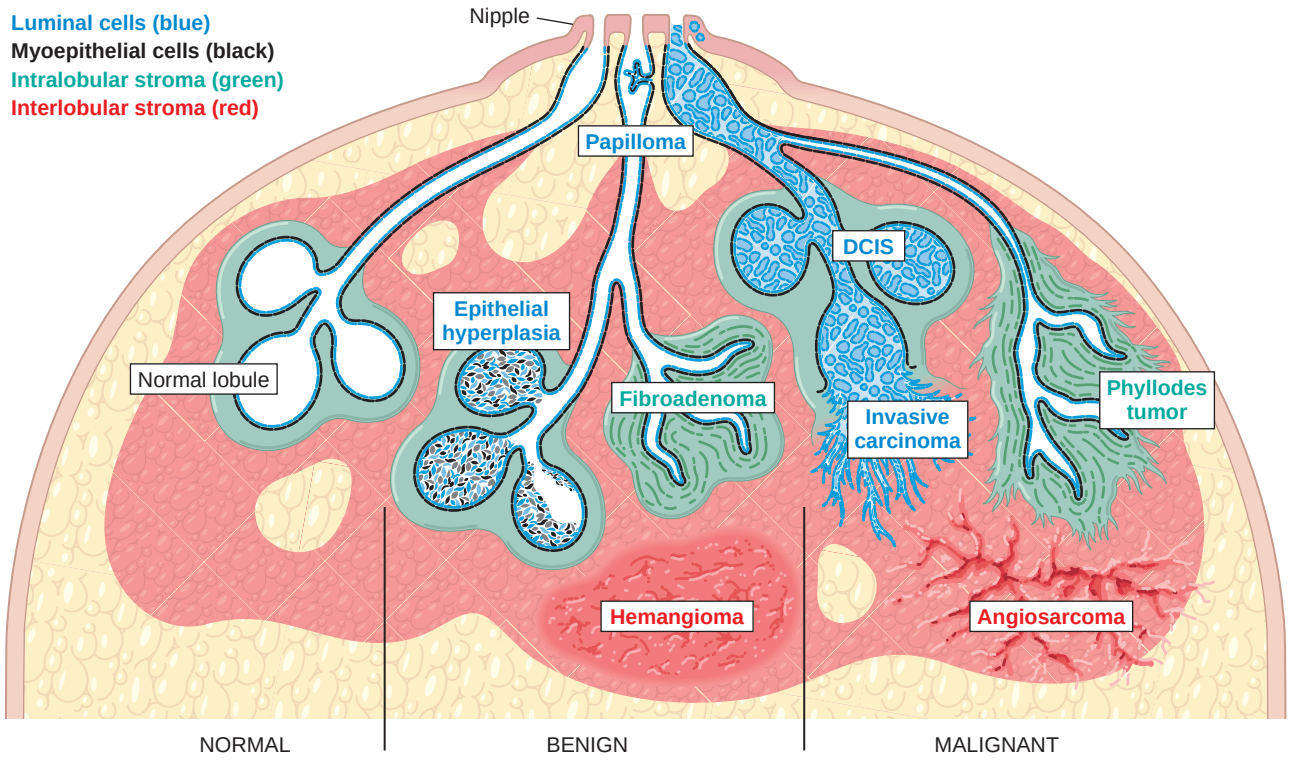

Figure 23.1 The normal cells and structures of the breast, including epithelial cells and myoepithelial cells, intralobular stromal cells and interlobular stromal cells, and large ducts and terminal duct lobular units, can give rise to both benign and malignant tumors. *DCIS*, Ductal carcinoma in situ.

and calories) over the next 10 days as progesterone levels drop. Upon cessation of lactation, epithelial cells undergo apoptosis and lobules regress, but only partially. The permanent changes that are produced by pregnancy may explain the reduction in breast cancer risk that is observed in women who give birth to children at young ages.

After the third decade, long before menopause, lobules and their specialized stroma start to involute, and the interlobular stroma is converted from radiodense fibrous stroma to radiolucent adipose tissue. These changes may be attenuated or delayed by hormones from endogenous (e.g., estrogen from fat stores in obese women) or exogenous (e.g., postmenopausal hormone replacement therapy) sources.

DISORDERS OF DEVELOPMENT

Milk Line Remnants

Supernumerary nipples or breasts result from the persistence of epidermal thickenings along the milk line, which extends from the axilla to the perineum. Disorders of normally situated breasts only very rarely arise in these heterotopic foci, which most commonly come to attention due to painful swelling prior to menstruation.

Accessory Axillary Breast Tissue

In some women the normal ductal system extends into the subcutaneous tissue of the chest wall or the axillary fossa (the axillary tail of Spence). Because this tissue may not be removed by prophylactic mastectomies, such procudures markedly reduce, but do not completely eliminate, the risk of breast cancer.

Congenital Nipple Inversion

The failure of the nipple to evert during development is common and may be unilateral. Congenitally inverted nipples are usually of little significance, since they correct spontaneously during pregnancy or can sometimes be everted by simple traction. Acquired nipple retraction is of more concern, since it may indicate the presence of an invasive cancer or an inflammatory nipple disease.

CLINICAL PRESENTATIONS OF BREAST DISEASE

The most common breast signs and symptoms reported by women are pain, inflammatory changes, nipple discharge, "lumpiness," or a palpable mass (Fig. 23.2A). Few symptoms are so severe as to require treatment, and the primary reason for investigating their cause is to evaluate the possibility of malignancy. Greater than 90% of symptomatic breast lesions are benign. Of women with cancer, about 45% have symptomatic disease, while the remainder come to attention through mammographic screening (Fig. 23.2B). Among the most common or significant signs and symptoms that bring breast lesions to clinical attention are the following:

- *Pain* (mastalgia or mastodynia) is a common symptom that may be cyclic with menses or noncyclic. Diffuse

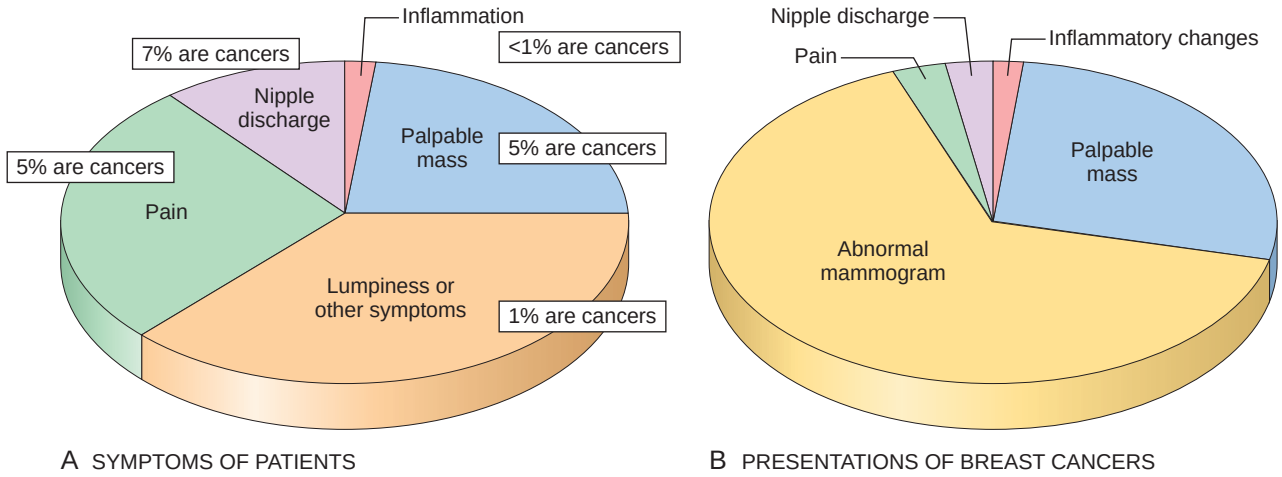

Figure 23.2 Symptoms of breast disease and presentations of breast cancer. (A) Common breast-related symptoms that bring patients to clinical attention include pain, inflammation, nipple discharge, "lumpiness," and palpable masses. Although these symptoms often cause concern, they are associated with cancer in less than 10% of affected women. (B) Presentations of breast cancer.

cyclic pain may be due to premenstrual edema. Noncyclic pain is usually localized to one area of the breast and may be caused by ruptured cysts, physical injury, and infections, but often no specific lesion is identified. Although most painful masses are benign, in about 5% of cases the underlying cause is breast cancer.

- *Inflammation* causes erythema and edema involving all or part of a breast. This is a rare symptom and is most often caused by infections, which only occur with any frequency during lactation and breastfeeding. An important mimic of reactive inflammation is inflammatory breast carcinoma (discussed later).
- *Nipple discharge* may be normal when small in quantity and bilateral. Milky discharge (galactorrhea) is associated with elevated prolactin levels (e.g., by a pituitary adenoma), hypothyroidism, or endocrine anovulatory syndromes and also may occur in patients taking oral contraceptives, tricyclic antidepressants, methyldopa, or phenothiazines. Repeated nipple stimulation also may induce lactation. Galactorrhea is not a feature of malignancy. Bloody or serous discharges are most commonly due to large duct papillomas and cysts. During pregnancy, rapid growth and remodeling of the breast may produce a bloody discharge. Discharge associated with malignancy is most commonly due to ductal carcinoma in situ (DCIS) and increases in prevalence with age; it is caused by an underlying carcinoma in 7% of women under age 60 and in 30% of women 60 years of age or older. Discharge in older women that is spontaneous, unilateral, and bloody is likely to have a malignant origin.
- *Lumpiness,* or diffuse nodularity of the breast, usually is a manifestation of normal glandular tissue. When pronounced, imaging studies may be needed to exclude the presence of a discrete mass.
- *Palpable masses* can arise from proliferations of stromal cells or epithelial cells and are generally detected when 2 to 3 cm in size. Most (~95%) are benign: these tend to be round or oval in shape, rubbery, and mobile and to have circumscribed borders. The most common benign masses are fibroadenomas and cysts. In contrast, malignant tumors invade across tissue planes, are often hard (scirrhous) in consistency, and usually have irregular borders. The likelihood that a mass is malignant increases with age, rising from 10% for women younger than age 40 to 60% for women older than age 50. Approximately 50% of carcinomas are located in the upper outer quadrant, 10% in each of the remaining quadrants, and about 20% in the central or subareolar region. Although about one-third of cancers are first detected as a palpable mass, screening by palpation has little effect on reducing breast cancer mortality. Unfortunately, the majority of cancers that have the capacity to metastasize do so before they reach a palpable size.

Mammographic screening was introduced in the 1980s in an effort to detect nonpalpable asymptomatic breast carcinomas before metastatic spread and is currently the most commonly used screening test for breast cancer (Fig. 23.2B). The sensitivity and specificity of mammography increase with age. At age 40, the probability that a mammographic lesion is cancer is only 10%, but this rises to greater than 25% in women older than 50. The principal mammographic signs of breast carcinoma are densities and calcifications:

- *Densities*. Breast lesions that replace adipose tissue with radiodense tissue form mammographic densities. Rounded densities are most commonly benign lesions such as fibroadenomas or cysts, whereas invasive carcinomas generally form irregular masses. The average size of invasive carcinomas detected by mammography is about 1 cm (significantly smaller than carcinomas detected by palpation), and only 15% will have metastasized to regional lymph nodes at the time of detection.
- *Calcifications*. Calcifications form on secretions, necrotic debris, or hyalinized stroma and are often associated with benign lesions such as apocrine cysts, hyalinized fibroadenomas, and sclerosing adenosis. Calcifications associated with malignancy are usually small, irregular, numerous, and clustered. A marked increase in the

diagnosis of DCIS, a form of breast cancer that is often associated with calcifications, was observed after the introduction of mammographic screening.

Approximately 10% of invasive carcinomas are not visible by standard two-dimensional mammographic techniques. Causes include the presence of surrounding radiodense tissue that obscures the tumor (especially in younger women); small tumor size; a diffuse infiltrative growth pattern with little or no tissue response; or a location close to the chest wall or in the periphery of the breast. Other imaging modalities can be useful adjuncts in such circumstances, particularly in evaluating palpable masses that are not seen well with standard mammography. Digital breast tomosynthesis (three-dimensional mammography) integrates additional views of the breast and can detect subtle changes in breast parenchymal texture. Ultrasonography distinguishes between solid and cystic lesions and more precisely defines the borders of solid lesions. Magnetic resonance imaging (MRI) detects cancers by the rapid uptake of contrast agents due to increased tumor vascularity and blood flow and can be particularly helpful in the evaluation of breasts of high density.

Although the recent downward trend in deaths from breast cancer is partially attributed to earlier diagnosis due to mammography, the beneficial effect of screening is smaller than originally anticipated for several reasons. By the time of detection, most (70% to 80%) cancers are invasive and some have metastasized. Even more troubling, the cancers that are most likely to cause death are least likely to be detected by mammography. These lethal cancers arise in young women of prescreening age or grow so rapidly that they present during the interval between mammograms. On the other side of the ledger, many cancers detected by mammography are clinically unimportant, being so indolent that they would never have caused harm had they gone undetected (a situation reminiscent of many prostate cancers in men; see Chapter 21). It is estimated that between 10% and 30% of invasive cancers detected by mammography fall into this category. Although this issue is sometimes referred to as a problem of overdiagnosis, it is more accurate to say that it reflects a need for reliable predictors of the behavior of invasive carcinomas; some predictors of outcome in current use are discussed later.

INFLAMMATORY DISORDERS

Inflammatory diseases of the breast are rare (accounting for less than 1% of breast symptoms) and are caused by infections, autoimmune disease, or foreign body–type reactions to extravasated keratin or secretions. Inflammatory breast cancer mimics inflammation by obstructing dermal vasculature with tumor emboli and should always be considered in a woman with an erythematous swollen breast (discussed later).

Acute Mastitis

Acute bacterial mastitis typically occurs during the first month of breastfeeding and is caused by a local infection when the breast is most vulnerable due to cracks and fissures in the nipples. From this portal of entry, *Staphylococcus aureus* or, less commonly, streptococci invade the breast tissue. The breast is erythematous and painful, and fever is often present. At the outset only one duct system or sector of the breast is involved. If not treated, the infection may spread to the entire breast. Staphylococci infection often leads to single or multiple abscesses, whereas streptococci cause spreading infection in the form of cellulitis.

Most cases of lactational mastitis are easily treated with appropriate antibiotics and continued expression of milk from the breast. Only rarely is surgical drainage required.

Squamous Metaplasia of Lactiferous Ducts

Squamous metaplasia of lactiferous ducts is known by a variety of names, including recurrent subareolar abscess, periductal mastitis, and Zuska disease. Women, and sometimes men, present with a painful erythematous subareolar mass that mimics a bacterial abscess. In recurrent cases, a fistula tract often develops under the smooth muscle of the nipple and opens onto the skin at the edge of the areola. In many affected women the nipple inverts due to traction produced by inflammation and scarring. More than 90% of afflicted individuals are smokers. It has been suggested that a relative deficiency of vitamin A associated with smoking or toxic substances in tobacco smoke alters the differentiation of the ductal epithelium.

MORPHOLOGY

The key feature is **keratinizing squamous metaplasia,** which extends into the nipple duct well past the usual point of transition from squamous to glandular epithelium (Fig. 23.3). Keratin shed from these cells is trapped and plugs the ductal system, causing

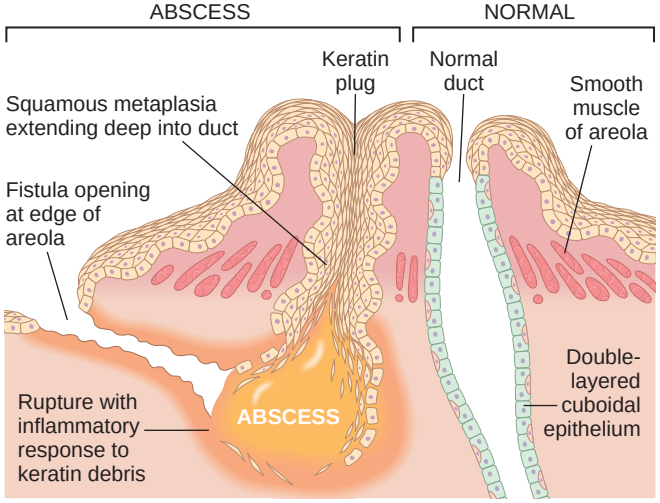

Figure 23.3 Squamous metaplasia of lactiferous ducts. When squamous metaplasia extends deep into a nipple duct, keratin becomes trapped and accumulates. If the duct ruptures, the ensuing intense inflammatory response to keratin results in an erythematous painful mass. A fistula tract may burrow beneath the smooth muscle of the nipple to open at the edge of the areola.

dilation and eventually rupture of the duct. An intense chronic granulomatous inflammatory response develops once keratin spills into the surrounding periductal tissue. With recurrences, a secondary anaerobic bacterial infection may supervene and cause acute inflammation.

Simple incision drains the abscess cavity, but the offending keratinizing epithelium remains, and recurrences are common. In most cases, en bloc surgical removal of the involved duct and contiguous fistula tract is curative. If secondary bacterial infection is present, antibiotics also have a therapeutic role.

Duct Ectasia

Duct ectasia presents as a palpable periareolar mass that is often associated with thick, white nipple secretions and occasionally with skin retraction. Pain and erythema are uncommon. This disorder tends to occur in the fifth or sixth decade of life, usually in multiparous women. Unlike squamous metaplasia of lactiferous ducts, it is not associated with cigarette smoking.

MORPHOLOGY

Ectatic dilated ducts are filled with inspissated secretions and numerous lipid-laden macrophages. With duct rupture, a marked periductal and interstitial chronic inflammatory reaction ensues, consisting of lymphocytes, macrophages, and variable numbers of plasma cells (Fig. 23.4). Granulomas may form around cholesterol deposits and secretions. Subsequent fibrosis produces an irregular mass with skin and nipple retraction.

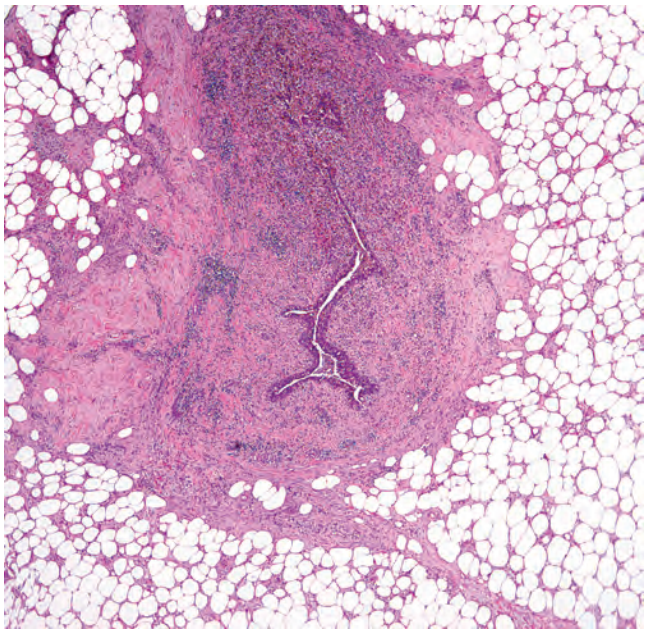

Figure 23.4 Duct ectasia. Chronic inflammation and fibrosis surround an ectatic duct filled with inspissated debris. The fibrotic response can produce a firm irregular mass that mimics invasive carcinoma on palpation or mammogram.

The principal significance of duct ectasia is that it may be difficult to distinguish on clinical and radiologic grounds from invasive carcinoma.

Fat Necrosis

The presentations of fat necrosis are protean and may closely mimic cancer. It may present as a painless palpable mass, skin thickening or retraction, or mammographic densities or calcifications. About half of affected women have a history of breast trauma or surgery.

MORPHOLOGY

Acute lesions may be hemorrhagic and contain central areas of liquefactive fat necrosis with neutrophils and macrophages. Over the next few days proliferating fibroblasts and chronic inflammatory cells surround the injured area. Subsequently, giant cells, calcifications, and hemosiderin appear, and eventually the lesion is replaced by scar tissue or is encircled and walled off by fibrous tissue. Ill-defined, firm, gray-white nodules containing small chalky-white foci are seen grossly.

Lymphocytic Mastopathy (Sclerosing Lymphocytic Lobulitis)

This condition presents with single or multiple hard palpable masses or mammographic densities. The masses are associated with areas of densely collagenized stroma, a feature that may make it difficult to obtain lesional tissue by needle biopsy. Within the stroma are atrophic ducts and lobules with thickened basement membranes that are surrounded by a prominent lymphocytic infiltrate. This condition is most common in women with type 1 (insulin-dependent) diabetes or autoimmune thyroid disease and is hypothesized to have an autoimmune basis. Its only clinical significance is that it must be distinguished from breast cancer.

Granulomatous Mastitis

Granulomatous inflammation of the breast may be a manifestation of systemic granulomatous diseases (e.g., granulomatosis with polyangiitis, sarcoidosis, tuberculosis) or of inflammatory or infectious disorders that are localized to the breast. *Granulomatous lobular mastitis* is an uncommon disease that occurs only in parous women. The granulomas are closely associated with lobules and may contain lipid vacuoles surrounded by neutrophils. A similar histologic pattern is seen in *cystic neutrophilic granulomatous mastitis,* which is often caused by lipophilic *Corynebacteria*. These histologic patterns may be manifestations of the same disease. Treatment includes antibiotics and sometimes steroids. Localized infections by mycobacteria or fungi are very rare and are most common in immunocompromised patients or adjacent to foreign objects such as breast prostheses or nipple piercings.

KEY CONCEPTS

INFLAMMATORY DISORDERS

- Inflammatory diseases of the breast are rare outside of the lactational period.
- The specific cause must be determined, as appropriate treatment may be antibiotics, steroids, or surgery.
- The possibility of inflammatory carcinoma mimicking a non-neoplastic inflammatory disorder should always be considered.

BENIGN EPITHELIAL LESIONS

Benign epithelial lesions are classified into three groups, each with a different risk for subsequent development of breast cancer: (1) *nonproliferative breast changes,* (2) *proliferative breast disease,* and (3) *atypical hyperplasia.* Most come to clinical attention when detected by mammography or as incidental findings in surgical specimens.

Nonproliferative Breast Changes (Fibrocystic Changes)

This group includes common morphologic alterations that are often grouped under the term *fibrocystic changes*. To the clinician, the term might mean "lumpy bumpy" breasts on palpation; to the radiologist, a dense breast with cysts; and to the pathologist, benign histologic findings. These lesions are termed nonproliferative to indicate that they are not associated with an increased risk of breast cancer; this name is somewhat unfortunate because some of these changes do involve increased proliferation and may even be associated with clonal genetic aberrations.

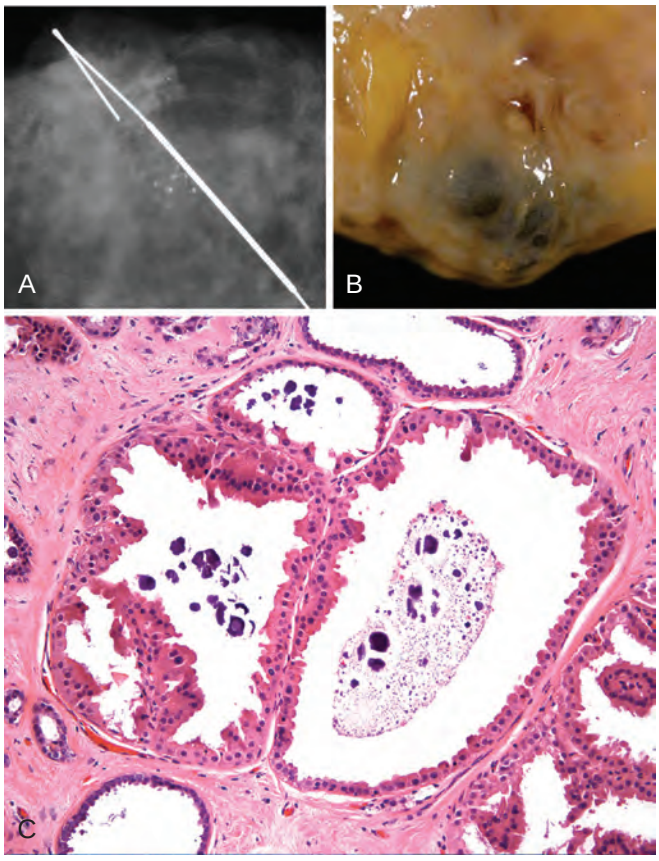

Figure 23.5 Apocrine cysts. (A) Clustered, rounded calcifications are seen in a specimen radiograph. (B) Gross appearance of typical cysts filled with dark, turbid fluid contents. (C) Cysts are lined by apocrine cells with round nuclei and abundant granular cytoplasm. Note the luminal calcifications, which form on secretory debris.

MORPHOLOGY

There are three principal nonproliferative morphologic changes: (1) cystic change, often with apocrine metaplasia; (2) fibrosis; and (3) adenosis.

- **Cysts.** Small cysts form by the dilation of lobules and in turn may coalesce to form larger cysts. Unopened cysts contain turbid, semitranslucent brown- or blue-colored fluid (blue-dome cysts) (Fig. 23.5B). Cysts are lined either by a flattened atrophic epithelium or by metaplastic apocrine cells. The latter cells have abundant granular, eosinophilic cytoplasm and closely resemble the normal apocrine epithelium of sweat glands (Fig. 23.5C). Calcifications are common (Fig. 23.5A). Cysts may cause concern when they are solitary and firm. The diagnosis is confirmed by the disappearance of the mass after fine-needle aspiration of its contents.
- **Fibrosis.** Cysts frequently rupture, releasing secretory material into the adjacent stroma. The resulting chronic inflammation and fibrosis contribute to palpable nodularity of the breast.
- **Adenosis.** Adenosis is defined as an increase in the number of acini per lobule. It is a normal feature of pregnancy. In nonpregnant women, adenosis can occur as a focal change. The acini are lined by columnar epithelial cells, and calcifications are occasionally present within the lumens.

Several other morphologic alterations fall into the category of "nonproliferative" changes. **Lactational adenomas** present as palpable masses in pregnant or lactating women and regress after cessation of breastfeeding. They consist of normal-appearing breast tissue with lactational changes. Their name may be a misnomer, as these lesions may be an exaggerated local response to gestational hormones rather than true neoplasms. **Flat epithelial atypia** is a clonal process characterized by the presence of dilated acini and cysts lined by epithelial cells that display mild cytologic atypia. It is associated with deletions of chromosome 16q and is the earliest morphologically recognizable clonal lesion of the breast. Flat epithelial atypia is often associated with lesions that increase the risk of cancer (e.g., atypical hyperplasia, described later) but has not been shown to increase risk in isolation.

Proliferative Breast Disease Without Atypia

Lesions characterized by proliferation of epithelial cells, without atypia, are associated with a small increase in the risk of subsequent carcinoma in either breast. They are commonly detected as mammographic densities, calcifications, or

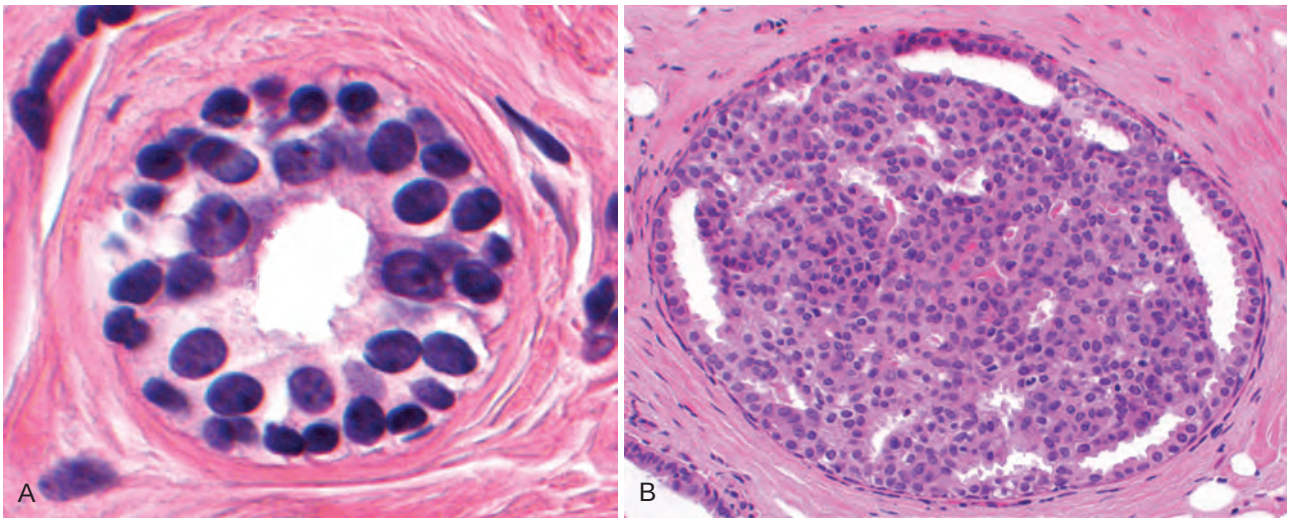

Figure 23.6 (A) Normal duct or acinus with a single basally located myoepithelial cell layer (cells with dark, compact nuclei and scant cytoplasm) and single luminal cell layer (cells with larger open nuclei, small nucleoli, and more abundant cytoplasm). (B) Epithelial hyperplasia. The lumen is filled with a heterogeneous, mixed population of luminal and myoepithelial cell types. Irregular slit-like fenestrations are prominent at the periphery.

incidental findings in biopsies performed for other reasons. These lesions are considered predictors of risk, rather than direct precursors, of carcinoma.

MORPHOLOGY

Several morphologically distinct patterns of proliferative breast disease without atypia are recognized:

- **Epithelial hyperplasia.** Normal breast ducts and lobules are lined by a double layer of myoepithelial cells and luminal cells (Fig. 23.6A). In epithelial hyperplasia, increased numbers of both luminal and myoepithelial cell types fill and distend ducts and lobules. Irregular lumens can often be discerned at the periphery of the cellular masses (Fig. 23.6B). Epithelial hyperplasia is usually an incidental finding.
- **Sclerosing adenosis.** There are an increased number of acini that are compressed and distorted in the central portion of the lesion. On occasion, stromal fibrosis completely compresses the lumens to create the appearance of solid cords or double strands of cells lying within dense stroma, a pattern that superficially resembles invasive carcinoma (Fig. 23.7). Sclerosing adenosis may come to attention as a palpable mass, a radiologic density, or calcifications.
- **Complex sclerosing lesion.** These lesions have components of sclerosing adenosis, papilloma, and epithelial hyperplasia. One member of this group, the radial sclerosing lesion ("radial scar"), has an irregular shape and closely mimics invasive carcinoma mammographically, grossly, and histologically (Fig. 23.8). A central nidus of entrapped glands in a hyalinized stroma is surrounded by long radiating projections into stroma. The term radial scar is a misnomer, as it is not associated with prior trauma or surgery.
- **Papilloma.** Papillomas grow within a dilated duct and are composed of multiple branching fibrovascular cores (Fig. 23.9). Epithelial hyperplasia and apocrine metaplasia are frequently present. Large duct papillomas are situated in the lactiferous sinuses of the nipple and are usually solitary. Small duct papillomas are commonly multiple and located deeper within the ductal system. More than 80% of large duct papillomas produce a nipple discharge, which may be bloody due to torsion of the stalk, leading to infarction. Serous discharge results from intermittent blockage and release of normal breast secretions or irritation of the duct by the papilloma. Most small duct papillomas come to clinical attention as small palpable masses, or as densities or calcifications seen on mammograms.

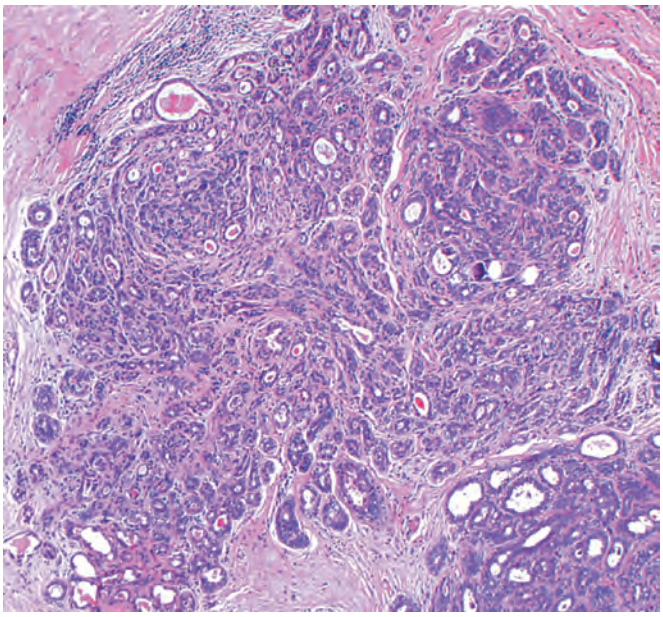

Figure 23.7 Sclerosing adenosis. The involved terminal duct lobular unit is enlarged, and the acini are compressed and distorted by dense stroma. Calcifications are present within some of the lumens. Unlike carcinomas, the acini are arranged in a swirling pattern, and the outer border is well circumscribed.

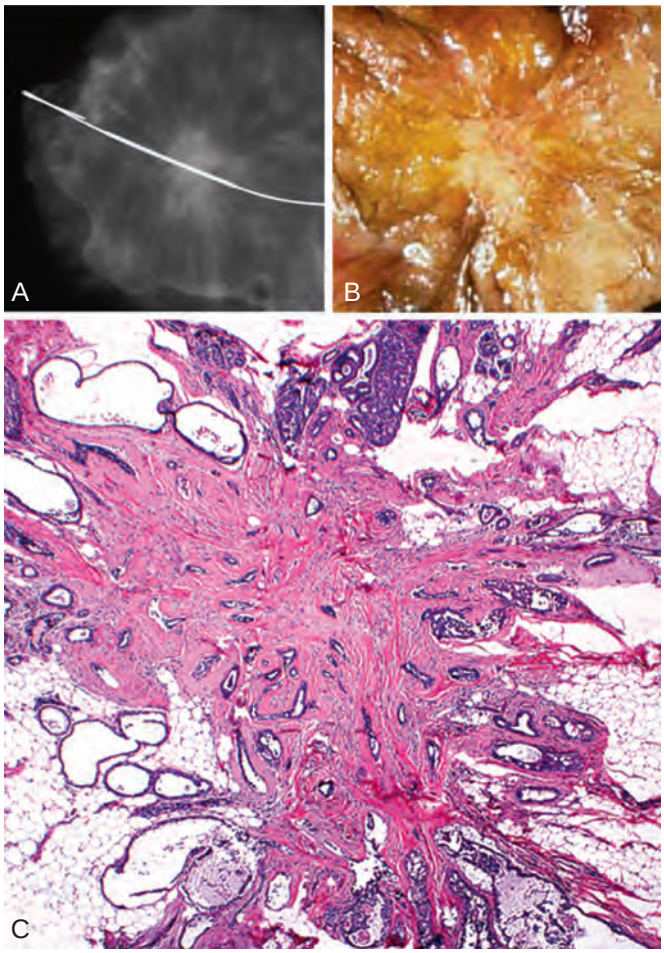

Figure 23.8 Radial sclerosing lesion. (A) Radiograph shows an irregular central mass with long radiodense projections. (B) Grossly the mass appears fibrotic and has irregular borders, but it is not as firm as an invasive carcinoma. (C) The mass consists of a central nidus of small tubules entrapped in a densely fibrotic stroma and numerous projections containing epithelium with varying degrees of cyst formation and hyperplasia.

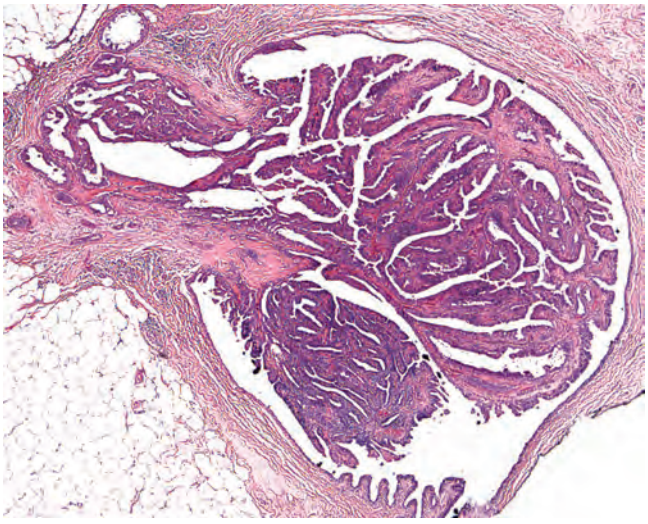

Figure 23.9 Intraductal papilloma. A central fibrovascular core extends from the wall of a duct. The papillae arborize within the lumen and are lined by myoepithelial and luminal cells.

Figure 23.10 Gynecomastia. Breast enlargement in males is due to an increase in the number of ducts accompanied by dense cellular stroma. Lobule formation is absent.

Gynecomastia

Gynecomastia (enlargement of the male breast) is the only benign lesion seen with any frequency in the male breast. It presents as a button-like subareolar enlargement and may be unilateral or bilateral. Microscopically, there is an increase in dense collagenous connective tissue associated with epithelial hyperplasia of the duct lining (Fig. 23.10). Lobule formation is almost never observed.

Gynecomastia occurs as a result of an imbalance between estrogens, which stimulate breast tissue, and androgens, which counteract these effects. It may appear during puberty, in the very aged, or at any time during adult life when there is cause for hyperestrinism. The most important of these is cirrhosis of the liver, since this organ is responsible for metabolizing estrogen. In older males, gynecomastia may stem from a relative increase in estrogens as testicular androgen production falls. Drugs such as alcohol, marijuana, heroin, antiretroviral therapy, and anabolic steroids have been associated with gynecomastia. Rarely, gynecomastia occurs as part of Klinefelter syndrome (XXY karyotype) or in association with functioning testicular neoplasms, such as Leydig cell or Sertoli cell tumors.

Proliferative Breast Disease With Atypia

Atypical hyperplasia is a clonal proliferation having some, but not all, of the histologic features of carcinoma in situ. It is associated with a moderately increased risk of carcinoma and is divided into two forms, atypical ductal hyperplasia and atypical lobular hyperplasia. Atypical ductal hyperplasia is present in 5% to 17% of specimens from biopsies performed for calcifications. Atypical lobular hyperplasia is an incidental finding and is found in fewer than 5% of biopsies.

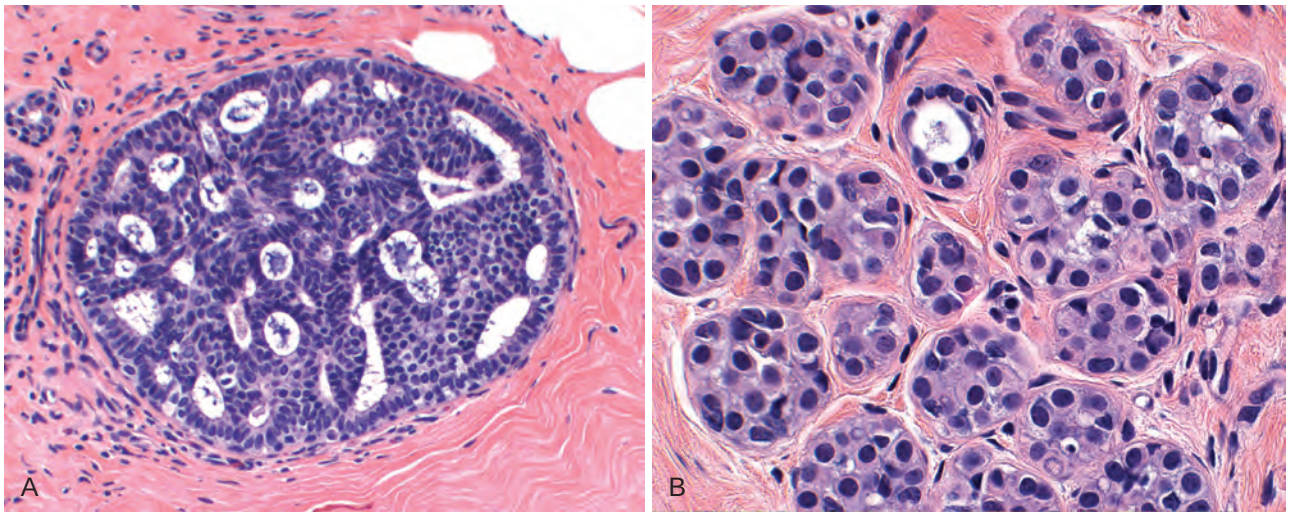

Figure 23.11 (A) Atypical ductal hyperplasia. A duct is filled with a mixed population of cells consisting of oriented columnar cells at the periphery and more rounded cells within the central portion. Although some of the spaces are round and regular, the peripheral spaces are irregular and slit-like. These features are highly atypical, but fall short of a diagnosis of ductal carcinoma in situ. (B) Atypical lobular hyperplasia. A population of monomorphic small, round, loosely cohesive cells partially fills a lobule. Although the cells are morphologically identical to the cells of lobular carcinoma in situ, the extent of involvement is not sufficient for this diagnosis.

MORPHOLOGY

Atypical ductal hyperplasia is recognized by its histologic resemblance to DCIS. It consists of a relatively monomorphic proliferation of regularly spaced cells, sometimes forming cribriform spaces. It is distinguished from DCIS in that it only partially fills involved ducts (Fig. 23.11A).

Atypical lobular hyperplasia consists of cells identical to those of lobular carcinoma in situ (LCIS) (described later), but the cells do not fill or distend more than 50% of the acini within a lobule (Fig. 23.11B).

Atypical ductal hyperplasia and atypical lobular hyperplasia express high levels of estrogen receptor (ER), have a low rate of proliferation, and may have acquired chromosomal aberrations such as losses of 16q and 17p or gains of 1q, features also found in low-grade carcinoma in situ and ER-positive invasive breast cancer. Atypical lobular hyperplasia also shows loss of E-cadherin expression, a feature it shares with LCIS (discussed later).

Clinical Significance of Benign Epithelial Changes

Epidemiologic studies have established the association of benign histologic changes with the later development of invasive cancer (Table 23.1). Proliferative changes are associated with a 1.5- to 2-fold increased risk compared to nonproliferative changes, while proliferative disease with atypia confers a 4- to 5-fold increased risk. Both breasts are at increased risk. Risk reduction can be achieved by bilateral prophylactic mastectomy or treatment with estrogen antagonists, such as tamoxifen. However, fewer than 20% of women with atypical hyperplasia develop breast cancer, and therefore many choose close clinical and radiologic surveillance over intervention.

Table 23.1 Epithelial Breast Lesions and Risk of Developing Invasive Carcinoma

Pathologic Lesions	Relative Risk (Absolute Lifetime Risk)[a]
Nonproliferative breast changes (mild hyperplasia, duct ectasia, cysts, apocrine metaplasia, adenosis, fibroadenoma without complex features)	1.0 (~3%)
Proliferative disease without atypia (moderate or florid hyperplasia, sclerosing adenosis, complex sclerosing lesion, fibroadenoma with complex features)	1.5–2 (~5%–7%)
Proliferative disease with atypia (atypical ductal hyperplasia, atypical lobular hyperplasia)	4–5 (~13%–17%)
Carcinoma in situ (lobular carcinoma in situ, ductal carcinoma in situ)	8–10 (~25%–30%)

[a]Relative risk is the likelihood of developing invasive carcinoma compared to women without any risk factors. Absolute lifetime risk is the percentage of women expected to develop invasive carcinoma in the absence of an intervention.

KEY CONCEPTS

BENIGN EPITHELIAL LESIONS

- Benign epithelial lesions usually do not cause symptoms but are frequently detected as mammographic calcifications or densities.
- The majority are not precursors of cancer.
- These lesions are classified according to the subsequent risk of cancer in either breast.
- Although risk reduction can be achieved by surgery or chemoprevention, the majority of women will not develop cancer, and many women choose surveillance instead of intervention.

CARCINOMA OF THE BREAST

Breast carcinoma is the most common and deadly malignancy of women globally; each year, 1.7 million women are diagnosed, and one in three of those afflicted die of disease. Although the incidence of breast cancer is four to seven times higher in the United States and Europe than elsewhere, the worldwide incidence and mortality is increasing at an alarming rate, and by 2020 it is estimated that 70% of cases will be in lower income countries. The factors underlying this trend are thought to be social changes that increase breast cancer risk—specifically delayed childbearing, fewer pregnancies, and reduced breastfeeding—combined with a lack of access to optimal health care.

The lifetime risk of breast cancer is 1 in 8 for women living to age 90 in the United States. In 2019, over 260,000 women in the United States were diagnosed with invasive breast cancer, and more than 40,000 women died of the disease—a toll among cancers second only to lung cancer. It is both ironic and tragic that a neoplasm arising in an exposed organ, readily accessible to self-examination and clinical surveillance, continues to exact such a heavy toll.

All breast cancers can be separated into three major groups defined by the expression of two proteins, ER and HER2 (also known as ERBB2). In this chapter, "luminal" cancers are defined as being positive for ER and negative for HER2. "HER2" cancers are defined as cancers overexpressing HER2 and can be either ER-positive or ER-negative. "Triple negative breast cancers" (TNBCs) are cancers that are negative for ER and HER2. These cancers are termed "triple negative" because they also fail to express progesterone receptor (PR), which is under the control of ER. These three groups of cancers differ with regard to patient characteristics, pathologic features, treatment response, metastatic patterns, time to relapse, and outcome and will be discussed in more detail later. However, it is important to note that breast cancer is biologically heterogeneous and that each of these three groups is comprised of numerous clinically important subtypes.

Incidence and Epidemiology

Breast cancer is rare in women younger than age 25 and increases in incidence rapidly after age 30 (Fig. 23.12). The incidence of TNBC and HER2 cancer plateaus in middle age, whereas the incidence of luminal cancer peaks later in life. As a result, TNBCs and HER2 cancers comprise almost half of cancers in young women and fewer than 20% of cancers in older women.

Starting in the 1980s, a marked increase in the apparent incidence of breast cancer was noted in older women. This change appears to be attributable to two factors: the introduction of mammographic screening and the increased use of postmenopausal hormonal therapy in older women. After 2000, the number of newly diagnosed breast cancers fell in older women, probably due to a leveling off of the rate of mammographic screening (approximately 65% to 75% of eligible women) and decreased use of postmenopausal hormone therapy. In contrast, over the same time the incidence of breast cancer remained relatively constant in younger women.

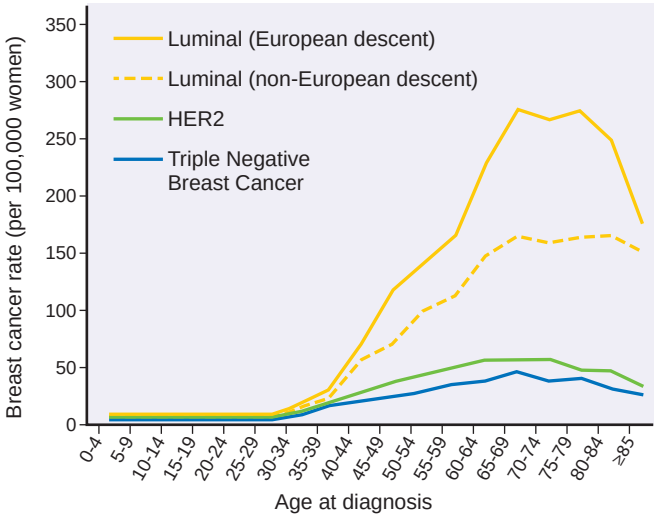

Figure 23.12 Incidence of luminal (ER-positive/HER2-negative), HER2 (HER2-positive), and triple negative (ER-negative/HER2-negative) breast cancers according to age. Rates are per 100,000 women. Triple negative *(solid blue line)* and HER2 *(solid green line)* cancers have a relatively constant incidence after age 40 years. In contrast, luminal cancers show a marked increase in incidence with age. This increase is greatest for women of European descent *(solid yellow line)* and less pronounced for women other ethnic backgrounds (African, Hispanic, and Asian) *(broken yellow line)*. *TNBC*, Triple negative breast cancer.

Breast cancer incidence and biology vary with ethnicity. The incidence of breast cancer is highest in women of European descent; in this group, the average age at diagnosis is 63 years, and only 20% of cases are diagnosed at an age younger than 50 years. In contrast, the average age at diagnosis for women of African descent is 59 years, and 35% of cancers are diagnosed at ages below 50. For Hispanic women, the average age at diagnosis is 56, and 20% are diagnosed at ages below 50. The "excess" cancers in women of European descent are mostly of luminal type (Fig. 23.12). Thus, TNBCs and HER2 cancers make up a greater proportion of cancers occurring in other ethnic groups.

The risk of death in those who develop invasive breast cancer has gradually declined in both younger and older women, most recently by 1% to 2% per year; the current overall risk of death is about 20%. This decrease is attributed to mammographic screening as well as to more effective treatment modalities. However, the decline in the death rate has lagged behind in women of African descent, who have the highest mortality rate. Although this difference is explained partly by unequal access to care, breast cancers in women of African descent are also more likely to be biologically aggressive (e.g., TNBC) and to fall into molecular subtypes that are difficult to treat.

Risk Factors

The most important risk factors are gender (99% of those affected are female), age, lifetime exposure to estrogen, genetic inheritance, and, to a lesser extent, environmental and lifestyle factors (Table 23.2). There is concern (but no proof) that environmental contaminants, such as organochlorine pesticides and certain plastics, have estrogenic effects on humans that may increase the risk of breast cancer. The

Table 23.2 Risk Factors for Developing Breast Cancer

Risk Factors	Relative Risk[a]
Female gender Increasing age Germline mutations of high penetrance Strong family history (>1 first-degree relative, young age, multiple cancers) Personal history of breast cancer High breast density	>4.0
Germline mutations of moderate penetrance High-dose radiation to chest at young age Family history (1 first-degree relative)	2.1–4.0
Early menarche (age <12 years) Late menopause (age >55 years) Late first pregnancy (age >35 years) Nulliparity Absence of breastfeeding Exogenous hormone therapy Postmenopausal obesity Physical inactivity High alcohol consumption	1.1–2.0

[a]Relative risk is the likelihood of developing invasive carcinoma compared to women without any risk factors.

major factors that decrease risk are early pregnancy (prior to 20 years of age) and prolonged breastfeeding. Societal changes in these factors in low income countries are thought to be contributing to the rise in breast cancer incidence.

Surgical and medical interventions also can decrease risk. Bilateral prophylactic mastectomy decreases risk by about 90%. Chemoprevention using ER antagonists decreases the incidence of ER-positive cancers. These interventions are mainly offered to women at very high risk for breast cancer.

Molecular Classification and Pathogenesis

Several different approaches have been used to subclassify breast cancer into clinically meaningful subtypes. Based on gene expression profiling, breast cancers cluster into three main groups: "luminal" (predominantly ER-positive/HER2-negative), "HER2-enriched" (predominantly HER2-positive), and "basal-like" (predominantly ER-negative/HER2-negative). Because these molecular subtypes correlate reasonably well with ER and HER2 protein expression (Fig. 23.13), which is easily assessed by standard clinical assays, molecular subtyping by expression profiling is not a routine part of breast cancer classification.

Like other cancers, breast cancers arise through several pathways that involve the stepwise acquisition of driver mutations in epithelial cells. Breast cancer develops in a hormonal milieu that facilitates mutagenesis and the outgrowth of abnormal clones. Carcinomas associated with germline mutations in cancer genes make up the minority of carcinomas, but provide generally important insights into the molecular pathogenesis of breast cancer; thus, we begin by discussing tumors with a strong familial basis and then turn to sporadic breast cancers.

Pathogenesis of Familial Breast Cancer

It is believed that one-quarter to one-third of breast cancers occur due to inheritance of a susceptibility gene or genes. Single gene mutations with moderate to high penetrance ("penetrance" refers to the risk of an individual with the mutated gene developing cancer) accounts for 8% to 17% of breast carcinomas (Table 23.3). Inheritance also is thought to play a role in an additional 15% to 20% of women based on a positive family history, defined as an affected first-degree relative (mother, sister, or daughter), cancer in multiple relatives, and early-onset cancers. In these women, inheritance of a single susceptibility gene with low penetrance or combinations of genes that interact to increase risk is believed to be the culprit.

The most important high penetrance susceptibility genes for familial breast cancer are tumor suppressor genes that regulate genomic stability or are involved in pro-growth signaling pathways (see Table 23.3). Risk is inherited in an autosomal dominant fashion and stems from alleles with loss-of-function mutations. As with other tumor suppressor genes, cancer development is associated with sporadic loss-of-function mutations in the single normal copy of the gene.

Mutations in *BRCA1* and *BRCA2* are responsible for 80% to 90% of single gene familial breast cancers and about 3% to 6% of all breast cancers. Penetrance, age of onset, and susceptibility to other types of cancers vary according to the specific *BRCA1* and *BRCA2* mutation that is inherited, but most carriers develop breast cancer by the age of 70 years. Mutations in *BRCA1* also markedly increase the risk of ovarian carcinoma, which occurs in 20% to 40% of carriers. *BRCA2* confers a smaller risk for ovarian carcinoma (10% to 20%) but is associated more frequently with male breast cancer. *BRCA1* and *BRCA2* carriers also are at higher risk for other epithelial cancers, such as prostatic and pancreatic carcinoma.

BRCA1 (on chromosome 17q21) and *BRCA2* (on chromosome 13q12.3) are both large genes, and hundreds of different mutations distributed throughout their coding regions have been associated with familial breast cancer. The frequency of mutations that increase breast cancer risk is about 1 in 400 persons in the general population, and inconsequential polymorphisms are common. As a result, genetic testing is complex and is generally restricted to individuals with a strong family history or those belonging to certain ethnic groups. For example, in Ashkenazi Jewish populations, about 1 in 40 individuals carry one of three specific mutations, two in *BRCA1* and one in *BRCA2*. Identification of carriers is important, since increased surveillance and prophylactic mastectomy and salpingo-oophorectomy can reduce cancer-related morbidity and mortality.

BRCA1-associated breast cancers are commonly poorly differentiated, often have characteristic morphologic features (described later), and usually fall in the TNBC subgroup. *BRCA2*-associated breast carcinomas also tend to be poorly differentiated, but are more often ER-positive than *BRCA1* cancers.

Other tumor suppressor genes associated with germline mutations that convey a high risk for breast cancer, often as part of well-described syndromes, include *TP53* (Li-Fraumeni syndrome), *PTEN* (Cowden syndrome), *STK11* (Peutz-Jeghers syndrome), *CDH1* (hereditary diffuse gastric cancer syndrome), and *PALPB2* (see Table 23.3). Moderately penetrant (10% to 30% risk) mutations occur in the tumor suppressor genes *ATM* (a cause of ataxia telangiectasia when homozygous mutations are present) and *CHEK2*.

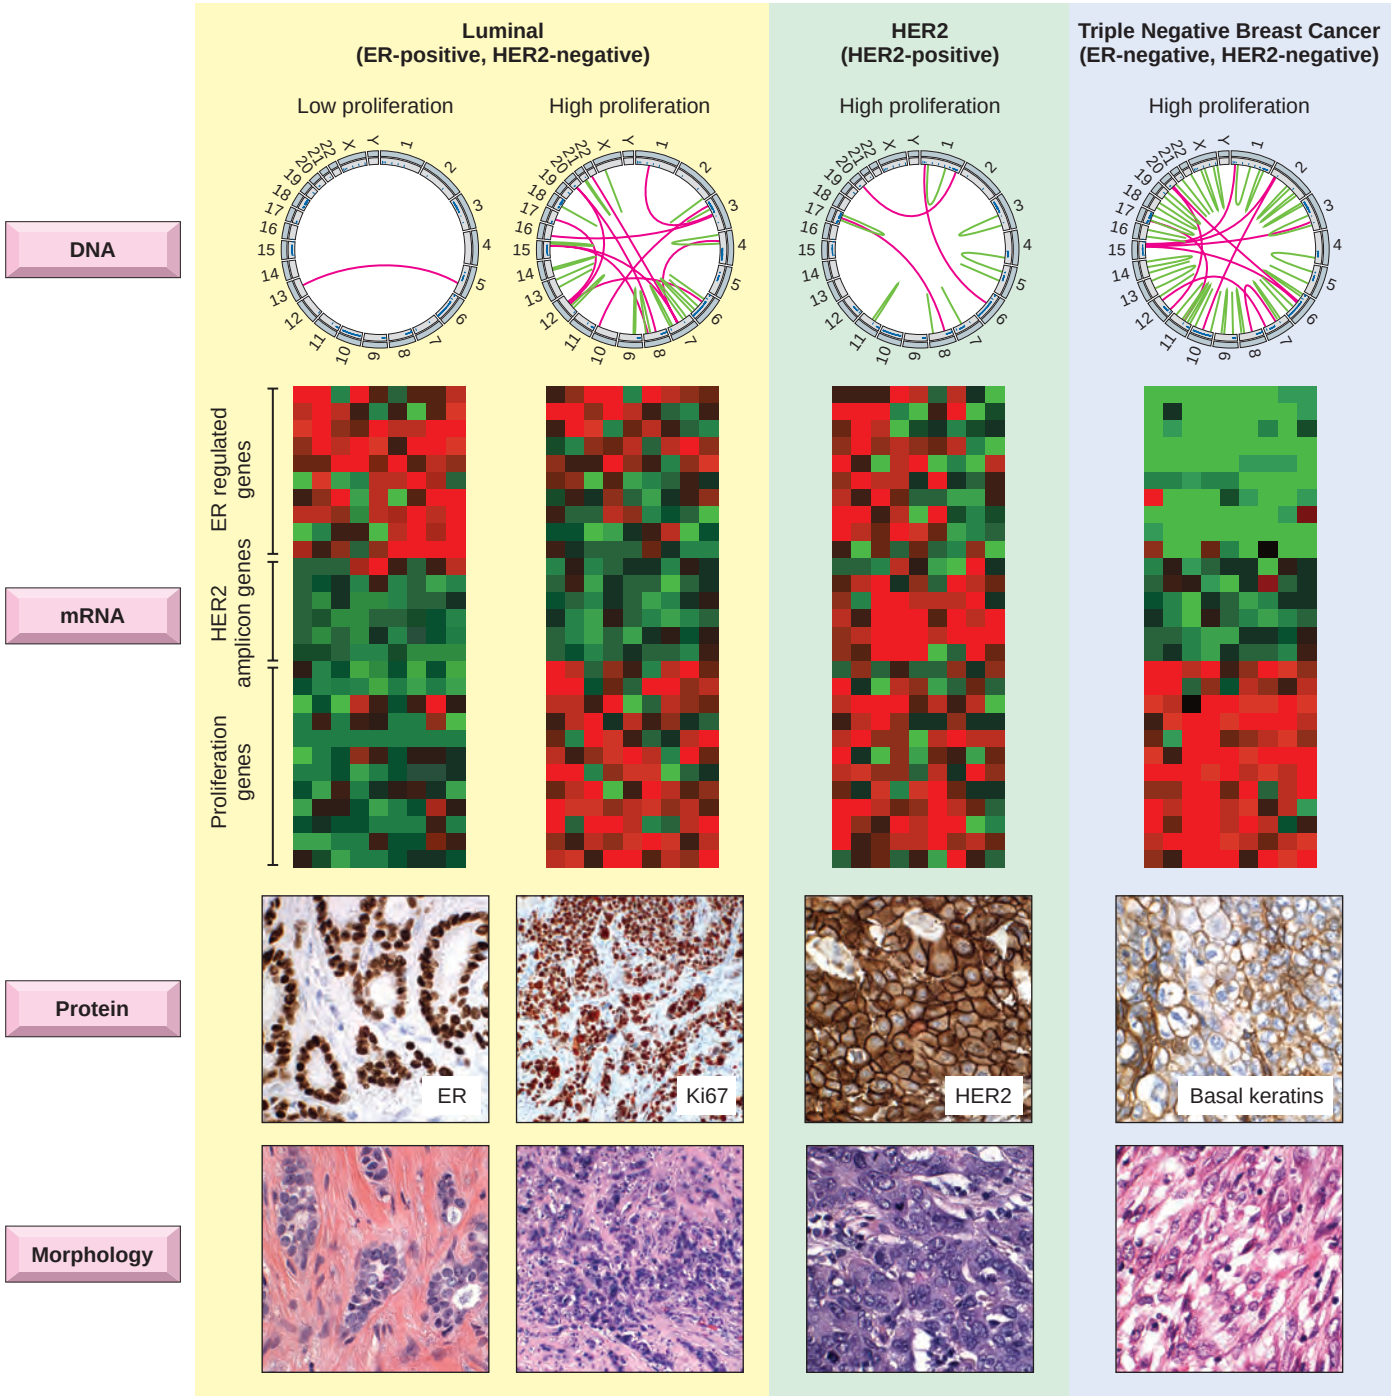

Figure 23.13 Molecular classification of invasive breast cancer. Three major groups of breast cancer are distinguished by characteristic changes in DNA, mRNA, protein, and morphology. Genomic abnormalities are shown in circos plots (Chapter 7), which present a snapshot of all of the genomic abnormalities within a particular tumor; these abnormalities are mapped onto the chromosomes, which are displayed at the periphery of a circle. *Green loops* show intrachromosomal rearrangements, while *red loops* show interchromosomal rearrangements. Gene expression (mRNA) profiling measures relative levels of mRNA expression. *Red* indicates a relative increase; *green,* a relative decrease; and *black,* no change in levels. Genes are arrayed from top to bottom and tumors from left to right. Immunohistochemical studies detect proteins using specific antibodies visualized with a brown chromogen. *Luminal (ER-positive/HER2-negative) cancers* are diverse, ranging from well-differentiated cancers with low proliferative rates and few chromosomal changes to poorly differentiated cancers with high proliferative rates and large numbers of chromosomal rearrangements. All of these cancers express ER (an estrogen-dependent transcription factor). Proliferation is estimated by counting mitoses or by staining for cell cycle–specific proteins such as Ki-67. *HER2-positive cancers* may be ER-positive or ER-negative, but when ER is present, levels are typically low. HER2 positivity can be detected as an increase in *HER2* gene copy number, an increase in HER2 mRNA, or an increase in HER2 protein, as shown here. *Triple negative breast cancers (ER-negative/HER2-negative; this group largely overlaps with "basal-like" carcinomas defined by mRNA expression)* are characterized by genomic instability (denoted by numerous chromosomal changes), a high proliferative rate, and expression of many proteins typical of myoepithelial cells (e.g., basal keratins).

Table 23.3 Most Common Single Gene Mutations Associated With Hereditary Susceptibility to Breast Cancer

Gene (Syndrome)	% of Single Gene Cancers[a]	Risk of Breast Cancer to Age 70[b]	Other Cancers	Comments
High Penetrance Germline Mutations (>4-fold increased risk; 3%–7% of breast cancers)				
BRCA1 (familial breast and ovarian cancer)	~55%	~40%–90%, females; 1%, males	Ovarian (~20%–40%), fallopian tube, pancreas, prostate, others	Majority of cancers are TNBC
BRCA2 (familial breast and ovarian cancer)	~35%	~30%–60%, females; 6%, males	Ovarian (~10%–20%), pancreas, prostate, others	Majority of cancers are ER positive. Biallelic mutations cause a form of Fanconi anemia.
TP53 (Li-Fraumeni)	<1%	~50%–60%, females; <1%, males	Sarcoma, leukemia, brain tumors, others	Majority of cancers are ER and HER2 positive
PTEN (Cowden)	<1%	~20%–80%, females; <1%, males	Thyroid, endometrium, others	Also associated with benign tumors
STK11 (Peutz-Jeghers)	<1%	~40%–60%, females	Ovarian, colon, pancreas, others	Also associated with benign colon polyps
CDH1 (hereditary diffuse gastric cancer)	<1%	~50%, females	Gastric signet ring cell carcinoma, colon	Majority of cancers are lobular in type
PALPB2 (hereditary breast cancer)	<1%	~30%–60%, females; <1%, males	Pancreas, prostate	Biallelic mutations cause a form of Fanconi anemia
Moderate Penetrance Germline Mutations (2- to 4-fold increased risk; 5% to 10% of breast cancers)				
ATM (ataxia-telangiectasia)	~5%	~15%–30%, females		Biallelic mutations cause ataxia-telangiectasia
CHEK2 (hereditary breast cancer)	~5%	~10%–30%, females	Prostate, thyroid, colon, kidney	Majority of cancers are ER positive

[a]The percentage of all breast cancers that are associated with a germline mutation conferring an increased risk of breast cancer.
[b]Risk for specific patients can vary with the specific mutation and the presence of other gene mutations.
ER, Estrogen receptor; *TNBC*, triple negative breast cancer.

Most of these genes play complex and interrelated roles in maintaining genomic integrity. Under normal circumstances, cells that sustain DNA damage undergo cell cycle arrest and either repair their DNA or die by apoptosis. *ATM* senses DNA damage and "activates" p53, the so-called guardian of the genome, which has a direct role in inducing cell cycle arrest and, if DNA repair is unsuccessful, apoptosis. *BRCA1, BRCA2,* and *CHEK2* all have important functions in repair of double-stranded DNA breaks. If any of these functions are impaired, the likelihood of permanent DNA damage increases, leading to potentially oncogenic mutations that will be passed to daughter cells.

What is mysterious is why malfunction of these genes, particularly *BRCA1* and *BRCA2*, is more highly associated with breast cancer than other cancers. BRCA1 and BRCA2 are components of a large complex of proteins that are required to repair double-stranded DNA breaks through a process called *homologous recombination,* in which a normal sister chromatid is used as a template for repairing the DNA break. BRCA1 and BRCA2 are expressed ubiquitously, so the link to breast cancer cannot be explained by tissue-specific patterns of gene expression. An alternative possibility is that breast (and ovarian) epithelial cells may be particularly prone to suffer the type of DNA damage that BRCA1 and BRCA2 are required to repair. BRCA1 also interacts with protein complexes that regulate chromatin structure and has a role in transcription, and it also remains possible that its tumor suppressive role, at least in part, involves functions that are independent of DNA repair.

Pathogenesis of Sporadic Breast Cancer

As with other forms of carcinoma, multiple pathways resulting in different types of breast carcinoma have been identified. The mutation that initiates the process, as demonstrated by inherited cancers, appears to strongly influence the phenotype of the cancer that ultimately develops, as may the specific cell type in which the initiating event occurs. Pathways leading to the three major molecular types of breast carcinoma, as well as how the biologic features of these types relate to response to treatment, recurrence, metastatic pattern, and survival, are summarized in Fig. 23.14 and Table 23.4 and are described next.

Luminal (ER-positive/HER2-negative) cancers arise via the dominant pathway of breast cancer development, constituting 50% to 65% of cases. By gene expression profiling, ER-positive cancers fall into the "luminal" subgroup, a pattern of gene expression that is dominated by a large number of genes that are regulated by estrogen. Luminal breast cancer has the widest spectrum of histologic grades and proliferation rates of the three molecular types. Cancers with high expression of ER usually also express high levels of PR, which is itself upregulated by estrogen and ER; such ER-positive/PR-positive tumors are usually well differentiated and slow-growing. In contrast, carcinomas with low ER and absent PR tend to lie at the other end of the spectrum, as they are typically poorly differentiated and have a high proliferative rate.

The major risk factor for luminal breast cancer is estrogen exposure (see Table 23.2), which may promote the

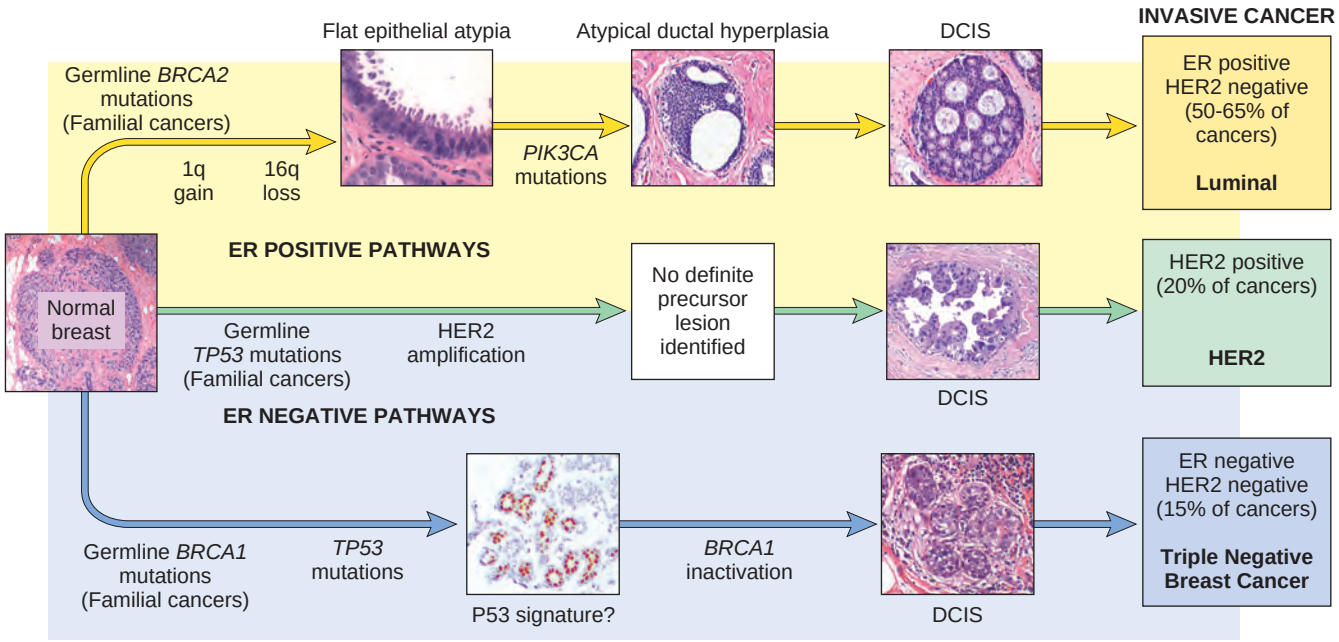

Figure 23.14 Major pathways of breast cancer development. Three main pathways have been identified. The most common pathway *(yellow arrow)* leads to luminal (ER-positive) carcinomas. Recognizable non-obligate precursor lesions include flat epithelial atypia and atypical hyperplasia. A less common pathway *(blue arrow)* leads to triple negative breast cancer (ER-negative/HER2-negative). A possible precursor lesion consisting of morphologically normal cells that overexpress p53 has been identified (analogous to the "p53 signature lesions" for ovarian carcinoma). The third pathway *(green arrow)* consists of HER2-positive cancers. Amplification of HER2 can occur in either ER-positive or ER-negative lesions. A definite HER2-positive precursor lesion has not been identified. See text for other details. *DCIS,* Ductal carcinoma in situ.

Table 23.4 Molecular Subtypes of Invasive Breast Cancer

Defining Features	Luminal (ER-Positive/HER2-Negative)		HER2 (HER2 Positive)	TNBC (ER-Negative/ HER2-Negative)[a]
Percent of breast cancers	~40%–55% (low to moderate proliferation)	~10% (high proliferation)	~20%	~15%
Most similar group defined by mRNA profiling[b]	Luminal A	Luminal B	HER2-enriched (ER-negative), luminal B (ER-positive)	Basal-like
Most common gene mutations	*PIK3CA* (45%), *TP53* (12%)	*PIK3CA* (29%), *TP53* (29%)	*PIK3CA* (39%), *TP53* (70%–80%)	*PIK3CA* (9%), *TP53* (70%–80%)
Typical special histologic types	Tubular, grade 1 or 2 lobular, mucinous, papillary	Grade 3 lobular	Some apocrine, some micropapillary	Medullary features, metaplastic[c]
Typical patient groups	Older women, men, cancers detected by mammographic screening	*BRCA2* mutation carriers	Young women, *TP53* mutation carriers (ER positive)	Young women, women of African heritage, *BRCA1* mutation carriers
Complete response to chemotherapy	<10%	~10%	ER positive ~15%; ER negative ~30%–60%	~30%
Metastatic pattern	Bone (70%), more common than viscera (25%) or brain (<10%)	Bone (80%) more common than viscera (30%) or brain (10%)	Bone (70%), viscera (45%), and brain (30%) all are common	Bone (40%), viscera (35%), and brain (25%) all are common
Relapse pattern	Low rate over many years, long survival possible with bone metastases	Early peak at <10 years, late recurrence possible	Bimodal with early and late (10 years) peaks	Early peak at <8 years, late recurrence rare, survival with metastases rare

[a]TNBC lacks expression of ER, progesterone receptor, and HER2.
[b]The three major groups of cancer identified by protein expression or mRNA profiling largely overlap but are not identical. "Luminal B" can refer to ER-positive cancers with high proliferation with or without HER2 expression.
[c]Some rare special histologic types have a more favorable prognosis than this group as a whole (e.g., adenoid cystic carcinoma, secretory carcinoma, low-grade adenosquamous carcinoma).

ER, Estrogen receptor; *mRNA,* messenger RNA; *TNBC,* triple negative breast cancer.

development of breast cancer through several mechanisms. Estrogen increases the local production of growth factors, such as transforming growth factor α, platelet-derived growth factor, and fibroblast growth factor, and regulates the expression of dozens of genes in breast epithelial cells that may directly contribute to tumor growth and development. Estrogen exposure also stimulates the proliferation of breast epithelial cells during puberty, menstrual cycles, and pregnancy, thereby increasing the number of cells that are "at risk" for transformation. The DNA replication that attends cellular proliferation is conducive to the accumulation of mutations, and the lull in cell division that occurs during the latter part of the menstrual cycle may allow time for defective DNA repair to occur and for mutations to become "fixed" in the genome. Repetition of this process during each cycle may underlie the association between the cumulative number of menstrual cycles a woman experiences and her risk of developing breast cancer, as well as the strong association between luminal cancers and age (see Fig. 23.12). A clear measure of the importance of estrogen is found in the therapeutic benefits of estrogen antagonists, which reduce the development of luminal cancers in women at high risk, and the increased incidence of luminal cancers in women treated with postmenopausal hormone therapy.

Once a clonal population of mutated ER-positive cells emerges, estrogen may also enhance the transformation of such precursor lesions to fully malignant cancers. ER-positive precursor lesions include flat epithelial atypia and atypical ductal and lobular hyperplasia. All of these may be associated with genomic changes found in invasive carcinomas, including gains of chromosome 1q, losses of chromosome 16q, and activating mutations in *PIK3CA,* the gene that encodes phosphoinositide-3 kinase (PI3K), which you will recall is an important component of signaling pathways downstream of growth factor receptors (Chapter 7). These are considered the earliest recognizable precursors of luminal breast cancers. It must be emphasized, however, that few of these lesions progress to malignancy, presumably because multiple additional events are needed before the cells acquire all of the hallmarks of cancer.

The precursor lesions mentioned above are mainly associated with the development of luminal cancers with low growth fractions and indolent clinical behavior; such tumors by gene expression profiling belong to the "luminal A" subgroup (see Fig. 23.13). More aggressive, high-grade luminal cancers also occur and cluster within the "luminal B" subgroup, defined by high levels of expression of genes associated with proliferation. These aggressive forms of luminal cancer share some genomic changes with low-grade carcinomas but tend to have a greater burden of chromosomal aberrations. They sometimes arise from low-grade luminal cancers following the acquisition of mutations in genes that regulate genomic stability such as *TP53* and also frequently occur in patients with germline *BRCA2* mutations.

Cancers detected by mammographic screening are usually small luminal cancers limited to the breast (see Table 23.4). These cancers typically respond well for many years to antiestrogen therapy and have a more favorable outcome than the other types of breast cancer. The rate of recurrence is low, and even when these carcinomas metastasize (most often to bone), they often can be held in check for a decade or longer by treatment with antiestrogens (Fig. 23.15). By contrast, cytotoxic chemotherapy provides little benefit, particularly in treating "luminal A" cancer with low growth fractions. Some luminal cancers eventually escape from estrogen dependence through several mechanisms, including outgrowth of clones that lack ER expression, compensatory alterations in related growth factor signaling pathways, or acquisition of mutations in the ER gene *(ESR1)* that lead to estrogen-independent ER function.

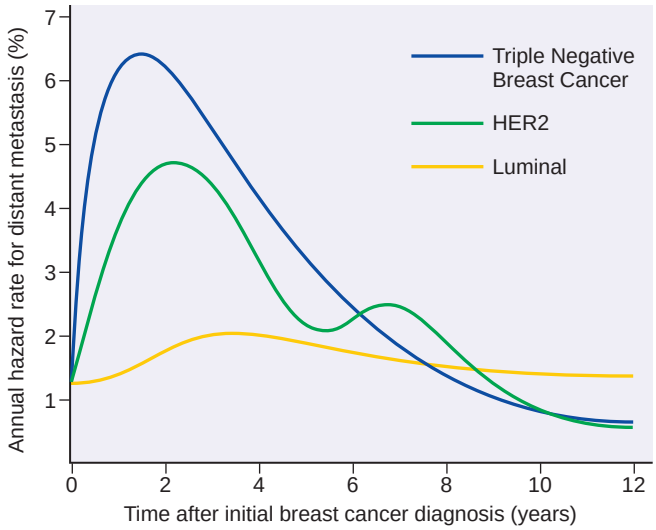

Figure 23.15 Each molecular group of breast cancer has characteristic patterns of recurrence over time. Luminal (ER-positive) cancers have the lowest rate of recurrence in the first 10 years, but recurrences continue with a steady rate over a long period of time. In contrast, almost all recurrences of triple negative breast cancer (ER-negative/HER2-negative) occur within the first 8 years. Recurrences after this time are rare. HER2-positive cancers show a mixed pattern with both early and late peaks. Although not yet fully explained, a late peak may be due to acquired resistance to targeted therapy or to selection of HER2-negative tumor cell populations.

HER2-positive cancers arise through a pathway that is strongly associated with amplification of the *HER2* gene on chromosome 17q. HER2 (also known as ERBB2) is a receptor tyrosine kinase that promotes cell proliferation and opposes apoptosis by stimulating the RAS- and PI3K-AKT signaling pathways. Cancers with *HER2* amplification constitute approximately 20% of all breast cancers and may be either ER-positive or ER-negative. This is the most common subtype of breast cancer in patients with germline *TP53* mutations (Li-Fraumeni syndrome).

The only common molecular mechanism for *HER2* overexpression is gene amplification, found in >95% of HER2-positive carcinomas. The size of the amplicon varies and typically includes at least 10 adjacent genes, some of which may cooperate with HER2 to promote tumor growth. In addition, these cancers characteristically have complex interchromosomal rearrangements and a high mutational load. The gene expression profile of HER2 cancers is dominated by transcripts encoded by *HER2,* co-amplified genes, and genes involved in pro-growth signaling pathways and proliferation. Variation in gene expression among HER2 cancers is largely based on their ER status and differing levels of expression of ER-regulated genes.

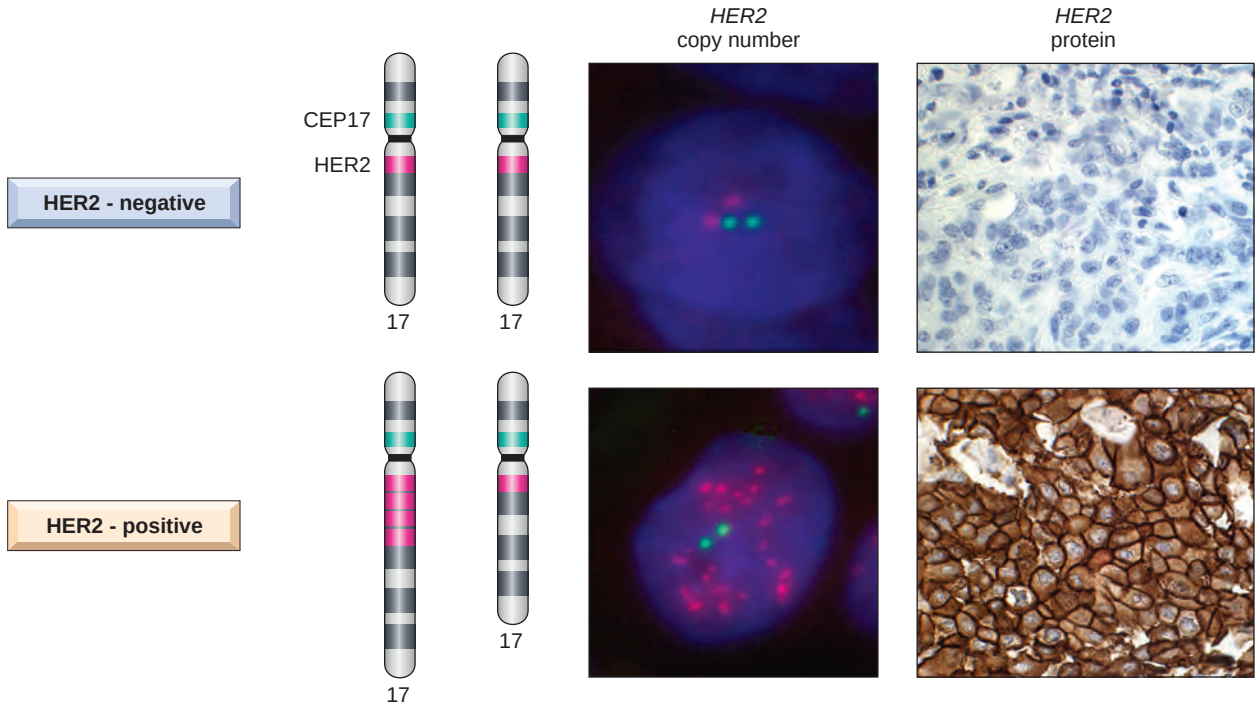

Figure 23.16 Identification of HER2-positive breast cancer. HER2 protein overexpression is virtually always caused by amplification of the region of chromosome 17q that contains the *HER2* gene. The increase in *HER2* gene copy number is detected by fluorescence in situ hybridization using a *HER2*-specific probe (red signal), which is typically co-hybridized to tumor cell nuclei with a second probe specific for the centromeric region of chromosome 17 (green signal), allowing the chromosome 17 copy number to be determined. Alternatively, HER2 protein overexpression in tumor cells can be detected by immunohistochemical staining with antibodies specific for HER2.

Clinically, HER2 carcinomas are diagnosed by detecting HER2 overexpression by immunohistochemistry or *HER2* gene amplification by in situ hybridization (Fig. 23.16). Before the implementation of HER2-targeted therapy, HER2-positive cancers had a poor clinical outcome. However, greater than half of patients with HER2 carcinomas have complete remissions when treated with antibodies that bind and block HER2 activity; such patients have an excellent prognosis (see Table 23.4). The remarkable efficacy of this form of therapy proves the importance of HER2 as an oncogenic "driver." However, not all HER2-positive carcinomas respond to targeted therapy, and some that initially respond become resistant (see Fig. 23.15). Multiple mechanisms of resistance to HER2 antagonists have been defined in cancers, and numerous therapeutic agents are under investigation in an effort to both improve response and overcome resistance.

TNBCs arise through an estrogen-independent pathway that is not associated with *HER2* gene amplification. They comprise about 15% of breast cancers and have a "basal-like" gene expression profile, so-called because many of the genes that comprise this signature are normally expressed in basally located myoepithelial cells. A possible precursor lesion has been identified that consists of lobular epithelial cells that are ER-negative and p53-positive, the latter being a feature that correlates with the presence of *TP53* mutations. These lesions resemble serous tubal intraepithelial carcinoma, the proposed precursor to serous carcinoma that is seen in the fallopian tubes of women with germline *BRCA1* mutations (see Chapter 22). As might be expected based on this similarity, TNBC also is associated with germline *BRCA1* mutations.

TNBC also shares other genetic features with serous ovarian carcinoma. Both are characterized by marked genomic instability due to defects in DNA repair by homologous recombination that manifests as complex copy number alterations and chromosomal rearrangements. In familial breast cancer, this defect is often related to germline *BRCA1* and *BRCA2* mutations. *BRCA1* mutations are rare in sporadic TNBC, but *BRCA1* is instead often silenced through epigenetic mechanisms and allelic loss. The only gene that is mutated in the majority of these cancers is *TP53*; presumably, other genes that contribute to the malignant phenotype are dysregulated by copy number variation or gene rearrangements.

Compared with luminal cancers, TNBC is more likely to present as a palpable mass and is less likely to be detected by mammographic screening (see Table 23.4). Cytotoxic therapy combined with agents that are selectively active against cancers with defective homologous recombination results in complete or almost complete responses in about a third of cases. The cancers that recur usually do so in the first 8 years after diagnosis (see Fig. 23.15). Metastases are often to visceral sites and brain and frequently result in death. Patients who survive 10 years are likely cured, as late recurrences are unusual. Development of more effective treatments for this breast cancer subtype has been challenging, as obvious drug targets (such as ER or HER2) are lacking. In addition, the genomic instability of these tumors leads to profound genetic heterogeneity, increasing the likelihood of emergence of more aggressive, therapy-resistant subclones. However, genomic instability also may lead to expression of tumor neoantigens, and one approach that shows some

promise in TNBC is use of immune checkpoint inhibitors (see Chapter 7), which are under evaluation in numerous clinical trials.

Finally, it must be said that as with other carcinomas that begin as in situ lesions, it is not clear what drives transition of any of the molecular subtypes of breast cancer from innocuous in situ lesions to potentially lethal invasive cancers. Maintenance of the basement membrane depends on the interaction of luminal cells, myoepithelial cells, and stromal cells in the local microenvironment. The majority of genomic changes observed in invasive carcinoma also are already present in carcinoma in situ, including major driver mutations, and genomic changes specific to invasive carcinoma have not been identified, suggesting that invasion may depend on changes in stromal cells rather than tumor cells. For example, in some in situ cancers, myoepithelial cells are mislocalized and reduced in number, and the associated basement membrane is thin and has gaps. Such changes may set the stage for stromal invasion by breast cancer cells. Stromal invasion also may expose cancer cells to increased host immune surveillance, and it may also be that alterations that enable cancer cells to evade the host immune response are necessary before effective invasion can occur.

With this as background, we next turn to discussion of the pathology of breast cancer.

KEY CONCEPTS

CARCINOMA OF THE BREAST

- Breast cancer is the most common non-skin malignancy in women and the second most common cause of cancer deaths in the United States.
- The most important risk factors for sporadic cancers in women are estrogenic stimulation and age.
- Approximately a quarter to a third of breast cancers are familial, being related to inheritance of genetic variants that increase breast cancer risk.
- High-risk genes associated with familial breast cancer include several involved with DNA repair and genomic stability, most notably *BRCA1*, *BRCA2*, and *TP53*.
- Breast cancers cluster into three major molecular groups, luminal (ER-positive), HER2, and triple negative, each with distinctive biologic and clinical features.
- Luminal cancers are further divided into two groups, A and B, that differ mainly in terms of proliferation, which is low in group A and high in group B.
- HER2 cancers are defined by overexpression of the HER2 receptor, usually due to *HER2* gene amplification, and respond well to HER2 inhibitors.
- TNBCs lack ER and HER2 expression, are often associated with defects in DNA repair or genomic stability (e.g., due to silencing of *BRCA1* or *TP53* mutation), and carry a relatively poor prognosis.

Types of Breast Carcinoma

Almost all breast malignancies are adenocarcinomas. The terms *ductal* and *lobular* are still used to describe subsets of both in situ and invasive carcinomas, but most evidence suggests all breast carcinomas arise from cells in the terminal duct lobular unit. Carcinoma in situ was originally classified as ductal carcinoma in situ (DCIS) or lobular carcinoma in situ (LCIS) based on the resemblance of the involved spaces to normal ducts or lobules, but it is now recognized that these growth patterns are not related to the cell of origin, but rather reflect differences in tumor cell genetics and biology. By current convention, "lobular" refers to invasive carcinomas that are biologically related to LCIS, and "ductal" is used more generally for adenocarcinomas that cannot be classified as a special histologic type.

Carcinoma in Situ

Carcinoma in situ (literally, "carcinoma in its original place") refers to cancer cells confined within ducts and lobules by a basement membrane. This type of cancer has no capacity to metastasize, as the location precludes access to blood vessels and lymphatics. Because many, if not all, of the molecular changes found in invasive carcinomas also are found in these lesions, carcinoma in situ is an apt description.

Ductal Carcinoma in Situ. DCIS is a clonal proliferation of epithelial cells limited to ducts and lobules by the basement membrane. Myoepithelial cells are preserved in involved ducts/lobules, although they may be diminished in number. DCIS can spread throughout the ductal system and produce extensive lesions involving an entire sector of a breast.

DCIS is almost always detected by mammography. Without mammography, fewer than 5% of carcinomas detected are in situ lesions, but this rises to 15% to 30% in screened populations. Most are identified as a result of calcifications associated with secretory material or necrosis; less commonly, periductal fibrosis surrounding DCIS results in a mammographic density or creates a vaguely palpable mass. Rarely, DCIS (often of micropapillary or papillary types) produces a nipple discharge or is detected as an incidental finding upon biopsy for another lesion.

MORPHOLOGY

DCIS grows in several architectural patterns, which vary in nuclear grade and the presence and extent of necrosis (Fig. 23.17). Some cases of DCIS have a single growth pattern, but most are comprised of a mixture of patterns. **Comedo DCIS** may occasionally produce a vague nodularity, but more often is detected as clustered or linear and branching areas of calcification (Fig. 23.17A). It is defined by two features: (1) tumor cells with pleomorphic, high-grade nuclei and (2) areas of central necrosis (Fig. 23.17B). **Cribriform DCIS** has rounded (cookie cutter–like) spaces, often filled with calcified secretory material (Fig. 23.17C). **Micropapillary DCIS** produces complex bulbous protrusions without fibrovascular cores (Fig. 23.17D). **Papillary DCIS** produces true papillae with fibrovascular cores that lack a myoepithelial cell layer. Varying degrees of necrosis can be associated with each architectural pattern as well as calcifications, which develop in association with intraluminal secretions or necrosis.

Paget disease of the nipple is a rare manifestation of breast cancer (1% to 4% of cases) that presents as a unilateral erythematous eruption with a scale crust. Pruritus is common, and the lesion may be mistaken for eczema. Malignant cells (Paget cells) extend from DCIS within the ductal system via the lactiferous

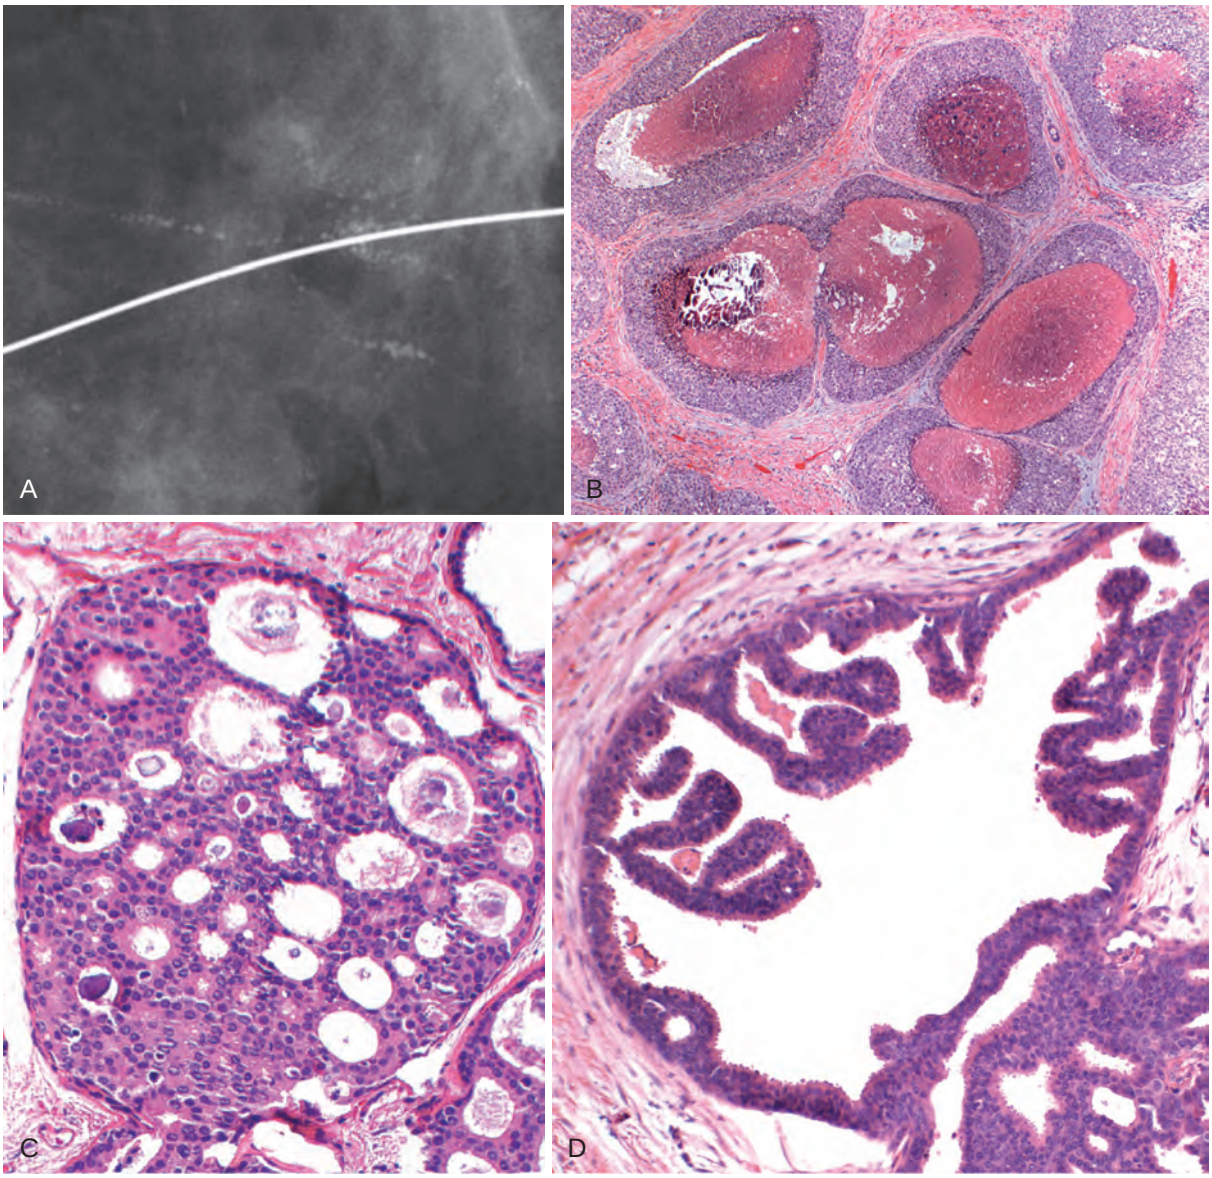

Figure 23.17 Ductal carcinoma in situ (DCIS). (A and B) Comedo type. (A) Specimen radiograph reveals linear and branching calcifications within the ductal system. (B) High-grade proliferation associated with large central zones of necrosis and calcifications fills several ducts. (C) Cribriform DCIS. Note the round, regular ("cookie cutter") spaces containing calcifying secretory material. (D) Micropapillary DCIS. The papillary projections lack fibrovascular cores.

sinuses into nipple skin without crossing the basement membrane (Fig. 23.18). The tumor cells disrupt the normal epithelial barrier, allowing extracellular fluid to seep out onto the nipple surface. Paget cells are readily detected by nipple biopsy or cytologic preparations of the exudate.

A palpable mass is present in 50% to 60% of women with Paget disease, and almost all of these masses prove to be invasive carcinoma. The carcinomas are usually ER-negative and overexpress HER2. In contrast, the majority of women without a palpable mass have only DCIS. Prognosis depends on the features of the underlying carcinoma and is not affected by the presence or absence of Paget disease.

Clinical Features

The natural history of DCIS has been difficult to determine because in the past all women were treated with mastectomy, and the current practice of surgical excision, usually followed by radiation, is largely curative. If untreated, women with small, low-grade DCIS develop invasive cancer at a rate of about 1% per year. When invasive cancer develops in the same breast quadrant, it tends to have a similar grade and expression pattern of ER and HER2 as the associated DCIS. Patients with high-grade or extensive DCIS are believed to have a higher risk for progression to invasive carcinoma.

Remarkably, the overall death rate for women with DCIS is lower than that for women in the population as a whole,

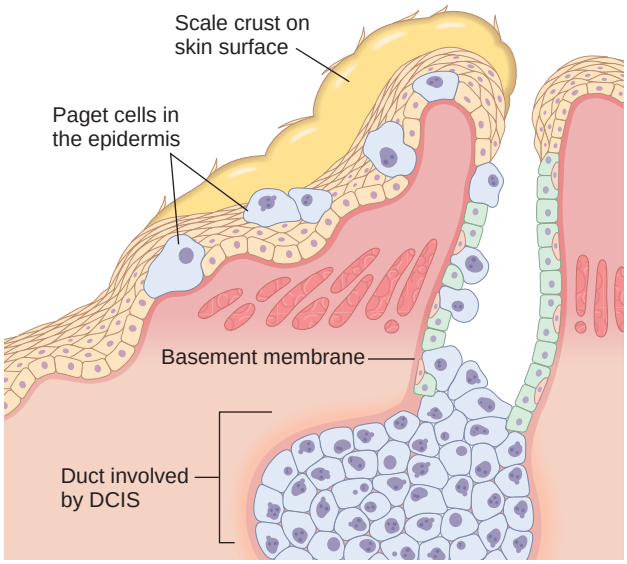

Figure 23.18 Paget disease of the nipple. Ductal carcinoma in situ *(DCIS)* arising within the ductal system of the breast can extend up the lactiferous ducts and into the skin of the nipple without crossing the basement membrane. The malignant cells disrupt the normally tight squamous epithelial cell barrier, allowing extracellular fluid to seep out and form an oozing scaly crust.

possibly because mammographic screening is a "marker" for better access to medical care or other socioeconomic factors that are associated with longevity. Death from metastatic breast cancer after a diagnosis of DCIS occurs in 1% to 3% of women. The origin of metastatic disease may be from a subsequent invasive carcinoma in the ipsilateral or contralateral breast or occult foci of invasion that were not detected at the time of DCIS diagnosis.

Mastectomy is curative in greater than 95% of women. Breast conservation is appropriate for most women but has a slightly higher risk of recurrence—about half of which are DCIS and half invasive carcinoma. The major risk factors for recurrence are (1) high nuclear grade and necrosis, (2) extent of disease, and (3) positive surgical margins. Ensuring complete excision of DCIS is not straightforward, since its distribution in the breast is not reliably predicted by imaging, and it is usually not grossly evident at surgery. Postoperative radiation therapy and tamoxifen also reduce the risk of recurrence; such treatments are reserved for cases that are deemed to be at particularly high risk of recurrence. Trials to identify patients who can safely undergo observation rather than treatment are ongoing.

Lobular Carcinoma in Situ. LCIS is a clonal proliferation of cells within ducts and lobules that grow in a dyscohesive fashion. It is almost always an incidental biopsy finding, since it is rarely associated with calcifications or stromal reactions that produce mammographic densities. As a result, the incidence of LCIS (1% to 6% of all carcinomas) has been unchanged by the introduction of mammographic screening. When both breasts are biopsied, LCIS is bilateral in 20% to 40% of cases compared with 10% to 20% of cases of DCIS.

The cells of atypical lobular hyperplasia, LCIS, and invasive lobular carcinoma are morphologically identical. The observed loss of cellular adhesion is usually due to dysfunction of E-cadherin, a transmembrane protein that contributes to the cohesion of normal epithelial cells in the breast and other glandular tissues. E-cadherin functions as a tumor suppressor protein in such tissues and may be lost in neoplastic proliferations through a variety of mechanisms, including mutation of the E-cadherin gene *(CDH1)*. In rare cases, there is dysregulation of other proteins, such as catenins, that are also needed for E-cadherin–mediated cellular cohesion. LCIS associated with invasive carcinoma shares the same mutations and, thus, in some cases is a true precursor lesion.

MORPHOLOGY

Classically, LCIS consists of a uniform population of cells with oval or round nuclei and small nucleoli involving ducts and lobules (Fig. 23.19A). Mucin-positive signet ring cells are commonly present. The lack of E-cadherin results in a rounded shape without attachment to adjacent cells (Fig. 23.19B). Pagetoid spread, defined by the presence of neoplastic cells between the basement membrane and overlying luminal cells, is commonly seen in breast ducts, but Paget disease (involvement of nipple skin) does not occur. Necrosis and secretory activity are not seen, and thus calcifications are absent. LCIS almost always expresses ER and PR and is HER2-negative.

LCIS is a risk factor for developing invasive carcinoma in either breast, with a slightly higher risk to the ipsilateral breast. Invasive carcinoma develops at a rate of about 1% per year, similar to that observed for untreated DCIS. However, unlike DCIS, it is unclear if surgical removal of the identified lesion lowers risk. Invasive carcinomas developing in women after LCIS are three-fold more likely to be lobular carcinoma; however, most are of other morphologies. Treatment choices include bilateral prophylactic mastectomy, tamoxifen, or, more typically, close clinical follow-up and mammographic screening.

Invasive (Infiltrating) Carcinoma

Breast carcinoma has a wide variety of morphologic appearances. About one-third can be classified into special histologic types that merit discussion because they have important biologic and clinical associations. We will first cover infiltrating carcinomas of "no special type" (typical ductal carcinomas) and will then discuss those that fall into special categories.

MORPHOLOGY

The majority of invasive breast cancers are ductal adenocarcinomas that are not classified further into a special type. In the absence of mammographic screening, these carcinomas usually present as a mass of at least 2 to 3 cm in size. The mammographic and gross appearance varies widely depending on the stromal reaction to the tumor (Fig. 23.20). They most commonly present as a hard, irregular radiodense mass (Fig. 23.20A, B) associated with a desmoplastic stromal reaction (Fig. 23.20C). When cut or scraped, such tumors typically produce a characteristic grating sound (similar to cutting a water chestnut) due to small, central pinpoint foci or streaks of chalky-white desmoplastic stroma and

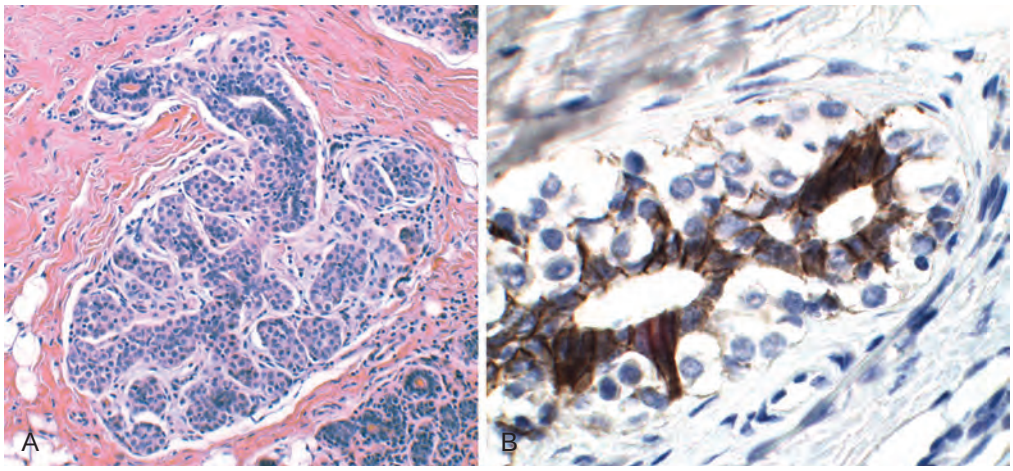

Figure 23.19 Lobular carcinoma in situ (LCIS). (A) Monomorphic population of small, rounded, loosely cohesive cells fills and expands the acini of a lobule. The underlying lobular architecture can still be recognized. The cells extend into the adjacent duct by pagetoid spread. (B) Immunoperoxidase study shows E-cadherin–positive normal luminal cells that have been undermined by E-cadherin–negative LCIS cells spreading along the basement membrane.

occasional foci of calcification. Less commonly, tumors present as deceptively well-circumscribed (Fig. 23.20D, E) masses composed of sheets of tumor cells with scant stromal reaction (Fig. 23.20F) or may be almost imperceptible (Fig. 23.20G, H), being comprised of scattered neoplastic glands or single tumor cells infiltrating otherwise unremarkable fibrofatty tissue (Fig. 23.20I).

Larger carcinomas may invade the pectoralis muscle and become fixed to the chest wall or invade the dermis and cause retraction (dimpling) of the skin. When the tumor involves the central portion of the breast, retraction of the nipple may develop. Rarely, breast cancer presents as metastasis to an axillary lymph node or a distant site before cancer is detected in the breast. In such cases, the primary carcinoma may be small, may be obscured by dense breast tissue, or may fail to produce a desmoplastic response. In most cases, these "occult" primary tumors (which are easily missed by palpation or mammography) can be detected by imaging studies using ultrasound or MRI.

Invasive carcinoma is graded using the Nottingham Histologic Score. Carcinomas are scored for tubule formation, nuclear pleomorphism, and mitotic rate. Grade 1 (well differentiated) carcinomas grow in a tubular or cribriform pattern, have small uniform nuclei, and have a low proliferative rate (Fig. 23.21A). Grade 2 (moderately differentiated) carcinomas have areas where cells grow as solid clusters or single infiltrating cells and show greater nuclear pleomorphism and high numbers of mitotic figures (Fig. 23.21B). Grade 3 (poorly differentiated) carcinomas invade as ragged nests or solid sheets of cells and have enlarged irregular nuclei. A high proliferative rate and areas of tumor necrosis are common in high-grade tumors (Fig. 23.21C).

Special Histologic Types of Invasive Carcinoma

As with all breast cancers, these special tumors can be organized into molecular groups based on expression of ER and HER2, which carry their usual therapeutic implications. However, special histologic types of breast cancer often harbor unique genetic aberrations, sometimes have distinct gene signatures, and frequently show associations with clinical behavior and prognosis that break the established "rules" for ductal carcinomas of no special type. Although relatively uncommon, study of these tumors has also provided important insights into breast cancer pathogenesis.

Lobular carcinoma is the subtype with the clearest association of phenotype and genotype. Like LCIS, most cases show biallelic loss of expression of *CDH1,* the gene that encodes E-cadherin. Lobular carcinomas are dyscohesive, typically infiltrate as single cells, and sometimes fail to produce a desmoplastic response, making it difficult to detect these cancers by palpation and imaging. They also have distinctive patterns of metastatic spread, often involving the peritoneum and retroperitoneum, the leptomeninges (carcinomatous meningitis), the gastrointestinal tract, and the ovaries and uterus. Males and females with heterozygous germline mutations in *CDH1* are at increased risk for developing lobular carcinoma and have a greatly increased risk for signet ring carcinoma of the stomach (Chapter 17).

Carcinomas with medullary pattern are of interest due to the finding that over half of *BRCA1*-associated carcinomas have this appearance (see Table 23.3). Although the majority of carcinomas with medullary pattern are not associated with germline *BRCA1* mutations, hypermethylation of the *BRCA1* promoter leading to downregulation of *BRCA1* expression is observed in 67% of these tumors. Of interest, this subtype has a better prognosis than other poorly differentiated carcinomas. Notably, these tumors also have unusually large number of infiltrating T lymphocytes, suggesting that improved outcomes may be related to a host immune response to tumor antigens.

Many other special histologic types of breast cancer (too numerous to list) have been described. There is much that remains to be learned about the biology and pathogenesis of these tumors, some of which are described below.

MORPHOLOGY

Some special histologic types of cancer almost always fall within the luminal (ER-positive/HER2-negative) group. These include lobular carcinoma, mucinous carcinoma, tubular carcinoma, and papillary carcinoma. **Lobular carcinoma** often (as already mentioned) insidiously infiltrates the breast while producing minimal

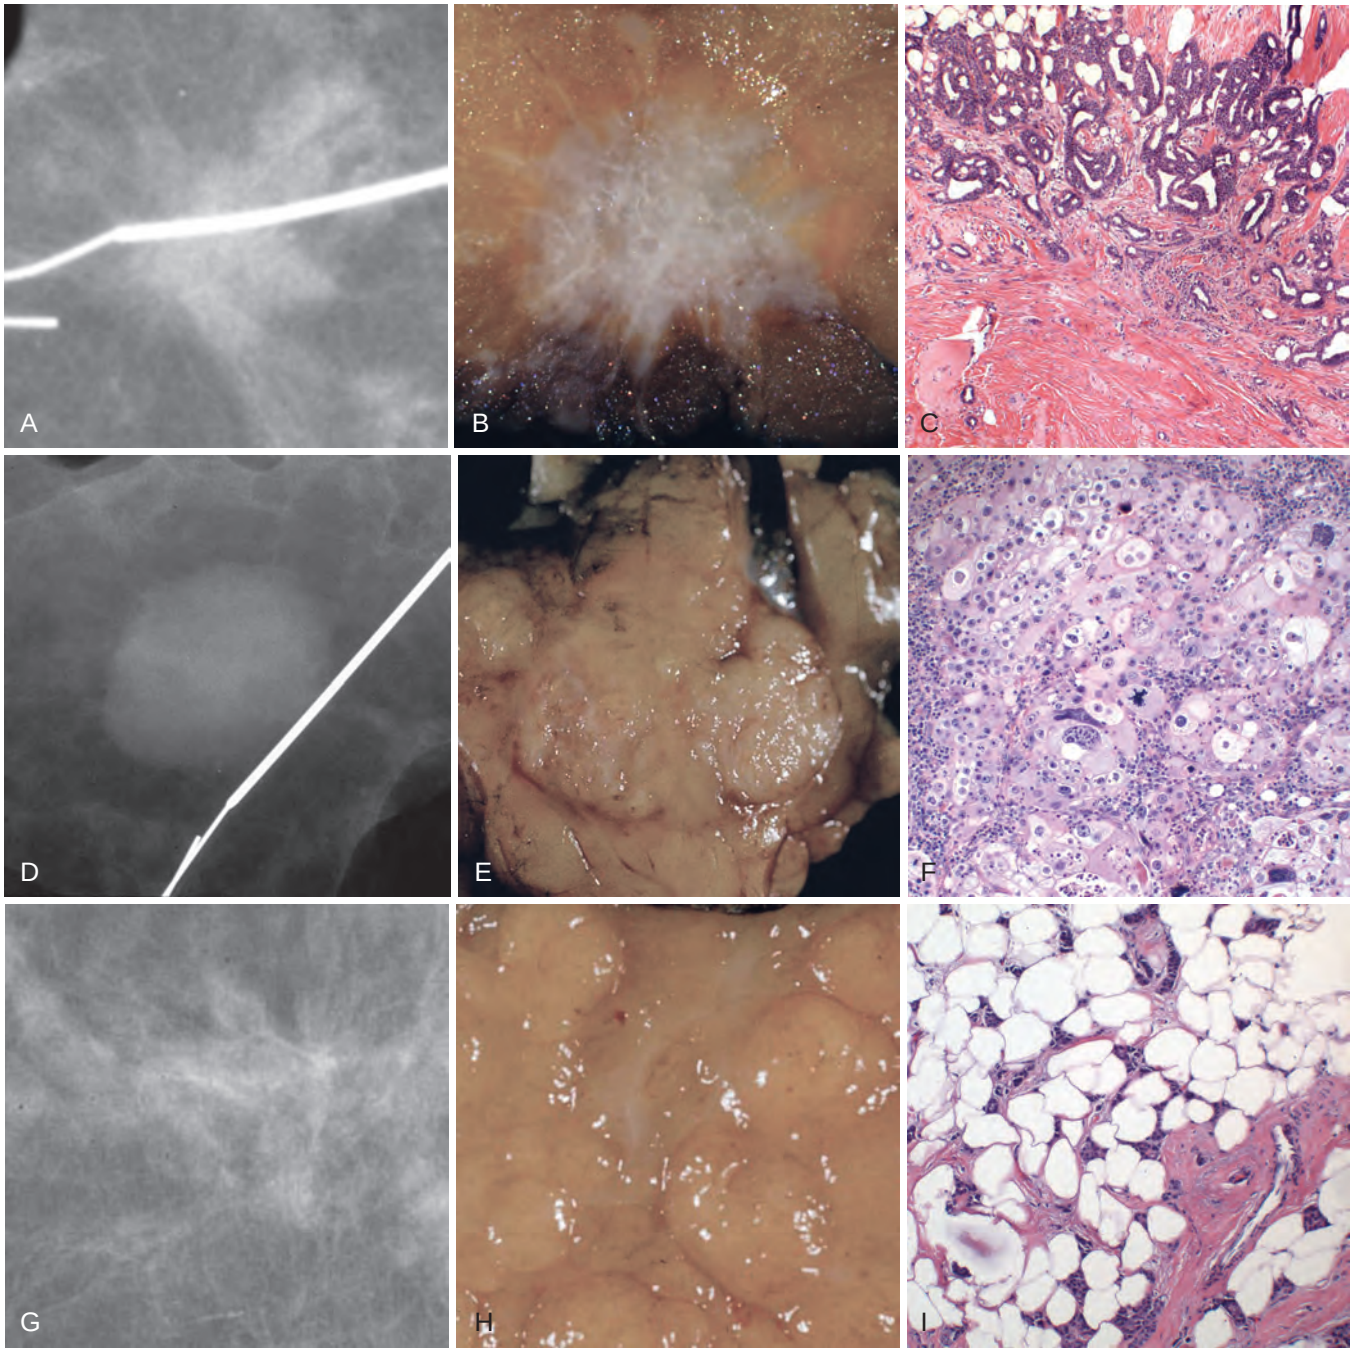

Figure 23.20 Invasive carcinoma of no special type. The majority of invasive carcinomas have a haphazard pattern of stromal invasion that produces masses with irregular margins on imaging (A) and gross examination (B). Microscopically, such tumors are marked by an exuberant desmoplastic stromal response (C). A subset of carcinomas grow as masses that appear to be well circumscribed or lobulated on imaging (D) and gross inspection (E). Microscopically, such cancers typically take on the appearance of expansile masses of cells with pushing borders; stromal response is often limited to a narrow zone of fibrosis at the tumor margin (F). Rarely, invasive cancers produce little or no stromal response. Such cancers may show only subtle architectural distortion on mammography (G) and may not produce palpable masses or be identifiable grossly (H). Microscopically, tumor cells are found scattered within normal-appearing fibroadipose tissue (I). (B, Courtesy Dr. David Hicks, University of Rochester Medical Center, Rochester, NY.)

desmoplasia. The histologic hallmark is the presence of dyscohesive infiltrating tumor cells, often including signet ring cells containing intracytoplasmic mucin droplets (Fig. 23.22A). Tubule formation is absent. **Mucinous (colloid) carcinoma** is soft or rubbery and has the appearance and consistency of pale gray-blue gelatin. The borders are pushing or circumscribed. The tumor cells are arranged in clusters and small islands of cells within large lakes of mucin (Fig. 23.22B). **Tubular carcinoma** consists exclusively of well-formed tubules and is sometimes mistaken for a benign sclerosing lesion (Fig. 23.22C). A cribriform pattern may also be present. Apocrine snouts are typical, and calcifications may be present within the lumens. **Papillary carcinoma,** as the name

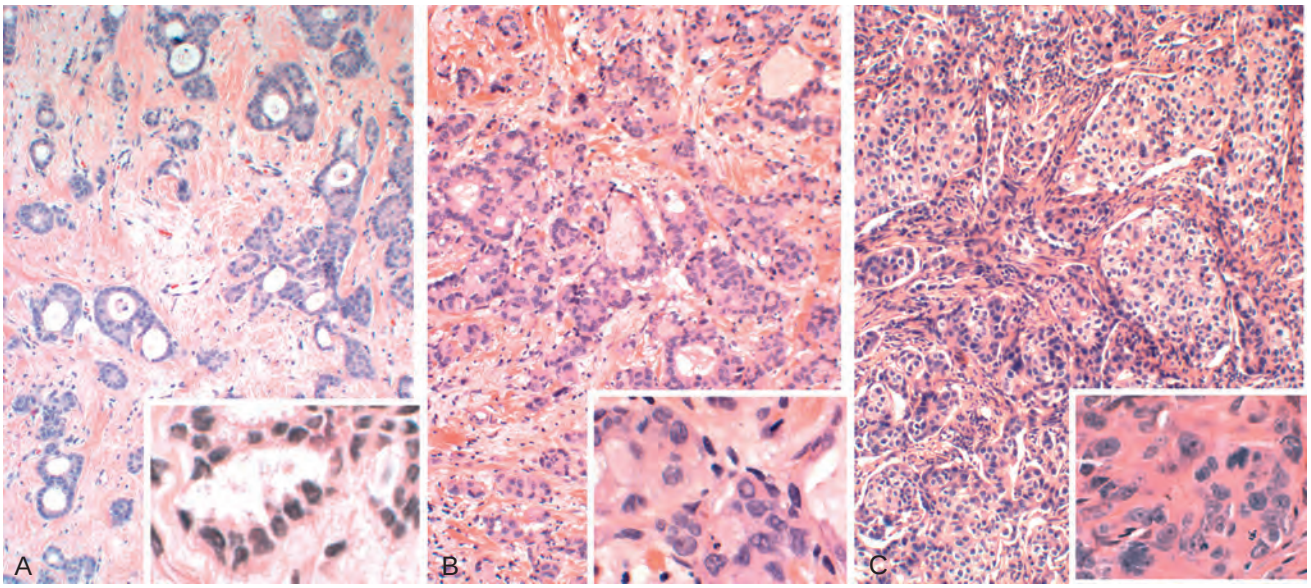

Figure 23.21 Invasive carcinomas are separated into three grades based on tubule formation, nuclear pleomorphism, and number of mitoses. (A) This example of a grade 1 well-differentiated carcinoma shows frequent tubules formed of cells with small monomorphic nuclei. Only rare mitoses are present. (B) In contrast, this grade 2 moderately differentiated carcinoma shows less tubule formation and some solid nests of cells with pleomorphic nuclei. Occasional mitotic figures are seen. (C) Grade 3 poorly differentiated carcinomas infiltrate as ragged sheets of cells with enlarged pleomorphic nuclei.

implies, produces true papillae, fronds of fibrovascular tissue lined by tumor cells (Fig. 23.22D).

Two special histologic types frequently overexpress HER2. The tumor cells of **apocrine carcinoma** resemble the cells that line sweat glands. These cells have enlarged round nuclei with prominent nucleoli and abundant eosinophilic, occasionally granular, cytoplasm (Fig. 23.22E). **Micropapillary carcinoma** (a misnomer) forms hollow balls of cells that float within intercellular fluid, creating structures that mimic the appearance of true papillae (Fig. 23.22F).

TNBC (ER-negative, HER2-negative) often corresponds to one of several special histologic types. Chief among these is **carcinoma with medullary pattern.** These carcinomas are softer than other carcinomas (*medulla* is Latin for "marrow") due to minimal desmoplasia and often form well-circumscribed masses. Histologic features include (1) solid sheets of large cells with pleomorphic nuclei and prominent nucleoli, (2) frequent mitotic figures, (3) a moderate to marked lymphoplasmacytic infiltrate surrounding and within the tumor, and (4) a pushing (noninfiltrative) border (Fig. 23.22G). DCIS is minimal or not seen. **Metaplastic carcinoma** includes spindle cell carcinomas and matrix-producing carcinomas. These carcinomas often have gene expression profiles resembling those of myoepithelial cells.

Rare special histologic types of TNBC have a favorable prognosis compared to other carcinomas in this molecular group and include secretory carcinoma, low-grade adenosquamous carcinoma, and adenoid cystic carcinoma. **Secretory carcinoma** mimics lactating breast by forming dilated spaces filled with eosinophilic material (Fig. 23.22H). These carcinomas rarely metastasize.

Another special subtype that merits mention is **inflammatory carcinoma.** This form of carcinoma has a characteristic gross appearance caused by extensive plugging of the lymphovascular spaces of the dermis with carcinoma cells and carries a very poor prognosis, as most patients prove to have distant metastases. It presents as breast erythema, swelling, and skin thickening. The edematous skin is tethered to the breast by Cooper ligaments and mimics the surface of an orange peel, an appearance referred to as *peau d'orange*. The name "inflammatory" is a misnomer, as typically no inflammation is present. The underlying carcinoma is usually diffusely infiltrative and typically does not form a discrete palpable mass. The presentation can be confused with a breast infection, leading to delayed diagnosis. These tumors are usually of high grade but do not belong to any particular molecular subtype.

Prognostic and Predictive Factors for Invasive Carcinoma

The outcome for women with breast cancer depends on the biologic features of the carcinoma (the molecular or histologic type) and the stage of disease at the time of diagnosis. Based on these factors, some women with breast cancer have a normal life expectancy, whereas others have only a 10% chance of being alive in 5 years. Patients who present with distant metastasis (5% of patients) or with inflammatory carcinoma (1% to 5% of patients) have a particularly poor prognosis. For other cancers, prognosis is determined by pathologic evaluation of the primary tumor and the axillary lymph nodes (Table 23.5).

Prognostic factors are important in counseling patients about the likely outcome of their disease, choosing the most appropriate treatment, and designing clinical trials. Predictive factors help to determine the likely response of a cancer to a specific type of treatment. Factors related to tumor biology are usually both prognostic and predictive (e.g., ER and HER2 expression, proliferation), whereas factors related to tumor extent (e.g., tumor size, lymph node metastases, distant metastases) are primarily prognostic.

The major prognostic factors are as follows (Table 23.5):

- *Lymph node metastases.* Axillary lymph node status is the most important prognostic factor for invasive carcinoma

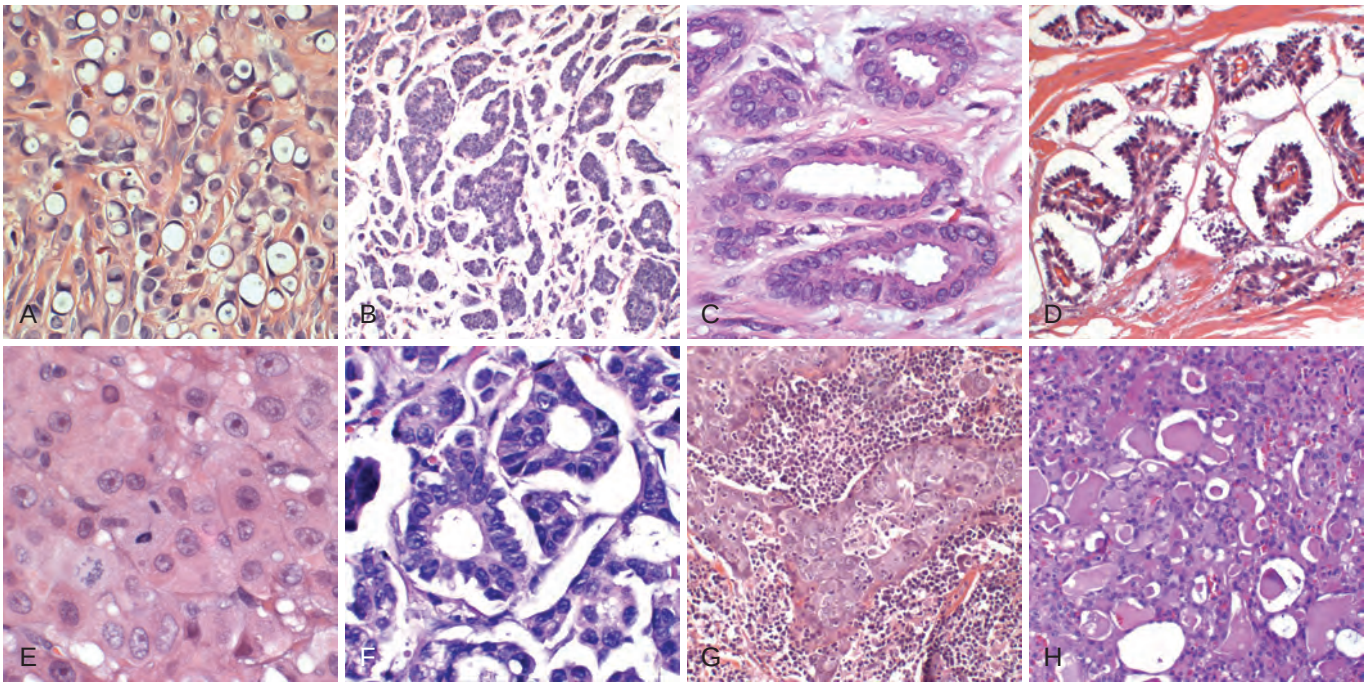

Figure 23.22 Special histologic types of invasive carcinoma. (A) Lobular carcinoma. (B) Mucinous carcinoma. (C) Tubular carcinoma. (D) Papillary carcinoma. (E) Apocrine carcinoma. (F) Micropapillary carcinoma. (G) Carcinoma with medullary pattern. (H) Secretory carcinoma. See text for morphologic descriptions.

Table 23.5 Prognostic Factors for Invasive Breast Carcinoma

Prognostic Factors	Comments
Elements of AJCC 8th Edition Staging	
Distant metastasis (M)	Metastasis beyond regional lymph nodes is the most important prognostic factor.
Regional lymph nodes (N)	Nodal metastasis (including the number of involved nodes) is the second most important prognostic factor.
Tumor (T)	Size, involvement of skin (e.g., ulceration or dermal metastases), invasion into chest wall, and presentation as inflammatory carcinoma are important features.
Histologic grade	Survival diminishes with higher histologic grade.
Expression of ER, PR, and HER2	Survival is highest for the most favorable combination (high ER and PR and absent HER2) and is lowest for the least favorable combination (absent ER, PR, and HER2).
Other Prognostic Factors	
Lymphovascular invasion	Tumor cells seen in vascular spaces at the periphery of carcinomas are a poor prognostic factor.
Special histologic types	Some histologic types of cancer are strongly correlated with very favorable survival (e.g., tubular, adenoid cystic).
Response to chemotherapy	The degree of response is a strong prognostic factor for TNBC and HER2 cancers, but not the majority of luminal cancers.
Gene expression profiling	The most important clinical value of these assays is to identify patients with antiestrogen-responsive cancers who do not need chemotherapy.

AJCC, American Joint Committee on Cancer; *ER*, estrogen receptor; *PR*, progesterone receptor; *TNBC*, triple negative breast cancer.

in the absence of distant metastases. The clinical assessment of lymph node status is unreliable due to both false-positives (e.g., palpable reactive nodes) and false-negatives (e.g., lymph nodes with small metastatic deposits). Therefore, biopsy is necessary for accurate assessment. With no nodal involvement, the 10-year disease-free survival rate is 70% to 80%; the rate falls to 35% to 40% with one to three positive nodes and to 10% to 15% when more than 10 nodes are positive. It is important to note that the presence of nodal metastases is correlated with the probability of distant metastasis, and that removal of involved lymph nodes does not lower the risk of future metastatic disease.

Lymphatic vessels in most breast carcinomas drain first to one or two *sentinel nodes*, which can be identified with radiotracer or colored dyes. If a biopsy of the sentinel nodes is negative for metastasis, it is unlikely that other, more distant nodes will be involved; this approach is used to spare patients the morbidity of a complete axillary dissection. Approximately 10% to 20% of women without axillary lymph node metastases experience recurrence with distant metastasis. In these patients, metastasis may occur via the internal mammary lymph nodes or hematogenously.

- *Distant metastases.* Once distant metastases are present, cure is unlikely, although long-term remissions and palliation can be achieved, especially in women with ER-positive tumors. As discussed earlier, the molecular group influences the timing and location of metastases (see Table 23.4).
- *Tumor size.* The risk of axillary lymph node metastasis increases with the size of the primary tumor, but size also is an independent prognostic factor. Women with node-negative carcinomas less than 1 cm in size have a

10-year survival rate of more than 90%, whereas survival drops to 77% for cancers greater than 2 cm.

- *Locally advanced disease.* Carcinomas invading the skin or skeletal muscle are usually large, making it difficult to achieve local control. Such cases are now rare in the United States but continue to be common in countries with limited access to care.
- *Lymphovascular invasion.* Tumor cells are present within vascular spaces (either lymphatics or small capillaries) in about half of all invasive carcinomas. This finding is strongly associated with the presence of lymph node metastases. It is a poor prognostic factor for overall survival in women without lymph node metastases and a risk factor for local recurrence.
- *Inflammatory carcinoma.* As already discussed, this subtype is characterized by extensive invasion of dermal lymphovascular channels and portends a poor outcome. The 3-year survival rate is only 3% to 10%. Only 1% to 5% of cancers are in this group, but the incidence is higher in women of African descent and younger women.

Additional prognostic factors are related to tumor biology (see Table 23.5). Molecular subtype, histologic grade (including proliferation), and special histologic types have already been discussed. A few other prognostic factors are clinically useful and merit brief mention.

- *Gene expression profiling.* A number of proprietary assays that quantify mRNA levels in breast cancer cells have been developed. Most are heavily weighted toward inclusion of genes that are involved in proliferation. The greatest clinical value of these assays is to identify patients with slowly growing, antiestrogen-responsive cancers who can be spared the toxicity of chemotherapy.
- *Response to neoadjuvant chemotherapy.* Treating patients prior to surgery provides the opportunity to observe the tumor response to chemotherapy. A third or more of TNBCs and HER2 cancers regress completely (termed a pathologic complete response). Patients with responsive cancers belonging to these subtypes have a better prognosis than patients with nonresponsive cancers. In contrast, very few luminal cancers respond completely to chemotherapy. However, these tumors are typically slow growing and can often be controlled with endocrine-based treatment for many years.

The most important prognostic factors are included in the latest American Joint Committee on Cancer (AJCC) staging system, which for the first time includes both an anatomic staging system (Table 23.6) and a prognostic staging system that integrates the anatomic stage and the molecular characteristics of individual breast cancers. The anatomic stage (0 to IV) considers the nature of the disease in the breast (T, for tumor), the involvement of regional lymph nodes (N, for nodes), and the presence of distant metastases (M, for metastases). The prognostic stage then takes into consideration biologic features that portend a more or less favorable outcome. For example, in some cases TNBC is "up-staged" in the new prognostic staging system to reflect its more aggressive behavior.

The main goals of breast cancer therapy are to control local disease and to prolong survival by treating known or potential distant metastases. Local control is achieved in the majority of patients with breast-conserving surgery and radiation therapy. Mastectomy is generally only necessary for locally advanced disease or for women at high risk of a second primary cancer who wish to reduce the risk of recurrence. In the absence of adequate control, some breast cancers can advance to *carcinoma en cuirasse* (literally "carcinoma of the breastplate"), a dreaded complication of infiltration of the skin and ulceration. Fortunately, this is now rarely seen in the United States, but it remains a common presentation for women living in areas with limited resources.

Systemic therapy is used to treat known or likely distant disease and also reduces the likelihood of local recurrence. The first effective systemic treatment for any cancer was the discovery that oophorectomy caused regression of breast cancer in the late 1800s. This remains a treatment modality, but there are now many other options to inhibit the growth of hormonally responsive cancers (Table 23.7). For many luminal cancers, endocrine therapy is the best and most effective therapeutic option. Chemotherapy is used for highly proliferative carcinomas, regardless of molecular subtype. For HER2 cancers, targeted therapy with HER2 antagonists has markedly improved prognosis. TNBC remains a therapeutic

Table 23.6 American Joint Committee on Cancer 8th Edition: Anatomic Stage[a]

Stage[b]	T: Primary Cancer (Tumor)	N: Lymph Nodes	M: Distant Metastasis	10-Year Survival (%)
0	Ductal carcinoma in situ	No metastases	Absent	97
I	Invasive carcinoma ≤2 cm	No metastases or only micrometastases	Absent	87
II	Invasive carcinoma >2 cm Invasive carcinoma >5 cm but ≤5 cm	1–3 positive LNs 0–3 positive LNs	Absent Absent	65
III	Invasive carcinoma >5 cm Any size invasive carcinoma Invasive carcinoma with skin or chest wall involvement or inflammatory carcinoma	Negative or positive LNs ≥4 positive LNs Negative or positive LNs	Absent Absent Absent	40
IV	Any size invasive carcinoma	Negative or positive LNs	Present	5

[a]In the 8th edition, prognostic stages are assigned using T, N, M, grade, ER, PR, and HER2. Pathologic prognostic stage is assigned for patients who undergo surgical excision prior to other treatment. A multigene assay, when available, can be used to assign stage in this setting. Clinical prognostic stage is assigned for all other patients including patients prior to surgery, patients not eligible for surgery, and patients undergoing systemic therapy prior to surgery.
[b]The anatomic stages listed are used only when information on grade, ER, PR, and HER2 are not available. The survival estimates include the average survival for patients with all biologic types of cancer.

ER, Estrogen receptor; *LNs,* lymph nodes; *PR,* progesterone receptor.

Table 23.7 Targeted Treatment of Breast Cancer

Target	Treatment	Companion Assay	Comments
ER	Estrogen deprivation (oophorectomy, aromatase inhibitors) Blockage of ER (tamoxifen) Degradation of ER (fulvestrant)	IHC for nuclear ER	Effective cytostatic (but not cytotoxic) therapy for ER-positive cancer
Cyclin-dependent kinases 4 and 6 (CDK4/6)	Kinase inhibitors (palbociclib, abemaciclib, ribociclib)		Used for ER-positive cancers, usually in conjunction with an aromatase inhibitor
HER2	Antibodies to HER2 Cytotoxic therapy linked to HER2 antibody Tyrosine kinase inhibitors Vaccines	IHC for membrane HER2 ISH for HER2 amplification DNA sequencing for *HER2* mutations	Effective for HER2-positive cancer
Defects in HRR[a]	Chemotherapy with agents causing DNA damage requiring HRR (e.g., platinum agents) Inhibition of alternative DNA repair pathway PARP inhibitors)	DNA sequencing to identify *BRCA1* and *BRCA2* mutations	May be effective in carcinomas with germline *BRCA1* or *BRCA2* mutations or carcinomas with somatic loss of BRCA function
P13K/AKT/mTOR pathway	Inhibition of proteins in the pathway	Activating mutations or pathway activation—ability to predict response under investigation	>80% of breast cancers have alterations in this pathway
Immune checkpoint proteins	Blocking antibodies to PD-L1, PD-I, and other immune checkpoint proteins such as TIM-1 and LAG-3	IHC for immune checkpoint proteins—ability to predict response under investigation	Under investigation for high-grade ER-negative carcinomas

[a]Mutations in *BRCA1* and *BRCA2* cause defects in HRR.

ER, Estrogen receptor; *HRR*, homologous recombination repair; *IHC*, immunohistochemistry; *ISH*, in situ hybridization; *PARP*, poly-ADP ribose polymerase

challenge. There is hope that the genetic instability of these cancers will make them susceptible to agents that inhibit DNA repair and to immune system–based therapies (see Table 23.7).

KEY CONCEPTS

TYPES OF CARCINOMA AND PROGNOSTIC FACTORS

- DCIS is treated locally, as subsequent invasive carcinomas usually occur at the same site, whereas LCIS confers bilateral risk.
- Special histologic types of carcinomas have prognostic importance and provide additional clues linking biologic changes to clinical behavior.
- Prognosis is dependent on both biologic features and the extent of cancer at the time of diagnosis (anatomic stage).
- In the AJCC 8th edition staging system, molecular group and anatomic stage are combined to create prognostic stage groups that provide better estimates of likely survival.
- Effective treatment requires both local and systemic control of disease.
- Improvements in treatment are being made as new targeted therapies are being developed and response to treatment is better understood.

Male Breast Cancer

The incidence of breast cancer in men is only 1% of that in women, which translates to a lifetime risk of 0.11%. There are about 2670 cases and 500 deaths in the United States each year. Risk factors are similar to those in women and include increasing age, first-degree relatives with breast cancer, exposure to exogenous estrogens or ionizing radiation, alcohol consumption, infertility, obesity, prior benign breast disease, Klinefelter syndrome, and residency in Western countries.

The most important familial factor conferring an increased risk for male breast cancer is germline mutation of the *BRCA2* tumor suppressor gene. Approximately 6% of male carriers develop breast cancer. Of men with breast cancer, 4% to 40% have germline *BRCA2* mutations depending on the population tested. A lower risk of male breast cancer is conferred by germline mutations in *BRCA1, PTEN, TP53,* and *PALB2* (see Table 23.3).

More than 90% of breast cancers in males are of luminal type, while TNBCs and HER2 cancers are very rare (<5%). Because breast epithelium in men is limited to large ducts near the nipple, carcinomas usually present as a palpable subareolar mass 2 to 3 cm in size and/or as nipple discharge. Male breast carcinomas are situated close to the skin and thoracic wall, and even small tumors can invade these structures and cause skin ulceration. Dissemination follows the same pattern as in women. Axillary lymph node involvement is present in about half of cases at the time of diagnosis, and distant metastases to the lungs, brain, bone, and liver are common. Although men present with higher stage disease, the prognosis is similar to that of women when matched for stage. Most cancers are treated locally with mastectomy and axillary node dissection. The same systemic treatment guidelines are used for men as for women, and response rates are similar.

STROMAL TUMORS

The two types of stroma in the breast, intralobular and interlobular, give rise to distinct types of neoplasms. Two closely related, breast-specific tumors, fibroadenoma and phyllodes tumor, arise from cells of the intralobular stroma.

These tumors are termed "biphasic" because they also include a non-neoplastic epithelial component, the proliferation of which may be stimulated by growth factors elaborated by the stromal cells. Both fibroadenoma and phyllodes tumor are driven by somatic mutations in *MED12*, a component of a multiple protein complex called mediator that links RNA polymerase II to specific DNA-binding transcription factors. It is no doubt not coincidental that the other tumor that is strongly associated with *MED12* mutations, uterine leiomyoma, also arises from stromal cells within an organ that is responsive to female sex hormones. Perhaps, by deranging mediator function, *MED12* mutations alter the expression of sex hormone–regulated genes that control the proliferation and survival of certain types of stromal cells. In contrast, interlobular stroma is the source of the same types of tumors found in connective tissue in other sites of the body (e.g., lipomas and angiosarcomas), as well as tumors arising more commonly in the breast (e.g., myofibroblastoma and fibrous tumors), and consist only of stromal cells.

Fibroadenoma

Fibroadenoma is the most common benign tumor of the female breast. Two-thirds of fibroadenomas harbor driver mutations in *MED12*. The pathogenesis of the remainder is uncertain.

MORPHOLOGY

Fibroadenomas vary in size from less than 1 cm to large tumors that replace most of the breast. They usually present as a palpable mass in young women and as a mammographic density (Fig. 23.23A) or clustered calcifications in older women. The tumors are well-circumscribed, rubbery, grayish white nodules that bulge above the surrounding tissue and often contain slit-like spaces lined by epithelium (Fig. 23.23B). The delicate and often myxoid stroma resembles normal intralobular stroma. The epithelium may be surrounded by stroma (pericanalicular pattern) or compressed and distorted by it (intracanalicular pattern) (Fig. 23.23C). In older women, the stroma typically becomes densely hyalinized and the epithelium atrophic.

Clinical Features

Most fibroadenomas occur in women in their 20s and 30s, and they are frequently multiple and bilateral. These tumors are hormonally responsive and may grow in size during pregnancy and regress after menopause. Rapid growth and infarction during pregnancy may raise a false suspicion of carcinoma. Curiously, almost half of women receiving cyclosporin A after renal transplantation develop multiple, bilateral fibroadenomas that regress after cessation of treatment. Whether these lesions are true neoplasms or reactive hyperplasias is unclear.

Fibroadenomas are associated with a slightly increased risk of carcinoma, a risk that may be higher if "complex" features are present (cysts larger than 0.3 cm, sclerosing adenosis, epithelial calcifications, or papillary apocrine change) (see Table 23.1). However, these changes are also associated with a higher likelihood of finding other lesions in the surrounding breast tissue (e.g., atypical hyperplasia), and these may be the true drivers of the increased risk.

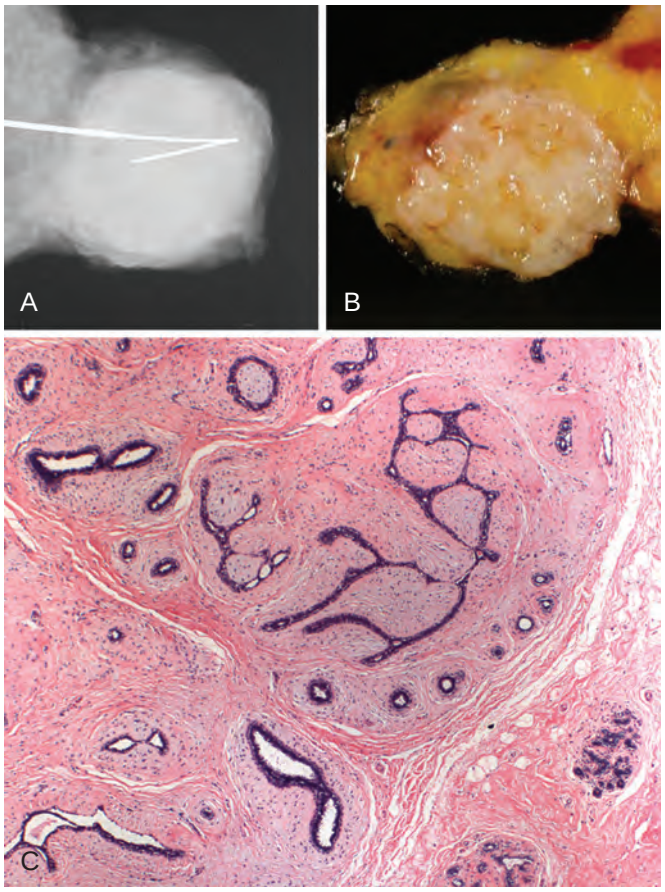

Figure 23.23 Fibroadenoma. (A) Radiograph shows a characteristically well-circumscribed mass. (B) Grossly, a rubbery, white, well-circumscribed mass is clearly demarcated from the surrounding yellow adipose tissue. The absence of adipose tissue accounts for the radiodensity of the lesion. (C) The proliferation of intralobular stroma surrounds, pushes, and distorts the associated epithelium. The border is sharply delimited from the surrounding tissue.

Phyllodes Tumor

Phyllodes tumor, like fibroadenoma, arises from intralobular stroma but is much less common. *Cystosarcoma phyllodes* is a term sometimes used for these lesions, but *phyllodes tumor* is preferred, since most behave in a benign fashion and are not cystic. Like fibroadenomas, the majority of phyllodes tumors have *MED12* mutations. Benign-appearing phyllodes tumors that have only a slight propensity to recur often have *MED12* mutations and few other genetic changes. In contrast, tumors that display malignant behavior are more likely to have mutations in additional genes, such as *TERT*, the gene that encodes telomerase.

MORPHOLOGY

Most phyllodes tumors are detected as palpable masses, while a few are found by mammography. The tumors vary in size from a few centimeters to massive lesions involving the entire breast. The larger lesions often have bulbous protrusions (*phyllodes* is Greek for "leaf-like") due to the presence of nodules of proliferating stroma covered by epithelium (Fig. 23.24). In some tumors these

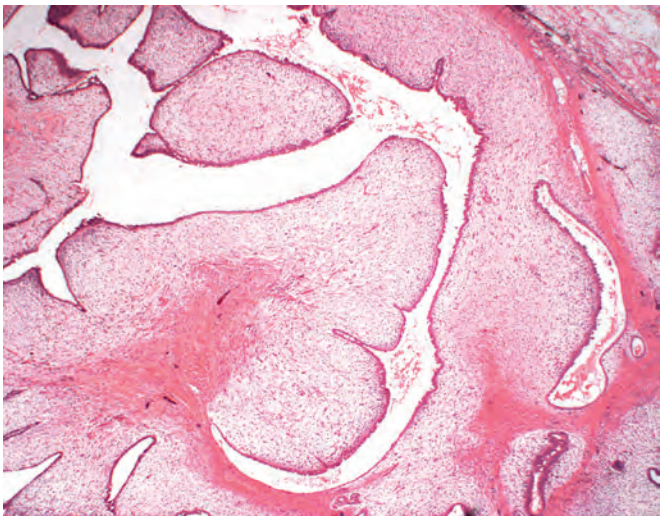

Figure 23.24 Phyllodes tumor. Compared to a fibroadenoma, there is increased stromal cellularity and overgrowth, giving rise to the typical leaf-like architecture.

protrusions extend into a cystic space. This growth pattern also may occasionally be seen in large fibroadenomas and is not an indication of malignancy. Phyllodes tumor is distinguished from fibroadenoma on the basis of higher cellularity, higher mitotic rate, nuclear pleomorphism, stromal overgrowth, and infiltrative borders. Low-grade (benign) lesions resemble fibroadenomas but are more cellular and are mitotically active. High-grade (malignant) lesions may be difficult to distinguish from sarcomas.

Clinical Features

Most phyllodes tumors present in the sixth decade, 10 to 20 years later than the peak age for fibroadenoma. Most have low-grade (benign) cytologic features; these occasionally recur locally but do not metastasize. In contrast, borderline and high-grade (malignant) phyllodes tumors often recur locally unless they are treated with wide excision or mastectomy. Regardless of grade, lymphatic spread is rare, and axillary lymph node dissection is contraindicated. The uncommon high-grade lesions give rise to distant hematogenous metastases in about one-third of cases. Only the stromal component metastasizes.

Lesions of Interlobular Stroma

Tumors of the interlobular stroma of the breast are composed of stromal cells without an accompanying epithelial component. These include benign as well as malignant tumors, all uncommon and hence considered briefly. *Myofibroblastoma* consists of myofibroblasts and is unusual in that it is the only breast tumor that is equally common in males. *Lipomas* are often palpable and can also be detected mammographically as fat-containing lesions. The only importance of these lesions is to distinguish them from malignancies.

Fibromatosis is a clonal proliferation of fibroblasts and myofibroblasts. It presents as an irregular, infiltrating mass that can involve muscle. Though locally aggressive, this lesion does not metastasize. Some cases are associated with prior trauma or surgery. Other cases occur as part of familial adenomatous polyposis, hereditary desmoid syndrome, and Gardner syndrome.

Malignant Tumors of Interlobular Stroma

Malignant stromal tumors of the breast are rare. The only sarcoma that occurs with any frequency in the breast is angiosarcoma—however, it accounts for less than 0.05% of breast malignancies. Angiosarcoma of the breast may be sporadic or arise as a complication of therapy. Most sporadic angiosarcomas occur in the breast parenchyma of young women (mean age 35) and have a poor prognosis. Tumors occurring after treatment for breast cancer typically arise in older women and are associated with radiation therapy or chronic edema. After radiation therapy, approximately 0.3% of women develop angiosarcomas in breast skin, with most cases being diagnosed 5 to 10 years after treatment.

OTHER MALIGNANT TUMORS OF THE BREAST

Malignancies of the breast arising from lymphocytes or skin, or metastatic from another site, comprise less than 5% of breast cancers. *Non-Hodgkin lymphoma* may arise primarily in the breast, or the breasts may be secondarily involved by systemic disease. Most primary breast lymphomas are of B-cell type, while rare T-cell lymphomas may arise in association with breast implants, possibly due to chronic inflammation, which is known to stimulate lymphoma development in other contexts. Young women with Burkitt lymphoma may present with massive bilateral breast involvement, often while pregnant or lactating. Malignant tumors may arise from the skin and dermis of the breast; these tumors are identical to their counterparts found in skin elsewhere (Chapter 25). Metastases to the breast are rare and most commonly arise from melanomas and ovarian cancers.

KEY CONCEPTS

STROMAL TUMORS

- Intralobular stroma is the origin of two biphasic tumors, fibroadenoma and phyllodes tumor.
- Fibroadenomas are the most common benign tumor of the breast.
- Tumors of interlobular stroma consist only of stromal cells and include both benign and malignant lesions.
- Angiosarcoma is the most common stromal malignancy and can either be sporadic or associated with radiation exposure or lymphedema.

CHAPTER 24

The Endocrine System

Anirban Maitra

CHAPTER CONTENTS

The endocrine system consists of a highly integrated and widely distributed group of organs, called glands, that orchestrate a state of metabolic equilibrium among the various organs of the body. Signaling by secreted molecules can be classified into three types—autocrine, paracrine, or endocrine—on the basis of the distance over which the signal acts. **In endocrine signaling, the secreted molecules, also known as hormones, act on target cells that are distant from their sites of synthesis.** An endocrine hormone is frequently carried by the blood from its site of release to its target. The production of several hormones from endocrine glands is stimulated by trophic factors released from the

pituitary. The endocrine hormone inhibits production of the trophic factors, a process known as *feedback inhibition*, thus maintaining physiologic levels of the hormone.

Several processes can disturb the normal activity of the endocrine system, including impaired synthesis or release of hormones, abnormal interactions between hormones and their target tissues, and abnormal responses of target organs. Endocrine diseases can be generally classified as (1) diseases of underproduction or overproduction of hormones and their resulting biochemical and clinical consequences, and (2) diseases associated with the development of mass lesions. Such lesions might be nonfunctional, or they might be associated with overproduction or underproduction of hormones. The study of endocrine diseases requires integration of morphologic findings with biochemical measurements of the levels of hormones, their regulators, and other metabolites.

Pituitary Gland

The pituitary gland is a small, bean-shaped structure that lies at the base of the brain within the sella turcica. Its function is controlled by the hypothalamus, to which it is connected by a stalk containing axons extending from the hypothalamus and a rich venous plexus. Along with the hypothalamus, the pituitary has a central role in regulating the function of most of the other endocrine glands.

The pituitary gland is composed of two morphologically and functionally distinct components: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). **The anterior pituitary, or adenohypophysis, which constitutes about 80% of the gland, produces trophic hormones that stimulate the production of hormones from the thyroid, adrenal, and other glands.** The anterior pituitary is composed of epithelial cells derived embryologically from the developing oral cavity. In routine histologic sections, it contains a colorful array of cells that variously have eosinophilic cytoplasm *(acidophils)*, basophilic cytoplasm *(basophils)*, or poorly staining cytoplasm *(chromophobe cells)* (Fig. 24.1). Detailed studies have demonstrated that the distinct staining properties of these cells are related to the presence of different polypeptide hormones within their cytoplasm that control the activity of other endocrine glands. There are six terminally differentiated cell types in the anterior pituitary, each of which is defined by the hormones that it synthesizes:

- *Somatotrophs* produce growth hormone (GH).
- *Mammosomatotrophs* produce GH and prolactin (PRL).
- *Lactotrophs* produce PRL.
- *Corticotrophs* produce adrenocorticotropic hormone (ACTH), pro-opiomelanocortin (POMC), and melanocyte-stimulating hormone (MSH).
- *Thyrotrophs* produce thyroid-stimulating hormone (TSH).
- *Gonadotrophs* produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In women, FSH stimulates the formation of graafian follicles in the ovary, and LH induces ovulation and the formation of corpora lutea in the ovary. The same two hormones also regulate spermatogenesis and testosterone production in males.

The production of most pituitary hormones is controlled by positively and negatively acting factors from the hypothalamus (Fig. 24.2), which are carried to the anterior pituitary by the portal venous plexus. While most hypothalamic factors promote pituitary hormone release, others (e.g., somatostatin and dopamine) are inhibitory. Rarely, signs and symptoms of pituitary disease may be caused by overproduction or underproduction of hypothalamic factors, rather than a primary pituitary abnormality. During embryogenesis, specific transcription factors regulate the differentiation of multipotent stem cells within the Rathke pouch into the various cell types of the anterior pituitary. For example, somatotrophs, mammosomatotrophs, lactotrophs, and thyrotrophs are all derived from a common precursor that expresses the transcription factor PIT-1 (lactrotrophs also express the alpha subunit of the estrogen receptor, ERα). By contrast, corticotrophs are derived from progenitor cells expressing the transcription factor TPIT (also known as T-box protein 19 or Tbx19), and gonadotrophs are derived from precursor cells expressing steroidogenic factor-1 (SF-1) and GATA-2. The expression of these lineage-specific transcription factors is retained in pituitary adenomas and is used to classify these tumors (see later).

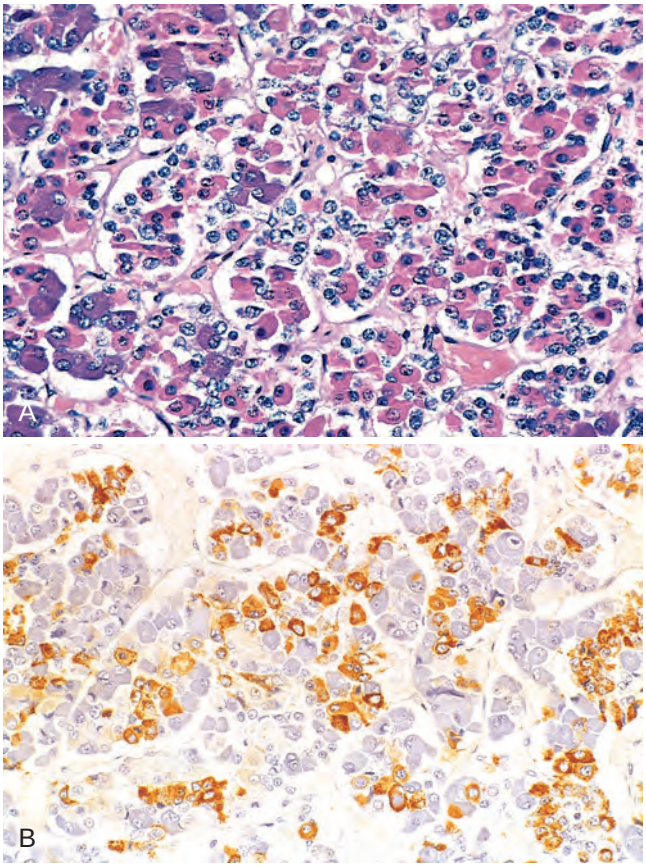

Figure 24.1 (A) Photomicrograph of a normal pituitary. The gland is populated by several distinct cell populations containing a variety of stimulating (tropic) hormones. Each hormone has different staining characteristics, resulting in a mixture of cell types in routine histologic preparations. (B) Immunostain for human growth hormone.

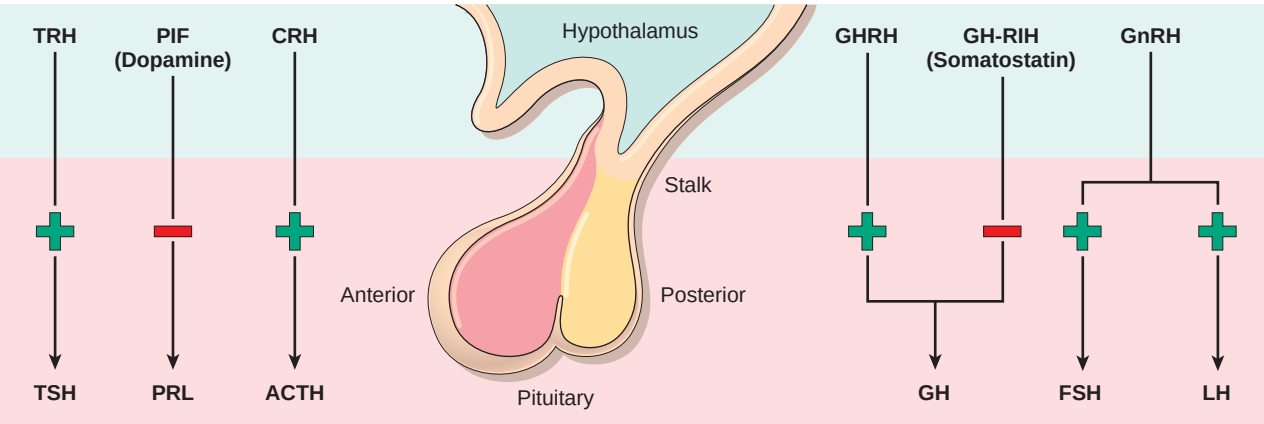

Figure 24.2 Hormones released by the anterior pituitary. The adenohypophysis (anterior pituitary) releases five hormones that are, in turn, under the control of various stimulatory and inhibitory hypothalamic releasing factors. The stimulatory releasing factors are TRH (thyrotropin-releasing hormone), CRH (corticotropin-releasing hormone), GHRH (growth hormone–releasing hormone), and GnRH (gonadotropin-releasing hormone). The inhibitory hypothalamic influences comprise PIF (prolactin inhibitory factor or dopamine) and growth hormone–release inhibiting hormone (GH-RIH or somatostatin). *TSH*, Thyroid-stimulating hormone (thyrotropin); *PRL*, prolactin; *ACTH*, adrenocorticotropic hormone (corticotropin); *GH*, growth hormone (somatotropin); *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

The posterior pituitary consists of modified glial cells (termed pituicytes) and axonal processes extending from the hypothalamus through the pituitary stalk to the posterior lobe (axon terminals). Two peptide hormones are secreted from the posterior pituitary, *oxytocin* and *antidiuretic hormone* (ADH, also called *arginine vasopressin* or AVP). These hormones are actually synthesized in the hypothalamus and are transported through axons to the posterior pituitary. In response to appropriate stimuli, the preformed hormones are then released directly into the systemic circulation. For example, dilation of the cervix in pregnancy results in oxytocin release, leading to contraction of the uterine smooth muscle, facilitating parturition (uterine labor). Similarly, oxytocin released on nipple stimulation in the postnatal period acts on the smooth muscles surrounding the lactiferous ducts of the mammary glands and facilitates lactation. Synthetic oxytocin can be given to pregnant women to induce labor. The most important function of ADH is to conserve water by restricting diuresis during periods of dehydration and hypovolemia. Decreased blood pressure, sensed by baroreceptors (pressure-sensing receptors) in the cardiac atria and carotids, stimulates ADH release. An increase in plasma osmotic pressure detected by osmoreceptors also triggers ADH secretion. In contrast, states of hypervolemia and increased atrial distention result in inhibition of ADH secretion.

CLINICAL MANIFESTATIONS OF PITUITARY DISEASE

The manifestations of pituitary disorders are related to either excess or deficiency of pituitary hormones, or to mass effects.

- *Hyperpituitarism* arises from excess secretion of trophic hormones. The causes of hyperpituitarism include hyperplasias, adenomas, and carcinomas of the anterior pituitary, secretion of hormones by nonpituitary tumors, and certain hypothalamic disorders. The symptoms of hyperpituitarism are discussed later in the context of individual tumors.
- *Hypopituitarism* results from deficiency of trophic hormones. It may be caused by ischemic injury, surgery or radiation, inflammatory disorders, and the mass effects of nonfunctional pituitary adenomas.
- *Symptoms related to local mass effects.* Because of the close proximity of the optic nerves and chiasm to the sella, expanding pituitary lesions often compress decussating fibers in the optic chiasm. This gives rise to visual field abnormalities, classically in the form of defects in both lateral (temporal) visual fields, so-called bitemporal hemianopsia. Like any expanding intracranial mass, pituitary adenomas can produce signs and symptoms of elevated intracranial pressure, including headache, nausea, and vomiting. On occasion, acute hemorrhage into an adenoma is associated with clinical evidence of rapid enlargement of the lesion, a situation appropriately termed *pituitary apoplexy*. Acute pituitary apoplexy is a neurosurgical emergency because it can cause sudden death (see later).

Diseases of the posterior pituitary often come to clinical attention because of increased or decreased secretion of ADH and associated changes in fluid and electrolyte balances.

PITUITARY ADENOMAS AND HYPERPITUITARISM

The most common cause of hyperpituitarism is an adenoma arising in the anterior lobe. Pituitary adenomas are classified on the basis of the hormones and cell type–specific transcription factors that are expressed by the tumor cells (Table 24.1). Some pituitary adenomas secrete two hormones (GH and prolactin being the most common combination), and rarely, pituitary adenomas are plurihormonal. Less common causes of hyperpituitarism include pituitary carcinomas and

Table 24.1 Classification of Pituitary Adenomas

Adenoma Type	Hormone	Transcription Factor	Morphologic Variant	Associated Syndrome[a]
Somatotroph adenoma	GH GH GH, PRL (in same cells) GH, PRL (in different cells)	PIT-1 PIT-1 PIT-1, ERα PIT-1, ERα	Densely granulated adenoma Sparsely granulated adenoma Mammosomatotroph adenoma Mixed somatotroph-lactotroph adenoma	Gigantism (children) Acromegaly (adults)
Lactotroph adenoma	PRL PRL PRL, GH (focal and variable)	PIT-1, ERα PIT-1, ERα PIT-1, ERα	Sparsely granulated adenoma Densely granulated adenoma Acidophilic stem cell adenoma	Galactorrhea and amenorrhea (in females) Sexual dysfunction, infertility
Thyrotroph adenoma	TSH	PIT-1	Thyrotroph adenoma	Hyperthyroidism
Corticotroph adenoma	ACTH ACTH ACTH	TPIT TPIT TPIT	Densely granulated adenoma Sparsely granulated adenoma Crooke cell adenoma (prominent intracytoplasmic cytokeratin filaments)	Cushing syndrome Nelson syndrome Mass effects (20% of corticotroph adenomas are hormonally silent)
Gonadotroph adenoma	FSH, LH	SF-1, GATA-2, ERα	Gonadotroph adenoma	Mass effects and hypopituitarism (most gonadotroph adenomas are hormonally silent)
Null cell adenoma	None	None		Mass effects
Plurihormonal adenoma	GH, PRL, TSH	PIT-1		

[a]Note that nonfunctional ("silent") adenomas in each category express the corresponding hormone(s) and transcription factor within the neoplastic cells, as determined by special immunohistochemical staining on tissues. However, these adenomas do not produce the associated clinical syndrome and typically present with *mass effects* accompanied by *hypopituitarism* due to destruction of normal pituitary parenchyma. These features are particularly common with gonadotroph adenomas and up to one-fifth of corticotroph adenomas, while rarely observed with somatotroph or lactotroph adenomas. Null cell adenomas, by definition, only present with mass effects.

ACTH, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *LH*, luteinizing hormone; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone.

Partially modified from Lopes MBS: The 2017 World Health Organization classification of tumors of the pituitary gland: a summary, *Acta Neuropathol* 134:521–535, 2017.

some hypothalamic disorders. By contrast, large pituitary adenomas, and particularly nonfunctioning ones, may cause hypopituitarism by destroying the adjacent normal anterior pituitary parenchyma.

Pituitary adenomas are usually found in adults; the peak incidence is from 35 to 60 years of age. They are designated, somewhat arbitrarily, *microadenomas* if they are less than 1 cm in diameter and *macroadenomas* if they exceed 1 cm in diameter. Nonfunctional adenomas are likely to come to clinical attention at a later stage than those associated with endocrine abnormalities and are therefore more likely to be macroadenomas. Based on autopsy studies, the prevalence of pituitary adenomas in the population is estimated to be about 14%, but the vast majority of these lesions are clinically silent microadenomas ("pituitary incidentaloma").

Pathogenesis

As with other neoplasms, pituitary adenomas are caused by mutations in cancer genes, which are most commonly acquired somatic mutations but which may also be germline mutations associated with an inherited predisposition to pituitary neoplasms (Table 24.2):

- *Activating G-protein mutations* are one of the most common alterations in pituitary adenomas. As described in Chapter 1, G-proteins normally play a critical role in signal transduction, transmitting signals from particular cell surface receptors (e.g., GHRH receptor) to intracellular effectors (e.g., adenyl cyclase), which then generate second messengers (e.g., cyclic adenosine monophosphate, cAMP). They are heterotrimeric proteins, composed of α-subunits that bind guanine nucleotide and interact with cell surface receptors and intracellular effectors (Fig. 24.3), and β- and γ-subunits that noncovalently bind α-subunits. G_s is a stimulatory G-protein with a pivotal role in signal transduction in several endocrine organs, including the pituitary. The α-subunit of G_s ($G_s\alpha$) is encoded by the *GNAS* gene, located on chromosome 20q13. In the basal state, G_s exists in an inactive state, with guanosine diphosphate (GDP) bound to the guanine nucleotide-binding site of $G_s\alpha$. On interaction with the ligand-bound cell surface receptor, GDP dissociates, and guanosine triphosphate (GTP) binds to $G_s\alpha$, activating the G-protein. The activation of $G_s\alpha$ generates cAMP, a potent mitogen for several types of endocrine cells (e.g., pituitary somatotrophs and corticotrophs, thyroid follicular cells, parathyroid cells). Normally, $G_s\alpha$ activation is transient because of an intrinsic GTPase activity in the α-subunit, which hydrolyzes GTP into GDP. Approximately 40% of somatotroph cell adenomas bear somatic *GNAS* mutations that abrogate the GTPase activity of $G_s\alpha$, leading to constitutive activation of $G_s\alpha$, persistent generation of cAMP, and unchecked cellular proliferation (see Table 24.2). *GNAS* mutations have also been described in a minority of corticotroph adenomas; in contrast, *GNAS* mutations are absent in thyrotroph, lactotroph, and gonadotroph adenomas, because their trophic hypothalamic release hormones act via other signaling pathways.
- Activating mutations of *ubiquitin-specific protease 8 (USP8)* also occur in 30% to 60% of corticotroph adenomas. The encoded protein is an enzyme that removes ubiquitin residues from proteins like epidermal growth factor receptor (EGFR), protecting them from proteasome-dependent

Table 24.2 Genetic Alterations in Pituitary Tumors

Gene	Protein Function	Oncogenic Mutations	Most Commonly Associated Pituitary Tumor
GNAS	α subunit of stimulatory G-protein, Gsα	*Somatic* activating mutation	Somatotroph adenoma
USP8	Deubiquitinase	*Somatic* activating mutation	Corticotroph adenoma
Protein kinase A, regulatory subunit 1α *(PRKAR1A)*[a]	Negative regulator of protein kinase A (PKA), leading to increased cAMP production	*Germline* inactivating mutations (Carney complex)	Somatotroph or lactotroph adenoma
MEN1[a]	Transcription regulator	*Germline* inactivating mutations (multiple endocrine neoplasia, type 1)	Somatotroph, lactotroph, or corticotroph adenoma
CDKN1B (p27/KIP1)[a]	Negative cell cycle regulator	*Germline* inactivating mutations ("MEN-1-like" syndrome)	Corticotroph adenoma
Aryl hydrocarbon receptor interacting protein *(AIP)*[a]	Receptor for aryl hydrocarbons and a ligand-activated transcription factor	*Germline* inactivating mutations (familial isolated pituitary adenoma syndrome)	Somatotroph or lactotroph adenoma (especially in patients younger than 35 years of age)
HRAS	Mitogenic signaling, cell growth and survival	*Somatic* activating mutation	Pituitary carcinoma
DICER1[a]	MicroRNA processing	*Germline* inactivating mutation	Pituitary blastoma

[a]Genetic alterations associated with *familial* or *germline* predisposition to pituitary adenomas.

degradation. Aberrant activation of USP8 thus enhances the activity of EGFR and other pro-growth signaling pathways in pituitary adenomas.

- Approximately 5% of pituitary adenomas are caused by germline loss-of-function mutations in genes such as *MEN1, CDKN1B, PRKAR1A,* or *AIP* (see Table 24.2). Of note, somatic mutations of these four genes are rarely encountered in sporadic pituitary adenomas.

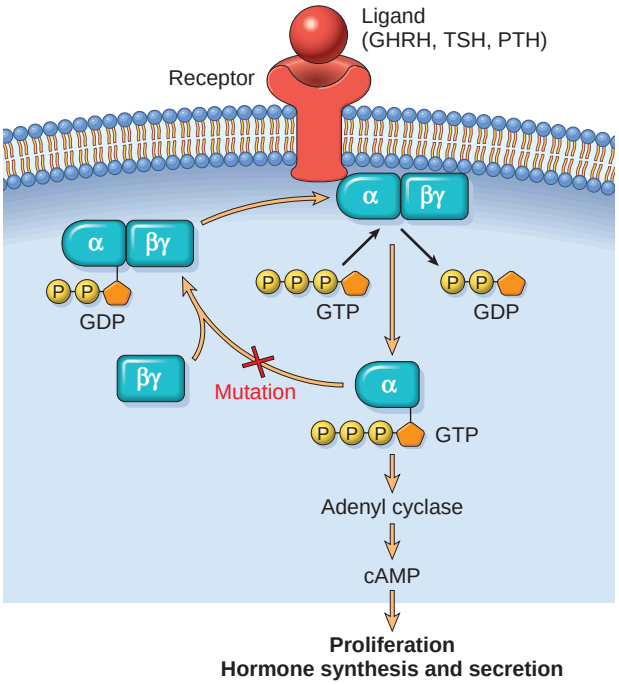

Figure 24.3 G-protein signaling in endocrine neoplasia. Mutations that lead to G-protein hyperactivity are seen in a variety of endocrine neoplasms, including pituitary, thyroid, and parathyroid adenomas. G-proteins (composed of α and βγ subunits) play a critical role in signal transduction, transmitting signals from cell surface receptors (GHRH, TSH, or PTH receptor) to intracellular effectors (e.g., adenyl cyclase), which then generate second messengers (*cAMP,* cyclic adenosine monophosphate) that stimulate cellular responses. *GDP,* Guanosine diphosphate; *GTP,* guanosine triphosphate; *Pi,* inorganic phosphate. See Fig. 24.2 for other abbreviations.

MORPHOLOGY

The **typical pituitary adenoma** is soft and well-circumscribed. Small adenomas may be confined to the sella turcica, but with expansion they frequently erode the sella turcica and anterior clinoid processes. Larger lesions may extend superiorly through the diaphragm sella into the suprasellar region, compressing the optic chiasm and adjacent structures, such as cranial nerves (Fig. 24.4). In as many as 30% of cases, the adenomas are not encapsulated and infiltrate neighboring tissues such as the cavernous and sphenoid sinuses, dura, and on occasion, the brain itself. Such lesions are termed **aggressive adenomas.** Not unexpectedly, macroadenomas are more likely to be invasive and to have foci of hemorrhage and necrosis.

Histologically, typical pituitary adenomas are composed of uniform (monomorphic), polygonal cells arrayed in sheets or cords.

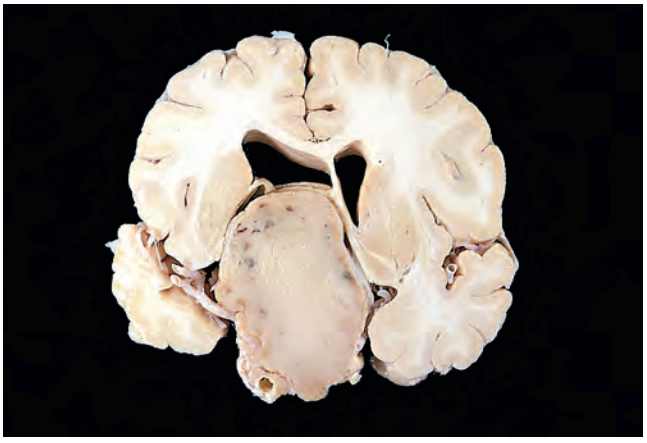

Figure 24.4 Pituitary adenoma. This massive, nonfunctional adenoma has grown beyond the confines of the sella turcica, distorting the overlying brain. On average, nonfunctional adenomas are larger at time of diagnosis.

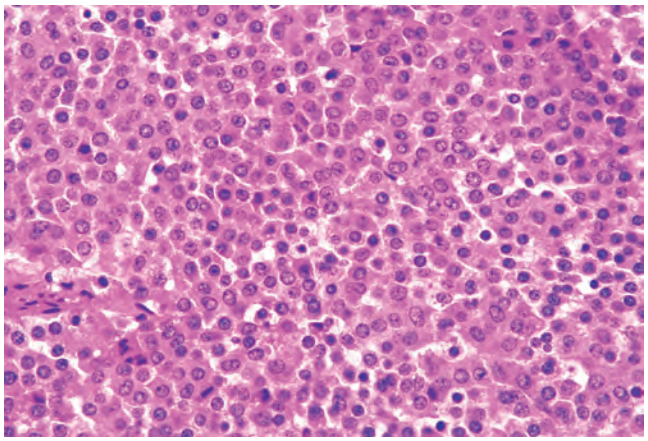

Figure 24.5 Pituitary adenoma. The monomorphism of these cells contrasts markedly with the mixture of cells seen in the normal anterior pituitary. Note also the absence of reticulin network.

The supporting connective tissue, or reticulin, is sparse, accounting for the soft, gelatinous consistency of many of these tumors. This cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from normal anterior pituitary parenchyma (Fig. 24.5). Immunohistochemical stains for hormones and lineage-specific transcription factors are used to identify specific pituitary adenoma subtypes (see Table 24.1). Mitotic activity and expression of Ki-67 (MIB-1, a marker of cycling cells) are typically low in pituitary adenomas; higher-than-normal rates of cell division are associated with more aggressive tumors.

Clinical Features

The signs and symptoms of pituitary adenomas are related to endocrine abnormalities and mass effects. The effects of excessive secretion of anterior pituitary hormones are mentioned later, when the specific types of pituitary adenoma are described. Local mass effects may be produced by any type of pituitary tumor. As mentioned earlier, these effects include radiographic abnormalities of the sella turcica, visual field abnormalities, signs and symptoms of elevated intracranial pressure, and occasionally hypopituitarism. Acute hemorrhage into an adenoma is sometimes associated with *pituitary apoplexy,* as noted earlier. The biologic behavior of a pituitary adenoma cannot always be reliably predicted from its histologic appearance. This has led some to suggest that the term "adenoma" (which implies a benign course) should be replaced by *pituitary neuroendocrine tumor*, a name that does not reflect any specific expectation about a tumor's behavior.

The following is a description of the individual types of tumors.

Lactotroph Adenoma

Prolactin-secreting lactotroph adenomas are the most common type of hyperfunctioning pituitary adenoma, accounting for about 30% of clinically recognized cases. These lesions range from small microadenomas to large, expansile tumors associated with symptomatic mass effects.

MORPHOLOGY

The large majority of lactotroph adenomas are composed of chromophobe cells with juxtanuclear localization of the transcription factor PIT-1; these are known as **sparsely granulated lactotroph adenomas** (Fig. 24.6A). Much rarer are the eosinophilic **densely granulated lactotroph adenomas,** characterized by diffuse cytoplasmic PIT-1 localization (Fig. 24.6B). Prolactin can be demonstrated within cytoplasmic secretory granules with immunohistochemical stains, and estrogen receptor alpha (ERα) is co-expressed along with PIT-1, consistent with lactotroph differentiation. Lactotroph adenomas often undergo dystrophic calcification, ranging from isolated psammoma bodies to extensive calcification ("pituitary stone"). Prolactin secretion by functioning adenomas is usually efficient and proportional, in that serum prolactin concentrations tend to correlate with the size of the adenoma.

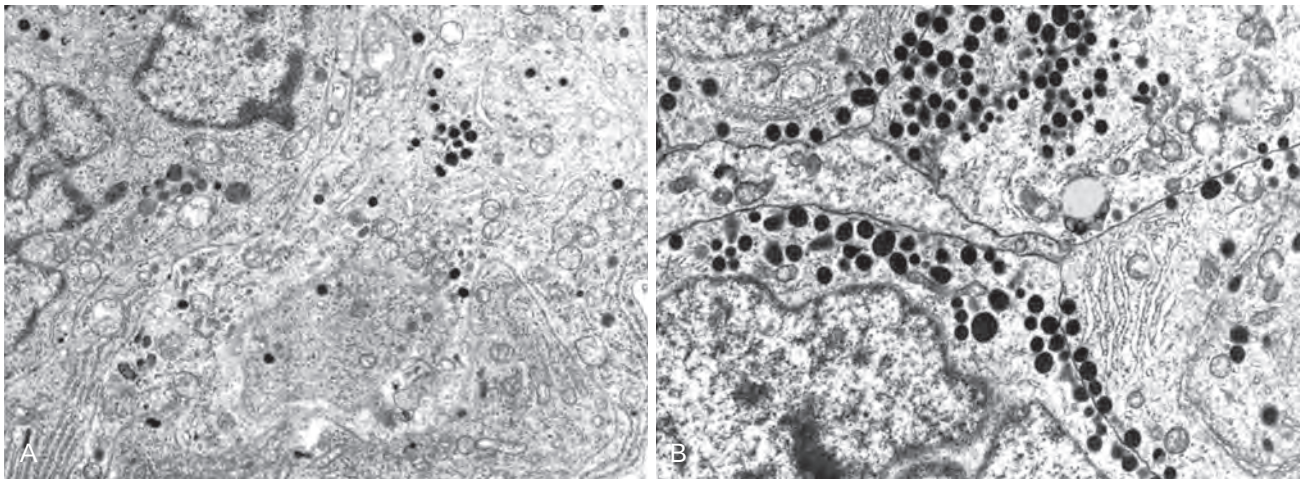

Figure 24.6 Ultrastructural features of prolactinoma. (A) Electron micrograph of a sparsely granulated prolactinoma. The tumor cells contain abundant granular endoplasmic reticulum (indicative of active protein synthesis) and small numbers of electron-dense secretory granules. (B) Electron micrograph of a densely granulated growth hormone–secreting adenoma. The tumor cells are filled with numerous large, electron-dense secretory granules. (Courtesy Dr. Eva Horvath, St. Michael's Hospital, Toronto, Ontario, Canada.)

Clinical Features

Increased serum levels of prolactin, or *prolactinemia,* cause amenorrhea, galactorrhea, loss of libido, and infertility. The diagnosis of an adenoma is made more readily in women than in men, especially between 20 and 40 years of age, because hyperprolactinemia disrupts the menstrual cycle. Lactotroph adenoma is the cause of almost one-fourth of cases of amenorrhea. In contrast, in men and older women, the hormonal manifestations may be subtle, allowing the tumors to reach considerable size (macroadenomas) before being detected clinically.

Hyperprolactinemia may result from causes other than prolactin-secreting pituitary adenomas. Physiologic hyperprolactinemia occurs in pregnancy. Prolactin levels are also elevated by nipple stimulation, as occurs during suckling in lactating women, and as a response to many types of stress. Pathologic hyperprolactinemia can also result from lactotroph hyperplasia caused by loss of dopamine-mediated inhibition of prolactin secretion. This may occur due to damage of the dopaminergic neurons of the hypothalamus or the pituitary stalk (e.g., due to head trauma), or exposure to drugs that block dopamine receptors on lactotroph cells. Any suprasellar mass (e.g., a pituitary adenoma) may disturb the inhibitory influence of the hypothalamus on prolactin secretion, resulting in hyperprolactinemia. Therefore, mild hyperprolactenemia in a person with a pituitary adenoma does not necessarily indicate a prolactin-secreting tumor. Other causes of hyperprolactinemia include renal failure and hypothyroidism. Lactotroph adenomas are treated by surgery or, more commonly, with bromocriptine, a dopamine receptor agonist that causes the lesions to diminish in size.

Somatotroph Adenoma

Growth hormone (GH)-secreting somatotroph adenomas are the second most common type of functioning pituitary adenoma, and cause gigantism in children and acromegaly in adults. Somatotroph adenomas may be quite large by the time they come to clinical attention because the manifestations of excessive GH may be subtle.

MORPHOLOGY

Histologically, pure somatotroph adenomas are also classified into densely granulated and sparsely granulated subtypes. **Densely granulated somatotroph adenomas** are composed of monomorphic, eosinophilic cells with granular cytoplasm and a large central nucleus with prominent nucleoli. The cells have diffuse, strong immunoreactivity for GH. In contrast, the **sparsely granulated variants** are composed of chromophobe cells with patchy, weak staining for GH and a characteristic paranuclear glossy inclusion known as a fibrous body, composed of intermediate filaments that stain for cytokeratin. Bihormonal **mammosomatotroph** adenomas that synthesize GH and prolactin in the same cell are being increasingly recognized; morphologically, most resemble densely granulated somatotroph adenomas, but have immunohistochemical reactivity for prolactin and GH. These are to be contrasted with mixed **somatotroph-lactotroph adenomas,** which have GH and prolactin expression in different cells.

Clinical Features

In contrast to corticotroph or gonadotroph adenomas, silent somatotroph adenomas are rare. Persistently elevated levels of GH stimulate the hepatic secretion of insulin-like growth factor-1 (IGF-1), which causes many of the clinical manifestations.

- If a somatotroph adenoma appears in children before the epiphyses have closed, the elevated levels of GH (and IGF-1) result in *gigantism*. This is characterized by a generalized increase in body size with disproportionately long arms and legs.
- If the levels of GH are increased after closure of the epiphyses, *acromegaly* develops. In this condition, growth is most conspicuous in skin and soft tissues, viscera (thyroid, heart, liver, and adrenals), and the bones of the face, hands, and feet. Bone density may increase (*hyperostosis*) in both the spine and the hips. Enlargement of the jaw results in its protrusion (*prognathism*) and broadening of the lower face. The feet and hands are enlarged, and the fingers become thickened and sausage-like. In most instances, gigantism is also accompanied by evidence of acromegaly. These changes may develop slowly over decades before being recognized, and hence the underlying adenoma may reach substantial size.
- GH excess can also be associated with a variety of other disturbances, including gonadal dysfunction, diabetes mellitus, generalized muscle weakness, hypertension, arthritis, congestive heart failure, and an increased risk of gastrointestinal cancers.

The diagnosis relies on documenting elevated serum GH and IGF-1 levels. In addition, failure to suppress GH production in response to an oral load of glucose is one of the most sensitive tests for acromegaly. The causative pituitary adenoma can be removed surgically or treated by pharmacologic means. The latter includes somatostatin analogues (recall that somatostatin inhibits pituitary GH secretion) and GH receptor antagonists, which prevent hormone binding to target organs such as the liver. When effective control of high GH levels is achieved, the characteristic tissue overgrowth and related symptoms gradually recede, and the metabolic abnormalities improve. Overall, sparsely granulated somatotroph adenomas tend to have a more aggressive course than densely granulated adenomas and may be less responsive to somatostatin analogues. Thus, accurate subtyping of somatotroph adenomas is of prognostic importance.

Corticotroph Adenoma

Excess production of ACTH by functioning corticotroph adenomas leads to adrenal hypersecretion of cortisol and the development of hypercortisolism (also known as *Cushing syndrome*).

MORPHOLOGY

Corticotroph adenomas are usually microadenomas at the time of diagnosis. These tumors are most often basophilic **(densely granulated)** and occasionally chromophobic **(sparsely**

granulated). Both variants stain positively with periodic acid-Schiff (PAS) because of the presence of carbohydrate in proopiomelanocortin (POMC), the precursor of ACTH. Nuclear TPIT is also positive in the neoplastic cells, consistent with corticotroph lineage. A third uncommon variant, called **Crooke cell adenoma,** is characterized by ringlike deposition of cytokeratin called Crooke change. This variant has an aggressive natural history compared with other subtypes of corticotroph adenomas.

Clinical Features

The manifestations of Cushing syndrome are discussed in more detail later with the diseases of the adrenal gland. The syndrome can be caused by a wide variety of conditions in addition to ACTH-producing pituitary tumors. When the hypercortisolism is due to excessive production of ACTH by the pituitary, it is designated *Cushing disease*. Large destructive pituitary adenomas can develop in patients after surgical removal of the adrenal glands for treatment of Cushing syndrome. This condition, known as *Nelson syndrome,* occurs because of loss of the inhibitory effect of adrenal corticosteroids on a corticotroph microadenoma. Because the adrenals are absent in persons with Nelson syndrome, hypercortisolism does not develop. Patients present with mass effects due to the pituitary tumor, and there can be hyperpigmentation because melanotropin, which has trophic effects on melanocytes, is also derived from POMC.

Other Anterior Pituitary Tumors

Several less frequent types of pituitary adenoma also merit brief comment (see Table 24.1).

- *Gonadotroph (LH-producing and FSH-producing) adenomas* can be difficult to recognize because they secrete small amounts of hormones that usually do not cause a recognizable clinical syndrome (i.e., most are nonfunctioning). Gonadotroph adenomas most frequently present in middle-aged men and women with neurologic symptoms, such as impaired vision, headaches, diplopia, or pituitary apoplexy. Pituitary hormone deficiencies can also be found, most commonly impaired secretion of LH, which causes decreased energy and libido in men (due to reduced testosterone) and amenorrhea in premenopausal women. The neoplastic cells express the common gonadotropin α-subunit and the specific β-FSH and β-LH subunits; FSH is usually the predominant secreted hormone. Gonadotroph adenomas also usually express steroidogenic factor-1 (SF-1), GATA-2, and ERα, transcription factors associated with normal gonadotroph differentiation.
- *Thyrotroph (TSH-producing)* adenomas are uncommon, accounting for approximately 1% of pituitary adenomas. They are a rare cause of hyperthyroidism. Due to their shared lineage with lactotroph and somatotroph adenomas, these tumors also express PIT-1.
- Pituitary adenomas may also secrete multiple hormones; such "plurihormonal" adenomas are usually aggressive. Most are derived from cells of PIT-1–expressing lineage.
- *Null cell adenomas* do not express any markers of hormonal or lineage differentiation. Not surprisingly, null cell adenomas typically present with symptoms stemming from mass effects. These lesions may also compromise the residual anterior pituitary and cause hypopituitarism, which may appear slowly due to gradual enlargement of the adenoma or abruptly because of acute intratumor hemorrhage (pituitary apoplexy).

Pituitary carcinoma is rare, accounting for less than 1% of pituitary tumors. The presence of craniospinal or systemic metastases is a sine qua non of a pituitary carcinoma. Most pituitary carcinomas are functional, with prolactin and ACTH being the most commonly secreted products. Metastases usually appear late in the course, following multiple local recurrences.

Pituitary blastoma is an entity that occurs in children (typically younger than 2 years of age) who carry germline mutations of *DICER1,* the gene encoding a microRNA-processing protein. Morphologically, these tumors are composed of immature "blastema-like" cells (so-called "small round blue cells") and rosette-like formations resembling the primitive Rathke epithelium from which the pituitary develops. Pituitary blastoma presents with signs and symptoms of Cushing disease. These children also develop primitive "blastema-like" neoplasms in other organs, most commonly pleuropulmonary blastoma.

KEY CONCEPTS

HYPERPITUITARISM

- The most common cause of hyperpituitarism is an anterior lobe pituitary adenoma.
- Pituitary adenomas can be macroadenomas (greater than 1 cm in diameter) or microadenomas.
- Functioning adenomas are associated with distinct endocrine signs and symptoms, while nonfunctioning (silent) adenomas typically present with mass effects, including visual disturbances.
- Lactotroph adenomas secrete prolactin and can present with amenorrhea, galactorrhea, loss of libido, and infertility.
- Somatotroph adenomas secrete GH and present with gigantism in children and acromegaly in adults, impaired glucose tolerance, and diabetes mellitus.
- Corticotroph adenomas secrete ACTH and present with Cushing syndrome and hyperpigmentation.
- The two distinctive morphologic features of most adenomas are their cellular monomorphism and absence of a reticulin network.

HYPOPITUITARISM

Hypopituitarism refers to decreased secretion of pituitary hormones, which can result from diseases of the hypothalamus or of the pituitary. Hypofunction of the anterior pituitary occurs when approximately 75% of the parenchyma is lost or absent. When accompanied by evidence of posterior pituitary dysfunction in the form of diabetes insipidus (see later), hypopituitarism is almost always of hypothalamic origin.

Most cases of hypopituitarism arise from destructive processes involving the anterior pituitary, as follows:

- *Tumors and other mass lesions:* Pituitary adenomas, other benign tumors arising within the sella, primary and metastatic malignancies, and cysts can cause hypopituitarism. Any mass lesion in the sella can cause damage by exerting pressure on adjacent normal pituitary cells.
- *Traumatic brain injury and subarachnoid hemorrhage* are among the most common causes of pituitary hypofunction.
- *Pituitary surgery or radiation:* Surgical excision of a pituitary adenoma may inadvertently include the nonadenomatous pituitary. Radiation of the pituitary, used to prevent regrowth of residual tumor after surgery, can damage the nonadenomatous pituitary.
- *Pituitary apoplexy:* As mentioned earlier, this is caused by a sudden hemorrhage into the pituitary gland, often occurring into a pituitary adenoma. In its most dramatic presentation, apoplexy causes the abrupt onset of excruciating headache, diplopia due to pressure on the oculomotor nerves, and acute hypopituitarism. In severe cases, it can cause cardiovascular collapse, loss of consciousness, and even sudden death. The combination of mass effect from the hemorrhage and acute hypopituitarism makes pituitary apoplexy a neurosurgical emergency.
- *Ischemic necrosis of the pituitary (Sheehan syndrome)*, also known as postpartum necrosis, is the most common form of ischemic necrosis of the anterior pituitary. During pregnancy, the anterior pituitary enlarges to almost twice its normal size. This physiologic expansion of the gland is not accompanied by an increase in blood supply from the low-pressure venous system; hence, there is relative hypoxia. Any further reduction in blood supply caused by obstetric hemorrhage or shock may precipitate infarction of the anterior lobe. Because the posterior pituitary is supplied directly from arterial branches, it is much less susceptible to ischemic injury and is therefore usually unaffected. Pituitary necrosis may also be encountered in disseminated intravascular coagulation and, less commonly, in sickle cell anemia, elevated intracranial pressure, traumatic injury, and shock of any origin. Whatever the pathogenesis, the ischemic area is resorbed and replaced by a nubbin of fibrous tissue attached to the wall of an empty sella.
- *Rathke cleft cyst:* These cysts, lined by ciliated cuboidal epithelium with occasional goblet cells and anterior pituitary cells, can accumulate proteinaceous fluid and expand, compromising the normal gland.
- *Empty sella syndrome:* Any condition or treatment that destroys part or all of the pituitary gland, such as ablation of the pituitary by surgery or radiation, can result in an empty sella and the empty sella syndrome. There are two types: (1) In a primary empty sella, a defect in the diaphragma sella allows the arachnoid mater and cerebrospinal fluid to herniate into the sella, expanding the sella and compressing the pituitary. Classically, this occurs in obese women with a history of multiple pregnancies. Affected individuals often present with visual field defects and occasionally with endocrine anomalies, such as hyperprolactinemia, due to interruption of inhibitory hypothalamic inputs. Sometimes the loss of functioning parenchyma is sufficient to produce hypopituitarism. (2) In secondary empty sella, a mass, such as a pituitary adenoma, enlarges the sella and is then either surgically removed or undergoes infarction, leading to loss of pituitary function.
- *Hypothalamic lesions:* As mentioned earlier, hypothalamic lesions can also affect the pituitary by causing a deficiency of pituitary hormone–releasing factors. In contrast to diseases that involve the pituitary directly, hypothalamic abnormalities can also diminish the secretion of ADH, resulting in diabetes insipidus (discussed later). Hypothalamic lesions that cause hypopituitarism include tumors, which may be benign (e.g., craniopharyngioma) or malignant; most of the latter are metastases from tumors such as breast and lung carcinoma. Hypothalamic insufficiency may also appear following irradiation of the brain.
- *Inflammatory disorders and infections,* such as sarcoidosis or tuberculous meningitis, can involve the hypothalamus and cause deficiencies of anterior pituitary hormones and diabetes insipidus.
- *Genetic defects:* Congenital deficiency of transcription factors required for normal pituitary function is a rare cause of hypopituitarism. For example, mutation of the pituitary-specific gene *PIT1* results in combined pituitary hormone deficiency, characterized by deficiencies of GH, prolactin, and TSH.

The clinical manifestations of anterior pituitary hypofunction vary depending on the specific hormones that are lacking.

- Children can develop growth failure *(pituitary dwarfism)* due to growth hormone deficiency.
- Gonadotropin (LH and FSH) deficiency leads to amenorrhea and infertility in women and decreased libido, impotence, and loss of pubic and axillary hair in men.
- TSH and ACTH deficiencies result in symptoms of hypothyroidism and hypoadrenalism, respectively, and are discussed later in this chapter.
- Prolactin deficiency results in failure of postpartum lactation.
- The anterior pituitary is also a rich source of melanotropins (also known as melanocyte-stimulating hormone), synthesized from the same precursor molecule that produces ACTH; therefore, one of the manifestations of hypopituitarism includes pallor due to a loss of stimulatory effects on melanocytes.

POSTERIOR PITUITARY SYNDROMES

The clinically relevant posterior pituitary syndromes involve ADH and include diabetes insipidus and syndrome of inappropriate secretion of ADH.

- *Diabetes insipidus.* ADH deficiency causes diabetes insipidus, a condition characterized by excessive urination (polyuria) due to an inability of the kidney to resorb water properly from the urine. Diabetes insipidus can occur in a variety of conditions, including head trauma, tumors, inflammatory disorders of the hypothalamus and pituitary, and surgical complications. Rarely, diabetes insipidus has a genetic basis, either because of autosomal dominant mutations of the arginine vasopressin (AVP) gene, or mutations of arginine vasopressin receptor type

2 (AVPR2), an X-linked condition that usually presents in young boys. Diabetes insipidus from ADH deficiency is designated as central to differentiate it from nephrogenic diabetes insipidus, which is a result of renal tubular unresponsiveness to circulating ADH. The clinical manifestations of these two disorders are similar and include the excretion of large volumes of dilute urine with a lower than normal specific gravity. Serum sodium and osmolality are increased by the excessive renal loss of free water, resulting in thirst and polydipsia. Patients who can drink water generally compensate for the urinary losses, but patients who are obtunded, bedridden, or otherwise limited in their ability to obtain water may develop life-threatening dehydration.

- *Syndrome of inappropriate ADH (SIADH) secretion.* ADH excess causes over-resorption of free water, resulting in hyponatremia. The most frequent causes of SIADH are the secretion of ectopic ADH by malignant neoplasms (particularly small-cell carcinoma of the lung), drugs that increase ADH secretion, and a variety of central nervous system disorders, including infections and trauma. The clinical manifestations of SIADH are dominated by hyponatremia, cerebral edema, and resultant neurologic dysfunction. Although total body water is increased, blood volume remains normal, and peripheral edema does not develop.

HYPOTHALAMIC SUPRASELLAR TUMORS

Neoplasms in this location may induce hypofunction or hyperfunction of the anterior pituitary, diabetes insipidus, or combinations of these manifestations. The most commonly implicated tumors are glioma (sometimes arising in the chiasm; Chapter 28) and craniopharyngioma. Craniopharyngioma is thought to arise from vestigial remnants of Rathke pouch. These slow-growing tumors account for 1% to 5% of intracranial tumors. A small minority of these lesions occurs within the sella, but most are suprasellar, with or without intrasellar extension. A bimodal age distribution is observed, with one peak in childhood (5 to 15 years) and a second peak in adults 65 years of age or older. Patients usually come to attention because of headaches and visual disturbances, while children sometimes present with growth retardation due to pituitary hypofunction and GH deficiency.

MORPHOLOGY

Craniopharyngiomas average 3 to 4 cm in diameter; they may be encapsulated and solid, but more commonly they are cystic and sometimes multiloculated. They often encroach on the optic chiasm or cranial nerves, and not infrequently they bulge into the floor of the third ventricle and base of the brain. Two distinct histologic variants are recognized: adamantinomatous craniopharyngioma (most often observed in children) and papillary craniopharyngioma (most often observed in adults). The adamantinomatous type frequently contains radiologically demonstrable calcifications; the papillary variant calcifies only rarely.

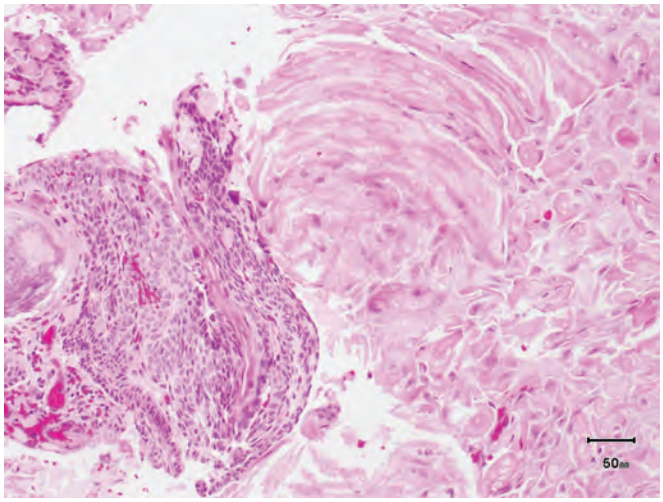

Figure 24.7 Adamantinomatous craniopharyngioma, demonstrating characteristic compact, lamellar "wet" keratin *(right half of photomicrograph)* and cords of squamous epithelium with peripheral palisading on the left. (Courtesy Dr. Charles Eberhart, Department of Pathology, Johns Hopkins University, Baltimore, Md.)

Adamantinomatous craniopharyngioma consists of nests or cords of stratified squamous epithelium embedded in a spongy "reticulum" that becomes more prominent in the internal layers. "Palisading" of the squamous epithelium is frequently observed at the periphery. Compact, lamellar keratin formation ("wet keratin") is a diagnostic feature of this tumor (Fig. 24.7). As mentioned earlier, **dystrophic calcification** is a frequent finding. Additional features include cyst formation, fibrosis, and chronic inflammation. The cysts of adamantinomatous craniopharyngiomas often contain a cholesterol-rich, thick brownish-yellow fluid that has been compared to "machine oil." These tumors extend fingerlets of epithelium into adjacent brain, where they elicit a brisk glial reaction. This subtype of craniopharyngioma is characterized by recurrent mutations of the *CTNNB1 (β-catenin)* gene, which leads to aberrant activation of the Wnt signaling pathway.

Papillary craniopharyngiomas contain both solid sheets of cells and papillae lined by well-differentiated squamous epithelium. These tumors usually are distinguished from the adamantinous type by the lack of lamellar keratin, calcification, cysts, peripheral palisading of squamous cells, and a spongy reticulum. Also unlike adamantinomatous craniopharyngioma, this subtype is characterized by activating mutations of the *BRAF* oncogene at codon 600. The identification of $BRAF^{V600E}$ mutations has therapeutic implications due to availability of small-molecule BRAF inhibitor drugs that inhibit the BRAF serine-threonine kinase (Chapter 7).

Patients with craniopharyngiomas, especially those less than 5 cm in diameter, have an excellent recurrence-free and overall survival. Larger lesions are more invasive, but this does not impact on the prognosis. Malignant transformation of craniopharyngiomas into squamous carcinomas is rare and usually occurs only after irradiation.

Thyroid Gland

The thyroid gland consists of two lateral lobes connected by a thin isthmus, usually located below and anterior to the larynx. It develops embryologically from an evagination of the pharyngeal epithelium that descends from the foramen cecum at the base of the tongue to its normal position in the anterior neck. This pattern of descent explains the occasional presence of ectopic thyroid tissue at the base of the tongue (lingual thyroid) or at other sites high in the neck. The thyroid is divided by thin fibrous septae into lobules composed of 20 to 40 follicles, lined by a cuboidal to low columnar epithelium and filled with PAS-positive thyroglobulin.

In response to hypothalamic factors, TSH *(thyrotropin)* is released by thyrotrophs in the anterior pituitary into the circulation. The binding of TSH to its receptor on thyroid follicular epithelial cells activates the receptor, which then associates with a G_s protein (Fig. 24.8). Activation of the G protein triggers downstream events that increase intracellular cAMP levels, which, in turn, stimulates thyroid growth and thyroid hormone synthesis and release via cAMP-dependent protein kinases.

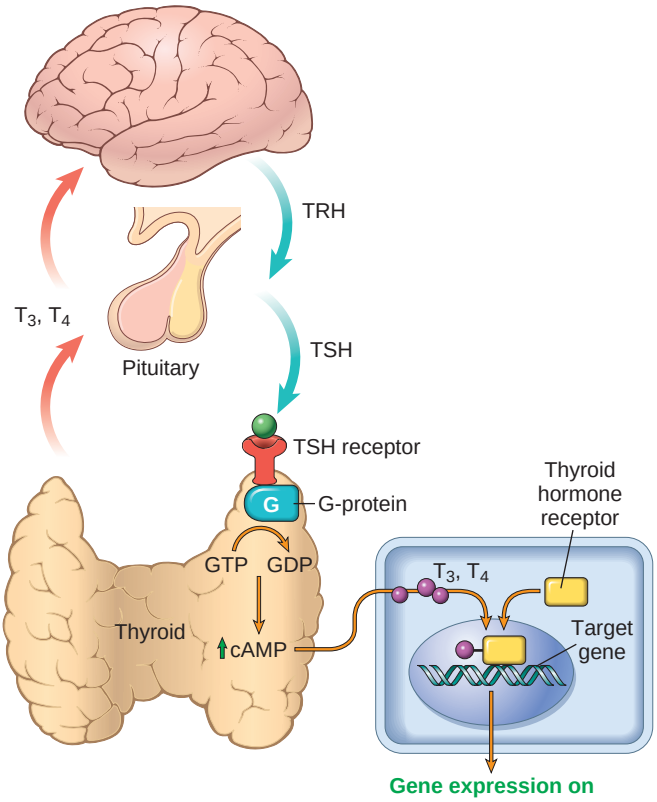

Figure 24.8 Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones (T_3 and T_4) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary. Decreased levels of T_3 and T_4 stimulate the release of thyrotropin-releasing hormone *(TRH)* from the hypothalamus and thyroid-stimulating hormone *(TSH)* from the anterior pituitary, causing T_3 and T_4 levels to rise. Elevated T_3 and T_4 levels, in turn, feed back to suppress the secretion of both TRH and TSH. TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G-proteins, and cAMP-mediated synthesis and release of thyroid hormones (T_3 and T_4). In the periphery, T_3 and T_4 interact with the thyroid hormone receptor to form a hormone-receptor complex that translocates to the nucleus and binds to so-called thyroid response elements on target genes to initiate transcription.

Thyroid follicular epithelial cells convert thyroglobulin into *thyroxine (T_4)* and lesser amounts of *triiodothyronine (T_3)*. T_4 and T_3 are released into the systemic circulation, where most of these peptide hormones are reversibly bound to circulating plasma proteins, such as thyroxine-binding globulin and transthyretin. The binding proteins act as a buffer that maintains the serum unbound ("free") T_3 and T_4 concentrations within narrow limits, while ensuring that adequate amounts of the hormones are readily available to the tissues. In the periphery, the majority of free T_4 is deiodinated to T_3; the latter binds to thyroid hormone nuclear receptors in target cells with tenfold greater affinity than does T_4 and has proportionately greater activity. Binding of thyroid hormone to its nuclear thyroid hormone receptor (TR) results in the assembly of a multiprotein hormone-receptor complex on thyroid hormone response elements (TREs) near target genes, increasing their transcription (see Fig. 24.8). Thyroid hormone has diverse cellular effects, including the stimulation of carbohydrate and lipid catabolism and protein synthesis in a wide range of cells. The net result is an increase in the basal metabolic rate. In addition, thyroid hormone has a critical role in brain development in the fetus and neonate (see later).

The function of the thyroid gland can be inhibited by a variety of chemical agents, collectively referred to as *goitrogens*. Because they suppress T_3 and T_4 synthesis, the level of TSH increases, causing subsequent hyperplastic enlargement of the gland *(goiter)*. The antithyroid agent propylthiouracil inhibits the oxidation of iodide and thus blocks the production of thyroid hormones; propylthiouracil also inhibits the peripheral deiodination of circulating T_4 into T_3, thus ameliorating symptoms of thyroid hormone excess (see later). Iodide, when given in large doses to individuals with thyroid hyperfunction, blocks the release of thyroid hormones by inhibiting the proteolysis of thyroglobulin. Thus, thyroid hormone is synthesized and incorporated into colloid, but it is not released into the blood.

The thyroid gland follicles also contain a population of parafollicular cells, or C cells, which synthesize and secrete the hormone calcitonin. This hormone promotes the absorption of calcium by the skeletal system and inhibits the resorption of bone by osteoclasts.

Diseases of the thyroid include conditions associated with excessive release of thyroid hormones (hyperthyroidism), thyroid hormone deficiency (hypothyroidism), and mass lesions of the thyroid. We will first consider the clinical consequences of disturbed thyroid function, and then turn to the disorders that generate these problems.

HYPERTHYROIDISM

Thyrotoxicosis is a hypermetabolic state caused by elevated circulating levels of free T_3 and T_4. Because it is caused

Table 24.3 Disorders Associated With Thyrotoxicosis

Associated With Hyperthyroidism
Primary
Diffuse hyperplasia (Graves disease)
Hyperfunctioning ("toxic") multinodular goiter
Hyperfunctioning ("toxic") adenoma
Iodine-induced hyperthyroidism
Neonatal thyrotoxicosis associated with maternal Graves disease
Secondary
TSH-secreting pituitary adenoma (rare)[a]
Not Associated With Hyperthyroidism
Granulomatous (de Quervain) thyroiditis (painful)
Subacute lymphocytic thyroiditis (painless)
Struma ovarii (ovarian teratoma with ectopic thyroid)
Factitious thyrotoxicosis (exogenous thyroxine intake)

[a]Associated with increased thyroid-stimulating hormone (TSH); all other causes of thyrotoxicosis associated with decreased TSH.

Figure 24.9 A person with hyperthyroidism. A wide-eyed, staring gaze, caused by overactivity of the sympathetic nervous system, is one feature of this disorder. In Graves disease, an important cause of hyperthyroidism, accumulation of loose connective tissue behind the orbit also adds to the protuberant appearance of the eyes.

most commonly by hyperfunction of the thyroid gland, it is often referred to as *hyperthyroidism*. However, in certain conditions the oversupply is related to either excessive release of preformed thyroid hormone (e.g., in thyroiditis) or to an extrathyroidal source, rather than hyperfunction of the gland (Table 24.3). Thus, strictly speaking, hyperthyroidism is only one (albeit the most common) cause of thyrotoxicosis. The terms *primary* and *secondary hyperthyroidism* are sometimes used to designate hyperthyroidism arising from an intrinsic thyroid abnormality and that arising from processes outside of the thyroid, such as a TSH-secreting pituitary tumor. With this caveat, we follow the common practice of using the terms thyrotoxicosis and hyperthyroidism interchangeably.

The most common causes of thyrotoxicosis are associated with hyperfunction of the gland and include the following:

- *Diffuse hyperplasia* of the thyroid associated with Graves disease (approximately 85% of cases)
- Hyperfunctional *multinodular goiter*
- Hyperfunctional thyroid *adenoma*

Clinical Features

The manifestations of hyperthyroidism are protean and include changes referable to the hypermetabolic state induced by excess thyroid hormone and to overactivity of the sympathetic nervous system (i.e., an increase in the β-adrenergic "tone").

- Excessive levels of thyroid hormone result in *an increase in the basal metabolic rate*. The skin of thyrotoxic patients tends to be soft, warm, and flushed because of increased blood flow and peripheral vasodilation, adaptations that serve to increase heat loss. Heat intolerance is common. Sweating is increased because of higher levels of calorigenesis. Heightened catabolic metabolism results in weight loss despite increased appetite.
- *Cardiac manifestations* are among the earliest and most consistent features. Individuals with hyperthyroidism can have elevated cardiac contractility and output, a response to increased peripheral oxygen requirements. Tachycardia, palpitations, and cardiomegaly are common. Arrhythmias such as atrial fibrillation occur frequently, particularly in older patients. Congestive heart failure may develop, especially in older adults with preexisting cardiac disease. Myocardial changes, including focal lymphocytic and eosinophilic infiltrates, mild fibrosis, myofibril fatty change, and an increase in size and number of mitochondria, have been described. Some individuals with thyrotoxicosis develop reversible left ventricular dysfunction and "low-output" heart failure, so-called *thyrotoxic* or *hyperthyroid cardiomyopathy*.
- *Overactivity of the sympathetic nervous system* produces tremor, hyperactivity, emotional lability, anxiety, inability to concentrate, and insomnia. Proximal muscle weakness and decreased muscle mass are common *(thyroid myopathy)*. In the gastrointestinal system, hypermotility and reduced transit times lead to hyperdefecation (not to be confused with diarrhea), which typically responds to beta-blockers, suggesting sympathetic hyperstimulation is the likely underlying pathophysiology. Most patients also develop some degree of fat malabsorption.
- *Ocular changes* often call attention to hyperthyroidism. A wide, staring gaze and lid lag are present because of sympathetic overstimulation of the superior tarsal muscle (also known as Müller's muscle), which functions alongside the levator palpebrae superioris muscle to raise the upper eyelid (Fig. 24.9). However, true *thyroid ophthalmopathy* associated with proptosis occurs only in Graves disease (see later).
- The *skeletal system* is also affected. Thyroid hormone stimulates bone resorption, increasing cortical bone porosity and reducing trabecular bone volume. The net effect is osteoporosis and an increased risk of fractures. Other findings include atrophy of skeletal muscle, with fatty infiltration and focal interstitial lymphocytic infiltrates; hepatic fatty change (steatosis) leading to mild hepatomegaly; and generalized lymphoid hyperplasia and lymphadenopathy in patients with Graves disease.
- *Thyroid storm* refers to the abrupt onset of severe hyperthyroidism. This condition occurs most commonly in patients with Graves disease and probably results from an acute elevation in catecholamine levels, as might be

encountered during infection, surgery, cessation of antithyroid medication, or any form of stress. Patients are often febrile and present with tachycardia out of proportion to the fever. Thyroid storm is a medical emergency. A significant number of untreated patients die of cardiac arrhythmias.

- *Apathetic hyperthyroidism* refers to thyrotoxicosis occurring in older adults, in whom advanced age and various comorbidities blunt the typical features of thyroid hormone excess. The diagnosis in these individuals is often made during laboratory workup for unexplained weight loss or worsening cardiovascular disease.

Laboratory findings that support the diagnosis of hyperthyroidism include a low TSH value accompanied by an increase in free T_4. The measurement of serum TSH concentration is the most useful single screening test for hyperthyroidism, because its levels are decreased even at the earliest stages, when the disease may still be subclinical. In occasional patients, hyperthyroidism results predominantly from increased circulating levels of T_3 ("T_3 toxicosis"). In these cases, free T_4 levels may be decreased, and direct measurement of serum T_3 is useful. In rare cases of pituitary-associated (secondary) hyperthyroidism, TSH levels are either normal or raised. Determining TSH levels after the injection of thyrotropin-releasing hormone (TRH stimulation test) is used in the evaluation of cases of suspected hyperthyroidism with equivocal changes in the baseline serum TSH level. A normal rise in TSH after administration of TRH excludes secondary hyperthyroidism. Once the diagnosis of thyrotoxicosis has been confirmed by a combination of TSH assays and free thyroid hormone levels, measurement of radioactive iodine uptake by the thyroid gland can help determine the etiology. For example, there may be diffusely increased uptake in the gland (Graves disease), increased uptake in a solitary nodule (toxic adenoma), or decreased uptake (thyroiditis).

The therapeutic options for hyperthyroidism include several medications, each with a different mechanism of action. Typically, these include a β-blocker to control symptoms induced by increased adrenergic tone, a thionamide (e.g., methimazole or propylthiouracil) to block new hormone synthesis, an iodine solution to block the release of thyroid hormone, and agents that inhibit peripheral conversion of T_4 to T_3. Radioactive iodine, which is incorporated into thyroid tissues, resulting in ablation of thyroid function over a period of 6 to 18 weeks, may also be used.

HYPOTHYROIDISM

Hypothyroidism is a condition caused by a structural or functional derangement that interferes with the production of thyroid hormone. Hypothyroidism is a common disorder. By some estimates, the prevalence of overt hypothyroidism is 0.3%, while that of subclinical hypothyroidism is greater than 4%. The prevalence increases with age, and it is nearly 10-fold more common in women than in men. Hypothyroidism can result from a defect anywhere in the hypothalamic-pituitary-thyroid axis. Like hyperthyroidism, it can be divided into *primary* and *secondary* forms, depending on whether it arises from an intrinsic thyroid abnormality or as a result of pituitary and hypothalamic disease (Table 24.4). Primary hypothyroidism accounts for the vast majority of cases and may be accompanied by enlargement of the thyroid gland (goiter).

Table 24.4 Causes of Hypothyroidism

Primary
Genetic defects in thyroid development (*PAX8*, *FOXE1*, TSH receptor mutations; rare)
Thyroid hormone resistance syndrome (*THRB* mutations; rare)
Postablative
Surgery, radioiodine therapy, or external irradiation
Autoimmune hypothyroidism
Hashimoto thyroiditis[a]
Iodine deficiency[a]
Drugs (lithium, iodides, p-aminosalicylic acid)[a]
Congenital biosynthetic defect (dyshormonogenetic goiter; rare)[a]
Secondary ("Central Hypothyroidism")
Pituitary failure (rare)
Hypothalamic failure (rare)

[a]Associated with enlargement of thyroid ("goitrous hypothyroidism"). Hashimoto thyroiditis and postablative hypothyroidism account for the majority of cases of hypothyroidism in high-income countries. *FOXE1*, Forkhead box E1; *PAX8*, paired box 8; *THRB*, thyroid hormone receptor β.

Primary hypothyroidism can be congenital, autoimmune, or iatrogenic.

- *Congenital hypothyroidism.* **Worldwide, congenital hypothyroidism is most often the result of endemic iodine deficiency in the diet** (see later). Other rare forms of congenital hypothyroidism include inborn errors of thyroid metabolism *(dyshormonogenetic goiter),* wherein one of the several steps leading to thyroid hormone synthesis is defective, such as (1) iodide transport into thyrocytes, (2) "organification" of iodine (covalent binding of iodine to tyrosine residues in thyroglobulin), and (3) further processing to form hormonally active T_3 and T_4. In rare instances, there may be complete absence of thyroid parenchyma *(thyroid agenesis),* or the gland may be greatly reduced in size *(thyroid hypoplasia)* due to germline mutations in genes responsible for thyroid development (see Table 24.4).
- *Autoimmune hypothyroidism.* **Autoimmune hypothyroidism is the most common cause of hypothyroidism in iodine-sufficient areas of the world.** The vast majority of cases of autoimmune hypothyroidism are due to Hashimoto thyroiditis. Circulating autoantibodies, including antimicrosomal, antithyroid peroxidase, and antithyroglobulin antibodies, are found in this disorder, and the thyroid is typically enlarged (goitrous). Autoimmune hypothyroidism can occur in isolation or in conjunction with autoimmune polyendocrine syndrome types 1 and 2 (APS-1 and APS-2; see discussion in the Adrenal Glands section later in this chapter).
- *Iatrogenic hypothyroidism.* This can be caused by either surgical or radiation-induced ablation. Resection of a large portion of the gland for the treatment of hyperthyroidism or a primary neoplasm can lead to hypothyroidism. The gland may also be ablated by radiation, whether in the form of radioiodine administered for the treatment of hyperthyroidism, or exogenous irradiation, such as external radiation therapy to the neck. Drugs given to decrease thyroid secretion (e.g., thionamides like methimazole and

propylthiouracil) can also cause acquired hypothyroidism, as can agents used to treat nonthyroid conditions (e.g., lithium, *p*-aminosalicylic acid).

Secondary (or central) hypothyroidism is caused by deficiencies of TSH or, far more uncommonly, TRH. Any of the causes of hypopituitarism (e.g., pituitary tumor, postpartum pituitary necrosis, trauma, and nonpituitary tumors) or hypothalamic damage (e.g., tumors, trauma, radiation therapy, or infiltrative diseases) can cause central hypothyroidism.

Cretinism

Cretinism refers to hypothyroidism that develops in infancy or early childhood. The term *cretin* was derived from the French *chrétien,* meaning "Christian" or "Christlike," and was applied to those affected because they were felt to be too mentally challenged to be capable of sinning. In the past, this disorder occurred fairly commonly in regions of the world where dietary iodine deficiency is endemic, such as the Himalayas, inland China, Africa, and other mountainous areas. It is now much less prevalent as a result of the widespread supplementation of foods with iodine. On rare occasions, cretinism results from genetic defects that interfere with the biosynthesis of thyroid hormone (dyshormonogenetic goiter).

Clinical features of cretinism include severe intellectual disability, short stature, coarse facial features, a protruding tongue, and umbilical hernia. The severity of the mental impairment seems to be related to the time at which thyroid deficiency occurs in utero. Normally, maternal T_3 and T_4 cross the placenta and are critical for fetal brain development. If there is maternal thyroid deficiency before the development of the fetal thyroid gland, intellectual disability is severe. In contrast, maternal thyroid hormone deficiency later in pregnancy, after the fetal thyroid has become functional, does not affect normal brain development.

Myxedema

The term myxedema is applied to hypothyroidism developing in the older child or adult. Myxedema was first linked with thyroid dysfunction in 1873 by Sir William Gull in an article addressing the development of a "cretinoid state" in adults. The clinical findings vary with age of onset. Older children show signs and symptoms intermediate between those of the cretin and those of the adult with hypothyroidism. In the adult, the condition appears insidiously and may take years before arousing clinical suspicion.

Myxedema is marked by a slowing of physical and mental activity. Early symptoms include generalized fatigue, apathy, and mental sluggishness, which may mimic depression. Speech and intellectual functions are slowed, and patients are listless, cold intolerant, and frequently overweight. Decreased sympathetic activity results in constipation and decreased sweating. The skin is cool and pale because of decreased blood flow. Reduced cardiac output probably contributes to shortness of breath and decreased exercise capacity, two frequent complaints. Thyroid hormones regulate the transcription of several sarcolemmal genes, such as calcium ATPases and the β-adrenergic receptor, and diminished expression of these genes results in a decrease in cardiac output. In addition, changes in lipid metabolism produce an increase in total cholesterol and low-density lipoprotein (LDL) levels that is pro-atherogenic, contributing to increased cardiovascular mortality. Histologically, there is an accumulation of matrix substances, such as glycosaminoglycans and hyaluronic acid, in skin, subcutaneous tissue, and visceral sites. This results in nonpitting edema, a broadening and coarsening of facial features, enlargement of the tongue, and deepening of the voice.

Laboratory evaluation plays a vital role in the diagnosis of suspected hypothyroidism because of the nonspecific nature of symptoms. Patients with unexplained increases in body weight or hypercholesterolemia should be assessed for potential hypothyroidism. **Measurement of the serum TSH level is the most sensitive screening test for this disorder.** The TSH level is increased in primary hypothyroidism as a result of a loss of feedback inhibition of TRH and TSH production by the hypothalamus and pituitary, respectively. The TSH level is not increased in persons with hypothyroidism due to primary hypothalamic or pituitary disease. T_4 levels are decreased in individuals with hypothyroidism of any origin.

THYROIDITIS

Thyroiditis encompasses a diverse group of disorders characterized by some form of thyroid inflammation. This discussion focuses on the three most common and clinically significant subtypes: (1) Hashimoto thyroiditis, (2) granulomatous (de Quervain) thyroiditis, and (3) subacute lymphocytic thyroiditis.

Hashimoto Thyroiditis

Hashimoto thyroiditis is an autoimmune disease that results in destruction of the thyroid gland and gradual and progressive thyroid failure. It is the most common cause of hypothyroidism in areas of the world where iodine levels are sufficient. The name is derived from the 1912 report by Hashimoto describing patients with goiter and lymphocytic infiltration of the thyroid *(struma lymphomatosa)*. It is most prevalent between 45 and 65 years of age and is more common in women than in men, with a female predominance of 10:1 to 20:1. It can also occur in children and is a major cause of nonendemic goiter in the pediatric population.

Pathogenesis

Hashimoto thyroiditis is caused by a breakdown in self-tolerance to thyroid autoantigens. This is exemplified by the presence of circulating autoantibodies against thyroglobulin and thyroid peroxidase in the vast majority of patients. The inciting events have not been elucidated, but possibilities include abnormalities of regulatory T cells (Tregs), or exposure of normally sequestered thyroid antigens (Chapter 6). Similar to other autoimmune diseases, Hashimoto thyroiditis predisposition has a strong genetic component. Increased susceptibility is associated with polymorphisms in several immune regulation–associated genes, such as cytotoxic T lymphocyte–associated antigen-4

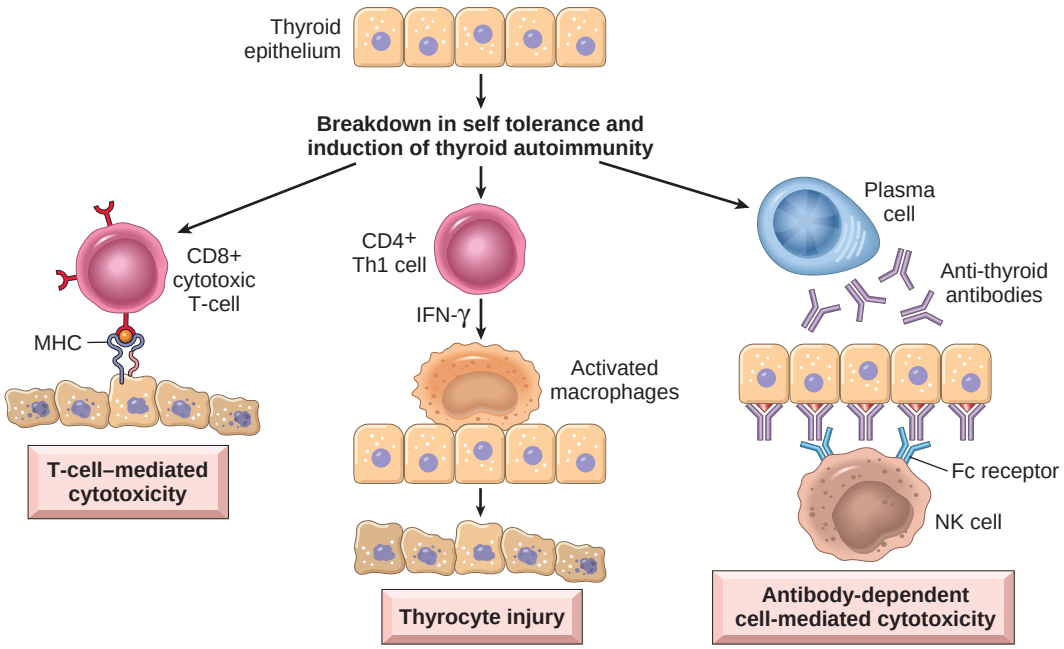

Figure 24.10 Pathogenesis of Hashimoto thyroiditis. Breakdown of peripheral tolerance to thyroid autoantigens results in progressive autoimmune destruction of thyroid cells by infiltrating cytotoxic T cells, locally released cytokines, or antibody-dependent cytotoxicity.

(CTLA4), protein tyrosine phosphatase-22 *(PTPN22),* and interleukin-2 receptor α chain *(IL2RA),* all of which encode regulators of T-cell responses. Not surprisingly, genome-wide association studies (GWAS) have found similar associations between *CTLA4, PTPN22,* and *IL2RA* polymorphisms and Graves disease, another type of autoimmune thyroid disease (discussed later), as well as with other systemic autoimmune diseases such as type 1 diabetes (T1D). The genetic associations support the idea that breakdown in immune tolerance is a common pathophysiologic theme for many autoimmune diseases, more than one of which can coexist in the same individual.

Induction of thyroid autoimmunity is accompanied by a progressive depletion of thyroid epithelial cells and replacement of the thyroid parenchyma by lymphocytic infiltrates and fibrosis. Multiple immunologic mechanisms may contribute to thyroid cell death, including (Fig. 24.10):

- *CD8+ cytotoxic T cell–mediated cell death:* CD8+ cytotoxic T cells may destroy thyroid follicular cells.
- *Cytokine-mediated cell death:* Activation of CD4+ Th1 cells leads to the production of inflammatory cytokines such as interferon-γ in the thyroid gland, with resultant recruitment and activation of macrophages and damage to follicles.
- A less likely mechanism involves binding of antithyroid antibodies (antithyroglobulin, and antithyroid peroxidase antibodies) followed by antibody-dependent cell-mediated cytotoxicity (Chapter 6).

MORPHOLOGY

The thyroid is usually diffusely enlarged. The capsule is intact, and the gland is well demarcated from adjacent structures. The cut surface is pale, yellow-tan, firm, and somewhat nodular. There is extensive infiltration of the parenchyma by a **mononuclear inflammatory infiltrate** containing small lymphocytes, plasma cells, and well-developed **germinal centers** (Fig. 24.11). The thyroid follicles are atrophic and are lined in many areas by epithelial cells with abundant eosinophilic, granular cytoplasm, termed **Hürthle cells**, which represent a metaplastic response of the normally low cuboidal follicular epithelium to chronic injury. In fine-needle aspiration biopsy samples, the presence of Hürthle cells in conjunction with a heterogeneous population of lymphocytes is characteristic of Hashimoto thyroiditis. In "classic" Hashimoto thyroiditis, interstitial connective tissue is increased and may be abundant. Unlike Reidel thyroiditis (see later), the fibrosis does not extend beyond the capsule of the gland.

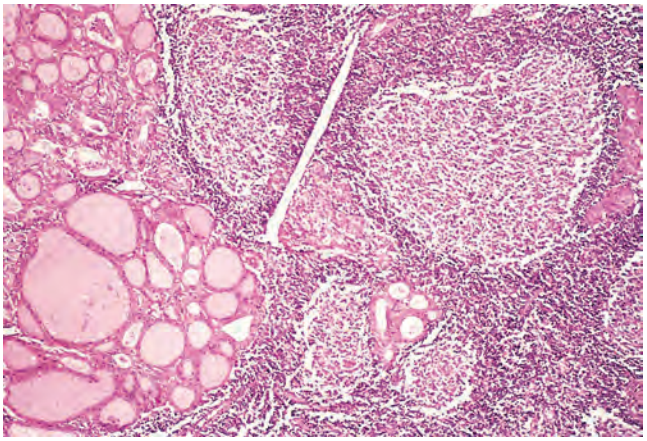

Figure 24.11 Hashimoto thyroiditis. The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centers. Residual thyroid follicles lined by deeply eosinophilic Hürthle cells are also seen.

Clinical Features

Hashimoto thyroiditis most often comes to attention as painless enlargement of the thyroid, usually associated with some degree of hypothyroidism, in a middle-aged woman. The enlargement of the gland is generally symmetric and diffuse, but in some cases it may be sufficiently localized to raise the suspicion of a neoplasm. In the typical case, hypothyroidism develops gradually. In some patients, however, it may be preceded by transient thyrotoxicosis caused by disruption of thyroid follicles and release of thyroid hormones *(hashitoxicosis)*. During this phase, free T_4 and T_3 levels are elevated, TSH is diminished, and radioactive iodine uptake is decreased. As hypothyroidism supervenes, T_4 and T_3 levels fall, accompanied by a compensatory increase in TSH.

Individuals with Hashimoto thyroiditis are at increased risk for developing other autoimmune diseases, both endocrine (type 1 diabetes, autoimmune adrenalitis) and non-endocrine (systemic lupus erythematosus, myasthenia gravis, and Sjögren syndrome; Chapter 6). They are also at increased risk for development of extranodal marginal zone B-cell lymphoma within the thyroid gland (Chapter 13). The relationship between Hashimoto disease and thyroid epithelial cancers remains controversial, with some morphologic and molecular studies suggesting a predisposition to papillary carcinoma.

Subacute Lymphocytic (Painless) Thyroiditis

Subacute lymphocytic thyroiditis, which is also referred to as *painless thyroiditis,* is a presumed autoimmune disease. Most patients have circulating antithyroid peroxidase antibodies or a family history of other autoimmune disorders. A similar disease process can occur during the postpartum period in up to 5% of women *(postpartum thyroiditis)*.

MORPHOLOGY

Except for possible mild symmetric enlargement, the thyroid appears grossly normal. Microscopic examination reveals lymphocytic infiltration with large germinal centers within the thyroid parenchyma and patchy disruption and collapse of thyroid follicles. Unlike Hashimoto thyroiditis, however, fibrosis and Hürthle cell metaplasia are not prominent.

Clinical Features

Painless thyroiditis usually comes to attention because of mild, transient hyperthyroidism, painless goiter, or both. Although it can occur at any age, it is most often seen in middle-aged adults and is more common in women. Some patients transition from hyperthyroidism to hypothyroidism before recovery. As many as one-third of cases evolve into overt hypothyroidism over a 10-year period, with pathogic features that resemble Hashimoto thyroiditis.

Granulomatous Thyroiditis

Granulomatous thyroiditis (also called *De Quervain thyroiditis*) occurs much less frequently than does Hashimoto thyroiditis. The disorder is most common between 40 and 50 years of age and, like other forms of thyroiditis, affects women more often than men (4:1).

Pathogenesis

Granulomatous thyroiditis is believed to be triggered by a viral infection. The majority of patients have a history of an upper respiratory infection just before the onset of thyroiditis. The disease is seasonal, with occurrences peaking in the summer, and clusters of cases have been reported in association with coxsackievirus, mumps, measles, adenovirus, and other viral infections. Although the pathogenesis of the disease is unclear, one model suggests that it results from virus-induced host tissue damage that stimulates a cytotoxic T-lymphocyte response to one or more thyroid antigens that damages thyroid follicle cells. In contrast to autoimmune thyroid disease, the immune response is virus-initiated and not self-perpetuating, so the process is limited.

MORPHOLOGY

The gland may be unilaterally or bilaterally enlarged and firm, with an intact capsule that may adhere to surrounding structures. On cut section, the involved areas are firm and yellow-white and stand out from adjacent normal rubbery, brown thyroid gland. Histologic changes are patchy and depend on the stage of the disease. Early in the active inflammatory phase, scattered follicles may be disrupted and replaced by neutrophils forming microabscesses. Later, more characteristic features appear in the form of aggregates of lymphocytes, activated macrophages, and plasma cells associated with collapsed and damaged thyroid follicles. **Multinucleate giant cells** enclose pools of colloid (Fig. 24.12), hence the designation **granulomatous thyroiditis.** In later stages of the disease, a chronic inflammatory infiltrate and fibrosis may replace the foci of injury. Different histologic stages are sometimes found in the same gland, suggesting waves of destruction over a period of time.

Clinical Features

Granulomatous thyroiditis is the most common cause of thyroid pain. There is variable enlargement of the gland. Inflammation of the thyroid and hyperthyroidism are

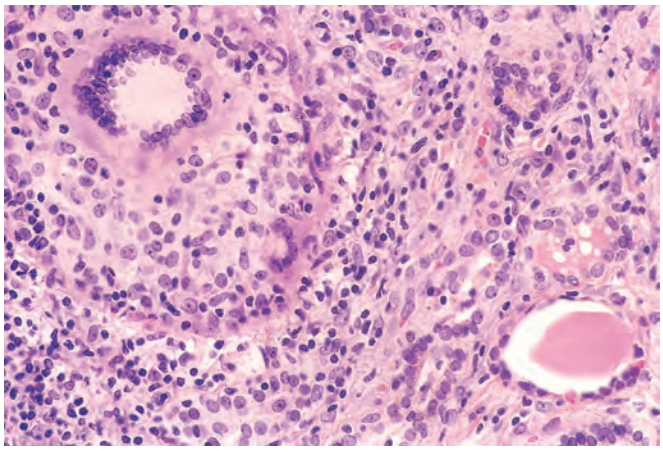

Figure 24.12 Granulomatous thyroiditis. The thyroid parenchyma contains a chronic inflammatory infiltrate with a multinucleate giant cell *(top left)* and a colloid follicle *(bottom right)*.

transient, usually diminishing in 2 to 6 weeks, even if the patient is not treated. Nearly all patients have high serum T_4 and T_3 levels and low serum TSH levels during this phase. However, unlike in hyperthyroid states such as Graves disease, radioactive iodine uptake is diminished. After recovery, generally in 6 to 8 weeks, normal thyroid function returns.

Other, less common forms of thyroiditis include *Riedel thyroiditis,* a rare disorder characterized by extensive fibrosis involving the thyroid and contiguous neck structures. The presence of a hard and fixed thyroid mass clinically simulates a thyroid carcinoma. It may be associated with fibrosis in other sites in the body, such as the retroperitoneum, and appears to be another manifestation of IgG4-related disease, which is associated with fibrosis and tissue infiltration by plasma cells producing IgG4 (Chapter 6).

KEY CONCEPTS

THYROIDITIS

- Hashimoto thyroiditis is the most common cause of hypothyroidism in regions where dietary iodine levels are sufficient.
- Hashimoto thyroiditis is an autoimmune thyroiditis characterized by progressive destruction of thyroid parenchyma, Hürthle cell change, and mononuclear (lymphoplasmacytic) infiltrates, with germinal centers and variable degrees of fibrosis.
- Subacute lymphocytic thyroiditis often occurs after pregnancy (postpartum thyroiditis), typically is painless, and is characterized by lymphocytic inflammation in the thyroid. It is another type of autoimmune thyroiditis.
- Granulomatous (de Quervain) thyroiditis is a self-limited disease, probably secondary to a viral infection, and is characterized by pain and granulomatous inflammation of the thyroid.

GRAVES DISEASE

Graves disease is the most common cause of endogenous hyperthyroidism. Graves reported in 1835 his observations of a disease characterized by "violent and long continued palpitations in females" associated with enlargement of the thyroid gland. The disease is characterized by a triad of clinical findings:

- *Hyperthyroidism* associated with diffuse enlargement of the gland
- Infiltrative *ophthalmopathy* and resultant exophthalmos
- Localized, infiltrative *dermopathy,* sometimes called *pretibial myxedema,* which is present in a minority of patients

Graves disease has a peak incidence between 20 and 40 years of age. Women are affected as much as 10 times more frequently than men. This disorder is said to affect 1.5% to 2% of women in the United States.

Pathogenesis

Graves disease is an autoimmune disorder characterized by the production of autoantibodies against multiple thyroid proteins, most importantly the TSH receptor. A variety of antibodies that either stimulate or block the TSH receptor are detected in the circulation. The most common antibody subtype, known as *thyroid-stimulating immunoglobulin* (TSI), is observed in approximately 90% of patients. In contrast to antibodies against thyroglobulin and thyroid peroxidase, TSI is almost never observed in other autoimmune diseases of the thyroid. TSI binds to the TSH receptor and mimics its actions, stimulating adenyl cyclase and increasing the release of thyroid hormones. As stated earlier, TSH receptor blocking antibodies may also be present, and in a minority of patients these lead to hypothyroidism.

Perhaps unsurprisingly, factors that predispose to Graves disease overlap with risk factors for Hashimoto thyroiditis, the other major form of autoimmune thyroid disease. The concordance rate in monozygotic twins is 30% to 40%, compared with less than 5% among dizygotic twins, and similar to Hashimoto thyroiditis, genetic susceptibility is associated with polymorphisms in immune-function genes like *CTLA4, PTPN22,* and *IL2RA*. In addition, GWAS data has also implicated variants in the TSH receptor *(TSHR)* gene locus in susceptibility to Graves disease.

Autoimmunity also plays a role in the development of the *infiltrative ophthalmopathy* that is characteristic of Graves disease. Activated CD4+ helper T cells secrete cytokines that stimulate fibroblast proliferation and synthesis of extracellular matrix proteins (glycosaminoglycans), leading to progressive infiltration of the retro-orbital space and ophthalmopathy. The protrusion of the eyeball (exopthalmos) is caused by an increase in the volume of the retro-orbital connective tissues and extraocular muscles, which occurs for several reasons: (1) marked infiltration of connective tissue by mononuclear cells, predominantly T cells; (2) inflammation, edema, and swelling of extraocular muscles; (3) accumulation of extracellular matrix components, specifically hydrophilic glycosaminoglycans such as hyaluronic acid and chondroitin sulfate; and (4) increased numbers of adipocytes (fatty infiltration). These changes not only displace the eyeball but also may interfere with the function of the extraocular muscles.

MORPHOLOGY

The thyroid gland is usually symmetrically enlarged due to **diffuse hypertrophy and hyperplasia** of thyroid follicular epithelial cells (Fig. 24.13A). Increases in weight to over 80 g are not uncommon. On cut section, the parenchyma has a soft, meaty appearance resembling muscle. Histologically, the follicle epithelial cells in untreated cases are tall and more crowded than usual. This crowding often results in the formation of small papillae that project into the follicle lumen and encroach on the colloid, sometimes filling the follicles (Fig. 24.13B). Such papillae lack fibrovascular cores, in contrast to those of papillary carcinoma (see later). The colloid within the follicle lumen is pale, with scalloped margins. Lymphoid infiltrates, consisting predominantly of T cells, along with scattered B cells and mature plasma cells, are present throughout the interstitium. Germinal centers are common.

Preoperative therapy alters the morphology of the thyroid in Graves disease. Administration of iodine causes involution of the epithelium and the accumulation of colloid by blocking thyroglobulin secretion. Treatment with the antithyroid drug propylthiouracil exaggerates the epithelial hypertrophy and hyperplasia by stimulating TSH secretion.

Changes in extrathyroidal tissue include lymphoid hyperplasia, especially enlargement of the thymus in younger patients. The

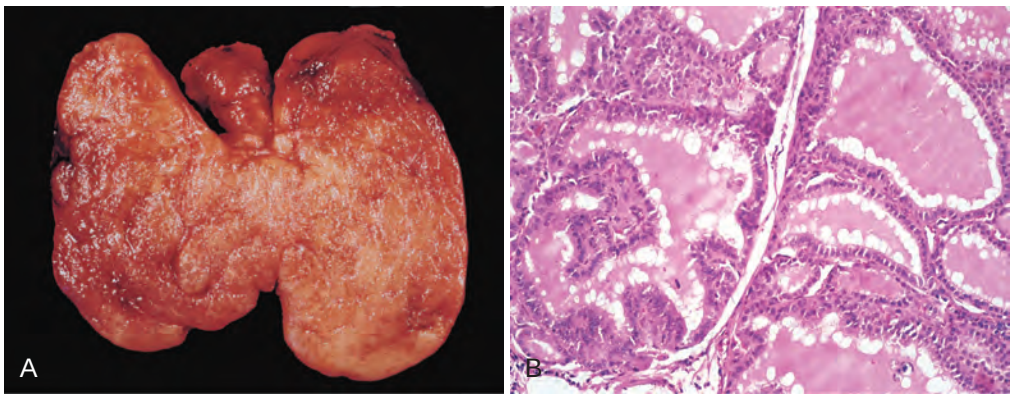

Figure 24.13 Graves disease. (A) There is diffuse symmetric enlargement of the gland and a beefy deep red parenchyma. Compare with gross photograph of multinodular goiter in Fig. 24.15. (B) Diffusely hyperplastic thyroid in a case of Graves disease. The follicles are lined by tall, columnar epithelium. The crowded, enlarged epithelial cells project into the lumens of the follicles. These cells actively resorb the colloid in the centers of the follicles, resulting in the scalloped appearance of the edges of the colloid. (A, Reproduced with permission from Lloyd RV, Douglas BR, Young WF Jr, editors: *Atlas of Nontumor Pathology: Endocrine Diseases*, Washington, DC, 2002, American Registry of Pathology.)

heart may be hypertrophied, and ischemic changes may be present, particularly in patients with preexisting coronary artery disease. In patients with ophthalmopathy, the tissues of the orbit are edematous because of the presence of hydrophilic mucopolysaccharides. In addition, there is infiltration by lymphocytes and fibrosis. Orbital muscles are edematous initially but may undergo fibrosis late in the course of the disease. The dermopathy, if present, is characterized by thickening of the dermis due to deposition of glycosaminoglycans and lymphocyte infiltration.

Clinical Features

The findings in Graves disease include changes associated with thyrotoxicosis and others associated uniquely with Graves disease, such as diffuse hyperplasia of the thyroid, ophthalmopathy, and dermopathy. The degree of thyrotoxicosis varies from case to case and is sometimes less conspicuous than other manifestations of the disease. Diffuse enlargement of the thyroid is present in all cases. The thyroid enlargement may be accompanied by increased flow of blood through the hyperactive gland, often producing an audible "bruit." Sympathetic overactivity produces a characteristic wide, staring gaze and lid lag, while the ophthalmopathy causes exophthalmos. The exophthalmos may persist or progress despite successful treatment of the thyrotoxicosis, sometimes resulting in corneal injury. The extraocular muscles are often weak. The infiltrative dermopathy *(pretibial myxedema)* is most common in the skin overlying the shins, where it presents as scaly thickening and induration. The basis of such localization is not clear, and it is present only in a minority of patients. Sometimes individuals spontaneously develop thyroid hypofunction. Patients are at increased risk for other autoimmune diseases, such as systemic lupus erythematosus, pernicious anemia, type 1 diabetes, and Addison disease.

Laboratory findings in Graves disease include elevated free T_4 and T_3 levels and depressed TSH levels. Because of ongoing stimulation by thyroid-stimulating immunoglobulins, radioiodine scans show a diffusely increased uptake of iodine in the thyroid gland.

Graves disease is treated with β-blockers, which dampen symptoms related to increased sympathetic nervous system activity (e.g., tachycardia, palpitations, tremulousness, and anxiety), and by measures that decrease thyroid hormone synthesis, such as the administration of thionamides (e.g., propylthiouracil), radioiodine ablation, and thyroidectomy. Surgery is used mostly in patients who have large goiters that are compressing surrounding structures.

KEY CONCEPTS

GRAVES DISEASE

- Graves disease, the most common cause of endogenous hyperthyroidism, is characterized by the triad of thyrotoxicosis, ophthalmopathy, and dermopathy.
- Graves disease is an autoimmune disorder caused by activation of thyroid epithelial cells by autoantibodies to the TSH receptor that mimic TSH action (thyroid-stimulating immunoglobulins).
- The thyroid in Graves disease shows diffuse hypertrophy and hyperplasia of follicles and lymphoid infiltrates; glycosaminoglycan deposition and lymphoid infiltrates are responsible for the ophthalmopathy and dermopathy.
- Laboratory features include elevations in serum free T_3 and T_4 and decreased serum TSH.

DIFFUSE AND MULTINODULAR GOITER

Enlargement of the thyroid, or goiter, is caused by impaired synthesis of thyroid hormone, which is most often the result of dietary iodine deficiency. Reduced thyroid hormone production leads to a compensatory rise in the serum TSH level, which, in turn, causes hypertrophy and hyperplasia of thyroid follicular cells and, ultimately, enlargement of the thyroid gland. This increase in functional mass of the gland usually overcomes the hormone deficiency, ensuring a euthyroid metabolic state in most individuals. If the underlying disorder is sufficiently severe

(e.g., a congenital biosynthetic defect or endemic iodine deficiency, discussed later), the compensatory responses may be inadequate, resulting in *goitrous hypothyroidism*. The degree of thyroid enlargement is proportional to the level and duration of thyroid hormone deficiency. Goiters can broadly be divided into two types: *diffuse nontoxic* and *multinodular*.

Diffuse Nontoxic (Simple) Goiter

Diffuse nontoxic (simple) goiter causes enlargement of the entire gland without producing nodularity. Because the enlarged follicles are filled with colloid, the term *colloid goiter* has been applied to this condition. This disorder occurs in both an endemic and a sporadic distribution.

- *Endemic goiter* occurs in geographic areas where the soil, water, and food supply contain low levels of iodine. The term endemic is used when goiters are present in more than 10% of the population in a given region. Such conditions are particularly common in mountainous areas of the world, including the Andes and Himalayas, where iodine deficiency is widespread. The lack of iodine leads to decreased synthesis of thyroid hormone and a compensatory increase in TSH, leading to follicular cell hypertrophy and hyperplasia and goitrous enlargement. With increasing dietary iodine supplementation, the frequency and severity of endemic goiter have declined significantly, although as many as 200 million people worldwide continue to be at risk for severe iodine deficiency.

  Variations in the prevalence of endemic goiter in regions with similar levels of iodine deficiency point to the existence of other causative influences, particularly dietary substances, referred to as *goitrogens*. The ingestion of substances that interfere with thyroid hormone synthesis at some level, such as vegetables belonging to the *Brassicaceae (Cruciferae)* family (e.g., cabbage, cauliflower, Brussels sprouts, turnips, and cassava), has been documented to be goitrogenic. Native populations subsisting on cassava root are particularly at risk. Cassava contains a thiocyanate that inhibits iodide transport within the thyroid, worsening any concurrent iodine deficiency.
- *Sporadic goiter* occurs less frequently than does endemic goiter. There is a striking female preponderance and a peak incidence at puberty or in young adult life. Sporadic goiter can be caused by several conditions, including the ingestion of substances that interfere with thyroid hormone synthesis. In other instances, goiter may result from hereditary enzymatic defects that interfere with thyroid hormone synthesis, all transmitted as autosomal recessive conditions (dyshormonogenetic goiter; see earlier). In most cases, however, the cause of sporadic goiter is not apparent.

MORPHOLOGY

Two phases can be identified in the evolution of diffuse nontoxic goiter: the **hyperplastic phase** and the phase of **colloid involution.** In the hyperplastic phase, the thyroid gland is diffusely and symmetrically enlarged, although the increase is usually modest, and the gland rarely exceeds 100 to 150 g. The follicles are lined by crowded columnar cells, which may pile up and form projections similar to those seen in Graves disease. The accumulation is not uniform throughout the gland, and some follicles are hugely distended, whereas others remain small. If dietary iodine subsequently increases or if the demand for thyroid hormone decreases, the stimulated follicle epithelium involutes to form an enlarged, colloid-rich gland **(colloid goiter).** In these cases, the cut surface of the thyroid is usually brown, somewhat glassy, and translucent. Histologically the follicle epithelium is flattened and cuboidal, and colloid is abundant during periods of involution.

Clinical Features

As stated earlier, most persons with simple goiters are clinically euthyroid. Therefore, the clinical manifestations are primarily related to *mass effects* from the enlarged thyroid gland (Fig. 24.14). Although serum T_3 and T_4 levels are normal, the serum TSH is usually elevated or at the upper range of normal, as is expected in marginally euthyroid individuals. In children, dyshormonogenetic goiter, caused by a congenital biosynthetic defect, may induce cretinism.

Multinodular Goiter

With time, recurrent episodes of hyperplasia and involution combine to produce a more irregular enlargement of the thyroid, termed *multinodular goiter*. Virtually all long-standing simple goiters convert into multinodular goiters. **Multinodular goiters produce the most extreme thyroid enlargements and are more frequently mistaken for neoplasms than any other form of thyroid disease.** Because they derive from simple goiter, they occur in both sporadic and endemic

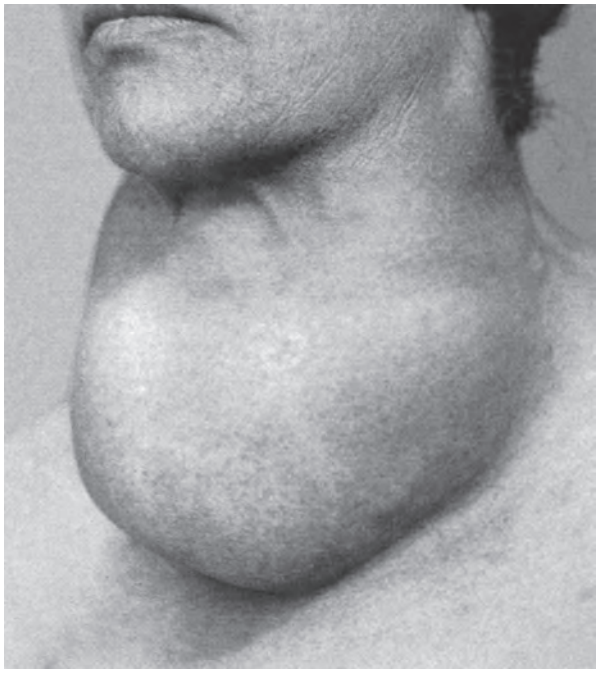

Figure 24.14 A 52-year-old woman with a huge colloid goiter who developed compressive symptoms. (Reproduced with permission from Lloyd RV, Douglas BR, Young WF Jr, editors: *Atlas of Nontumor Pathology: Endocrine Diseases*, Washington, DC, 2002, American Registry of Pathology.)

forms, having the same female-to-male distribution and presumably the same origins but affecting older individuals because they are late complications.

Pathogenesis

It is believed that multinodular goiters arise because of variations among follicular cells in their response to external stimuli, such as trophic hormones. If some cells in a follicle have a growth advantage, perhaps because of acquired genetic abnormalities similar to those that give rise to adenomas, they may begin to proliferate autonomously, producing a nodule. Consistent with this model, both polyclonal and monoclonal nodules coexist within the same multinodular goiter, the latter presumably having arisen because of the acquisition of a genetic abnormality favoring growth. Not surprisingly, activating mutations affecting proteins of the TSH signaling pathway have been identified in a subset of autonomous thyroid nodules (TSH signaling pathway mutations and their implications in adenomas are discussed later). The follicle hyperplasia and accumulation of colloid produce physical stress that may lead to rupture of follicles and vessels followed by hemorrhages, scarring, and calcifications. With scarring, nodularity appears, which may be accentuated by the preexisting stromal framework of the gland.

MORPHOLOGY

Multinodular goiters are multilobulated, asymmetrically enlarged glands that can reach weights of more than 2000 g. The pattern of enlargement is unpredictable and may involve one lobe far more than the other, producing pressure on midline structures, such as the trachea and esophagus. In other instances, the goiter grows behind the sternum and clavicles to produce the **intrathoracic** or **plunging goiter.** Occasionally, most of it is hidden behind the trachea and esophagus; in other instances, one nodule may stand out, mimicking a solitary tumor. On cut section, irregular nodules containing variable amounts of brown, gelatinous colloid are present (Fig. 24.15A). Older lesions have areas of hemorrhage, fibrosis, calcification, and cystic change. The microscopic appearance includes colloid-rich follicles lined by flattened, inactive epithelium and areas of **follicle hyperplasia,** accompanied by degenerative changes related to physical stress. In contrast to follicular neoplasms, a prominent capsule between the hyperplastic nodules and residual compressed thyroid parenchyma is not present (Fig. 24.15B).

Clinical Features

The dominant clinical features of multinodular goiter are those caused by mass effects. In addition to their cosmetic effects, goiters may cause airway obstruction, dysphagia, and compression of large vessels in the neck and upper thorax *(superior vena cava syndrome)*. Most patients are euthyroid or have subclinical hyperthyroidism (identified by reduced TSH levels), but about 10% of patients over a 10-year period develop an autonomous nodule within a long-standing goiter that produces hyperthyroidism *(toxic multinodular goiter)*, also known as *Plummer syndrome*. The incidence of malignancy in long-standing multinodular goiters is low (<5%) but not zero, and concern for malignancy arises in goiters that demonstrate sudden changes in size or symptoms (e.g., hoarseness). Dominant nodules in a multinodular goiter can present as a "solitary thyroid nodule," mimicking a thyroid neoplasm. A radioiodine scan demonstrates uneven iodine uptake (including the occasional "hot" autonomous nodule), consistent with an admixture of hyperplastic and involuting nodules. A fine-needle aspiration biopsy is helpful and can often, albeit not always, distinguish between follicular hyperplasia and thyroid neoplasm (see later).

NEOPLASMS OF THE THYROID

The solitary thyroid nodule is a palpably discrete swelling within an otherwise apparently normal thyroid gland. The estimated incidence of solitary palpable nodules in the adult population of the United States varies between 1% and 10%, but it is significantly higher in endemic goitrous regions. Single nodules are about four times more common in women than in men. The incidence of thyroid nodules increases throughout life.

From a clinical standpoint, the major concern in persons who present with thyroid nodules is the possibility of a malignant neoplasm. Fortunately, the overwhelming majority of solitary nodules of the thyroid prove to be localized, nonneoplastic lesions (e.g., a dominant nodule in multinodular goiter, simple cysts, or foci of thyroiditis) or benign neoplasms such as follicular adenoma. In fact, benign neoplasms outnumber thyroid carcinomas by a ratio of nearly 10:1. While only 1% of solitary thyroid nodules are

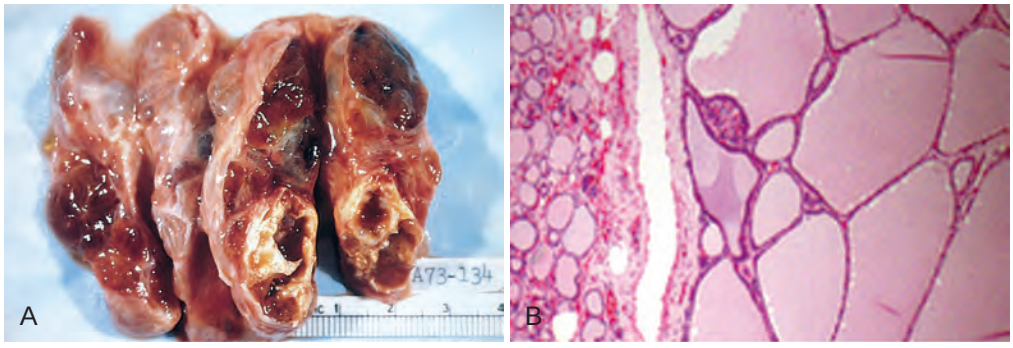

Figure 24.15 Multinodular goiter. (A) Gross morphology demonstrating a coarsely nodular gland containing areas of fibrosis and cystic change. (B) Photomicrograph of a hyperplastic nodule with compressed residual thyroid parenchyma on the periphery. Note the absence of a prominent capsule, a distinguishing feature from follicular neoplasms. (B, Courtesy Dr. William Westra, Department of Pathology, Johns Hopkins University, Baltimore, Md.)

malignant, this still represents about 15,000 new cases of thyroid carcinoma per year in the United States. Fortunately, most of these cancers are indolent; more than 90% of affected patients are alive 20 years after being diagnosed.

Several criteria provide clues to the nature of a thyroid nodule:

- *Solitary nodules, nodules in younger patients, and nodules in males* are more likely to be neoplastic.
- A history of *radiation treatment* to the head and neck region is associated with an increased incidence of thyroid malignancy.
- Functional nodules that take up radioactive iodine in imaging studies *(hot nodules)* are much more likely to be benign.

These associations and statistics, however, are of little comfort to a patient, in whom the timely recognition of a malignancy can be lifesaving. Ultimately, morphologic evaluation of a given thyroid nodule by fine-needle aspiration or surgical resection provides the most definitive information about its nature. The following sections consider the major thyroid neoplasms.

Thyroid Adenomas

Adenomas of the thyroid are typically discrete, solitary masses, derived from follicle epithelium, and hence they are also known as follicular adenomas. Clinically, follicular adenomas can be difficult to distinguish from dominant nodules of follicular hyperplasia or from the less common follicular carcinomas. In general, follicular adenomas are *not* forerunners to carcinomas; nevertheless, shared genetic alterations raise the possibility that at least a subset of follicular carcinomas arises in preexisting adenomas (see later). Although the vast majority of adenomas are nonfunctional, a small minority produces thyroid hormones and causes clinically apparent thyrotoxicosis. Hormone production in functional adenomas (called *toxic adenomas*) is independent of TSH stimulation.

Pathogenesis

Somatic mutations that lead to constitutive activation of the TSH receptor signaling pathway are found in toxic adenomas and toxic multinodular goiter. Gain-of-function mutations—most often in the gene encoding the TSH receptor *(TSHR),* and less commonly, the α-subunit of G_s *(GNAS)*—cause follicular cells to secrete thyroid hormone independent of TSH stimulation ("thyroid autonomy"). This leads to hyperthyroidism and produces a functional "hot" nodule on imaging. Overall, such mutations are present in 50% to 80% of toxic thyroid adenomas. Approximately one-third of toxic adenomas also harbor activating mutations of enhancer of zeste, homolog 1 (*EZH1*), which encodes a histone methyltransferase that functions as an epigenetic regulator of gene expression. Notably, *TSHR, GNAS,* and *EZH1* mutations are rarely seen in follicular carcinomas; thus, toxic adenomas (and toxic multinodular goiters) do not seem to be precancerous lesions.

In contrast, a minority (20% to 40%) of nonfunctioning follicular adenomas harbor oncogenic mutations of *RAS,* and a smaller percentage (5% to 10%) express fusion proteins containing the nuclear receptor PPARγ. Notably, both genetic alterations are seen at greater frequencies in follicular carcinomas, suggesting that nonfunctioning adenomas carrying these alterations are precursors to carcinomas. These are discussed in further detail later in this chapter.

MORPHOLOGY

The typical thyroid adenoma is a solitary, spherical, encapsulated lesion that is demarcated by a well-defined, intact capsule (Fig. 24.16A). By contrast, as the name implies, multinodular goiter contains numerous nodules, even in patients presenting with a solitary dominant nodule. Follicular adenomas average about 3 cm in diameter, but some are much larger (≥10 cm in diameter). In freshly resected specimens, the adenoma bulges from the cut surface and compresses the adjacent thyroid. The color ranges from gray-white to red-brown, depending on the cellularity of the adenoma and its colloid content. Areas of hemorrhage, fibrosis, calcification, and cystic change, similar to those encountered in multinodular goiters, are common in follicular adenomas, particularly within larger lesions.

Microscopically, the constituent cells often form uniform-appearing follicles that contain colloid (Fig. 24.16B). The follicular growth pattern is usually quite distinct from the adjacent nonneoplastic thyroid. The neoplastic cells show little variation in cell size, shape, or nuclear morphology, and mitotic figures are rare. Occasionally the neoplastic cells acquire brightly eosinophilic granular cytoplasm (**oxyphil** or **Hürthle cell change**) (Fig. 24.17). The hallmark of all follicular adenomas is the presence of an

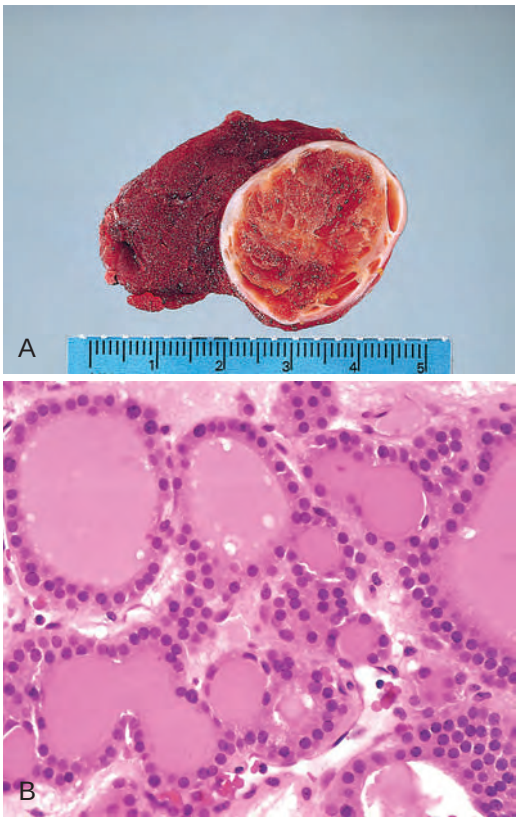

Figure 24.16 Follicular adenoma of the thyroid. (A) A solitary, well-circumscribed nodule is seen. (B) The photomicrograph shows well-differentiated follicles resembling normal thyroid parenchyma.

intact, well-formed capsule encircling the tumor. **Careful evaluation of the integrity of the capsule is therefore critical in distinguishing follicular adenoma from follicular carcinoma,** which demonstrates capsular and/or vascular invasion (see later). Mitotic activity, necrosis, or high cellularity also warrants close inspection to exclude follicular carcinoma and the encapsulated follicular variant of papillary carcinoma (see later).

Clinical Features

Many follicular adenomas present as solitary painless masses that are discovered on routine physical examination. Larger masses may produce local symptoms, such as difficulty in swallowing. Nonfunctioning adenomas take up less radioactive iodine than does normal thyroid parenchyma and on radionuclide scanning appear as cold nodules. Other techniques used to evaluate suspected adenomas are ultrasonography and fine-needle aspiration biopsy. **Because of the need for evaluating capsular integrity, the definitive diagnosis of adenoma can be made only after careful histologic examination of the resected specimen.** Suspected adenomas of the thyroid are therefore removed surgically to exclude malignancy. Follicular adenomas do not recur or metastasize and have an excellent prognosis.

Thyroid Carcinomas

It is estimated that there were than 52,000 new cases of thyroid cancer in the United States in 2019, and about 2000 individuals succumbed to the disease. The rate of newly diagnosed thyroid cancer has been rising dramatically (currently, at the rate of 3% increase in incidence each year in the United States), and in countries like South Korea, which has seen a veritable "epidemic" of thyroid cancer, it is the most common cause of newly diagnosed cancer in women. In contrast to the rising rates of newly diagnosed cancer, mortality from this disease is one of the lowest among solid tumors, with a 5-year survival greater than 98%. The major reason for this good outcome is that many of these cancers are found incidentally during neck palpation or by ultrasonography, and consist of small, localized lesions (typically papillary cancers) that have an excellent prognosis. To address this so-called "overdiagnosis" of thyroid cancer, the nomenclature of a subset of papillary cancers has undergone an important change in the past 2 years (see later).

The major subtypes of thyroid carcinoma and their relative frequencies are as follows:

- *Papillary thyroid carcinoma* (PTC), including "conventional" PTC and the "encapsulated follicular variant" (80% to 85%% of cases). This category includes the newly described lesion known as *"noninvasive follicular thyroid neoplasm with papillary-like nuclear features,"* a low-grade neoplasm with such a minimal risk of recurrence that "carcinoma" has been removed from its name.
- *Follicular carcinoma* (10% to 15% of cases)
- *Poorly differentiated* and *anaplastic (undifferentiated) carcinoma* (<5% of cases)
- *Medullary carcinoma* (5% of cases)

Most thyroid carcinomas are derived from thyroid follicle epithelium (except medullary carcinoma, which is derived from parafollicular C cells), and, of these, the vast majority are well-differentiated lesions. In the past decade, with increasing knowledge of the molecular pathology of follicular neoplasms, the concept of "multistep pathogenesis" from precursor lesions, which is well established in other epithelial cancers, has gained greater acceptance. In particular, the following three precursor lesion relationships have been recognized:

- Papillary microcarcinoma as a precursor to conventional PTC
- Noninvasive thryoid neoplasma with papillary-like nuclear features as a precursor to invasive encapsulated follicular variant PTC
- Nonfunctioning follicular adenoma as a precursor to follicular carcinoma

Further, it is now accepted that most poorly differentiated and anaplastic (undifferentiated) carcinomas arise from well-differentiated PTC or follicular carcinomas, through acquisition of additional mutations. These aggressive neoplasms and medullary thyroid carcinomas are the major causes of mortality from thyroid cancer.

We begin with a discussion of the molecular pathogenesis of thyroid neoplasms.

Pathogenesis

Driver Mutations. Distinct sets of driver mutations in cancer genes are found in the four major histologic variants of thyroid cancer. Among follicular neoplasms, there are both unique and shared genetic alterations between the histologic subtypes (Fig. 24.18), most of which involve components of the receptor tyrosine kinase (RTK) pathway, which you will recall is frequently mutated in many different cancers (Chapter 7). As is also true with other epithelial neoplasms, precursor lesions (listed earlier) share genetic alterations with the corresponding variant of carcinoma, albeit at a lower frequency.

- *Conventional papillary thyroid carcinomas.* Conventional PTCs have two defining genetic abnormalities: translocations that result in gene fusions of *RET* or *NTRK,* and point mutations in *BRAF* (see Fig. 24.18).

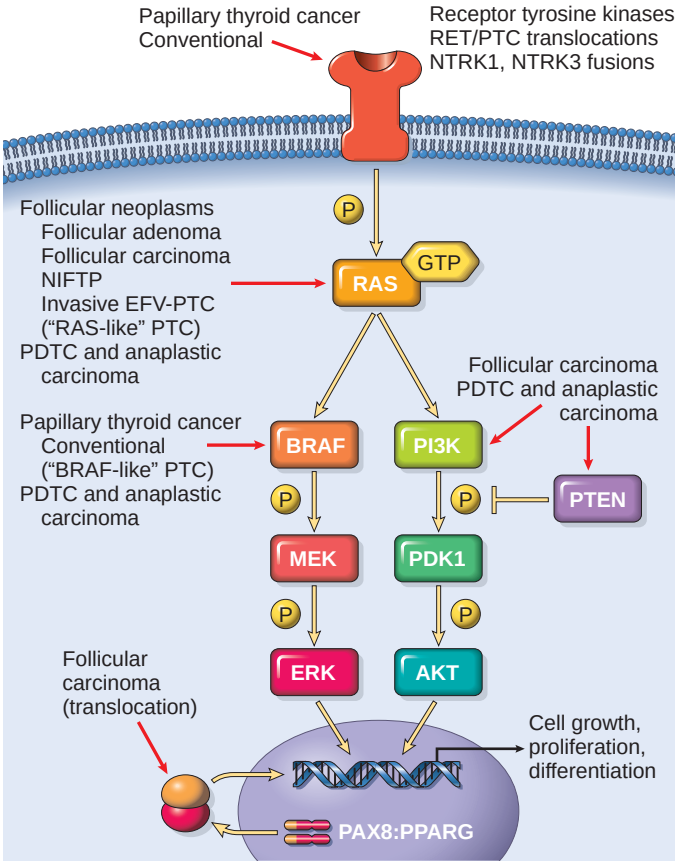

Figure 24.18 Genetic alterations in follicle cell–derived neoplasms of the thyroid gland. *EFV-PTC*, Encapsulated follicular variant of papillary thyroid carcinoma; *NIFTP*, noninvasive follicular thyroid neoplasm with papillary-like nuclear features; *PDTC*, poorly differentiated thyroid carcinoma.

- The *RET* gene is located on chromosome 10q11, and encodes an RTK that is normally not expressed in thyroid follicular cells. As with many other RTKs implicated in cancer, PTC rearrangements involving *RET* create fusion genes that encode constitutively active forms of RET tyrosine kinase. There are more than 15 fusion partners of *RET*, and two—designated *PTC1* and *PTC2*—are most commonly observed in sporadic papillary cancers. Similarly, paracentric inversions or translocations of *NTRK1*, another gene encoding a receptor tyrosine kinase on chromosome 1q21, are present in ~5% of PTCs. These rearrangements also produce constitutively active NTRK1 fusion proteins.
- Between 50% and 80% of conventional PTCs harbor gain-of-function mutations in the *BRAF* gene, most commonly a valine-to-glutamate change in codon 600 ($BRAF^{V600E}$). BRAF encodes a serine/threonine kinase that lies downstream of receptor tyrosine kinases in growth factor signaling pathways. In a subtype of conventional PTCs, known as "tall cell variant" (see later), $BRAF^{V600E}$ mutations are virtually a diagnostic *sine qua non*. The presence of *BRAF* mutations in conventional PTCs is associated with reduced expression of thyroid differentiation markers (such as thyroglobulin and thyroid peroxidase) and may be associated with a higher risk of extrathyroidal extension and recurrence. As discussed elsewhere, the $BRAF^{V600E}$ mutation is found in many other cancers including melanoma and hairy cell leukemia (Chapter 7).
- *Follicular neoplasms.* In contrast to papillary carcinomas, follicular neoplasms are often associated with gain-of-function mutations in *RAS*. Neoplasms with *RAS* mutations retain expression of thyroid differentiation factors (e.g., thyroglobulin, thyroid peroxidase), which may contribute to their follicular growth pattern. Overall, approximately 20% to 40% of follicular adenomas and 30% to 50% of follicular carcinomas harbor *RAS* mutations (see Fig. 24.18). Similarly, approximately one-half of invasive encapsulated follicular variants of PTC and their putative precursor, noninvasive follicular thyroid neoplasm with papillary-like nuclear features, demonstrate *RAS* point mutations.

  A unique (2;3)(q13;p25) translocation has been described in 20% to 50% of follicular carcinomas and ~10% of follicular adenomas. This translocation creates a fusion gene composed of portions of *PAX8*, a paired homeobox gene that is important in thyroid development, and the peroxisome proliferator–activated receptor gene *(PPARG)*, which encodes a nuclear hormone receptor implicated in terminal differentiation of thyrocytes. Some noninvasive follicular thyroid neoplasms with papillary-like nuclear features and invasive encapsulated follicular variant of PTC (up to one-third in some series) also harbor *PAX8-PPARG* fusion genes, which are almost never seen in poorly differentiated or anaplastic carcinomas. Finally, up to 10% of follicular carcinomas exhibit gain-of-function mutations of *PIK3CA* (the gene that encodes phosphoinositide 3-kinase [PI3K]) or loss-of-function mutations of *PTEN*, a tumor suppressor gene and negative regulator of this pathway (see Fig. 24.18).
- *Poorly differentiated and anaplastic (undifferentiated) carcinomas.* These highly aggressive and lethal tumors can arise *de novo*, or, much more commonly, by "de-differentiation" of a papillary or follicular thyroid carcinoma. In addition to driver mutations that are also seen in well-differentiated thyoid cancers, three recurrent genetic "hits"—point mutations of *TP53*, beta-catenin *(CTNNB1)*, and *TERT* (which encodes the catalytic component of the enzyme telomerase)—are essentially restricted to poorly differentiated and anaplastic carcinomas and likely have central roles in their genesis and aggressive behavior.
- *Medullary thyroid carcinomas.* Familial medullary thyroid carcinomas occur in multiple endocrine neoplasia, type 2 (MEN-2, see later) and are associated with germline *RET* mutations that lead to constitutive activation of the receptor. *RET* mutations are also seen in approximately one-half of nonfamilial (sporadic) medullary thyroid cancers. Chromosomal rearrangements involving *RET*, such as the *RET/PTC* translocations reported in papillary cancers, are not seen in medullary carcinomas.

Environmental Factors. The major risk factor predisposing to thyroid cancer is exposure to *ionizing radiation*, particularly during the first two decades of life. In keeping with this, there was a marked increase in the incidence of conventional PTCs among children exposed to ionizing radiation after the Chernobyl nuclear disaster in 1986. Of

interest, radiation-induced PTCs have a higher frequency of chromosome rearrangements that produce gene fusions, possibly because of the ability of ionizing radiation to induce double-stranded DNA breaks. Deficiency of dietary iodine (and by extension, goiter) is associated with a higher frequency of follicular lesions.

Papillary Carcinoma and Follicular Variants, Including Invasive Encapsulated Follicular Variant of PTC and Noninvasive Follicular Thyroid Neoplasm With Papillary-like Nuclear Features

Papillary carcinomas are the most common form of thyroid cancer, accounting for nearly 85% of cases in the United States. They occur throughout life but most often between 25 and 50 years of age, and account for the majority of thyroid carcinomas associated with previous exposure to ionizing radiation. The incidence of papillary carcinoma has increased markedly in the last 30 years, partly because of the rise in detection of papillary microcarcinomas and noninvasive encapsulated variants found incidentally during neck examination.

MORPHOLOGY

Conventional papillary carcinomas may be solitary or multifocal. Some tumors are well circumscribed, while others infiltrate the adjacent parenchyma and have ill-defined margins. The tumors may contain areas of fibrosis and calcification and are often cystic. The cut surface sometimes reveals papillary foci that point to the diagnosis. **Papillary microcarcinoma** is defined as an otherwise conventional papillary carcinoma, but less than 1 cm in size. As stated earlier, they are considered putative precursor lesions of more typical papillary carcinomas.

The microscopic hallmarks of papillary neoplasms include the following (Fig. 24.19):

- Branching **papillae** having a fibrovascular stalk covered by a single to multiple layers of cuboidal epithelial cells. In most neoplasms, the epithelium covering the papillae consists of well-differentiated, uniform, orderly cuboidal cells, but at the other extreme are those with fairly anaplastic epithelium showing considerable variation in cell and nuclear morphology. When present, the papillae differ from those seen in areas of hyperplasia in being more complex and having dense fibrovascular cores.
- Nuclei with finely dispersed chromatin and an optically clear or empty appearance, giving rise to the designation **ground-glass** or **Orphan Annie eye nuclei.** In addition, invaginations of the nuclear membrane may give the appearance of nuclear inclusions ("pseudo-inclusions") or grooves. **The diagnosis of papillary carcinoma can be made based on these nuclear features,** even in the absence of papillary architecture.
- Concentrically calcified structures termed **psammoma bodies** are often present, usually within the cores of papillae. These

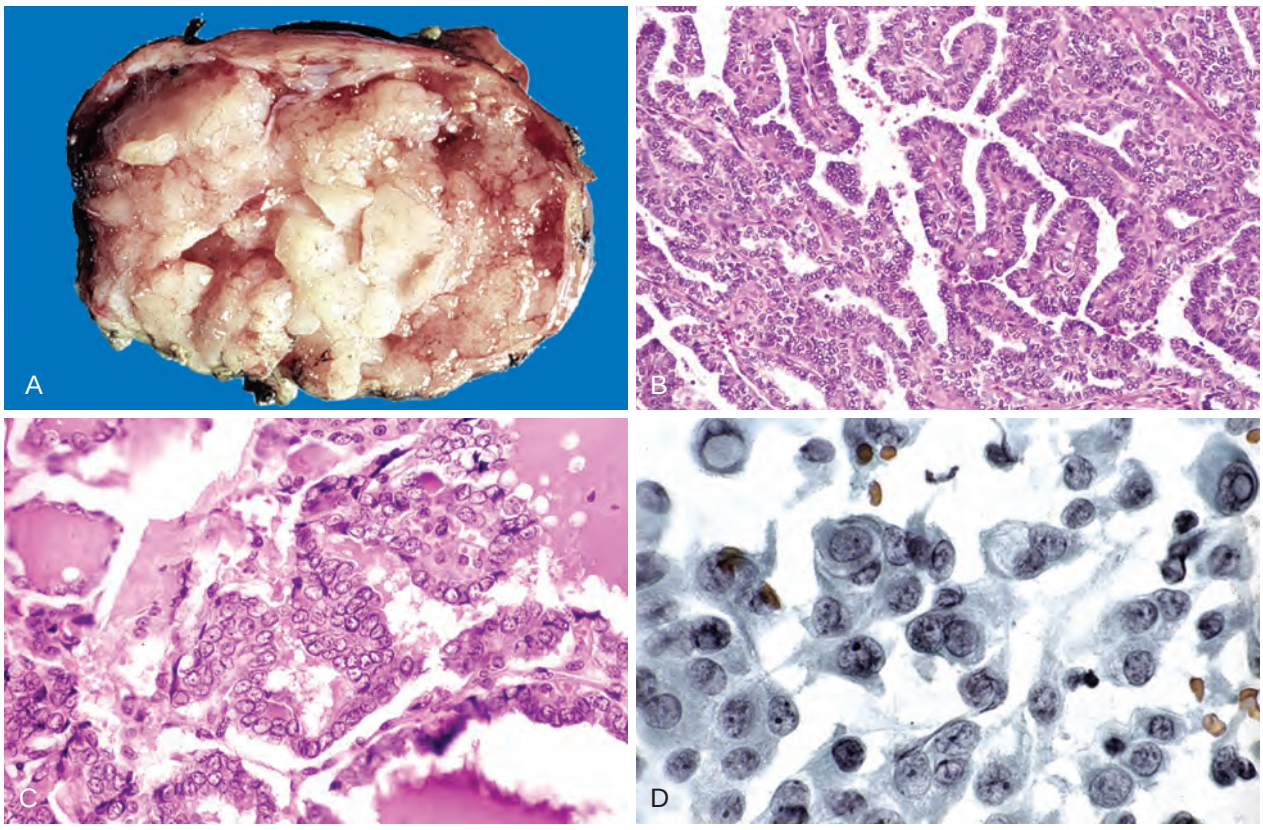

Figure 24.19 Papillary carcinoma of the thyroid. (A) The macroscopic appearance of a papillary carcinoma with grossly discernible papillary structures. (B) This particular example contains well-formed papillae. (C) High power shows cells with characteristic empty-appearing nuclei, sometimes called "Orphan Annie eye" nuclei. (D) Cells obtained by fine-needle aspiration of a papillary carcinoma. Characteristic intranuclear inclusions are visible in some of the aspirated cells.

structures are almost never found in follicular and medullary carcinomas, and they are a strong indication that the lesion is a papillary carcinoma when present in fine-needle aspiration material.

- Foci of lymphatic invasion by tumor are often present, but involvement of blood vessels is uncommon, particularly in smaller lesions. Metastases to adjacent cervical lymph nodes occur in up to one-half of cases.

There are over a dozen histologic variants of papillary carcinoma that can mimic other thyroid lesions or harbor distinct prognostic implications; most are beyond the scope of this book. The **tall cell variant** has tall columnar cells with intensely eosinophilic cytoplasm. These tumors tend to occur in older individuals and have higher frequencies of vascular invasion, extrathyroidal extension, and cervical and distant metastases than conventional PTC. Tall cell variant papillary carcinomas almost always harbor *BRAF* mutations, and often have *RET/PTC* translocations as well. The co-occurrence of these two aberrations may contribute to the aggressive behavior of this variant.

An unusual **diffuse sclerosing variant** of papillary carcinoma occurs in younger individuals, including children. The tumor has a prominent papillary growth pattern intermixed with solid areas containing nests of squamous metaplasia. As the name suggests, there is extensive, diffuse fibrosis throughout the thyroid gland, often associated with a prominent lymphocytic infiltrate, simulating Hashimoto thyroiditis. Lymph node metastases are present in almost all cases. The diffuse sclerosing variant carcinomas lack *BRAF* mutations, but *RET/PTC* translocations are found in approximately one-half of cases.

The **follicular variant of PTC** has the characteristic nuclear features of papillary carcinoma and an almost totally follicular architecture. As mentioned earlier, genetic analyses have shown that encapsulated follicular variants of PTC harbor distinct molecular abnormalities from conventional PTCs. As already discussed, encapsulated follicular variants of papillary thyroid cancer without capsular invasion are designated noninvasive follicular thyroid carcinoma with papillary-like nuclear features and have a very low risk of recurrence or metastasis, whereas invasive tumors are referred to as invasive encapsulated follicular variant of papillary thyroid carcinoma.

Clinical Features

Most conventional papillary carcinomas present as asymptomatic thyroid nodules, but the first manifestation may be a mass in a cervical lymph node. Interestingly, the presence of isolated cervical nodal metastases does not have a significant impact on prognosis, which is generally good. Most carcinomas are single nodules that move freely with the thyroid gland during swallowing and are not distinguishable on examination from benign nodules. Hoarseness, dysphagia, cough, or dyspnea suggests advanced disease. In a minority of patients, hematogenous metastases are present at the time of diagnosis, most commonly in the lung.

A variety of diagnostic tests have been used to help separate benign from malignant thyroid nodules, including radionuclide scanning and fine-needle aspiration. Papillary carcinomas are cold masses on scintigraphy. Improvements in cytologic analysis have made fine-needle aspiration cytology a reliable test for distinguishing between benign and malignant nodules.

Papillary thyroid cancers have an excellent prognosis, with a 10-year survival rate in excess of 95%. Patients with papillary microcarcinomas and noninvasive follicular thyroid neoplasms with papillary-like nuclear features have an outstanding prognosis on lobectomy alone, and they typically do not require total thyroidectomy. This has become especially important since thyroidectomy may lead to vocal cord palsy (due to injury to the laryngeal nerve) and iatrogenic hypoparathyroidism.

Between 5% and 20% of patients with more typical PTCs have local or regional recurrences, and 10% to 15% have distant metastases. The prognosis is dependent on several factors including age (in general, being less favorable among patients older than 40 years), presence of extrathyroidal extension, and presence of distant metastases (stage).

Follicular Carcinoma

Follicular carcinoma accounts for 5% to 15% of primary thyroid cancers; it is more frequent in areas with dietary iodine deficiency, where it constitutes 25% to 40% of thyroid cancers. It is more common in women (3:1) and presents more often in older patients than does papillary carcinoma; the peak incidence is between 40 and 60 years of age.

MORPHOLOGY

Follicular carcinomas are single nodules that may be well circumscribed or widely infiltrative (Fig. 24.20A). Sharply demarcated lesions may be exceedingly difficult to distinguish from follicular adenomas by gross examination. Larger lesions may penetrate the capsule and infiltrate into the adjacent neck. They are gray to tan to pink on cut section and may be translucent due to the presence of large, colloid-filled follicles. Degenerative changes, such as central fibrosis and foci of calcification, may be present.

Microscopically, most follicular carcinomas are composed of fairly uniform cells forming small follicles containing colloid, quite reminiscent of normal thyroid (Fig. 24.20B). In other cases, follicular differentiation may be less apparent, and there may be nests or sheets of cells without colloid. Occasional tumors are dominated by cells with abundant granular, eosinophilic cytoplasm **(Hürthle cell or oncocytic variant of follicular carcinoma).** Whatever the pattern, the nuclei lack the features typical of papillary carcinoma, and psammoma bodies are not present. **There is no reliable cytologic difference between follicular adenomas and minimally invasive follicular carcinomas**. Making this distinction requires extensive histologic sampling of the tumor capsule to exclude capsular and/or vascular invasion (Fig. 24.21). The criterion for vascular invasion is applicable only to capsular vessels and vascular spaces beyond the capsule; the presence of tumor plugs within intra-tumoral blood vessels has little prognostic significance. Unlike in papillary cancers, lymphatic spread is uncommon in follicular cancers. By contrast, the diagnosis of carcinoma is obvious in widely invasive follicular carcinomas, which infiltrate the thyroid parenchyma and extrathyroidal soft tissues. Histologically, these cancers tend to have a greater proportion of solid or trabecular growth pattern, less evidence of follicular differentiation, and increased mitotic activity.

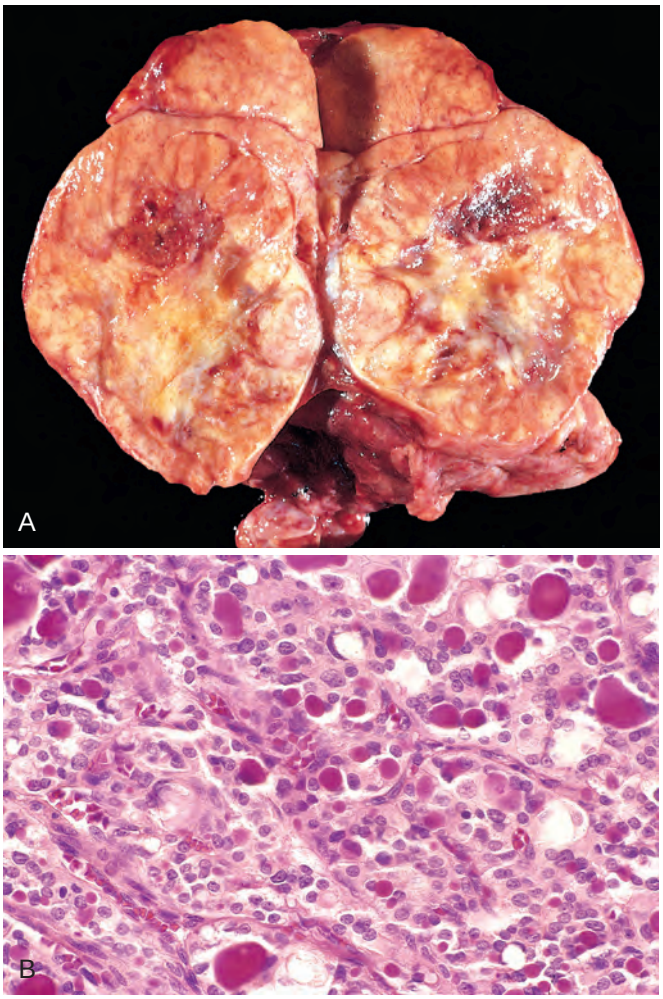

Figure 24.20 Follicular carcinoma. (A) Cut surface of a follicular carcinoma with substantial replacement of the lobe of the thyroid. The tumor has a light-tan appearance and contains small foci of hemorrhage. (B) A few of the glandular lumens contain recognizable colloid.

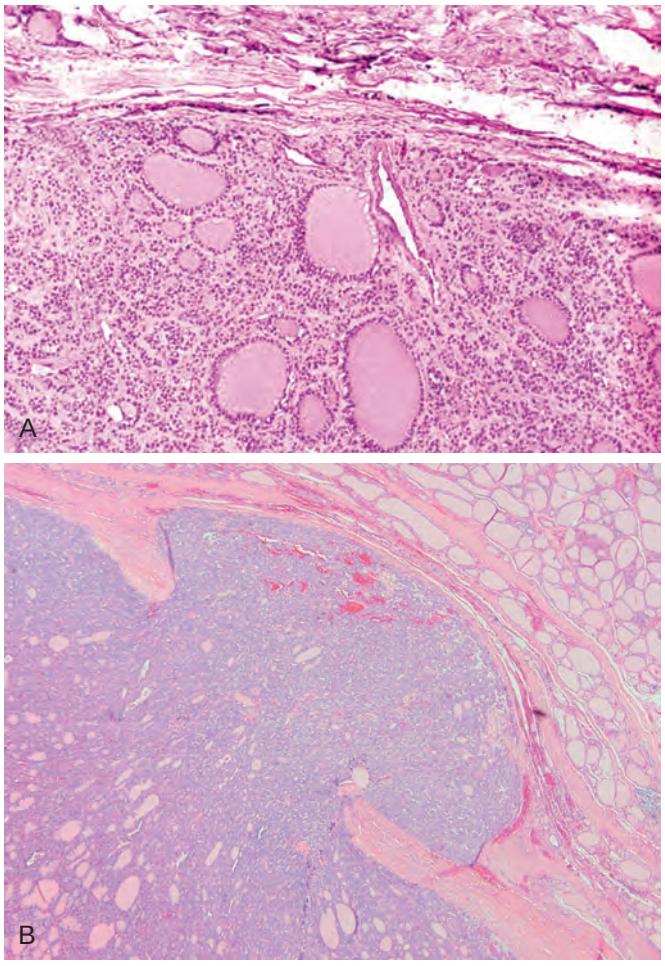

Figure 24.21 Capsular integrity in follicular neoplasms. In adenomas (A), a fibrous capsule, usually thin but occasionally more prominent, circumferentially surrounds the neoplastic follicles, and no capsular invasion is seen; compressed normal thyroid parenchyma is usually present external to the capsule *(top of panel)*. In contrast, follicular carcinomas demonstrate capsular invasion (B) that may be minimal, as in this case, or widespread. The presence of vascular invasion is another feature of follicular carcinomas.

Clinical Features

Follicular carcinomas present as slowly enlarging painless nodules. Most frequently they are cold nodules on scintigrams, although rare, better-differentiated lesions may be hyperfunctional, take up radioactive iodine, and appear warm on scintigraphy. Because follicular carcinomas have little propensity for invading lymphatics, regional lymph nodes are typically not involved, while vascular (hematogenous) dissemination is common, with metastases to bone, lungs, liver, and elsewhere.

The prognosis depends largely on the extent of invasion and stage at presentation. Widely invasive follicular carcinoma often presents with systemic metastases, and as many as one-half of affected patients succumb to their disease within 10 years. This is in sharp contrast to minimally invasive follicular carcinomas, which have a 10-year survival rate of greater than 90%. Most follicular carcinomas are treated with total thyroidectomy followed by the administration of radioactive iodine, which can be used to identify metastases and to ablate such lesions. In addition, because any residual follicular carcinoma may respond to TSH stimulation, patients are usually treated with thyroid hormone after surgery to suppress endogenous TSH levels. Serum thyroglobulin levels are used for monitoring tumor recurrence, because this thyroid protein should be barely detectable in a patient who is free of disease.

Poorly Differentiated and Anaplastic (Undifferentiated) Carcinoma

Poorly differentiated and anaplastic (undifferentiated) carcinomas represent aggressive neoplasms of the thyroid follicular epithelium, cumulatively accounting for less than 5% of thyroid tumors, but with a high mortality rate (approaching 100% for anaplastic lesions). Patients with either carcinoma are older than those with other types of thyroid cancer, with a mean age of 65 years. Approximately

one-fourth of patients with poorly differentiated or anaplastic thyroid carcinomas have a past history of a well-differentiated follicular neoplasm, and another one-fourth harbor a concurrent well-differentiated neoplasm in the resected specimen.

MORPHOLOGY

Microscopically, poorly differentiated carcinomas are composed of cells with minimal follicular differentiation, arranged in insular or trabecular growth patterns; intratumoral necrosis and frequent mitoses are often seen. Anaplastic carcinomas demonstrate variable morphology, including (1) large, pleomorphic **giant cells,** including occasional osteoclast-like multinucleate giant **cells;** (2) **spindle cells** with a sarcomatous appearance; and (3) **mixed spindle and giant cells.** Foci of papillary or follicular differentiation may be present in some tumors, suggesting an origin from a well-differentiated carcinoma. The neoplastic cells express epithelial markers like cytokeratin, but are usually negative for markers of thyroid differentiation, like thyroglobulin.

Clinical Features

Poorly differentiated and anaplastic carcinomas usually present as rapidly enlarging bulky neck masses. In most cases, the disease has spread beyond the thyroid into adjacent neck structures or has metastasized to the lungs at the time of presentation. Symptoms related to compression and invasion of adjacent structures, such as dyspnea, dysphagia, hoarseness, and cough, are common. Anaplastic carcinomas of the thyroid are one of the most aggressive cancers known; in most cases death occurs in less than 1 year. Poorly differentiated carcinomas fare somewhat better with radical surgery, external beam radiotherapy, and radioactive iodine. More recently, immunotherapy using immune checkpoint inhibitors has been used in these neoplasms in an attempt to improve their dire prognosis.

Medullary Carcinoma

Medullary carcinomas of the thyroid are neuroendocrine neoplasms derived from the parafollicular cells (C cells). They account for approximately 5% of thyroid neoplasms. Medullary carcinomas, like normal C cells, secrete *calcitonin,* the measurement of which plays an important role in the diagnosis and postoperative follow-up of patients. Calcitonin is a regulator of calcium metabolism. It is normally produced in response to hypercalcemia, and it reduces serum calcium by inhibiting osteoclast activity and renal tubular reabsorption of calcium. In some instances, the tumor cells elaborate other polypeptide hormones, such as serotonin, ACTH, and vasoactive intestinal peptide (VIP). About 70% of tumors arise sporadically. The remainder occur in the setting of MEN-2A or MEN-2B syndromes. Recall that activating point mutations in the *RET* proto-oncogene play an important role in the development of both familial and sporadic medullary carcinomas. Cases associated with MEN-2A or MEN-2B occur in younger patients, and they may even arise during the first decade of life. In contrast, sporadic and familial medullary carcinomas are neoplasms of adulthood, with a peak incidence in the 40s and 50s.

MORPHOLOGY

Sporadic medullary thyroid carcinomas present as a solitary nodule (Fig. 24.22A). In contrast, **bilaterality and multicentricity are common in familial cases.** Larger lesions often contain areas of necrosis and hemorrhage and may extend through the capsule of the thyroid. The tumors are firm, pale gray to tan, and infiltrative. There may be foci of hemorrhage and necrosis in larger lesions.

Microscopically, medullary carcinomas are composed of polygonal to spindle-shaped cells, which may form nests, trabeculae, and even follicles. Small, more anaplastic cells are present in some tumors and may be the predominant cell type. **Amyloid deposits** derived from calcitonin polypeptides are present in the stroma in many cases (Fig. 24.22B). Calcitonin is readily demonstrable within the cytoplasm of the tumor cells as well as in the stromal amyloid by immunohistochemical methods. As with all neuroendocrine tumors, electron microscopy reveals variable numbers of membrane-bound electron-dense granules within the cytoplasm of the neoplastic cells (Fig. 24.23). One of the features of familial

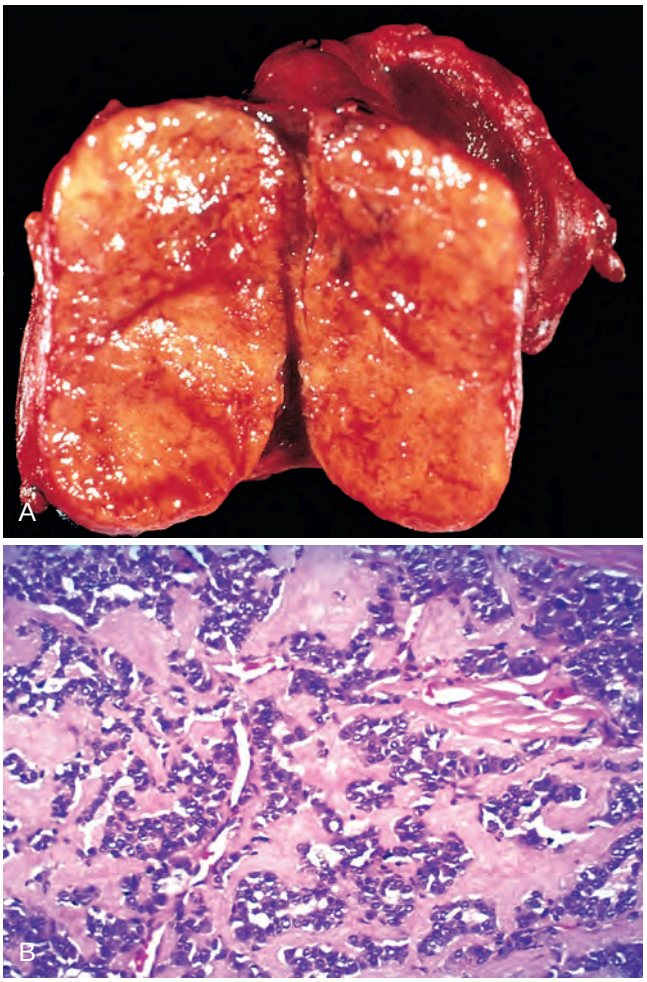

Figure 24.22 Medullary carcinoma of the thyroid. (A) These tumors typically show a solid pattern of growth and do not have connective tissue capsules. (B) Histology demonstrates abundant deposition of amyloid, visible here as homogeneous extracellular material, derived from calcitonin secreted by the neoplastic cells. (A, Courtesy Dr. Joseph Corson, Brigham and Women's Hospital, Boston, Mass.)

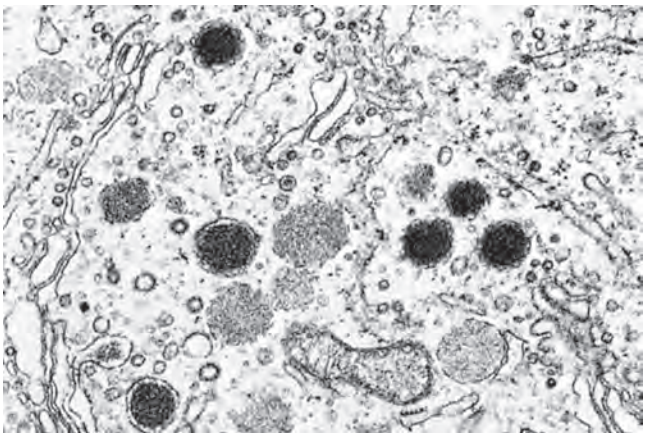

Figure 24.23 Electron micrograph of medullary thyroid carcinoma. These cells contain membrane-bound secretory granules that are the sites of storage of calcitonin and other peptides.

medullary cancers is the presence of multicentric **C-cell hyperplasia** in the surrounding thyroid parenchyma, a feature that is usually absent in sporadic lesions, and that is believed to be a precursor lesion in familial cases. Thus, the presence of multiple prominent clusters of C cells scattered throughout the parenchyma should raise the specter of an inherited predisposition, even if a family history is not present.

Clinical Features

Sporadic cases of medullary carcinoma come to medical attention most often as a mass in the neck, sometimes associated with dysphagia or hoarseness. In some instances, the initial manifestations are those of a paraneoplastic syndrome caused by the secretion of a peptide hormone (e.g., diarrhea due to the secretion of VIP, or Cushing syndrome due to ACTH). Notably, hypocalcemia is not a prominent feature, despite the presence of raised calcitonin levels. In addition to circulating calcitonin, secretion of carcinoembryonic antigen by the neoplastic cells is a useful biomarker, especially for presurgical assessment of tumor load and in calcitonin-negative tumors.

Patients with familial syndromes may come to attention because of symptoms localized to the thyroid or as a result of endocrine neoplasms in other organs (e.g., adrenal or parathyroid glands). Medullary carcinomas arising in the context of MEN-2B are generally more aggressive and metastasize more frequently than those occurring in patients with sporadic tumors or MEN-2A. As discussed later, asymptomatic MEN-2 individuals carrying germline *RET* mutations are offered prophylactic thyroidectomy as early as possible to prevent the otherwise inevitable development of medullary carcinoma, the major risk factor for poor outcome in these individuals. Sometimes the only histologic finding in the resected thyroid of asymptomatic carriers is the presence of C-cell hyperplasia or small (<1 cm) "micromedullary" carcinomas. Several small-molecule inhibitors of RET tyrosine kinase have recently been developed and have shown considerable promise in clinical trials of patients with medullary carcinoma.

KEY CONCEPTS

THYROID NEOPLASMS

- Most thyroid neoplasms manifest as solitary thyroid nodules; only 1% of all thyroid nodules are neoplastic.
- Multiple genetic pathways are involved in thyroid carcinogenesis. Conventional papillary carcinomas harbor either fusions *(RET/PTC, NTRK)* or *BRAF* point mutations. Follicular neoplasms of all subtypes are characterized by oncogenic *RAS* mutations and *PAX8/PPARG* fusions. Progression to aggressive neoplasms is associated with *TP53*, *CTNNB1*, and *TERT* mutations.
- Follicular adenomas and carcinomas both are composed of well-differentiated follicular epithelial cells; the latter are distinguished by evidence of capsular and/or vascular invasion.
- Conventional papillary carcinomas are recognized based on nuclear features (ground-glass nuclei, pseudoinclusions), even in the absence of papillae. Psammoma bodies are a characteristic feature of papillary cancers; these neoplasms often metastasize by way of lymphatics, but the prognosis is excellent.
- Encapsulated variants of papillary carcinoma without capsular or lymphatic invasion have recently been named noninvasive follicular thyroid neoplasm with papillary-like nuclear features to emphasize their ultra–low-risk potential for metastasis or recurrence.
- Poorly differentiated and anaplastic carcinomas are thought to arise from more differentiated thyroid carcinomas. They are highly aggressive, often lethal cancers.
- Medullary cancers are neoplasms arising from parafollicular C cells and can occur in either sporadic (70%) or familial (30%) settings. Multicentricity and C cell hyperplasia are features of familial cases. Amyloid deposits are a characteristic histologic finding.

CONGENITAL ANOMALIES

Thyroglossal duct cyst is the most common clinically significant congenital anomaly of the thyroid. A sinus tract may persist as a vestige of the tubular development of the thyroid gland. Parts of this tube may be obliterated, leaving small segments that form cysts. These occur at any age and might not become evident until adult life. Mucinous, clear secretions may collect within the cysts to form either spherical masses or fusiform swellings, rarely over 2 to 3 cm in diameter, that present in the midline of the neck anterior to the trachea. Segments of the duct and cysts that occur high in the neck are lined by stratified squamous epithelium resembling the covering of the posterior portion of the tongue in the region of the foramen cecum. Anomalies that occur in the lower neck more proximal to the thyroid gland are lined by epithelium resembling the thyroidal acinar epithelium. Characteristically, subjacent to the lining epithelium, there is an intense lymphocytic infiltrate. Superimposed infection may convert these lesions into abscess cavities, and rarely, they give rise to cancers.

Parathyroid Glands

The parathyroid glands are derived developmentally from pharyngeal pouches that also give rise to the thymus. They are most commonly located in close proximity to the upper and lower poles of each thyroid lobe but may be found anywhere along the pathway of descent of the pharyngeal pouches, including the carotid sheath, the thymus, and elsewhere in the anterior mediastinum. The four parathyroid glands are composed of two cell types: chief cells and oxyphil cells. *Chief cells* predominate; they are polygonal, 12 to 20 μm in diameter, and have central, round, uniform nuclei and light to dark pink cytoplasm. Chief cells have secretory granules containing *parathyroid hormone (PTH)*. *Oxyphil cells* and transitional oxyphils are found throughout the normal parathyroid, either singly or in small clusters. They are slightly larger than the chief cells, have acidophilic cytoplasm, and are tightly packed with mitochondria. Glycogen granules are also present in these cells, but secretory granules are sparse or absent. In early infancy and childhood, the parathyroid glands are composed almost entirely of solid sheets of chief cells. The amount of stromal fat increases up to 25 years of age, reaching a maximum of approximately 30% of the gland, and then plateaus.

The function of the parathyroid glands is to regulate calcium homeostasis. The activity of the parathyroid glands is controlled by the level of free (ionized) calcium in the blood. Normally, decreased levels of free calcium stimulate the synthesis and secretion of PTH. Several metabolic functions of PTH regulate serum calcium levels:

- Increased renal tubular reabsorption of calcium, thereby conserving free calcium
- Increased conversion of vitamin D to its active dihydroxy form in the kidneys, which, in turn, augments gastrointestinal calcium absorption
- Increased urinary phosphate excretion, thereby lowering serum phosphate levels and further increasing calcium (since phosphate binds to ionized calcium)
- Enhanced osteoclastic activity (i.e., bone resorption, thus releasing ionized calcium), by promoting the differentiation of osteoclast progenitor cells into mature osteoclasts

The net result of these activities is to elevate the level of free calcium, which, in turn, inhibits further PTH secretion in a classic feedback loop.

Similar to the other endocrine organs, abnormalities of the parathyroid glands include both hyperfunction and hypofunction. Tumors of the parathyroid glands, in contrast to thyroid tumors, usually come to attention because of excessive secretion of PTH rather than mass effects.

HYPERPARATHYROIDISM

Hyperparathyroidism is caused by elevated PTH and is classified into primary, secondary, and tertiary types.

- *Primary hyperparathyroidism:* an autonomous overproduction of PTH, usually resulting from an adenoma or hyperplasia of parathyroid tissue
- *Secondary hyperparathyroidism:* compensatory hypersecretion of PTH in response to prolonged hypocalcemia, most commonly from chronic renal failure
- *Tertiary hyperparathyroidism:* persistent hypersecretion of PTH, even after the cause of prolonged hypocalcemia is corrected (e.g., after renal transplant)

Primary Hyperparathyroidism

Primary hyperparathyroidism is one of the most common endocrine disorders, and it is an important cause of hypercalcemia. The frequency of the various parathyroid lesions underlying hyperfunction is as follows:

- Adenoma: 85% to 95%
- Primary hyperplasia (diffuse or nodular): 5% to 10%
- Parathyroid carcinoma: ~1%

Primary hyperparathyroidism is usually a disease of adults and is more common in women than in men by a ratio of nearly 4:1. The annual incidence is now estimated to be about 25 cases per 100,000 in the United States and Europe; as many as 80% of patients with this condition are identified in the outpatient setting, when hypercalcemia is discovered incidentally on a serum electrolyte panel. Most cases occur in the 50s or later in life.

The most common cause of primary hyperparathyroidism is a solitary sporadic parathyroid adenoma (Fig. 24.24). Most, if not all, sporadic parathyroid adenomas are monoclonal, consistent with a neoplastic origin. As with nodules in goitrous thyroids, sporadic parathyroid "hyperplasia" is also monoclonal in many instances, particularly when associated with a persistent stimulus for parathyroid growth (refractory secondary or tertiary parathyroidism; see later), suggesting that these lesions lie in the gray zone between reactive hyperplasia and neoplasia. There are two molecular

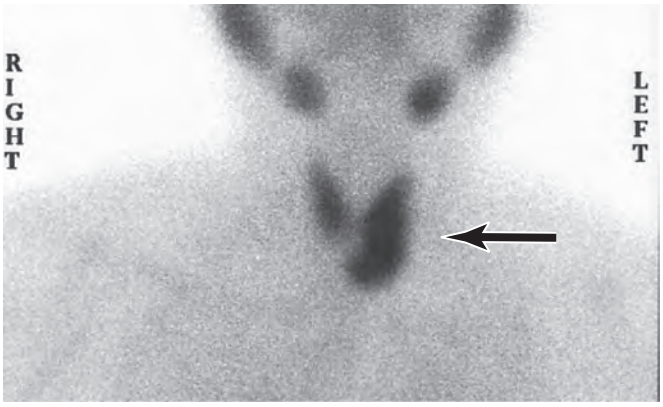

Figure 24.24 Parathyroid adenoma imaging. Technetium-99m-sestamibi radionuclide scan demonstrates an area of increased uptake corresponding to the left inferior parathyroid gland *(arrow)*, which contained a parathyroid adenoma. Preoperative scintigraphy is useful in localizing and distinguishing adenomas from parathyroid hyperplasia, where more than one gland demonstrates increased uptake.

defects that have an established role in the development of sporadic adenomas:

- *Cyclin D1 (CCDN1)* gene inversions leading to overexpression of cyclin D1 protein, a major regulator of the cell cycle. A pericentromeric inversion on chromosome 11 results in relocation of *CCDN1* (normally on 11q), so that it is positioned adjacent to the 5′-flanking region of the *PTH* gene (on 11p). As a consequence of these changes, a 5′-regulatory element flanking the *PTH* gene directs overexpression of cyclin D1, causing the cells to proliferate. Between 10% and 20% of sporadic parathyroid adenomas have this clonal rearrangement. In addition, cyclin D1 is overexpressed in approximately 40% of parathyroid adenomas, suggesting that mechanisms other than *CCDN1* gene inversion can lead to its overexpression.
- *MEN1 mutations:* Approximately 30% to 35% of sporadic parathyroid tumors have somatic mutations of the *MEN1* gene, a tumor suppressor gene on chromosome 11q13, with loss of heterozygosity (LOH) of the second allele. Germline mutations of *MEN1* are also found in patients with familial parathyroid adenomas (see later). The spectrum of *MEN1* mutations in sporadic tumors is virtually identical to that in familial parathyroid adenomas.
- In addition, *CDC73,* which encodes a protein known as parafibromin, is mutated in ~70% of sporadic parathyroid carcinomas, but rarely in adenomas. Germline mutations of *CDC73* lead to a rare syndrome known as hyperparathyroidism–jaw tumor syndrome, which includes parathyroid carcinomas and ossifying jaw tumors as part of the disease spectrum.

Familial syndromes are a distant second to sporadic parathyroid adenomas as causes of primary hyperparathyroidism. The genetic syndromes associated with *familial parathyroid adenomas* include MEN-1, MEN-2, and MEN-4 (discussed in further detail later), as well as familial hypocalciuric hypercalcemia, a rare autosomal dominant disorder caused by loss-of-function mutations in the parathyroid calcium-sensing receptor (*CASR*) gene, which results in decreased sensitivity to extracellular calcium.

MORPHOLOGY

The morphologic changes seen in primary hyperparathyroidism involve the parathyroid glands and organs that are affected by elevated levels of PTH and calcium. Parathyroid **adenomas** are almost always solitary and, like normal parathyroid glands, may be in close proximity to the thyroid or in an ectopic site (e.g., the mediastinum). The typical adenoma averages 0.5 to 5 g and consists of a well-circumscribed, soft, tan to reddish-brown nodule invested by a delicate capsule. In contrast to primary hyperplasia, the glands outside the adenoma are usually normal in size or shrunken because of feedback inhibition by elevated levels of serum calcium. Microscopically, parathyroid adenomas are mostly composed of uniform, polygonal chief cells with small, centrally placed nuclei (Fig. 24.25). At least a few nests of larger oxyphil cells are present as well; uncommonly, adenomas are composed entirely of this cell type **(oxyphil adenomas).** These may resemble Hürthle cell tumors in the thyroid. A rim of compressed, nonneoplastic parathyroid tissue, generally separated by a fibrous capsule, is often visible at the edge of the adenoma. Mitotic figures are rare, but it is not uncommon to find bizarre and pleomorphic nuclei even within adenomas (so-called **endocrine atypia**); this is not a criterion for malignancy. In contrast to the normal parathyroid parenchyma, adipose tissue is inconspicuous.

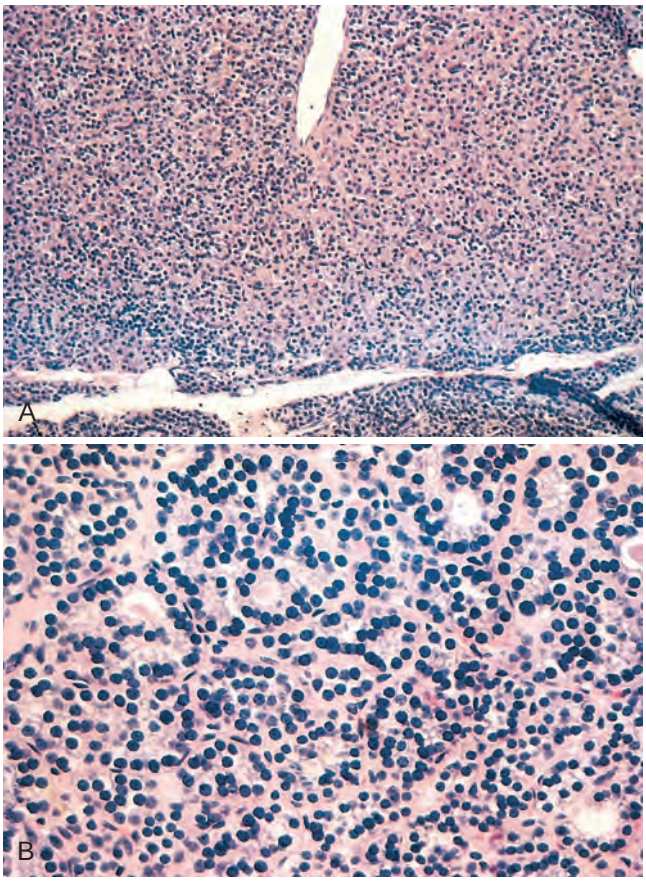

Figure 24.25 Parathyroid adenoma. (A) Solitary chief cell parathyroid adenoma (low-power photomicrograph) revealing delineation from the residual gland below. (B) High-power detail of a chief cell parathyroid adenoma. There is slight variation in nuclear size but no anaplasia and a tendency for follicle formation.

Primary hyperplasia may occur sporadically or as a component of MEN syndrome. Although classically all four glands are involved, there is frequently asymmetry with apparent sparing of one or two glands, making the distinction between hyperplasia and adenoma difficult. The combined weight of all glands rarely exceeds 1 g and is often less. Microscopically, the most common pattern seen is that of chief cell hyperplasia, which may involve the glands in a diffuse or multinodular pattern. Less commonly, the constituent cells contain abundant glycogen, giving them a clear appearance in histologic sections ("water-clear cell hyperplasia"). In many instances, there are islands of oxyphils, and poorly developed, delicate fibrous strands may envelop the nodules. As in the case of adenomas, stromal fat is inconspicuous within hyperplastic glands.

Parathyroid carcinomas may be circumscribed lesions that are difficult to distinguish from adenomas, or they may be clearly invasive neoplasms. These tumors enlarge one parathyroid gland and consist of gray-white, irregular masses that sometimes exceed 10 g in weight. The cells are usually uniform and resemble normal parathyroid cells, and are arrayed in nodular or trabecular patterns.

The mass is usually enclosed by a dense, fibrous capsule. **Diagnosis of carcinoma based on cytologic detail is unreliable, and invasion of surrounding tissues and metastasis are the only reliable criteria.** Local recurrence occurs in one-third of cases, and more distant dissemination occurs in another third.

Morphologic changes of hyperparathyroidism in the skeletal system (Chapter 26) and the urinary tract deserve special mention. Symptomatic, untreated primary hyperparathyroidism manifests with three interrelated skeletal abnormalities: osteoporosis, brown tumors, and osteitis fibrosa cystica. The osteoporosis results in decreased bone mass, with preferential involvement of the phalanges, vertebrae, and proximal femur. For unknown reasons, the increased osteoclast activity in hyperparathyroidism affects cortical bone (subperiosteal and endosteal surfaces) more severely than medullary bone. In medullary bone, osteoclasts tunnel centrally along the length of the trabeculae, creating the appearance of railroad tracks and producing what is known as dissecting osteitis (Fig. 24.26). The marrow spaces around the affected surfaces are replaced by fibrovascular tissue.

The bone loss predisposes to microfractures and secondary hemorrhages that elicit an influx of macrophages and an ingrowth of reparative fibrous tissue, creating a mass of reactive tissue, known as a **brown tumor** (see Fig. 26.13, Chapter 26). The brown color is the result of the vascularity, hemorrhage, and hemosiderin deposition, and it is not uncommon for the lesions to undergo cystic degeneration. The combination of increased osteoclast activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica (von Recklinghausen disease of bone).** Osteitis fibrosa cystica is now rarely encountered because hyperparathyroidism is usually diagnosed on routine blood tests and treated at an early, asymptomatic stage (see later).

PTH-induced hypercalcemia favors formation of **urinary tract stones** (nephrolithiasis) as well as calcification of the renal interstitium and tubules (nephrocalcinosis). Metastatic calcification secondary to hypercalcemia may also be seen in other sites, including the stomach, lungs, myocardium, and blood vessels.

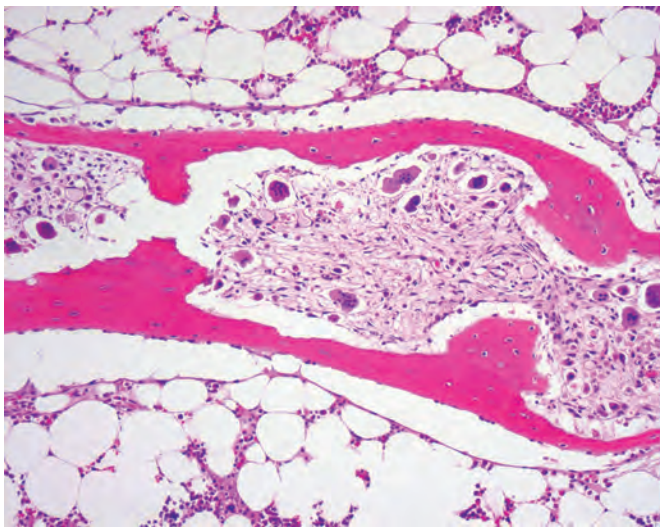

Figure 24.26 Hyperparathyroidism with osteoclasts boring into the center of the trabeculum (dissecting osteitis). (Photomicrograph reproduced from Horvai A: *Bone and Soft Tissue Pathology: A Volume in the High Yield Pathology Series,* Philadelphia, 2012, Elsevier.)

Clinical Features

Primary hyperparathyroidism may be (1) asymptomatic and identified on routine blood chemistry profile, or (2) associated with the classic clinical manifestations of primary hyperparathyroidism.

- *Asymptomatic hyperparathyroidism.* Because serum calcium levels are routinely assessed, most patients with primary hyperparathyroidism are diagnosed incidentally. In fact, primary hyperparathyroidism is the most common cause of asymptomatic hypercalcemia. Hence, many of the classic manifestations, particularly those referable to bone and renal disease, are now seen infrequently in clinical practice. Among other causes of hypercalcemia (Table 24.5), malignancy stands out as the most frequent cause of symptomatic hypercalcemia in adults, and must be excluded by appropriate clinical and laboratory investigations. As discussed in Chapter 7, hypercalcemia can occur with solid tumors, such as lung, breast, head and neck, and renal cancers, and with hematologic malignancies, notably multiple myeloma. The most common mechanism (in ~80% of cases) through which osteolytic tumors induce hypercalcemia is by secretion of PTH-related peptide (PTHrP), which (like PTH) induces osteoclastic bone resorption and hypercalcemia; the remaining 20% induce hypercalcemia through metastases to the bone and subsequent cytokine-induced bone resorption. In individuals with primary hyperparathyroidism, serum PTH levels are inappropriately elevated for the level of serum calcium, whereas PTH levels are low to undetectable in hypercalcemia caused by nonparathyroid diseases (see Table 24.5). Radioimmunoassays specific for PTH and PTHrP are available and can be useful in distinguishing primary hyperparathyroidism and malignancy-associated hypercalcemia. Other laboratory alterations referable to PTH excess include hypophosphatemia and increased urinary excretion of both calcium and phosphate. Secondary renal disease may in turn lead to phosphate retention, "normalizing" the serum phosphate levels.
- *Symptomatic primary hyperparathyroidism.* The signs and symptoms of hyperparathyroidism reflect the combined effects of increased PTH secretion and hypercalcemia. Primary hyperparathyroidism is associated with "painful bones, renal stones, abdominal groans, and psychic moans." The constellation of symptoms includes the following:

Table 24.5 Causes of Hypercalcemia

Increased PTH	Decreased PTH
Hyperparathyroidism	Hypercalcemia of malignancy[a]
Primary (adenoma > hyperplasia)[a]	Vitamin D toxicity
Secondary[†]	Immobilization
Tertiary[†]	Thiazide diuretics
Familial hypocalciuric hypercalcemia	Granulomatous disease (sarcoidosis)

PTH, Parathyroid hormone.

[a]Primary hyperparathyroidism is the most common cause of hypercalcemia overall. Malignancy is the most common cause of symptomatic hypercalcemia. Primary hyperparathyroidism and malignancy account for nearly 90% of cases of hypercalcemia.

[†]Secondary and tertiary hyperparathyroidism are most commonly associated with progressive renal failure.

- *Bone disease* and bone pain secondary to fractures of bones weakened by osteoporosis or osteitis fibrosa cystica
- *Nephrolithiasis* (renal stones) in 20% of newly diagnosed patients, with attendant pain and obstructive uropathy. Chronic renal insufficiency and abnormalities in renal function lead to polyuria and secondary polydipsia.
- Gastrointestinal disturbances, including constipation, nausea, peptic ulcers, pancreatitis, and gallstones
- Central nervous system alterations, including depression, lethargy, and eventually seizures
- Neuromuscular abnormalities, including weakness and fatigue
- Cardiac manifestations, including aortic or mitral valve calcifications (or both)

The abnormalities most directly related to hyperparathyroidism are nephrolithiasis and bone disease, whereas those attributable to hypercalcemia include fatigue, weakness, pancreatitis, metastatic calcifications, and constipation.

Secondary Hyperparathyroidism

Secondary hyperparathyroidism is caused by any condition that gives rise to chronic hypocalcemia, which, in turn, leads to compensatory overactivity of the parathyroid glands. Renal failure is by far the most common cause of secondary hyperparathyroidism, although several other diseases, including inadequate dietary intake of calcium, steatorrhea, and vitamin D deficiency, may also cause this disorder. The mechanisms by which chronic renal failure induces secondary hyperparathyroidism are complex and not fully understood. Chronic renal insufficiency is associated with decreased phosphate excretion, which, in turn, results in hyperphosphatemia. The elevated serum phosphate levels directly depress serum calcium levels and thereby stimulate parathyroid gland activity. In addition, loss of renal substance reduces the availability of α_1-hydroxylase, which is necessary for the synthesis of the active form of vitamin D, leading in turn to reduced intestinal absorption of calcium (Chapter 9). Because vitamin D has suppressive effects on parathyroid growth and PTH secretion, its deficiency compounds the hyperparathyroidism in renal failure.

MORPHOLOGY

The parathyroid glands in secondary hyperparathyroidism are hyperplastic. As in primary hyperparathyroidism, the degree of glandular enlargement may be asymmetric. Microscopically, the hyperplastic glands contain an increased number of chief cells, or water-clear cells in a diffuse or multinodular distribution. Fat cells are decreased in number. **Metastatic calcification** may be seen in many tissues, including the lungs, heart, stomach, and blood vessels.

Clinical Features

The clinical features of secondary hyperparathyroidism are usually dominated by the inciting chronic renal failure. Secondary hyperparathyroidism is usually not as severe or as prolonged as primary hyperparathyroidism, hence the skeletal abnormalities (referred to as *renal osteodystrophy)* tend to be milder. Control of the hyperparathyroidism allows the bony changes to regress significantly or disappear completely. The vascular calcification associated with secondary hyperparathyroidism may occasionally result in significant ischemic damage to skin and other organs, a process referred to as *calciphylaxis*. Patients with secondary hyperparathyroidism often respond to dietary vitamin D supplementation as well as phosphate binders, which decrease the prevailing hyperphosphatemia.

In a minority of patients, parathyroid activity may become autonomous and excessive, with resultant hypercalcemia, a process termed *tertiary hyperparathyroidism*. Parathyroidectomy may be necessary to control the hyperparathyroidism in such patients.

KEY CONCEPTS

HYPERPARATHYROIDISM

- Primary hyperparathyroidism is the most common cause of asymptomatic hypercalcemia.
- In a majority of cases, primary hyperparathyroidism is caused by a sporadic parathyroid adenoma and, less commonly, by parathyroid hyperplasia.
- Parathyroid adenomas are solitary, while hyperplasia typically is a multiglandular process.
- Skeletal manifestations of hyperparathyroidism include bone resorption, osteitis fibrosa cystica, and brown tumors. Renal changes include nephrolithiasis (stones) and nephrocalcinosis.
- The clinical manifestations of hyperparathyroidism have been classically summarized as "painful bones, renal stones, abdominal groans, and psychic moans."
- Secondary hyperparathyroidism most often is caused by renal failure, which lowers serum calcium levels, resulting in reactive hyperplasia of parathyroid glands.
- Malignancies are the most important cause of symptomatic hypercalcemia, which results from osteolytic metastases or release of PTH-related protein from nonparathyroid tumors.

HYPOPARATHYROIDISM

Hypoparathyroidism is far less common than is hyperparathyroidism. Acquired hypoparathyroidism is almost always an inadvertent consequence of surgery; in addition, there are several genetic causes of hypoparathyroidism.

- *Surgically induced hypoparathyroidism* occurs with inadvertent removal of all parathyroid glands during thyroidectomy, excision of parathyroid glands in the mistaken belief that they are lymph nodes during radical neck dissection for some form of malignant disease, or removal of too large a proportion of parathyroid tissue in the treatment of primary hyperparathyroidism.
- *Autoimmune hypoparathyroidism* is often associated with chronic mucocutaneous candidiasis and primary adrenal insufficiency; this syndrome is known as APS-1 and is caused by mutations in the *autoimmune regulator (AIRE)* gene. The syndrome typically presents in childhood with the onset of candidiasis, followed several years later by hypoparathyroidism and then adrenal insufficiency during adolescence. APS-1 is discussed further later in this chapter.

- *Autosomal-dominant hypoparathyroidism* is caused by gain-of-function mutations in the *calcium-sensing receptor (CASR)* gene. Inappropriate CASR activity due to heightened calcium sensing suppresses PTH, resulting in hypocalcemia and hypercalciuria. Recall that loss-of-function *CASR* mutations are a rare cause of familial parathyroid adenomas.
- *Familial isolated hypoparathyroidism* (FIH) is a rare condition with either autosomal dominant or autosomal recessive patterns of inheritance. Autosomal dominant FIH is caused by a mutation in the gene encoding PTH that impairs PTH processing to the mature active hormone. Autosomal recessive FIH is caused by loss-of-function mutations in the transcription factor gene *GCM2,* which is essential for development of the parathyroid.
- *Congenital absence* of parathyroid glands can occur in conjunction with other malformations, such as thymic aplasia and cardiovascular defects, or as a component of the 22q11 deletion syndrome. As discussed in Chapter 6, when thymic defects are present, the condition is called *DiGeorge syndrome.*

Clinical Features

The major manifestations of hypoparathyroidism are related to the severity and chronicity of the hypocalcemia.

- The hallmark of hypocalcemia is *tetany,* which is characterized by neuromuscular irritability, resulting from decreased serum calcium levels. The symptoms range from circumoral numbness or paresthesias (tingling) of the distal extremities and carpopedal spasm, to life-threatening laryngospasm and generalized seizures. The classic findings on physical examination are *Chvostek sign* and *Trousseau sign*. Chvostek sign is elicited in subclinical disease by tapping along the course of the facial nerve, which induces contractions of the muscles of the eye, mouth, or nose. Trousseau sign refers to carpal spasms produced by occlusion of the circulation to the distal arm with a blood pressure cuff for several minutes.
- *Mental status changes* include emotional instability, anxiety and depression, confusional states, hallucinations, and frank psychosis.
- *Intracranial manifestations* include calcifications of the basal ganglia, parkinsonian-like movement disorders, and increased intracranial pressure with resultant papilledema. The paradoxical association of hypocalcemia with calcifications may be because of an increase in phosphate levels, leading to deposition of calcium phosphate in vulnerable tissues.
- *Ocular disease* takes the form of calcification of the lens and cataract formation.
- *Cardiovascular manifestations* include a conduction defect that produces a characteristic prolongation of the QT interval in the electrocardiogram.
- *Dental abnormalities* occur when hypocalcemia is present during early development. These findings are highly characteristic of hypoparathyroidism and include dental hypoplasia, failure of eruption, defective enamel and root formation, and abraded carious teeth.

Pseudohypoparathyroidism

In this condition, hypoparathyroidism occurs because of end-organ resistance to the actions of PTH. Indeed, serum PTH levels are normal or elevated. In one form of pseudohypoparathyroidism, there is end-organ resistance to TSH and FSH/LH as well as PTH. All of these hormones signal via G-protein–coupled receptors, and the disorder results from genetic defects in components of this pathway that are shared across endocrine tissues. PTH resistance is the most obvious clinical manifestation. It presents as hypocalcemia, hyperphosphatemia, and elevated circulating PTH. TSH resistance is generally mild, while LH/FSH resistance manifests as hypergonadotropic hypogonadism in females.

The Endocrine Pancreas

The endocrine pancreas consists of about 1 million clusters of cells, the *islets of Langerhans,* which contain four major and two minor cell types. The four main types are β, α, δ, and PP (pancreatic polypeptide) cells. They can be differentiated by the ultrastructural characteristics of their granules, and by their hormone content (Fig. 24.27).

- The *β cells* produce insulin, which regulates glucose utilization in tissues and reduces blood glucose levels, as will be detailed in the discussion of diabetes.
- The *α cells* secrete glucagon, which stimulates glycogenolysis in the liver and thus increases blood sugar.
- The *δ cells* secrete somatostatin, which suppresses both insulin and glucagon release.
- The *PP cells* secrete pancreatic polypeptide, which exerts several gastrointestinal effects, such as stimulation of secretion of gastric and intestinal enzymes and inhibition of intestinal motility. These cells not only are present in islets but also are scattered throughout the exocrine pancreas.
- There are also two rare cell types, *D1 cells* and *enterochromaffin cells*. D1 cells elaborate vasoactive intestinal polypeptide (VIP), a hormone that induces glycogenolysis and hyperglycemia; it also stimulates gastrointestinal fluid secretion and causes secretory diarrhea.
- *Enterochromaffin cells* synthesize serotonin and are the source of pancreatic tumors that cause the carcinoid syndrome (Chapter 19).

The following discussion focuses on the two main disorders of islet cells: diabetes mellitus and pancreatic endocrine tumors.

DIABETES MELLITUS

Diabetes mellitus is a group of metabolic disorders sharing the common feature of hyperglycemia caused by defects in insulin secretion, insulin action, or, most

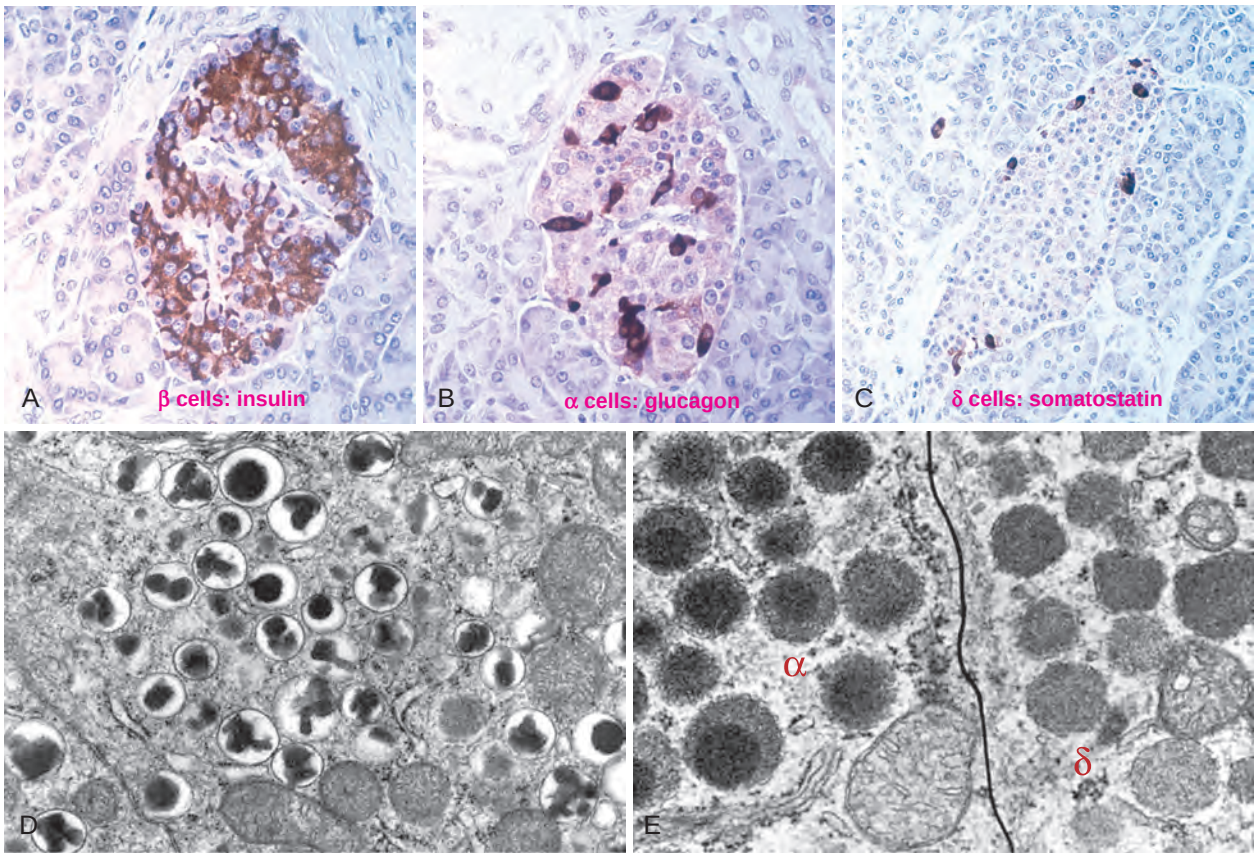

Figure 24.27 Hormone production in pancreatic islet cells. Immunoperoxidase staining shows insulin in β cells (A), glucagon in α cells (B), and somatostatin in δ cells (C). (D) Electron micrograph of a β cell shows the characteristic membrane-bound granules, each containing a dense, often rectangular core and distinct halo. (E) Portions of an α cell *(left)* and a δ cell *(right)* also show granules, but with closely apportioned membranes. The α-cell granule shows a dense, round center. (Electron micrographs courtesy Dr. Arthur Like, University of Massachusetts Medical School, Worcester, Mass.)

commonly, both. The chronic hyperglycemia and attendant metabolic deregulation may be associated with secondary damage in multiple organ systems, especially the kidneys, eyes, nerves, and blood vessels. **In the United States, diabetes is the leading cause of end-stage renal disease, adult-onset blindness, and nontraumatic lower extremity amputations**.

Diabetes and related disorders of glucose metabolism are common. According to the American Diabetes Association, diabetes affects more than 30 million children and adults, or more than 9% of the population, in the United States, of which about 1.2 million have the form of diabetes called type 1 and the remainder have type 2. Astonishingly, nearly one-fourth of these individuals are currently unaware that they have hyperglycemia. Approximately 1.5 million new cases of adult diabetes are diagnosed each year in the United States. Furthermore, a staggering 84 million adults in this country have impaired glucose tolerance or "prediabetes," which is defined as elevated blood sugar that does not reach the criterion used for an outright diagnosis of type 2 diabetes (T2D; see later), and individuals with prediabetes are at risk for developing frank T2D. Compared to non-Hispanic Caucasians, Native Americans, African Americans, and Hispanics are 1.5 to 2 times more likely to develop diabetes in their lifetimes. The World Health Organization estimates that as many as 422 million people suffer from diabetes worldwide, with India and China being the largest contributors to the world's diabetic burden. Increasingly sedentary lifestyles and poor eating habits have contributed to the simultaneous escalation of T2D and obesity, which some have called the *diabesity epidemic*. Sadly, this epidemic has now spread to children living in "food deserts" who subsist on highly processed foods rich in carbohydrates and sugar and do not exercise adequately.

The mortality rate from diabetes varies across countries, with middle- and low-income nations accounting for almost 80% of diabetes-related deaths and nearly double the mortality rates observed in high-income nations. Nonetheless, diabetes remains in the top 10 "killers" in the United States. The total yearly cost related to diabetes in the United States is estimated to be an astounding $327 billion, including $237 billion in direct medical costs and $90 billion in indirect costs stemming from the reduced productivity of individuals with diabetes.

Diagnosis

Blood glucose is normally maintained in a very narrow range of 70 to 120 mg/dL. According to the ADA and WHO, diagnostic criteria for diabetes include the following:

1. A fasting plasma glucose ≥126 mg/dL
2. A random plasma glucose ≥200 mg/dL (in a patient with classic hyperglycemic signs, as discussed later)

3. A 2-hour plasma glucose ≥200 mg/dL during an oral glucose tolerance test (OGTT) with a loading dose of 75 g
4. A glycated hemoglobin (HbA1c) level ≥6.5% (glycated hemoglobin is further discussed later in the chapter)

All tests, except the random blood glucose test in a patient with classic hyperglycemic signs, need to be repeated and confirmed on a separate day. If there is discordance between two assays (e.g., fasting glucose and HbA1c level), the result with the greatest degree of abnormality is considered the "readout." Of note, many acute stresses, such as severe infections, burns, or trauma, can lead to transient hyperglycemia due to secretion of hormones such as catecholamines and cortisol that oppose the action of insulin. The diagnosis of diabetes requires persistence of hyperglycemia following resolution of the acute illness.

Prediabetes, a state of dysglycemia that often precedes development of frank T2D, is defined by one or more of the following:

1. A fasting plasma glucose between 100 and 125 mg/dL ("impaired fasting glucose"),
2. A 2-hour plasma glucose between 140 and 199 mg/dL following a 75-g oral glucose tolerance test (OGTT) ("impaired glucose tolerance"), and/or
3. A glycated hemoglobin (HbA1c) level between 5.7% and 6.4%

As many as one-fourth of individuals with impaired glucose tolerance will develop overt diabetes over 5 years, with additional factors such as obesity and family history compounding the risk. In addition, individuals with prediabetes also are at significant risk for cardiovascular complications.

Classification

Although all forms of diabetes have hyperglycemia as a common feature, the underlying abnormalities involved in its development vary widely. The previous classification schemes of diabetes were based on clinical features, such as the age of onset of disease and the mode of therapy; in contrast, the current classification reflects our greater understanding of the pathogenesis of each variant (Table 24.6). The vast majority of cases of diabetes fall into one of two broad classes:

- *Type 1 diabetes (T1D)* is an autoimmune disease characterized by pancreatic β-cell destruction and an absolute deficiency of insulin. It accounts for approximately 5% to 10% of diabetes and is the most common subtype diagnosed in patients younger than 20 years of age.
- *Type 2 diabetes (T2D)* is caused by a combination of peripheral resistance to insulin action and a secretory response by pancreatic β cells that is inadequate to overcome insulin resistance ("relative insulin deficiency"). Approximately 90% to 95% of diabetes patients have T2D, and the vast majority of such individuals are overweight. Although classically considered "adult-onset," the prevalence of T2D in children and adolescents has been increasing at an alarming pace due to the increasing rates of obesity in children and young adults, particularly in Hispanic, Native American, and Asian ethnic groups.

Table 24.6 Classification of Diabetes

Type 1 Diabetes (β-Cell Destruction, Usually Leading to Absolute Insulin Deficiency)
Immune-mediated
Idiopathic (autoantibody-negative)
Type 2 Diabetes (Combination of Insulin Resistance and β-Cell Dysfunction)
Other Types
Genetic Defects of β-Cell Function
Maturity-onset diabetes of the young (MODY) caused by mutations in:
Hepatocyte nuclear factor 4α *(HNF4A)* (MODY1)
Glucokinase *(GCK)* (MODY2)
Hepatocyte nuclear factor 1α *(HNF1A)*, (MODY3)
Pancreatic and duodenal homeobox 1 *(PDX1)* (MODY4)
Hepatocyte nuclear factor 1β *(HNF1B)* (MODY5)
Neurogenic differentiation factor 1 *(NEUROD1)* (MODY6)
Neonatal diabetes (activating mutations in *KCNJ11* and *ABCC8*, encoding Kir6.2 and SUR1, respectively)
Maternally inherited diabetes and deafness (MIDD) due to mitochondrial DNA mutations (m.3243A→G)
Defects in proinsulin conversion
Insulin gene mutations
Genetic Defects in Insulin Action
Type A insulin resistance
Lipoatrophic diabetes
Exocrine Pancreatic Defects ("Pancreatogenic" or Type 3C Diabetes)
Chronic pancreatitis
Pancreatectomy/trauma
Pancreatic cancer
Cystic fibrosis
Hemochromatosis
Fibrocalculous pancreatopathy
Endocrinopathies
Acromegaly
Cushing syndrome
Hyperthyroidism
Pheochromocytoma
Glucagonoma
Infections
Cytomegalovirus
Coxsackie B virus
Congenital rubella
Drugs
Glucocorticoids
Thyroid hormone
Interferon-α
Protease inhibitors
β-adrenergic agonists
Thiazides
Nicotinic acid
Phenytoin (Dilantin)
Vacor
Genetic Syndromes Associated With Diabetes
Down syndrome
Klinefelter syndrome
Turner syndrome
Prader-Willi syndrome
Gestational Diabetes Mellitus

Modified from American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 37(Suppl 1):S81–S90, 2014.

Table 24.7 Comparative Features of Type 1 and Type 2 Diabetes

Type 1 Diabetes	Type 2 Diabetes
Clinical	
Onset: usually childhood and adolescence	Onset: usually adult; increasing incidence in childhood and adolescence
Normal weight or weight loss preceding diagnosis	Vast majority are obese (80%)
Progressive decrease in insulin levels	Increased blood insulin (early); normal or moderate decrease in insulin (late)
Circulating islet autoantibodies (anti-insulin, anti-GAD, anti-ICA512)	No islet autoantibodies
Diabetic ketoacidosis in absence of insulin therapy	Nonketotic hyperosmolar coma more common
Genetics	
Major linkage to MHC class II genes; also linked to polymorphisms in *CTLA4* and *PTPN22*, and insulin gene VNTRs	No HLA linkage; linkage to candidate diabetogenic and obesity-related genes (e.g., *TCF7L2*, *PPARG*, *FTO*)
Pathogenesis	
Dysfunction in T-cell selection and regulation leading to breakdown in self-tolerance to islet autoantigens	Insulin resistance in peripheral tissues, failure of compensation by β cells
Pathology	
Insulitis (inflammatory infiltrate of T cells and macrophages) β-cell depletion, islet atrophy	No insulitis; amyloid deposition in islets Mild β-cell depletion

HLA, Human leukocyte antigen; *MHC*, major histocompatibility complex; *VNTRs*, variable number of tandem repeats.

The important similarities and differences between T1D and T2D are summarized in Table 24.7. A variety of monogenic and secondary causes are responsible for the remaining cases (discussed later). Before discussing the pathogenesis of the two major types, we will first briefly review normal insulin secretion and the mechanism of insulin action, since these are critical to understanding the pathogenesis of diabetes.

Glucose Homeostasis

Glucose homeostasis is tightly regulated by three interrelated processes: glucose production in the liver; glucose uptake and utilization by peripheral tissues, chiefly skeletal muscle; and actions of insulin and counter-regulatory hormones, including glucagon, on glucose uptake and metabolism. Insulin and glucagon have opposing effects on glucose homeostasis. During fasting states, low insulin and high glucagon levels facilitate hepatic gluconeogenesis and glycogenolysis (glycogen breakdown) while decreasing glycogen synthesis, thereby preventing hypoglycemia. Thus, fasting plasma glucose levels are determined primarily by hepatic glucose output. Following a meal, insulin levels rise and glucagon levels fall in response to the large glucose load. Insulin promotes glucose uptake and utilization in tissues (discussed later). The skeletal muscle is the major

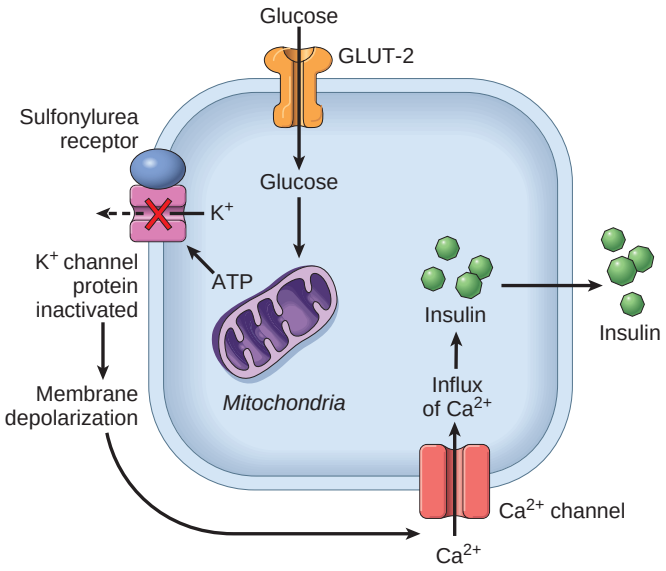

Figure 24.28 Insulin synthesis and secretion. The influx of glucose into β cells through the GLUT-2 receptors initiates a cascade of signaling events that culminates in Ca^{2+}-induced release of stored insulin (see text for details).

insulin-responsive site for postprandial glucose utilization, and it is critical for preventing hyperglycemia and maintaining glucose homeostasis. Although less dependent on insulin, brain and adipose tissues also extract a significant amount of glucose from the circulation.

Regulation of Insulin Release

Insulin is produced in the β cells of the pancreatic islets (see Fig. 24.27) as a precursor protein and is proteolytically cleaved in the Golgi complex to generate the mature hormone and a peptide byproduct, *C-peptide*. Both insulin and C-peptide are then stored in secretory granules and secreted in equimolar quantities after physiologic stimulation; thus, C-peptide levels serve as a surrogate for β-cell function, decreasing with loss of β-cell mass in T1D and increasing with insulin resistance–associated hyperinsulinemia.

The most important stimulus for insulin synthesis and release is glucose. An increase in blood glucose levels results in glucose uptake into pancreatic β cells, facilitated by an insulin-independent glucose transporter, GLUT2 (Fig. 24.28). Metabolism of glucose generates ATP, which leads to the influx of Ca^{2+} through plasma membrane calcium channels. The resultant increase in intracellular Ca^{2+} stimulates secretion of insulin, presumably from hormone stored in β-cell granules. This is the phase of immediate insulin release, sometimes called the first phase of β-cell insulin secretion. If the secretory stimulus persists, a delayed and protracted response follows that involves active synthesis of insulin, the second phase.

Oral intake of food leads to secretion of multiple hormones that play a role in glucose homeostasis and satiety. Of these, the most important class of hormones responsible for promoting insulin secretion from pancreatic β cells following feeding is the *incretins*, which act by binding G-protein–coupled receptors that are expressed on pancreatic β cells. The two most important incretins are glucose-dependent insulinotropic polypeptide (GIP) and

glucagon-like peptide-1 (GLP-1), both secreted by cells in the intestines following oral food intake. The elevation in GIP and GLP-1 levels is known as the "incretin effect." In addition to increasing insulin secretion from β cells, these hormones reduce glucagon secretion from pancreatic α cells and delay gastric emptying, which promotes satiety. Once released, circulating GIP and GLP-1 are degraded in the circulation by a class of enzymes known as dipeptidyl peptidases (DPPs), especially DPP-4. The "incretin effect" is significantly blunted in patients with T2D, and efforts to restore incretin function can improve glycemic control and promote weight loss (through restoration of satiety). These insights have led to the recent development of two classes of drugs for treating T2D: GLP-1 receptor agonists, which are synthetic GLP-1 mimetics that bind to and activate the GLP-1 receptor on islet and extrapancreatic cells; and DPP-4 inhibitors, which enhance levels of endogenous incretins by delaying their degradation. GLP-1 also increases energy expenditure, so the weight-loss–inducing effects are likely multifactorial. Indeed, GLP-1 receptor agonists are also now approved for treatment of obesity.

Insulin Action and Insulin-Signaling Pathways

Insulin is the most potent anabolic hormone known, with multiple synthetic and growth-promoting effects (Fig. 24.29). The principal metabolic function of insulin is to increase the rate of glucose transport into certain cells in the body, thus providing a major source of energy and metabolic intermediates derived from glucose that are used in the biosynthesis of cellular building blocks such as lipids, nucleotides, and amino acids. The most important targets of insulin action are striated muscle cells (including cardiomyocytes) and, to a lesser extent, adipocytes, which together normally represent about two-thirds of the body's weight. The type of adipose tissue that utilizes the most glucose is "beige" adipose tissue, which develops with exercise, and not the "white" adipose tissue that accumulates in obese individuals. This is one reason why exercise is beneficial and obesity detrimental to glucose control. In muscle cells, glucose is either stored as glycogen or oxidized to generate ATP. In adipose tissue, glucose is primarily used as a substrate for synthesis of lipids, which are stored as triglycerides. Besides promoting lipid synthesis, insulin also inhibits triglyceride hydrolysis and lipid release by adipocytes. Similarly, insulin promotes amino acid uptake and protein synthesis, while inhibiting protein degradation. Thus, the anabolic effects of insulin are attributable to increased synthesis and reduced degradation of glycogen, lipids, and proteins. In addition, insulin has several mitogenic activities, including initiation of DNA synthesis in certain cells and stimulation of their growth and differentiation.

The metabolic effects of insulin are exerted through its binding to the insulin receptor, which, in turn, sets into motion a series of signaling events through an array of mediators, the more pertinent of which are summarized in Fig. 24.30. The insulin receptor is a tetrameric protein composed of two α-subunits and two β-subunits. The β-subunit cytosolic domain possesses tyrosine kinase activity. Insulin binding to the α-subunit extracellular domain activates the β-subunit tyrosine kinase, which autophosphorylates itself and also phosphorylates several intracellular docking or bridging proteins, including so-called insulin receptor substrate (IRS) proteins. These molecules in turn activate downstream factors such as PI-3-kinase and Akt, a serine/threonine kinase that serves as a central signaling hub that mediates many insulin-dependent activities, including increased glucose uptake, reduced glucose synthesis, and increased glycogen and protein synthesis.

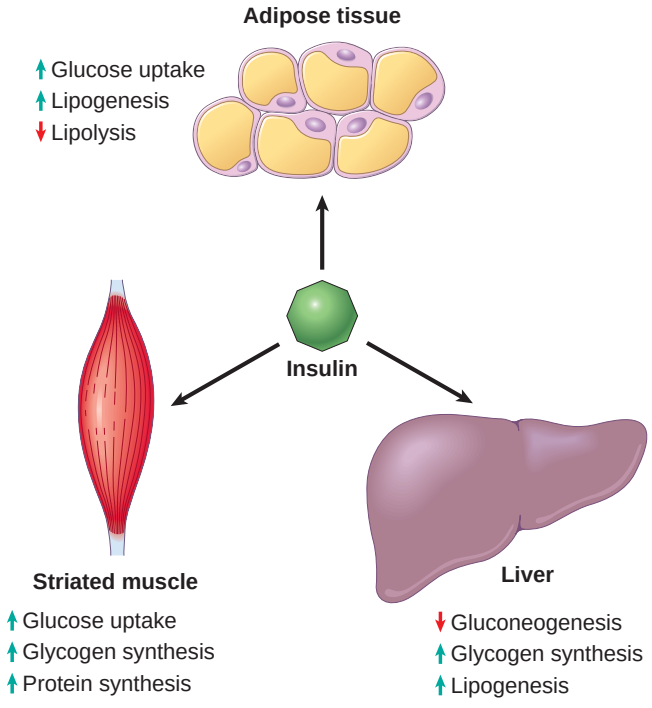

Figure 24.29 Metabolic actions of insulin in striated muscle, adipose tissue, and liver.

Pathogenesis of Type 1 Diabetes

T1D is an autoimmune disease in which islet destruction is caused primarily by immune effector cells reacting against endogenous β-cell antigens. T1D most commonly develops in childhood, becomes manifest at puberty, and progresses with age. Because the disease can develop at any age, including late adulthood, the old moniker "juvenile-onset diabetes" is no longer used. Similarly, "insulin-dependent diabetes mellitus" has been excluded from the current classification of diabetes because many forms of diabetes eventually require treatment with insulin. Nevertheless, most patients with T1D require insulin for survival; without insulin, they may develop serious metabolic complications such as ketoacidosis and coma.

As with most autoimmune diseases, the pathogenesis of T1D involves an interplay of genetic and environmental factors.

Genetic Susceptibility

Epidemiologic studies, such as those demonstrating higher concordance rates in monozygotic versus dizygotic twins, have convincingly established a genetic basis for T1D. More recently, GWAS have identified multiple genetic susceptibility loci for T1D, as well as for T2D (see later). **Of these, the most important locus is the *HLA* gene cluster, which according to some estimates contributes as much as 50% of the genetic susceptibility for T1D.** Ninety percent to 95%

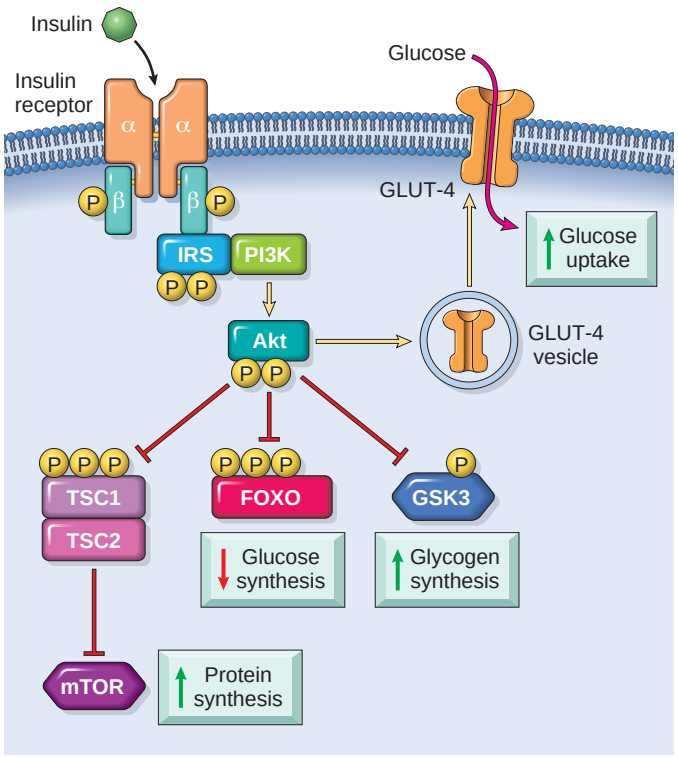

Figure 24.30 Insulin action on a target cell. Insulin binding to the tetrameric receptor initiates a cascade of phosphorylation events that result in activation of PI-3-kinase/Akt signaling. Akt is a serine threonine kinase that mediates its effector functions via phosphorylation-dependent events. For example, Akt phosphorylates and inhibits the function of the tuberous sclerosis complex *(TSC)* proteins, leading to activation of the downstream mammalian TOR *(mTOR)* complex, which enhances protein synthesis. Akt also inhibits the function of Forkhead box O *(FOXO)* protein, which, in turn, reduces glucose synthesis, while inhibition of glycogen synthase kinase 3 *(GSK3)* enhances glycogen production. Finally, Akt enhances intracellular glucose uptake by translocation of GLUT-4 vesicles to the cell membrane. *IRS*, Insulin receptor substrate; *PI3K*, phosphoinositide 3-kinase. (Modified from Brendan Manning, Harvard T.H. Chan School of Public Health.)

of Caucasians with this disease have either an *HLA-DR3* or *HLA-DR4* haplotype, in contrast to about 40% of normal subjects; moreover, 40% to 50% of patients with T1D are *DR3/DR4* compound heterozygotes, in contrast to 5% of normal subjects. Individuals who have either *DR3* or *DR4* concurrently with a *DQ8* haplotype demonstrate one of the highest inherited risks for T1D in sibling studies. Predictably, the polymorphisms in the HLA molecules that are associated with risk are located in or adjacent to the peptide-binding pockets, consistent with the notion that disease-associated alleles code for HLA molecules that have the capacity to display particular antigens. However, as discussed in Chapter 6, it is still not known how particular HLA alleles contribute to the pathogenesis of T1D (and other autoimmune diseases).

Several *non-HLA genes* also confer susceptibility to T1D. The first disease-associated non-*MHC* gene variant to be identified consisted of variable number of tandem repeats in the promoter region of the *insulin* gene. The mechanism underlying this association is unknown. It is possible that these polymorphisms influence insulin expression by thymic antigen-presenting cells, thus affecting the negative selection of insulin-reactive T cells (Chapter 6). The association between polymorphisms in *CTLA4* and *PTPN22* and autoimmune thyroiditis was mentioned earlier; not surprisingly, these genes have also been linked with susceptibility to T1D. The relationship of T1D to altered T-cell selection and regulation is also underscored by the striking prevalence of this disease in individuals with rare germline defects in genes that code for immune regulators, such as *AIRE*, mutations of which cause APS-1 (discussed later).

Environmental Factors

As in other autoimmune diseases, genetic susceptibility contributes to only a part of diabetes risk, and the concordance rate in monozygotic twins is only about 50%, so environmental factors must play a role. The nature of these environmental influences remains an enigma. Although antecedent viral infections have been suggested as triggers, neither the type of virus nor how it promotes islet-specific autoimmunity is established. Some studies suggest that viruses might share epitopes with islet antigens, and the immune response to the virus results in cross-reactivity and destruction of islet tissues, a phenomenon known as *molecular mimicry*. On the other hand, certain infections are also thought to be protective against T1D.

Mechanisms of β-Cell Destruction

While the clinical onset of T1D is often abrupt, there is a lengthy lag period between initiation of the autoimmune process and the appearance of symptomatic disease, during which there is progressive loss of insulin reserves. Three distinct stages of T1D are now recognized (Fig. 24.31). In stage 1 *(autoimmunity positive, normoglycemia, presymptomatic T1D)*, individuals have developed two or more islet autoantibodies but are still normoglycemic. In stage 2 *(autoimmunity positive, dysglycemia, presymptomatic T1D)*, there is increasingly severe loss of glucose tolerance due to progressive loss of β-cell mass, but frank symptoms are absent. Nonetheless, the 5-year risk of developing symptomatic T1D increases from less than 50% in stage 1 to 75% in stage 2. Finally, in stage 3 *(autoimmunity positive, dysglycemia, symptomatic T1D)*, classic manifestations of the disease (polyuria, polydipsia, polyphagia, ketoacidosis; see later) appear, typically after more than 90% of the β cells have been destroyed.

The fundamental immune abnormality in T1D is a failure of self-tolerance in T cells specific for islet antigens. This failure of tolerance may be a result of some combination of defective clonal deletion of self-reactive T cells in the thymus, as well as defects in the functions of regulatory T cells or abnormal resistance of effector T cells to suppression by regulatory cells. Thus, autoreactive T cells not only survive, but are poised to respond to self antigens. The initial activation of these cells is thought to occur in the peripancreatic lymph nodes, perhaps in response to antigens that are released from damaged islets. The activated T cells then traffic to the pancreas, where they cause β-cell injury. Multiple T-cell populations have been implicated in this damage, including Th1 cells (which may secrete cytokines, including IFN-γ and TNF, that injure β cells), and CD8+ CTLs (which kill β cells directly). The islet autoantigens that are the targets of immune attack may include insulin, the β-cell enzyme glutamic acid decarboxylase (GAD), and others. Consistent with the idea that failure of self-tolerance is fundamental to the pathogenesis of T1D, cancer patients

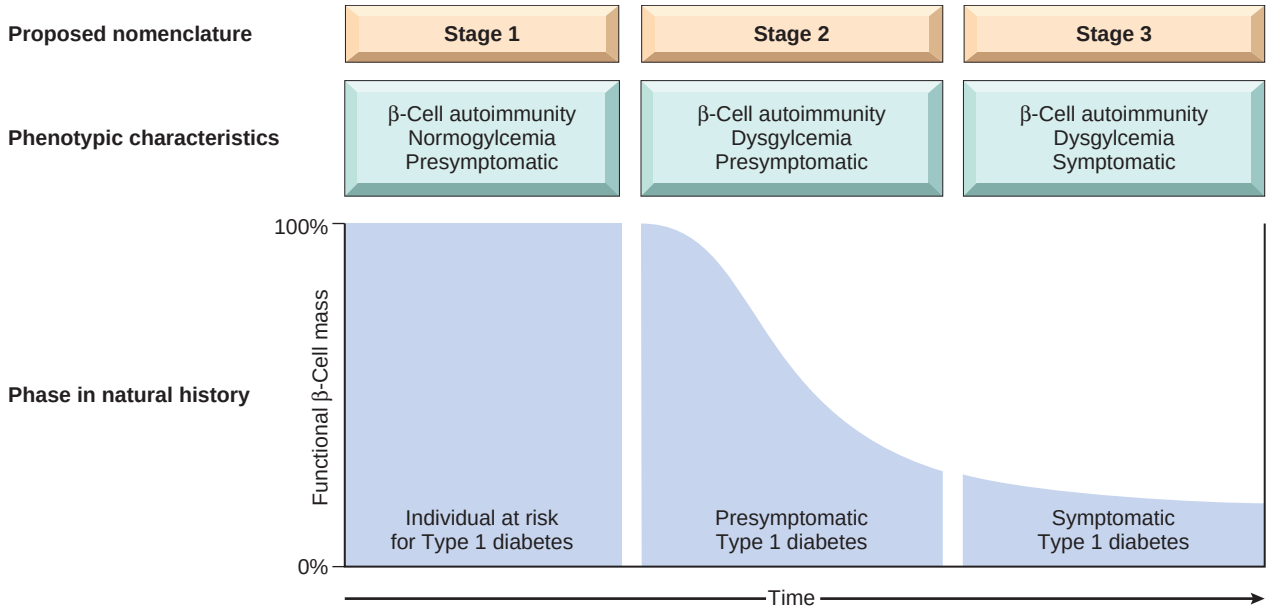

Figure 24.31 The three stages of type 1 diabetes. (Modified with permission from Insel RA, Dunne JL, Atkinson MA, et al: Staging presymptomatic type 1 diabetes: a scientific statement of JDRF, the Endocrine Society, and the American Diabetes Association, *Diabetes Care* 38(10):1964–1974, 2015.)

treated with immune checkpoint blockade therapy, which disrupts tolerance mechanisms, sometimes develop the disease.

A role for antibodies in T1D is suspected because autoantibodies against islet antigens are found in the vast majority of patients with T1D, including at the presymptomatic stages of disease, as described earlier. However, it is not clear if the autoantibodies cause injury or are merely a consequence of islet injury.

Pathogenesis of Type 2 Diabetes

T2D is a complex disease that involves the interplay of genetic and environmental factors and a pro-inflammatory state. Unlike T1D, there is no evidence of an autoimmune basis.

Genetic Factors

Genetic susceptibility contributes to the pathogenesis, as evidenced by the disease concordance rate of greater than 90% in monozygotic twins, a rate higher than in T1D. Furthermore, first-degree relatives have 5- to 10-fold higher risk of developing T2D than those without a family history, when matched for age and weight. GWAS performed over the past decade have identified at least 30 loci that individually confer a minimal to modest increase in the lifetime risk for T2D. Many of these genes are involved in adipose tissue function (through effects on bodily fat distribution [visceral vs. subcutaneous]), islet β-cell function, and obesity. It is believed that together, these genetic polymorphisms conspire to provide the genetic basis for T2D risk. However, heritable risk remains a minor player impacting disease susceptibility, and environmental factors are the major contributors.

Environmental Factors

The most important environmental risk factor for T2D is obesity, particularly central or visceral obesity. Greater than 80% of individuals with T2D are obese, and the incidence of diabetes worldwide has risen in proportion to obesity. Obesity contributes to the cardinal metabolic abnormalities of diabetes (see later) and to insulin resistance early in disease. In fact, even modest weight loss through dietary modifications can reduce insulin resistance and improve glucose tolerance. A sedentary lifestyle (typified by lack of exercise) is another risk factor for diabetes, independent of obesity. Weight loss and exercise usually increase insulin sensitivity additively and are often first-line interventions in patients with milder T2D. The combination of obesity, hyperglycemia, increased serum cholesterol and triglycerides, and hypertension is called the *metabolic syndrome*.

Despite this general risk, several populations worldwide in which T2D rates are increasing most rapidly (e.g., East Asian, South Asian, and Middle Eastern) do not show comparable increases in obesity (increased body mass index [BMI], a measure of total body fat). This has suggested that risk is related not only to the amount of body fat but also to its anatomic distribution, as discussed later.

Sleep disorders (such as obstructive sleep apnea) and circadian disruption are additional environmental risk factors for T2D. Circadian disruption is defined as misalignment between the endogenous circadian rhythm and the cycle or rhythm created by individual behaviors. Those at risk for circadian disruption include shift workers and those with sleep disorders or other conditions that restrict nighttime sleep and daytime wakefulness. Studies have shown that circadian disruption impairs glucose homeostasis by affecting both insulin secretion and insulin action. In addition, GWAS have shown an association between circadian-controlled genes and T2D. Disruption of "clock" genes not only affects insulin secretion and action but also activity level and feeding behaviors, resulting in increased risk for hyperglycemia and diabetes.

Metabolic Defects in Type 2 Diabetes

The development of T2D involves two key abnormalities:

- *Insulin resistance:* Decreased response of peripheral tissues, especially skeletal muscle, adipose tissue, and liver, to insulin
- *β-cell dysfunction:* Inadequate insulin secretion in the face of insulin resistance and hyperglycemia

Insulin resistance predates the development of hyperglycemia and is usually accompanied by compensatory β-cell hyperfunction and hyperinsulinemia in the early stages of the evolution of T2D (Fig. 24.32). Over time, the inability of β cells to adapt to increasing secretory needs for maintaining a euglycemic state results in chronic hyperglycemia and the resulting long-standing complications of diabetes.

Insulin Resistance

Insulin resistance is the failure of target tissues to respond normally to insulin. The liver, skeletal muscle, and adipose tissue are the major tissues where insulin resistance gives rise to abnormal glucose tolerance. Insulin resistance results in the following:

- Failure to inhibit endogenous glucose production (gluconeogenesis) in the liver, which contributes to high fasting blood glucose levels
- Failure of glucose uptake and glycogen synthesis to occur in skeletal muscle following a meal, which contributes to high postprandial blood glucose level
- Failure to inhibit activation of "hormone-sensitive" lipases in adipose tissue, leading to excess triglyceride breakdown in adipocytes and high levels of circulating free fatty acids (FFAs).

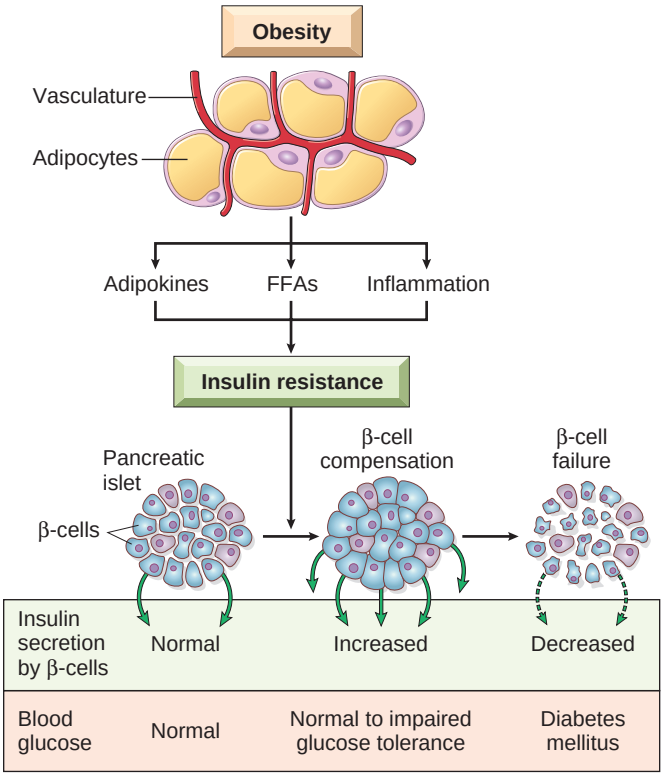

Figure 24.32 Development of type 2 diabetes. Insulin resistance associated with obesity is induced by adipokines, free fatty acids *(FFAs)*, and chronic inflammation in adipose tissue. Pancreatic β cells compensate for insulin resistance by hypersecretion of insulin. However, at some point, β-cell compensation is followed by β-cell failure, and diabetes ensues. (Reproduced with permission from Kasuga M: Insulin resistance and pancreatic β-cell failure, *J Clin Invest* 116(7):1756–1760, 2006.)

A variety of functional defects in the insulin-signaling pathway underlie insulin resistance. For example, reduced tyrosine phosphorylation of the insulin receptor and IRS proteins is observed in peripheral tissues, which compromises insulin signaling and reduces the level of the glucose transporter GLUT-4 on the cell surface (see Fig. 24.30). In fact, one of the mechanisms by which exercise improves insulin sensitivity is by increasing the translocation of GLUT-4 to the plasma membrane of skeletal muscle cells.

Obesity

Multiple factors contribute to insulin resistance, of which obesity is probably the most important. The risk for diabetes rises as the BMI increases. Not only the absolute amount of fat but also its distribution determines insulin sensitivity: central obesity (abdominal fat) is more likely to be linked with insulin resistance than is peripheral (gluteal/subcutaneous) obesity. In fact, individuals from Asia and the Middle East who develop diabetes without overt obesity have primarily visceral adiposity, and it is this increase in visceral fat that appears to engender T2D risk for them. By contrast, individuals who develop primarily subcutaneous adiposity may be relatively protected from T2D. Studies of these so-called "metabolically healthy obese" individuals is an emerging field.

Obesity can adversely impact insulin sensitivity in numerous ways (see Fig. 24.32):

- *Free fatty acids (FFAs).* Cross-sectional studies have demonstrated an inverse correlation between fasting plasma FFAs and insulin sensitivity. Central adipose tissue is more "lipolytic" than peripheral sites, which might explain the particularly deleterious consequences of this pattern of fat distribution. Excess FFAs overwhelm the intracellular fatty acid oxidation pathways, leading to the accumulation of cytoplasmic intermediates like diacylglycerol (DAG), phospholipids, and sphingolipids, including ceramides. These "toxic" lipid metabolites can attenuate signaling through the insulin receptor and activate inflammatory pathways in the islets, which further promote β-cell abnormalities. In liver cells, insulin normally inhibits gluconeogenesis by blocking the activity of phosphoenolpyruvate carboxykinase, the first enzymatic step in this process. Attenuated insulin signaling allows phosphoenolpyruvate carboxykinase to "ramp up" gluconeogenesis. Excess FFAs also compete with glucose as substrates for oxidation, further exacerbating the reduced glucose utilization.
- *Adipokines.* You will recall that adipose tissue is not merely a storage depot for fat but is also an endocrine organ that releases hormones in response to changes in metabolism (Chapter 9). A variety of proteins secreted into the circulation by adipose tissue have been identified that are collectively termed *adipokines* (or adipose cytokines). Some of these promote hyperglycemia, while others (such

as leptin and adiponectin) decrease blood glucose, in part by increasing insulin sensitivity in peripheral tissues. Adiponectin levels are reduced in obesity, thus contributing to insulin resistance.

- *Inflammation:* Over the past several years, inflammation has emerged as an important factor in the pathogenesis of T2D. It is now known that an inflammatory milieu—mediated not by an autoimmune process, as in T1D, but rather by pro-inflammatory cytokines that are secreted in response to excess nutrients such as FFAs and glucose—results in both insulin resistance and β-cell dysfunction. Excess FFAs within macrophages and β cells can activate the inflammasome, a multiprotein cytoplasmic complex that leads to secretion of the cytokine interleukin IL-1β (Chapter 3). IL-1β, in turn, mediates the secretion of additional pro-inflammatory cytokines from macrophages, islet cells, and other cells. IL-1 and other cytokines act on the major sites of insulin action to promote insulin resistance. Thus, excess FFAs can impede insulin signaling directly within peripheral tissues, as well as indirectly through the release of pro-inflammatory cytokines.
- *Liver steatosis:* High circulating levels of FFAs may result in the accumulation of excess fat (steatosis) in hepatocytes. This form of nonalcoholic fatty liver disease (NAFLD) ranges in severity from hepatic steatosis without evidence of liver injury to nonalcoholic steatohepatitis (NASH) with evidence of inflammation and hepatocyte injury with or without fibrosis (Chapter 18). NAFLD is common in those with metabolic syndrome and T2D, an association that cuts both ways: NAFLD promotes the development of T2D, which in turn increases the risk of developing the more severe forms of NAFLD.

β-Cell Dysfunction

While insulin resistance by itself can lead to impaired glucose tolerance, **β-cell dysfunction is a requirement for the development of overt diabetes.** In contrast to the severe genetic defects in β-cell function that occur in monogenic forms of diabetes (see later), β-cell function actually increases early in the disease process in most patients with "sporadic" T2D as a compensatory measure to counter insulin resistance and maintain euglycemia. Eventually, however, β cells seemingly exhaust their capacity to adapt to the long-term demands posed by insulin resistance, and the hyperinsulinemic state gives way to a state of relative insulin deficiency, that is, insulin levels are deficient for the level of blood glucose.

Several mechanisms have been implicated in promoting β-cell dysfunction in T2D, including the following:

- Excess FFAs that compromise β-cell function and attenuate insulin release *(lipotoxicity)*
- The impact of chronic hyperglycemia *(glucotoxicity)*
- An abnormal *incretin effect,* leading to reduced secretion of GIP and GLP-1, hormones that promote insulin release (see earlier)
- Amyloid deposition within islets. This is a characteristic finding in individuals with long-standing T2D, being present in more than 90% of diabetic islets examined, but it is unclear whether it is a cause or an effect of β-cell "burnout."
- Finally, the impact of genetics cannot be discounted, as many of the polymorphisms associated with an increased lifetime risk for T2D occur in genes that control insulin secretion (see earlier).

Monogenic Forms of Diabetes

Although genetically defined causes of diabetes are uncommon, they have been intensively studied in the hope of gaining insights into the disease. As Table 24.6 illustrates, monogenic forms of diabetes are classified separately from types 1 and 2 diabetes. Monogenic forms of diabetes result from either a primary defect in β-cell function or a defect in insulin receptor signaling (described later).

Genetic Defects in β-Cell Function

Approximately 1% to 2% of patients with diabetes harbor a primary defect in β-cell function that affects either β-cell mass and/or insulin production. This form of monogenic diabetes is caused by a heterogeneous group of genetic defects. The largest subgroup of patients in this category was designated as having "maturity-onset diabetes of the young" (MODY) because of its superficial resemblance to T2D and its occurrence in younger patients. MODY can result from germline loss-of-function mutations in one of six genes (see Table 24.6), of which mutations of *glucokinase (GCK)* are the most common. Glucokinase is a rate-limiting step in oxidative glucose metabolism, which, in turn, is coupled to insulin secretion within islet β cells (see Fig. 24.28).

Genetic Defects That Impair Tissue Response to Insulin

Rare insulin receptor mutations that affect receptor synthesis, insulin binding, or RTK activity can cause severe insulin resistance, accompanied by hyperinsulinemia and diabetes (*type A insulin resistance*). Such patients often show a velvety hyperpigmentation of the skin known as *acanthosis nigricans*. Females with type A insulin resistance also frequently have polycystic ovaries and elevated androgen levels.

Diabetes and Pregnancy

Pregnancy can be complicated by diabetes in one of two settings: when women with preexisting diabetes become pregnant ("pregestational" or overt diabetes) or women who were previously euglycemic develop impaired glucose tolerance and diabetes for the first time during pregnancy ("gestational" diabetes). Approximately 5% to 9% of pregnancies occurring in the United States are complicated by hyperglycemia, and the incidence of both pregestational and gestational diabetes is increasing in the general population. Pregnancy is a "diabetogenic" state in which the prevailing hormonal milieu favors insulin resistance. In a previously euglycemic woman who is otherwise susceptible due to concurrent genetic and environmental factors, the consequence may be gestational diabetes. Of even greater concern, women with pregestational diabetes have an increased risk of *stillbirth* and *congenital malformations* in the fetus. Poorly controlled diabetes that arises later in pregnancy, regardless of prior history, can lead to excessive birth weight in the newborn *(macrosomia)* and may have long-term sequelae for the child later in life, including an increased risk of obesity and diabetes. Gestational diabetes typically resolves following delivery; however, the majority of affected women develop overt diabetes over the next 10 to 20 years.

Clinical Features of Diabetes

It is difficult to sketch with brevity the diverse clinical presentations of diabetes. We will discuss the most common initial presentation or mode of diagnosis for each of the two major subtypes, followed by a discussion of acute and then chronic (long-term) complications of the disease.

T1D may arise at any age. In the initial 1 or 2 years following the onset of overt T1D, exogenous insulin requirements may be minimal because of residual endogenous insulin secretion (referred to as the *honeymoon period*). Eventually, however, β-cell function declines to a tipping point, and insulin requirements increase dramatically. Although β-cell destruction is a prolonged process, the transition from impaired glucose tolerance (stage 2, see earlier) to overt diabetes (stage 3) may be abrupt and is often brought on by a superimposed stress, such as infection, because of associated increase in insulin requirements.

In contrast to T1D, T2D is typically seen in obese patients older than 40 years of age; however, it is now being diagnosed in children and adolescents with increasing frequency due to increases in obesity and sedentary lifestyle. In some cases, medical attention is sought because of unexplained fatigue, dizziness, or blurred vision. Most frequently, however, the diagnosis of T2D is made after routine blood testing in asymptomatic persons. In fact, in light of the large number of asymptomatic individuals with undiagnosed hyperglycemia in the United States, routine blood glucose testing is recommended for everyone older than 45 years of age, and in younger individuals with obesity, family history, or the presence of the metabolic syndrome.

The Classic Triad of Diabetes

The onset of T1D is usually marked by the triad of polyuria, polydipsia, polyphagia, and, when severe, diabetic ketoacidosis, all resulting from metabolic derangements. Because insulin is a major anabolic hormone, its deficiency results in a catabolic state that affects glucose, fat, and protein metabolism. Unopposed secretion of counterregulatory hormones (such as glucagon) also plays a role in these metabolic derangements. The assimilation of glucose into muscle and adipose tissue is sharply diminished or abolished. Not only does storage of glycogen in liver and muscle cease, but reserves are depleted by glycogenolysis. The resultant *hyperglycemia* leads to filtration of so much glucose in the kidney that the renal tubular threshold for reabsorption is exceeded. This leads to glycosuria, which induces an osmotic diuresis and thus *polyuria,* causing a profound loss of water and electrolytes (Fig. 24.33). The renal water loss combined with the hyperosmolarity owing to increased levels of glucose in the blood depletes intracellular water, triggering the osmoreceptors of the thirst centers of the brain. Thus, intense thirst *(polydipsia)* appears. With a deficiency of insulin, the scales swing from insulin-promoted anabolism to catabolism of proteins and fats. Proteolysis follows, releasing gluconeogenic amino acids that are removed by the liver and used as building blocks for glucose. The catabolism of proteins and fats tends to induce a negative energy balance, which in turn leads to increasing appetite *(polyphagia),* thus completing the classic triad of polyuria, polydipsia, and polyphagia. Despite the increased appetite, catabolic effects prevail, resulting in weight loss and muscle weakness. The combination of polyphagia and weight loss is paradoxical and should always raise the suspicion of diabetes.

Acute Metabolic Complications of Diabetes

Diabetic ketoacidosis is a severe acute metabolic complication of T1D; it is not as common or as severe in T2D. The most frequent precipitating factor is a failure to take insulin, although other stressors such as infections, other illnesses, trauma, and certain drugs may also serve as triggers. It may also occur less commonly in T2D but only under condition of very severe stress such as caused by serious infections and trauma. Many of these factors are associated with the release of the catecholamine epinephrine, which blocks residual insulin action and stimulates the secretion of glucagon. The insulin deficiency coupled with glucagon excess decreases peripheral utilization of glucose while increasing gluconeogenesis, severely exacerbating hyperglycemia (the plasma glucose levels are usually in the range of 250 to 600 mg/dL). The hyperglycemia causes an osmotic diuresis and dehydration characteristic of the ketoacidotic state.

A second major effect of insulin deficiency is increased synthesis of ketone bodies. Insulin deficiency stimulates hormone-sensitive lipase, with a resultant breakdown of adipose stores and an increase in levels of FFAs. When these FFAs reach the liver, they are esterified to fatty acyl coenzyme A. Oxidation of fatty acyl coenzyme A molecules within the hepatic mitochondria produces *ketone bodies* (acetoacetic acid and β-hydroxybutyric acid). The rate at which ketone bodies are formed may exceed the rate at which they can be utilized by peripheral tissues, leading to *ketonemia* and *ketonuria*. If the urinary excretion of ketones is compromised by dehydration, the result is a systemic *metabolic ketoacidosis*. Release of ketogenic amino acids by protein catabolism aggravates the ketotic state.

The clinical manifestations of diabetic ketoacidosis include fatigue, nausea and vomiting, severe abdominal pain, a characteristic fruity odor, and deep, labored breathing (also known as *Kussmaul breathing*). Persistence of the ketotic state eventually leads to depressed consciousness and coma. Reversal of ketoacidosis requires administration of insulin, correction of metabolic acidosis, and treatment of any underlying precipitating factors, such as infection.

The lower frequency of ketoacidosis in T2D is believed to be due to higher portal vein insulin levels in these patients, which prevents unrestricted hepatic fatty acid oxidation and keeps the formation of ketone bodies in check. Instead, patients with T2D may develop a condition known as *hyperosmolar hyperglycemic state* due to severe dehydration resulting from sustained osmotic diuresis (particularly in patients who do not drink enough water to compensate for urinary losses from chronic hyperglycemia). Typically, this occurs in an older patient who has diabetes and is disabled by a stroke or an infection and thus unable to maintain adequate water intake. Furthermore, the absence of ketoacidosis and its symptoms (nausea, vomiting, Kussmaul breathing) delays the seeking of medical attention until severe dehydration and impairment of mental status occur. The hyperglycemia is usually more severe than in diabetic ketoacidosis, in the range of 600 to 1200 mg/dL.

Once treatment commences, ironically, the most common acute metabolic complication in either type of diabetes is

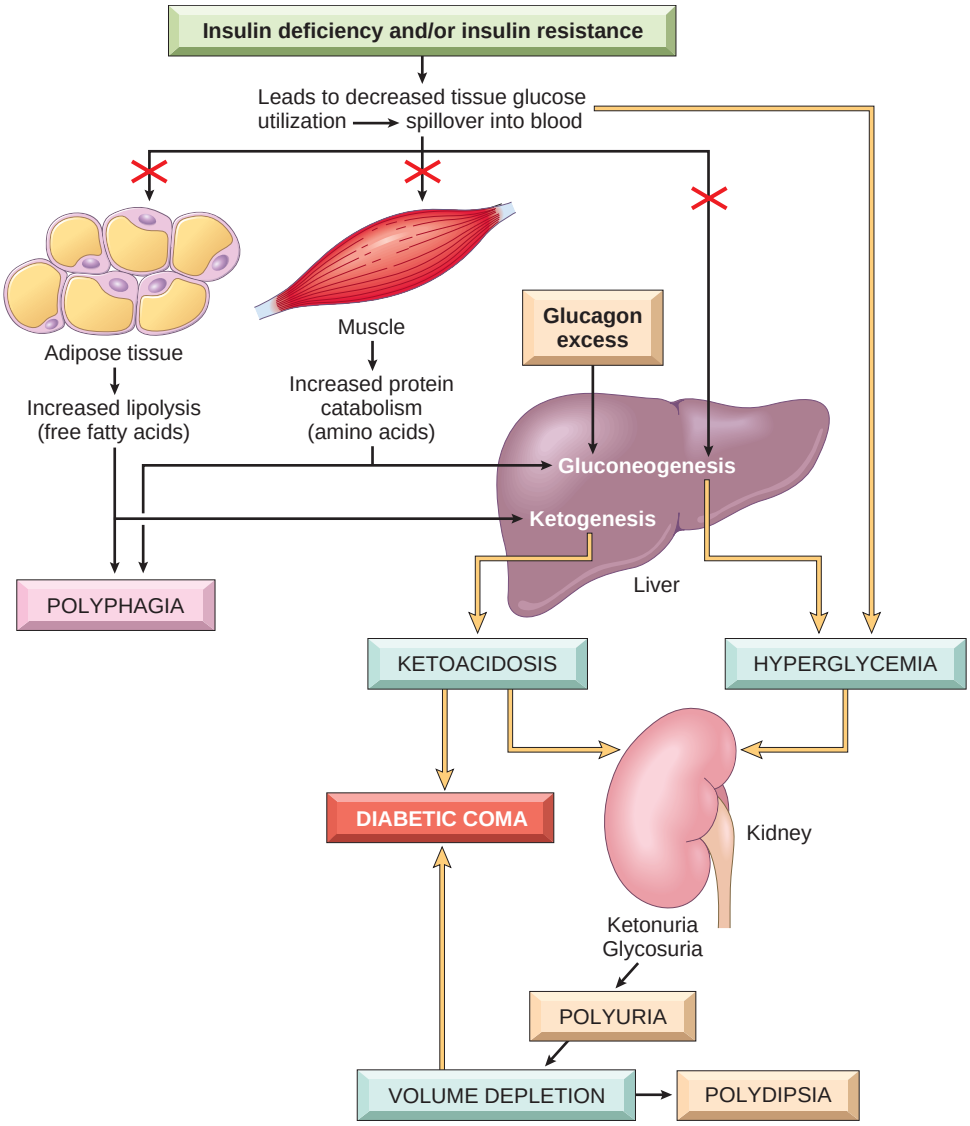

Figure 24.33 Sequence of metabolic derangements underlying the clinical manifestations of diabetes. An absolute insulin deficiency leads to a catabolic state, culminating in ketoacidosis and severe volume depletion. These cause sufficient central nervous system compromise to lead to coma and eventual death if left untreated.

hypoglycemia. Causes include missing a meal, excessive physical exertion, excessive insulin administration, or "misdosing" during the phase of dose finding for antidiabetic agents such as sulfonylureas. The signs and symptoms of hypoglycemia include dizziness, confusion, sweating, palpitations, and tachycardia; if hypoglycemia persists, loss of consciousness may occur. Rapid reversal of hypoglycemia through oral or intravenous glucose intake is critical for preventing permanent neurologic damage.

Chronic Complications of Diabetes

The morbidity associated with long-standing diabetes of either type is due to damage induced in large- and medium-sized muscular arteries (diabetic macrovascular disease) and in small vessels (diabetic microvascular disease) by chronic hyperglycemia. Macrovascular disease causes accelerated atherosclerosis among patients with diabetes, resulting in increased risk of myocardial infarction, stroke, and lower extremity ischemia. The effects of microvascular disease are most profound in the retina, kidneys, and peripheral nerves, resulting in *diabetic retinopathy, nephropathy, and neuropathy,* respectively (see later).

Pathogenesis

Persistent hyperglycemia (glucotoxicity) seems to be responsible for the long-term complications of diabetes. Much of the evidence supporting a role for glycemic control in ameliorating the long-term complications of diabetes has come from large randomized trials. The assessment of glycemic control in these trials has been based on the percentage of *glycated hemoglobin,* also known as HbA1c, which is formed by nonenzymatic covalent addition of glucose moieties to hemoglobin in red cells. Unlike blood glucose levels, HbA1c provides a measure of glycemic control over the lifespan of a red cell (120 days) and is affected little by day-to-day variation in glucose levels. It is recommended that HbA1c be maintained below 7% in patients with diabetes. The emergence of new technology, including

continuous glucose-monitoring systems, has introduced a new goal, increasing "time-in-range" (set at 70 to 180 mg/dL), which may be a better predictor of the risk of chronic complications than HbA1c level. It is important to stress, however, that hyperglycemia is not the only factor responsible for the long-term complications of diabetes, and that other underlying abnormalities, such as insulin resistance, and comorbidities like obesity, also play an important role.

At least four distinct mechanisms have been implicated in the deleterious effects of persistent hyperglycemia on peripheral tissues. **In each proposed mechanism, increased flux through metabolic pathways due to hyperglycemia is thought to generate harmful precursors that contribute to end-organ damage.**

- *Formation of advanced glycation end products.* Advanced glycation end products (AGEs) are formed as a result of nonenzymatic reactions between glucose-derived metabolites (glyoxal, methylglyoxal, and 3-deoxyglucosone) and the amino groups of intracellular and extracellular proteins. The rate of AGE formation is accelerated by hyperglycemia. AGEs bind to a specific receptor (RAGE) that is expressed on inflammatory cells (macrophages and T cells), endothelium, and vascular smooth muscle. The detrimental effects of the AGE-RAGE signaling axis within the vascular compartment include the following:
  - Release of *cytokines and growth factors,* including transforming growth factor-β (TGF-β), which leads to deposition of excess basement membrane material, and vascular endothelial growth factor (VEGF), implicated in diabetic retinopathy (see later)
  - Generation of *reactive oxygen species* (ROS) in endothelial cells
  - Increased *procoagulant activity* on endothelial cells and macrophages
  - Enhanced *proliferation of vascular smooth muscle cells* and *synthesis of extracellular matrix*

  Not surprisingly, endothelium-specific overexpression of RAGE in diabetic mice accelerates large vessel injury and microangiopathy, while RAGE-null mice show attenuation of these features. Antagonists of RAGE have emerged as therapeutic agents in diabetes and are being tested in clinical trials.

  In addition to receptor-mediated effects, AGEs can directly cross-link extracellular matrix proteins. Cross-linking of collagen type I molecules in large vessels decreases their elasticity, which may predispose these vessels to shear stress and endothelial injury (Chapter 11). Similarly, AGE-induced cross-linking of type IV collagen in basement membrane decreases endothelial cell adhesion and increases extravasation of fluid. Proteins cross-linked by AGEs are resistant to proteolytic digestion. Thus, cross-linking decreases protein removal, enhancing protein accumulation. AGE-modified matrix components also trap nonglycated plasma or interstitial proteins. In large vessels, trapping of LDL, for example, retards its efflux from the vessel wall and contributes to the deposition of cholesterol in the intima, thus accelerating atherogenesis (Chapter 11). In capillaries, including those of renal glomeruli, plasma proteins such as albumin bind to the glycated basement membrane, accounting in part for the basement membrane thickening that is characteristic of diabetic microangiopathy.
- *Activation of protein kinase C.* Calcium-dependent activation of intracellular protein kinase C (PKC) and the second messenger diacyl glycerol (DAG) is an important signal transduction pathway. Intracellular hyperglycemia stimulates the *de novo* synthesis of DAG from glycolytic intermediates, and hence causes excessive PKC activation. The downstream effects of PKC activation are numerous, including production of VEGF, TGF-β, and the procoagulant protein plasminogen activator inhibitor-1 (PAI-1) (Chapter 4) by the vascular endothelium. It should be evident that some effects of AGEs and activated PKC are overlapping, and both likely contribute to diabetic microangiopathy.
- *Oxidative stress and disturbances in polyol pathways.* Even in tissues that do not require insulin for glucose transport (e.g., nerves, lenses, kidneys, blood vessels), persistent hyperglycemia leads to an increase in intracellular glucose. This excess glucose is metabolized by the enzyme aldose reductase to sorbitol, a polyol, and eventually to fructose, in a reaction that uses NADPH (the reduced form of nicotinamide dinucleotide phosphate) as a cofactor. NADPH is also required by the enzyme glutathione reductase in a reaction that regenerates reduced glutathione (GSH). GSH is one of the important antioxidant mechanisms in the cell (Chapter 2), and any reduction in GSH increases cellular susceptibility to reactive oxygen species ("oxidative stress"). In the face of sustained hyperglycemia, progressive depletion of intracellular NADPH by aldose reductase compromises GSH regeneration, increasing cellular susceptibility to oxidative stress. Sorbitol accumulation in the lens contributes to cataract formation.
- *Hexosamine pathways and generation of fructose-6-phosphate.* Finally, it is postulated that hyperglycemia induces flux of glycolytic intermediates through the hexosamine pathway, which results in cell damage and enhanced oxidative stress.

Morphology of Chronic Complications of Diabetes

The important morphologic changes are related to the many late systemic complications of diabetes. As discussed earlier, these changes are seen in both T1D and T2D (Fig. 24.34).

MORPHOLOGY

PANCREAS

Alterations in the pancreas are inconstant and often subtle. Distinctive changes are more commonly associated with T1D than with T2D. One or more of the following alterations may be present:

- **Reduction in the number and size of islets.** This is most often seen in T1D, particularly with rapidly advancing disease. Most of the islets are small and inconspicuous.
- **Leukocytic infiltrates in the islets** (insulitis) are principally composed of T lymphocytes and are also seen in animal models of autoimmune diabetes (Fig. 24.35A). Lymphocytic infiltrates may be present in T1D at the time of clinical presentation.
- **In T2D there may be a subtle reduction in islet cell mass,** demonstrated only by special morphometric studies.
- **Amyloid deposition within islets in T2D** begins in and around capillaries and between cells. At advanced stages, the

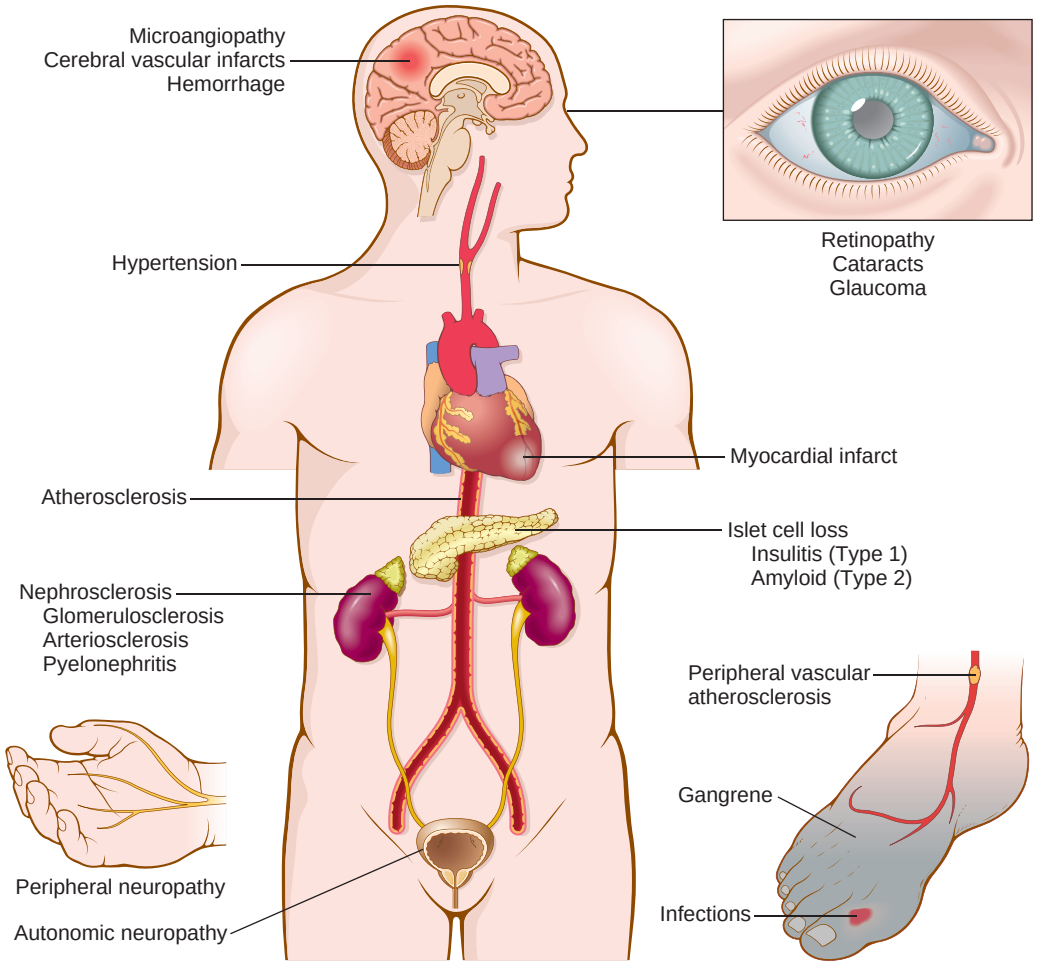

Figure 24.34 Long-term complications of diabetes.

islets may be virtually obliterated (see Fig. 24.35B); fibrosis may also be observed. Similar lesions may be found in older individuals without diabetes, apparently as part of normal aging.

- **An increase in the number and size of islets** is especially characteristic of nondiabetic newborns of mothers with diabetes. Presumably, fetal islets undergo hyperplasia in response to the maternal hyperglycemia.

Diabetic Macrovascular Disease

Diabetes exacts a heavy toll on the vascular system. *Endothelial dysfunction* (Chapter 11), which predisposes to atherosclerosis and other cardiovascular morbidities, is widespread in diabetes, as a consequence of the deleterious effects of persistent hyperglycemia and insulin resistance on the vascular compartment. The hallmark of diabetic macrovascular disease is *accelerated atherosclerosis* involving the aorta and large- and medium-sized arteries. The morphology of atherosclerosis in patients with diabetes is indistinguishable from that in individuals without diabetes (Chapter 11). **Myocardial infarction, caused by atherosclerosis of the coronary arteries, is the most common cause of death in diabetes.** *Gangrene of the lower extremities,* as a result of advanced vascular disease, is about 100 times more common in diabetes patients than in the general population. The larger renal arteries are also subject to severe atherosclerosis, but the most damaging effect of diabetes on the kidneys is exerted at the level of the glomeruli and the microcirculation (discussed later).

Hyaline arteriolosclerosis, the vascular lesion associated with essential hypertension (Chapters 11 and 20), is both more prevalent and more severe in patients with diabetes than those without, but it is not specific for diabetes and may be seen in older patients without hypertension. It takes the form of an amorphous, hyaline thickening of the wall of the arterioles, which causes narrowing of the lumen (Fig. 24.36). Not surprisingly, in diabetic patients, it is related not only to the duration of the disease but also to the level of blood pressure.

Diabetic Microangiopathy

One of the most consistent morphologic features of diabetes is *diffuse thickening of basement membranes.* The thickening is most evident in the capillaries of the skin, skeletal muscle, retina, renal glomeruli, and renal medulla. However, it may also be seen in such nonvascular structures as renal tubules, the Bowman capsule, peripheral nerves, and placenta. It should be noted that despite the increase in the thickness of basement membranes, capillaries in patients with diabetes are leakier than normal to plasma proteins. **The microangiopathy underlies the development of**

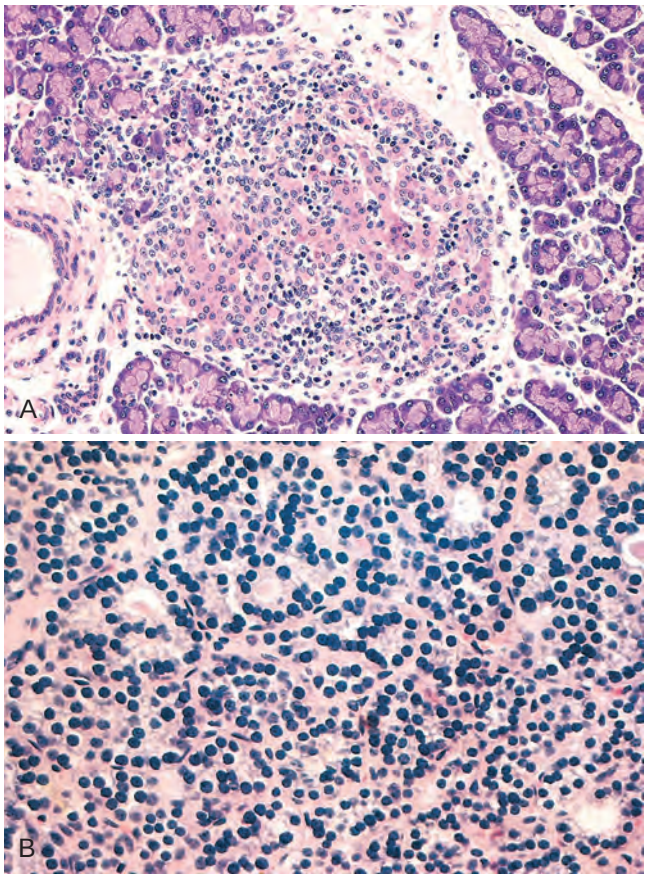

Figure 24.35 (A) Insulitis, shown here from a rat (BB) model of autoimmune diabetes, also seen in type 1 human diabetes. (B) Amyloidosis of a pancreatic islet in type 2 diabetes. (A, Courtesy Dr. Arthur Like, University of Massachusetts, Worchester, Mass.)

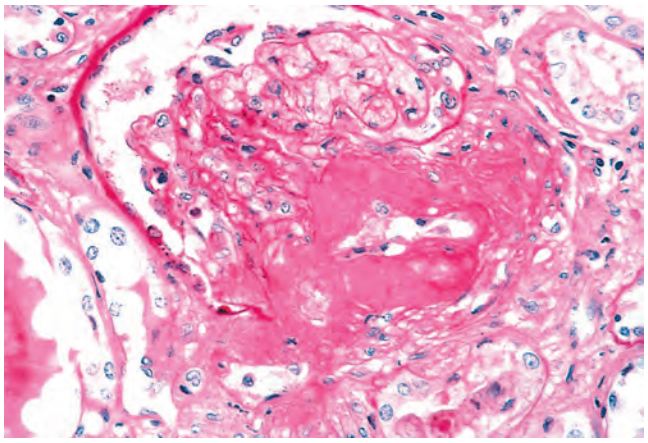

Figure 24.36 Severe renal hyaline arteriolosclerosis. Note a markedly thickened, tortuous afferent arteriole. The amorphous nature of the thickened vascular wall is evident (periodic acid–Schiff stain). diabetic nephropathy, retinopathy, and some forms of neuropathy.

Diabetic Nephropathy

The kidneys are prime targets of diabetes. Renal failure is second only to myocardial infarction as a cause of death from this disease. **Three lesions are encountered: (1) glomerular lesions; (2) renal vascular lesions, principally arteriolosclerosis; and (3) pyelonephritis, including necrotizing papillitis.**

The most important glomerular lesions are capillary basement membrane thickening, diffuse mesangial sclerosis, and nodular glomerulosclerosis.

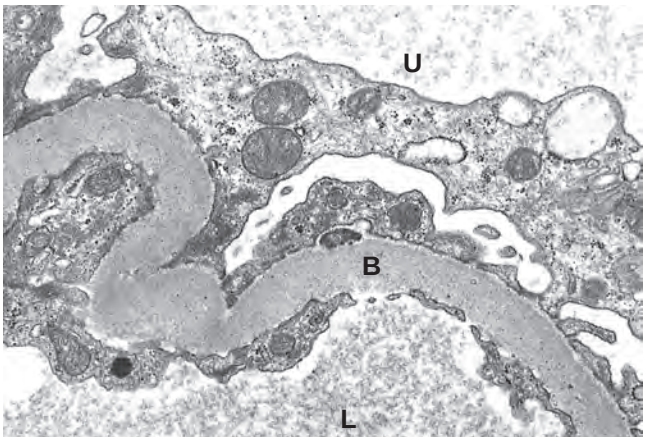

Figure 24.37 Electron micrograph of a renal glomerulus showing markedly thickened glomerular basement membrane *(B)* in a diabetic. *L,* Glomerular capillary lumen; *U,* urinary space. (Courtesy Dr. Michael Kashgarian, Department of Pathology, Yale University School of Medicine, New Haven, Conn.)

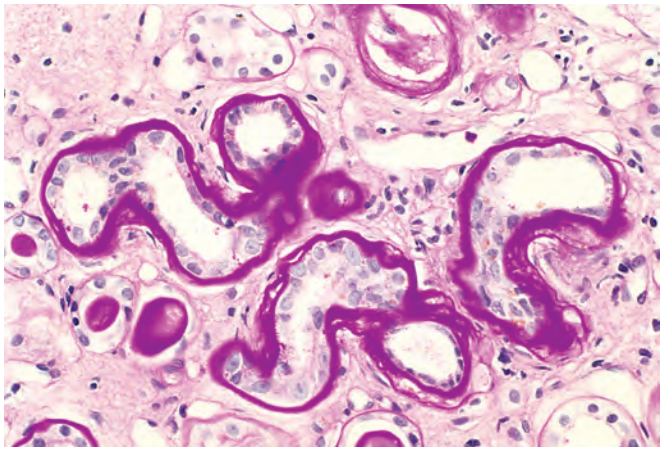

Figure 24.38 Renal cortex showing thickening of tubular basement membranes in a diabetic patient (periodic acid–Schiff stain).

Capillary Basement Membrane Thickening. Widespread thickening of the glomerular capillary basement membrane (GBM) occurs in virtually all cases of diabetic nephropathy and is part and parcel of diabetic microangiopathy. Capillary basement membrane thickening is best appreciated by electron microscopy (Fig. 24.37). Morphometric studies demonstrate that thickening begins as early as 2 years after the onset of T1D and by 5 years amounts to about a 30% increase. These progressive changes in the GBM are usually accompanied by mesangial widening and thickening of the tubular basement membranes (Fig. 24.38).

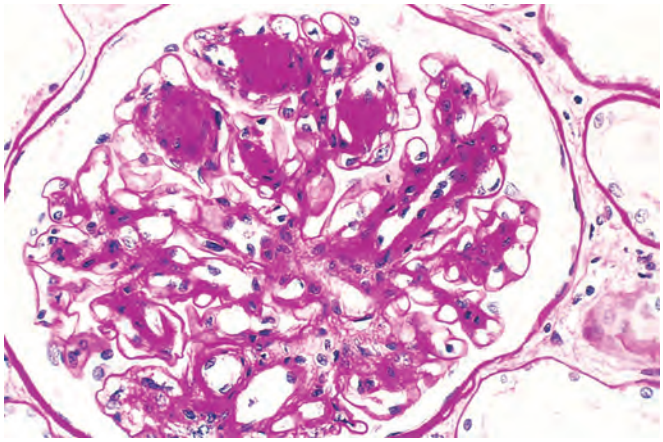

Figure 24.39 Diffuse and nodular diabetic glomerulosclerosis (periodic acid–Schiff [PAS] stain). Note the diffuse increase in mesangial matrix and characteristic acellular PAS-positive nodules.

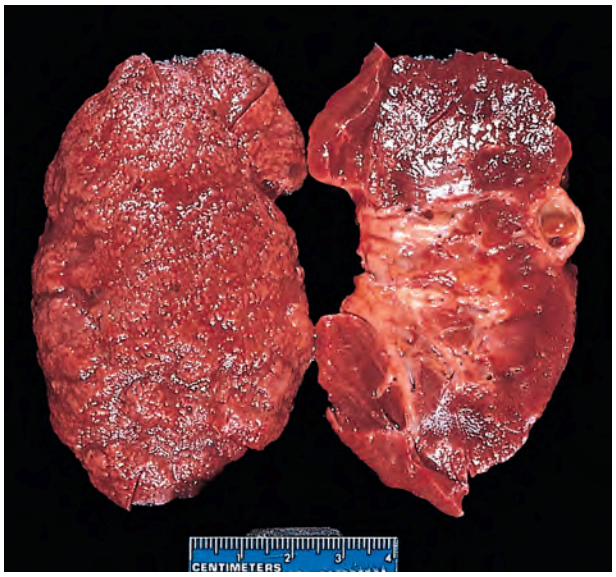

Figure 24.40 Nephrosclerosis in a patient with long-standing diabetes. The kidney has been bisected to demonstrate both diffuse granular transformation of the surface *(left)* and marked thinning of the cortical tissue *(right)*. Additional features include some irregular depressions, the result of pyelonephritis, and an incidental cortical cyst *(far right)*.

Diffuse Mesangial Sclerosis. This lesion consists of diffuse increase in mesangial matrix. The matrix depositions are PAS-positive (Fig. 24.39). As the disease progresses, the mesangial matrix deposits may take on a nodular appearance. The progressive expansion of the mesangium has been shown to correlate well with measures of deteriorating renal function such as increasing proteinuria.

Nodular Glomerulosclerosis. This is also known as intercapillary glomerulosclerosis or *Kimmelstiel-Wilson disease.* The glomerular lesions take the form of ovoid or spherical, often laminated, PAS-positive nodules of matrix situated in the periphery of the glomerulus. They lie within the mesangial core of the glomerular lobules and may be surrounded by patent peripheral capillary loops (see Fig. 24.39) or loops that are markedly dilated. The nodules often show features of mesangiolysis, defined by disruption of anchoring interactions between the capillaries and the mesangial stalks. The loss of these support structures may lead to the formation of capillary microaneurysms. While not all the lobules in individual glomeruli are involved by nodular lesions, even uninvolved lobules and glomeruli show striking diffuse mesangial sclerosis. The nodular lesions are frequently accompanied by prominent accumulations of hyaline material in capillary loops ("fibrin caps") or adherent to Bowman capsules ("capsular drops"). Both afferent and efferent glomerular hilar arterioles show hyalinosis. As a consequence of the glomerular and arteriolar lesions, the kidney becomes ischemic, develops tubular atrophy and interstitial fibrosis, and usually contracts in size (Fig. 24.40). Approximately 15% to 30% of individuals with long-term diabetes develop nodular glomerulosclerosis, and in most instances it is associated with renal failure.

Renal atherosclerosis and arteriolosclerosis also contribute to renal dysfunction in patients with diabetes. Hyaline arteriolosclerosis affects not only the afferent but also the efferent arteriole. Such efferent arteriolosclerosis is rarely, if ever, encountered in individuals who do not have diabetes.

Pyelonephritis is an acute or chronic inflammation of the kidneys that usually begins in the interstitial tissue and then spreads to affect the tubules. Both the acute and chronic forms of this disease are more common and more severe in patients with diabetes than in the general population. One special pattern of acute pyelonephritis, papillary necrosis, is much more prevalent in diabetes patients than in those without diabetes.

Diabetic Ocular Complications

The eye is profoundly affected by diabetes mellitus. The architecture and microanatomy of the eye are discussed in Chapter 29.

Diabetes-induced hyperglycemia leads to acquired opacification of the lens, a condition known as *cataract.* Long-standing diabetes is also associated with increased intraocular pressure (**glaucoma;** see later), and resulting damage to the optic nerve.

The most profound ocular changes of diabetes are seen in the retina. The retinal vasculopathy of diabetes mellitus can be classified into background (preproliferative) diabetic retinopathy and proliferative diabetic retinopathy (Chapter 29).

Diabetic Neuropathy

The prevalence of peripheral neuropathy in individuals with diabetes depends on the duration of the disease; up to 50% of diabetes patients overall have peripheral neuropathy clinically, and up to 80% of those who have had the disease for more than 15 years. This is discussed further in Chapter 27.

Clinical Manifestations of Chronic Diabetes

Table 24.7 summarizes some of the pertinent clinical, genetic, and histopathologic features that distinguish T1D and T2D. **In both types, it is the long-term effects of diabetes, rather than acute metabolic complications, that are responsible for much of the morbidity and mortality.** In most instances, these complications appear approximately 15 to 20 years after the onset of hyperglycemia. The severity of chronic

complications is related to both the degree and the duration of hyperglycemia, as evidenced by the attenuation of end-organ damage by effective glycemic control in prospective studies.

- **Macrovascular complications such as myocardial infarction, renal vascular insufficiency, and cerebrovascular accidents are the most common causes of mortality in long-standing diabetes.** Patients with diabetes have a two to four times greater incidence of coronary artery disease and a fourfold higher risk of dying from cardiovascular complications than age-matched individuals without diabetes. An elevated risk for cardiovascular disease is even observed in patients with prediabetes. Significantly, myocardial infarction is almost as common in women with diabetes as in men. In contrast, myocardial infarction is uncommon in women of reproductive age without diabetes. Diabetes is often accompanied by underlying conditions that favor the development of adverse cardiovascular events. For example, *hypertension* is found in approximately 75% of individuals with T2D and potentiates the effects of hyperglycemia and insulin resistance on endothelial dysfunction and atherosclerosis. Another cardiovascular risk frequently seen in diabetes patients is *dyslipidemia,* which includes both increased triglycerides and LDL levels and decreased levels of the "protective" lipoprotein, high-density lipoprotein (Chapter 11). Insulin resistance is believed to contribute to "diabetic dyslipidemia" by favoring the hepatic production of atherogenic lipoproteins and by suppressing the uptake of circulating lipids in peripheral tissues.
- **Diabetic nephropathy is a leading cause of end-stage renal disease in the United States.** Approximately 30% to 40% of all patients with diabetes develop clinical evidence of nephropathy. Development of end-stage renal disease is more likely with T1D than T2D, but because of the greater prevalence of T2D, these patients constitute slightly over one-half of the patients with diabetes starting dialysis each year. The progression from overt nephropathy to end-stage renal disease is highly variable, but by 20 years, more than 75% of patients with T1D and approximately 20% of those with T2D with overt nephropathy will develop end-stage renal disease, requiring dialysis or renal transplantation.

  The likelihood of diabetic nephropathy is greatly influenced by ethnicity; for example, Native Americans, Hispanics, and African Americans have a greater risk of developing end-stage renal disease than do non-Hispanic Caucasians with T2D. These differences are suspected to be genetic in origin, but responsible genes have yet to be identified. The earliest manifestation of diabetic nephropathy is the appearance of low amounts of albumin (*microalbuminuria*) in the urine (>30 mg and <300 mg/day). Without specific interventions, approximately 80% of patients with T1D and 20% to 40% of patients with T2D will develop *overt nephropathy with macroalbuminuria* (>300 mg/day of urinary albumin) over 10 to 15 years, usually accompanied by the appearance of hypertension.
- **Visual impairment, including total blindness, is one of the more feared consequences of long-standing diabetes.** Approximately 60% to 80% of patients develop some form of *diabetic retinopathy* approximately 15 to 20 years after diagnosis, and diabetic retinopathy is the leading cause of adult blindness in the United States. The fundamental lesion of retinopathy—neovascularization—is attributable to hypoxia-induced expression of VEGF in the retina. Current treatment for this condition includes administration of antiangiogenic agents that block the action of VEGF. As stated earlier, patients with diabetes also have an increased propensity for *glaucoma* and *cataract formation,* which also contribute to visual impairment.
- **Diabetic neuropathy can result in damage to the central nervous system, peripheral sensorimotor nerves, and the autonomic nervous system.** It most frequently takes the form of a *distal symmetric polyneuropathy* of the lower extremities that affects both motor and sensory function. Over time, the upper extremities may be involved as well, thus approximating a "glove-and-stocking" pattern of polyneuropathy. Other forms include *autonomic neuropathy,* which produces disturbances in bowel and bladder function and sometimes erectile dysfunction, and *diabetic mononeuropathy,* which may manifest as sudden footdrop, wristdrop, or isolated cranial nerve palsies.
- **Patients with diabetes are plagued by enhanced susceptibility to infections of the skin and to tuberculosis, pneumonia, and pyelonephritis.** Such infections cause the deaths of about 5% of these patients. In an individual with diabetic neuropathy, a trivial infection in a toe may be the first event in a long succession of complications (gangrene, bacteremia, pneumonia) that ultimately leads to death. The basis of enhanced susceptibility is multifactorial and includes decreased neutrophil function (chemotaxis, adherence to the endothelium, phagocytosis, and microbicidal activity) and impaired cytokine production by macrophages. The vascular compromise also impairs the delivery of immune cells and molecules to sites of infection.

The staggering societal and economic impact of diabetes has already been discussed. For the most part, diabetes remains a lifelong disease, although pancreatic islet cell transplantation has the potential to ameliorate T1D for many patients. For some individuals with T2D, dietary modifications, exercise, and weight-loss regimens can reduce insulin resistance and hyperglycemia at least early in the disease. However, all patients will ultimately require some form of therapeutic intervention to maintain glycemic control.

KEY CONCEPTS

DIABETES MELLITUS: PATHOGENESIS AND LONG-TERM COMPLICATIONS

- T1D is an autoimmune disease characterized by progressive destruction of islet β cells, leading to absolute insulin deficiency. T1D stems from a failure of self-tolerance in T cells, and circulating autoantibodies to islet cell antigens (including insulin) often are detected in affected patients.
- T2D has no autoimmune basis; instead, features central to its pathogenesis are insulin resistance and β-cell dysfunction, resulting in relative insulin deficiency.
- Obesity has an important relationship with insulin resistance (and hence T2D), mediated through multiple factors including excess FFAs, cytokines released from adipose tissues (adipocytokines), and inflammation.

- Monogenic forms of diabetes are uncommon and are caused by single-gene defects that result in primary β-cell dysfunction (e.g., glucokinase mutation) or lead to abnormalities of insulin-insulin receptor signaling (e.g., insulin receptor gene mutations).
- The long-term complications of diabetes are similar in both types and involve four potential mechanisms resulting from sustained hyperglycemia: formation of AGEs, activation of PKC, disturbances in the polyol pathways leading to oxidative stress, and overload of the hexosamine pathway.
- Long-term complications of diabetes include both large-vessel disease (macroangiopathy), such as atherosclerosis, ischemic heart disease, and lower extremity ischemia, as well as small vessel disease (microangiopathy), the latter manifesting mainly as retinopathy, nephropathy, and neuropathy.

PANCREATIC NEUROENDOCRINE TUMORS

The preferred term for tumors of the pancreatic islet cells ("islet cell tumors") is *pancreatic neuroendocrine tumors* or *PanNETs*. They are rare in comparison with tumors of the exocrine pancreas, accounting for 2% of all pancreatic neoplasms. PanNETs can occur anywhere within the pancreas or in the immediate peripancreatic tissues. They resemble their counterparts, carcinoid tumors, found elsewhere in the alimentary tract (Chapter 17). These tumors may be single or multiple and benign or malignant. Pancreatic endocrine neoplasms often elaborate pancreatic hormones, but are sometimes nonfunctional.

Like other endocrine neoplasms, it is difficult to predict the behavior of a PanNET based on its light microscopic appearance alone, although tumors with a higher proliferation index (measured as 3% or more neoplastic nuclei expressing Ki-67) can have an aggressive biological potential. Unequivocal criteria for malignancy include metastases, vascular invasion, and local infiltration. The functional status of the tumor has some impact on prognosis, in that approximately 90% of insulin-producing tumors are benign, and 60% to 90% of other functioning and nonfunctioning pancreatic endocrine neoplasms are malignant. Fortunately, insulinomas are the most common subtype of pancreatic endocrine neoplasms.

Pathogenesis

The genome of sporadic PanNETs recently has been sequenced, with identification of recurrent somatic alterations in three major genes or pathways:

- *MEN1,* which causes familial MEN syndrome, type 1, also is mutated in some sporadic neuroendocrine tumors
- Loss-of-function mutations in tumor suppressor genes such *PTEN* and *TSC2* (Chapter 7), which result in activation of the oncogenic mammalian TOR (mTOR) signaling pathway.
- Inactivating mutations in two genes, alpha-thalassemia/mental retardation syndrome, X-linked *(ATRX)* and death-domain–associated protein *(DAXX),* which have multiple cellular functions, including telomere maintenance. PanNETs with *DAXX* or *ATRX* mutations demonstrate a phenomenon known as "alternative lengthening of telomeres" (ALT), which allows telomeres to be maintained in noeplastic cells that do not express telomerase (Chapter 7). Of note, nearly one-half of PanNETs have a somatic mutation in either *ATRX* or *DAXX,* but not both, consistent with their function in the same oncogenic pathway.

The three most common and distinctive clinical syndromes associated with functional pancreatic endocrine neoplasms are (1) *hyperinsulinism,* (2) *hypergastrinemia and the Zollinger-Ellison syndrome,* and (3) *MEN* (described later).

Hyperinsulinism (Insulinoma)

β-cell tumors (insulinomas) are the most common pancreatic endocrine neoplasms and often produce sufficient insulin to induce clinically significant hypoglycemia. The characteristic clinical picture is dominated by hypoglycemic episodes, which occur when the blood glucose level falls below 50 mg/dL. Clinical manifestations include confusion, stupor, and loss of consciousness. These episodes are precipitated by fasting or exercise and are promptly relieved by feeding or parenteral administration of glucose.

MORPHOLOGY

Insulinomas are most often found within the pancreas and are usually benign. Most are solitary, although multiple tumors may be encountered. *Bona fide* carcinomas, making up only about 10% of cases, are diagnosed on the basis of local invasion and distant metastases. On rare occasions an insulinoma may arise in ectopic pancreatic tissue. In such cases, electron microscopy reveals the distinctive granules of β cells (see Fig. 24.27).

Solitary tumors are usually small (often <2 cm in diameter), encapsulated, pale to red-brown nodules located anywhere in the pancreas. Histologically, these benign tumors look remarkably like giant islets, with preservation of the regular cords of monotonous cells and their orientation to the vasculature. Malignant tumors are also well-differentiated, and they may be deceptively encapsulated. **Deposition of amyloid** is a characteristic feature of many insulinomas (Fig. 24.41).

Hyperinsulinism may also be caused by **focal or diffuse hyperplasia of the islets.** This change is found occasionally in adults but is far more commonly encountered as congenital hyperinsulinism with hypoglycemia in neonates and infants. Several clinical scenarios may result in islet hyperplasia (previously known as nesidioblastosis), including maternal diabetes, Beckwith-Wiedemann syndrome (Chapter 10), and rare mutations in the β-cell K^+-channel protein or sulfonylurea receptor. In maternal diabetes, the fetal islets respond to hyperglycemia by increasing their size and number. In the postnatal period, these hyperactive islets may be responsible for serious episodes of hypoglycemia. This phenomenon is usually transient.

Clinical Features

While up to 80% of islet cell tumors demonstrate excessive insulin secretion, the hypoglycemia is mild in all but about 20%, and many cases never become clinically symptomatic. The critical laboratory findings in insulinomas are high circulating levels of insulin and a high insulin-to-glucose ratio. Surgical removal of the tumor is usually followed by prompt reversal of the hypoglycemia.

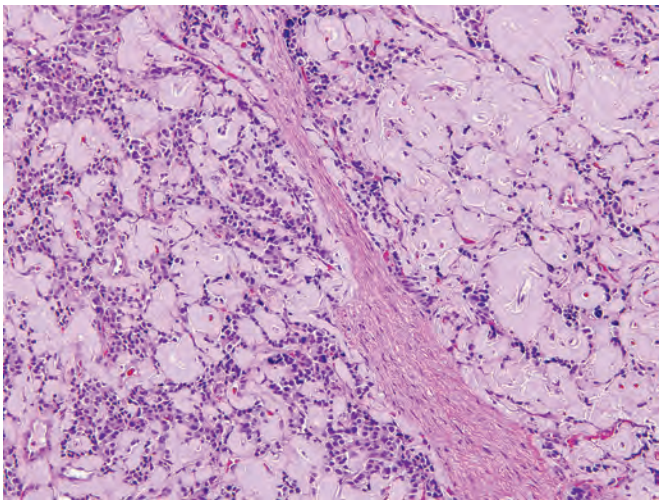

Figure 24.41 Pancreatic endocrine neoplasm ("islet cell tumor"). The neoplastic cells are monotonous and demonstrate minimal pleomorphism or mitotic activity. There is abundant amyloid deposition, characteristic of an insulinoma. Clinically, the patient had episodic hypoglycemia.

It is important to note that there are many other causes of hypoglycemia besides insulinoma. The differential diagnosis includes such conditions as abnormal insulin sensitivity, diffuse liver disease, inherited glycogenoses, and ectopic production of insulin by certain fibromas and fibrosarcomas. Depending on the clinical circumstances, hypoglycemia induced by self-injection of insulin should also be considered.

Zollinger-Ellison Syndrome (Gastrinoma)

Marked hypersecretion of gastrin usually has its origin in gastrin-producing tumors *(gastrinomas)*, which are just as likely to arise in the duodenum and peripancreatic soft tissues as in the pancreas (so-called gastrinoma triangle). There has been lack of agreement regarding the cell of origin of these tumors, although it seems likely that endocrine cells of either the gut or the pancreas could be the source. Zollinger and Ellison first called attention to the **association of pancreatic islet cell lesions, hypersecretion of gastric acid and severe peptic ulceration**, which are present in 90% to 95% of patients.

MORPHOLOGY

More than half of gastrin-producing tumors are locally invasive or have already metastasized at the time of diagnosis. In approximately 25% of patients, gastrinomas arise in conjunction with other endocrine tumors, as part of the MEN-1 syndrome (see later). MEN-1-associated gastrinomas are frequently multifocal, while sporadic gastrinomas are usually single. As with insulin-secreting tumors of the pancreas, gastrin-producing tumors are histologically bland and rarely show marked anaplasia.

In the Zollinger-Ellison syndrome, hypergastrinemia gives rise to excessive gastric acid secretion, which in turn causes **peptic ulceration** (Chapter 17). The duodenal and gastric ulcers are often multiple; although they are identical to those found in the general population, they are often unresponsive to therapy. In addition, ulcers may occur in unusual locations such as the jejunum; **when intractable jejunal ulcers are found, Zollinger-Ellison syndrome should be considered**.

Clinical Features

Treatment of Zollinger-Ellison syndrome involves control of gastric acid secretion by use of H^+K^+-ATPase inhibitors and excision of the neoplasm. Total resection of the neoplasm, when possible, eliminates the syndrome. Patients with hepatic metastases have a shortened life expectancy, with progressive tumor growth leading to liver failure, usually within 10 years.

Other Rare Pancreatic Endocrine Neoplasms

- α*-cell tumors (glucagonomas)* are associated with increased serum levels of glucagon and a syndrome consisting of mild diabetes mellitus, a characteristic skin rash *(necrolytic migratory erythema)*, and anemia. They occur most frequently in perimenopausal and postmenopausal women and are characterized by extremely high plasma glucagon levels.
- δ*-cell tumors (somatostatinomas)* are associated with diabetes mellitus, cholelithiasis, steatorrhea, and hypochlorhydria. They may be very difficult to localize preoperatively. High plasma somatostatin levels are required for diagnosis.
- *VIPoma* induces a characteristic syndrome *(watery diarrhea, hypokalemia, achlorhydria, or WDHA syndrome)* that is caused by release of vasoactive intestinal peptide (VIP) from the tumor. Some of these tumors are locally invasive and metastatic. A VIP assay should be performed on all patients with severe secretory diarrhea. Neural crest tumors, such as neuroblastomas, ganglioneuroblastomas, and ganglioneuromas (Chapter 10), and pheochromocytomas (see later) can also be associated with the VIPoma syndrome.
- *Pancreatic carcinoid tumors* producing serotonin and an atypical carcinoid syndrome are exceedingly rare.
- *Pancreatic polypeptide-secreting endocrine tumors* present as mass lesions as even high plasma levels of this hormone fail to cause symptoms.
- Some pancreatic and extrapancreatic endocrine tumors produce two or more hormones. In addition to insulin, glucagon, and gastrin, pancreatic endocrine tumors may produce ACTH, MSH, ADH, serotonin, and norepinephrine. These *multihormonal tumors* are to be distinguished from the MEN syndromes (discussed later), in which a multiplicity of hormones is produced by tumors in several different glands.

Adrenal Glands

The adrenal glands are paired endocrine organs consisting of a cortex and a medulla, which differ in their development, structure, and function. In essence, the cortex and medulla are two glands packaged into one structure. The adrenal cortex

has three zones. Beneath the capsule is the narrow layer of zona glomerulosa. An equally narrow zona reticularis abuts the medulla. Intervening is the broad zona fasciculata, which makes up about 75% of the total cortex. The *adrenal cortex* synthesizes three different types of steroids: (1) *glucocorticoids* (principally cortisol), which are synthesized primarily in the zona fasciculata and to a lesser degree in the zona reticularis; (2) *mineralocorticoids,* the most important being aldosterone, which is generated in the zona glomerulosa; and (3) *sex steroids* (estrogens and androgens), which are produced largely in the zona reticularis. The *adrenal medulla* is composed of chromaffin cells, which synthesize and secrete *catecholamines,* mainly epinephrine. Catecholamines have many effects that allow rapid adaptations to changes in the environment.

ADRENAL CORTEX

Diseases of the adrenal cortex can be conveniently divided into those associated with hyperfunction and those associated with hypofunction.

Adrenocortical Hyperfunction (Hyperadrenalism)

The syndromes of adrenal hyperfunction are caused by overproduction of the three major hormones of the adrenal cortex (1) *Cushing syndrome,* characterized by an excess of cortisol; (2) *hyperaldosteronism* as a result of excessive aldosterone; and (3) *adrenogenital or virilizing syndromes* caused by an excess of androgens. The clinical features of these syndromes overlap somewhat because of the overlapping functions of some of the adrenal steroids.

Hypercortisolism (Cushing Syndrome)

Pathogenesis

This disorder is caused by conditions that produce elevated glucocorticoid levels. Cushing syndrome can be broadly divided into *exogenous* and *endogenous* causes. The vast majority of cases of Cushing syndrome are the result of the administration of exogenous glucocorticoids (*iatrogenic* Cushing syndrome). The endogenous causes can, in turn, be divided into those that are *ACTH dependent* and those that are *ACTH independent* (Table 24.8).

ACTH-secreting pituitary adenomas account for 60% to 70% of cases of endogenous hypercortisolism. The pituitary form of this syndrome is referred to as *Cushing disease*. The disorder affects women about four times more frequently than men and occurs most frequently in young adults. In the vast majority of cases, it is caused by an *ACTH-producing pituitary microadenoma*. In some cases there is an underlying macroadenoma, and rarely there is *corticotroph cell hyperplasia* without a discrete adenoma. Corticotroph cell hyperplasia may be primary or arise secondarily from excessive stimulation of ACTH release by a hypothalamic corticotrophin-releasing hormone (CRH)-producing tumor. The adrenal glands in individuals with Cushing disease are characterized by variable degrees of *nodular cortical hyperplasia* (discussed later) caused by the elevated levels of ACTH. The cortical hyperplasia, in turn, is responsible for hypercortisolism.

Secretion of ectopic ACTH by nonpituitary tumors accounts for about 5% to 10% of ACTH-dependent Cushing syndrome cases. In many instances, the responsible tumor is a *small-cell carcinoma of the lung,* although other neoplasms, including carcinoids, medullary carcinomas of the thyroid, and PanNETs, have been associated with the syndrome. In addition to tumors that elaborate ectopic ACTH, occasionally a neuroendocrine neoplasm may produce ectopic CRH, which, in turn, causes ACTH secretion and hypercortisolism. As in the pituitary variant, the adrenal glands undergo bilateral cortical hyperplasia, but the rapid downhill course of patients with these cancers often limits the extent of the adrenal enlargement. This variant of Cushing syndrome is more common in men and usually occurs in the 40s and 50s.

Primary adrenal neoplasms, such as adrenal adenoma (~10% to 20%) and carcinoma (~5% to 7%) are the most common underlying causes of ACTH-independent Cushing syndrome. The biochemical *sine qua non* of ACTH-independent Cushing syndrome is elevated serum levels of cortisol with low levels of ACTH. Cortical carcinomas tend to produce more marked hypercortisolism than adenomas or hyperplasias. Recent large-scale gene-sequencing studies have helped define the molecular features of adrenocortical carcinomas, including recurrent activating mutations of *beta-catenin* (*CTNNB1*) and inactivating mutations of *TP53, MEN1,* and *PRKAR1A*. Interestingly, *PRKAR1A* mutations are observed in both adrenocortical adenomas and carcinomas, as well as in micronodular hyperplasia (see earlier), suggesting shared molecular mechanisms and ontogeny are at play in these cortisol-secreting lesions.

Primary cortical hyperplasia (i.e., ACTH-independent hyperplasia) is much less common than ACTH-dependent adrenal cortical hyperplasia. In *bilateral macronodular adrenal hyperplasia* (BMAH), the nodules are usually greater than 10 mm in diameter. Familial forms associated with germline mutations in the armadillo repeat containing 5 *(ARMC5)* gene, a putative tumor suppressor gene, have been reported; of note, up to 50% of apparently sporadic BMAH cases harbor germline *ARMC5* mutations with somatic loss of the second allele in the hyperplastic nodules. In true sporadic cases of BMAH, nodular hyperplasia is not entirely "autonomous." Specifically, cortisol production is regulated by hormones other than ACTH because of ectopic overexpression of the corresponding G-protein–coupled hormone receptors in the hyperplastic adrenocortical cells. Implicated hormones other than ACTH include gastric inhibitory peptide (GIP), LH, and ADH (vasopressin). The mechanism by which these receptors are overexpressed is not known, but epigenetic changes may be involved. A subset of BMAH arises in the setting of McCune-Albright syndrome (Chapter 26), a multisystemic disease characterized by germline mutations that activate *GNAS,* which encodes a stimulatory $G_s\alpha$. This $G_s\alpha$ mutation causes hyperplasia by increasing intracellular levels of cAMP, which you will recall is an important second messenger in many endocrine cell types.

ACTH-independent bilateral hyperplasia can also be *micronodular* (<10 mm in size), and these arise mainly in two settings: primary pigmented nodular adrenocortical disease or as part of the so-called Carney complex, a multisystem syndrome resulting in both endocrine and non-endocrine neoplasms. Both primary pigmented nodular adrenocortical disease and Carney complex are most

Table 24.8 Causes of Endogenous Cushing Syndrome

	Proportion (%)	Age (Peak)	Female:Male	Features
ACTH-Dependent	**70–80**	..	..	..
Cushing disease	60–70	..	..	..
Corticotroph adenoma	60–70	3rd–4th decades	3–5:1	Roughly 50% nonvisible on MRI
Corticotroph hyperplasia	Very rare	..	..	..
Ectopic ACTH[a]	5–10	..	..	..
Malignant neuroendocrine tumours	~4	5th–6th decades	0.6–1:1	May have very high ACTH
Benign neuroendocrine tumours	~6	3rd–4th decades	..	May respond to dexamethasone, CRH, desmopressin
Occult neuroendocrine tumours	~2	..	..	..
Ectopic CRH	Very rare	..	..	Causes pituitary corticotroph hyperplasia
ACTH-Independent	**20–30**	..	..	..
Unilateral adrenal	..	..	..	..
Adenoma	10–22	4th–5th decades	4–8:1	Most secrete only cortisol
Carcinoma	5–7	1st, 5th–6th decades	1.5–3:1	Mixed cortisol and androgen secretion frequent
Bilateral macronodular adrenal hyperplasia[b]	<2	5th–6th decades	2–3:1	Modest cortisol secretion compared with size; may also secrete androgen and mineralocorticoid
Aberrant G-protein-coupled receptors	..	..	..	..
Autocrine ACTH production	..	..	..	..
Sporadic or familial (*ARMC*$_5$)	..	..	..	..

ACTH, Adrenocorticotropic hormone; *ARMC*$_5$, armadillo repeat containing 5; *CRH,* corticotrophin-releasing hormone.

[a]Most frequent sources of ectopic ACTH syndromes are small cell lung carcinoma and neuroendocrine tumors of lung, thymus, and pancreas. Less frequent causes include medullary thyroid carcinoma, gastrinoma, phaeochromocytoma, prostate carcinoma, and several others.
[b]In bilateral macronodular adrenal hyperplasia tissues, autocrine and paracrine ACTH might be produced and contribute to cortisol secretion. If confirmed by in vivo studies, the ACTH-independent classification will need to be modified in the future.

From Lacroix A, Feelders RA, Stratakis CA, Nieman LK: Cushing syndrome, *Lancet* 386(9996):913–927, 2015.

commonly associated with mutations of the regulatory subunit of cAMP-dependent protein kinase (encoded by the *PRKAR1A* gene), which, like activating *GNAS* mutations, act by increasing intracellular cAMP levels.

MORPHOLOGY

The main lesions of Cushing syndrome are found in the pituitary and adrenal glands. The **pituitary** shows changes regardless of the cause. The most common alteration, resulting from high levels of endogenous or exogenous glucocorticoids, is termed **Crooke hyaline change.** In this condition, the normal granular, basophilic cytoplasm of the ACTH-producing cells in the anterior pituitary becomes homogeneous and paler. This alteration is the result of the accumulation of intermediate keratin filaments in the cytoplasm, a finding that is also seen in "Crooke cell" corticotroph adenoma (discussed earlier).

Depending on the cause of the hypercortisolism, the **adrenals** show one of the following abnormalities: (1) cortical atrophy, (2) diffuse hyperplasia, (3) macronodular or micronodular hyperplasia, and (4) an adenoma or carcinoma. In patients in whom the syndrome results from exogenous glucocorticoids, suppression of endogenous ACTH results in bilateral **cortical atrophy,** due to a lack of stimulation of the zonae fasciculata and reticularis by ACTH. The zona glomerulosa is of normal thickness in such cases, because this portion of the cortex functions independently of ACTH. In contrast, in cases of endogenous hypercortisolism, the adrenals either are hyperplastic or contain a cortical neoplasm.

Diffuse hyperplasia is found in individuals with ACTH-dependent Cushing syndrome (Fig. 24.42). Both glands are enlarged, either subtly or markedly, weighing up to 30 g. The adrenal cortex is diffusely thickened and variably nodular, although the latter is not as pronounced as seen in cases of ACTH-independent nodular hyperplasia. Microscopically, the hyperplastic cortex demonstrates an expanded "lipid-poor" zona reticularis, comprising compact, eosinophilic cells, surrounded by an outer zone of vacuolated "lipid-rich" cells, resembling those seen in the zona fasciculata. Any nodules present are usually composed of vacuolated "lipid-rich" cells, which account for the yellow color of diffusely hyperplastic glands. In contrast, in **macronodular hyperplasia** the adrenals are almost entirely replaced by prominent nodules of varying sizes (10 to 30 mm), which contain an admixture of lipid-poor and lipid-rich cells. Unlike diffuse hyperplasia, the areas between the macroscopic nodules also demonstrate evidence of microscopic nodularity. **Micronodular hyperplasia** is composed of 1- to 3-mm (typically <10 mm) darkly pigmented (brown to black) micronodules with atrophic intervening areas (Fig. 24.43). The pigment is believed to be lipofuscin, a wear-and-tear pigment (Chapter 2).

Primary adrenocortical neoplasms causing Cushing syndrome may be malignant or benign. Functional adenomas or carcinomas are not morphologically distinct from nonfunctioning adrenal neoplasms (described later). Both the benign and malignant lesions are more common in women in their 30s to 50s. Adrenocortical **adenomas** are yellow tumors surrounded by thin or well-developed capsules, and most weigh less than 30 g. Microscopically, they are composed of cells that are similar to those encountered in the normal zona fasciculata. The **carcinomas** associated with Cushing syndrome, by contrast, tend to be larger than the adenomas. These tumors (detailed later) are unencapsulated masses frequently exceeding 200 to 300 g in weight that have all of the anaplastic characteristics of cancer. With functioning tumors, both benign and malignant, the adjacent adrenal cortex and that of the contralateral adrenal gland are atrophic, as a result of suppression of endogenous ACTH by high cortisol levels.

Figure 24.42 Diffuse hyperplasia of the adrenal gland contrasted with a normal adrenal gland (top). In cross-section, the hyperplastic adrenal cortex is yellow and thickened, and a subtle nodularity is seen (contrast with Fig. 24.43) in this gland from a patient with ACTH dependent Cushing syndrome.

Clinical Features

Cushing syndrome develops slowly and its onset may be subtle. Early stages may present with hypertension and weight gain (Table 24.9). With time, the more characteristic central pattern of adipose tissue deposition becomes apparent in the form of truncal obesity, moon facies, and accumulation of fat in the posterior neck and back *(buffalo hump)*. Hypercortisolism causes selective atrophy of fast-twitch (type 2) myofibers, resulting in decreased muscle mass and proximal limb weakness. Glucocorticoids induce gluconeogenesis and inhibit the uptake of glucose by cells, with resultant hyperglycemia, glucosuria, and polydipsia *(secondary diabetes)*. The catabolic effects cause loss of collagen and resorption of bones. Consequently, the skin is thin, fragile, and easily bruised; wound healing is poor; and cutaneous striae are particularly common in the abdominal area (Fig. 24.44). Bone resorption results in the development of *osteoporosis,* with consequent backache and increased susceptibility to fractures. Persons with Cushing syndrome are at increased risk for a variety of infections, because glucocorticoids suppress the immune response. Additional manifestations

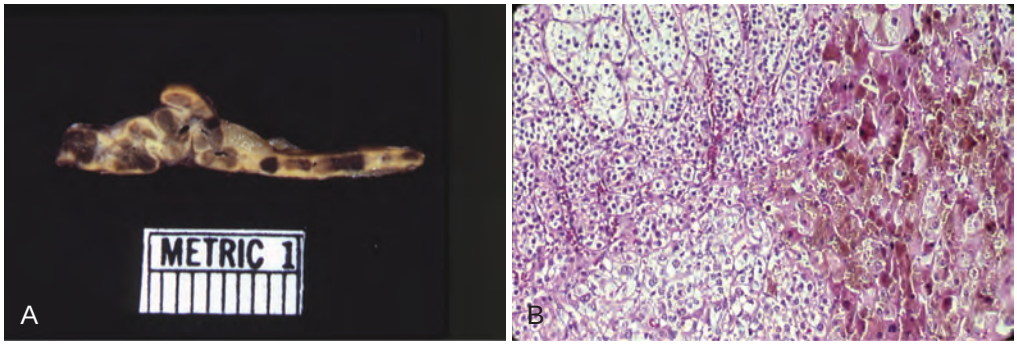

Figure 24.43 (A) Micronodular adrenocortical hyperplasia with prominent pigmented nodules in the adrenal gland. (B) On histologic examination, the nodules are composed of cells containing lipofuscin pigment, seen in the right part of the field. include several *mental disturbances,* including mood swings, depression, and frank psychosis, as well as *hirsutism* and *menstrual abnormalities*.

The laboratory diagnosis of Cushing syndrome is based on the following: (1) the 24-hour urine free-cortisol concentration, which is increased; and (2) loss of normal diurnal pattern of cortisol secretion. Determining the cause of Cushing syndrome depends on measurement of the serum ACTH and the dexamethasone suppression test, in which urinary steroid excretion is measured after administration of the glucocorticoid dexamethasone. The results of these tests fall into three patterns:

- In pituitary Cushing syndrome, the most common form, ACTH levels are elevated and are not suppressed by the administration of a low dose of dexamethasone. Hence, there is no reduction in urinary excretion of 17-hydroxycorticosteroids. After higher doses of injected dexamethasone, however, the pituitary responds by reducing ACTH secretion, which is reflected by suppression of urinary steroid secretion.
- Ectopic ACTH secretion results in an elevated level of ACTH, but its secretion is completely insensitive to low or high doses of exogenous dexamethasone.
- When Cushing syndrome is caused by an adrenal tumor, the ACTH level is quite low because of feedback inhibition of the pituitary. As with ectopic ACTH secretion, both low-dose and high-dose dexamethasone fail to suppress cortisol excretion.

KEY CONCEPTS

HYPERCORTISOLISM (CUSHING SYNDROME)

- The most common cause of hypercortisolism is exogenous administration of steroids.
- Endogenous hypercortisolism most often is secondary to an ACTH-producing pituitary microadenoma (Cushing disease), followed by primary adrenal neoplasms (ACTH-independent hypercortisolism) and paraneoplastic ACTH production by tumors (e.g., small cell lung cancer).
- The morphologic features in the adrenal vary from bilateral cortical atrophy (in exogenous steroid-induced disease), to bilateral diffuse or nodular hyperplasia (most common finding in endogenous Cushing syndrome), to an adrenocortical neoplasm.

Primary Hyperaldosteronism

Hyperaldosteronism is the generic term for a group of closely related conditions characterized by chronic excess aldosterone secretion. Hyperaldosteronism may be primary, or it may be secondary to an extra-adrenal cause. *Primary hyperaldosteronism* stems from an autonomous overproduction of aldosterone, with resultant hypertension, suppression of the renin-angiotensin system, and decreased plasma renin activity. Primary hyperaldosteronism is caused by one of three conditions (Fig. 24.45):

- *Bilateral idiopathic hyperaldosteronism,* characterized by bilateral nodular hyperplasia of aldosterone-secreting zona glomerulosa cells of the adrenal glands, is the most common underlying cause, accounting for about 60% of cases, most of which are sporadic. Individuals with bilateral idiopathic hyperaldosteronism tend to be older and to have less severe hypertension than those presenting with adrenal neoplasms. The molecular basis of this entity remains unclear, although recent studies suggest that a minority of patients harbor germline mutations of *KCNJ5,* consistent with their being part of a subtype that is now classified as *familial hyperaldosteronism, type III* (see later).

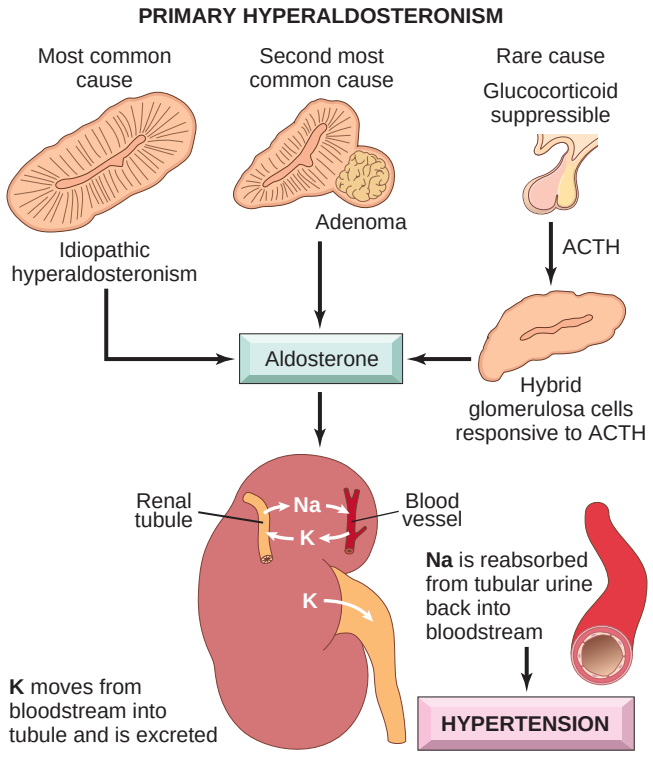

Figure 24.45 The major causes of primary hyperaldosteronism and its principal effects on the kidney.

- *Adrenocortical neoplasm,* either an aldosterone-producing adenoma (the most common cause) or, rarely, an adrenocortical carcinoma. In approximately 35% of cases, primary hyperaldosteronism is caused by a solitary aldosterone-secreting adenoma, a condition referred to as *Conn syndrome.* This condition occurs most frequently in mid-adult life and is more common in women than in men (2:1). Recent gene-sequencing studies have helped elucidate the genomic landscape of aldosterone-producing adenomas. Up to 50% harbor somatic mutations of *KCNJ5,* which encodes a potassium ion channel protein known as GIRK4 expressed in zona glomerulosa cells. GIRK4 mutations result in loss of selectivity of the channel to potassium ions, leading to nonspecific influx of sodium, and subsequent calcium-dependent activation of the aldosterone synthase enzyme. Disruption of intracellular ion homeostasis in zona glomerulosa cells is a common theme with other somatic mutations observed in aldosterone-producing adenomas as well. These include mutations in *CACNA1H,* which encodes a calcium channel, and *ATP1A1,* which encodes a sodium/potassium exchanging ATPase. The functional consequence of these mutations is to maintain cells in a chronic state of depolarization, resulting in autonomous aldosterone synthesis.
- *Familial hyperaldosteronism* accounts for ~5% of cases. Four distinct subtypes (FH-I to FH-IV) have been described, of which FH-I, or *glucocorticoid-remediable aldosteronism,* is the most common. FH-I stems from a rearrangement in chromosome 8 that places *CYP11B2* (the gene encoding aldosterone synthase, the enzyme that carries out the last step in aldosterone synthesis) under the control of the ACTH-responsive *CYP11B1* gene promoter. ACTH thus stimulates the synthesis of aldosterone synthase from the chimeric gene. Because in this unusual circumstance aldosterone production is under the control of ACTH, it is suppressible by dexamethasone. The remaining three subtypes of FH are rare, with FH-III being ascribed to germline *KCNJ5* mutations and FH-IV to germline *CACNA1H* mutations, two genes that are also somatically mutated in subsets of aldosterone-secreting adenomas.

In *secondary hyperaldosteronism,* in contrast, aldosterone release occurs in response to activation of the renin-angiotensin system (Chapter 11). It is characterized by increased levels of plasma renin and is encountered in conditions such as the following:

- Decreased renal perfusion (arteriolar nephrosclerosis, renal artery stenosis)
- Arterial hypovolemia and edema (congestive heart failure, cirrhosis, nephrotic syndrome)
- Pregnancy (due to estrogen-induced increases in plasma renin substrate)

MORPHOLOGY

Aldosterone-producing adenomas are almost always solitary, small (<2 cm in diameter), well-circumscribed lesions, more often found on the left than on the right. They tend to occur in the 30s and 40s, and in women more often than in men. They are often buried within the gland and do not produce visible enlargement, making them difficult to locate by imaging. They are bright yellow on cut section and, surprisingly, are composed of lipid-laden cortical cells that more closely resemble fasciculata cells than glomerulosa cells (the normal source of aldosterone). In general, the cells tend to be uniform in size and shape; occasionally, there is modest nuclear and cellular pleomorphism (see Fig. 24.51). A characteristic feature of aldosterone-producing adenomas is the presence of eosinophilic, laminated cytoplasmic inclusions, known as **spironolactone bodies,** found after treatment with the antihypertensive drug spironolactone. In contrast to cortical adenomas associated with Cushing syndrome, those associated with hyperaldosteronism do not usually suppress ACTH secretion. Therefore, the adjacent adrenal cortex and that of the contralateral gland are not atrophic.

Bilateral idiopathic hyperaldosteronism is marked by diffuse and focal hyperplasia of cells resembling those of the normal zona glomerulosa. The hyperplasia is often wedge-shaped, extending from the periphery toward the center of the gland. The enlargement may be subtle, and as a rule an adrenocortical adenoma must be carefully excluded as the cause for hyperaldosteronism.

Clinical Features

With an estimated prevalence rate of 5% to 10% among nonselected hypertensive patients, primary hyperaldosteronism may be the most common cause of secondary hypertension (i.e., hypertension secondary to an identifiable cause). The prevalence of hyperaldosteronism increases with the severity of hypertension, reaching nearly 20% in patients who are classified as having treatment-resistant hypertension. Through its effects on the renal mineralocorticoid receptor, aldosterone

promotes sodium reabsorption, which secondarily increases the reabsorption of water, expanding the extracellular fluid volume and elevating cardiac output.

The long-term effects of hyperaldosteronism-induced hypertension are cardiovascular compromise (e.g., left ventricular hypertrophy and reduced diastolic volumes) and an increase in the prevalence of adverse events such as stroke and myocardial infarction. *Hypokalemia* was considered a mandatory feature of primary hyperaldosteronism, but increasing numbers of normokalemic patients are now diagnosed. Hypokalemia results from renal potassium wasting and, when present, can cause a variety of neuromuscular manifestations, including weakness, paresthesias, visual disturbances, and occasionally frank tetany.

The diagnosis of primary hyperaldosteronism is confirmed by elevated ratios of plasma aldosterone concentration to plasma renin activity; if this screening test is positive, a confirmatory aldosterone suppression test is performed, as many other disorders can alter the plasma aldosterone and renin ratios.

In primary hyperaldosteronism, the therapy varies according to cause. Adenomas are amenable to surgical excision. In contrast, surgical intervention is not very beneficial in patients with bilateral hyperplasia, which often occurs in children and young adults. These patients are best managed medically with an aldosterone antagonist such as spironolactone. The treatment of secondary hyperaldosteronism rests on correcting the underlying cause of the hyperactivity of the renin-angiotensin system.

Adrenogenital Syndromes

Disorders of sexual differentiation, such as *virilization* or *feminization,* can be caused by primary gonadal disorders (Chapter 22) and several primary adrenal disorders. The adrenal cortex secretes dehydroepiandrosterone and androstenedione, two compounds that can be converted to testosterone in peripheral tissues. Unlike gonadal androgens, ACTH regulates adrenal androgen formation (Fig. 24.46); thus, excess secretion can occur either as a "pure" syndrome or as a component of Cushing disease. The adrenal causes of androgen excess include *adrenocortical neoplasms* and a group of disorders that have been designated *congenital adrenal hyperplasia* (CAH).

Adrenocortical neoplasms associated with virilization are more likely to be androgen-secreting adrenal carcinomas than adenomas. Such tumors are often also associated with hypercortisolism ("mixed syndrome"). They are morphologically identical to other cortical neoplasms and are discussed later.

Congenital adrenal hyperplasia stems from several autosomal recessive, inherited metabolic errors, each characterized by a deficiency of a particular enzyme

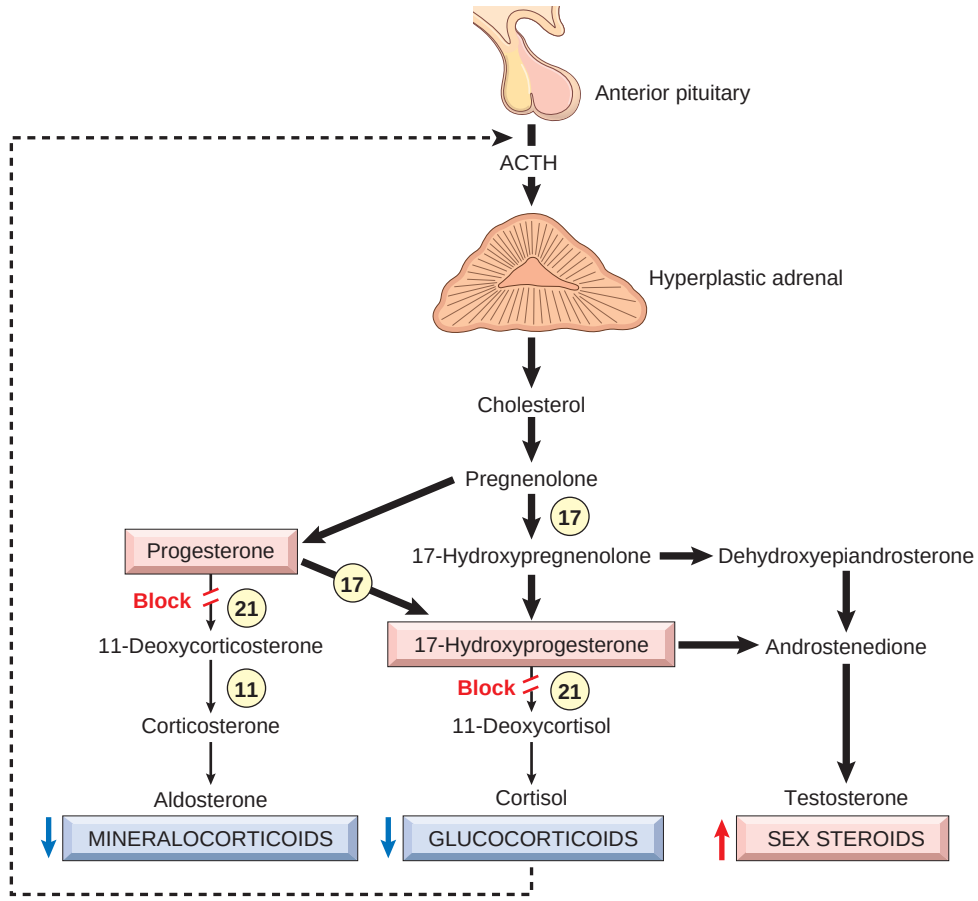

Figure 24.46 Consequences of C-21 hydroxylase deficiency. 21-Hydroxylase deficiency impairs the synthesis of both cortisol and aldosterone at different steps (shown as "Block" in the biosynthesis pathway). The resultant decrease in feedback inhibition *(dashed line)* causes increased secretion of adrenocorticotropic hormone, resulting ultimately in adrenal hyperplasia and increased synthesis of testosterone. The sites of action of 11-, 17-, and 21-hydroxylase are shown as numbers in circles.

involved in the biosynthesis of cortisol (see Fig. 24.46). Steroid precursors that build behind the defective step in the pathway are channeled into other pathways, resulting in increased production of androgens, which accounts for *virilization*. Simultaneously, the deficiency of cortisol leads to increased secretion of ACTH, culminating in adrenal hyperplasia. Certain enzyme defects may also impair aldosterone secretion, adding *salt wasting* to the virilizing syndrome. Other enzyme deficiencies may be incompatible with life or, in rare instances, may involve only the aldosterone pathway.

21-hydroxylase deficiency (caused by mutations of *CYP21A2*) is by far the most common genetic cause of CAH, accounting for over 90% of cases. Fig. 24.46 illustrates normal adrenal steroidogenesis and the consequences of 21-hydroxylase deficiency, which varies in severity depending on the nature of the *CYP21A2* mutation. Three distinctive syndromes have been described: (1) salt-wasting ("classic") adrenogenitalism, (2) simple virilizing adrenogenitalism, and (3) "nonclassic" adrenogenitalism.

- The *salt-wasting syndrome* results from an inability to convert progesterone into deoxycorticosterone because of a total lack of 21-hydroxylase. Thus, there is virtually no synthesis of mineralocorticoids, and, concomitantly, there is a block in the conversion of hydroxyprogesterone into deoxycortisol resulting in deficient cortisol synthesis. This pattern usually comes to light soon after birth, as in utero, electrolyte and fluid balance can be maintained by the maternal kidneys. There is salt wasting, hyponatremia, and hyperkalemia, which induce acidosis, hypotension, cardiovascular collapse, and possibly death. The concomitant block in cortisol synthesis and excess production of androgens, however, lead to virilization, which is easily recognized in the female at birth or in utero. Males with this disorder are generally unrecognized at birth but come to clinical attention 5 to 15 days later because of salt loss, hypotension, and other abnormalities.
- *Simple virilizing adrenogenital syndrome without salt wasting* (presenting as genital ambiguity) occurs in approximately one-third of patients with 21-hydroxylase deficiency. These patients generate sufficient mineralocorticoid to prevent a salt-wasting "crisis." However, the lowered glucocorticoid level fails to cause feedback inhibition of ACTH secretion. Thus, the level of testosterone is increased, with resultant progressive virilization.
- *Nonclassic or late-onset adrenal virilism* is significantly more common than the classic patterns already described. There is only a partial deficiency of 21-hydroxylase, which accounts for the later onset. Individuals with this syndrome may present with mild manifestations, such as hirsutism, acne, and menstrual irregularities. Nonclassical CAH cannot be diagnosed on routine newborn screening, and the diagnosis is usually made by demonstration of biosynthetic defects in steroidogenesis.

MORPHOLOGY

In all cases of CAH, the adrenals are bilaterally hyperplastic, sometimes increasing to 10 to 15 times their normal weight because of the sustained elevation in ACTH. The adrenal cortex is thickened and nodular, and on cut section the widened cortex appears brown because of lipid depletion. The proliferating cells are mostly compact, eosinophilic, lipid-depleted cells intermixed with lipid-laden clear cells. Hyperplasia of corticotroph (ACTH-producing) cells is present in the anterior pituitary in most persons with CAH.

Clinical Features

The clinical features of these disorders are determined by the specific enzyme deficiency and include abnormalities related to androgen excess, with or without aldosterone and glucocorticoid deficiency. CAH also affects the function of the adrenal medulla. Specifically, high levels of intra-adrenal glucocorticoids are required to facilitate medullary catecholamine (epinephrine and norepinephrine) synthesis. In patients with severe salt-wasting 21-hydroxylase deficiency, a combination of low cortisol levels and developmental defects of the medulla *(adrenomedullary dysplasia)* profoundly affects catecholamine secretion, further predisposing these individuals to hypotension and circulatory collapse.

Depending on the nature and severity of the enzymatic defect, the onset of clinical symptoms may occur in the perinatal period, later childhood, or, less commonly, adulthood. For example, in 21-hydroxylase deficiency excessive androgenic activity causes signs of masculinization in females, ranging from clitoral hypertrophy and pseudohermaphroditism in infants, to oligomenorrhea, hirsutism, and acne in postpubertal females. In males, androgen excess is associated with enlargement of the external genitalia and other evidence of precocious puberty in prepubertal patients and oligospermia in older males.

CAH should be suspected in any neonate with ambiguous genitalia. Severe enzyme deficiency in infancy can be a life-threatening condition with vomiting, dehydration, and salt wasting. Individuals with CAH are treated with exogenous glucocorticoids, which, in addition to providing glucocorticoids, also suppress ACTH levels and thus decrease the excessive synthesis of the steroid hormones responsible for many of the clinical abnormalities. Mineralocorticoid supplementation is required in the salt-wasting variants of CAH. With the availability of routine neonatal metabolic screens for CAH and the feasibility of molecular testing for antenatal detection of 21-hydroxylase mutations, the outcome for even the most severe variants has improved significantly.

KEY CONCEPTS

ADRENOGENITAL SYNDROMES

- The adrenal cortex can secrete excess androgens in either of two settings: adrenocortical neoplasms (usually virilizing carcinomas) or congenital adrenal hyperplasia (CAH).
- CAH consists of a group of autosomal recessive disorders characterized by defects in steroid biosynthesis, usually cortisol; the most common subtype is caused by deficiency of the enzyme 21-hydroxylase.
- Reduction in cortisol production causes a compensatory increase in ACTH secretion, which, in turn, stimulates androgen production. Androgens have virilizing effects, including masculinization

in females (ambiguous genitalia, oligomenorrhea, hirsutism), precocious puberty in males, and, in some instances, salt (sodium) wasting and hypotension.
- Bilateral hyperplasia of the adrenal cortex is characteristic, and a subset of 21-hydroxylase–deficient patients also demonstrates adrenomedullary dysplasia.

Adrenocortical Insufficiency

Adrenocortical insufficiency, or hypofunction, may be caused by primary adrenal disease (primary hypoadrenalism) or decreased stimulation of the adrenals due to a deficiency of ACTH (secondary hypoadrenalism) (Table 24.10). Three major patterns of adrenocortical insufficiency are recognized: (1) primary acute adrenocortical insufficiency (adrenal crisis), (2) primary chronic adrenocortical insufficiency *(Addison disease),* and (3) secondary adrenocortical insufficiency.

Primary Acute Adrenocortical Insufficiency

Acute adrenal cortical insufficiency occurs in a variety of clinical settings.
- In individuals with chronic adrenocortical insufficiency, a *crisis* may be precipitated by any form of stress that requires an immediate increase in steroid output to maintain homeostasis
- In patients maintained on exogenous corticosteroids, in whom *rapid withdrawal of steroids* or failure to increase steroid doses in response to an acute stress may precipitate an adrenal crisis because of the inability of the atrophic adrenals to produce glucocorticoid hormones
- As a result of *massive adrenal hemorrhage,* which damages the adrenal cortex sufficiently to cause acute adrenocortical insufficiency—as occurs in newborns following prolonged and difficult delivery with considerable trauma and hypoxia. It also occurs in some patients maintained on anticoagulant therapy, in postsurgical patients who develop disseminated intravascular coagulation and consequent hemorrhagic infarction of the adrenals, and as a complication of disseminated bacterial infection; in this last setting, it is called *Waterhouse-Friderichsen syndrome*.

Waterhouse-Friderichsen Syndrome

This uncommon but catastrophic syndrome is characterized by the following:
- Overwhelming bacterial infection, classically *Neisseria meningitidis* septicemia but occasionally caused by other highly virulent organisms, such as *Pseudomonas* species, pneumococci, *Haemophilus influenzae,* or even staphylococci
- Rapidly progressive hypotension leading to shock
- Disseminated intravascular coagulation associated with widespread purpura, particularly of the skin (Fig. 24.47)
- Rapidly developing adrenocortical insufficiency associated with massive bilateral adrenal hemorrhage

Waterhouse-Friderichsen syndrome can occur at any age but is more common in children. The basis for the adrenal hemorrhage is uncertain but may be due to direct bacterial seeding of small vessels in the adrenal, the development of disseminated intravascular coagulation, or endothelial dysfunction caused by microbial products and inflammatory mediators. Whatever the basis, the adrenals are converted to sacs of clotted blood, which obscures virtually all of the

Table 24.10 Adrenocortical Insufficiency

Primary Insufficiency
Loss of Cortical Cells
Congenital adrenal hypoplasia
X-linked adrenal hypoplasia (*NR0B1* mutation)
Adrenoleukodystrophy (*ABCD1* mutation)
Autoimmune adrenal insufficiency
Autoimmune polyendocrinopathy syndrome type 1 (*AIRE1* gene)
Autoimmune polyendocrinopathy syndrome types 2 and 4 (polygenic)
Infection
Acquired immune deficiency syndrome
Tuberculosis
Fungi
Acute hemorrhagic necrosis (Waterhouse-Friderichsen syndrome)
Amyloidosis, sarcoidosis, hemochromatosis
Metastatic carcinoma
Metabolic Failure in Hormone Production
Congenital adrenal hyperplasia (cortisol and aldosterone deficiency with virilization)
Drug- and steroid-induced inhibition of ACTH or cortical cell function
Secondary Insufficiency
Hypothalamic Pituitary Disease
Neoplasm, inflammation (sarcoidosis, tuberculosis, pyogens, fungi)
Hypothalamic Pituitary Suppression
Long-term steroid administration
Steroid-producing neoplasms

ACTH, Adrenocorticotropic hormone.

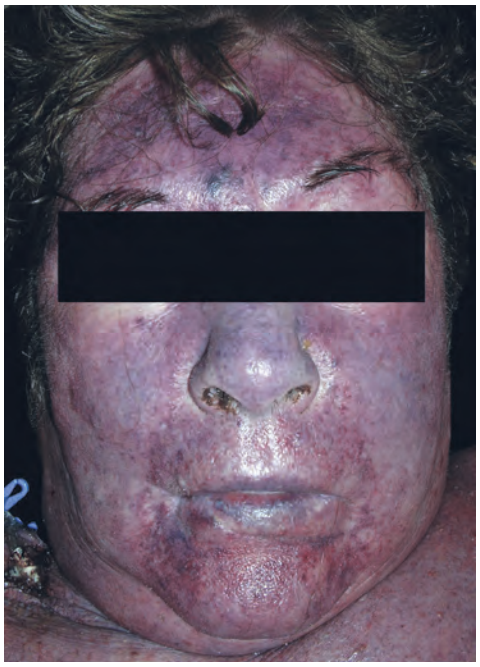

Figure 24.47 Diffuse purpuric rash in a patient with Waterhouse-Friderichsen syndrome. (Reproduced with permission from Vincentelli C, Molina EG, Robinson MJ: Fatal pneumococcal Waterhouse-Friderichsen syndrome in a vaccinated adult with congenital asplenia, *Am J Emerg Med* 27(6):751.e3–751.e5, 2009.)

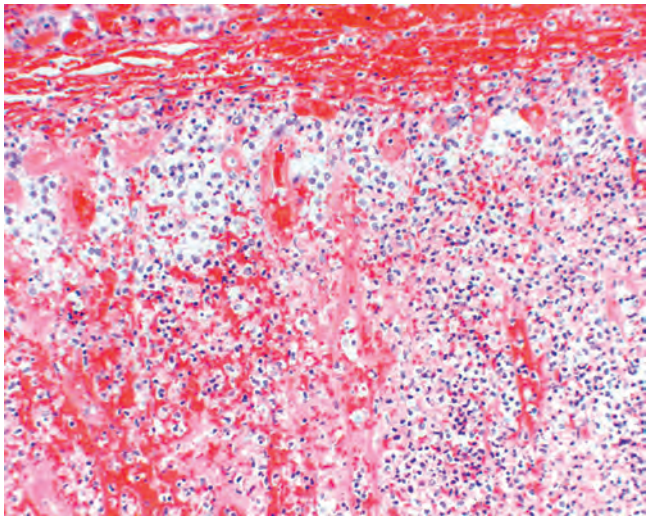

Figure 24.48 Waterhouse-Friderichsen syndrome. At autopsy, the adrenals were grossly hemorrhagic and shrunken; microscopically, little residual cortical architecture is discernible.

underlying detail. Histologic examination reveals that the hemorrhage starts within the medulla near thin-walled venous sinusoids, then suffuses peripherally into the cortex, often leaving islands of recognizable cortical cells (Fig. 24.48). Prompt recognition and appropriate therapy must be instituted immediately, or death follows within hours to a few days.

Primary Chronic Adrenocortical Insufficiency (Addison Disease)

In an article published in 1855, Thomas Addison described a group of patients suffering from a constellation of symptoms, including "general languor and debility, remarkable feebleness of the heart's action, and a peculiar change in the color of the skin" associated with disease of the "suprarenal capsules" or, in more modern parlance, the adrenal glands. Addison disease, or chronic adrenocortical insufficiency, is an uncommon disorder resulting from progressive destruction of the adrenal cortex. Typically, clinical manifestations of adrenocortical insufficiency do not appear until at least 90% of the adrenal cortex has been compromised. The causes of chronic adrenocortical insufficiency are listed in Table 24.10. Although all races and both sexes may be affected, certain causes of Addison disease (e.g., autoimmune adrenalitis) are much more common in Caucasians and in women.

Pathogenesis

A large number of diseases may affect the adrenal cortex, including lymphoma, amyloidosis, sarcoidosis, hemochromatosis, fungal infections, and adrenal hemorrhage, but more than 90% of all cases are attributable to one of four disorders: autoimmune adrenalitis, tuberculosis, AIDS, or metastatic cancers.

- *Autoimmune adrenalitis* accounts for 80% to 90% of cases of primary adrenal insufficiency in high-income countries. As the name implies, there is autoimmune destruction of steroidogenic cells, and autoantibodies to several key steroidogenic enzymes (21-hydroxylase, 17-hydroxylase) are detected in the majority of patients. Autoimmune adrenalitis occurs as an isolated condition in 40% of cases, or as part of an autoimmune polyendocrinopathy syndrome in the remaining 60%. The latter encompasses several distinct entities:
  - *APS-1,* also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy, is characterized by chronic mucocutaneous candidiasis and abnormalities of skin, dental enamel, and nails (ectodermal dystrophy) in association with a combination of organ-specific autoimmune disorders (autoimmune adrenalitis, autoimmune hypoparathyroidism, idiopathic hypogonadism, pernicious anemia) that result in immune destruction of target organs. APS-1 is caused by mutations in the autoimmune regulator *(AIRE)* gene on chromosome 21q22. AIRE is expressed primarily in the thymus, where it functions as a transcription factor that promotes the expression of many peripheral tissue antigens. Self-reactive T cells that recognize these antigens are eliminated (Chapter 6). In the absence of AIRE function, central T-cell tolerance to peripheral tissue antigens is compromised, promoting autoimmunity. Individuals with APS-1 develop autoantibodies against IL-17 and IL-22, which are the principal effector cytokines secreted by Th17 T cells (Chapter 6). Because these two Th17-derived cytokines are crucial for defense against fungal infections, it is not surprising that patients develop chronic mucocutaneous candidiasis.
  - *APS-2* usually starts in the fourth decade of life and presents as a combination of adrenal insufficiency and autoimmune thyroiditis, with or without T1D. Unlike in APS-1, mucocutaneous candidiasis, ectodermal dysplasia, and autoimmune hypoparathyroidism do not develop. Overall, APS-2 is more prevalent than APS-1. In contrast, APS-4 is a rare condition characterized by adrenalitis plus other autoimmune phenomena (e.g., gastritis, vitiligo, alopecia, pernicious anemia) but neither thyroiditis nor T1D. The pathogenesis of these other autoimmune polyendocrinopathies is not understood.
- *Infections,* particularly tuberculosis and those produced by fungi, may also cause primary chronic adrenocortical insufficiency. *Tuberculous adrenalitis,* which once accounted for as much as 90% of cases of Addison disease, has become less common with the development of antimycobacterial drugs. With the resurgence of tuberculosis in most urban centers and the persistence of the disease in lower-income countries, however, this cause of adrenal insufficiency must be kept in mind. When present, tuberculous adrenalitis is usually associated with active infection in other sites, particularly in the lungs and genitourinary tract. Among fungi, disseminated infections caused by *Histoplasma capsulatum* and *Coccidioides immitis* may result in chronic adrenocortical insufficiency. AIDS patients are at risk for developing adrenal insufficiency from several infectious (cytomegalovirus, *Mycobacterium avium-intracellulare*) and noninfectious (Kaposi sarcoma) complications.
- *Metastatic neoplasms* involving the adrenals are another cause of adrenal insufficiency. The adrenals are a fairly common site for metastases in patients with disseminated carcinomas. Although adrenal function is preserved in

most such patients, the metastatic tumors occasionally destroy enough adrenal cortex to produce a degree of adrenal insufficiency. Carcinomas of the lung and breast are the source of a majority of metastases, although many other neoplasms, including gastrointestinal carcinomas, malignant melanoma, and hematopoietic neoplasms, may also metastasize to the adrenals.

- *Genetic causes of adrenal insufficiency* include congenital adrenal hypoplasia *(adrenal hypoplasia congenita)* and *adrenoleukodystrophy*. Adrenoleukodystrophy is caused by mutations of the ATP-binding cassette, subfamily D, member 1 *(ABCD1)* gene and is further described in Chapter 28. Congenital adrenal hypoplasia is a rare X-linked disease caused by mutations in the *NR0B1* gene that encodes DAX1, a transcription factor implicated in adrenal development.

MORPHOLOGY

The anatomic changes in the adrenal glands depend on the underlying disease. **Primary autoimmune adrenalitis** is characterized by irregularly shrunken glands, which may be difficult to identify within the suprarenal adipose tissue. Histologically, the cortex contains only scattered residual cortical cells in a collapsed network of connective tissue. A variable lymphoid infiltrate is present in the cortex and may extend into the adjacent medulla, although the medulla is otherwise preserved (Fig. 24.49). In cases of **tuberculous and fungal disease,** the adrenal architecture is effaced by a granulomatous inflammatory reaction identical to that encountered in other sites of infection. When hypoadrenalism is caused by **metastatic carcinoma,** the adrenals are enlarged and the normal architecture is obscured by the infiltrating neoplasm.

Clinical Features

Addison disease begins insidiously and does not come to attention until the levels of circulating glucocorticoids and mineralocorticoids are significantly decreased. The initial manifestations include progressive weakness and easy fatigability, which may be dismissed as nonspecific complaints. Gastrointestinal disturbances are common and include anorexia, nausea, vomiting, weight loss, and diarrhea. In individuals with primary adrenal disease, hyperpigmentation of the skin, particularly of sun-exposed areas and at pressure points, such as the neck, elbows, knees, and knuckles, is quite characteristic. This is caused by elevated levels of pro-opiomelanocortin (POMC), which is derived from the anterior pituitary and is a precursor of both ACTH and melanocyte-stimulating hormone (MSH). By contrast, hyperpigmentation is not seen in persons with adrenocortical insufficiency caused by primary pituitary or hypothalamic disease. Decreased mineralocorticoid activity in persons with primary adrenal insufficiency results in potassium retention and sodium loss, with consequent hyperkalemia, hyponatremia, volume depletion, and hypotension. Hypoglycemia may occasionally occur as a result of glucocorticoid deficiency and impaired gluconeogenesis. Stresses such as infections, trauma, or surgical procedures in such patients can precipitate an acute adrenal crisis, manifested by intractable vomiting, abdominal pain, hypotension, coma, and vascular collapse. Death occurs rapidly unless corticosteroid therapy begins immediately.

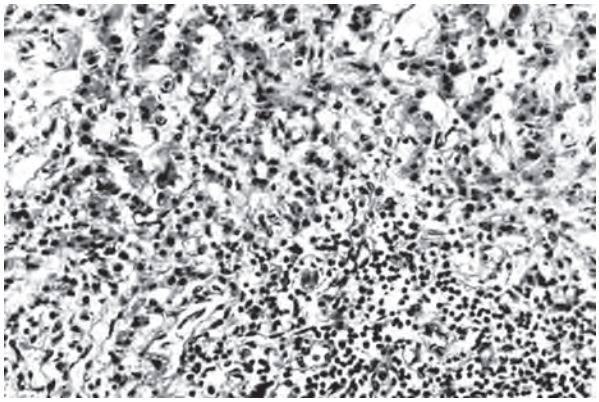

Figure 24.49 Autoimmune adrenalitis. In addition to loss of all but a subcapsular rim of cortical cells, there is an extensive mononuclear cell infiltrate.

KEY CONCEPTS

ADRENOCORTICAL INSUFFICIENCY (HYPOADRENALISM)

- Primary adrenocortical insufficiency can be acute (Waterhouse-Friderichsen syndrome) or chronic (Addison disease)
- Chronic adrenal insufficiency in the developed world most often is secondary to autoimmune adrenalitis, which occurs most commonly in the context of one of two autoimmune polyendocrine syndromes: APS-1 (caused by mutations in the *AIRE* gene) or APS-2. APS-1 is characterized by an autoimmune attack against multiple endocrine organs and autoantibodies against IL-17 and IL-22.
- Tuberculosis and infections due to opportunistic pathogens associated with the human immunodeficiency virus and tumors metastatic to the adrenals are the other important causes of chronic hypoadrenalism.
- Patients typically present with fatigue, weakness, and gastrointestinal disturbances. Primary adrenocortical insufficiency also is characterized by high ACTH levels with associated skin pigmentation.

Secondary Adrenocortical Insufficiency

Any disorder of the hypothalamus and pituitary, such as metastatic cancer, infection, infarction, or irradiation, that reduces the output of ACTH leads to a syndrome of hypoadrenalism that has many similarities to Addison disease. Analogously, prolonged administration of exogenous glucocorticoids suppresses the output of ACTH and adrenal function. With secondary disease, the hyperpigmentation of primary Addison disease is lacking, because levels of melanocyte-stimulating hormone are not elevated. The manifestations also differ in that secondary hypoadrenalism is characterized by deficient cortisol and androgen output but normal or near-normal aldosterone synthesis. Thus, in adrenal insufficiency secondary to pituitary malfunction, marked hyponatremia and hyperkalemia are not seen.

ACTH deficiency can occur alone, but in some instances, it is only one component of panhypopituitarism, associated with multiple trophic hormone deficiencies. Secondary

disease can be differentiated from Addison disease by demonstration of low levels of plasma ACTH in the former. In patients with primary disease, the destruction of the adrenal cortex reduces the response to exogenously administered ACTH, whereas in those with secondary hypofunction, there is a prompt rise in plasma cortisol levels.

MORPHOLOGY

In cases of hypoadrenalism secondary to hypothalamic or pituitary disease **(secondary hypoadrenalism),** depending on the severity of ACTH deficiency, the adrenals may be moderately to markedly decreased in size. The small, flattened glands usually retain their yellow color as a result of a small amount of residual lipid. The cortex may be reduced to a thin ribbon composed largely of zona glomerulosa. The medulla is not affected.

Adrenocortical Neoplasms

It should be evident from the preceding sections that functional adrenal neoplasms may be responsible for any of the various forms of hyperadrenalism. Adenomas and carcinomas are about equally common in adults; in children, carcinomas predominate. While most cortical neoplasms are sporadic, two familial cancer syndromes are associated with a predisposition for developing adrenocortical carcinomas: Li-Fraumeni syndrome, caused by germline *TP53* mutations (Chapter 7), and Beckwith-Wiedemann syndrome, a disorder of epigenetic imprinting involving the gene for insulin-like growth factor 2 (IGF-2) (Chapter 10). Interestingly, somatic *TP53* mutations and overexpression of IGF-2 also occur in sporadic adrenocortical carcinomas, reiterating an oft-observed phenomenon of shared molecular mechanisms in familial and sporadic neoplasms.

Functional adenomas are most commonly associated with hyperaldosteronism and Cushing syndrome, whereas a virilizing neoplasm is more likely to be a carcinoma. However, not all adrenocortical neoplasms elaborate steroid hormones. Determination of functionality is based on clinical evaluation, and measurement of hormones or hormone metabolites in the blood.

MORPHOLOGY

Most **adrenocortical adenomas** are clinically silent and are usually incidental findings at autopsy or during abdominal imaging for an unrelated cause (see the discussion of adrenal "incidentalomas" later). The typical cortical adenoma is a well-circumscribed, nodular lesion up to 2.5 cm in diameter that expands the adrenal (Fig. 24.50). In contrast to a functional adenoma, which is associated with atrophy of the adjacent cortex, the cortex adjacent to a nonfunctional adenoma is normal. On cut surface, adenomas are usually yellow to yellow-brown because of the presence of lipid.

Microscopically, adenomas are composed of cells similar to those populating the normal adrenal cortex. The nuclei tend to be small, although some degree of pleomorphism may be encountered, even in benign lesions ("endocrine atypia"). The cytoplasm of the neoplastic cells ranges from eosinophilic to vacuolated, depending on their lipid content (Fig. 24.51). Mitotic activity is generally inconspicuous, with a Ki-67 labeling index less than 5% (in contrast to adrenocortical carcinomas). Adrenocortical lesions—both adenomas and carcinomas—express steroidogenic factor-1 (SF-1) and inhibin-alpha.

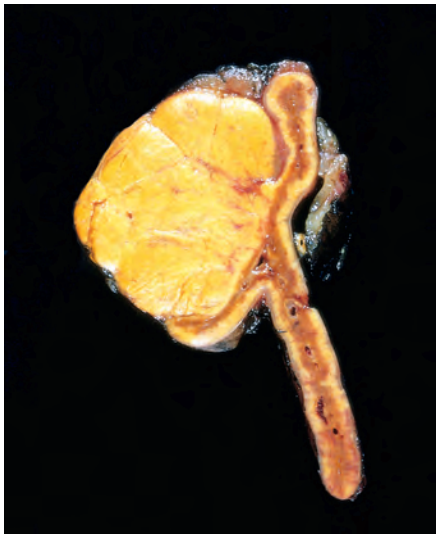

Figure 24.50 Adrenal cortical adenoma. The adenoma is distinguished from nodular hyperplasia by its solitary, circumscribed nature. The functional status of an adrenal cortical adenoma cannot be predicted from its gross or microscopic appearance.

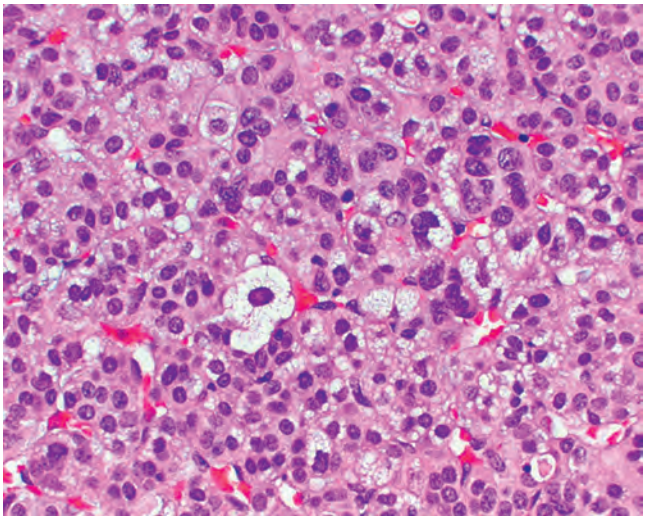

Figure 24.51 Histologic features of an adrenal cortical adenoma. The neoplastic cells are vacuolated because of the presence of intracytoplasmic lipid. There is mild nuclear pleomorphism. Mitotic activity and necrosis are not seen.

Adrenocortical carcinomas are rare neoplasms that have a bimodal distribution in the first and fifth decades of life. They are more likely to be functional than adenomas and are often associated with virilism or other clinical manifestations of hyperadrenalism. In most cases, adrenocortical carcinomas are large, invasive lesions, many exceeding 20 cm in diameter, which efface the native adrenal gland (Fig. 24.52). The less common, smaller, and better-circumscribed lesions may be difficult to distinguish from an adenoma. On cut surface, adrenocortical carcinomas are typically variegated, poorly demarcated lesions containing areas of necrosis, hemorrhage, and cystic change. Adrenal cancers have

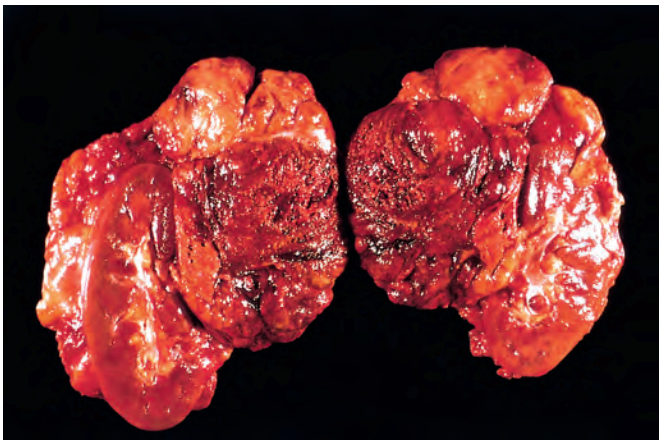

Figure 24.52 Adrenal carcinoma. The hemorrhagic and necrotic tumor dwarfs the kidney and compresses the upper pole.

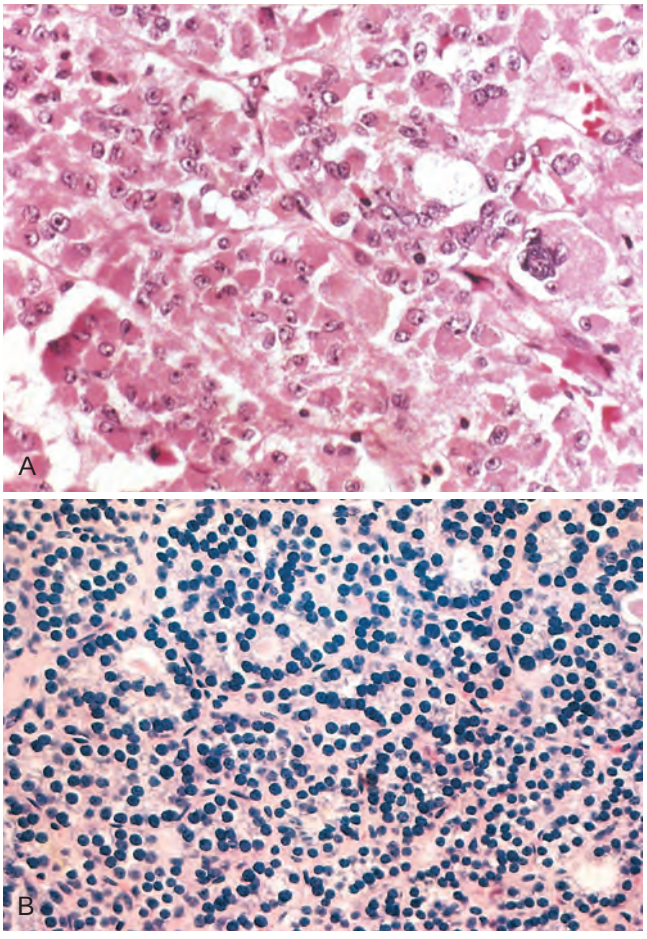

Figure 24.53 Adrenal carcinoma (A) revealing marked anaplasia, contrasted with normal adrenal cortical cells (B).

a strong tendency to invade the adrenal vein, vena cava, and lymphatics. Metastases to regional and periaortic nodes are common, as is distant hematogenous spread to the lungs and other viscera. The median patient survival is about 2 years.

Microscopically, adrenocortical carcinomas may be composed of well-differentiated cells, resembling those seen in cortical adenomas, or bizarre, monstrous giant cells (Fig. 24.53), which may be difficult to distinguish from those of an undifferentiated carcinoma metastatic to the adrenal. Between these extremes are cancers with moderate degrees of anaplasia, some composed predominantly of spindle cells. In addition to higher Ki-67 index, carcinomas also have significantly higher IGF-2 levels compared to adrenocortical adenomas.

Carcinomas, particularly those of bronchogenic origin, may metastasize to the adrenals and may be difficult to differentiate from primary cortical carcinomas. Of note, metastases to the adrenal cortex are significantly more common than primary adrenocortical carcinomas.

Other Adrenal Lesions

Adrenal cysts are relatively uncommon; however, with the use of sophisticated abdominal imaging techniques, the frequency of detection of these lesions is increasing. Larger cysts may produce an abdominal mass and flank pain. Both cortical and medullary neoplasms may undergo necrosis and cystic degeneration and may present as "nonfunctional cysts."

Adrenal myelolipomas are unusual benign lesions composed of mature fat and hematopoietic cells. Although most of these lesions represent incidental findings, occasional myelolipomas may reach massive proportions. Histologically, mature adipocytes are admixed with aggregates of differentiating hematopoietic cells belonging to all three lineages. Foci of myelolipomatous change may be seen in cortical tumors and in adrenals with cortical hyperplasia.

The term *adrenal incidentaloma* is a half-facetious moniker that has crept into the medical lexicon as advancements in medical imaging have led to the incidental discovery of adrenal masses in asymptomatic individuals or in individuals in whom the presenting complaint is not directly related to the adrenal gland. The estimated population prevalence of "incidentalomas" discovered by imaging is approximately 4%, with an age-dependent increase in prevalence. Fortunately, the vast majority of these lesions are small nonsecreting cortical adenomas of no clinical importance.

ADRENAL MEDULLA

The adrenal medulla is developmentally, functionally, and structurally distinct from the adrenal cortex. It is composed of specialized neural crest (neuroendocrine) cells, termed *chromaffin* cells, and their supporting (sustentacular) cells. The adrenal medulla is the major source of catecholamines (epinephrine, norepinephrine) in the body. Neuroendocrine cells similar to chromaffin cells are widely dispersed in an extra-adrenal system of clusters and nodules that, together with the adrenal medulla, make up the *paraganglion system*. These extra-adrenal paraganglia are closely associated with the autonomic nervous system and can be divided into three groups based on their anatomic distribution: (1) branchiomeric, (2) intravagal, and (3) aorticosympathetic. The branchiomeric and intravagal paraganglia associated with the parasympathetic system are located close to the major arteries and cranial nerves of the head and neck and

include the carotid bodies (Chapter 16). The intravagal paraganglia, as the term implies, are distributed along the vagus nerve. The aorticosympathetic chain is found in association with segmental ganglia of the sympathetic system and therefore is distributed mainly alongside of the abdominal aorta. The organs of Zuckerkandl, close to the aortic bifurcation, belong to this group.

The most important diseases of the adrenal medulla are neoplasms, which include neoplasms of chromaffin cells *(pheochromocytomas)* and neuronal neoplasms *(neuroblastic tumors)*. Neuroblastomas and other neuroblastic tumors are discussed in Chapter 10.

Pheochromocytoma

Pheochromocytomas are neoplasms composed of chromaffin cells, which synthesize and release catecholamines and, in some instances, peptide hormones. It is important to recognize these tumors because they are a rare cause of surgically correctable hypertension. Traditionally, the features of pheochromocytomas have been summarized by the "rule of 10s".

- *Ten percent of pheochromocytomas are extra-adrenal*, occurring in sites such as the organs of Zuckerkandl and the carotid body. Pheochromocytomas that develop in extra-adrenal paraganglia are designated *paragangliomas* and are discussed in Chapter 16.
- *Ten percent of sporadic adrenal pheochromocytomas are bilateral*; this figure may rise to as high as 50% in cases that are associated with familial tumor syndromes (see later).
- *Ten percent of adrenal pheochromocytomas are biologically malignant,* defined by the presence of metastatic disease. Malignancy is more common (20% to 40%) in extra-adrenal paragangliomas, and in tumors arising in the setting of certain germline mutations (see later).
- *Ten percent of adrenal pheochromocytomas are not associated with hypertension*. Of the 90% that present with hypertension, approximately two-thirds have "paroxysmal" episodes associated with a sudden rise in blood pressure and palpitations, which can, on occasion, be fatal.

One "traditional" 10% rule that has now been modified pertains to familial cases. It is now recognized that as many as 25% of individuals with pheochromocytomas and paragangliomas harbor an oncogenic germline mutation. These mutations can involve at least a dozen genes, the most common of which are listed in Table 24.11. Patients with germline mutations are typically younger at presentation than those with sporadic tumors and more often have bilateral tumors. The affected genes fall into two broad classes, those that enhance growth factor receptor pathway signaling (e.g., *RET, NF1*) and those that increase the activity and stability of two hypoxia-induced transcription factors, HIF-1α and HIF-2α (thus, creating a so-called "pseudohypoxia" phenotype). You will recall that the *VHL* gene encodes a tumor-suppressor protein that is needed for the oxygen-dependent degradation of HIF-1α and that is disrupted by loss-of-function mutations in patients with von Hippel-Lindau (VHL) syndrome. VHL syndrome is associated with a number of tumors, including pheochromocytomas and paragangliomas. Similarly, *EPAS1* encodes HIF-2α, and gain-of-function mutations are found in individuals with the "polycythemia paraganglioma syndrome" that stabilize HIF-2α by mutating amino acid residues that are required for its degradation. Other familial cases of pheochromocytoma are associated with germline mutations in genes encoding several components of the succinate dehydrogenase complex (most commonly, *SDHB, SDHC,* and *SDHD*). This complex is involved in mitochondrial electron transport and oxygen sensing, and it is believed that these mutations also lead to up-regulation of HIF protein, recapitulating "pseudohypoxia." Recent integrated molecular analyses of pheochromocytomas and paragangliomas have shown that many of the genes implicated in a germline predisposition to these neoplasms (e.g., *NF1, VHL, EPAS1,* and *RET*) also are involved by somatic mutations in sporadic tumors.

Table 24.11 Familial Syndromes Associated With Pheochromocytoma and Extra-Adrenal Paragangliomas

Syndrome	Gene	Associated Lesion	Other Features
Multiple endocrine neoplasia, type 2A (MEN-2A)	*RET*	Pheochromocytoma/paraganglioma	Medullary thyroid carcinoma Parathyroid hyperplasia
Multiple endocrine neoplasia, type 2B (MEN-2B)	*RET*	Pheochromocytoma/paraganglioma	Medullary thyroid carcinoma Marfanoid habitus Mucocutaneous GNs
Neurofibromatosis, type 1 (NF1)	*NF1*	Pheochromocytoma	Neurofibromatosis Café-au-lait spots Optic nerve glioma
Von Hippel-Lindau (VHL)	*VHL*	Pheochromocytoma/paraganglioma	Renal cell carcinoma Hemangioblastoma Pancreatic endocrine neoplasm
Hereditary paraganglioma 1	*SDHD*	Pheochromocytoma, paraganglioma	GIST
Hereditary paraganglioma 3	*SDHC*	Paraganglioma	GIST
Hereditary paraganglioma 4	*SDHB*	Pheochromocytoma, paraganglioma	GIST
Polycythemia paraganglioma syndrome	*EPAS1*	Pheochromocytoma, paraganglioma	Polycythemia

GIST, Gastrointestinal stromal tumor; *GN,* ganglioneuroma; *NF1*, neurofibromin; *SDHB*, succinate dehydrogenase complex, subunit B; *SDHC*, succinate dehydrogenase complex, subunit C; *SDHD*, succinate dehydrogenase complex, subunit D; *EPAS1*, endothelial PAS-domain containing 1 (encodes for HIF-2alpha).
Note: Additional rare syndromes associated with pheochromocytoma or paragangliomas are not included in this table.

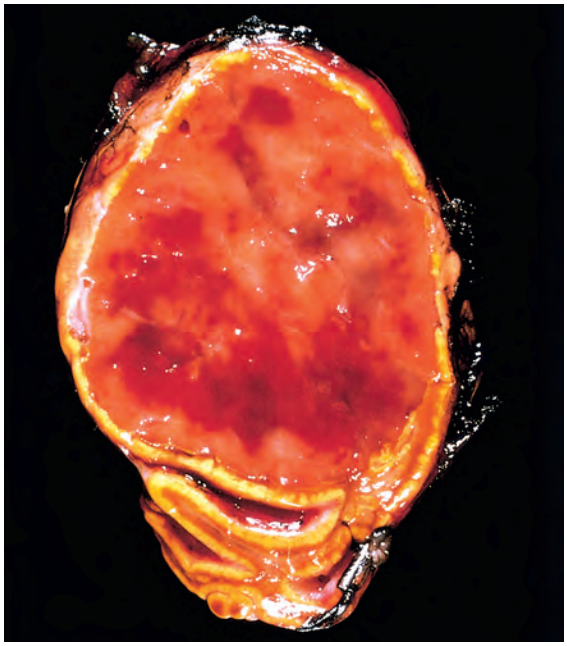

Figure 24.54 Pheochromocytoma. The tumor is enclosed within an attenuated cortex and demonstrates areas of hemorrhage. The comma-shaped residual adrenal is seen below. (Courtesy Dr. Jerrold R. Turner, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

MORPHOLOGY

Pheochromocytomas range from small, circumscribed lesions confined to the adrenal (Fig. 24.54) to large hemorrhagic masses weighing kilograms. The average weight of a pheochromocytoma is 100 g, but weights from just over 1 g to almost 4000 g have been reported. The larger tumors are well demarcated by either connective tissue or compressed cortical or medullary tissue. Richly vascularized fibrous trabeculae within the tumor produce a lobular pattern. In many tumors, remnants of the adrenal gland can be seen, stretched over the surface or attached at one pole. On section, the cut surfaces of smaller pheochromocytomas are yellow-tan. Larger lesions tend to be hemorrhagic, necrotic, and cystic and typically efface the adrenal gland. Incubation of fresh tissue with a potassium dichromate solution turns the tumor a dark brown color due to oxidation of stored catecholamines, thus the term **chromaffin.**

The histologic pattern in pheochromocytoma is quite variable. The tumors are composed of clusters of polygonal to spindle-shaped chromaffin cells or chief cells that are surrounded by supporting sustentacular cells, creating small nests or alveoli **(zellballen)** that are supplied by a rich vascular network (Fig. 24.55). Uncommonly, the dominant cell type is a spindle or small cell; various patterns can be found in any one tumor. The cytoplasm has a finely granular appearance, best demonstrated with silver stains, due to the presence of granules containing catecholamines. The nuclei are usually round to ovoid, with a stippled "salt-and-pepper" chromatin that is characteristic of neuroendocrine tumors. Electron microscopy reveals variable numbers of membrane-bound, electron-dense secretory granules (Fig. 24.56). Immunoreactivity for neuroendocrine markers (chromogranin and synaptophysin) is seen in the chief cells, while the peripheral sustentacular cells stain with antibodies against S-100, a calcium-binding protein expressed by a variety of mesenchymal cell types.

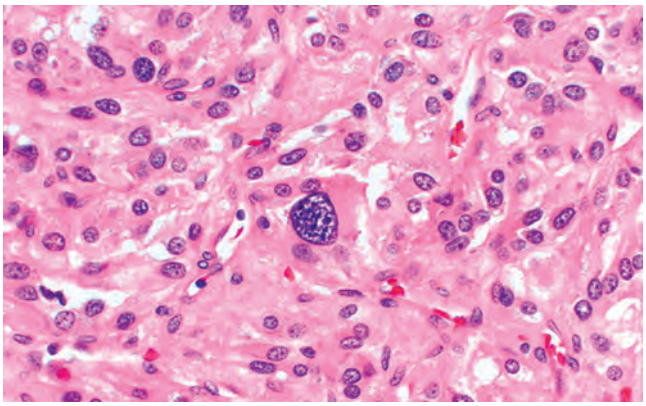

Figure 24.55 Pheochromocytoma demonstrating characteristic nests of cells ("zellballen") with abundant cytoplasm. Granules containing catecholamine are not visible in this preparation. It is not uncommon to find bizarre cells, even in pheochromocytomas that are biologically benign. (Courtesy Dr. Jerrold R. Turner, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

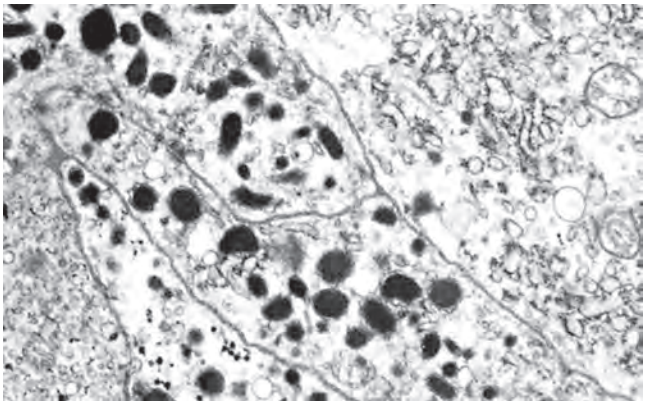

Figure 24.56 Electron micrograph of pheochromocytoma. This tumor contains membrane-bound secretory granules in which catecholamines are stored (30,000×).

Determining malignancy in pheochromocytomas can be vexing. Several histologic features, such as numbers of mitoses, confluent tumor necrosis, and spindle cell morphology, have been associated with an aggressive behavior and increased risk of metastasis, but are not entirely reliable. Tumors with "benign" histologic features may metastasize, while bizarrely pleomorphic tumors may remain confined to the adrenal gland. In fact, cellular and nuclear pleomorphism, including the presence of giant cells, and mitotic figures are often seen in benign pheochromocytomas, while cellular monotony is paradoxically associated with aggressive behavior. Even capsular and vascular invasion may be encountered in benign lesions. Therefore, the definitive diagnosis of malignancy in pheochromocytomas is based exclusively on the presence of metastases. These may involve regional lymph nodes as well as more distant sites, including liver, lung, and bone.

Clinical Features

The dominant clinical manifestation of pheochromocytoma is *hypertension,* observed in 90% of patients. Approximately two-thirds of patients with hypertension demonstrate *paroxysmal episodes,* which are described as an abrupt, precipitous

elevation in blood pressure associated with tachycardia, palpitations, headache, sweating, tremor, and a sense of apprehension. These episodes may also be associated with pain in the abdomen or chest, nausea, and vomiting. Isolated paroxysmal episodes of hypertension occur in less than one-half of patients; more commonly, patients demonstrate chronic, sustained elevation in blood pressure punctuated by the aforementioned paroxysms. The paroxysms may be precipitated by emotional stress, exercise, changes in posture, and palpation in the region of the tumor; urinary bladder paragangliomas occasionally precipitate a paroxysm during micturition. The elevations of blood pressure are induced by the sudden release of catecholamines that may acutely precipitate congestive heart failure, pulmonary edema, myocardial infarction, ventricular fibrillation, and cerebrovascular accident.

The cardiac complications have been attributed to what has been called *catecholamine cardiomyopathy,* or catecholamine-induced myocardial instability and ventricular arrhythmias. Nonspecific myocardial changes, such as focal necrosis, mononuclear infiltrates, and interstitial fibrosis, have been attributed either to ischemic damage secondary to catecholamine-induced constriction of myocardial blood vessels or to direct catecholamine toxicity. In some cases, pheochromocytomas secrete other hormones, such as ACTH and somatostatin, and may therefore be associated with clinical features related to the secretion of these or other peptide hormones. Laboratory diagnosis of pheochromocytoma is based on the demonstration of increased urinary excretion of free catecholamines and their metabolites, such as vanillylmandelic acid and metanephrines.

Isolated benign tumors are treated with surgical excision after preoperative and intraoperative medication with adrenergic-blocking agents to prevent a hypertensive crisis. Multifocal lesions require long-term medical treatment for hypertension.

Multiple Endocrine Neoplasia Syndromes

The MEN syndromes are a group of inherited diseases resulting in proliferative lesions (hyperplasia, adenomas, and carcinomas) of multiple endocrine organs. Like other inherited cancer disorders (Chapter 7), endocrine tumors arising in the context of MEN syndromes have certain distinct features that contrast with their sporadic counterparts.

- Tumors occur at a *younger age* than sporadic tumors.
- They arise in *multiple endocrine organs,* either *synchronously* (at the same time) or *metachronously* (at different times).
- Even in one organ, the tumors are often *multifocal*.
- The tumors are usually preceded by an *asymptomatic stage of hyperplasia* involving the cell of origin. For example, individuals with MEN-2 almost universally demonstrate C-cell hyperplasia in the thyroid parenchyma adjacent to medullary thyroid carcinomas.
- These tumors are usually *more aggressive* and *recur* in a higher proportion of cases than do similar sporadic endocrine tumors.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 1

MEN-1, or *Wermer syndrome,* is a rare heritable disorder with a prevalence of about 2 per 100,000. MEN-1 is characterized by abnormalities involving the parathyroid, pancreas, and pituitary gland; thus the mnemonic device, the three P's:

- *Parathyroid:* Primary hyperparathyroidism is the most common manifestation of MEN-1 (80% to 95% of patients) and is the initial manifestation of the disorder in most patients, appearing in almost all patients by 40 to 50 years of age. Parathyroid abnormalities include both hyperplasia and adenomas.
- *Pancreas:* Endocrine tumors of the pancreas are a leading cause of morbidity and mortality in persons with MEN-1. These tumors are usually aggressive and often present with metastatic disease. It is not uncommon to find multiple "microadenomas" scattered throughout the pancreas in conjunction with one or two dominant lesions. MEN-1–associated pancreatic endocrine tumors are often functional; however, because pancreatic polypeptide is the most commonly secreted product, many tumors fail to produce an endocrine hypersecretion syndrome. Among those that do, Zollinger-Ellison syndrome (associated with gastrinomas) and hypoglycemia and neurologic manifestations (associated with insulinomas) are most common.
- *Pituitary:* The most frequent anterior pituitary tumor encountered in MEN-1 is a prolactinoma; some patients develop acromegaly from somatotropin-secreting tumors.
- It is now recognized that the spectrum of this disease extends beyond the three *P's*. The duodenum is the most common site of gastrinomas in individuals with MEN-1 (far in excess of the frequency of pancreatic gastrinomas), and synchronous duodenal and pancreatic tumors may be present in the same individual. In addition, carcinoid tumors, thyroid and adrenocortical adenomas, and lipomas are more frequent than in the general population.

MEN-1 syndrome is caused by germline mutations in the *MEN1* tumor suppressor gene, which encodes a protein called menin. Menin is a component of several different transcription factor complexes, which (depending on the specific binding partner) may either promote or inhibit tumorigenesis. This dichotomy in menin function is best exemplified in the interactions of menin with two oncogenic transcription factors—JunD and KMT2A (previously known as MLL), a chromatin-modifying histone methyltransferase. When menin partners with JunD, it blocks transcriptional activation and cellular proliferation induced by JunD; in fact, loss of this tumor-suppressor interaction is believed to contribute to the MEN observed in the setting of *MEN-1* inactivating mutations. On the contrary, the association of wild-type menin with KMT2A leads to the formation of a tumor-promoting transcriptional complex in a subset of acute leukemias through upregulated expression of *HOX* genes (Chapter 13).

The dominant manifestations of MEN-1 usually result from the peptide hormones that are overproduced and include such abnormalities as recurrent hypoglycemia due to insulinomas, intractable peptic ulcers in persons with Zollinger-Ellison syndrome, nephrolithiasis caused by PTH-induced hypercalcemia, or symptoms of prolactin excess from a pituitary tumor. As expected, malignant behavior by one or more of the endocrine tumors arising in these patients is often the proximate cause of death.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 2

MEN-2 is subclassified into three distinct syndromes: MEN-2A, MEN-2B, and MEN-4.

- *MEN-2A*, or *Sipple syndrome,* is characterized by *pheochromocytoma, medullary carcinoma of the thyroid,* and *parathyroid hyperplasia* (see Table 24.11). Medullary carcinomas of the thyroid occur in almost 100% of patients. They are usually multifocal and are virtually always associated with foci of C-cell hyperplasia in the adjacent thyroid. The medullary carcinomas may elaborate calcitonin and other active products and are usually clinically aggressive. Among individuals with MEN-2A, 40% to 50% have pheochromocytomas, which are often bilateral and may arise in extra-adrenal sites. Parathyroid hyperplasia and evidence of hypercalcemia or renal stones occur in 10% to 20% of patients. **MEN-2A is clinically and genetically distinct from MEN-1 and is caused by germline gain-of-function mutations in the *RET* proto-oncogene**. As noted earlier, the *RET* proto-oncogene encodes a receptor tyrosine kinase that binds glial-derived neurotrophic factor and other related ligands and transmits growth and differentiation signals (Chapter 7). Loss-of-function mutations in *RET* result in intestinal aganglionosis and Hirschsprung disease (Chapter 17). In contrast, in MEN-2A (as well as in MEN-2B), germline mutations constitutively activate the RET receptor.
- *MEN-2B* has significant clinical overlap with MEN-2A. Patients develop medullary thyroid carcinomas, which are usually multifocal and more aggressive than in MEN-2A, and pheochromocytomas. However, unlike in MEN-2A, primary hyperparathyroidism is not present. In addition, MEN-2B is accompanied by neuromas or ganglioneuromas involving the skin, oral mucosa, eyes, respiratory tract, and gastrointestinal tract, and a marfanoid habitus, with long axial skeletal features and hyperextensible joints (see Table 24.11). Previously, families with isolated medullary thyroid carcinomas and germline *RET* mutations without additional features of MEN-2B were classified as a separate entity ("familial medullary thyroid carcinoma"), but have recently been grouped under the umbrella of MEN-2B. A germline missense mutation leading to a single amino acid change in RET, distinct from the mutations that are seen in MEN-2A, seems to be responsible for virtually all cases of MEN-2B. This point substitution affects a critical region of the tyrosine kinase domain of the protein and leads to constitutive activation of RET in the absence of ligand.

  In contrast to MEN-1, in which the long-term benefit of early diagnosis by genetic screening is not well established, diagnosis via screening of at-risk family members in MEN-2A kindred is important because medullary thyroid carcinoma is a life-threatening disease that can be prevented by early thyroidectomy. According to updated recommendations issued in 2015, all patients with medullary thyroid carcinoma are advised to undergo germline *RET* mutation testing, since even "apparently sporadic" cases might harbor a germline mutation, which has implications for genetic counseling and testing for unaffected family members. Routine genetic testing identifies *RET* mutation carriers earlier and more reliably in MEN-2 kindreds; all individuals carrying germline *RET* mutations are advised to undergo prophylactic thyroidectomy to prevent the inevitable development of medullary carcinomas.
- *MEN-4* has emerged as a new entity in the past decade. These patients have clinical features that phenocopy MEN-1 patients, but in contrast to that syndrome, harbor germline *CDKN1B* mutations, leading to reduced levels of the cell-cycle checkpoint protein, p27.

Pineal Gland

The rarity of clinically significant lesions (virtually only tumors) justifies brevity in the consideration of the pineal gland. It is a minute, pinecone-shaped organ (hence its name), weighing 100 to 180 mg and lying between the superior colliculi at the base of the brain. It is composed of a loose, neuroglial stroma enclosing nests of epithelial-appearing *pineocytes,* cells with photosensory and neuroendocrine functions (hence the designation of the pineal gland as the "third eye"). Silver impregnation stains reveal that these cells have long, slender processes reminiscent of primitive neuronal precursors intermixed with the processes of astrocytic cells. The principal secretory product of the pineal gland is melatonin, which is involved in the control of circadian rhythms, including the sleep-wake cycle; hence the popular use of melatonin for the treatment of jet lag.

All tumors involving the pineal gland are rare; most (50% to 70%) arise from sequestered embryonic germ cells (Chapter 28). They most commonly take the form of so-called *germinomas,* resembling testicular seminoma (Chapter 21) or ovarian dysgerminoma (Chapter 22). Other lines of germ cell differentiation include embryonal carcinomas; choriocarcinomas; mixtures of germinoma, embryonal carcinoma, and choriocarcinoma; and, uncommonly, typical teratomas (usually benign). Whether to characterize these germ cell neoplasms as pinealomas is debated, but most "pinealophiles" favor restricting the term *pinealoma* to neoplasms arising from the pineocytes.

PINEALOMA

These neoplasms are divided into two categories, *pineoblastomas* and *pineocytomas*, based on their level of differentiation, which, in turn, correlates with their aggressiveness. These tumors are rare and are described in specialized texts.

CHAPTER 25

The Skin

Alexander J. Lazar

CHAPTER CONTENTS

THE SKIN: MORE THAN A MECHANICAL BARRIER

More than a century and a half ago, the noted pathologist Rudolph Virchow described the skin as a mere protective covering for more delicate and functionally sophisticated internal viscera. Subsequently, the skin was viewed as a necessary but rather uninteresting barrier to fluid loss and mechanical injury. Over the last several decades, however, the skin has come to be appreciated as a surprisingly complicated organ—the largest in the body—in which precisely regulated cellular and molecular interactions govern many essential processes.

Although the human integument may appear drab compared with the skin and pelage of other members of the animal kingdom, it is extraordinarily vibrant with regard to the diversity of functions that it carries out. Chief among these is its role as one of the first lines of defense against potentially harmful infectious and physical agents. However, the skin is also a highly sophisticated sensory organ and even has important endocrine roles, particularly the synthesis of vitamin D (Chapter 9), which is "powered" by sun exposure. It is composed of several cell types and structures that function interdependently and cooperatively (Fig. 25.1).

- *Squamous epithelial cells (keratinocytes)* are normally "glued" tightly together by cell junctions known as desmosomes and produce abundant amounts of keratin protein, both of which serve to create a tough, durable physical barrier. In addition, keratinocytes secrete soluble molecules such as cytokines and defensins that augment and regulate cutaneous immune responses (described later).
- *Melanocytes* within the epidermis are responsible for the production of melanin, a brown pigment that absorbs and protects against potentially injurious ultraviolet (UV) radiation in sunlight.
- *Dendritic cells.* Skin serves as one of the first lines of defense against microorganisms and is constantly exposed to microbial and nonmicrobial antigens, which are processed by intraepidermal dendritic cells known as *Langerhans*

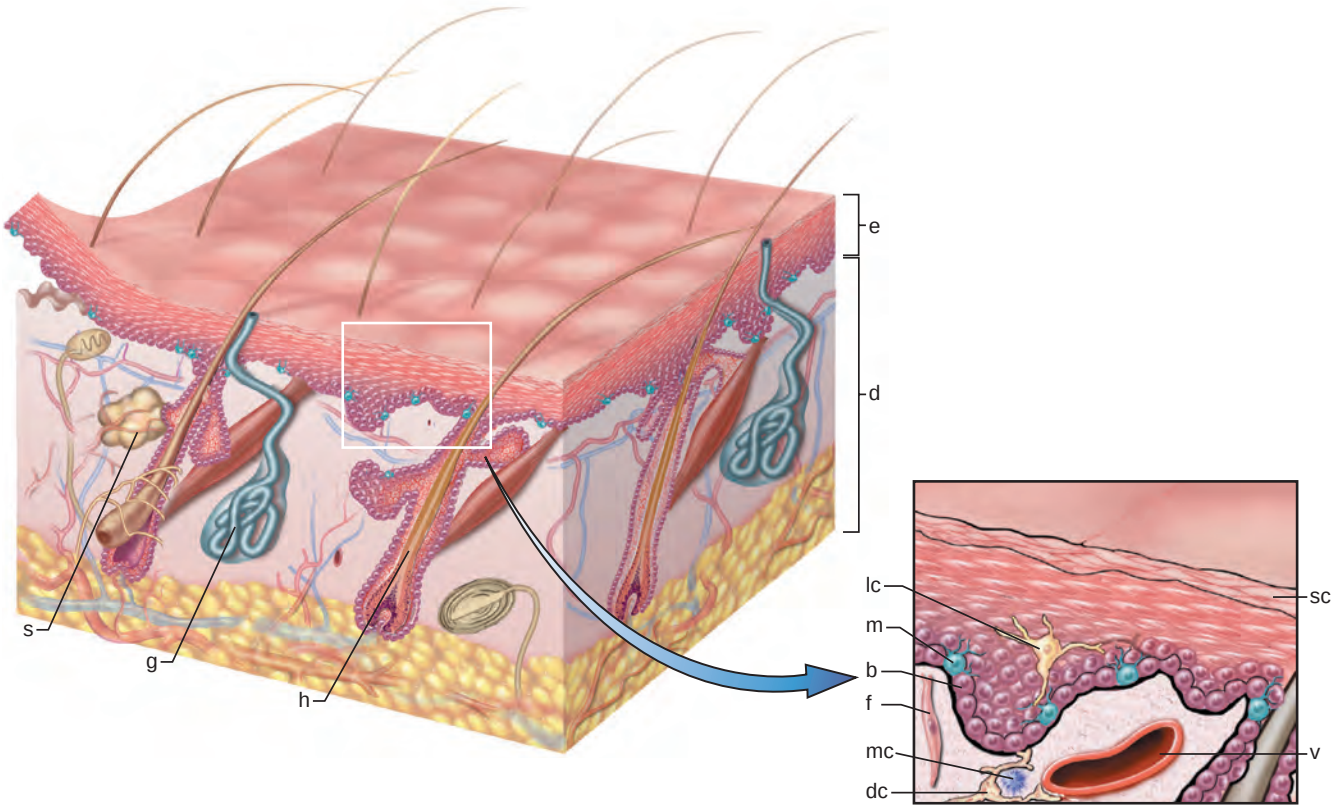

Figure 25.1 *Left*, The skin is composed of an epidermal layer *(e)*, from which specialized adnexa—hair follicles *(h)*, sweat glands *(g)*, and sebaceous glands *(s)*—descend into the underlying dermis *(d)*. *Inset*, This projection of the epidermal layer and underlying superficial dermis demonstrates the progressive upward maturation of basal cells *(b)* into cornified squamous epithelial cells of the stratum corneum *(sc)*. Melanin-containing dendritic melanocytes *(m)* (and rare Merkel cells containing neurosecretory granules) and mid-epidermal dendritic Langerhans cells *(lc)* are also present. The underlying dermis contains small vessels *(v)*, fibroblasts *(f)*, perivascular mast cells *(mc)*, and dendrocytes *(dc)*, which participate in dermal immune responses and repair.

cells. Langerhans cells secrete factors that augment innate immune responses and migrate from the skin to regional lymph nodes where they present their antigenic cargoes to T lymphocytes, thereby stimulating the adaptive immune system. Specialized *dendrocytes,* another type of dendritic cell found within the dermis, perform similar functions.

- *Lymphocytes.* Following their stimulation by dendritic cells in regional lymph nodes, T cells expressing an adhesion molecule called cutaneous lymphocyte-associated antigen (CLA) and chemokine receptors such as CCR4 and CCR10 leave the lymph node and home back to the dermis, a process that is directed in part by chemokines secreted by activated keratinocytes. Cytokines produced by these T cells mediate the microscopic patterns and clinical expressions of cutaneous inflammatory and infectious diseases. In addition, small numbers of B cells are found in the dermis that can participate in humoral responses to antigens encountered in the skin.
- *The skin is a large and complex ecosystem that provides niches for a broad spectrum of organisms, including bacteria, fungi, viruses, and mites.* These organisms have evolved symbiotic relationships with their human hosts and appear to contribute to health in a number of ways. By occupying skin niches, the normal "zoo" of organisms (the skin microbiome) prevents colonization of the skin by other potentially harmful organisms, just as the gut microbiome may protect against gastrointestinal pathogens (Chapter 17). In addition, the skin fauna primes and "educates" the cutaneous immune system in a manner that is believed to enhance immune responses to potential pathogens.
- *Afferent nerve fibers and a diverse set of associated specialized structures referred to as neural end organs* are responsible for physical sensations that run that gamut from pleasurable to painful, including touch, vibration, itchiness, cold, and heat. In addition, autonomic efferent nerve fibers regulate adnexal components such as sweat glands and effector pili muscles (see later) and can also influence the function of innate and adaptive immune cells in the dermis. Another cell type found in skin that remains cloaked in mystery is the *Merkel cell;* these cells are located in the epithelial basal cell layer and may have neuroendocrine or mechanoreceptor functions.
- *Adnexal components.* Sweat glands guard against deleterious variations in body temperature, and hair follicles, in addition to manufacturing hair shafts, have protected niches harboring epithelial stem cells capable of regenerating superficial epithelial skin structures following their disrupted by trauma, burns, and other types of injuries.

Perturbations that disrupt the delicate homeostasis that exists among skin cells may produce conditions as varied as wrinkles and hair loss, blisters and rashes, life-threatening cancers, and disorders of immune regulation. For example,

long-term exposure to sunlight fosters premature cutaneous aging, blunts immunologic responses to environmental antigens, and favors the development of a variety of premalignant and malignant cutaneous neoplasms. Ingested agents, such as therapeutic drugs, can cause an enormous number of rashes or exanthems. Systemic disorders, such as diabetes mellitus, amyloidosis, and lupus erythematosus, can also have important manifestations in the skin.

Skin conditions are very common, affecting about one-third of the US population each year. Since skin is uniquely accessible to visual examination, for the experienced observer it can yield numerous insights into the functional state of the body (if not the very soul of a patient). Close attention to the appearance and distribution of skin lesions is critical, as these characteristics are essential in formulating diagnoses and in understanding pathogenesis. To underscore this point, special emphasis is placed on the gross appearance of skin lesions under each specific entity.

Thousands of diseases affect the skin. Only those that are common or that illustrate important pathologic mechanisms are described here. Dermatologists and dermatopathologists have developed a set of terms to describe the gross and microscopic appearance of skin lesions that every student must be familiar with in order to be fluent in dermatopathology; the most important of these terms and their respective definitions are given in Table 25.1.

Table 25.1 Nomenclature of Skin Lesions

	Definition
Macroscopic Lesions	
Excoriation	Traumatic lesion breaking the epidermis and causing a raw linear defect (i.e., deep scratch); often self-induced.
Lichenification	Thickened, rough skin (similar to lichen on a rock); usually the result of repeated rubbing.
Macule, Patch	Circumscribed, flat lesion distinguished from surrounding skin by color. Macules are 5 mm in diameter or less; patches are greater than 5 mm.
Onycholysis	Separation of nail plate from nail bed.
Papule, Nodule	Elevated dome-shaped or flat-topped lesion. Papules are 5 mm or less across; nodules are greater than 5 mm in size.
Plaque	Elevated flat-topped lesion, usually greater than 5 mm across (may be caused by coalescent papules).
Pustule	Discrete, pus-filled, raised lesion.
Scale	Dry, horny, plate-like excrescence; usually the result of imperfect cornification.
Vesicle, Bulla, Blister	Fluid-filled raised lesion 5 mm or less across (vesicle) or greater than 5 mm across (bulla). Blister is the common term for either lesion.
Wheal	Itchy, transient, elevated lesion with variable blanching and erythema formed as the result of dermal edema.
Microscopic Lesions	
Acanthosis	Diffuse epidermal hyperplasia.
Dyskeratosis	Abnormal, premature keratinization within cells below the stratum granulosum.
Erosion	Discontinuity of the skin showing incomplete loss of the epidermis.
Exocytosis	Infiltration of the epidermis by inflammatory cells.
Hydropic swelling (ballooning)	Intracellular edema of keratinocytes, often seen in viral infections.
Hypergranulosis	Hyperplasia of the stratum granulosum, often due to intense rubbing.
Hyperkeratosis	Thickening of the stratum corneum, often associated with a qualitative abnormality of the keratin.
Lentiginous	Linear pattern of melanocyte proliferation within the epidermal basal cell layer.
Papillomatosis	Surface elevation caused by hyperplasia and enlargement of contiguous dermal papillae.
Parakeratosis	Keratinization with retained nuclei in the stratum corneum. On mucous membranes, parakeratosis is normal.
Spongiosis	Intercellular edema of the epidermis.
Ulceration	Discontinuity of the skin marked by complete loss of the epidermis revealing dermis or subcutis.
Vacuolization	Formation of vacuoles within or adjacent to cells; often refers to basal cell–basement membrane zone area.

DISORDERS OF PIGMENTATION AND MELANOCYTES

Focal or widespread loss of normal protective pigmentation can make individuals extraordinarily vulnerable to the harmful effects of sunlight (as in albinism). Changes in preexisting skin pigmentation may signify important primary skin disorders (e.g., malignant transformation of a mole) or point to the existence of an underlying systemic disorder (e.g., Addison disease; see Chapter 24).

Freckle (Ephelis)

Freckles are the most common pigmented lesions of childhood in lightly pigmented individuals. It is unclear whether freckles result from a focal abnormality in pigment production in a discrete field of melanocytes, enhanced melanin transfer to adjacent basal keratinocytes, or some combination thereof. The *café au lait* spots seen in neurofibromatosis type 1 (Chapter 27) are similar to freckles histologically, but differ in that they are larger, arise independently of sun exposure, and contain aggregated melanosomes (macromelanosomes), which can be seen within the cytoplasm of melanocytes in electron micrographs.

MORPHOLOGY

Freckles are generally small (1 mm to several millimeters in diameter), tan-red or light brown macules that appear after sun exposure. Hyperpigmentation of freckles results from increased amounts of melanin pigment within basal keratinocytes. Associated melanocytes may be slightly enlarged but are normal in density.

Once present, freckles fade and darken in a cyclic fashion during winter and summer, respectively. This is not because of changes in the number of melanocytes, but in the degree of pigmentation.

Lentigo

The term *lentigo* (plural, lentigines) refers to a common benign localized hyperplasia of melanocytes. It occurs at all ages, but most commonly appears in infants and children. There is no sex or racial predilection, and the cause and pathogenesis are unknown.

MORPHOLOGY

Lentigines may involve mucous membranes as well as the skin and consist of small (5 to 10 mm across), oval, tan-brown macules or patches. The essential histologic feature is **linear (nonnested) melanocytic hyperplasia** restricted to the cell layer immediately above the basement membrane that produces a hyperpigmented basal cell layer. Unlike freckles, lentigines do not darken when exposed to sunlight.

Melanocytic Nevus (Pigmented Nevus, Mole)

Melanocytic nevi (known colloquially as moles) are common benign neoplasms caused in most cases by acquired activating mutations in components of the RAS signaling pathway. Most of us have at least a few "moles" and probably regard them as mundane and uninteresting. However, in truth, moles (or melanocytic nevi) are diverse, dynamic, and biologically fascinating neoplasms. There are numerous subtypes of melanocytic nevi that are distinguished based on their clinical and histologic features; Table 25.2 provides a summary of salient features of some commonly encountered forms. Acquired melanocytic nevi are the most common type and are found in virtually all individuals.

Pathogenesis

Proof that nevi are neoplasms comes from studies showing that many have acquired mutations that lead to constitutive activation of RAS or the serine/threonine kinase BRAF, which lies immediately downstream of RAS (described in Chapter 7 and later under Melanoma). Given that RAS signals have potent transforming activity and have key roles in many full-blown cancers, it is reasonable to ask why nevi only rarely give rise to melanomas. One answer appears to lie in the phenomenon referred to as oncogene-induced senescence. Expression of either activated RAS or BRAF in normal human melanocytes causes only a limited period of proliferation that is followed by a permanent growth arrest mediated by the accumulation of p16/INK4a, a potent inhibitor of several cyclin-dependent kinases, including CDK4 and CDK6 (Chapter 7). This protective response is disrupted in melanoma and some precursor lesions that give rise to melanoma.

MORPHOLOGY

Common acquired melanocytic nevi are tan to brown, uniformly pigmented, small (usually less than 6 mm across), relatively flat macules or elevated papules with well-defined, rounded borders (Figs. 25.2A and 25.3A). They may become more prominent during pregnancy, indicating a degree of hormone sensitivity. Melanocytic nevi are thought to progress through a series of morphologic changes over time. The earliest lesions are believed to be **junctional nevi,** which consist of aggregates or nests of round cells that grow along the dermoepidermal junction (Fig. 25.2B). Nuclei of nevus cells are uniform and rounded in contour, contain inconspicuous nucleoli, and show little or no mitotic activity. Eventually, most junctional nevi grow into the underlying dermis as nests or cords of cells to form **compound nevi** (Fig. 25.3B). In older lesions the epidermal nests may be lost entirely to form pure **intradermal nevi.** Compound and dermal nevi are often more elevated than junctional nevi.

Growth of nevus cells from the dermoepidermal junction into the underlying dermis is accompanied by morphologic changes that are taken to reflect oncogene-induced senescence (Fig. 25.4). Whereas superficial nevus cells are larger, tend to produce melanin, and grow in nests, deeper nevus cells are smaller, produce little or no pigment, and appear as cords and single cells. At the deepest extent of the lesions, these cells often acquire fusiform contours and grow in fascicles resembling neural tissue (**neurotization;** see Fig. 25.4E). This striking metamorphosis correlates with enzymatic changes (progressive loss of tyrosinase activity and acquisition of cholinesterase activity) in deeper, nonpigmented, "nerve-like" nevus cells. These changes are helpful in distinguishing benign nevi from melanomas, which lack such features.

Table 25.2 Representative Variant Forms of Melanocytic Nevi

Nevus Variant	Diagnostic Architectural Features	Cytologic Features	Clinical Significance
Congenital nevus	Deep dermal and sometimes subcutaneous growth around adnexa, neurovascular bundles, and blood vessel walls	Identical to ordinary acquired nevi	Present at birth; large variants have increased melanoma risk
Blue nevus	Non-nested dermal infiltration, often with associated fibrosis	Highly dendritic, heavily pigmented nevus cells	Black-blue nodule; often confused with melanoma clinically
Spindle and epithelioid cell nevus (Spitz nevus)	Fascicular growth	Large, plump cells with pink-blue cytoplasm; fusiform cells	Common in children; red-pink nodule; often confused with hemangioma clinically
Halo nevus	Lymphocytic infiltration surrounding nevus cells	Identical to ordinary acquired nevi	Host immune response against nevus cells and surrounding normal melanocytes
Dysplastic nevus	Coalescent intraepidermal nests	Cytologic atypia	Potential marker or precursor of melanoma

Although melanocytic nevi are common, their clinical and histologic diversity necessitates thorough knowledge of their appearance and natural history, lest they be confused with other skin conditions, most notably melanoma. The biologic importance of some nevi, however, resides in their possible transformation to melanoma or as markers of increased risk for melanoma (described next).

Dysplastic Nevi

Dysplastic nevi are important because they can be direct precursors of melanoma and when multiple in number are a marker of an increased risk for melanoma. The association of melanocytic nevi with melanoma was made almost 200 years ago, but a potential precursor of melanoma was not identified until 1978 when Clark and colleagues described lesions now referred to as dysplastic nevi. Several lines of evidence support the concept that some dysplastic nevi are precursors of melanoma. One of the most compelling involves studies of families affected by *dysplastic nevus syndrome* (also known as familial atypical mole and melanoma syndrome), an autosomal dominant disorder in which a tendency to develop multiple dysplastic nevi and melanoma are co-inherited. The probability that a person with dysplastic nevus syndrome will develop melanoma is over 50% by

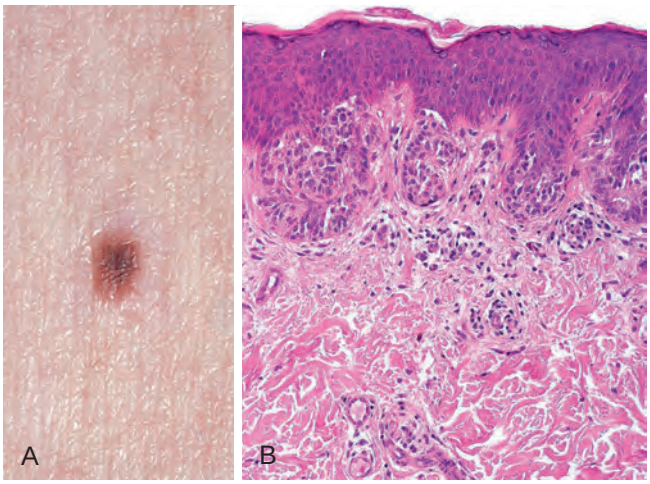

Figure 25.2 Melanocytic nevus, junctional type. (A) Grossly, lesions are small, relatively flat, symmetric, and uniform. (B) On histologic examination, junctional nevi are characterized by rounded nests of nevus cells originating at the tips of rete ridges along the dermoepidermal junction.

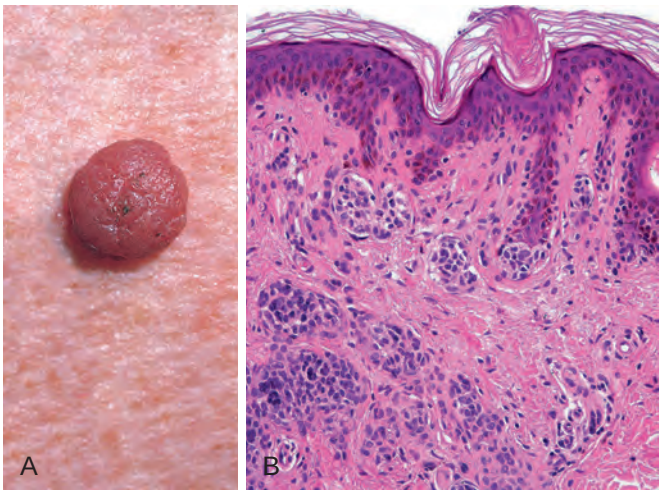

Figure 25.3 Melanocytic nevus, compound type. (A) In contrast to the junctional nevus, the compound nevus is raised and dome-shaped. The symmetry and uniform pigment distribution suggest a benign process. (B) Histologically, compound nevi combine the features of junctional nevi (intraepidermal nevus cell nests) with nests and cords of dermal nevus cells.

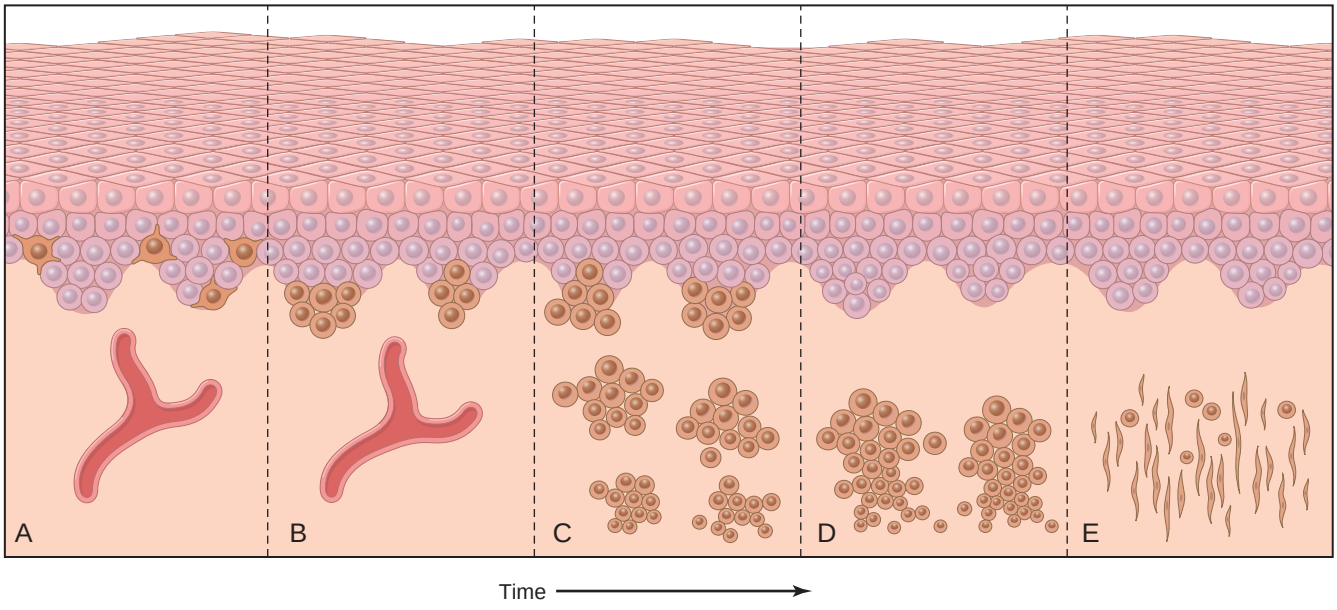

Figure 25.4 Maturation sequence of nondysplastic melanocytic nevi. (A) Normal skin shows only scattered dendritic melanocytes within the epidermal basal cell layer. (B) Junctional nevus. (C) Compound nevus. (D) Dermal nevus. (E) Dermal nevus with neurotization, a change that is also referred to as maturation. Nevi may exist at any stage in this sequence for variable periods of time, although many are believed to progress through this sequence.

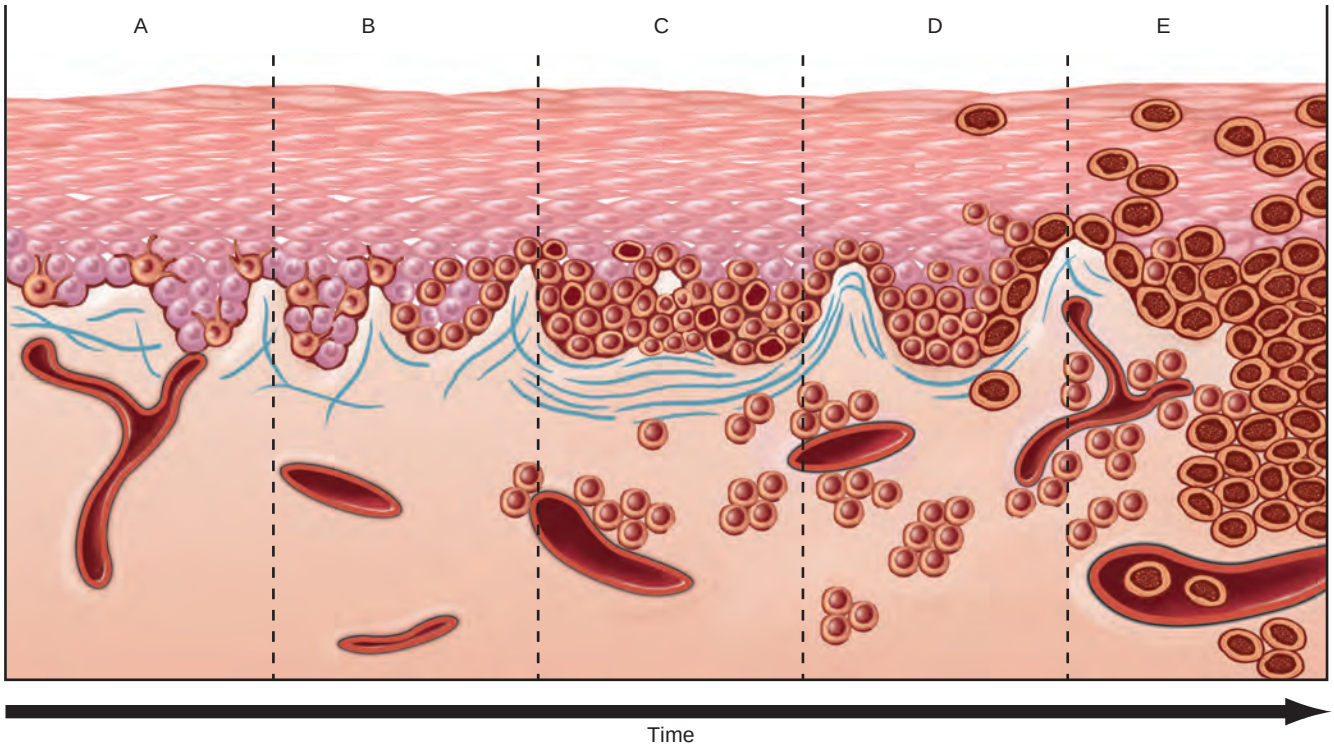

Figure 25.5 Potential steps of tumor progression in dysplastic nevi. (A) Lentiginous melanocytic hyperplasia. (B) Lentiginous junctional nevus. (C) Lentiginous compound nevus with abnormal architectural and cytologic features (dysplastic nevus). (D) Early melanoma, or melanoma in radial growth phase (large dark cells in epidermis). (E) Advanced melanoma (vertical growth phase) with malignant spread into the dermis and vessels. The risk of malignant transformation of any single dysplastic nevus is small, but appears to be higher than that of typical nevi.

age 60, and at-risk individuals sometimes develop melanomas at multiple sites. Even more directly, apparent transformation of dysplastic nevi to melanoma has been documented histologically.

Although dysplastic nevi can give rise to melanoma, the vast majority of such lesions are clinically stable and never progress. Conversely, not all melanomas in individuals with dysplastic nevus syndrome arise from dysplastic nevi, suggesting that these lesions are best viewed as indicators of increased melanoma risk. Dysplastic nevi may also occur as isolated lesions in otherwise normal individuals, in which case the risk of malignant transformation is very low.

Pathogenesis

Clark and associates first proposed morphologic stages in the development of dysplastic nevi and their eventual progression to melanoma (Fig. 25.5), and other workers have subsequently correlated these morphologic changes with the stepwise acquisition of oncogenic mutations and epigenetic changes. Like conventional nevi, dysplastic nevi also frequently have acquired activating mutations in the *NRAS* and *BRAF* genes. What then distinguishes dysplastic nevi from typical melanocytic nevi? An important clue comes from individuals with dysplastic nevus syndrome. Such individuals often have inherited loss-of-function mutations in *CDKN2A*. *CDKN2A* encodes several proteins including p16 (described in more detail under Melanoma), which you will recall is a negative regulator of cyclin-dependent kinase 4 (CDK4) and CDK6. Other affected families have mutations in the *CDK4* gene that make the CDK4 protein resistant to inhibition by p16. Thus, it appears that RAS or BRAF activation and increased CDK4 activity contribute to the development of dysplastic nevi. However, not all patients with germline mutations in *CDKN2A* or *CDK4* have dysplastic nevi, and not all familial dysplastic nevi are associated with mutations in these genes. As a result it is suspected that additional genes influence whether dysplastic nevi occur in a particular individual; the identities of these modifier genes as well as the other genes that are responsible for the syndrome are being sought.

MORPHOLOGY

Dysplastic nevi are larger than most acquired nevi (often greater than 5 mm across) and in individuals with the dysplastic nevus syndrome may number in the hundreds (Fig. 25.6A). They may appear as flat macules, slightly raised plaques with a "pebbly" surface, or target-like lesions with a darker raised center and irregular flat periphery. They can be recognized based on their large size, variability in pigmentation (variegation), and irregular borders. Most seem to be acquired rather than congenital. Unlike ordinary moles, dysplastic nevi occur on both sun-exposed and protected body surfaces.

Microscopically, dysplastic nevi usually involve both the epidermis and the dermis and exhibit architectural and cytologic atypia (Fig. 25.6A, B). **Nevus cell nests within the epidermis may be enlarged and often fuse or coalesce with adjacent nests.** As part of this process, single nevus cells begin to replace the normal basal cell layer along the dermoepidermal junction, producing **lentiginous hyperplasia.** Cytologic atypia takes the form of nuclear enlargement; irregular, often angulated, nuclear

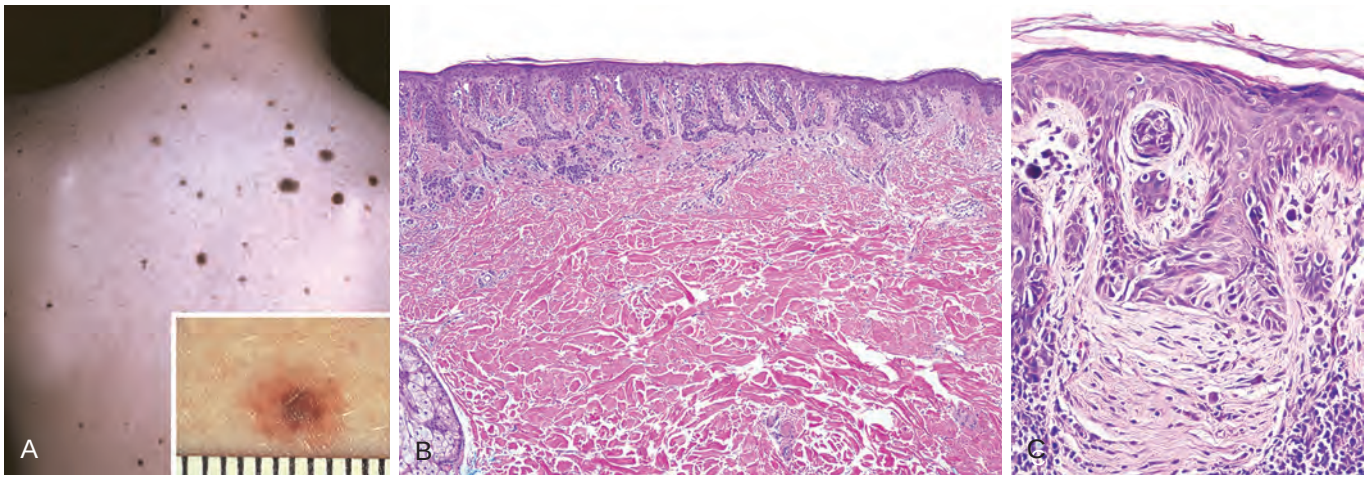

Figure 25.6 Dysplastic nevus. (A) Numerous atypical nevi on the back. (B) One such lesion (A, *inset*) has a compound nevus component *(left)* and an asymmetric junctional nevus component *(right)*. The former corresponds to the more pigmented and raised central zone, and the latter corresponds to the less pigmented, flat peripheral rim of the lesion shown in A. (C) An important feature is the presence of cytologic atypia (irregularly shaped, dark-staining nuclei). The dermis underlying the atypical cells characteristically shows linear, or lamellar, fibrosis.

contours; and hyperchromasia (Fig. 25.6C). Associated alterations in the superficial dermis include lymphocytic infiltrates (usually sparse); release of melanin from dead nevus cells into the dermis (melanin incontinence), where it is phagocytosed by dermal macrophages; and a peculiar **linear fibrosis** surrounding the epidermal rete ridges that are involved by the nevus. The diagnosis is based on this constellation of features, rather than any single finding.

Melanoma

Melanoma is the most deadly of all skin cancers and is strongly linked to acquired mutations caused by exposure to UV radiation in sunlight. Melanoma is a relatively common neoplasm that can be cured if it is detected and treated when it is in its earliest stages. The great preponderance of melanoma arises in the skin; other sites of origin include the oral and anogenital mucosal surfaces (i.e., oropharynx, gastrointestinal and genitourinary tracts), the esophagus, the meninges, and the uvea of the eye (Chapter 29). The following comments apply to cutaneous melanomas.

Today, as a result of increased public awareness of the signs of cutaneous melanoma, most are cured surgically. Nevertheless, the reported incidence of melanoma is increasing; more than 100,000 cases and more than 6800 deaths are expected in the United States in 2020. Notably, there has been a decrease in death rates over the past several years, which may reflect the effectiveness of immune checkpoint inhibitor therapy in this disease (Chapter 7).

Pathogenesis

In about 10% to 15% of affected patients, the risk of melanoma is inherited as an autosomal dominant trait with variable penetrance. As mentioned when discussing dysplastic nevi, some of these familial cases are associated with germline mutations affecting genes that regulate cell cycle progression, whereas others are associated with germline mutations affecting telomerase expression (described later). In the remaining patients, melanoma is sporadic and is strongly related to a single predisposing environmental factor: UV radiation exposure from sunlight. Because repair of UV radiation–induced DNA damage is imperfect, UV radiation leads to the accumulation of mutations in melanocytes over time. Sequencing of melanoma genomes has demonstrated a very high rate of point mutations that bear the signature of the damaging effects of UV radiation on DNA. In line with this molecular evidence, melanomas most commonly arise on sun-exposed surfaces, particularly the upper back in men and the back and legs in women, and lightly pigmented individuals are at higher risk than darkly pigmented individuals. Other inherited genetic variants linked to an increased risk of melanoma in fair-skinned populations act by diminishing melanin production in skin, thus increasing the amount of damage that sun exposure wreaks on melanocytes.

Nevertheless, the relationship between sun exposure and melanoma is not as straightforward as with other skin cancers, such as squamous cell carcinoma (discussed later). Some studies suggest that periodic severe sunburns early in life are the most important risk factor. Furthermore, since melanomas sometimes occur in dark-skinned individuals and at body sites that are not sun-exposed, sunlight is not always an essential predisposing factor, and other environmental factors may also contribute to risk.

The most frequent "driver" mutations in melanoma affect cell cycle control, pro-growth pathways, and telomerase. Some of the more common mutations are as follows:

- *Mutations that disrupt cell cycle control genes.* The *CDKN2A* gene is mutated in approximately 40% of pedigrees with autosomal dominant familial melanoma. *CDKN2A* is a complex locus that encodes three different tumor suppressors, p15, p16, and ARF. Of these, loss of p16 is clearly implicated in human melanoma, and experimental evidence also supports a role for loss of ARF. As already mentioned, p16 inhibits CDK4 and CDK6, thus reinforcing the ability of the RB tumor suppressor to block cells in the G_1 phase of the cell cycle. By contrast, ARF enhances the activity of the p53 tumor suppressor by inhibiting MDM2, an oncoprotein that stimulates p53 degradation.

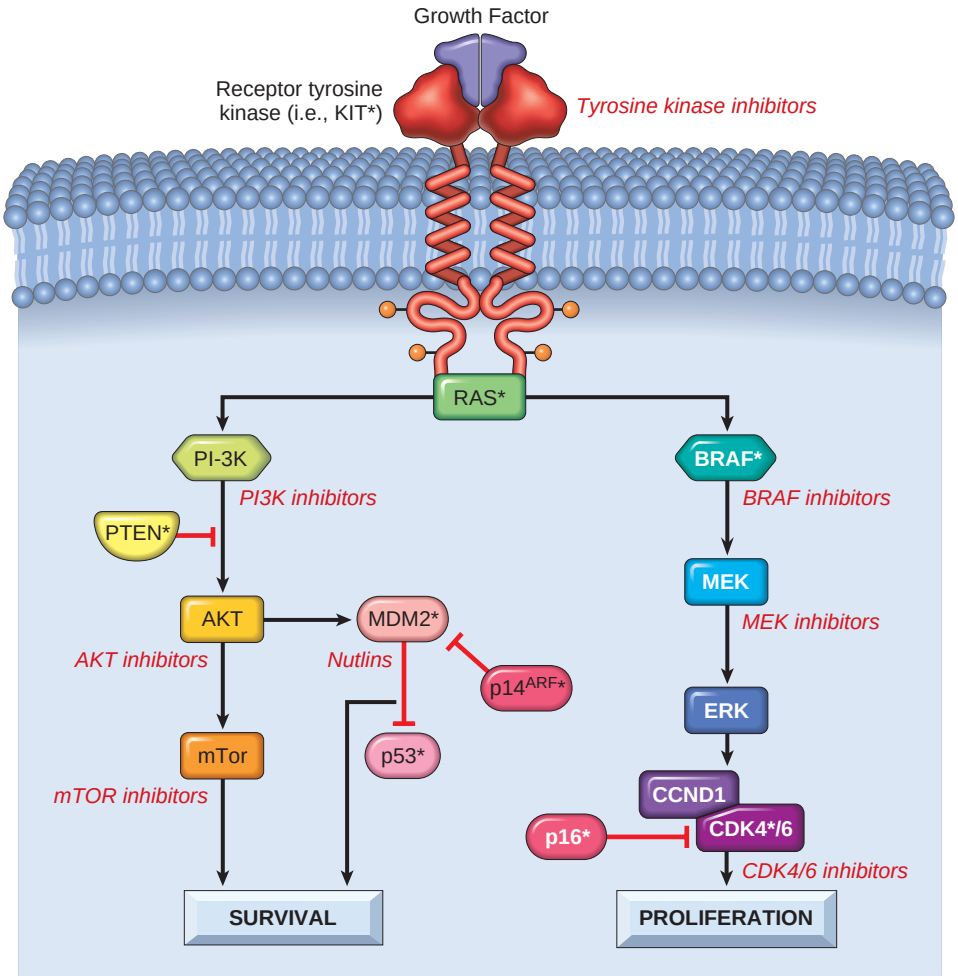

Figure 25.7 Pathways important in melanoma. Growth factors activate signaling circuits involving receptor tyrosine kinases (e.g., KIT), RAS, and two key downstream pathways that include the serine/threonine kinase BRAF and the phospholipid kinase PI3K. Proteins indicated by *asterisks* are mutated in melanoma. Components of these pathways that are being targeted by drugs are indicated.

CDKN2A is commonly mutated in sporadic melanomas, though other mechanisms controlling the G_1 checkpoint may also be involved. The net effect of all of these alterations is the same: increased melanocytic proliferation due to loss of cell cycle control and escape from oncogene-induced cellular senescence.

- *Mutations that activate pro-growth signaling pathways.* A second common group of molecular lesions in sporadic melanoma leads to aberrant increases in RAS and PI3K/AKT signaling (Fig. 25.7), which promote cell growth and survival (Chapter 7). Activating mutations in BRAF, a serine/threonine kinase that is downstream of RAS, are seen in 40% to 50% of melanomas, while activating mutations in RAS occur in an additional 15% to 20% of tumors. Melanomas with BRAF mutations also often show loss of the *PTEN* tumor suppressor gene, leading to heightened activation of the PI3K/AKT pathway. For reasons that are unclear, melanomas arising in non–sun-exposed cutaneous sites rarely have mutations in BRAF or RAS and are more likely to have activating mutations in the receptor tyrosine kinase KIT, which sits upstream of both RAS and PI3K/AKT. *PTEN* is also silenced in 20% of melanomas arising in non–sun-exposed sites. Other melanomas have loss-of-function mutations in the tumor-suppressor gene encoding neurofibromin 1 (*NF1*), a negative regulator of RAS, yet another mechanism of unleashing RAS signaling.
- *Mutations that activate telomerase.* Reactivation of telomerase, the enzyme activity that preserves telomeres and protects cells from senescence, has long been known to be important in cancer (Chapter 7). Sequencing of sporadic melanomas has identified mutations in the promoter of *TERT*, the gene that encodes the catalytic subunit of telomerase, in roughly 70% of tumors, making *TERT* the most commonly mutated gene yet identified in this cancer. Rare melanoma-prone families have also been identified that have germline *TERT* promoter mutations. As might be anticipated, the mutations increase *TERT* expression, suggesting that they act as an antidote to senescence.

MORPHOLOGY

Unlike benign nevi, melanomas show striking **variations in color,** appearing in shades of black, brown, red, dark blue, and gray (Fig. 25.8A). On occasion, zones of white or flesh-colored hypopigmentation also appear, sometimes due to focal regression of the tumor. **The borders of melanomas are irregular and**

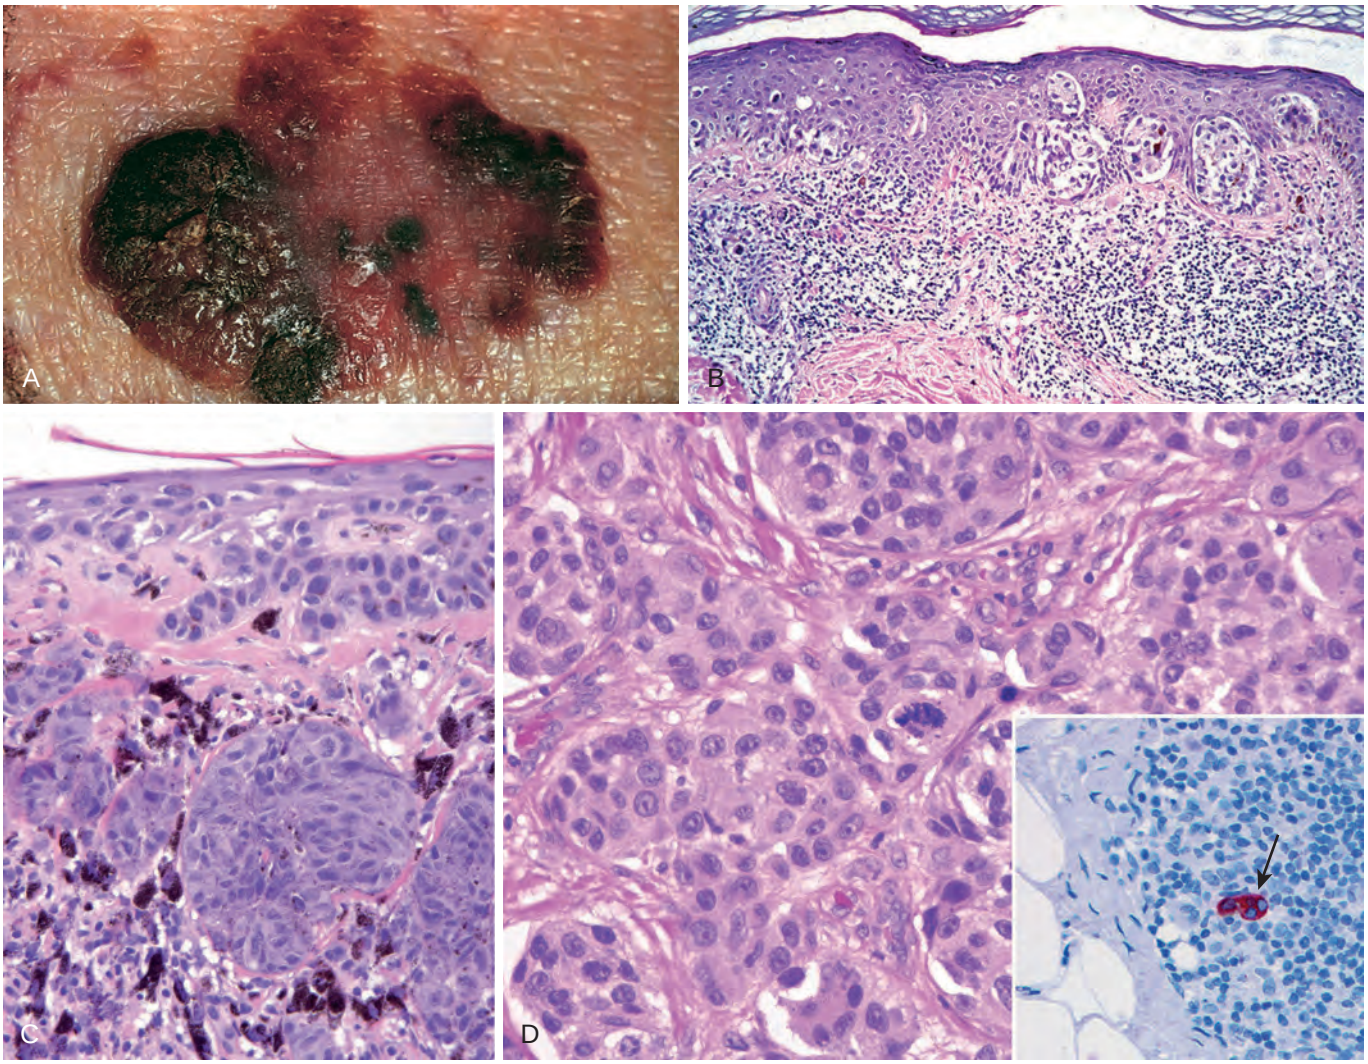

Figure 25.8 Melanoma. (A) Typical lesions are irregular in contour and pigmentation. Macular areas correlate with the radial growth phase, while raised areas correspond to nodular aggregates of malignant cells in vertical growth phase. (B) Radial growth phase showing irregular nested and single-cell growth of melanoma cells within the epidermis and an underlying inflammatory response within the dermis. (C) Vertical growth phase demonstrating nodular aggregates of infiltrating cells. (D) High-power view of melanoma cells. The *inset* shows a sentinel lymph node with a tiny cluster of melanoma cells *(arrow)* staining for the melanocytic marker HMB-45. Even small numbers of malignant cells in a draining lymph node may confer a worse prognosis.

often notched, unlike the smooth, round, and uniform borders of melanocytic nevi.

Central to understanding the progression of melanoma is the concept of radial and vertical growth phases. **Radial growth** describes the horizontal spread of melanoma within the epidermis and superficial dermis (Fig. 25.8B). During this initial stage the tumor cells seem to lack the capacity to metastasize. Tumors in radial growth phase fall into several clinicopathologic classes, including **lentigo maligna,** usually presenting as an indolent lesion on the face of older men that may remain in the radial growth phase for several decades; **superficial spreading,** the most common type of melanoma, usually involving sun-exposed skin; and **acral/mucosal lentiginous** melanoma, which is unrelated to sun exposure.

After a variable (and unpredictable) period of time, melanoma shifts from the radial phase to a **vertical growth phase,** during which the tumor cells invade downward into the deep dermis as an expansile mass (Fig. 25.8C). **The vertical growth phase is often heralded by the appearance of a nodule and correlates with the emergence of a tumor subclone with metastatic potential.** Unlike melanocytic nevi, maturation or "neurotization" is absent from the deep invasive portion of melanoma.

Individual melanoma cells are usually larger than normal melanocytes or cells found in melanocytic nevi. They have enlarged nuclei with irregular contours, chromatin that is characteristically clumped at the periphery of the nuclear membrane, and prominent red (eosinophilic) nucleoli (Fig. 25.8D). The appearance of the tumor cells is similar in the radial and vertical phases of growth. While most nevi and melanomas are easily distinguished based on their appearance, a small fraction of "atypical" lesions fall in a histologic gray zone and have been termed melanocytic tumors of uncertain malignant potential; such lesions require complete excision and close clinical follow-up.

Once a melanoma is excised, a number of pathologic features are used to gauge the probability of metastatic spread and prognosis. One model used to predict outcome is based in part on the following pathologic variables: (1) tumor depth of invasion

(Breslow thickness), (2) number of mitoses, (3) evidence of tumor regression (presumably due to the host immune response), (4) ulceration of overlying skin, (5) presence and number of tumor-infiltrating lymphocytes, and (6) location (central body or extremity). Determinants of a more favorable prognosis in this model include thinner tumor depth, no or few mitoses (<1/mm^2), a brisk tumor-infiltrating lymphocyte response, absence of regression, and lack of ulceration. Since most melanomas initially metastasize to regional lymph nodes, additional prognostic information may be obtained by performing a sentinel lymph node biopsy, as in breast cancer (Chapter 23). Microscopic involvement of a sentinel node by even a small number of melanoma cells (micrometastases, Fig. 25.8D, *inset*) confers a worse prognosis. The degree of involvement and the total number of lymph nodes involved correlate well with overall survival.

Clinical Features

The most important warning signs, sometimes called the ABCDEs of melanoma, are (1) asymmetry; (2) irregular borders; and (3) variegated color, (4) increasing diameter, and (5) evolution or change over time, especially if rapid. Because locally advanced melanomas often metastasize, early recognition and complete excision are critical. Melanoma of the skin is usually asymptomatic, although itching or pain may be early manifestations. The majority of lesions are greater than 10 mm in diameter at diagnosis. The most consistent clinical signs are changes in the color, size, or shape of a pigmented lesion.

Molecular insights into the pathogenesis of melanoma have led to success in treating this cancer with drugs that target the RAS and PI3K/AKT pathways (see Fig. 25.7). Such approaches are urgently needed, as metastatic melanoma is resistant to both conventional chemotherapy and radiation treatment. Ultimately, it is likely that these types of targeted therapies will be used in combinations tailored to fit the oncogenic molecular lesions found in individual tumors. This idea is based on the observation that a high fraction of tumors with BRAF mutations respond to BRAF inhibitors, whereas tumors belonging to other molecular subtypes do not.

Recognition that melanoma is inherently immunogenic has also resulted in successful development of therapeutic regimens using antibodies that inhibit immune checkpoint proteins, such as CTLA4 and PD1. Melanoma is one of the most responsive cancers to these checkpoint inhibitors, which take the brakes off an immune system that is poised to respond to tumor neoantigens (Chapter 7). Current efforts are focused at maximizing tumor response to checkpoint inhibitors without undue toxicity, which stems from autoimmune attack on normal host tissues.

KEY CONCEPTS

MELANOCYTIC LESIONS, BENIGN AND MALIGNANT

- Most melanocytic nevi have activating mutations in *BRAF*, or less often *RAS*, but the vast majority never undergo malignant transformation.
- Most sporadic dysplastic nevi are best regarded as markers of melanoma risk rather than premalignant lesions.
- Melanoma is a highly aggressive malignancy linked to sun exposure; risk of spread is predicted by several tumor characteristics, particularly the vertical thickness of excised tumors.
- Melanoma often incites a host immune response and often shows dramatic responses to immune checkpoint therapies that enhance T-cell immunity.

BENIGN EPITHELIAL TUMORS

Benign cutaneous epithelial neoplasms are common tumors that are derived from the keratinizing stratified squamous epithelium of the epidermis and hair follicles and the ductular epithelium of cutaneous glands. They often recapitulate the structures from which they arise. Their appearance sometimes raises a concern of malignancy, particularly when they are pigmented or inflamed, and biopsy is frequently required to establish a definitive diagnosis. In very rare instances they are a telltale sign of syndromes associated with potentially life-threatening visceral malignancies, such as multiple trichilemmomas in *Cowden syndrome* or multiple sebaceous neoplasms in *Muir-Torre syndrome.* Diagnosis of epithelial tumors in these instances can facilitate recognition of the underlying syndrome and implementation of appropriate clinical interventions.

Seborrheic Keratosis

These common epidermal tumors occur most frequently in middle-aged or older individuals. They arise spontaneously and are particularly numerous on the trunk, although the extremities, head, and neck may also be involved. In people of color, multiple small seborrheic keratoses on the face are termed *dermatosis papulosa nigra,* a condition that is present in up to 35% of African-American adults.

Pathogenesis

Activating mutations in fibroblast growth factor receptor-3 (FGFR3), a receptor tyrosine kinase, are found in many sporadic seborrheic keratoses and are thought to drive the growth of the tumor. Seborrheic keratoses may suddenly appear in large numbers as part of a paraneoplastic syndrome *(Leser-Trélat sign),* possibly due to stimulation of keratinocytes by transforming growth factor-α (TGF-α) produced by tumor cells, most commonly carcinomas of the gastrointestinal tract.

MORPHOLOGY

Seborrheic keratosis characteristically appears as round, flat, coin-like, waxy plaque that varies in diameter from millimeters to several centimeters (Fig. 25.9, *inset*). It is uniformly tan to dark brown and usually has a velvety to granular surface. Inspection with a hand lens typically reveals small, round, pore-like ostia impacted with keratin, a feature helpful in differentiating these pigmented lesions from melanoma.

On histologic examination, these neoplasms are exophytic and sharply demarcated from the adjacent epidermis. They are composed of sheets of small cells that closely resemble basal

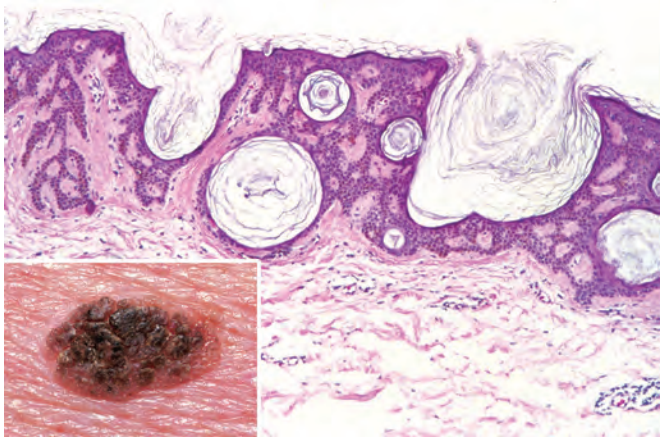

Figure 25.9 Seborrheic keratosis. A well-demarcated coin-like pigmented lesion containing dark keratin-filled surface plugs *(inset)* is composed of benign basaloid cells associated with prominent keratin-filled "horn" cysts, some of which communicate with the surface (pseudohorn cysts).

cells of the normal epidermis (Fig. 25.9). Variable melanin pigmentation is present within these basaloid cells, accounting for the brown coloration. Exuberant keratin production (hyperkeratosis) occurs at the surface, and small keratin-filled cysts (horn cysts) and invaginations of keratin into the main mass (invagination cysts) are characteristic features. If irritated and inflamed, seborrheic keratoses develop whirling foci of squamous differentiation resembling eddy currents in a stream.

Acanthosis Nigricans

Acanthosis nigricans can be an important cutaneous sign of several underlying benign and malignant conditions. It is a condition marked by thickened, hyperpigmented skin with a velvet-like texture that most commonly appears in the flexural areas (axillae, skin folds of the neck, groin, and anogenital regions). It is divided into two types based on the underlying condition.

- *In at least 80% of cases, acanthosis nigricans is associated with benign conditions and develops gradually,* usually during childhood or puberty. It may occur (1) as an autosomal dominant trait with variable penetrance, (2) in association with obesity or endocrine abnormalities (particularly with pituitary or pineal tumors, or with diabetes), and (3) as part of several rare congenital syndromes. The most common associations are with obesity and diabetes.
- *In the remaining cases, acanthosis nigricans arises in association with cancers,* most commonly gastrointestinal adenocarcinoma, usually in middle-aged and older individuals. In this setting, acanthosis nigricans is best viewed as a paraneoplastic phenomenon that is likely caused by growth factors released from tumors.

Pathogenesis

The unifying feature in all types of acanthosis nigricans is a disturbance that leads to increased growth factor receptor signaling in the skin. The familial form is associated with germline activating mutations in the receptor tyrosine kinase FGFR3, the same receptor that is frequently mutated in seborrheic keratosis. Depending on the mutation, acanthosis may be an isolated finding or be seen together with skeletal deformities, including achondroplasia and thanatophoric dysplasia. Why in some cases FGFR3 mutation gives rise to seborrheic keratosis and in others acanthosis nigricans is not clear. In those with type 2 diabetes, hyperinsulinemia is believed to provoke increased stimulation of insulin-like growth factor receptor-1 (IGFR1), another receptor tyrosine kinase that activates the same signaling pathways as FGFR3. Factors responsible for paraneoplastic acanthosis nigricans are uncertain; some cases have been linked to high levels of TGF-α, which may result in excessive activation of epidermal growth factor receptor (EGFR), yet another receptor tyrosine kinase, in the skin.

MORPHOLOGY

All forms of acanthosis nigricans have similar histologic features. The epidermis and underlying enlarged dermal papillae undulate sharply to form numerous repeating peaks and valleys. Variable hyperplasia may be seen, along with hyperkeratosis and slight basal cell layer hyperpigmentation (but no melanocytic hyperplasia).

Fibroepithelial Polyp

The fibroepithelial polyp has many names (acrochordon, squamous papilloma, skin tag) and is one of the most common cutaneous lesions. It usually comes to attention in middle-aged and older individuals on the neck, trunk, face, and intertriginous areas. Rarely, fibroepithelial polyps and tumors of perifollicular mesenchyme (specialized fibroblasts associated with the hair bulb) are seen together in *Birt-Hogg-Dubé syndrome,* but the vast majority of polyps are sporadic.

MORPHOLOGY

Fibroepithelial polyps are soft, flesh-colored, bag-like tumors that are often attached to the surrounding skin by a slender stalk. On histologic examination, they consist of fibrovascular cores covered by benign squamous epithelium. It is not uncommon for the polyps to undergo ischemic necrosis due to torsion, which may cause pain and precipitate their removal.

Fibroepithelial polyps are usually inconsequential, but can occasionally be associated with diabetes, obesity, and intestinal polyposis. Of interest, like melanocytic nevi and hemangiomas, they often become more numerous or prominent during pregnancy, presumably related to hormonal stimulation.

Epithelial or Follicular Inclusion Cyst (Wen)

Epithelial cysts are common lesions formed by the invagination and cystic expansion of the epidermis or, perhaps more commonly, a hair follicle. The lay term, *wen,* derives from the Anglo-Saxon *wenn,* meaning a lump or tumor. When large, they may be subject to traumatic rupture, which can spill keratin into the dermis and lead to an extensive and often painful granulomatous inflammatory response.

ADNEXAL (APPENDAGE) TUMORS

There are literally hundreds of neoplasms arising from or showing differentiation toward cutaneous appendages. Their significance varies according to type and clinical context, as follows:

- *Some are benign* but may be confused with cutaneous cancers such as basal cell carcinoma.
- *Other appendage tumors are associated with germline mutations in tumor suppressor genes.* In some such instances, the disorder presents with multiple adnexal tumors that may be disfiguring. In other cases, the appendage tumors are relatively trivial but warn of a predisposition for internal malignancy; such is the relationship between multiple *trichilemmomas* and *Cowden syndrome,* a disorder caused by germline mutations in the tumor suppressor gene *PTEN* that is associated with an increased risk of endometrial cancer, breast cancer, and other malignancies.

Appendage tumors often appear as nondescript, flesh-colored solitary or multiple papules and nodules. Some have a predisposition to occur on specific body surfaces. Selected examples are provided here to illustrate neoplasms of hair follicles and sebaceous, eccrine, and apocrine glands.

- *Eccrine poroma* occurs predominantly on the palms and soles where sweat glands are numerous.
- *Cylindroma,* an appendage tumor with ductal (apocrine or eccrine) differentiation, usually occurs on the forehead and scalp (Fig. 25.10A), where coalescence of nodules with time may produce a hat-like growth—hence the name *turban tumor.* These lesions can be dominantly inherited; in such cases they appear early in life and are associated with inactivating mutations in the tumor suppressor gene *CYLD,* which encodes a deubiquitinating enzyme that negatively regulates the oncogenic transcription factor NF-κB and other factors that contribute to cell cycle progression. In addition to familial cylindromatosis, germline mutations in *CYLD* are associated with two other genetic syndromes marked by the occurrence of multiple adnexal tumors, multiple *familial trichoepithelioma* (a follicular tumor) and *Brooke-Spiegler syndrome* (associated with both trichoepithelioma and cylindroma).
- *Syringoma,* a lesion with eccrine differentiation, usually occurs as multiple, small, tan papules in the vicinity of the lower eyelids.
- *Sebaceous adenoma* can be associated with internal malignancy in *Muir-Torre syndrome* and also is associated in a subset of cases with hereditary nonpolyposis colorectal carcinoma syndrome (also known as *Lynch syndrome;* see Chapter 17), which is caused by germline defects in DNA mismatch repair genes.
- *Pilomatricoma,* showing hair follicle differentiation, is associated with activating mutations in *CTNNB1,* the gene encoding β-catenin. Mutations in this gene are seen in numerous neoplasms but are of interest here since Wnt signaling through β-catenin is critical for early hair development and regulates hair growth and maintenance.
- *Adnexal tumors can also show apocrine differentiation;* these usually arise in body areas where apocrine glands are most prevalent such as the axilla and scalp.

MORPHOLOGY

The **cylindroma** is composed of islands of cells resembling the normal epidermal or adnexal basal cell layer (basaloid cells). These islands fit together like pieces of a jigsaw puzzle within a fibrous

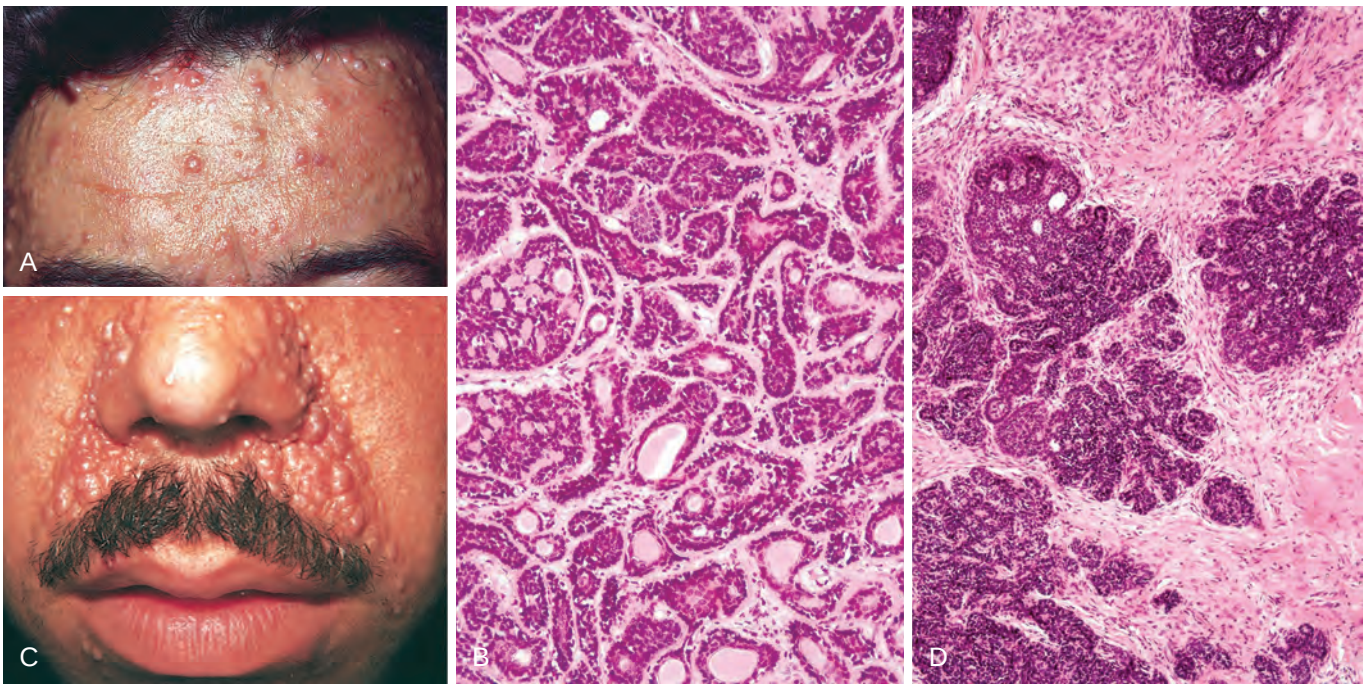

Figure 25.10 Cylindroma and trichoepithelioma. (A, B) Multiple cylindromas (papules) on the forehead (A) are composed of islands of basaloid cells (B) containing occasional ducts that fit together like pieces of a jigsaw puzzle. (C, D) Perinasal papules and small nodules of trichoepithelioma (C) are composed of buds of basaloid cells (D) that resemble primitive hair follicles.

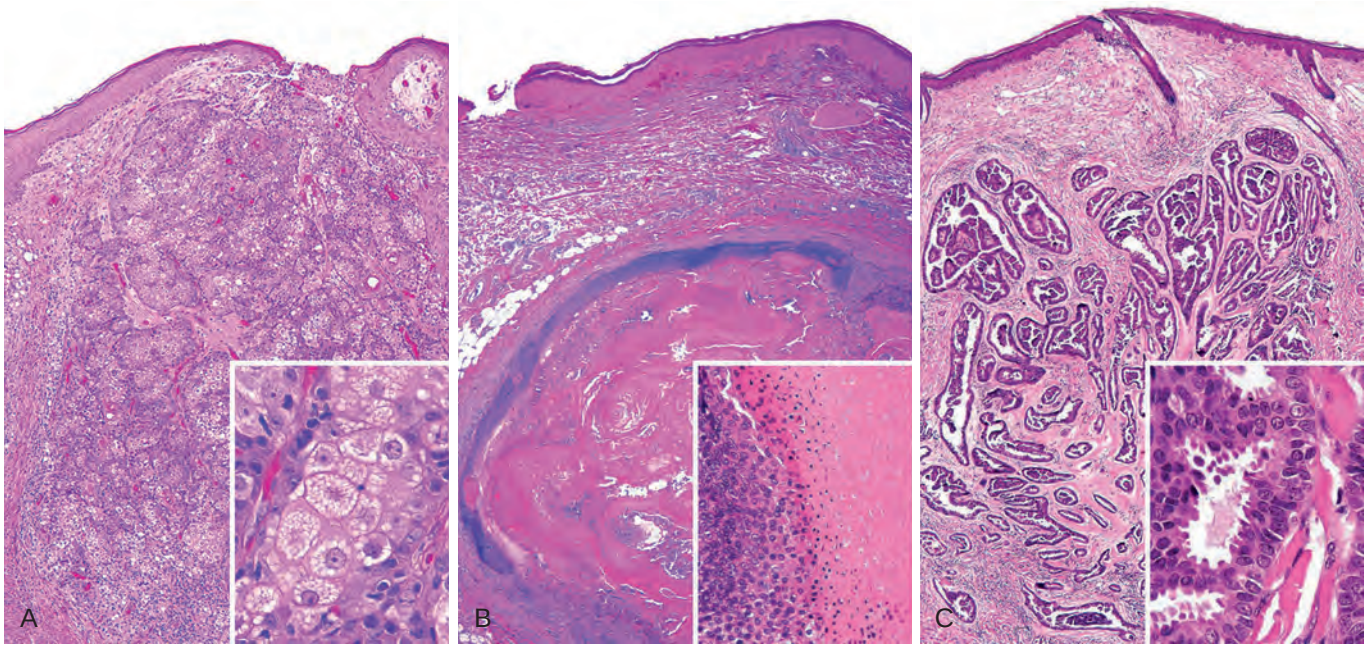

Figure 25.11 Diverse adnexal tumors. (A) Sebaceous adenoma; *inset* demonstrates sebaceous differentiation. (B) Pilomatrixoma; *inset* shows hair matrix differentiation to anucleate "ghost cells." (C) Apocrine carcinoma (well differentiated); *inset* shows apocrine differentiation and luminal secretions produced by decapitation of the lining cells.

dermal matrix (Fig. 25.10B). **Trichoepithelioma** is a proliferation of basaloid cells that forms primitive structures resembling hair follicles (Fig. 25.10C, D). **Sebaceous adenoma** shows a lobular proliferation of sebocytes with increased peripheral basaloid cells and more mature sebocytes in the central portion that have frothy or bubbly cytoplasm due to the presence of lipid vesicles (Fig. 25.11A). **Pilomatrixomas** are composed of basaloid cells that show trichilemmal or hair-like differentiation similar to that seen in the germinal portion of the normal hair bulb in the anagen growth phase (Fig. 25.11B). **Apocrine carcinoma** shows ductal differentiation with prominent decapitation secretion similar to that seen in the normal apocrine gland (Fig. 25.11C). The infiltrative growth pattern is a hint of malignancy in this otherwise well-differentiated tumor.

Although most appendage tumors are benign, malignant variants exist. Apocrine tumors are unusual in that malignant forms appear to be more common than benign forms. *Sebaceous carcinoma* arises from the meibomian glands of the eyelid and may follow an aggressive course replete with systemic metastases. *Eccrine* and *apocrine carcinomas* can be confused with metastatic adenocarcinoma because of their tendency to form gland-like structures.

PREMALIGNANT AND MALIGNANT EPIDERMAL TUMORS

Actinic Keratosis

Actinic keratosis (as the name implies) usually occurs in sun-damaged skin and exhibits hyperkeratosis. As expected, these tumors have a particularly high incidence in lightly pigmented individuals. Exposure to ionizing radiation, industrial hydrocarbons, and arsenicals may induce similar lesions. These lesions may show progressively worsening dysplastic changes that culminate in cutaneous squamous cell carcinoma and are analogous in this regard to the precursor lesions that give rise to squamous carcinomas of the uterine cervix (Chapter 22).

MORPHOLOGY

Actinic keratoses are usually less than 1 cm in diameter. They are typically tan-brown, red, or skin-colored and have a rough, sandpaper-like consistency. Some lesions produce so much keratin that a "cutaneous horn" develops (Fig. 25.12A), which in extreme cases may become so prominent that they resemble the actual horns of animals! Sun-exposed sites (face, arms, dorsum of hands) are most frequently affected. The lips may also develop similar lesions (termed **actinic cheilitis**).

Cytologic atypia is seen in the lowermost layers of the epidermis and may be associated with hyperplasia of basal cells (Fig. 25.12B) or, alternatively, with atrophy that results in thinning of the epidermis. The atypical basal cells usually have pink or reddish cytoplasm due to dyskeratosis. Intercellular bridges are present, in contrast to basal cell carcinoma, in which they are not visible. The superficial dermis contains thickened, blue-gray elastic fibers **(elastosis),** a probable result of abnormal elastic fiber synthesis by sun-damaged fibroblasts. The stratum corneum is thickened, and, unlike normal skin, the cells in this layer often retain their nuclei **(parakeratosis).**

Actinic keratoses may regress or remain stable throughout life, but enough transform to malignancy that local eradication is warranted. This can be accomplished by gentle curettage,

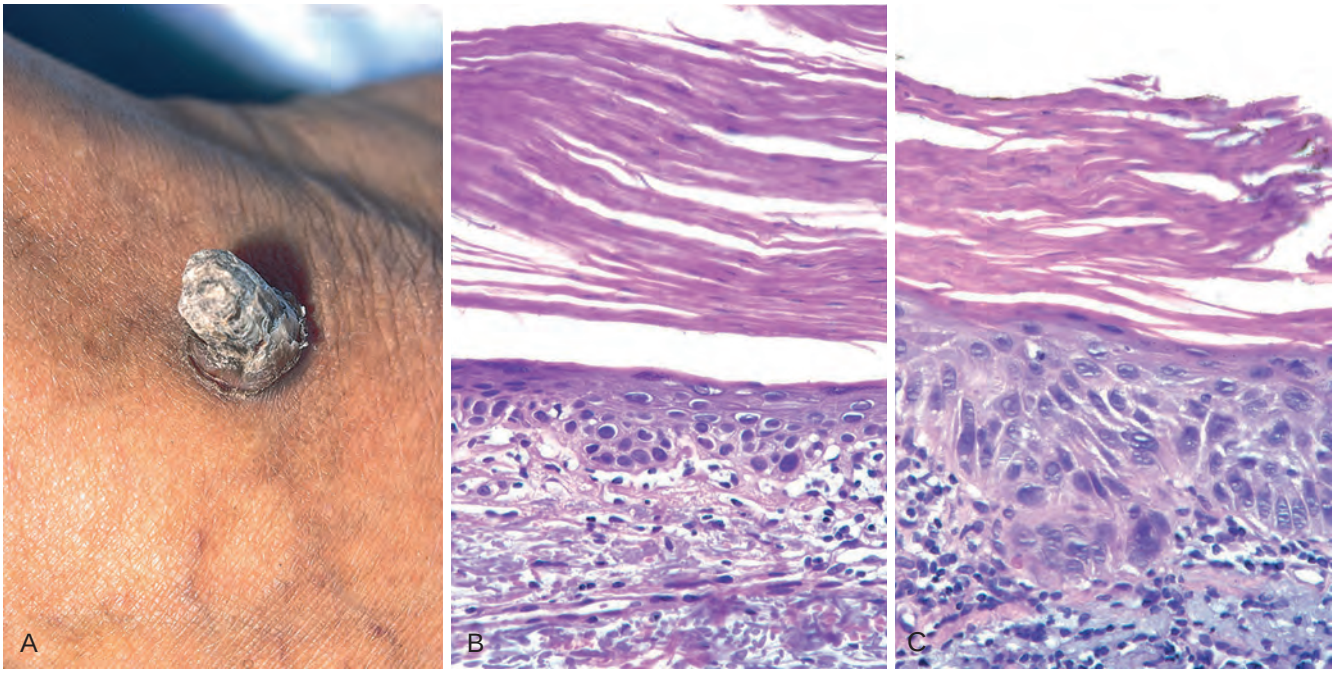

Figure 25.12 Actinic keratosis. (A) Excessive keratotic scale in this lesion has produced a "cutaneous horn." (B) Basal cell layer atypia (dysplasia) is associated with marked hyperkeratosis and parakeratosis. (C) Progression to full-thickness nuclear atypia, with or without the presence of superficial epidermal maturation, heralds the development of squamous cell carcinoma in situ.

freezing, or topical application of chemotherapeutic agents. Of interest, topical administration of imiquimod, a drug that activates Toll-like receptors (TLRs), eradicates up to 50% of lesions, a rate considerably higher than the spontaneous regression rate of approximately 5%. By stimulating TLR signaling, imiquimod activates cutaneous innate immune cells, which may recognize and eradicate precancerous lesions.

Squamous Cell Carcinoma

Squamous cell carcinoma is the second most common tumor arising on sun-exposed sites in older people, exceeded only by basal cell carcinoma. Except for lesions on the lower legs, these tumors have a higher incidence in men than in women. Invasive squamous cell carcinomas are usually discovered while they are small and resectable. Less than 5% of these tumors metastasize to regional nodes; these lesions are generally deeply invasive and involve the subcutis.

Pathogenesis

The most important cause of cutaneous squamous cell carcinoma is DNA damage induced by exposure to UV light. Tumor incidence is proportional to the degree of lifetime sun exposure. A second common association is with immunosuppression, most notably chronic immunosuppression as a result of chemotherapy or organ transplantation. Immunosuppression may contribute to carcinogenesis by reducing host surveillance and increasing the susceptibility of keratinocytes to infection and transformation by viruses, particularly human papillomavirus (HPV) subtypes 5 and 8. These same HPVs have been implicated in tumors arising in patients with the rare autosomal recessive condition *epidermodysplasia verruciformis,* which is marked by a high susceptibility to cutaneous squamous cell carcinomas. In addition to its damaging effect on DNA, sunlight, through uncertain mechanisms, seems to cause a transient defect in cutaneous innate immunity that may diminish immune-mediated elimination of sun-damaged cells. Other risk factors for squamous cell carcinoma include industrial carcinogens (tars and oils), chronic ulcers and draining osteomyelitis, old burn scars, ingestion of arsenicals, ionizing radiation, and (in the oral cavity) tobacco and betel nut chewing.

Most studies on the genetics of squamous cell carcinoma have focused on acquired defects in sporadic tumors and their precursors (actinic keratoses) and the relationships between these defects and sun exposure. The incidence of *TP53* mutations in actinic keratoses found in Caucasians is high, suggesting that p53 dysfunction is an early event in the development of tumors induced by sunlight. Normally, DNA damaged by UV light is sensed by checkpoint kinases such as ATM and ATR, which send out signals that upregulate the expression and stability of p53. p53 in turn arrests cells in the G_1 phase of the cell cycle and promotes either "high-fidelity" DNA repair or the elimination of cells that are damaged beyond repair (Chapter 7). When these protective functions of p53 are lost, DNA damage induced by UV light is more likely to be "repaired" by error-prone mechanisms, creating mutations that are passed down to daughter cells. Of note, the mutations that are seen in *TP53* often occur at pyrimidine dimers, indicating that they, too, stem from damage caused by UV light. A similar story underlies the remarkable susceptibility of patients with *xeroderma pigmentosum* to squamous cell carcinoma. This disorder is caused by inherited mutations in genes in the nucleotide excision repair pathway, which is required for accurate repair of pyrimidine dimers; when this pathway is defective,

error-prone repair pathways take over, leading to the rapid accumulation of mutations and eventual carcinogenesis.

As with all other forms of cancer, cutaneous squamous cell carcinoma stems from multiple driver mutations. In addition to defects in p53, mutations that increase RAS signaling and decrease Notch signaling are common and also contribute to the transformation process.

MORPHOLOGY

Squamous cell carcinomas that have not invaded through the basement membrane of the dermoepidermal junction (termed in situ carcinoma) appear as sharply defined, red, scaling plaques. More advanced, invasive lesions are nodular, show variable keratin production (appreciated grossly as hyperkeratotic scale), and may ulcerate (Fig. 25.13A).

Unlike actinic keratoses, in squamous cell carcinoma in situ, cells with atypical (enlarged and hyperchromatic) nuclei involve all levels of the epidermis (Fig. 25.12C). Invasive squamous cell carcinoma (Fig. 25.13B, C) shows variable degrees of differentiation, ranging from tumors composed of polygonal cells arranged in orderly lobules and having numerous large areas of keratinization to neoplasms consisting of highly anaplastic cells that exhibit only abortive, single-cell keratinization (dyskeratosis). The latter tumors may be so poorly differentiated that immunohistochemical stains for keratins are needed to confirm the diagnosis.

Basal Cell Carcinoma

Basal cell carcinoma is a distinctive locally aggressive cutaneous tumor that is associated with mutations that activate the Hedgehog signaling pathway. Basal cell carcinoma is the most common invasive cancer in humans, numbering nearly 1 million cases per year in the United States. These are slow-growing tumors that rarely metastasize. The vast majority are recognized at an early stage and cured by local excision. However, a small number of tumors (<0.5%) are locally aggressive and potentially disfiguring, and on rare occasions metastasis to distant sites is seen. Basal cell carcinoma occurs at sun-exposed sites in lightly pigmented elderly adults. As with squamous cell carcinoma, the incidence of basal cell carcinoma is increased in the setting of immunosuppression and in disorders of DNA repair, such as *xeroderma pigmentosum* (Chapter 7).

Pathogenesis

Most basal cell carcinomas have mutations that lead to unbridled Hedgehog signaling. As is often the case in biology and medicine, study of a rare genetic syndrome associated with a high risk of a common disease (basal cell carcinoma) has led to the elucidation of pathogenic mechanisms of general importance. The syndrome in question, *nevoid basal cell carcinoma syndrome* (NBCCS) (also known as basal cell nevus or *Gorlin syndrome*), is an autosomal dominant disorder characterized by the development of multiple basal cell carcinomas, often before age 20, accompanied by various other tumors (especially medulloblastomas and ovarian fibromas), odontogenic keratocysts, pits of the palms and soles, and certain developmental abnormalities. NBCCS is one of a number of cancer syndromes associated with skin manifestations (Table 25.3). The gene associated with NBCCS is *PTCH,* a tumor suppressor gene that is the human homologue of the *Drosophila* developmental gene *patched*. Individuals with NBCCS are born with a germline loss-of-function mutation in one *PTCH* allele; the second normal allele is inactivated in tumors by an acquired

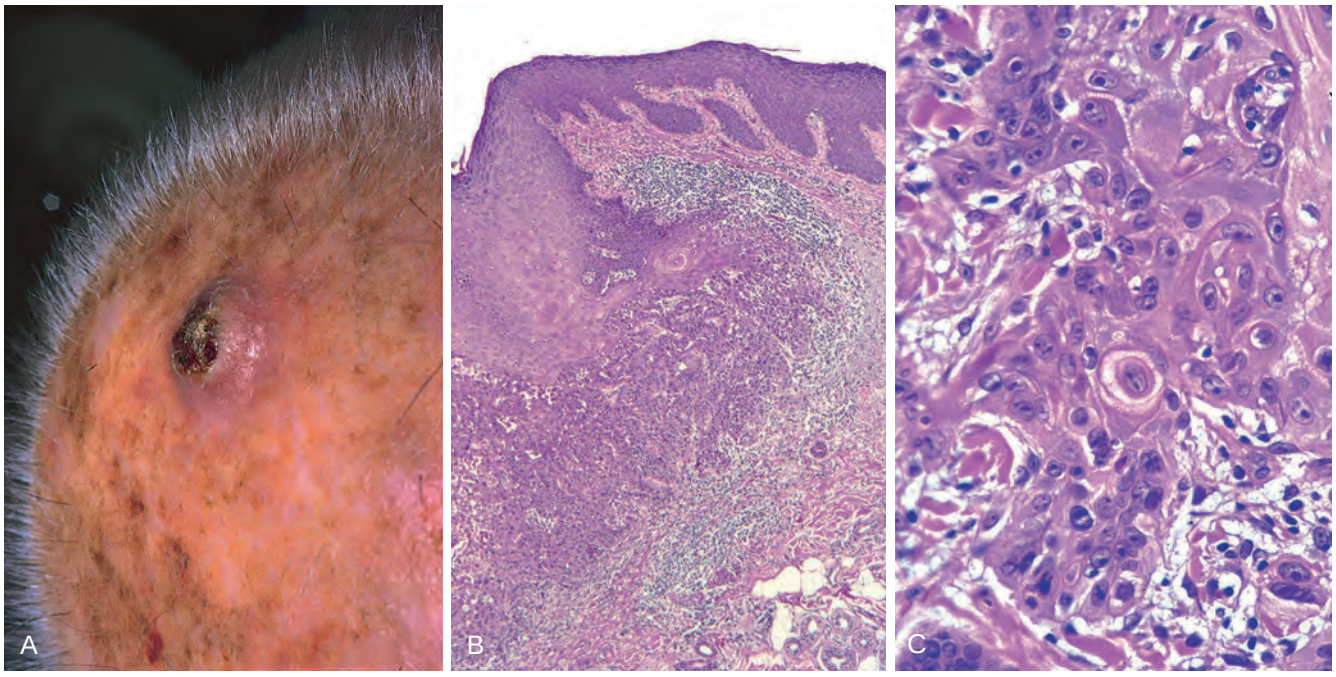

Figure 25.13 Invasive squamous cell carcinoma. (A) Lesions are often nodular and ulcerated, as seen in this scalp tumor. (B) Tongues of atypical squamous epithelium have transgressed the basement membrane and invaded deeply into the dermis. (C) Invasive tumor cells show enlarged nuclei with angulated contours and prominent nucleoli.

Table 25.3 Survey of Familial Cancer Syndromes With Cutaneous Manifestations

Disease	Inheritance	Chromosomal Location	Gene/Protein	Normal Function/Manifestation of Loss
Ataxia-telangiectasia	AR	11q22.3	*ATM*/ATM	DNA repair after radiation injury/neurologic and vascular lesions
Nevoid basal cell carcinoma syndrome	AD	9q22	*PTCH*/PTCH	Developmental patterning gene/multiple basal cell carcinomas; medulloblastoma; jaw cysts
Cowden syndrome	AD	10q23	*PTEN*/PTEN	Lipid phosphatase/benign follicular appendage tumors (trichilemmomas); internal adenocarcinoma (often breast or endometrial)
Familial atypical mole and melanoma syndrome	AD	9p21	*CDKN2A*/p16, INK4 *CDKN2A*/p14, ARF	Inhibits CDK4/6 phosphorylation of RB, promoting cell cycle arrest/melanoma; pancreatic carcinoma Binds MDM2, promoting p53 function/melanoma; pancreatic carcinoma
Muir-Torre syndrome	AD	2p22 3p21	*MSH2*/MSH2 *MLH1*/MLH1	Involved in DNA mismatch repair/sebaceous neoplasia; internal malignancy (colon and others)
Neurofibromatosis 1	AD	17q11	*NF1*/neurofibromin	Negatively regulates RAS signaling/neurofibromas
Neurofibromatosis 2	AD	22q12	*NF2*/merlin	Integrates cytoskeletal signaling/neurofibromas; acoustic neuromas
Tuberous sclerosis	AD	9q34 16p13	*TSC1*/hamartin *TSC2*/tuberin	Work together in a complex that negatively regulates mTOR/angiofibromas; intellectual disability
Xeroderma pigmentosum	AR	9q22 and others	*XPA*/XPA and others	Nucleotide excision repair/melanoma; nonmelanoma skin cancers

AD, Autosomal dominant; *AR*, autosomal recessive.

From Tsai KY, Tsao H: The genetics of skin cancer, *Am J Med Genet C Semin Med Genet* 131C:82, 2004.

mutation, usually caused by exposure to mutagens (particularly UV light).

PTCH protein is a receptor for *sonic hedgehog* (SHH), a component of the Hedgehog signaling pathway, which controls polarity and CNS development during embryogenesis and also regulates hair follicle formation and hair growth. In the "off" state, PTCH exists in a complex with another transmembrane protein called SMO (for "smoothened"). Binding of SHH to PTCH releases SMO, which in turn activates the transcription factor GLI1 (Fig. 25.14), thus turning on the expression of genes that support tumor cell growth and survival. Mice engineered to have excessive GLI1 activation are prone to develop skin tumors resembling basal cell carcinomas. Similarly, in NBCCS the loss of PTCH function causes constitutive activation of SMO and GLI1, leading to the development of basal cell carcinoma.

Mutations that activate Hedgehog signaling are also prevalent in sporadic basal cell carcinomas. Loss-of-function *PTCH* mutations are common, and about one-third of these mutations consist of C→T transitions that are hallmarks of UV damage. This insight has paved the way for the development and clinical implementation of small molecule inhibitors of the Hedgehog pathway.

MORPHOLOGY

Basal cell carcinomas usually present as **pearly papules** containing prominent dilated subepidermal blood vessels **(telangiectasias)** (Fig. 25.15A). Some tumors contain melanin and superficially resemble melanocytic nevi or melanomas. Advanced lesions may ulcerate, and extensive local invasion of bone or facial sinuses may occur after many years of neglect or in unusually aggressive tumors, explaining the archaic designation **rodent ulcers.** One common and important variant, the superficial basal cell carcinoma, presents as an erythematous, occasionally pigmented plaque that may resemble early forms of melanoma.

Histologically, the tumor cells resemble those in the normal basal cell layer of the epidermis. They arise from the epidermis or follicular epithelium and do not occur on mucosal surfaces. Two patterns are seen: **multifocal growths** originating from the epidermis and sometimes extending over several square centimeters or more of skin surface (multifocal superficial type) and **nodular lesions** growing downward deeply into the dermis as cords and islands of variably basophilic cells with hyperchromatic nuclei, embedded in a mucinous matrix and often surrounded by many fibroblasts and lymphocytes (Fig. 25.15B). The cells at the periphery of the tumor cell islands tend to be arranged radially with their long axes in parallel alignment **(palisading).** In sections, the stroma retracts away from the carcinoma (Fig. 25.15C), creating clefts or separation artifacts that assist in differentiating basal cell carcinomas from certain appendage tumors that are also characterized by proliferation of basaloid cells, such as trichoepithelioma.

KEY CONCEPTS

MALIGNANT EPIDERMAL TUMORS

- The incidence of both basal cell carcinoma and squamous cell carcinoma is strongly correlated with increasing lifetime sun exposure.
- Cutaneous squamous cell carcinoma can progress from actinic keratoses but also arises from chemical exposure, at thermal

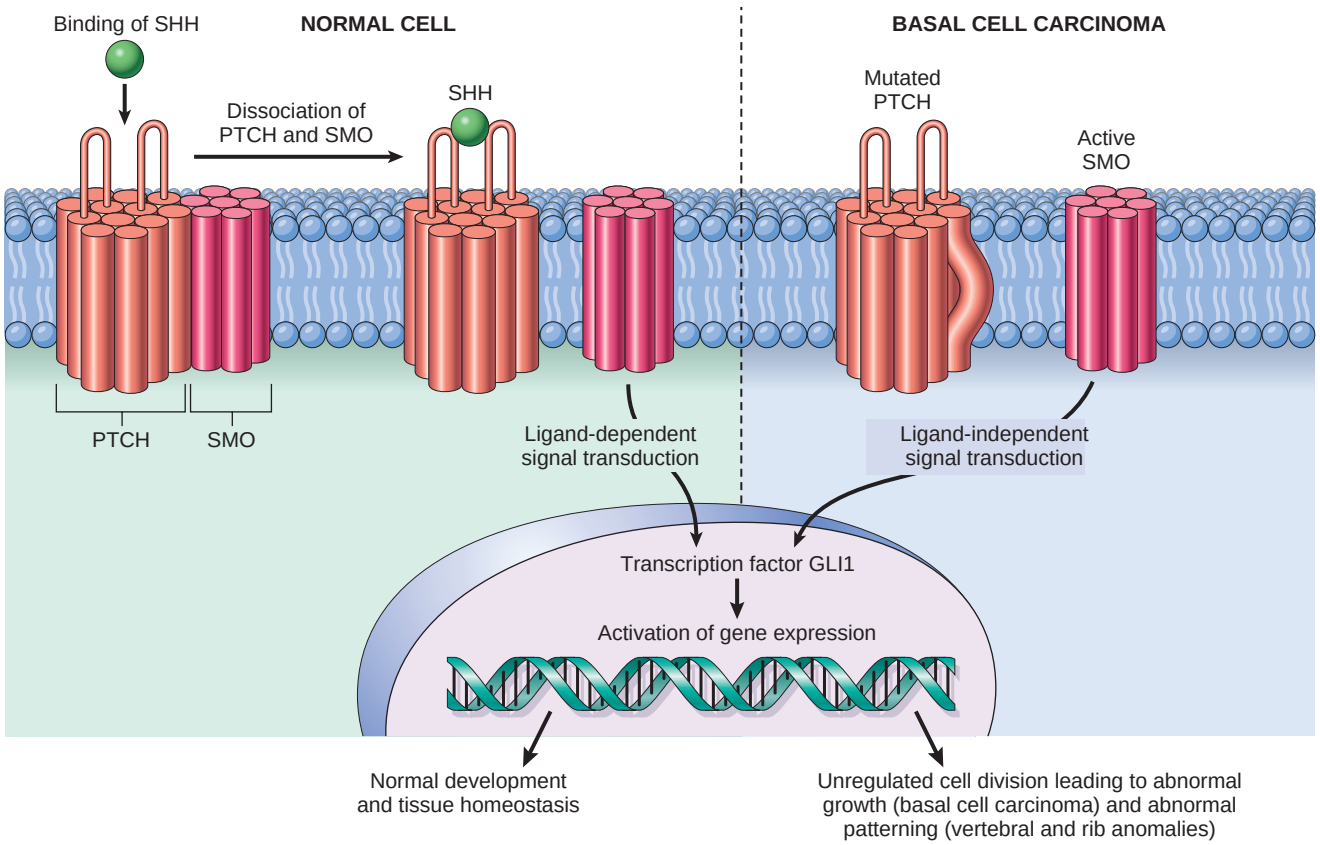

Figure 25.14 Normal and oncogenic hedgehog signaling. *Left,* Normally, PTCH and SMO form a receptor complex that can bind sonic hedgehog *(SHH).* In the absence of SHH, PTCH blocks SMO activity. When SHH binds PTCH, SMO is released to trigger a signal transduction cascade that leads to activation of GLI1 and other transcription factors. *Right,* Mutations in *PTCH,* and less often in *SMO,* allow SMO to signal without SHH binding and produce constitutive activation of GLI1. GLI signaling is a characteristic feature of sporadic basal cell carcinomas and tumors associated with nevoid basal cell carcinoma (Gorlin) syndrome.

burn sites, or in association with HPV infection in the setting of immunosuppression.
- Cutaneous squamous cell carcinoma has potential for metastasis but is much less aggressive than squamous cell carcinoma at mucosal sites.
- Basal cell carcinoma, the most common malignancy worldwide, is a locally aggressive tumor associated with mutations that activate Hedgehog signaling. Metastasis is very rare.

TUMORS OF THE DERMIS

The dermis contains a variety of elements such as smooth muscle, pericytes, fibroblasts, neural tissue, and endothelium. Neoplasms comprised of cells resembling all of these elements occur in the skin, but most also involve other soft tissues and viscera and are discussed elsewhere or are too rare to merit mention. This section discusses two dermal neoplasms—one benign, one malignant—that arise primarily in the skin.

Benign Fibrous Histiocytoma (Dermatofibroma)

Benign fibrous histiocytoma refers to a heterogeneous family of morphologically and histogenetically related benign dermal neoplasms of uncertain lineage. These tumors are usually seen in adults and often occur on the legs of young and middle-aged women. Lesions are asymptomatic or tender and may increase and decrease slightly in size over time. Their biologic behavior is indolent.

The cause of fibrous histiocytomas remains a mystery. Some cases have a history of antecedent trauma, suggesting an abnormal response to injury and inflammation, perhaps analogous to the deposition of increased amounts of altered collagen in a hypertrophic scar or keloid. However, several fusion genes, including one in which one partner is the gene for the receptor tyrosine kinase ALK, have been identified in a subset of cases, suggesting that these proliferations are best considered true neoplasms. These tumors appear to be composed at least partially of dermal dendritic cells.

MORPHOLOGY

These neoplasms appear as firm, tan to brown papules (Fig. 25.16A). Most are less than 1 cm in diameter, but actively growing lesions may reach several centimeters in diameter; with time they often become flattened.

The most common form of fibrous histiocytoma is referred to as a **dermatofibroma.** These tumors consist of benign, spindle-shaped cells that are usually arranged in a well-defined, nonencapsulated mass within the mid-dermis (Fig. 25.16B, C). Extension of these cells into the subcutaneous fat is sometimes

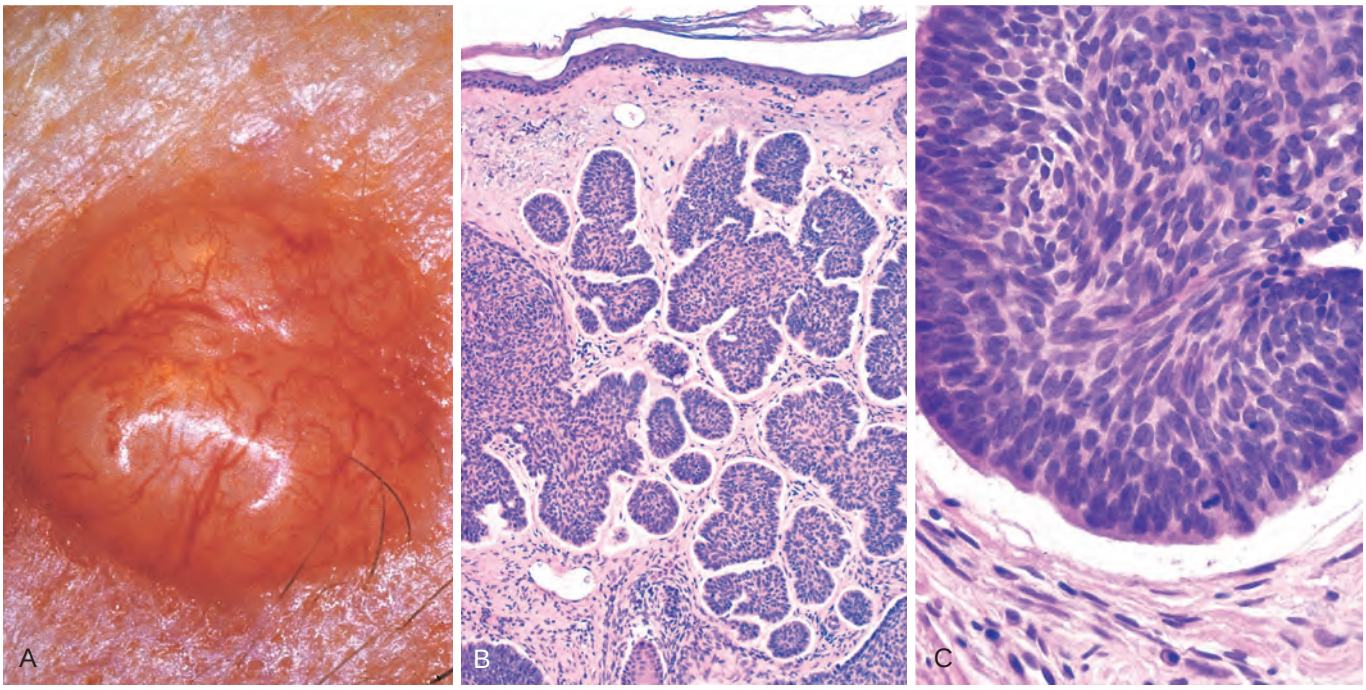

Figure 25.15 Basal cell carcinoma. Pearly, telangiectatic nodules (A) are composed of nests of uniform basaloid cells within the dermis (B) that are often separated from the adjacent stroma by thin clefts (C), an artifact of sectioning.

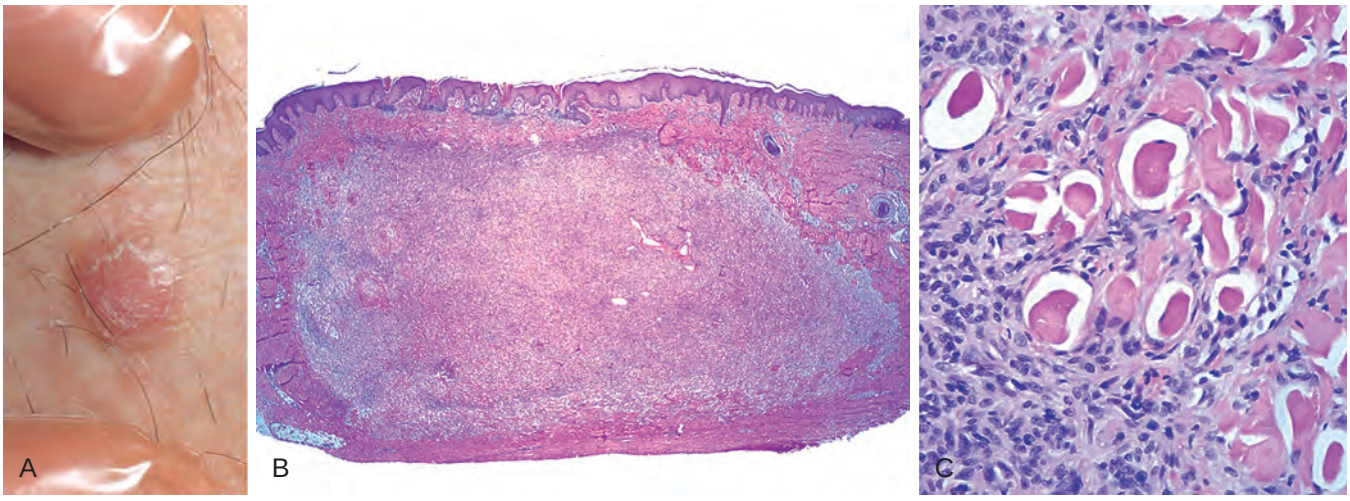

Figure 25.16 Benign fibrous histiocytoma (dermatofibroma). This firm, tan papule on the leg (A) contains a circumscribed dermal proliferation of benign-appearing spindle cells (B). Note the characteristic overlying epidermal hyperplasia (B) and the tendency of fibroblasts to surround individual collagen bundles (C).

observed. Many cases demonstrate a peculiar form of overlying epidermal hyperplasia, characterized by downward elongation of hyperpigmented rete ridges **(pseudoepitheliomatous hyperplasia).** Numerous histologic variants are noted, such as more cellular forms or tumors with pools of extravascular blood and hemosiderin (aneurysmal variants).

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is best regarded as a well-differentiated, primary fibrosarcoma of the skin. These tumors are slow growing, and although they are locally aggressive and can recur, they rarely metastasize. Metastasis most often is seen with tumors that exhibit greater cytologic atypia.

Pathogenesis

The molecular hallmark of dermatofibrosarcoma protuberans is a translocation involving the genes encoding collagen 1A1 *(COL1A1)* and platelet-derived growth factor-β *(PDGFB).* The resulting rearrangement juxtaposes the *COL1A1* promoter sequences and the coding region of *PDGFB* and leads to overexpression and increased secretion of PDGFβ, which drives tumor cell growth through an autocrine loop. While the primary mode of treatment is wide local

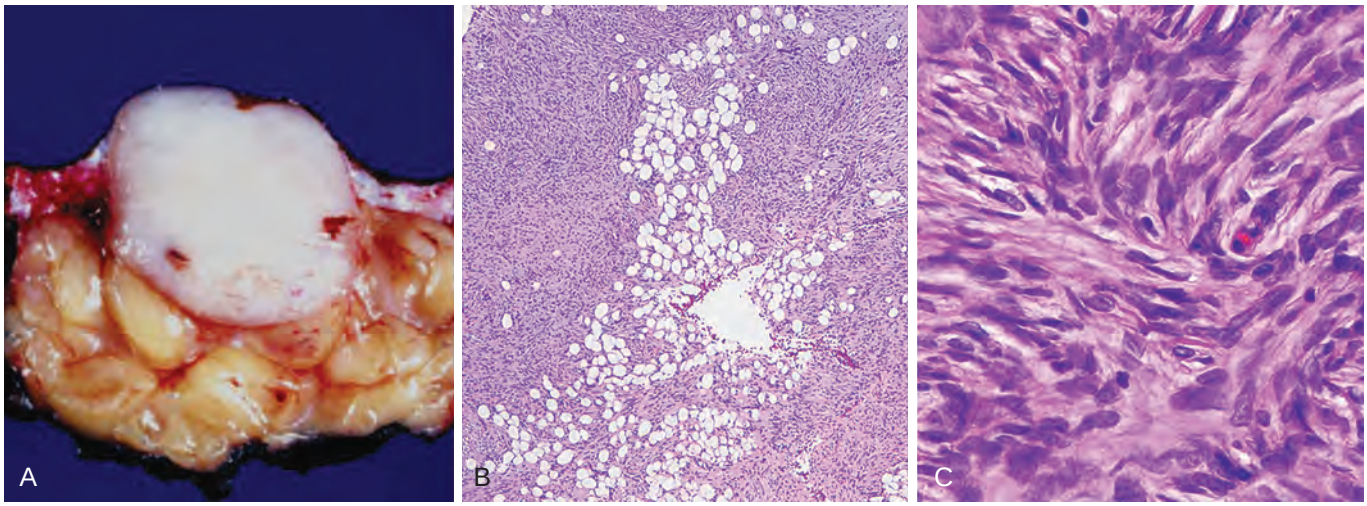

Figure 25.17 Dermatofibrosarcoma protuberans. (A) The tumor consists of a flesh-colored fibrotic nodule on sectioning. (B) The lesion often infiltrates the subcutis in a manner reminiscent of "Swiss cheese" to aficionados. (C) Characteristic storiform (swirling) alignment of the spindled cells is apparent.

excision, rare cases that are unresectable due to their location or because of metastatic spread can be treated with inhibitors of the PDGFβ receptor tyrosine kinase. Withdrawal of tyrosine kinase inhibitor therapy leads to regrowth of the tumor, so treatment must be lifelong.

MORPHOLOGY

Dermatofibrosarcoma protuberans usually appears as a "protuberant" nodule, most often on the trunk, within a firm (indurated) plaque that may sometimes ulcerate (Fig. 25.17A). These neoplasms are composed of closely packed fibroblasts arranged radially, reminiscent of blades of a pinwheel, a pattern referred to as **storiform.** Mitoses are rare. In contrast to dermatofibroma, the overlying epidermis is generally thinned. Deep extension from the dermis into subcutaneous fat, producing a characteristic "honeycomb" pattern, is frequently seen (Fig. 25.17B, C). These tumors may extend down into the subcutis and thus require wide excision to prevent local recurrence.

TUMORS OF CELLULAR MIGRANTS TO THE SKIN

Aside from tumors that arise directly from epidermal and dermal cells, several proliferative disorders of the skin involve cells whose progenitors arise elsewhere and then specifically home to the cutaneous microenvironment.

Mycosis Fungoides (Cutaneous T-Cell Lymphoma)

Cutaneous T-cell lymphoma (CTCL) spans a spectrum of lymphoproliferative disorders affecting the skin (Chapter 13), many with distinctive presentations. This section focuses on *mycosis fungoides,* a lymphoma of skin-homing CD4+ T-helper cells that presents in the skin. In most affected individuals, the disease remains localized to the skin for many years, but it may eventually evolve into a systemic lymphoma. This tumor may occur at any age, but most commonly afflicts persons older than age 40.

Lesions of mycosis fungoides usually involve truncal areas and include scaly, red-brown patches; raised, scaling plaques that may be confused with psoriasis; and fungating nodules. Prognosis is related to the percentage of body surface involved and progression from patch to plaque to nodular forms. Eczema-like lesions typify early stages of disease when obvious visceral or nodal spread has not occurred. Raised, indurated, irregularly outlined erythematous plaques may then supervene. Development of multiple tumor nodules correlates with systemic spread. Sometimes the plaques and nodules ulcerate (Fig. 25.18A). Ultimately, lesions may affect numerous body surfaces including the trunk, extremities, face, and scalp. In some individuals, seeding of the blood by malignant T cells is accompanied by diffuse erythema and scaling of the entire body surface (erythroderma), a condition known as *Sézary syndrome* (Chapter 13).

The proliferating cells in CTCL are usually clonal populations of CD4+ T-helper cells that home to the skin due to expression of cutaneous lymphocyte antigen. A wide variety of driver gene mutations in oncogenes and tumor suppressor genes have been described, none of which appear to be specific for CTCL. The neoplastic cells have clonal T-cell receptor gene rearrangements and sometimes express aberrant combinations of T-cell surface antigens. Topical therapy with steroids or UV light is often used for early skin lesions, whereas more aggressive systemic chemotherapy is indicated for advanced disease.

MORPHOLOGY

The histologic hallmark of CTCL of the mycosis fungoides type is the presence of atypical cells that characteristically form band-like aggregates within the superficial dermis (Fig. 25.18B) and invade the epidermis as single cells and small clusters **(Pautrier microabscesses).** These cells have markedly infolded nuclear membranes, imparting a convoluted or cerebriform contour. Although patches and plaques show pronounced epidermal infiltration by neoplastic cells (epidermotropism), in more advanced nodular lesions the malignant T cells often lose their epidermotropism, grow deeply into the dermis to produce nodules, and eventually spread systemically.

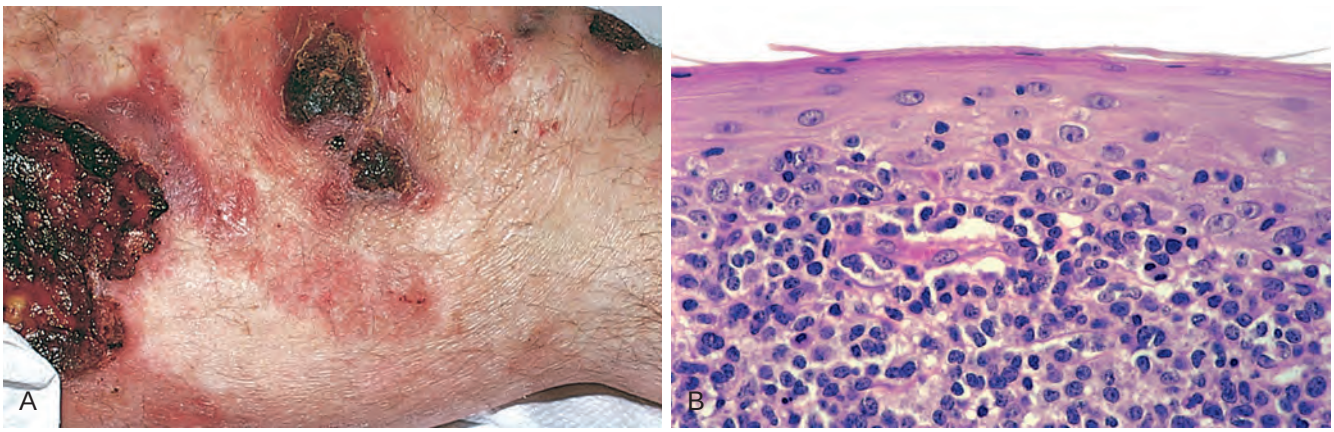

Figure 25.18 Cutaneous T-cell lymphoma. (A) Several erythematous plaques with scaling and ulceration are evident. (B) Microscopically, there is an infiltrate of atypical lymphocytes that accumulates beneath and invades the epidermis.

Mastocytosis

The term *mastocytosis* encompasses a spectrum of rare disorders characterized by increased numbers of mast cells in the skin and, in some instances, in other organs as well. A cutaneous form of the disease that affects predominantly children and accounts for more than 50% of all cases is termed *urticaria pigmentosa.* The cutaneous lesions are usually multiple, although solitary mastocytomas may also occur in very young children. About 10% of individuals with mast cell disease have systemic disease, with mast cell infiltration of many organs. These individuals are often adults, and unlike those with localized cutaneous disease, the prognosis in individuals with systemic disease is more guarded.

Many of the signs and symptoms of mastocytosis are due to the release of histamine, heparin, and other substances when mast cells degranulate. *Darier sign* refers to a localized area of dermal edema and erythema (wheal) that occurs when lesional skin is rubbed. *Dermatographism* refers to an area of dermal edema resembling a hive that occurs as a result of localized stroking of apparently normal skin with a pointed instrument. In systemic disease, all of the following may be seen: pruritus and flushing, triggered by certain foods, temperature changes, alcohol, and certain drugs (morphine, codeine, aspirin); watery nasal discharge (rhinorrhea); rarely, gastrointestinal or nasal bleeding, possibly due to the anticoagulant effects of heparin; and bone pain, which may be caused by mast cell infiltration or by pathologic fractures stemming from osteoporosis. Osteoporosis is caused by excessive histamine release in the marrow microenvironment and can be a clue to the diagnosis, particularly in premenopausal women and in men.

Pathogenesis

Many cases of mastocytosis have acquired activating point mutations in the KIT, or less frequently, the PDGFR-α receptor tyrosine kinases. The resulting increase in KIT signaling drives mast cell growth and survival. This insight has led to the clinical development of KIT kinase inhibitors, which often produce dramatic tumor regression, even in patients with advanced aggressive systemic disease.

MORPHOLOGY

The pathologic findings are highly variable. In **urticaria pigmentosa,** lesions are multiple and widely distributed, consisting of round to oval, red-brown, nonscaling papules and small plaques. Solitary **mastocytoma** presents as a pink to tan-brown nodule that may be pruritic or show blister formation (Fig. 25.19A). The histologic picture in urticaria pigmentosa or solitary mastocytoma varies from a subtle increase in mast cells around superficial dermal blood vessels to large numbers of tightly packed mast cells in the upper to mid-dermis (Fig. 25.19B). Fibrosis, edema, and eosinophils may also be present. Mast cells may be difficult to differentiate from lymphocytes in routine, hematoxylin and eosin–stained sections, and special metachromatic stains (toluidine blue or Giemsa) are used to visualize their granules (Fig. 25.19C). Even with these stains, extensive degranulation may result in failure to recognize these cells by light microscopy, but their identity can be readily confirmed with immunohistochemical stains for mast cell markers, such as mast cell tryptase and KIT.

DISORDERS OF EPIDERMAL MATURATION

Ichthyosis

Of the numerous disorders that impair epidermal maturation, ichthyosis is one of the most striking. The term is derived from the Greek root *ichthy,* meaning "fishy," and accordingly, this group of inherited disorders is associated with chronic, excessive keratin buildup (hyperkeratosis) that results in fish-like scaliness (Fig. 25.20A). Ichthyosis is subtyped according to the mode of inheritance, histology, and clinical features; the primary categories include *ichthyosis vulgaris* (autosomal dominant or acquired), *congenital ichthyosiform erythroderma* (autosomal recessive), *lamellar ichthyosis* (autosomal recessive), and *X-linked ichthyosis*. Most ichthyoses become apparent either at or around the time of birth. Acquired (noninherited) variants also exist; one such variant,

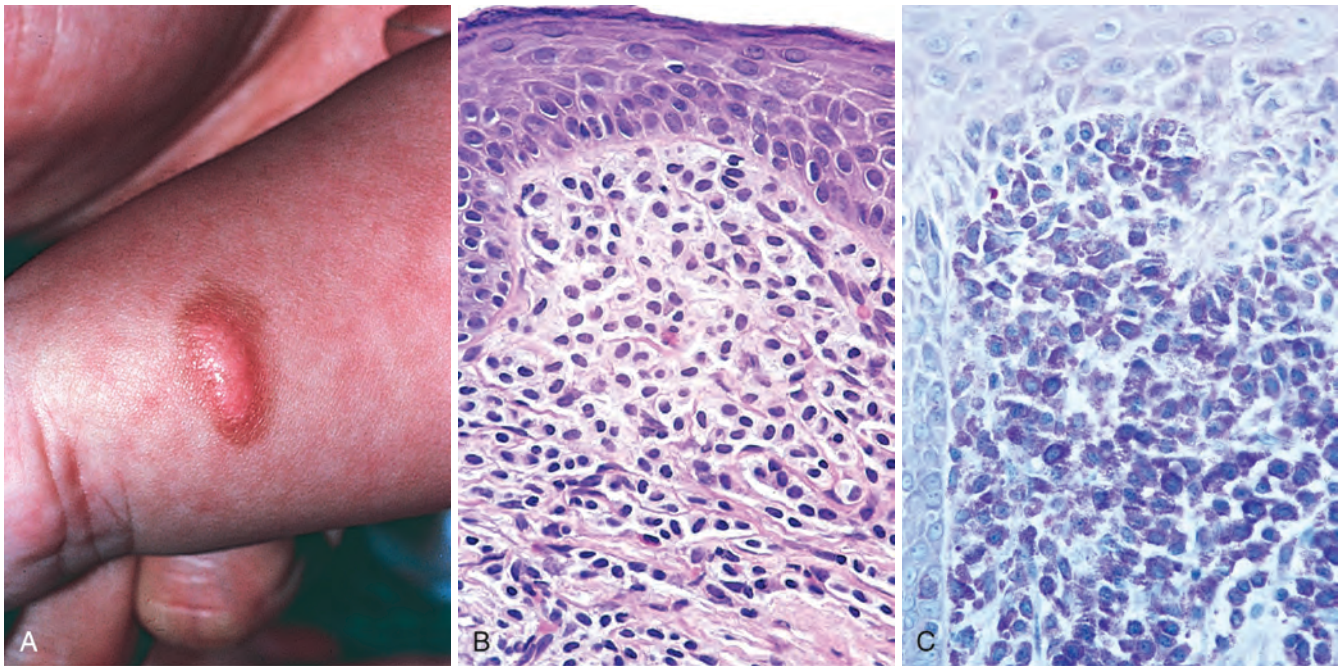

Figure 25.19 Mastocytosis. (A) Solitary mastocytoma in a 1-year-old child. (B) By histology, numerous ovoid cells with uniform, centrally located nuclei are observed in the dermis. (C) Giemsa staining reveals purple "metachromatic" granules within the cytoplasm of the mast cells.

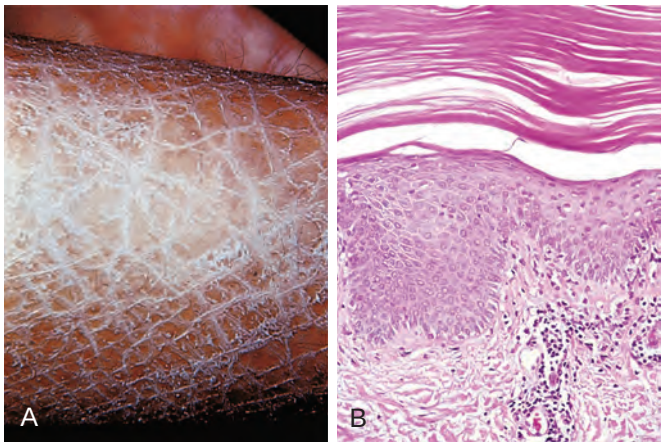

Figure 25.20 Ichthyosis. Note prominent fish-like scales (A) and compacted, thickened stratum corneum (B).

ichthyosis vulgaris, may be associated with lymphoid and visceral malignancies.

Pathogenesis

The primary abnormality in ichthyosis is defective desquamation, leading to retention of abnormally formed scales. For example, X-linked ichthyosis is caused by a deficiency of steroid sulfatase, an enzyme that helps to remove proadhesive cholesterol sulfate from intercellular spaces. In its absence, cholesterol sulfate accumulates, resulting in persistent cell-to-cell adhesion within the stratum corneum and a failure of desquamation.

MORPHOLOGY

All forms of ichthyosis exhibit a buildup of compacted stratum corneum that is associated with loss of the normal basket-weave pattern (Fig. 25.20B). There is generally little or no inflammation. Variations in the thickness of the epidermis and the stratum granulosum and the gross appearance and distribution of lesions are used to subclassify these disorders.

ACUTE INFLAMMATORY DERMATOSES

Innumerable inflammatory dermatoses have been described and can be broadly classified as acute and chronic. Acute lesions last from days to weeks and are characterized by inflammatory infiltrates (usually composed of lymphocytes and macrophages rather than neutrophils), edema, and variable degrees of epidermal, vascular, or subcutaneous injury. Chronic lesions, on the other hand, persist for months to years and are often associated with changes in epidermal growth (atrophy or hyperplasia) or dermal fibrosis. Discussed here are examples of the more commonly encountered acute dermatoses.

Urticaria

Urticaria (hives) is a common disorder of the skin that is usually caused by localized mast cell degranulation and is uniformly associated with dermal microvascular hyperpermeability. This combination of effects produces pruritic edematous plaques called *wheals.* Angioedema is closely

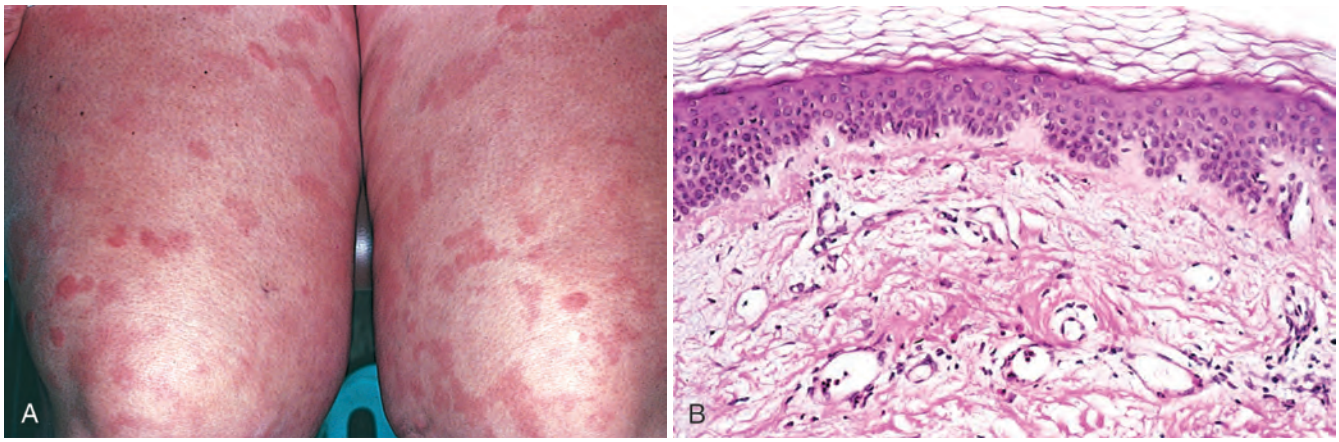

Figure 25.21 Urticaria. (A) Erythematous, edematous, often circular plaques are characteristic. (B) Histologically, there is superficial dermal edema, manifested by spaces between collagen bundles, and dilated lymphatic and blood-filled vascular spaces; the epithelium is normal.

related to urticaria and is characterized by edema of the deeper dermis and the subcutaneous fat.

Urticaria most often occurs between ages 20 and 40, but all age groups are susceptible. Individual lesions develop and fade within hours (usually less than 24 hours), and episodes may last for days or persist for months. Sites of predilection for urticarial eruptions include any area exposed to pressure, such as the trunk, distal extremities, and ears. Persistent episodes of urticaria may herald an underlying disease (e.g., collagen vascular disorders, Hodgkin lymphoma), but in the majority of cases no underlying cause is identified.

Pathogenesis

Urticaria is most commonly the result of antigen-induced release of vasoactive mediators from mast cells. The various forms can be classified based on their dependence on IgE antibody and mast cells, as follows:

- *Mast cell–dependent, immunoglobulin E (IgE)–dependent*. Urticaria of this type follows exposure to many different antigens (pollens, foods, drugs, insect venom) and is an example of a localized immediate hypersensitivity (type I) reaction triggered by the binding of antigen to IgE antibodies that are attached to mast cells through Fc receptors (Chapter 6).
- *Mast cell–dependent, IgE-independent*. This subset results from substances that directly incite the degranulation of mast cells, such as opiates, certain antibiotics, and radiographic contrast media.
- *Mast cell–independent, IgE-independent*. These forms of urticaria are triggered by local factors that increase vascular permeability. One form is initiated by exposure to chemicals or drugs, such as aspirin, that inhibit cyclooxygenase and arachidonic acid production. The precise mechanism of aspirin-induced urticaria is unknown. A second form is *hereditary angioneurotic edema* (Chapter 6), caused by an inherited deficiency of C1 inhibitor that results in excessive activation of the early components of the complement system and production of vasoactive mediators.

MORPHOLOGY

Lesions vary from small, pruritic papules to large edematous plaques (Fig. 25.21A). Individual lesions may coalesce to form annular, linear, or arciform configurations. The histologic features of urticaria may be very subtle. There is usually a sparse superficial perivenular infiltrate consisting of mononuclear cells and rare neutrophils. Eosinophils may also be present. Collagen bundles are more widely spaced than in normal skin, a result of dermal edema (Fig. 25.21B). Dermal lymphatic channels may also be dilated due to increased absorption of edema fluid. There are no changes in the epidermis.

Acute Eczematous Dermatitis

The Greek word *eczema,* meaning "to boil over," vividly describes the appearance of acute eczematous dermatitis—one of the most common skin disorders. Based on initiating factors, eczematous dermatitis can be subdivided into the following categories: (1) allergic contact dermatitis, (2) atopic dermatitis, (3) drug-related eczematous dermatitis, (4) photoeczematous dermatitis, and (5) primary irritant dermatitis.

The causes of eczema are sometimes broadly separated into "inside and outside jobs": disease resulting from external application of an antigen (e.g., poison ivy) or a reaction to an internal circulating antigen (which may be derived from ingested food or a drug). Treatment involves a search for offending substances that can be removed from the environment. Topical steroids can be used to block the inflammatory response. While such treatments are only palliative and do not cure, they are nevertheless helpful in interrupting acute exacerbations of eczema, which can become self-perpetuating if unchecked.

Pathogenesis

Eczematous dermatitis typically results from T cell–mediated inflammatory reactions (type IV hypersensitivity). This has been well studied in dermatitis triggered by contact

antigens (e.g., urushiol from poison ivy). It is believed that chemicals rubbed onto the skin react with self proteins, thereby acting as "haptens" that create neoantigens. These antigens are taken up by Langerhans cells, which then migrate through dermal lymphatics to draining lymph nodes. Here they present the neoantigens to naive CD4+ T cells, which are activated and develop into effector and memory cells (Chapter 6). On antigen reexposure, memory T cells expressing homing molecules, such as common lymphocyte antigen and particular chemokine receptors, migrate to cutaneous sites where antigen is localized. Here they release cytokines and chemokines, which serve to recruit numerous additional inflammatory cells. This process occurs within 24 hours and accounts for the initial erythema and pruritus that characterize the acute, spongiotic phase of eczema.

Langerhans cells within the epidermis play a central role in contact dermatitis, and understandably factors that affect Langerhans cell function impact the inflammatory reaction. For example, chronic exposure to UV light is injurious to epidermal Langerhans cells and can prevent sensitization to contact antigens, but UV light can also alter antigens and generate forms that are more likely to induce sensitivity reactions.

MORPHOLOGY

All types of eczematous dermatitis are characterized by red, papulovesicular, crusted lesions that, if persistent, develop reactive **acanthosis** and **hyperkeratosis** and take on the appearance of raised scaling plaques (Fig. 25.22). A striking example of eczema is an acute contact reaction to topical antigens such as urushiol in poison ivy/oak *(Rhus toxicodendron)*, which is characterized by pruritic, edematous, oozing plaques that often contain small and large blisters (vesicles and bullae) (Fig. 25.23A). Such lesions are prone to bacterial superinfection, which produces a yellow crust (impetiginization). With time, persistent lesions become less "wet" (fail to ooze or form vesicles) and become progressively more hyperkeratotic and acanthotic. **Spongiosis** characterizes acute eczematous dermatitis—hence the histologic synonym spongiotic dermatitis. Unlike urticaria, in which edema is restricted to the superficial dermis, edema seeps into the intercellular spaces of the epidermis, splaying apart keratinocytes, particularly in the stratum spinosum. Mechanical shearing of intercellular attachment sites (desmosomes) and cell membranes by progressive accumulation of intercellular fluid may result in the formation of intraepidermal vesicles (Fig. 25.23B).

During the earliest stages of eczematous dermatitis, there is a superficial, perivascular, lymphocytic infiltrate associated with papillary dermal edema and mast cell degranulation. The pattern and composition of this infiltrate may provide clues to the underlying cause. For example, eczema resulting from certain ingested drugs is marked by perivascular infiltrates that often contain eosinophils in the superficial and deep dermis. By contrast, eczematous dermatitis resulting from contact antigens tends to produce a mononuclear inflammatory reaction without eosinophils that preferentially affects the superficial dermis.

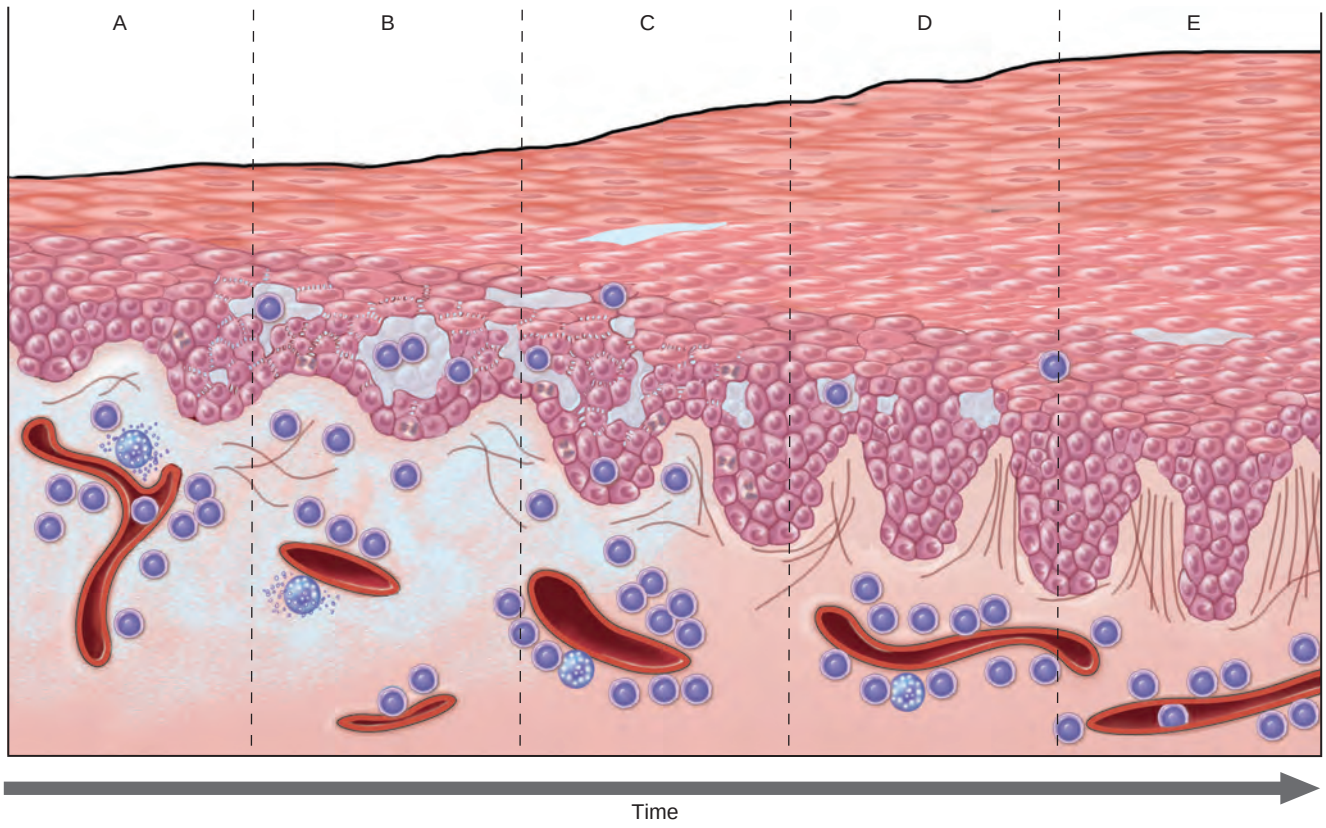

Figure 25.22 Stages of eczema development. (A) Initial dermal edema and perivascular infiltration by inflammatory cells is followed within 24 to 48 hours by (B) epidermal spongiosis and microvesicle formation. (C) Abnormal scale, including parakeratosis, as well as progressive acanthosis (D) and hyperkeratosis (E) appear as the lesion becomes chronic.

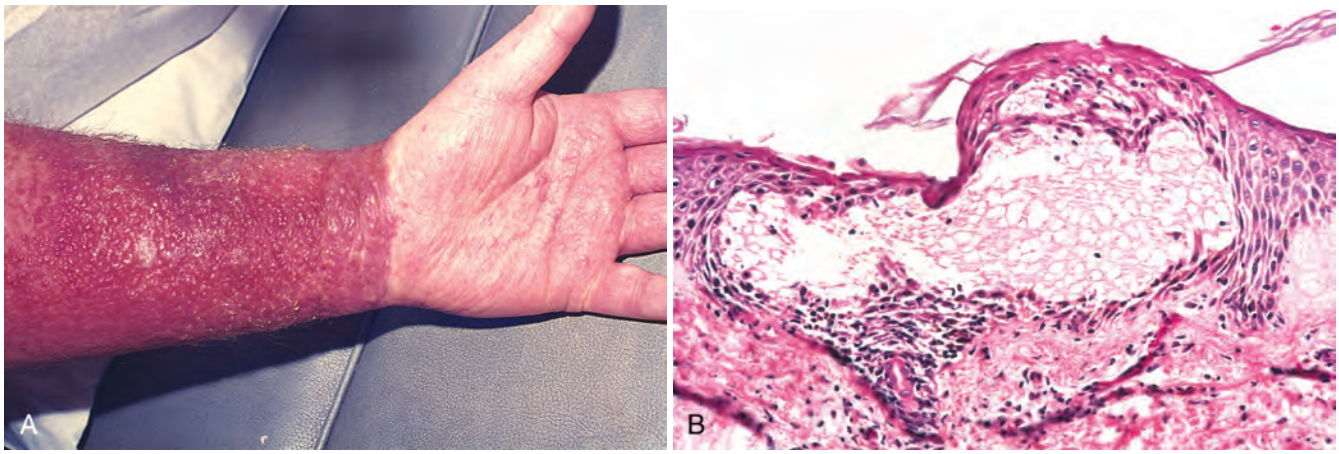

Figure 25.23 Eczematous dermatitis. (A) Acute allergic contact dermatitis due to antigen exposure (in this case, laundry detergent in clothing) marked by numerous vesicular lesions on erythematous skin. (B) Edema within the epidermis creates fluid-filled intraepidermal vesicles.

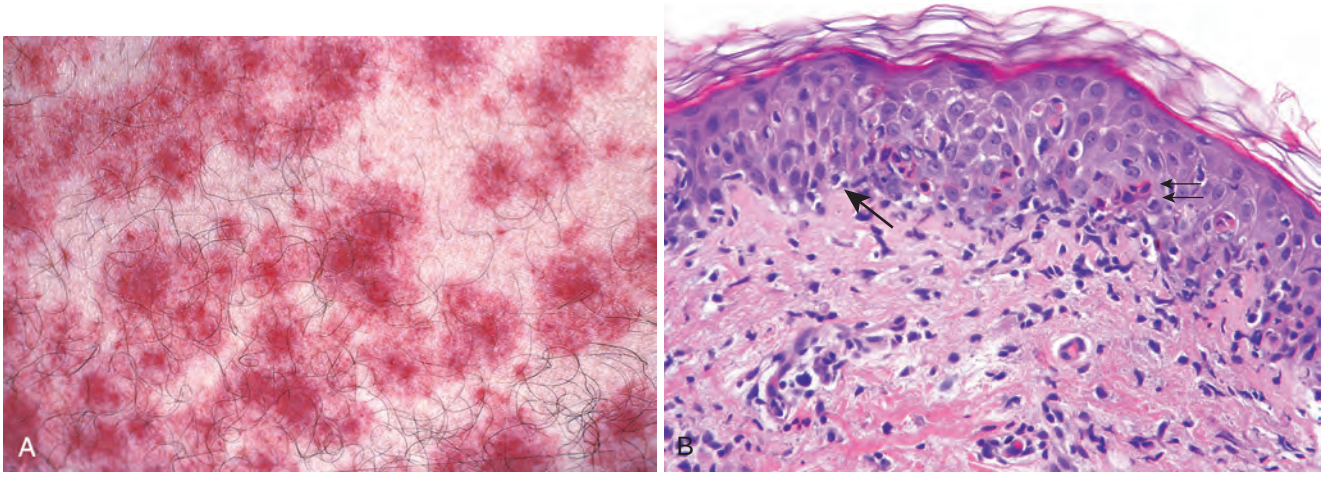

Figure 25.24 Erythema multiforme. (A) Target-like lesions consist of a central blister or zone of epidermal necrosis surrounded by macular erythema. (B) An early lesion shows lymphocytes accumulating along the dermoepidermal junction where basal keratinocytes are becoming vacuolated *(arrow)*. With time, necrotic/apoptotic keratinocytes appear in the overlying epithelium *(double arrow)*.

Erythema Multiforme

Erythema multiforme is an uncommon self-limited hypersensitivity reaction to certain infections and drugs. It affects individuals of any age and is associated with the following conditions: (1) infections such as herpes simplex, mycoplasmal infections, histoplasmosis, coccidioidomycosis, typhoid, and leprosy, among others; (2) exposure to certain drugs (sulfonamides, penicillin, barbiturates, salicylates, hydantoins, and antimalarials); (3) cancer (carcinomas and lymphomas); and (4) collagen vascular diseases (lupus erythematosus, dermatomyositis, and polyarteritis nodosa).

Pathogenesis

Erythema multiforme is characterized by keratinocyte injury mediated by skin-homing CD8+ cytotoxic T lymphocytes. This mechanism of injury is shared with a number of other conditions, including acute graft-versus-host disease, skin allograft rejection, and fixed drug eruptions. In erythema multiforme, CD8+ cytotoxic T cells are more prominent in the central portion of the lesions, while CD4+ helper T cells and Langerhans cells are more prevalent in the peripheral portions. The epidermal antigens that are recognized by the infiltrating T cells in erythema multiforme remain unknown.

MORPHOLOGY

Affected individuals present with a diverse array of lesions (hence the term multiforme), including macules, papules, vesicles, bullae, and characteristic targetoid (target-like) lesions (Fig. 25.24A). The lesions may occur in a variety of distributions. Cases that are limited in extent often show symmetric involvement of the extremities. A febrile form associated with extensive involvement of the skin is called **Stevens-Johnson syndrome,** which is often (but not exclusively) seen in children. In Stevens-Johnson syndrome, lesions involve not only the skin but also the lips and oral mucosa, conjunctiva, urethra, and genital and perianal areas. Secondary infection of involved areas due to loss of skin integrity may result in life-threatening sepsis. Another variant termed **toxic epidermal necrolysis** is characterized by diffuse necrosis and sloughing of

cutaneous and mucosal epithelial surfaces. The widespread epidermal damage produces a clinical picture similar to that seen in patients with extensive burns.

On histologic examination, the "targetoid" lesions show a superficial perivascular, lymphocytic infiltrate associated with dermal edema and accumulation of lymphocytes along the dermoepidermal junction, where they are intimately associated with degenerating and necrotic keratinocytes, a pattern termed *interface dermatitis* (Fig. 25.24B). With time there is upward migration of lymphocytes into the epidermis. Discrete and confluent zones of epidermal necrosis occur with concomitant blister formation. Epidermal sloughing leads to shallow erosions.

CHRONIC INFLAMMATORY DERMATOSES

This category includes inflammatory skin disorders that persist for months to years. The skin surface in chronic inflammatory dermatoses is often roughened as a result of excessive or abnormal scale formation and shedding.

Psoriasis

Psoriasis is a chronic inflammatory dermatosis that appears to have an autoimmune basis. It is a common disorder, affecting as many as 1% to 2% of people in the United States. Persons of all ages develop the disease. Approximately 15% of patients with psoriasis have associated arthritis, which may be mild or may produce severe deformities resembling the joint changes seen in rheumatoid arthritis. It can affect any joint in the body and may be symmetric or asymmetric. In addition, psoriasis may be associated with myopathy, enteropathy, and acquired immunodeficiency syndrome (AIDS).

Pathogenesis

As with other suspected disorders of autoimmunity, psoriasis is believed to be the product of environmental and genetic factors, including particular HLA gene variants. The culprit antigens remain elusive, but it appears that sensitized populations of CD4+ Th1 and Th17 cells and activated CD8+ cytotoxic effector T cells enter the skin and accumulate in the epidermis. These T cells may create an abnormal microenvironment by stimulating the secretion of cytokines and growth factors that induce keratinocyte proliferation, resulting in the characteristic lesions. The interactions between CD4+ T cells, CD8+ T cells, dendritic cells, and keratinocytes give rise to a cytokine "soup" dominated by Th1-type and Th17-type cytokines such as IL-12, interferon-γ, tumor necrosis factor (TNF), and IL-17. The importance of these factors is highlighted by the generally excellent clinical responses that are observed in patients treated with TNF inhibitors. Lymphocytes also produce growth factors for keratinocytes that may contribute to epidermal thickening. Psoriatic lesions can be induced in susceptible individuals by local trauma, a process known as the Koebner phenomenon, presumably because trauma sets in motion a local inflammatory response that becomes self-perpetuating.

MORPHOLOGY

Psoriasis most frequently affects the skin of the elbows, knees, scalp, lumbosacral areas, intergluteal cleft, and glans penis. The typical lesion is a well-demarcated, **pink to salmon-colored plaque covered by loosely adherent silver-white scale** (Fig. 25.25A). Variations exist, with some lesions occurring in annular, linear, gyrate, or serpiginous configurations. Psoriasis is one cause of total body erythema and scaling known as erythroderma. **Nail changes** occur in 30% of cases of psoriasis and consist of yellow-brown discoloration (often likened to an oil slick), with pitting, dimpling, separation of the nail plate from the underlying bed (onycholysis), thickening, and crumbling.

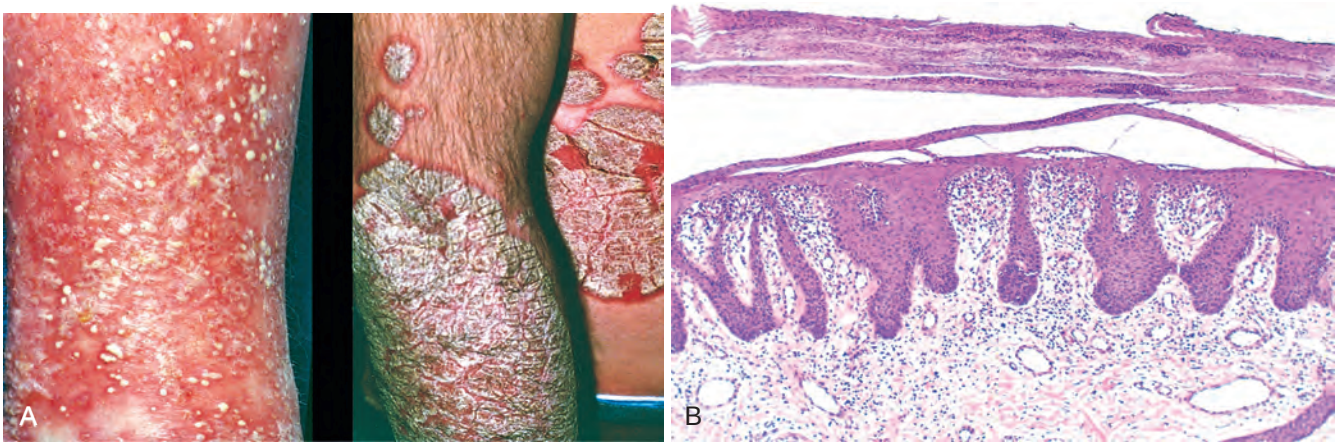

Figure 25.25 Psoriasis. (A) Early lesions may be dominated by inflammation, marked by the presence of small pustules and erythema *(left)*. Established chronic lesions are erythematous and covered by a characteristic silver-white scale *(right)*. (B) Microscopically, there is epidermal hyperplasia, parakeratotic scale, and accumulation of neutrophils within the superficial epidermis.

Established lesions of psoriasis have a characteristic histologic picture. Increased epidermal cell proliferation results in marked epidermal thickening (acanthosis), with regular downward elongation of the rete ridges sometimes described as appearing like test tubes in a rack (Fig. 25.25B). Mitotic figures are easily identified well above the basal cell layer, where mitotic activity is confined in normal skin. **The stratum granulosum is thinned or absent, and extensive overlying parakeratotic scale is seen.** Typical of psoriatic plaques is thinning of the portion of the epidermal cell layer that overlies the tips of the dermal papillae (suprapapillary plates), which contain dilated, tortuous blood vessels. This abnormal proximity of vessels within the dermal papillae to the overlying parakeratotic scale accounts for the characteristic clinical phenomenon of multiple, minute, bleeding points when the scale is lifted from the plaque **(Auspitz sign).** Neutrophils form small aggregates within the superficial epidermis **(spongiform pustules)** and the parakeratotic stratum corneum **(Munro microabscesses).** In pustular psoriasis, larger abscess-like accumulations of neutrophils are present directly beneath the stratum corneum.

Seborrheic Dermatitis

Seborrheic dermatitis is a chronic inflammatory dermatosis that is even more common than psoriasis, affecting up to 5% of the general population. It classically involves regions with a high density of sebaceous glands, such as the scalp, forehead (especially the glabella), external auditory canal, retroauricular area, nasolabial folds, and presternal area. Despite this association and its name, seborrheic dermatitis is associated with inflammation of the epidermis and is not a disease of the sebaceous glands per se.

Pathogenesis

The precise etiology of seborrheic dermatitis is unknown. Increased sebum production, often in response to androgens, is one possible contributory factor. Involvement of sebum is supported by clinical observations of patients with Parkinson disease, who typically show increased sebum production secondary to dopamine deficiency and have a markedly increased incidence of seborrheic dermatitis. Once treated with levodopa, the oiliness of the skin decreases and the seborrheic dermatitis improves. However, other conditions associated with increased sebum production such as acne (discussed later) are not associated with seborrheic dermatitis, and sebum production is probably best viewed as being necessary but not sufficient to cause the disorder. Other work has suggested a relationship with colonization of the skin by certain fungal species of the genus *Malassezia,* but there is no definitive evidence of a cause-and-effect relationship. A severe form of seborrheic dermatitis that is difficult to treat was once common in many human immunodeficiency virus (HIV)–infected individuals with low CD4 counts, but its incidence has fallen with the advent of effective antiviral therapy.

MORPHOLOGY

The individual lesions are macules and papules on an erythematous-yellow, often greasy base, typically in association with extensive scaling and crusting. Fissures may also be present, particularly behind the ears. Dandruff is the common clinical expression of seborrheic dermatitis of the scalp. Microscopically, seborrheic dermatitis shares features with spongiotic dermatitis and psoriasis, with earlier lesions being more spongiotic and later ones more acanthotic. Typically, mounds of parakeratosis containing neutrophils and serum are present at the ostia of hair follicles (so-called **follicular lipping**). A superficial perivascular inflammatory infiltrate generally consists of a mixture of lymphocytes and neutrophils.

Lichen Planus

"Pruritic, purple, polygonal, planar, papules, and plaques" are the tongue-twisting "six Ps" of lichen planus, a disorder of skin and mucosa. Lichen planus is usually self-limited, most commonly resolving spontaneously 1 to 2 years after onset. Resolution often leaves a residuum of postinflammatory hyperpigmentation. Oral lesions, however, may persist for years. Squamous cell carcinoma sometime arises from chronic mucosal and paramucosal lichen planus and may be an example of carcinogenesis fostered by chronic inflammation. As in psoriasis, the Koebner phenomenon may be seen in lichen planus.

Pathogenesis

The pathogenesis of lichen planus is not known. It is possible that expression of altered antigens in basal epidermal cells or the dermoepidermal junction elicits a cell-mediated cytotoxic (CD8+) T-cell response.

MORPHOLOGY

Cutaneous lesions consist of itchy, violaceous, flat-topped papules that may coalesce to form plaques (Fig. 25.26A). The papules are often highlighted by white dots or lines called **Wickham striae,** which are created by areas of hypergranulosis. In darkly pigmented individuals, lesions may acquire a dark brown color due to release of melanin into the dermis as the basal cell layer is destroyed. Lesions are usually multiple and symmetrically distributed, particularly on the extremities and often about the wrists and elbows. The glans penis is another common site of involvement. In 70% of cases, oral mucosal lesions are present that have a white, reticulated, or net-like appearance.

Lichen planus is characterized histologically by a dense, continuous infiltrate of lymphocytes along the dermoepidermal junction, a prototypic example of **interface dermatitis** (Fig. 25.26B). The lymphocytes are intimately associated with basal keratinocytes, which show degeneration, necrosis, and a resemblance in size and contour to more mature cells of the stratum spinosum (squamatization). As a consequence of this destructive lymphocytic infiltrate, the dermoepidermal interface takes on an angulated zigzag contour (sawtoothing). Anucleate, necrotic basal cells may become incorporated into the inflamed papillary dermis, where they are referred to as **colloid** or **Civatte bodies.** Although the lesions bear some similarities to those in erythema multiforme, lichen planus shows changes of chronicity, namely, epidermal hyperplasia (or rarely atrophy) and thickening of the granular cell layer and stratum corneum (hypergranulosis and hyperkeratosis, respectively).

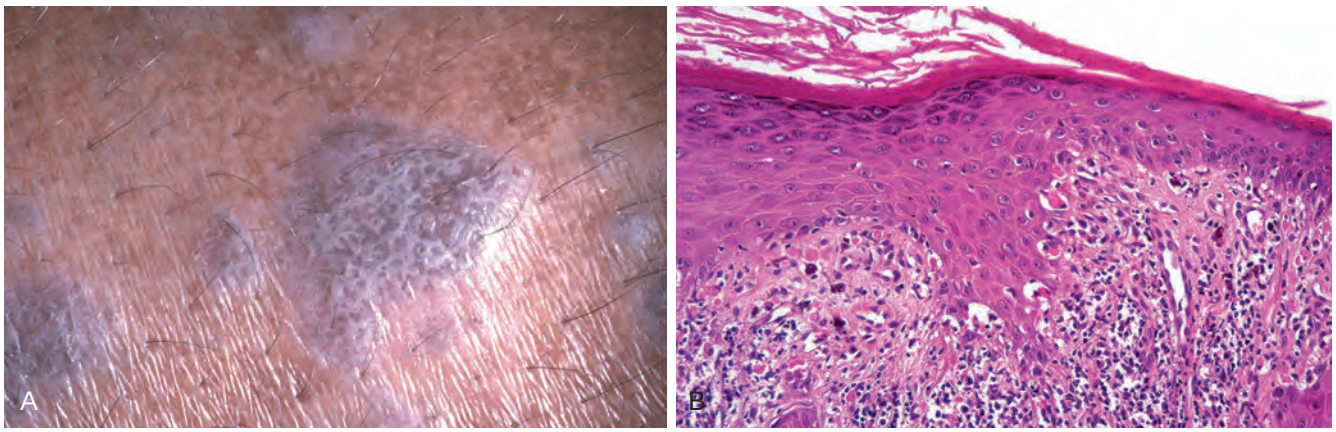

Figure 25.26 Lichen planus. (A) This flat-topped pink-purple, polygonal papule has a white lace-like pattern of lines that are referred to as Wickham striae. (B) There is a band-like infiltrate of lymphocytes at the dermoepidermal junction, hyperkeratosis, and pointed rete ridges (sawtoothing), the last as a result of chronic basal cell layer injury.

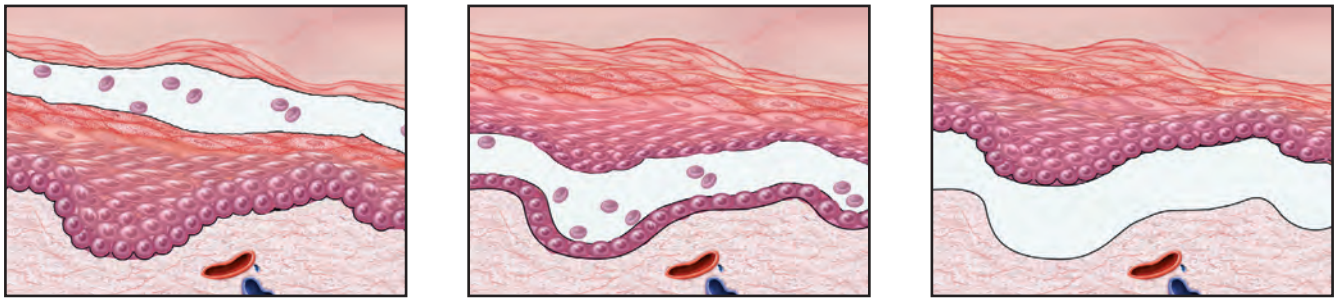

Figure 25.27 Schematic representation of different types of blisters. (A) In subcorneal blisters, the stratum corneum forms the roof of the bulla (as in pemphigus foliaceus). (B) In a suprabasilar blister, a portion of the epidermis, including the stratum corneum, forms the roof (as in pemphigus vulgaris). (C) In a subepidermal blister, the entire epidermis separates from the dermis (as in bullous pemphigoid).

KEY CONCEPTS

INFLAMMATORY DERMATOSES

- Many specific inflammatory dermatoses exist, which can be mediated by IgE antibodies (urticaria) or antigen-specific T cells (eczema, erythema multiforme, and psoriasis).
- These disorders are diagnosed based on the distribution and gross appearance of skin lesions and the microscopic patterns of inflammation (e.g., interface dermatitis in lichen planus and erythema multiforme).

BLISTERING (BULLOUS) DISEASES

Although vesicles and bullae (blisters) occur in several unrelated conditions such as herpesvirus infection, spongiotic dermatitis, erythema multiforme, and thermal burns, there exists a group of disorders in which blisters are the primary and most distinctive features. These *bullous diseases,* as they are called, produce dramatic lesions and in some instances are fatal if untreated. Blisters in the various disorders occur at different levels within the skin (Fig. 25.27); histologic assessment is essential for accurate diagnosis and provides insight into the pathogenic mechanisms. Knowledge of the structure of desmosomes and hemidesmosomes (described in Chapter 1), which, you will recall, provide the skin with mechanical stability, is helpful in understanding these diseases, as they are often caused by acquired or inherited defects in proteins that make up or bind to these structures (Fig. 25.28).

Inflammatory Blistering Disorders

Pemphigus

Pemphigus is a blistering disorder caused by autoantibodies that result in the dissolution of intercellular attachments within the epidermis and mucosal epithelium. The pathobiology of blistering disorders provides important insights into the molecular underpinnings of keratinocyte adhesion. The majority of individuals who develop pemphigus are in the fourth to sixth decades of life, and men and women are affected equally. There are multiple variants: (1) pemphigus vulgaris, (2) pemphigus vegetans, (3) pemphigus foliaceus, (4) pemphigus erythematosus, and (5) paraneoplastic pemphigus. These disorders are usually benign, but in extreme cases can be fatal without treatment.

- *Pemphigus vulgaris,* by far the most common type (accounting for more than 80% of cases worldwide), involves the

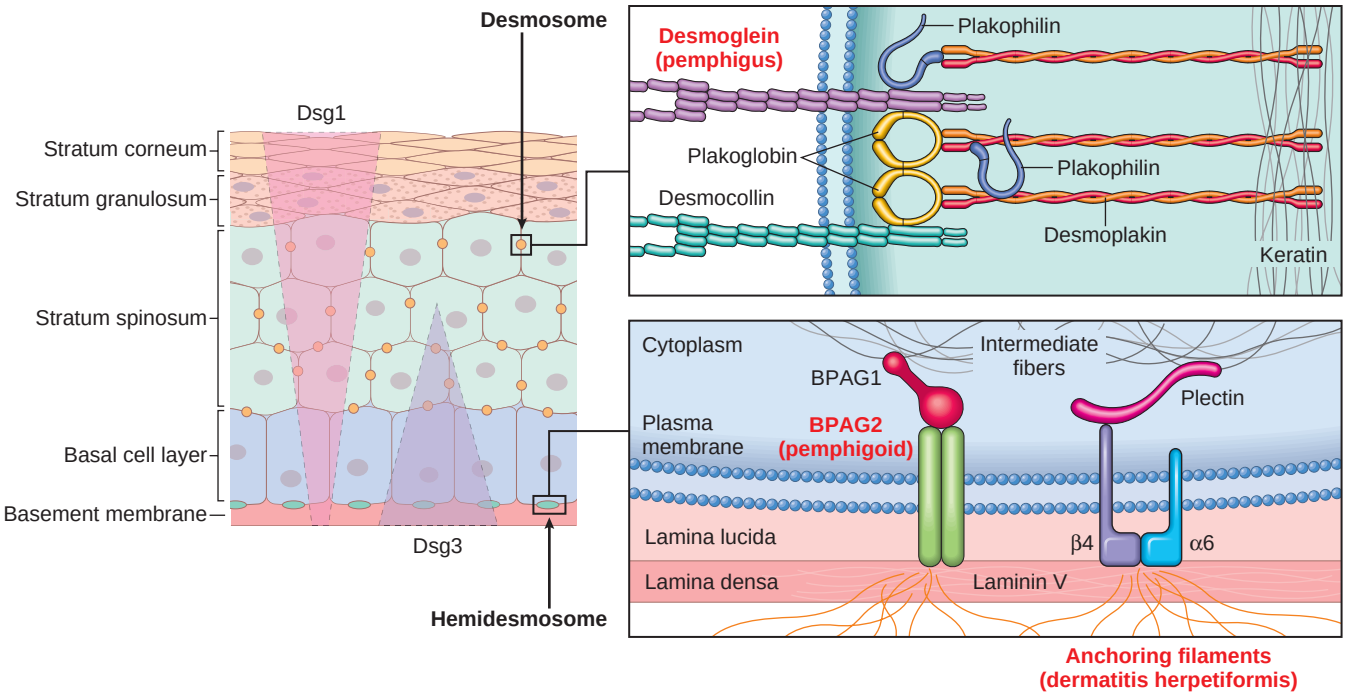

Figure 25.28 Keratinocyte adhesion molecules and blistering inflammatory disorders. Knowledge of the proteins composing desmosomes and hemidesmosomes is key to understanding blistering disorders. Desmogleins 1 and 3 *(Dsg1, Dsg3)* are functionally interchangeable components of desmosomes but have different distributions within the epidermis *(left panel)*. The major structural proteins of desmosomes and hemidesmosomes are shown in the *right panel*. In pemphigus vulgaris, autoantibodies against Dsg1 and Dsg3 cause blisters in the deep suprabasal epidermis, whereas in pemphigus foliaceus, autoantibodies are against Dsg1 alone, leading to superficial, subcorneal blisters. In bullous pemphigoid, autoantibodies bind BPAG2, a component of the hemidesmosomes, leading to blister formation at the level of the lamina lucida of the basement membrane. Dermatitis herpetiformis is caused by IgA autoantibodies to the fibrils that anchor hemidesmosomes to the dermis.

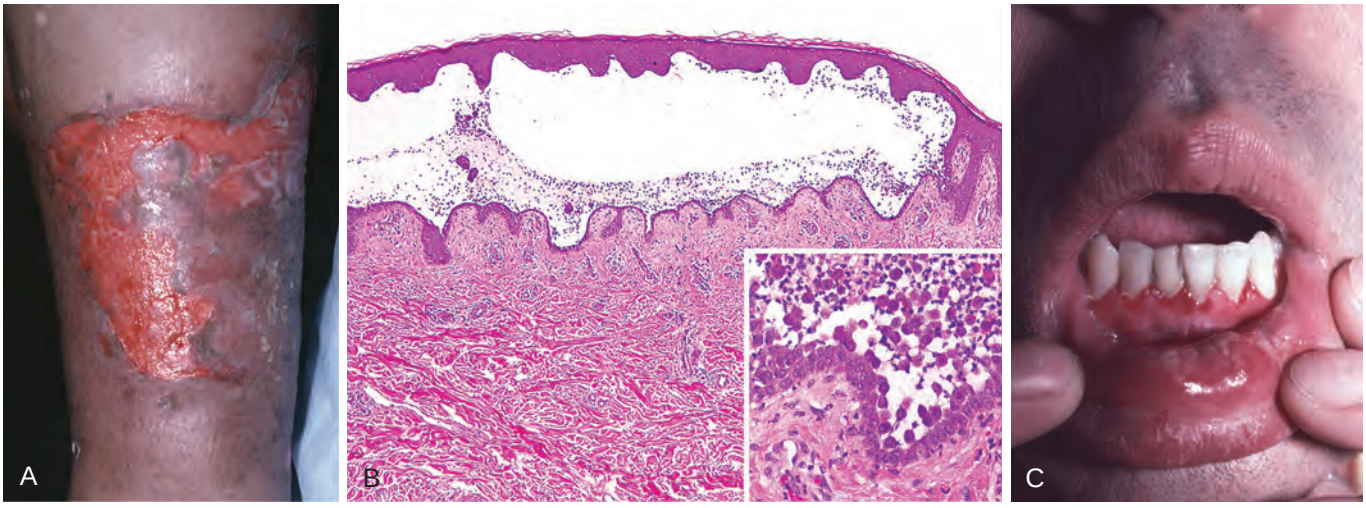

Figure 25.29 Pemphigus vulgaris. (A) Eroded plaques are formed following the rupture of confluent, thin-roofed bullae. (B) Suprabasal acantholysis results in an intraepidermal blister in which dyscohesive (acantholytic) epidermal cells are present *(inset)*. (C) Ulcerated blisters in the oral mucosa are also common, as seen here on the lip.

mucosa and skin, especially on the scalp, face, axilla, groin, trunk, and points of pressure. It may present as oral ulcers that may persist for months before skin involvement appears. Primary lesions are superficial vesicles and bullae that rupture easily, leaving shallow erosions covered with dried serum and crust (Fig. 25.29A).

- *Pemphigus vegetans* is a rare form that usually presents not with blisters but with large, moist, verrucous (wart-like), vegetating plaques studded with pustules on the groin, axillae, and flexural surfaces.
- *Pemphigus foliaceus* is a more benign form that is endemic in Brazil (where it is called *fogo selvagem*) and occurs sporadically in other geographic regions. Lesions are most common on the scalp, face, chest, and back; the mucous membranes are only rarely affected. Bullae are so superficial that they mainly present as areas of

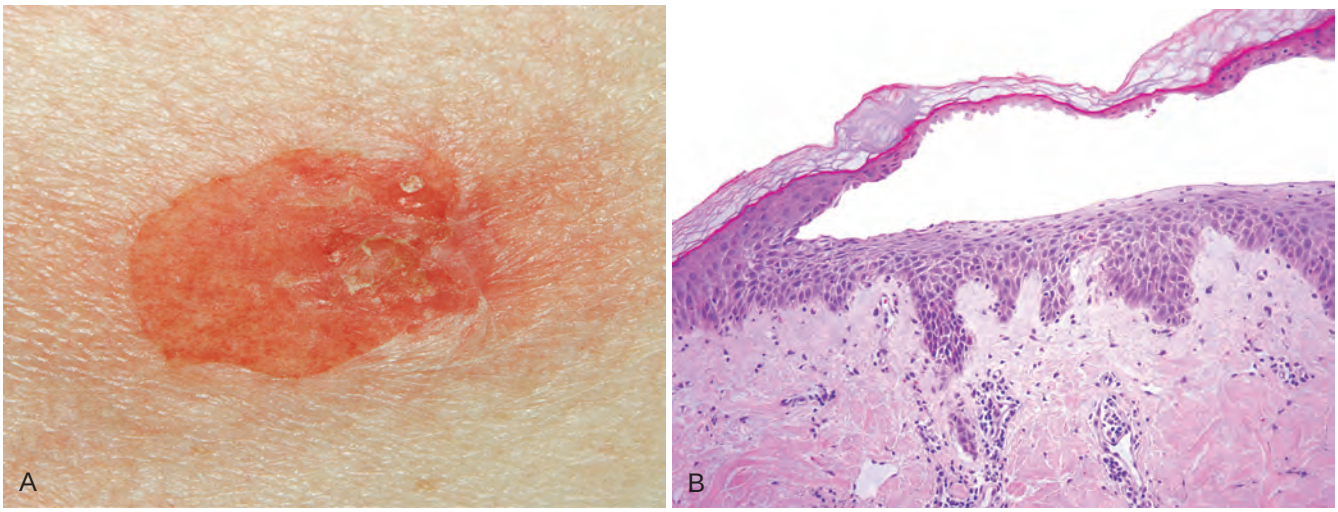

Figure 25.30 Pemphigus foliaceus. (A) The delicate superficial (subcorneal) blisters are much less erosive than those seen in pemphigus vulgaris. (B) Subcorneal separation of the epithelium is seen.

erythema and crusting; these represent superficial erosions at sites of blister rupture (Fig. 25.30A).

- *Pemphigus erythematosus* is considered to be a localized, less severe form of pemphigus foliaceus that may selectively involve the malar area of the face in a lupus erythematosus–like fashion.
- *Paraneoplastic pemphigus* occurs in association with various malignancies, most commonly non-Hodgkin lymphoma.

Pathogenesis

All forms of pemphigus are autoimmune diseases caused by IgG autoantibodies against desmogleins that disrupt intercellular adhesions and result in the formation of blisters. By direct immunofluorescence, lesions show a characteristic net-like pattern of intercellular IgG deposits. IgG is usually seen at all levels of the epithelium in pemphigus vulgaris, but tends to be more superficial in pemphigus foliaceus (Fig. 25.31). The distribution of desmoglein 1 and 3 in the epidermis and whether there are autoantibodies to one or both proteins appear to explain the position and severity of the blisters (see Fig. 25.28). The antibodies cause these lesions primarily by disrupting the intercellular adhesive function of the desmosomes; they may also act indirectly by activating intercellular proteases. Paraneoplastic pemphigus arises most often in the setting of lymphoid neoplasms and is also caused by autoantibodies that recognize desmogleins or other proteins involved in intercellular adhesion.

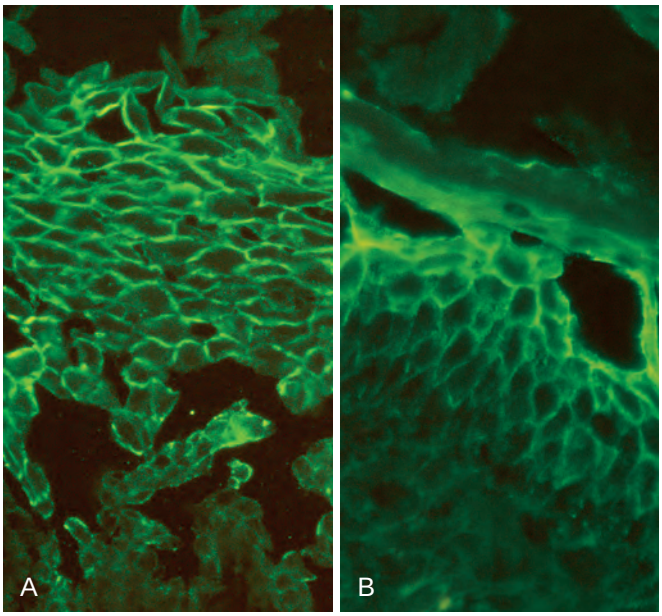

Figure 25.31 Direct immunofluorescence staining for immunoglobulin of epidermis involved by pemphigus. (A) In pemphigus vulgaris there is deposition of immunoglobulin along the plasma membranes of keratinocytes in a reticular or fishnet-like pattern accompanied by suprabasalar loss of cell-to-cell adhesion (acantholysis). (B) In pemphigus foliaceus the immunoglobulin deposits and acantholysis are more superficial.

MORPHOLOGY

The common histologic feature in all forms of pemphigus is **acantholysis,** the dissolution of the intercellular bridges that connect squamous epithelial cells. Acantholytic cells dissociate from one another, lose their polyhedral shape, and become rounded. In pemphigus vulgaris (see Fig. 25.29B) and pemphigus vegetans, acantholysis selectively involves the cells immediately above the basal cell layer, producing a suprabasal blister. In the vegetans variant, there is also overlying epidermal hyperplasia. The single layer of intact basal cells that forms the blister base in pemphigus vulgarus has been likened to a row of tombstones. In pemphigus foliaceus, blisters form by similar mechanisms but are found in the superficial epidermis at the level of the stratum granulosum (see Fig. 25.30B). Variable superficial dermal infiltration by lymphocytes, macrophages, and eosinophils accompanies each type of pemphigus.

The mainstay of treatment in all forms of pemphigus is immunosuppressive agents, which decrease the titers of the pathogenic antibodies.

Bullous Pemphigoid

Generally affecting elderly individuals, bullous pemphigoid shows a wide range of clinical presentations. Sites of involvement include the inner aspects of the thighs, flexor surfaces of the forearms, axillae, groin, and lower abdomen. Oral lesions are present in 10% to 15% of affected individuals, usually appearing after the cutaneous lesions. Some patients present with urticarial plaques and severe pruritus.

MORPHOLOGY

The lesions are tense bullae filled with clear fluid involving erythematous or normal-appearing skin (Fig. 25.32A). The bullae are usually less than 2 cm in diameter but occasionally may reach 4 to 8 cm in diameter. They do not rupture easily, unlike the blisters seen in pemphigus, and heal without scarring unless they become infected secondarily. The separation of bullous pemphigoid from pemphigus is based on the identification of **subepidermal, nonacantholytic** blisters. Early lesions show a superficial and sometimes deep perivascular infiltrate of lymphocytes and variable numbers of eosinophils, occasional neutrophils, superficial dermal edema, and basal cell layer vacuolization (Fig. 25.32B). Eosinophils are typically present directly beneath the epidermal basal cell layer. The vacuolated basal cell layer eventually lifts away, allowing space for a fluid-filled blister to form.

Pathogenesis

Bullous pemphigoid is caused by autoantibodies that bind to proteins that are required for adherence of basal keratinocytes to the basement membrane. Most antibody deposition occurs in a continuous linear pattern at the dermoepidermal junction (Fig. 25.33A), where specialized structures called hemidesmosomes link basal keratinocytes to the underlying basement membrane (Fig. 25.33B). The so-called bullous pemphigoid antigens (BPAGs) are components of hemidesmosomes

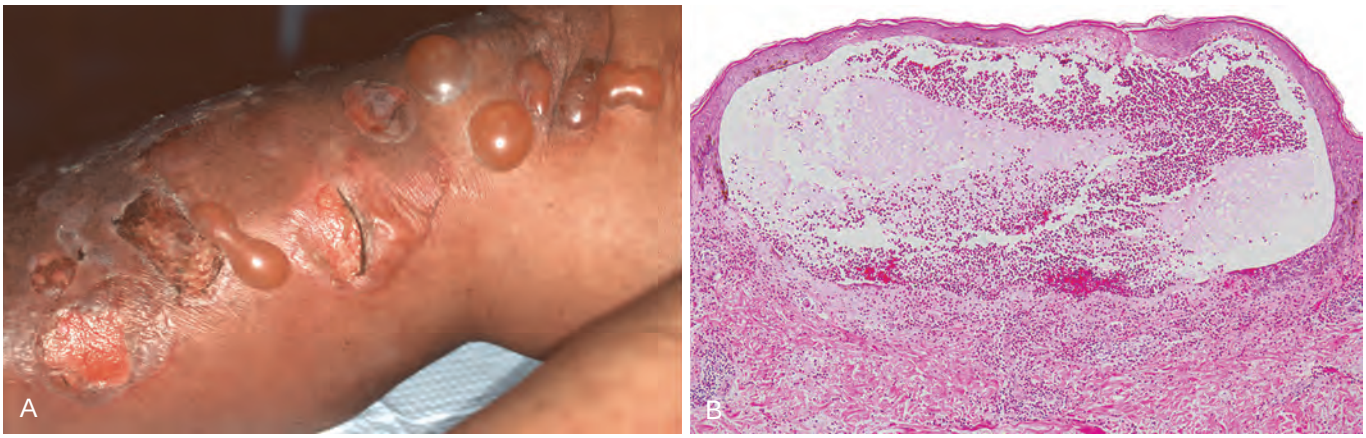

Figure 25.32 Bullous pemphigoid. (A) Bullae consist of tense blisters that usually fail to rupture, as their roof consists of intact epidermis. Ulcers form if the blisters rupture. (B) Intact subepidermal blister associated with eosinophils, lymphocytes, and occasional neutrophils.

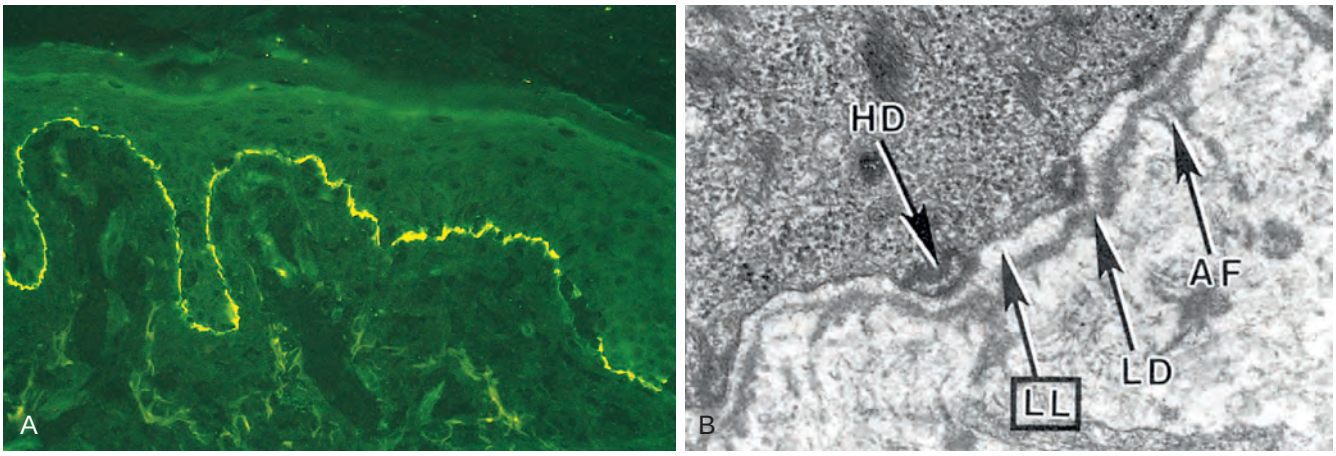

Figure 25.33 (A) Linear deposition of complement along the dermoepidermal junction in bullous pemphigoid. (B) Electron micrograph showing the ultrastructural features of the dermoepidermal junction. The bullous pemphigoid antigen (BPAG) is located in the basal portion of basal keratinocytes in association with hemidesmosomes *(HD)*, which attach the epidermis to the lamina lucida *(LL)* of the basement membrane. *AF,* Anchoring fibrils; *LD,* lamina densa. (See also Fig. 25.31.)

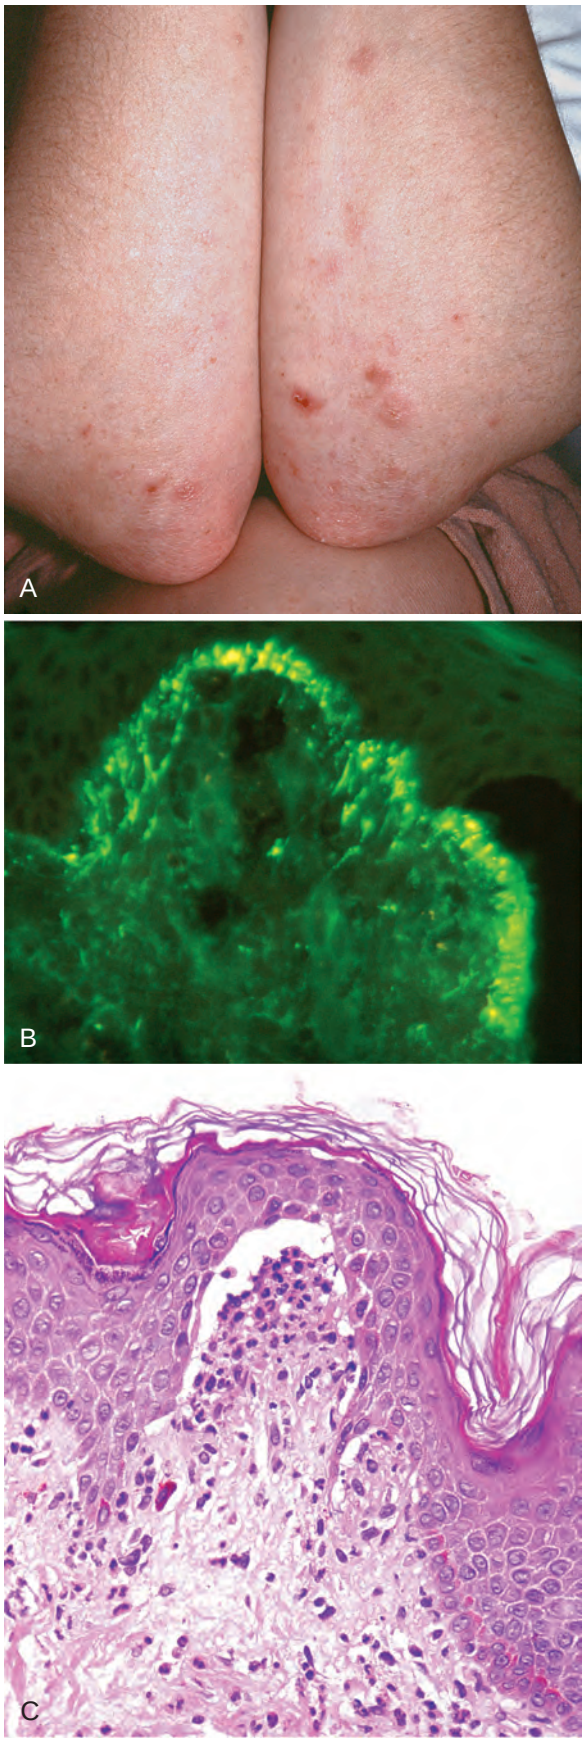

Figure 25.34 Dermatitis herpetiformis. (A) Lesions consist of groups of intact and eroded erythematous blisters (seen here on elbows and arms). (B) Selective deposition of IgA autoantibody at the tips of dermal papillae is characteristic. (C) The blisters are associated with the accumulation of neutrophils (microabscesses) at the tips of dermal papillae. (B, Courtesy Dr. Victor G. Prieto, Houston, Tex.)

(see Fig. 25.29). Antibodies against one such component called BPAG2 are proven to cause blistering. Pathogenic autoantibodies also activate complement, leading to the recruitment of neutrophils and eosinophils, inflammation, and disruption of epidermal attachments.

Dermatitis Herpetiformis

Dermatitis herpetiformis is a rare disorder characterized by urticaria and grouped vesicles. The disease affects predominantly males, most often in the third and fourth decades of life. In some cases it occurs in association with intestinal celiac disease (Chapter 17). The plaques and vesicles are extremely pruritic.

Pathogenesis

The association of dermatitis herpetiformis with celiac disease provides a clue to its pathogenesis. Genetically predisposed individuals develop IgA antibodies to dietary gluten (derived from the wheat protein gliadin). The antibodies cross-react with reticulin, a component of the anchoring fibrils that tether the epidermal basement membrane to the superficial dermis. The resultant injury and inflammation produce a subepidermal blister. In some people with dermatitis herpetiformis and gluten-sensitive enteropathy, both disorders respond to a gluten-free diet.

MORPHOLOGY

The lesions are bilateral, symmetric, and grouped, involving preferentially the extensor surfaces, elbows, knees, upper back, and buttocks (Fig. 25.34C). Fibrin and neutrophils accumulate selectively at the **tips of dermal papillae,** forming small microabscesses (Fig. 25.34A). The basal cells overlying these microabscesses show vacuolization and focal dermoepidermal separation that ultimately coalesce to form a true **subepidermal blister.** By direct immunofluorescence, dermatitis herpetiformis shows discontinuous, **granular deposits of IgA** that selectively localize in the tips of dermal papillae (Fig. 25.34B).

Noninflammatory Blistering Disorders

Epidermolysis Bullosa and Porphyria

Some disorders characterized by vesicles and bullae are mediated by inherited or, in some cases, acquired defects involving structural proteins that maintain the integrity of the skin. Two such disorders are epidermolysis bullosa and porphyria.

Epidermolysis Bullosa. Epidermolysis bullosa is a blanket term for a group of disorders caused by inherited defects

Figure 25.35 Epidermolysis bullosa. (A) Junctional epidermolysis bullosa showing typical erosions in flexural creases. (B) Subepidermal blister at the level of the lamina lucida. There is no associated inflammation.

in structural proteins that lend mechanical stability to the skin. The common feature is a proclivity to form blisters at sites of pressure, rubbing, or trauma, at or soon after birth. The histologic changes in all forms are so subtle that electron microscopy may be required to differentiate among the various types.

- In the *simplex type,* defects of the basal cell layer of the epidermis almost always result from mutations in the genes encoding keratin 14 or keratin 5. These two proteins normally pair with one another to make a functional keratin fiber, thus explaining the similar phenotype resulting from mutations in either gene. The mutated proteins have a dominant negative activity, and as a result the disorder shows an autosomal dominant mode of inheritance. This is the most common type of epidermolysis bullosa, encompassing 75% to 85% of cases.
- In the *junctional type,* blisters occur in otherwise histologically normal skin at precisely the level of the lamina lucida (Fig. 25.35; see Fig. 25.28). Most cases are caused by autosomal recessive defects in one of the subunits of laminin, a multicomponent protein located in the lamina lucida that binds to both hemidesmosomes and anchoring filaments. Some of the remaining cases are caused by mutations in BPAG2, the same protein that is targeted by autoantibodies in bullous pemphigoid.
- In the scarring *dystrophic types,* blisters develop beneath the lamina densa in association with rudimentary or defective anchoring fibrils. Dystrophic epidermolysis bullosa usually results from mutations in the *COL7A1* gene, which encodes type VII collagen (Chapter 3), a major component of the basement membrane anchoring fibrils. Depending on the mutation, the disorder may follow an autosomal dominant or autosomal recessive mode of inheritance.
- *Mixed types,* marked by defects at several levels, are also recognized.

Porphyria. Porphyria refers to a group of uncommon inborn or acquired disturbances of porphyrin metabolism. Porphyrins are pigments that are normally present in hemoglobin, myoglobin, and cytochromes. The classification of porphyria is based on both clinical and biochemical features. The five major types are (1) congenital erythropoietic porphyria, (2) erythrohepatic protoporphyria, (3) acute intermittent porphyria, (4) porphyria cutanea tarda, and (5) mixed porphyria. Cutaneous manifestations consist of urticaria and vesicles associated with scarring that are exacerbated by exposure to sunlight. The vesicles are subepidermal in location, and the adjacent dermis contains vessels with walls that are thickened by glassy deposits of serum proteins, including immunoglobulins (Fig. 25.36). The pathogenesis of these alterations is not understood.

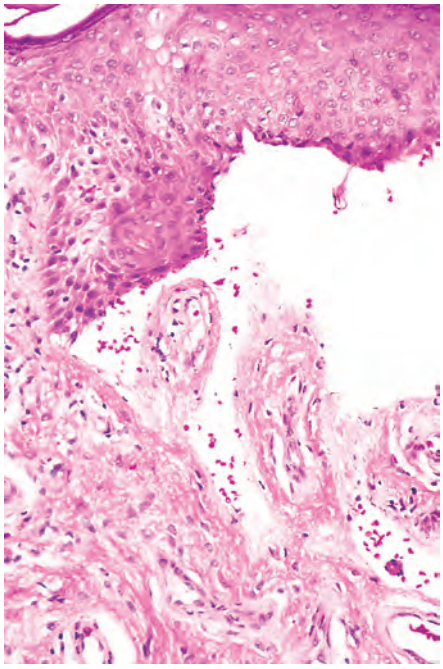

Figure 25.36 Porphyria. A noninflammatory blister at the dermoepidermal junction; note the seemingly rigid dermal papillae at the base that contain abnormal superficial vessels.

KEY CONCEPTS

BLISTERING DISORDERS

- Blistering disorders are classified based on the level of epidermal separation.

- These disorders are often caused by autoantibodies specific for epithelial or basement membrane proteins that lead to unmooring of keratinocytes (acantholysis).
- Pemphigus is associated with IgG autoantibodies to various intercellular desmogleins, resulting in bullae that are either subcorneal (pemphigus foliaceus) or suprabasilar (pemphigus vulgaris).
- Bullous pemphigoid is associated with IgG autoantibodies to basement membrane proteins and produces a subepidermal blister.
- Dermatitis herpetiformis is associated with IgA autoantibodies to fibrils that bind the epidermal basement membrane to the dermis and also produces subepidermal blisters.
- Noninflammatory blistering disorders include inherited defects in proteins that stabilize the epidermis (e.g., epidermolysis bullosa), as well as defects in porphyrin synthesis (the porphyrias) that lead to sun-induced skin damage through uncertain mechanisms.

DISORDERS OF EPIDERMAL APPENDAGES

Acne Vulgaris

Virtually universal in the middle to late teenage years, acne vulgaris affects males and females, with males tending to have more severe disease. Acne is seen in all races but is usually milder in people of Asian descent. It may be induced or exacerbated by drugs (corticosteroids, adrenocorticotropic hormone, testosterone, gonadotropins, contraceptives, trimethadione, iodides, and bromides), occupational exposures (cutting oils, chlorinated hydrocarbons, and coal tars), and conditions that favor occlusion of sebaceous glands, such as heavy clothing, cosmetics, and tropical climates. Some families seem to be particularly prone to acne, suggesting a hereditary component.

Acne is divided into noninflammatory and inflammatory types, although both types may coexist. Noninflammatory acne may take the form of open and closed comedones.

- *Open comedones* are small follicular papules containing a central black keratin plug. This color is the result of oxidation of melanin pigment (not dirt).
- *Closed comedones* are follicular papules without a visible central plug. Because the keratin plug is trapped beneath the epidermal surface, these lesions are potential sources of follicle rupture and inflammation.

Pathogenesis

The pathogenesis of acne is incompletely understood and is likely multifactorial. At least four factors contribute to its development: (1) keratinization of the lower portion of the follicular infundibulum and development of a keratin plug that blocks outflow of sebum to the skin surface; (2) hypertrophy of sebaceous glands during puberty under the influence of androgens; (3) lipase-synthesizing bacteria *(Propionibacterium acnes)* colonizing the upper and mid-portion of the hair follicle, converting lipids within sebum to proinflammatory fatty acids; and (4) secondary inflammation of the involved follicle. Androgens were first implicated in times past when it was noted that young castrated males generally did not develop the condition (a questionable tradeoff). Elimination of *P. acnes* is the rationale for administration of antibiotics to individuals with inflammatory acne. The synthetic vitamin A derivative 13-*cis*-retinoic acid (isotretinoin) brings about remarkable improvement in some cases of severe acne through its strong antisebaceous action.

MORPHOLOGY

Inflammatory acne is marked by erythematous papules, nodules, and pustules (Fig. 25.37A). Severe variants (e.g., **acne conglobata**) result in sinus tract formation and dermal scarring. Depending on the stage of the disease, open or closed comedones, papules, pustules, or deep inflammatory nodules may develop. **Open comedones** have large, patulous orifices, whereas the orifices of **closed comedones** are identifiable only microscopically (Fig. 25.37B, C). Variable infiltrates of lymphocytes and macrophages are present in and around affected follicles, and extensive acute inflammation accompanies follicle rupture. Dermal abscesses may form in association with rupture (Fig. 25.37B) and lead to scarring.

Rosacea

Rosacea is a common disease of middle age and beyond, affecting up to 3% of the U.S. population, with a predilection for females. Four stages are recognized: (1) flushing episodes (pre-rosacea), (2) persistent erythema and telangiectasia, (3) pustules and papules, and (4) rhinophyma (permanent thickening of the nasal skin by confluent erythematous papules and prominent follicles).

Pathogenesis

A clue to the cause comes from observations showing that individuals with rosacea have high cutaneous levels of the antimicrobial peptide cathelicidin, an important mediator of the cutaneous innate immune response. The cathelicidin peptides present in affected individuals are qualitatively distinct from those seen in individuals without rosacea as a result of alternative processing by proteases such as kallikrein 5 (also known as stratum corneum tryptic enzyme). Injection of cathelicidin peptides from patients into mice induces some of the cutaneous changes seen in rosacea, including inflammation and vascular dilation. In addition, it has been noted that activation of TLR2 upregulates kallikrein 5 expression in keratinocytes, suggesting that factors that stimulate TLR2 are involved. Several microbial triggers have been proposed, but none are proven.

MORPHOLOGY

Rosacea is characterized by a nonspecific perifollicular infiltrate composed of lymphocytes surrounded by dermal edema and telangiectasia. In the pustular phase, neutrophils may colonize the follicles, and folicle rupture may occur and cause a granulomatous dermal response. The development of rhinophyma is associated with hypertrophy of sebaceous glands and follicular plugging by keratotic debris.

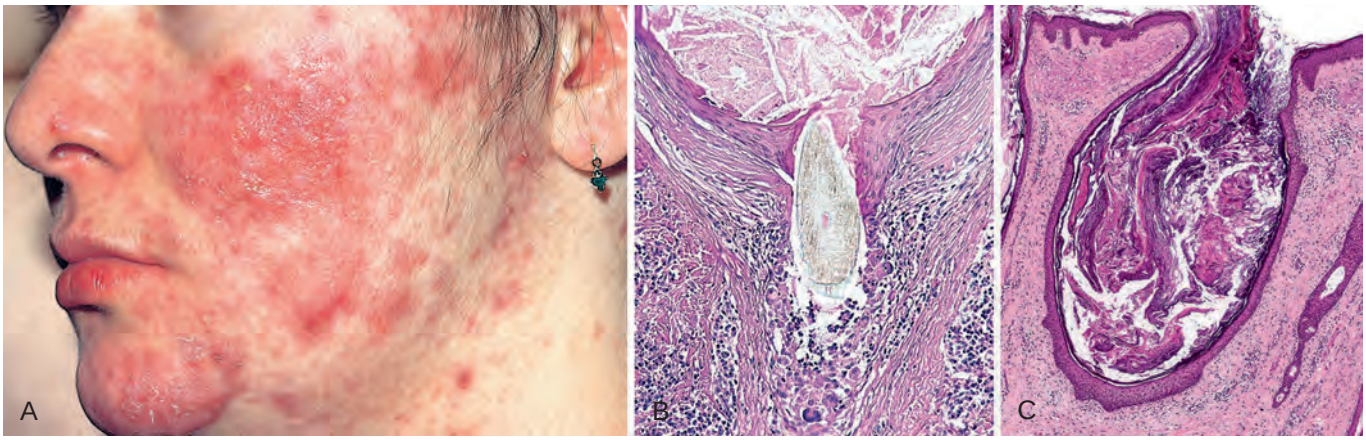

Figure 25.37 Acne. (A) Inflammatory acne associated with erythematous papules and pustules. (B) A hair shaft pierces the follicular epithelium, eliciting inflammation and fibrosis. (C) An open comedone.

PANNICULITIS

Erythema Nodosum and Erythema Induratum

Panniculitis is an inflammatory reaction in the subcutaneous adipose tissue that may preferentially affect (1) the lobules of fat or (2) the connective tissue that separates fat into lobules. Panniculitis often involves the lower legs. *Erythema nodosum* is the most common form and usually has a subacute presentation. A second somewhat distinctive form, erythema induratum, also merits brief discussion.

- *Erythema nodosum* presents as poorly defined, exquisitely tender, erythematous plaques and nodules that may be more readily palpated than seen. Its occurrence is often associated with infections (β-hemolytic streptococcal infection and tuberculosis and, less commonly, coccidioidomycosis, histoplasmosis, and leprosy), drug administration (sulfonamides and oral contraceptives), sarcoidosis, inflammatory bowel disease, and certain malignant neoplasms, but many times a cause cannot be identified. Fever and malaise may accompany the cutaneous signs. It is thought to be caused by a delayed hypersensitivity reaction to microbial or drug-related antigens. In some cases, immune complexes have been implicated, but in many cases the pathogenesis is mysterious. Over the course of weeks, lesions usually flatten and become bruise-like, leaving no residual clinical scars, while new lesions develop. Biopsy of a deep wedge of tissue to generously sample the subcutis is usually required for histologic diagnosis.
- *Erythema induratum* is an uncommon type of panniculitis that affects primarily adolescents and menopausal women. Although the cause is not known, most observers regard this as a primary vasculitis of deep vessels supplying the fat lobules of the subcutis; the associated vascular compromise leads to fat necrosis and inflammation. Erythema induratum presents as an erythematous, slightly tender nodule that usually goes on to ulcerate. Originally considered a hypersensitivity response to tuberculosis, erythema induratum today most commonly occurs without an associated underlying disease.

MORPHOLOGY

The histopathology of **erythema nodosum** is distinctive. In early lesions the connective tissue septa are widened by edema, fibrin exudation, and neutrophilic infiltration. Later, infiltration by lymphocytes, histiocytes, multinucleated giant cells, and occasional eosinophils is associated with septal fibrosis. Vasculitis is not present. In **erythema induratum,** on the other hand, granulomatous inflammation and zones of caseous necrosis involve the fat lobule. Early lesions show necrotizing vasculitis affecting small- to medium-sized arteries and veins in the deep dermis and subcutis.

Other Types of Panniculitis

Many other types of panniculitis have also been described, a few of which merit brief mention.

- *Weber-Christian disease (relapsing febrile nodular panniculitis)* is a rare form of lobular, nonvasculitic panniculitis seen in children and adults. It is marked by crops of erythematous plaques or nodules, predominantly on the lower extremities, created by deep-seated foci of inflammation containing aggregates of foamy macrophages admixed with lymphocytes, neutrophils, and giant cells.
- *Factitial panniculitis* is a form of secondary panniculitis caused by self-inflicted trauma or injection of foreign or toxic substances.
- Rare types of *T-cell lymphoma* home to fat lobules, producing fat necrosis and superimposed inflammation that mimics panniculitis.
- *Systemic lupus erythematosus* may occasionally cause inflammation of the subcutis and an associated panniculitis.

INFECTION

Despite its ample protective mechanisms, the exposure of the skin to frequent trauma and the external environment leaves it vulnerable to infection by microorganisms, parasites, and insects. We have already discussed the possible role of bacteria in the pathogenesis of common acne, and the

dermatoses resulting from viruses are too numerous to list. In the setting of the immunocompromised individual, ordinarily trivial cutaneous infections may become life threatening. Many disorders, such as herpes simplex and herpes zoster, viral exanthems, deep fungal infections, and immune reactions in skin provoked by infectious agents, are discussed in Chapter 8. Here we cover a representative sampling of common infections whose primary clinical manifestations are in the skin.

Verrucae (Warts)

Verrucae are squamoproliferative lesions caused by human papillomaviruses (HPVs). They are common lesions of children and adolescents, although they may be encountered at any age. Transmission of disease usually involves direct contact between individuals or autoinoculation. Verrucae are generally self-limited, regressing spontaneously within 6 months to 2 years.

Pathogenesis

More than 150 types of papillomavirus have been identified, many of them capable of producing warts in humans. The clinical variants of warts are often associated with distinct HPV subtypes. For example, anogenital warts are caused predominantly by HPV types 6 and 11. HPV type 16 has been associated with in situ squamous cell carcinoma of the genitalia and with bowenoid papulosis; the latter is a genital lesion of young adults with the histologic appearance of carcinoma in situ, but which usually regresses spontaneously (see also Chapter 21). The relationship of HPV subtypes 5 and 8 to squamous cell carcinomas, particularly in individuals affected by the rare condition epidermodysplasia verruciformis, was mentioned earlier. These patients develop multiple flat warts that contain HPV genomes, some of which progress to carcinoma. Viral typing can be accomplished by either in situ hybridization (Fig. 25.38D) or polymerase chain reaction.

HPVs that are associated with a high risk of cancer produce E6 proteins that abolish p53 function (Chapter 7). By contrast, HPV subtypes 5 and 8 produce variant E6 proteins that do not affect p53, explaining why these forms of HPV have low oncogenic potential. By contrast, the E6 proteins of low-risk HPVs interfere with Notch signaling, which is required for the normal maturation of keratinocytes; this effect likely contributes to the epidermal hyperplasia that characterizes warts.

MORPHOLOGY

The classification of verrucae is based largely on appearance and location. **Verruca vulgaris** is the most common type of wart. The lesions of verruca vulgaris may occur anywhere but are most often found on the hands, particularly on the dorsal surfaces and periungual areas, where they appear as gray-white to tan, flat to

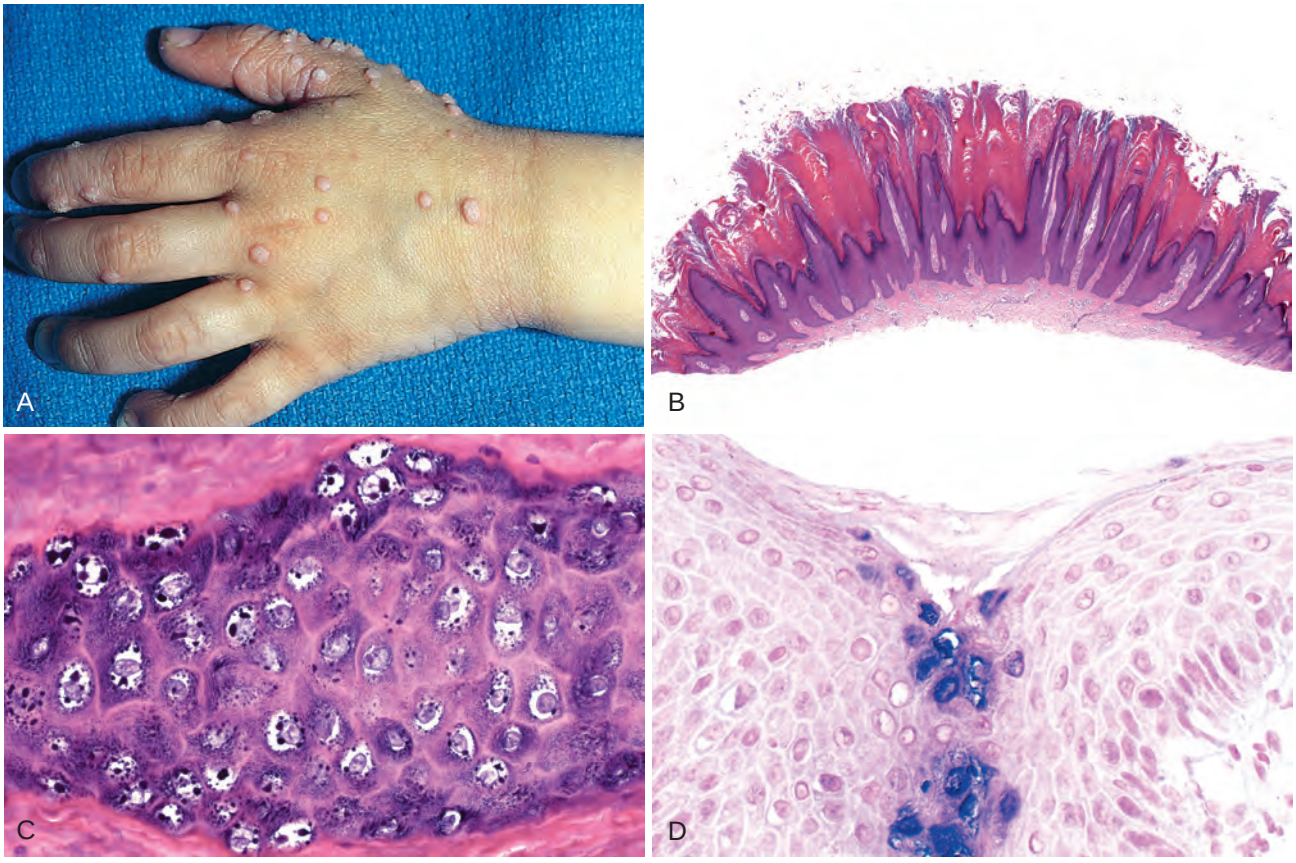

Figure 25.38 Verruca vulgaris. (A) Multiple papules with rough pebble-like surfaces. Low-power (B) and high-power (C) lesions showing papillomatous epidermal hyperplasia and cytopathic alterations including nuclear pallor and prominent keratohyaline granules. (D) In situ hybridization demonstrating human papillomavirus DNA within epidermal cells.

convex, 0.1- to 1-cm papules with a rough, pebble-like surface (Fig. 25.38A). **Verruca plana,** or **flat wart,** is common on the face or the dorsal surfaces of the hands. The warts are slightly elevated, flat, smooth, tan papules that are generally smaller than verruca vulgaris. **Verruca plantaris** and **verruca palmaris** occur on the soles and palms, respectively. These rough, scaly lesions may reach 1 to 2 cm in diameter, may sometimes coalesce, and may be confused with ordinary calluses. **Condyloma acuminatum (venereal wart)** occurs on the penis, female genitalia, urethra, perianal areas, and rectum. Venereal warts appear as soft, tan, cauliflower-like masses that occasionally reach many centimeters in diameter.

Histologic features common to verrucae include epidermal hyperplasia that is often undulant or spire-like in character, termed **verrucous** or **papillomatous epidermal hyperplasia** (Fig. 25.38B), and **cytoplasmic vacuolization (koilocytosis)** involving the more superficial epidermal layers, producing haloes of pallor surrounding infected nuclei. Electron microscopy of these zones reveals numerous HPV virions within nuclei. Infected cells may also demonstrate prominent, condensed keratohyaline granules and jagged eosinophilic intracytoplasmic keratin aggregates as a result of viral cytopathic effects (Fig. 25.38C). These cellular alterations are not as prominent in condylomas; hence, their diagnosis is based primarily on hyperplastic papillary architecture containing wedge-shaped zones of koilocytosis.

Molluscum Contagiosum

Molluscum contagiosum is a common, self-limited viral disease of the skin caused by a poxvirus. The virus is characteristically brick shaped, has a dumbbell-shaped DNA core, and measures 300 nm in maximal dimension, making it one of the largest pathogenic poxviruses in humans and one of the largest viruses in nature. Infection is usually spread by direct contact, particularly among children and young adults.

MORPHOLOGY

Multiple lesions may occur on the skin and mucous membranes, with a predilection for the trunk and anogenital areas. Individual lesions are firm, often pruritic, pink to skin-colored umbilicated papules, generally ranging in diameter from 0.2 to 0.4 cm. Rarely, "giant" forms occur measuring up to 2 cm in diameter. A curd-like material can be expressed from the central umbilication. Smearing this material onto a glass slide and staining with Giemsa often shows diagnostic molluscum bodies.

On microscopic examination, lesions show cup-like verrucous epidermal hyperplasia. The diagnostically specific structure is the **molluscum body,** which is a large (up to 35 μm), ellipsoid, homogeneous, cytoplasmic inclusion that is found in the cells of the stratum granulosum and the stratum corneum (Fig. 25.39). In hematoxylin and eosin stains, the inclusions are eosinophilic in the stratum granulosum and acquire a pale blue hue in the stratum corneum. Numerous virions are present within molluscum bodies.

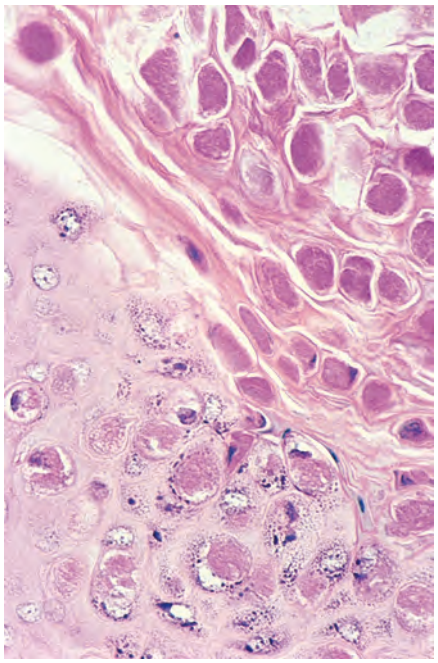

Figure 25.39 Molluscum contagiosum. A focus of verrucous epidermal hyperplasia contains numerous cells with ellipsoid cytoplasmic inclusions (molluscum bodies) within the stratum granulosum and stratum corneum.

Impetigo

Impetigo is a common superficial bacterial infection of skin. It is highly contagious and is frequently seen in otherwise healthy children as well as occasionally in adults in poor health. The infection usually involves exposed skin, particularly that of the face and hands. Two forms exist, classically referred to as *impetigo contagiosa* and *impetigo bullosa;* they differ from each other simply by the size of the pustules. Over the past several decades a remarkable shift in etiology has been observed. Whereas in the past impetigo contagiosa was almost exclusively caused by group A β-hemolytic streptococci and impetigo bullosa by *Staphylococcus aureus,* both are now usually caused by *S. aureus.*

Pathogenesis

Bacteria in the epidermis evoke an innate immune response that causes epidermal injury, leading to local serous exudate and formation of a scale crust (scab). The pathogenesis of blister formation in impetigo is related to bacterial production of a toxin that specifically cleaves desmoglein 1, the protein responsible for cell-to-cell adhesion within the uppermost epidermal layers. Recall that in pemphigus foliaceus, which has a similar plane of blister formation, desmoglein 1 is compromised not by a toxin but by an autoantibody (see Fig. 25.28). Because there is virtually no involvement of the dermis, once the bacteria are eliminated the lesions heal without scarring.

MORPHOLOGY

Impetigo presents as an erythematous macule, but multiple small pustules rapidly supervene. As pustules break, shallow erosions

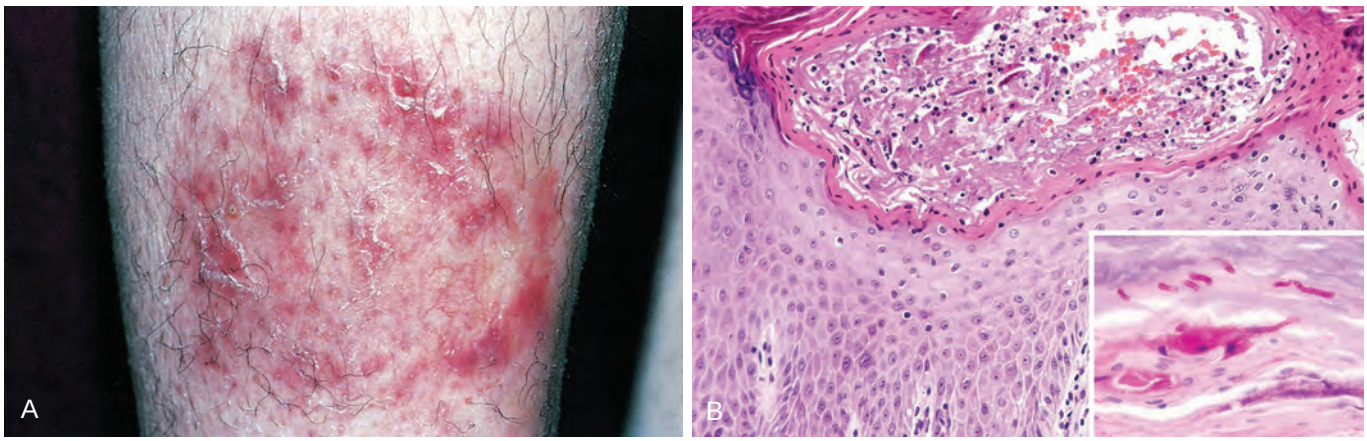

Figure 25.40 Tinea. (A) Characteristic plaque of tinea corporis. (B) Routine histology shows a mild eczematous (spongiotic) dermatitis and focal neutrophilic abscesses. Periodic acid–Schiff stain *(inset)* reveals deep red hyphae within the stratum corneum.

form, covered with drying serum, giving the characteristic appearance of **honey-colored crust.** If the crust is not removed, new lesions form about the periphery, and extensive epidermal damage may ensue. A bullous form of impetigo mainly occurs in children.

The characteristic microscopic feature of impetigo is **accumulation of neutrophils beneath the stratum corneum,** often producing a subcorneal pustule containing serum proteins and inflammatory cells. Special stains reveal the presence of bacteria in these foci. Nonspecific, reactive epidermal alterations and superficial dermal inflammation accompany these findings. Rupture of pustules releases serum, neutrophils, and cellular debris, which layer out and dry to form the characteristic crust.

Superficial Fungal Infections

As opposed to deep fungal infections of the skin, where the dermis or subcutis is primarily involved, superficial fungal infections of the skin are confined to the stratum corneum and are caused primarily by dermatophytes. These organisms grow in the soil and on animals and produce a number of diverse lesions with characteristic distributions, as follows:

- *Tinea capitis* usually occurs in children and is only rarely seen in infants and adults. It is a dermatophytosis of the scalp characterized by asymptomatic, patchy skin lesions associated with mild erythema, crust formation, scaling, and frequent hair loss.
- *Tinea barbae* is a dermatophyte infection of the beard area that affects adult men; it is relatively uncommon.
- *Tinea corporis,* on the other hand, is a common superficial fungal infection of skin that affects persons of all ages, but particularly children. Predisposing factors include excessive heat and humidity, exposure to infected animals, and chronic dermatophytosis of the feet or nails. The most common type of tinea corporis is an expanding, round, slightly erythematous plaque with an elevated scaling border (Fig. 25.40A).
- *Tinea cruris* occurs most frequently in the inguinal areas of obese men during warm weather. Heat, friction, and maceration all predispose to its development. The infection usually first appears on the upper inner thighs as moist, red patches with raised scaly borders.
- *Tinea pedis (athlete's foot)* affects 30% to 40% of the population at some time in their lives. There is diffuse erythema and scaling, often initially localized to the web spaces. Most of the inflammatory reaction, however, appears to be the result of bacterial superinfection and is not directly related to the primary dermatophytosis. Spread to (or primary infection of the nails) is referred to as *onychomycosis*. This produces discoloration, thickening, and deformity of the nail plate.
- *Tinea versicolor* usually occurs on the upper trunk and is highly distinctive in appearance. Caused by *Malassezia furfur* (a yeast, not a dermatophyte), the lesions consist of groups of macules of varied size and color with a fine peripheral scale.

MORPHOLOGY

The histologic features of dermatophytoses are variable, depending on the properties of the organism, the host response, and the degree of bacterial superinfection. There may be mild eczematous dermatitis associated with intraepidermal neutrophils (Fig. 25.40B). Due to cell walls rich in mucopolysaccharides, fungi stain bright pink to red with periodic acid–Schiff stain. They are found in the anucleate cornified layer of lesional skin, hair, or nails (Fig. 25.40B, *inset*). Culture of material scraped from these areas usually permits identification of the offending species.

CHAPTER 26

Bones, Joints, and Soft Tissue Tumors

Andrew Horvai

CHAPTER CONTENTS

Bone

BASIC STRUCTURE AND FUNCTION OF BONE

The adult human skeleton is composed of 206 bones that account for ~12% of body weight. Bone functions include mechanical support, force transmission, internal organ protection, and mineral homeostasis, and it also serves as the major site of hematopoiesis during postnatal life. Bone consists of extracellular matrix and several cell types.

Matrix

The extracellular component of bone, the matrix, is composed of osteoid (35%) and minerals (65%). The latter,

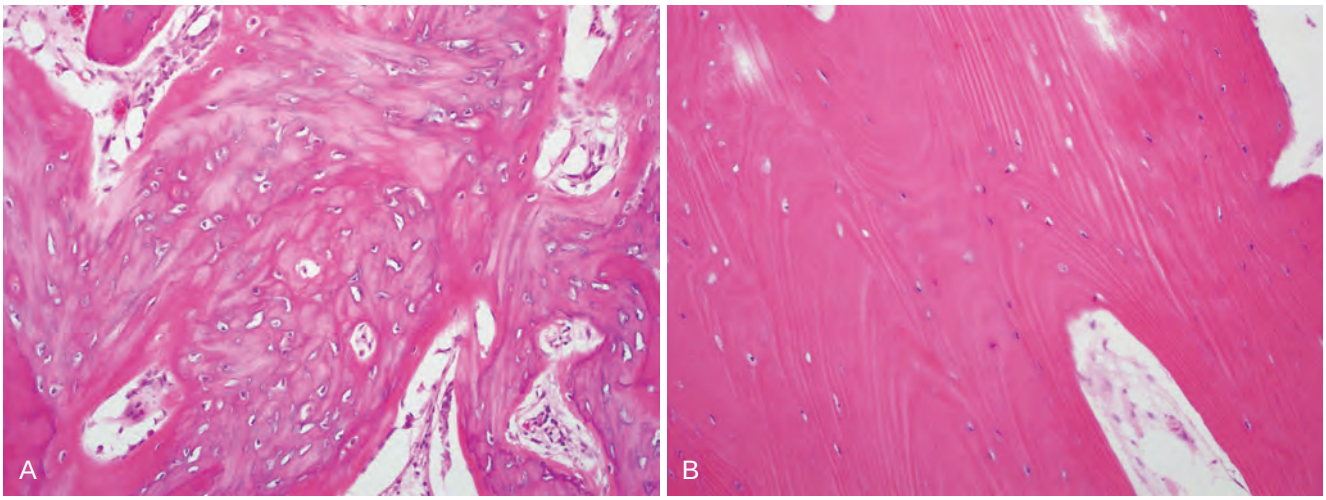

Figure 26.1 (A) Woven bone. (B) Lamellar bone contrasts with the more cellular, disorganized appearance of woven bone.

primarily hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], give bone its hardness and serves as a repository for 99% of the calcium and 85% of the phosphorus in the body.

Osteoid consists of type I collagen and smaller amounts of glycosaminoglycans and other proteins. One of these proteins, osteopontin (also called osteocalcin), is produced by osteoblasts and contributes to the regulation of bone formation, mineralization, and calcium homeostasis. Serum osteopontin levels are used as a specific marker of osteoblast activity. Bone maturation and metabolism are also sensitive to cytokines and growth factors and are thus regulated by diverse inputs, which include locally and systemically produced factors, as well as mechanical force.

Bone matrix can be woven or lamellar (Fig. 26.1). Woven bone is produced rapidly (e.g., during fetal development or fracture repair), but the haphazard arrangement of collagen fibers imparts less structural integrity than the parallel collagen fibers of lamellar bone. Woven bone is always abnormal in adults, but its presence is not specific for any particular disease. Long bones are composed of a dense outer cortex and a central medulla. The latter is supported by bony trabeculae interspersed with marrow, which may be fatty (white) or hematopoietic (red).

Cells

The cellular components of bone include osteoblasts, osteocytes, and osteoclasts.

- *Osteoblasts* on the surface of the osteoid matrix synthesize, transport, and assemble matrix and regulate mineralization (Fig. 26.2A). Osteoblast activity is tightly regulated by hormonal and local mediators. Quiescent osteoblasts, which can be recognized by a decrease in cytoplasmic volume, may remain on the trabecular surface or become embedded within the matrix as osteocytes.
- *Osteocytes* are interconnected by an intricate network of dendritic cytoplasmic processes through tunnels (canaliculi) within the matrix. Osteocytes help control calcium and phosphate levels in the microenvironment, detect mechanical forces, and translate those forces into biologic activity—a process called mechanotransduction.

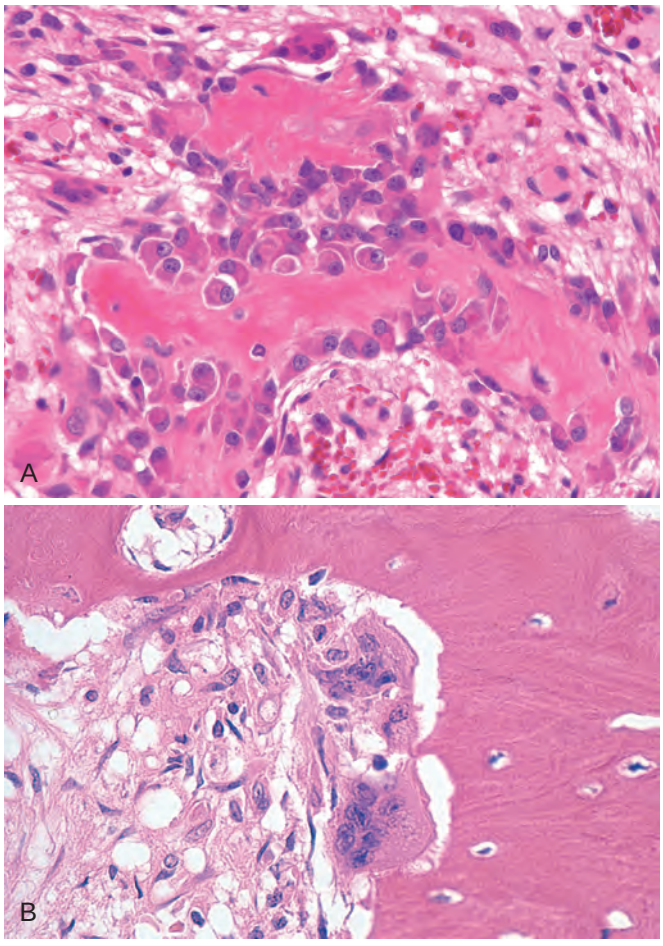

Figure 26.2 (A) Active osteoblasts synthesizing bone matrix. The surrounding spindle cells represent osteoprogenitor cells. (B) Two osteoclasts resorbing bone.

- *Osteoclasts* are specialized multinucleated macrophages that are derived from circulating monocytes and resorb bone (Fig. 26.2B). Surface integrin proteins allow osteoclasts to attach to the matrix and create a sealed extracellular trench (resorption pit). Secretion of acid and neutral

proteases, predominantly matrix metalloproteases (MMPs), into the pit results in dissolution of inorganic and organic bone components.

Development

Most bones that form during embryogenesis develop from a cartilage mold via endochondral ossification. The cartilage mold (anlagen) is synthesized by mesenchymal precursor cells. A central medullary canal within the anlagen is created by chondroblasts at approximately 8 weeks of gestation. Simultaneously, osteoblasts begin to deposit the cortex beneath the nascent periosteum of the midshaft (diaphysis). This forms a primary center of ossification resulting in radial bone growth. At the longitudinal ends (epiphysis), endochondral ossification forms secondary centers of ossification. Eventually, plates of cartilage anlage become entrapped between the expanding centers of ossification forming physes or growth plates (Fig. 26.3). Chondrocytes within the growth plates undergo sequential proliferation, hypertrophy, and apoptosis. Matrix mineralizes during apoptosis and is invaded by capillaries, providing the nutrients for activation of osteoblasts and osteoid synthesis. Most calcified cartilage matrix is ultimately resorbed leaving only strut-shaped remnants that serve as scaffolding for bone deposits known as primary spongiosa, the earliest bone trabeculae (see Fig. 26.3). Over time, this process produces longitudinal bone growth.

Flat bones, for example the cranium, are formed by intramembranous ossification, in which a dense layer of mesenchyme is directly ossified by osteoblasts without a cartilage anlagen. Bones enlarge by deposition of new bone on a preexisting surface, a process called appositional growth.

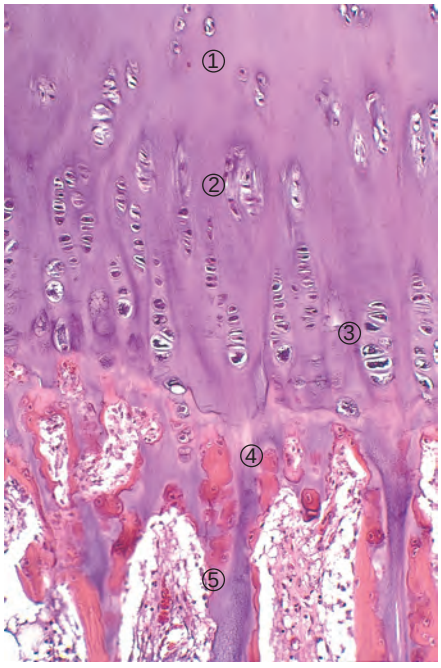

Figure 26.3 Active growth plate with ongoing endochondral ossification. 1, Reserve zone. 2, Zone of proliferation. 3, Zone of hypertrophy. 4, Zone of mineralization. 5, Primary spongiosa.

Local and systemic factors that regulate bone development include the following:

- Growth hormone (GH) secreted by the anterior pituitary gland induces and maintains chondrocyte proliferation.
- Thyroid hormone secreted by the thyroid gland acts on proliferating chondrocytes to induce hypertrophy.
- Indian hedgehog (Ihh) is secreted locally by prehypertrophic chondrocytes and coordinates chondrocyte proliferation and differentiation with osteoblast proliferation.
- Parathyroid hormone–related protein (PTHrP) produced by perichondrial stromal cells and early proliferating chondrocytes activates the PTH receptor to maintain chondrocyte proliferation.
- Wnt growth factors are expressed in the growth plate–proliferating zone and, via Frizzled and LRP5/6 receptors, activate β-catenin to promote chondrocyte proliferation and maturation.
- SOX9 is a transcription factor expressed by proliferating, but not hypertrophic, chondrocytes that is essential for differentiation of chondrocyte precursors.
- RUNX2 is a transcription factor expressed in early hypertrophic chondrocytes and immature mesenchymal cells that controls terminal chondrocyte and osteoblast differentiation.
- Fibroblast growth factors (FGFs) are secreted by a variety of mesenchymal cells. FGFs (most notably FGF-3) act on hypertrophic chondrocytes to inhibit proliferation and promote differentiation.
- Bone morphogenic proteins (BMPs), members of the TGF-β family, are expressed at various stages of chondrocyte development and have diverse effects on chondrocyte proliferation and hypertrophy at the growth plate.

Homeostasis and Remodeling

The adult skeleton appears static but actually undergoes continuous change via a tightly regulated process known as remodeling. This process, which turns over approximately 10% of the skeleton each year, repairs damage, and may change the shape of bones in response to mechanical forces. Remodeling occurs within the *bone (*or *basic) multicellular unit (BMU),* which consists of a unit of coupled osteoblast and osteoclast activity on the bone surface. Osteoclast attachment, bone resorption, osteoblast attachment and proliferation, and, finally, matrix synthesis occur sequentially at the BMU.

Events at the BMU are regulated by cell-to-cell interactions and cytokines, and several signaling pathways (Fig. 26.4). One pathway involves three factors: (1) the transmembrane receptor activator for NF-κB (RANK), which is expressed on osteoclast precursors; (2) RANK ligand (RANKL), which is expressed on osteoblasts and marrow stromal cells; and (3) osteoprotegerin (OPG), a secreted decoy receptor made by osteoblasts and several other types of cells that binds RANKL and thus prevents its interaction with RANK. When stimulated by RANKL, RANK signaling activates NF-κB, which is essential for the generation and survival of osteoclasts. A second important pathway involves macrophage colony-stimulating factor (M-CSF), a factor produced by osteoblasts that is also crucial for the generation of osteoclasts. Finally, WNT proteins produced by osteoprogenitor cells bind to LRP5 and LRP6 on osteoblasts to activate β-catenin signaling and osteoprotogerin (OPG) synthesis (Fig. 26.5).

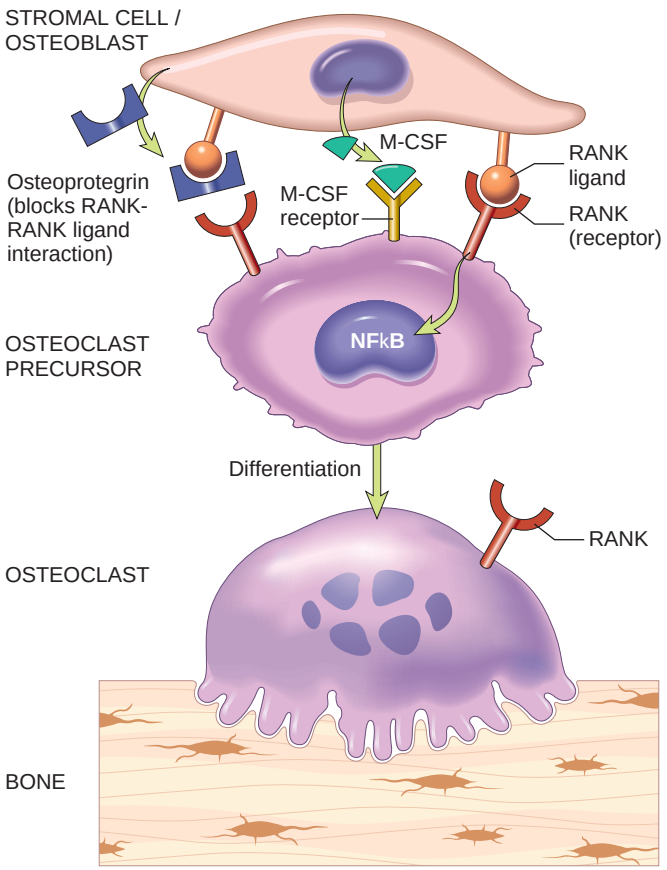

Figure 26.4 Paracrine molecular mechanisms that regulate osteoclast formation and function. Osteoclasts are derived from the same mononuclear cells that differentiate into macrophages. Osteoblast/stromal cell membrane-associated RANKL binds to its receptor RANK located on the cell surface of osteoclast precursors functions in concert with macrophage colony-stimulating factor (M-CSF). RANK activation induces precursor cells to become functional osteoclasts. Osteoblasts and stromal cells also secrete osteoprotegerin (OPG), which acts as a decoy receptor for RANKL, preventing it from binding the RANK on osteoclast precursors. Consequently, OPG prevents bone resorption by inhibiting osteoclast differentiation.

Conversely, osteocytes produce sclerostin, which inhibits WNT/β-catenin signaling and promotes bone formation. The importance of these pathways is emphasized by rare germline mutations in *OPG, RANK, RANKL, LRP5,* and *sclerostin* genes, which severely disrupt bone metabolism and produce congenital bone disorders (described later).

The balance between bone formation and resorption is modulated by RANK and WNT signaling. For example, because OPG and RANKL oppose one another, bone resorption or formation can be favored by increasing or decreasing the RANK-to-OPG ratio, respectively. Systemic factors affecting this balance include hormones (parathyroid hormone, estrogen, testosterone, and glucocorticoids), vitamin D, inflammatory cytokines (e.g., IL-1), and growth factors (e.g., bone morphogenetic factors). Each of these acts by altering RANK/NF-κB and WNT/β-catenin signaling. Parathyroid hormone, IL-1, and glucocorticoids promote osteoclast differentiation and bone turnover, while bone morphogenic proteins and sex hormones generally block osteoclast differentiation or activity by promoting OPG expression, alterations that favor bone deposition.

Another level of control involves paracrine signaling between osteoblasts and osteoclasts. Matrix breakdown by osteoclasts liberates and activates growth factors, cytokines, and enzymes (e.g., collagenase), some of which stimulate osteoblasts. Thus, substances that initiate bone deposition are released into the microenvironment during bone resorption (see Fig. 26.5).

Peak bone mass is achieved in early adulthood after the cessation of skeletal growth and is determined by factors that include vitamin D receptor and *LRP5/6* polymorphisms, nutrition, physical activity, age, and hormonal status. Beginning in the fourth decade, however, resorption exceeds formation, resulting in a steady decline in skeletal mass.

DEVELOPMENTAL DISORDERS OF BONE AND CARTILAGE

Developmental abnormalities of the skeleton often stem from inherited mutations and become apparent during the earliest stages of bone formation. In contrast, acquired diseases usually appear in adulthood. The spectrum of disorders of bone development is broad, and there is no standard approach to their classification. Here we will categorize the major diseases according to their pathogenesis.

Developmental anomalies can result from localized disruption of the migration and condensation of mesenchyme (dysostosis) or global disorganization of bone and/or cartilage (dysplasia). Dysostoses may occur in isolation or as part of more complex syndromes, and are caused by defects in mesenchymal condensation and differentiation into cartilage anlage. The most common forms include complete absence of a bone or entire digit (aplasia), extra bones or digits (supernumerary digit), and abnormal fusion of bones (e.g., syndactyly, craniosynostosis). Genetic alterations that affect genes encoding transcription factors (especially homeobox genes), cytokines, and cytokine receptors are especially common among dysostoses. In contrast, dysplasias arise from mutations in genes that control development or remodeling of the entire skeleton. It is important to note that while the term dysplasia in this context implies abnormal growth, it is not a precursor of neoplasia, as is the case with dysplasias of epithelial cells (Chapter 7).

More than 350 skeletal dysostoses and dysplasias are recognized, most of which are extremely rare. The classification has evolved from clinical and radiographic descriptions to one that includes the causative genetic defects. Table 26.1 lists some of the better characterized developmental abnormalities and their associated defective genes. The relationships between specific mutations and phenotypes are complex; different point mutations in a single gene (e.g., *COL2A1*) can result in distinct phenotypes, while mutations in disparate genes (e.g., *LRP5, RANKL*) can lead to similar phenotypes.

Defects in Nuclear Proteins and Transcription Factors

Defects in nuclear proteins and transcription factors, especially homeobox proteins, result in disorganized mesenchymal condensation and differentiation of osteoblasts and chondrocytes, leading to abnormal bone development.

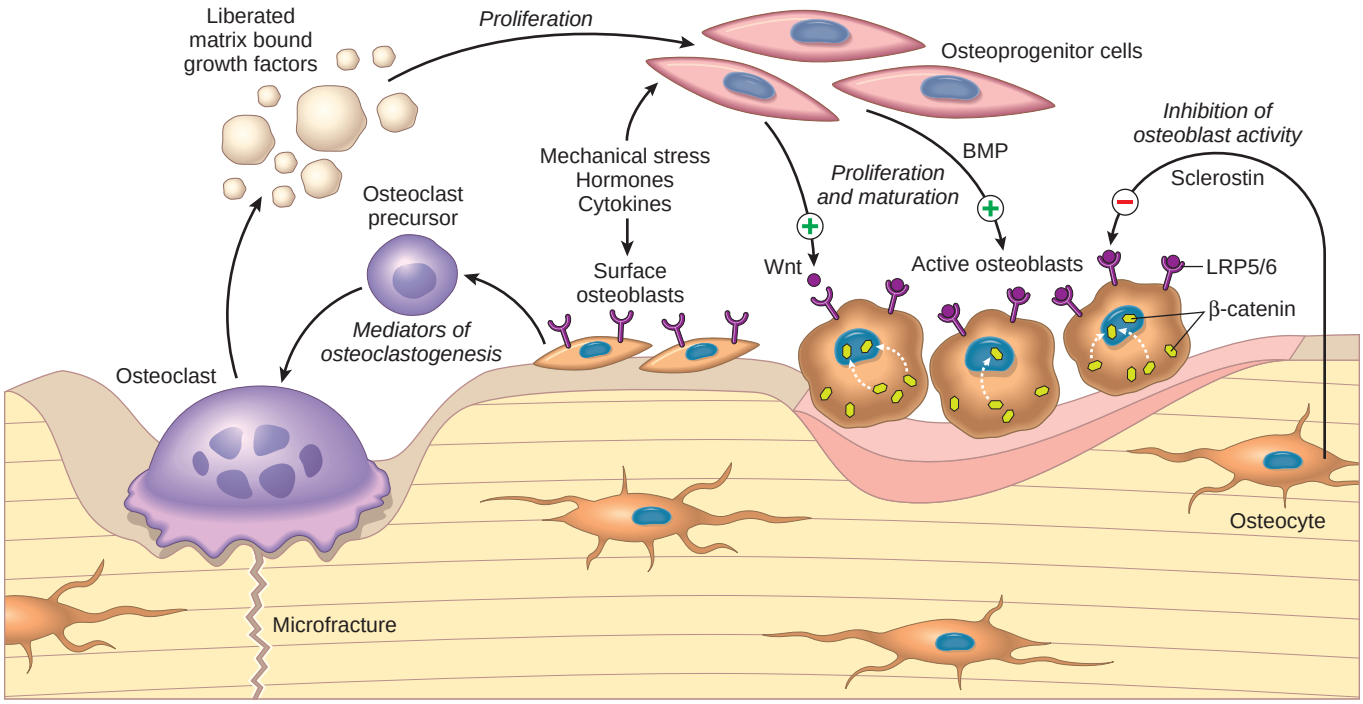

Figure 26.5 Bone cells and their interrelated activities. Hormones, cytokines, growth factors, and signal-transducing molecules are instrumental in bone formation and maturation and allow communication between osteoblasts and osteoclasts. Bone resorption and formation in remodeling are coupled processes controlled by systemic factors and local cytokines, some of which are deposited in the bone matrix. *BMP,* Bone morphogenic protein; *LRP5/6,* LDL receptor–related proteins 5 and 6.

- *Brachydactyly types D and E* are caused by mutations in the homeobox *HOXD13* gene and are characterized by shortening of the terminal phalanges of the thumb and big toe, respectively.
- Loss-of-function mutations in *RUNX2* result in *cleidocranial dysplasia,* an autosomal dominant disorder characterized by patent fontanelles, delayed closure of cranial sutures, Wormian bones (extra bones that occur within a cranial suture), delayed eruption of secondary teeth, primitive clavicles, and short stature.

Defects in Hormones and Signal Transduction Proteins

Achondroplasia is the most common skeletal dysplasia and a major cause of dwarfism. It is an autosomal dominant disorder caused by gain-of-function mutations in the FGF receptor 3 *(FGFR3)* gene, ~90% of which stem from new mutations in the paternal allele. FGF-mediated FGFR3 activation normally inhibits endochondral growth. This effect is exaggerated by *FGFR3* gain-of-function mutations. The retarded cartilage growth results in shortened proximal extremities, an enlarged head with bulging forehead, and depression of the root of the nose despite a trunk of relatively normal length. These skeletal abnormalities are not usually associated with changes in longevity, intelligence, or reproductive status.

Thanatophoric dysplasia is the most common lethal form of dwarfism. It affects ~1 in every 20,000 live births and is caused by *FGFR3* gain-of-function mutations distinct from those that cause achondroplasia, which appear to cause greater increases in FGFR3 signaling than those that produce achondroplasia, and thus a more severe phenotype. Affected individuals have disproportionately short (micromelic) limbs, frontal bossing, relative macrocephaly, a small chest cavity, and a bell-shaped abdomen. The underdeveloped thoracic cavity leads to respiratory insufficiency, and these individuals frequently die at birth or soon after. Histologic examination of the growth plate reveals reduced chondrocyte proliferation and disorganization within the zone of proliferation.

Defects in Extracellular Structural Proteins

Mutations in the major bone and cartilage collagens (types I, II, IX, X, and XI) give rise to highly variable presentations ranging from lethal disease to premature osteoarthritis (OA).

Type I Collagen Diseases (Osteogenesis Imperfecta)

Osteogenesis imperfecta (OI), or brittle bone disease, the most common inherited disorder of connective tissue, is a phenotypically heterogenous disorder caused by deficiencies in type I collagen synthesis. OI principally affects bone, but it also impacts other tissues rich in type I collagen (joints, eyes, ears, skin, and teeth). It is caused by mutations in genes encoding the α1 and α2 chains of type I collagen. Many of the over 800 mutations identified lead to replacement of a glycine residue within the triple-helical domain with another amino acid. Collagen synthesis and extracellular transport require triple-helix formation, and these mutations result in misfolding of collagen polypeptides and defective assembly of higher-order collagen chains. Mutant collagens also interfere with assembly of wild-type collagen chains, that is, they exert a dominant negative effect, thereby explaining the autosomal dominant inheritance pattern.

Table 26.1 Diseases of the Skeleton With Identified Genetic Defects

Disorder	Gene Symbol	Affected Molecule	Clinical Phenotype
Defects in Transcription Factors Producing Abnormalities in Mesenchymal Condensation and Related Cell Differentiation			
Brachydactyly types D and E	*HOXD13*	Transcription factor	Short, broad terminal phalanges of first digits
Camptomelic dysplasia	*SOX9*	Transcription factor	Sex reversal, abnormal skeletal development
Cleidocranial dysplasia	*RUNX2*	Transcription factor	Abnormal clavicles, Wormian bones, supernumerary teeth
Holt-Oram syndrome	*TBX5*	Transcription factor	Congenital abnormalities, forelimb anomalies
Nail-patella syndrome	*LMX1B*	Transcription factor	Hypoplastic nails, hypoplastic or aplastic patellas, dislocated radial head, progressive nephropathy
Waardenburg syndrome types 1 and 3	*PAX3*	Transcription factor	Hearing loss, abnormal pigmentation, craniofacial abnormalities
Defects in Hormones and Signal Transduction Proteins Producing Abnormal Proliferation or Maturation of Osteoblasts, Osteoclasts, or Chondrocytes			
Achondroplasia	*FGFR3*	Receptor	Short stature, rhizomelic shortening of limbs, frontal bossing, midface deficiency
Hypochondroplasia	*FGFR3*	Receptor	Disproportionately short stature, micromelia, relative macrocephaly
Osteopetrosis, autosomal dominant	*LRP5*	Receptor	Increased bone density, hearing loss, skeletal fragility
Osteopetrosis, infantile form	*RANKL*	Receptor ligand	Increased bone density
Osteoporosis-pseudoglioma syndrome	*LRP5*	Receptor	Congenital or infant-onset loss of vision, skeletal fragility
Thanatophoric dysplasia	*FGFR3*	Receptor	Severe limb shortening and bowing, frontal bossing, depressed nasal bridge
Defects in Extracellular Structural Proteins			
Achondrogenesis type 2	*COL2A1*	Type II collagen	Short trunk
Metaphyseal dysplasia, Schmid type	*COL10A1*	Type X collagen	Mildly short stature
Osteogenesis imperfecta types 1 to 4	*COL1A1, COL1A2*	Type I collagen	Bone fragility
Defects in Metabolic Enzymes and Transporters			
Osteopetrosis with renal tubular acidosis	*CA2*	Carbonic anhydrase	Increased bone density, fragility, renal tubular acidosis
Osteopetrosis, late onset type 2	*CLCN7*	Chloride channel	Increased bone density, fragility

Modified from Mundlos S, Olsen BR: Heritable diseases of the skeleton. Part I: Molecular insights into skeletal development—transcription factors and signaling pathways, *FASEB J* 11(2):125–132, 1997; Mundlos S, Olsen BR: Heritable diseases of the skeleton. Part II: Molecular insights into skeletal development—matrix components and their homeostasis, *FASEB J* 11(4):227–233, 1997; Superti-Furga A, Bonafé L, Rimoin DL: Molecular-pathogenetic classification of genetic disorders of the skeleton, *Am J Med Genet* 106(4):262–293, 2001; Krakow D, Rimoin DL: The skeletal dysplasias, *Genet Med* 12(6):327–341, 2010.

The fundamental abnormality in OI is too little bone, resulting in extreme skeletal fragility. Other findings include blue sclerae caused by decreased collagen content, making the sclera translucent and allowing partial visualization of the underlying choroid; hearing loss related to both a sensorineural deficit and impeded conduction due to abnormalities in the bones of the middle and inner ear; and dental imperfections (small, misshapen, and blue-yellow teeth) secondary to dentin deficiency.

OI is separated into four major clinical subtypes of varying severity (Table 26.2). Mutations that result in decreased synthesis of qualitatively normal collagen are associated with mild skeletal abnormalities. More severe or lethal phenotypes are associated with mutant collagens that interfere with triple helix formation. The type 2 variant, which is uniformly fatal in utero or during the perinatal period, is characterized by extraordinary bone fragility and multiple intrauterine fractures (Fig. 26.6). In contrast, individuals with type 1 OI have a normal life span but experience childhood fractures that decrease in frequency following puberty.

Defects in Metabolic Pathways (Enzymes, Ion Channels, and Transporters)

Osteopetrosis

Osteopetrosis comprises a group of rare genetic diseases characterized by reduced bone resorption due to deficient osteoclast development or function, which leads to diffuse, symmetric skeletal sclerosis. Although the term osteopetrosis implies that the bones are stonelike, they are actually brittle and fracture easily. Osteopetrosis is classified into variants based on both the mode of inheritance and the severity of clinical findings.

Pathogenesis

Most of the mutations underlying osteopetrosis interfere with acidification of the osteoclast resorption pit, which is required for the dissolution of calcium hydroxyapatite within the matrix. For example, *Albers-Schönberg disease,* a mild autosomal dominant form of osteopetrosis, is caused by mutation of *CLCN7,* which encodes a proton-chloride

Table 26.2 Subtypes of Osteogenesis Imperfecta

Subtype	Collagen Defect	Inheritance	Major Clinical Features	Prognosis
I	Decreased synthesis of pro-α1(I) chain Abnormal pro-α1(I) or pro-α2(I) chains	Autosomal dominant	Postnatal fractures, blue sclera Normal stature Skeletal fragility Dentinogenesis imperfecta Hearing impairment Joint laxity Blue sclerae	Compatible with survival
II	Abnormally short pro-α1(I) chain Unstable triple helix Abnormal or insufficient pro-α2(I)	Most autosomal recessive Some autosomal dominant New mutations	Death in utero or within days of birth Skeletal deformity with excessive fragility and multiple fractures Blue sclera	Perinatal lethal
III	Altered structure of pro-peptides of pro-α2(I) Impaired formation of triple helix	Autosomal dominant (75%) Autosomal recessive (25%)	Compatible with survival Growth retardation Multiple fractures Progressive kyphoscoliosis Blue sclera at birth that become white Hearing impairment Dentinogenesis imperfecta	Progressive, deforming
IV	Short pro-α2(I) chain Unstable triple helix	Autosomal dominant	Postnatal fractures, normal sclerae Moderate skeletal fragility Short stature Sometimes dentinogenesis imperfecta	Compatible with survival

Figure 26.6 Skeletal radiograph of a fetus with lethal type 2 osteogenesis imperfecta. Note the numerous fractures of virtually all bones, resulting in accordion-like shortening of the limbs.

exchanger on the osteoclast surface that is required for resorption pit acidification. Similarly, most cases of autosomal recessive osteopetrosis are caused by a mutation of *TCIRG1,* which encodes a subunit of the osteoclast vacuolar H^+-ATPase that is also necessary for acidification of the resorption pit. Other causes of autosomal recessive osteopetrosis include defects in carbonic anhydrase 2 (CA2), which, like all carbonic anhydrase isozymes, generates protons and bicarbonate from carbon dioxide and water. CA2 facilitates resorption pit acidification by osteoclasts and urinary acidification by renal tubular epithelial cells. Osteopetrosis due to *CA2* mutations is, therefore, accompanied by renal tubular acidosis. Mutations in *IKBKG,* which encodes NEMO, the regulatory subunit of the inhibitor of kappaB kinase (IKK) complex that is involved in NF-κB activation, is a cause of osteopetrosis that is not due to defective acidification. NEMO, which is X-linked, is required for osteoclastogenesis and osteoclast survival, which are regulated by NF-κB. Because NF-κB serves many other functions, *IKBKG* mutations result in a multisystem disorder called X-linked anhidrotic ectodermal dysplasia with immunodeficiency that includes osteopetrosis.

MORPHOLOGY

Due to deficient osteoclast activity, bones involved by osteopetrosis lack a medullary canal, and the ends of long bones are bulbous (Erlenmeyer flask deformity) and misshapen (Fig. 26.7). The neural foramina are small and can compress exiting nerves. The primary spongiosa, which is normally removed during growth, persists and fills the medullary cavity, leaving no room for the hematopoietic marrow and preventing the formation of mature trabeculae (Fig. 26.8). Deposited bone is not remodeled and tends to be woven rather than lamellar. Depending on the underlying genetic defect, the number of osteoclasts may be normal, increased, or decreased.

Figure 26.7 Radiograph of the upper extremity in an individual with osteopetrosis. The bones are diffusely sclerotic, and the distal metaphyses of the ulna and radius are poorly formed.

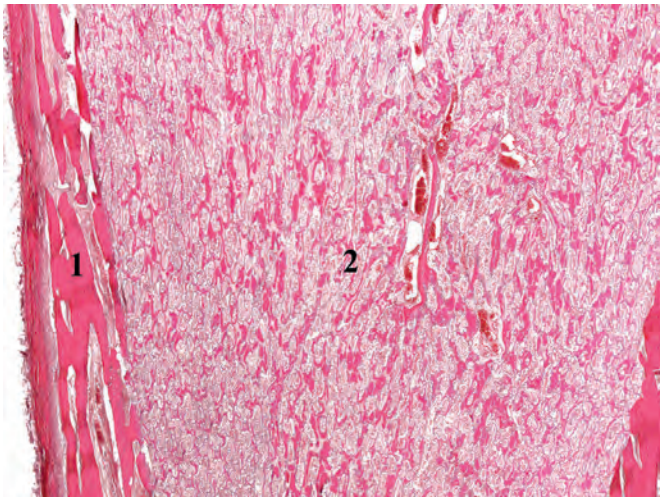

Figure 26.8 Section of proximal tibial diaphysis from a fetus with osteopetrosis. The cortex (1) is present, but the medullary cavity (2) is filled with primary spongiosa, which replaces the hematopoietic elements.

Clinical Features

Severe infantile osteopetrosis is an autosomal recessive disorder that usually becomes evident in utero or soon after birth. Fracture, anemia, and hydrocephaly are often seen, resulting in postpartum mortality. Affected individuals who survive into their infancy have cranial nerve defects (optic atrophy, deafness, and facial paralysis) and repeated—often fatal—infections because of leukopenia due to reduced marrow space and decreased hematopoiesis. The compensatory extramedullary hematopoiesis can lead to prominent hepatosplenomegaly. Autosomal dominant forms are milder and may not be detected until adolescence or adulthood when discovered on x-ray studies, either incidentally or because of repeated fractures.

Osteopetrosis was the first genetic bone disease treated with hematopoietic stem cell transplantation, which is effective because osteoclasts are derived from hematopoietic precursors. The normal osteoclasts produced from donor stem cells reverse many of the skeletal abnormalities.

Diseases Associated With Defects in Degradation of Macromolecules

Mucopolysaccharidoses

The mucopolysaccharidoses, discussed in Chapter 5, are lysosomal storage diseases. They are caused by deficiencies in enzymes, primarily acid hydrolases, that degrade dermatan sulfate, heparan sulfate, and keratan sulfate. Mesenchymal cells, particularly chondrocytes, degrade extracellular matrix mucopolysaccharides. In these diseases, mucopolysaccharides accumulate within chondrocytes and induce apoptosis. Extracellular mucopolysaccharide accumulation leads to structural defects in articular cartilage. Consequently, many of the skeletal manifestations of the mucopolysaccharidoses result from abnormalities in the cartilage anlage, growth plates, costal cartilages, and articular surfaces. Affected individuals are frequently of short stature and have chest wall abnormalities and malformed bones.

KEY CONCEPTS

DEVELOPMENTAL DISORDERS OF BONE AND CARTILAGE

Abnormalities in a single bone or a localized group of bones are called dysostoses and arise from defects in mesenchyme migration and condensation. They manifest as absent, supernumerary, or abnormally fused bones. Global disorganization of bone and/or cartilage is termed dysplasia. Developmental abnormalities can be categorized by the associated genetic defect.

- Transcription factors: Homeobox genes, such as *HOXD13*, are frequently mutated in brachydactyly syndromes.
- Signal transduction molecules: *FGFR3* mutations are responsible for achondroplasia and thanatophoric dysplasia, both of which manifest as dwarfism.
- Structural proteins: Mutations in the genes for type I collagen underlie most types of osteogenesis imperfecta (brittle bone disease), characterized by defective bone formation and skeletal fragility.
- Metabolic enzymes and transporters: Mutations that interfere with osteoclast acidification of the resorption pit or osteoclastogenesis cause osteopetrosis, in which bones are hard but brittle. Depending on the gene mutated, extraskeletal manifestations may also be present.

METABOLIC DISEASES OF BONE

Osteopenia and Osteoporosis

Osteopenia refers to decreased bone mass; osteoporosis is defined as osteopenia that is severe enough to significantly increase the risk of fracture. Radiographically, osteoporosis is considered bone mass at least 2.5 standard deviations below mean peak bone mass in young adults. Osteopenia is 1 to 2.5 standard deviations below the mean. The disorder may be localized to a certain bone or region, as in disuse osteoporosis of a limb, or may involve the entire skeleton as a manifestation of a metabolic bone disease. Generalized osteoporosis may be primary or secondary to a variety of conditions (Table 26.3). Each year, approximately 1 million Americans experience an osteoporosis-related fracture with an estimated cost of more than $14 billion. The following discussion relates largely to these forms of osteoporosis.

Pathogenesis

Peak bone mass is achieved during young adulthood. Its magnitude is determined largely by hereditary factors, especially polymorphisms in the genes that influence bone metabolism (Fig. 26.9). Physical activity, muscle strength, diet, and hormonal state also make important contributions.

Table 26.3 Categories of Generalized Osteoporosis

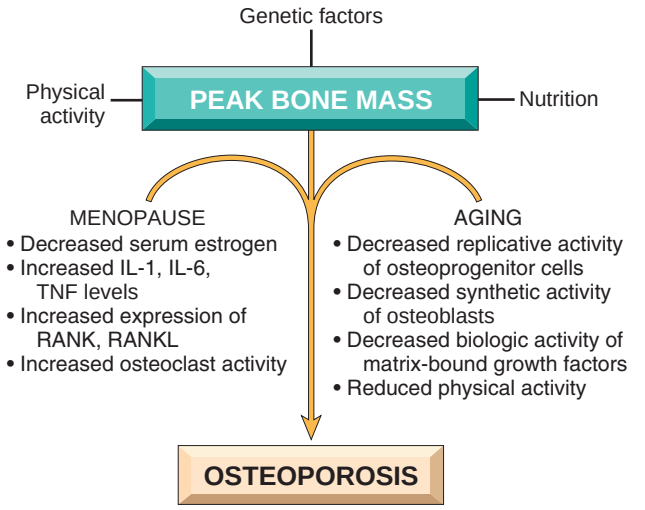

Figure 26.9 Pathophysiology of postmenopausal and senile osteoporosis *(see text).*

Once maximal skeletal mass is attained, bone resorption slightly exceeds formation, resulting in age-related bone loss that averages 0.7% per year. Both sexes are affected equally, but the process is more rapid on average in Caucasians than in those of African descent.

Although numerous factors affect bone mass, the most common forms of osteoporosis are senile and postmenopausal.

- *Age-related changes* include a reduced proliferative and biosynthetic capacity, and attenuated response to growth factors of osteoblasts, resulting in a diminished ability to make bone. This form of osteoporosis, known as *senile osteoporosis,* is categorized as a low-turnover variant.
- *Reduced physical activity* increases the rate of bone loss in experimental animals and humans, because mechanical forces normally stimulate bone remodeling. Bone loss in an immobilized or paralyzed extremity or in astronauts experiencing reduced gravitational forces for prolonged periods, and, conversely, increased bone density in athletes, exemplify the importance of physical forces in bone maintenance. When considering physical activity, the effect of load magnitude on bone density is greater than load repetition, explaining why resistance exercises, such as weight training, increase bone mass more effectively than endurance activities such as bicycling. The decreased physical activity that is associated with normal aging contributes to senile osteoporosis.
- *Genetic factors* such as single-gene defects are rare causes of osteoporosis. However, polymorphisms in certain genes may contribute to variation in peak bone density within populations. The most strongly linked genes identified by genome-wide association studies include *RANK, RANKL,* and *OPG,* all of which encode key osteoclast regulators; the HLA locus (for unknown reasons); and the estrogen receptor gene (discussed later).
- *Calcium nutritional state* contributes to peak bone mass. Adolescent girls (more than boys) tend to have insufficient calcium intake in the diet. If it occurs during a period of rapid bone growth, calcium deficiency reduces peak bone mass and increases the risk of osteoporosis. Relative

deficiencies of calcium and vitamin D and elevated PTH levels may also contribute to development of senile osteoporosis.

- *Hormonal influences.* In the decade after menopause, up to 2% of cortical bone and 9% of cancellous bone may be lost each year. Estrogen deficiency plays the major role in this phenomenon, and close to 40% of postmenopausal women are affected by *postmenopausal osteoporosis*. Although decreased estrogen increases both bone formation and resorption, the latter dominates, resulting in high-turnover osteoporosis. Estrogen loss leads to increased secretion of inflammatory cytokines, such as IL-6, TNF, and IL-1, by innate immune cells in the blood and marrow through unknown mechanisms. The resulting increases and decreases in RANKL and OPG, respectively, stimulate osteoclast recruitment and activity.

MORPHOLOGY

The hallmark of osteoporosis is histologically normal bone that is decreased in quantity. The entire skeleton is affected (Fig. 26.10), but certain bones tend to be more severely impacted. Postmenopausal osteoporosis affects mainly bones or portions of bones that have increased surface area, such as the cancellous compartment of vertebral bodies. The trabecular plates become perforated and thinned, and lose their interconnections (Fig. 26.11), leading to microfractures and eventually to vertebral collapse. In senile osteoporosis, the cortex is thinned by subperiosteal and endosteal resorption, and the Haversian systems are widened.

Clinical Features

The clinical manifestations of osteoporosis depend on which bones are involved. Vertebral fractures that frequently occur in the thoracic and lumbar regions are painful, and, when multiple, can cause significant loss of height and deformities such as lumbar lordosis and kyphoscoliosis. Fractures of the femoral neck, pelvis, or spine lead to immobilization and complications such as pulmonary embolism and pneumonia, resulting in 40,000 to 50,000 deaths per year.

Osteoporosis cannot be reliably detected in plain radiographs until 30% to 40% of the bone mass is lost. The best estimates of bone loss, aside from biopsy (which is rarely performed), are specialized radiographic imaging techniques, such as dual-energy x-ray absorptiometry and quantitative computed tomography, both of which measure bone density.

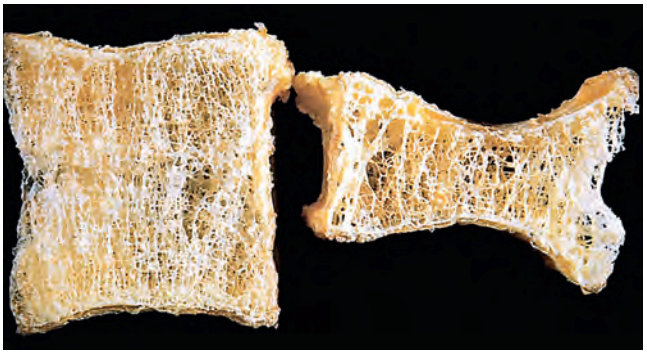

Figure 26.10 Osteoporotic vertebral body *(right)* shortened by compression fractures compared with a normal vertebral body *(left)*. Note that the osteoporotic vertebra has a characteristic loss of horizontal trabeculae and thickened vertical trabeculae.

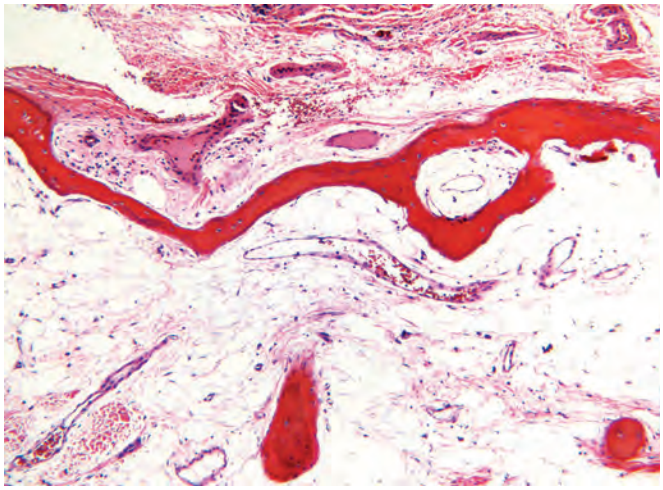

Figure 26.11 In advanced osteoporosis, both the trabecular bone of the medulla *(bottom)* and the cortical bone *(top)* are markedly thinned.

Preventive and therapeutic management of osteoporosis includes exercise, appropriate calcium and vitamin D intake, and pharmacologic agents, most commonly bisphosphonates, which reduce osteoclast activity and induce their apoptosis. Denosumab, an anti-RANKL antibody, has shown promise in treating some forms of postmenopausal osteoporosis. Although menopausal hormone therapy has been used to prevent osteoporosis and associated fractures, complications, particularly deep vein thrombosis and stroke, have prompted search for more selective estrogen receptor modulators.

Osteomalacia and Rickets

Osteomalacia and rickets are manifestations of impaired mineralization of bone matrix. This contrasts with osteoporosis, in which mineralization of bone is normal and bone mass is decreased. Most examples of undermineralized matrix result from abnormal vitamin D metabolism or vitamin D deficiency (detailed in Chapter 9). Rickets refers to the disorder in children, in whom it interferes with the deposition of bone in the growth plates. Osteomalacia is the adult counterpart, in which bone formed during remodeling is undermineralized and predisposed to fractures.

Hyperparathyroidism

Hyperparathyroidism causes increased bone resorption. As discussed in Chapter 24, parathyroid hormone (PTH) has a central role in calcium homeostasis through the following effects:

- *Activation of osteoclasts,* increasing bone resorption and calcium mobilization. PTH mediates the effect indirectly by increasing RANKL expression on osteoblasts.
- *Increasing calcium resorption* by the renal tubules
- *Increasing urinary phosphate excretion*
- *Increasing synthesis of active vitamin D, $1,2_5$(OH)2-D,* by the kidneys, thereby enhancing intestinal calcium absorption and mobilizing bone calcium by inducing RANKL expression on osteoblasts

The net result of PTH action is elevated serum calcium, which normally inhibits PTH production. Excessive or inappropriate PTH release may stem from autonomous parathyroid secretion *(primary hyperparathyroidism)* or may be the result of renal disease *(secondary hyperparathyroidism)* (see Chapter 24). In either setting, hyperparathyroidism produces changes throughout the skeleton as a consequence of unrestrained osteoclast activity. Elevated PTH is responsible for bone changes in primary hyperparathyroidism, but additional factors contribute in secondary hyperparathyroidism. In chronic renal insufficiency, 1,25-$(OH)_2$- vitamin D synthesis is reduced due to decreased α1-hydroxylase activity, which stems from loss of renal function and the suppressive effects of hyperphosphatemia on α_1-hydroxylase. Inadequate vitamin D ultimately limits intestinal calcium absorption. Secondary hyperparathyroidism can also be complicated by metabolic acidosis and aluminum deposition in bone. With time, loss of bone mass increases susceptibility to fractures, bone deformation, and joint problems.

MORPHOLOGY

Symptomatic, untreated primary hyperparathyroidism manifests with three interrelated skeletal abnormalities: osteoporosis, brown tumors, and osteitis fibrosa cystica. The **osteoporosis** is generalized but is most severe in the phalanges, vertebrae, and proximal femur. Hyperparathyroidism most prominently enhances osteoclast activity within cortical bone (subperiosteal and endosteal surfaces), but cancellous bone can also be affected. At these sites, osteoclasts may tunnel into and dissect centrally along the length of the trabeculae, leaving adjacent marrow spaces to be replaced by fibrovascular tissue, producing **dissecting osteitis** (Fig. 26.12). Radiographically, dissecting osteitis is seen as decreased bone density or osteoporosis.

Bone loss in hyperparathyroidism predisposes to microfractures, secondary hemorrhage, macrophage recruitment, and ingrowth of reparative fibrous tissue to create a mass lesion called **brown tumor** (Fig. 26.13). The brown color reflects vascularity, hemorrhage, and hemosiderin deposition. Cystic degeneration of brown tumors is common. The combination of increased bone cell activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica (von Recklinghausen disease of bone)**.

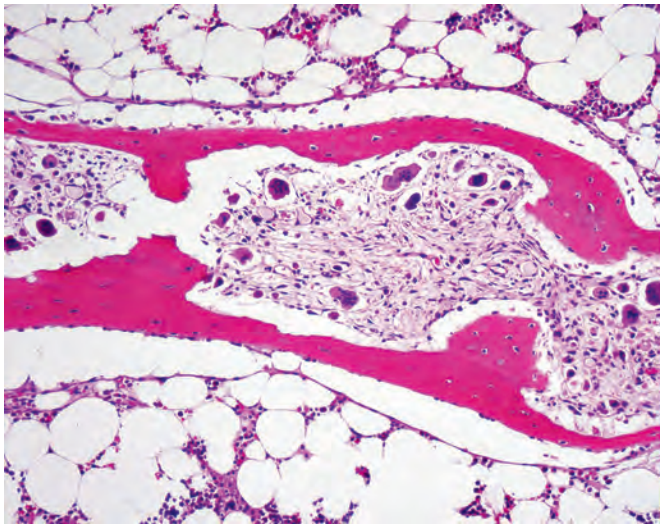

Figure 26.12 Hyperparathyroidism with osteoclasts boring into the center of the trabeculum (dissecting osteitis).

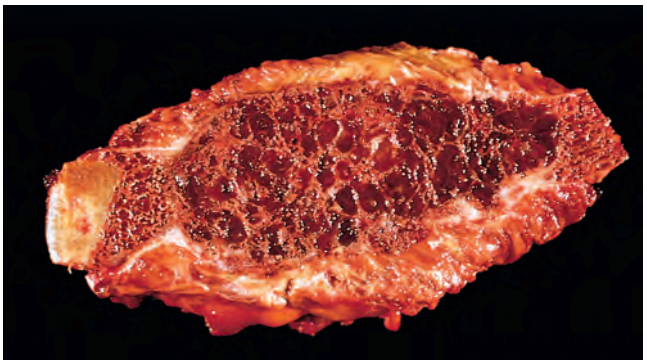

Figure 26.13 Resected rib, harboring an expansile brown tumor adjacent to the costal cartilage.

Osteitis fibrosa cystica is now uncommon because hyperparathyroidism is usually diagnosed on routine blood tests and treated at an early stage. Although secondary hyperparathyroidism can cause similar changes, the process is usually less severe, and skeletal abnormalities tend to be milder. Bony changes regress or disappear completely when hyperparathyroidism is controlled.

Renal Osteodystrophy

The term renal osteodystrophy describes the collective skeletal changes that occur in chronic renal disease, including those associated with dialysis. The manifestations include many of the entities described earlier including (1) osteopenia/osteoporosis, (2) osteomalacia, (3) secondary hyperparathyroidism, and (4) growth retardation. As medical advances have prolonged the lives of individuals with renal disease, the impact of this disease on skeletal homeostasis has assumed greater clinical importance. Histologic bone changes in individuals with end-stage renal failure can be divided into three major types of disorders:

- *High-turnover osteodystrophy* is characterized by increased bone resorption and bone formation, with the former predominating.
- *Low-turnover* or *aplastic disease* is manifested by adynamic bone (little osteoclastic and osteoblastic activity) and, less commonly, osteomalacia.
- *Mixed pattern disease* with areas of high turnover and low turnover.

Pathogenesis

Kidney disease causes skeletal abnormalities through three mechanisms (Fig. 26.14):

- *Tubular dysfunction* most commonly leading to renal tubular acidosis. The associated systemic acidosis dissolves hydroxyapatite, resulting in matrix demineralization and osteomalacia.
- *Secondary hyperparathyroidism,* due to reduced phosphate excretion, chronic hyperphosphatemia, and hypocalcemia.

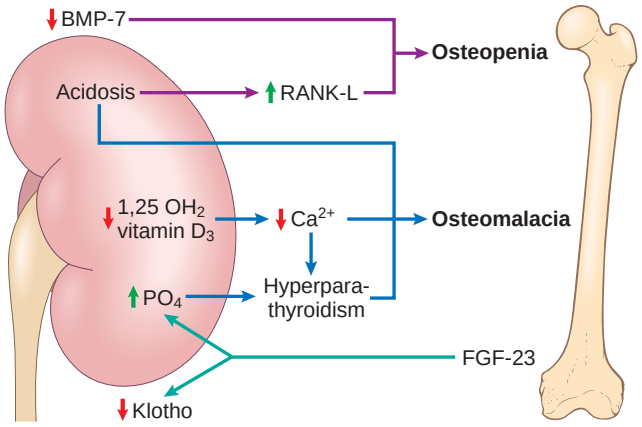

Figure 26.14 Mechanisms of renal osteodystrophy involve homeostasis and endocrine signaling between bone and kidney.

As discussed earlier, the resulting metabolic state is not completely analogous to primary hyperparathyroidism, and bone volume, turnover, and mineralization can vary independently.

- *Decreased biosynthetic function,* including reduced renal vitamin D hydroxylation to generate 1,25-OH_2-vitamin D_3. This results in hypocalcemia that contributes to secondary hyperparathyroidism. A hormonal feedback loop between kidney and bone that regulates calcium and phosphate homeostasis involves the secreted proteins BMP-7 and FGF-23 and the membrane protein Klotho. BMP-7, produced by renal tubular cells, induces osteoblast differentiation and proliferation, whereas FGF-23, made by osteocytes, acts on the kidney to regulate Klotho-dependent renal phosphate homeostasis and vitamin D hydroxylation. Chronic renal failure disrupts this signaling axis and contributes to osteopenia and osteomalacia.

KEY CONCEPTS

METABOLIC DISEASES OF BONE

- Osteopenia and osteoporosis are conditions in which bone is normally mineralized but decreased in quantity. Osteoporosis is defined as bone loss sufficient to increase fracture risk and is associated with significant morbidity and mortality from fractures. Multiple factors including peak bone mass, age, activity, genetics, nutrition, and hormonal influences contribute to its pathogenesis.
- Osteomalacia is defined by the presence of bone that is insufficiently mineralized. In the developing skeleton, this results in rickets.
- Hyperparathyroidism arises from either autonomous or compensatory hypersecretion of PTH and can lead to osteoporosis, brown tumors, and osteitis fibrosa cystica. In high income countries, where early diagnosis is the norm, these manifestations are rare.
- Renal osteodystrophy is marked by a constellation of bone abnormalities (osteopenia, osteomalacia, hyperparathyroidism, and growth retardation) that occur as a consequence of chronic renal failure. The bone changes stem from decreased tubular, glomerular, and hormonal renal functions.

Paget Disease (Osteitis Deformans)

Paget disease is a disorder marked by increased, but disordered and structurally unsound, bone mass. It develops in three sequential phases: (1) an initial osteolytic stage; (2) a mixed osteoclastic-osteoblastic stage; and (3) a burned-out quiescent osteosclerotic stage in which osteoblast activity predominates (Fig. 26.15).

Paget disease often presents in late adulthood and becomes progressively more common with increasing age. An intriguing aspect is the striking geographic variation in its prevalence. It is relatively common in Caucasians in England, France, Austria, regions of Germany, Australia, New Zealand, and the United States, and is rare in native populations of Scandinavia, China, Japan, and Africa. Its

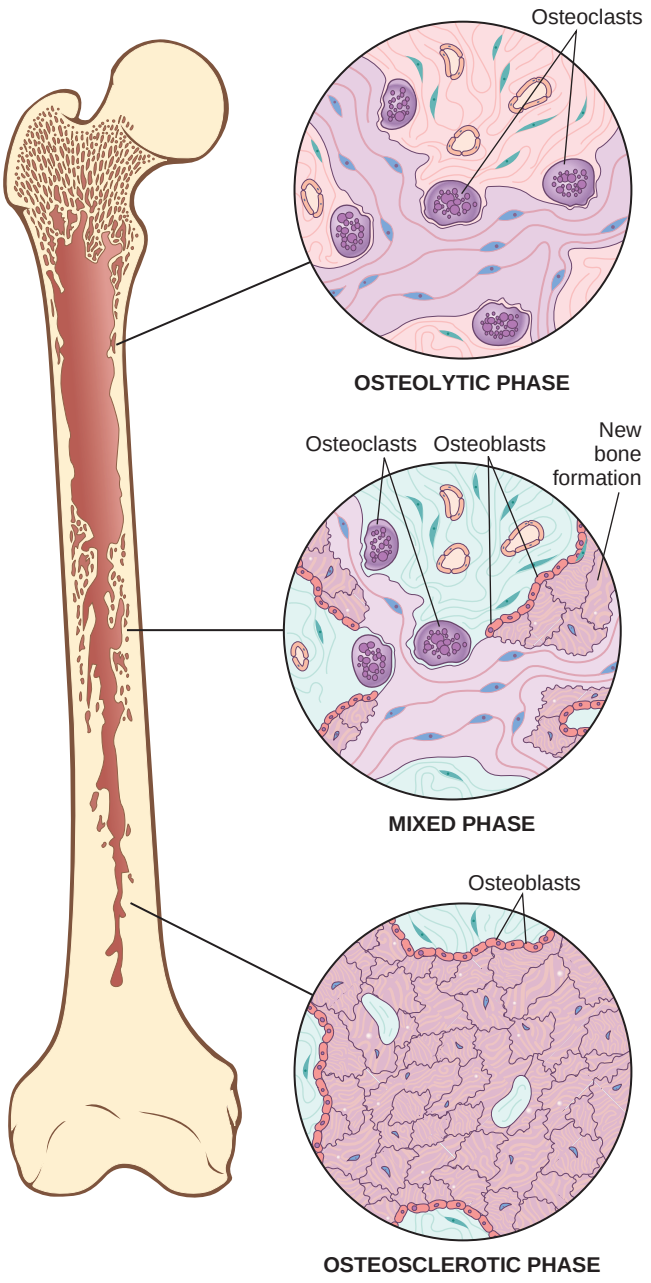

Figure 26.15 Diagrammatic representation of Paget disease of bone demonstrating the three phases of disease evolution.

exact incidence is difficult to determine because many affected individuals are asymptomatic; it is estimated that 1% of the US population older than 40 years of age is affected. The prevalence in England is 2.5% for men and 1.6% for women 55 years of age or older. A decrease in new cases has been observed in some countries over the past 30 years.

Pathogenesis

The cause of Paget disease remains uncertain, but current evidence suggests both genetic and environmental contributions. Approximately 50% of cases of familial Paget disease and 10% of sporadic cases are associated with mutations in the *SQSTM1* gene that increase NF-κB activity and thus enhance osteoclast activity. Activating *RANK* mutations and inactivating *OPG* mutations account for some cases of juvenile Paget disease. In vitro studies suggest that chronic infection of osteoclast precursors by measles or other RNA viruses may also play a role.

MORPHOLOGY

Paget disease shows remarkable histologic variation over time and across sites. Its hallmark is a mosaic pattern of lamellar bone that develops in the sclerotic phase. This jigsaw puzzle–like appearance is produced by unusually prominent **cement lines,** which join haphazardly oriented units of lamellar bone (Fig. 26.16). The features are less specific during other phases of disease, but include waves of osteoclastic activity and numerous resorption pits in the lytic phase. The osteoclasts are abnormally large and have many more than the normal 10 to 12 nuclei; sometimes 100 nuclei are present. Osteoclasts persist in the mixed phase, but many of the bone surfaces are also lined by plump osteoblasts. The marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels. The newly formed bone may be woven or lamellar, but eventually it is all remodeled into lamellar bone. As the mosaic pattern takes hold and cell activity decreases, periosseous fibrovascular tissue recedes and is replaced by normal marrow. In the end, the coarsely thickened trabeculae and soft and porous cortices lack structural stability and make the bone vulnerable to fractures.

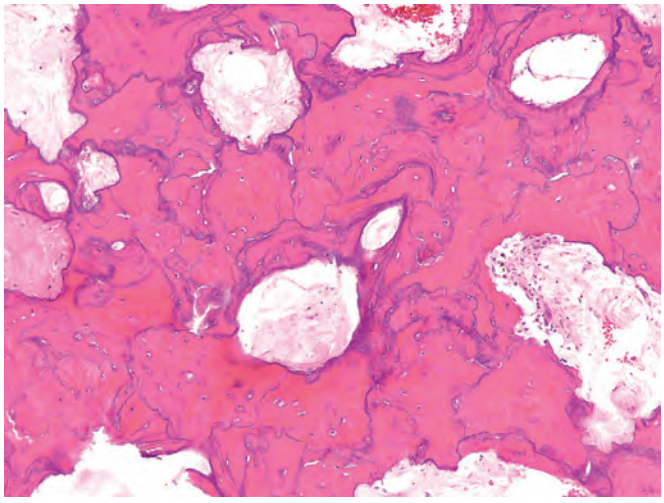

Figure 26.16 Mosaic pattern of lamellar bone pathognomonic in Paget disease.

Clinical Features

Clinical findings are extremely variable and depend on the extent and site of the disease. Paget disease is monostotic in about 15% of cases and polyostotic in the remainder. The axial skeleton or proximal femur is involved in up to 80% of cases. Most cases are asymptomatic and are discovered as an incidental radiographic finding. Pain localized to the affected bone may be present due to microfractures or bone overgrowth that compresses spinal and cranial nerve roots. Enlargement of the craniofacial skeleton may produce leontiasis ossea (lion face) and a cranium so heavy that it is difficult for the person to hold the head erect. The weakened Pagetic bone may lead to invagination of the skull base (platybasia) and compression of the posterior fossa. Weight bearing causes anterior bowing of the femurs and tibiae and distorts the femoral heads, resulting in the development of severe secondary osteoarthritis. Chalk stick–type fractures are common and usually involve the long bones of the lower extremities. Vertebral compression fractures can result in spinal cord injury and kyphosis. Rarely, the hypervascularity of Pagetic bone warms the overlying skin, and in severe polyostotic disease the increased blood flow can act as an arteriovenous shunt, leading to high-output heart failure or exacerbation of underlying cardiac disease.

The most dreaded complication of Paget disease is sarcoma, which occurs in less than 1% of all individuals with Paget disease, and in 5% to 10% of those with severe polyostotic disease. The sarcomas, usually osteosarcoma or fibrosarcoma, arise in Paget lesions in the long bones, pelvis, skull, and spine.

The diagnosis of Paget disease can be made radiographically. Pagetic bone is typically enlarged with thick, coarsened cortices and medulla (Fig. 26.17). Active disease has a wedge-shaped lytic leading edge that may progress along the length of the bone at a rate of 1 cm per year. Many affected individuals have elevated serum alkaline phosphatase levels, but serum calcium and phosphate levels are normal.

In the absence of malignant transformation, Paget disease is usually not serious or life-threatening. Most affected individuals have mild symptoms that are readily suppressed by treatment with calcitonin and bisphosphonates.

FRACTURES

Fractures are defined as loss of bone integrity. They are some of the most common pathologic conditions affecting bone. The following qualifiers describe fracture types and affect treatment:

- *Simple:* the overlying skin is intact.
- *Compound:* the bone communicates with the skin surface.
- *Comminuted:* the bone is fragmented.
- *Displaced:* the ends of the bone at the fracture site are not aligned.
- *Stress:* a slowly developing fracture that follows a period of increased physical activity in which the bone is subjected to repetitive loads.
- *Greenstick:* extending only partially through the bone, common in infants when bones are soft.

Figure 26.17 Severe Paget disease. The tibia is bowed. The affected portion is enlarged and sclerotic, and it exhibits irregular thickening of both cortical and cancellous bone.

- *Pathologic:* involving bone weakened by an underlying disease process, such as a tumor.

Healing of Fractures

Bone has a remarkable capacity for repair. This process involves regulated expression of a multitude of genes and can be separated into overlapping stages. Immediately after fracture, rupture of blood vessels results in a hematoma that fills and surrounds the area of injury (Fig. 26.18). The clot provides a fibrin mesh that seals the fracture site and provides a framework for the inflammatory cell influx, fibroblast ingrowth, and capillary proliferation that characterize granulation tissue. Release of PDGF, TGF-β, FGF, and other growth factors by degranulated platelets and inflammatory cells activates osteoprogenitor cells in the periosteum, medullary cavity, and surrounding soft tissues to stimulate osteoclastic and osteoblastic activity. Uncalcified tissue known as *soft tissue callus* or *procallus* forms, providing some anchorage but not structural rigidity for weight bearing.

Within 2 weeks of injury, the activated osteoprogenitor cells deposit subperiosteal trabeculae of woven bone oriented perpendicular to the cortical axis and within the medullary cavity. These processes transform the procallus into *bony callus,* which reaches maximal girth at the end of the second or third week and helps stabilize the fracture site. Activated soft tissue mesenchymal cells may also differentiate into chondrocytes that produce fibrocartilage and hyaline cartilage. Endochondral ossification creates a contiguous

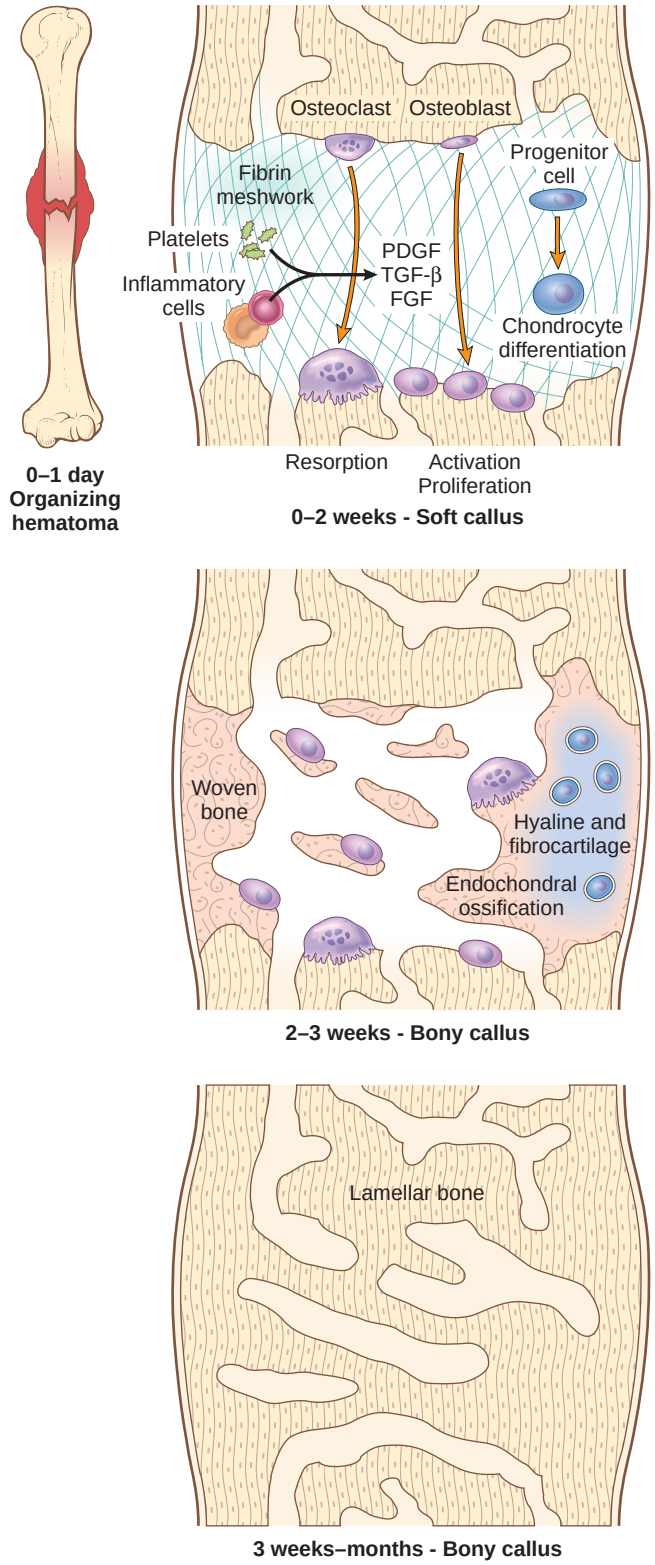

Figure 26.18 The reaction to a fracture begins with an organizing hematoma. Within 2 weeks, the two ends of the bone are bridged by a fibrin meshwork in which osteoclasts, osteoblasts, and chondrocytes differentiate from precursors. These cells produce cartilage and bone matrix, which, with adequate immobilization, remodels into normal lamellar bone.

network of bone and newly deposited bone trabeculae in the medulla and beneath the periosteum. As a result, fractured bone ends are bridged and, with progressive mineralization, the stiffness and strength of the callus increases to allow weight bearing.

In the early stages of callus formation, excess fibrous tissue, cartilage, and woven bone is produced. The portions that are not subjected to physical stress are resorbed as the callus matures, which both reduces the size of the healing bone and recreates lamellar bone. The healing process is completed by restoration of the medullary cavity.

In children and young adults, near-perfect union is the norm, although some deformity typically persists after healing of displaced and comminuted fractures. In older adults, fractures often occur in the background of other bone disorders (e.g., osteoporosis and osteomalacia). In such settings, surgical immobilization is often needed for adequate repair. Other factors may also interfere with healing. Inadequate immobilization, which permits movement of the callus and interferes with normal maturation, can result in *delayed union* or *nonunion*. If nonunion persists, the malformed callus undergoes cystic degeneration and the luminal surface can become lined by synovial-like cells, creating a false joint or *pseudoarthrosis*. Infection of the fracture site, especially common in open fractures, is another serious obstacle to healing, as are malnutrition and skeletal dysplasia.

OSTEONECROSIS (AVASCULAR NECROSIS)

Infarction of bone and marrow is relatively common. It can be limited to the medullary cavity or involve both the medulla and cortex. Fractures and corticosteroid administration are the two most common causes, but many other conditions also predispose to osteonecrosis, including alcohol abuse, bisphosphonate therapy, connective tissue disease, chronic pancreatitis, Gaucher disease, pregnancy, radiation therapy, sickle cell crisis (Chapter 14), tumors, and dysbarism (e.g., decompression sickness).

MORPHOLOGY

Medullary infarcts are geographic in shape and involve both trabecular bone and marrow. Collateral blood flow usually limits cortical involvement. In subchondral infarcts, a triangular or wedge-shaped segment with the subchondral bone plate as its base undergoes necrosis; the overlying articular cartilage remains viable due to nutrients within synovial fluid. Microscopically, dead bone is characterized by empty lacunae surrounded by necrotic adipocytes. The released fatty acids bind calcium and form insoluble calcium soaps. The remaining trabeculae act as scaffolding for deposition of new bone, while osteoclasts resorb necrotic trabeculae. The slow pace of substitution in subchondral infarcts (Fig. 26.19) results in collapse of the necrotic bone, fracture, and sloughing of the articular cartilage.

Clinical Features

Symptoms depend on location and extent of infarction. Typically, subchondral infarcts cause pain that is initially associated with activity but becomes constant as secondary changes supervene. Subchondral infarcts often collapse, resulting in secondary osteoarthritis. Medullary infarcts are usually small and clinically silent.

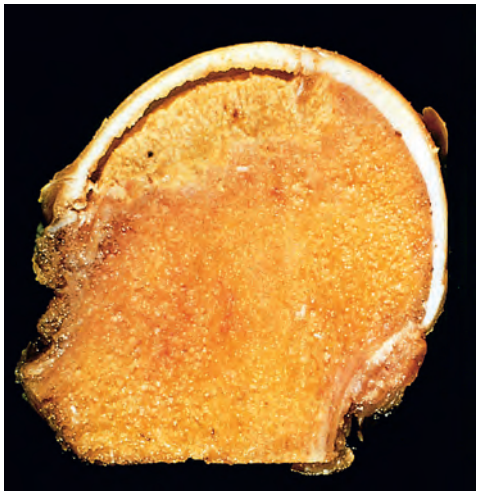

Figure 26.19 Femoral head with a subchondral, wedge-shaped pale area of osteonecrosis. The space between the overlying articular cartilage and bone is caused by trabecular compression fractures without repair.

OSTEOMYELITIS

Osteomyelitis denotes inflammation of bone and marrow, virtually always secondary to infection. Osteomyelitis frequently manifests as a primary solitary focus of disease, but can also be a complication of any systemic infection. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but certain pyogenic bacteria and mycobacteria are the most common culprits. In the United States, unusual infections in immigrants from lower income countries and opportunistic infections in immunosuppressed individuals have made diagnosis and treatment of osteomyelitis challenging.

Pyogenic Osteomyelitis

Pyogenic osteomyelitis is almost always caused by bacterial infection. Organisms may reach the bone by hematogenous spread, extension from a contiguous site, or direct implantation (e.g., in traumatic injury). In otherwise healthy children, osteomyelitis is most often due to hematogenous spread and involves long bones. The initiating bacteremia may stem from seemingly trivial mucosal injuries, such as may occur during defecation or vigorous chewing of hard foods, or from minor skin infections. In adults, osteomyelitis more often occurs as a complication of open fractures, surgical procedures, and infections of the feet in the setting of diabetes. Osteomyelitis is particularly worrisome in infants, in whom epiphyseal infection can spread to a joint, resulting in septic or suppurative arthritis, articular cartilage destruction, and permanent disability.

Staphylococcus aureus is responsible for 80% to 90% of culture-positive pyogenic osteomyelitis. Bacterial cell wall proteins bind to bone matrix components, such as collagen, which facilitates adherence to bone. *Escherichia coli*,

Pseudomonas, and *Klebsiella* are more frequently isolated from individuals with genitourinary tract infections or intravenous drug users. Mixed bacterial infections typically reflect direct spread or inoculation during surgery or in open fractures. *Haemophilus influenzae* and group B streptococci are common in neonates, and sickle cell disease predisposes to *Salmonella* infection. No specific organism is identified in nearly 50% of patients.

The location of bone infections is influenced by the osseous vascular circulation, which varies with age. In neonates, metaphyseal vessels penetrate the growth plate, resulting in frequent infection of the metaphysis, epiphysis, or both. In older children, involvement of the metaphysis is typical. The epiphyses and subchondral regions are more commonly involved in adults, after growth plate closure, in which merger of metaphyseal and epiphyseal vessels provides a route for bacterial spread.

MORPHOLOGY

Changes associated with osteomyelitis vary temporally and by location. In the acute phase, bacteria proliferate and recruit neutrophils to the site. Necrosis of bone cells and marrow ensues within 48 hours. Bacteria and the associated inflammatory response then spread longitudinally and access the Haversian systems to reach the periosteum. Because the periosteum is loosely attached to the cortex in children, subperiosteal abscesses may form and extend for long distances. Associated periosteal lifting further impairs blood supply and contributes to the necrosis. Soft tissue abscesses may also form after periosteal rupture, and these can channel to the skin as draining sinuses. Dead bone, or **sequestrum,** can crumble and release fragments into the sinus tract.

As the inflammatory process evolves, chronic inflammatory cells recruited during the first week release cytokines that stimulate bone resorption, fibrous tissue ingrowth, and peripheral deposition of reactive bone. This new bone can form a living shell, or **involucrum,** around the devitalized, infected bone (Fig. 26.20).

Figure 26.20 Resected femur in a person with draining osteomyelitis. The drainage tract in the subperiosteal shell of viable new bone (involucrum) reveals the inner native necrotic cortex (sequestrum).

Clinical Features

Hematogenous osteomyelitis may present acutely as a systemic illness with malaise, fever, chills, leukocytosis, and intense throbbing pain over the infected bone. In other instances, the presentation is subtle, with only unexplained fever (infants) or localized pain (adults). The characteristic radiographic finding of a lytic focus of bone destruction surrounded by sclerosis strongly suggests osteomyelitis. Blood cultures can be positive before treatment, but biopsy and bone cultures are required to identify the pathogen in most instances. The combination of antibiotics and surgical drainage is usually curative.

Acute osteomyelitis fails to resolve and persists as a chronic infection in 5% to 25% of cases. These are typically associated with delayed diagnosis, extensive bone necrosis, inadequate antibiotic therapy or surgical debridement, or weakened host defenses. Chronic infections may be punctuated by spontaneous flares that may occur after years of dormancy. Other complications of chronic osteomyelitis include pathologic fracture, secondary amyloidosis, endocarditis, and sepsis.

Mycobacterial Osteomyelitis

Mycobacterial osteomyelitis tends to be more destructive and resistant to control than pyogenic osteomyelitis. Mycobacterial osteomyelitis was previously limited to lower income countries, but the incidence has risen worldwide due to immigration and increased numbers of immunocompromised individuals. Risk of mycobacterial osteomyelitis is also increased in those with pulmonary or extrapulmonary tuberculosis, up to 3% of whom have osseous infection. The infection may persist for years before diagnosis and typically presents with localized pain, low-grade fever, chills, or weight loss. Infection is usually solitary in immunocompetent patients but can disseminate in the immunocompromised.

Mycobacteria are usually blood borne and originate from a focus of active visceral disease during the initial stages of primary infection. Bone involvement may occur by direct extension (e.g., from a pulmonary focus into a rib or from tracheobronchial nodes into adjacent vertebrae) or following spread via blood vessels and lymphatics. The histologic findings of granulomatous inflammation and caseous necrosis are typical of tuberculosis (Chapter 8).

Forty percent of mycobacterial osteomyelitis cases involve the spine *(Pott disease)*. Infection breaks through intervertebral discs to involve multiple vertebrae and surrounding soft tissues. Discs and vertebral destruction result in compression fractures that culminate in scoliosis, kyphosis, and neurologic deficits. Tuberculous osteomyelitis may also cause tuberculous arthritis, sinus tract formation, psoas abscess, and amyloidosis.

Skeletal Syphilis

Syphilis *(Treponema pallidum)* and yaws *(Treponema pertenue)* can involve bone. Although syphilis incidence is increasing, bone involvement remains rare because diagnosis and treatment typically occur before this develops.

In congenital syphilis, bone lesions appear in the fifth month of gestation and are fully developed at birth. The spirochetes concentrate at sites of active endochondral ossification and within the periosteum to cause osteochondritis and periostitis, respectively. The characteristic *saber shin* is produced by reactive periosteal bone deposition on the medial and anterior surfaces of the tibia.

In acquired syphilis, bone disease begins early in the tertiary stage, usually 2 to 5 years after the initial infection. Bones of the nose, palate, skull, and extremities, especially the long tubular bones such as the tibia, are involved most frequently.

MORPHOLOGY

Spirochetes can be detected with silver stains or by immunohistochemistry. Edematous granulation tissue with numerous plasma cells and necrotic bone characterizes syphilitic bone disease. **Obliterative endarteritis** typically accompanies caseous necrosis as part of gummas, which may be present in congenital or acquired syphilis (Chapter 8).

BONE TUMORS AND TUMOR-LIKE LESIONS

Primary bone tumors are rare and are vastly outnumbered by metastases and hematopoietic tumors. Nevertheless, the dismal survival of only 50% and disfiguring surgery often required for treatment make management of bone malignancies challenging. Therapy for the ~2400 new bone sarcomas diagnosed each year in the United States aims to optimize survival and maintain function of affected body parts.

Most bone neoplasms have a propensity for the long bones of the extremities. The age groups and anatomic sites affected are typical of specific tumor types. For example, osteosarcoma incidence peaks during adolescence and most frequently involves the knee. In contrast, chondrosarcoma affects the pelvis and proximal extremities of older adults.

Benign bone tumors are often asymptomatic and identified incidentally. Others, however, produce pain, cause a slow-growing mass, or produce a pathologic fracture. Radiologic imaging defines tumor location and can also detect features that narrow the differential diagnosis, but biopsy is necessary for definitive diagnosis in almost all cases.

Bone tumors are classified according to the normal cell types recapitulated or matrix produced. Lesions that do not have normal tissue counterparts are grouped according to clinicopathologic features (Table 26.4). After exclusion of hematopoietic neoplasms, the most common primary bone cancers are osteosarcoma, chondrosarcoma, and Ewing sarcoma.

Bone-Forming Tumors

Tumors in this category produce unmineralized osteoid or mineralized woven bone.

Table 26.4 Classification of Major Nonhematopoietic Primary Bone Tumors

Category and Fraction (%)	Behavior	Tumor Type	Common Locations	Age (years)	Morphology
Cartilage forming (40)	Benign	Osteochondroma	Metaphysis of long bones	10–30	Bony excrescence with cartilage cap
		Chondroma	Small bones of hands and feet	30–50	Circumscribed hyaline cartilage nodule in medulla
		Chondroblastoma	Epiphysis of long bones	10–20	Circumscribed, pericellular calcification
		Chondromyxoid fibroma	Tibia, pelvis	20–30	Collagenous to myxoid matrix, stellate cells
	Malignant	Chondrosarcoma (conventional)	Pelvis, shoulder	40–60	Extends from medulla through cortex into soft tissue, chondrocytes with increased cellularity and atypia
Bone forming (32)	Benign	Osteoid osteoma	Metaphysis of long bones	10–20	Cortical, interlacing microtrabeculae of woven bone
		Osteoblastoma	Vertebral column	10–20	Posterior elements of vertebra, histology similar to osteoid osteoma
	Malignant	Osteosarcoma	Metaphysis of distal femur, proximal tibia	10–20	Extends from medulla to lift periosteum, malignant cells producing woven bone
Unknown origin (19)	Benign	Giant cell tumor	Epiphysis of long bones	20–40	Destroys medulla and cortex, sheets of osteoclasts
		Aneurysmal bone cyst	Proximal tibia, distal femur, vertebra	10–20	Vertebral body, hemorrhagic spaces separated by cellular, fibrous septae
	Malignant	Ewing sarcoma	Diaphysis of long bones	10–20	Sheets of primitive small round cells
		Adamantinoma	Tibia	30–40	Cortical, fibrous bone matrix with epithelial islands
Notochordal (5)	Malignant	Chordoma	Clivus, sacrum	30–60	Destroys medulla and cortex, foamy cells in myxoid matrix

Modified from Unni KK, Inwards CY: *Dahlin's Bone Tumors*, ed 6, Philadelphia, 2010, Lippincott-Williams & Wilkins, p 5; by permission of Mayo Foundation.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and osteoblastoma are benign bone-producing tumors with similar histologic features but different sizes, sites of origin, and symptoms; malignant transformation is rare. By definition, osteoid osteomas are less than 2 cm in diameter. They are most common in young men in their teens and 20s and have a predilection for the appendicular skeleton, with about 50% involving the cortex of the femur or tibia. A thick rim of reactive cortical bone may be the only radiographic clue. Despite their small size, osteoid osteomas present with severe nocturnal pain that is probably caused by prostaglandin E_2 (PGE_2) produced by the proliferating osteoblasts and is relieved by aspirin and other NSAIDs. Osteoblastomas are larger than 2 cm, typically involve the posterior spine (laminae and pedicles), cause pain that is unresponsive to aspirin, and do not induce reactive cortical bone. Osteoid osteoma can be treated by radiofrequency ablation, but osteoblastoma usually requires curettage or en bloc excision.

MORPHOLOGY

Osteoid osteoma and osteoblastoma are round-to-oval, well-circumscribed masses of hemorrhagic, gritty tan tissue. Microscopic examination demonstrates randomly interconnected trabeculae of woven bone rimmed by a single layer of prominent osteoblasts (Fig. 26.21) and surrounded by loose connective tissue with many dilated and congested capillaries. The relatively small size, well-defined margins, and benign cytologic features of the neoplastic osteoblasts help distinguish these tumors from osteosarcoma. Reactive bone encircles the actual neoplasm, or nidus, which forms a small radiolucent core that may be centrally mineralized (Fig. 26.22).

Osteosarcoma

Osteosarcoma is the most common primary malignant tumor of bone and accounts for approximately 20% of bone cancers. The age distribution of osteosarcoma is bimodal, with 75% occurring before 20 years of age. A smaller peak occurs in older adults, in whom it is frequently associated with predisposing conditions such as Paget disease, bone infarcts, and prior radiation (sometimes called secondary osteosarcomas). Men are affected slightly more often than women (1.6:1). Although any bone can be involved, tumors usually arise in the metaphyseal region of the long bones; almost 50% are near the knee in the distal femur or proximal tibia.

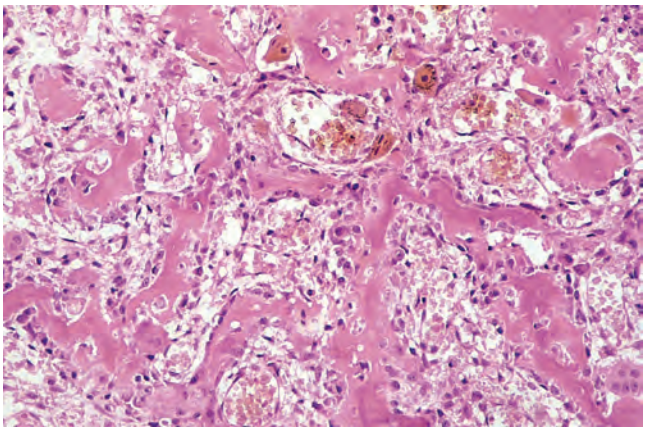

Figure 26.21 Osteoid osteoma composed of haphazardly interconnecting trabeculae of woven bone that are rimmed by prominent osteoblasts. The intertrabecular spaces are filled by vascularized loose connective tissue.

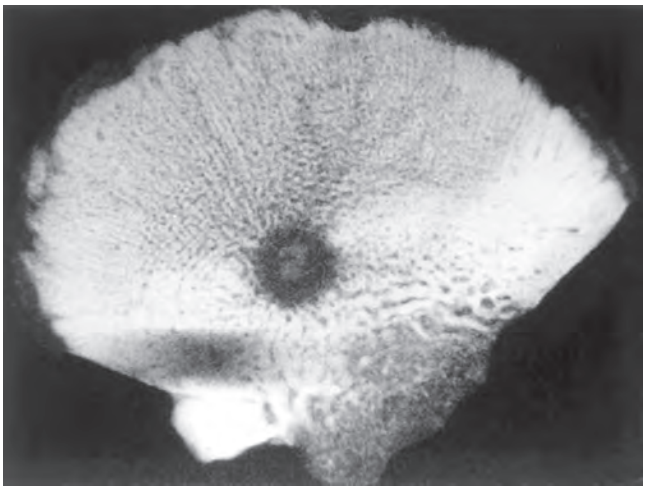

Figure 26.22 Specimen radiograph of intracortical osteoid osteoma. The round radiolucency with central mineralization represents the lesion and is surrounded by abundant reactive bone that has massively thickened the cortex.

Osteosarcomas often present with pain, sometimes due to pathologic fractures. Radiographically, the enlarging tumor forms a destructive, mixed lytic and blastic mass with infiltrative margins (Fig. 26.23). The tumor frequently breaks through the cortex and lifts the periosteum, inducing reactive periosteal bone formation. The triangular shadow between the cortex and raised periosteal ends, known radiographically as a *Codman triangle,* indicates an aggressive tumor.

Pathogenesis

The peak incidence of osteosarcoma is during the adolescent growth spurt. The tumor occurs most frequently in the growth plate of rapidly growing bones, where increased proliferation may predispose to mutations that drive oncogenesis. Approximately 70% of osteosarcomas have acquired genetic abnormalities including chromosomal aberrations. These are usually associated with mutations in well-known tumor suppressor genes and oncogenes (Chapter 7), including the following:

- *RB* mutations are present in up to 70% of sporadic osteosarcomas; germline *RB* mutations confer a 1000-fold increased risk of osteosarcoma.
- *TP53* is mutated in the germline of individuals with Li-Fraumeni syndrome, who have a greatly increased incidence of osteosarcoma. Abnormalities that interfere with p53 function are common in sporadic osteosarcomas.
- *CDKN2A* (also known as *INK4a*), which encodes two tumor suppressors, p16 and p14, is inactivated in many osteosarcomas.
- *MDM2* and *CDK4,* which inhibit p53 and RB function, respectively, are overexpressed in many low-grade osteosarcomas, often through chromosomal amplification of region 12q13–q15.

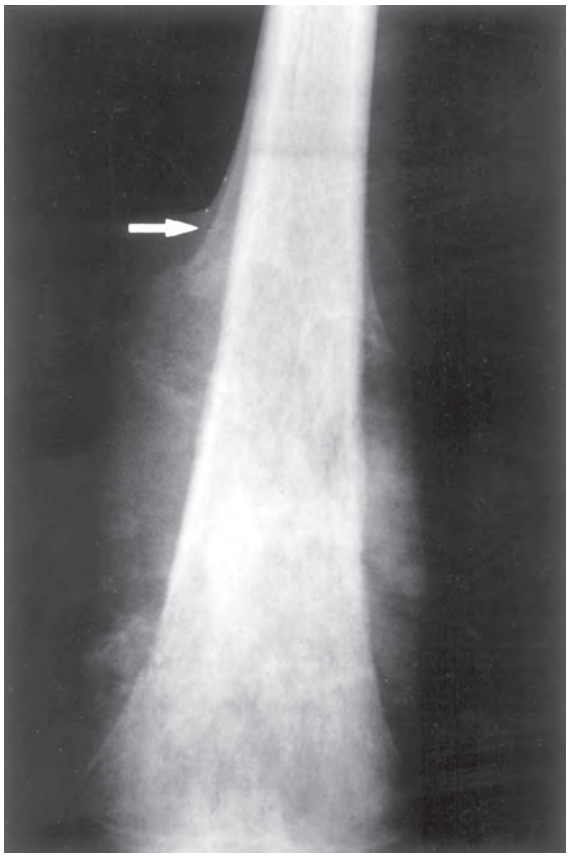

Figure 26.23 Distal femoral osteosarcoma with prominent bone formation extending into the soft tissues. The periosteum, which has been lifted, has laid down a proximal triangular shell of reactive bone known as a Codman triangle *(arrow)*.

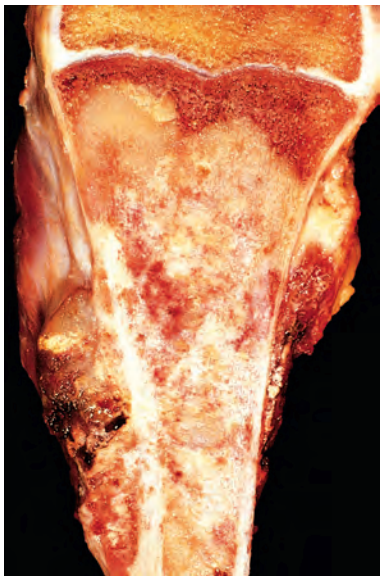

Figure 26.24 Osteosarcoma of the proximal tibia. The tan-white tumor fills most of the medullary cavity of the metaphysis and proximal diaphysis. It has infiltrated through the cortex, lifted the periosteum, and formed soft tissue masses on both sides of the bone.

MORPHOLOGY

Osteosarcomas are bulky, gritty, gray-white tumors that often contain hemorrhage and cystic degeneration (Fig. 26.24). The tumor frequently destroys the surrounding cortices to produce soft tissue masses, spread extensively in the medullary canal, and replace hematopoietic marrow. Tumors infrequently penetrate the epiphyseal plate or enter the joint, where they may grow along tendoligamentous structures or through the attachment site of the joint capsule.

Osteosarcomas demonstrate pleomorphism, large hyperchromatic nuclei, bizarre tumor giant cells, and abundant mitoses including abnormal (e.g., tripolar) forms. Extensive necrosis and intravascular invasion are also common. Diagnosis of osteosarcoma requires the presence of malignant tumor cells producing unmineralized osteoid or mineralized bone (Fig. 26.25), which is typically fine and lacelike, but can also form broad sheets or primitive trabeculae. Neoplastic cells can also produce cartilage; if abundant, such tumors are classified as **chondroblastic osteosarcoma.**

Clinical Features

Based on their known natural history, all osteosarcoma patients are assumed to have occult metastases at the time of diagnosis. As a result, treatment generally includes neoadjuvant chemotherapy, surgery, and postoperative adjuvant chemotherapy. Chemotherapy has greatly improved osteosarcoma prognosis, with 5-year survival reaching 70% in individuals without overt metastases at initial diagnosis. Osteosarcoma metastasizes hematogenously to the lungs, bones, brain, and other sites. The outcome for those with clinically evident metastases, recurrent disease, or secondary osteosarcoma remains guarded, with a 5-year survival rate less than 20%.

Cartilage-Forming Tumors

Cartilaginous tumors account for the majority of benign and malignant primary bone tumors. They are characterized by the formation of hyaline or myxoid cartilage; fibrocartilage and elastic cartilage are rare. Benign cartilage tumors are much more common than malignant lesions.

Osteochondroma

Osteochondroma, or exostosis, is the most common benign bone tumor. It is attached to the skeleton by a bony stalk

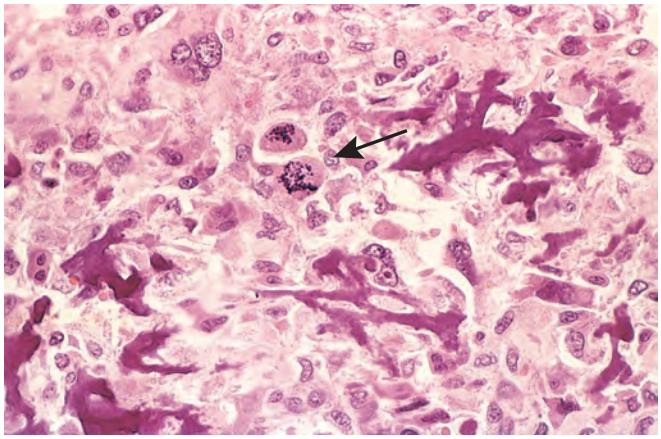

Figure 26.25 Fine, lacelike pattern of neoplastic bone produced by anaplastic malignant tumor cells in an osteosarcoma. Note the abnormal mitotic figures *(arrow)*.

capped by cartilage. About 85% of osteochondromas are solitary and sporadic, with the remainder occurring as part of autosomal dominant *multiple hereditary exostosis syndrome.* Solitary osteochondromas are usually diagnosed in late adolescence and early adulthood, but multiple osteochondromas become apparent during childhood. Men are affected three times more often than women. Osteochondromas develop only in bones of endochondral origin. The most common site is the metaphysis near the growth plate of long tubular bones, especially near the knee, followed by the bones of the pelvis, scapula, and ribs, where they tend to have short stalks. Osteochondromas present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases, they are detected incidentally. In multiple hereditary exostosis syndrome, the underlying bones may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth.

Pathogenesis

Hereditary exostoses are associated with germline loss-of-function mutations in either the *EXT1* or the *EXT2* gene and subsequent loss of the remaining wild-type allele in chondrocytes of the growth plate. Reduced expression of *EXT1* or *EXT2* has also been observed in sporadic osteochondromas. These genes encode enzymes that synthesize heparan sulfate glycosaminoglycans. The reduced or abnormal glycosaminoglycans may prevent normal diffusion of Indian hedgehog (Ihh), a local regulator of cartilage growth, thereby disrupting Hedgehog signaling and chondrocyte differentiation.

MORPHOLOGY

Osteochondromas are sessile or pedunculated and range in size from 1 to 20 cm. The cap is composed of benign hyaline cartilage (Fig. 26.26) and is covered by perichondrium. The cartilage has the histologic appearance of a disorganized growth plate and undergoes endochondral ossification, with newly made bone forming the inner portion of the head and stalk. The cortex of the stalk merges with the cortex of the host bone, so that the medullary cavity of the osteochondroma is in continuity with that of the bone from which it arises.

Clinical Features

Osteochondromas usually stop expanding at the time of growth plate closure and, when symptomatic, are cured by simple excision. Secondary chondrosarcoma occurs rarely, usually in tumors associated with multiple hereditary exostosis.

Chondroma

Chondroma is a benign tumor of hyaline cartilage that occurs in bones of endochondral origin. Tumors can arise within the medullary cavity, where they are termed *enchondromas,* or on the bone surface, where they are called *juxtacortical chondromas.* Enchondromas are the most common intraosseous cartilage tumor; they are typically solitary metaphyseal lesions of tubular bones of the hands and feet. Radiographically, enchondromas display a circumscribed lucency with central irregular calcifications, a sclerotic rim, and an intact cortex (Fig. 26.27). *Ollier disease* and *Maffucci syndrome* are nonhereditary disorders characterized by multiple enchondromas. Maffucci syndrome is distinguished by the presence of spindle cell hemangiomas and other noncartilage neoplasms.

Enchondromas are most often diagnosed between 20 and 50 years of age. When they involve large bones, enchondromas are usually asymptomatic and detected incidentally.

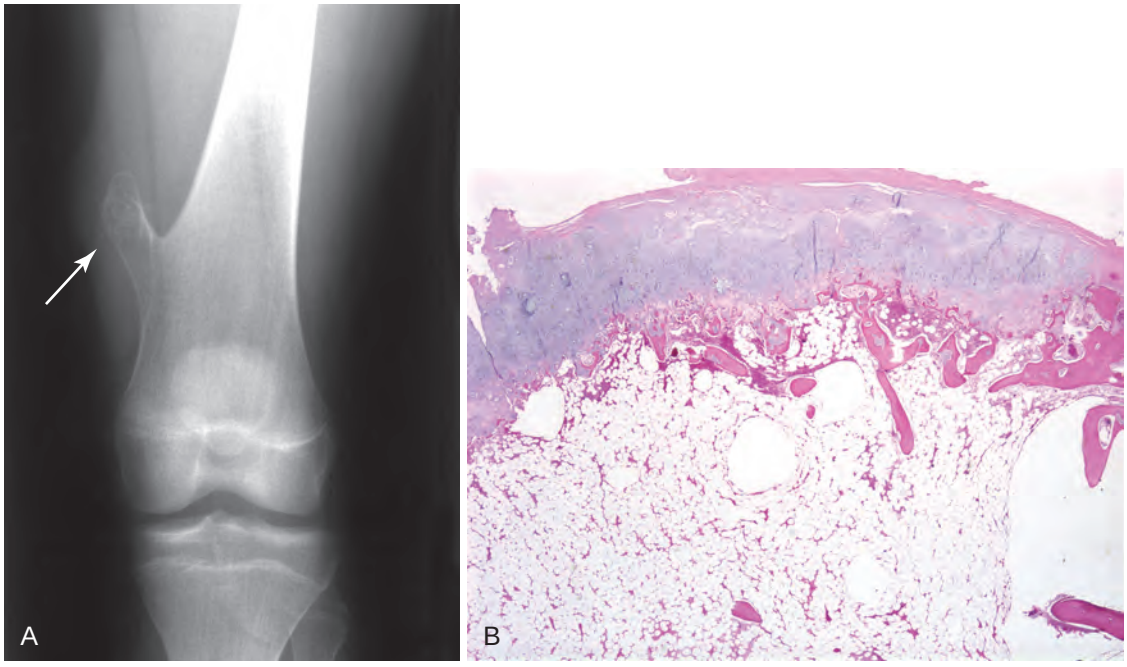

Figure 26.26 Osteochondroma. (A) Radiograph of an osteochondroma arising from the distal femur *(arrow).* (B) The cartilage cap has the histologic appearance of disorganized growth plate–like cartilage.

Figure 26.27 Enchondroma of the proximal phalanx. The radiolucent nodule of cartilage with central calcification thins but does not penetrate the cortex.

Occasionally, they can be painful or cause pathologic fractures. In enchondromatosis, the tumors may be numerous and large, producing severe deformities.

Pathogenesis

Heterozygous mutations in the *IDH1* and *IDH2* genes are present within enchondromas. Individuals with enchondroma syndromes are genetically mosaic, harboring *IDH* mutations in a subset of otherwise normal cells throughout their bodies. Similarly, *IDH* mutations are present in only a subset of tumor cells in both syndromic and sporadic enchondromas. This unusual situation may be explained by the functional consequences of *IDH* mutations, which cause the encoded proteins, two isoforms of the enzyme isocitrate dehydrogenase, to acquire a new enzymatic activity that leads to the synthesis of 2-hydroxyglutarate. This "oncometabolite" interferes with regulation of DNA methylation (Chapter 7). It is hypothesized that 2-hydroxyglutarate produced by *IDH*-mutated cells diffuses into neighboring cells with normal *IDH* genes, thereby causing oncogenic epigenetic changes in genetically normal neighbors, a phenomenon referred to as transformation by association.

MORPHOLOGY

Enchondromas are well-circumscribed nodules that are usually smaller than 3 cm, gray-blue, and translucent. Histologically, enchondromas are composed of hyaline cartilage containing cytologically benign chondrocytes (Fig. 26.28). Peripheral endochondral ossification may occur, and the center can calcify and infarct. The enchondromas in Ollier disease and Maffucci syndrome are sometimes more cellular than sporadic enchondromas and can exhibit cytologic atypia, making them difficult to distinguish from chondrosarcomas.

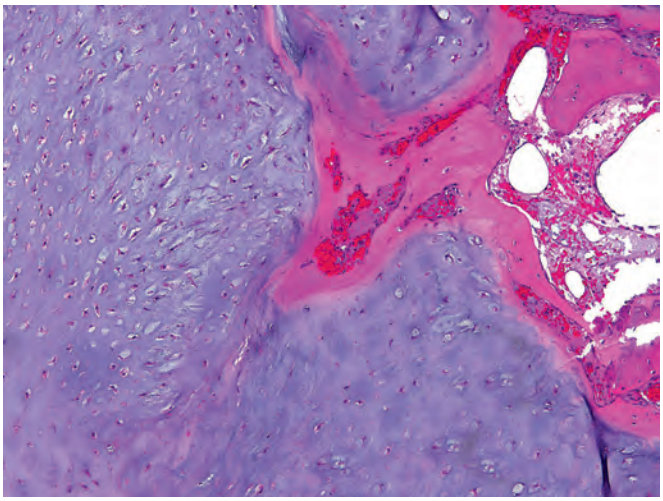

Figure 26.28 Enchondroma composed of a nodule of hyaline cartilage encased by a thin layer of reactive bone.

Clinical Features

The growth potential of chondromas is limited. Treatment depends on the clinical situation and is usually observation or curettage. Solitary chondromas rarely undergo sarcomatous transformation, but those associated with enchondromatosis do so more frequently. Individuals with Maffucci syndrome develop multiple enchondromas and spindle cell hemangiomas and are also at risk of developing other malignancies, including brain gliomas, another type of cancer associated with IDH gene mutations (Chapter 28).

Chondrosarcoma

Chondrosarcomas are malignant cartilage-producing tumors. They are subclassified histologically as conventional, clear cell, dedifferentiated, and mesenchymal variants. After osteosarcoma, chondrosarcoma is the second most common malignant matrix-producing tumor of bone. Individuals with chondrosarcoma are usually in their 40s or older, and men are affected twice as frequently as women; most are of the conventional histologic type. The clear cell and mesenchymal variants occur in younger people, in their teens or 20s. Chondrosarcomas commonly arise in the axial skeleton, especially the pelvis, shoulder, and ribs, but, unlike benign enchondroma, distal extremities are rarely involved. On imaging, the calcified matrix of chondrosarcomas appears as foci of flocculent densities. Slow-growing, low-grade tumors cause reactive cortical thickening, whereas aggressive high-grade neoplasms destroy the cortex and form soft tissue masses. The clear cell variant is unique in that it originates in the epiphyses of long tubular bones. About 15% of conventional chondrosarcomas are secondary and arise from enchondromas or osteochondromas.

Pathogenesis

Although chondrosarcomas are genetically heterogeneous, a few recurrent driver mutations are recognized. Chondrosarcomas arising in multiple osteochondroma syndrome exhibit mutations in the *EXT* genes, while both chondromatosis-related and sporadic chondrosarcomas may have *IDH1* or *IDH2* mutations. Silencing of the *CDKN2A* tumor suppressor

locus by DNA methylation is relatively common in sporadic tumors.

MORPHOLOGY

Conventional chondrosarcomas are large bulky tumors made up of nodules of glistening gray-white, translucent cartilage, but the matrix is often gelatinous or myxoid and can ooze from the cut surface (Fig. 26.29A). Spotty calcifications are typically present, and central necrosis may create cystic spaces. Tumor spreads through the cortex and into surrounding muscle and fat. Histologically, neoplastic cartilage infiltrates the marrow space and surrounds preexisting bony trabeculae (Fig. 26.29B). Chondrosarcomas vary in cellularity, degree of cytologic atypia, and mitotic activity and, on this basis, are graded from 1 to 3 (Fig. 26.29C).

Dedifferentiated chondrosarcoma is a low-grade chondrosarcoma with a second, high-grade component that does not produce cartilage. **Clear cell chondrosarcoma** contains sheets of large, malignant chondrocytes that have abundant clear cytoplasm, numerous osteoclast-type giant cells, and intralesional bone formation. **Mesenchymal chondrosarcoma** is composed of islands of well-differentiated hyaline cartilage surrounded by sheets of primitive appearing small round cells.

Clinical Features

Chondrosarcomas present as painful, progressively enlarging masses. The histologic grade correlates directly with biologic behavior. Most conventional chondrosarcomas are grade 1 tumors, which only rarely metastasize and have 5-year survival rates of 80% to 90%. In contrast, 70% of grade 3 tumors spread hematogenously, especially to the lungs, and 5-year survival is only 43%. Treatment of conventional chondrosarcoma is wide surgical excision, but mesenchymal and dedifferentiated tumors require excision and adjuvant chemotherapy because of their more aggressive clinical course.

Tumors of Unknown Origin

Ewing Sarcoma

Ewing sarcoma is a malignant bone tumor characterized by primitive round cells without obvious differentiation. Ewing sarcomas account for approximately 6% to 10% of primary malignant bone tumors and follow osteosarcoma as the second most common group of bone sarcomas in children. Approximately 80% of patients are younger than 20 years of age. Boys are affected slightly more often than girls, and there is a striking predilection for Caucasians; individuals of African or Asian descent are rarely afflicted.

Ewing sarcoma usually arises in the diaphysis of long tubular bones, especially the femur and the flat bones of the pelvis and presents as a painful, enlarging mass. The affected site is frequently tender, warm, and swollen, and there may be systemic findings that mimic infection, including fever, elevated sedimentation rate, anemia, and leukocytosis. Radiographs show a destructive lytic tumor with permeative, or moth-eaten, margins that extend into surrounding soft tissues. The characteristic periosteal reaction produces layers of reactive bone deposited in an onion-skin fashion.

Pathogenesis

Greater than 90% of Ewing sarcomas contain a balanced translocation involving the *EWSR1* gene on chromosome 22; in a large majority of tumors, the other partner is the *FLI1* gene on chromosome 11, creating an *EWSR1/FLI1* fusion gene. This gene encodes a chimeric EWS/FLI1 protein that binds to chromatin and dysregulates transcription, leading to uncontrolled growth and abnormal differentiation through uncertain mechanisms. The cell of origin is not certain, but mesenchymal stem cells and primitive neuroectodermal cells are most likely.

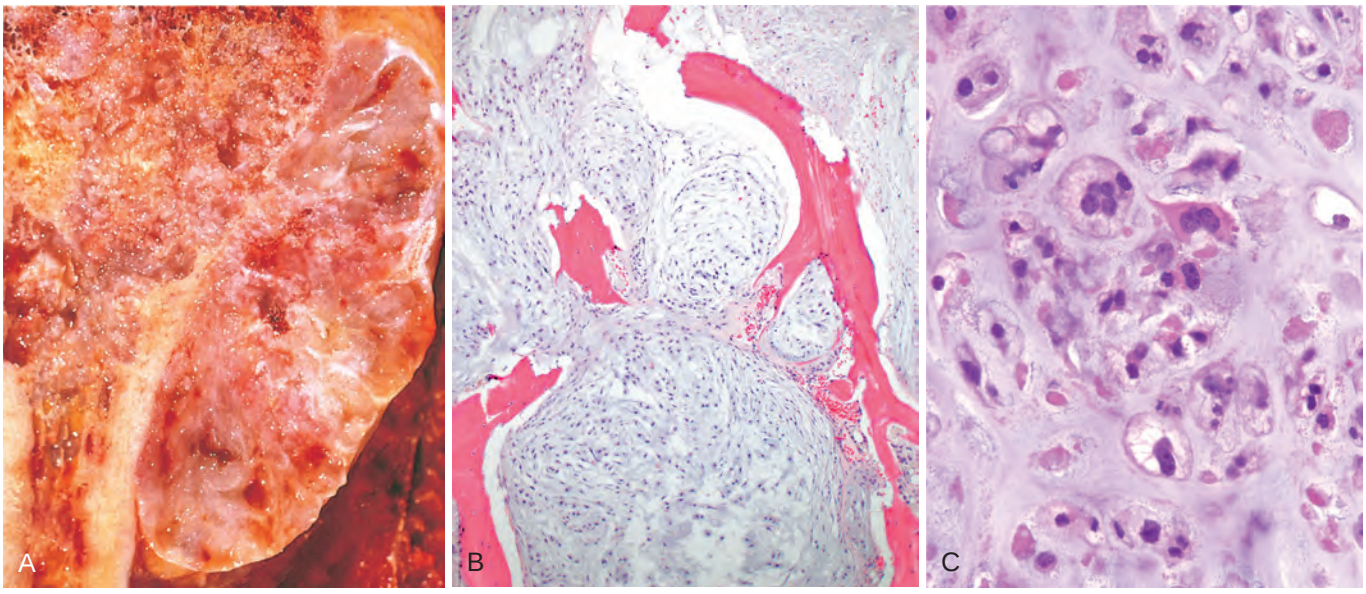

Figure 26.29 Chondrosarcoma. (A) Nodules of hyaline and myxoid cartilage permeate the medullary cavity, grow through the cortex, and form a relatively well-circumscribed soft tissue mass. (B) Conventional chondrosarcoma appearing as a hypercellular cartilaginous mass with entrapped normal bone trabeculae. (C) Anaplastic chondrocytes amid hyaline cartilage matrix in a grade 3 chondrosarcoma.

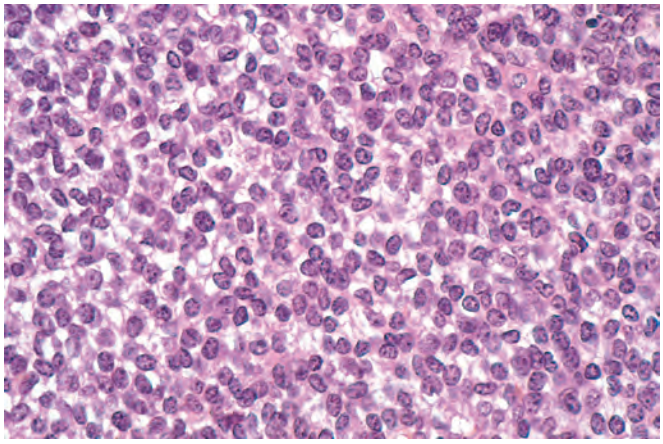

Figure 26.30 Ewing sarcoma composed of sheets of uniform, small round cells with scant clear cytoplasm.

MORPHOLOGY

Ewing sarcoma usually arises in the medullary cavity and invades the cortex, periosteum, and soft tissue. The tumor is soft, tan-white, and frequently contains areas of hemorrhage and necrosis. It is composed of sheets of uniform small, round cells with scant cytoplasm that may be clear due to abundant glycogen (Fig. 26.30). When present, **Homer-Wright rosettes,** which are rounded cell clusters with a central fibrillary core, indicate neuroectodermal differentiation. Fibrous septae may also be present, but there is little stroma. Geographic necrosis may be prominent.

Clinical Features

Although Ewing sarcoma is aggressive, neoadjuvant chemotherapy followed by surgical excision and adjuvant chemotherapy, with or without irradiation, has achieved 75% 5-year survival and 50% long-term cure rates. Chemotherapy-induced necrosis is a positive prognostic indicator.

Giant Cell Tumor

Giant cell tumor is characterized by the presence of numerous multinucleated osteoclast-type giant cells, and is also called *osteoclastoma*. Although giant cell tumors are benign, they can be locally aggressive. This uncommon tumor usually arises in the third through fifth decades of life.

Pathogenesis

Most cells within giant cell tumors are non-neoplastic osteoclasts and their precursors. The neoplastic cells are primitive osteoblast precursors that express high levels of RANKL, which in turn promotes the proliferation of osteoclast precursors and their differentiation into mature osteoclasts. The absence of normal feedback between osteoblasts and osteoclasts results in localized, but highly destructive, bone resorption. The neoplastic cells have acquired mutations in the gene encoding histone 3.3, a chromatin packaging protein; precisely how this leads to tumor formation is unknown.

Giant cell tumors develop within the epiphysis and may extend into the metaphysis. The majority are near the knee, involving the distal femur or proximal tibia, but virtually any bone can be involved. Because they typically arise near joints, giant cell tumors may cause arthritis-like symptoms. They can also present with pathologic fractures.

Figure 26.31 Giant cell tumor of the proximal fibula is predominantly lytic and expansile with destruction of the cortex. A pathologic fracture is also present.

MORPHOLOGY

Giant cell tumors often destroy the overlying cortex, resulting in a bulging soft tissue mass delineated by a thin shell of reactive bone (Fig. 26.31). Grossly, the tumors are large, red-brown masses that frequently undergo cystic degeneration. Histologically, the tumors consist of uniform oval mononuclear tumor cells and abundant osteoclast-type giant cells with 100 or more nuclei (Fig. 26.32). Necrosis and mitotic activity may be prominent. Although reactive bone may be present, especially at the periphery, tumor cells do not synthesize bone or cartilage.

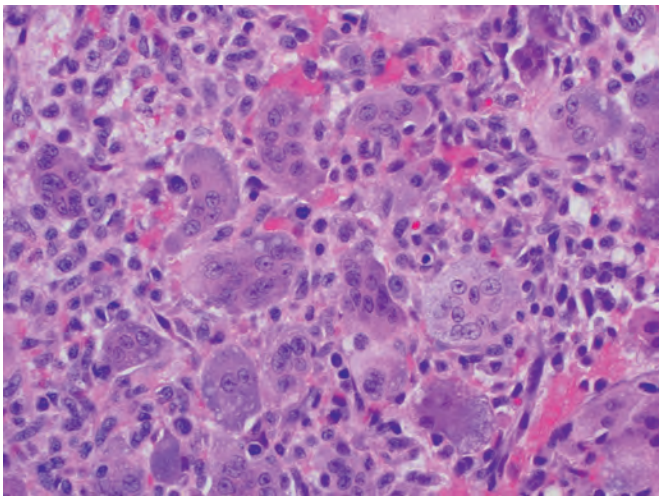

Figure 26.32 Benign giant cell tumor illustrating an abundance of multinucleated giant cells with background mononuclear stromal cells.

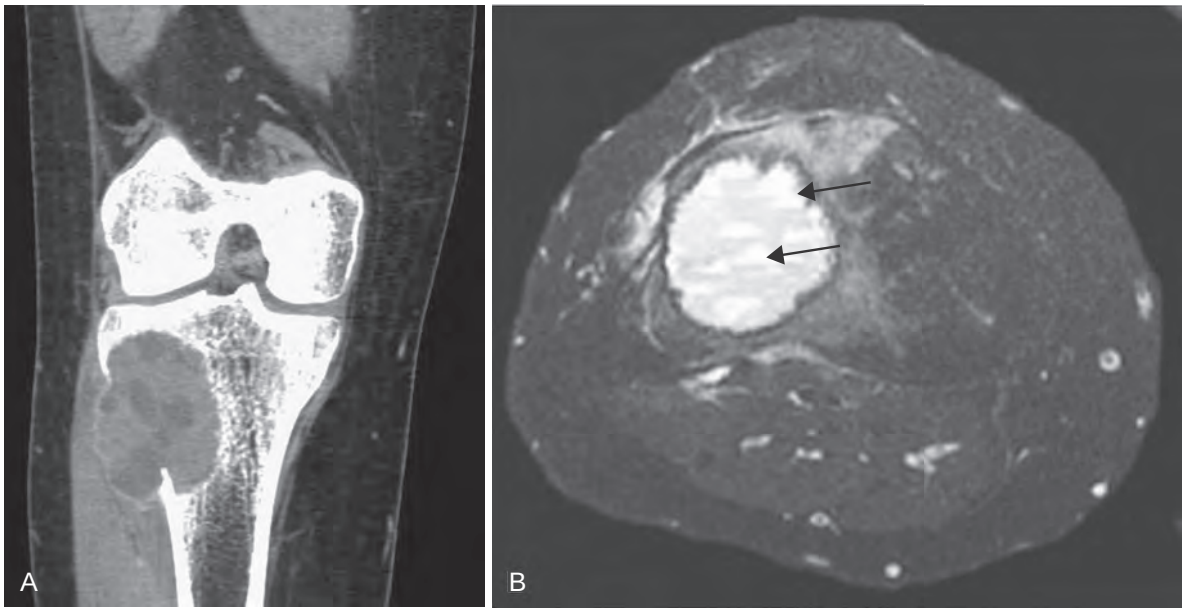

Figure 26.33 (A) Coronal computed axial tomography scan showing an eccentric aneurysmal bone cyst of the tibia. The soft tissue component is delineated by a thin rim of reactive subperiosteal bone. (B) Axial magnetic resonance image demonstrating characteristic fluid levels *(arrows)*.

Clinical Features

Giant cell tumors are treated by curettage, but 40% to 60% recur locally. Although up to 4% metastasize to the lungs, these can regress spontaneously and are seldom fatal. The RANKL inhibitor denosumab has shown promise as an adjuvant therapy.

Aneurysmal Bone Cyst

Aneurysmal bone cyst (ABC) is characterized by multiloculated blood-filled spaces. All age groups are affected, but most cases present in adolescence. ABC develops most frequently in the femur, tibia, and vertebral body posterior elements.

Radiographically, ABC is usually an expansile, well-circumscribed lytic lesion with well-defined margins (Fig. 26.33A). Most show central lysis and a thin sclerotic "eggshell" of reactive bone at the periphery. Supporting trabeculae may create a "soap bubble" appearance on plain films and internal septae with air-fluid levels by computed tomography and magnetic resonance imaging (Fig. 26.33B). These findings are not specific, as similar radiographic (and histologic) changes can also occur as a reaction to trauma and in association with other bone tumors.

Pathogenesis

In nearly 70% of cases of ABC, chromosome 17p13 rearrangements are present within the plump spindle cells, but not in multinucleated giant cells, inflammatory cells, endothelial cells, or osteoblasts. The chromosomal rearrangement results in fusion of the *USP6* coding region with the promoters of genes that are highly expressed in osteoblasts, such as *CDH11*. *USP6* encodes a ubiquitin-specific protease that regulates the activity of the transcription factor NF-κB, which in turn up-regulates expression of proteins, such as matrix metalloproteases, that lead to cystic bone resorption.

MORPHOLOGY

ABCs consist of multiple blood-filled cystic spaces separated by thin, tan-white septa (Fig. 26.34). The septa are composed of plump spindle cells, multinucleated osteoclast-like giant cells, and reactive woven bone lined by osteoblasts. Bone deposition typically follows the contours of fibrous septa. Approximately one-third of cases contain an unusual densely calcified, basophilic metaplastic matrix referred to as **"blue bone."** Necrosis is uncommon unless a pathologic fracture is present.

Clinical Features

ABC presents with localized pain and swelling that may result in a limp, vertebral lesions, and nerve compression.

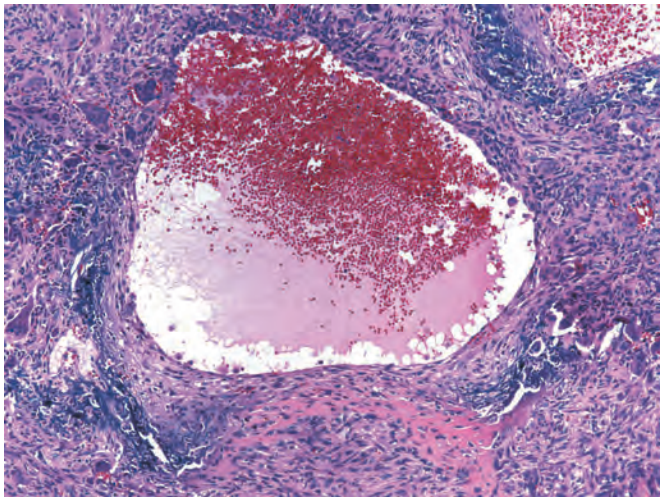

Figure 26.34 Aneurysmal bone cyst with blood-filled cystic space surrounded by a fibrous wall containing proliferating fibroblasts, reactive woven bone, and osteoclast-type giant cells.

Despite being benign, ABC is locally aggressive. Treatment of ABC is by curettage or excision. Recurrence occurs in 10% to 50% of cases.

Lesions Simulating Primary Neoplasms

Fibrous Cortical Defect and Nonossifying Fibroma

Fibrous cortical defects, also known as metaphyseal fibrous defects, are common developmental abnormalities in which fibrous connective tissue replaces bone. These lesions are present in up to 50% of children older than 2 years of age and typically present as an incidental finding in adolescents. The vast majority arise eccentrically in the metaphysis of the distal femur and proximal tibia; almost half are bilateral or multiple. Most are less than 0.5 cm in diameter, but those that grow to 5 or 6 cm are classified as *nonossifying fibromas*.

MORPHOLOGY

Both fibrous cortical defects and nonossifying fibromas are small, sharply demarcated radiolucent masses surrounded by a thin rim of sclerosis (Fig. 26.35). They are grossly yellow-brown and consist histologically of bland fibroblasts that are frequently arranged in a storiform (pinwheel) pattern and macrophages that can take the form of clustered cells with foamy cytoplasm or multinucleated giant cells (Fig. 26.36). Hemosiderin is commonly present.

Figure 26.35 Nonossifying fibroma of the distal tibial metaphysis producing an eccentric, lobulated radiolucency surrounded by a sclerotic margin.

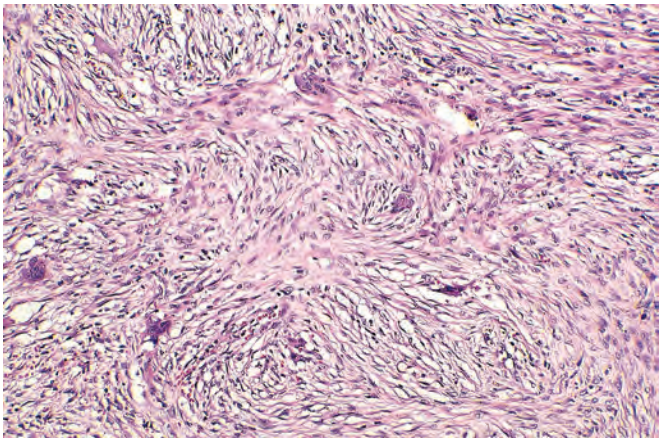

Figure 26.36 Storiform pattern created by benign spindle cells with scattered osteoclast-type giant cells characteristic of a fibrous cortical defect and nonossifying fibroma.

Clinical Features

Fibrous cortical defects are asymptomatic and are detected incidentally on radiographic studies. The radiographic findings are sufficiently specific that biopsy is rarely necessary. Most fibrous cortical defects have limited growth potential and undergo spontaneous resolution over time as they are replaced by normal cortical bone. The few that progressively enlarge into nonossifying fibromas may present with pathologic fracture or require biopsy to exclude other types of tumors. They are treated with curettage and may require bone-grafting for proper healing.

Fibrous Dysplasia

Fibrous dysplasia is a benign tumor that has been likened to localized developmental arrest; all of the components of normal bone are present, but they do not differentiate into mature structures. The lesions arise during skeletal development and appear in several distinctive but sometimes overlapping clinical patterns:

- *Monostotic:* involvement of a single bone
- *Polyostotic:* involvement of multiple bones
- *Mazabraud syndrome:* fibrous dysplasia (usually polyostotic) and soft tissue myxomas
- *McCune-Albright syndrome:* polyostotic disease, associated with café-au-lait skin pigmentations and endocrine abnormalities, especially precocious puberty

Pathogenesis

All forms of fibrous dysplasia result from somatic gain-of-function mutations in *GNAS1*, which encodes the stimulatory α subunit of G_s and is also mutated in pituitary adenomas (Chapter 24). The resulting constitutively active G_s protein promotes cellular proliferation and disturbs osteoblast differentiation. These mutations occur early in embryogenesis, and affected individuals are genetic mosaics. The phenotype depends on (1) the stage of embryogenesis when the mutation is acquired and (2) the fate of the cell harboring the mutation. At one extreme, a mutation during early embryogenesis produces McCune-Albright syndrome. In contrast, a mutation in an osteoblast precursor, during or after formation of the skeleton, results in monostotic fibrous dysplasia.

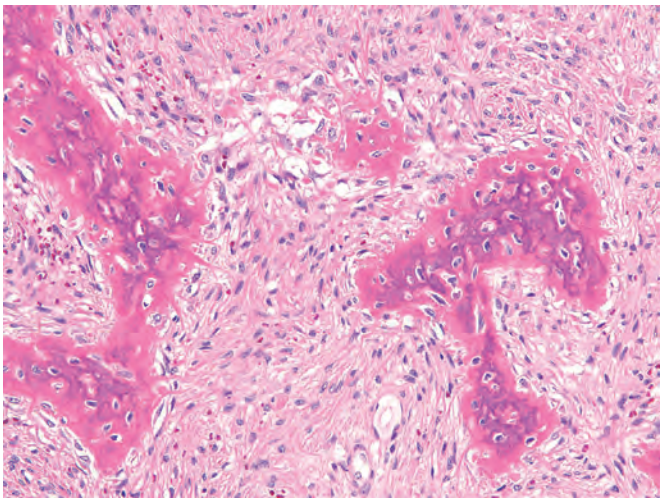

Figure 26.37 Fibrous dysplasia composed of curvilinear trabeculae of woven bone that lack conspicuous osteoblastic rimming and arise in a background of fibrous tissue.

MORPHOLOGY

The lesions of fibrous dysplasia are intramedullary lytic lesions that may expand and cause bowing and cortical thinning. Periosteal reaction usually is absent. Lesional tissue is tan-white and gritty on gross examination and is composed of curvilinear trabeculae of woven bone surrounded by a moderately cellular fibroblastic proliferation without prominent osteoblastic rimming (Fig. 26.37). Nodules of hyaline cartilage with the appearance of disorganized growth plates are present in approximately 20% of cases. Cystic degeneration, hemorrhage, and foamy macrophages are also common.

Clinical Features

Monostotic fibrous dysplasia occurs in early adolescence and often stops enlarging at the time of growth plate closure. The femur, tibia, ribs, jawbones, and calvarium are most commonly affected. The lesion is frequently asymptomatic and usually discovered incidentally but may cause pain, discrepancies in limb length, and pathologic fracture. Growth of the lesions may be reactivated during pregnancy. Symptomatic lesions are treated by curettage, but recurrence is common.

Polyostotic fibrous dysplasia manifests at a slightly earlier age than the monostotic type and may continue to cause problems into adulthood. The femur, skull, and tibia are most frequently affected. Craniofacial involvement is present in 50% of those who have a moderate number of bones affected and in 100% of those with extensive skeletal disease. Involvement of the shoulder and pelvic girdles results in progressive disease and may produce crippling deformities and fractures that require multiple corrective orthopedic surgical procedures. Bisphosphonates can be used to reduce the severity of the bone pain. A rare complication, usually in the setting of polyostotic involvement, is malignant transformation of a lesion into a sarcoma.

Mazabraud syndrome presents with skeletal features of polyostotic fibrous dysplasia in childhood followed by the appearance of intramuscular myxomas in adulthood, often in the same anatomic region as existing fibrous dysplasia. Although benign, myxomas can cause local compression symptoms or limb deformity but are cured by surgical excision.

The most common clinical presentation of McCune-Albright syndrome is precocious sexual development, primarily in girls. The syndrome can include other endocrinopathies such as hyperthyroidism, pituitary adenomas that secrete growth hormone, and primary adrenal hyperplasia. Bone lesions are often unilateral, and skin lesions, when present, are limited to the same side of the body. The cutaneous lesions are classically large macules, dark to café-au-lait in color, with irregular serpiginous borders. Skeletal manifestations are managed as for polyostotic fibrous dysplasia, while the endocrinopathies are treated medically (e.g., with aromatase inhibitors for precocious puberty).

Metastatic Tumors

Metastatic tumors are the most common form of skeletal malignancy, greatly outnumbering primary bone cancers. The pathways of spread to bone include (1) direct extension, (2) lymphatic or hematogenous dissemination, and (3) intraspinal seeding (via the Batson plexus of veins). Any cancer can spread to bone, but in adults more than 75% of skeletal metastases originate from cancers of the prostate, breast, kidney, and lung. In children, neuroblastoma, Wilms tumor, osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma are the most common metastases to bone.

Skeletal metastases are typically multifocal. However, carcinomas of the kidney and thyroid may present with solitary lesions. Most metastases involve the axial skeleton (vertebral column, pelvis, ribs, skull, and sternum) in which the marrow has a rich capillary network.

The radiographic appearance of metastases may be *lytic* (bone destroying), *blastic* (bone forming), or *mixed* lytic and blastic. Some cancers are associated with predominantly one pattern. For example, prostatic adenocarcinoma is predominantly blastic, whereas carcinomas of the kidney, lung, and gastrointestinal tract and malignant melanoma produce lytic lesions. Bidirectional interactions between metastatic cancer cells and native bone cells account for changes in the bone matrix. Tumor cells do not directly resorb bone in lytic lesions, but they secrete substances such as prostaglandins, cytokines, and PTHrP that up-regulate RANKL on osteoblasts and stromal cells, thereby stimulating osteoclast activity. Conversely, tumor cell growth is supported by the release of matrix-bound growth factors (e.g., TGF-β, IGF-1, and FGF) as bone is resorbed. Sclerotic metastases may result from tumor cells secreting WNT proteins that stimulate osteoblastic bone formation.

The presence of bone metastases portends a poor prognosis because it indicates wide dissemination of the cancer. Goals of therapy are symptomatic relief and prevention of further spread. When treated, options include systemic chemotherapy or immunotherapy, localized radiation, and bisphosphonates. Surgery may be necessary to stabilize pathologic fractures, particularly when metastases involve the spine.

KEY CONCEPTS

BONE TUMORS AND TUMOR-LIKE LESIONS

The majority of bone tumors are classified according to the normal cell they resemble or matrix produced; the remainder are grouped by clinicopathologic features. Most primary bone tumors are benign. Metastases, especially adenocarcinomas, are more common than primary bone neoplasms.

Major categories of primary bone tumors include the following:

- Bone forming: Osteoblastoma and osteoid osteoma consist of benign osteoblasts that synthesize osteoid. Osteosarcoma is a tumor of malignant osteoblasts with an aggressive clinical course that predominantly involves adolescents.
- Cartilage forming: Osteochondroma is a polypoid exostosis with a cartilage cap. Syndromic forms are most often associated with mutations in *EXT* genes. Chondromas are benign intramedullary tumors that produce hyaline cartilage and usually arise in the digits. Chondrosarcomas are malignant tumors of cartilage involving the axial skeleton in adults.
- Ewing sarcoma is an aggressive malignant small round cell tumor associated with t(11;22).
- Fibrous cortical defect and fibrous dysplasia are unusual developmental abnormalities; the latter is caused by somatic gain-of-function mutations in the *GNAS1* gene during embryogenesis.

Joints

Joints allow movement while providing mechanical stability. They are classified as solid (nonsynovial) and cavitated (synovial). Solid joints, or synarthroses, provide structural integrity, lack a joint space, and allow only minimal movement. They are grouped according to the type of connective tissue (fibrous tissue or cartilage) that bridges the ends of the bones. Fibrous synarthroses include the cranial sutures and the bonds between roots of teeth and the jawbones. Immobile cartilaginous joints, or synchondroses, include symphyses (manubriosternalis and pubic). Synovial joints, in contrast, have a joint space that allows for a wide range of motion. Situated between the ends of bones formed via endochondral ossification, they are strengthened by a dense fibrous capsule reinforced by ligaments and muscles. The boundary of the joint space consists of the synovial membrane, which is firmly anchored to the underlying capsule and does not cover the articular surface. The synovium is smooth except near the osseous insertion, where it is thrown into numerous villous folds. Synovial membranes are lined by two types of cells arranged in one to four cell deep layers. Type A synoviocytes are specialized macrophages with phagocytic activity. Type B synoviocytes are similar to fibroblasts and synthesize hyaluronic acid and various proteins. The synovial lining lacks a basement membrane, which allows for efficient exchange of nutrients, waste, and gases between blood and synovial fluid. Synovial fluid is therefore a hyaluronic acid–rich plasma filtrate that acts as a viscous lubricant and provides nutrition for the articular hyaline cartilage.

Hyaline cartilage is a unique connective tissue ideally suited to serve as an elastic shock absorber and wear-resistant surface. Hyaline cartilage is composed of water (70%), type II collagen (10%), proteoglycans (8%), and chondrocytes. The collagen fibers enable resistance to tensile stresses and transmit vertical loads; water and proteoglycans limit compression and friction. Hyaline cartilage lacks blood vessels, lymphatics, and nerves. Chondrocytes synthesize and enzymatically digest matrix, with the half-life of the different components ranging from weeks (proteoglycans) to years (type II collagen). Chondrocytes secrete degradative enzymes in inactive forms and enrich the matrix with enzyme inhibitors. Diseases that destroy articular cartilage do so by activating the degradative enzymes and decreasing the production of their inhibitors, leading to matrix breakdown. Cytokines such as IL-1 and TNF are released by chondrocytes, synoviocytes, fibroblasts, and inflammatory cells and trigger degradative processes. Articular cartilage destruction by indigenous cells contributes to pathogenesis of many joint diseases.

ARTHRITIS

Arthritis refers to inflammation of joints. The clinically most important forms of arthritis are osteoarthritis and rheumatoid arthritis, which differ in pathogenesis and clinical and pathologic manifestations (Table 26.5). Other types of arthritis

Table 26.5 Comparative Features of Osteoarthritis and Rheumatoid Arthritis

	Osteoarthritis	Rheumatoid Arthritis
Primary pathogenic abnormality	Mechanical injury to articular cartilage	Autoimmunity
Role of inflammation	May be secondary; inflammatory mediators exacerbate cartilage damage	Primary: cartilage destruction is caused by T cells and antibodies reactive with joint antigens
Joints involved	Primarily weight bearing (knees, hips)	Often begins with small joints of fingers; progression leads to multiple joints involved
Pathology	Cartilage degeneration and fragmentation, bone spurs, subchondral cysts; minimal inflammation	Inflammatory pannus invading and destroying cartilage; severe chronic inflammation; joint fusion (ankylosis)
Serum antibodies	None	Various, including ACPA, rheumatoid factor
Involvement of other organs	No	Yes (lungs, heart, other organs)

ACPA, Anti-citrullinated peptide antibody.

are caused by immune reactions, infections, and crystal deposition.

Osteoarthritis

Osteoarthritis (OA), also called degenerative joint disease, is characterized by cartilage degeneration that results in structural and functional failure of synovial joints. It is the most common type of joint disease. Although the term osteoarthritis implies an inflammatory disease, it is considered to be primarily a degenerative disease of cartilage.

In most instances, OA appears insidiously, without apparent initiating cause, as an aging phenomenon *(idiopathic* or *primary OA)*. In these cases, the disease usually affects few joints (oligoarticular) but may be generalized. In about 5% of cases, OA appears in younger individuals with predisposing conditions, such as a joint deformity, a previous joint injury, or an underlying systemic disease such as diabetes, ochronosis, hemochromatosis, or marked obesity that places joints at risk. In these settings, the disease is called *secondary OA*. Gender has some influence on distribution. The knees and hands are more commonly affected in women and the hips in men. The association with aging is strong; the prevalence of OA increases exponentially beyond 50 years of age, and about 40% of people older than 70 years of age are affected.

Pathogenesis

The lesions of OA stem from degeneration of the articular cartilage and disordered repair. Biomechanical stress is the principal pathogenic mechanism, but genetic factors, including polymorphisms in genes encoding components of the matrix and signaling molecules, may predispose to chondrocyte injury that causes matrix alteration (Fig. 26.38). Chondrocytes proliferate and continuously synthesize proteoglycans, but disease develops when degradation exceeds synthesis. This leads to changes in proteoglycan composition as the disease progresses. Chondrocytes also secrete matrix metalloproteases (MMPs) that degrade the type II collagen network. Cytokines and diffusible factors from chondrocytes and synovial cells, particularly TGF-β (which induces the production of MMPs), TNF, prostaglandins, and nitric oxide, are also implicated in OA, and chronic, low-level inflammation contributes to disease progression. Advanced disease is characterized by chondrocyte loss and severe matrix degradation.

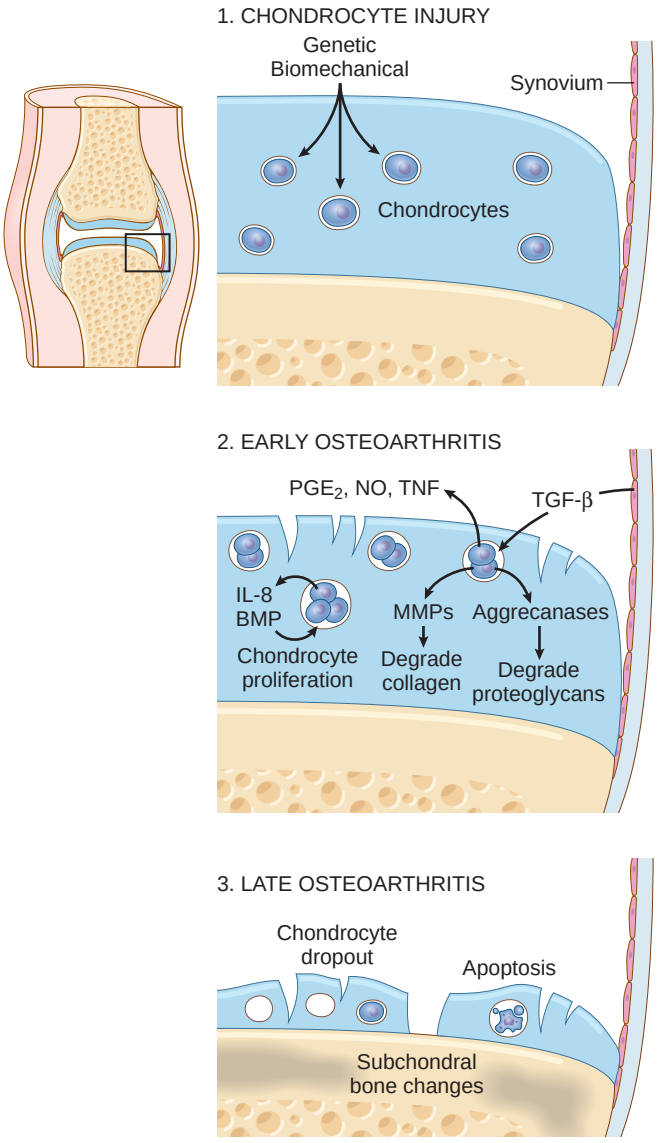

Figure 26.38 Schematic view of osteoarthritis (OA). The process is initiated by biomechanical cartilage injury (1) that can be accelerated in genetically predisposed individuals and results in changes to the extracellular matrix. (2) Although chondrocytes may proliferate and attempt to repair damaged matrix, continued degradation exceeds repair in early OA. (3) Late OA is evidenced by loss of both matrix and chondrocytes with subchondral bone damage.

MORPHOLOGY

Chondrocytes proliferate and form clusters in early stages of OA. Concurrently, matrix water content increases, proteoglycan concentration decreases, and horizontally arranged collagen type II fibers in the superficial zone are cleaved. These processes result in fissures and clefts that create a granular and soft articular surface (Fig. 26.39A). As chondrocytes die, full-thickness portions of cartilage are sloughed into the joint, forming **loose bodies.** Exposed subchondral bone becomes the new articular surface, which is burnished by friction with the opposing surface, giving it the appearance of polished ivory **(bone eburnation)** (Fig. 26.39B). Underlying articular bone undergoes rebuttressing and sclerosis, and develops small fractures, creating gaps that allow synovial fluid to be forced into the subchondral regions. As the loculated fluid collection increases in size, fibrous-walled cysts form. Mushroom-shaped bony outgrowths **(osteophytes)** develop at the margins of the articular surface and are capped by fibrocartilage and hyaline cartilage that gradually ossify. The synovium is usually only mildly congested and fibrotic and contains few inflammatory cells.

Clinical Features

Individuals with primary osteoarthritis are usually asymptomatic until they are in their 50s. If a young person has significant manifestations of OA, a search for some underlying cause should be made. Characteristic symptoms include deep, achy pain that worsens with use, morning stiffness, crepitus, and limitation of range of movement.

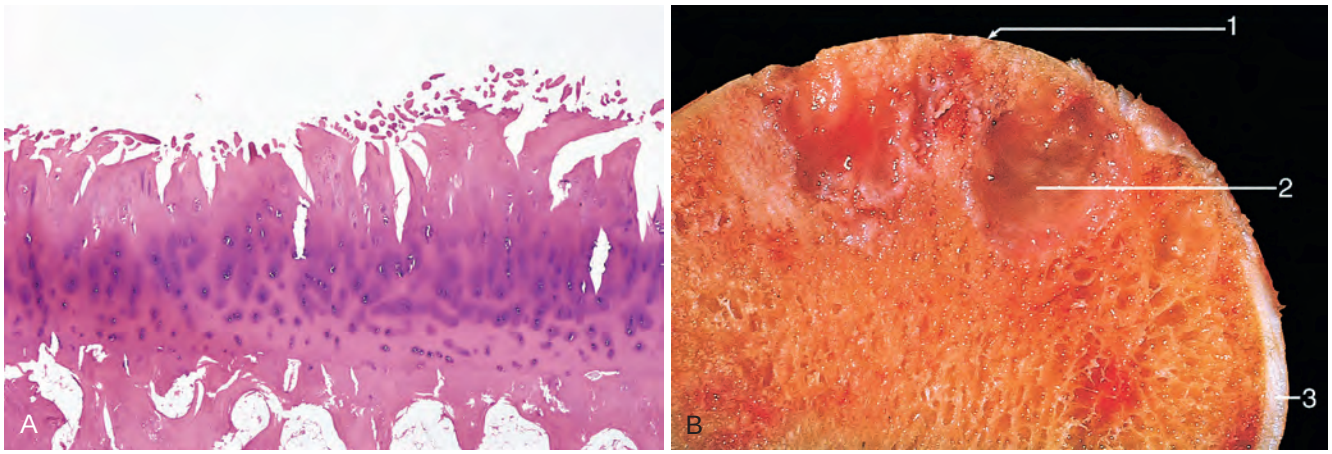

Figure 26.39 Osteoarthritis. (A) Histologic demonstration of the characteristic fibrillation of articular cartilage. (B) Eburnated articular surface exposing subchondral bone (1), subchondral cysts (2), and residual articular cartilage (3).

Impingement on spinal foramina by osteophytes results in cervical and lumbar nerve root compression and radicular pain, muscle spasms, muscle atrophy, and neurologic deficits. Typically, only one or a few joints are involved, except in the uncommon generalized variant. The joints commonly involved include the hips (Fig. 26.40), knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints. *Heberden nodes,* prominent osteophytes at the distal interphalangeal joints, are common in women. Wrists, elbows, and shoulders are usually spared. Joint deformities can develop over time, but unlike rheumatoid arthritis (RA; discussed next), fusion does not occur (Fig. 26.41). The level of disease severity detected radiographically does not correlate well with pain and disability. There are no treatments to prevent or halt progression of primary OA, and therapies include pain management, NSAIDs to reduce inflammation, intraarticular corticosteroids, activity modification, and, for severe cases, arthroplasty.

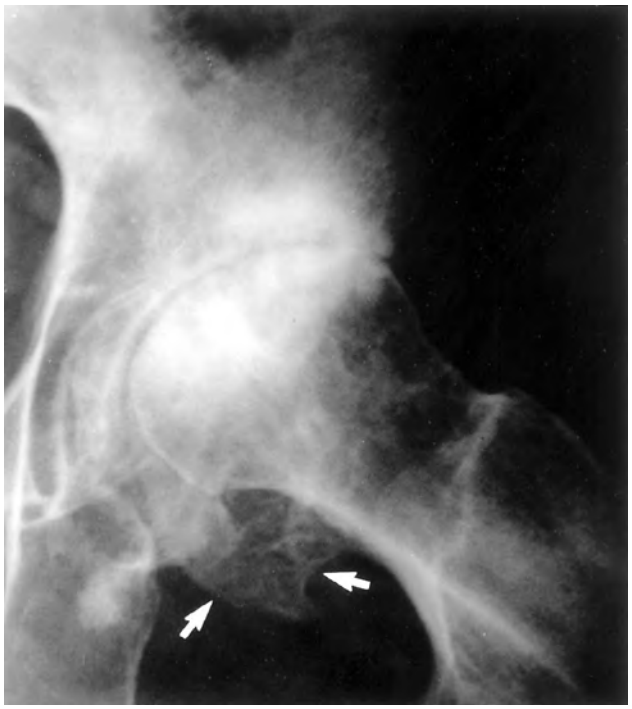

Figure 26.40 Severe osteoarthritis of the hip. The joint space is narrowed, and there is subchondral sclerosis with scattered oval radiolucent cysts and peripheral osteophyte lipping *(arrows).*

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic autoimmune disorder that principally attacks the joints, producing a nonsuppurative proliferative and inflammatory synovitis. RA often progresses to articular cartilage destruction and, in some cases, joint fusion *(ankylosis)*. Extraarticular lesions may involve skin, heart, blood vessels, and lungs, leading to clinical manifestations that overlap with other autoimmune disorders including systemic lupus erythematosus and scleroderma. The prevalence of RA in the United States is approximately 1%. The incidence peaks in the second to fourth decades. RA is three times more common in women than in men.

Pathogenesis

The autoimmune response in RA is initiated by CD4+ helper T cells. As in other autoimmune diseases, genetic predisposition and environmental factors contribute to the development, progression, and persistence of disease. The pathologic changes in RA are mediated by antibodies against self antigens and inflammation induced by cytokines, predominantly those secreted by CD4+ T cells (Fig. 26.42).

The activated CD4+ T cells release inflammatory mediators that stimulate other inflammatory cells, leading to tissue injury. Although many cytokine mediators can be isolated from inflamed joints, the most important ones include:

- IFN-γ from Th1 cells, which activates macrophages and resident synovial cells.
- IL-17 from Th17 cells that recruits neutrophils and monocytes.
- RANKL, which is expressed on activated T cells and stimulates bone resorption.
- TNF and IL-1 from macrophages stimulate resident synovial cells to secrete proteases that destroy hyaline cartilage.

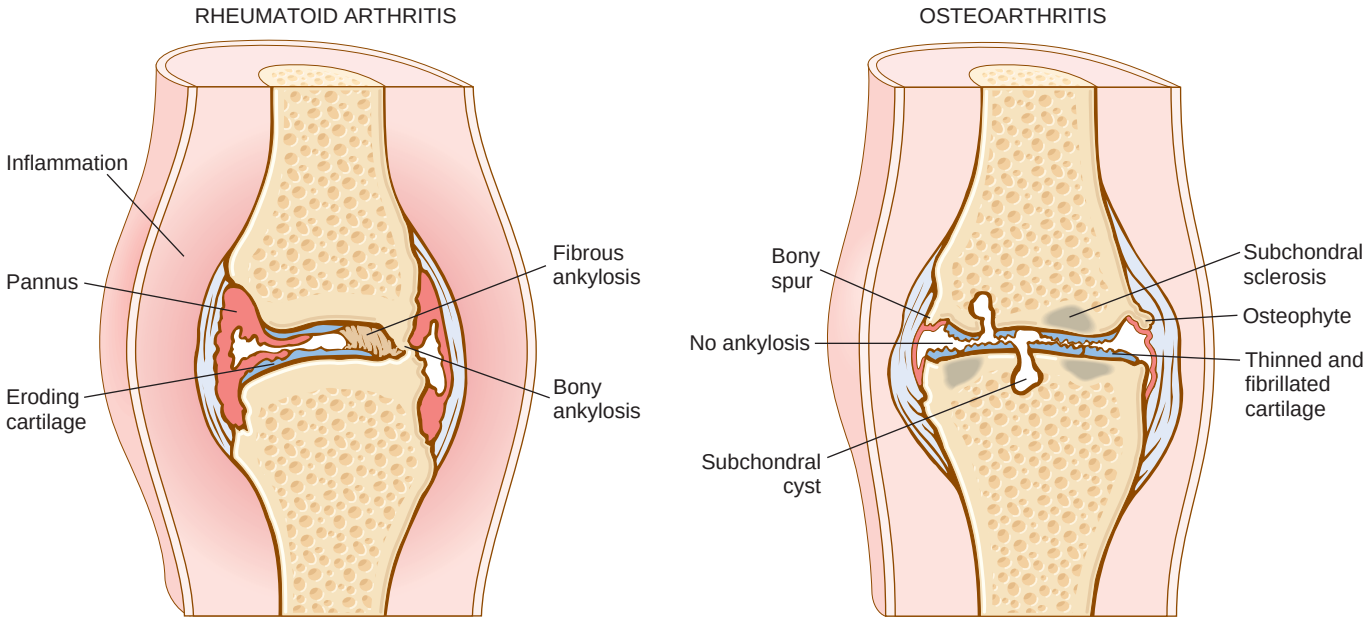

Figure 26.41 Comparison of the morphologic features of rheumatoid arthritis and osteoarthritis.

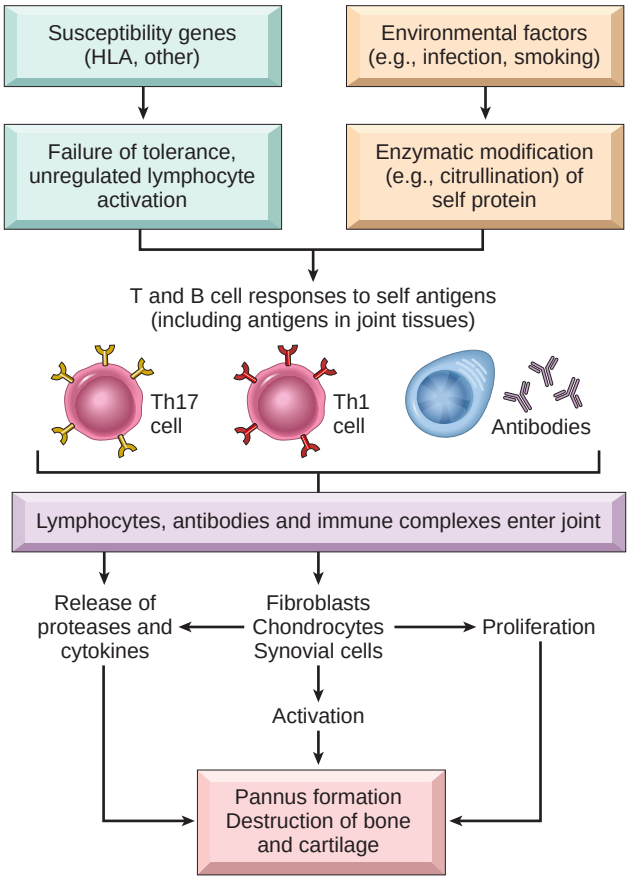

Figure 26.42 Major processes involved in the pathogenesis of rheumatoid arthritis.

Of these, TNF has been most firmly implicated in RA pathogenesis, and anti-TNF biologics have revolutionized its treatment (see later).

In RA, the synovium often contains germinal centers with secondary follicles and abundant plasma cells. Some of these plasma cells secrete antibodies that recognize self antigens. Many of these autoantibodies, which are produced in lymphoid organs as well as synovium, are specific for citrullinated peptides (CCPs) in which arginine residues are post-translationally converted to citrulline. The modified epitopes are found in several proteins found in joints, including fibrinogen, type II collagen, α-enolase, and vimentin. *Anti-citrullinated peptide antibodies* (ACPAs) are diagnostic markers that can be detected in serum of up to 70% of RA patients. Some data suggest that, in combination with T cells reactive to citrullinated proteins, ACPAs drive disease persistence. IgM and IgA autoantibodies that bind to IgG Fc regions are present in 80% of individuals. These autoantibodies, collectively referred to as *rheumatoid factor,* may be deposited in joints as immune complexes, but are not present in all patients and can be detected in some individuals without RA.

It is estimated that 50% of the risk of developing RA is related to inherited genetic susceptibility. The *HLA-DR4* allele is associated with ACPA-positive RA. Evidence suggests that an epitope on a citrullinated protein, vinculin, mimics an epitope on many microbes and can be presented by the class II HLA-DR4 molecule.

Environmental factors that promote autoimmunity are involved, but as in many autoimmune diseases, they have not been clearly defined. For example, infection (including periodontitis) and smoking may promote citrullination of self proteins, creating new epitopes that trigger autoantibody production.

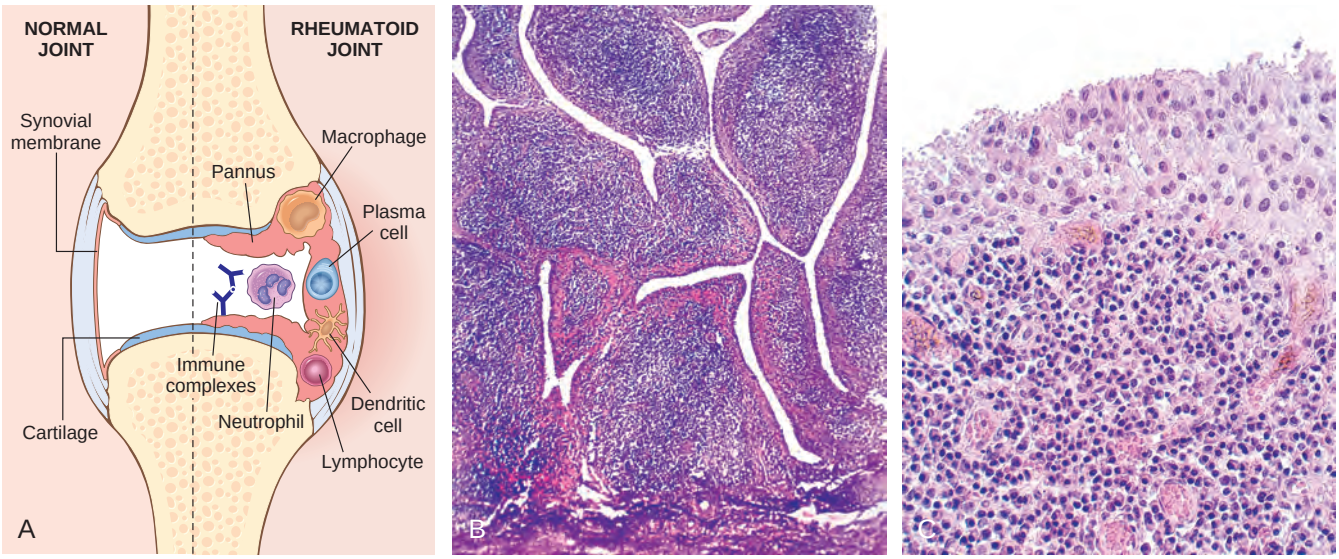

Figure 26.43 Rheumatoid arthritis. (A) Schematic view of the joint lesion. (B) Low magnification reveals marked synovial hypertrophy with formation of villi. (C) At higher magnification, subsynovial tissue containing a dense lymphoid aggregate. (A, Modified from Feldmann M: Development of anti-TNF therapy for rheumatoid arthritis, *Nat Rev Immunol* 2(5):364–371, 2002.)

MORPHOLOGY

RA typically affects small joints of the hands and feet. The synovium becomes grossly edematous, thickened, and hyperplastic, transforming its smooth contour to one covered by delicate and bulbous villi (Fig. 26.43A–B). The characteristic histologic features include (1) synovial cell hyperplasia and proliferation; (2) dense inflammatory infiltrates (frequently forming lymphoid follicles) of CD4+ helper T cells, B cells, plasma cells, dendritic cells, and macrophages (see Fig. 26.43); (3) increased vascularity due to angiogenesis; (4) fibrinopurulent exudate on the synovial and joint surfaces; and (5) osteoclastic activity in subchondral bone, allowing the inflamed synovium to penetrate the bone and cause periarticular erosions and subchondral cysts. Together, these changes produce the **pannus,** a mass of edematous synovium, inflammatory cells, granulation tissue, and fibroblasts that grows over and causes erosion of articular cartilage. In time, after the cartilage has been destroyed, the pannus bridges the apposing bones to form a **fibrous ankylosis,** which eventually ossifies and results in bone fusion, or bony ankylosis.

Rheumatoid nodules are an infrequent manifestation of RA and typically occur in the subcutaneous tissue of the forearm, elbows, occiput, and lumbosacral area. These small masses are firm, nontender, and round to oval. Microscopically, they resemble necrotizing granulomas with a central zone of fibrinoid necrosis surrounded by a prominent rim of activated macrophages and numerous lymphocytes and plasma cells (Fig. 26.44). Severe disease may be associated with **leukocytoclastic vasculitis** (Chapter 11), an acute necrotizing vasculitis of small and large arteries that may involve pleura, pericardium, or lung and evolve into a chronic fibrosing process. Leukocytoclastic vasculitis produces purpura, cutaneous ulcers, and nail bed infarction. Ocular changes such as uveitis and keratoconjunctivitis (similar to Sjögren syndrome, Chapter 6) may also occur.

Clinical Features

RA may be distinguished from other forms of polyarticular inflammatory arthritis serologically by ACPA detection and radiographically by characteristic changes (see later). It begins with malaise, fatigue, and generalized musculoskeletal pain in about half of patients; joint involvement develops after weeks to months. The pattern of joint involvement varies, but it is generally symmetrical and affects small joints before larger ones. Symptoms usually develop in the hands and feet, followed in decreasing frequency by the wrists, ankles, elbows, and knees. In the hands, the metacarpophalangeal and proximal interphalangeal joints are involved, in contrast to OA (see earlier).

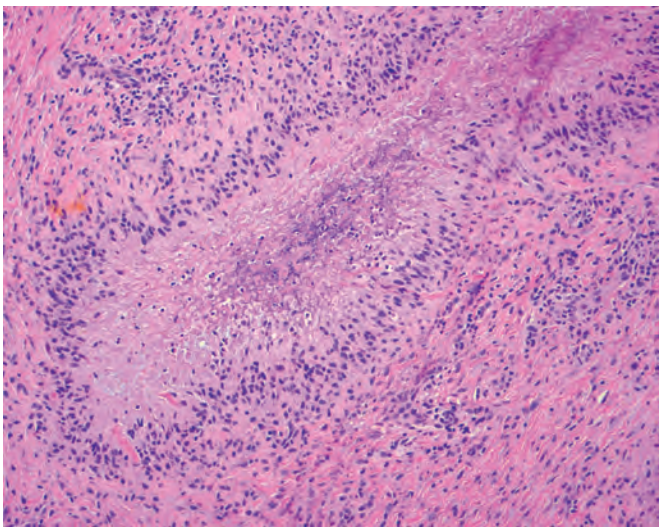

Figure 26.44 Rheumatoid nodule composed of central necrosis rimmed by palisaded macropahges.

Involved joints are swollen, warm, and painful. Unlike OA, morning joint stiffness does not subside with activity. The typical patient has progressive joint enlargement and decreasing range of motion during a chronic waxing and waning course. In a minority of individuals, especially those lacking ACPA and rheumatoid factor, disease may stabilize or even regress. A small number of patients (about 10%) develop acute-onset RA, with severe symptoms and polyarticular involvement that develops over several days.

Inflammation in tendons, ligaments, and occasionally adjacent skeletal muscle frequently accompanies the arthritis and produces characteristic radial deviation of the wrist, ulnar deviation of the fingers, and flexion-hyperextension of the fingers (swan-neck and boutonnière deformities). Radiographic hallmarks include joint effusions and juxta-articular osteopenia with erosions and narrowing of the joint space and loss of articular cartilage (Fig. 26.45).

RA treatment is aimed at relieving pain and inflammation and slowing or arresting joint destruction. Therapies include corticosteroids, other immunosuppressants such as methotrexate, and, most notably, TNF antagonists, which are effective in many patients. Unfortunately, individuals must be maintained on anti-TNF therapy to avoid disease flares.

Figure 26.45 Rheumatoid arthritis of the hand. Characteristic features include diffuse osteopenia, periarticular bony erosions, and marked loss of the joint spaces of the carpal, metacarpal, phalangeal, and interphalangeal joints.

This long-term treatment with anti-TNF agents predisposes individuals to infection with opportunistic organisms such as *M. tuberculosis*. Other biologic agents that interfere with T- and B-lymphocyte responses have also been approved for therapeutic use.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a heterogeneous group of disorders of unknown cause that present with arthritis before 16 years of age and persist for at least 6 weeks. In the United States, 30,000 to 50,000 individuals are affected. Relative to RA, JIA is more commonly associated with oligoarthritis, systemic disease, and involvement of large joints. Antinuclear antibody (ANA) seropositivity is typical, but rheumatoid nodules are usually absent. JIA pathogenesis is undefined, but, it shares features with adult RA, including associations with certain HLA and PTPN22 gene variants and studies that link its pathogenesis to involvement of Th1 and Th17 cells and inflammatory mediators such as IL-1, IL-17, TNF, and IFN-γ.

Current subclassification of JIA is based on clinical (e.g., oligoarticular, systemic) and laboratory (ANA, rheumatoid factor titers) features. Some subgroups (e.g., systemic, polyarticular rheumatoid factor–positive; enthesitis-related, which refers to involvement of sites of ligament and cartilage insertion into bone [entheses]; oligoarticular) are similar, while others (e.g., polyarticular rheumatoid factor–negative; psoriatic) are highly heterogeneous. Treatment of all subgroups is similar to adult RA, and there has been some success using a systemic IL-6 receptor antibody. Long-term JIA prognosis is variable; many patients have chronic disease, but only about 10% develop serious functional disability.

Seronegative Spondyloarthropathies

Spondyloarthropathies are a heterogeneous group of disorders unified by the following features:

- Absence of rheumatoid factor
- Pathologic changes in the ligamentous attachments (i.e. entheses) rather than synovium
- Sacroiliac joint involvement
- Association with HLA-B27
- Bony proliferation leading to ankylosis

The manifestations are immune mediated and triggered by T-cell responses, presumably against undefined microbial antigens, that cross-react with musculoskeletal system components.

Ankylosing Spondylitis

Ankylosing spondylitis causes destruction of articular cartilage and bony ankyloses, especially of the sacroiliac and vertebral apophyseal joints between tuberosities and processes. The disease presents as lower back pain and spinal immobility, usually in the second and third decades of life. Peripheral joints, such as the hips, knees, and shoulders, are involved in at least one-third of cases. Approximately 90% of patients are HLA-B27 positive. The role of HLA-B27 is unknown; it is presumably related to the ability of this MHC variant to present one or more antigens that

somehow trigger the disease, but neither the antigen nor the pathogenic immune cell is known.

Reactive Arthritis

Reactive arthritis is defined by the triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis following an infection. More recently, the definition has been broadened to include mono- or oligoarticular arthritis that occurs days to weeks after genitourinary *(Chlamydia)* or gastrointestinal (*Shigella, Salmonella, Yersinia, Campylobacter,* and *Clostrdioides difficile*) infections. HIV-positive patients may also be affected; the reactive arthritis in these individuals is thought to be caused by pathogens other than HIV. HLA-B27 is common in patients with reactive arthritis. The disease most often presents in young adults, with a global prevalence of approximately 30 per 100,000 adults. Arthritic episodes usually wax and wane for about 6 months, but nearly 50% of patients have recurrent arthritis, tendonitis, and lumbosacral pain. When active disease persists for more than 6 months, the term chronic reactive arthritis is used. Spondyloarthritis can occur in these patients, and spine involvement can be indistinguishable from ankylosing spondylitis.

Patients initially experience an acute-onset asymmetric oligoarthritis, often affecting the lower extremities, especially the knee. Inflammatory low back pain is a common accompanying symptom but is rarely the only symptom. Enthesitis occurs frequently and often involves the insertions of the Achilles tendon and plantar fascia on the calcaneus, resulting in swelling of the heel. *Dactylitis,* or inflammation of the digits, is present in a minority of patients and typically presents as sausage-like digits, joint stiffness, and low back pain. Synovitis of a digital tendon sheath produces "sausage" finger or toe. This may progress to ossification at tendoligamentous insertion sites and development of calcaneal spurs and bony outgrowths in those with chronic reactive arthritis. Extraarticular involvement includes conjunctivitis and uveitis; dysuria, pelvic pain, urethritis, balanitis, cervicitis, mucosal ulcers, skin rashes, and other cutaneous manifestations (e.g., psoriasis-like nail changes); and cardiac valvular disease (e.g., aortic insufficiency).

Infectious Arthritis

Microorganisms of all types can seed joints during hematogenous dissemination. Articular structures can also become infected by direct inoculation or contiguous spread from a soft tissue abscess or focus of osteomyelitis. Because cartilage, unlike bone, has a limited regenerative capacity, the rapid joint destruction that may ensue can result in permanent deformities.

Suppurative Arthritis

Bacterial infections that cause acute suppurative arthritis usually enter the joints from distant sites by hematogenous spread. In neonates, contiguous spread from underlying epiphyseal osteomyelitis is relatively common. *H. influenzae* arthritis predominates in children younger than 2 years of age. *S. aureus* is the main causative agent in older children and adults, while gonococcus is prevalent during late adolescence and young adulthood. Individuals with sickle cell disease are prone to *Salmonella* infection at any age. Except for gonococcal arthritis, which is seen mainly in women, joint infections are equally common in males and females. Individuals with deficiencies of components of the complement membrane attack complex (C5–C9) are especially susceptible to disseminated gonococcal infections and arthritis. Other predisposing conditions include immunodeficiencies (congenital and acquired), debilitating illness, joint trauma, chronic arthritis of any cause, and intravenous drug use.

The classic presentation is the sudden development of an acutely painful and swollen joint with a restricted range of motion. Fever, leukocytosis, and elevated sedimentation rate are common. In disseminated gonococcal infection, the symptoms are often subacute, and the infection usually involves only a single joint, most commonly the knee, hip, shoulder, elbow, wrist, or sternoclavicular joints. Axial joint involvement is most frequent in drug users. Joint aspiration is diagnostic if it yields purulent fluid in which the infectious organism can be identified. Prompt recognition and effective antimicrobial therapy can prevent joint destruction.

Mycobacterial Arthritis

Mycobacterial arthritis is a chronic progressive monoarticular infection caused by *M. tuberculosis*. It primarily occurs in adults as a complication of adjacent osteomyelitis or after hematogenous dissemination from a visceral (usually pulmonary) site of infection. Onset is insidious and associated with gradually increasing pain. Systemic symptoms may or may not be present. Mycobacterial seeding of the joint induces formation of confluent granulomas with caseous necrosis. The synovium may grow as a pannus over the articular cartilage and erode the bone along the joint margins. Chronic disease results in fibrous ankylosis and obliteration of the joint space. Weight-bearing joints, especially the hips, knees, and ankles, in descending order of frequency, are most commonly affected.

Viral Arthritis

Arthritis can occur with a variety of viral infections. The most common are alphavirus, parvovirus B19, rubella, Epstein-Barr virus, and hepatitis B and C viruses. The manifestations range from acute to subacute arthritis. Joint symptoms may be caused by direct infection of the joint by the virus, as in rubella and some alphavirus infections, or by an autoimmune reaction triggered by the infection.

Lyme Arthritis

Lyme arthritis is caused by the spirochete *Borrelia burgdorferi,* which is transmitted by deer ticks of the Ixodes ricinus complex. It is the leading arthropod-borne disease in the United States. It most often occurs in New England, the mid-Atlantic states, and the upper Midwest, but its geographic distribution is expanding. In the classic form, Lyme disease involves multiple organ systems through three clinical phases (Chapter 8). The initial skin infection *(early localized stage)* is followed within days or weeks by dissemination of the organism to other cutaneous sites, cranial nerves, heart, and meninges *(early disseminated stage)*. If left untreated, arthritis *(late disseminated stage)* occurs months after infection.

Currently, arthritis occurs in less than 10% of cases of *Borrelia* infection because most individuals are treated and

cured at an earlier stage. However, if left untreated, up to 80% of individuals develop a migratory arthritis *(Lyme arthritis)* lasting weeks to months. Large joints, especially the knees, shoulders, elbows, and ankles, in descending order of frequency, are usually involved. Initial attacks last for a few weeks to months, and are usually limited to one or two joints at a time. Arthritis may subsequently develop at new sites. Spirochetes are only identified in 25% of those with arthritis, but serologic detection of anti-*Borrelia* antibodies is diagnostic. Histologically, infected synovium exhibits chronic synovitis, synoviocyte hyperplasia, fibrin deposition, mononuclear cell infiltrates (especially CD4+ T cells), and *obliterative endarteritis*. In severe cases, the histopathology mimics rheumatoid arthritis.

Lyme disease treatment relies on antibiotics active against *Borrelia* and results in cure rates of 90%. Although an effective vaccine was briefly available, it was withdrawn from the market as a result of negative media reports, coverage of only the most common North American species, lack of safety data in children, and other concerns.

Chronic, antibiotic-refractory arthritis can develop in the late disseminated stage of Lyme disease. In many of these cases, *Borrelia* cannot be detected in the joint fluid, even by polymerase chain reaction. Some have hypothesized that this antibiotic-refractory arthritis is an autoimmune disease triggered by immune responses to *Borrelia* outer surface protein A. Chronic disease is also associated with nonspecific symptoms such as fatigue and cognitive complaints collectively termed *posttreatment Lyme disease syndrome*.

Crystal-Induced Arthritis

Articular crystal deposits are associated with a variety of acute and chronic joint disorders. Endogenous crystals include monosodium urate *(gout)*, calcium pyrophosphate dihydrate *(pseudogout)*, and basic calcium phosphate. Exogenous crystals, such as the biomaterials used in prosthetic joints, can also induce arthritis as they accumulate with wear. Endogenous and exogenous crystals produce disease by triggering inflammatory reactions that destroy cartilage.

Gout

Gout is marked by transient attacks of acute arthritis initiated by monosodium urate crystals deposited within and around joints. Whether gout is primary or secondary to another underlying disease (Table 26.6), the common feature is excessive uric acid in the tissues and body fluids. In the primary form (90% of cases), gout is the major manifestation of the disease; the cause is unknown.

Pathogenesis

Hyperuricemia (plasma urate above 6.8 mg/dL) is necessary, but not sufficient, for development of gout. Elevated uric acid can result from overproduction, reduced excretion, or both (Table 26.6). Uric acid levels are determined by several factors:

- *Uric acid production.* Urate synthesis is the end product of purine catabolism. Purines are themselves the product of two interlinked pathways: the de novo pathway, in which purine nucleotides are synthesized from nonpurine precursors, and the salvage pathways, in which nucleotides are synthesized from free purine bases in the diet and those generated by purine nucleotide catabolism.
- *Uric acid excretion.* In the kidney, uric acid is filtered by the glomerulus, but is almost completely resorbed by the proximal tubule. The small fraction of total uric acid in the urine is the result of secretion in the distal nephron.

Table 26.6 Classification of Gout

Clinical Category	Uric Acid Production	Uric Acid Excretion
Primary Gout (90%)		
Unknown enzyme defects (85%–90%)	Normal ↑	↓ Normal
Known enzyme defects (e.g., partial HGPRT deficiency)	↑	Normal
Secondary Gout (10%)		
Increased nucleic acid turnover (e.g., leukemia)	↑↑	↑
Chronic renal disease	Normal	↓
Congenital (e.g., Lesch-Nyhan syndrome, HGPRT deficiency)	↑↑	↑

HGPRT, Hypoxanthine guanine phosphoribosyl transferase.

Asymptomatic hyperuricemia appears around puberty in males and after menopause in females. In primary gout, hyperuricemia is usually due to reduced excretion. The mechanism is not known, but genome-wide association studies have identified polymorphisms in genes including *URAT1, GLUT9,* and *KCNQ1,* which are involved in transport and homeostasis of urate and other ions. A small fraction of primary gout cases are caused by uric acid overproduction due to identifiable enzymatic defects. For example, partial deficiency of hypoxanthine guanine phosphoribosyl transferase (HGPRT) interrupts the salvage pathway, so purine metabolites cannot be salvaged and are, instead, degraded into uric acid. Complete absence of HGPRT also results in hyperuricemia, but the significant neurologic manifestations of this condition *(Lesch-Nyhan syndrome)* dominate the clinical picture, which is therefore classified as secondary gout. Secondary gout can also be caused by increased production (e.g., rapid cell lysis during chemotherapy for leukemia) or decreased excretion (chronic renal disease).

Inflammation is triggered by precipitation of monosodium urate crystals into the joints, which result in the production of cytokines that recruit leukocytes (Fig. 26.46). Macrophages and neutrophils phagocytose the urate crystals. This activates the inflammasome (Chapter 3) and leads to the secretion of cytokines, including IL-1, which promote accumulation of more neutrophils and macrophages within the joint. A vicious cycle develops as newly recruited inflammatory cells release cytokines, free radicals, proteases, and arachidonic acid metabolites to recruit even more leukocytes. Complement activation by the alternative pathway may also contribute to leukocyte recruitment. Rupture of phagolysosomes induced by ingested urate crystals can cause further release of proteases and inflammatory mediators. The resulting acute arthritis typically remits spontaneously in days to weeks. Repeated attacks of acute arthritis lead eventually to the formation of *tophi,* aggregates of urate crystals and inflammatory tissue in the inflamed synovial membrane

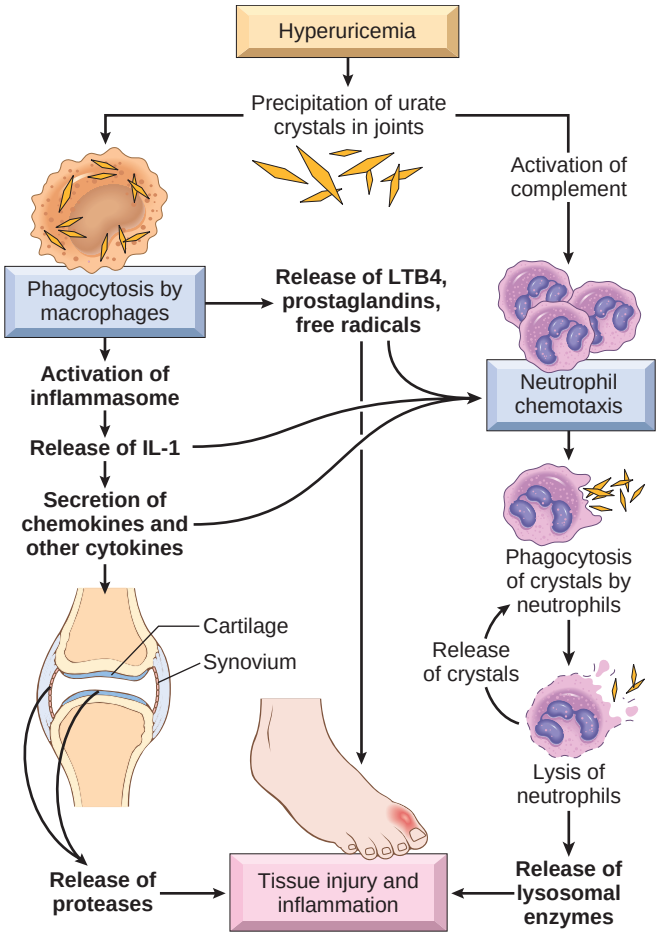

Figure 26.46 Pathogenesis of acute gouty arthritis. Urate crystals are phagocytosed by macrophages and stimulate the production of various inflammatory mediators that elicit the inflammation characteristic of gout. Note that IL-1 stimulates the production of chemokines and other cytokines from a variety of cells. *LTB4*, Leukotriene B4.

and periarticular tissue as well as severe cartilage damage that compromises joint function.

Only about 10% of individuals with hyperuricemia develop gout. Other factors linked to disease include the following:

- Age of the individual and duration of the hyperuricemia, as gout usually appears after 20 to 30 years of hyperuricemia
- Male sex
- Genetic predisposition, including X-linked *HGPRT* abnormalities and primary gout, which has a multigenic pattern of inheritance
- Alcohol consumption
- Obesity
- Drugs (e.g., thiazides) that reduce urate excretion

MORPHOLOGY

The distinctive patterns of gout are (1) acute arthritis, (2) chronic tophaceous arthritis, (3) accumulation of tophi in extraarticular sites, and (4) urate (gouty) nephropathy.

Acute arthritis is characterized by a dense neutrophilic infiltrate that permeates the synovium and synovial fluid. Slender, needle-shaped urate crystals are arranged in small clusters in the synovium and are frequently found in the cytoplasm of neutrophils within aspirated joint fluid (Fig. 26.47A). The edematous and congested synovium also contains scattered lymphocytes, plasma cells, and macrophages. The acute attack remits when the episode of crystallization abates and crystals are solubilized.

Chronic tophaceous arthritis evolves from repetitive precipitation of urate crystals during acute attacks. Urate encrusts the articular surface and forms visible deposits in the synovium, which becomes hyperplastic, fibrotic, and thickened by inflammatory cells. The resulting pannus destroys the underlying cartilage and leads to juxta-articular bone erosions. In severe cases, fibrous or bony ankylosis ensues, resulting in loss of joint function.

Tophi are the pathognomonic hallmark of gout. They are formed by large aggregations of urate crystals surrounded by an intense inflammatory reaction of foreign-body giant cells. (Fig. 26.47B–C). Tophi may appear in the articular cartilage, ligaments, tendons, and bursae. Less frequently they occur in soft tissues (earlobes, fingertips) or kidneys. Superficial tophi can ulcerate through the overlying skin.

Urate nephropathy refers to the renal complications caused by urate crystals or tophi in the renal medullary interstitium or tubules. Complications include uric acid nephrolithiasis and pyelonephritis, particularly when urinary obstruction occurs.

Clinical Features

Primary gout initially presents as acute arthritis with sudden-onset, excruciating joint pain, localized hyperemia and warmth, and, occasionally, mild fever; constitutional symptoms are uncommon. Most first attacks are monoarticular, and 50% occur in the first metatarsophalangeal joint of the big toe. Untreated, acute gouty arthritis may last for hours to weeks, but gradually there is complete resolution followed by a symptom-free interval, known as the intercritical period. Some individuals never have another attack, but most experience a second acute episode within months to a few years. In the absence of appropriate therapy, the attacks recur at shorter intervals and frequently become polyarticular, involving other parts of the foot and less commonly the upper extremity. Chronic tophaceous gout develops about 10 years after the initial acute attack and is characterized by juxta-articular bone erosion caused by osteoclastic bone resorption and loss of the joint space.

Nonpharmacologic treatments for gout include lifestyle modifications, such as weight loss in obese individuals; dietary changes to reduce purine intake, particularly of animal and seafood proteins; reduced alcohol and sugar-sweetened beverage consumption; and regular exercise. Pharmacologic therapies include uricosuric drugs (e.g., probenecid), xanthine oxidase inhibitors (e.g., allopurinol), urate oxidases (uricases), NSAIDs, and colchicine. Finally, gout can be precipitated by serum urate–increasing drugs taken for comorbidities; their replacement with alternatives may be helpful. Generally, gout does not shorten the life span, but it does impact quality of life.

Calcium Pyrophosphate Crystal Deposition Disease (Pseudogout)

Calcium pyrophosphate crystal deposition disease (CPPD), also known as *pseudogout,* usually occurs in individuals older than 50 years of age and becomes more common

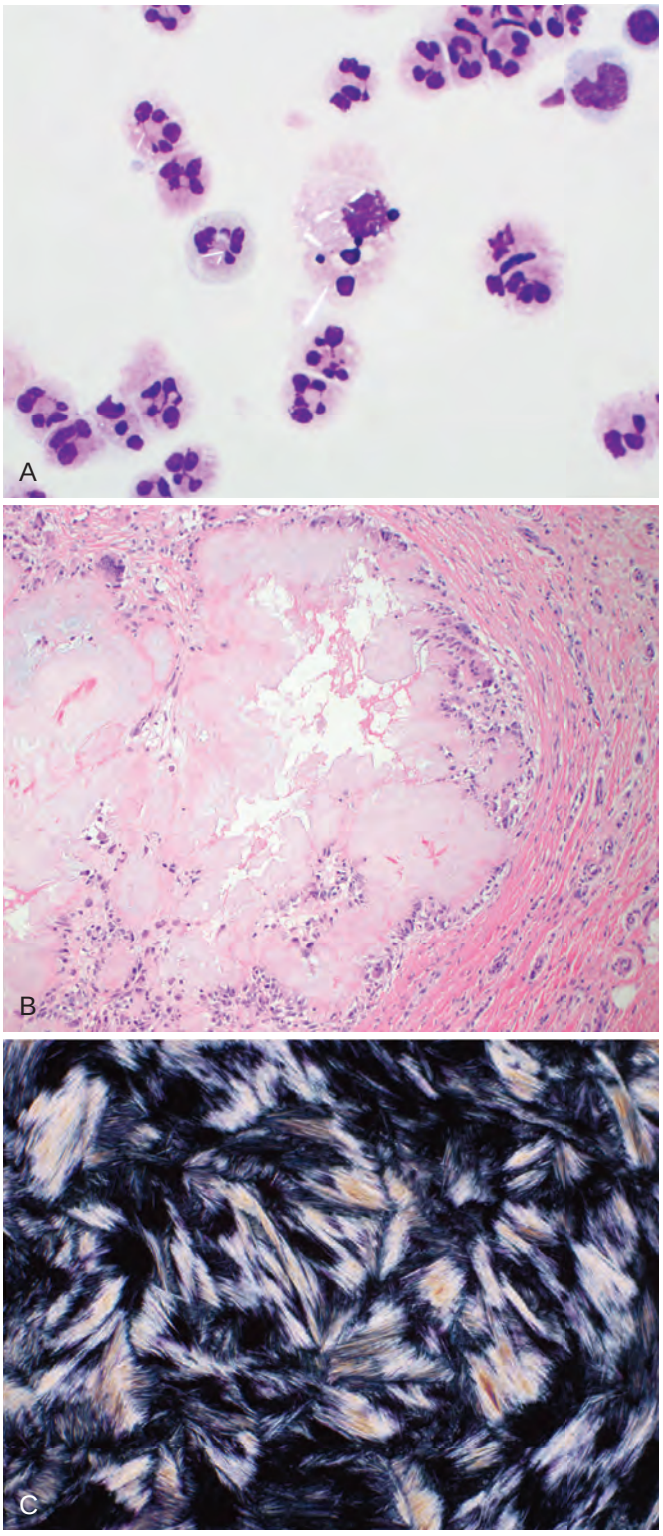

Figure 26.47 Gout. (A) Joint aspirate from acute gout arthritis demonstrates polarizable needle shape urate crystals in neutrophils. (B) Gouty tophus—an aggregate of dissolved urate crystals is surrounded by reactive fibroblasts, mononuclear inflammatory cells, and giant cells. (C) Needle-shaped urate crystals are easily identified under polarized light.

with increasing age; up to 60% of those 85 years of age or older are affected. There is no sex or racial predisposition. CPPD is divided into sporadic (idiopathic), hereditary, and secondary types. An autosomal dominant variant is caused by germline gain-of-function mutations in *ANKH,* an inorganic pyrophosphate transporter, that result in crystal deposition and osteoarthritis at relatively early ages. These mutations are distinct from those associated with craniometaphyseal dysplasia. Various disorders, including previous joint damage, hyperparathyroidism, hemochromatosis, hypomagnesemia, hypothyroidism, ochronosis, and diabetes predispose to secondary CPPD.

Pathogenesis

The basis for crystal formation is not known, but studies suggest that degradation of articular cartilage proteoglycans, which normally inhibit mineralization, allows crystallization around chondrocytes. As in gout, inflammation is caused by activation of the inflammasome in macrophages (see Fig. 26.46).

MORPHOLOGY

The crystals first develop in the articular cartilage, menisci, and intervertebral discs; as the deposits enlarge they may rupture and seed the joint. The crystals form chalky, white friable deposits, which are seen histologically in stained preparations as oval blue-purple aggregates (Fig. 26.48A). Individual crystals are rhomboid, 0.5 to 5 μm in greatest dimension (Fig. 26.48B), and birefringent. Inflammation is usually milder than in gout.

Clinical Features

CPPD is frequently asymptomatic. However, it may produce acute, subacute, or chronic arthritis that can be confused with osteoarthritis or rheumatoid arthritis clinically. Joint involvement may last from several days to weeks and may be monoarticular or polyarticular; the knees, followed by the wrists, elbows, shoulders, and ankles, are most commonly affected. Chondrocalcinosis, radiographically evident calcification of hyaline or fibrocartilage, is often present but is not synonymous with CPPD. Ultimately, approximately 50% of affected individuals experience significant joint damage. Therapy is supportive to minimize symptoms. There is no known treatment that prevents or slows crystal formation.

KEY CONCEPTS

ARTHRITIS

- Osteoarthritis (degenerative joint disease), the most common disease of joints, is a degenerative disorder of articular cartilage in which matrix breakdown exceeds synthesis. Inflammation is minimal and typically secondary, but locally produced cytokines may contribute to progression of joint degeneration.
- Rheumatoid arthritis is a chronic autoimmune inflammatory disease that affects mainly small joints but can be systemic. RA is caused by a cellular and humoral immune response against self antigens, particularly citrullinated proteins. TNF plays a central role, and anti-TNF biologics are effective.
- Seronegative spondyloarthropathies are a heterogeneous group of autoimmune arthritides that preferentially involve the

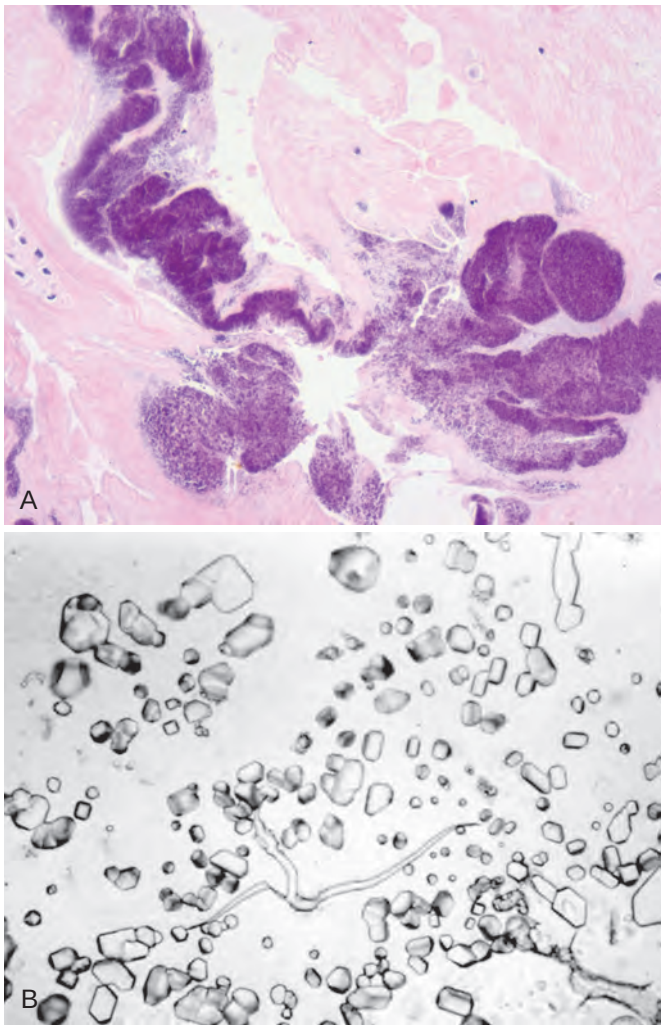

Figure 26.48 Pseudogout. (A) Deposits are present in cartilage and consist of amorphous basophilic material. (B) Smear preparation of calcium pyrophosphate crystals.

sacroiliac, vertebral joints and entheses and are associated with HLA-B27. Reactive arthritis is an uncommon immune-mediated disorder that develops after resolution of genitourinary or gastrointestinal infection.

- Suppurative arthritis describes direct infection of a joint space by bacterial organisms.
- Lyme disease is a systemic infection by *B. burgdorferi* that manifests, in part, as an infectious arthritis, possibly with an autoimmune component in chronic stages.
- Gout and pseudogout result from inflammatory responses to precipitated urate or calcium pyrophosphate, respectively.

JOINT TUMORS AND TUMOR-LIKE CONDITIONS

Reactive tumor-like lesions, such as ganglion cysts, synovial cysts, and osteochondral loose bodies, commonly involve joints and tendon sheaths. They usually result from trauma or degenerative processes and are much more common than neoplasms. Primary neoplasms are rare, usually benign, and tend to recapitulate the cells and tissue types (synovial membrane, fat, blood vessels, fibrous tissue, and cartilage) native to joints and related structures. The rare malignant tumors are discussed with soft tissue tumors.

Ganglion and Synovial Cysts

Ganglion cysts are small, up to 1.5 cm, and nearly always located near a joint capsule or tendon sheath. A common location is around the joints of the wrist, where the cysts appear as firm, fluctuant, pea-sized translucent nodules. Ganglion cysts develop due to cystic or myxoid connective tissue degeneration; hence the cyst wall lacks a cell lining. Lesions may be multilocular and can enlarge through coalescence and degeneration of adjacent connective tissue. The fluid that fills ganglion cysts is similar to synovial fluid, but there is no communication with the joint space. Despite the name, the lesion is unrelated to ganglia of the nervous system.

Herniation of synovium through a joint capsule or massive enlargement of a bursa may produce a *synovial cyst.* A well-recognized example is the popliteal synovial cyst, or *Baker cyst,* associated with rheumatoid arthritis. The cyst lining resembles the synovium, and both cyst and synovium may be hyperplastic. Cyst fluid often contains inflammatory cells and fibrin.

Tenosynovial Giant Cell Tumor

Tenosynovial giant cell tumor is a benign neoplasm that develops in the synovial lining of joints, tendon sheaths, and bursae. Tenosynovial giant cell tumor can be diffuse (previously known as *pigmented villonodular synovitis*) or localized. The diffuse type tends to involve large joints, while the localized type usually occurs as a discrete nodule attached to a tendon sheath, commonly in the hand. Both variants are most often diagnosed in the 20s to 40s and affect the sexes equally.

Pathogenesis

Both diffuse and localized tenosynovial giant cell tumors harbor a reciprocal somatic chromosomal translocation, t(1;2)(p13;q37), resulting in fusion of the type VI collagen α-3 promoter upstream of the coding sequence of the *MCSF* gene. As a result, the tumor cells overexpress M-CSF, which, through autocrine and paracrine effects, stimulates proliferation of macrophages in a manner similar to giant cell tumor of bone (described earlier).

MORPHOLOGY

Tenosynovial giant cell tumors are red-brown to orange-yellow. In diffuse tumors, the normally smooth joint synovium is converted into a tangled mat by red-brown folds, fingerlike projections, and nodules (Fig. 26.49A); localized tumors are well circumscribed. The neoplastic cells, which are a minority of the cells in the mass, are polygonal, moderately sized, and resemble synoviocytes (Fig. 26.49B). In the diffuse variant, they spread along the surface and infiltrate the subsynovial tissue. A solid aggregate may be attached to the synovium by a pedicle. Both diffuse and localized types are densely infiltrated by macrophages that may contain hemosiderin or foamy lipids and can be multinucleated. Older lesions may become fibrotic.

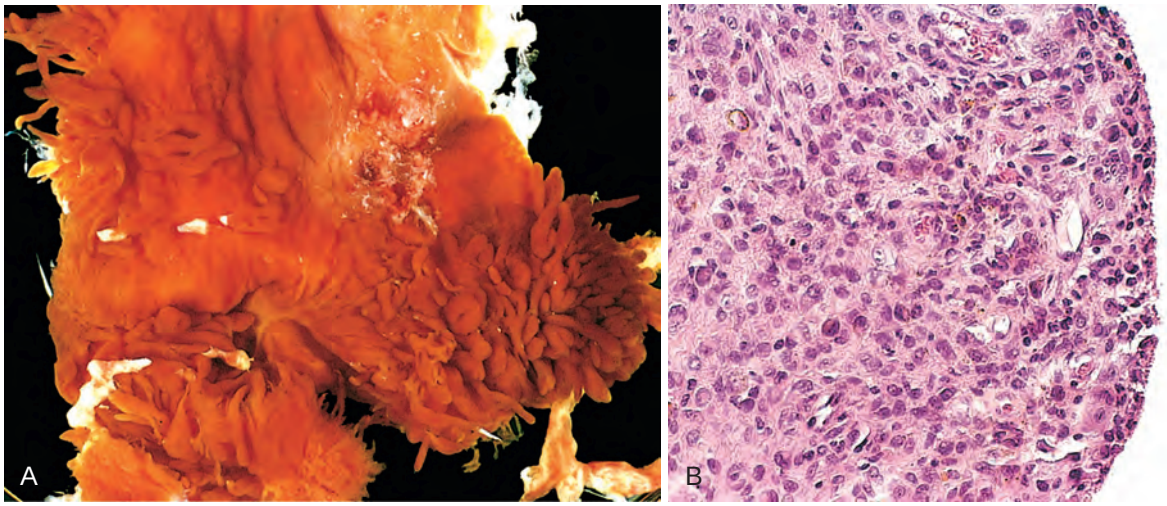

Figure 26.49 Tenosynovial giant cell tumor, diffuse type. (A) Excised synovium with fronds and nodules typical of diffuse tenosynovial giant cell tumor. The color and texture explain the old name of pigmented villonodular synovitis. (B) Sheets of proliferating cells in tenosynovial giant cell tumor bulging the synovial lining.

Clinical Features

Diffuse tenosynovial giant cell tumors present in the knee in 80% of cases. Affected individuals complain of pain, locking, and recurrent swelling, similar to monoarticular arthritis. Sometimes a palpable mass is appreciated. Aggressive tumors erode into adjacent bones and soft tissues, causing confusion with other types of neoplasms. Recurrence is common. Localized tenosynovial giant cell tumors present as a solitary, slow-growing, painless mass that frequently involves the tendon sheaths along the wrists and fingers. Bone erosion and recurrence are less common than in the diffuse type. Surgical excision is the mainstay of treatment. Clinical trials using antagonists of M-CSF signaling have had promising results.

Soft Tissue Tumors

By convention, soft tissue refers to non-epithelial tissue excluding the skeleton, joints, central nervous system, and hematopoietic and lymphoid tissues. Although nonneoplastic conditions can involve soft tissue, they are seldom confined to this compartment, so the area of soft tissue pathology is restricted to neoplasms. With the exception of skeletal muscle neoplasms, benign soft tissue tumors are 100-fold more frequent than their malignant counterparts, the sarcomas. In the United States, the incidence of soft tissue sarcomas is approximately 12,000 per year, which is less than 1% of all cancers. Sarcomas, however, cause 2% of all cancer mortality, reflecting their aggressive behavior and resistance to chemotherapy. Most soft tissue tumors arise in the extremities, particularly the thigh. Approximately 15% arise in children; the incidence increases with age.

Pathogenesis

Most sarcomas are sporadic and have no known predisposing cause. A small minority are associated with germline mutations in tumor suppressor genes that are associated with well-described syndromes (neurofibromatosis 1, Gardner syndrome, Li-Fraumeni syndrome, Osler-Weber Rendu syndrome). Others are linked to known environmental exposures such as radiation, burns, or toxins.

Unlike carcinomas and certain hematologic malignancies, which often arise from well-recognized precursor lesions, sarcoma precursors are undefined. Some sarcomas recapitulate a recognizable mesenchymal lineage (e.g. skeletal muscle), but they are thought to arise from pluripotent mesenchymal stem cells, which acquire somatic "driver" mutations in oncogenes and tumor suppressor genes. The genetics of tumorigenesis are heterogeneous, but some generalizations can be made based on karyotypic complexity:

- *Simple karyotype* (20%): Like many leukemias and lymphomas, sarcomas are occasionally euploid tumors with a single or limited number of chromosomal changes (Table 26.7) that occur early in tumorigenesis and are specific enough to serve as diagnostic markers. Tumors with these features most commonly arise in younger individuals and tend to have a monomorphic microscopic appearance. Examples include Ewing sarcoma (discussed earlier) and synovial sarcoma. In some cases, the oncogenic effect of chromosomal rearrangements is reasonably well understood (see Table 26.7). In others, the mechanisms are unknown. Oncogenic tumor-specific fusion proteins represent potential targets for therapy.
- *Complex karyotype* (80%): These tumors are usually aneuploid or polyploid and demonstrate multiple chromosomal gains and losses, a feature that suggests an underlying abnormality producing genomic instability. Examples include leiomyosarcomas and undifferentiated pleomorphic sarcoma. Such tumors are more common in adults and tend to be microscopically diverse, with a

Table 26.7 Chromosomal Abnormalities in Soft Tissue Tumors

Tumor	Cytogenetic Abnormality	Gene Fusion	Proposed Function
Ewing sarcoma	t(11;22)(q24;q12) t(21;22)(q22;q12)	*EWS–FLI1* *EWS–ERG*	Disordered protein with multiple functions, including aberrant transcription, cell cycle regulation, RNA splicing, and telomerase
Extraskeletal myxoid chondrosarcoma	t(9;22)(q22;q12)	*EWS–CHN*	
Desmoplastic small round-cell tumor	t(11;22)(p13;q12)	*EWS–WT1*	
Clear-cell sarcoma	t(12;22)(q13;q12)	*EWS–ATF1*	
Liposarcoma—myxoid type	t(12;16)(q13;p11)	*FUS–DDIT3*	Arrests adipocytic differentiation
Synovial sarcoma	t(x;18)(p11;q11)	*SS18–SSX1* *SS18–SSX2* *SS18–SSX4*	Chimeric transcription factors, interrupts cell cycle control
Rhabdomyosarcoma—alveolar type	t(2;13)(q35;q14) t(1;13)(p36;q14)	*PAX3–FOXO1* *PAX7–FOXO1*	Chimeric transcription factors, disrupts skeletal muscle differentiation
Dermatofibrosarcoma protuberans	t(17;22)(q22;q15)	*COL1A1–PDGFB*	Promoter driven overexpression of PDGF-β, autocrine stimulation
Alveolar soft-part sarcoma	t(X;17)(p11.2;q25)	*TFE3–ASPL*	Unknown
Infantile fibrosarcoma	t(12;15)(p13;q23)	*ETV6–NTRK3*	Chimeric tyrosine kinase leads to constitutively active Ras/MAPK pathway
Nodular fasciitis	t(22;17)	*MYH9–USP6*	Increased Wnt/β-catenin signaling

range of cell sizes and shapes within a single tumor (i.e., they are pleomorphic).

Classification of soft tissue tumors continues to evolve as new molecular genetic abnormalities are identified. Clinically, soft tissue tumors range from benign, self-limited lesions that require minimal treatment to intermediate-grade, locally aggressive tumors with limited metastatic risk to highly aggressive malignancies with significant metastatic risk and mortality. All highly aggressive malignancies are classified as *sarcomas,* but this term is used less consistently among locally aggressive, nonmetastasizing tumors. Pathologic classification integrates morphology (e.g., muscle differentiation), immunohistochemistry, and molecular diagnostics (Table 26.8). In addition to accurate diagnosis, grade (degree of differentiation) and stage (size and depth) are important prognostic indicators. The next section will consider representative soft tissue tumors.

TUMORS OF ADIPOSE TISSUE

Lipoma

Lipoma, a benign tumor of fat, is the most common soft tissue tumor in adults. The conventional lipoma is the most common subtype, from which rare variants are distinguished according to characteristic morphologic and genetic features.

MORPHOLOGY

The conventional lipoma is a well-encapsulated mass of mature adipocytes. It usually arises in the subcutis of the proximal extremities and trunk during middle adulthood. Infrequently, lipomas are large, intramuscular, and poorly circumscribed. **Lipomatosis** occurs when multifocal lipomas involve a limb. Most lipomas are soft, mobile, painless, and cured by simple excision.

Liposarcoma

Liposarcomas, malignant tumors of adipose tissue, are the most common sarcomas of adulthood. These tumors typically develop in deep soft tissues of the proximal extremities and retroperitoneum of individuals in the sixth and seventh decades of life.

Pathogenesis

The three distinct subtypes of liposarcoma, well-differentiated, myxoid, and pleomorphic, have different genetic aberrations. Well-differentiated liposarcomas harbor amplifications of chromosome region 12q13–q15, which includes the p53 inhibitor *MDM2*. In myxoid liposarcoma, a fusion gene generated by a t(12;16) translocation arrests adipocyte differentiation, leading to unregulated proliferation of primitive cells. Pleomorphic liposarcomas have complex karyotypes without reproducible genetic abnormalities.

MORPHOLOGY

Liposarcomas are histologically divided into **well-differentiated, myxoid,** and **pleomorphic** subtypes. Well-differentiated liposarcomas are composed of mature adipocytes with scattered atypical spindle cells (Fig. 26.50A). Myxoid liposarcoma is characterized by abundant basophilic extracellular matrix, arborizing capillaries, and primitive cells at various stages of adipocyte differentiation resembling fetal fat (Fig. 26.50B). Pleomorphic liposarcomas are characterized by sheets of anaplastic cells with bizarre nuclei admixed with variable numbers of immature adipocytes, termed lipoblasts.

Clinical Features

Liposarcomas recur locally, and often repeatedly, unless adequately excised. Well-differentiated tumors can be indolent, while pleomorphic liposarcomas are aggressive and frequently metastasize; the behavior of myxoid tumors is intermediate between these extremes.

Table 26.8 Clinical Features of Soft Tissue Tumors

Category	Behavior	Tumor Type	Common Locations	Age (years)	Morphology
Adipose	Benign	Lipoma	Superficial extremity, trunk	40–60	Mature adipose tissue
	Malignant	Well-differentiated liposarcoma	Deep extremity, retroperitoneum	50–60	Adipose tissue with scattered atypical spindle cells
		Myxoid liposarcoma	Thigh, leg	30s	Myxoid matrix, "chicken wire" vessels, round cells, lipoblasts
Fibrous	Benign	Nodular fasciitis	Arm, forearm	20–30	Tissue culture growth, extravasated erythrocytes,
		Deep fibromatosis	Abdominal wall	30–40	Dense collagen, long, unidirectional fascicles
Skeletal muscle	Benign	Rhabdomyoma	Head and neck	0–60	Polygonal rhabdomyoblasts, "spider" cells
	Malignant	Alveolar rhabdomyosarcoma	Extremities, sinuses	5–15	Uniform round discohesive cells between septae
		Embryonal rhabdomyosarcoma	Genitourinary tract	1–5	Primitive spindle cells, "strap" cells
Smooth muscle	Benign	Leiomyoma	Extremity	20s	Uniform, plump eosinophilic cells in fascicles
	Malignant	Leiomyosarcoma	Thigh, retroperitoneum	40–60	Pleomorphic eosinophilic cells
Vascular	Benign	Hemangioma	Head and neck	0–10	Circumscribed mass of capillary or venous channels
	Malignant	Angiosarcoma	Skin, deep lower extremity	50–80	Infiltrating capillary channels
Nerve sheath	Benign	Schwannoma	Head and neck	20–50	Encapsulated, fibrillar stroma, nuclear palisading
		Neurofibroma	Wide, cutaneous, subcutis	10–20+	Myxoid, ropy collagen, loose fascicles, mast cells
	Malignant	Malignant peripheral nerve sheath tumor	Extremities, shoulder girdle	20–50	Tight fascicles, atypia, mitotic activity, necrosis
Uncertain histotype	Benign	Solitary fibrous tumor	Pelvis, pleura	20–70	Branching ectatic vessels
	Malignant	Synovial sarcoma	Thigh, leg	15–40	Tight fascicles of uniform basophilic spindle cells, pseudoglandular structures
		Undifferentiated pleomorphic sarcoma	Thigh	40–70	High-grade anaplastic polygonal, round, or spindle cells, bizarre nuclei, atypical mitoses, necrosis

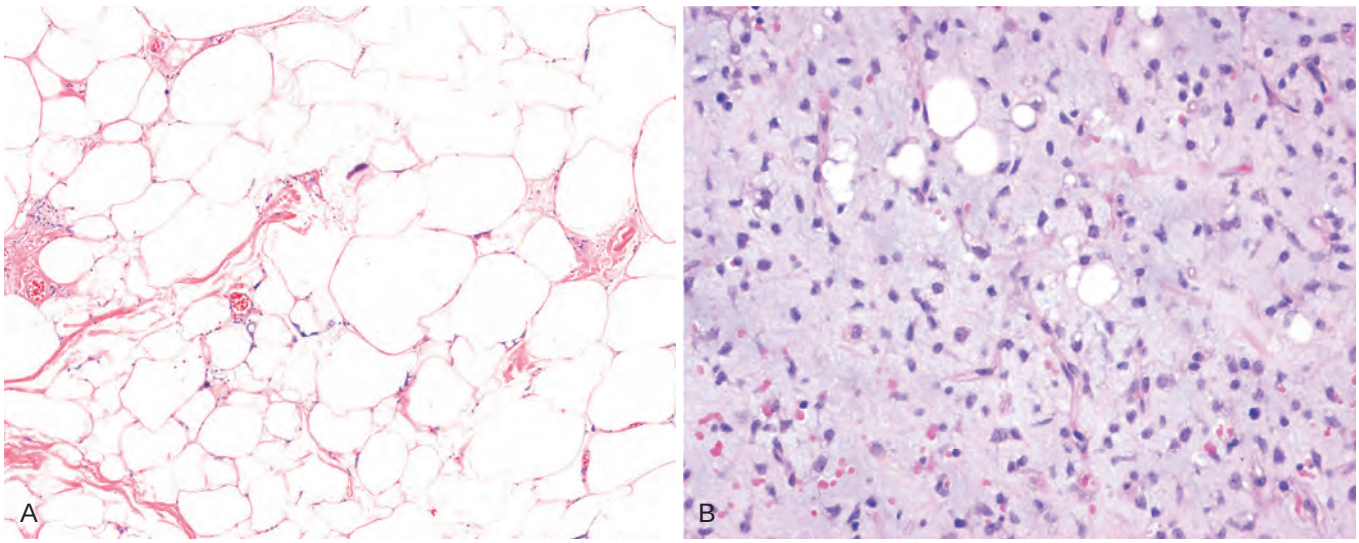

Figure 26.50 Liposarcoma. (A) the well-differentiated subtype consists of mature adipocytes and scattered spindle cells with hyperchromatic nuclei. (B) Myxoid liposarcoma with abundant basophilic ground substance and a rich capillary network with scattered immature adipocytes and more primitive round to stellate cells.

FIBROUS TUMORS

Nodular Fasciitis

Nodular fasciitis is a self-limited fibroblastic and myofibroblastic proliferation that occurs in young adults. The tumors occur most frequently on the forearm, chest, and back and grow rapidly over weeks to months. Due to a history of trauma in 10% to 50% of cases, this lesion was previously considered a reactive lesion. It is, however, a clonal proliferation that harbors a t(17;22) translocation that produces a *MYH9-USP6* fusion. The defect that prevents neoplastic cells from becoming malignant has not been defined. It is, however, interesting to note that aneurysmal bone cyst, a benign neoplasm previously considered reactive, also contains a *USP6* fusion gene, albeit to partners other than *MYH9*. Nodular fasciitis typically regresses spontaneously and, if excised, rarely recurs.

MORPHOLOGY

Nodular fasciitis arises in the deep dermis, subcutis, fascia, or muscle. Grossly the non-encapsulated lesions are well-circumscribed or slightly infiltrative and less than 3 cm in diameter. Histologically, nodular fasciitis is composed of plump, immature-appearing fibroblasts and myofibroblasts containing elongated nuclei with punctate nucleoli. Mitoses are frequent, but atypical forms are notably absent (Fig. 26.51). A gradient, termed zonation, transitions from hypercellular regions with myxoid stroma to hypocellular areas with fibrous stroma. Storiform or fascicular patterns are common in cellular areas. Metaplastic bone, cystic areas, ganglion-like cells, prominent vessels, extravasated red cells, and infiltrating lymphocytes are common.

Fibromatoses

Superficial Fibromatosis

Superficial fibromatosis is a benign growth that can cause local deformity but has an innocuous clinical course. It affects males more frequently than females. These nodular, proliferative lesions are composed of plump spindle cells arranged in poorly defined broad bundles or long, sweeping fascicles surrounded by abundant dense collagen. Clinical subtypes include Dupuytren contracture, Ledderhose disease, and Peyronie disease.

- *Dupuytren contracture,* or *palmar fibromatosis,* is an irregular or nodular thickening of the palmar fascia that can be unilateral or bilateral. Incidence increases with age. Attachment to overlying skin can cause puckering or dimpling and a slowly progressive flexion contracture.
- *Ledderhose disease,* or *plantar fibromatosis,* occurs in boys from under 10 years of age into adolescence. It is unilateral and does not cause contractures but can be associated with palmar and penile fibromatosis.
- *Peyronie disease,* or *penile fibromatosis,* is a palpable induration or mass on the dorsolateral aspect of the penis. Eventually, it may cause abnormal curvature of the shaft and constriction of the urethra.

Palmar and plantar fibromatoses progress in about 50% of cases. The remainder stabilize and do not progress; some resolve spontaneously. Nevertheless, recurrence is common, even after excision.

Deep Fibromatosis (Desmoid Tumors)

Deep fibromatoses, also called desmoid tumors, are large, infiltrative masses that frequently recur but do not metastasize. They arise most frequently in the teens to 30s, predominantly in women. Abdominal fibromatosis generally arises in the musculoaponeurotic structures of the anterior abdominal wall, but tumors can also arise in the limb girdles or mesentery. Deep fibromatoses contain mutations in the *APC* or *CTNNB1* (β-catenin) genes, both of which lead to increased Wnt signaling. The majority of tumors harbor sporadic *CTNNB1* mutations, but individuals with familial adenomatous polyposis, who have germline *APC* mutations, are predisposed to deep fibromatosis (Gardner syndrome, Chapter 17).

MORPHOLOGY

Fibromatoses are gray-white, firm, poorly demarcated masses varying from 1 to 15 cm in diameter. They are rubbery and tough and infiltrate surrounding muscle, nerve, and fat. Bland fibroblasts arranged in long parallel fascicles amid dense collagen are characteristic (Fig. 26.52). The resulting histologic appearance can resemble a scar.

Clinical Features

In addition to possibly being disfiguring or disabling, deep-seated fibromatosis can be painful. Because they are infiltrative, complete excision of deep fibromatosis can be difficult. Recent efforts have concentrated on medical or radiation therapy as alternatives to surgery.

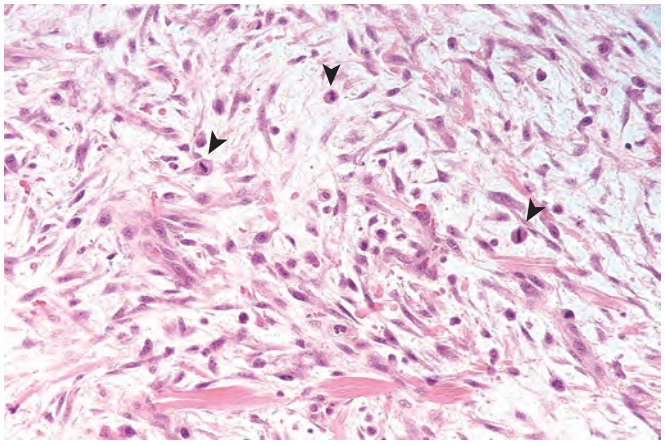

Figure 26.51 Nodular fasciitis with plump, randomly oriented spindle cells surrounded by myxoid stroma. Note the mitotic activity *(arrowheads)* and extravasated red blood cells.

SKELETAL MUSCLE TUMORS

In contrast to tumors of other cell types, skeletal muscle neoplasms are almost all malignant. The benign variant,

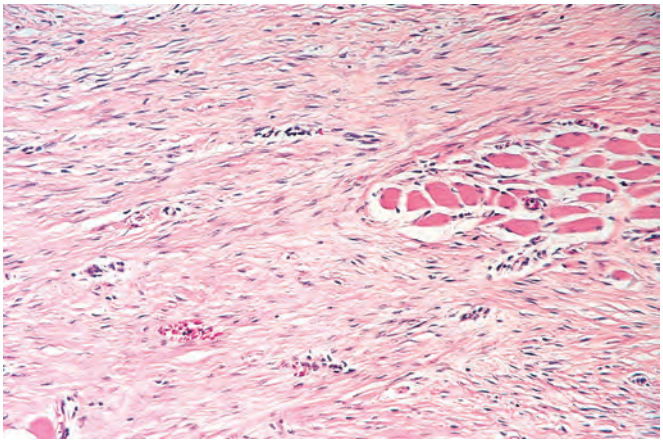

Figure 26.52 Deep fibromatosis infiltrating skeletal muscle.

rhabdomyoma, is frequently associated with tuberous sclerosis (Chapter 28).

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant mesenchymal tumor with skeletal muscle differentiation. Four subtypes are recognized: alveolar (20%), embryonal (50%), pleomorphic (20%), and spindle cell/sclerosing (10%). Alveolar and embryonal subtypes of rhabdomyosarcoma are the most common soft tissue sarcoms a of childhood and adolescence, usually appearing before 20 years of age. Pleomorphic rhabdomyosarcoma occurs in adults, while the spindle cell/sclerosing type affects all ages. Pediatric rhabdomyosarcomas often arise in the sinuses, head and neck, and genitourinary tract; these locations do not normally contain much skeletal muscle, underscoring the hypothesis that sarcomas do not arise from mature, terminally differentiated cells. Alveolar rhabdomyosarcoma frequently contains fusions of the *FOXO1* gene to either *PAX3* or *PAX7* due to t(2;13) or t(1;13) translocations, respectively. PAX3 is a transcription factor that initiates skeletal muscle differentiation; the chimeric PAX3-FOXO1 fusion protein interferes with differentiation, a mechanism similar to many of transcription factor fusion proteins found in acute leukemia. The remaining subtypes of rhabdomyosarcoma are genetically heterogeneous.

MORPHOLOGY

Embryonal rhabdomyosarcoma is a soft, gray, infiltrative mass. The tumor cells recapitulate skeletal muscle at various stages of differentiation and include sheets of primitive round and spindled cells in myxoid stroma (Fig. 26.53A). Rhabdomyoblasts with visible cross-striations may be present. **Sarcoma botryoides** (Chapter 22) is an embryonal rhabdomyosarcoma variant that develops in the walls of hollow, mucosal-lined structures, such as the nasopharynx, common bile duct, bladder, and vagina.

Alveolar rhabdomyosarcoma is traversed by a network of fibrous septae that divide the cells into clusters or aggregates, creating a crude resemblance to pulmonary alveoli. Cells in the center of the aggregates are only minimally cohesive, while those at the periphery adhere to the septae. Tumor cells are uniform and round with little cytoplasm. Cross-striations are uncommon (Fig. 26.53B).

Pleomorphic rhabdomyosarcoma is composed of large, sometimes multinucleated, bizarre eosinophilic tumor cells that can overlap histologically with other pleomorphic sarcomas. Immunohistochemistry (e.g., myogenin staining) is usually necessary to confirm rhabdomyoblastic differentiation.

Spindle cell/sclerosing rhabdomyosarcomas consist of fusiform cells with vesicular chromatin arranged in long fascicles or in a storiform pattern. Rhabdomyoblasts are occasionally present. Dense, collagenous, sclerotic stroma may be more common in adults.

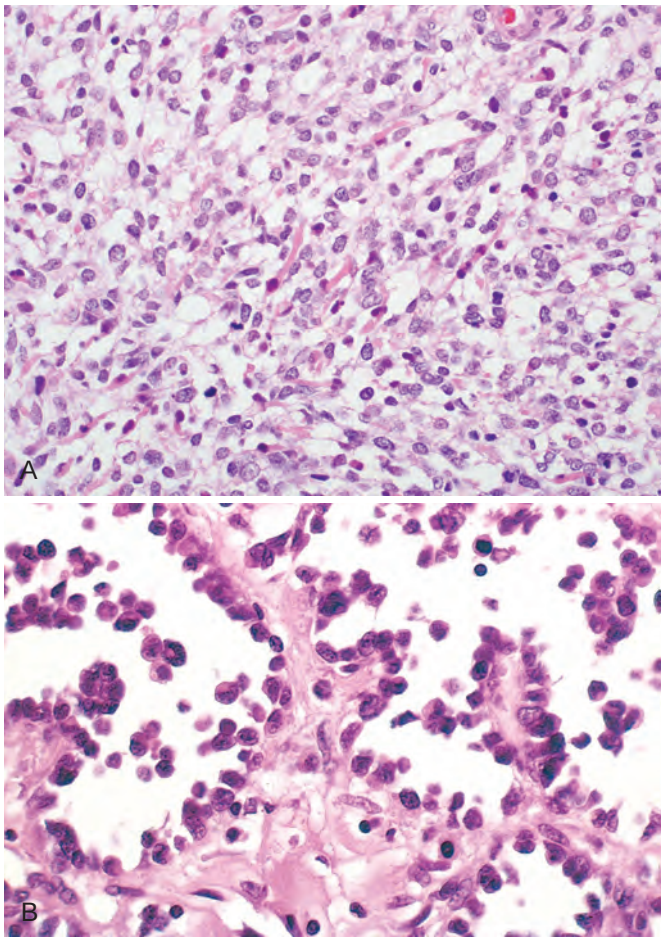

Figure 26.53 Rhabdomyosarcoma. (A) Embryonal subtype composed of malignant cells ranging from primitive and round to densely eosinophilic with skeletal muscle differentiation. (B) Alveolar rhabdomyosarcoma with numerous spaces lined by discohesive, uniform round tumor cells.

Clinical Features

Rhabdomyosarcomas are aggressive and usually treated by surgical resection and chemotherapy, with or without radiation therapy. Histologic type and location are correlated with survival; sarcoma botryoides has the most favorable prognosis, while pleomorphic rhabdomyosarcoma is often fatal.

SMOOTH MUSCLE TUMORS

Leiomyoma

Leiomyomas, benign smooth muscle tumors, often arise in the uterus and are the most common neoplasm in women (Chapter 22). Depending on their number, size, and location, uterine leiomyomas may cause a variety of symptoms including infertility and menorrhagia. *Pilar leiomyomas* arise from cutaneous erector pili muscles and, rarely, develop in deep soft tissues or the gastrointestinal tract. A germline loss-of-function mutation in the fumarate hydratase gene on chromosome 1q42.3 leads to multiple cutaneous leiomyomas, uterine leiomyomas, and renal cell carcinoma. Fumarase hydratase is a Krebs cycle enzyme, and this association is another example of the link between metabolic abnormalities and neoplasia.

Soft tissue leiomyomas are usually 1 to 2 cm and are composed of fascicles of densely eosinophilic spindle cells that often intersect each other at right angles. Tumor cells have blunt-ended, elongated nuclei with minimal atypia and few mitotic figures. Solitary lesions are easily cured. However, multiple tumors may be so numerous that surgical removal is impractical.

Leiomyosarcoma

Leiomyosarcoma, a malignant tumor of smooth muscle, most often develops in the deep soft tissues of the extremities and the retroperitoneum. It accounts for 10% to 20% of soft tissue sarcomas. They occur in adults and afflict women more frequently than men. A particularly deadly form arises from the great vessels, often the inferior vena cava. Leiomyosarcomas have underlying defects in genomic stability leading to complex genotypes.

MORPHOLOGY

Leiomyosarcomas present as painless firm masses. Retroperitoneal tumors may be large and bulky and cause abdominal symptoms. Histologically, they consist of eosinophilic spindle cells with blunt-ended, hyperchromatic nuclei arranged in interweaving fascicles. Immunohistochemical detection of smooth muscle proteins, including smooth muscle actin, desmin, and caldesmon, can aid in diagnosis.

Clinical Features

Leiomyosarcoma treatment depends on tumor size, location, and grade. Superficial or cutaneous leiomyosarcomas are usually small and have a good prognosis, while those involving retroperitoneum are large, frequently unresectable, and often fatal as a result of local extension and metastatic spread, especially to the lungs.

TUMORS OF UNCERTAIN ORIGIN

Although many soft tissue tumors can be assigned to recognizable histologic types, a large proportion do not recapitulate known mesenchymal lineages. This group includes tumors with simple or complex karyotypes; an example of each is described here.

Synovial Sarcoma

The first described cases of synovial sarcoma arose in soft tissues near the knee joint and led to speculation of a relationship with synovium. The proved to be mistaken, as **synovial sarcoma can present in locations that lack synovium, and its morphologic features are inconsistent with an origin from synoviocytes.** Synovial sarcomas account for approximately 10% of all soft tissue sarcomas and typically occur in people in their 20s to 40s. Individuals often present with a deep-seated mass that has been present for several years. A characteristic chromosomal translocation t(x;18)(p11;q11) that produces fusion of the *SS18* gene to one of three *SSX* genes is present in most synovial sarcomas. The fusions encode chimeric proteins that interfere with normal chromatin remodeling, the repositioning of nucleosomes on chromatin that influences gene expression.

MORPHOLOGY

Synovial sarcomas can be monophasic or biphasic. Monophasic synovial sarcomas consist of uniform spindle cells with scant cytoplasm and dense chromatin arranged in short, tightly packed fascicles. The biphasic type also contains glandlike structures composed of cuboidal to columnar epithelioid cells (Fig. 26.54). Immunohistochemistry is helpful because tumor cells, especially in the biphasic type, are positive for epithelial antigens (e.g., keratins), thereby differentiating them from most other sarcomas.

Clinical Features

Synovial sarcomas are treated aggressively with limb-sparing surgery and chemotherapy. The 5-year survival varies from 25% to 62% and is related to tumor stage and patient age. Common sites of metastases are the lung and, unusually for sarcomas, regional lymph nodes.

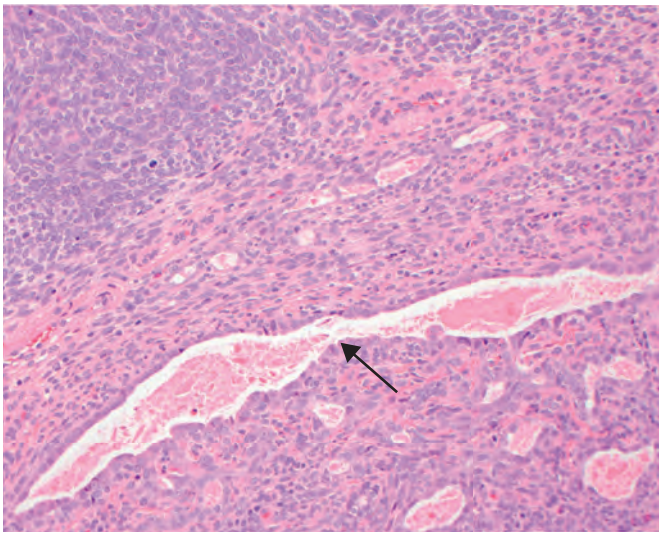

Figure 26.54 Synovial sarcoma revealing the classic biphasic spindle cell and glandlike *(arrow)* histologic appearance.

Undifferentiated Pleomorphic Sarcoma

Undifferentiated pleomorphic sarcomas include malignant mesenchymal tumors with high-grade, pleomorphic cells that cannot be classified into another category by histomorphology, immunophenotype, and genetics. Most arise in the deep soft tissues of the extremities, especially the thigh of middle-aged or older adults. Most undifferentiated pleomorphic sarcomas are aneuploid with multiple structural and numerical chromosomal changes.

MORPHOLOGY

Undifferentiated pleomorphic sarcomas are usually large, gray-white fleshy masses and can grow to 20 cm, depending on the anatomic compartment. Necrosis and hemorrhage common. Microscopically, they are extremely pleomorphic and composed of sheets of large, anaplastic spindled to polygonal cells with hyperchromatic irregular, sometimes bizarre nuclei (Fig. 26.55). Mitotic figures, including atypical asymmetric forms, are abundant. By definition, tumor cells lack both differentiation along recognized lineages and characteristic genetic defects.

Clinical Features

Undifferentiated pleomorphic sarcomas are aggressive malignancies that are treated with surgery and adjuvant chemotherapy and/or radiation. Despite this, prognosis is generally poor. Metastases occur in 30% to 50% of cases.

KEY CONCEPTS

SOFT TISSUE TUMORS

- Soft tissue tumors are malignant mesenchymal lesions that are distinct from tumors of epithelial, skeletal, central nervous system, hematopoietic, or lymphoid tissues.
- Soft tissue tumors likely arise from pluripotent mesenchymal stem cells rather than mature cells.
- Tumors that recapitulate a mature mesenchymal tissue (e.g., smooth muscle) can be subdivided into benign and malignant forms.
- Some tumors are composed of cells for which there is no normal counterpart (e.g., synovial sarcoma and undifferentiated pleomorphic sarcoma).
- Sarcomas with simple karyotypes demonstrate reproducible, chromosomal, and molecular abnormalities that contribute to pathogenesis and have diagnostic utility.
- Most adult sarcomas are genetically heterogeneous with complex karyotypes, histologically pleomorphic, and associated with a poor prognosis.

CHAPTER 27

Peripheral Nerves and Skeletal Muscles

Peter Pytel • Douglas C. Anthony

CHAPTER CONTENTS

Neuromuscular diseases are a complex group of disorders that typically present with weakness, muscle pain, or sensory deficits and may be inherited or acquired. They can be grouped according to anatomy, disease course, and pathogenesis. Physicians keep all these characteristics in mind when evaluating a patient with neuromuscular symptoms. This chapter uses an anatomic approach, grouping neuromuscular disorders into those that preferentially affect the peripheral nerves, the neuromuscular junction, or the skeletal muscles. A discussion of neoplasms that arise from peripheral nerves ends the chapter. Conditions that can produce similar clinical symptoms but are caused by disorders of the central nervous system (CNS) are discussed in Chapter 28.

DISEASES OF PERIPHERAL NERVES

The two components of peripheral nerves involved in impulse transmission are axons and myelin sheaths made by Schwann cells. Injury to either of these components may result in a peripheral neuropathy. Before discussing the pathology of these disorders, a brief review of peripheral nerve structure and function is in order. *Somatic motor function* is carried out by the motor unit, which consists of (1) a lower motor neuron located in the anterior horn of the spinal cord or in the brainstem; (2) an axon that travels in a nerve to a target; (3) the neuromuscular junctions; and (4) multiple innervated myofibers (muscle fibers). *Somatic sensory function* depends on (1) the distal nerve endings, which may contain specialized structures that serve to register specific sensory modalities; (2) a distal axon segment that travels as part of a peripheral nerve to the dorsal root ganglion; and (3) a proximal axon segment that synapses on neurons in the spinal cord or brainstem. *Autonomic nerve fibers,* which transmit all visceral motor and sensory functions, outnumber somatic fibers in the peripheral nervous system, but signs and symptoms related to their involvement are generally not prominent features of peripheral neuropathies, with a few important exceptions (e.g., in some cases of diabetic neuropathy, discussed later).

Specific sensations (pain, temperature, touch) and motor signals are each conveyed by axons that can be distinguished, in part, based on their diameter. Axonal diameters are in turn correlated with the thickness of their myelin sheaths and with their conduction speeds:

- *Thin unmyelinated fibers* mediate autonomic functions as well as certain pain and temperature sensations and have

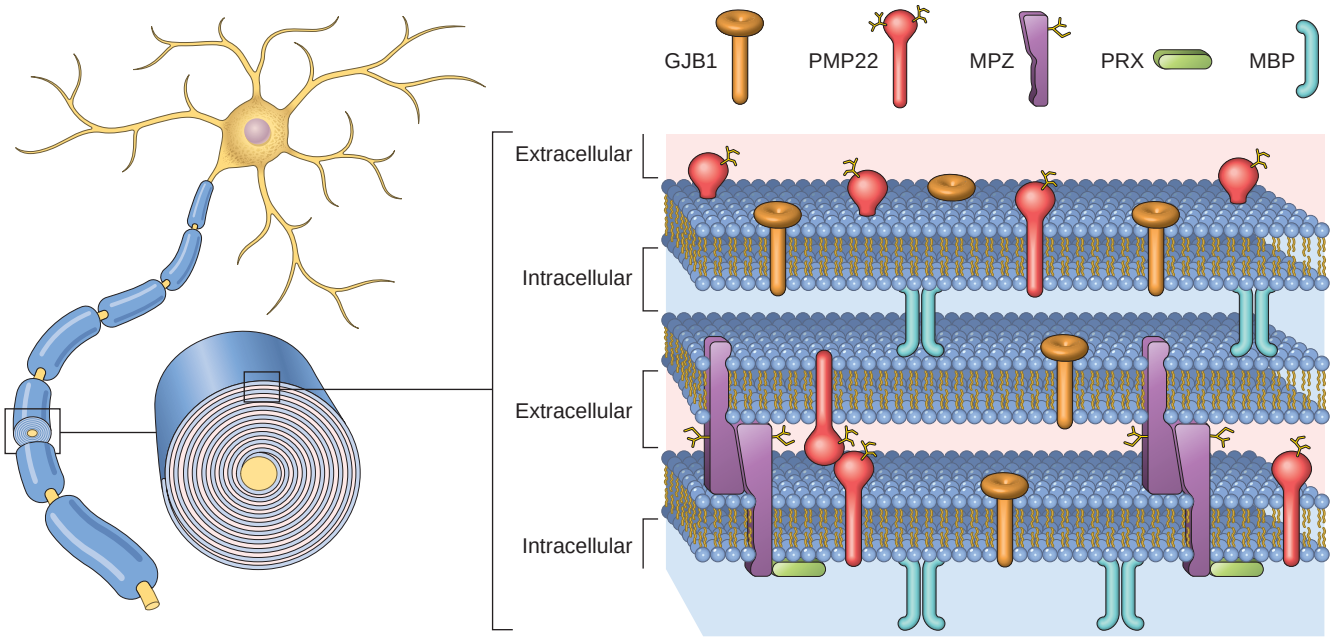

Figure 27.1 Relationship between lipid bilayers and associated proteins in myelin within internodes. Myelin basic protein *(MBP)* is an intracellular protein that has a role in myelin compaction. Mutant forms of myelin protein zero *(MPZ)*, peripheral myelin protein 22 *(PMP22)*, gap junction protein, beta 1 *(GJB1)*, and periaxin *(PRX)* cause some forms of Charcot-Marie-Tooth disease, a hereditary demyelinating neuropathy.

the slowest conduction speeds due to their lack of myelin and small axonal diameter.

- *Large diameter axons* with thick myelin sheaths transmit light touch and motor signals and have fast conduction speeds.

In the case of myelinated axons, individual Schwann cells make exactly one myelin sheath that wraps around a single axon to create a myelinated segment called an *internode*. Internodes are separated by unmyelinated gaps referred to as *nodes of Ranvier,* which are uniformly spaced along the length of the axon. A number of specialized proteins are essential for normal assembly and function of myelin within internodes (Fig. 27.1). Unmyelinated axons are also intimately associated with Schwann cells but in a different arrangement in which one cell surrounds segments of multiple axons.

Most peripheral nerves carry out both motor and sensory functions and thus contain axons of varying diameter and myelin thickness. **The axons are bundled together by three major connective tissue components: the epineurium, which encloses the entire nerve; the perineurium, a multilayered concentric connective tissue sheath that groups subsets of axons into fascicles; and the endoneurium, which surrounds individual nerve fibers.**

General Types of Peripheral Nerve Injury

Axonal Neuropathies

Axons are the primary target of the damage in this large group of peripheral neuropathies (Fig. 27.2). The morphologic hallmarks of axonal neuropathies can be produced experimentally by cutting a peripheral nerve, which results in a prototypical pattern of injury described as *Wallerian degeneration*. Portions of axons that are distal to the point of transection are disconnected from the cell bodies *(perikarya)* and degenerate. Within a day of injury, the distal axons begin to fragment, and the associated myelin sheaths unravel (Fig. 27.3) and disintegrate into spherical structures *(myelin ovoids)*. Macrophages are recruited and participate in the removal of axonal and myelin debris. Regeneration starts at the site of transection with the formation of a growth cone and the outgrowth of new branches from the stump of the proximal axon. Schwann cells and their associated basement membranes guide the sprouting axons, which grow at about 1 mm per day, toward their distal target. Continuous pruning of the sprouting axons removes misguided branches. The Schwann cells create new myelin sheaths around the regenerating axons, but these myelin internodes tend to be thinner and shorter than in the original ones. The regeneration is successful only if the two transected ends remain closely approximated. A failure of the outgrowing axons to find their distal target can produce a "pseudotumor" termed *traumatic neuroma*—a nonneoplastic haphazard proliferation of axonal processes and associated Schwann cells that results in a painful nodule (Fig. 27.4).

The changes observed following experimental nerve transections only partially resemble those seen in various axonal neuropathies. One key difference is that in these neuropathies (unlike nerve transection) damage occurs over an extended period of time. As a result, degenerating and regenerating axons coexist in a single biopsy. With time, damage tends to outpace repair, resulting in progressive loss of axons. In cases of toxic and metabolic insults, axons often degenerate in a length-dependent fashion with the longest axons being most susceptible, resulting in a *"dying-back"* type of pattern of progression. The electrophysiologic hallmark of axonal neuropathies is a reduction in signal amplitude owing to the dropout of axons from affected peripheral nerves, with relative preservation of conduction velocity.

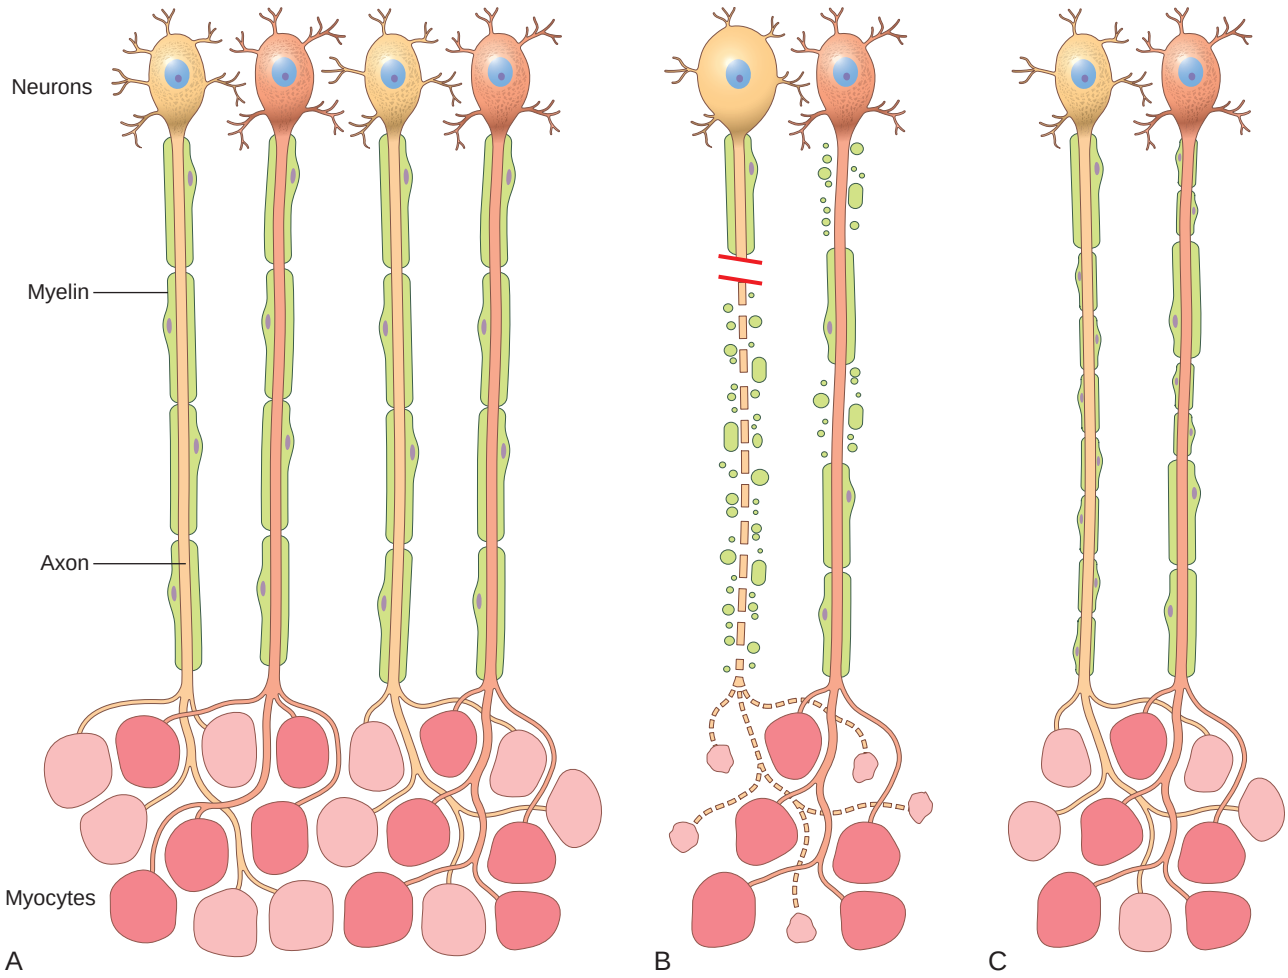

Figure 27.2 Patterns of peripheral nerve damage. (A) In normal motor units, type I and type II myofibers are arranged in a "checkerboard" distribution, and the internodes along the motor axons are uniform in thickness and length. (B) Acute axonal injury *(left axon)* results in degeneration of the distal axon and its associated myelin sheath, with atrophy of denervated myofibers. In contrast, acute demyelinating disease *(right axon)* produces random segmental degeneration of individual myelin internodes, while sparing the axons. (C) Regeneration of axons after injury *(left axon)* allows reinnervation of myofibers. The regenerated axon is myelinated by proliferating Schwann cells, but the new internodes are shorter and the myelin sheaths are thinner than the original ones. Remission of demyelinating disease *(right axon)* allows remyelination to take place, but the new internodes are shorter and have thinner myelin sheaths than flanking normal undamaged internodes. See Fig. 27.7 for comparison with reinnervation.

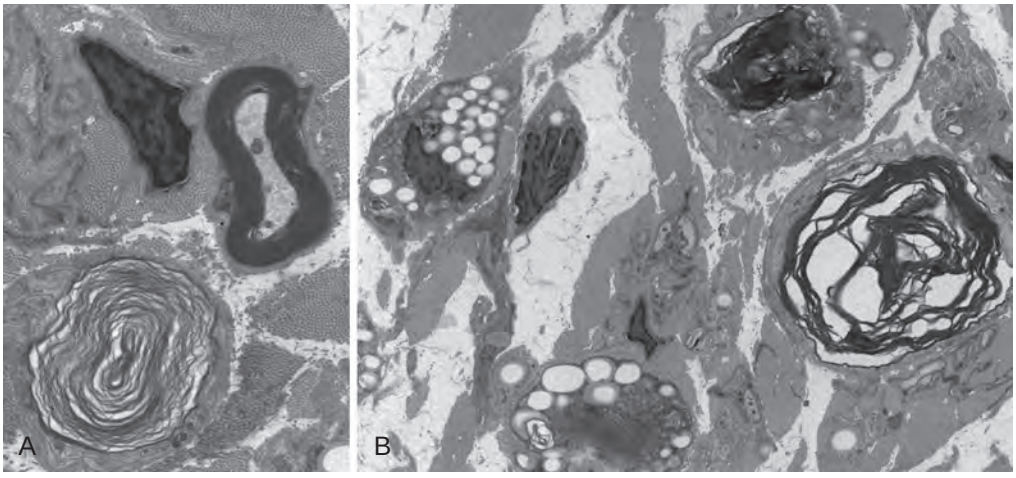

Figure 27.3 Electron micrographs illustrating features of axonal degeneration. (A) Degenerating myelin with loosened myelin layers is seen in the degenerating axon in the lower left corner, to be contrasted with a normal myelin sheath with tightly packed myelin and intact axon in the upper right corner. (B) In addition to an unraveling myelin sheath, several cells contain lipid droplets (seen as vacuoles) derived from degenerating myelin.

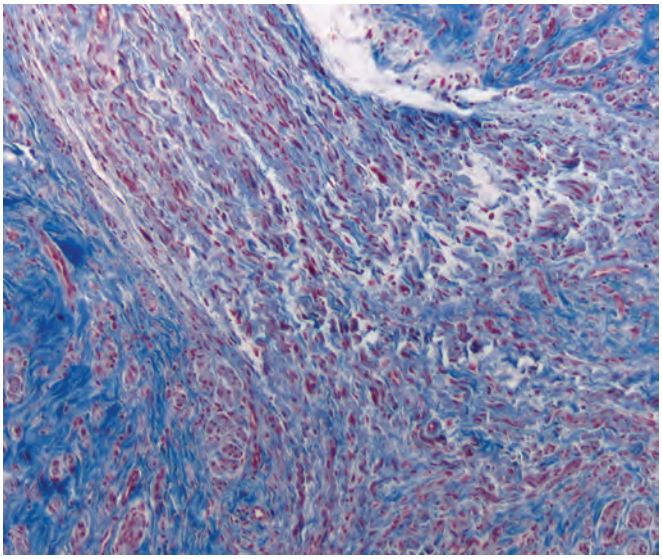

Figure 27.4 Trichrome-stained section of a traumatic neuroma showing the transition from normal nerve containing a parallel arrangement of axons *(upper left corner)* to a haphazard swirl of red-stained axons associated with admixture of Schwann cells and blue-staining connective tissue.

Demyelinating Neuropathies

In these disorders, Schwann cells with their myelin sheaths are the primary targets of damage (see Fig. 27.2), whereas axons are relatively preserved. This definition is similar to that of demyelinating diseases that affect the CNS (Chapter 28). Individual myelin sheaths degenerate in a seemingly random pattern, resulting in discontinuous damage of myelin segments. In response to this damage, Schwann cells or Schwann cell precursors proliferate and initiate repair through the formation of new myelin sheaths, but these again tend to be shorter and thinner than the original ones. The electrophysiologic hallmark of demyelinating neuropathies is slowed nerve conduction velocity, reflective of the loss of myelin.

Neuronopathies

Neuronopathies result from destruction of neurons, leading to secondary degeneration of axonal processes. Infections like herpes zoster and toxins like platinum compounds are examples of insults that may lead to neuronopathies. Because the damage is at the level of the neuronal cell body, peripheral nerve dysfunction caused by neuronopathies is equally likely to affect proximal and distal parts of the body (unlike peripheral axonopathies, which preferentially affect the distal extremities).

Anatomic Patterns of Peripheral Neuropathies

Peripheral neuropathies can be separated into several groups according to the anatomic distribution of involvement and the associated neurologic deficits. This approach can be helpful clinically, since each pattern has a different set of potential underlying causes. These anatomic patterns of injury are as follows:

- *Mononeuropathies* affect a single nerve and result in deficits in a restricted distribution dictated by nerve anatomy. Trauma, entrapment, and infections are common causes of mononeuropathy.
- *Polyneuropathies* are characterized by involvement of multiple nerves, usually in a symmetric fashion. In most cases axons are affected in a length-dependent fashion leading to deficits that start in the feet and ascend with disease progression. The hands often start to show involvement by the time deficits extend to the level of the knee, resulting in a characteristic "stocking and glove" distribution of sensory deficits.
- *Mononeuritis multiplex* describes a disease process that damages individual nerves in a haphazard fashion. An affected patient might have a right wrist drop from involvement of the right radial nerve and a left foot drop from peroneal nerve damage. Vasculitis is a common cause of this pattern of injury.
- *Polyradiculoneuropathies* affect nerve roots as well as peripheral nerves, leading to diffuse symmetric symptoms in proximal and distal parts of the body.

Specific Peripheral Neuropathies

Patients with peripheral neuropathy often complain of numbness, painful "pins and needles" sensations, and weakness, most often in the distal portions of the extremities. Many different types of disease processes can damage peripheral nerves, including inflammatory diseases, infections, metabolic changes, toxic injury, trauma, paraneoplastic disease, and inherited gene defects.

Inflammatory Neuropathies

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyneuropathy)

Guillain-Barré syndrome is an immunologically mediated demyelinating peripheral neuropathy that may lead to life-threatening respiratory paralysis. The overall annual incidence is approximately 1 case per 100,000 persons. The disease is characterized clinically by weakness beginning in the distal limbs that rapidly advances to affect proximal muscle function ("ascending paralysis"). Histologic features are inflammation and demyelination of spinal nerve roots and peripheral nerves (radiculoneuropathy).

Pathogenesis

In most cases, Guillain-Barré syndrome is thought to be an acute-onset immune-mediated demyelinating neuropathy. Approximately two-thirds of cases are preceded by an acute, influenza-like illness from which the affected individual has recovered by the time the neuropathy becomes symptomatic. Infections with *Campylobacter jejuni,* cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumoniae* as well as prior vaccination have significant epidemiologic associations with Guillain-Barré syndrome. No infectious agent has been demonstrated in affected nerves, and an immunologic reaction is favored as the underlying cause. A similar inflammatory disease of peripheral nerves can be reproduced in experimental animals by immunization with a peripheral nerve myelin protein. A T-cell–mediated immune response ensues, accompanied by segmental demyelination induced by the actions of activated macrophages. Transfer of these T cells to a naive animal results in comparable lesions.

Moreover, lymphocytes from individuals with Guillain-Barré syndrome have been shown to produce demyelination in tissue cultures of myelinated nerve fibers. Circulating antibodies that cross-react with components of peripheral nerves may also play a role.

MORPHOLOGY

The dominant finding in sections stained with hematoxylin and eosin is **inflammation of peripheral nerves,** manifested as perivenular and endoneurial infiltration by lymphocytes, macrophages, and a few plasma cells. Segmental demyelination affecting peripheral nerves is the most prominent lesion, but damage to axons is also seen, particularly when the disease is severe. Electron microscopy has identified an early effect on myelin sheaths. The cytoplasmic processes of macrophages penetrate the basement membrane of Schwann cells, particularly in the vicinity of the nodes of Ranvier, and extend between the myelin lamellae, stripping the myelin sheath from the axon. Ultimately, the remnants of the myelin sheath are engulfed by the macrophages. Inflammation and demyelination can be widespread in the peripheral nervous system but are typically most prominent proximally, close to the nerve roots.

Clinical Features

The clinical picture is dominated by ascending paralysis and areflexia. Deep tendon reflexes disappear early in the process. Sensory involvement, including loss of pain sensation, is often present but is usually not a prominent feature. Nerve conduction velocities are slowed because of multifocal destruction of myelin segments in many axons within a nerve. Cerebrospinal fluid (CSF) protein levels are elevated due to inflammation and altered permeability of the microcirculation within the spinal roots as they traverse the subarachnoid space. Inflammatory cells, on the other hand, remain confined to the roots; therefore, there is little or no CSF pleocytosis. Many patients spend weeks in the intensive care unit (ICU) before recovering normal function. With improved supportive respiratory care, cardiovascular monitoring, and prophylaxis against deep venous thrombosis, the mortality rate has fallen. Plasmapheresis and intravenous immunoglobulin therapy hasten recovery, apparently because these remove pathogenic antibodies and suppress immune function, respectively. However, 2% to 5% of affected patients die of respiratory paralysis, autonomic instability, cardiac arrest, or related complications, and up to 20% of hospitalized survivors suffer long-term disability.

Chronic Inflammatory Demyelinating Poly(radiculo)neuropathy

This is the most common chronic acquired inflammatory peripheral neuropathy, characterized by symmetric mixed sensorimotor polyneuropathy that persists for 2 months or more. By definition, signs and symptoms must be present for at least 2 months, but often the disease evolves over years, usually with relapses and remissions. Typically there is a symmetric, mixed sensorimotor polyneuropathy, but some patients may present with predominantly sensory or motor impairment. Clinical remissions can often be achieved with intravenous immunoglobulin, or with other immunosuppressive therapies, such as plasmapheresis, glucocorticoids, and cytotoxic agents directed against T cells or B cells. The time course and the response to steroids distinguish chronic inflammatory demyelinating polyradiculoneuropathy from Guillain-Barré syndrome.

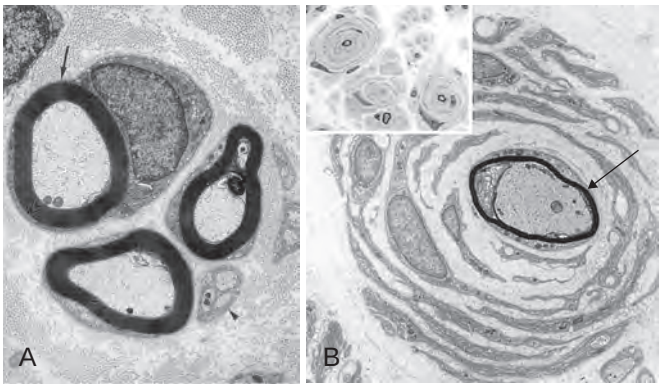

Figure 27.5 Onion bulb neuropathy. (A) shows normal myelinated axons (one that includes the nucleus of the associated Schwann cells is marked with an arrow) and unmyelinated axons *(arrowhead)*. Compared with the normal ultrastructure of axons in a nerve (A), an "onion bulb" (B) is composed of a thinly myelinated axon *(arrow)* surrounded by multiple concentrically arranged Schwann cells. *Inset,* Light microscopic appearance of an onion bulb neuropathy, characterized by "onion bulbs" surrounding axons. (B, Courtesy G. Richard Dickersin, MD, from *Diagnostic Electron Microscopy: A Text Atlas,* New York, 2000, Igaku-Shoin Medical Publishers, p 984.)

Pathogenesis

T cells as well as antibodies are implicated in the inflammatory process. Molecules expressed at the Schwann cell–axon junction and in noncompact areas of myelin appear to be the target of the immune response. Complement-fixing immunoglobulin G (IgG) and IgM can be found on the myelin sheaths, and the deposition of these opsonins leads to recruitment of macrophages that strip myelin from axons. Sural nerve biopsies show evidence of recurrent demyelination and remyelination associated with proliferation of Schwann cells. When excessive, this proliferation leads to the formation of so-called *onion bulbs*—structures in which multiple layers of Schwann cells wrap around an axon like the layers of an onion (Fig. 27.5).

Neuropathy Associated With Systemic Autoimmune Diseases

Systemic autoimmune diseases like rheumatoid arthritis, Sjögren syndrome, or systemic lupus erythematosus may be associated with peripheral neuropathies that often take the form of distal sensory or sensorimotor polyneuropathies. These neuropathies are distinct from vasculitic peripheral neuropathies, which can arise as secondary manifestations of these same diseases.

Neuropathy Associated With Vasculitis

Vasculitis is a noninfectious inflammation of blood vessels that can involve and damage peripheral nerves. About one-third of patients with vasculitis, depending on the type of vasculitis, have peripheral nerve involvement, and neuropathy may be the presenting feature. Vasculitis often presents as mononeuritis multiplex, but mononeuritis and polyneuropathy are also encountered.

When peripheral neuropathy occurs in systemic vasculitis, it is most common in the MPO-ANCA–associated vasculitides (microscopic polyangiitis and eosinophilic granulomatosis with polyangiitis/Churg-Strauss syndrome) and polyarteritis nodosa and much less common in PR3-ANCA–associated granulomatosis with polyangiitis. The most common form of vasculitis associated with peripheral neuropathy is a localized form referred to as *nonsystemic vasculitic neuropathy,* which is not associated with any anti-neutrophil cytoplasmic antibodies (ANCAs). Regardless of the type of vasculitis, peripheral nerves involved by vasculitis typically show patchy axonal degeneration and loss, with some fascicles being more severely affected than others. Perivascular inflammatory infiltrates are often present. Identification of blood vessels with characteristic forms of acute or chronic damage (Chapter 11) helps establish the diagnosis.

Infectious Neuropathies

Many infectious processes affect peripheral nerves. Among these, leprosy, diphtheria, and varicella-zoster cause relatively specific pathologic changes in nerves that are the focus here. Each of these disorders is also discussed in more detail in Chapter 8.

Leprosy (Hansen Disease)

Peripheral nerves are involved in both lepromatous and tuberculoid leprosy (discussed in Chapter 8).

- In *lepromatous leprosy,* Schwann cells are invaded by *Mycobacterium leprae,* which proliferate and eventually infect other cells. There is evidence of segmental demyelination and remyelination and loss of both myelinated and unmyelinated axons. As the infection advances, endoneurial fibrosis and multilayered thickening of the perineurial sheaths occur. Affected individuals develop a symmetric polyneuropathy that is most severe in the relatively cool distal extremities and in the face because lower temperatures favor mycobacterial growth. The infection prominently involves pain fibers, and the resulting loss of sensation contributes to injury, since the patient is rendered unaware of injurious stimuli and damaged tissues. Thus, large traumatic ulcers may develop.
- *Tuberculoid leprosy* is characterized by an active cell-mediated immune response to *M. leprae* that usually manifests as dermal nodules containing granulomatous inflammation. The inflammation injures cutaneous nerves in the vicinity; axons, Schwann cells, and myelin are lost; and there is fibrosis of the perineurium and endoneurium. In tuberculoid leprosy, affected individuals have much more localized nerve involvement.

Lyme Disease

Lyme disease causes various neurologic manifestations in the second and third stages of the disease. These include polyradiculoneuropathy and unilateral or bilateral facial nerve palsies.

HIV/AIDS

Patients infected with human immunodeficiency virus (HIV) develop several patterns of peripheral neuropathy that are poorly understood, but all appear to be related in some way to immune dysregulation. Early-stage HIV infection can be associated with mononeuritis multiplex and demyelinating disorders that may resemble Guillain-Barré syndrome or chronic inflammatory demyelinating polyradiculoneuropathy. More commonly, later stages of HIV infection are associated with a distal sensory neuropathy that is often painful.

Diphtheria

Peripheral nerve dysfunction results from the effects of the diphtheria exotoxin. It produces an acute peripheral neuropathy associated with prominent bulbar and respiratory muscle dysfunction, which can lead to death or long-term disability. The mechanism of action of diphtheria toxin is described in Chapter 8. Diphtheria is most commonly found in low income countries and is a continuing medical problem because of incomplete immunization or waning immunity in adults.

Varicella-Zoster Virus

Varicella-zoster is one of the most common viral infections of the peripheral nervous system. Following chickenpox, a latent infection persists within neurons of sensory ganglia. If the virus is reactivated, sometimes many years later, it may be transported along the sensory nerves to the skin. Here it infects keratinocytes, leading to a **painful, vesicular skin eruption in a distribution that follows sensory dermatomes (shingles).** Most common is the involvement of thoracic or trigeminal nerve dermatomes. The factors underlying reactivation of the virus are not fully understood, but decreased cell-mediated immunity is suspected to play a role. In a small proportion of patients, weakness is also apparent in the same distributions. Affected ganglia show neuronal death, usually accompanied by abundant mononuclear inflammatory cell infiltrates; focal necrosis and hemorrhage may also be found. Peripheral nerves show degeneration of the axons that belong to the dead sensory neurons. Focal destruction of the large motor neurons of the anterior horns or cranial nerve motor nuclei may be seen at the corresponding levels. Intranuclear inclusions generally are not found in the peripheral nervous system.

Metabolic, Hormonal, and Nutritional Neuropathies

Diabetes

Diabetes is the most common cause of peripheral neuropathy. The prevalence of this complication depends on the duration of the disease; up to 50% of patients with diabetes overall and up to 80% of those who have had the disease for more than 15 years have clinical evidence of peripheral neuropathy. Patients with both type 1 and type 2 diabetes are affected (Chapter 24). Several distinct clinicopathologic patterns of diabetes-related peripheral neuropathy are recognized (described later), but the most common by far is an ascending distal symmetric sensorimotor polyneuropathy.

Pathogenesis

The mechanism of diabetic neuropathy is complex and not completely resolved; both metabolic and secondary vascular changes are believed to contribute to the damage of axons and Schwann cells. Hyperglycemia causes the nonenzymatic glycosylation of proteins, lipids, and nucleic acids. The resulting advanced glycosylation end-products (AGEs)

may interfere with normal protein function and activate inflammatory signaling through the receptor for the AGE. Excess glucose within cells is reduced to sorbitol, a process that depletes NADPH and increases intracellular osmolality. These and other metabolic disturbances may predispose peripheral nerves to injury by reactive oxygen species. In addition, the vascular injuries that occur in chronic diabetes due to hyperlipidemia and other metabolic alterations may cause ischemic damage of the nerves.

MORPHOLOGY

In individuals with a distal symmetric sensorimotor neuropathy, the predominant pathologic finding is an axonal neuropathy. Nerve biopsies show reduced numbers of axons. Variable degrees of ongoing axonal damage, marked by degenerating myelin sheaths and regenerative axonal clusters, may be present. Endoneurial arterioles show thickening, hyalinization, and intense periodic acid–Schiff positivity of their walls and extensive reduplication of basement membranes (Fig. 27.6).

Clinical Features

Distal symmetric diabetic polyneuropathy typically presents with sensory symptoms like numbness, loss of pain sensation, difficulty with balance, and paresthesias or dysesthesias. Paresthesias or dysesthesias (abnormal painful sense of touch) are so-called "positive" symptoms—painful sensations that result from abnormal discharges of damaged nerves. Neuropathy leads to considerable morbidity, in particular an increased susceptibility to foot and ankle fractures and chronic skin ulcers, which may eventually lead to amputations.

Another manifestation is dysfunction of the autonomic nervous system; this affects 20% to 40% of individuals with diabetes mellitus, nearly always in association with a distal sensorimotor neuropathy. Diabetic autonomic neuropathy has protean manifestations, including postural hypotension, incomplete emptying of the bladder (resulting in recurrent infections), and sexual dysfunction. Some affected individuals, especially older adults with a long history of diabetes, develop a peripheral neuropathy that manifests with asymmetric presentations, including *mononeuropathy, cranial neuropathy, and radiculoplexus neuropathy*. The last-mentioned is a devastatingly painful acute disorder that presents in the distribution of the brachial or lumbosacral nerve plexus. It is often monophasic and can improve over several months. These asymmetric manifestations may be caused by microvascular disease.

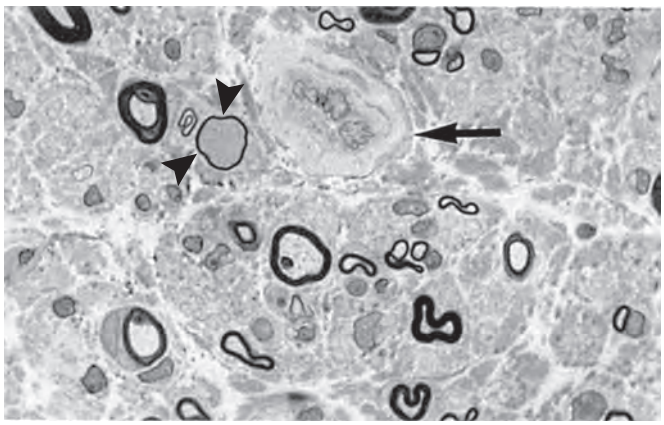

Figure 27.6 Diabetic neuropathy with marked loss of myelinated fibers, a thinly myelinated fiber *(arrowheads)*, and thickening of endoneurial vessel wall *(arrow)*.

Other Metabolic, Hormonal, and Nutritional Neuropathies

A diverse group of metabolic, hormonal, and nutritional disorders are associated with peripheral neuropathy, including the following:

- *Uremic neuropathy.* Most individuals with renal failure have a peripheral neuropathy. Typically this is a distal, symmetric neuropathy that may be asymptomatic or may be associated with muscle cramps, distal dysesthesias, and diminished deep tendon reflexes. In these patients, axonal degeneration is the primary event; occasionally there is secondary demyelination. Regeneration and recovery are common after dialysis.
- *Thyroid dysfunction.* Hypothyroidism can lead to compression mononeuropathies such as carpal tunnel syndrome or cause a distal symmetric predominantly sensory polyneuropathy. In rare cases, hyperthyroidism is associated with a neuropathy resembling Guillain-Barré syndrome.
- *Vitamin B_{12} (cyanocobalamin) deficiency* classically results in subacute combined degeneration with damage to long tracts in the spinal cord (Chapter 28) and also peripheral nerves.
- *Deficiencies of vitamin B_1 (thiamine), vitamin B_6 (pyridoxine), folate, copper, and zinc* all have been associated with peripheral neuropathy.

Toxic Neuropathies

Peripheral neuropathies may appear after exposure to industrial or environmental chemicals, biologic toxins, or therapeutic drugs. Important causes of toxic peripheral nerve damage include alcohol (independent of associated nutritional deficiencies), heavy metals (lead, mercury, arsenic, and thallium), and organic solvents. Various medications can cause toxic nerve damage, but the most notorious are chemotherapeutic agents. These include vinca alkaloids and taxanes, microtubule inhibitors that interfere with axonal transport, and cisplatin, which may cause a neuronopathy.

Neuropathies Associated With Malignancy

Neuropathies associated with cancers may stem from local effects, complications of therapy, paraneoplastic effects, or (in the case of B-cell tumors) tumor-derived immunoglobulins.

- *Direct infiltration or compression of peripheral nerves* by tumors is a common cause of mononeuropathy and may be a presenting symptom of cancer. These neuropathies include brachial plexopathy from neoplasms of the apex of the lung, obturator palsy from pelvic malignant neoplasms, and cranial nerve palsies from intracranial tumors or tumors of the base of the skull. A polyradiculopathy involving the lower extremity may develop when the cauda equina is involved by meningeal carcinomatosis.
- *Paraneoplastic neuropathies*. These can occur at any time during the patient's course, but often precede the diagnosis of the underlying tumor. Sensorimotor neuropathy is the

most common paraneoplastic form, but a pure sensory neuronopathy, chronic inflammatory demyelinating polyneuropathy, plexopathy, and autonomic neuropathy may also be seen. Paraneoplastic sensory neuronopathy is most commonly associated with small cell lung cancer. Antibodies that recognize proteins expressed by cancer cells and normal neurons (for example, anti-Hu antibodies) are often present, but the damage appears to be mediated by a CD8+ cytotoxic T-cell attack on dorsal root ganglion cells. Sensory symptoms usually start distally in an asymmetric and multifocal pattern. Other patients with anti-CV2 autoantibodies (which recognize CRMP5, an intracellular signaling protein) tend to present with a painful axonal asymmetric sensorimotor neuropathy.

- *Neuropathies associated with monoclonal gammopathies*. Neoplastic B cells may secrete monoclonal immunoglobulins or immunoglobulin fragments (so-called paraproteins) that damage nerves. For example, tumors that secrete IgM immunoglobulin may be associated with a demyelinating peripheral neuropathy. In most cases, the pathogenic IgM paraprotein is thought to bind directly to myelin-associated antigens such as myelin-associated glycoprotein. Deposition of IgM can be seen ultrastructurally between the membrane layers of the myelin sheath. IgG or IgA paraproteins may also be associated with peripheral neuropathy. One distinctive presentation is *POEMS syndrome* (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes), in which patients develop a demyelinating neuropathy associated with deposition of paraprotein between noncompacted myelin lamellae. Finally, excess immunoglobulin light chain may deposit as amyloid (Chapter 6), which can lead to peripheral neuropathy due to vascular insufficiency or a direct toxic effect.

Neuropathies Caused by Physical Forces

Peripheral nerves are commonly injured by trauma or entrapment.

- *Lacerations* result from cutting injuries and from sharp fragments of fractured bone, both of which may sever a nerve.
- *Avulsion* of a nerve may occur when tension is applied, often to one of the limbs.
- *Compression neuropathy (entrapment neuropathy)* occurs when a peripheral nerve is chronically subjected to increased pressure, often within an anatomic compartment. Carpal tunnel syndrome, the most common entrapment neuropathy, results from compression of the median nerve at the level of the wrist within the compartment delimited by the transverse carpal ligament. Women are more commonly affected than men, and the problem is frequently bilateral. The disorder may be observed in association with many conditions including tissue edema, pregnancy, inflammatory arthritis, hypothyroidism, amyloidosis (especially related to β_2-microglobulin deposition in individuals on renal dialysis), acromegaly, diabetes mellitus, and excessive repetitive motions of the wrist. Symptoms are limited to dysfunction of the median nerve and typically include numbness and paresthesias of the tips of the thumb and first two digits. Other nerves prone to compression neuropathies include the ulnar nerve at the level of the elbow, the peroneal nerve at the level of the knee, and the radial nerve in the upper arm; the latter occurs from sleeping with the arm in an awkward position ("Saturday night palsy"). Another form of compression neuropathy is found in the foot, affecting the interdigital nerve at intermetatarsal sites. This problem, which occurs more often in women than in men, leads to foot pain (metatarsalgia) and is associated with a histologic lesion called a *Morton neuroma,* which is marked by perineural fibrosis.

Inherited Peripheral Neuropathies

Inherited peripheral neuropathies are a group of genetically diverse disorders with overlapping clinical phenotypes that often present in adults. Because of the delayed onset, the possibility of an inherited neuropathy has to be considered in the differential diagnosis for any patient who presents with a peripheral neuropathy. The major types of inherited peripheral neuropathies include (1) hereditary motor and sensory neuropathies, sometimes known as *Charcot-Marie-Tooth* (CMT) disease, described below, which is a genetically heterogeneous disorder caused by mutations in genes that encode proteins involved in the structure and function of either the peripheral nerve axon or the myelin sheath; (2) hereditary motor neuropathies; (3) hereditary sensory neuropathies, with or without autonomic neuropathy; and (4) other inherited conditions causing neuropathy, including familial amyloidosis and inherited metabolic diseases.

Historically, these diseases were classified based on their inheritance pattern and clinical features. Now there is a continuously growing list of altered genes that are linked to these diseases. The complexity of the genetics of inherited neuropathies is no doubt a reflection of the complicated homeostatic mechanisms that sustain normal peripheral nerve function. There is no simple unifying concept tying all the implicated genes together; some of the implicated genes are illustrated in Fig. 27.1. Below, some of the more common and distinctive types of inherited peripheral neuropathies are described in brief.

Hereditary Motor and Sensory Neuropathies/ Charcot-Marie-Tooth Disease

These are by far the most common inherited peripheral neuropathies, affecting up to 1 in 2500 people. The initial description of these disorders, based on clinical features, was deceptively simple—an inherited disease associated with distal muscle atrophy, sensory loss, and foot deformities. It is now appreciated that this clinical phenotype can result from mutations in more than 50 different genes. Current systems classify hereditary motor and sensory neuropathies based on the mode of inheritance and the pattern of injury (e.g., axonal or demyelinating). Demyelinating forms of CMT disease are associated with morphologic features of demyelination and remyelination including Schwann cell hyperplasia and onion bulb formation, which may be so severe that the involved nerve is palpably enlarged. Listed are the four most common types, which together account for over 90% of patients with CMT disease:

- *CMT1 encompasses a group of autosomal dominant demyelinating neuropathies* that collectively are the most common subtype of hereditary motor and sensory neuropathy. *CMT1A* accounts for some 55% of genetically defined CMT. It is caused by a duplication of a region on

chromosome 17 that includes the peripheral myelin protein 22 *(PMP22)* gene. The disease usually presents in the second decade of life as a slowly progressive distal demyelinating motor and sensory neuropathy. *CMT1B* is also a demyelinating neuropathy caused by mutations in the myelin protein zero gene *(MPZ)* and accounts for about 9% of genetically defined cases of CMT.

- *CMTX* encompasses X-linked forms of CMT disease. *CMT1X* is the most common of these, accounting for 15% of genetically defined cases of CMT. It is linked to mutations in the *GJB1* gene, which encodes connexin32, a gap junction component that is expressed in Schwann cells.
- *CMT2* includes autosomal dominant neuropathies associated with axonal rather than demyelinating injury. *CMT2A* is the most common subtype, accounting for 4% of all CMT disease. It is caused by mutations in the *MFN2* gene, which is required for normal mitochondrial fusion. The phenotype is typically severe, with disease onset in early childhood.

Hereditary Sensory Neuropathies With or Without Autonomic Neuropathy

This is a diverse group of diseases marked by loss of sensation and variable autonomic disturbances, but with preserved motor strength. Loss of pain and temperature sensation is the most common symptom. The inability to sense pain leads to traumatic injury of the hands and feet. These are typically axonal neuropathies.

Familial Amyloid Polyneuropathies

These are hereditary disorders characterized by amyloid deposition within peripheral nerves. Most are caused by germline mutations of the transthyretin gene. The mutated transthyretin protein, which is normally involved in serum binding and transport of thyroid hormone, is prone to deposit as amyloid fibrils in a number of tissues including peripheral nerve (Chapter 6). The clinical presentation is similar to that of hereditary sensory and autonomic neuropathies.

KEY CONCEPTS

PERIPHERAL NEUROPATHIES

- Anatomic patterns include mononeuropathy, mononeuritis multiplex, polyneuropathy, and polyradiculoneuropathy.
- Damage may occur primarily in Schwann cells (demyelinating neuropathy), axons (axonal neuropathy), or central neurons (neuronopathy); mixed patterns of injury occur.
- Inflammatory disease, infections, metabolic changes, toxic injury, trauma, paraneoplastic disorders, and inherited gene defects all can cause peripheral neuropathy.
- Diabetes mellitus is the most common cause of peripheral neuropathy, which most often presents as a distal symmetric neuropathy.
- Guillain-Barré syndrome and chronic inflammatory demyelinating polyradiculoneuropathy are the major acute and chronic acquired demyelinating peripheral neuropathies, respectively.
- Inherited peripheral neuropathies are genetically and phenotypically diverse disorders that often present in adulthood and may be marked by sensory, motor, or autonomic dysfunction, alone or in combination.

DISEASES OF THE NEUROMUSCULAR JUNCTION

The neuromuscular junction is a complex specialized structure located at the interface of motor nerve axons and skeletal muscle that serves to control muscle contraction. Neuromuscular junctions are found midway along the length of myofibers. Here, the distal ends of peripheral motor nerves branch into small processes that terminate in bulbous synaptic boutons. Upon depolarization, these presynaptic nerve terminals release acetylcholine (ACh) into the synaptic cleft, the space separating the nerve endings from the myofiber membrane (referred to as the *sarcolemma*). The postsynaptic sarcolemma is characterized by complex infoldings and exhibits distinct specializations with localized clustering of ACh receptors. These receptors are responsible for the initiation of signals leading to muscle contraction.

Regardless of cause, patients with disorders that impair the function of neuromuscular junctions complain of painless weakness and fatigue. Autoantibodies that recognize key neuromuscular junction proteins are the most common cause of disrupted neuromuscular transmission, as found in *myasthenia gravis* (literally, "grave weakness"). Understandably, inherited defects in specialized neuromuscular junction proteins are also associated with myasthenic syndromes. Disorders caused by toxins that alter neuromuscular transmission are rarely encountered, but had an important role historically in elucidating how the neuromuscular junction functions.

Antibody-Mediated Diseases of the Neuromuscular Junction

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease that is usually associated with autoantibodies directed against ACh receptors. It has a prevalence of 150 to 200 per 1 million and shows a bimodal age distribution. In young adults, the female-to-male ratio is 2:1, but in older adults there is a male predominance.

Pathogenesis

About 85% of patients have autoantibodies against postsynaptic ACh receptors, while most of the remaining patients have antibodies against the sarcolemmal protein muscle-specific receptor tyrosine kinase. These autoantibodies appear to be pathogenic, as the disease can be passively transferred to animals with serum from affected individuals, and therapeutic maneuvers that decrease autoantibody levels are associated with a reduction in symptoms.

The mechanism of action of the various autoantibodies appears to differ. Anti–ACh receptor antibodies are thought to lead to the aggregation and degradation of the receptors, as well as to damage of the postsynaptic membrane through complement fixation. As a result, postsynaptic membranes show alterations in morphology and are depleted of ACh receptors. This limits the ability of myofibers to respond to ACh. Autoantibodies directed against muscle-specific receptor tyrosine kinase do not fix complement. Instead, these antibodies seem to interfere with the trafficking and

clustering of ACh receptor within the sarcolemmal membrane, the net effect again being decreased ACh receptor function.

There is a strong association between pathogenic anti–ACh receptor autoantibodies and thymic abnormalities. Approximately 10% of patients with myasthenia gravis have a *thymoma,* a tumor of thymic epithelial cells (Chapter 13). An additional 30% of patients (and particularly young patients) have a different thymic abnormality called thymic hyperplasia. This peculiar condition is marked by the appearance of B-cell follicles in the thymus. The thymus normally contains small numbers of myoid cells, stromal cells that express skeletal muscle antigens. It is hypothesized that both thymoma and thymic hyperplasia disrupt normal thymic function in a manner that promotes autoimmunity against ACh receptors expressed on thymic myoid cells. In contrast, thymic abnormalities are usually absent in cases of myasthenia gravis that occur in older patients; the basis for the development of autoantibodies in such cases is unknown.

Clinical Features

Patients with anti–ACh receptor antibodies typically present with fluctuating weakness that worsens with exertion and often over the course of the day. Diplopia and ptosis due to involvement of extraocular muscles are common and distinguish myasthenia gravis from myopathies, in which involvement of extraocular muscles is unusual. In some patients, symptoms are confined to ocular muscles, while others develop generalized weakness that can be so severe as to require mechanical ventilation. Cases with antibodies against muscle-specific receptor tyrosine kinase differ from typical cases by exhibiting more focal muscle involvement (neck, shoulder, facial, respiratory, and bulbar muscles).

Diagnosis is based on clinical history, physical findings, identification of autoantibodies, and electrophysiologic studies. Electrophysiologic studies reveal a decrement in muscle response with repeated stimulation, a characteristic of this disorder. Overall mortality has dropped from over 30% in the 1950s to less than 5% with current therapies. Acetylcholinesterase inhibitors that increase the half-life of ACh are the first line of treatment. Other treatments, such as plasmapheresis and immunosuppressive drugs (e.g., glucocorticoids, cyclosporine, rituximab), can bring symptoms under control by decreasing autoantibody production. Thymectomy is often effective in patients with thymoma, but is of uncertain benefit in those with thymic hyperplasia or lacking thymic abnormalities.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome is an autoimmune disorder caused by antibodies that block ACh release by inhibiting a presynaptic calcium channel. In contrast to myasthenia gravis, rapid repetitive stimulation increases muscle response. Muscle strength is augmented after a few seconds of muscle activity. Patients typically present with weakness of their extremities. In about half of cases there is an underlying malignancy, most often neuroendocrine carcinoma of the lung. Symptoms may precede the diagnosis of cancer, sometimes by years. It is thought that the stimulus for autoantibody formation in paraneoplastic cases may be the expression of the same calcium channel in the neoplastic cells. Patients without cancer often have other autoimmune diseases, such as vitiligo or thyroid disease. Treatment consists of drugs that increase ACh release by depolarizing synaptic membranes and immunosuppressive agents, such as those used to treat myasthenia gravis.

Congenital Myasthenic Syndromes

These rare disorders, which most commonly have an autosomal recessive mode of inheritance, are marked by varying degrees of muscle weakness. Causative mutations have been identified in genes encoding several different presynaptic, synaptic, or postsynaptic proteins. The most common of these are loss-of-function mutations in the gene encoding the ε-subunit of the ACh receptor. Another group of mutations affect proteins that are important in normal clustering of ACh receptors on postsynaptic membranes. Many patients with congenital myasthenic syndromes present in the perinatal period with poor muscle tone, external eye muscle weakness, and breathing difficulties, but others have milder forms of the disease and may not come to clinical attention until adolescence or adulthood. The clinical presentation, response to drugs such as acetylcholinesterase inhibitors, and prognosis depend largely on the underlying mutation.

Disorders Caused by Toxins

Botulism is caused by exposure to a neurotoxin (botulinum toxin, popularly known as Botox) that is produced by the anaerobic gram-positive organism *Clostridium botulinum*. Botox acts by blocking the release of ACh from presynaptic neurons (Chapter 8). Curare is the common name for plant-derived muscle relaxants that block ACh receptors, resulting in flaccid paralysis. It was initially discovered and used as poison on arrow tips by indigenous people in the Amazon rain forest. At one time it was used as a muscle relaxant during certain forms of surgery, but has now been supplanted by other related drugs with a similar mechanism of action.

KEY CONCEPTS

DISEASES OF THE NEUROMUSCULAR JUNCTION

- Disorders of neuromuscular junctions present with painless weakness.
- Myasthenia gravis and Lambert-Eaton myasthenic syndrome, the most common forms, are both immune mediated, being caused by antibodies to postsynaptic ACh receptors and presynaptic calcium channels, respectively.
- Myasthenia gravis is often associated with thymic hyperplasia or thymoma, frequently involves ocular muscles, and is marked by fluctuating weakness that worsens with exertion.
- Lambert-Eaton myasthenic syndrome presents with weakness in the extremities that improves with repetitive stimulation and is often a paraneoplastic disorder associated with lung cancer.
- Genetic defects in neuromuscular junction proteins give rise to congenital myasthenic syndromes.
- Biologic toxins such as Botox can block neuromuscular transmission by blocking the release of ACh from presynaptic neurons.

DISEASES OF SKELETAL MUSCLE

Skeletal muscle has unique structural, cellular, and molecular characteristics and accordingly unique patterns of injury and repair. During embryogenesis, skeletal muscle develops through the fusion of mononucleated precursor cells (myoblasts) into multinucleated myotubes. These subsequently mature into myofibers (muscle fibers) of varying length that contain thousands of nuclei. In adult tissues, these myofibers are arranged in fascicles, each associated with a small pool of tissue stem cells referred to as satellite cells, which can contribute to muscle regeneration following injury (outlined later). Myofibers are of two main functional types, type I and type II (Table 27.1), which are admixed in a checkerboard pattern in normal skeletal muscle. Fiber type is determined by signals received from innervating motor neurons, and as a result all fibers that are part of a motor unit are of the same type.

Skeletal Muscle Atrophy

Skeletal muscle atrophy is a common feature of many disorders. Loss of innervation, disuse, cachexia, old age, and primary myopathies all can produce muscle atrophy and, if the atrophy is severe, loss of muscle mass. Although muscle atrophy may occur under many conditions, certain patterns of atrophy are suggestive of specific underlying etiologies:

- *Clusters or groups of atrophic fibers* are seen in neurogenic disease (Fig. 27.7).
- *Perifascicular atrophy* is seen in dermatomyositis (see later).
- *Type II fiber atrophy* with sparing of type I fibers is seen with prolonged corticosteroid therapy or disuse.

Table 27.1 Muscle Fiber Types

	Type I	Type II
Action	Sustained force	Fast movement
Activity type	Aerobic exercise	Anaerobic exercise
Power produced	Low	High
Resistance to fatigue	High	Low
Lipid content	High	Low
Glycogen content	Low	High
Energy metabolism	Low glycolytic capacity, high oxidative capacity	High glycolytic capacity, low oxidative capacity
Mitochondrial density	High	Low
Enzyme activity	NADH-TR, dark staining ATPase at pH 4.3, dark staining ATPase at pH 9.4, light staining	NADH-TR, light staining ATPase at pH 4.3, light staining ATPase at pH 9.4, dark staining
Myosin heavy chain gene expressed	*MYH7*	*MYH2, MYH4, MYH1*
Color	Red (high myoglobin content)	Pale red/tan (low myoglobin content)
Prototype	Soleus (pigeon)	Pectoral (pigeon)

ATPase, Adenosine triphosphatase; *NADH-TR*, nicotinamide adenine dinucleotide, reduced form, tetrazolium reductase.

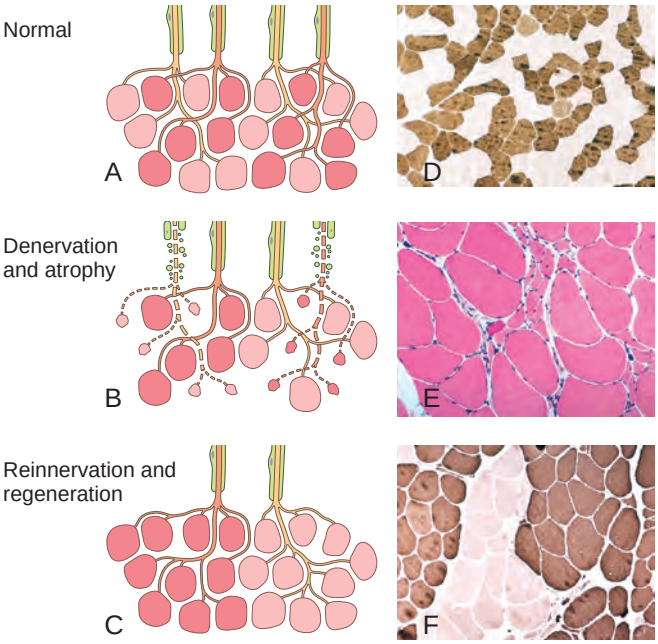

Figure 27.7 (A) This diagrammatic representation of four normal motor units shows a normal checkerboard-type admixture of light- and dark-stained fibers of opposite type. (B) Damage to innervating axons leads to loss of trophic input and atrophy of myofibers. (C) Reinnervation of myofibers can lead to a switch in fiber type and segregation of fibers of like type. As illustrated here, reinnervation is also often associated with an increase in motor unit size, with more myofibers innervated by an individual axon. (D) Normal muscle has a checkerboard-type distribution of type I (light) and type II (dark) fibers on this adenosine triphosphatase reaction (pH 9.4) corresponding to findings in diagram in A. (E) Clustered flattened, "angulated" atrophic fibers *(group atrophy)* are a typical finding associated with disrupted innervation. (F) With ongoing denervation and reinnervation, large clusters of fibers appear that all share the same fiber type *(type grouping)*, corresponding to diagram in C.

Neurogenic and Myopathic Changes in Skeletal Muscle

Disorders of skeletal muscles may be caused by direct injury to myofibers (myopathic injury) or by disruption of muscle innervation (neurogenic injury). Each type is described next.

Neurogenic injuries lead to *fiber type grouping* and *grouped atrophy* (see Fig. 27.7), both of which stem from the disruption of muscle innervation. The key to understanding these abnormalities is to recognize that muscle fiber type is determined by the innervating motor neuron. Following denervation, myofibers undergo atrophy, often assuming a flattened, angulated shape. Reinnervation restores fiber size and shape, but may make a denervated myofiber part of a different motor unit, in turn leading to a change in fiber type. In the face of ongoing axonal or neuronal damage and dropout, residual motor axons may innervate increasingly larger numbers of myofibers, leading to enlargement of motor units, each comprised of a single type of muscle fiber (fiber type grouping). These large motor units are also susceptible to grouped atrophy if the innervating axon is damaged.

In contrast, most primary myopathic injuries are associated with a distinct set of morphologic changes that include the following:

- *Segmental myofiber degeneration and regeneration* is seen when only part of a myofiber undergoes necrosis. Degeneration is associated with release of cytoplasmic enzymes such as creatine kinase into the blood, making these useful markers of muscle damage. The sarcomeres and other components of the damaged myofiber segment are engulfed by macrophages in a process termed myophagocytosis. Removal of the degenerated debris sets the stage for regeneration. Fusion of activated satellite cells to damaged myofibers is an important step for regeneration. Eventually, new sarcomeres are generated, and the continuity of the original myofiber is restored. Regenerating myofibers are rich in RNA and therefore blue (basophilic) in hematoxylin and eosin–stained sections. They have enlarged nuclei with prominent nucleoli that are often randomly distributed in the cytoplasm, instead of occupying their normal subsarcolemmal location. Depending on the nature of the primary insult, atrophic myofibers may also be seen. Regeneration can restore normal muscle following an acute, transient injury, but in chronic disease states regeneration often fails to keep pace with damage. In this setting, muscles often show endomysial fibrosis (collagen deposition), dropout of myofibers, and fatty replacement.
- *Myofiber hypertrophy* can be seen as a physiologic adaptation to exercise or in association with certain chronic myopathic conditions.
- *Cytoplasmic inclusions* in the form of vacuoles, aggregates of proteins, or clustered organelles are characteristic of several primary forms of myopathy.

Inflammatory Myopathies

Historically, dermatomyositis, polymyositis, and inclusion body myositis have been considered the three main primary inflammatory myopathies:

- *Dermatomyositis* as a disease that affects skin as well as skeletal muscles. The histologic hallmark, discussed below, is perifascicular atrophy.
- *Inclusion body myositis,* as a slowly progressive disease associated with distinct inclusions termed "rimmed vacuoles" with some similarities to neurodegenerative diseases of the CNS.
- *Polymyositis,* to some extent a diagnosis of exclusion, as a T cell–mediated autoimmune disease affecting skeletal muscles that lacks the features of dermatomyositis or inclusion body myositis.

In addition to the triad mentioned above, other entities have been described and updated classifications have been proposed, but the old historical triad is still used by many physicians. In a more granular classification system, many cases traditionally viewed as polymyositis are now regarded as immune-mediated necrotizing myopathy (IMNM), or as a connective tissue disease–associated myositis. With that, polymyositis is a less common diagnosis than in the past. The systemic connective tissue disorders that can affect skeletal muscle include systemic lupus erythematosus, systemic sclerosis, and sarcoidosis (Chapter 6). Rarely certain infectious agents can cause inflammation of skeletal muscle (Chapter 8).

Dermatomyositis

Dermatomyositis is a systemic autoimmune disease that typically presents with proximal muscle weakness and skin changes.

Pathogenesis

Dermatomyositis is an immunologic disease in which damage to small blood vessels contributes to muscle injury. The vasculopathic changes can be seen as *telangiectasias* (dilated capillary loops) in the nail folds, eyelids, and gums and as dropout of capillary vessels in skeletal muscle. Biopsies of muscle and skin may show deposition of the complement membrane attack complex (C5b-9) within capillary beds. An inflammatory signature enriched for genes that are upregulated by type I interferons is seen in muscle and in leukocytes. The prominence of this signature appears to correlate with disease activity. Direct immunologic injury to the muscle fibers may also play a role. Various autoantibodies are detected by serologic studies, and B lymphocytes as well as plasma cells are part of the inflammatory infiltrate that is seen in muscles. Certain autoantibodies detected in the circulation tend to be associated with specific clinical features:

- *Anti-Mi2 antibodies* (directed against a helicase implicated in nucleosome remodeling) show a strong association with prominent Gottron papules and heliotrope rash (described later).
- *Anti-Jo1 antibodies* (directed against the enzyme histidyl t-RNA synthetase) are associated with interstitial lung disease, nonerosive arthritis, and a skin rash described as "mechanic's hands." In some classification schemes myopathies with anti-Jo1 antibodies are described separately as "anti-synthetase syndrome associated myositis."
- *Anti-P155/P140 antibodies* (directed against several transcriptional regulators) are associated with paraneoplastic and juvenile cases of dermatomyositis.

A direct link between these autoantibodies and disease pathogenesis has not yet been established.

MORPHOLOGY

Muscle biopsies of affected patients show infiltrates of mononuclear inflammatory cells that tend to be most pronounced in the perimysial connective tissue and around blood vessels. Sometimes there is a distinctive pattern in which myofiber atrophy is accentuated at the edges of the fascicles—*perifascicular atrophy* (Fig. 27.8B). Segmental fiber necrosis and regeneration may also be seen. Immunohistochemical studies may identify an infiltrate rich in CD4+ T-helper cells and the deposition of C5b-9 in capillary vessels. Electron microscopic studies may show tubuloreticular endothelial cell inclusions, a feature of a number of inflammatory disorders that are linked to a type I interferon response.

Clinical Features

Muscle weakness is slow in onset, symmetric, and often accompanied by myalgias. It typically affects the proximal muscles first. As a result, tasks such as getting up from a

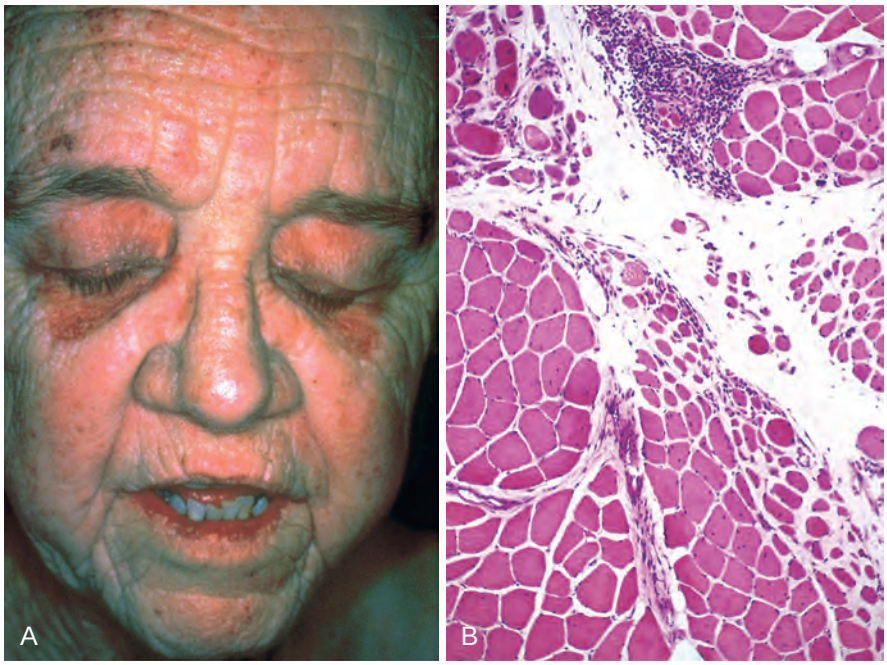

Figure 27.8 (A) Dermatomyositis. Note the heliotrope rash affecting the eyelids. (B) Dermatomyositis. The histologic appearance of muscle shows perifascicular atrophy of muscle fibers and inflammation. (Courtesy Dr. Dennis Burns, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

chair and climbing steps become increasingly difficult. Fine movements controlled by distal muscles are affected only late in the disease. Associated myopathic changes on electrophysiologic studies and elevation in serum creatine kinase levels are reflective of muscle damage. Various rashes are described in dermatomyositis, but the most characteristic ones are a lilac-colored discoloration of the upper eyelids *(heliotrope rash)* associated with periorbital edema (Fig. 27.8A) and a scaling erythematous eruption or dusky red patches over the knuckles, elbows, and knees *(Gottron papules)*. Dysphagia resulting from involvement of oropharyngeal and esophageal muscles occurs in one-third of the affected individuals, and another 10% of patients have interstitial lung disease, which can sometimes be rapidly progressive and lead to death. Cardiac involvement is common, but rarely leads to cardiac failure.

Dermatomyositis may occur in adults or in children. The average age of onset of juvenile dermatomyositis is 7 years, whereas adult cases tend to present from the fourth to sixth decade of life. Dermatomyositis is the most common inflammatory myopathy in children. Compared to adult disease, childhood disease is more likely to be associated with calcinosis and lipodystrophy and less likely to be associated with myositis-specific antibodies, cardiac involvement, interstitial lung disease, or an underlying malignancy. As might be expected based on these differences, the overall prognosis is better in children than in adults. From 15% to 24% of adult patients have an associated malignancy, and in such patients, dermatomyositis may be viewed as a paraneoplastic disorder. A dermatomyositis-like picture with myositis and rash has also been described following treatment of cancer with check-point inhibitors (Chapter 7).

Immune-Mediated Necrotizing Myopathy (IMNM)

IMNM represents an autoimmune disease that is often associated with distinct autoantibodies (sometimes also referred to as necrotizing autoimmune myopathy). Affected patients present with subacute muscle weakness that is typically associated with significantly increased creatine kinase levels. Muscle biopsies show fairly prominent myofiber necrosis and regeneration in most cases, while inflammatory cell infiltrates are usually absent or minimal despite the autoimmune nature of the disease. In many patients, IMNM is associated with autoantibodies against HMG-CoA reductase. Their formation is often attributed to prior statin exposure, but some patients develop these autoantibodies without prior use of these medications. In some patients IMNM has been linked to antibodies to the signal recognition particle

Polymyositis

Polymyositis is an adult-onset inflammatory myopathy that shares myalgia and weakness with dermatomyositis but lacks its distinctive cutaneous features and is therefore to some degree a diagnosis of exclusion. Descriptions of other entities have made cases of polymyositis less common as outlined above.

Pathogenesis

The pathogenesis of polymyositis is uncertain, but it is believed to have an immunologic basis. CD8+ cytotoxic T cells are a prominent part of the inflammatory infiltrate in affected muscle, and it is hypothesized that these cells are the mediators of tissue damage. Unlike dermatomyositis, vascular injury does not have a major role in the pathogenesis of polymyositis.

MORPHOLOGY

Mononuclear inflammatory cell infiltrates are present, but in contrast to dermatomyositis, these are usually endomysial in location. Sometimes myofibers with otherwise normal morphology appear to be invaded by mononuclear inflammatory cells, predominantly CD8+ T cells. Degenerating necrotic, regenerating, and atrophic myofibers are typically found in a random or patchy distribution. The perifascicular pattern of atrophy that is characteristic of dermatomyositis is absent.

Inclusion Body Myositis

Inclusion body myositis is a disease of late adulthood that typically affects patients older than 50 years and is the most common inflammatory myopathy in patients older than age 65 years. Most affected individuals present with slowly progressive muscle weakness that tends to be most severe in the quadriceps and the distal upper extremity muscles. Dysphagia from esophageal and pharyngeal muscle involvement is not uncommon. Laboratory studies usually show modestly elevated creatine kinase levels; most myositis-associated autoantibodies are absent, although an antibody to cytosolic 5′-nucleotidase 1A (cN1A) has recently been described. It is present in about half of the patients and is a useful marker of the disease.

MORPHOLOGY

Inclusion body myositis has a number of features that are similar to those found in polymyositis, including:

- Patchy, often endomysial mononuclear inflammatory cell infiltrates rich in CD8+ T cells
- Increased sarcolemmal expression of major histocompatibility complex class I antigens
- Focal invasion of normal-appearing myofibers by inflammatory cells
- Admixed degenerating and regenerating myofibers

Other associated changes, however, are more typical or even specific for inclusion body myositis, as follows:

- Abnormal cytoplasmic inclusions described as "rimmed vacuoles" (Fig. 27.9)
- Tubolofilamentous inclusions in myofibers, seen by electron microscopy
- Cytoplasmic inclusions containing proteins typically associated with neurodegenerative diseases, like beta-amyloid, TDP-43, and ubiquitin
- Endomysial fibrosis and fatty replacement, reflective of a chronic disease course

Whether inclusion body myositis is indeed an inflammatory condition or a degenerative process with secondary inflammatory changes remains an unresolved question. It has certain features in common with polymyositis, as discussed earlier. On the other hand, it shares some features with neurodegenerative diseases, such as the presence of abnormal protein aggregates. Furthermore, there are several familial inclusion body myopathies that are also associated with chronic myopathic changes and rimmed vacuoles. These typically lack any associated inflammation—hence the designation *inclusion body "myopathy"* rather than *"myositis."* Inflammatory myopathies are treated with immunosuppresive drugs such as steroids, azathioprine, and in some cases intravenous immunoglobulins (IVIG). Such treatments have improved the prognosis of dermatomyositis and polymyositis, but inclusion body myositis responds poorly. This is another feature that argues against an inflammatory or immune origin of inclusion body myositis.

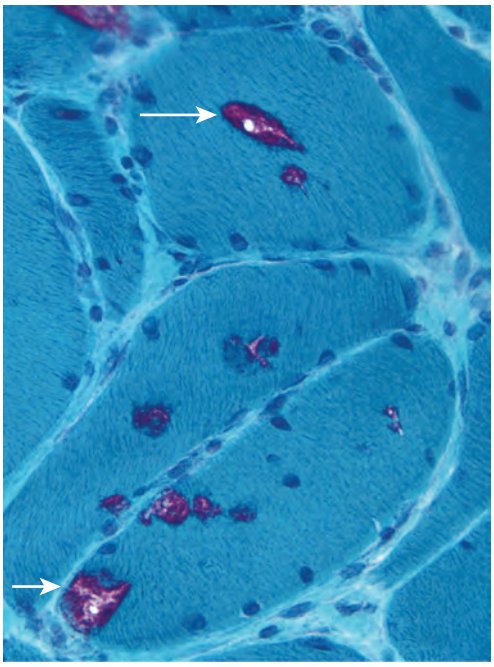

Figure 27.9 Inclusion body myositis, showing myofibers containing rimmed vacuoles—inclusions with reddish granular rimming *(arrows)*. Modified Gomori trichrome stain.

Toxic Myopathies

Toxic myopathies can be caused by prescription or recreational drugs or by certain hormonal imbalances. Among prescription drugs, *statins* are among the leading culprits. Statins are cholesterol-lowering drugs that are widely used to reduce the risks of acute ischemic cardiac events and stroke. **Myopathy is the most common complication of statins** (e.g., atorvastatin, simvastatin, pravastatin). Pure toxic injury is in part linked to dose and statin type and has to be distinguished from IMNM, which is often caused by statin-induced autoantibodies.

Chloroquine and hydroxychloroquine were originally used as antimalarial agents and are currently given as long-term therapy to some patients with systemic autoimmune diseases. These drugs interfere with normal lysosomal function and can cause a drug-induced lysosomal storage myopathy that presents with slowly progressive muscle weakness. The muscle tissue shows myopathic changes including vacuolation that predominantly affects type I fibers. Ultrastructural studies identify aggregates of whorled, lamellar membranous structures, including curvilinear bodies that mimic those seen in ceroid lipofuscinoses (Chapter 28). Cardiac muscle can also be affected by these drugs and can exhibit similar pathologic changes.

ICU myopathy, also known as myosin-deficient myopathy, is a neuromuscular disorder seen in patients during the course of treatment for critical illness (usually in an ICU) especially with corticosteroid therapy. There may be relatively selective degradation of sarcomeric myosin thick

filaments, producing profound weakness that can complicate the clinical course (e.g., by interfering with the weaning of a patient from a mechanical respirator).

Thyroid dysfunction can lead to several types of myopathy. *Thyrotoxic myopathy* presents most commonly as an acute or chronic proximal muscle weakness that may precede other signs of hyperthyroidism. Such patients may also present with exophthalmic ophthalmoplegia, characterized by swelling of the eyelids, edema of the conjunctiva, and diplopia. Hypothyroidism can cause cramping or aching of muscles, and decreased movement. Reflexes may be slowed. Findings in skeletal muscle include fiber atrophy, an increased number of abnormally localized nuclei, glycogen aggregates, and (occasionally) deposition of mucopolysaccharides in connective tissue.

Alcohol can also be myopathic. Most notably, binge drinking may produce an acute toxic syndrome of rhabdomyolysis, myoglobinuria, and renal failure. The affected individual may complain of acute myalgias that are generalized or confined to a single muscle group.

Inherited Diseases of Skeletal Muscle

Inherited mutations are responsible for a diverse collection of disorders marked by defects in skeletal muscle. In some of these disorders, skeletal muscle is the main site of disease, but in others multiple organs are involved. Of the other organs involved, the heart is of particular importance, since cardiac involvement is common and often life limiting.

Historically, inherited myopathies have been subdivided into several broad categories based on inheritance pattern, anatomic pattern of muscle involvement, onset age, clinical course, and underlying pathogenesis. These categories should largely be understood as illustrative of key concepts. On closer inspection, there are exceptions and there is significant overlap between these disease categories. Included in the group of inherited muscular disorders are the following.

Congenital myopathies (Table 27.2) typically present in infancy with muscle defects that tend to be static or to even improve over time. They are often associated with distinct structural abnormalities of the muscle.

Muscular dystrophies, characterized by progressive muscle damage that typically comes to attention after infancy.

Congenital muscular dystrophies, by contrast, tend to present in infancy and are often associated with developmental abnormalities of the CNS as well as progressive muscle damage. Congenital muscular dystrophies include two important groups:

- *Conditions with defects in extracellular matrix surrounding myofibers.* These are exemplified by Ullrich congenital muscular dystrophy (UCMD) and merosin deficiency. In the former the causative mutations involve one of

Table 27.2 Congenital Myopathies

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
Central core disease; autosomal dominant	Ryanodine receptor-1 *(RYR1)* gene; 19q13.2	Early-onset hypotonia and weakness; "floppy infant"; associated skeletal abnormalities like scoliosis, hip dislocation, or foot deformities; some *RYR1* mutations cause central core disease, some cause malignant hyperthermia, and some cause both	Cytoplasmic cores represent demarcated central zones in which the normal arrangement of sarcomeres is disrupted and mitochondria are decreased in number
Nemaline myopathy (NEM)	AD NEM1—α-tropomyosin 3 *(TPM3)* gene; 1q21.3 AR NEM2—nebulin *(NEB)* gene; 2q23.3 AR NEM3—α-actin-1 *(ACTA1)* gene; 1q42.13 AD NEM4—tropomyosin-2 *(TPM2)* gene; 9p13.3 AR NEM5—troponin T1 *(TNNT1)* gene; 19q13.42 AR NEM7—coffilin-2 *(CFL2)* gene; 14q13.1	Childhood weakness; some with more severe weakness, hypotonia at birth ("floppy infant")	Aggregates of spindle-shaped particles *(nemaline rods)*; occur predominantly in type 1 fibers; derived from Z-band material (α-actinin) and best seen on modified Gomori stain or by electron microscopy
Centronuclear (myotubular) myopathy	XL—myotubularin *(MTM1)* gene; Xq28 AD—dynamin-2 *(DNM2)* gene (and others); 19p13.2 AR—amphiphysin-2 *(BIN1)* gene; 2q14.3	Severe congenital hypotonia, "floppy infant," and poor prognosis in X-linked form ("myotubular myopathy") Childhood onset or young adult onset with other variants with weakness and hypotonia	Many fibers contain nuclei in the geometric center of the myofiber; central nuclei are more common in type 1 fibers, which are small in diameter, but can occur in both fiber types
Congenital fiber type disproportion	Selenoprotein 1 *(SELENON)* gene; 1p36.11 α-actin-1 *(ACTA1)* gene; 1q42.13 Tropomyosin 3 *(TPM3)* gene; 1q21.3	Hypotonia, weakness, failure to thrive, facial and respiratory weakness, contractures Wide phenotypic spectrum Mutations in *SELENON* are also associated with protein aggregate myopathy and rigid spine muscular dystrophy; mutations in *ACTA1* are also associated with nemaline myopathy and protein aggregate myopathy; mutations in *TPM3* are also associated with nemaline myopathy	Predominance and atrophy of type 1 fibers (not specific)

AD, Autosomal dominant; *AR,* autosomal recessive; *XL,* X-linked.

three collagen VI alpha genes; in the case of merosin deficiency, the gene encoding merosin is disrupted. UCMD is characterized by hypotonia, proximal contractures, and distal hyperextensibility. A morphologic hallmark is mismatched expression of normally co-localized matrix proteins perlecan and collagen VI.

- *Conditions with abnormalities in receptors for extracellular matrix*. In this group are diseases that disrupt the post-translational modification of alpha-dystroglycan (Fig. 27.10) by *O*-linked glycosylation. Mutations of alpha-dystroglycan itself result in fetal demise, but defects in its post-translational modification result in milder forms of dystroglycan deficiency. Alpha-dystroglycan expression is important for CNS and eye development. Severe cases exhibit features of congenital muscular dystrophy as well as developmental defects of the CNS and eyes that cause seizures, intellectual disability, and blindness. Milder forms may only cause skeletal muscle disease. Some of these mutations are also linked to a presentation described as limb-girdle muscular dystrophy (see later).

The following section focuses on the most common and best understood forms of inherited myopathies.

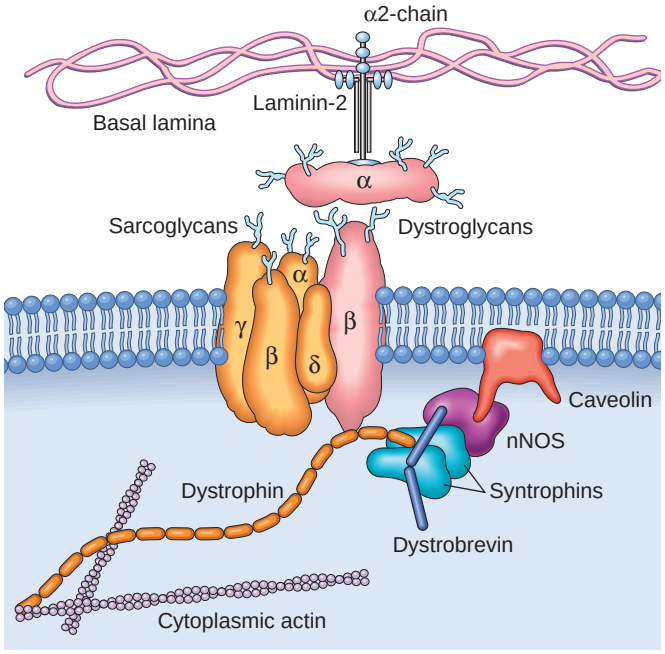

Figure 27.10 Relationship between the cell membrane (sarcolemma) and the sarcolemmal associated proteins. Dystrophin, an intracellular protein, forms an interface between the cytoskeletal proteins and a group of transmembrane proteins, the dystroglycans and the sarcoglycans. These transmembrane proteins have interactions with the extracellular matrix, including the laminin proteins. Dystrophin also interacts with dystrobrevin and the syntrophins, which form a link with neuronal-type nitric oxide synthetase *(nNOS)* and caveolin. Mutations in dystrophin are associated with the X-linked muscular dystrophies; mutations in caveolin and the sarcoglycan proteins are associated with the limb-girdle muscular dystrophies, which can be autosomal dominant or recessive disorders; and mutations in the α_2-laminin (merosin) are associated with autosomal recessive congenital muscular dystrophy. Sugar moieties on the dystroglycans are affected by disruption of enzymes responsible for this post-translational modification. Mutations in genes that encode these glycosylation enzymes can cause myopathy as discussed below. These moieties are depicted as light blue branching structure.

Muscular Dystrophies

Muscular dystrophies include many inherited disorders of skeletal muscle that have in common progressive muscle damage that typically manifests between childhood and adulthood. As mentioned earlier, with the exception of congenital muscular dystrophies, these diseases do not present in infancy. While our focus is on X-linked muscular dystrophies, other forms in which the disease pathogenesis is reasonably well understood are also briefly discussed.

X-Linked Muscular Dystrophy With Dystrophin Mutation Including Duchenne and Becker Muscular Dystrophy

The most common muscular dystrophies are X-linked and stem from mutations that disrupt the function of a large structural protein called dystrophin. As a result, these diseases are sometimes referred to as *dystrophinopathies*. The most common early-onset form is referred to as *Duchenne muscular dystrophy*. It has an incidence of 1 per 3500 live male births and has a severe progressive phenotype. *Becker muscular dystrophy* is a second relatively common dystrophinopathy that is characterized by later disease onset and a milder phenotype. Other rare dystrophinopathies may present with isolated cardiomyopathy, asymptomatic elevations of creatine kinase levels, or exercise intolerance because of myalgias and cramps. As with many X-linked diseases, female carriers of dystrophin mutations may be mildly symptomatic due to unfavorable X-chromosome inactivation.

Pathogenesis

Duchenne and Becker muscular dystrophy are caused by loss-of-function mutations in the dystrophin gene on the X chromosome. *Dystrophin* is one of the largest human genes, spanning 2.3 million base pairs and composed of 79 exons. The encoded protein, dystrophin, is a key component of the dystrophin glycoprotein complex (see Fig. 27.10). This complex spans the plasma membrane and serves as a link between the cytoskeleton inside the myofiber and the basement membrane outside of the cell. By doing so, dystrophin is thought to provide mechanical stability to the myofiber and its cell membrane during muscle contraction. Defects in the complex may lead to small membrane tears that permit influx of calcium, triggering events that result in myofiber degeneration. In addition to its mechanical function, dystrophin may have a role in signaling pathways; for example, its carboxy terminus interacts with nitric oxide synthase, which generates NO.

Identification and characterization of specific *dystrophin* mutations has provided an explanation for some of the phenotypic variation in patients with dystrophinopathies. Duchenne muscular dystrophy is typically associated with deletions or frameshift mutations that result in total absence of dystrophin. In contrast, the mutations in Becker muscular dystrophy typically permit the synthesis of a truncated version of dystrophin, which presumably retains partial function.

MORPHOLOGY

The basic morphologic changes that muscular dystrophies elicit in skeletal muscle tissue may differ in severity but do not

discriminate between different forms of dystrophy. The changes in Duchenne muscular dystrophy serve as an example. This disease is marked by chronic muscle damage that outpaces the capacity for repair (Fig. 27.11). Muscle biopsies in young boys show ongoing damage in the form of segmental myofiber degeneration and regeneration associated with an admixture of atrophic myofibers. The fascicular architecture is preserved at this stage of the disease, and there is usually no inflammation except for the presence of myophagocytosis. As the disease progresses, muscle tissue is replaced by collagen and fat cells ("fatty replacement" or "fatty infiltration"). The remaining myofibers at this point in the course show prominent variation in size, from small atrophic fibers to large hypertrophied fibers. This remodeling distorts the fascicular architecture of the muscle, which becomes markedly abnormal over time. **Immunohistochemical studies for dystrophin show absence of the normal sarcolemmal staining pattern in Duchenne muscular dystrophy and reduced staining in Becker muscular dystrophy.**

Clinical Features

Boys with Duchenne muscular dystrophy appear normal at birth. Very early motor milestones are met, but walking is often delayed. The first indications of muscle weakness are clumsiness and inability to keep up with peers. Weakness begins in the pelvic girdle muscles and then extends to the shoulder girdle. Enlargement of the muscles of the lower leg associated with weakness, termed pseudohypertrophy, is often present. The mean age of wheelchair dependence is around 9.5 years. Patients develop joint contractures, scoliosis, worsening respiratory reserve, and sleep hypoventilation.

Dystrophin is also expressed in the heart and the CNS. Dystrophin deficiency in cardiac muscle often leads to the development of cardiomyopathy and arrhythmias, particularly in older patients. Cognitive impairment and learning disabilities, presumably due to a functional role for dystrophin in the brain, is also common and sometimes produces frank intellectual disability. Despite supportive care, the mean age of death for patients with Duchenne muscular dystrophy is 25 to 30 years of age, with most patients succumbing to respiratory insufficiency, pulmonary infection, or heart failure. This is in contrast to Becker muscular dystrophy, which typically presents in later childhood, adolescence, or adult life; has slower progression; and may have a near-normal life expectancy.

The diagnosis is based on the history, physical examination, and laboratory studies. Serum creatine kinase is markedly elevated during the first decade of life due to ongoing muscle damage, and then falls as the disease progresses and muscle mass is lost. The detection of a dystrophin mutation offers definitive diagnosis.

Treatment of patients with dystrophinopathies is challenging. Current treatment consists primarily of supportive care. Definitive therapy requires restoration of dystrophin levels in skeletal and cardiac muscle fibers. Work in this area is emboldened by the recognition that expression of some dystrophin protein (as in patients with Becker muscular dystrophy) is sufficient to substantially ameliorate the disease phenotype. One approach involves the expression of antisense RNAs that alter RNA splicing so as to cause "skipping" of exons containing deleterious mutations, thus permitting the expression of a truncated, but partially functional, dystrophin protein. A second strategy is exploring the use of drugs that promote ribosomal "read-through" of stop codons, another ploy that may enable the expression of some dystrophin protein. Both of these approaches are mutation-specific and thus need to be tailored to individual

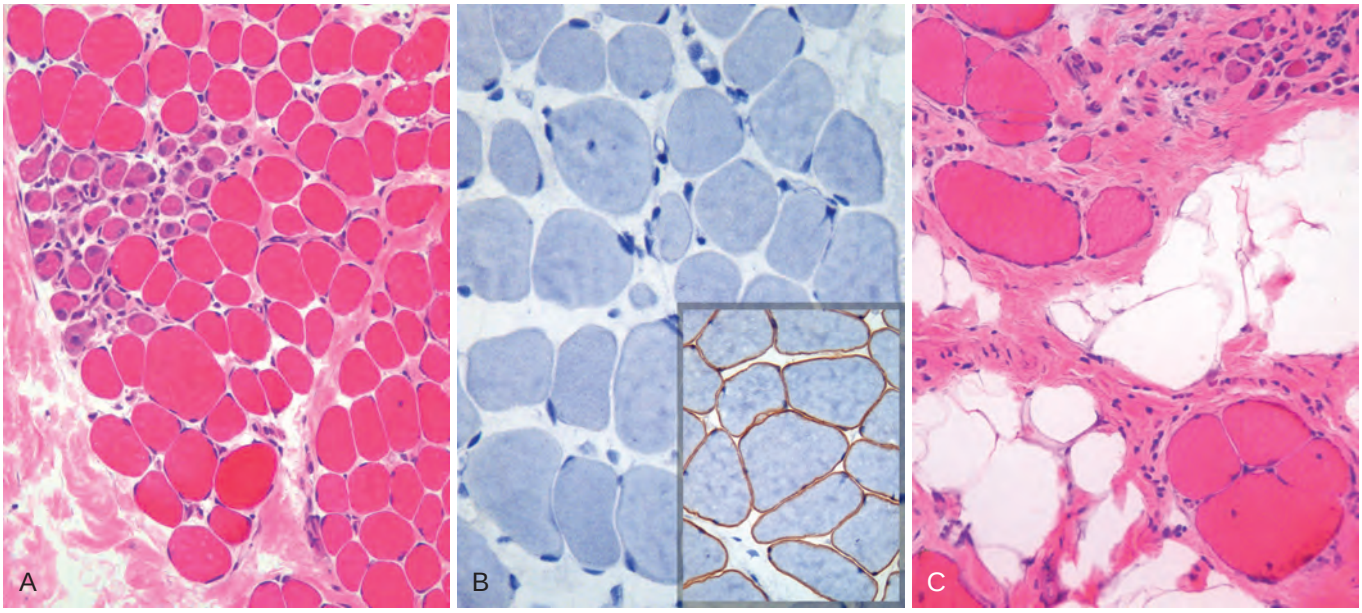

Figure 27.11 Duchenne muscular dystrophy. Histologic images of muscle biopsy specimens from two brothers. (A and B) Specimens from a 3-year-old boy. (C) Specimen from his 9-year-old brother. (A) At a younger age, fascicular muscle architecture is maintained, but myofibers show variation in size. Additionally, there is a cluster of basophilic regenerating myofibers *(left side)* and slight endomysial fibrosis, seen as focal pink-staining connective tissue between myofibers. (B) Immunohistochemical staining shows complete absence of membrane-associated dystrophin, seen as a brown stain in normal muscle *(inset)*. (C) Biopsy specimen from the older brother illustrates disease progression, which is marked by extensive variation in myofiber size, fatty replacement, and endomysial fibrosis.

patients. Gene therapy (introduction of a normal dystrophin gene) is being investigated, but gene delivery to skeletal muscle cells remains a daunting hurdle.

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophies are a heterogeneous group of at least 8 autosomal dominant and 23 autosomal recessive entities. Their overall incidence is 1 in 25,000 to 50,000 individuals. As indicated by the name, all forms are characterized by muscle weakness that preferentially involves proximal muscle groups. Both age of onset and disease severity are highly variable. The causative mutations involve genes that participate in diverse cellular functions, making it difficult to discern a unifying mechanism of disease pathogenesis. Based on current knowledge, the implicated genes can be grouped according to function as follows:

- *Genes encoding structural components* (sarcoglycans) of the dystrophin glycoprotein complex
- *Genes encoding enzymes that are responsible for glycosylation of α-dystroglycan,* a component of the dystrophin glycoprotein complex (see Fig. 27.10)
- *Genes encoding proteins that associate with the Z-disks of sarcomeres*
- *Genes encoding proteins involved in vesicle trafficking and cell signaling*
- *Genes that seemingly stand alone, such as CAPN3 encoding the protease calpain 3 and lamin A/C* (which is also mutated in some patients with Emery-Dreifuss muscular dystrophy [EMD]; see below)

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant multisystem disorder associated with skeletal muscle weakness, cataracts, endocrinopathy, and cardiomyopathy. It affects about 1 in 10,000 individuals. Myotonia, a sustained involuntary contraction of muscles, is a key feature of the disease. Rarely, patients present with "*congenital myotonia,*" marked by severe manifestations in infancy.

Pathogenesis

The disease is caused by expansions of CTG triplet repeats in the 3′-noncoding region of the myotonic dystrophy protein kinase *(DMPK)* gene, but precisely how this genetic aberration produces the disease phenotype is unknown. The correlation between the length of expansion and disease severity is variable compared to some other triplet repeat expansion disorders like Huntington disease (Chapter 28). Experimental studies suggest that the skeletal muscle phenotype stems from a "toxic" gain-of-function caused by the triplet repeat expansion. Specifically, the expanded CUG-repeats in the *DMPK* mRNA transcript appear to bind and sequester proteins like muscleblind-like splicing regulator 1, which have an important role in RNA splicing. The resulting disruption of normal splicing events leads to missplicing of other RNA transcripts, including the transcript for a chloride channel called *CLC1*. It is believed that the resulting deficiency of CLC1 is responsible for the characteristic myotonia. In support of this scenario, one rare form of congenital myotonia is caused by germline loss-of-function mutations in *CLC1,* indicating that CLC1 is required for normal muscle relaxation.

Emery-Dreifuss Muscular Dystrophy (EMD)

EMD is caused by mutations in genes that encode nuclear lamin proteins. Clinically, it is marked by a triad consisting of slowly progressive humeroperoneal weakness; cardiomyopathy associated with conduction defects; and early contractures of the Achilles tendon, spine, and elbows. The X-linked form (EMD1) and the autosomal form (EMD2) are caused by mutations in the genes encoding *emerin* and *lamin A/C,* respectively, both of which localize to the inner face of the nuclear membrane. It is hypothesized that these proteins help maintain the shape and mechanical stability of the nucleus during muscle contraction. They may also influence gene expression by affecting chromatin organization in the nucleus. How defects in these proteins produce the observed phenotypes is unknown.

Fascioscapulohumeral Dystrophy

Fascioscapulohumeral dystrophy is associated with a characteristic pattern of muscle involvement that includes prominent weakness of facial muscles and muscles of the shoulder girdle. It is an autosomal dominant disease affecting about 1 in 20,000 individuals.

Pathogenesis

The pathogenesis of fascioscapulohumeral dystrophy is complex and only partly understood. It results from various mechanisms that culminate in the (over)expression of a retrogene called *DUX4* that is located in a region of subtelomeric repeats on the long arm of chromosome 4. *DUX4* encodes a transcription factor, suggesting that the disease ultimately results from the overexpression of *DUX4* target genes.

Diseases of Lipid or Glycogen Metabolism

Many inborn errors of lipid or glycogen metabolism affect skeletal muscle. These disorders tend to produce one of two general patterns of muscle dysfunction: In some, patients become symptomatic only with exercise or fasting, which may produce severe muscle cramping and pain or even extensive muscle necrosis *(rhabdomyolysis)*. In others, there is slowly progressive damage of muscle, without episodic manifestations. Listed below are some examples:

- *Carnitine palmitoyltransferase II deficiency* is the most common disorder of lipid metabolism to cause episodic muscle damage with exercise or fasting. The defect in this disorder impairs the transport of free fatty acids into mitochondria.
- *Myophosphorylase deficiency (McArdle disease)* is one of the more common glycogen storage diseases affecting skeletal muscle; it also results in episodic muscle damage with exercise.
- *Acid maltase deficiency* results in impaired lysosomal conversion of glycogen to glucose, causing glycogen to accumulate within lysosomes. Severe deficiency results in the generalized glycogenosis of infancy, *Pompe disease* (Chapter 5). Milder deficiency can cause a progressive adult-onset myopathy that preferentially involves the respiratory and truncal muscles. Enzyme replacement therapy has been used to treat some affected patients.

Mitochondrial Myopathies

Mitochondrial diseases are complex systemic conditions that can involve many organ systems, including skeletal muscle. The genetics of these disorders are varied and unusually complex (discussed later), but many of the causative mutations appear to impair the ability of mitochondria to generate adenosine triphosphate (ATP). As a result, these diseases tend to affect skeletal muscles and other tissues rich in cell types with high ATP requirements, particularly cardiac muscle cells and neurons.

Skeletal muscle involvement can manifest as weakness, elevations in serum creatine kinase levels, or rhabdomyolysis. Although the anatomic pattern of muscle weakness is variable, involvement of extraocular eye muscles is common and can be a clue to the diagnosis. Indeed, *chronic progressive external ophthalmoplegia* is a common feature of mitochondrial disorders and may occur as an isolated phenomenon or a part of a multisystem syndrome. The reason that extraocular eye muscles are particularly sensitive to mitochondrial disease is uncertain, but it may be that these muscles have exceptionally high requirements for ATP. In line with this idea, extraocular eye muscles have the most mitochondria per mass of any of the body's muscles.

Mitochondrial proteins and tRNAs may be encoded by either the nuclear genome or the mitochondrial genome (mtDNA). While mutations in nuclear mitochondrial genes follow Mendelian inheritance patterns, mutations in mtDNA are maternally inherited, since all of the mitochondria in the embryo are contributed by the oocyte (Chapter 5). In addition, unlike nuclear DNA, which is present in only two copies and is evenly distributed from a mother cell to daughter cells during cell division, each cell contains thousands of mtDNA copies, which are distributed in a random fashion to daughter cells at the time of cell division. It is believed that disease results only when a certain threshold of mutated mtDNA copies is exceeded within a substantial fraction of "at-risk" cells (e.g., skeletal muscle cells) in a tissue.

MORPHOLOGY

The most consistent pathologic change in skeletal muscle is abnormal aggregates of mitochondria that are seen preferentially in the subsarcolemmal area of affected myofibers, producing an appearance that is referred to as "ragged red fibers" (Fig. 27.12). By electron microscopy, morphologically abnormal mitochondria may be seen. Loss of particular mitochondrial enzyme activities characterizes some mitochondrial diseases and may be appreciated by histochemical staining for cytochrome oxidase. Some mitochondrial diseases lack morphologic changes and can be diagnosed only through enzymatic assays or genetic analyses.

Clinical Features

Due to the complexity of mitochondrial genetics, genotype/phenotype relationships in mitochondrial disorders are not straightforward. For example, a single point mutation in the mitochondrial leucine tRNA gene may produce isolated chronic progressive external ophthalmoplegia in one patient and in another, a much more severe phenotype, *mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes*.

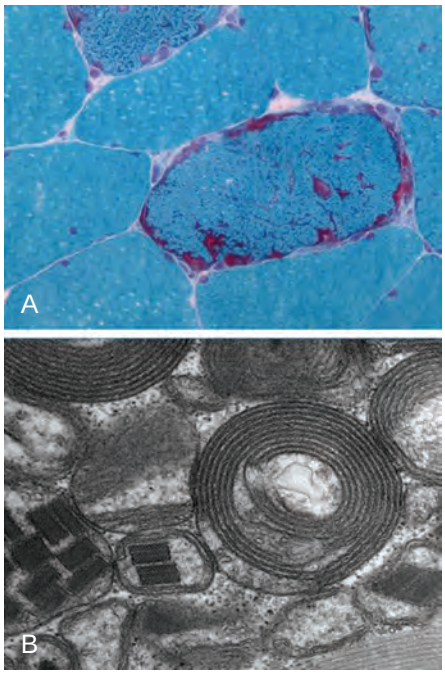

Figure 27.12 (A) Ragged red fiber with increased reddish granular subsarcolemmal staining reflective of abnormal aggregation of mitochondria. (B) Electron micrograph showing morphologically abnormal mitochondria with concentric membranous rings (so-called "phonograph records") and rhomboid paracrystalline inclusions *(lower left side)*.

Similarly, deletions in mtDNA may lead to either isolated ophthalmoplegia or to *Kearns-Sayre syndrome,* characterized by ophthalmoplegia, pigmentary degeneration of the retina, and complete heart block. *Myoclonic epilepsy with ragged red fibers* and *Leber hereditary optic neuropathy* are other examples of mitochondrial disease caused by point mutations in mtDNA. Many mitochondrial disorders, such as subacute necrotizing encephalopathy *(Leigh syndrome),* are remarkably heterogeneous genetically and may be caused by mutations in either mtDNA or the nuclear genome. In the case of Leigh syndrome, causative mutations have been identified in more than 30 different genes, the common feature being that all of the affected genes encode proteins with essential roles in mitochondrial metabolism.

Spinal Muscular Atrophy and Differential Diagnosis of a Hypotonic Infant

Spinal muscular atrophy is a neuropathic disorder in which loss of motor neurons leads to muscle weakness and atrophy. Infants with neurologic or neuromuscular disease may present with generalized hypotonia ("floppy infant"). The differential diagnosis of infantile hypotonia includes primary diseases of skeletal muscle (e.g., congenital myasthenic syndrome, congenital myotonia, congenital myopathies, and congenital muscular dystrophies); abnormalities of the brain (e.g., encephalopathy); and neuronopathies, of which spinal muscular atrophy is a prototypic example.

Spinal muscular atrophy is an autosomal recessive disorder with an incidence of 1 in 6000 births and is caused by loss-of-function mutations in the *SMN1* (survival of motor neuron-1) gene. The function of the gene is uncertain—the

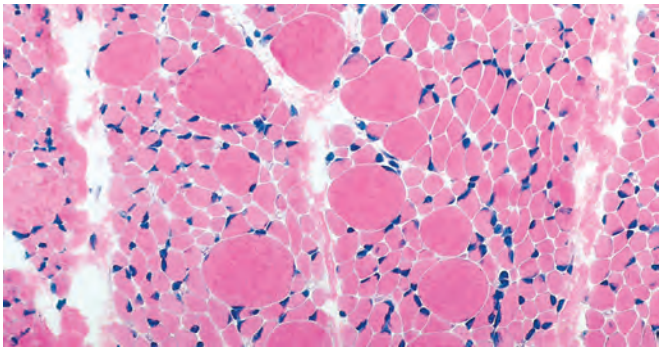

Figure 27.13 Spinal muscular atrophy with only rare hypertrophied myofibers admixed with numerous atrophic rounded myofibers. The larger fibers are those that are innervated and have undergone compensatory hypertrophy.

encoded protein may have a role in RNA splicing—but SMN1 deficiency has a dramatic effect on motor neuron survival, sometimes leading to loss of motor neurons in utero. The resulting denervation of skeletal muscle may lead to characteristic morphologic changes consisting of large zones of severely atrophic myofibers mixed with scattered normal-sized or hypertrophied myofibers, found individually or in small groups (Fig. 27.13). These normal or hypertrophied fibers are those that retain innervation from remaining motor neurons.

Ion Channel Myopathies (Channelopathies)

Channelopathies are a group of inherited diseases caused by mutations affecting the function of ion channel proteins. Most channelopathies are autosomal dominant disorders with variable penetrance. Depending on the channel that is affected, clinical manifestations may include epilepsy, migraine, movement disorders with cerebellar dysfunction, peripheral nerve disease, and muscle disease.

Different ion channel myopathies may cause decreased or increased excitability resulting in hypotonia or hypertonia. Disorders associated with hypotonia can be further subclassified based on whether symptomatic patients have elevated, depressed, or normal serum potassium levels and are called *hyperkalemic, hypokalemic,* or *normokalemic periodic paralysis,* respectively. Examples of gene mutations that are associated with muscle dysfunction are the following:

- *KCNJ2:* Mutations affecting this potassium channel cause *Andersen-Tawil syndrome,* an autosomal disorder associated with periodic paralysis, cardiac arrhythmias, and skeletal abnormalities.
- *SCN4A:* Mutations affecting this sodium channel cause several autosomal disorders with presentations ranging from myotonia to periodic paralysis.
- *CACNA1S:* Missense mutations in this protein, a subunit of a muscle calcium channel, are the most common cause of hypokalemic paralysis.
- *CLC1:* Mutations affecting this chloride channel cause myotonia congenita. As already discussed, *CLC1* expression is decreased in myotonic dystrophy.
- *RYR1:* Mutations in the *RYR1* gene disrupt the function of the ryanodine receptor, which regulates calcium release from the sarcoplasmic reticulum. *RYR1* mutations are linked to a congenital myopathy (central core disease) and to *malignant hyperthermia*. The latter is characterized by a hypermetabolic state (tachycardia, tachypnea, muscle spasms, and later hyperpyrexia) that can be triggered by anesthetics, most commonly halogenated inhalational agents and succinylcholine. Upon exposure to anesthetic, the mutated receptor allows increased efflux of calcium from the sarcoplasmic reticulum, leading to tetany and excessive heat production.

KEY CONCEPTS

DISORDERS OF SKELETAL MUSCLE

- Altered muscle function may stem from neurogenic or primary myopathic processes.
- Myopathic disorders are often marked by degeneration and regeneration of myofibers.
- The three traditional inflammatory myopathies are polymyositis, dermatomyositis, and inclusion body myositis, but other forms like immune-mediated necrotizing myopathy (IMNMs) are now recognized.
  - Inclusion body myositis is a chronic progressive disease of older patients associated with rimmed vacuoles.
  - Dermatomyositis occurs in children and adults, the latter frequently as a paraneoplastic disorder. Immune damage to small blood vessels and perifascicular atrophy are common features.
  - Polymyositis is an adult-onset myopathy caused by CD8+ T cells. This disease is less common than originally thought because many patients are reclassified as having IMNM, systemic connective tissue disease, or even early inclusion body myositis.
- Muscular dystrophies and congenital myopathies result from genetic mutations that disrupt the function of proteins that are important for various aspects of muscle development, function, and regeneration. Some of these diseases present in infancy, others in adulthood. They may be relentlessly progressive or cause relatively static deficits.
- Myopathy can result from toxic injury or be the result of metabolic diseases including those of lipid metabolism, glycogen metabolism, and mitochondria.

PERIPHERAL NERVE SHEATH TUMORS

The vast majority of benign and malignant neoplasms of peripheral nerve sheaths are composed of cells that show evidence of Schwann cell differentiation. These include the three common types: schwannoma, neurofibroma, and malignant peripheral nerve sheath tumor (MPNST). Other rare tumors arising from nerves may show evidence of perineurial cell differentiation. There is an abrupt transition between myelination by oligodendrocytes (central myelin) and myelination by Schwann cells (peripheral myelin) that occurs as nerves extend out from the substance of the brain. Thus, peripheral nerve tumors sometimes arise within the dura as well as along the distal course of peripheral nerves.

Peripheral nerve sheath tumors have several unique features. Firstly, their association with relatively common familial tumor syndromes, including neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), and schwannomatosis.

Secondly, MPNSTs seen in the context of NF1 are thought to arise through malignant transformation of preexisting benign plexiform neurofibromas. Although malignant transformation of a preexisting benign lesion is a common origin for certain carcinomas (e.g., colon cancer), it is unusual in soft tissue tumors. Tumors with skeletal muscle differentiation are discussed in Chapter 26.

Schwannomas

These are benign tumors that exhibit Schwann cell differentiation and often arise directly from peripheral nerves. Schwannomas are a component of NF2, and even sporadic schwannomas are commonly associated with inactivating mutations in the *NF2* gene on chromosome 22. Loss of expression of the *NF2* gene product, merlin, is a consistent finding in all schwannomas. Through interactions affecting the actin cytoskeleton, merlin participates in the regulation of several key signaling pathways that are involved in control of cell shape, cell growth, and the attachment of cells to one another (cell adhesion).

MORPHOLOGY

Schwannomas are well-circumscribed, encapsulated masses that are attached loosely to the associated nerve without invading it. As a result they can often be resected without sacrificing nerve function. Grossly, these tumors form firm, gray masses. Microscopically, they are comprised of an admixture of dense and loose areas referred to as **Antoni A** and **Antoni B** areas, respectively (Fig. 27.14A). The dense eosinophilic Antoni A areas often contain spindle cells arranged into cellular intersecting fascicles. Palisading of nuclei is common. Resulting structures with central "nuclear-free zones" ramified by palisading nuclei are termed **Verocay bodies** (Fig. 27.14B). In the loose, hypocellular **Antoni B** areas the spindle cells are spread apart by a prominent myxoid extracellular matrix that may be associated with microcyst formation. Schwann cells are characterized by the presence of a spindled elongated nucleus with a wavy or buckled shape. Electron microscopy shows basement membrane deposits encasing single cells and collagen fibers. Because the lesion displaces the nerve of origin as it grows, axons are largely excluded from the tumor, although they may become entrapped in the capsule. The Schwann cell origin of these tumors is borne out by their uniform immunoreactivity for S-100. A variety of degenerative changes may be found in schwannomas, including nuclear pleomorphism, xanthomatous change, vascular hyalinization, cystic change, and necrosis. Some large mitotically active schwannomas lacking Antoni B areas can mimic a sarcoma. Schwannomas may recur locally if incompletely resected, but malignant transformation is extremely rare (in contrast to plexiform neurofibromas, discussed later).

Clinical Features

Most schwannomas cause symptoms by local compression of the involved nerve or adjacent structures (e.g., brainstem or spinal cord). Within the cranial vault, most schwannomas occur at the cerebellopontine angle, where they are attached to the vestibular branch of the eighth nerve. Affected individuals often present with tinnitus and hearing loss; the tumor is commonly referred to as an *acoustic neuroma*—a double misnomer, since the tumor neither arises from the acoustic portion of the nerve nor is it a neuroma. Elsewhere within the dura, sensory nerves are preferentially involved, including branches of the trigeminal nerve and dorsal roots. When extradural, schwannomas can arise in association with large nerve trunks or as soft tissue lesions without an identifiable associated nerve. Surgical removal is curative.

Neurofibromas

Neurofibromas are benign nerve sheath tumors that are more heterogeneous in composition than schwannomas. **The neoplastic Schwann cells are admixed with perineurial-like cells, fibroblasts, mast cells, and CD34+ spindle cells**. Neurofibromas may be either sporadic or NF1-associated. Different types of neurofibroma can be distinguished depending on their growth pattern.

- *Superficial cutaneous neurofibromas* often present as pedunculated nodules that can be seen isolated (if sporadic) or multiple (if NF1-associated).
- *Diffuse neurofibromas* often present as a large plaque-like elevation of skin and are typically NF1-associated.
- *Plexiform neurofibromas* can be found in deep or superficial locations in association with nerve roots or large nerves and are uniformly NF1-associated.

Pathogenesis

Only the Schwann cells in neurofibromas show complete loss of the *NF1* gene product, neurofibromin, indicating that these are the neoplastic cells. You will recall from Chapter 7 that neurofibromin is a tumor suppressor that inhibits RAS activity by stimulating the activity of a guanosine triphosphatase (GTPase). Loss of the GTPase activity causes RAS to be trapped in GTP bound active state. Haploinsufficiency for the *NF1* gene in other associated cells may also contribute to the growth of NF1-associated tumors. For example, there is evidence that *NF1*-haploinsufficient mast cells are hypersensitive to KIT ligand produced by Schwann cells and in response secrete factors that stimulate Schwann cell growth. This form of tumor/stromal cell cross-talk may be targetable with inhibitors of the KIT receptor tyrosine kinase. Other studies suggest that plexiform neurofibromas and dermal neurofibromas arise from different neural crest–derived precursor cells. Malignant transformation of neurofibroma to MPNST is usually observed in the plexiform variant but is sometimes also seen in the diffuse type. The overall incidence of MPNST in NF1 patients is about 5% to 10%, but patients with large numbers of plexiform neurofibromas and large deletions in the *NF1* gene are at higher risk.

MORPHOLOGY

Localized cutaneous neurofibroma. These are small, well-delineated but unencapsulated nodular lesions that arise in the dermis and subcutaneous fat. They have relatively low cellularity and contain bland Schwann cells admixed with stromal cells such as mast cells, perineurial cells, CD34+ spindle cells, and fibroblasts. Adnexal structures are sometimes entrapped at the edges of the lesion. The stroma of these tumors contains loose collagen.

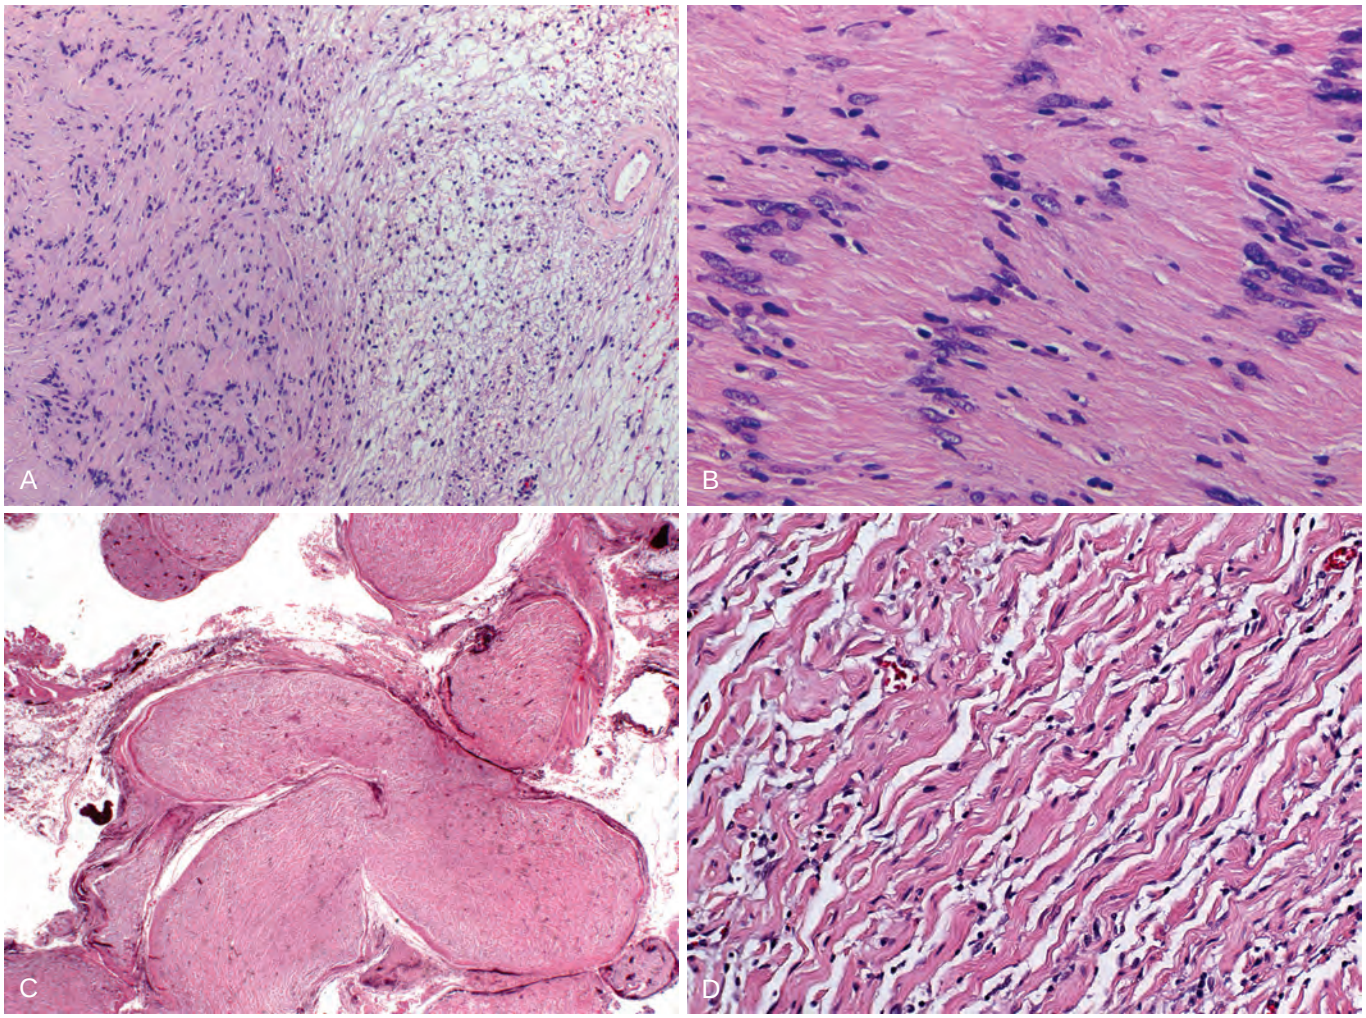

Figure 27.14 Schwannoma and plexiform neurofibroma. (A and B) Schwannoma. (A) Schwannomas often contain dense eosinophilic Antoni A areas *(left)* and loose, pale Antoni B areas *(right)*, as well as hyalinized blood vessels *(right)*. (B) Antoni A area with the tumor cell nuclei aligned in palisading rows leaving anuclear zones and resulting in the formation of structures termed *Verocay bodies*. (C and D) Plexiform neurofibroma. (C) Multiple nerve fascicles are expanded by infiltrating tumor cells. (D) At high power, bland spindle cells are admixed with wavy collagen bundles resembling carrot shavings.

Diffuse neurofibroma. This tumor has morphologic features similar to those seen in localized cutaneous neurofibromas but exhibits a distinctly different growth pattern. The tumor diffusely infiltrates the dermis and subcutaneous connective tissue, entrapping fat and appendage structures and producing a plaque-like appearance. Some of these neurofibromas can grow to large sizes. Focal collections of cells mimicking the appearance of Meissner corpuscles (so-called **pseudo-Meissner corpuscles** or **tactile-like bodies**) are an associated feature.

Plexiform neurofibroma. These tumors grow within and expand nerve fascicles (Fig. 27.14C), entrapping associated axons. The external perineurial layer of the nerve is preserved, giving individual nodules an encapsulated appearance. The expanded, ropy thickening of multiple nerve fascicles results in what is sometimes referred to as a "bag of worms" appearance. The tumor has cellular composition similar to that of other neurofibromas. The extracellular matrix varies from loose and myxoid to more collagenous and fibrous. Often the collagen is seen in bundles likened to "shredded carrot" (Fig. 27.14D).

Malignant Peripheral Nerve Sheath Tumors

Most MPNSTs (approximately 85%) are high-grade tumors, but low-grade variants are recognized. About half arise in NF1 patients and are assumed to result from malignant transformation of a plexiform neurofibroma. Sporadic cases may arise de novo. Most are associated with larger peripheral nerves in the chest, abdomen, pelvis, neck, or limb-girdle. MPNSTs exhibit complex chromosomal aberrations including chromosome gains, losses, and rearrangements. The molecular alterations driving malignant transformation of a neurofibroma to MPNST are still poorly understood.

MORPHOLOGY

The lesions are poorly defined tumor masses that frequently infiltrate along the axis of the parent nerve and invade adjacent soft tissues. A wide range of histologic appearance can be encountered. Typical cases show a fasciculated arrangement of

spindle cells. At low power the tumor often appears "marbleized" due to variations in cellularity. Mitoses, necrosis, and nuclear anaplasia are common. An interesting phenomenon observed in MPNST is described as "divergent differentiation." This term refers to the presence of focal areas that exhibit other lines of differentiation, including glandular, cartilaginous, osseous, or rhabdomyoblastic morphology. A tumor exhibiting the latter is referred to as **Triton tumor.** Due to the poorly differentiated nature of MPNST, the distinction from an undifferentiated sarcoma may not be straightforward. Helpful clues include a diagnosis of NF1 in the affected patient and a clearly demonstrated anatomic relationship to a nerve or to a preexisting neurofibroma.

Neurofibromatosis Type 1 and Type 2

Neurofibromatosis Type 1

This is a common autosomal dominant disorder with a frequency of 1 in 3000. It is a systemic disease associated with nonneoplastic manifestations and with a variety of tumors, including neurofibromas of all types, MPNSTs, gliomas of the optic nerve, other glial tumors and hamartomatous lesions, and pheochromocytomas. Other features include intellectual disability or seizures, skeletal defects, pigmented nodules of the iris *(Lisch nodules)*, and cutaneous hyperpigmented macules *(café au lait spots)*. The disease is caused by loss-of-function mutations in the *NF1* gene, located at 17q11.2, which encodes the tumor suppressor neurofibromin. The neoplastic cells in NF1-related tumors lack neurofibromin due to biallelic defects in the *NF1* gene. As has been mentioned earlier, NF-1 protein has GTPase activity that restrains RAS function. In the absence of NF-1, RAS remains trapped in its active state.

The disease has a high penetrance but variable expressivity. Some patients exhibit only subtle features, while others show disease that is restricted to certain parts of the body, a distribution that is attributable to mosaicism. An unfortunate subset has severe disease. Large chromosomal deletions that span *NF1* and extend to involve adjacent genes tend to be associated with more severe phenotypes.

Neurofibromatosis Type 2

This is an autosomal dominant disorder resulting in a range of tumors, most commonly bilateral eighth nerve schwannomas, multiple meningiomas, and ependymomas of the spinal cord. Many individuals with NF2 also have nonneoplastic lesions, which include nodular ingrowth of Schwann cells into the spinal cord (schwannosis), meningioangiomatosis (a proliferation of meningeal cells and blood vessels that grows into the brain), and glial hamartia (microscopic nodular collections of glial cells at abnormal locations, often in the superficial and deep layers of cerebral cortex). This disorder is much less common than NF1, having a frequency of 1 in 40,000 to 50,000. Certain other rare familial syndromes are also associated with multiple schwannomas, such as schwannomatosis and Carney complex.

The *NF2* gene is located on chromosome 22q12 and is also commonly mutated in sporadic meningiomas and schwannomas. The *NF2* gene product, merlin, is a cytoskeletal protein that participates in the regulation of several key signaling pathways that are involved in control of cell shape, cell growth, and the attachment of cells to one another (cell adhesion). There is some correlation between the type of mutation and clinical symptoms, with nonsense and frameshift mutations causing more severe phenotypes than missense mutations.

KEY CONCEPTS

PERIPHERAL NERVE SHEATH TUMORS

- The three common peripheral nerve sheath tumors—schwannoma, neurofibroma, and MPNST—all likely arise from cells of Schwann cell lineage.
- Schwannomas are encapsulated benign tumors that can be associated with NF2.
- Neurofibromas are benign peripheral nerve sheath tumors sometimes associated with NF1 that can be subtyped as localized cutaneous, diffuse, or plexiform.
- MPNSTs can be de novo sporadic neoplasms or NF1-associated tumors arising through malignant transformation of a (plexiform) neurofibroma.

CHAPTER 28

The Central Nervous System

Marta Margeta • Arie Perry

CHAPTER CONTENTS

The principal functional unit of the central nervous system (CNS) is the *neuron*. Neurons of different types and in different locations have distinct properties, including diverse functional roles, patterns of synaptic connections, neurotransmitters used, and metabolic requirements, which vary with electrical activity. A set of neurons, not necessarily clustered together in a region of the brain, may thus show *selective vulnerability* to particular insults because they share one or more of these properties. Because brain functions are anatomically compartmentalized, the pattern of clinical signs and symptoms that follow injury depend as much on the region of brain that is affected as on the pathologic process. Mature neurons are incapable of cell division, so destruction of even a small number of neurons essential for a specific function may produce a neurologic deficit.

In addition to neurons, the CNS contains other cells, such as *astrocytes* and *oligodendrocytes*, which make up the *glia*. Different cellular components of the CNS are affected by distinct unique neurologic disorders and also respond to common insults (e.g., ischemia, infection) in a manner that is distinct from other tissues. We start our discussion of diseases of the CNS with an overview of the patterns of injury of different cells and the reactions of these cells to various insults.

CELLULAR PATHOLOGY OF THE CENTRAL NERVOUS SYSTEM

Neurons and glia of the CNS display a range of functional and morphologic changes following injury. Understanding these patterns can provide information about the mechanism of cellular injury and type of disease.

Reactions of Neurons to Injury

Neuronal injury may be an acute process, often as a consequence of depletion of oxygen or glucose or trauma, or may develop over a period of years, as occurs in degenerative disorders of the brain. Neurons are highly metabolically active and require a continuous supply of oxygen and glucose to meet their metabolic needs. Moreover, since neurons are postmitotic cells that are incapable of proliferation, they must be maintained throughout life. Perhaps because of their lengthy lifespan and high metabolic activity, neurons are unusually susceptible to the accumulation of misfolded proteins, which trigger the unfolded protein response (Chapter 2) and appear to be central to the pathogenesis of many degenerative disorders of the CNS.

MORPHOLOGY

Acute neuronal injury ("red neurons") refers to changes seen following acute CNS hypoxia/ischemia, severe hypoglycemia, and other acute insults, and are the earliest morphologic markers of neuronal cell death (see Fig. 28.15A). "Red neurons" are evident by 6 to 12 hours after an irreversible hypoxic/ischemic insult. Typical features include shrinkage of the cell body, pyknosis of the nucleus, disappearance of the nucleolus, loss of Nissl substance, and intense cytoplasmic eosinophilia.

Subacute and chronic neuronal injury ("degeneration") refers to neuronal death that occurs as a result of a progressive disease of months to years duration, as is seen in slowly evolving neurodegenerative diseases such as amyotrophic lateral sclerosis and Alzheimer disease. Prior to death, neurons often suffer a loss of synapses (sites of interneuronal communication), which may stem from aberrations in synaptic pruning (a process responsible for normal brain development and plasticity). Loss of synapses is followed by cell death (often selectively involving functionally related groups of neurons) and reactive gliosis. At an early stage, the cell loss is difficult to appreciate; the associated reactive glial changes are often the best indicator of neuronal injury. In many of these diseases, the predominant mechanism of cell death appears to be apoptosis.

Axonal reaction is a change observed in the cell body during regeneration of the axon; it is best seen in anterior horn cells of the spinal cord when motor axons are cut or seriously damaged. The increase in protein synthesis that occurs in response to the injury is reflected in enlargement and rounding up of the cell body, peripheral displacement of the nucleus, enlargement of the nucleolus, and dispersion of Nissl substance from the center to the periphery of the cell (central chromatolysis).

Neuronal damage may be associated with a wide range of subcellular alterations in the neuronal organelles and cytoskeleton. **Neuronal inclusions** may occur as a manifestation of aging, and consist of intracytoplasmic accumulations of complex lipids (lipofuscin), proteins, or carbohydrates. Abnormal cytoplasmic accumulations of lipids and other substances also occur with certain inborn errors of metabolism, genetic disorders caused by mutations that lead to the loss of specific enzyme activities (Chapter 5). Viral infection can lead to the appearance of viral inclusions, e.g., in herpetic infection (Cowdry A or B bodies), rabies (Negri body), and cytomegalovirus infection.

Some degenerative diseases of the CNS are associated with neuronal intracytoplasmic inclusions, such as neurofibrillary tangles of Alzheimer disease and Lewy bodies of Parkinson disease; others cause abnormal vacuolization of the perikaryon and neuronal cell processes in the neuropil (Creutzfeldt-Jakob disease).

Wallerian degeneration refers to degeneration of axons after disruption of nerve fibers (see Chapter 27).

Reactions of Astrocytes to Injury

Gliosis is the most important histopathologic marker of CNS injury, regardless of etiology, and is characterized by hypertrophy and hyperplasia of astrocytes. The astrocyte derives its name from its star-shaped appearance. These cells have multipolar, extensively branched cytoplasmic processes that emanate from the cell body and express glial fibrillary acidic protein (GFAP), a cell type–specific intermediate filament. Astrocytes act as metabolic buffers and detoxifiers within the brain. Additionally, through the foot processes (which surround capillaries or extend to the subpial and subependymal zones), they contribute to barrier functions by controlling the flow of macromolecules between the blood, the cerebrospinal fluid (CSF), and the brain.

MORPHOLOGY

In gliosis, the nuclei of astrocytes (which are typically oval with evenly dispersed, pale chromatin) enlarge, become vesicular, and

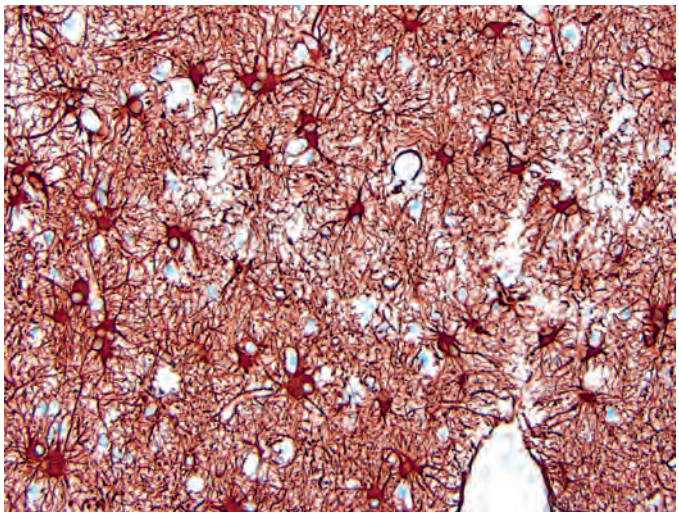

Figure 28.1 Reactive astrocytes. Immunohistochemical staining for glial fibrillary acidic protein *(brown)* highlights the stellate astrocytic processes from which the cell's name is derived.

occasionally develop prominent nucleoli. The previously indistinct cytoplasm becomes bright pink due to increased expression of GFAP, and the cells develop numerous stout, ramifying processes; these cells are called **reactive or gemistocytic astrocytes** (Fig. 28.1). There are at least two subtypes of reactive astrocytes; although morphologically indistinguishable, these cells form in response to different injurious stimuli, have distinct gene expression patterns, and have different effects on neuronal health and survival, with one subtype promoting CNS injury and the other contributing to CNS repair.

Acute astrocytic injury, as occurs in hypoxia, hypoglycemia, and toxic injuries, is manifested by cellular swelling, as in other cells (Chapter 2). The **Alzheimer type II astrocyte** (unrelated to the disease but first described by the same neuroscientist) is a gray matter cell with a large (two to three times normal) nucleus, pale-staining central chromatin, an intranuclear glycogen droplet, and a prominent nuclear membrane and nucleolus. Alzheimer type II astrocytes are mainly seen in individuals with hyperammonemia due to chronic liver disease, Wilson disease, or hereditary metabolic disorders of the urea cycle.

Other types of astrocyte injury lead to the formation of cytoplasmic inclusion bodies. **Rosenthal fibers** are thick, elongated, brightly eosinophilic, irregular structures that occur within astrocytic processes and contain two heat-shock proteins (αB-crystallin and hsp27) as well as ubiquitin. Rosenthal fibers are typically found in regions of long-standing gliosis; they are also characteristic of one type of glial tumor, pilocytic astrocytoma (see Fig. 28.49C). In Alexander disease, a leukodystrophy associated with mutations in the gene encoding GFAP, abundant Rosenthal fibers are found in periventricular, perivascular, and subpial locations. More commonly seen are **corpora amylacea,** or polyglucosan bodies. These are round, faintly basophilic, periodic acid-Schiff (PAS)–positive, concentrically lamellated structures of 5 to 50 μm in diameter that are located wherever there are astrocytic end processes, especially in the subpial and perivascular zones. They consist primarily of glycosaminoglycan polymers, as well as heat-shock proteins and ubiquitin. Corpora amylacea occur in increasing numbers with advancing age and are thought to represent a degenerative change in the astrocyte. **Lafora bodies**, which are seen in the cytoplasm of neurons (as well as hepatocytes, myocytes, and other cells) in a variant of myoclonic epilepsy, have a similar structure and biochemical composition.

Reactions of Microglia to Injury

Microglia are phagocytic cells derived early in embryonic development from the yolk sac or fetal liver that serve as the resident macrophages of the CNS and share many surface markers with bone marrow–derived peripheral monocytes/macrophages. At rest, microglia are tiled (i.e., cover non-overlapping territories) and have highly branched, amoeboid processes. During development, microglia prune unused synaptic connections, most likely through a phagocytic process that may involve the complement system; aberrant reactivation of this developmental process has recently been implicated in a number of different brain diseases, including schizophrenia, encephalitis, Alzheimer disease, and frontotemporal dementia. Microglia respond to injury by (1) proliferating; (2) developing elongated nuclei; (3) forming aggregates around small foci of tissue necrosis *(microglial nodules);* or (4) congregating around cell bodies of dying neurons *(neuronophagia)*. In addition to resident microglia, blood-derived macrophages may also be present in inflammatory foci.

Reactions of Other Glial Cells to Injury

Oligodendrocytes are cells that wrap their cytoplasmic processes around axons and form myelin. Each oligodendrocyte myelinates numerous internodes on multiple axons, in contrast to the myelinating Schwann cell in peripheral nerves, which only myelinates the internode of a single axon. Injury or apoptosis of oligodendrocytes is a feature of acquired demyelinating disorders and leukodystrophies. Oligodendroglial nuclei may harbor viral inclusions in progressive multifocal leukoencephalopathy (PML). Glial cytoplasmic inclusions, primarily composed of α-synuclein, are found in oligodendrocytes in multiple system atrophy (MSA).

Ependymal cells, the ciliated columnar epithelial cells lining the ventricles, do not show specific reaction patterns. When there is inflammation or marked dilation of the ventricular system, disruption of the ependymal lining is paired with proliferation of subependymal astrocytes to produce small irregularities on the ventricular surfaces *(ependymal granulations)*. Certain infectious agents, particularly CMV, may produce extensive ependymal injury, with viral inclusions in ependymal cells. However, neither oligodendrocytes nor ependymal cells mediate significant responses to most forms of injury in the CNS.

KEY CONCEPTS

CELLULAR PATHOLOGY OF THE CENTRAL NERVOUS SYSTEM

- Each cellular component of the nervous system responds to injury in a distinctive way.

- Neuronal injury commonly results in cell death, either by apoptosis or necrosis. Loss of neurons or synapses is often difficult to detect morphologically, but is a major contributor to neurologic dysfunction.
- Astrocytes respond to injury through apparent hypertrophy (increased cytoplasm due to accumulation of the intermediate filament protein GFAP) and hyperplasia; this response can be beneficial or harmful, depending on the type of injurious stimulus and the exact nature of astrocytic response.
- Microglia, the resident monocyte-lineage population of the CNS, proliferate and accumulate in response to injury. Aberrant activation of microglia- and complement-mediated synaptic pruning plays an important role in the pathogenesis of many different neurologic disorders.

CEREBRAL EDEMA, HYDROCEPHALUS, RAISED INTRACRANIAL PRESSURE, AND HERNIATION

The brain and the spinal cord are encased and protected by the rigid skull, dural reflections, and the bony spinal canal. The pressure within the cranial cavity may rise in any one of three commonly observed clinical settings: generalized brain edema, increased CSF volume, and focally expanding mass lesions. Depending on the degree and rapidity of the pressure increase and the nature of the underlying lesion, the consequences range from subtle neurologic deficits to death.

Cerebral Edema

Cerebral edema (more precisely, brain parenchymal edema) is the result of increased fluid leakage from blood vessels and injury to various cells of the CNS. There are two main pathways of edema formation in the brain.

- *Vasogenic edema* is an increase in extracellular fluid caused by blood-brain barrier disruption and increased vascular permeability, allowing fluid to shift from the intravascular compartment to the intercellular spaces of the brain. The paucity of lymphatics greatly impairs the resorption of excess extracellular fluid. Vasogenic edema may be either localized, e.g., adjacent to inflammation or neoplasms, or generalized, as may occur following a global ischemic injury.
- *Cytotoxic edema* is an increase in intracellular fluid secondary to neuronal, glial, or endothelial cell membrane injury, as might be encountered with a generalized hypoxic/ischemic insult or with a metabolic derangement that prevents maintenance of the normal membrane ionic gradients.

In practice, conditions associated with generalized edema often have elements of both vasogenic and cytotoxic edema. In generalized edema, the gyri are flattened, the intervening sulci are narrowed, and the ventricular cavities are compressed. As the brain expands, herniation may occur.

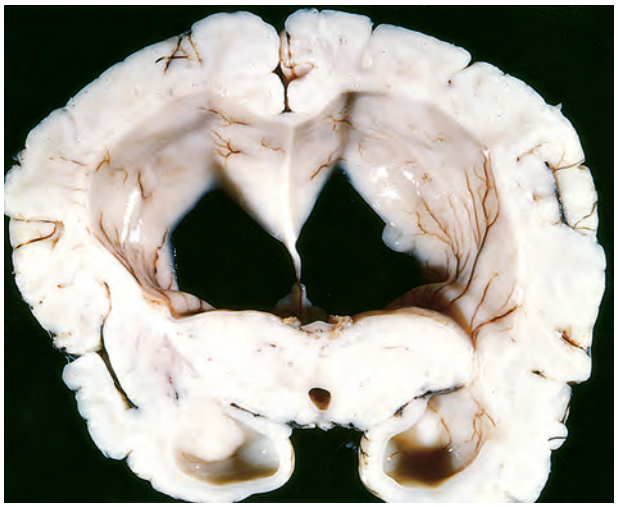

Figure 28.2 Hydrocephalus. Dilated lateral ventricles seen in a coronal section through the midthalamus.

Hydrocephalus

Hydrocephalus is the accumulation of excessive CSF within the ventricular system (Fig. 28.2). The choroid plexus within the ventricular system produces CSF, which normally circulates through the ventricular system and enters the cisterna magna at the base of the brainstem through the foramina of Luschka and Magendie. Subarachnoid CSF bathes the superior cerebral convexities and is absorbed by the arachnoid granulations. Most cases of hydrocephalus are a consequence of impaired flow and resorption of CSF; overproduction is a rare cause that can accompany tumors of the choroid plexus. In all forms, the increased volume of CSF expands the ventricles and can elevate the intracranial pressure.

When hydrocephalus develops in infancy before closure of the cranial sutures, the head enlarges. By contrast, after the sutures close, hydrocephalus is associated with expansion of the ventricles and increased intracranial pressure, without a change in head circumference. If the ventricular system is only focally obstructed, due to a mass in the third ventricle or to aqueductal stenosis, it is called *noncommunicating (obstructive) hydrocephalus*. In *communicating hydrocephalus,* the ventricular system remains in continuity with the subarachnoid space and there is enlargement of the entire ventricular system; causes include overproduction of CSF from a choroid plexus tumor and arachnoid fibrosis following meningitis. The term *hydrocephalus ex vacuo* refers to a compensatory increase in ventricular volume secondary to a loss of brain parenchyma.

Raised Intracranial Pressure and Herniation

Herniation is the displacement of brain tissue past rigid dural folds (the falx and tentorium) or through openings in the skull because of increased intracranial pressure. As the volume of the brain increases, CSF is displaced, leading to increasing pressure within the cranial cavity; herniation occurs when this pressure exceeds the brain's limited capacity to accommodate the increased intracranial pressure. Brain herniation is mostly caused by mass effects, either diffuse

(generalized brain edema) or focal (tumors, abscesses, or hemorrhages). Elevated intracranial pressure may also compress the vasculature and reduce perfusion of the brain, causing ischemic injury and further exacerbating cerebral edema.

MORPHOLOGY

The brain may herniate through different openings, and if the expansion is sufficiently severe, herniation may occur simultaneously in several locations (Fig. 28.3):

- **Subfalcine (cingulate) herniation** occurs when unilateral or asymmetric expansion of a cerebral hemisphere displaces the cingulate gyrus under the falx. This may lead to compression of the anterior cerebral artery and its branches, resulting in secondary infarcts.
- **Transtentorial (uncal, mesial temporal) herniation** occurs when the medial aspect of the temporal lobe is compressed against the free margin of the tentorium. With increasing displacement of the temporal lobe, the third cranial nerve is compromised, resulting in pupillary dilation and impaired ocular movements on the side of the lesion. The posterior cerebral artery may also be compressed, resulting in an infarct of its territory (which includes the primary visual cortex). When the extent of herniation is large enough, the contralateral cerebral peduncle may be compressed, resulting in hemiparesis ipsilateral to the side of the herniation. Progression of transtentorial herniation is often accompanied by secondary hemorrhagic lesions in the midbrain and pons, termed **Duret hemorrhages** (Fig. 28.4). These linear or flame-shaped lesions usually occur in the midline and paramedian regions and are believed to be due to distortion or tearing of penetrating veins and arteries supplying the upper brainstem.
- **Tonsillar herniation** refers to displacement of the cerebellar tonsils through the foramen magnum. This pattern of herniation is life-threatening because it causes brainstem compression and compromises vital respiratory and cardiac centers in the medulla.

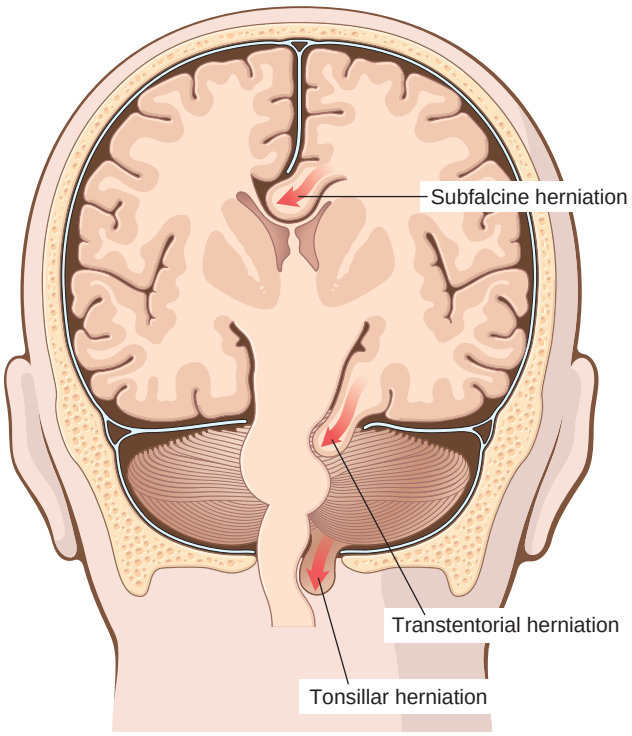

Figure 28.3 Major herniation syndromes of the brain: subfalcine, transtentorial, and tonsillar.

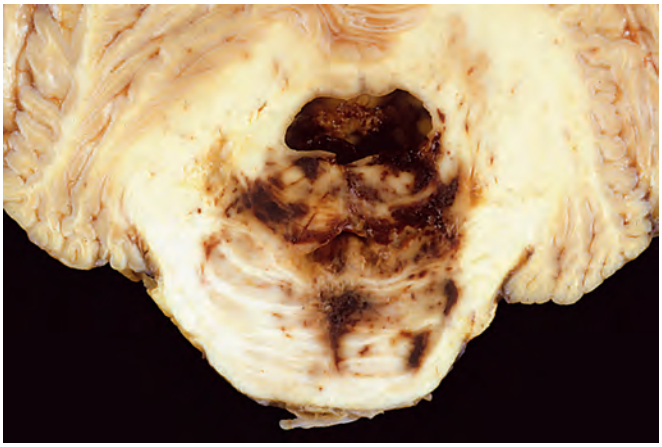

Figure 28.4 Duret hemorrhage. As mass effect displaces the brain downward, there is disruption of the vessels that enter the pons along the midline, leading to hemorrhage.

KEY CONCEPTS

CEREBRAL EDEMA, HYDROCEPHALUS, RAISED INTRACRANIAL PRESSURE, AND HERNIATION

- Cerebral edema is the accumulation of excess fluid within the brain parenchyma. Hydrocephalus is an increase in CSF volume within all or part of the ventricular system.
- Increase in the intracranial volume (due to increased CSF volume, parenchymal edema, hemorrhage, or tumor) raises intracranial pressure.
- Increased intracranial pressure may result in cerebral herniation, decreased perfusion, and secondary infarction of the affected areas.

MALFORMATIONS AND DEVELOPMENTAL DISORDERS

Although the pathogenesis and etiology of many CNS malformations remain unknown, both genetic and environmental influences appear to be involved. Genomic sequencing has begun to uncover a range of genetic variants that are associated with certain malformations. The causal relationship between these genetic alterations and the pathogenesis of the malformations is the subject of active research. Besides genetic factors, many toxic compounds and infectious agents also have teratogenic effects and may cause brain malformations.

Neural Tube Defects

Neural tube defects are midline malformations that involve some combination of neural tissue, meninges, and overlying

bone or soft tissue; collectively, they are the most common CNS malformations. Two distinct pathogenic mechanisms are contributory: (1) failure of neural tube closure, in which secondary mesenchymal tissue defects stem from aberrant skeletal modeling around the malformed tube (e.g., anencephaly and myelomeningocele); and (2) primary bony defects that are caused by abnormal axial mesoderm development and lead to secondary CNS abnormalities (e.g., encephalocele, meningocele, and spina bifida).

MORPHOLOGY

- **Anencephaly** is a malformation of the anterior end of the neural tube that leads to absence of most of the brain and calvarium. Forebrain development is disrupted at approximately 28 days of gestation, and all that remains in its place is the **area cerebrovasculosa,** a flattened remnant of disorganized brain tissue with admixed ependyma, choroid plexus, and meningothelial cells. The posterior fossa structures may be spared, depending on the extent of the skull deficit; descending tracts associated with disrupted structures are, as expected, absent.
- **Myelomeningocele** (or meningomyelocele) refers to extension of CNS tissue through a defect in the vertebral column; the term **meningocele** applies when there is only a meningeal extrusion. Myelomeningoceles occur most commonly in the lumbosacral region (Fig. 28.5). Affected individuals have motor and sensory deficits in the lower extremities as well as disturbances of bowel and bladder control. They are often complicated by superimposed infection of the cord due to defective barrier function of the thin, overlying skin.

Figure 28.5 Myelomeningocele. Both meninges and spinal cord parenchyma are included in the cystlike structure visible just above the buttocks.

- **Encephalocele** refers to an extrusion of malformed brain tissue through a midline defect in the cranium. It most often occurs in the occiput, although nasofrontal variants involving the orbit, ethmoid, or cribriform plate (sometimes misleadingly referred to as a "nasal glioma") also are seen.
- **Spinal dysraphism** or **spina bifida** (the most common neural tube defects) may be an asymptomatic bony defect (spina bifida occulta) or a severe malformation with a flattened, disorganized segment of spinal cord, associated with an overlying meningeal outpouching.

Clinical Features

The frequency of neural tube defects varies widely among different ethnic groups, with the overall recurrence rate for a neural tube defect in subsequent pregnancies estimated at 4% to 5%. Folate deficiency during the first several weeks of gestation is a well-established risk factor; differences in rates of neural tube defects among populations can be attributed in part to polymorphisms in enzymes involved in folic acid metabolism. Folate supplementation can lower the risk of neural tube defects, but because neural tube closure is normally complete by day 28 of embryonic development (before most pregnancies are recognized), it must be given to women throughout their reproductive years to be fully effective. Precisely how folate deficiency increases the risk is uncertain; effects on DNA methylation (an important epigenetic mode of gene regulation) are suspected.

Forebrain Anomalies

Abnormalities in the generation and migration of neurons result in malformations of the forebrain that may be focal or involve entire structures. The pool of proliferating precursor cells in the developing brain lies in the germinal matrix adjacent to the ventricular system; the total number of neurons is determined by the fraction of proliferating cells that undergo transition into migrating cells with each cell cycle. The migration of neurons from the germinal matrix to the cerebral cortex follows two paths: radial migration, for progenitor cells destined to become excitatory neurons; and tangential migration, for those that will become inhibitory interneurons.

A range of different anatomic malformation patterns has been defined. Recently, it has become clear that many of these patterns are caused by mutations in genes that are required for proper cerebral development. Changes may be seen in the complexity of the brain surface (either too few or too many gyri present), the organization of the brain into normal lobes, the structure of the cerebral cortex, or the distribution of neurons within the brain.

- The volume of brain may be abnormally large *(megalencephaly)* or abnormally small *(microencephaly)*. Microencephaly, by far the more common of the two, is typically accompanied by a small head circumference. It is associated with a number of conditions, including chromosome abnormalities, fetal alcohol syndrome, and viral infection acquired in utero (e.g., with human immunodeficiency virus 1 [HIV-1] or Zika virus). It is postulated that the underlying anomaly is a reduction in the number of

neurons that reach the neocortex, which leads to a simplification of gyral folding, a mechanism supported by experimental results in mouse models.

- *Lissencephaly* is a malformation characterized by reduction in the number of gyri, which in the extreme case may show no gyral pattern *(agyria)*. Two general patterns are observed, a smooth-surface form (type 1), and a rough- or cobblestone-surface form (type 2). In general, type 1 forms are associated with mutations that disrupt mechanisms involved in cell migration, such as mutations in the cytoskeletal "motor" proteins that drive migration of neuroblasts. In contrast, type 2 lissencephaly is most commonly associated with genetic alterations that disrupt the "stop signal" for migration. This signal depends on a set of specifically glycosylated proteins, and mutations in the enzymes that place sugars onto these proteins are the most common causes of this form of lissencephaly.
- *Polymicrogyria* is characterized by numerous small, irregularly formed cerebral convolutions with shallow sulci. The cerebral cortex is composed of four or fewer layers (instead of the normal six layers), with fusion of the molecular layers between gyri. Polymicrogyria can be induced by localized tissue injury toward the end of neuronal migration, although genetically determined forms, which are typically bilateral and symmetric, are also recognized.
- *Neuronal heterotopias* are a group of migrational disorders defined by collections of subcortical neurons in inappropriate locations along the pathway of migration. As might be expected, one location is along the ventricular surface—as though the cells never left their place of birth. Periventricular nodular heterotopias can be caused by mutations in the gene encoding filamin A, an actin-binding protein responsible for assembly of complex meshworks of filaments. This gene is on the X chromosome, and the mutant allele causes male lethality; in females, the process of X inactivation separates neurons into those with a normal allele (in the correct location) and those with the mutant allele (in the heterotopia). Another microtubule-associated protein, doublecortin (DCX), is also encoded by a gene on the X chromosome; mutations in this gene result in lissencephaly in males and in subcortical bandlike heterotopias in females (this parallel layer of gray matter imparts the impression of a "double cortex"). Nodular subcortical heterotopias may also be encountered.
- *Holoprosencephaly* is a spectrum of malformations characterized by incomplete separation of the cerebral hemispheres across the midline. Severe forms manifest midline facial abnormalities, including cyclopia; less severe variants *(arrhinencephaly)* show absence of the olfactory cranial nerves and related structures. Intrauterine diagnosis of severe forms by ultrasonography is now possible. Holoprosencephaly is associated with trisomy 13 as well as other genetic syndromes. Mutations in genes that encode components of the sonic hedgehog signaling pathway may also produce holoprosencephaly.
- *Agenesis of the corpus callosum*, a relatively common malformation, is the absence of the white matter bundles that carry cortical projections from one hemisphere to the other (Fig. 28.6). Radiologic imaging studies show misshapen lateral ventricles ("bat-wing" deformity); on coronal whole-mount sections of the brain, "Probst bundles" of anteroposteriorly oriented white matter can be demonstrated. Agenesis of the corpus callosum is sometimes associated with intellectual disability but may also be found in normal individuals. It may be sporadic or familial and can be present in isolation or in association with a range of other malformations.

Figure 28.6 Agenesis of the corpus callosum. The midsagittal view of the left hemisphere shows the lack of a corpus callosum and cingulate gyrus.

Posterior Fossa Anomalies

A distinct set of malformations primarily affect the brainstem and the cerebellum, which often show dramatic changes in size and shape. These may be accompanied by morphologic changes in other regions of the brain.

MORPHOLOGY

- **Arnold-Chiari malformation** (Chiari type II malformation) consists of a small posterior fossa, a misshapen midline cerebellum with downward extension of vermis through the foramen magnum (Fig. 28.7), and, almost invariably, hydrocephalus and a lumbar myelomeningocele. Other associated changes may include caudal displacement of the medulla, malformation of the tectum, aqueductal stenosis, cerebral heterotopias, and hydromyelia (see later).
- **Chiari type I malformation** is a less severe disorder in which low-lying cerebellar tonsils extend down into the vertebral canal. It may be a silent abnormality or may become symptomatic because of impaired CSF flow and medullary compression; if present, these symptoms can usually be corrected by neurosurgical intervention.
- **Dandy-Walker malformation** is characterized by an enlarged posterior fossa. The cerebellar vermis is absent or present only in rudimentary form in its anterior portion; in its place is a large midline cyst that is lined by ependyma and is contiguous with leptomeninges on its outer surface. This cyst represents the expanded, roofless fourth ventricle in the absence of a normally formed vermis. Dysplasias of brainstem nuclei are commonly found in association with Dandy-Walker malformation.

Figure 28.7 Arnold-Chiari malformation. Midsagittal section showing small posterior fossa contents, downward displacement of the cerebellar vermis, and deformity of the medulla (*arrows* indicate the approximate level of the foramen magnum).

- **Joubert syndrome** and related disorders share hypoplasia of the cerebellar vermis with apparent elongation of the superior cerebellar peduncles and an altered shape of the brainstem; together these changes give rise to the "molar tooth sign" on imaging. This group of malformations has been found to be caused by diverse mutations affecting genes that encode components of the primary (nonmotile) cilium.

Syringomyelia and Hydromyelia

These disorders are characterized by expansion of the ependyma-lined central canal of the cord *(hydromyelia)* or by the formation of a fluid-filled cleftlike cavity in the inner portion of the cord *(syringomyelia, syrinx)* that may extend into the brainstem *(syringobulbia)*.

Syringomyelia may be associated with a Chiari malformation; it may also occur in association with intraspinal tumors or following traumatic injury. In general, the histologic appearance is similar in all of these conditions, with destruction of the adjacent gray and white matter, surrounded by dense reactive gliosis. The disease generally becomes manifest in the second or third decade of life. The distinctive symptoms and signs of a syrinx are the isolated loss of pain and temperature sensation in the upper extremities because of disruption of the crossing anterior spinal commissural fibers of the spinal cord.

KEY CONCEPTS

MALFORMATIONS AND DEVELOPMENTAL DISORDERS

- Malformations may be associated with single-gene mutations, larger-scale genetic alterations, or exogenous factors.
- Overall, the earlier in development a malformation occurs, the more severe the morphologic and functional phenotype.
- Neural tube defects are caused by the failure of the tube to close or by skeletal bony defects that lead to secondary tube abnormalities; they range from incidental findings to severe malformations.
- Cortical development depends on proper orchestration of progenitor cell proliferation in the germinal matrix and migration of progenitors upward into the developing cortex. Disruption of these processes can alter the size, shape, and organization of the brain.
- Malformations involving the posterior fossa are typically distinct from those that affect the cerebral hemispheres.

PERINATAL BRAIN INJURY

Brain injury occurring in the perinatal period is an important cause of childhood-onset neurologic disability. Injuries that occur early in gestation may destroy brain tissue without eliciting the reactive changes observed in adult brain and, therefore, may be difficult to distinguish from malformations. Different patterns of injury may occur.

- The term *cerebral palsy* refers to a nonprogressive neurologic motor deficit characterized by combinations of spasticity, dystonia, ataxia/athetosis, and paresis, attributable to brain injury occurring during the prenatal and perinatal periods. Signs and symptoms may not be apparent at birth and only declare themselves later, as development proceeds. Postmortem examinations of children with cerebral palsy have shown a wide range of neuropathologic findings, including destructive lesions traced to remote events that may have caused hemorrhage and infarction.
- In premature infants, there is an increased risk of *germinal matrix hemorrhage,* often near the junction between the developing thalamus and caudate nucleus. Hemorrhages may remain small and localized or extend into the ventricular system and subarachnoid space, sometimes leading to hydrocephalus and death in severe cases.
- Infarcts may occur in the supratentorial periventricular white matter *(periventricular leukomalacia),* especially in premature infants; they take the form of chalky yellow plaques that consist of discrete white matter necrosis, often with dystrophic calcification. Ultimately, the infarcted areas develop into large cystic lesions (Fig. 28.8); when damage is extensive and involves both gray and white matter, the condition is termed *multicystic encephalopathy*.
- In perinatal ischemic lesions of the cerebral cortex, the depths of sulci bear the brunt of injury and result in mushroom-shaped gyri with thinned-out, gliotic stalks *(ulegyria)*. The basal ganglia and thalamus may also suffer ischemic injury, with patchy neuronal loss and reactive gliosis. Later, aberrant and irregular myelinization gives rise to a marble-like appearance of the deep nuclei *(status marmoratus)*. Because the lesions are in the caudate, putamen, and thalamus, movement disorders such as choreoathetosis are common clinical sequelae.

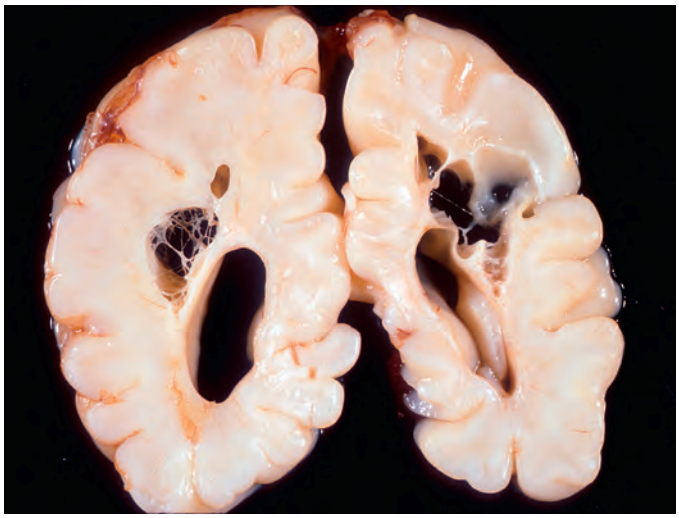

Figure 28.8 Chronic stage of periventricular leukomalacia. Large cystic spaces in the periventricular white matter (seen in both hemispheres of this brain) are the long-term sequalae of a severe prenatal or perinatal ischemic injury.

TRAUMA

The anatomic location of the lesion and the limited capacity of the brain for functional repair are major determinants of the consequences of CNS trauma. Injury of several cubic centimeters of brain parenchyma may be clinically silent (e.g., in the frontal lobe), severely disabling (e.g., in the spinal cord), or fatal (e.g., in the brainstem).

The physical forces associated with head injury may result in skull fractures, parenchymal injury, and vascular injury; all three can coexist. The magnitude and distribution of a traumatic brain lesion depends on the shape of the object causing the trauma, the force of impact, and whether the head is in motion at the time of injury. A blow to the head may be penetrating or blunt; it may cause either an open or a closed injury.

Skull Fractures

A fracture in which bone is displaced into the cranial cavity by a distance greater than the thickness of the bone is called a *displaced skull fracture*. The thickness of the cranial bones varies; therefore, their resistance to fracture differs greatly. Also, the relative incidence of fractures among skull bones is related to the pattern of falls. For example, when an individual falls while awake (such as might occur when stepping off a ladder), the site of impact is often the occipital portion of the skull; in contrast, a fall that follows loss of consciousness (as might follow a syncopal attack) can result in either frontal or occipital impact. Symptoms referable to the lower cranial nerves or the cervicomedullary region, and the presence of orbital or mastoid hematomas distant from the point of impact, raise the suspicion of a basal skull fracture, which typically follows impact to the occiput or sides of the head; CSF leakage from the nose or ear and infection (meningitis) may follow.

Parenchymal Injuries

The structural consequences and clinical manifestations of the parenchymal injury depend on the nature and severity of the causative head trauma and range from mild (concussion) to severe (contusions and lacerations).

Concussion

Concussion is a clinical syndrome of altered consciousness secondary to head injury, typically brought about by a change in the momentum of the head (e.g., following impact with a rigid object). The characteristic clinical picture includes the sudden onset of transient neurologic dysfunction, including loss of consciousness, temporary respiratory arrest, and loss of reflexes. Although neurologic recovery is usually complete, amnesia for the event often persists. The pathogenesis of the disruption of neurologic function is unknown, but likely involves dysregulation of the reticular activating system in the brainstem. Postconcussive neuropsychiatric syndromes, typically associated with repetitive injuries, are well recognized, and there is increasing evidence that significant cognitive impairment can emerge along with distinct pathologic findings termed chronic traumatic encephalopathy (discussed later).

Direct Parenchymal Injury

Contusions and *lacerations* are brain injuries caused by transmission of kinetic energy to the brain. A contusion is analogous to the familiar bruise caused by blunt trauma, and a laceration is an injury caused by penetration of an object and tearing of tissue. As with any other organ, a blow to the surface of the brain, transmitted through the skull, leads to rapid tissue displacement, disruption of vascular channels, and subsequent hemorrhage, tissue injury, and edema. Hemorrhage can extend into the subarachnoid space from these lesions. The crests of gyri are most susceptible because this is where the direct force is greatest. The most common locations for contusions correspond to the most frequent sites of direct impact and to regions of the brain that overlie a rough and irregular inner skull surface, such as the frontal lobes along the orbital ridges and the temporal lobes. Contusions are less frequent over the occipital lobes, brainstem, and cerebellum, but may be seen when there is an adjacent skull fracture (fracture contusions).

A person who suffers a blow to the head may develop a contusion at the point of contact (a *coup* injury) or on the brain surface diametrically opposite to it (a *contrecoup* injury). Their macroscopic and microscopic appearances are indistinguishable, and the distinction between them is based on identification of the point of impact. In general, if the head is immobile at the time of trauma, only a coup injury is found. If the head is mobile, both coup and contrecoup lesions may be found, though the latter predominate and are thought to develop when the brain strikes the opposite inner surface of the skull after sudden deceleration.

Sudden impacts that result in violent posterior or lateral hyperextension of the neck (as occurs when a pedestrian is struck from the rear by a vehicle) may avulse the pons from the medulla or the medulla from the cervical cord, causing instant death.

MORPHOLOGY

When seen on cross-section, contusions are wedge shaped, with the broad base lying along the surface at the point of impact (Fig. 28.9A). The appearance of contusions is similar regardless of the source of the trauma. In the earliest stages, there is edema and hemorrhage, which is often pericapillary. During the next few hours, the extravasation of blood extends throughout the involved tissue, across the width of the cerebral cortex, and into the white matter and subarachnoid space. Morphologic evidence of neuronal injury (pyknosis of the nucleus, eosinophilia of the cytoplasm, and disintegration of the cell) takes 12 to 24 hours to appear, although functional deficits generally occur earlier. Axonal swellings develop along the full length of the damaged neurons. The inflammatory response to the injured tissue follows its usual course, with the appearance of sparse neutrophils followed by abundant macrophages. Old traumatic lesions on the surface of the brain have a characteristic gross appearance. They are depressed, retracted, yellowish brown patches involving the crests of gyri, most commonly those that are located at the sites of contrecoup injuries (inferior frontal cortex, temporal and occipital poles); these lesions, called **plaque jaune** (Fig. 28.9B), can become epileptic foci.

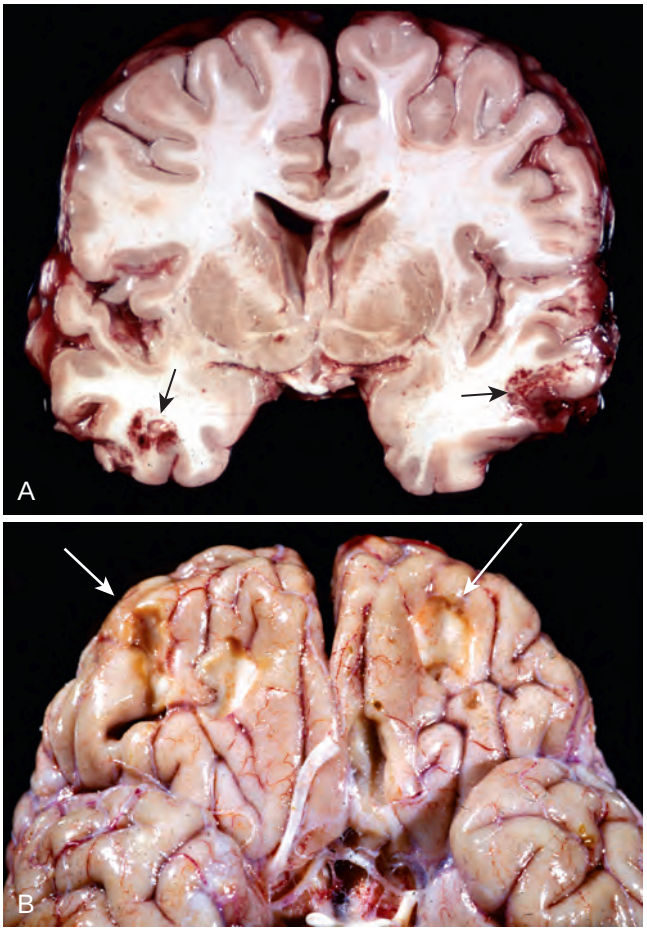

Figure 28.9 (A) Acute contusions are present in both temporal lobes, with areas of hemorrhage and tissue disruption *(arrows)*. (B) Remote contusions *(arrows)* are present on the inferior frontal surface of this brain and have a yellow color (plaque jaune) that reflects hemosiderin accumulation.

More extensive hemorrhagic regions of brain trauma give rise to larger cavitated lesions, which resemble remote infarcts. In old contusions, gliosis and residual hemosiderin-laden macrophages predominate.

Diffuse Axonal Injury

Traumatic brain injuries may also damage the deep white matter regions, cerebral peduncles, superior colliculi, and deep reticular formation in the brainstem. The microscopic findings include axonal swelling, indicative of *diffuse axonal injury,* and focal hemorrhagic lesions. As many as 50% of individuals who develop coma shortly after trauma, even without cerebral contusions, are believed to have diffuse axonal injury. Axons are injured directly by mechanical forces, with subsequent alterations in axoplasmic flow. Such injuries may occur from marked changes in angular acceleration (e.g., from blast injuries), even in the absence of physical impacts involving the skull.

MORPHOLOGY

Diffuse axonal injury is characterized by widespread, often asymmetric axonal swellings that appear within hours of the injury and may persist for much longer. The swelling is best demonstrated with silver impregnation techniques or with immunoperoxidase stains for axonally transported proteins, such as amyloid precursor protein and α-synuclein. Later, increased numbers of microglia are seen in damaged areas of the cerebral cortex, and subsequently there is degeneration of the involved fiber tracts.

Traumatic Vascular Injury

Vascular injury is a frequent component of CNS trauma. It results from disruption of the vessel wall and leads to hemorrhage in different anatomic sites (Table 28.1). Depending on the position of the ruptured vessel, hemorrhage may occur in the epidural, subdural, subarachnoid, and intraparenchymal compartments, sometimes in combination (Fig. 28.10). Epidural and subdural hemorrhages rarely occur outside of the setting of trauma; in some settings, such as coagulopathy or significant cerebral atrophy, subdural hemorrhages can follow even minor trauma. Subarachnoid hemorrhage almost always accompanies parenchymal trauma, but can also develop spontaneously secondary to vascular anomalies (discussed later).

Epidural Hematoma

The dura is fused with the periosteum and is supplied by a number of dural arteries. These arteries, most notably the middle meningeal artery, are vulnerable to traumatic injury. In adults, this most often occurs with temporal skull fractures in which the fracture crosses the course of the vessel. In children, in whom the skull is deformable, a temporary displacement of the skull bones leading to laceration of a vessel can occur in the absence of a skull fracture.

Once a vessel has been torn, the extravasation of blood under arterial pressure can cause the dura to separate from the periosteum, creating a space (Fig. 28.11). The expanding hematoma compresses the underlying brain. When blood accumulates slowly, patients may experience a lucid period

Table 28.1 Patterns of Hemorrhage in the Central Nervous System

Location	Etiology	Additional Features
Epidural space	Trauma	Usually associated with skull fracture (in adults); rapidly evolving neurologic symptoms (often after a short lucid period) that require intervention
Subdural space	Trauma	May follow minor trauma; slowly evolving neurologic symptoms, often with a delay from the time of injury
Subarachnoid space	Trauma	Typically associated with underlying parenchymal injury
	Vascular abnormality (arteriovenous malformation or aneurysm)	Sudden onset of severe headache, often with rapid neurologic deterioration; secondary injury may emerge and is associated with vasospasm
Intraparenchymal space	Trauma (contusions)	Selective involvement of the crests of gyri, where the brain is in contact with the inner surface of the skull (frontal and temporal tips, orbitofrontal surface)
	Ischemia (hemorrhagic conversion of an ischemic infarct)	Petechial hemorrhages in an area of previously ischemic brain, usually following the cortical ribbon
	Cerebral amyloid angiopathy	"Lobar" hemorrhage, involving subcortical white matter and often with extension into the subarachnoid space
	Hypertension	Centered in the deep white matter, thalamus, basal ganglia, or brainstem; may extend into the ventricular system
	Tumors (primary or metastatic)	Associated with high-grade gliomas or certain metastases (melanoma, choriocarcinoma, renal cell carcinoma)

before the onset of neurologic signs. A symptomatic epidural hematoma is a neurosurgical emergency; without prompt diagnosis and drainage, fatal brain herniation may occur within a few hours.

Subdural Hematoma

The dura is composed of two layers—an external collagenous layer and an inner more cellular layer containing fibroblasts. Bridging veins travel from the convexities of the cerebral hemispheres through the subarachnoid space and dura to empty into the dural sinuses. The brain is suspended in CSF, but the venous sinuses are fixed relative to the dura; as a result, traumatic displacement of the brain can tear the veins at the point where they penetrate the dura. The extravasated blood dissects through the two layers of the dura, producing a subdural hematoma. In older individuals with brain atrophy, the bridging veins are stretched, hence the increasing incidence of subdural hematoma with aging. Infants are also very susceptible to subdural hematomas because their bridging veins are thin-walled.

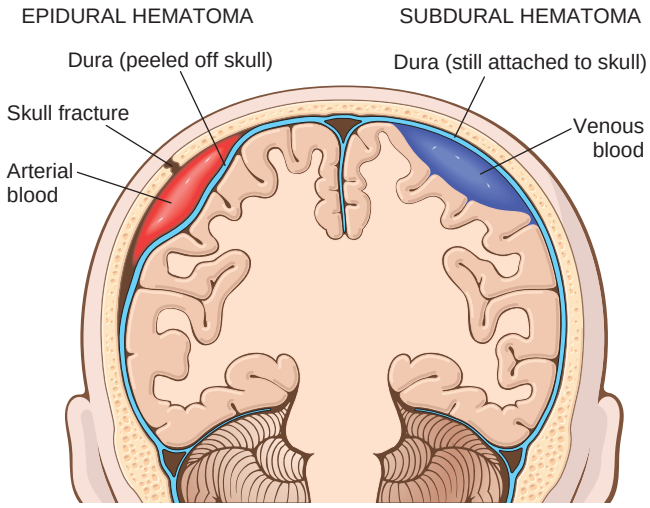

Figure 28.10 Epidural hematoma *(left)* in which rupture of a meningeal artery, usually associated with a skull fracture, leads to accumulation of arterial blood between the dura and the skull. In a subdural hematoma *(right)*, damage to bridging veins between the brain and the superior sagittal sinus leads to the accumulation of blood between the dura and the arachnoid.

MORPHOLOGY

Grossly, **acute subdural hematomas** appear as a collection of freshly clotted blood along the brain surface, without extension into the depths of sulci (Fig. 28.12). The underlying brain is flattened, and the subarachnoid space is often clear. Usually, venous bleeding is self-limited and the resulting hematoma is broken down and organized over time; this most often occurs in the following sequence:

- Lysis of the clot (about 1 week)
- Growth of fibroblasts from the dural surface into the hematoma (2 weeks)

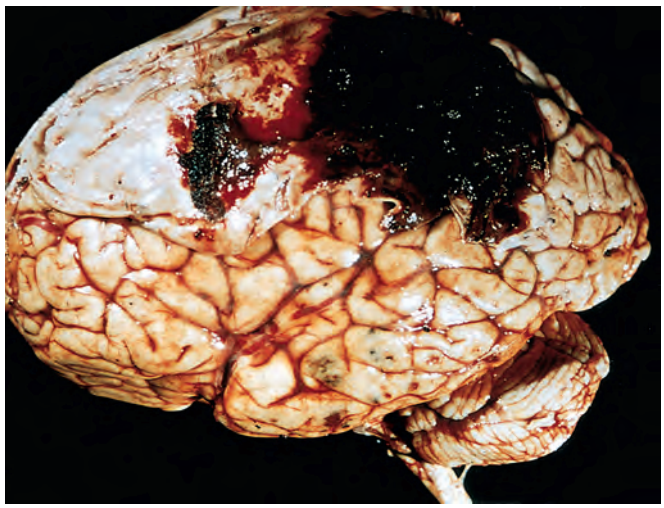

Figure 28.11 Epidural hematoma covering a portion of the dura. Also present are multiple small contusions in the temporal lobe. (Courtesy the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston, Mass.)

Figure 28.12 (A) Large organizing subdural hematoma attached to the dura. (B) Coronal section of the brain showing atrophy of the hemisphere compressed by the subdural hematoma shown in A.

- Early development of hyalinized connective tissue (1 to 3 months)

Typically, the organized hematoma is firmly attached to the inner surface of the dura by ingrowing fibrous tissue and is free of the underlying arachnoid, which does not contribute to healing. The lesion can eventually retract as the granulation tissue matures until only a thin layer of reactive connective tissue remains ("subdural membranes"). In other cases, however, multiple recurrent episodes of bleeding occur **(chronic subdural hematoma),** presumably from the thin-walled vessels of the granulation tissue.

Clinical Features

Symptomatic subdural hematomas most often manifest within 48 hours of injury. They are most common over the lateral aspects of the cerebral hemispheres and are bilateral in about 10% of cases. Neurologic signs are attributable to the pressure exerted on the adjacent brain. There may be focal signs, but often the clinical manifestations are nonlocalizing and include headache and confusion. Slowly progressive neurologic deterioration is typical, but acute decompensation may also occur. The treatment of subdural hematomas is to remove the blood and associated organizing tissue. The risk of repeat bleeding is greatest in the first few months after the initial hemorrhage.

Sequelae of Brain Trauma

A broad range of neurologic syndromes may become manifest months or years after brain trauma of any cause. These have gained increasing notice in the context of litigation involving issues of compensation for those in the civilian work force, professional athletes, and the military services.

- *Posttraumatic hydrocephalus* is largely due to obstruction of CSF resorption from hemorrhage into the subarachnoid space.
- *Chronic traumatic encephalopathy* (CTE, previously referred to as "dementia pugilistica") is a dementing illness that develops after repeated head trauma. Affected brains are atrophic, with enlarged ventricles, and show accumulation of tau-containing neurofibrillary tangles in a characteristic pattern involving gyral depths and perivascular regions in the frontal and temporal lobe cortices. Although concussion is thought of as having no structural consequences, it is clear that repeated events are antecedents to CTE; however, it remains uncertain which factors determine whether encephalopathy will ultimately develop (the number, frequency, and/or severity of individual traumatic events, or some combination of these).
- Other important sequelae of brain trauma include posttraumatic epilepsy, risk of infection, and psychiatric disorders.

Spinal Cord Injury

The spinal cord is vulnerable to trauma from its skeletal encasement. Most injuries that damage the cord are associated with the transient or permanent displacement of the vertebral column. The level of cord injury determines the extent of the neurologic manifestations: lesions involving the thoracic vertebrae or below can lead to paraplegia; cervical lesions result in quadriplegia; those above C4 can, in addition, lead to respiratory compromise from paralysis of the diaphragm. Damage at the region of impact to descending and ascending white matter tracts isolates the distal spinal cord from the rest of the brain. This interruption, paired with the localized gray matter damage at the level of the impact, is the principal cause of neurologic deficits.

MORPHOLOGY

The histologic features of traumatic injury of the spinal cord are similar to those found at other sites in the CNS. At the level of injury the acute phase consists of hemorrhage, necrosis, and axonal swelling in the surrounding white matter. The lesion tapers above and below the level of injury. In time, central areas of neuronal destruction become cystic and gliotic; cord sections above and below the lesion show secondary ascending and descending Wallerian degeneration, respectively, involving the long white-matter tracts at the site of trauma.

KEY CONCEPTS

Perinatal Brain Injury

- Timing of injury is critical, with earlier events resulting in greater damage and deficits.

- Cerebral palsy is the term used for nonprogressive deficits associated with injury during the prenatal and perinatal periods.

Trauma

- Physical injury to the brain can occur when the inside of the skull comes into forceful contact with the brain.
- In blunt trauma, if the head is mobile there may be brain injury both at the original point of contact (coup injury) and on the opposite side of the brain (contrecoup injury).
- Parenchymal injuries take the form of contusions, with hemorrhage extending into the subarachnoid space.
- Rapid displacement of the head and brain can tear axons (diffuse axonal injury), often immediately causing severe, irreversible neurologic deficits.
- Traumatic tearing of blood vessels leads to epidural or subdural hematoma.

CEREBROVASCULAR DISEASE

Cerebrovascular disease—injury to the brain as a consequence of altered blood flow—can be grouped into ischemic and hemorrhagic etiologies, with tissue infarction the ultimate consequence of both. "Stroke" is the clinical designation applied to these conditions and is defined as neurologic signs and symptoms that can be explained by a vascular mechanism, have an acute onset, and persist beyond 24 hours. (If symptoms disappear within 24 hours, the event is termed "transient ischemic event.") Cerebrovascular disease is the third leading cause of death (after heart disease and cancer) in the United States, and the most prevalent cause of morbidity and mortality from neurologic disease. Stroke stems from two major mechanisms:

- *Ischemia and/or hypoxia* resulting from impairment of blood supply and oxygenation of CNS tissue. This can be either a global or focal process, with the clinical manifestations determined by the region of brain affected. In the brain, embolism is a more common cause of vascular occlusion than thrombosis.
- *Hemorrhage* resulting from rupture of CNS vessels. Common etiologies include hypertension and vascular anomalies (aneurysms and malformations; see Table 28.1).

Hypoxia and Ischemia

Although the brain accounts for only 1% to 2% of body weight, it receives approximately 15% of the resting cardiac output and accounts for 20% of the body's oxygen consumption. Cerebral blood flow remains relatively constant over a wide range of blood pressure and intracranial pressure because of autoregulation of vascular resistance. The brain is strictly dependent on aerobic metabolism to meet its constant energy demands, and it may be deprived of oxygen by either hypoxemia (low blood oxygen content) or ischemia (inadequate blood flow). Inadequate blood flow may result from a reduction in perfusion pressure (as in hypotension), small- or large-vessel obstruction, or both.

When blood flow to a portion of the brain is reduced, the survival of the tissue at risk depends on the presence of collateral circulation, the duration of ischemia, and the magnitude and rapidity of the reduction of flow. These factors determine, in turn, the precise anatomic site and size of the lesion and, consequently, the clinical deficit.

The general biochemical changes in cells resulting from ischemia are discussed in Chapter 2. In addition to processes shared with ischemia in other parts of the body, ischemia in the CNS can result in inappropriate release of excitatory amino acid neurotransmitters such as glutamate, which can damage neurons by allowing excessive influx of calcium ions through N-methyl-D-aspartate (NMDA)-type glutamate receptors; this phenomenon is termed *excitotoxicity*. In the region of transition between necrotic tissue and the normal brain, there is an area of "at-risk" brain, referred to as the *penumbra;* this region can be rescued from cell death in many animal models with a variety of anti-apoptotic interventions, implying that ischemic neurons may die by apoptosis as well as necrosis.

Focal Cerebral Ischemia

Focal cerebral ischemia follows reduction or cessation of blood flow to a localized area of the brain due to partial or complete arterial obstruction. When the ischemia is sustained, infarction follows in the territory of the compromised vessel. The size, location, and shape of the infarct and the extent of tissue damage that results are influenced by the duration of the ischemia and the adequacy of collateral flow. The major source of collateral flow is the circle of Willis (supplemented by external carotid-ophthalmic artery collaterals). Inconstant collateral leptomeningeal vessels from the surface of the brain may also supply the distal branches of the anterior, middle, and posterior cerebral arteries through cortical-leptomeningeal anastomoses; in contrast, there is little if any collateral flow for the deep penetrating vessels of the thalamus, basal ganglia, and deep white matter.

Occlusive vascular disease of severity sufficient to lead to cerebral infarction may be due to embolization from a distant source, in situ thrombosis, or various vasculitides; the pathology of these conditions is also discussed in Chapters 4 and 11.

- *Embolism* to the brain occurs from a variety of sources. Cardiac mural thrombi are among the most common culprits; myocardial infarct, valvular disease, and atrial fibrillation are important predisposing factors. Next in frequency are thromboemboli originating from arteries, most often atheromatous plaques within the carotids. Other sources of emboli include paradoxical thromboemboli, particularly in children with cardiac anomalies; thromboemboli associated with cardiac surgery; and emboli of other types (tumor, fat, or air). The territory supplied by the middle cerebral artery—the direct extension of the internal carotid artery—is most frequently affected by embolic infarction; the incidence is about equal in the two hemispheres. Emboli tend to lodge where blood vessels branch or in areas of preexisting luminal stenosis. "Shower embolization," as in fat embolism, may occur after fractures; affected individuals manifest generalized cerebral dysfunction with disturbances of higher

cortical function and consciousness, often without localizing signs. Widespread hemorrhagic lesions involving the white matter are characteristic of embolization of bone marrow after trauma.

- *Thrombotic occlusion of the cerebral arteries* is most commonly caused by acute change of vulnerable atherosclerotic plaques, as in coronary artery disease (Chapter 12). The most common sites are the carotid bifurcation, the origin of the middle cerebral artery, and either end of the basilar artery. Thrombi cause progressive narrowing of the lumen, may be accompanied by anterograde extension, and may progress to fragmentation and distal embolization. Atherosclerotic cerebrovascular disease is frequently associated with systemic diseases such as hypertension and diabetes.
- *Inflammatory processes* that involve blood vessels may also lead to luminal narrowing, occlusion, and, hence, cerebral infarcts. Although infectious vasculitis of small and large vessels occurs with syphilis and tuberculosis, it is now more common in the setting of immunosuppression and opportunistic infection (e.g., aspergillosis). *Polyarteritis nodosa* and other noninfectious vasculitides may involve cerebral vessels and cause single or multiple infarcts throughout the brain. *Primary angiitis of the CNS* can also develop in the absence of systemic vasculitis.
- Other conditions that may cause thrombosis (and intracranial hemorrhage) include hypercoagulable states, dissecting aneurysm of extracranial arteries in the neck that supply the brain, and drug abuse (amphetamines, heroin, cocaine).

Brain infarcts are subdivided into two broad groups based on the presence of secondary hemorrhage. Because the brain has end-organ circulation with limited collateral supply, occlusive brain infarcts generally start as nonhemorrhagic (pale/anemic; Fig. 28.13A); clinically, these nonhemorrhagic infarcts are called ischemic, a confusing term as every infarct, not just this type, is caused by tissue ischemia. Secondary hemorrhage can occur from ischemia-reperfusion injury following spontaneous or therapeutic dissolution or fragmentation of the intravascular occlusive material. This process (termed *secondary hemorrhagic transformation* and leading to a hemorrhagic infarct) develops if the causative ischemic event lasts long enough to damage small blood vessels in the affected area; the resulting reperfusion hemorrhages are largely petechial in nature, but may be multiple or even confluent (see Fig. 28.13B). The clinical management of patients with nonhemorrhagic and hemorrhagic infarcts differs greatly, although the underlying causes are the same (for instance, thrombolytic therapy is contraindicated in a patient with brain hemorrhage of any etiology).

MORPHOLOGY

Both the gross and microscopic appearance of a **nonhemorrhagic infarct** changes over time. Grossly, there is little change in appearance during the first 6 hours of irreversible injury. By 48 hours, however, the tissue becomes pale, soft, and swollen, and the gray-white matter junction becomes indistinct. From 2 to 10 days, the brain becomes gelatinous and friable, and the previously ill-defined boundary between normal and infarcted tissue becomes more distinct as edema resolves in the viable adjacent tissue. From 10 days to 3 weeks, the tissue liquefies, eventually leaving a fluid-filled cavity that continues to expand until all of the dead tissue has been removed (Fig. 28.14).

Microscopically, the tissue reaction evolves along the following sequence:

- **Acute infarct** (Fig. 28.15A). After the first 6 to 12 hours, neurons in the affected area show eosinophilic neuronal necrosis (increased eosinophilia of the cytoplasm followed by nuclear pyknosis and karyorrhexis; "dead red neurons"); both cytotoxic and vasogenic edema are present. There is loss of the usual tinctorial characteristics of white- and gray-matter structures. Endothelial and glial cells, mainly astrocytes, swell, and myelinated fibers begin to disintegrate. Up to 48 hours, neutrophilic emigration progressively increases and then falls off (but is never as prominent as in myocardial infarction).
- **Subacute (evolving) infarct** (Fig. 28.15B). Phagocytic cells, derived from circulating monocytes and activated microglia, are evident at 48 to 72 hours and become the predominant cell type in the ensuing 2 to 3 weeks. The macrophages become stuffed with the products of myelin breakdown or blood and may persist in the lesion for months to years. Reactive astrocytes

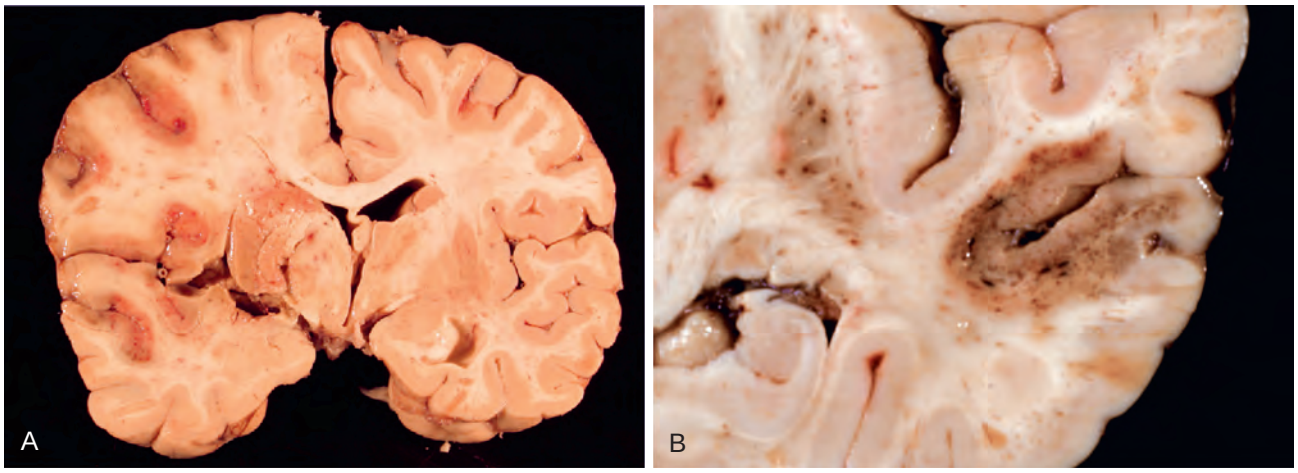

Figure 28.13 (A) An ischemic infarct involves the territory of the middle cerebral artery, including the striatum, on the left side of this brain. (B) A hemorrhagic infarct with punctate hemorrhages, consistent with ischemia-reperfusion injury, is present in the temporal lobe.

Figure 28.14 Old cystic infarct showing cavitation from loss of brain parenchyma.

and newly formed vessels can be seen at the periphery of the lesion as early as 1 week after the insult. As the process of liquefaction and phagocytosis proceeds, astrocytes at the edges of the lesion progressively enlarge, divide, and develop a prominent network of cytoplasmic extensions.

- **Healed infarct** (Fig. 28.15C). After several months, the astrocytic response recedes, leaving behind a dense meshwork of glial fibers admixed with new capillaries and some perivascular connective tissue. In the cerebral cortex, the cavity is separated from the meninges and subarachnoid space by a gliotic layer of tissue, which is derived from the molecular layer of the cortex. The pia and arachnoid are not affected. Infarcts undergo these reactive and reparative stages from the edges inward; thus, different areas of a lesion may appear chronologically divergent, revealing the natural progression of the response.

The features and temporal evolution of **hemorrhagic infarctions** parallel ischemic infarctions, with the addition of blood extravasation and resorption. In individuals receiving anticoagulant treatment, hemorrhagic infarcts may be associated with extensive intracerebral hematomas. Venous infarcts are often hemorrhagic and may occur after thrombotic occlusion of the superior sagittal sinus or other sinuses, or after occlusion of the deep cerebral veins. Neoplasms, localized infections, and other conditions leading to a hypercoagulable state increase the risk for venous thrombosis.

Lacunar Infarcts

Hypertension affects the deep penetrating arteries and arterioles that supply the basal ganglia and hemispheric white matter as well as the brainstem; these cerebral vessels develop *arteriolosclerosis,* also known as small vessel disease because it affects arteries 40 to 900 μm in diameter, described in more detail later. If this disease process progresses to thrombosis and complete vessel occlusion, the end-result is development of small cavitary infarcts known as *lacunes* or *lacunar infarcts* (Fig. 28.16). These lakelike spaces, arbitrarily defined as less than 15 mm wide, can be single or multiple and involve the putamen, globus pallidus, thalamus, internal capsule, deep white matter, caudate nucleus, and pons, in descending order of frequency. On microscopic

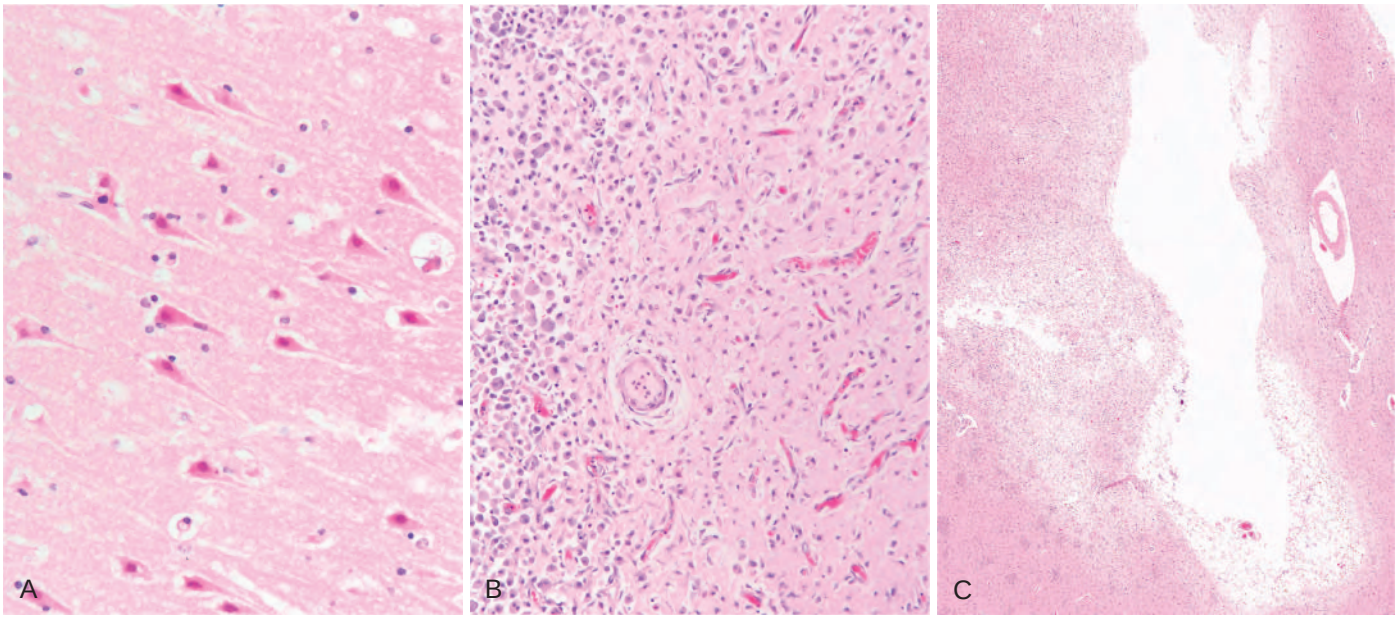

Figure 28.15 Cerebral infarcts. (A) Acute ischemic injury causes diffuse eosinophilia of neurons, which are beginning to shrink. (B) After about 10 days, the lesion is characterized by the presence of foamy macrophages *(best seen on the left)* and adjacent reactive gliosis with neovascularization *(on the right).* (C) Remote small infarct is seen as an area of tissue loss surrounded by residual gliosis.

Figure 28.16 Lacunar infarcts in the caudate and putamen *(arrows)*.

examination, there is tissue loss surrounded by gliosis. Depending on their location in the CNS, lacunar infarcts can be clinically silent or cause severe neurologic impairment. Affected vessels may also be associated with widening of the perivascular spaces without tissue infarction (*état criblé*).

Clinical Features

Deficits produced by infarction are determined by the anatomic distribution of the damage, rather than the underlying cause. Neurologic symptoms referable to the area of injury often develop rapidly, over minutes, and may continue to evolve over hours. There can be improvement in severity of symptoms that is associated with reversal of injury in the ischemic penumbra and resolution of associated local edema. In general, there is often slow improvement during a period of months. Because strokes are frequently associated with cardiovascular disease, many of the genetic and lifestyle risk factors are shared. Early diagnosis is of critical importance, as rapid treatment of nonhemorrhagic strokes with thrombolytic agents can often limit or entirely prevent the development of permanent neurologic deficits.

Global Cerebral Hypoxia/Ischemia

Global cerebral hypoxia or ischemia occurs when there is a generalized reduction of cerebral perfusion (as in cardiac arrest, shock, and severe hypotension) or decreased oxygen carrying capacity of the blood (e.g., in carbon monoxide poisoning). The clinical outcome varies with the severity and length of the insult. In mild cases, there may only be a transient postischemic confusional state, followed by complete recovery. Nevertheless, irreversible CNS damage may occur in individuals who experience global hypoxic and/or ischemic insults *(diffuse hypoxic/ischemic encephalopathy)*. Among CNS cells, there is a hierarchy of sensitivity to hypoxia/ischemia: neurons are the most sensitive, although glial cells (oligodendrocytes and astrocytes) are also vulnerable. The most sensitive neurons in the brain are pyramidal neurons in the hippocampus (especially area CA1, also referred to as Sommer sector), cerebellar Purkinje cells, and pyramidal neurons in the cerebral cortex (especially layers III and V); the molecular mechanisms underlying this selective vulnerability are not understood. With severe global cerebral hypoxia/ischemia, widespread neuronal death occurs, irrespective of regional vulnerability; patients who survive this injury often remain in a persistent vegetative state. Other patients meet the current clinical criteria for "brain death," including evidence of irreversible diffuse cortical injury (isoelectric, or "flat," electroencephalogram), brainstem damage (such as absent reflexes and respiratory drive), and absent cerebral perfusion. When individuals with this pervasive form of injury are maintained on mechanical ventilation, the brain gradually undergoes widespread liquefaction, producing so-called "respirator brain."

Border zone ("watershed") infarcts occur in the regions of the brain or spinal cord that lie at the most distal reaches of the arterial blood supply (i.e., the border zones between arterial territories). In the cerebral hemispheres, the border zone between the anterior and the middle cerebral artery distributions is at greatest risk. Damage to this region, located a few centimeters lateral to the interhemispheric fissure, results in a cortical wedge-shaped infarct that usually shows secondary hemorrhagic transformation (Fig. 28.17) and is often bilateral. Border zone infarcts usually develop after severe hypotensive episodes and are most commonly seen in patients resuscitated after cardiac arrest.

MORPHOLOGY

In the setting of global ischemia, the brain becomes edematous and swollen, producing widening of the gyri and narrowing of the sulci. The cut surface shows poor demarcation between gray and white matter. The microscopic features of irreversible ischemic injury evolve over time and mimic the changes seen in infarcts; the distinction between global and focal ischemic injury is based not on the nature of cellular pathology but on the overall pattern of brain involvement. **Early changes,** occurring 6 to 12 hours

Figure 28.17 Classic watershed infarct with secondary hemorrhagic transformation *(arrow)*; boundary between anterior and middle cerebral artery circulations.

after the insult, are seen in neurons (dead red neurons described earlier); similar acute changes occur somewhat later in astrocytes and oligodendroglia. **Subacute changes,** occurring at 24 hours to 2 weeks, include tissue necrosis, influx of macrophages, vascular proliferation, and reactive gliosis. **Repair,** robust after approximately 2 weeks, is characterized by removal of necrotic tissue, loss of normal CNS architecture, and gliosis. In the cerebral neocortex, the neuronal loss and gliosis are uneven, with preservation of some layers and destruction of others, producing a pattern of injury termed **laminar necrosis.**

Intracranial Hemorrhage

Hemorrhages may occur at any site within the cranium—outside the brain or within it (intraparenchymal). Hemorrhages in the epidural or subdural space are typically associated with trauma and were discussed earlier; hemorrhages within the brain parenchyma and in the subarachnoid space, in contrast, are more often a manifestation of underlying cerebrovascular disease and are discussed in the following sections (see Table 28.1).

Intraparenchymal Hemorrhage

Rupture of a small intraparenchymal vessel can result in a primary hemorrhage within the brain, often associated with sudden onset of neurologic symptoms (stroke); this should not be confused with the secondary hemorrhagic transformation of an occlusive infarct (described earlier). Spontaneous (nontraumatic) intraparenchymal hemorrhages occur most commonly in middle to late adult life, with a peak incidence at about 60 years of age. Hemorrhages in the basal ganglia and thalamus are commonly designated "ganglionic hemorrhages," whereas those that occur in the lobes of the cerebral hemispheres are called "lobar hemorrhages"; the two major causes of these patterns of hemorrhage are hypertension and cerebral amyloid angiopathy, respectively. In addition, other local and systemic factors may cause or contribute to nontraumatic hemorrhage, including systemic coagulation disorders, neoplasms, vasculitis, aneurysms, and vascular malformations.

Hypertension is the risk factor most commonly associated with deep brain parenchymal hemorrhages, accounting for more than 50% of clinically significant hemorrhages and for roughly 15% of deaths among individuals with chronic hypertension. *Hypertensive intraparenchymal hemorrhage* may originate in the putamen (50% to 60% of cases), thalamus, pons, cerebellar hemispheres (rarely), and other regions of the brain (Fig. 28.18A). Hypertension leads to a number of vessel wall abnormalities, including accelerated atherosclerosis in larger arteries, hyaline arteriolosclerosis in smaller arteries, and (in severe cases) proliferative changes and frank necrosis of arterioles. Arteriolar walls affected by hyaline change (Fig. 28.18B) are thickened but more vulnerable to rupture than normal vessels; these changes are most prominent in the basal ganglia and the subcortical white matter. As described earlier, if small arteries affected by hyaline arteriolosclerosis do not rupture but are occluded, the result is lacunar infarction.

Cerebral amyloid angiopathy (CAA) is the risk factor most commonly associated with lobar hemorrhages (Fig. 28.18C). In CAA, amyloidogenic peptides, usually the same ones found in Alzheimer disease (Aβ; see later), are deposited in the walls of medium- and small-caliber meningeal, cortical, and cerebellar vessels; involved vessels are rigid, and as a result fail to collapse during tissue processing and sectioning. Although similar to hyaline arteriolosclerosis on routine hematoxylin and eosin (H&E) stain, the hyaline material in CAA consists of β amyloid rather than collagen (Fig. 28.18D) and is primarily seen in the leptomeningeal and cortical (rather than basal ganglia and white matter) vessels. Amyloid deposition can weaken the vessel wall and lead to hemorrhage; as a result, many individuals with CAA have evidence of numerous small hemorrhages within the brain ("microbleeds") that can be visualized by various imaging methods. As with Alzheimer disease (discussed later), there is a relationship between polymorphisms in the gene that encodes apolipoprotein E (ApoE) and risk of disease; specifically, the presence of either an ε2 or ε4 allele increases the risk of bleeding. Autosomal dominant forms of CAA are associated with certain mutations in the *APP* gene, which encodes the precursor for the Aβ peptides that are prone to deposit as amyloid.

Other forms of hereditary small-vessel diseases of the CNS have been identified. *Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy* (CADASIL) is an autosomal dominant disorder caused by mutations in the *NOTCH3* gene that lead to misfolding of the extracellular domain of the NOTCH3 receptor. The disease is characterized clinically by recurrent small vessel strokes (usually infarcts, less often hemorrhages) and dementia. Imaging studies show that the first detectable changes are in white matter, usually presenting around 35 years of age and then progressing further over time. Other forms of the heritable small vessel disease include a disorder associated with mutations in the gene for COL4A1, a component of the vascular basement membrane.

MORPHOLOGY

Acute primary intraparenchymal hemorrhages are characterized by a central core of clotted blood that compresses the adjacent parenchyma; this compression leads to secondary infarction of the affected brain tissue, with anoxic neuronal and glial changes as well as edema. Eventually the edema resolves, hemosiderin- and lipid-laden macrophages appear, and proliferation of reactive astrocytes is seen at the periphery of the lesion; the cellular events then follow the same time course that is observed after cerebral infarction. Old hemorrhages show areas of parenchymal cavitary destruction with a rim of brownish discoloration.

Clinical Features

Intracerebral hemorrhage can be clinically devastating if it involves a large part of the brain or extends into the ventricular system. When hemorrhage affects smaller regions, it is either clinically silent or evolves like an infarct; over weeks or months, there is a gradual removal of the hematoma, sometimes with considerable clinical improvement. Again, the location of the hemorrhage determines the clinical manifestations.

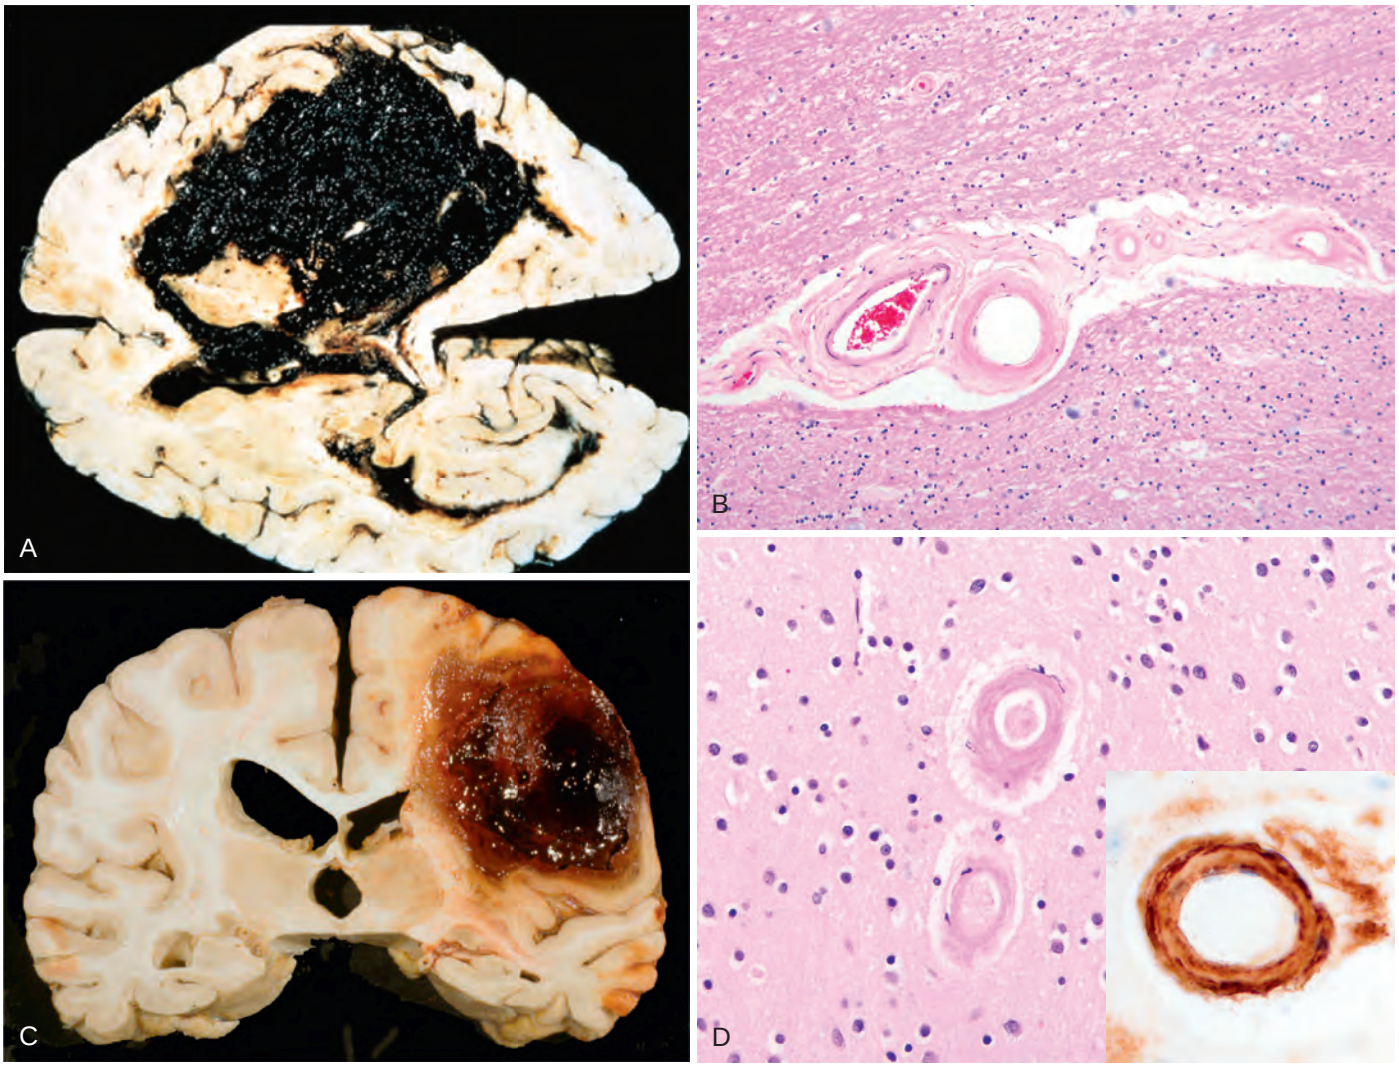

Figure 28.18 (A) Massive hypertensive ganglionic hemorrhage rupturing into a lateral ventricle. (B) Hyaline arteriolosclerosis (fibrosis and thickening of the arteriolar walls) develops in the basal ganglia and subcortical white matter of patients with long-standing hypertension; it is a risk factor for hypertensive hemorrhages as well as lacunar infarcts. (C) Large lobar hemorrhage due to cerebral amyloid angiopathy; it focally dissects into the subarachnoid space. (D) Amyloid deposition in cortical arterioles in cerebral amyloid angiopathy; *inset,* immunohistochemical staining for Aβ highlights the deposited material in the vessel wall. (C, Courtesy Dr. Dimitri Agamanolis, http://neuropathology-web.org.)

Subarachnoid Hemorrhage and Ruptured Saccular Aneurysm

The most frequent cause of spontaneous subarachnoid hemorrhage is rupture of a saccular ("berry") aneurysm in a cerebral artery. (As noted earlier, brain trauma is the most common cause of subarachnoid hemorrhage overall.) Nontraumatic subarachnoid hemorrhage may also result from rupture of a primary intracerebral hemorrhage into the ventricular system, vascular malformation, hematologic disturbances, and tumors.

Saccular aneurysm is the most common type of intracranial aneurysm; other aneurysm types include atherosclerotic (fusiform; mostly of the basilar artery), mycotic, traumatic, and dissecting. These latter three, like saccular aneurysms, are most often found in the anterior circulation, but more often cause cerebral infarction rather than subarachnoid hemorrhage.

Saccular aneurysms are found in about 2% of the population according to recent data from community-based radiologic studies. About 90% of saccular aneurysms are found near major arterial branch points in the anterior circulation (Fig. 28.19); multiple aneurysms exist in 20% to 30% of cases based on autopsy series.

Pathogenesis

Although the etiology of saccular aneurysms remains obscure, the structural abnormality of the involved vessel (absence of smooth muscle and intimal elastic lamina) suggests that they are developmental anomalies. The majority occur sporadically, but genetic factors may be important in their pathogenesis because there is an increased incidence of aneurysms in first-degree relatives of those affected. There is also an increased incidence in individuals with certain Mendelian disorders (e.g., autosomal dominant polycystic kidney disease, Ehlers-Danlos syndrome type

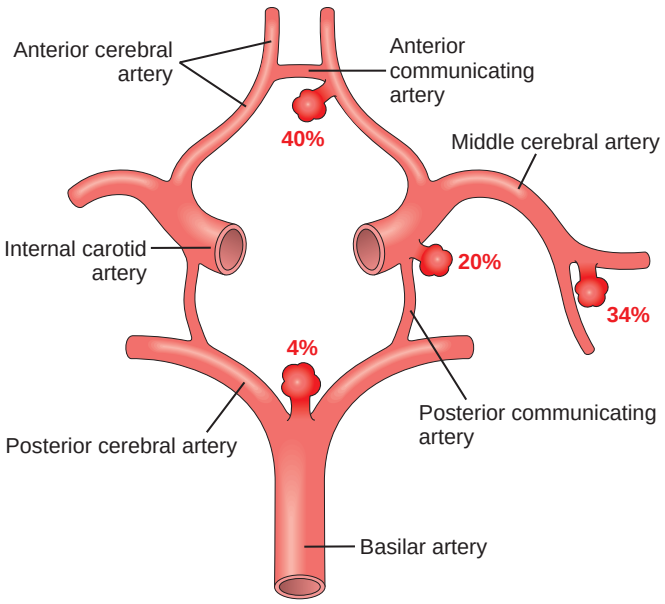

Figure 28.19 Common sites of saccular (berry) aneurysms in the circle of Willis.

IV, neurofibromatosis type 1 [NF1], and Marfan syndrome), fibromuscular dysplasia of extracranial arteries, and coarctation of the aorta. Other predisposing factors include cigarette smoking and hypertension (estimated to be present in about half of affected individuals). Although they are sometimes referred to as "congenital," the aneurysms are not present at birth but develop over time because of an underlying defect in the media of the vessel wall.

MORPHOLOGY

An unruptured saccular aneurysm is a thin-walled outpouching, usually at an arterial branch point along the circle of Willis or a major vessel just beyond. Saccular aneurysms measure from a few millimeters to 2 or 3 cm in diameter and have a bright red, shiny surface and a thin, translucent wall (Fig. 28.20). Atheromatous plaques, calcification, or thrombi may be found in the wall or lumen of the aneurysm. Sometimes there is evidence of prior hemorrhage, in the form of brownish discoloration of the adjacent brain and meninges. The neck of the aneurysm may be wide or narrow. Rupture usually occurs at the apex of the sac and leads to extravasation of blood into the subarachnoid space, the substance of the brain, or both. The arterial wall adjacent to the neck of the aneurysm often shows some intimal thickening and attenuation of the media. Smooth muscle and intimal elastic lamina do not extend into the neck and are absent from the aneurysm sac itself, which is made up of thickened hyalinized intima and a covering of adventitia.

Clinical Features

Rupture of an aneurysm leading to subarachnoid hemorrhage is most frequent in the fifth decade and is slightly more frequent in women. Overall, aneurysms rupture at a rate of 1.3% per year, but the risk is higher for larger aneurysms; for example, aneurysms greater than 10 mm in diameter have a roughly 50% risk of bleeding per year. Rupture may occur at any time, but in about one-third of cases it is associated with acute increases in intracranial pressure, such as with straining at stool or sexual orgasm. Blood under arterial pressure is forced into the subarachnoid space, and affected individuals are stricken with a sudden, excruciating headache ("the worst headache I've ever had") and rapidly lose consciousness. Between 25% and 50% of patients die with the first rupture, but patients who survive often improve and recover consciousness in minutes. Repeat bleeding is common in survivors and unpredictable in timing. With each episode of bleeding, the prognosis is worse.

The clinical consequences of blood in the subarachnoid space can be separated into acute events (occurring within

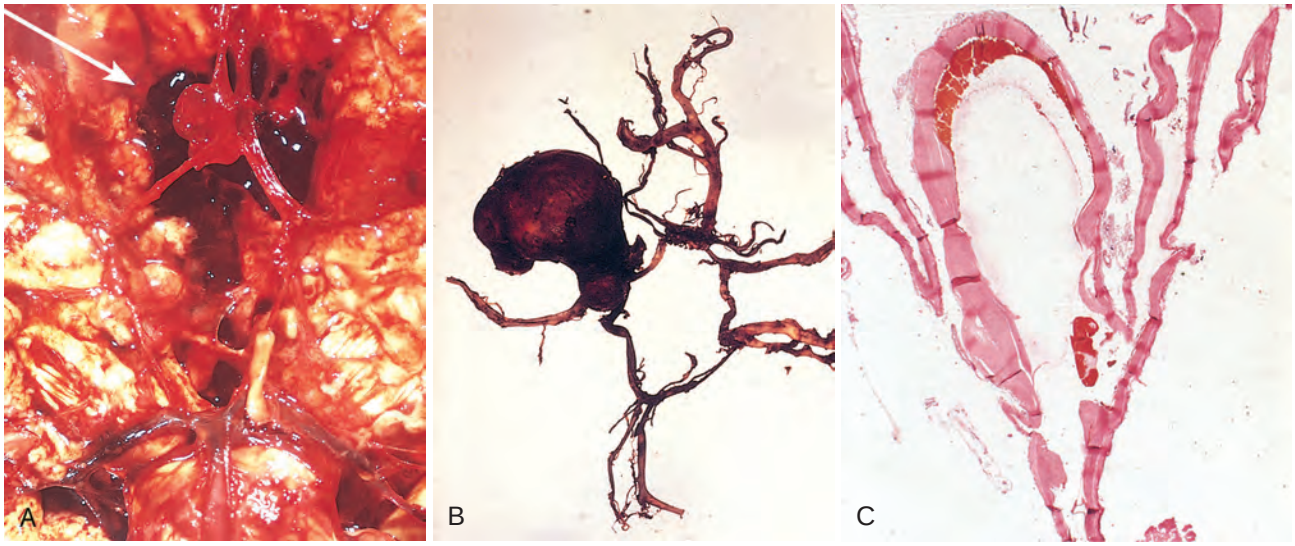

Figure 28.20 (A) View of the base of the brain, dissected to show the circle of Willis with an aneurysm of the anterior cerebral artery *(arrow)*. (B) Dissected circle of Willis to show large aneurysm. (C) Section through a saccular aneurysm showing the hyalinized fibrous vessel wall (hematoxylin and eosin).

hours to days after the hemorrhage) and late sequelae associated with the healing process. In the first few days after a subarachnoid hemorrhage, regardless of the etiology, there is an increased risk of additional ischemic injury from vasospasm affecting vessels bathed in the extravasated blood. This problem is of greatest significance in cases of basal subarachnoid hemorrhage, in which vasospasm can involve major vessels of the circle of Willis. Various mediators have been proposed to have a role in this process, including endothelins, nitric oxide, and arachidonic acid metabolites. In the healing phase of subarachnoid hemorrhage, meningeal fibrosis and scarring occur, sometimes leading to obstruction of CSF flow as well as interruption of the normal pathways of CSF resorption.

Vascular Malformations

Vascular malformations of the brain are classified into four principal groups: arteriovenous malformations, cavernous malformations, capillary telangiectasias, and venous angiomas. Of these, the first two are the types associated with risk of hemorrhage and development of neurologic symptoms. Although lacking morphologic features that typify neoplasms, arteriovenous malformations are frequently associated with activating somatic mutations in the *KRAS* oncogene within the endothelial cells that line the malformed vessels, suggesting that dysregulated RAS signaling has a central role in their pathogenesis.

MORPHOLOGY

Arteriovenous malformations (tangled networks of wormlike vascular channels with high blood flow due to prominent, pulsatile arteriovenous shunting) may involve vessels in the subarachnoid space, the brain, or both (Fig. 28.21). They are composed of greatly enlarged blood vessels separated by gliotic tissue, often with evidence of prior hemorrhage. Some vessels can be recognized as arteries with duplication and fragmentation of the internal elastic lamina, while others show marked thickening or partial replacement of the media by hyalinized connective tissue.

Cavernous malformations consist of distended, loosely organized vascular channels arranged back to back with collagenized walls of variable thickness; there is usually no brain parenchyma between vessels in this type of malformation. They occur most often in the cerebellum, pons, and subcortical regions, in decreasing order of frequency, and are "low-flow" channels that do not participate in arteriovenous shunting. Foci of old hemorrhage, infarction, and calcification frequently surround the abnormal vessels.

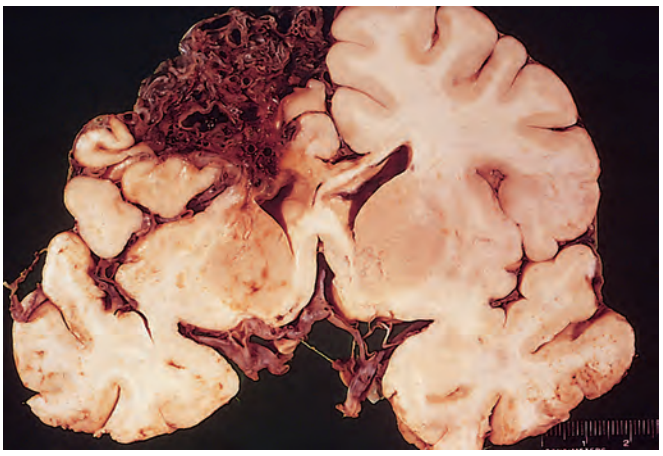

Figure 28.21 Large arteriovenous malformation in the left cerebral hemisphere.

Clinical Features

Arteriovenous malformations are the most common clinically significant vascular malformation. Males are affected twice as frequently as females. The lesion often presents between 10 and 30 years of age as a seizure disorder, an intracerebral hemorrhage, or a subarachnoid hemorrhage. The most common site is the territory of the middle cerebral artery, particularly its posterior branches. Large arteriovenous malformations occurring in the newborn period can lead to congestive heart failure because of shunt effects, especially if the malformation involves the vein of Galen. Cavernous malformations are unique among this group of disorders in that familial forms are relatively common. Multiplicity of lesions is a hallmark of familial cases, which are inherited as a highly penetrant autosomal dominant trait.

Vascular Dementia

Individuals who, over the course of many months and years, suffer multiple, bilateral, gray matter (cortex, thalamus, basal ganglia) and white matter (centrum semiovale) infarcts may develop a distinctive clinical syndrome characterized by dementia, gait abnormalities, and pseudobulbar signs, often with superimposed focal neurologic deficits. The syndrome, generally referred to as *vascular dementia,* is caused by multifocal vascular disease of several types, including (1) cerebral atherosclerosis, (2) vessel thrombosis or embolization from carotid vessels or from the heart, and (3) cerebral arteriolosclerosis from chronic hypertension. When the pattern of injury preferentially involves large areas of the subcortical white matter with myelin and axon loss, the disorder is referred to as *Binswanger disease (subcortical white matter dementia);* this distribution of vascular white-matter injury must be distinguished clinically and radiologically from other diseases that affect the hemispheral white matter. In addition, many individuals with neurodegenerative diseases resulting in cognitive impairment or dementia also have evidence of cerebrovascular disease. The presence of significant cerebrovascular disease increases risk of neurologic impairment for a given level of lesions associated with the degenerative diseases, suggesting that it is an independent contributing factor to disruption of normal brain function.

KEY CONCEPTS

CEREBROVASCULAR DISEASES

- Stroke is the clinical term for acute-onset neurologic deficits that last longer than 24 hours and that are a consequence of vessel occlusion or vessel rupture.
- Cerebral infarction follows loss of blood supply and can be focal, widespread, or restricted to regions with the least robust vascular supply (boundary zones).

- Large artery infarcts are most commonly embolic; with subsequent dissolution of the embolus and reperfusion, a nonhemorrhagic infarct can become hemorrhagic.
- Primary intraparenchymal hemorrhages lead to infarction of the adjacent brain parenchyma and are typically either ganglionic (most commonly due to hypertension) or lobar (most commonly due to CAA).
- Hyaline arteriolosclerosis (small vessel disease), which is caused by a long-standing hypertension, can lead to either lumen occlusion (resulting in a lacunar infarct) or wall rupture (resulting in a ganglionic hemorrhage).
- Spontaneous subarachnoid hemorrhage is usually caused by a structural vascular abnormality, such as an aneurysm or arteriovenous malformation.

INFECTIONS

Infection may damage the nervous system directly through injury of neurons or glia by the infectious agent, or indirectly through microbial toxins, the destructive effects of the inflammatory response, or as a result of immune-mediated mechanisms. There are four principal routes by which microbes enter the nervous system.

- *Hematogenous spread* is the most common; infectious agents ordinarily gain access through the arterial circulation, but retrograde venous spread can occur via anastomoses with veins of the face.
- *Direct implantation* of microorganisms is most often traumatic, but can be sometimes associated with congenital malformations (e.g., meningomyelocele) that provide ready access for microorganisms.
- *Local extension* can originate from infected adjacent structures, such as air sinuses, teeth, skull, or vertebrae.
- Viruses also may be transported along the *peripheral nervous system,* as occurs with rabies and herpes zoster viruses.

General aspects of the pathology of infectious agents are discussed in Chapter 8; distinctive forms of CNS infections are described herein (Table 28.2).

Acute Meningitis

Meningitis is an inflammatory process of the leptomeninges and CSF within the subarachnoid space, usually caused by an infection. *Meningoencephalitis* refers to inflammation of the meninges and brain parenchyma. Although infections are the most common causes of meningitis and meningoencephalitis, this reaction may also occur in response to a nonbacterial irritant introduced into the subarachnoid space *(chemical meningitis)* or in the context of a systemic autoimmune disease. Based on the etiology and clinical evolution of the illness, infectious meningitis is broadly classified into *acute pyogenic* (usually bacterial), *aseptic* (usually acute or subacute viral), and *chronic* (usually tuberculous, spirochetal, or cryptococcal). Each type is accompanied by characteristic changes in the CSF.

Table 28.2 Common Central Nervous System Infections

Type of Infection	Clinical Syndrome	Common Causative Organisms
Bacterial Infections		
Meningitis	Acute pyogenic meningitis	*Escherichia coli* or group B streptococci (infants) *Neisseria meningitidis* (young adults) *Streptococcus pneumoniae* or *Listeria monocytogenes* (older adults)
	Chronic meningitis	*Mycobacterium tuberculosis*
Localized infections	Abscess	Streptococci and staphylococci
	Empyema	Polymicrobial (staphylococci, anaerobic gram-negative)
Viral Infections		
Meningitis	Acute aseptic meningitis	Enteroviruses Influenza species Lymphocytic choriomeningitis virus
Encephalitis	Encephalitic syndromes	Herpes simplex (HSV-1, HSV-2) Cytomegalovirus Human immunodeficiency virus JC polyomavirus (progressive multifocal leukoencephalopathy)
	Arthropod-borne encephalitis	West Nile virus Eastern equine encephalitis virus Western equine encephalitis virus St. Louis encephalitis virus La Crosse encephalitis virus Venezuelan equine encephalitis virus Japanese encephalitis virus Tick-borne encephalitis virus
Brainstem and spinal cord syndromes	Rhombencephalitis	Rabies
	Acute flaccid myelitis/ poliomyelitis	Poliovirus West Nile virus Enterovirus D68
Spirochetes and Fungi		
Meningoencephalitic syndromes	Neurosyphilis	*Treponema pallidum*
	Lyme disease (neuroborreliosis)	*Borrelia burgdorferi*
	Fungal meningitis	*Cryptococcus neoformans* *Candida albicans*
Protozoa and Metazoa		
Encephalitis	Amebic encephalitis	*Balamuthia* and *Acanthamoeba* species *Naegleria* species
Localized infections	Toxoplasmosis	*Toxoplasma gondii*
	Cysticercosis	*Taenia solium*

Acute Pyogenic (Bacterial) Meningitis

Distinctive microorganisms cause acute pyogenic meningitis in various age groups: *Escherichia coli* and the group B streptococci in neonates; *Streptococcus pneumoniae* and *Listeria monocytogenes* in the elderly; and *Neisseria meningitidis* in adolescents and young adults, with clusters of cases raising public health concerns. The introduction of immunization against *Haemophilus influenzae* has markedly reduced the incidence of this infection in the developed world, particularly among infants (who used to be at high risk).

Affected individuals typically show systemic signs of infection superimposed on symptoms related to meningeal irritation and neurologic impairment, including headache, photophobia, irritability, clouding of consciousness, and neck stiffness. A spinal tap yields cloudy or frankly purulent CSF with as many as 90,000 neutrophils per cubic millimeter, increased CSF pressure and increased protein concentration, and markedly reduced glucose content. Untreated pyogenic meningitis can be fatal, while effective treatment with antibiotics markedly reduces mortality. One feared complication is the *Waterhouse-Frederichsen syndrome,* which results from meningitis-associated septicemia and hemorrhagic infarction of the adrenal glands (Chapter 24). It occurs most often with meningococcal and pneumococcal meningitis. In the immunosuppressed individual, purulent meningitis may be caused by several other infectious agents, such as *Klebsiella* or anaerobic organisms, and may have an atypical clinical course and uncharacteristic CSF findings, rendering timely diagnosis more difficult.

MORPHOLOGY

In acute meningitis, an exudate is evident within the leptomeninges over the surface of the brain (Fig. 28.22). The meningeal vessels are engorged and stand out prominently. The anatomic distribution of the exudate varies; in *H. influenzae* meningitis, for example, it is usually basal, whereas in pneumococcal meningitis it is often densest over the cerebral convexities near the sagittal sinus. From the areas of greatest accumulation, tracts of pus follow along blood vessels on the surface of the brain. When the meningitis is fulminant, the inflammation may extend to the ventricles, producing ventriculitis. The ventricles may also be the portal for CSF involvement by blood-borne infections because the choroid plexus lacks a blood-brain barrier.

On microscopic examination, neutrophils fill the subarachnoid space in severely affected areas and are found predominantly around the leptomeningeal blood vessels in less severe cases. Particularly in untreated meningitis, Gram stain reveals variable numbers of bacteria. In fulminant meningitis, the inflammatory cells infiltrate the walls of the leptomeningeal veins and may extend focally into the substance of the brain (cerebritis); secondary vasculitis and venous thrombosis may lead to hemorrhagic cerebral infarction.

Leptomeningeal fibrosis may follow pyogenic meningitis and cause hydrocephalus. Particularly in pneumococcal meningitis, large quantities of the capsular polysaccharide of the organism produce a gelatinous exudate that promotes arachnoid fibrosis, a condition referred to as *chronic adhesive arachnoiditis*.

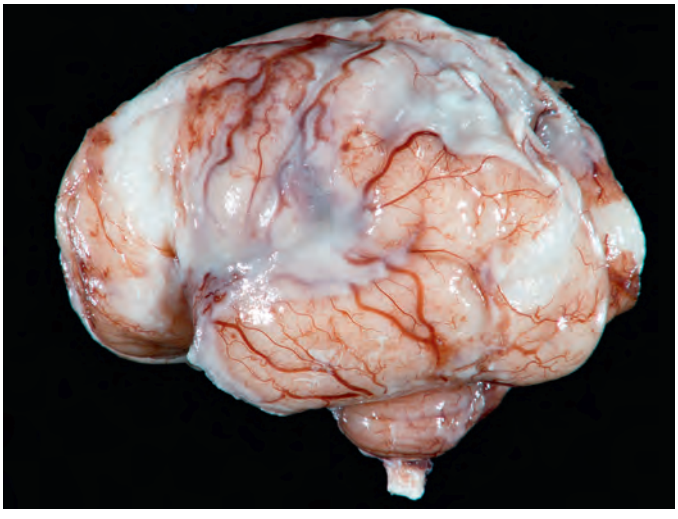

Figure 28.22 Pyogenic meningitis. A thick layer of suppurative exudate covers the brain surface and thickens the leptomeninges.

Acute Aseptic (Viral) Meningitis

Aseptic meningitis is a clinical term used for an absence of organisms by bacterial culture in a patient with manifestations of meningitis, including meningeal irritation, fever, and alterations of consciousness of relatively acute onset. The disease is generally of viral etiology, but may be bacterial, rickettsial, or autoimmune in origin. The clinical course is less fulminant than that of pyogenic meningitis, and the CSF findings also differ; in aseptic meningitis, there is a lymphocytic pleocytosis, the protein elevation is only moderate, and the glucose content is nearly always normal. The viral aseptic meningitides are usually self-limited and are treated symptomatically. Remarkably, the etiologic agent is identified in only a minority of cases; however, this may change through use of more sensitive and specific detection techniques (such as next-generation sequencing), which are under development. When pathogens are identified, enteroviruses are the most common etiology, accounting for 80% of cases. The spectrum of pathogens varies seasonally and geographically. An aseptic meningitis-like picture may also develop subsequent to rupture of an epidermoid cyst into the subarachnoid space or the introduction of a chemical irritant (chemical meningitis). The CSF is sterile in these cases, and there is pleocytosis with neutrophils and an increased protein concentration, but the sugar content is usually normal.

Acute Focal Suppurative Infections

Focal suppurative infections are typically caused by pyogenic bacteria or fungi, and can arise in several different compartments including the brain parenchyma, subdural space, and extradural space.

Brain Abscess

A brain abscess is a localized focus of necrosis of brain tissue with accompanying inflammation, usually caused by a bacterial infection. Brain abscesses may arise by direct implantation of organisms, local extension from adjacent

foci (mastoiditis, paranasal sinusitis), or hematogenous spread (usually from a primary site in the heart, lungs, or bones of the extremities, or secondary to bacteremia from dental procedures). Predisposing conditions include acute bacterial endocarditis, which may give rise to multiple brain abscesses; congenital heart disease with right-to-left shunting and loss of pulmonary filtration of organisms; chronic pulmonary sepsis, as in bronchiectasis; and systemic disease with immunosuppression. Streptococci and staphylococci are the most common offending organisms identified in nonimmunosuppressed patients.

MORPHOLOGY

Abscesses are discrete lesions with central liquefactive necrosis surrounded by brain swelling (Fig. 28.23). At the outer margin of the necrotic lesion, there is exuberant granulation tissue with neovascularization. The newly formed vessels are abnormally permeable, accounting for marked vasogenic edema in the adjacent brain tissue. In well-established lesions, a collagenous capsule is produced by fibroblasts derived from the walls of blood vessels. Outside the fibrous capsule is a zone of reactive gliosis containing numerous gemistocytic astrocytes.

Clinical Features

Cerebral abscesses are destructive lesions, and patients often present with progressive focal neurologic deficits; signs and symptoms related to increased intracranial pressure may also develop. Typically, the CSF has a high white cell count and an increased protein concentration, but the glucose content is normal. The source of infection may be apparent or may be traced to a small distant focus that is not symptomatic. The increased intracranial pressure can lead to fatal herniation; other complications include abscess rupture with ventriculitis or meningitis, and venous sinus thrombosis. With surgery and antibiotic treatment, the otherwise high mortality rate can be reduced to less than 10%.

Subdural Empyema

Bacterial, and rarely fungal, infections of the skull bones or air sinuses can spread to the subdural space, producing a subdural empyema. Although the underlying arachnoid and subarachnoid spaces are usually not affected, a large subdural empyema with mass effect and/or thrombophlebitis of the bridging veins can cause venous occlusion and infarction of the brain. In addition to symptoms referable to the source of the infection, most patients are febrile and have headache and neck stiffness. The CSF profile is similar to that seen in brain abscesses because both are parameningeal infectious processes. If untreated, focal neurologic signs, lethargy, and coma may develop. With prompt diagnosis and treatment, including surgical drainage, resolution and full recovery is possible, the only residuum being a thickened dura.

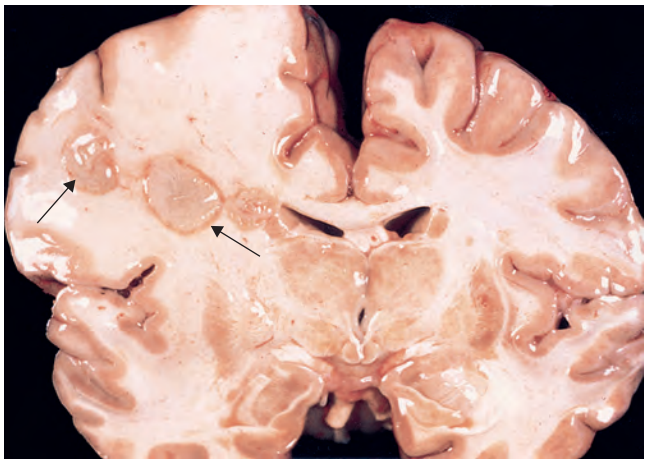

Figure 28.23 Cerebral abscesses *(arrows)*.

Extradural Abscess

Extradural abscess, commonly associated with osteomyelitis, often arises from an adjacent focus of infection, such as sinusitis, or following a surgical procedure. When the process occurs in the spinal epidural space, it may cause spinal cord compression and constitute a neurosurgical emergency.

Chronic Bacterial Meningoencephalitis

Chronic bacterial infection of the meninges and the brain may be caused by *Mycobacterium tuberculosis*, *Treponema pallidum*, and *Borrelia* species.

Tuberculosis

Tuberculosis of the CNS may be part of active disease elsewhere in the body, or appear in isolation following seeding from silent lesions elsewhere, usually the lungs. It may involve the meninges or the brain.

MORPHOLOGY

The most common pattern of tuberculous involvement is a diffuse **meningoencephalitis.** The subarachnoid space contains a gelatinous or fibrinous exudate that characteristically involves the base of the brain, effacing the cisterns and encasing cranial nerves. There may be discrete, white areas of inflammation scattered over the leptomeninges. On microscopic examination, involved areas contain a mixed inflammatory infiltrate with lymphocytes, plasma cells, and macrophages. Florid cases show well-formed granulomas with caseous necrosis and giant cells. Arteries running through the subarachnoid space may show obliterative endarteritis and marked intimal thickening. Organisms can often be seen with acid-fast stains. The infectious process may spread to the choroid plexus and ependymal surface, traveling through the CSF. In long-standing cases, a dense, fibrous adhesive arachnoiditis may develop, most conspicuous around the base of the brain. Hydrocephalus may result.

CNS involvement may also take the form of one or more well-circumscribed intraparenchymal masses **(tuberculomas),** which may be associated with meningitis. A tuberculoma may be as large as several centimeters in diameter, causing significant mass effect. These granulomas usually have central caseous necrosis; calcification may occur in inactive lesions.

Clinical Features

Patients with tuberculous meningitis usually have headache, malaise, mental confusion, and vomiting. The CSF typically shows a pleocytosis made up of mononuclear cells or a

mixture of neutrophils and mononuclear cells, an elevated protein concentration (often strikingly so), and a moderately reduced or normal glucose. The most serious complications of chronic tuberculous meningitis are arachnoid fibrosis producing hydrocephalus and obliterative endarteritis producing arterial occlusion and brain infarction. When the process involves the spinal cord subarachnoid space, nerve roots may also be affected. Tuberculomas produce symptoms typical of space-occupying brain lesions and must be distinguished from CNS tumors.

CNS tuberculosis in patients with acquired immunodeficiency syndrome (AIDS) is pathologically similar, but there may be less host reaction than in immunocompetent individuals.

Neurosyphilis

Neurosyphilis is a manifestation of the tertiary stage of syphilis and occurs in only about 10% of individuals with untreated infection. The major patterns of CNS involvement are meningovascular neurosyphilis, paretic neurosyphilis, and tabes dorsalis. Affected individuals often show an incomplete or mixed picture, most commonly the combination of tabes dorsalis and paretic disease (taboparesis). Because of impaired cell-mediated immunity, individuals infected with HIV are at increased risk for neurosyphilis, particularly acute syphilitic meningitis or meningovascular disease; the rate of disease progression and severity are also accelerated.

MORPHOLOGY

Neurosyphilis presents in several distinct forms.

- **Meningovascular neurosyphilis** is chronic meningitis involving the base of the brain and more variably the cerebral convexities and spinal leptomeninges. In addition, there may be an associated obliterative endarteritis (Heubner arteritis) accompanied by a distinctive perivascular inflammatory reaction rich in plasma cells and lymphocytes. Cerebral gummas (plasma cell-rich mass lesions) may also occur in the meninges and extend into the parenchyma.
- **Paretic neurosyphilis** is caused by invasion of the brain by *T. pallidum* and manifests as insidious but progressive cognitive impairment associated with mood alterations (including delusions of grandeur) that terminate in severe dementia **(general paresis of the insane).** Parenchymal damage of the cerebral cortex is particularly common in the frontal lobe, but also occurs in other areas of the isocortex. The lesions are characterized by loss of neurons, proliferation of microglia, gliosis, and iron deposits; the latter are demonstrable with the Prussian blue stain perivascularly and in the neuropil, and are presumably the sequelae of small bleeds stemming from microvascular damage. The spirochetes can, at times, be demonstrated in tissue sections.
- **Tabes dorsalis** is the result of damage to the sensory axons in the dorsal roots. This causes impaired joint position sense and ataxia (locomotor ataxia); loss of pain sensation, leading to skin and joint damage (Charcot joints); other sensory disturbances, particularly the characteristic "lightning pains"; and absence of deep tendon reflexes. On microscopic examination, there is loss of both axons and myelin in the dorsal roots, with corresponding pallor and atrophy in the dorsal columns of the spinal cord. Organisms are not demonstrable in the cord lesions.

Neuroborreliosis (Lyme Disease)

Lyme disease is caused by the spirochete *Borrelia burgdorferi,* which is transmitted by various species of *Ixodes* tick (Chapter 8). Involvement of the nervous system is referred to as *neuroborreliosis*. Neurologic symptoms are highly variable and include aseptic meningitis, facial nerve palsies and other polyneuropathies, as well as encephalopathy. The rare cases that have come to autopsy have shown a focal proliferation of microglial cells in the brain as well as scattered extracellular organisms.

Viral Meningoencephalitis

Viral encephalitis is a parenchymal infection of the brain almost invariably associated with meningeal inflammation (meningoencephalitis) and sometimes with simultaneous involvement of the spinal cord (encephalomyelitis).

Some viruses have a propensity to infect the nervous system. Such neural tropism takes several forms: some infect specific cell types (e.g., oligodendrocytes), while others preferentially involve particular areas of the brain (e.g., medial temporal lobes or the limbic system). Latency is an important phase of several viral infections of the CNS (e.g., herpes zoster and progressive multifocal leukoencephalopathy). Systemic viral infections in the absence of direct evidence of viral penetration into the CNS may be followed by an immune-mediated disease, such as perivenous demyelination. Viral infection of the fetus may cause congenital malformations, as occurs with rubella and Zika virus. A slowly progressive degenerative disease syndrome may follow many years after a viral illness; an example is postencephalitic parkinsonism after the 1918 viral influenza pandemic.

Arthropod-Borne Viral Encephalitis

Arboviruses are an important cause of epidemic encephalitis, especially in tropical regions of the world, and are capable of causing serious morbidity and high mortality. In the Western hemisphere, the most important arboviruses are Eastern and Western equine, West Nile, Venezuelan, St. Louis, and La Crosse; elsewhere in the world, pathogenic arboviruses include Japanese B (Far East), Murray Valley (Australia and New Guinea), and tick-borne (Russia and Eastern Europe).

All of these viruses have animal hosts and insect vectors. Clinically, affected individuals develop generalized neurologic deficits, such as seizures, confusion, delirium, and stupor or coma, as well as focal signs, such as reflex asymmetry and ocular palsies. Involvement of the spinal cord in West Nile encephalitis can lead to a polio-like syndrome with paralysis. In general, the CSF is usually colorless, with slightly elevated pressure, an elevated protein level, and a normal glucose. Initially the CSF exhibits a neutrophilic pleocytosis, but this rapidly converts to a lymphocytosis.

MORPHOLOGY

The encephalitides caused by various arboviruses produce similar histopathologic changes that differ only in severity and extent. Characteristically, there is a meningoencephalitis marked by the perivascular accumulation of lymphocytes (and sometimes

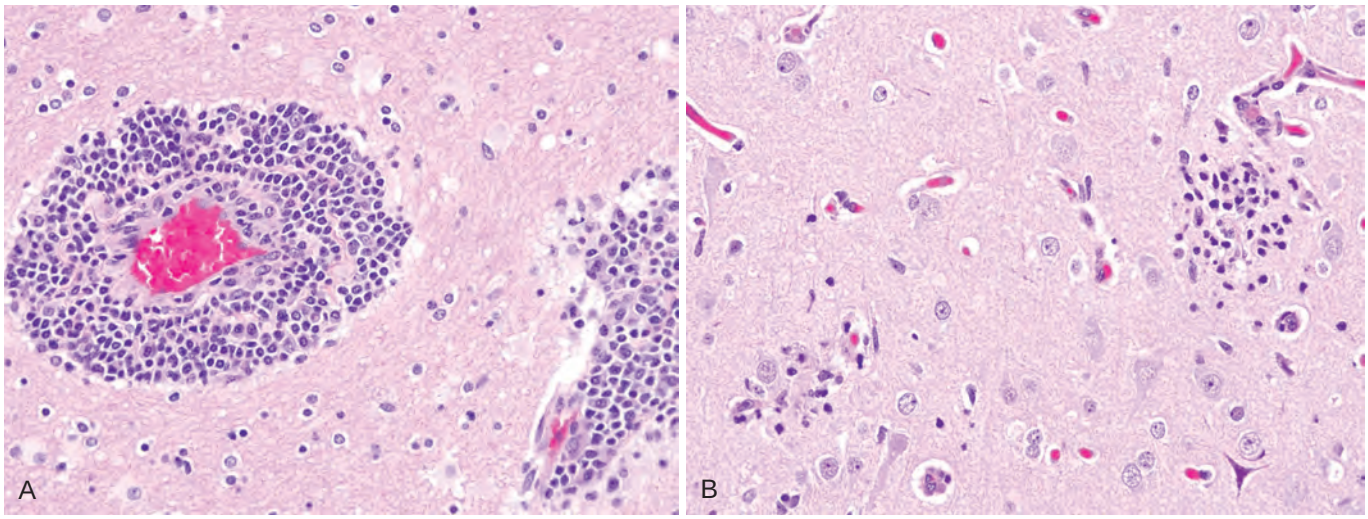

Figure 28.24 Characteristic findings of viral encephalitis include perivascular cuffs of lymphocytes (A) and microglial nodules (B).

neutrophils) (Fig. 28.24A). Multiple foci of necrosis of gray and white matter are found; in particular, there is evidence of single-cell neuronal necrosis with phagocytosis of the debris **(neuronophagia).** Microglial cells form small aggregates, called **microglial nodules** (see Fig. 28.24B). In severe cases, there may be a necrotizing vasculitis with associated focal hemorrhages. Although some viruses declare their presence by formation of intracellular inclusions, in tissue samples the causative virus is most often identified by a combination of ultrastructural, immunohistochemical, and molecular methods.

Herpes Simplex Virus Type 1

Herpes simplex virus type 1 (HSV-1) encephalitis occurs most commonly in children and young adults; only about 10% of affected individuals have a history of prior herpetic infection. The typical presenting symptoms are alterations in mood, memory, and behavior. Antiviral agents now provide effective treatment in many cases, with a significant reduction in the mortality rate. In some individuals, HSV-1 encephalitis follows a subacute course with clinical manifestations (weakness, lethargy, ataxia, seizures) that evolve during a more protracted period (4 to 6 weeks).

MORPHOLOGY

This encephalitis starts in and most severely involves the inferior and medial regions of the temporal lobes and the orbital gyri of the frontal lobes (Fig. 28.25A). The infection is necrotizing and often hemorrhagic in the most severely affected regions. Perivascular inflammatory infiltrates are usually present, and Cowdry type A intranuclear viral inclusions may be found in both neurons and glia (Fig. 28.25B). In individuals with slowly evolving HSV-1 encephalitis, there is more diffuse involvement of the brain.

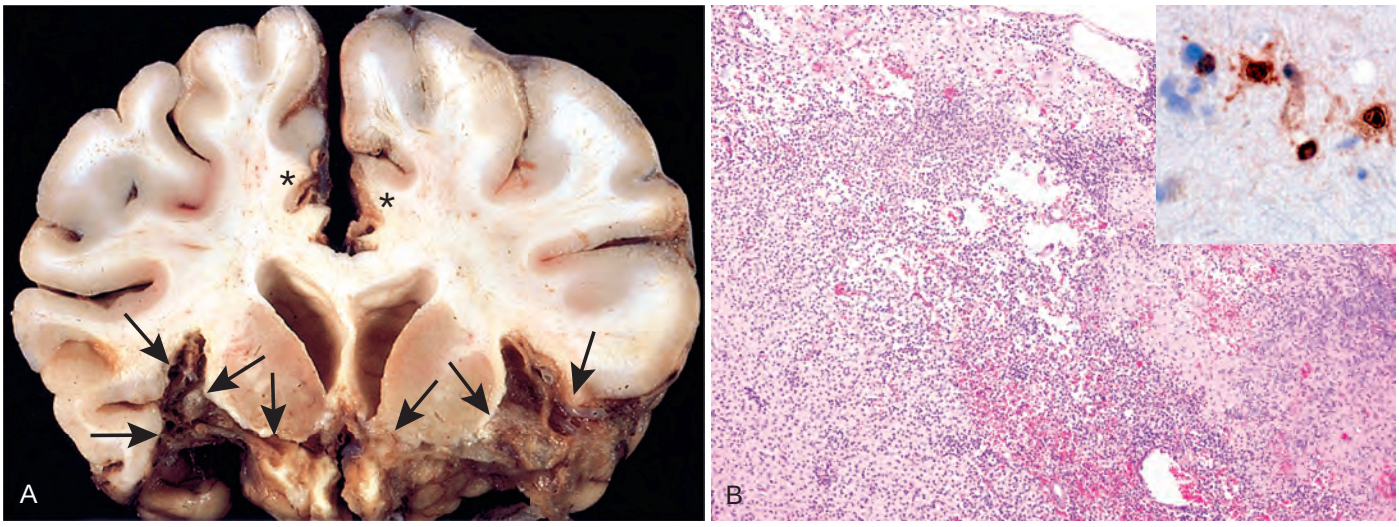

Figure 28.25 (A) Herpes encephalitis showing extensive destruction of inferior frontal and anterior temporal lobes *(arrows)* and the cingulate gyri *(asterisks)*. (B) Necrotizing inflammatory process characterizes acute herpes encephalitis; nuclear viral inclusions can be highlighted by immunostaining *(inset)*. (A, Courtesy Dr. T.W. Smith, University of Massachusetts Medical School, Worcester, Mass.)

Herpes Simplex Virus Type 2

Herpes simplex virus type 2 (HSV-2) can infect the nervous system. In adults it causes meningitis, but as many as 50% of neonates born by vaginal delivery to women with active primary HSV genital infections acquire the infection during passage through the birth canal and develop severe encephalitis. In individuals with active HIV infection, HSV-2 may cause an acute hemorrhagic and necrotizing encephalitis.

Varicella-Zoster Virus

Primary infection with varicella-zoster virus causes one of the childhood exanthems *(chickenpox),* without evidence of neurologic involvement. Following the cutaneous infection, the virus enters a latent phase within sensory neurons of the dorsal root or trigeminal ganglia. Reactivation of infection in adults *(shingles* or *herpes zoster)* usually manifests as a painful, vesicular skin eruption confined to one or several dermatomes. Herpes zoster is typically self-limited, but there may be a postherpetic neuralgia syndrome (particularly after 60 years of age) characterized by persistent pain, sometimes induced by stimuli that are otherwise not painful. Vaccination is now available to prevent these complications of varicella-zoster virus reactivation.

Cytomegalovirus

CMV infection of the nervous system occurs in fetuses and immunosuppressed individuals. The outcome of infection in utero is periventricular necrosis that produces severe brain destruction followed later by microcephaly and periventricular calcification. CMV is a common opportunistic viral pathogen in individuals with AIDS, with CNS involvement also occurring in this setting.

MORPHOLOGY

In the immunosuppressed individual, CMV most commonly causes subacute encephalitis, which may be associated with CMV inclusion-bearing cells (see Fig. 8.12). The infection tends to localize in the subependymal regions of the brain, where it results in a severe hemorrhagic necrotizing ventriculoencephalitis and choroid plexitis. The virus can also attack the lower spinal cord and roots, producing a painful radiculoneuritis. Any cell in the CNS (neurons, glia, ependyma, or endothelium) may be infected. Prominent enlarged cells with intranuclear and intracytoplasmic inclusions can be readily identified by conventional light microscopy; CMV infection is confirmed by immunohistochemistry.

Poliomyelitis

Although paralytic poliomyelitis has been eradicated by vaccination in many parts of the world, there are still a few countries where it remains a serious problem. In addition, a cluster of cases of acute flaccid myelitis (a polio-like syndrome) has recently occurred in the United States and seems to have been caused by a novel strain of enterovirus D68 (which usually causes only a mild respiratory infection). In nonimmunized individuals, poliovirus infection causes a subclinical or mild gastroenteritis, similar to that caused by other members of the picornavirus group of enteroviruses. In a small fraction of the vulnerable population, however, the virus secondarily invades the nervous system.

MORPHOLOGY

Acute cases show mononuclear cell perivascular cuffs and neuronophagia of the **anterior horn motor neurons of the spinal cord.** The inflammatory reaction is usually confined to the anterior horns but may extend into the posterior horns, and the damage is occasionally severe enough to produce cavitation. Poliovirus RNA has been detected in anterior horn cell motor neurons; the cranial motor nuclei are sometimes involved as well. Postmortem examination in long-term survivors of symptomatic poliomyelitis shows loss of neurons and gliosis in the affected anterior horns of the spinal cord, atrophy of the anterior (motor) spinal roots, and neurogenic atrophy of denervated muscle.

Clinical Features

CNS infection manifests initially with meningeal irritation and a CSF picture consistent with aseptic meningitis; the disease may progress no further or may advance to involve the spinal cord. When the disease affects the motor neurons of the spinal cord, it produces a flaccid paralysis associated with muscle wasting and hyporeflexia in the corresponding region of the body—the permanent neurologic residue of poliomyelitis. Because of the destruction of motor neurons, paresis or paralysis follows; when the diaphragm and intercostal muscles are affected, severe respiratory compromise and even death may occur. A myocarditis sometimes complicates the acute infection. *Postpolio syndrome* can develop in patients 25 to 35 years after resolution of the initial illness. It is characterized by progressive weakness associated with decreased muscle mass and pain, and has been attributed to superimposed loss of remaining motor neurons, without any convincing evidence of viral re-activation.

Rabies

Rabies is severe encephalitis transmitted to humans by the bite of a rabid animal, usually a dog or various wild mammals that are natural reservoirs. Exposure to certain species of bats, even without a known bite, can also lead to rabies.

MORPHOLOGY

External examination of the brain shows intense edema and vascular congestion. Microscopically, there is widespread neuronal degeneration and an inflammatory reaction that is most severe in the brainstem; the basal ganglia, spinal cord, and dorsal root ganglia may also be involved. **Negri bodies,** the pathognomonic microscopic finding, are cytoplasmic, round to oval, eosinophilic inclusions found in pyramidal neurons of the hippocampus and Purkinje cells of the cerebellum, sites usually devoid of inflammation (Fig. 28.26). Rabies virus can be detected within Negri bodies by ultrastructural and immunohistochemical methods.

Clinical Features

Because the virus enters the CNS by ascending along the peripheral nerves from the wound site, the incubation period (usually between 1 and 3 months) depends on the distance between the wound and the brain. The disease begins with nonspecific symptoms such as malaise, headache, and fever, but the conjunction of these symptoms with local paresthesias around the wound is diagnostic. As the infection advances,

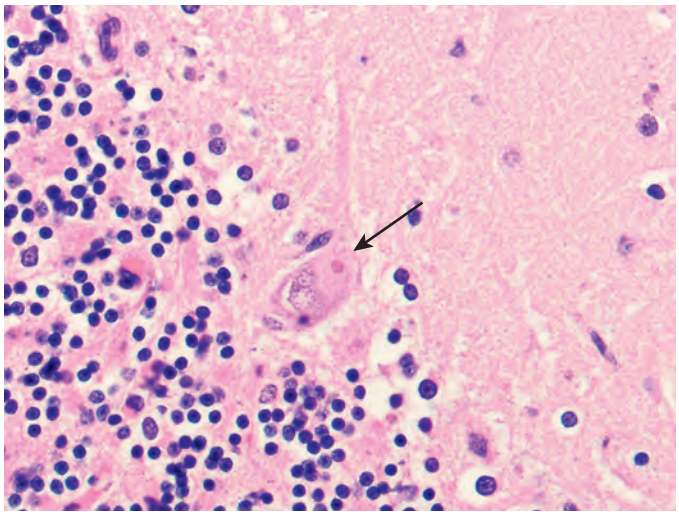

Figure 28.26 The diagnostic histologic finding in rabies is the eosinophilic Negri body, as seen here in a Purkinje cell *(arrow)*.

the affected individual exhibits extraordinary CNS excitability; the slightest touch is painful and produces violent motor responses or even convulsions. Contracture of the pharyngeal musculature on swallowing produces foaming at the mouth, which may create an aversion to swallowing even water (hydrophobia). There are signs of meningeal irritation and, as the disease progresses, flaccid paralysis. Alternating periods of mania and stupor progress to coma and eventually death ensues from respiratory failure.

Human Immunodeficiency Virus

In the period before the availability of effective antiretroviral therapy, neuropathologic changes were demonstrated at postmortem examination in as many as 80% to 90% of cases of AIDS. These changes stem from direct effects of the virus on the nervous system, opportunistic infections, and primary CNS lymphoma, most commonly an EBV-positive B-cell tumor. There has been a decrease in the frequency of these secondary effects of HIV infection thanks to the efficacy of multidrug antiretroviral therapy.

HIV aseptic meningitis occurs within 1 to 2 weeks of seroconversion in about 10% of patients; antibodies to HIV can be demonstrated, and the virus can be isolated from the CSF. The neuropathologic studies of the early, acute phases of HIV invasion of the CNS have shown mild lymphocytic meningitis, perivascular inflammation, and some myelin loss. Among CNS cell types, only microglia express both the CD4 coreceptor and the chemokine receptors (CCR5 or CXCR4) that are required in combination for efficient infection by HIV. During the chronic phase, HIV encephalitis is commonly found when symptomatic individuals come to autopsy.

An *immune reconstitution inflammatory syndrome* (IRIS) has been identified in patients with AIDS after effective treatment; the syndrome is recognized as a paradoxical deterioration after starting therapy, and consists of an exuberant "reconstituted" inflammatory response while on antiretroviral therapy (Chapter 6). In the CNS of patients with opportunistic infections, IRIS has caused paradoxical exacerbation of symptoms; neuropathologic studies confirm intense inflammation with an influx of CD8+ lymphocytes.

MORPHOLOGY

HIV encephalitis is a chronic inflammatory reaction associated with widely distributed **microglial nodules,** often containing macrophage-derived **multinucleated giant cells** (Fig. 28.27); foci of tissue necrosis and reactive gliosis are sometimes seen together with these lesions. Some of the microglial nodules are found near small blood vessels, which show abnormally prominent endothelial cells and perivascular foamy or pigment-laden macrophages. These changes are especially prominent in the subcortical white matter, diencephalon, and brainstem. In some cases, there is also a disorder of white matter characterized by multifocal or diffuse areas of myelin pallor, axonal swelling, and gliosis. HIV can be detected in CD4+ microglia and mononuclear or multinucleated macrophages.

Clinical Features

Cognitive changes, some mild and others florid enough to be termed *HIV-associated dementia,* appear to have persisted in the era of effective anti-HIV treatment regimens; collectively, they are termed *HIV-associated neurocognitive disorders* (HAND). Rather than having a specific pathologic lesion as its correlate, HAND is most closely related to inflammatory activation of microglial and perivascular macrophages, some of which are infected by HIV. A wide range of possible mechanisms for neuronal dysfunction and injury have been proposed, including the actions of inflammatory cytokines, a cascade of toxic effects of HIV-derived proteins, neurotoxic effects of anti-HIV therapy, accelerated aging, and aberrant synaptic pruning; in all probability, most (if not all) of these mechanisms contribute to the pathogenesis of this disorder.

Progressive Multifocal Leukoencephalopathy

PML is an encephalitis caused by the JC polyomavirus; because the virus preferentially infects oligodendrocytes, demyelination is its principal pathologic effect. The disease occurs almost exclusively in immunosuppressed individuals in various clinical settings, including chronic lymphoproliferative or myeloproliferative illnesses, immunosuppressive chemotherapy

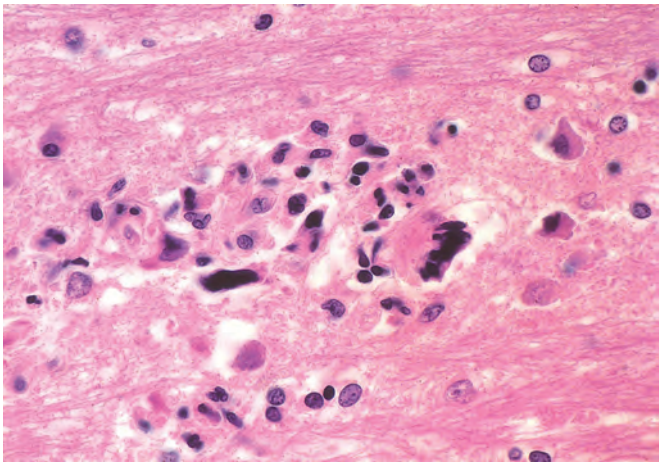

Figure 28.27 HIV encephalitis. Note the microglial nodule and multinucleated giant cells.

(including monoclonal antibody therapy targeting certain integrins), granulomatous diseases, and AIDS.

Although most people have serologic evidence of exposure to JC virus by 14 years of age, primary infection is asymptomatic; PML results from the reactivation of virus in the setting of immunosuppression. Clinically, affected individuals develop focal and relentlessly progressive neurologic symptoms and signs, with imaging studies showing extensive, often multifocal, cerebral or cerebellar white matter lesions.

MORPHOLOGY

The lesions consist of patches of irregular, ill-defined white matter injury that range in size from millimeters to large confluent regions (Fig. 28.28A). Microscopically, a PML lesion shows an area of demyelination, most often in a subcortical location, in the center of which are sheets of lipid-laden macrophages and a reduced number of axons (Fig. 28.28B). Greatly enlarged oligodendrocyte nuclei containing glassy amphophilic viral inclusions (Fig. 28.28B, *inset*), which can be identified by immunohistochemistry, are typically found at the lesion edge. Bizarre giant astrocytes with one to several irregular, hyperchromatic nuclei are intermixed with more typical reactive astrocytes. Infection of granule cell neurons in the cerebellum has been demonstrated in rare instances.

Fungal Meningoencephalitis

Fungal infections of the CNS are encountered primarily in immunocompromised individuals. The brain is usually involved following widespread hematogenous dissemination of fungi; the most frequent offenders are *Candida albicans,* Mucor species, *Aspergillus fumigatus,* and *Cryptococcus neoformans*. In endemic areas, pathogens such as *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis* may involve the CNS after a primary pulmonary or cutaneous infection; again, this often follows immunosuppression. Although most fungi reach the brain by hematogenous dissemination, direct extension may also occur, particularly in mucormycosis in the setting of diabetes mellitus.

The three main forms of injury in CNS fungal infection are chronic meningitis, vasculitis, and parenchymal invasion. Vasculitis is most frequently seen with *Mucormycosis* and *Aspergillosis,* both of which directly invade blood vessel walls, but it occasionally occurs with other infections such as candidiasis. The resultant vascular thrombosis produces infarction that is often strikingly hemorrhagic.

Parenchymal infection, usually in the form of granulomas or abscesses, can occur with most of the fungi and often coexists with meningitis. The most commonly encountered fungi that invade the brain are *Candida* and *Cryptococcus*. Candidiasis usually produces multiple microabscesses, with or without granuloma formation; in contrast, parenchymal aggregates of *Cryptococcal* organisms are typically found within expanded perivascular (Virchow-Robin) spaces and are associated with minimal to no inflammation or gliosis.

Cryptococcal meningitis, a common opportunistic infection in the setting of AIDS, may be fulminant and fatal in as little as 2 weeks or indolent, evolving over months or years. The CSF may contain few cells but usually has a high concentration of protein. The mucoid-encapsulated yeasts can be visualized in the CSF with special stains or detected indirectly using assays for cryptococcal antigens (see Fig. 8.43).

Most cases of cryptococcal infection in immunosuppressed individuals are caused by *C. neoformans*. Recently, a second species, *C. gattii,* has been recognized and appears more likely to cause disease in immunocompetent individuals. Some case studies suggest that *C. gattii* involvement of the CNS is more likely to take the form of mass lesions ("cryptococcomas") and to present with symptoms related to increased CNS pressure due to mass effects.

Other Infectious Diseases of the Nervous System

Protozoal diseases (including malaria, toxoplasmosis, amebiasis, and trypanosomiasis), rickettsial infections (e.g.,

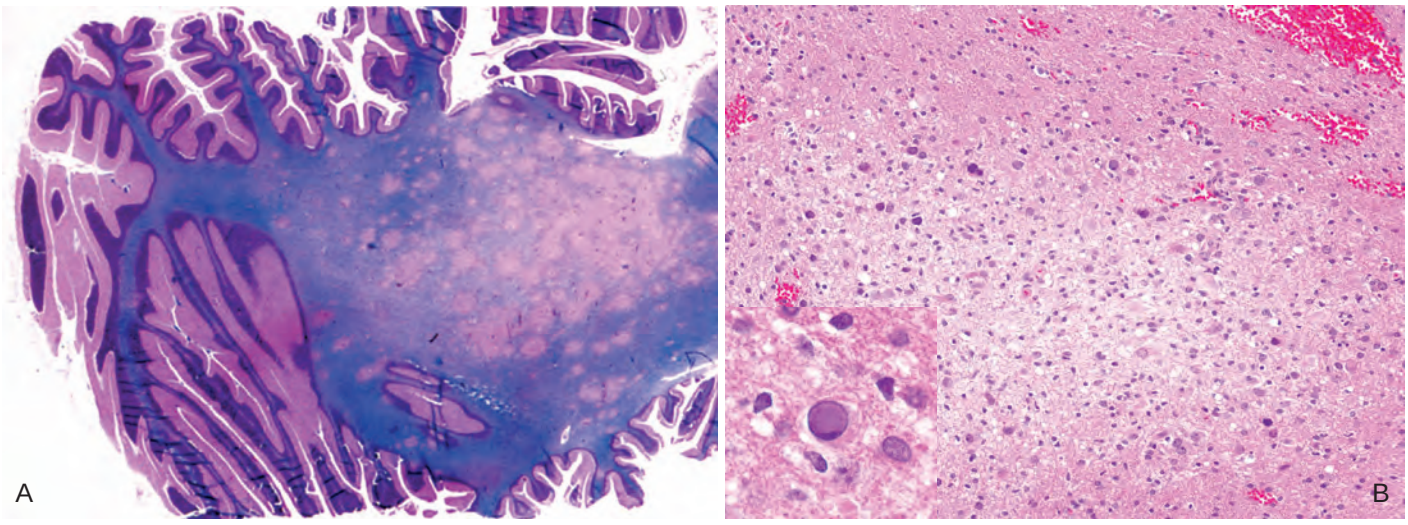

Figure 28.28 (A) Progressive multifocal leukoencephalopathy. Section stained for myelin showing irregular, poorly defined areas of demyelination, which become confluent in places. (B) Microscopically, the lesions consists of areas of demyelination. *Inset,* Enlarged oligodendrocyte nucleus represents the effect of viral infection.

typhus and Rocky Mountain spotted fever), and metazoal diseases (especially cysticercosis and echinococcosis) may also involve the CNS and are discussed in Chapter 8.

- *Cerebral toxoplasmosis* is an opportunistic infection commonly found in the setting of HIV-associated immunosuppression. The clinical symptoms of infection of the brain by *Toxoplasma gondii* are subacute, evolving during a 1- or 2-week period, and may be both focal and diffuse. Computed tomography and magnetic resonance imaging studies may show multiple ring-enhancing lesions; however, this radiographic appearance is not specific, as CNS lymphoma, tuberculosis, and fungal infections produce similar findings. In nonimmunosuppressed hosts, the impact of toxoplasmosis on the brain is most often seen when primary maternal infection occurs early in pregnancy. Such infections often spread to the brain of the developing fetus and cause severe damage in the form of multifocal necrotizing lesions that may calcify. With early diagnosis, cerebral toxoplasmosis is often treatable with antibiotics, which may also be administered empirically if this infection is in the differential diagnosis.
- *Cerebral amebiasis.* A rapidly fatal necrotizing encephalitis results from infection with *Naegleria* species, and a chronic granulomatous meningoencephalitis has been associated with infection with *Acanthamoeba.* The amebae may be difficult to distinguish morphologically from activated macrophages (Fig. 28.29). Methenamine silver or PAS stains are helpful in visualizing the organisms, although definitive identification ultimately depends on immunofluorescence studies, culture, and molecular methods.
- *Cerebral malaria.* Cerebral malaria is a complication of infection by *Plasmodium falciparum,* the species with the highest mortality. Most likely the result of sticking of infected red cells to inflamed vascular endothelium, cerebral involvement by malaria is accompanied by reduced cerebral blood flow and results in ataxia, seizures, and coma in the acute phase, and leads to long-term cognitive deficits in up to 20% of affected children (Chapter 8).

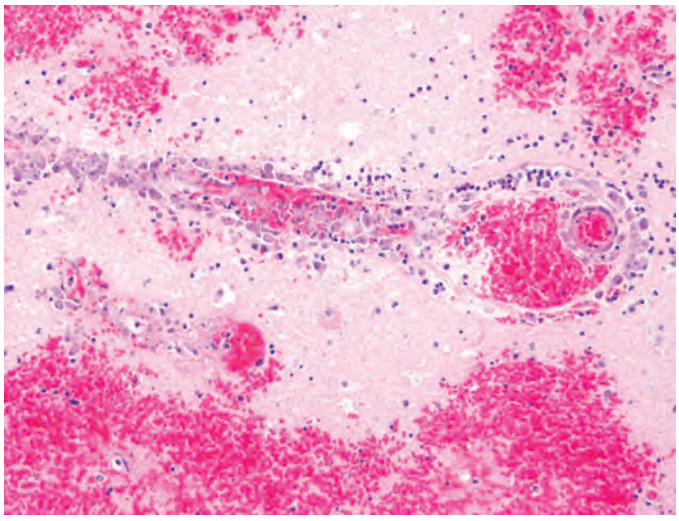

Figure 28.29 Necrotizing amebic meningoencephalitis; in this image, the organisms are largely perivascular. (*Acanthamoeba* resemble macrophages on routine stains, but are slightly smaller and less granular.)

MORPHOLOGY

Toxoplasmosis of the CNS produces brain abscesses, which are found most often in the cerebral cortex (near the gray-white junction) and deep gray nuclei, less often in the cerebellum and brainstem, and rarely in the spinal cord (Fig. 28.30A). Acute lesions exhibit central necrosis, petechial hemorrhages surrounded by acute and chronic inflammation, macrophage infiltration, and vascular proliferation. Both free tachyzoites and encysted bradyzoites may be found at the periphery of the necrotic foci. The organisms are often seen on routine H&E or Giemsa stains, but are more easily recognized by immunohistochemical methods (Fig. 28.30B). The blood vessels near these lesions often show intimal proliferation or frank vasculitis with fibrinoid necrosis and thrombosis.

KEY CONCEPTS

INFECTIONS

- Pathogens from viruses through parasites can infect the brain. Different pathogens use distinct routes to reach the brain and cause different patterns of disease.
- Routes of access of organisms to the brain include: hematogenous spread (e.g., abscess formation in the setting of endocarditis), direct extension (following trauma or with extension from the sinuses), and retrograde transport along nerves (e.g., rabies).
- Bacterial infections may cause meningitis, cerebral abscesses, or a chronic meningoencephalitis. The distribution of pathogens is influenced by various host factors, such as age and level of immune function.
- Viral infections can cause meningitis or meningoencephalitis. Some viruses have characteristic patterns of infection (HSV-1 in the temporal lobes, polio in the anterior horn).
- HIV can directly cause meningoencephalitis, or indirectly affect the brain by increasing the risk of opportunistic infections (toxoplasmosis, CMV) and EBV-positive CNS lymphoma.

DEMYELINATING DISEASES

Demyelinating diseases of the CNS are acquired conditions characterized by preferential damage to myelin with relative preservation of axons. The clinical deficits, at least initially, are due to the effect of myelin loss on the transmission of electrical impulses along axons. The natural history of demyelinating diseases is determined, in part, by the limited capacity of the CNS to regenerate normal myelin and by the degree of secondary damage to axons that occurs as the disease runs its course.

Several pathologic processes can cause loss of myelin. These include immune-mediated destruction of myelin (as in multiple sclerosis [MS]) and infections (as in PML, described earlier). In addition, inherited disorders may affect synthesis or turnover of myelin components; these are termed *leukodystrophies* and are discussed with metabolic disorders.

Multiple Sclerosis (MS)

MS is an autoimmune demyelinating disorder characterized by distinct episodes of neurologic deficits that are

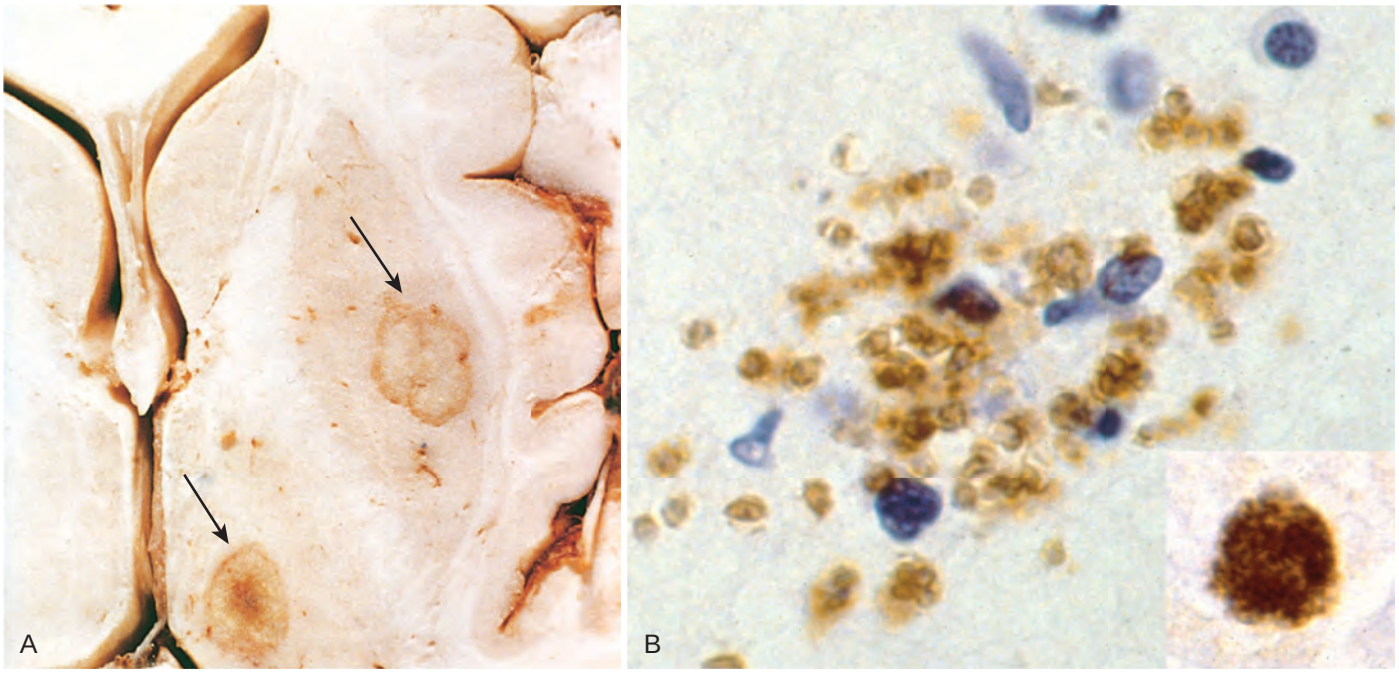

Figure 28.30 (A) Toxoplasma abscesses in the putamen and thalamus *(arrows).* (B) Free tachyzoites demonstrated by immunostaining; *inset, Toxoplasma* pseudocyst with bradyzoites highlighted by immunostaining.

separated in time and are attributable to patchy white matter lesions that are separated in space. It is the most common of the demyelinating disorders, having a prevalence of approximately 1 per 1000 persons in most of the United States and Europe. The disease may become clinically apparent at any age, although onset in childhood or after 50 years of age is relatively rare. Women are affected twice as often as are men. In most individuals with MS, the clinical course takes the form of relapsing and remitting episodes of variable duration (weeks to months to years) marked by neurologic defects, followed by gradual and partial recovery of neurologic function. The frequency of relapses tends to decrease over time, but there is a steady neurologic deterioration in most affected individuals.

Pathogenesis

MS is caused by an autoimmune response directed against components of the myelin sheath. As in other autoimmune disorders, the pathogenesis of this disease involves both genetic and environmental factors (Chapter 6). The incidence of MS is 15-fold higher when the disease is present in a first-degree relative and roughly 150-fold higher with an affected monozygotic twin. Despite a series of well-powered studies, only a portion of the genetic basis of the disease has been explained. There is a strong association with a DR haplotype of the major histocompatibility complex. Genome-wide association studies have identified additional associations with the IL-2 and IL-7 receptor genes, and subsequently with a number of other genes encoding proteins involved in the immune response, including cytokines and their receptors, costimulatory molecules, and cytoplasmic signaling molecules; many of these loci are associated with other autoimmune diseases. These genetic studies have not explained why the clinical course for individuals with MS is so variable.

Environmental factors are also important. For example, there is geographic variation in the prevalence of MS, with a higher number of cases diagnosed away from the equator; it has been proposed that this latitude dependence may be related to a low level of vitamin D (an immune system modulator) in people who are not exposed to sunlight during winter.

Immune mechanisms that underlie the destruction of myelin are the focus of much investigation. The available evidence indicates that the disease is initiated by Th1 and Th17 T cells that react against myelin antigens and secrete cytokines. Th1 cells secrete IFN-γ, which activates macrophages, while Th17 cells promote the recruitment of leukocytes (Chapter 6). The demyelination is caused by these activated leukocytes and their injurious products. The infiltrate in plaques and surrounding regions of the brain consists of T cells (mainly CD4+, some CD8+) and macrophages. How the autoimmune reaction is initiated is not understood; a role of viral infection (e.g., EBV) has been proposed but remains controversial.

Based on the growing understanding of the pathogenesis of MS, therapies are being developed that modulate or inhibit T-cell responses and block the recruitment of T cells to the brain. A potential contribution of humoral immunity has also long been suspected, based on the early observation of oligoclonal bands of immunoglobulin in CSF; the demonstration that treatment with agents that deplete B cells decreases the incidence of demyelinating lesions in patients with MS lends support to this idea.

MORPHOLOGY

MS is a white matter disease that is best appreciated in sections of the brain and spinal cord. In the fresh state, the lesions are

firmer than the surrounding white matter **("sclerosis")** and appear as well circumscribed, somewhat depressed, glassy, gray-tan, irregularly shaped **plaques** (Fig. 28.31A). The area of demyelination often has sharply defined borders, a feature best appreciated with stains for myelin (Fig. 28.31B). The size of lesions varies considerably, from small foci that are only recognizable microscopically to large confluent plaques. Plaques commonly occur adjacent to the lateral ventricles and are also frequent in the corpus callosum, optic nerves and chiasm, brainstem, ascending and descending fiber tracts, cerebellum, and spinal cord. Plaques can extend into gray matter because myelinated fibers are present there as well.

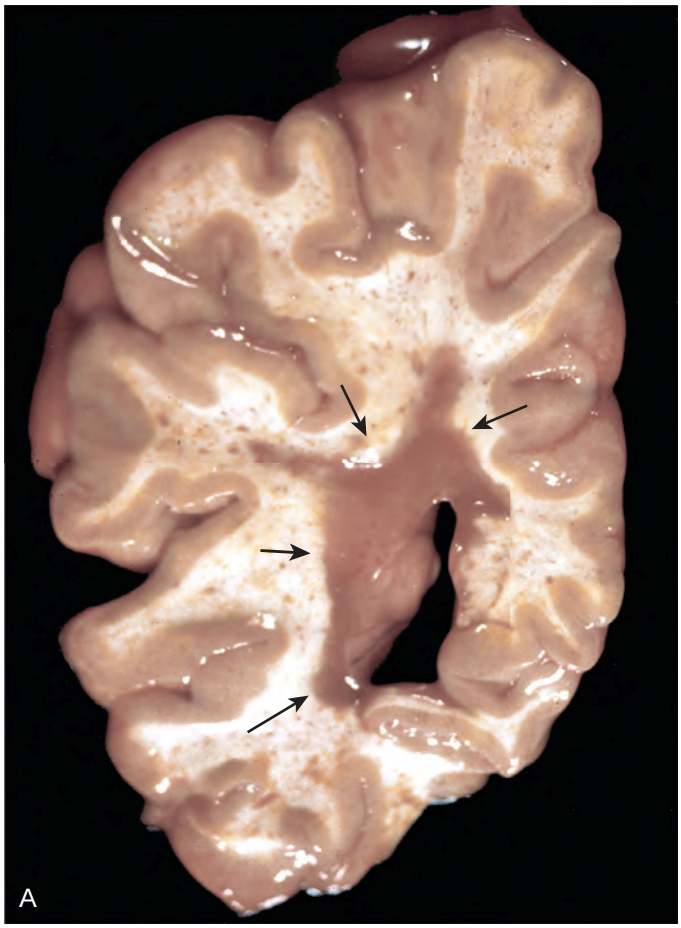
Microscopically, in an **active plaque,** there is ongoing myelin breakdown associated with abundant foamy macrophages (Fig. 28.32A); lymphocytes are also present, mostly as perivascular cuffs, especially at the outer edge of the lesion. Active lesions are often centered on small veins; myelin is usually completely absent (Fig. 28.32B), but axons are relatively preserved (Fig. 28.32C). In time, astrocytes undergo reactive changes. As lesions become quiescent, the inflammatory cells slowly disappear. Within **inactive plaques,** there is no macrophage-rich infiltrate, little to no myelin is found, and there is a reduction in the number of oligodendrocyte nuclei; instead, reactive gliosis is prominent. Axons in old gliotic plaques are usually greatly diminished in number.

In some MS plaques (shadow plaques), the white matter pallor is less severe, and abnormally thinned-out myelin sheaths can be demonstrated, especially at the outer edges. This phenomenon is most commonly interpreted as evidence of partial and incomplete remyelination by surviving oligodendrocytes. Abnormally myelinated fibers have also been observed at the edges of typical plaques. Although these histologic findings suggest a limited potential for remyelination in the CNS, the remaining axons within most MS plaques remain unmyelinated.

Clinical Features

Although MS lesions can occur anywhere in the CNS and consequently may induce a wide range of clinical manifestations, certain patterns of neurologic symptoms and signs are more common. Unilateral visual impairment due to involvement of the optic nerve *(optic neuritis)* is a frequent initial manifestation of MS. However, only a minority of individuals (10% to 50%, depending on the population studied) with an episode of optic neuritis go on to develop MS (which requires multiple episodes to support the diagnosis). Involvement of the brainstem produces cranial nerve signs (ataxia, nystagmus, and internuclear ophthalmoplegia from interruption of the fibers of the medial longitudinal fasciculus). Spinal cord lesions give rise to motor and sensory impairment of trunk and limbs, spasticity, and loss of bladder control.

Examination of the CSF in individuals with MS shows a mildly elevated protein level and in one-third of cases a moderate pleocytosis. IgG levels in the CSF are increased, and oligoclonal IgG bands are usually observed on immunoelectrophoresis; these are indicative of the presence of a small number of activated B-cell clones in the CNS, which are postulated to be self-reactive. Magnetic resonance imaging has taken on a prominent role in assessing disease progression; these studies, along with autopsy and clinical findings, indicate that some plaques may be clinically silent even in otherwise symptomatic patients. Treatment consists of several types of immunosuppressive or immunomodulatory



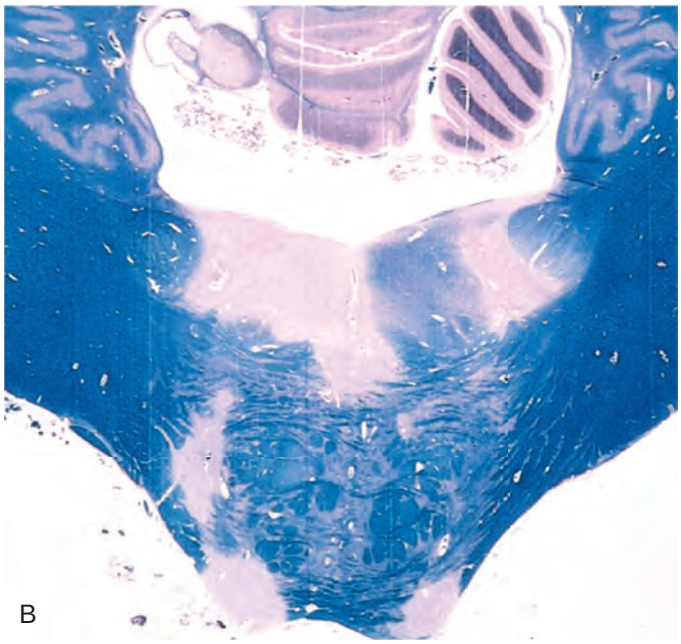


Figure 28.31 Multiple sclerosis. (A) Section of fresh brain shows gray-brown plaque around occipital horn of the lateral ventricle *(arrows)*. (B) Regions of demyelination (MS plaques) around the fourth ventricle lack the normal blue staining of myelin (Luxol fast blue periodic acid–Schiff stain).

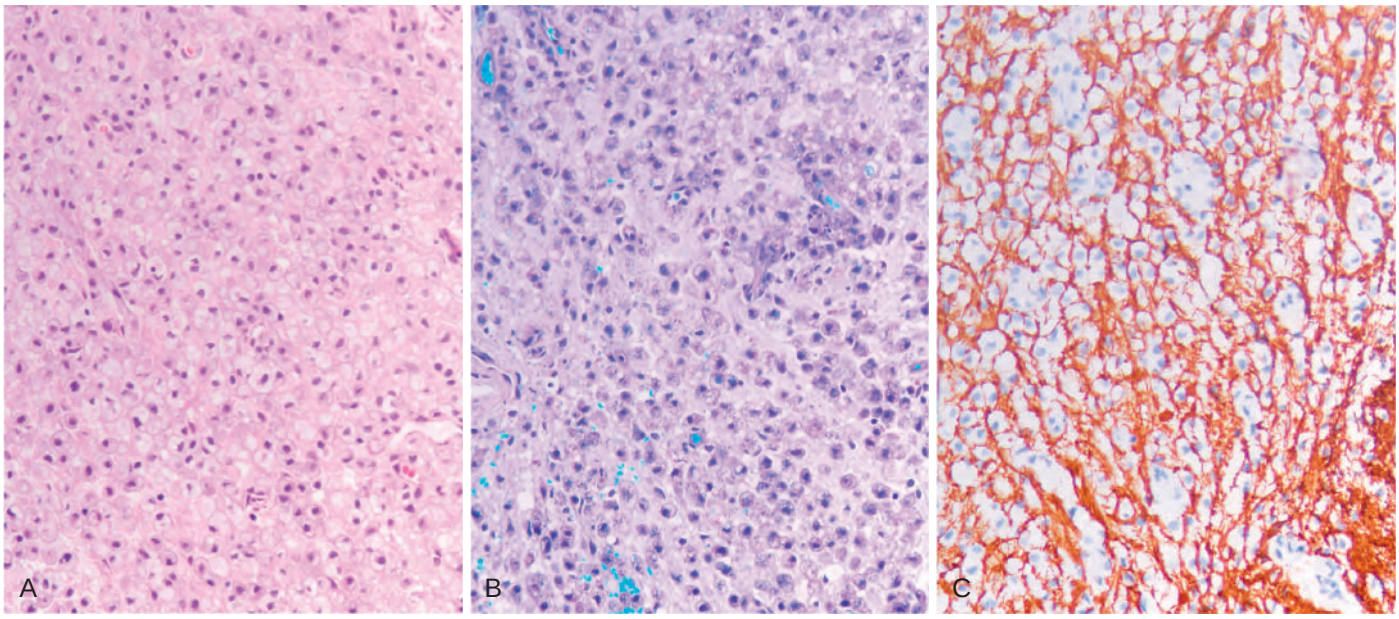

Figure 28.32 Multiple sclerosis. (A) Active demyelinating plaques appear very cellular due to the presence of numerous lipid-laden macrophages. (B) The same lesion stained with the Luxol fast blue periodic acid–Schiff stain shows a complete lack of myelin. (C) Relative preservation of axons is seen on the neurofilament immunostain (*brown*).

agents, which may slow the progression of the disease but are not curative.

Neuromyelitis Optica

Neuromyelitis optica (NMO) is a syndrome with synchronous (or near-synchronous) bilateral optic neuritis and spinal cord demyelination. Once considered a variant of MS, it is clearly a distinct disorder. NMO has an even greater skewing toward women than MS, is more commonly associated with poor recovery from the first attack, and is often characterized by the presence of aquaporin-4 antibodies, which appear to be pathogenic. Areas of demyelination in NMO show loss of aquaporin-4, the major water channel of astrocytes. White cells (often including neutrophils) are common in the CSF. Within the damaged areas of white matter, there is typically necrosis, an inflammatory infiltrate including neutrophils and eosinophils, and vascular immunoglobulin and complement deposition. Acute attacks are treated with glucocorticoids or plasma exchange, while long-term treatments include agents that decrease antibody titers (e.g., by depleting B cells) or that inhibit complement (e.g., inhibitors of the C5–C9 membrane attack complex).

Acute Disseminated Encephalomyelitis and Acute Necrotizing Hemorrhagic Encephalomyelitis

Acute disseminated encephalomyelitis is a diffuse, monophasic demyelinating disease that follows a viral infection or, rarely, a viral immunization. Symptoms typically develop 1 or 2 weeks after the antecedent event and include headache, lethargy, and coma rather than focal findings, as seen in MS; in contrast to MS, all brain lesions appear similar, consistent with the clinically monophasic nature of the disorder. The clinical course is rapid, and as many as 20% of those affected die; the remaining patients usually recover completely.

Acute necrotizing hemorrhagic encephalomyelitis (also known as acute hemorrhagic leukoencephalitis or Weston Hurst disease) is a fulminant syndrome of CNS demyelination, typically affecting young adults and children. The illness is almost invariably preceded by a recent episode of upper respiratory infection, most often of unknown cause. This disorder shows histologic similarities with acute disseminated encephalomyelitis; however, the damage is more severe. The disease is fatal in many patients, with significant deficits present in most survivors.

The lesions of acute disseminated encephalomyelitis are similar to those induced by immunization of animals with myelin components or with early rabies vaccines that had been prepared from brains of infected animals. This has led to the suggestion that acute disseminated encephalomyelitis is an acute autoimmune reaction to myelin and that acute necrotizing hemorrhagic encephalomyelitis is a hyperacute variant, but inciting antigens have yet to be identified.

Central Pontine Myelinolysis

Central pontine myelinolysis is an acute disorder characterized by loss of myelin in the base of the pons and portions of the pontine tegmentum, typically in a roughly symmetric pattern. It most commonly arises 2 to 6 days after rapid correction of hyponatremia, although it can also be associated with other severe electrolyte disturbances or osmolar imbalances, and is clinically known as osmotic demyelination syndrome. It appears that rapid increases in osmolality damage oligodendrocytes through uncertain mechanisms. Inflammation is absent from the lesions, and neurons and axons are well preserved. Because of the synchronous onset of damage, all lesions appear to be at the same stage of myelin loss and reaction. Although originally described in the pons, extra-pontine lesions with similar appearance and apparent etiology may also occur.

Although it can involve most parts of the brain, periventricular and subpial regions are spared, and it is extremely rare for the process to extend below the pontomedullary junction. The clinical presentation is a rapidly evolving quadriplegia, which may be fatal or lead to severe long-term deficits, including the "locked-in" syndrome, in which patients are fully conscious yet unresponsive. It is imperative that hyponatremia be corrected slowly and carefully to prevent this tragic complication.

KEY CONCEPTS

DEMYELINATING DISEASES

- Because of the critical role of myelin in nerve conduction, diseases of myelin can lead to widespread and severe neurologic deficits.
- Demyelinating diseases show evidence of breakdown and destruction of previously normal myelin, often by inflammatory processes. Secondary injury to axons typically emerges over time.
- MS, an autoimmune demyelinating disease primarily affecting young adults, is the most common disorder of myelin. It often pursues a relapsing-remitting course, with eventual progressive accumulation of neurologic deficits that is thought to reflect secondary axon loss.
- Less common forms of immune-mediated demyelination generally follow infections and have an acute, monophasic clinical course.

NEURODEGENERATIVE DISEASES

Neurodegenerative diseases are disorders characterized by the progressive loss of particular groups of neurons, which often have shared functions. Thus, the different diseases tend to involve particular neural systems and have relatively stereotypic presenting signs and symptoms.

The pathologic process that is common across most of the neurodegenerative diseases is the accumulation of protein aggregates (hence the occasional use of the term "proteinopathy"). Protein aggregates may arise because of mutations that alter the affected protein's conformation or disrupt the pathways that are involved in the processing or clearance of an otherwise normal protein. In other situations, there may be a subtle imbalance between protein synthesis and clearance (from genetic, environmental, or stochastic factors) that allows gradual accumulation of proteins.

Regardless of how they arise, the protein aggregates typically are resistant to degradation and show aberrant localization within neurons. The current evidence suggests that large (i.e., microscopically visible) protein aggregates are not toxic to cells; their formation appears to be an adaptive response that enables cells to sequester smaller (oligomeric) aggregates of the same proteins, which are directly toxic to neurons. However, as more and more protein is shunted into the aggregates, the normal function of the protein may also be lost, and this may also contribute to cell injury. Other recent evidence suggests that protein aggregates are capable of behaving like prions (see later); that is, aggregates derived from one cell may be taken up by another and provoke additional protein aggregation. The data supporting this concept are largely derived from experimental animal studies, but studies of patients who died with Alzheimer or Parkinson disease are consistent with the idea that these diseases spread from one site in the brain to another. However, only classic prion diseases have been shown to be truly transmissible.

The protein aggregates are recognized histologically as inclusions, which serve as diagnostic hallmarks. The basis for aggregation varies from one disease to another. It may be directly related to an intrinsic feature of a mutated protein (e.g., expanded polyglutamine repeats in Huntington disease [HD]), an intrinsic feature of a peptide derived from a larger precursor protein (e.g., Aβ in Alzheimer disease [AD]), or an unexplained alteration of a normal cellular protein (e.g., α-synuclein in sporadic Parkinson disease [PD]).

Neurodegenerative diseases vary with respect to the anatomic localization of involved areas and their specific cellular abnormalities (e.g., tangles, plaques, Lewy bodies). Accordingly, they can be classified using two different approaches:

- *Symptomatic/anatomic:* based on the anatomic regions that are most affected, which is typically reflected in the clinical symptoms (e.g., neocortical involvement results in cognitive impairment and dementia)
- *Pathologic:* based on the types of inclusions or abnormal structures observed (e.g., diseases with inclusions containing tau or containing synuclein)

Nevertheless, within the spectrum of degenerative diseases there is remarkable overlap in terms of characteristic neurologic deficits, functional/anatomic distribution of lesions, and cellular pathology (Tables 28.3 and 28.4). For the sake of simplicity, we will follow the time-honored classification based on the original description of these diseases.

Prion Diseases

Prion diseases are rapidly progressive neurodegenerative disorders caused by aggregation and intercellular spread of a misfolded prion protein (PrP); they may be sporadic, familial, or transmitted. Prion diseases include Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia, and kuru in humans; scrapie in sheep and goats; mink-transmissible encephalopathy; chronic wasting disease of deer and elk; and bovine spongiform encephalopathy. All of these diseases are characterized morphologically by "spongiform change" caused by intracellular vacuoles in neurons and glia, and clinically by a rapidly progressive dementia.

Pathogenesis

Prion diseases are conceptually important because they exemplify degenerative disorders that are caused by "spreading" of misfolded proteins, a remarkable phenomenon that allows a pathogenic protein to acquire some of the characteristics of an infectious organism. Normal PrP is a 30-kD cytoplasmic protein of unknown function. Disease occurs when PrP undergoes a conformational change from its normal α-helix–containing isoform (PrP^c) to an abnormal β-pleated sheet isoform, usually termed PrP^{sc} (for scrapie) (Fig. 28.33); associated with this conformational change, PrP acquires resistance to digestion with proteases, such as

Table 28.3 Features of the Major Neurodegenerative Diseases

Disease	Clinical Pattern	Inclusions	Genetic Causes
Prion diseases	Rapidly progressive dementia	Kuru plaques and diffuse PrP^{sc} deposits	PrP
Alzheimer disease (AD)	Dementia	Aβ (plaques) and tau (tangles)	APP, PS-1, PS-2, trisomy 21
Frontotemporal lobar degeneration (FTLD)	Behavioral changes, language disturbance	tau TDP-43 FUS	tau TDP-43, progranulin, C9orf72 FUS
Parkinson disease (PD)	Hypokinetic movement disorder with or without dementia	α-synuclein tau α-synuclein or none	α-synuclein (mutations or amplification) LRRK2 DJ-1, PINK1, parkin
Progressive supranuclear palsy (PSP)	Parkinsonism with abnormal eye movements	tau	tau
Corticobasal degeneration (CBD)	Parkinsonism with asymmetric movement disorder	tau	
Multiple system atrophy (MSA)	Parkinsonism, cerebellar ataxia, autonomic failure	α-synuclein	
Huntington disease (HD)	Hyperkinetic movement disorder	Huntington (polyglutamine)	Htt
Spinocerebellar ataxias (SCA-1, 2, 3, 6, 7, 17 and DRPLA)	Cerebellar ataxia	Various proteins (polyglutamine containing)	Multiple loci
Amyotrophic lateral sclerosis (ALS)	Weakness with upper and lower motor neurons signs	SOD1 TDP-43 FUS	SOD1 TDP-43, C9orf72 FUS
Spinal bulbar muscular atrophy (SBMA)	Lower motor neuron weakness, diminished androgen	Androgen receptor (polyglutamine containing)	Androgen receptor

proteinase K. Accumulation of PrP^{sc} in neural tissue seems to be the cause of the pathologic changes in these diseases, but how this material induces the development of cytoplasmic vacuoles and eventual neuronal death is still unknown. Immunostaining for PrP after partial digestion with proteinase K allows detection of PrP^{sc}, which is diagnostic.

The conformational change resulting in PrP^{sc} may occur spontaneously at an extremely low rate (resulting in sporadic cases of CJD) or at a higher rate if various mutations are present in PrP^{c}, such as occurs in familial forms of CJD, Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia. Independent of the means by which it originates, PrP^{sc} then facilitates, in a cooperative fashion, the conversion of other PrP^{c} molecules to PrP^{sc} molecules; it is this propagation of PrP^{sc} that accounts for the transmissible variants of prion diseases, which include iatrogenic CJD, variant CJD, and kuru. The suggestion that, at least within an individual, there may be cell-to-cell spread of disease-associated protein aggregates provides a link between prion diseases and other neurodegenerative disorders such as Alzheimer and Parkinson disease.

Table 28.4 Relationship Between Proteins and Neurodegenerative Diseases

Protein	Diseases With Inclusions
Aβ	Alzheimer disease
tau	Alzheimer disease Frontotemporal lobar degeneration Parkinson disease (with *LRRK2* mutations) Progressive supranuclear palsy Corticobasal degeneration Chronic traumatic encephalopathy
TPD-43	Frontotemporal lobar degeneration Amyotrophic lateral sclerosis
FUS	Frontotemporal lobar degeneration Amyotrophic lateral sclerosis
α-synuclein	Parkinson disease Multiple system atrophy
Polyglutamine aggregates (different protein in each disease)	Huntington disease Some forms of spinocerebellar ataxia Spinal bulbar muscular atrophy

Creutzfeldt-Jakob Disease (CJD)

The most common prion disease, CJD is a rare disorder that manifests clinically as a rapidly progressive dementia. The sporadic form of CJD has an annual incidence of approximately 1 per 1,000,000 people and accounts for about 90% of CJD cases; familial forms are caused by mutations in *PRNP,* the gene that encodes PrP. The disease has a peak incidence in the seventh decade. There are also well-established cases of iatrogenic transmission, notably by corneal or dural transplantation, deep implantation of electrodes in the brain, and administration of contaminated preparations of cadaveric human growth hormone. The onset is marked by subtle changes in memory and behavior followed by a rapidly progressive dementia, often associated with pronounced involuntary jerking muscle contractions on sudden stimulation (startle myoclonus). Signs of cerebellar dysfunction, usually manifested as ataxia, are present in a minority of affected individuals. The disease is uniformly fatal; the average survival is only 7 months after the onset of symptoms. A few patients have lived for several years, and these long-surviving cases show extensive atrophy of involved gray matter.

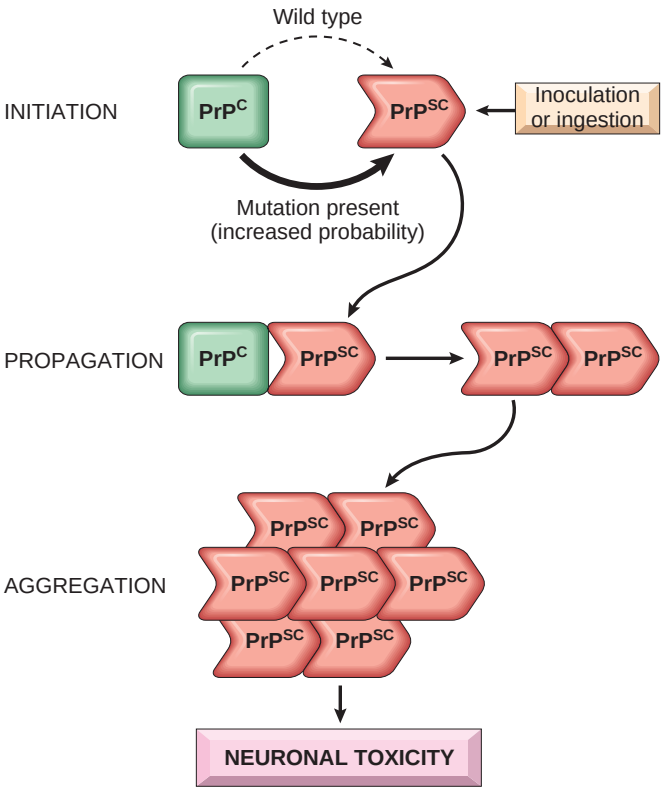

Figure 28.33 Pathogenesis of prion disease. α-helical PrP^c may spontaneously shift to the β-sheet PrP^{sc} conformation, an event that occurs at a much higher rate in familial diseases associated with germline PrP mutations. PrP^{sc} may also be acquired from exogenous sources, such as contaminated food, medical instrumentation, or medicines. Once present, PrP^{sc} converts additional molecules of PrP^c into PrP^{sc} through physical interaction, eventually leading to the formation of pathogenic PrP^{sc} aggregates.

Variant Creutzfeldt-Jakob Disease

Starting in 1995, a new CJD-like illness came to medical attention in the United Kingdom. This illness was different from classical CJD in several important respects: the disease affected young adults, behavioral disorders figured prominently in the early stages of the disease, and the neurologic syndrome progressed more slowly than in individuals with other forms of CJD. Multiple lines of evidence indicated that the new variant of CJD (vCJD) was linked to exposure to bovine spongiform encephalopathy, either through consumption of contaminated foods or via transfusion of blood from patients in the asymptomatic/preclinical stage of vCJD. Recognition of this link led to public health measures that have been effective in limiting the spread of vCJD; the incidence in the United Kingdom peaked in 2000 and dropped precipitously since that time.

MORPHOLOGY

The progression of the dementia in CJD is usually so rapid that there is little if any grossly evident brain atrophy. The pathognomonic finding is a **spongiform** transformation of the cerebral cortex and deep gray matter structures (caudate, putamen); this multifocal process results in the uneven formation of small and apparently empty microscopic vacuoles of varying sizes within the neuropil and sometimes in the perikaryon of neurons (Fig. 28.34A). In advanced cases, there is severe neuronal loss, reactive gliosis, and sometimes expansion of the vacuolated areas into cystlike spaces ("status spongiosus"). Inflammation is notably absent. Electron microscopy shows the vacuoles to be membrane-bound and located within the cytoplasm of neuronal processes. **Kuru plaques** are extracellular deposits of aggregated abnormal PrP. They are Congo red– and PAS-positive and usually occur in the cerebellum (Fig. 28.34B), but are abundant in the cerebral cortex in cases of vCJD (Fig. 28.34C). In all forms of prion disease, immunohistochemical staining demonstrates the presence of proteinase K–resistant PrP^{sc} in tissue.

Alzheimer Disease (AD)

AD is the most common cause of dementia in older adults, with an increasing incidence as a function of age. The disease usually becomes clinically apparent as insidious impairment of higher cognitive functions. As the disease progresses, deficits in memory, visuospatial orientation, judgment, personality, and language gradually emerge; over a course of 5 to 10 years, the affected individual becomes profoundly disabled, mute, and immobile. Patients rarely become symptomatic before 50 years of age; the incidence of the disease increases with age, and the prevalence roughly doubles every 5 years, starting from a level of 1% for the 60- to 64-year-old population and reaching 40% or more for the 85- to 89-year-old cohort. This progressive increase in incidence with increasing age has given rise to major medical, social, and economic concerns in countries with aging populations. About 5% to 10% of cases are familial; these have provided important insight into the pathogenesis of the more common sporadic form of the disease. Although pathologic examination of brain tissue obtained at autopsy remains necessary for definitive diagnosis of AD, the combination of clinical assessment and currrent radiologic methods allows accurate premortem diagnosis in 80% to 90% of cases.

Pathogenesis

The fundamental abnormality in AD is the accumulation of two proteins (Aβ and tau) in specific brain regions, likely as a result of excessive production and defective removal (Fig. 28.35). The two pathologic hallmarks of AD, particularly evident in the end stages of the illness, are *amyloid plaques* and *neurofibrillary tangles*. Plaques are deposits of aggregated Aβ peptides in the neuropil, while tangles are aggregates of the microtubule binding protein tau, which develop intracellularly and then persist extracellularly after neuronal death. Both plaques and tangles appear to contribute to the neural dysfunction, and the interplay between the processes that lead to the accumulation of these two types of abnormal protein aggregates is a critically important aspect of AD pathogenesis that has yet to be fully unraveled.

Several lines of evidence strongly support a model in which **Aβ generation is the critical initiating event for the development of AD**. First, there are diseases in which tau deposits appear, such as frontotemporal lobar degenerations, progressive supranuclear palsy, and corticobasal degeneration (discussed later), but Aβ deposits do not ensue, and full-blown AD does not develop. This suggests that having

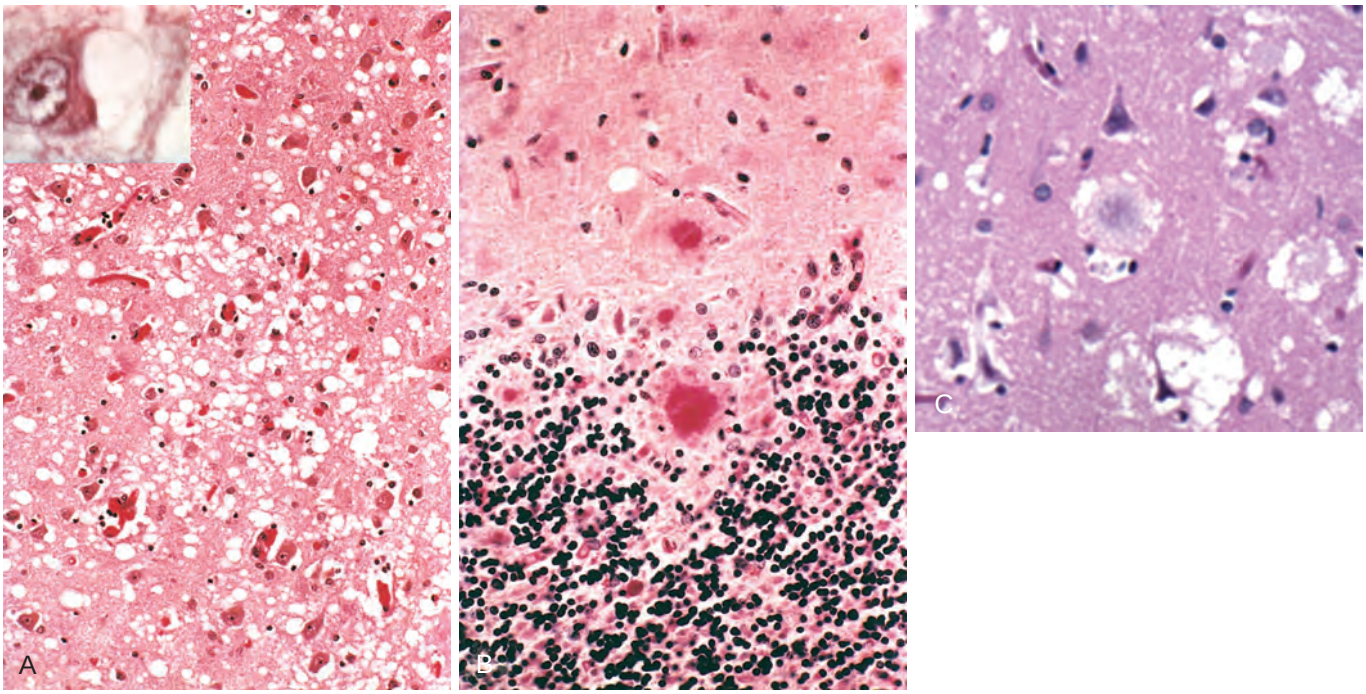

Figure 28.34 Prion disease. (A) Spongiform change in the cerebral cortex. *Inset*, High magnification of neuron with vacuoles. (B) Cerebellar cortex showing kuru plaques (periodic acid–Schiff stain) that consist of aggregated PrP^{sc}. (C) Cortical kuru plaques surrounded by spongiform change in variant Creutzfeldt-Jakob disease.

abnormal deposits of tau in the brain is not a sufficient stimulus to elicit deposition of Aβ. Additionally, multiple lines of genetic evidence (discussed later) point to the likely importance of altered Aβ metabolism. In contrast, mutations in the *MAPT* gene that encodes tau do not give rise to AD but rather cause frontotemporal lobar degeneration (discussed later).

The pathogenesis of AD thus involves Aβ, tau, and several other genetic and host factors, as follows:

- *Role of Aβ.* APP is a cell surface protein with a single transmembrane domain that may function as a receptor, possibly for prion protein (PrP^c) among other ligands. The Aβ portion of the protein extends from the extracellular region into the transmembrane domain (see Fig. 28.35). Processing of APP begins with cleavage in the extracellular domain, followed by an intramembranous cleavage. There are two potential extracellular sites of cleavage, which may be carried out by two different classes of proteases, α-secretase and β-secretase. If the first cut occurs at the α-secretase site, then Aβ is not generated (the non-amyloidogenic pathway); this cleavage event mostly occurs at the cell surface because proteases with α-secretase activity are involved in the shedding of surface proteins. Surface APP may also be endocytosed into vesicles, where it can be cleaved by β-secretase, which cuts at a slightly more N-terminal site within APP (the amyloidogenic pathway). Following cleavage of APP at either of these sites, the γ-secretase complex performs an intramembranous cleavage. Cleavage by α-secretase and β-secretase releases Aβ42, which is prone to aggregation and amyloid formation. The γ-secretase complex—containing presenilin-1 or presenilin-2, nicastrin, PEN2, and APH1—is also responsible for processing of Notch receptors and many other membrane proteins. Once generated, Aβ42 is highly prone to aggregation—first into small oligomers (which appear to be the toxic form responsible for neuronal dysfunction), and eventually into large aggregates and fibrils that can be visualized by microscopy.

  Familial forms of AD support the central role of Aβ generation as a critical step for initiation of AD pathogenesis. The gene encoding APP, on chromosome 21, lies in the Down syndrome region; AD pathology contributes to the cognitive impairment of patients with this chromosomal abnormality, with appearance of histopathologic AD findings in the second and third decades followed by neurologic decline about 20 years later. A similar gene dosage effect is produced by localized chromosome 21 duplications that span the *APP* locus in some patients with familial AD. Point mutations in *APP* are another cause of familial AD. Some mutations lie near the β-secretase and γ-secretase cleavage sites, and others sit in the Aβ sequence and increase its propensity to aggregate. The two loci identified as causes of the majority of early-onset familial AD (*PSEN1* on chromosome 14 and *PSEN2* on chromosome 1) encode presenilin-1 and presenilin-2. These mutations lead to a gain of function, such that the γ-secretase complex generates increased amounts of Aβ, particularly $Aβ_{42}$.
- *Role of tau.* Because neurofibrillary tangles contain the tau protein, there has been much interest in the role of this protein in AD. Tau is a microtubule-associated protein present in axons in association with the microtubular network. With the development of tangles in AD, it shifts to a somatic-dendritic distribution, becomes hyperphosphorylated, and loses the ability to bind to microtubules. The formation of tangles is an important component of AD, and the increased tangle burden in the brain over

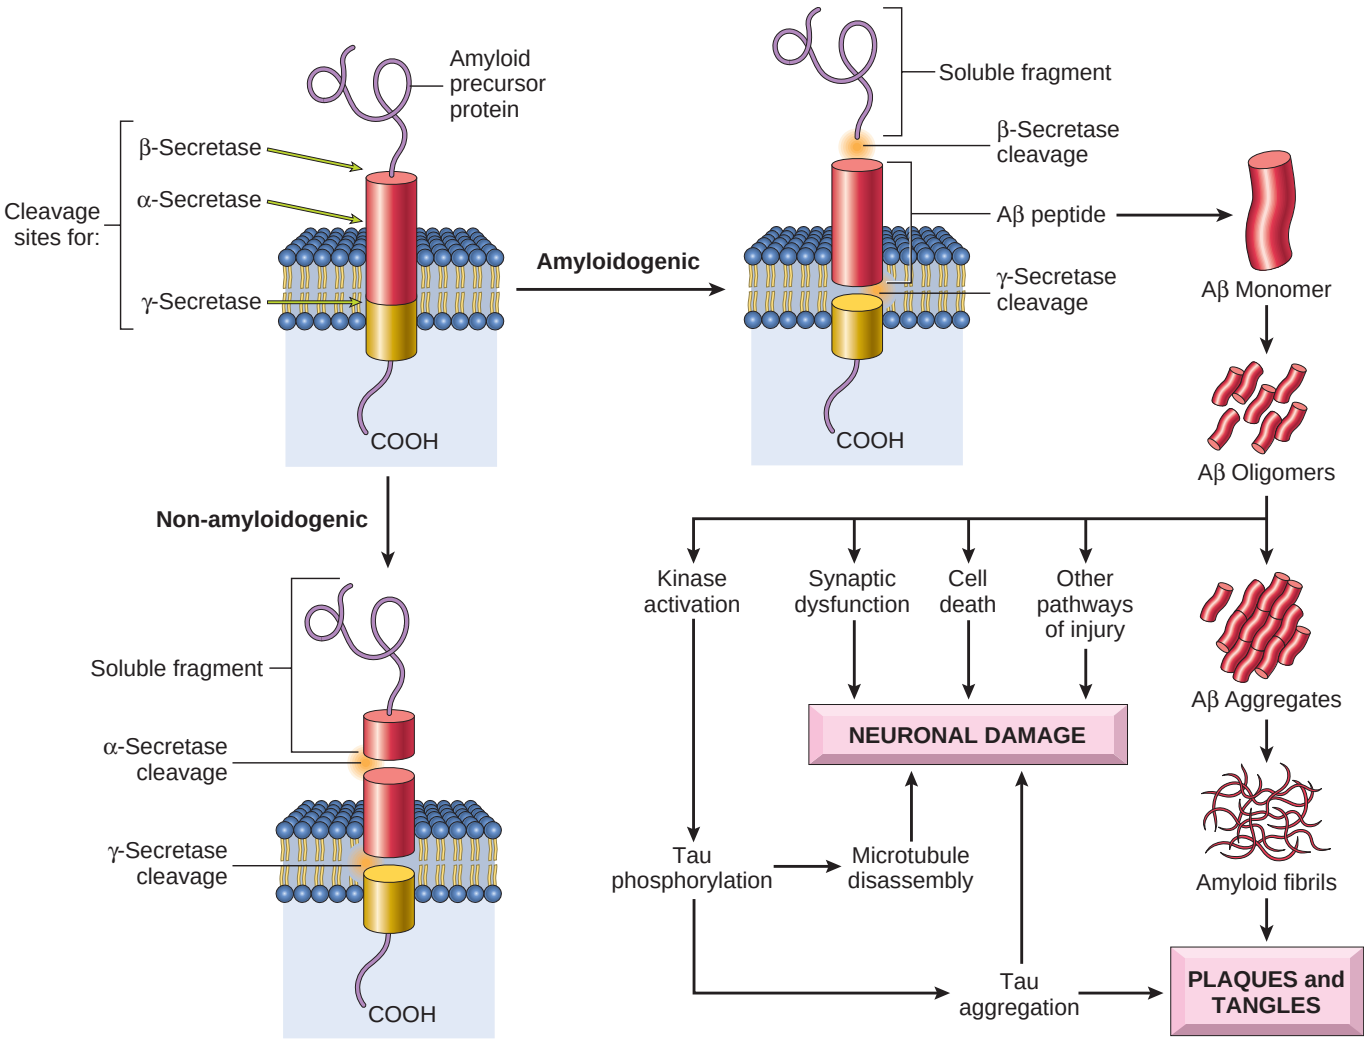

Figure 28.35 Protein aggregation in Alzheimer disease. Amyloid precursor protein cleavage by α-secretase and γ-secretase produces a harmless soluble peptide, whereas amyloid precursor protein cleavage by β-amyloid–converting enzyme and γ-secretase releases Aβ peptides, which form pathogenic aggregates and contribute to the characteristic plaques and tangles of Alzheimer disease.

the course of the illness eventually appears to become independent of the Aβ. How tangles injure neurons remains poorly understood, but two possible pathways have been suggested, which are not mutually exclusive: (1) the aggregates of tau protein elicit a stress response; and (2) the loss of tau protein destabilizes microtubules.

- *Other genetic risk factors.* The genetic locus on chromosome 19 that encodes apolipoprotein E (ApoE) has a strong influence on the risk of developing AD. Three alleles exist (ε2, ε3, and ε4) based on two amino acid polymorphisms. The dosage of the ε4 allele increases the risk of AD and lowers the age of onset of the disease, such that individuals with the ε4 allele are overrepresented in populations of patients with AD. This ApoE isoform promotes Aβ generation and deposition, but also appears to exacerbate Aβ-independent, *tau*-mediated neurodegeneration. Overall, this locus has been estimated to convey about one-fourth of the risk for development of late-onset AD. Genome-wide association studies have identified several other loci that contribute to the risk of AD; the connection between these genetic loci and the pathogenesis of AD remains to be explored.
- *Role of inflammation.* Both small aggregates and larger deposits of Aβ elicit an inflammatory response from microglia and astrocytes. This response probably assists in the clearance of the aggregated peptide, but it may also stimulate the secretion of mediators that cause damage. Additional consequences of the activation of these inflammatory cascades may include alterations in tau phosphorylation, oxidative injury to neurons, and aberrant pruning of synapses.
- *Basis for cognitive impairment.* Although there remains disagreement regarding the best correlate of dementia in individuals with AD, it is clear that the presence of a large burden of plaques and tangles is highly associated with severe cognitive dysfunction. The number of neurofibrillary tangles correlates better with the degree of dementia than does the number of neuritic plaques. Biochemical markers that have been correlated with the degree of dementia include loss of choline acetyltransferase, loss of synaptophysin immunoreactivity, and amyloid burden.
- *Biomarkers.* Among the more important recent developments in the understanding of AD is the discovery of

possible biomarkers, which draw on the understanding of the biologic processes discussed earlier. It is now possible to demonstrate Aβ deposition in the brain through imaging methods that rely on 18F-labeled amyloid-binding compounds; this approach can identify asymptomatic patients who are in the early stages of AD. Additional evidence of neuronal degeneration associated with AD-related pathologic processes includes the presence of increased phosphorylated tau and reduced Aβ in the CSF. Together, these biomarkers have allowed for the identification of preclinical stages of AD, well in advance of the development of dementia or other signs and symptoms; this in turn has enabled the focus of pharmacologic trials to shift toward individuals in the earliest stages of the illness, in whom it is hoped interventions will slow or prevent disease progression and limit disability.

MORPHOLOGY

Grossly, the brain shows variable **cortical atrophy** marked by gyral narrowing and sulcal widening that is most pronounced in the frontal, temporal, and parietal lobes (Fig. 28.36). With significant atrophy, there is compensatory ventricular enlargement (hydrocephalus *ex vacuo*) secondary to reduced brain volume. Structures of the medial temporal lobe, including the hippocampus, entorhinal cortex, and amygdala, are involved early in the disease course and are usually severely atrophied in the later stages.

The major microscopic abnormalities of AD are **neuritic (senile) plaques** and **neurofibrillary tangles.** There is progressive, eventually severe, neuronal loss and reactive gliosis in the same regions that bear the burden of plaques and tangles.

Neuritic plaques are focal, spherical collections of dilated, tortuous, axonal or dendritic processes (dystrophic neurites) often around a central amyloid core, which may be surrounded by a clear halo (Fig. 28.37A). Dystrophic neurites contain tau aggregates that are biochemically similar to neurofibrillary tangles.

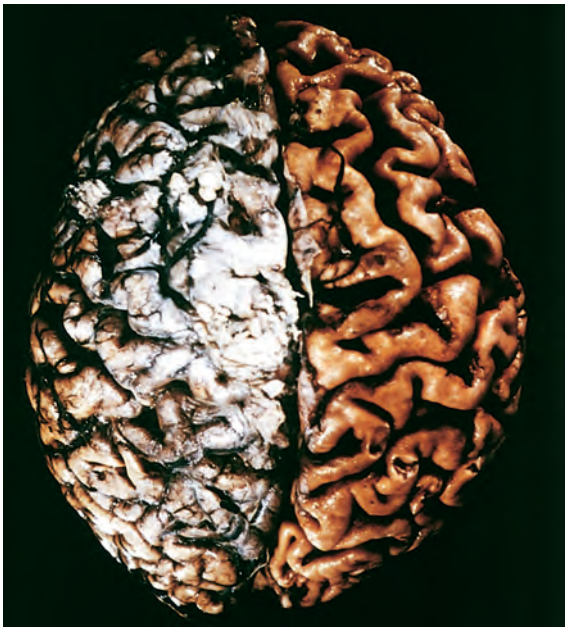

Figure 28.36 Alzheimer disease with cortical atrophy most evident on the right, where meninges have been removed. (Courtesy the late Dr. E.P. Richardson, Jr., Massachusetts General Hospital, Boston, Mass.)

Neuritic plaques range in size from 20 to 200 μm in diameter; microglial cells and reactive astrocytes are present at their periphery. Plaques are found in the hippocampus, amygdala, and neocortex, although there is usually relative sparing of primary motor and sensory cortices (this also applies to neurofibrillary tangles). The amyloid core, which can be stained by Congo red or a beta amyloid immunostain, contains several abnormal proteins. The dominant component of the amyloid plaque core is Aβ, a peptide derived by proteolytic cleavage of APP (Figs. 28.37B and 28.35); other proteins, including components of the complement cascade, proinflammatory cytokines, α_1-antichymotrypsin, and apolipoproteins, are present in lesser abundance. In some cases, there is deposition of Aβ peptides in the absence of the surrounding dystrophic neurites. These lesions, termed **diffuse plaques,** are found mainly in superficial portions of the cerebral cortex, the basal ganglia, and the cerebellar cortex. Based on studies of individuals with trisomy 21, diffuse plaques are believed to be an early stage of plaque development. Although neuritic plaques contain both $A\beta_{40}$ and $A\beta_{42}$, diffuse plaques are predominantly made up of $A\beta_{42}$.

Neurofibrillary tangles are tau-containing bundles of filaments in the cytoplasm of the neurons that displace or encircle the nucleus. In pyramidal neurons, they often have an elongated "flame" shape; in rounder cells, the basket weave of fibers around the nucleus takes on a rounded contour ("globose" tangles). Neurofibrillary tangles are visible as basophilic fibrillary structures with H&E staining (Fig. 28.37C) but are demonstrated much more clearly by silver (Bielschowsky) staining (Fig. 28.37D) and with tau immunohistochemistry (Fig. 28.37E). They are commonly found in cortical neurons, especially in the entorhinal cortex, as well as in other sites such as pyramidal cells of the hippocampus, the amygdala, the basal forebrain, and the raphe nuclei. Neurofibrillary tangles are insoluble and apparently resistant to clearance in vivo, thus remaining visible in tissue sections as "ghost" or "tombstone" tangles long after the death of the parent neuron. Ultrastructurally, neurofibrillary tangles are composed predominantly of paired helical filaments along with some straight filaments that appear to have a similar composition. Aggregated tau is also present in dystrophic neurites that form the outer portions of neuritic plaques and in axons coursing through the affected gray matter as neuropil threads. In contrast to neuritic and diffuse plaques, tangles are found in other neurodegenerative diseases and are thus not specific for AD.

In addition to the diagnostic features of plaques and tangles, several other pathologic findings are seen in the setting of AD. **Cerebral amyloid angiopathy (CAA)** (Fig. 28.18D) is an almost invariable accompaniment of AD; however, it can also be found in brains of individuals without AD. In contrast to the amyloid deposited in neuritic and diffuse plaques, which mainly consists of Aβ42, the amyloid in CAA is predominantly comprised of Aβ40.

Although abundant burdens of plaques and tangles characterize the end stage of AD, in which affected individuals are fully demented, it is clear that these histologic changes appear well in advance of clinical symptoms. To provide a correlation between neuropathologic findings and clinical symptomatology, the most recent recommendations for describing these lesions consider all deposition of Aβ in brain parenchyma to be a form of AD neuropathologic change. The scheme then generates a histopathologic score based on the distribution of Aβ deposits, plaques, and tangles, which is used to predict the likelihood of an individual being cognitively impaired that is based on population studies.

(C) Neurofibrillary tangle is present within one neuron, and several extracellular tangles are also present *(arrows)*. (D) Silver stain highlights a neurofibrillary tangle *(black)* within the neuronal cytoplasm. (E) Tangle *(upper left)* and neurites around a plaque *(lower right)* contain tau, demonstrated by immunohistochemistry.

Clinical Features

The progression of AD is slow but relentless, with a symptomatic course often running more than 10 years. Initial symptoms are forgetfulness and other memory disturbances; with progression, other symptoms emerge, including language deficits, loss of mathematical skills, and loss of learned motor skills. In the final stages, affected individuals may become incontinent, mute, and unable to walk; intercurrent disease, often pneumonia, is usually the terminal event. Current clinical trials are focused on treating subjects in early, preclinical stages of the illness, using strategies that include clearing Aβ from the brain through immunologic approaches, disrupting the generation of Aβ with pharmacologic agents that target secretases, as well as approaches aimed at preventing alterations in tau.

Frontotemporal Lobar Degenerations (FTLDs)

FTLDs are a heterogeneous group of disorders associated with focal degeneration of frontal and/or temporal lobes. They are clinically distinguished from AD by the pattern of involvement, with alterations in personality, behavior, and language (aphasias) preceding memory loss; however, as with other neurodegenerative diseases, postmortem pathologic evaluation is required for definitive diagnosis. Global dementia occurs with progressive disease, and a subset of patients develops extrapyramidal motor loss. Several clinical variants have been described based on whether the behavioral change or aphasias dominate, but they have overlapping features. FTLDs are one of the more common causes of early-onset dementia and occur at the same frequency as AD in those younger than 65 years of age. Commonly referred to in the clinical setting as *frontotemporal dementia* (FTD), the preferred pathologic terminology highlights the anatomic pattern of involvement (lobar degeneration) rather than the clinical symptom (dementia).

Like most neurodegenerative diseases, FTLD is associated with cellular inclusions comprised of specific proteins; the two most common patterns are those with tau inclusions (FTLD-tau) and those with TDP-43 inclusions (FTLD-TDP). Within each of these groups, there are heritable and sporadic forms. There is no fixed relationship between the clinical subtypes of FTLD and the type of neuronal inclusions.

FTLD-tau

These are forms of FTLD in which the affected cortical regions demonstrate progressive neuronal loss and reactive gliosis, along with the presence of cytoplasmic tau inclusions in neurons. Unlike Alzheimer disease, which is characterized by the combination of Aβ and tau deposition, FTLD-tau shows only tau aggregation and accumulation. In some cases FTLD-tau inclusions resemble the tangles seen in AD, and in other forms of the disease there are smooth contoured inclusions (Pick bodies).

Pathogenesis

FTLD-tau may be associated with mutations in *MAPT,* the gene that encodes tau, or it may arise sporadically. As mentioned earlier, tau interacts with microtubules; its binding to microtubules may be regulated by phosphorylation. There is an inverse relationship between the degree of tau phosphorylation and its ability to bind microtubules. Tau, particularly when phosphorylated, has a propensity to aggregate. Interestingly, tau exists as a complex series of isoforms that are encoded by different mRNA splice variants; the balance between these isoforms appears to be critical for normal tau function in neurons, and disturbances in isoform ratio may also provoke tau aggregation.

Two different types of tau mutations have been described. Some missense point mutations effect tau phosphorylation, tipping the balance from microtubule binding to aggregation. Other mutations include point mutations that affect splicing; many of these are intronic and alter the loop-stem structures recognized by the spliceosome. The resulting change in isoform ratio is thought to lead to neuronal dysfunction and, as discussed earlier, may also enhance tau aggregation.

It remains unclear how abnormal tau injures neurons, although there appears to be both a loss-of-function component, as aggregation depletes neurons of tau, and a toxic gain-of-function component due to presence of aberrantly hyperphosphorylated aggregated protein.

MORPHOLOGY

There is atrophy of frontal and temporal lobes to variable extent and severity. The pattern of atrophy can often be predicted from the clinical symptoms. The atrophic regions of cortex are marked by neuronal loss, gliosis, and the presence of tau-containing neurofibrillary tangles (Fig. 28.38A). These tangles may contain a variety of tau isoforms. Nigral degeneration may occur. Inclusions can also be found in glial cells in some forms of the disease.

In **Pick disease** (a subtype of FTD-tau), the brain invariably shows a pronounced and frequently asymmetric atrophy of the frontal and temporal lobes, with conspicuous sparing of the posterior two-thirds of the superior temporal gyrus and only rare involvement of the parietal and occipital lobes. The atrophy can be severe, reducing gyri to a wafer-thin ("knife-edge") appearance. The neuronal loss is most severe in the outer three layers of the cortex. Some of the surviving neurons show a characteristic swelling (Pick cells), and others contain **Pick bodies,** cytoplasmic, round to oval, filamentous inclusions that stain strongly with silver methods (Fig. 28.38B).

FTLD-TDP

Some individuals with clinically diagnosed FTD and macroscopic changes of relatively localized cortical atrophy (the "lobar degeneration" of the term) have inclusions that do not contain tau and instead contain TDP-43, an RNA-binding protein. Individuals with FTLD-TDP typically present with either behavioral problems or language deficits, features similar to FTLD-tau.

Pathogenesis

Mutations in three different genes have been found in the inherited forms of FTLD-TDP.

- The most common familial form of FTLD-TDP is the result of an expansion of a hexanucleotide repeat in the 5′ region of *C9orf72* (a gene encoding a protein of unknown function); the spectrum of disease associated with *C9orf72* expansion also includes amyotrophic lateral sclerosis

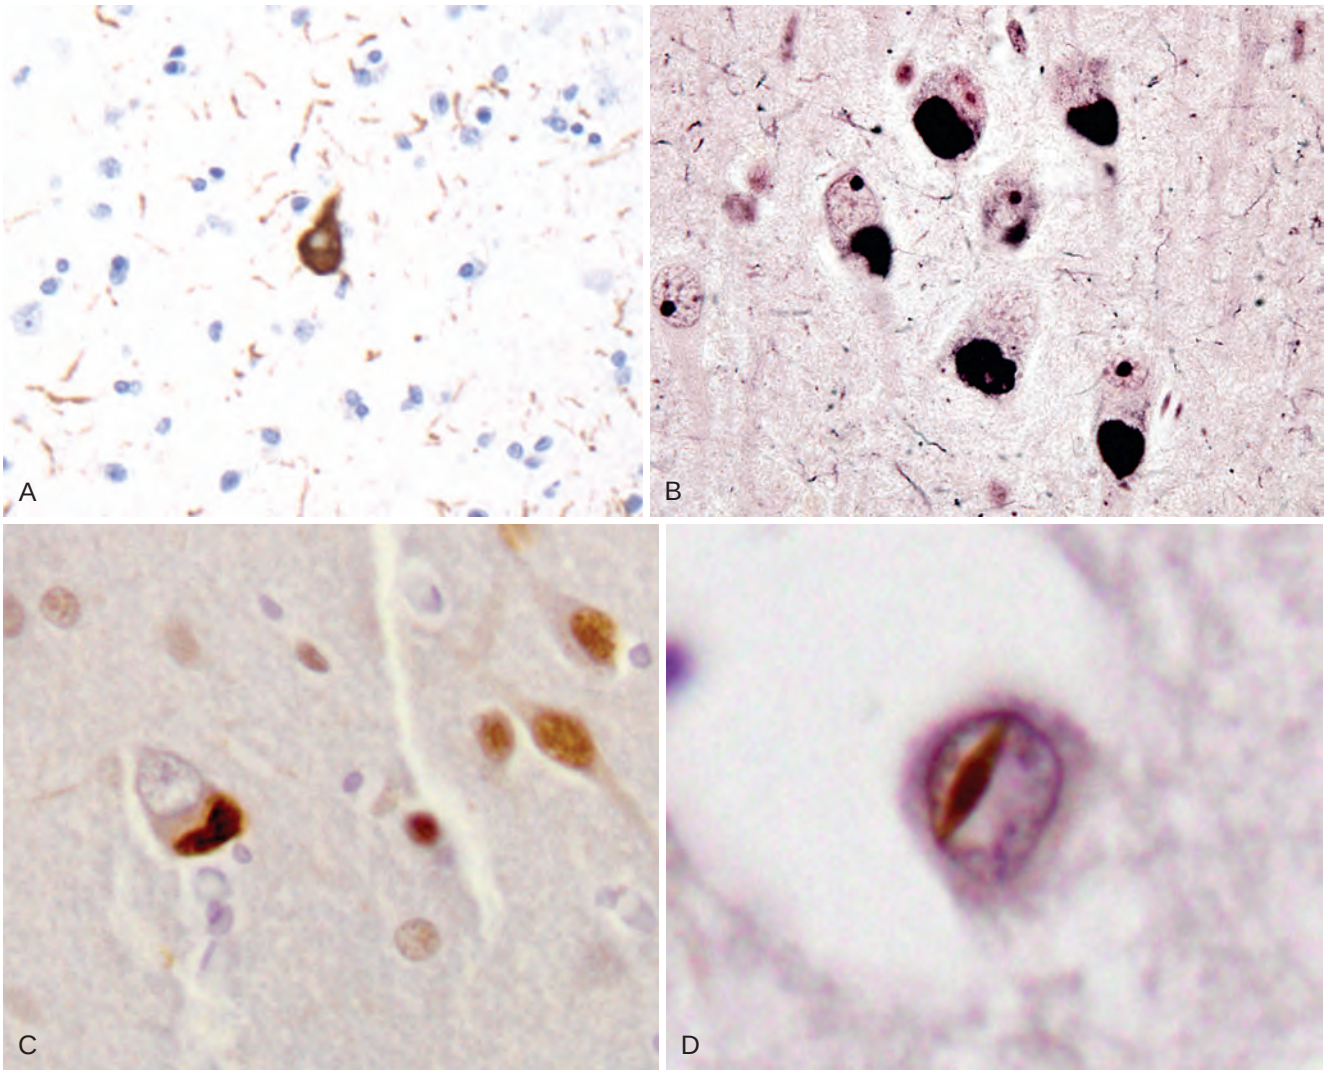

Figure 28.38 Frontotemporal lobar degenerations (FTLDs). (A) FTLD-tau. A tangle is present along with numerous tau-containing neurites. (B) Pick disease. Pick bodies are round, homogeneous neuronal cytoplasmic inclusions that stain intensely with silver stains. (C) FTLD-TDP. Cytoplasmic inclusions containing TDP-43 are seen in association with loss of normal nuclear immunoreactivity. (D) FLTD-TDP. With progranulin mutations, the TDP-43–containing inclusions are commonly intranuclear.

(discussed later). How the repeat expansion results in formation of aggregates of TDP-43 is a mystery at present. Interestingly, the brains from *C9orf72*-associated FTLD and amyotrophic lateral sclerosis cases also contain ubiquitin-positive inclusions that consist of dipeptide repeats generated by aberrant translation of the expanded repeats (in individuals without repeat expansion, this region of the gene contains regulatory sequences and is not translated).

- Mutations in the *TARDBP* gene (encoding TDP-43) are less common and also occur in some familial cases of amyotrophic lateral sclerosis. TDP-43 is an RNA-binding protein with roles in RNA processing and the formation of stress granules, RNA-protein aggregates of uncertain function. Both loss of function and toxic gain of function may contribute to this form of FTD.
- A third form of FTLD-TDP is the result of mutations in the *GRN* gene, which encodes a protein called progranulin; in contrast to *TARDBP* and *C9orf72,* mutations in *GRN* have not been linked to amyotrphic lateral sclerosis. Progranulin mutations cause loss of function, and the disease is believed to stem from deficient progranulin activity. Progranulin is a secreted protein expressed in glia and neurons that is cleaved into multiple small peptides; these peptides have been implicated in regulation of inflammation in the brain, but the link between this activity and the accumulation of TDP-43–containing inclusions in FTLD is currently obscure.

There are forms of FTLD in which there are neither tau- nor TDP-containing inclusions. Although these are infrequent, the underlying genetic causes show overlap with the pathways involved in other forms of FTLD-TPD. Mutations in the *FUS* (fused in sarcoma) gene may cause either FTLD or ALS, and FUS is another RNA-binding protein that may be involved in formation of stress granules.

MORPHOLOGY

The appearance is similar to the other forms of FLTD, with variable atrophy of frontal and temporal lobes accompanied by neuronal loss and gliosis. Normally, TDP-43 is found diffusely in the nucleus but in FTLD-TDP, TDP-43 is found in inclusions (Fig. 28.38C) that may be in the cell body (neuronal cytoplasmic inclusions), in the nucleus (neuronal intranuclear inclusions), or in neurites (TDP-43 threads). In the inclusions, TDP-43 is phosphorylated and ubiquitinated. Inclusions are most abundant in the frontal and temporal cortex, the striatum, and the dentate gyrus of the hippocampus. There is a strong correlation between the presence of needle-like intranuclear inclusions and progranulin mutations (Fig. 28.38D).

There are also forms of FTLD in which there are neither tau- nor TDP-containing inclusions. Although these are infrequent, the underlying genetic causes show connections with the pathways involved in other forms of FTLD-TDP. Mutations in the *FUS* (fused in sarcoma) gene may cause either FTLD or amyotrophic lateral sclerosis, and FUS is another RNA-binding protein that may be involved in formation of stress granules.

Parkinson Disease (PD)

PD is a neurodegenerative disease marked by a hypokinetic movement disorder that is caused by loss of dopaminergic neurons from the substantia nigra. The clinical syndrome of *parkinsonism* combines diminished facial expression (often termed masked facies), stooped posture, slowing of voluntary movement, festinating gait (progressively shortened, accelerated steps), rigidity, and a "pill-rolling" tremor. This type of motor disturbance is seen in a number of conditions that are associated with damage to the nigrostriatal dopaminergic system. Although PD is the most common cause of parkinsonism, similar symptoms can be induced by dopaminergic antagonists or by toxins that selectively damage the dopaminergic system. Also discussed later are other rare diseases that have parkinsonism as part of the clinical presentation.

The clinical diagnosis of PD is based on the presence of the triad of parkinsonism—tremor, rigidity, and bradykinesia—in the absence of a toxic or other known underlying etiology. This clinical impression is confirmed by symptomatic response to L-DOPA replacement therapy. Although the diagnosis of PD is based in large part on the presence of the motor symptoms, which reflect the decreased dopaminergic innervation of the striatum, the disease is not restricted to dopaminergic neurons or to the basal ganglia; in fact, degeneration of the substantia nigra (which results in the motor symptoms) represents a mid-stage in a progressive disease that begins lower in the brainstem and eventually progresses to involve the cerebral cortex, leading to cognitive impairment (see "Dementia with Lewy Bodies," later in this chapter).

The dopaminergic neurons of the substantia nigra project to the striatum, and their degeneration in PD is associated with a reduction in striatal dopamine content. The severity of the motor syndrome is proportional to the dopamine deficiency, which can, at least in part, be corrected by replacement therapy with L-DOPA (the immediate precursor of dopamine). However, treatment does not reverse the structural changes or arrest the progress of the disease; with progression, drug therapy becomes less effective, and symptoms more difficult to manage. Deep brain stimulation has emerged over the past decade as a therapy for the motor symptoms of PD. In addition, the well-characterized neural and biochemical deficits in PD have also provided a rationale for therapeutic trials of neural transplantation and gene therapy.

An acute parkinsonian syndrome and destruction of neurons in the substantia nigra follows exposure to MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), discovered as a contaminant in illicitly synthesized batches of the opioid meperidine. This toxin has been used to generate animal models of PD, which are used to test new therapies. Epidemiologic evidence has also suggested that pesticide exposure is a risk factor for PD, while caffeine and nicotine appear to be protective.

Pathogenesis

PD is associated with protein accumulation and aggregation, mitochondrial abnormalities, and neuronal loss in the substantia nigra and elsewhere in the brain. Although most PD is sporadic, identification of genetic causes helped shed light on its pathogenesis.

- The first mutations identified as a cause of autosomal dominant PD involved *SNCA,* a gene that encodes α-synuclein, an abundant lipid-binding protein normally localized to synapses. This protein is a major component of the *Lewy body,* which is the diagnostic hallmark of PD. Mutations in *SCNA* are rare; they include point mutations and amplifications of the region of chromosome 4q21 that contains the gene. The occurrence of disease caused by increases in gene copy number implies a gene dosage effect and suggests that polymorphisms in the α-synuclein promoter influence the risk of PD. Like Aβ in AD, α-synuclein forms aggregates; of these, small oligomers appear to be the most toxic to neurons. There is also evidence that aggregates can be released from one neuron and taken up by another, suggesting a prion-like pattern of spread within the brain. Consistent with this idea, α-synuclein–containing aggregates (Lewy bodies and Lewy neurites) are first seen in the medulla and then in contiguous areas of the brain, ascending through the brainstem and extending into limbic structures and finally the neocortex. Remarkably, emerging evidence suggests that α-synuclein aggregates are initially formed in the neurons of the enteric nervous system and spread from the gut to the medulla via the vagus nerve; this "gut-brain" hypothesis of PD pathogenesis provides a possible explanation for association of PD with exposure to pesticides and other environmental toxins.
- *Mitochondrial dysfunction* has been implicated as a contributing factor based on autosomal recessive forms of PD that are caused by mutations in genes that encode the proteins DJ-1, PINK1, and parkin. DJ-1 has multiple cellular roles, including acting as a transcriptional regulator, but in settings of oxidative stress, it can relocate to the mitochondria and have cytoprotective effects. PINK1 is a kinase that localizes to the outer membrane of dysfunctional mitochondria, where it recruits and phosphorylates

parkin. This modification activates parkin, an E3 ubiquitin ligase that targets a number of substrates for proteasomal destruction. Under normal circumstances, the combination of PINK1 and parkin results in clearance of dysfunctional mitochondria through mitophagy; this process is impaired by defects in PINK1 or parkin. Intriguingly, levels of mitochondrial complex I, a component of the oxidative phosphorylation cascade, are reduced in the brains of patients with sporadic PD.

- Heterozygous mutations in the lysosomal enzyme glucorebrosidase are the most important risk factor for development of PD, accounting for ~5% of PD cases (homozygous mutations in this enzyme cause Gaucher disease, a lysosomal storage disease described in more detail in Chapter 5); this genetic link suggests that dysfunction of the lysosome-autophagy pathway contributes to PD pathogenesis, most likely through abnormal metabolism of α-synuclein, activation of the unfolded protein response, and increased inflammation.
- Mutations in the gene encoding *LRRK2* (leucine-rich repeat kinase 2) are the most common cause of autosomal dominant PD and are also found in some late-onset, apparently sporadic cases of the disease. LRRK2 is a cytoplasmic kinase; several of the pathogenic mutations increase its kinase activity, suggesting that gains in LRRK2 function—either hyperphosphorylation of normal targets or emergence of novel targets—might contribute to the development of PD. However, the molecular mechanism linking LRRK2 dysfunction and α-synuclein accumulation has not yet been elucidated.

MORPHOLOGY

A characteristic gross finding in PD is **pallor of the substantia nigra** (compare Fig. 28.39A and B) and locus ceruleus, which is due to loss of the pigmented, catecholaminergic neurons in these nuclei. **Lewy bodies** (Fig. 28.39C) are usually found in some of the remaining neurons; these are single or multiple, cytoplasmic, eosinophilic, round to elongated inclusions that often have a dense core surrounded by a pale halo. Ultrastructurally, Lewy bodies are composed of fine filaments, densely packed in the core but loose at the rim; these filaments are composed of α-synuclein. Lewy bodies can also be found in the cholinergic neurons of the basal nucleus of Meynert, as well as in other brainstem nuclei including the locus ceruleus and the dorsal motor nucleus of the vagus. Areas of neuronal loss also typically show gliosis. Lewy neurites are dystrophic processes that contain aggregated α-synuclein.

Dementia With Lewy Bodies

About 10% to 15% of individuals with PD develop dementia, particularly with advancing age. Characteristic features of this disorder include a fluctuating course, visual hallucinations, and prominent frontal signs. Although some affected individuals have pathologic evidence of Alzheimer disease (or, less frequently, other degenerative diseases associated with cognitive changes) in combination with PD, in others the most prominent histologic correlate is the presence of widespread Lewy bodies in neurons of the cortex and brainstem. In some cases, dementia with Lewy bodies represents an advanced stage of PD in which protein aggregates appear to have "spread," possibly through propagation of misfolded proteins, to neurons in the cerebral cortex. In other individuals, however, the dementia is the first presenting symptom, and the motor symptoms appear later, suggesting a descending rather than ascending pattern of disease spread.

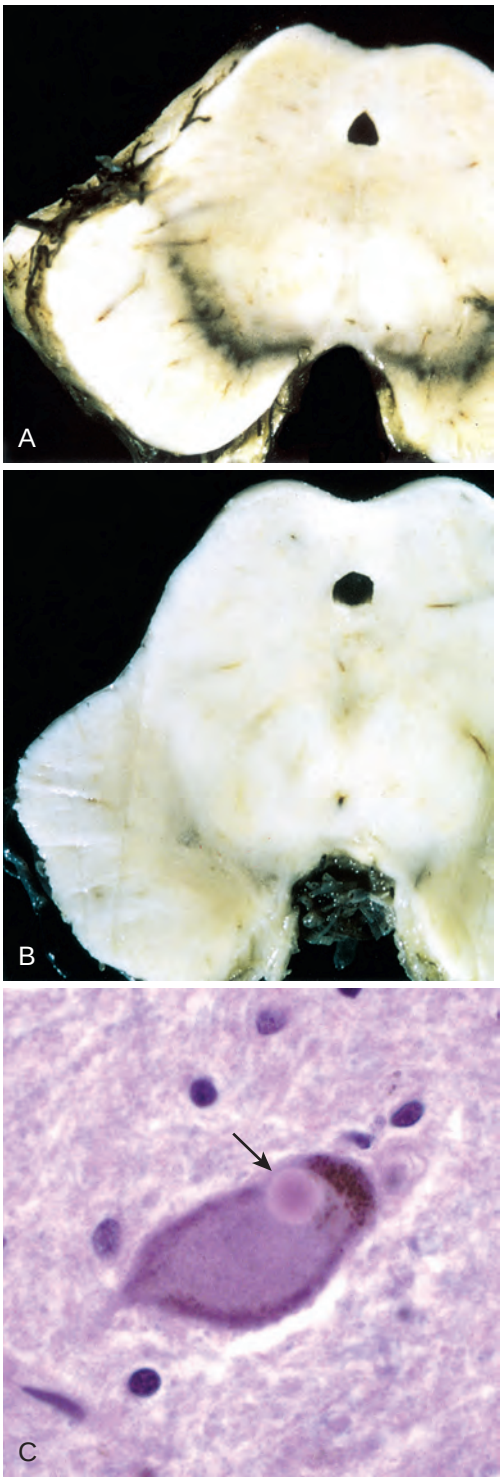

Figure 28.39 Parkinson disease. (A) Normal substantia nigra. (B) Depigmented substantia nigra in idiopathic Parkinson disease. (C) Lewy body in a substantia nigra neuron, staining bright pink *(arrow)*.

Cortical Lewy bodies are less distinctive than those in the brainstem, but are also composed predominantly of α-synuclein. Immunohistochemical staining for α-synuclein also reveals the presence of abnormal neurites that contain aggregated protein—called *Lewy neurites* even though Lewy never saw them! In this setting, the gross pathologic findings typically include depigmentation of the substantia nigra and locus ceruleus, paired with relative preservation of the cortex, hippocampus, and amygdala. The burden of cortical Lewy bodies is usually extremely low, and the mechanism by which this disease wreaks havoc on cognitive functioning is not clear. There is evidence that the burden of oligomeric α-synuclein in cortical neurons is more important in disease causation than the Lewy bodies.

Atypical Parkinsonian Syndromes

As discussed earlier, the clinical syndrome of parkinsonism, with bradykinesia and rigidity, reflects dysfunction of the dopaminergic nigrostriatal pathway. In addition to the forms of PD already discussed, there are a variety of disorders that include parkinsonism as a component of the symptoms. These diseases, in general, are minimally responsive to treatment with L-DOPA; they are also distinguished from PD through the presence of additional signs and symptoms. For these reasons, they are considered to be *atypical parkinsonian syndromes* or *Parkinson-plus syndromes*. These disorders include progressive supranuclear palsy and corticobasal degeneration, both of which are tauopathies, and multisystem atrophy, a synucleinopathy.

Progressive Supranuclear Palsy (PSP)

PSP is a tauopathy in which affected individuals develop progressive truncal rigidity, disequilibrium with frequent falls, and difficulty with voluntary eye movements. Other common symptoms include nuchal dystonia, pseudobulbar palsy, and a mild progressive dementia. The onset is usually between the fifth and seventh decades, with males affected approximately twice as frequently as females. The disease is often fatal within 5 to 7 years of onset.

Although the pathologic hallmark of PSP is the presence of tau-containing inclusions in neurons and glia, causative mutations in the tau gene have been identified in only a few cases. However, risk for sporadic PSP is linked to single nucleotide polymorphisms that map near the tau gene locus. Other risk alleles have been identified through genome-wide association studies, but how they influence development of PSP is unclear.

Corticobasal Degeneration (CBD)

CBD is a progressive tauopathy that is most often characterized by extrapyramidal rigidity, asymmetric motor disturbances (jerking movements of limbs), and impaired higher cortical function (typically in the form of apraxia). As with PSP, cognitive decline may occur, typically later in the illness. The same tau variant linked to PSP is also highly associated with CBD. Overall, CBD and PSP share many clinical and pathologic features; in general, with PSP there is a greater burden of tau-containing lesions in brainstem and deep gray matter, while in CBD the balance is shifted toward involvement of the cerebral cortex.

MORPHOLOGY

In PSP, there is widespread neuronal loss in the globus pallidus, subthalamic nucleus, substantia nigra, colliculi, periaqueductal gray matter, and dentate nucleus of the cerebellum; globose fibrillary tangles are found in these affected regions, in neurons as well as in glia. In CBD, the brain shows cortical atrophy, mainly of the motor, premotor, and anterior parietal lobes. In affected regions of cortex, there is severe loss of neurons, gliosis, and **"ballooned" neurons.** Tau immunoreactivity has been found in astrocytes ("tufted astrocytes"), oligodendrocytes ("coiled bodies"), basal ganglionic neurons, and, variably, cortical neurons. Clusters of tau-positive processes around astrocytes ("astrocytic plaques") and the presence of tau-positive threads in gray and white matter may be the most specific pathologic findings of CBD. The substantia nigra and locus ceruleus show neuronal loss, ballooned neurons, and tangles.

Multiple System Atrophy (MSA)

MSA is a sporadic disorder that affects several functional systems in the brain and is characterized by α-synuclein inclusions in the cytoplasm of oligodendrocytes. In contrast to other degenerative diseases, which primarily affect neurons, the histopathologic changes in MSA are primarily observed in glial cells and are associated with degeneration of white matter tracts. In addition, there is accompanying neuronal degeneration, but typically without the presence of inclusions. The "multiple" in the term *multiple system atrophy* refers to three distinct neuroanatomic circuits that are commonly involved: the striatonigral circuit (leading to parkinsonism), the olivopontocerebellar circuit (leading to ataxia), and the autonomic nervous system including the central elements (leading to autonomic dysfunction, with orthostatic hypotension as a prominent component). In a given individual, one of these components may predominate at the onset of the illness, but typically the other systems become affected as MSA progresses.

Pathogenesis

As in PD, α-synuclein is the major component of the inclusions. MSA is a sporadic disease, and no causative mutations in the gene encoding α-synuclein have been identified; nonetheless, polymorphisms near this gene appear to confer increased risk. The relationship between glial cytoplasmic inclusions and disease is supported by the observation that the burden of inclusions increases as the disease progresses, although inclusions eventually disappear as cells die in the final stages. It appears that glial cytoplasmic inclusions can occur in the absence of neuronal loss, suggesting that they are the primary pathologic event; for example, glial cytoplasmic inclusions are consistently observed in the white matter projecting to and from the motor cortex. The origin of the α-synuclein in oligodendrocytes remains perplexing because this is a neuronal protein associated with synaptic vesicles. Several studies have shown that there is no upregulation of α-synuclein expression in white matter or in oligodendrocytes in MSA. It has been suggested that oligodendrocytes may acquire α-synuclein aggregates secondarily from injured or dying neurons. When α-synuclein is present in oligodendrocytes, they become more sensitive

to oxidative stress and show impaired interaction with the extracellular matrix.

MORPHOLOGY

The pathologic findings in MSA match the clinical presentation in any particular case. In cerebellar forms, there is atrophy of the cerebellum, including the cerebellar peduncles, pons (especially the base, Fig. 28.40A), and medulla (especially the inferior olive); in parkinsonian forms, the atrophy involves the substantia nigra and striatum (especially the putamen). Autonomic symptoms are related to cell loss from the catecholaminergic nuclei of the medulla and the intermediolateral cell column of the spinal cord. Atrophic brain regions show evidence of neuronal loss as well as variable numbers of neuronal cytoplasmic and nuclear inclusions.

The diagnostic glial cytoplasmic inclusions were originally demonstrated in oligodendrocytes with silver impregnation methods and contain α-synuclein as well as ubiquitin (see Fig. 28.40B). Similar inclusions may also be found in the cytoplasm of neurons, in neuronal and glial nuclei, and in axons.

Huntington Disease (HD)

HD is an autosomal dominant disease caused by degeneration of striatal neurons and characterized by a progressive movement disorder and dementia. Jerky, hyperkinetic, sometimes dystonic movements involving all parts of the body (chorea) are characteristic; affected individuals may later develop bradykinesia and rigidity. The disease is relentlessly progressive and uniformly fatal, with an average course of about 15 years.

Pathogenesis

HD is a prototypic polyglutamine trinucleotide repeat expansion disease (Chapter 5). The gene for HD, *HTT,* located on chromosome 4p16.3, encodes a 348-kD protein known as *huntingtin*. In the first exon of the gene, there is a stretch of CAG repeats that encodes a polyglutamine region near the N terminus of the protein. Normal *HTT* genes contain 6 to 35 copies of the repeat; when the number of repeats is increased beyond this level, it is associated with disease. There is an inverse relationship between repeat number and age of onset, such that longer repeats tend to be associated with earlier onset. Repeat expansions occur during spermatogenesis, so that paternal transmission is associated with earlier onset in the next generation, a phenomenon termed *anticipation*. In contrast to many other degenerative diseases, there is no sporadic form of HD. New mutations are uncommon; most apparently sporadic cases are explained by nonpaternity, the death of a parent before the disease develops, or an unaffected father with a mild repeat expansion that enlarges to a pathogenic size during spermatogenesis.

The biologic function of normal huntingtin remains unknown, but it appears that the expansion of the polyglutamine region bestows a toxic gain-of-function on huntingtin. For this reason, various approaches to silencing expression of the mutant allele are being investigated as potential therapies. It is interesting to note that although huntingtin is expressed in all tissues of the body, the deleterious effects of mutant huntingtin occur only in selected parts of the central nervous system.

Although development of intranuclear inclusions containing huntingtin is a pathologic hallmark of HD, this process is not directly involved in cellular injury and, based on in vitro evidence, actually appears to be neuroprotective (among the

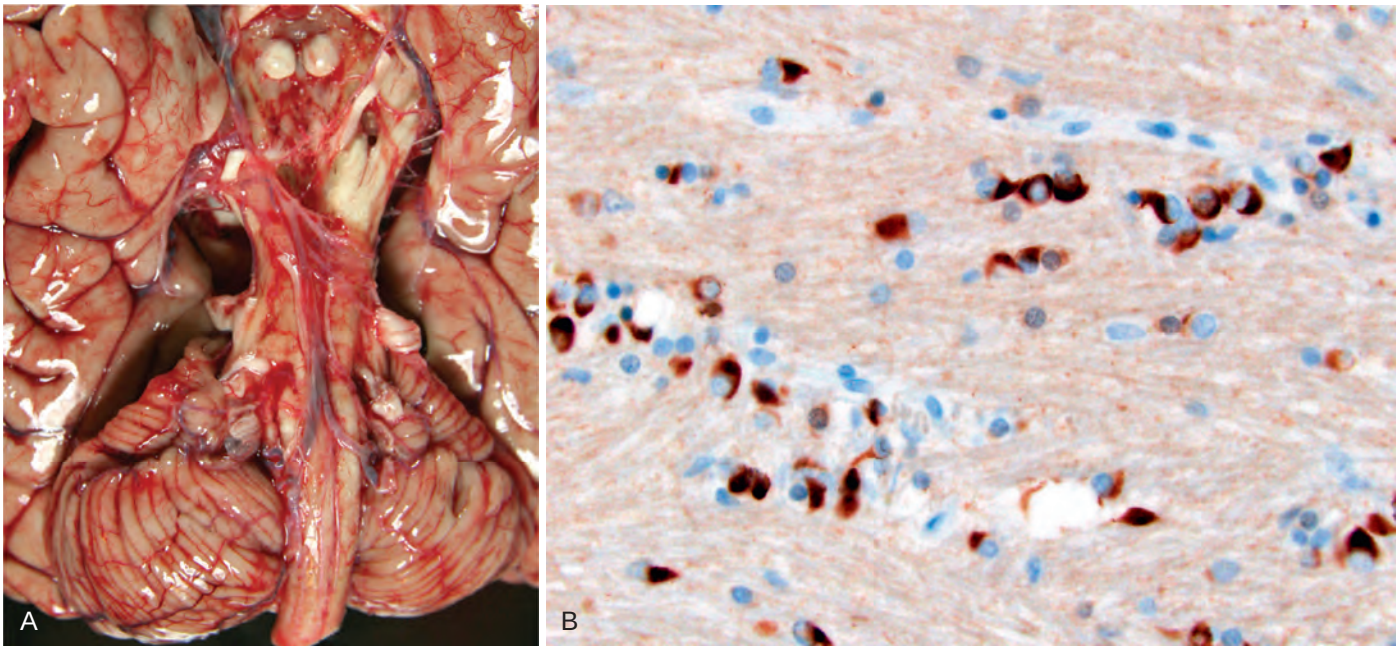

Figure 28.40 Multiple system atrophy (MSA). (A) Severe atrophy of the basis pontis in a case of MSA-C. (B) Inclusions in oligodendrocytes contain α-synuclein.

striatal neurons overexpressing mutant huntingtin, those that form inclusions survive the longest). Although the mechanism for this neuroprotective effect is not clear, it is generally thought that it stems from the sequestration of neurotoxic forms of mutated huntingtin. Transcriptional dysregulation has been implicated in HD, based on the observation that mutant forms of huntingtin bind various transcriptional regulators. Some of the transcription factors that interact with mutant huntingtin are involved in mitochondrial biogenesis and protection against oxidative injury, and their reduced activity may result in increased susceptibility to oxidative stress. Other alterations that may contribute to the pathogenesis of HD include reduced expression of the growth factor brain-derived neurotrophic factor (BDNF), and disruption of proteasomal and autophagic degradation pathways. Interestingly, emerging evidence suggests that aggregated huntingtin can be transferred between cells, another example of possible prion-like spread of a pathogenic protein.

MORPHOLOGY

The brain is small and shows striking **atrophy of the caudate nucleus and the putamen,** components of the dorsal striatum; the globus pallidus may atrophy secondarily, and the lateral and third ventricles are dilated (Fig. 28.41A). Atrophy is frequently also seen in the frontal lobe, less often in the parietal lobe, and occasionally throughout the entire cortex. On microscopic examination, there is profound loss of striatal neurons; the most marked changes are found in the caudate nucleus, especially in the tail and in portions nearer the ventricle. Pathologic changes develop in a medial-to-lateral direction in the caudate and from dorsal to ventral in the putamen. Medium-sized, spiny neurons that use γ-aminobutyric acid as their neurotransmitter, along with enkephalin, dynorphin, and substance P, are especially affected; fibrillary gliosis is more extensive than in the usual reaction to neuronal loss. There is a direct relationship between the degree of degeneration in the striatum and the severity of clinical symptoms. Protein aggregates containing huntingtin can be found in neurons in the striatum and cerebral cortex (see Fig. 28.41, *inset*).

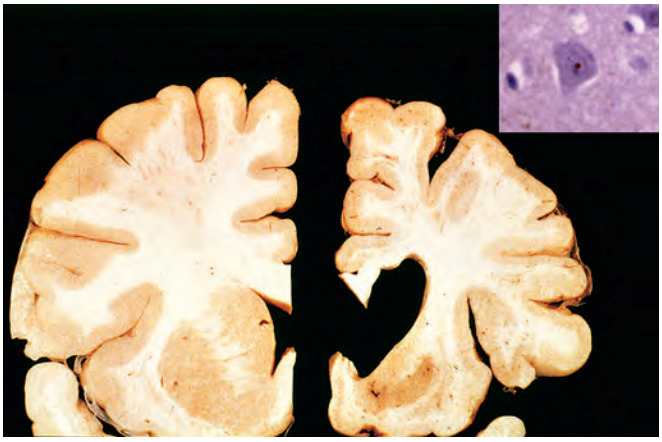

Figure 28.41 Huntington disease. Normal hemisphere on the left compared with the hemisphere with Huntington disease on the right showing atrophy of the striatum and ventricular dilation. *Inset,* Intranuclear inclusions in neurons are highlighted by an immunohistochemical stain for ubiquitin. (Courtesy Dr. J-P Vonsattel, Columbia University, NY.)

Clinical Features

The loss of striatal neurons, which function to dampen motor activity, results in increased motor output, often manifested as choreoathetosis. The cognitive changes associated with the disease are probably related to the neuronal loss in cerebral cortex. The age at onset is most commonly in the fourth and fifth decades and is related to the length of the CAG repeat in the *HTT* gene. Motor symptoms often precede the cognitive impairment. The movement disorder of HD is choreiform, with increased and involuntary jerky movements of all parts of the body; writhing movements of the extremities are typical. Early symptoms of higher cortical dysfunction include forgetfulness as well as cognitive and affective dysfunction, with progression to a severe dementia.

The most common immediate cause of death in HD patients is pneumonia, typically occurring at an advanced stage of the disease. Tragically, HD patients resort to suicide at a rate that is approximately twice that of the general population. Given the ability to screen for disease-causing mutations, one might assume that genetic screening of individuals at risk would be routine; however, this is a situation in which the ability to detect the likelihood of disease has surpassed any possible treatment. In the absence of effective therapy and given the devastating nature of the disease, the ethics of screening is debatable.

Spinocerebellar Degenerations

The shared feature of this group of degenerative diseases is that they cause neuronal loss and dysfunction in the cerebellum, the spinal cord, and peripheral nerves. In other regards, they are quite heterogeneous, with differences in genetics, age at onset, and signs and symptoms. Genetic analysis has impacted the classification of these diseases, but has yet to lead to clearer insight into their pathogenesis or to effective treatments.

The term *spinocerebellar ataxia* (SCA) is applied to a group of autosomal dominant inherited spinocerebellar degenerations. We will also briefly discuss Friedreich ataxia and ataxia-telangiectasia, two of the more common autosomal recessive disorders that are characterized by spinocerebellar degeneration. Finally, there is a small set of hereditary disorders characterized by episodes of ataxia or other symptoms of isolated cerebellar dysfunction, which are mostly associated with mutations in genes for ion channel subunits.

Spinocerebellar Ataxias (SCA)

This group of spinocerebellar degenerations is remarkably heterogeneous; current classifications that rely on a combination of genetic, clinical, and pathologic findings include 35 distinct subtypes. Here we focus on the common varieties of pathogenic mutations that are found in SCA.

Pathogenesis

The genes responsible for over half of the numerous SCAs have been identified. Three distinct types of pathogenic mutations are recognized:

- *Polyglutamine diseases* linked to expansion of a CAG repeat, similar to HD. Seven types of SCA are caused by this type of mutation, and in each the mutated protein

accumulates in neurons as nuclear inclusions, suggesting the involvement of pathogenic mechanisms previously discussed for HD. The group of polyglutamine diseases includes SCA1, SCA2, SCA3 (also known as *Machado-Joseph disease*), SCA6, SCA7 (relatively unique in that it includes visual impairment), SCA17, and dentatorubropallidoluysian atrophy.

- *Expansion of noncoding repeats,* similar to myotonic dystrophy. This mechanism is involved in five forms of SCA (SCA8, SCA10, SCA12, SCA31, and SCA36); in most, the genetic locus underlying the disease has been defined, and each involves a different locus. The pathogenic connection between expansion of these repeats and disease is obscure.
- *Other mutations*. The remaining SCAs are associated with deletions, insertions, and/or point mutations in a variety of genes that encode proteins involved in signal transduction (e.g., receptors, ion channels, kinases).

Friedreich Ataxia

Friedreich ataxia is an autosomal recessive disease characterized by progressive ataxia, spasticity, weakness, sensory neuropathy, and cardiomyopathy. It generally begins in the first decade of life with gait ataxia, followed by hand clumsiness and dysarthria. Deep tendon reflexes are depressed or absent, but an extensor plantar reflex is typically present. Joint position and vibratory sense are impaired, and there is sometimes loss of pain, temperature sensation, and light touch; many affected individuals develop pes cavus and kyphoscoliosis. Most patients become wheelchair-bound within about 5 years of onset, and life expectancy is typically limited to 40 or 50 years of age. The accompanying cardiomyopathy is associated with a high incidence of arrhythmias and congestive heart failure, which contribute to the deaths of most affected individuals. Concomitant diabetes is found in up to 25% of patients.

Friedreich ataxia is caused by expansion of a GAA trinucleotide repeat in the first intron of a gene on chromosome 9q13 that encodes frataxin, a protein found in the mitochondrial inner membrane, where it is involved in assembly of iron-sulfur cluster enzymes of mitochondrial complexes I and II. Affected individuals have extremely low levels of this protein, and the severity of the disease course may correlate better with the loss of frataxin than with the size of the GAA-repeat expansion. With reduced frataxin, there is decreased mitochondrial oxidative phosphorylation (similar to the defect in mitochondrial encephalomyopathies) as well as increased free iron; the presence of free iron within the mitochondria may contribute to oxidative stress. Most cases of Friedreich ataxia are associated with GAA repeat expansion in both alleles, but sometimes one allele has a repeat expansion and the other harbors a point mutation. Both of these patterns of inheritance are consistent with the disease stemming from loss of frataxin function.

Ataxia-Telangiectasia

Ataxia-telangiectasia (Chapter 7) is an autosomal recessive disorder characterized by an ataxic-dyskinetic syndrome beginning in early childhood, with the subsequent development of telangiectasias in the conjunctiva and skin, along with immunodeficiency. The ataxia-telangiectasia mutated *(ATM)* gene on chromosome 11q22-q23 encodes a kinase with a critical role in orchestrating the cellular response to double-stranded DNA breaks. In addition to this critical cellular role, signals mediated through ATM also regulate apoptosis, maintenance of telomeres, mitochondrial homeostasis, response to oxidative stress, and the ubiquitin-proteosomal degradation system. It remains unclear which of these pathways contribute to the degenerative phenotype observed in the setting of loss of ATM protein in neurons. Intriguingly, there are comparable patterns of neurodegeneration associated with other diseases in which repair of single-stranded DNA breaks is disrupted.

Clinical Features

The disease is relentlessly progressive, with death early in the second decade. Common initial symptoms are recurrent sinopulmonary infections and unsteadiness in walking; later on, speech is noted to become dysarthric, and eye movement abnormalities develop. Many affected individuals develop lymphoid neoplasms, which are most often T-cell leukemias.

Amyotrophic Lateral Sclerosis (ALS)

ALS is a progressive disorder in which there is loss of upper motor neurons in the cerebral cortex and lower motor neurons in the spinal cord and brainstem. Loss of these neurons results in denervation of muscles, producing weakness that becomes profound as the disease progresses. The disease has an overall incidence of about 2 per 100,000 people, affects men slightly more frequently than women, and commonly emerges in the fifth decade or later. Sporadic ALS is more common than familial ALS, which may account for up to 20% of cases.

Pathogenesis

Both sporadic and familial ALS are associated with degeneration of upper and lower motor neurons, often in association with toxic protein accumulation. Close to two dozen genetic loci have been identified as causing familial ALS, with nearly all being autosomal dominant disorders.

One of the earliest discovered hereditary forms of ALS has mutations in the gene encoding copper-zinc superoxide dismutase *(SOD1)* on chromosome 21; this variant accounts for about 20% of familial cases. Initially, identification of *SOD1* mutations suggested that neuronal injury in ALS might reflect an impaired capacity to detoxify free radicals, but it is now believed that mutations lead to an adverse gain-of-function phenotype associated with mutant SOD1 protein. It appears that mutated SOD1 protein misfolds and forms aggregates (which can include wild-type protein) that cause cellular injury through a variety of postulated mechanisms, including dysregulation of proteasomal and autophagic catabolism, disruption of axonal transport and mitochondrial function, and sequestration of other proteins within the aggregates. Accumulation of protein aggregates can eventually trigger the unfolded protein response, with subsequent initiation of apoptosis. The overall importance of protein degradation pathways is reinforced by discovery of a range of uncommon mutations in genes implicated in protein degradation that are also associated with familial ALS.

The most common mutation that gives rise to ALS and FTLD simultaneously is an expansion of a hexanucleotide

repeat in the 5′-untranslated region of a transcript of unknown function, *C9orf72*. This mutation is estimated to be the basis of up to 40% of familial ALS and a smaller fraction of what appear to be sporadic cases of ALS. Non–AUG-initiated translation (in all three reading frames) can occur from these expanded repeats, and neuronal deposits of the derived peptides have been found in the setting of the mutation; whether these novel peptide aggregates contribute to cellular injury remains obscure.

Other genetic loci that cause ALS and FTLD encode stress granule proteins with RNA-binding capacity, such as TDP-43 and FUS. The underlying link between alterations in RNA-binding proteins and manifestations of motor neuron disease remains unclear; possibly, nuclear depletion of TDP-43 results in inappropriate processing of some RNAs, while the aggregation of the protein in the cytoplasm activates the unfolded protein response common to many of the proteinopathies.

MORPHOLOGY

The anterior roots of the spinal cord are thin (Fig. 28.42A) due to loss of lower motor neuron axons, and the precentral motor gyrus in the cortex may be atrophic in especially severe cases. There is a reduction in the number of anterior horn neurons throughout the length of the spinal cord, associated with reactive gliosis. Similar findings are seen in the hypoglossal, ambiguus, and motor trigeminal cranial nerve nuclei. Remaining neurons often contain PAS-positive cytoplasmic inclusions called Bunina bodies (which appear to be remnants of autophagic vacuoles) and TDP-43-positive cytoplasmic inclusions (which are seen in sporadic cases and familial cases caused by mutations in *C9orf72* and the TDP-43 gene [*TARDBP*], but are absent in *SOD1*-mutant and *FUS*-mutant cases). Skeletal muscles innervated by the degenerated lower motor neurons show neurogenic atrophy. Loss of the upper motor neurons leads to degeneration of the corticospinal tracts, resulting in volume loss and absence of myelinated fibers, which may be particularly evident at the lower segmental levels (Fig. 28.42B).

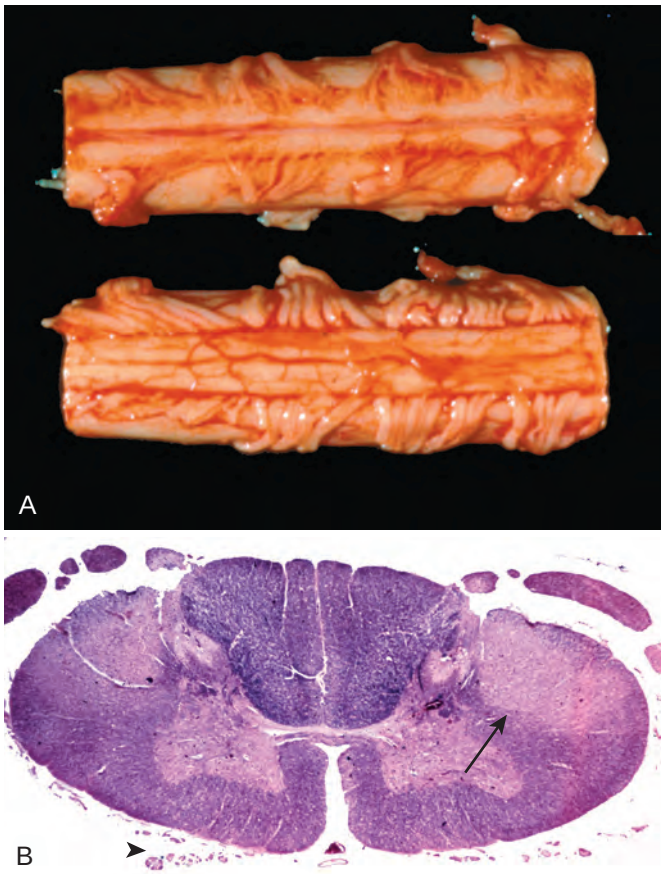

Figure 28.42 Amyotrophic lateral sclerosis. (A) Segment of spinal cord viewed from anterior *(upper)* and posterior *(lower)* surfaces showing attenuation of anterior (motor) roots compared with posterior (sensory) roots. (B) Spinal cord showing loss of myelinated fibers (lack of stain) in corticospinal tracts (best seen on the right side of this specimen; *arrow*) as well as degeneration of anterior roots *(arrowhead)*.

Clinical Features

Early symptoms of ALS include asymmetric weakness of the hands, manifested as dropping of objects and difficulty performing fine-motor tasks, and cramping and spasticity of the arms and legs. As the disease progresses, muscle strength and bulk diminish, and involuntary contractions of individual motor units, termed fasciculations, occur. The disease eventually involves the respiratory muscles, leading to recurrent bouts of pneumonia. Although most affected individuals have a combination of upper and lower motor neuron involvement, other patterns are observed. The term *progressive muscular atrophy* applies to uncommon cases in which lower motor neuron involvement predominates, while *primary lateral sclerosis* refers to cases with mostly upper motor neuron involvement. In some affected individuals, degeneration of the lower brainstem cranial motor nuclei occurs early and progresses rapidly, a pattern referred to as *progressive bulbar palsy* or *bulbar ALS*. In these individuals, abnormalities of swallowing and speech dominate, and the clinical course is inexorable during a 1- or 2-year period. When bulbar involvement is less severe, about half of affected individuals are alive 2 years after diagnosis. The motor neurons innervating extra-ocular muscles are among the last to be involved in ALS; with long survival, usually associated with ventilator support, even this form of motor output fails. Familial cases develop symptoms earlier than most sporadic cases, but the clinical course is comparable.

Although ALS is considered a disease of the motor system, a significant fraction of affected individuals have evidence of more widespread cerebral cortical disease. The clinical presentation of cerebral disease is usually a frontotemporal dementia, with pathologic findings most often matching those of FTLD associated with TDP-43 inclusions. The mechanistic link between these two processes is further strengthened by the presence of TDP-43–containing inclusions in many cases of ALS as well as overlap of genetic alterations in ALS and FTLD.

Other Motor Neuron Diseases

In addition to ALS, motor neurons are the primary target in a few other neurodegenerative diseases with distinct etiology and pathogenesis.

Spinal and Bulbar Muscular Atrophy (Kennedy Disease)

This X-linked polyglutamine repeat-expansion disease is characterized by distal limb amyotrophy and bulbar signs, such as atrophy and fasciculations of the tongue and dysphagia, that are associated with degeneration of lower motor neurons in the spinal cord and brainstem. The expanded repeat occurs in the first exon of the androgen receptor and results in androgen insensitivity, gynecomastia, testicular atrophy, and oligospermia. The basis for the selective motor neuron involvement is unclear, but as in other polyglutamine expansion diseases such as HD and some forms of spinocerebellar atrophy, there are intranuclear inclusions that contain the involved protein. Progression of the disease is slow, and most affected individuals remain ambulatory until late in the disease course. Life span is normal.

Spinal Muscular Atrophy (SMA)

SMA includes a group of genetically linked disorders of childhood characterized by marked loss of lower motor neurons that results in progressive weakness. The most severe form (SMA type I, Werdnig-Hoffmann disease) has onset during the first year of life, and is usually fatal by the age of 2 years. Other forms, with later onset, have more gradual courses; in SMA type III (Kugelberg-Welander disease), motor disability usually emerges during later childhood and adolescence.

The severity of SMA is related to loss of a protein (termed SMN) that is involved in the assembly of the spliceosome. Most SMN protein comes from mRNA transcripts derived from the *SMN1* gene on chromosome 5q. There is an adjacent *SMN2* gene that differs by a few base pairs; these changes alter mRNA splicing and increase the production of SMN protein that is unstable and rapidly degraded. *SMN2* is an example of a gene that shows copy number variation, such that normal individuals may have one or multiple copies of *SMN2* on each chromosome 5. All forms of SMA are caused by loss-of-function mutations in *SMN1* (usually deletions), with the differences in clinical phenotype being determined by the number of *SMN2* gene copies. A novel gene therapy for SMA is now available that uses an adeno-associated virus to express SMN in motor neurons, albeit at a cost of over $2 million. Genetic therapies that alter the splicing of *SMN2*-derived transcripts have also been approved for treatment of this devastating disease.

KEY CONCEPTS

NEURODEGENERATIVE DISEASES

- Neurodegenerative diseases are characterized by progressive neuronal loss involving specific neuronal circuits and brain regions. Most of these diseases are associated with accumulation of abnormal protein aggregates, typically in the form of cellular inclusions. The disease phenotype reflects the patterns of brain involvement rather than the type of inclusion.
- These diseases can be grouped by clinical presentation into dementias, hypokinetic movement disorders, hyperkinetic movement disorders, cerebellar ataxias, and motor neuron diseases.
- Prion diseases may be sporadic, familial, or transmissible. Regardless of the cause, the disease is driven by the conversion of a normal cellular protein (PrP^{c}) into an abnormal conformation (PrP^{sc}), with the acquisition of distinct characteristics including relative resistance to protease digestion, self-propagation, and the ability to spread. The most common clinical presentation is that of rapidly progressive dementia.
- Among dementias, Alzheimer disease (with plaques of Aβ and tangles of tau) is the most common; other predominantly dementing diseases include the various forms of frontotemporal lobar degeneration (usually with either TDP-43– or tau-containing inclusions) and dementia with Lewy bodies (with α-synuclein inclusions).
- Among the hypokinetic movement disorders, Parkinson disease is the most common (again with α-synuclein–containing inclusions); other diseases with parkinsonism include progressive supranuclear palsy and corticobasal degeneration (both forms of tauopathy).
- Amyotrophic lateral sclerosis is the most common form of motor neuron disease, with diverse genetic causes as well as sporadic forms.

GENETIC METABOLIC DISEASES

Genetic disorders that disrupt metabolic processes in neurons and glia typically present early in life and are often relentlessly progressive. Some of these disorders manifest in the immediate postnatal period, while others emerge later in life. Overall, metabolic diseases with earlier onset tend to have a more rapid and aggressive clinical course.

This heterogeneous group of disorders can be organized based on the organelles or the type of cell that is affected, and by the anatomic distribution of disease, as follows:

- *Neuronal storage diseases* are predominantly autosomal recessive disorders caused by the deficiency of an enzyme or trafficking protein that is required for the catabolism of sphingolipids (including the gangliosides), mucopolysaccharides, or mucolipids.
- *Leukodystrophies* are mostly autosomal recessive disorders caused by mutations in genes encoding enzymes involved in myelin synthesis or catabolism.
- *Mitochondrial encephalomyopathies* are disorders of oxidative phosphorylation, often affecting multiple tissues including skeletal muscle (Chapter 27). These disorders may be caused by mutations in the mitochondrial or the nuclear genomes.

Neuronal Storage Diseases

These disorders are characterized by the accumulation of storage material within neurons, typically followed by neuronal death. The neurologic manifestations that result from this neuronal dysfunction or death are most often seizures and generalized loss of neurologic function. Although many of these disorders are associated with deficits of specific enzymes, others appear to be caused by defects in protein or lipid trafficking within neurons. This is a large class of disorders, with genetic heterogeneity even within clinically homogeneous entities. A few diseases in this category (Tay-Sachs and Niemann-Pick diseases, mucopolysaccharidoses, and others) are described in more detail in Chapter 5.

Leukodystrophies

These disorders are caused by mutations of genes whose products are involved in the generation, turnover, or maintenance of myelin. Normal brain function depends as much on the connections between neurons as it does on the integrity of the neurons themselves; therefore, the progressive and cumulative damage to myelinated axons in leukodystrophies has devastating consequences. Several clinical features separate these dysmyelinating leukodystrophies from demyelinating diseases such as MS: the leukodystrophies typically present with an insidious and progressive loss of cerebral function, often at younger ages, and are associated with diffuse and symmetric changes on imaging studies. Although many of the leukodystrophies are caused by single enzyme defects resulting in altered metabolism of myelin-associated lipids, a variety of other genetic alterations can lead to white matter diseases. The following examples are representative of this spectrum of disorders.

- *Krabbe disease* is an autosomal recessive leukodystrophy resulting from a deficiency of galactocerebroside β-galactosidase, the enzyme required for the catabolism of galactocerebroside to ceramide and galactose. As a consequence of the impaired catabolism of galactocerebroside in the brain, an alternative catabolic pathway shunts galactocerebroside to galactosylsphingosine; elevated levels of this compound are toxic to both oligodendrocytes and astrocytes. The clinical course is rapidly progressive, with onset of symptoms (dominated by motor signs such as stiffness and weakness) between 3 and 6 months of age; survival beyond 2 years of age is uncommon. The brain shows loss of myelin and oligodendrocytes (Fig. 28.43); a similar process affects peripheral nerves. Neurons and axons are relatively spared. A unique and diagnostic feature of Krabbe disease is the aggregation of engorged macrophages *(globoid cells)* in the brain parenchyma and around blood vessels (Fig. 28.43, *inset*).
- *Metachromatic leukodystrophy* is an autosomal recessive disease that results from a deficiency of the lysosomal enzyme, arylsulfatase A. This enzyme, present in a variety of tissues, cleaves the sulfate from sulfate-containing lipids (sulfatides) as the first step in their degradation. The enzyme deficiency thus leads to an accumulation of the sulfatides, especially cerebroside sulfate, that are toxic to white matter. The most striking histologic finding is demyelination with resulting gliosis. Macrophages with vacuolated cytoplasm are scattered throughout the white matter. The membrane-bound vacuoles contain complex crystalloid structures composed of sulfatides; when bound to certain dyes such as toluidine blue, sulfatides shift the absorbance spectrum of the dye, a property called *metachromasia*. Similar metachromatic material can be detected in peripheral nerves and in urine, the latter being a sensitive method of establishing the diagnosis.
- *Adrenoleukodystrophy* is an X-linked recessive disease caused by loss-of-function mutations in *ABCD1,* which encodes an ATP-binding cassette transporter protein that is required for transport of fatty acids into peroxisomes. In the typical form, young boys present with behavioral changes and adrenal insufficiency. The loss of ABCD1 leads to an inability to catabolize very-long-chain fatty acids within peroxisomes, resulting in elevated serum levels of these lipids. The symptoms result from progressive CNS, peripheral nerve, and adrenal disease. In the white matter, myelin loss is accompanied by gliosis and extensive lymphocytic infiltration. Adrenal cortical atrophy explains the hypocortisolism.

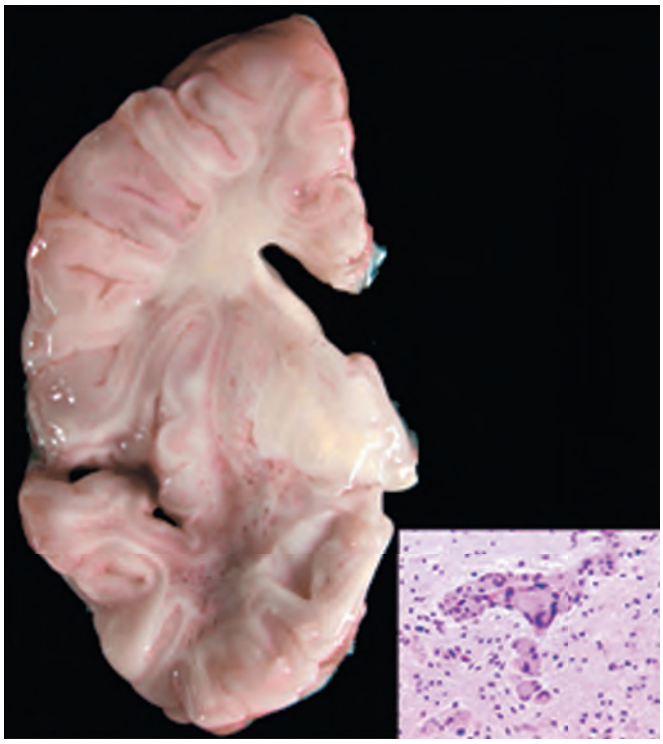

Figure 28.43 Krabbe disease. Much of the white matter is gray/yellow because of the loss of myelin. *Inset,* "Globoid" cells are the hallmark of the disease.

A wide range of other leukodystrophies are recognized, some with defects in lipid metabolism. Several other mechanisms of white matter injury have been identified, including pathogenic mutations in genes that encode proteins required for myelin formation *(Pelizaeus-Merzbacher disease)*, the intermediate filament protein GFAP *(Alexander disease)*, or the translation initiation factor eIF2B *(vanishing white matter leukoencephalopathy)*.

Mitochondrial Encephalomyopathies

Disorders of energy generation can cause a range of neurologic disease, often in association with abnormalities in other tissues. Although many of the inherited disorders of mitochondrial oxidative phosphorylation present as muscle diseases (Chapter 27), the critical dependence of neurons on oxidative phosphorylation for generation of ATP is reflected in frequent CNS involvement.

The mitochondrial genome, which is entirely inherited from the mother, encodes only 13 proteins, 22 tRNAs, and two rRNAs. The remaining proteins that are required for mitochondrial structure and function are encoded by the nuclear genome. Thus, some mitochondrial disorders show maternal transmission because the affected genes lie in the mitochondrial genome, but many others do not. There is a

complex genotype-phenotype relationship in these disorders: the same mutation may manifest as different phenotypes, and the same phenotype may be caused by different mutations.

A critical mitochondrial disease concept is *heteroplasmy*, defined as the presence of both wild type and mutated mitochondrial genomes within different populations of mitochondria in single cells. Because mitochondria are distributed in a more or less random fashion when "mother cells" divide, daughter cells may inherit different proportions of functional and dysfunctional mitochondria, leading to wide cell-to-cell variation in disease expression. In general, mitochondrial disorders in the CNS selectively target neurons; the disruption of energy generation is often reflected in elevated tissue lactate levels, which can be demonstrated by spectroscopic imaging methods. At the histologic level, there can be loss of enzymatic activity of cytochrome C oxidase, which can be assessed with special histochemical stains.

Some of the better recognized mitochondrial encephalopathies include the following entities:

- *Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS)* is characterized by recurrent episodes of acute neurologic dysfunction, cognitive changes, muscle weakness, and lactic acidosis. The strokelike episodes are often associated with reversible deficits that do not correspond to specific vascular territories. Pathologically, areas of infarction are observed, sometimes with vascular proliferation and focal calcification. The most common mutation observed in MELAS is in the gene encoding mitochondrial tRNA-leucine *(MTTL1)*.
- *Myoclonic epilepsy with ragged red fibers (MERRF)* is a maternally transmitted disease in which affected individuals have myoclonus (a seizure disorder) and a myopathy that is characterized by ragged red fibers on muscle biopsy (Chapter 27). Ataxia, associated with neuronal loss from the cerebellar system, is also common. Most cases of MERRF are associated with mutations in mitochondrial tRNA genes.
- *Leigh syndrome* is a disease of infancy characterized by lactic acidemia, arrest of psychomotor development, feeding problems, seizures, extraocular palsies, and weakness with hypotonia; death usually occurs within 1 to 2 years. On histologic examination, there are multifocal regions of destruction of brain tissue associated with a spongiform appearance and vascular proliferation. Brainstem nuclei, the thalamus, and the hypothalamus are typically involved, usually in a symmetric manner. A wide spectrum of nuclear and mitochondrial DNA mutations has been identified.

KEY CONCEPTS

GENETIC METABOLIC DISEASES

- Mutations that disrupt metabolic or synthetic pathways can affect the nervous system. These pathways can involve general cellular processes or those that are relatively specific to the nervous system.
- Diseases with earlier onset are typically more severe in the degree of damage and pace of illness.
- Neuronal storage diseases are usually autosomal recessive disorders. The characteristic finding is accumulation of material within neurons, along with evidence of neuronal death.
- Leukodystrophies are also typically autosomal recessive disorders associated with disruption of the synthesis or turnover of myelin components.
- Mitochondrial encephalomyopathies are a pleiotropic set of disorders that involves neurons and tissues outside of the nervous system. These can be caused by mutations in the nuclear or mitochondrial genomes.

TOXIC AND ACQUIRED METABOLIC DISEASES

Toxic and acquired metabolic diseases are relatively common causes of neurologic illnesses. These diseases are discussed in Chapter 9; only aspects that are relevant to CNS pathology are presented here.

Vitamin Deficiencies

Neural tissue has a very high metabolic demand and is thus mainly affected by deficiencies of B vitamins, which play a key role in cellular metabolism; two distinct clinicopathologic syndromes are recognized.

Thiamine (Vitamin B_1) Deficiency

The classical neurologic disease resulting from thiamine deficiency is called the *Wernicke-Korsakoff syndrome* and consists of two related manifestations. *Wernicke encephalopathy* is characterized by acute psychosis and ophthalmoplegia. These symptoms are reversible when treated with thiamine. However, if unrecognized and untreated, they may be followed by a prolonged and largely irreversible condition *(Korsakoff syndrome)* that is marked by disturbances of short-term memory and confabulation. The syndrome is particularly common in the setting of chronic alcoholism, but it may also be encountered in individuals with thiamine deficiency resulting from gastric disorders, including carcinoma, chronic gastritis, or persistent vomiting.

MORPHOLOGY

In Wernicke encephalopathy, there are foci of hemorrhage and necrosis in the mamillary bodies and the walls of the third and fourth ventricles. Early lesions show dilated capillaries with prominent endothelial cells; subsequently, the capillaries become leaky, producing hemorrhagic areas. With time, there is infiltration of macrophages and development of a cystic space containing hemosiderin-laden macrophages. These chronic lesions predominate in individuals with Korsakoff syndrome. Lesions in the dorsomedial nucleus of the thalamus seem to correlate best with memory disturbance and confabulation.

Vitamin B_{12} Deficiency

Subacute combined degeneration of the spinal cord is caused by deficiency of vitamin B_{12} and is marked by degeneration of the ascending and descending spinal tracts. The lesions result from a defect in myelin formation; the mechanism of this defect is not known. Symptoms may present over a few weeks, initially with bilaterally symmetrical numbness,

tingling, and slight ataxia in the lower extremities, which may progress to include spastic weakness of the lower extremities. Complete paraplegia may occur, usually only later in the course. With prompt vitamin replacement therapy, clinical improvement occurs; however, once complete paraplegia has developed, recovery is poor. On microscopic examination, there is swelling of myelin layers, producing vacuoles in the affected tracts; with time, axons degenerate as well. In the early stages of the disease, the mid-thoracic level of the spinal cord is preferentially affected, from which the process may extend proximally and distally.

Neurologic Sequelae of Metabolic Disturbances

Hypoglycemia

Because the brain requires glucose and oxygen for its energy production, the cellular effects of diminished glucose resemble those of oxygen deprivation, described earlier. Some regions of the brain are more sensitive to hypoglycemia than others. Glucose deprivation initially leads to selective injury to large cortical pyramidal neurons, which, if severe, may result in pseudolaminar necrosis of the cortex, predominantly involving deep layers. The Sommer sector (area CA1) of the hippocampus is also vulnerable, as are cerebellar Purkinje cells, albeit to a lesser extent than with hypoxia. If the level and duration of hypoglycemia are of sufficient severity, there may be widespread injury to many areas of the brain.

Hyperglycemia

Hyperglycemia, most commonly associated with inadequately controlled diabetes mellitus and associated with either ketoacidosis or hyperosmolar coma, does not elicit significant morphologic changes in the brain. The affected individual becomes dehydrated and develops confusion, stupor, and eventually coma. The fluid depletion must be corrected gradually; otherwise, severe cerebral edema may follow.

Hepatic Encephalopathy

The encephalopathy found in the setting of impaired liver function (Chapter 18) is accompanied by a glial response within the CNS; critical mediators appear to include elevated ammonia levels as well as proinflammatory cytokines. Astrocytes with enlarged nuclei and minimal cytoplasm, known as Alzheimer type II cells, appear in the cerebral cortex, basal ganglia, and other subcortical gray matter regions.

Toxic Disorders

Cellular and tissue injury from toxic agents is discussed in Chapter 9. Aspects of several important toxic disorders that are of unique neurologic importance are discussed here.

Carbon Monoxide

Many of the pathologic findings that follow acute carbon monoxide exposure are the result of impaired oxygen-carrying capacity of hemoglobin; in addition, CO can interact with the heme of cytochrome C oxidase, inhibiting tissue utilization of oxygen by blocking electron transport in the mitochondria. Selective injury of the neurons in layers III and V of the cerebral cortex, Sommer sector of the hippocampus, and Purkinje cells is characteristic. A unique pattern of bilateral globus pallidus necrosis may also occur. Demyelination of white matter tracts may be a later event.

Ethanol

The effects of acute ethanol intoxication are reversible, but chronic alcohol abuse is associated with a variety of neurologic sequelae, including Wernicke-Korsakoff syndrome from thiamine deficiency (see earlier). The toxic effects of chronic alcohol intake may be either direct or secondary to nutritional deficits. Cerebellar dysfunction occurs in about 1% of chronic alcoholics, and is associated with a clinical syndrome of truncal ataxia, unsteady gait, and nystagmus. The histologic changes are atrophy and loss of granule cells, predominantly in the superior anterior vermis (Fig. 28.44). In advanced cases, there is loss of Purkinje cells and proliferation of the adjacent astrocytes *(Bergmann gliosis)* between the depleted granular cell layer and the molecular layer of the cerebellum. The fetal alcohol syndrome is discussed in Chapter 10.

Radiation

Exposure of the brain to radiation can occur accidentally or as part of therapeutic regimens for tumors. As discussed in Chapter 9, exposure to very high doses of radiation (>10 Gy) can cause intractable nausea, confusion, convulsions, and rapid onset of coma, followed by death. Delayed effects of radiation can also present with rapidly evolving symptoms, including headaches, nausea, vomiting, and papilledema, which may appear months to years after irradiation.

The pathologic findings consist of large areas of coagulative necrosis, primarily in white matter, with all tissue elements within the area affected. This is accompanied by marked edema and gliosis in the surrounding tissue, along with vascular fibrinoid necrosis and sclerosis. The combination of radiation and methotrexate, administered either concurrently or sequentially, can act synergistically to cause tissue injury; in this setting, the pattern of injury is similar in appearance to that caused by radiation alone. Axons and cell bodies in the vicinity of the radiation-induced lesions

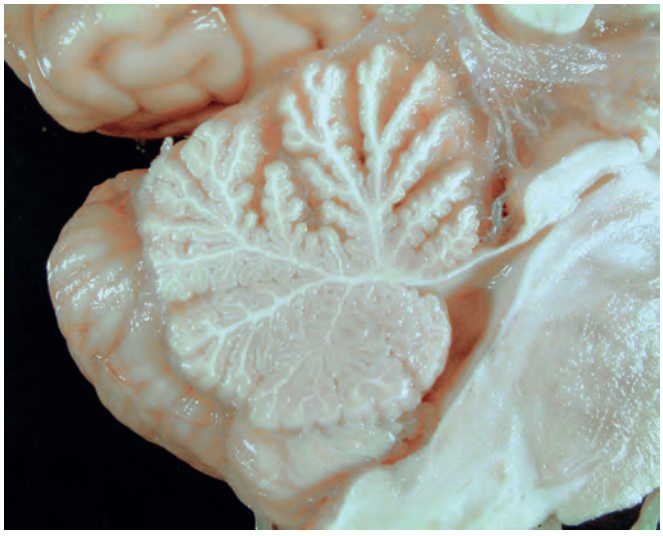

Figure 28.44 Alcoholic cerebellar degeneration. The anterior and superior portion of the vermis *(upper portion of figure)* is atrophic, with widened spaces between the folia.

undergo dystrophic mineralization. Radiation can also induce tumors, which usually develop years after radiation therapy and include sarcomas, gliomas, and meningiomas.

KEY CONCEPTS

TOXIC AND ACQUIRED METABOLIC DISEASES

- Certain vitamin deficiencies result in neurologic disease as well as systemic disorders, with thiamine and vitamin B_{12} deficiencies being the most common.
- The metabolic demand of the CNS makes it highly susceptible to injury from hypoglycemia and carbon monoxide poisoning.
- Chronic alcohol exposure may result in several forms of brain injury; atrophy of the superior anterior cerebellar vermis is particularly characteristic.
- Metabolic disturbances may disrupt brain function, often without detectable morphologic changes.

TUMORS

The annual incidence of tumors of the CNS ranges from 10 to 17 per 100,000 persons for intracranial tumors and 1 to 2 per 100,000 persons for intraspinal tumors; the majority of these are primary tumors. Tumors of the CNS account for nearly 20% of all cancers of childhood. Seventy percent of childhood CNS tumors arise in the posterior fossa; a comparable number of tumors in adults arise within the cerebral hemispheres above the tentorium.

Although pathologists have developed classification schemes that distinguish between benign and malignant lesions on histologic grounds, the clinical course of a patient with a brain tumor is strongly influenced by patterns of growth and location. Thus, even benign tumors and low-grade malignanices can lead to serious clinical deficits and may prove fatal. Because of the capacity of diffuse gliomas to widely infiltrate the brain parenchyma, such tumors are not amenable to complete surgical resection without compromising neurologic function. Also, any CNS neoplasm, regardless of histologic grade or classification, may be lethal if situated in a critical brain region; for example, a benign posterior fossa meningioma may cause cardiorespiratory arrest by compressing vital centers in the medulla. Even the most highly malignant gliomas rarely metastasize outside the CNS. Some malignant pediatric tumors spread through the CSF when they encroach on the subarachnoid space, resulting in cerebrospinal dissemination far from the original tumor site.

Classification of tumors is one of the arts of pathology, drawing on long-recognized histologic and biologic features and newer molecular analyses. Treatment protocols and clinical trials are currently based on the 2016 World Health Organization (WHO) classification, which segregates tumors into one of four grades according to their biologic behavior, ranging from grade I to grade IV. Like most cancers, malignant brain tumors tend to progress and become more aggressive with time due to clonal evolution, a change in behavior that is often reflected in a change to a higher tumor grade (which, in this case, also means a new tumor name).

The major classes of primary brain tumors to be considered here include gliomas, neuronal/glioneuronal tumors, embryonal tumors, and a few less common categories. In addition, meningeal tumors and familial tumor syndromes will be covered.

Gliomas

Gliomas, the most common group of primary brain tumors, include *astrocytomas, oligodendrogliomas*, and *ependymomas*. These tumor types have characteristic histologic features that form the basis for the classification. However, as is true of many hematologic malignancies (Chapter 13), it appears that these tumors are derived from a multipotent progenitor cell that preferentially differentiates down a particular cellular lineage. Many CNS tumors have a predilection for specific anatomic regions within the brain and tend to occur within particular age groups.

Astrocytoma

The two major categories of astrocytic tumors are the diffusely infiltrating astrocytomas (WHO grade II to IV) and the more localized astrocytomas, the most common example of which is the pilocytic astrocytoma, WHO grade I. Astrocytomas may occur from the first decade of life onward and may be found anywhere along the neuroaxis from the cerebral hemispheres to the spinal cord.

Infiltrating Astrocytomas (WHO Grades II to IV)

Infiltrating astrocytoma and glioblastoma (the synonym for "grade IV astrocytoma") account for about 80% of primary brain tumors in adults. Usually found in the cerebral hemispheres, they may also occur in the cerebellum, brainstem, or spinal cord, most often in the fourth through sixth decades. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the anatomic site of involvement. The degree of histologic differentiation of infiltrating astrocytomas correlates well with clinical outcome; tumors range from *diffuse astrocytoma* (grade II) to *anaplastic astrocytoma* (grade III) and *glioblastoma* (grade IV), and are further stratified based on mutations of the isocitrate dehydrogenase genes (*IDH1* or *IDH2*) into *IDH-mutant* and *IDH–wild-type* forms, the former associated with considerably better prognosis than the latter (Table 28.5). There are no WHO grade I infiltrating astrocytomas because they are considered malignant by definition.

Pathogenesis

Glioblastoma tends to occur in two different clinical settings—most commonly as a new onset disease, typically in older individuals (primary glioblastoma), and less frequently in younger patients due to progression of a lower-grade astrocytoma (secondary glioblastoma). Secondary glioblastomas and their lower-grade precursors are associated with driver mutations of *IDH1,* or (less often) its homologue *IDH2* (see Chapter 7 for a discussion of these oncometabolites and their role in tumorigenesis). In contrast, most primary glioblastomas are IDH–wild type, WHO grade IV; they harbor other common genetic alterations, most commonly gains of chromosome 7, loss of chromosome 10, *TERT*-promoter mutations, and *EGFR* gene amplification. These and other less common genetic and genomic alterations contribute to the acquisition of cancer hallmarks (Chapter 7). For example, most gliomas have genetic aberrations that

Table 28.5 Features of Diffuse Gliomas

	Low-Grade or Anaplastic Astrocytoma (WHO Grade II or III)	Low-Grade or Anaplastic Oligodendroglioma (WHO Grade II or III)	Glioblastoma, *IDH*-mut (WHO Grade IV)	Glioblastoma, *IDH*-wt (WHO Grade IV)
IDH status	Mutant	Mutant	Mutant	Wild-type
Other genetics	*TP53*-mut, *ATRX*-mut	1p/19q-codeleted	*TP53*-mut, *ATRX*-mut	+7/–10, *pTERT*-mut, *EGFR*-amp
Primary or secondary	Usually primary	Usually primary	Usually secondary	Usually primary
Typical morphology	Nuclear atypia; mitoses in grade III	Round nuclei, clear haloes; mitoses, MVP, and/or necrosis in grade III	Nuclear atypia, mitoses, MVP, necrosis	Nuclear atypia, mitoses, MVP, necrosis
Prognosis	OS: 5 to 15 years	OS: 10 to 20 years	OS: 2 to 4 years	OS: 6 months to 2 years

amp, Amplification; *mut*, mutant; *MVP*, microvascular proliferation; *OS*, overall survival time after onset of disease (average); *p*, promoter *wt*, wild-type; +, whole-chromosome gain; –, whole-chromosome loss.

lead to evasion of senescence (either telomerase mutations or mutations that lead to alternative lengthening of telomeres); escape from normal growth controls (biallelic *CDKN2A* deletion); activation of growth factor signaling pathways (*EGFR* or *PDGFR* gene amplification); and resistance to apoptosis (*TP53* mutation).

MORPHOLOGY

Diffuse astrocytomas are poorly defined, gray, infiltrative tumors that expand and distort involved brain (Fig. 28.45A). These tumors range in size from a few centimeters to lesions that replace nearly the entire brain. The cut surface of the tumor may be either firm or soft and gelatinous; cystic degeneration may be seen. The tumor may appear well demarcated, but is more commonly ill-defined due to infiltration beyond the perceived margins.

Microscopically, these tumors are hypercellular compared to normal white matter and feature enlarged, elongated or irregular, hyperchromatic nuclei embedded within a fibrillar background (Fig. 28.45B) that is often GFAP-immunoreactive. An immunostain for the IDH1 R132H mutant protein highlights the tumor cells in up to 90% of cases (Fig. 28.45B, *inset*); *IDH1* and *IDH2* sequencing is required to identify less common pathogenic IDH mutations, and is done when the immunostain is negative. Individual tumor cells infiltrate brain tissue some distance away from the main lesion.

Anaplastic astrocytomas have a similar appearance, but are more densely cellular and have readily detectable mitotic activity.

In **glioblastomas**, variation in the appearance of the tumor from region to region is characteristic; some areas are firm and gray-white, while others are soft and yellow due to necrosis or red due to hemorrhage and hypervascularity (Fig. 28.46). The histologic appearance is similar to anaplastic astrocytoma with the additional features of necrosis and/or microvascular proliferation. Necrosis in glioblastoma often occurs in a serpentine pattern with tumor hypercellularity along the edges of the necrotic regions, a histologic pattern referred to as palisading (Fig. 28.47). The microvascular cell proliferation produces tufts of cells that pile

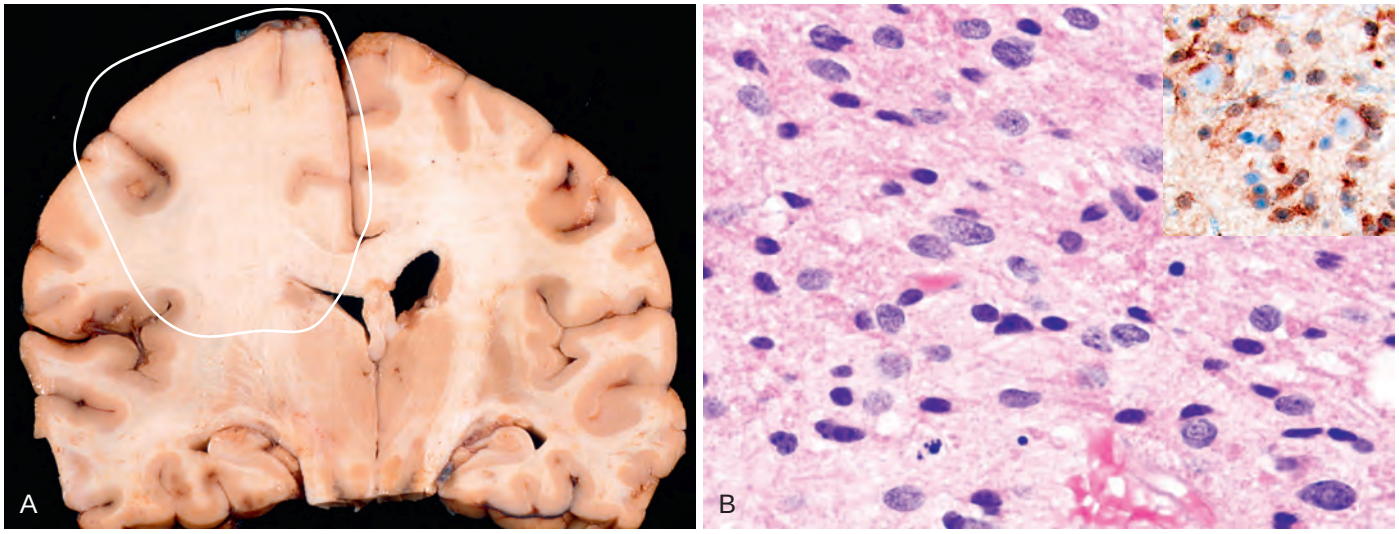

Figure 28.45 Diffuse astrocytoma. (A) On coronal section at autopsy, the left frontal white matter is expanded, and there is blurring of the corticomedullary junction due to infiltrative tumor *(circled region)*. (B) This histologic section from the white matter shows enlarged, irregular, hyperchromatic nuclei that appear embedded within the native fibrillary matrix of the brain; the smaller round and oval nuclei are native oligodendrocytes and reactive astrocytes, respectively. *Inset*, An immunostain for IDH1 R132H is positive for mutant protein in tumor cells, some of which surround the larger immunonegative cortical neurons ("perineuronal satellitosis").

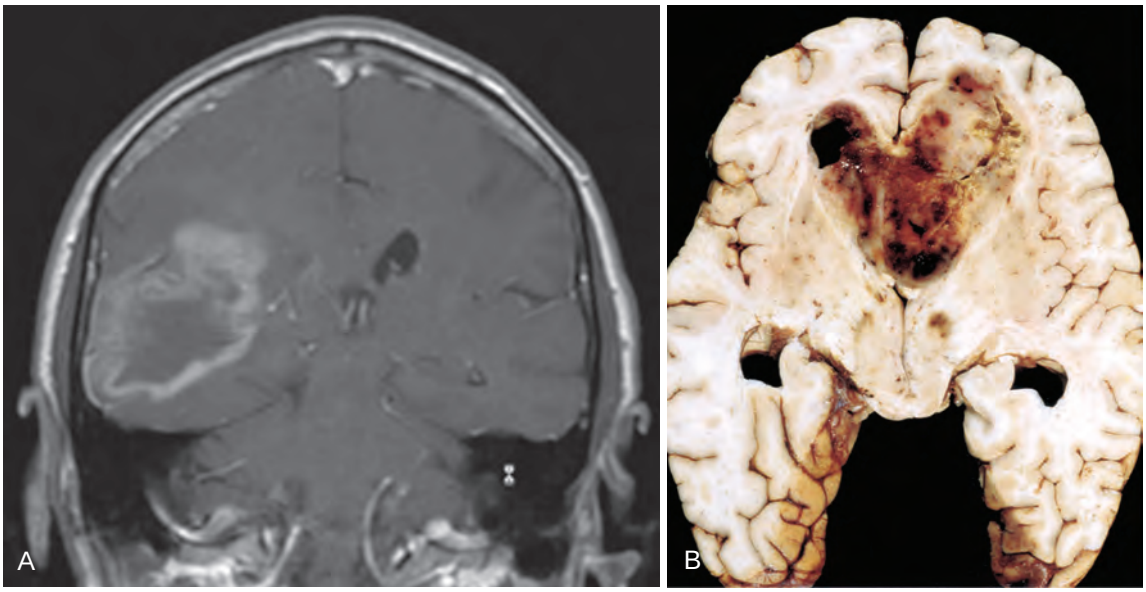

Figure 28.46 (A) Contrast T1-weighted coronal magnetic resonance image shows a large mass in the right temporal lobe with "ring" enhancement. (B) Glioblastoma appearing as a necrotic, hemorrhagic, infiltrating mass.

up and bulge into the lumen of small blood vessels (Fig. 28.47 *inset*); VEGF, produced by malignant astrocytes in response to hypoxia, contributes to this distinctive vascular change. Because histologic features can be extremely variable from one region to another, small biopsy specimens may not be representative, and the tumor may be undergraded.

Clinical Features

The presenting symptoms of infiltrating astrocytomas depend, in part, on the location and growth rate of the tumor. WHO grade II astrocytomas may remain stable or progress slowly; mean survival exceeds 5 years. Eventually, however, clinical deterioration occurs due to the emergence of a more rapidly growing subclone of higher histologic grade. Radiologic studies show a non-enhancing mass and adjacent "edema," which often includes a tumor infiltrate. High-grade astrocytomas have abnormal vessels that are "leaky," with an abnormally permeable blood-brain barrier, and therefore demonstrate contrast enhancement, which is often ringlike in glioblastomas (Fig. 28.46A). The prognosis for individuals with IDH–wild-type glioblastoma (~90% of glioblastomas) is very poor, although the use of newer chemotherapeutic agents has provided some benefit. Epigenetic silencing of the promoter for the gene encoding the DNA repair enzyme MGMT predicts responsiveness to DNA alkylating drugs (e.g., temozolomide), as would be expected given that MGMT is critical for the repair of chemotherapy-induced DNA modifications. With current treatment, which consists of resection followed by radiation therapy and chemotherapy, the mean length of survival after diagnosis has increased to 15 months; 25% of such patients are alive after 2 years. Survival is substantially shorter in older patients and in patients with lower performance status or with large unresectable lesions. As stated earlier, the IDH-mutant glioblastomas are also aggressive but have a better prognosis overall, with an average survival of 2 to 3 years.

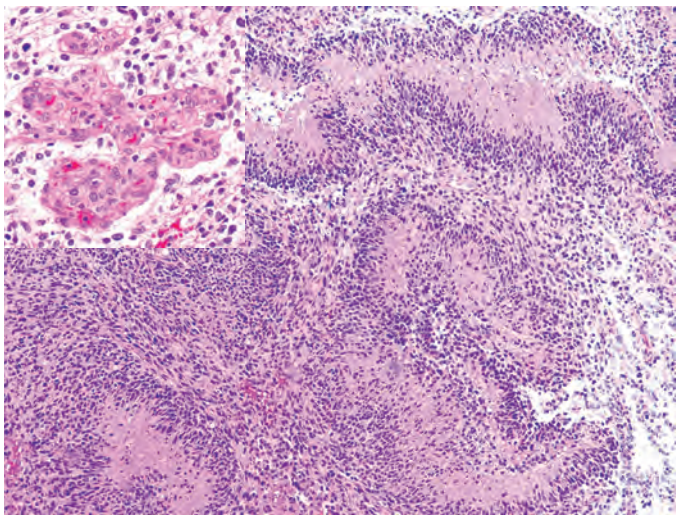

Figure 28.47 Glioblastoma. Serpiginous foci of palisading necrosis (tumor nuclei lined up around the red anucleate zones of necrosis). *Inset,* Microvascular proliferation.

Oligodendroglioma

The other major subtype of infiltrating glioma is comprised of cells that resemble oligodendrocytes. When corrected for tumor grade, the oligodendrogliomas have the best prognosis among glial tumors; as with their astrocytic counterparts, they are now defined using morphologic and genetic features. These tumors constitute 5% to 15% of gliomas and are most common in the fourth and fifth decades. Patients may have had several years of neurologic complaints, often including seizures. The lesions are found mostly in the cerebral hemispheres and have a predilection for white matter.

Pathogenesis

Oligodendroglioma is molecularly defined by an *IDH* mutation in combination with whole-arm chromosomal codeletion

of 1p and 19q. Additional genetic alterations occur with progression to anaplastic oligodendroglioma; the more common of these include losses of chromosome 9p, which result in deletion of the *CDKN2A* tumor suppressor gene. In contrast to high-grade astrocytic tumors, *EGFR* gene amplification is not seen. The vast majority of oligodendrogliomas feature the same *TERT*-promoter mutations as those encountered in glioblastoma.

MORPHOLOGY

Oligodendrogliomas are gelatinous, gray masses, often with cysts, focal hemorrhage, and calcification. The tumors are composed of sheets of regular cells with spherical nuclei containing finely granular chromatin (similar to normal oligodendrocytes) surrounded by a clear halo of vacuolated cytoplasm (Fig. 28.48). The tumor typically contains a delicate network of anastomosing capillaries, resembling "chicken wire." Calcification, present in as many as 90% of these tumors, ranges from microscopic foci to massive depositions. Tumor cells that infiltrate the cerebral cortex often collect around neurons (perineuronal satellitosis). Mitotic activity and proliferation indices are low in low-grade (WHO grade II) oligodendroglioma.

Anaplastic oligodendrogliomas (WHO grade III) are characterized by a higher cell density, nuclear anaplasia, increased mitotic activity, and occasionally necrosis. Such cases may arise de novo, but more often progress from WHO grade II oligodendrogliomas.

Clinical Features

In general, individuals with oligodendrogliomas have a better prognosis than do those with astrocytomas. Current treatment with surgery, chemotherapy, and radiation therapy has yielded average survivals of 15 to 20 and 10 to 15 years for WHO grades II and III tumors, respectively. Progression from low- to higher-grade lesions occurs, typically over a period of 5 or more years.

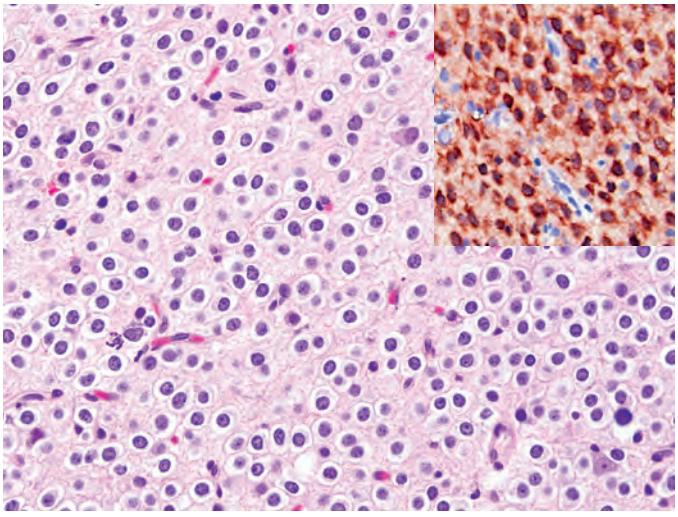

Figure 28.48 Oligodendroglioma. Tumor nuclei are round, with cleared cytoplasm forming "halos" and vasculature composed of thin-walled capillaries. Similar to diffuse astrocytoma (see Fig. 28.46B), tumor cells are usually positive for IDH1 R132H–mutant protein *(inset)*.

Pilocytic Astrocytoma

Pilocytic astrocytomas (WHO grade I) are distinguished from infiltrative astrocytomas by their more discrete borders, unique histopathologic and molecular characteristics, and relatively benign behavior. They typically occur in children and young adults and are usually located in the cerebellum, but they may also appear in the region around the third ventricle, optic nerves, spinal cord, and occasionally in the cerebral hemispheres. The histologic separation of these tumors from other astrocytomas is supported by their relative circumscription, unique histopathologic features, and distinct genetic alterations of the MAP kinase pathway, the most common being a *KIAA1549-BRAF* gene fusion/duplication. Pilocytic astrocytomas grow very slowly and can often be treated by resection alone. Symptomatic recurrence and incompletely resected lesions may be treated with repeat surgery, chemotherapy, or targeted therapies.

MORPHOLOGY

Pilocytic astrocytoma is often radiologically and grossly well demarcated and cystic (Fig. 28.49A), with a contrast-enhancing mural nodule. Histologically, it differs from infiltrative astrocytoma of any grade by showing only limited brain invasion, with an often biphasic architecture combining loose "microcystic" and compact, densely fibrillar areas (Fig. 28.49B). The tumor is composed of bipolar cells with long, thin "hairlike" processes that are GFAP-positive and form a dense fibrillary meshwork; Rosenthal fibers (eosinophilic corkscrew-shaped inclusions) and eosinophilic granular bodies (mulberry-like inclusions) are characteristic findings (Fig. 28.49C). In contrast to diffuse gliomas, the presence of microvascular proliferation or necrosis does not imply an unfavorable prognosis.

Ependymoma

Ependymomas are tumors that most often arise in proximity to the ependyma-lined ventricular system, including the oft-obliterated central canal of the spinal cord. In the first two decades of life, they typically occur near the fourth ventricle and constitute 5% to 10% of the primary brain tumors in this age group; less commonly, they are found in the cerebral hemispheres, where some lack an obvious connection to the ventricles. In adults, the spinal cord is the most common location; tumors in this site are more frequent in the setting of neurofibromatosis type 2 (NF2).

Pathogenesis

Given the association of spinal ependymomas with NF2, it is not surprising that the *NF2* gene on chromosome 22 is commonly mutated in ependymomas arising in the spinal cord but not at other sites. Ependymomas do not share the genetic alterations that are found in infiltrating gliomas. Despite their similar morphologic appearance, ependymomas occurring at different sites (supratentorial, posterior fossa, spinal) tend to be associated with distinct sets of driver mutations.

MORPHOLOGY

Grossly and on MRI, ependymomas are solid (i.e., noninfiltrative) masses. In the posterior fossa, they typically arise from the floor of

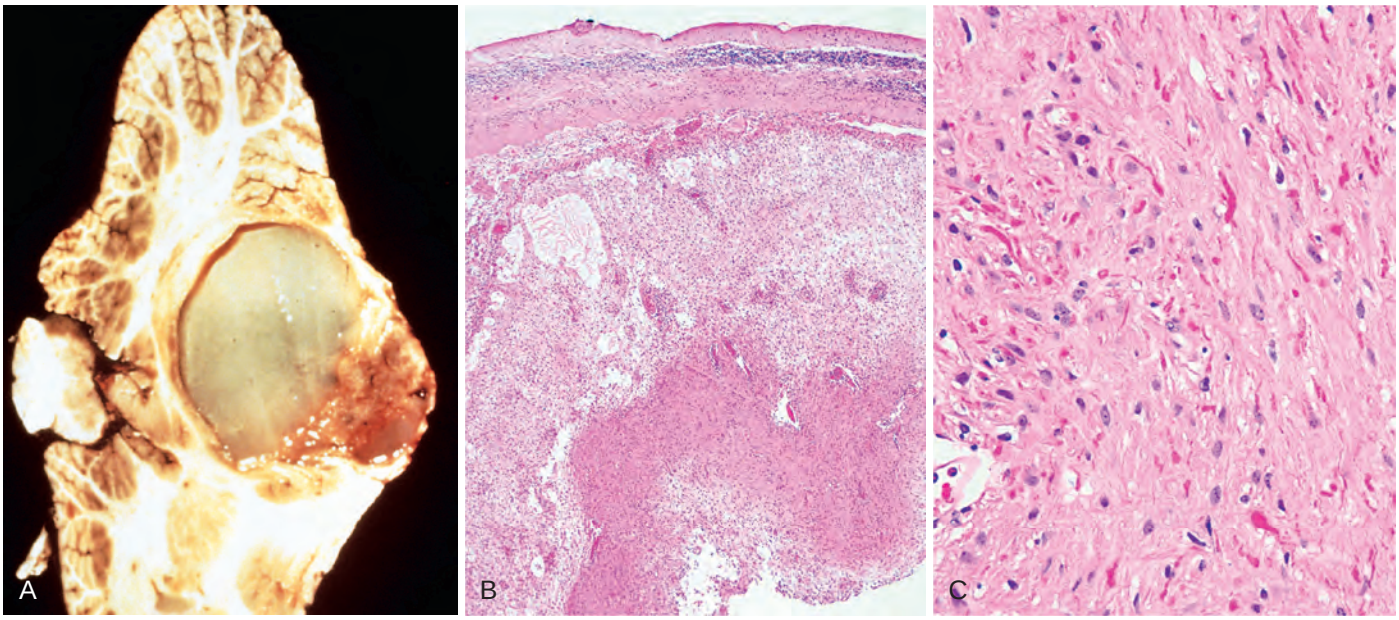

Figure 28.49 Pilocytic astrocytoma. (A) Grossly, this cerebellar tumor forms a mural nodule within a cyst. (B) At low magnification, one can appreciate atrophic cerebellar cortex *(top),* sharp circumscription, and a biphasic pattern with alternating loose *(middle)* and compact *(bottom)* regions of tumor growth. (C) Higher magnification reveals oval to irregular tumor nuclei resembling those of diffuse astrocytoma, but with numerous Rosenthal fibers (brightly eosinophilic corkscrew-shaped inclusions) in the background.

the fourth ventricle (Fig. 28.50A), occasionally growing through the foramina of Magendie or Luschka and extending below the foramen magnum into the cervical spinal canal. Although ependymomas are moderately well demarcated from adjacent brain, the proximity to vital structures often makes complete removal impossible; in the spinal cord, however, total resection is more feasible. Ependymomas are composed of cells with fibrillary processes that contain regular, round to oval nuclei with granular chromatin. Tumor cells may form glandlike round or elongated structures (rosettes, canals) that resemble the embryologic ependymal canal, with long, delicate processes extending into a lumen (Fig. 28.50B); more frequently present are **perivascular pseudorosettes** (Fig. 28.50B) in which there is a perivascular nuclear-free zone consisting of thin ependymal processes radiating toward the central blood vessel. Although most ependymomas are well differentiated and behave as WHO grade II lesions, anaplastic ependymomas (WHO grade III) feature increased cell density, high mitotic rates, areas of palisading necrosis, and/or microvascular proliferation. However, the tumor grade is less predictive of outcome than either the extent of surgical resection or the molecular subtype.

Two other variants of ependymoma merit brief mention. **Myxopapillary ependymomas** (WHO grade I) are distinct lesions that occur in the filum terminale of the spinal cord. Cuboidal tumor cells are arranged in a variably papillary architecture around mucin-rich fibrovascular cores. Prognosis depends on completeness of surgical resection.

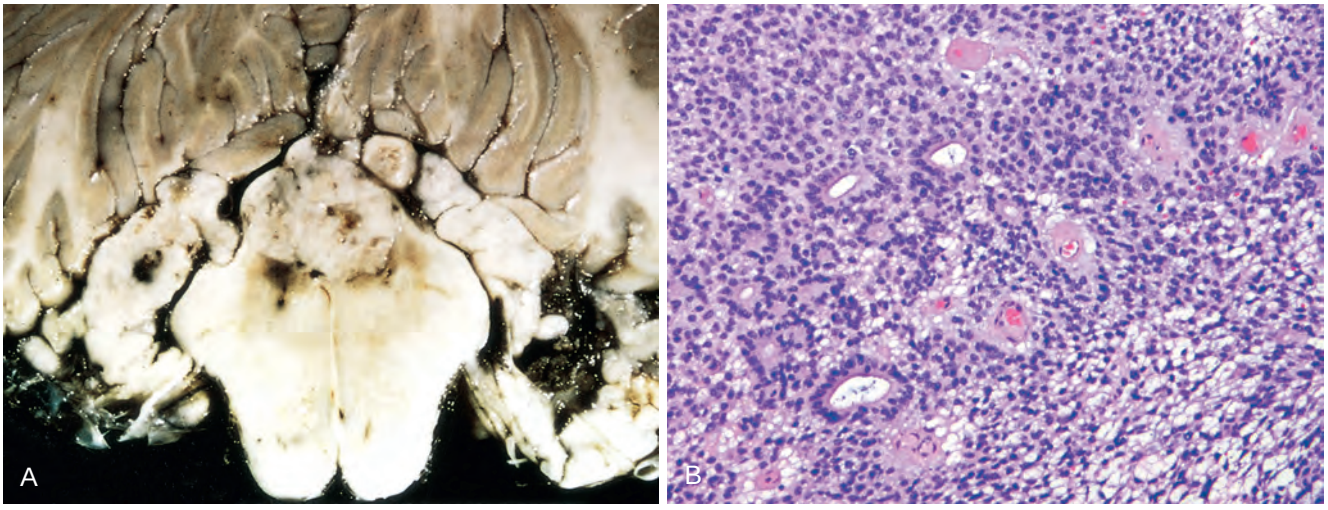

Figure 28.50 Ependymoma. (A) Tumor of the fourth ventricle, distorting, compressing, and infiltrating surrounding structures. (B) The microscopic appearance includes both true rosettes (with a glandlike central lumen) and perivascular pseudorosettes (nuclear-free zone composed of fibrillary processes radiating toward a central blood vessel).

Subependymomas (WHO grade I) are solid, sometimes calcified, slow-growing nodules that are usually found protruding into the lateral or fourth ventricle by growing under the ependyma. They are usually asymptomatic and are incidental findings at autopsy or imaging. However, if they are sufficiently large or strategically located, they can cause obstructive hydrocephalus. Subependymomas have a characteristic microscopic appearance, consisting of clusters of ependymal-appearing nuclei scattered in a dense fibrillar background of glial processes.

Clinical Features

Posterior fossa ependymomas often manifest with hydrocephalus secondary to progressive obstruction of the fourth ventricle. Despite the relationship of ependymomas to the ventricular system, CSF dissemination is uncommon. The clinical outcome for completely resected ependymomas is considerably better than for their subtotally resected counterparts.

Choroid Plexus Tumors

Both benign and malignant choroid plexus tumors are recognized, all of which are rare. *Choroid plexus papillomas* are intraventricular tumors that are most common in children, in whom they tend to occur in the lateral ventricle; in adults, they more frequently involve the fourth ventricle. These papillary growths recapitulate the structure of the normal choroid plexus, wherein epithelioid tumor cells cover fibrovascular stalks. Clinically, choroid plexus papillomas usually present with hydrocephalus due to obstruction of the ventricular system by tumor or overproduction of CSF. The far rarer *choroid plexus carcinomas* resemble adenocarcinoma; these tumors are almost always found in young children, where metastatic carcinoma is not typically encountered.

Neuronal and Glioneuronal Tumors

Far less common than glial tumors are those that exhibit neuronal differentiation. In general, neuronal tumors are more often seen in children and young adults with epilepsy.

- *Gangliogliomas* (WHO grade I) are tumors composed of a mixture of mature neuronal and glial cells. They are typically superficial lesions that present with seizures and are the most common neuronal tumors in the CNS. Most of these tumors are slow growing. When gangliogliomas present with medically refractory epilepsy, surgical resection is usually effective in controlling the seizures. Approximately 20% to 50% of these tumors have an activating mutation in the *BRAF* gene (V600E), which occasionally serves as the basis of targeted therapy.

  Gangliogliomas are most commonly found in the temporal lobe and often have a cystic component. The neoplastic ganglion cells are irregularly clustered and often have random orientation of processes; dysmorphic and/or binucleate forms are found. The glial component of these lesions most often resembles a pilocytic astrocytoma.
- *Dysembryoplastic neuroepithelial tumor* is a rare, benign (WHO Grade I) tumor often associated with epilepsy. It has a good prognosis following surgical resection, with both low recurrence rates and favorable seizure control. These lesions are typically located in the superficial temporal lobe, although other sites may be seen; they usually form multiple discrete, mucin-rich, intracortical nodules of small, oligodendrocyte-like cells arranged in columns around central axonal bundles or capillaries. There are also "floating neurons" that sit in basophilic, mucin-rich pools.

Embryonal Neoplasms

A large category of mostly pediatric tumors is described as embryonal, meaning that they appear primitive or undifferentiated, although a limited degree of neuronal and less commonly glial differentiation is often encountered. The most common embryonal neoplasm is the *medulloblastoma,* which accounts for 20% of pediatric brain tumors.

Medulloblastoma

This malignant embryonal tumor occurs predominantly in children and exclusively in the cerebellum (by definition). Although histologically, molecularly, and prognostically distinct subtypes have been identified, all are considered grade IV tumors. Rapid growth may occlude the flow of CSF, leading to hydrocephalus.

Pathogenesis

Molecular subtypes of medulloblastoma have been identified through genomic studies, revealing alterations of signaling pathways involved in normal cerebellar development, such as the sonic hedgehog–patched (SHH) pathway (which is involved in control of normal proliferation of cerebellar granule cells) and the WNT/β-catenin signaling pathway. Medulloblastomas in which the Wnt pathway is activated are often located around the anterior fourth ventricle or middle cerebellar peduncle, while sonic hedgehog–activated medulloblastomas most often involve the vermis or lateral cerebellum. On the basis of molecular alterations, medulloblastoma can be divided into four or five molecular groups that vary in terms of age of onset, tumor location, and prognosis.

MORPHOLOGY

Medulloblastoma is often well circumscribed, gray, and friable, and may extend to the surface of the cerebellar folia and involve the leptomeninges (Fig. 28.51A). On microscopic examination, the tumor is very densely cellular, with sheets of small primitive-appearing cells (see Fig. 28.51B); individual tumor cells have scant cytoplasm and hyperchromatic nuclei that are frequently elongated or crescent-shaped. Mitoses are abundant, and markers of cellular proliferation, such as Ki-67, are positive in a high percentage of the cells. In the **classic** subtype, tumor cells form **Homer Wright rosettes** (Fig. 28.51B; also seen in neuroblastoma described in Chapter 10) and often express neuronal markers such as synaptophysin; the expression of glial markers (e.g., GFAP) is less common. The **desmoplastic/nodular variant** is characterized by internodular areas of stromal response, marked by collagen and reticulin deposition (i.e., desmoplasia), and "pale islands" or nodules that have more neuropil and show greater neuronal differentiation (Fig. 28.51C). The **large cell/anaplastic variant**

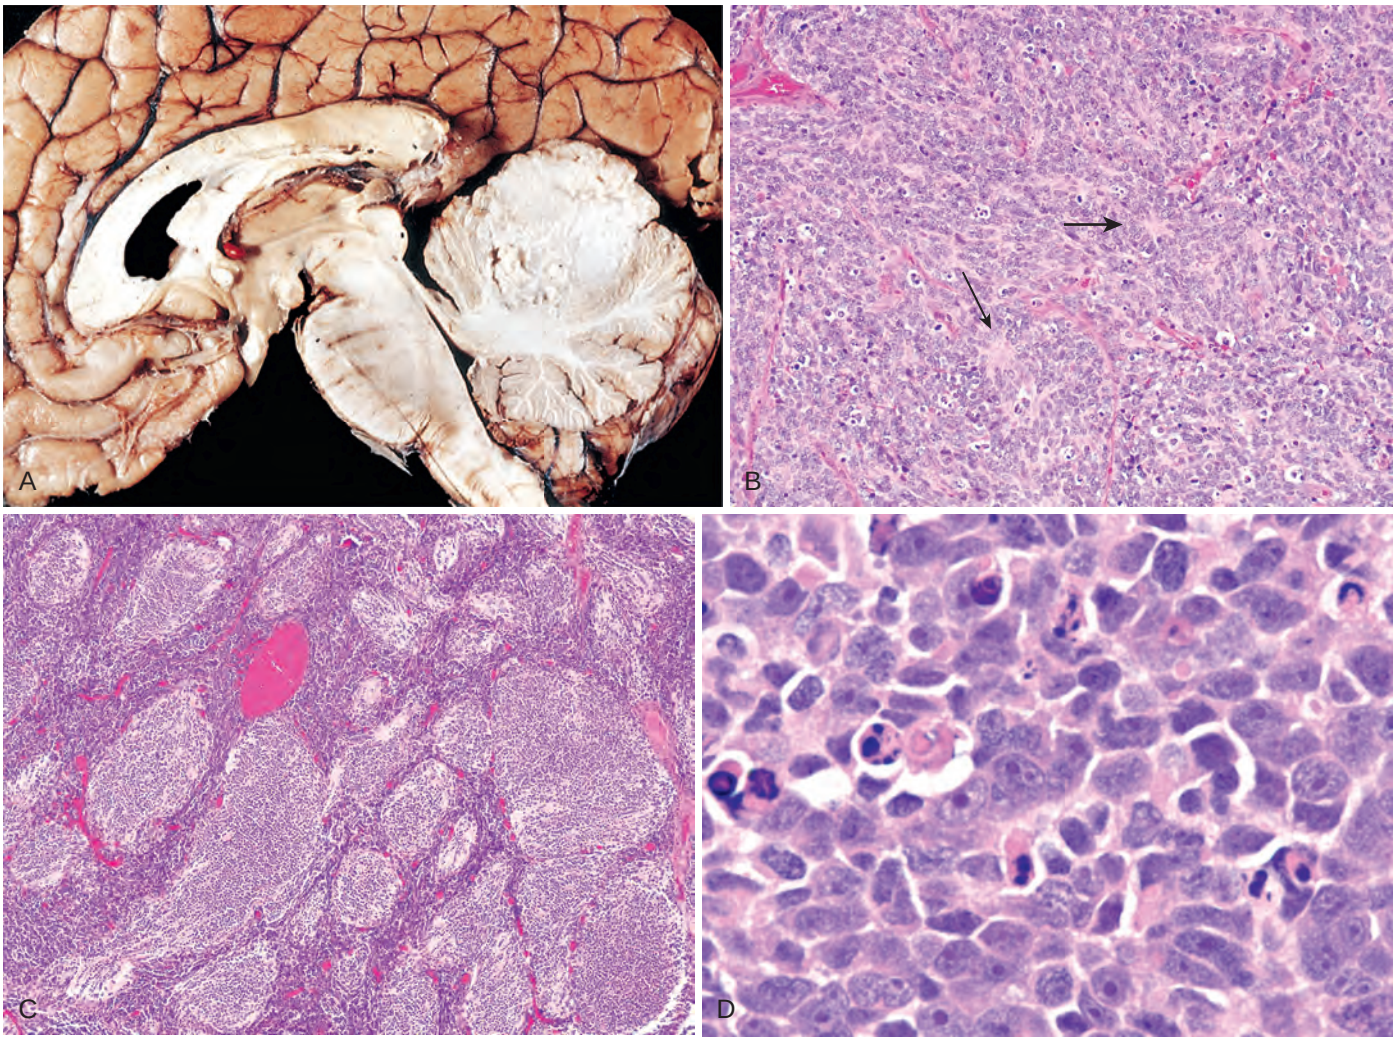

Figure 28.51 Medulloblastoma. (A) Sagittal section of brain showing medulloblastoma replacing part of the superior cerebellar vermis. (B) The microscopic appearance of classic medulloblastoma includes primitive appearing "small blue cells" that form sheets and Homer Wright (neuroblastic) rosettes with central neuropil *(arrows)*. (C) The desmoplastic/nodular variant includes reticulin-rich internodular zones with more primitive appearing cells and "pale nodules" representing centers of partial neuronal differentiation; this variant is nearly always the SHH-activated molecular subtype. (D) The large cell/anaplastic variant features increased cell size, large cherry red nucleoli, and cell wrapping (wherein tumor cells wrap around one another or surround pyknotic nuclei of dying tumor cells).

is characterized by large and irregular vesicular nuclei, prominent nucleoli, cell wrapping (a cell-in-cell appearance), and high mitotic/apoptotic indices (Fig. 28.51D).

Medulloblastomas have a propensity to spread to the subarachnoid space. Dissemination through the CSF is a common complication, giving rise to either extensive growth along the surface likened to "icing," or nodular "drop metastases," which tend to involve the cauda equina.

Clinical Features

Medulloblastomas are highly malignant, and the prognosis for untreated patients is dismal; however, it is exquisitely radiosensitive. The molecular and histologic subtype dramatically influences prognosis, with WNT-activated medulloblastomas associated with nearly 100% survival at 5 years, whereas more aggressive subtypes fall into the 20% to 30% survival range. To account for these differences, ongoing clinical trials are exploring the option of either less aggressive or more aggressive treatment regimens based on subtype. Similarly, targeted therapies are being explored for those with actionable molecular alterations.

Other rare embryonal neoplasms that have unique clinicopathologic and genetic features are now being recognized throughout the CNS; their classification continues to evolve.

Primary CNS Lymphoma

Primary CNS lymphoma accounts for 2% of extranodal lymphomas and 1% of intracranial tumors. It is the most common CNS neoplasm in immunosuppressed individuals, including those with AIDS and immunosuppression after transplantation. In non-immunosuppressed populations, the age spectrum is relatively wide, but the frequency increases after 60 years of age.

The term *primary* emphasizes the distinction between these lesions and secondary involvement of the CNS by

lymphoma arising elsewhere in the body (Chapter 13). Primary brain lymphoma is often multifocal and may also involve the eye, yet involvement outside of the CNS (in lymph nodes or bone marrow) is a rare and late complication. Conversely, lymphoma arising outside the CNS rarely involves the brain parenchyma; in this situation, secondary CNS involvement usually affects the meninges or the CSF, the latter sometimes diagnosed by the presence of malignant cells in a lumbar puncture specimen.

The vast majority of primary CNS tumors are diffuse large B-cell lymphomas; they are aggressive and generally have worse outcomes than tumors of comparable histology that occur at non-CNS sites (Chapter 13). In the setting of immunosuppression, the malignant B cells are usually latently infected by Epstein-Barr virus. In those who are not immunosuppressed, primary CNS large B-cell lymphomas often have amplification and overexpression of the *PDL1* gene, which encodes an important immune checkpoint protein that inhibits T-cell responses (Chapter 7). Trials of immune checkpoint inhibitors are ongoing and have produced excellent responses in some patients.

MORPHOLOGY

Primary CNS lymphomas are frequently multiple, soft gray-white masses in the deep subcortical parts of the brain; periventricular spread is common. The malignant cells infiltrate the parenchyma of the brain and accumulate around blood vessels, express B-cell markers such as CD20, and have high proliferative indices. When tumors arise in the setting of immunosuppression, necrosis is often prominent and the Epstein-Barr virus is detectable by in situ hybridization for EBERs, small nuclear RNAs that are encoded by the viral genome.

Meningiomas

Meningiomas are predominantly benign tumors of adults that arise from the meningothelial cells of the arachnoid and are usually attached to the dura. Meningiomas may be found along any of the external surfaces of the brain as well as within the ventricular system, where they arise from the stromal arachnoid cells of the choroid plexus. Prior radiation therapy to the head and neck, typically decades earlier, is a risk factor for development of meningioma. Other tumors such as metastases, solitary fibrous tumors, and a range of poorly differentiated sarcomas may also grow as dura-based masses.

Pathogenesis

The most common cytogenetic abnormality is loss of chromosome 22, especially the long arm (22q). The deletions include the region of 22q12 that harbors the *NF2* gene, which encodes the protein merlin; as expected, meningiomas are a common lesion in the setting of NF2 (see later). Of sporadic meningiomas, 50% to 60% harbor mutations in the *NF2* gene; these are most commonly seen in convexity tumors, including those that eventually become higher grade. In meningiomas without *NF2* mutations, the most common mutations occur in *TRAF7, KLF4, AKT1,* and *SMO;* most such tumors involve the skull base and have a lower risk of malignant progression. Higher-grade meningiomas more often have chromosomal losses involving several chromosomes, *TERT*-promoter mutations, and homozygous *CDKN2A* gene deletions.

MORPHOLOGY

Meningiomas are usually rubbery, rounded, or bosselated dural masses that compress underlying brain but are easily separated from it (Fig. 28.52A). They may also grow **en plaque,** in which the tumor spreads in a sheetlike fashion along the surface of the dura; this form is commonly associated with hyperostotic changes in the adjacent bone due to invasion, although this by itself does not signify malignancy. The lesions range from firm to finely gritty (sandlike), the latter typically due to numerous psammomatous calcifications ("psammos" is Greek for *sand*).

Most meningiomas have a relatively low risk of recurrence or aggressive growth, and so are considered WHO grade I. Many histologic patterns are observed, with most showing no prognostic

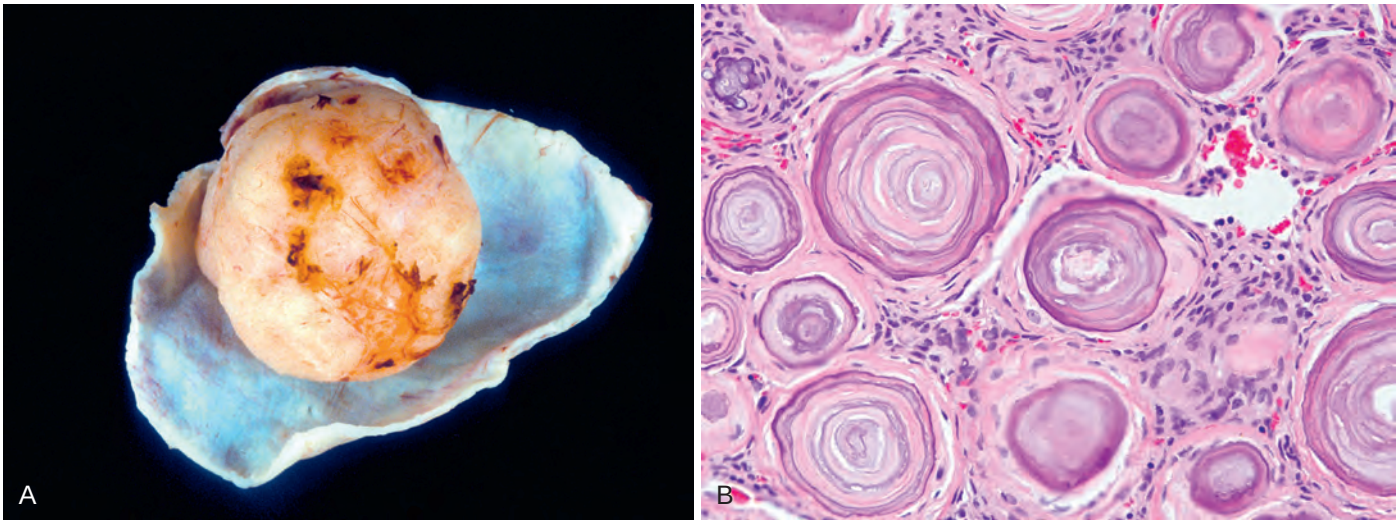

Figure 28.52 (A) Resected meningioma specimen showing rounded contour and dural attachment. (B) Meningioma with a whorled pattern of cell growth and numerous psammoma bodies (calcifications with concentric rings).

significance. The most common include **meningothelial,** containing clusters of epithelioid cells with fuzzy or indiscernible cell membranes; **fibroblastic,** with intersecting fascicles of spindled cells and abundant collagen deposition; **transitional,** with mixed meningothelial and fibroblastic features, often including many whorls (concentric wrapping of tumor cells around one another); and **psammomatous,** with a predominance of psammoma bodies, the latter representing concentric rings of calcification deposited over pre-existing whorls (see Fig. 28.52B).

Atypical meningiomas (WHO grade II) represent about one-fourth of meningiomas and are associated with higher recurrence rates and more aggressive local growth, which may require radiation therapy in addition to surgery. They are distinguished from lower-grade meningiomas by having an increased mitotic index, brain invasion, or other aggressive features. Certain histologic patterns (**clear cell** and **chordoid**) are considered grade II by definition because of their more aggressive behavior.

Anaplastic (malignant) meningioma (WHO grade III) is a highly aggressive malignancy that often resembles a carcinoma or sarcoma, but retains some evidence of meningothelial origin. They account for 1% to 3% of all meningiomas and may arise de novo or from malignant progression of lower-grade meningiomas. Mitotic rates are often markedly elevated. **Papillary** and **rhabdoid** meningiomas are rare WHO grade III variants that also feature high recurrence and mortality rates.

Clinical Features

Meningiomas are usually slow-growing tumors. Patients present either with vague nonlocalizing symptoms or with focal findings referable to compression of underlying brain. Common sites of involvement include the parasagittal aspect of the brain convexity, dura over the lateral convexity, wing of the sphenoid, olfactory groove, sella turcica, and foramen magnum. Meningiomas are uncommon in children and generally show a moderate (3:2) female predominance, although the ratio is 10:1 for spinal meningiomas (which are also commonly psammomatous). Lesions are usually solitary, but when present at multiple sites, especially in association with vestibular schwannoma and/or spinal ependymoma, the possibility of NF2 should be considered. Meningiomas often express a variety of hormone (e.g., progesterone) receptors and may grow more rapidly during pregnancy, only to regress after delivery.

Metastatic Tumors

Metastatic lesions, mostly carcinomas, account for approximately one-fourth to one-half of intracranial tumors in hospitalized patients. The five most common primary sites are lung, breast, skin (melanoma), kidney, and gastrointestinal tract, accounting for about 80% of all metastases combined. Some rare tumors (e.g., choriocarcinoma) have a high likelihood of metastasizing to the brain, whereas other more common tumors (e.g., prostatic adenocarcinoma) almost never do so. The meninges are also a frequent site of involvement by metastatic disease, where they may either form discrete masses or a more disseminated subarachnoid, meningitis-like pattern known as "meningeal carcinomatosis"; the latter is often highly challenging to treat and is associated with both cranial and spinal neuropathies from nerve root compression. Metastatic tumors present clinically as mass lesions and may occasionally be the first manifestation of systemic cancer. In general, localized treatment of solitary brain metastases improves the quality and duration of the patient's life.

MORPHOLOGY

Intraparenchymal metastases form sharply demarcated masses, often at the junction of gray and white matter, usually surrounded by a zone of edema. The boundary between tumor and brain parenchyma is usually well-defined microscopically, although melanoma does not always follow this rule and may be more infiltrative. The tumors typically resemble their parent tumor type, but can be very poorly differentiated in some cases; for the roughly 10% that present as a metastasis of unknown primary, immunohistochemistry is often helpful for further subtyping. Meningeal carcinomatosis, with tumor nodules studding the surface of the brain, spinal cord, and intradural nerve roots, is most commonly associated with carcinomas of the lung and breast.

Paraneoplastic Syndromes

In addition to the direct and localized effects produced by CNS metastases, peripheral neoplasms sometimes produce *paraneoplastic syndromes* that involve the peripheral and/or central nervous systems and can precede the clinical recognition of the primary tumor. A variety of paraneoplastic syndromes has been described; a shared underlying mechanism appears to be the development of an immune response against tumor antigens that cross-reacts with antigens in the central or peripheral nervous system. The spectrum of known circulating antibodies and target antigens continues to expand; illustrative CNS examples are as follows:

- *Subacute cerebellar degeneration* is associated with destruction of Purkinje cells, gliosis, and a chronic inflammatory cell infiltrate. One group of affected patients has a circulating PCA-1 antibody (anti-Yo) that recognizes cerebellar Purkinje cells; this antibody occurs predominantly in women with ovarian, uterine, or breast carcinomas.
- *Limbic encephalitis* is characterized by subacute dementia and shows perivascular inflammatory cuffs, microglial nodules, some neuronal loss, and gliosis, all of which are most evident in the anterior and medial portions of the temporal lobe; the microscopic picture resembles that of a viral encephalitis. A comparable process involving the brainstem can be seen in isolation or together with limbic system involvement. Some affected patients have a circulating ANNA-1 antibody (anti-Hu) that recognizes neuronal nuclei in the central and peripheral nervous systems; ANNA-1 is most commonly associated with small cell carcinoma of the lung. Another group of patients has a circulating antibody that recognizes the NMDA receptor and cross-reacts with hippocampal neurons. Originally identified in women with ovarian teratomas, the same clinical syndrome is now also recognized in a small proportion of patients with sporadic encephalitis. A third group of patients has a circulating VGKC-complex antibody that recognizes the voltage-gated potassium channel; this antibody may also be associated with peripheral neuropathy.

- *Eye movement disorders,* most commonly opsoclonus, may occur by themselves or in association with other evidence of cerebellar and brainstem dysfunction. In children, this is most commonly associated with neuroblastoma and is often accompanied by myoclonus.

The peripheral nervous system can also be affected by the following paraneoplastic syndromes:

- *Subacute sensory neuropathy* may be found in association with limbic encephalitis or in isolation. It is marked by loss of sensory neurons and lymphocytic inflammation in the dorsal root ganglia.
- *Lambert-Eaton myasthenic syndrome* is caused by antibodies against the voltage-gated calcium channel in the presynaptic elements of the neuromuscular junction. This syndrome can also be seen in the absence of malignancy.

For some paraneoplastic syndromes, there is evidence that immunotherapy (removal of circulating antibodies and immunosuppression) and tumor removal lead to clinical improvement. In general, clinical syndromes associated with plasma membrane–reactive antibodies (e.g., antibodies that recognize VGKC or NMDA receptor) respond to immunotherapy better than those associated with intracellular antigens (e.g., ANNA-1 and PCA-1).

Familial Tumor Syndromes

A number of inherited diseases is associated with increased risk of neoplasms (Chapter 7). In several of these (discussed in the following sections), tumors of the nervous system are a prominent aspect of the disease.

Neurofibromatoses and Schwannomatosis

The two forms of neurofibromatosis, NF1 and NF2, are familial autosomal dominant syndromes characterized by tumors of the peripheral and central nervous systems; in contrast, schwannomatosis involves the peripheral nervous system only and may be either familial or sporadic. NF1 is most common, with a frequency of 1 in 3000, and is characterized by neurofibromas of peripheral nerves, gliomas of the optic nerve, pigmented nodules of the iris (Lisch nodules), and cutaneous hyperpigmented macules (café au lait spots). NF2 has a frequency of 1 in 40,000 to 50,000 and is characterized by the occurrence of bilateral vestibular (cranial nerve VIII) schwannomas, multiple meningiomas, and ependymomas of the cervical spinal cord. Schwannomatosis, roughly as common as NF2, is the most recently recognized syndrome; it is defined by multiple nonvestibular schwannomas, either throughout the body or limited to one region. These disorders are discussed in greater detail in Chapter 27.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is an autosomal dominant syndrome that occurs at a frequency of approximately 1 in 6000 births. It is characterized by the development of hamartomas and benign neoplasms involving the brain and other tissues; the most frequent clinical manifestations are seizures, autism, and intellectual disability. Hamartomas within the CNS take the form of cortical tubers and subependymal nodules; subependymal giant cell astrocytomas are benign neoplasms that appear to develop from the hamartomatous nodules in the same location. Cortical tubers are often epileptogenic, and surgical resection can be beneficial when medical management of the seizures fails. Elsewhere in the body, renal angiomyolipomas, retinal glial hamartomas, pulmonary lymphangioleiomyomatosis, and cardiac rhabdomyomas develop during childhood and adolescence. Cysts may be found at various sites, including the liver, kidneys, and pancreas. Cutaneous lesions include angiofibromas, localized leathery thickenings (shagreen patches), hypopigmented areas (ash-leaf patches), and subungual fibromas.

One tuberous sclerosis gene *(TSC1)* is found on chromosome 9q34 and encodes a protein known as hamartin; the more commonly mutated gene *(TSC2)* is on 16p13.3 and encodes tuberin. These two proteins form a complex that inhibits the kinase mTOR, a key regulator of protein synthesis and other aspects of anabolic metabolism. Mutations in *TSC1* or *TSC2* disrupt this control and lead to increased and unregulated mTOR activity. Of note, mTOR controls cell size, and the tumor cells associated with TSC, particularly the subependymal giant cell astrocytomas, are remarkable for having voluminous cytoplasm. Treatment is usually symptomatic, including anticonvulsant therapy for control of seizures; however, treatment with mTOR inhibitors has sometimes resulted in dramatic clinical improvement.

MORPHOLOGY

Cortical hamartomas of TSC are firm areas that, in contrast to the softer adjacent cortex, have been likened to potatoes (hence the appellation "tubers"). The tubers are composed of haphazardly arranged neurons that lack the normal laminar organization. In addition, some dysplastic cells have an appearance intermediate between glia and neurons (large vesicular nuclei with nucleoli, resembling neurons, and abundant eosinophilic cytoplasm resembling gemistocytic astrocytes); they often express intermediate filaments of both neuronal (neurofilament) and glial (GFAP) types. Similar hamartomatous features are present in the subependymal nodules, where the large astrocyte-like cells cluster beneath the ventricular surface. These small waxlike masses that bulge into the ventricular system gave rise to the term **candle-gutterings.** Subependymal giant cell astrocytoma is histologically similar, but larger; it often presents with obstructive hydrocephalus.

Von Hippel-Lindau Disease

Individuals with this autosomal dominant disease develop hemangioblastomas of the CNS; cysts that involve the pancreas, liver, and kidneys; renal cell carcinomas; and pheochromocytomas. Hemangioblastomas are most common in the cerebellum and retina, but may also occur in other CNS locations. The disease frequency is 1 in 30,000 to 40,000.

The gene associated with von Hippel-Lindau disease, called *VHL,* is a tumor-suppressor gene located on chromosome 3p25.3; it encodes a protein (VHL) that is a component of a ubiquitin ligase complex that down-regulates hypoxia-induced factor 1 (HIF-1). HIF-1 is a transcription factor that regulates expression of vascular endothelial growth factor (VEGF), erythropoietin, and other growth factors. VEGF leads to excessive vessel growth, contributing to the development of hemangioblastomas. Erythropoietin overexpression leads to polycythemia in about 10% of hemangioblastoma patients.

HIF also regulates the expression of genes that control cellular metabolism and cell growth, activities that likely contribute to tumor formation.

MORPHOLOGY

Hemangioblastomas are highly vascular neoplasms that form a mural nodule associated with a large fluid-filled cyst. The lesion consists of numerous capillary-size or somewhat larger thin-walled vessels with intervening neoplastic cells that have vacuolated, lipid-rich cytoplasm. The neoplastic stromal cells express erythropoietin, VEGF, and inhibin (a diagnostically useful marker), and are believed to be derived from an early mesenchymal progenitor cell capable of differentiating into both endothelial and hemopoietic cells.

Therapy is directed at the symptomatic neoplasms, including resection of the cerebellar hemangioblastomas and laser therapy for retinal hemangioblastomas.

KEY CONCEPTS

TUMORS

- Tumors of the CNS may arise from the brain coverings (meningiomas), the brain parenchyma (gliomas, neuronal tumors, choroid plexus tumors), and other resident CNS cell populations (primary CNS lymphoma); they can also originate elsewhere in the body (metastases).
- Even low-grade or benign tumors can have poor clinical outcomes, depending on where they occur in the brain.
- Distinct types of tumors affect specific brain regions (e.g., cerebellum for medulloblastoma) and specific age populations (medulloblastoma and pilocytic astrocytoma in pediatric age groups; glioblastoma and lymphoma in older patients).
- Glial tumors are broadly classified into astrocytomas, oligodendrogliomas, and ependymomas. Increasing tumor malignancy is associated with more cytologic anaplasia, increased cell density, necrosis, and mitotic activity. Diagnostic, prognostic, and/or predictive genetic alterations have recently been recognized in some of these tumors.
- Metastatic spread of brain tumors to other regions of the body is rare, but the brain is a common recipient of metastatic disease from systemic malignancies. Carcinomas are most common.

ACKNOWLEDGMENT

The contributions of Dr. Matt Frosch to previous versions of this chapter are gratefully acknowledged.

CHAPTER 29

The Eye

Robert Folberg

CHAPTER CONTENTS

Although this chapter comes at the end of the book, it is not an afterthought. Vision is a major quality-of-life issue. Before the public awareness of acquired immunodeficiency syndrome (AIDS) and Alzheimer disease, the most feared disease among Americans was cancer, and the second most feared disease was blindness. So great is the fear of blindness that even today, people often tell their physicians, "Doctor, I'd rather be dead than be blind!"

In general, diseases that produce loss of vision do not attract as much attention as do many of the life-threatening conditions described in this book. For example, age-related macular degeneration (AMD) is the most common cause of irreversible visual loss in the United States. Most individuals with AMD do not suffer from a total loss of vision—an immersion into darkness. The histopathology is unimpressive: small scars develop in the macula. But consider the effect of these tiny scars in a retired schoolteacher with AMD. The central portion of her or his vision is lost. The faces of spouse or grandchildren are not visible. He or she cannot read a book or newspaper. Once a model of independence, this teacher can no longer drive a car and must be chauffeured everywhere. In short, this person is robbed of the common joys that most of us take for granted.

To study the eye, one needs to comprehend all that has come before. For example, the pathology of the eyelids builds on knowledge of dermatopathology (see Chapter 25), and the pathology of the retina and optic nerve extends what was learned in Chapter 28 about the brain and central nervous system. However, the study of ocular pathology does not merely repeat what has been presented thus far. **The eye provides the only site in which a physician can directly visualize a variety of microcirculatory disturbances ranging from arteriosclerosis to angiogenesis in the clinic.** Although there are conditions that are unique to the eye (e.g., cataract and glaucoma), many ocular conditions share similarities with disease processes elsewhere in the body that are modified by the unique structure and function of the eye (Fig. 29.1).

In recent years, the elucidation of the molecular pathogenesis of disease has been translated rapidly to therapeutic applications in the eye. Many blinding conditions, such as corneal neovascularization, diabetic retinopathy, and certain

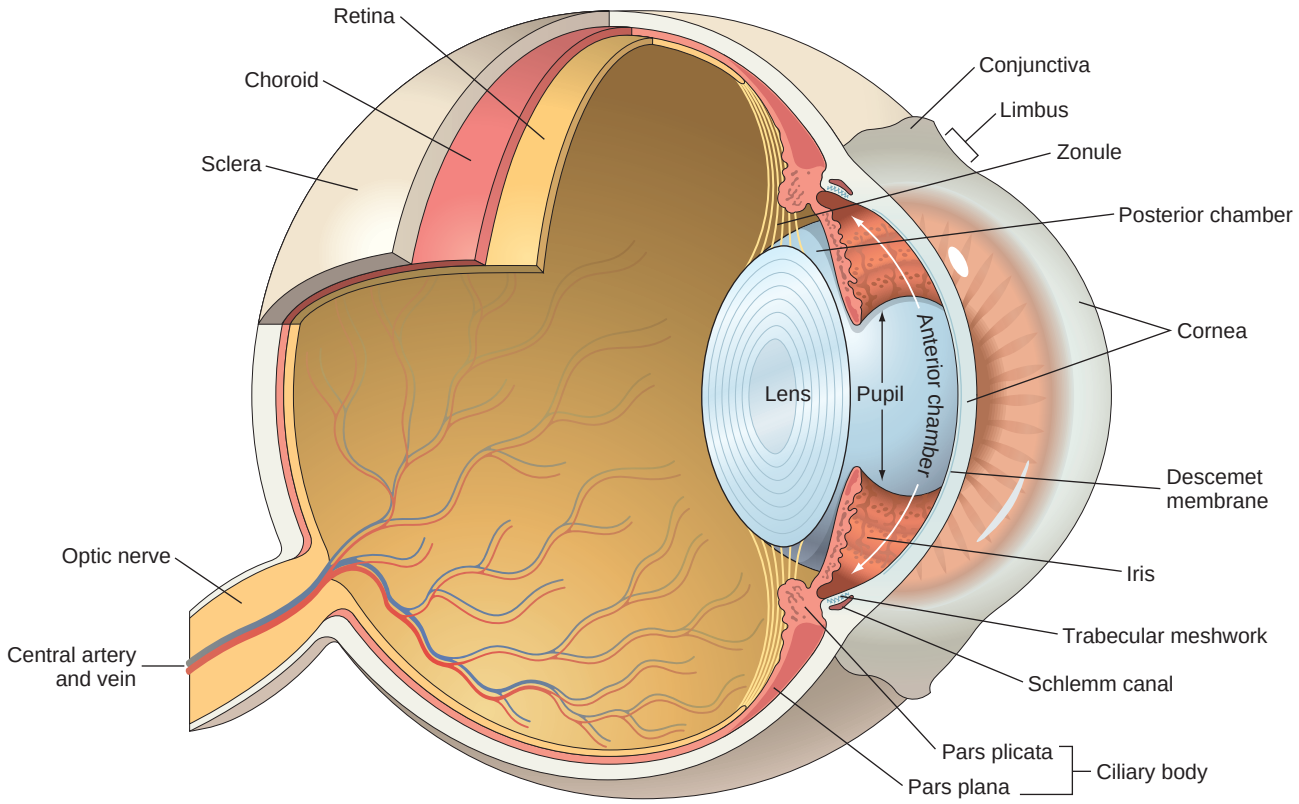

Figure 29.1 Anatomy of the eye.

forms of age-related neovascularization, result from pathologic angiogenesis. Successful treatment of these conditions with vascular endothelial growth factor (VEGF) antagonists has saved vision in patients who might have been blinded just a few years ago.

This chapter is organized on the basis of ocular anatomy. The discussion of each region of the eye begins with anatomic and functional considerations and their impact on the understanding of ocular diseases.

ORBIT

Functional Anatomy and Proptosis

The orbit is a compartment that is closed medially, laterally, and posteriorly. Diseases that increase orbital contents therefore displace the eye forward, a condition known as *proptosis*. Aside from the obvious cosmetic concerns, the proptotic eye might not be covered completely by the eyelids, and the tear film might not be distributed evenly across the cornea. Chronic corneal exposure to air is injurious, leading to pain and predisposing to corneal ulceration and infection. Proptosis may be axial (directly forward) or positional. For example, any enlargement of the lacrimal gland from inflammation (e.g., *sarcoidosis*) or neoplasm (e.g., *lymphoma, pleomorphic adenoma,* or *adenoid cystic carcinoma*) produces a proptosis that displaces the eye inferiorly and medially because the lacrimal gland is positioned superotemporally within the orbit.

Masses contained within the cone formed by the horizontal rectus muscles generate axial proptosis: the eye bulges straight forward. The two most common primary tumors of the optic nerve (a tract of the central nervous system), *glioma* and *meningioma,* produce axial proptosis because the optic nerve is positioned within the muscle cone. The orbital contents are subject to the same disease processes that affect other tissues. Representative inflammatory conditions and neoplasms of the orbit are discussed briefly next.

Thyroid Ophthalmopathy (Graves Disease)

In the chapter on endocrine disorders (Chapter 24) it was noted that axial proptosis is an important clinical manifestation of Graves disease. Proptosis is caused by the accumulation of extracellular matrix proteins and variable degrees of fibrosis in the rectus muscles (Fig. 29.2). The development of thyroid ophthalmopathy may, in some cases, be independent of the status of thyroid function.

Other Orbital Inflammatory Conditions

The floor of the orbit is the roof of the maxillary sinus, and the medial wall of the orbit—the lamina papyracea—separates the orbit from the ethmoidal sinuses. As a result, uncontrolled sinus infection may spread to the orbit either as an acute bacterial infection or as a component of a fungal infection. This occurs most commonly in immunosuppressed individuals, in patients with diabetic ketoacidosis, or, rarely, in persons without any predisposition. Systemic conditions such as *granulomatosis with polyangiitis* (Chapter 11) may present first in the orbit and may be confined there for

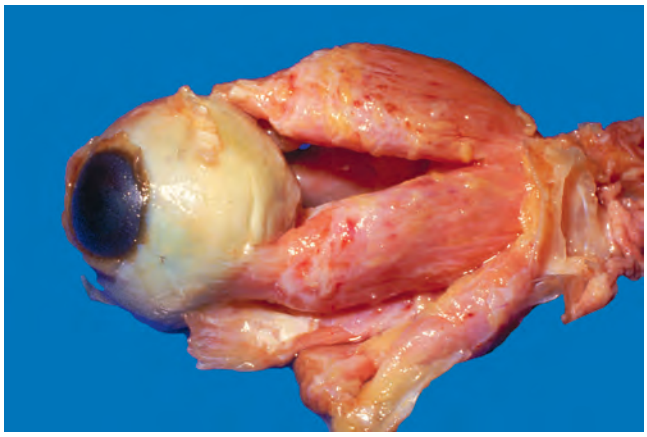

Figure 29.2 The extraocular muscles are greatly distended in this postmortem dissection of tissues from a patient with thyroid (Graves) ophthalmopathy. Note that the tendons of the muscles are spared. (Courtesy Dr. Ralph C. Eagle, Jr., Wills Eye Hospital, Philadelphia, Pa.)

prolonged periods of time, or alternatively, it may involve the orbit secondarily by extension from the sinuses.

Idiopathic orbital inflammation, also known as orbital inflammatory pseudotumor (Fig. 29.3), is another inflammatory condition affecting the orbit. This condition may be unilateral or bilateral and may affect all orbital tissue elements or may be confined to the lacrimal gland *(sclerosing dacryoadenitis),* extraocular muscles *(orbital myositis),* or Tenon capsule, the fascial layer that wraps around the eye *(posterior scleritis).* IgG4-related disease (Chapter 6) should be excluded before declaring an orbital inflammation to be idiopathic.

MORPHOLOGY

Idiopathic orbital inflammation is characterized histologically by chronic inflammation and variable degrees of fibrosis. The inflammatory infiltrate typically includes lymphocytes and plasma cells and occasionally eosinophils. Germinal centers, when present, raise the suspicion of a reactive lymphoid hyperplasia. Vasculitis may be present, suggesting an underlying systemic condition. The presence of necrosis and degenerating collagen along with vasculitis should raise the suspicion of granulomatosis with polyangiitis. Idiopathic orbital inflammation is typically confined to the orbit but may develop concomitantly with sclerosing inflammation in the retroperitoneum, the mediastinum, and the thyroid, especially as a manifestation of IgG4-related disease.

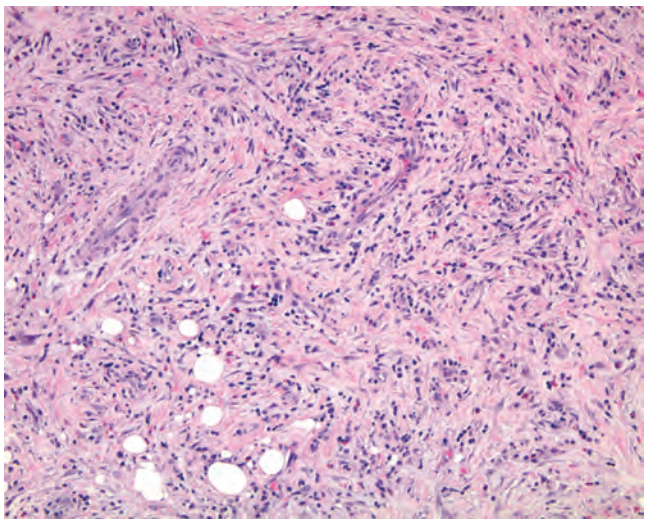

Figure 29.3 In idiopathic orbital inflammation (orbital inflammatory pseudotumor) the orbital fat is replaced by fibrosis. Note the chronic inflammation, accompanied in this case by eosinophils.

Neoplasms

The most frequently encountered primary neoplasms of the orbit are vascular in origin: capillary hemangioma of infancy and early childhood and lymphangioma (both of which are unencapsulated) and encapsulated cavernous hemangioma found typically in adults. These are described in other chapters. Only a handful of orbital masses are encapsulated (e.g., pleomorphic adenoma of the lacrimal gland, dermoid cyst, neurilemmoma), and the recognition of encapsulation on imaging studies allows the surgeon to anticipate pathologic findings.

Non-Hodgkin lymphoma, like idiopathic orbital inflammation, can affect the entire orbit or can be confined to compartments of the orbit such as the lacrimal gland. Orbital lymphomas are classified according to the World Health Organization (WHO) classification system (Chapter 13).

Primary orbital malignancies may arise from any of the orbital tissues and are classified according to the scheme used for the parent tissue. For example, the lacrimal gland may be considered a minor salivary gland, and tumors of the lacrimal gland are classified as salivary gland tumors.

Metastases to the orbit may present with distinctive signs and symptoms that point to the origin of the tumor. For example, metastatic prostatic carcinoma may present clinically like idiopathic orbital inflammation; metastatic neuroblastoma and Wilms tumor—richly vascular neoplasms—may produce characteristic periocular ecchymoses. Neoplasms may also invade from the sinuses into the orbit.

KEY CONCEPTS

- Proptosis results from lesions or pathologic changes in tissue that occupy space in the orbit. The orbit is a compartment that is only open anteriorly and is closed in all other dimensions by bone.
- Inflammation in the orbit may develop by extension of local disease in adjacent tissues (e.g., sinusitis) or as a component of systemic disease (e.g., granulomatosis with polyangiitis).
- The most common primary tumors of the orbit are vascular (e.g., capillary and cavernous hemangiomas).

EYELID

Functional Anatomy

The eyelid is composed of skin externally and mucosa (the conjunctiva) on the surface apposed to the eye (Fig. 29.4). In addition to covering and protecting the eye, elements within

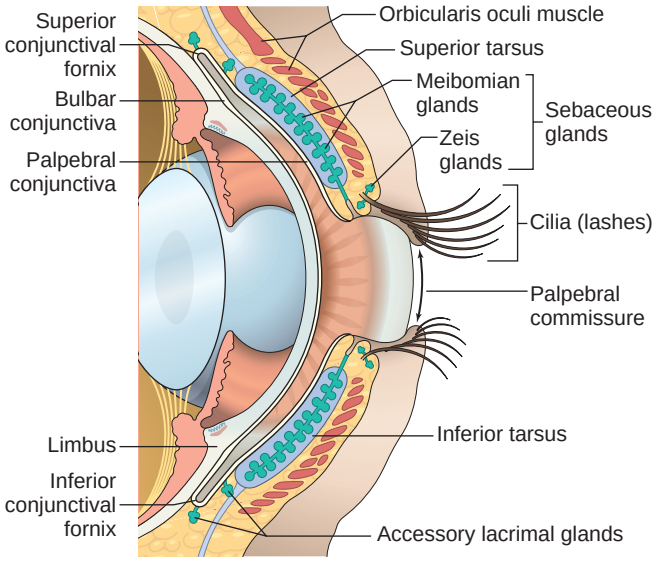

Figure 29.4 Anatomy of the conjunctiva and eyelids.

the eyelid generate critical components of the tear film. If the drainage system of the sebaceous glands is obstructed by chronic inflammation at the eyelid margin *(blepharitis)* or, less commonly, by neoplasm, lipid may extravasate into surrounding tissue and provoke a granulomatous response producing a lipogranuloma, or *chalazion*.

Neoplasms

The most common malignancy of the eyelid is basal cell carcinoma. Surprisingly, primary melanomas of the eyelid skin are extremely rare. Regardless of histogenesis, eyelid neoplasms may distort tissue and prevent the eyelids from closing completely. Because chronic exposure to air damages the cornea, prompt treatment of locally invasive basal cell carcinomas is imperative to preserve vision. Basal cell carcinoma has a distinct predilection for the lower eyelid and the medial canthus.

Sebaceous carcinoma may form a local mass that mimics *chalazion* or may diffusely thicken the eyelid. This neoplasm may also resemble inflammatory processes such as blepharitis or *ocular cicatricial pemphigoid* because of a predilection for intraepithelial spread as occurs in Paget disease of the nipple (Chapter 23) or vulva (Chapter 22). Sebaceous carcinoma tends to spread first to the parotid and submandibular nodes. The overall mortality rate can be as high as 22%. Sebaceous carcinoma of the eyelid is less likely to be associated with Muir-Torre syndrome than sebaceous neoplasms developing elsewhere.

MORPHOLOGY

In moderately differentiated or well-differentiated sebaceous carcinoma, vacuolization of the cytoplasm is present and helps in the diagnosis. This cancer may, however, resemble a variety of other malignancies histologically, including basal cell carcinoma; hence establishing the correct diagnosis can be difficult. Pagetoid spread (Fig. 29.5) may mimic Bowenoid actinic keratosis in the eyelid and carcinoma in situ in the conjunctiva. Sebaceous carcinoma may spread through the conjunctival epithelium and the epidermis to the lacrimal drainage system and the nasopharynx. It may also extend into the lacrimal gland ductules and thereby into the main lacrimal gland.

In individuals with AIDS, *Kaposi sarcoma* may develop in either the eyelid or the conjunctiva. In the eyelid the lesion may appear clinically to have a purple hue because the vascular lesion is embedded in the dermis, but in the thin mucous membrane of the conjunctiva, Kaposi sarcoma appears bright red and may be confused clinically with a subconjunctival hemorrhage.

KEY CONCEPTS

- Basal cell carcinoma is the most common primary malignancy of the eyelid and may be very invasive locally.
- Sebaceous carcinoma of the eyelid, by contrast, may metastasize and is therefore a serious and potentially life-threatening condition.

CONJUNCTIVA

Functional Anatomy

The conjunctiva is divided into zones (see Fig. 29.4), each with distinctive histologic features and responses to disease. The conjunctiva lining the interior of the eyelid, the *palpebral conjunctiva,* is tightly tethered to the tarsus and may respond to inflammation by being thrown into minute papillary folds as may occur in allergic conjunctivitis and bacterial conjunctivitis. The conjunctiva in the *fornix* is a pseudostratified columnar epithelium rich in goblet cells. The fornix also contains accessory lacrimal tissue, and the ductules of the

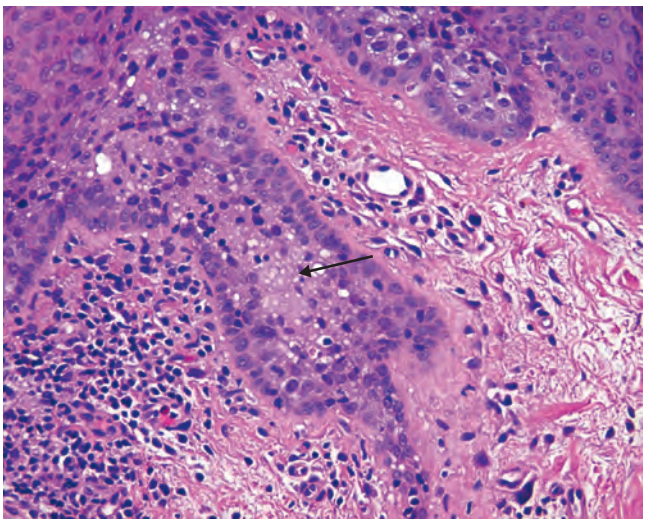

Figure 29.5 Pagetoid spread of sebaceous carcinoma. Neoplastic cells with foamy cytoplasm are present within the epidermis *(arrow)*. Invasive sebaceous carcinoma was identified elsewhere in this biopsy sample.

main lacrimal gland pierce through the conjunctiva in the fornix superiorly and laterally. The lymphoid population of the conjunctiva is most noticeable in the fornix, and *in viral conjunctivitis, lymphoid follicles may enlarge sufficiently to be visualized clinically* by slit-lamp examination. *Granulomas* associated with systemic sarcoidosis may be detected in the conjunctival fornix, and the yield of granulomas from a nondirected conjunctival biopsy in individuals suspected of having sarcoid may be as high as 50%. Primary lymphoma of the conjunctiva (typically indolent marginal zone B-cell lymphoma) is most likely to develop in the fornix. The *bulbar conjunctiva*—the conjunctiva that covers the surface of the eye—is a nonkeratinizing stratified squamous epithelium. The limbus, the intersection between the sclera and cornea, also marks the transition between conjunctival and corneal epithelium (see Fig. 29.1).

The conjunctiva, like the eyelid, is richly invested with lymphatic channels. Malignant neoplasms arising in the eyelid and conjunctiva tend to spread to regional lymph nodes (parotid and submandibular node groups).

Conjunctival Scarring

Many cases of bacterial or viral conjunctivitis cause redness and itching, but most heal without sequelae. However, infection with *Chlamydia trachomatis* (*trachoma*) may produce significant conjunctival scarring. Conjunctival scarring is also seen after exposure of the ocular surface to caustic alkalis or as a sequela to ocular cicatricial *pemphigoid* (Chapter 25). A reduction in the number of goblet cells due to conjunctival scarring leads to a decrease in surface mucin, which is essential for the adherence of the aqueous component of tears to the corneal epithelium. Thus, even if the aqueous component of the tear film is adequate, the affected individual will suffer from a dry eye. More commonly, however, dry eye results from a deficiency in the aqueous component of the tear film generated by the accessory lacrimal glands embedded within the eyelid and fornix.

The conjunctiva may be scarred iatrogenically through reaction to drugs or as a consequence of surgery. In other parts of the body, cancer surgery requires excision of the lesion with a margin of normal tissue to ensure complete removal. However, extensive surgical excision of even diseased conjunctiva can remove a large number of goblet cells or compromise lacrimal gland ductules that traverse the conjunctiva. Thus, removal of a conjunctival neoplasm or a precursor lesion may leave the affected individual with a painful dry eye that can compromise vision. Therefore, surgeons often remove only the invasive components of conjunctival neoplasms and treat the intraepithelial components with tissue-sparing modalities such as cryotherapy or topical chemotherapy delivered as eyedrops.

Pinguecula and Pterygium

Both *pinguecula* and *pterygium* appear as submucosal elevations on the conjunctiva. They result from actinic damage and are therefore located in the sun-exposed regions of the conjunctiva (i.e., in the fissure between both the upper and the lower eyelids—the interpalpebral fissure). Pterygium typically originates in the conjunctiva astride the limbus. It is formed by a submucosal growth *of fibrovascular connective tissue that migrates onto the cornea,* dissecting into the plane occupied normally by the Bowman layer. Pterygium does not cross the pupillary axis and, aside from the possible induction of mild astigmatism, does not pose a threat to vision. Although most pterygia are entirely benign, it is worthwhile submitting the excised tissue for pathologic examination because, on occasion, precursors of actinic-induced neoplasms—squamous cell carcinoma and melanoma—are detected in these lesions. Pinguecula, which, like pterygium, appears astride the limbus, is a small, yellowish submucosal elevation.

Neoplasms

Both squamous neoplasms and melanocytic neoplasms and their precursors tend to develop at the limbus. Conjunctival *squamous cell carcinoma* may be preceded by intraepithelial neoplastic changes analogous to those seen in the evolution of cervical squamous cell carcinoma. In the conjunctiva the spectrum of changes from mild dysplasia through carcinoma in situ is designated as *ocular surface squamous neoplasia*. Squamous papillomas and conjunctival intraepithelial neoplasia may be associated with the presence of human papillomavirus types 16 and 18.

Conjunctival nevi are encountered commonly but seldom invade the cornea or appear in the fornix or over the palpebral conjunctiva. Pigmented lesions in these zones of the conjunctiva most likely represent melanomas or melanoma precursors. Compound nevi of the conjunctiva characteristically contain subepithelial cysts lined by surface epithelium (Fig. 29.6A, B). In late childhood or adolescence, conjunctival nevi may acquire an inflammatory component rich in lymphocytes, plasma cells, and eosinophils. The resultant *inflamed juvenile nevus* is completely benign.

Conjunctival melanomas are unilateral neoplasms, typically affecting fair-complexioned individuals in middle age (Fig. 29.6C, D). Most cases of conjunctival melanoma develop through a phase of intraepithelial growth termed *primary acquired melanosis with atypia* or *conjunctival melanocytic intraepithelial neoplasia (C-MIN)*. Between 50% and 90% of individuals with incompletely treated primary acquired melanosis with atypia develop conjunctival melanoma. *BRAF* V600 mutations may be identified in nearly 40% of conjunctival melanomas. Perhaps the best treatment of conjunctival melanoma is its prevention through extirpation of its precursor lesion. The lesions tend to spread first to the parotid or submandibular lymph nodes. Approximately 25% of conjunctival melanomas prove to be fatal.

KEY CONCEPTS

- Conjunctival scarring, a consequence of a variety of conditions, may result in painful loss of vision by interfering with the delivery and maintenance of the tear film.
- Many conjunctival neoplasms originate at the limbus, the seat of stem cells of the ocular surface.
- Conjunctival malignancies—especially conjunctival melanomas—tend to spread through the rich lymphatics of the conjunctiva to regional lymph nodes.

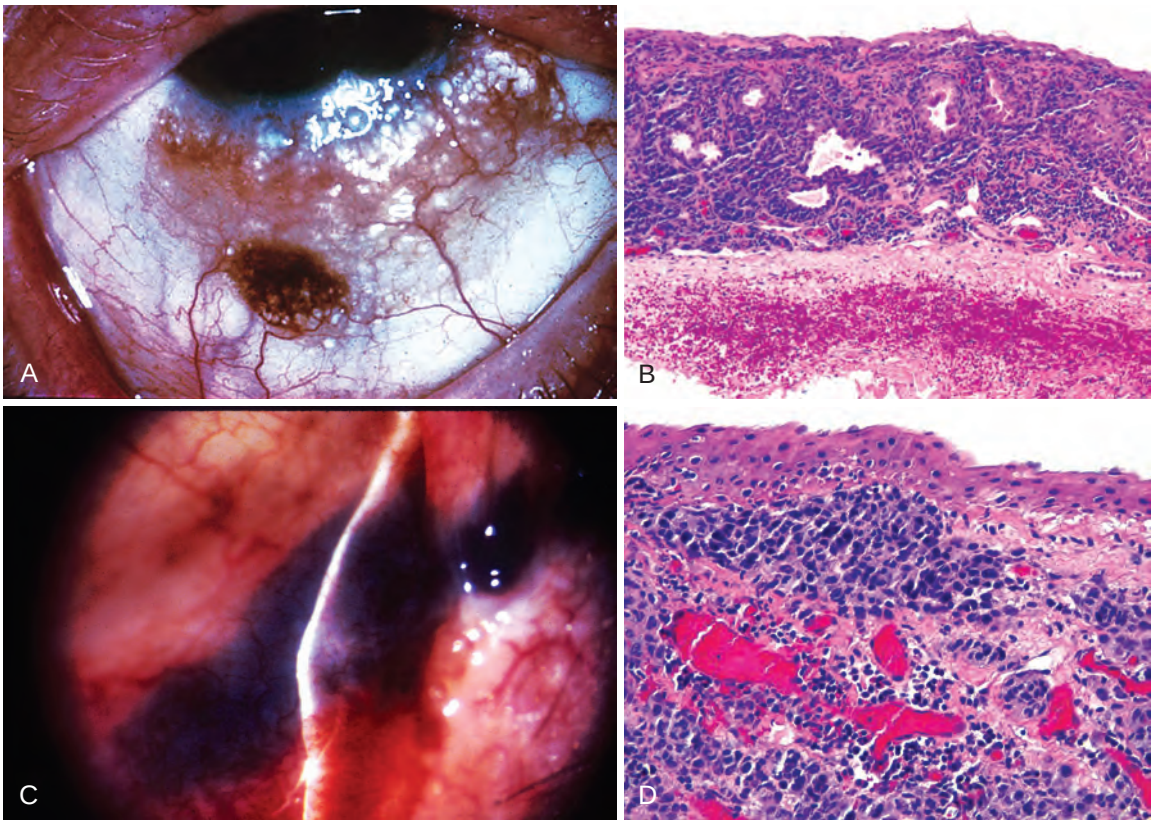

Figure 29.6 (A, B) Cystic compound nevus of the conjunctiva. (C, D) Conjunctival malignant melanoma. In C, note the deflection of the beam of the slit lamp over the surface of the lesion, indicative of invasion. (A, B, From Folberg R, et al: Benign conjunctival melanocytic lesions: clinicopathologic features, *Ophthalmology* 96:436, 1989.)

SCLERA

The sclera consists mainly of collagen and contains few blood vessels and fibroblasts; hence wounds and surgical incisions tend to heal poorly. Immune complex deposits within the sclera, such as in *rheumatoid arthritis,* may produce a necrotizing *scleritis*.

The sclera may appear "blue" in a variety of conditions. Some of these are:

- It may become thin following episodes of *scleritis,* and the normally brown color of the uvea may appear blue clinically because of the optical Tyndall effect.
- *Sclera may be thinned in eyes with exceptionally high intraocular pressure* and because this zone of scleral ectasia is lined by uveal tissue, the resulting lesion, known as a *staphyloma,* also appears blue.
- The sclera may appear blue in *osteogenesis imperfecta.*
- The sclera may appear blue because of a heavily pigmented congenital nevus of the underlying uvea, a condition known as *congenital melanosis oculi*. When accompanied by periocular cutaneous pigmentation, this condition is known as *nevus of Ota*.

CORNEA

Functional Anatomy

The cornea and its overlying tear film—not the lens—make up the major refractive surface of the eye (Fig. 29.7). Parenthetically, *myopia* typically develops because the eye is too long for its refractive power, and *hyperopia* results from an eye that is too short. The popularity of procedures such as laser-assisted in situ keratomileusis (LASIK) to sculpt the cornea and change its refractive properties attests to the importance of corneal shape in contributing to the refractive power of the eye.

Anteriorly, the cornea is covered by *epithelium* that rests on a basement membrane. The *Bowman layer,* situated just beneath the epithelial basement membrane, is acellular and forms an efficient barrier against the penetration of malignant cells from the epithelium into the underlying stroma.

The *corneal stroma* lacks blood vessels and lymphatics, a feature that contributes not only to the transparency of the cornea, but also to high rate of success of corneal transplantation. Indeed, nonimmunologic graft failure

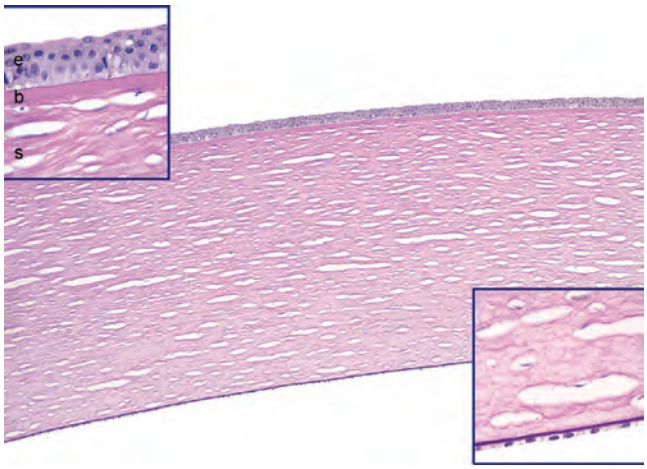

Figure 29.7 Normal corneal microarchitecture. The corneal tissue is stained by periodic acid–Schiff (PAS) to highlight basement membranes. The inset at the upper left is a high magnification of the anterior layers of the cornea: epithelium *(e)*, Bowman layer *(b)*, and stroma *(s)*. A very thin PAS-positive basement membrane separates the epithelium from the Bowman layer. Note that the Bowman layer is acellular. The inset at the lower right is a high magnification of the PAS-positive Descemet membrane and the corneal endothelium. The "holes" in the stroma are artifactitious spaces between parallel collagenous stromal lamellae.

(associated with loss of endothelial cells and subsequent corneal edema) is seen more commonly than is immunologic graft rejection. The risk of corneal graft rejection increases with stromal vascularization and inflammation. A precise alignment of collagen in the corneal stroma also contributes to transparency.

Corneal vascularization may accompany chronic corneal edema, inflammation, and scarring. The application of topical VEGF antagonists affords a promising approach to preventing corneal vascularization. Scarring and edema both disrupt the spatial alignment of stromal collagen and contribute to corneal opacification. Scars may result from trauma or inflammation. Normally, the corneal stroma is in a state of relative deturgescence (dehydration), maintained in large part by active pumping of fluid from the stroma back into the anterior chamber by the corneal endothelium.

The corneal *endothelium* is derived from neural crest and is not related to vascular endothelium. It rests on its basement membrane, Descemet membrane. A decrease in endothelial cells or a malfunction of endothelium results in stromal edema, which may be complicated by bullous separation of the epithelium *(bullous keratopathy)*. *Descemet membrane* increases in thickness with age. It is the site of copper deposition in the Kayser-Fleischer ring of Wilson disease (Chapter 18).

Keratitis and Ulcers

Various pathogens—bacterial, fungal, viral (especially herpes simplex and herpes zoster), and protozoal (*Acanthamoeba*)—can cause corneal ulceration. In all forms of keratitis, dissolution of the corneal stroma may be accelerated by activation of collagenases within corneal epithelium and stromal fibroblasts (also known as keratocytes). Exudate

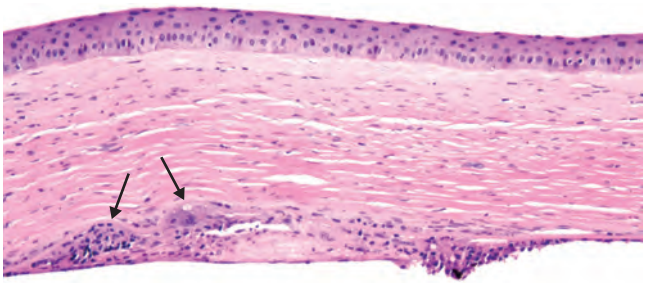

Figure 29.8 Chronic herpes simplex keratitis. The cornea is thin and scarred (note the increased number of fibroblast nuclei). Granulomatous reaction in the Descemet membrane, illustrated in this photomicrograph *(arrows)*, is a histologic hallmark of chronic herpes simplex keratitis.

and cells leaking from iris and ciliary body vessels into the anterior chamber may be visible by slit-lamp examination and may accumulate in sufficient quantity to become visible even by a penlight examination *(hypopyon)*. Although the corneal ulcer may be infectious, the hypopyon seldom contains organisms and is an example par excellence of the vascular response to acute inflammation. The specific forms of keratitis may have certain distinctive features. For example, chronic herpes simplex keratitis may be associated with a granulomatous reaction involving the Descemet membrane (Fig. 29.8).

Corneal Degenerations and Dystrophies

Ophthalmologists have traditionally divided many corneal disorders into degenerations and dystrophies. Corneal degenerations may be either unilateral or bilateral and are typically nonfamilial. By contrast, corneal dystrophies are typically bilateral and are hereditary. Corneal dystrophies may affect selective corneal layers or the changes may be distributed throughout multiple layers.

Band Keratopathies

Two types of band keratopathy serve as examples of corneal degenerations. *Calcific band keratopathy* is characterized by deposition of calcium in the Bowman layer. This condition may complicate chronic uveitis, especially in individuals with chronic juvenile rheumatoid arthritis. *Actinic band keratopathy* develops in individuals who are exposed chronically to high levels of ultraviolet light. In this condition, extensive solar elastosis develops in the superficial layers of corneal collagen in the sun-exposed interpalpebral fissure—hence the horizontally distributed band of pathology. Similar to pinguecula, the sun-damaged collagen of the cornea may take on a yellow hue to the point that this condition is sometimes erroneously called "oil-droplet keratopathy."

Keratoconus

With an incidence of 1 in 2000, *keratoconus* is a fairly common disorder characterized by progressive thinning and ectasia of the cornea without evidence of inflammation or vascularization. Such thinning results in a cornea that has a conical rather than spherical shape. This abnormal shape generates irregular astigmatism that is difficult to correct with spectacles. Rigid contact lenses generate a smooth, spherical

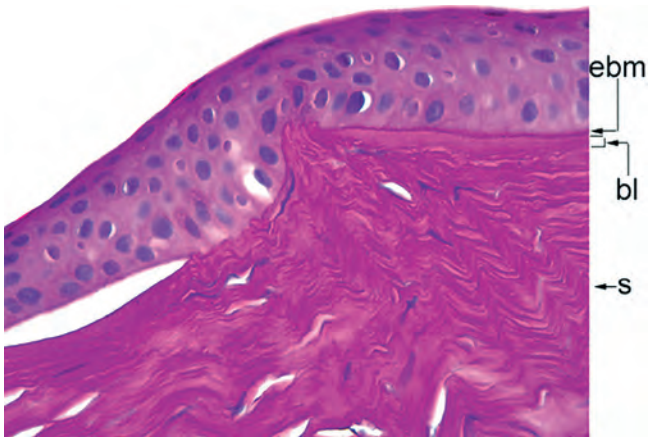

Figure 29.9 Keratoconus. The tissue section is stained by periodic acid–Schiff to highlight the epithelial basement membrane *(ebm)*, which is intact; the Bowman layer *(bl)*, situated between the epithelial basement membrane; and the stroma *(s)*. Following the Bowman layer from the *right side* of the photomicrograph toward the *center*, there is a discontinuity, diagnostic of keratoconus. The epithelial separation just to the *left* of the Bowman layer discontinuity resulted from an episode of corneal hydrops, caused by a break in the Descemet membrane (not shown).

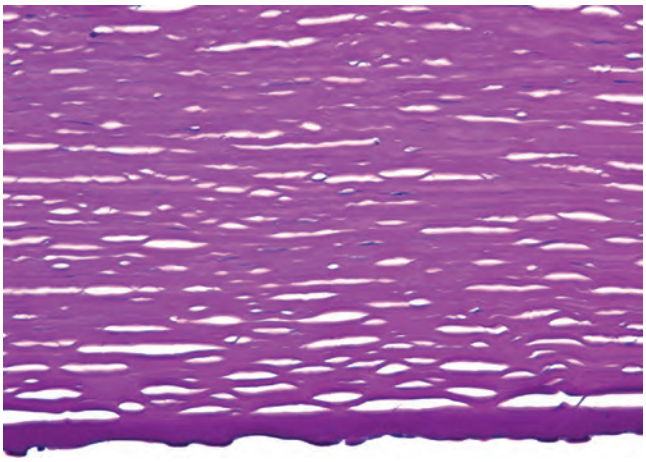

Figure 29.10 Fuchs dystrophy. This tissue section is stained by periodic acid–Schiff to highlight the Descemet membrane, which is thick. Numerous drop-like excrescences—guttata—protrude downward from the Descemet membrane. Endothelial cell nuclei are not seen. Epithelial bullae, not shown in this micrograph, were present, reflecting corneal edema.

surface to the cornea and may provide refractive relief for individuals with keratoconus. Patients whose vision cannot be corrected with spectacles or contact lenses are excellent candidates for corneal transplantation, which has a high degree of success in this condition. Unlike many types of degeneration, keratoconus is typically bilateral. Keratoconus is associated with Down syndrome, Marfan syndrome, and atopic disorders. Its development may stem from a genetic predisposition superimposed by an environmental insult, such as eye rubbing in response to atopic conditions.

MORPHOLOGY

Thinning of the cornea with breaks in the Bowman layer are the histologic hallmarks of keratoconus (Fig. 29.9). In some patients the Descemet membrane may rupture precipitously, allowing the aqueous humor in the anterior chamber to gain access to the corneal stroma. The sudden effusion of aqueous humor through a gap in the Descemet membrane—corneal **hydrops**—may also cause vision to worsen suddenly. An episode of hydrops may be followed by corneal scarring that can also contribute to visual loss. Acute corneal hydrops can complicate Descemet membrane ruptures that develop secondary to extraordinary elevations of intraocular pressure in *infantile glaucoma (Haab striae)* or following the now uncommon obstetric forceps injury to the eye.

Fuchs Endothelial Dystrophy

Fuchs endothelial dystrophy, one of several dystrophies, results from loss of endothelial cells and the resulting edema and thickening of the stroma. It is one of the principal indications for corneal transplantation in the United States. The two major clinical manifestations of Fuchs endothelial dystrophy—*stromal edema and bullous keratopathy*—are both related to a primary loss of endothelial cells. Early in the course of the disease, endothelial cells produce drop-like deposits of abnormal basement membrane material *(guttata)* that can be visualized clinically by slit-lamp examination. With disease progression, there is a decrease in the total number of endothelial cells, and the residual cells are incapable of maintaining stromal deturgescence. Consequently the stroma becomes edematous and thickens; it acquires a ground-glass appearance clinically, and vision is blurred (Fig. 29.10). Because of chronic edema, the stroma may eventually become vascularized. On occasion the number of endothelial cells may decrease following cataract surgery even in individuals who do not have early forms of Fuchs dystrophy. This condition, known as *pseudophakic bullous keratopathy,* is also a common indication for corneal transplantation.

KEY CONCEPTS

- The cornea—not the lens—is the major refractive surface of the eye. Keratoconus is an example of a condition that distorts the contour of the cornea and alters this refractive surface, producing an irregular form of astigmatism.
- The normal cornea is avascular, a feature that contributes to transparency and the low incidence of graft rejection after corneal transplantation.
- Inflammations of the cornea may be accompanied by a noninfectious exudative process in the anterior chamber that may organize to distort anterior segment anatomy and contribute to secondary glaucoma and to cataract.
- Corneal dystrophies are generally inherited and degenerations are typically not inherited. Fuchs dystrophy and pseudophakic bullous keratopathy both produce visual loss through the final common pathway of corneal edema, and both of these conditions are leading indications for corneal transplantation in the United States.

ANTERIOR SEGMENT

Functional Anatomy

The anterior chamber is bounded anteriorly by the cornea, laterally by the trabecular meshwork, and posteriorly by the iris (Fig. 29.11). Aqueous humor, formed by the pars plicata of the ciliary body, enters the posterior chamber, bathes the lens, and circulates through the pupil to gain access to the anterior chamber. The posterior chamber lies behind the iris and in front of the lens.

The lens is a closed epithelial system; the basement membrane of the lens epithelium (known as the lens capsule) totally envelops the lens. Thus, the lens epithelium does not exfoliate like the epidermis or a mucosal epithelium. Instead, the lens epithelium and its derivative fibers accumulate within the confines of the lens capsule, thus "infoliating." With aging, therefore, the size of the lens increases. Neoplasms of the lens have not been described.

Cataract

The term *cataract* describes lenticular opacities that may be congenital or acquired. Systemic diseases (e.g., galactosemia, diabetes mellitus, Wilson disease, and atopic dermatitis), drugs (especially corticosteroids), radiation, trauma, and many intraocular disorders are associated with cataract. Age-related cataract typically results from opacification of the lens nucleus *(nuclear sclerosis)*. The accumulation of urochrome pigment may render the lens nucleus brown, thus distorting the individual's perception of blue color (the predominance of yellow hues in Rembrandt's paintings later in life might have been a consequence of nuclear sclerotic cataracts). Other physical changes in the lens may generate opacities. For example, the lens cortex may liquefy. Migration

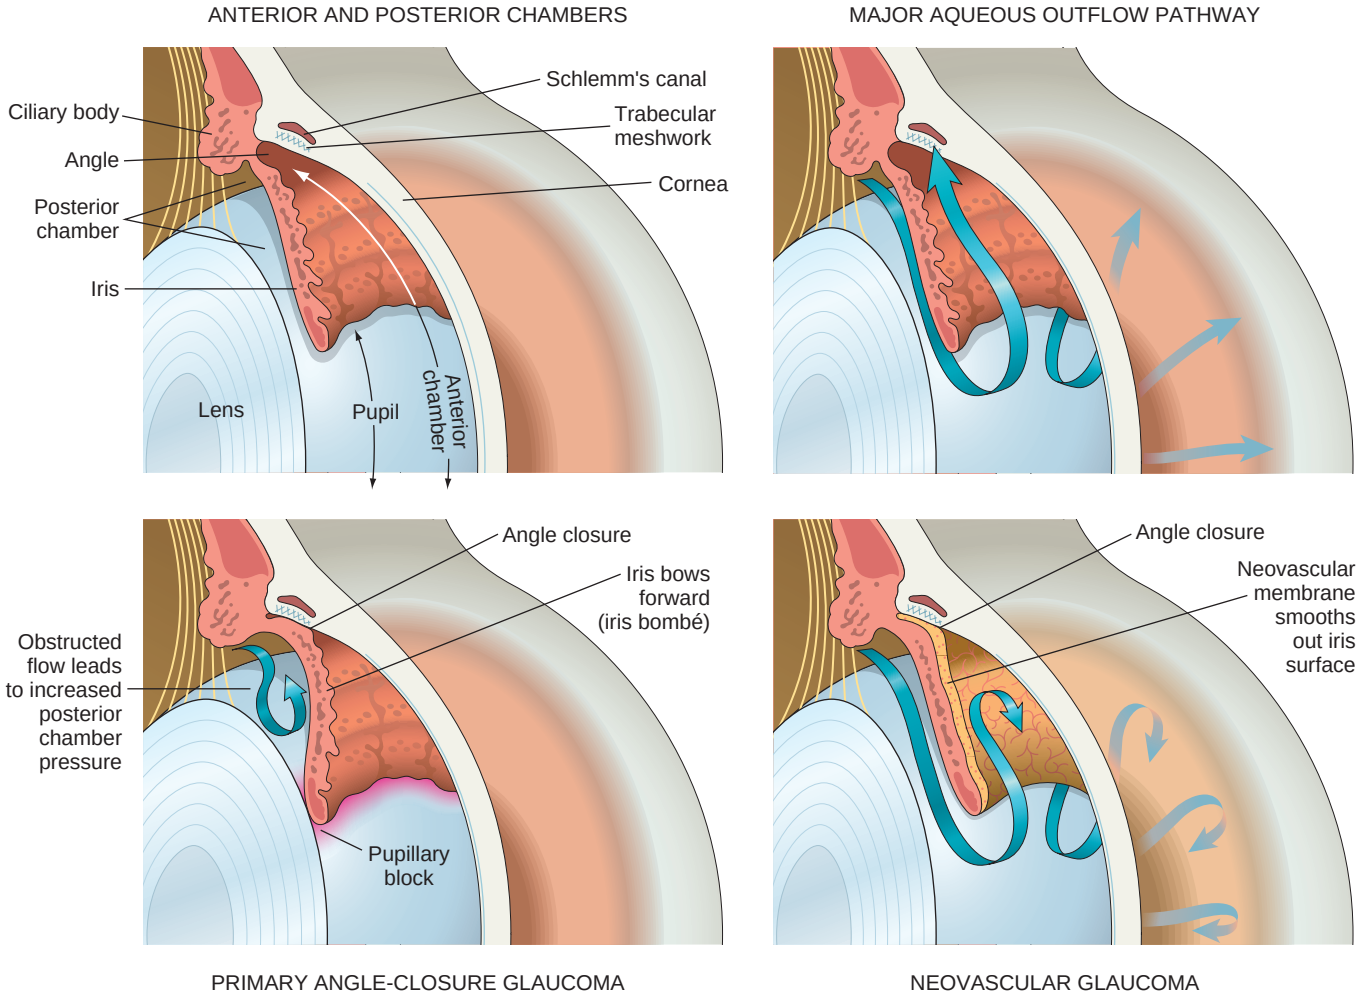

Figure 29.11 *Upper left,* The normal eye. Note that the surface of the iris is highly textured with crypts and folds. *Upper right,* The normal flow of aqueous humor. Aqueous humor, produced in the posterior chamber, flows through the pupil into the anterior chamber. The major pathway for the egress of aqueous humor is through the trabecular meshwork, into the Schlemm canal. Minor outflow pathways (uveoscleral and iris, not depicted) contribute to a limited extent to aqueous outflow. *Lower left,* Primary angle-closure glaucoma. In anatomically predisposed eyes, transient apposition of the iris at the pupillary margin to the lens blocks the passage of aqueous humor from the posterior chamber to the anterior chamber. Pressure builds in the posterior chamber, bowing the iris forward (iris bombé) and occluding the trabecular meshwork. *Lower right,* A neovascular membrane has grown over the surface of the iris, smoothing the iris folds and crypts. Myofibroblasts within the neovascular membrane cause the membrane to contract and to become apposed to the trabecular meshwork (peripheral anterior synechiae). Outflow of aqueous humor is blocked, and the intraocular pressure becomes elevated.

of the lens epithelium posterior to the lens equator may result in *posterior subcapsular cataract* secondary to enlargement of abnormally positioned lens epithelium. The technique that is most commonly used to remove opacified lenses extracts the lens contents, leaving the lens capsule intact. A prosthetic intraocular lens is typically inserted into the eye.

Anterior Segment and Glaucoma

The term *glaucoma* refers to a collection of diseases characterized by distinctive changes in the visual field and in the cup of the optic nerve. Most of the glaucomas are associated with elevated intraocular pressure, although some individuals with normal intraocular pressure may develop characteristic optic nerve and visual field changes (*normal* or *low-tension glaucoma*). The relationship between intraocular pressure and optic nerve damage is discussed later under Optic Nerve.

To understand the pathophysiology of glaucoma it is useful to consider the formation and drainage of aqueous humor. As Fig. 29.11 illustrates, aqueous humor is produced in the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber. Although there are multiple pathways for the egress of fluid from the anterior chamber, most of the aqueous humor drains through the trabecular meshwork, situated in the angle formed by the intersection between the corneal periphery and the anterior surface of the iris. With this background, glaucoma can be classified into two major categories.

- In *open-angle glaucoma* the aqueous humor has complete physical access to the trabecular meshwork, and the elevation in intraocular pressure results from an increased resistance to aqueous outflow in the open angle.
- In *angle-closure glaucoma* the peripheral zone of the iris adheres to the trabecular meshwork and physically impedes the egress of aqueous humor from the eye.

Both open-angle and angle-closure glaucoma can be subclassified into primary and secondary types. In *primary open-angle glaucoma,* the most common form of glaucoma, the angle is open, and few changes are apparent structurally.

There are multiple causes of *secondary open-angle glaucoma*. Pseudoexfoliation glaucoma, perhaps the most common form of secondary open-angle glaucoma, is associated with the deposition of fibrillar material of varying composition throughout the anterior segment. In addition to deposition in the anterior chamber, fibrillar material is deposited around blood vessels in connective tissue and in many visceral organs such as liver, kidney, and gallbladder.

Particulate material such as high-molecular-weight lens proteins produced by phacolysis, senescent red cells after trauma *(ghost cell glaucoma),* iris epithelial pigment granules *(pigmentary glaucoma),* and necrotic tumors *(melanomalytic glaucoma)* can clog the trabecular meshwork in the presence of an open angle. Elevations in the pressure on the surface of the eye (episcleral venous pressure) in the presence of an open angle also contribute to secondary open-angle glaucoma. This type of glaucoma is associated with surface ocular vascular malformations seen in *Sturge-Weber syndrome* or is a consequence of arterialization of the episcleral veins following a spontaneous or traumatic carotid-cavernous fistula.

Primary angle-closure glaucoma typically develops in eyes with shallow anterior chambers, often found in individuals with hyperopia. Transient apposition of the pupillary margin of the iris to the anterior surface of the lens may result in obstruction to the flow of aqueous humor through the pupillary aperture *(pupillary block)*. Continued production of aqueous humor by the ciliary body thus elevates pressure in the posterior chamber and may bow the iris periphery forward *(iris bombé),* apposing it to the trabecular meshwork. These anatomic changes provoke a marked elevation in intraocular pressure (see Fig. 29.11). Since the crystalline lens is avascular and the lens epithelium receives its nutrition from the aqueous humor, unremitting elevation in intraocular pressure in primary angle-closure glaucoma can damage the lens epithelium. This leads to minute anterior subcapsular opacities that are visible by slit-lamp examination. Although the affected individual might have a normal complement of healthy corneal endothelial cells, sustained elevated intraocular pressure can produce corneal edema and bullous keratopathy.

There are many causes of *secondary angle-closure glaucoma*. Contraction of various types of pathologic membranes that form over the surface of the iris can draw the iris over the trabecular meshwork, occluding aqueous outflow. For example, chronic retinal ischemia is associated with the upregulation of VEGF and other proangiogenic factors. The appearance of VEGF in the aqueous humor is thought to induce the development of thin, clinically transparent fibrovascular membranes over the surface of the iris. Contraction of myofibroblastic elements in these membranes leads to occlusion of the trabecular meshwork by the iris: *neovascular glaucoma* (see Fig. 29.11). Necrotic tumors, especially retinoblastomas, can also induce iris neovascularization and glaucoma. Secondary angle-closure glaucoma may be caused by other mechanisms as well; for example, tumors in the ciliary body can mechanically compress the iris onto the trabecular meshwork, closing off the major pathway of aqueous outflow.

Endophthalmitis and Panophthalmitis

In intraocular inflammation, vessels in the ciliary body and iris become leaky, allowing cells and exudate to accumulate in the anterior chamber. These changes can be visualized with a slit lamp; at times the inflammatory cells may adhere to the corneal endothelium, forming clinically visible *keratic precipitates*. The size and shape of these precipitates can provide clues to the underlying cause of the inflammation. For example, aggregates of macrophages on the endothelium in sarcoid produce characteristic "mutton-fat" keratic precipitates.

Just as pleural exudate in acute bronchopneumonia can lead to adhesions between the visceral and parietal pleura, the presence of exudate in the anterior chamber can lead to the formation of adhesions between the iris and the trabecular meshwork or cornea *(anterior synechiae)* or between the iris and the anterior surface of the lens *(posterior synechiae)*. Anterior synechiae can lead to elevation in intraocular pressure, which may lead to optic nerve damage. Prolonged contact between the iris and the anterior surface of the lens can deprive lens epithelium of contact with aqueous humor and can induce fibrous metaplasia of the lens epithelium:

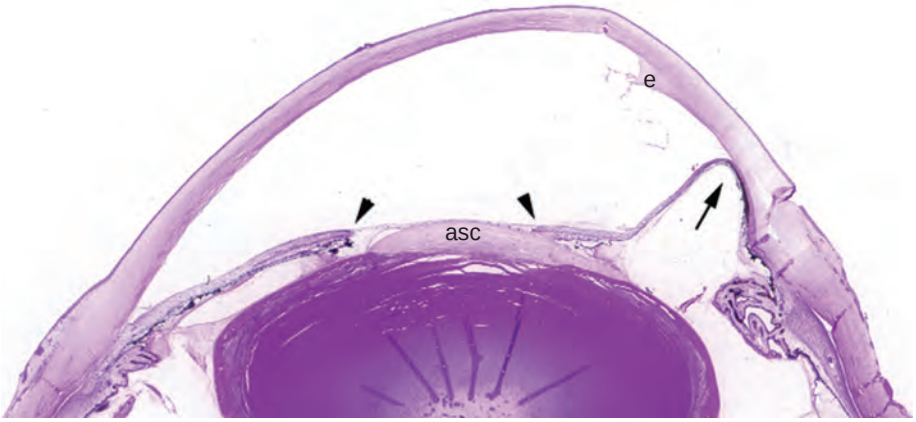

Figure 29.12 Sequelae of anterior segment inflammation. This eye was removed for complications of chronic corneal inflammation (not visible at this magnification). The exudate *(e)* present in the anterior chamber would have been visualized with a slit lamp as an optical "flare." The iris is adherent focally to the cornea, obstructing the trabecular meshwork (anterior synechia, *arrow*), and to the lens (posterior synechiae, *arrowheads*). An anterior subcapsular cataract *(asc)* has formed. The radial folds in the lens are artifacts.

anterior subcapsular cataract (Fig. 29.12). The pharmacologic induction of pupillary dilation and cycloplegia in individuals with intraocular inflammation is intended in part to prevent the formation of synechiae and their sequelae.

Although inflammation confined to the anterior segment is technically intraocular inflammation, the term *endophthalmitis* is reserved for inflammation within the vitreous humor. The retina lines the vitreous cavity, and suppurative inflammation in the vitreous humor is poorly tolerated by the retina; a few hours may be sufficient to cause irreversible retinal injury. Endophthalmitis is classified as *exogenous* (originating in the environment and gaining access to the interior of the eye through a wound) or *endogenous* (delivered to the eye hematogenously). The term *panophthalmitis* is applied to inflammation within the eye that involves the retina, choroid, and sclera and extends into the orbit (Fig. 29.13).

KEY CONCEPTS

- The term cataract describes opacities of the lens that may be congenital or acquired.
- The term glaucoma describes a group of conditions characterized by distinctive changes in the visual field and the size and shape of the optic nerve cup and usually by an elevation in intraocular pressure.
- Glaucoma may develop in the context of either an open or closed angle. Open-angle and angle-closure glaucomas are further subclassified into primary and secondary types.
- Endophthalmitis is a term used to describe inflammation of the interior of the eye involving the vitreous humor, and panophthalmitis is the term used to describe inflammation of the interior of the eye that also extends into the uvea and sclera.
- Endophthalmitis may originate from infection within the body (endogenous endophthalmitis complicating generalized sepsis) or as a complication of corneal infection or a wound, an accidental injury, or a surgical procedure (exogenous endophthalmitis).
- In panophthalmitis, inflammation extends from the interior of the eye into the ocular coats: the retina, choroid, and the sclera.

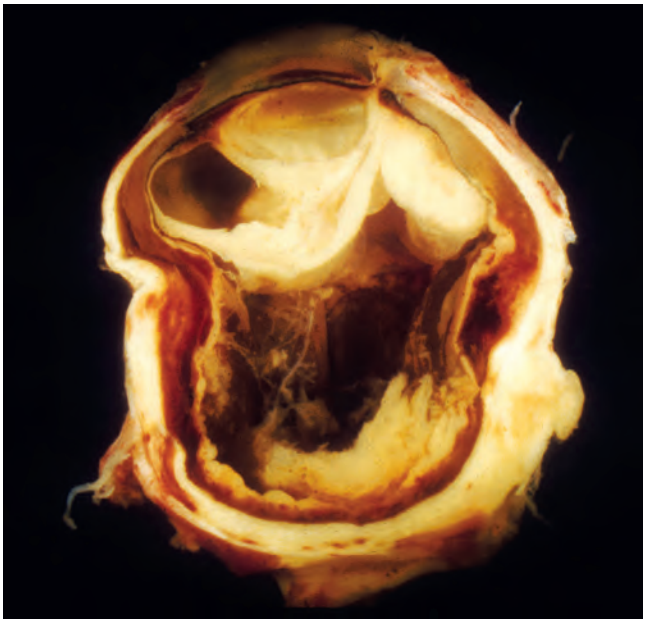

Figure 29.13 Exogenous panophthalmitis. This eye was removed after a foreign body injury. Note the suppurative inflammation behind the lens that is drawn up to the right of the lens to the cornea, the site of the wound. The central portion of the vitreous humor was extracted surgically (by vitrectomy). Note the adhesions to the surface of the eye at the 8 o'clock position, indicating that the intraocular inflammation has spread through the sclera into the orbit: panophthalmitis. (From Folberg R: The eye. In Spencer WH, editor: *Ophthalmic Pathology—An Atlas and Textbook,* ed 4, Philadelphia, 1985, WB Saunders.)

UVEA

Together with the iris, the choroid and ciliary body constitute the uvea. The choroid is among the most richly vascularized sites in the body.

Uveitis

The term *uveitis* can be applied to any type of inflammation in one or more of the tissues that compose the uvea. Thus, the iritis that develops after blunt trauma to the eye or that accompanies a corneal ulcer is technically a form of uveitis. However, in clinical practice the term *uveitis* is restricted to a diverse group of chronic diseases that may be either components of a systemic process or localized to the eye. Uveal inflammation may be manifest principally in the anterior segment (e.g., in *juvenile rheumatoid arthritis*) or may affect both the anterior and the posterior segments. The complications of chronic anterior segment inflammation were discussed earlier; the remainder of this discussion therefore focuses on the effects of uveal inflammation on the posterior segment of the eye. As will be described briefly, uveitis is frequently accompanied by retinal pathology. Uveitis may be caused by infectious agents (e.g., *Pneumocystis carinii*), may be idiopathic (e.g., sarcoidosis), or may be autoimmune in origin (sympathetic ophthalmia). Examples are described later.

Granulomatous uveitis is a common complication of sarcoidosis (Chapter 15). In the anterior segment it gives rise to an exudate that evolves into "mutton-fat" keratic precipitates described earlier. In the posterior segment, sarcoid may involve the choroid and retina. Thus, granulomas may be seen in the choroid. Retinal pathology is characterized by perivascular inflammation; this is responsible for the well-known ophthalmoscopic sign of "candle wax drippings." Conjunctival biopsy can be used to detect granulomatous inflammation and confirm the diagnosis of ocular sarcoid.

Numerous infectious processes can affect the choroid or the retina. Inflammation in one compartment is typically associated with inflammation in the other. Retinal *toxoplasmosis* is usually accompanied by uveitis and even scleritis. Individuals with AIDS may develop cytomegalovirus retinitis and uveal infection such as *Pneumocystis* or mycobacterial choroiditis.

Sympathetic ophthalmia is an example of noninfectious uveitis limited to the eye. This condition is characterized by bilateral granulomatous inflammation typically affecting all components of the uvea: a panuveitis. Sympathetic ophthalmia, which blinded young Louis Braille, may complicate a penetrating injury of the eye. In the injured eye, retinal antigens sequestered from the immune system may gain access to lymphatics in the conjunctiva and thus set up a delayed hypersensitivity reaction that affects not only the injured eye but also the contralateral, noninjured eye. The condition may develop from 2 weeks to many years after injury. Enucleation of a blind eye (which can be the sympathizing eye rather than the directly injured eye) may yield diagnostic findings. It is characterized by diffuse granulomatous inflammation of the uvea (choroid, ciliary body, and iris). Plasma cells are typically absent, but eosinophils may be identified in the infiltrate (Fig. 29.14). Sympathetic ophthalmia is treated by the administration of systemic immunosuppressive agents.

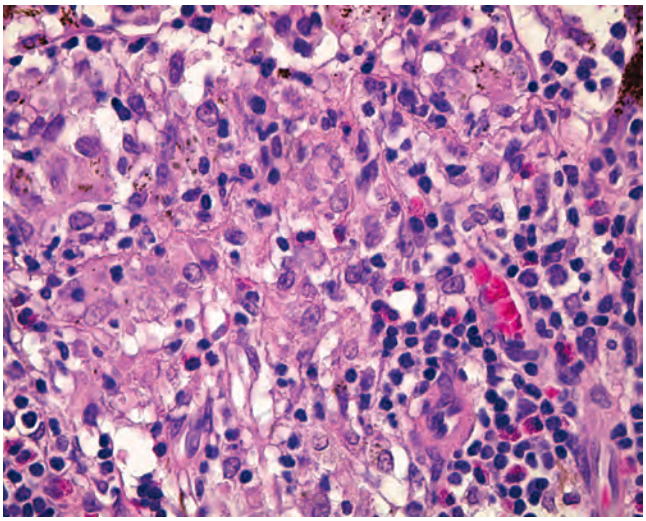

Figure 29.14 Sympathetic ophthalmia. The granulomatous inflammation depicted here was identified diffusely throughout the uvea. The uveal granulomas may contain melanin pigment and may be accompanied by eosinophils.

Neoplasms

The most common intraocular malignancy of adults is metastasis to the uvea, typically to the choroid. The occurrence of metastases to the eye is associated with an extremely short survival, and treatment of ocular metastases, usually by radiotherapy, is palliative.

Uveal Nevi and Melanomas

Uveal melanoma is the most common primary intraocular malignancy of adults. In the United States, these tumors account for approximately 5% of melanomas and have an age-adjusted incidence of 5.1 per 1 million per year. Uveal nevi, especially choroidal nevi, are rather common, affecting an estimated 5% of the Caucasian population.

Epidemiology and Pathogenesis

Unlike cutaneous melanoma, the occurrence of uveal melanoma has remained stable over many years, and there is no clear link between exposure to ultraviolet light and risk. In line with this observation, sequencing of tumor genomes has revealed that the molecular pathogenesis of uveal melanoma is distinct from that of cutaneous melanoma. Unlike cutaneous and conjunctival melanomas, *BRAF* mutations do not appear to play a role in the pathogenesis of uveal melanomas. The most important oncogenes in uveal melanoma are *GNAQ* and *GNA11*, both of which encode G protein–coupled receptors. Roughly 85% of uveal melanomas harbor a gain-of-function mutation in one of these genes that activates pathways that promote proliferation, such as the mitogen-activated protein kinase (MAPK) pathway (Chapter 7). Notably, uveal nevi are also associated with *GNAQ* and *GNA11* mutations, yet rarely transform to melanoma, indicating that other genetic events are required for the development of uveal melanoma. One such event is loss of chromosome 3, which appears to be selected for because it leads to deletion of *BAP1*, a tumor suppressor gene on chromosome 3 that encodes a deubiquitinating enzyme. BAP1 is a component of protein complexes that place repressive marks on chromatin that lead to gene silencing; thus, uveal melanoma has joined the increasing list of cancers in which epigenetic alterations appear to have a central role in tumor pathogenesis (Chapter

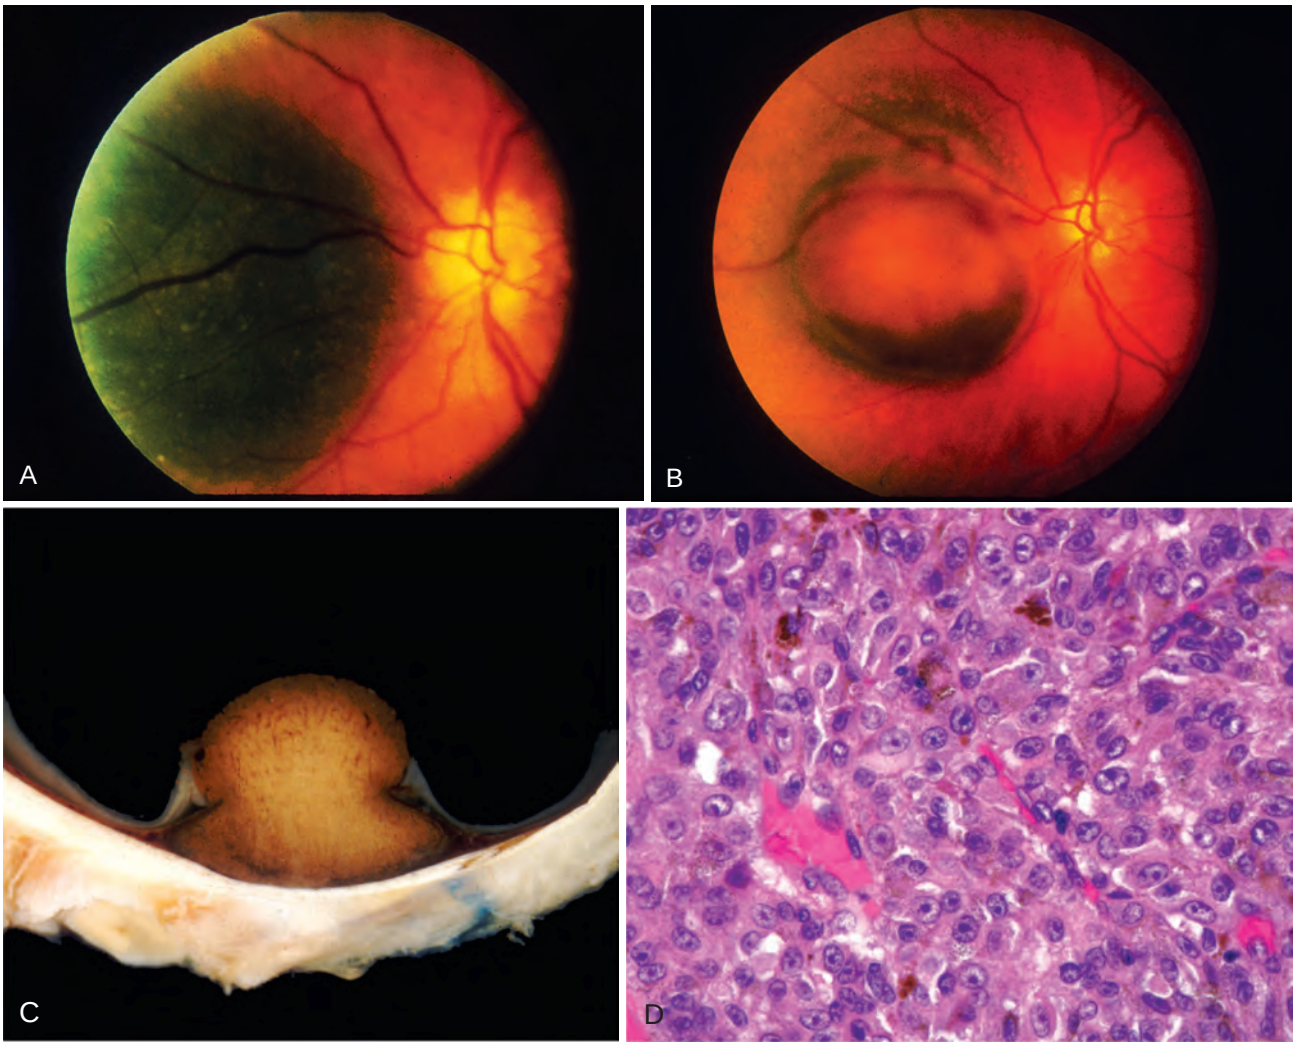

Figure 29.15 Uveal melanoma. (A) Fundus photograph from an individual with a relatively flat pigmented lesion of the choroid near the optic disc. (B) Fundus photograph of the same individual several years later; the tumor has grown and has ruptured through the Bruch membrane. (C) Gross photograph of a choroidal melanoma that has ruptured the Bruch membrane. The overlying retina is detached. (D) Epithelioid melanoma cells associated with an adverse outcome. (A–C, From Folberg R: *Pathology of the Eye—An Interactive CD-ROM Program,* Philadelphia, 1996, Mosby.)

7). Germline mutations in *BAP1* may predispose patients to the development of uveal melanomas, renal cell carcinomas, and malignant mesothelioma among several others.

MORPHOLOGY

Histologically, uveal melanomas may contain two types of cells, spindle and epithelioid, in various proportions (Fig. 29.15). **Spindle cells** are fusiform in shape, whereas **epithelioid cells** are spherical and have greater cytologic atypicality. Like cutaneous melanomas, large numbers of tumor-infiltrating lymphocytes may be seen in some cases. An unusual feature that is commonly seen is the presence of looping slit-like spaces lined by laminin that surround packets of tumor cells. These spaces (which are not blood vessels) connect to blood vessels and serve as extravascular conduits for the transport of plasma and possibly blood. In vitro studies and examination of human tissues suggest that these unusual growth patterns are promoted by tumor cells through a process termed **vasculogenic mimicry.**

Uveal melanomas, with very rare exception, spread exclusively by a hematogenous route (the only exception being the rare case of melanoma that spreads through the sclera and invades the conjunctiva, thereby gaining access to conjunctival lymphatics). Most uveal melanomas spread first to the liver, an excellent example of a tumor-specific tropism for a particular metastatic site.

Clinical Features

Most uveal melanomas are incidental findings or present with visual symptoms, which may be related to retinal detachment or glaucoma. The prognosis of choroidal and ciliary body melanomas is related to (1) size (in contrast to cutaneous melanoma, the lateral extent of the tumor rather than tumor depth is the size dimension related to adverse outcome); (2) cell type (tumors containing epithelioid cells have a worse prognosis than do those containing exclusively spindle cells); (3) and proliferative index. Cytogenetic profiles, especially monosomy 3, and gene expression profiling may

be helpful in stratifying patients into categories with differing risks of developing metastatic disease.

There seems to be no difference in survival between tumors treated by removal of the eye (enucleation) and those receiving eye-sparing radiotherapy, which is the treatment of choice. Melanomas situated exclusively in the iris tend to follow a relatively indolent course, whereas melanomas of the ciliary body and choroid are more aggressive.

Although the 5-year survival rate is approximately 80%, the cumulative melanoma mortality rate is 40% at 10 years, increasing 1% per year thereafter. Metastases may appear "out of the blue" many years after treatment, making uveal melanoma a prime candidate for the investigation of the phenomenon of tumor dormancy. Targeted therapies such as MAPK inhibitors have shown some encouraging responses in clinical trials, but currently there is no effective treatment for metastatic uveal melanoma.

KEY CONCEPTS

- Uveitis is restricted to a diverse group of chronic diseases that may be either components of a systemic process or localized to the eye.
- Sarcoid is an example of a systemic condition that may produce granulomatous uveitis, and sympathetic ophthalmia may produce bilateral granulomatous inflammation as a possible consequence of penetrating injury to one eye.
- The most common intraocular tumor of adults is metastasis to the eye.
- The most common primary intraocular tumor of adults is uveal melanoma.
- Uveal melanoma disseminates hematogenously, and the first evidence of metastasis is typically detected in the liver.
- Uveal melanoma shows marked differences in epidemiologic risk factors and driver mutations compared to cutaneous melanoma.

RETINA AND VITREOUS

Functional Anatomy

The neurosensory retina, like the optic nerve, is an embryologic derivative of the diencephalon. The retina therefore responds to injury by means of gliosis. As in the brain, there are no lymphatics. The architecture of the retina accounts for the ophthalmoscopic appearance of a variety of ocular disorders. Hemorrhages in the nerve fiber layer of the retina are oriented horizontally and appear as streaks or "flames"; the external retinal layers are oriented perpendicular to the retinal surface, and hemorrhages in these outer layers appear as dots (the tips of cylinders). Exudates tend to accumulate in the outer plexiform layer of the retina, especially in the macula (Fig. 29.16).

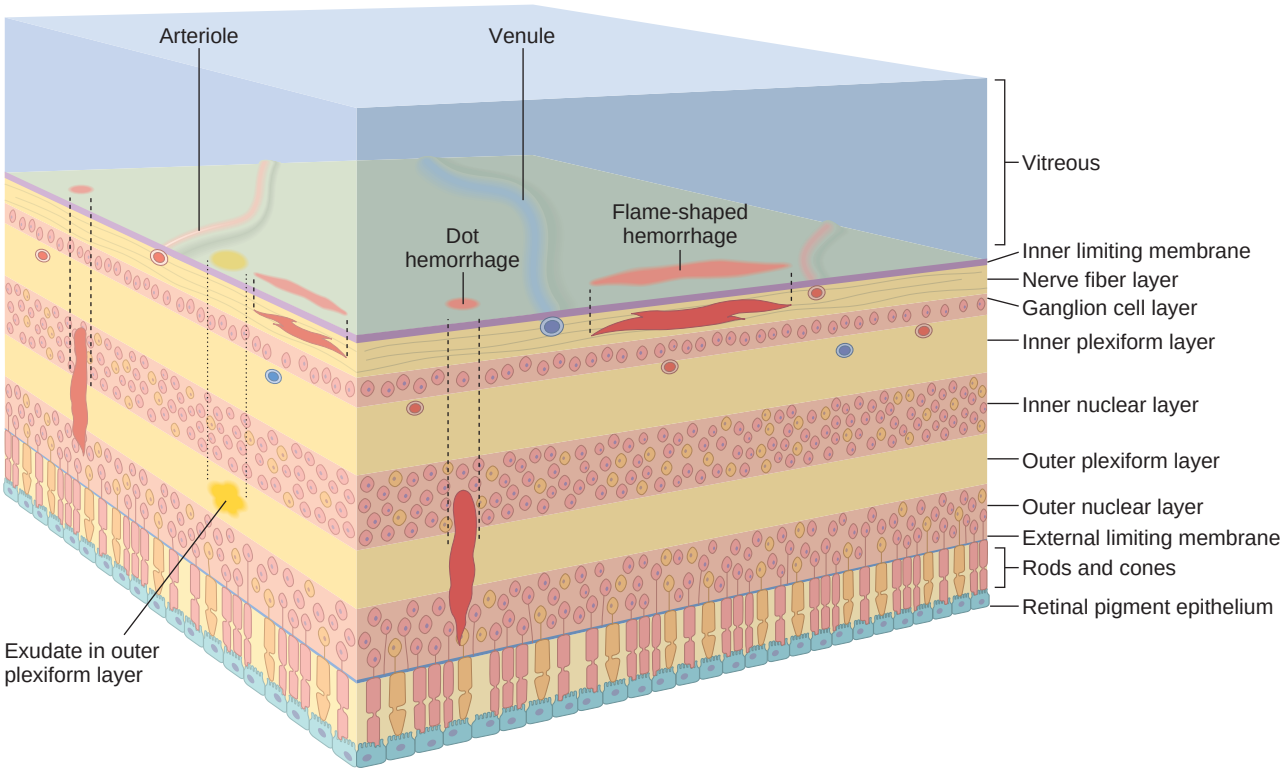

Figure 29.16 Clinicopathologic correlations of retinal hemorrhages and exudates. The location of the hemorrhage within the retina determines its appearance by ophthalmoscopy. The retinal nerve fiber layer is oriented parallel to the internal limiting membrane, and hemorrhages of this layer appear to be flame-shaped ophthalmoscopically. The deeper retinal layers are oriented perpendicular to the internal limiting membrane, and hemorrhages in this location appear as cross-sections of a cylinder, or "dot" hemorrhages. Exudates that originate from leaky retinal vessels accumulate in the outer plexiform layer.

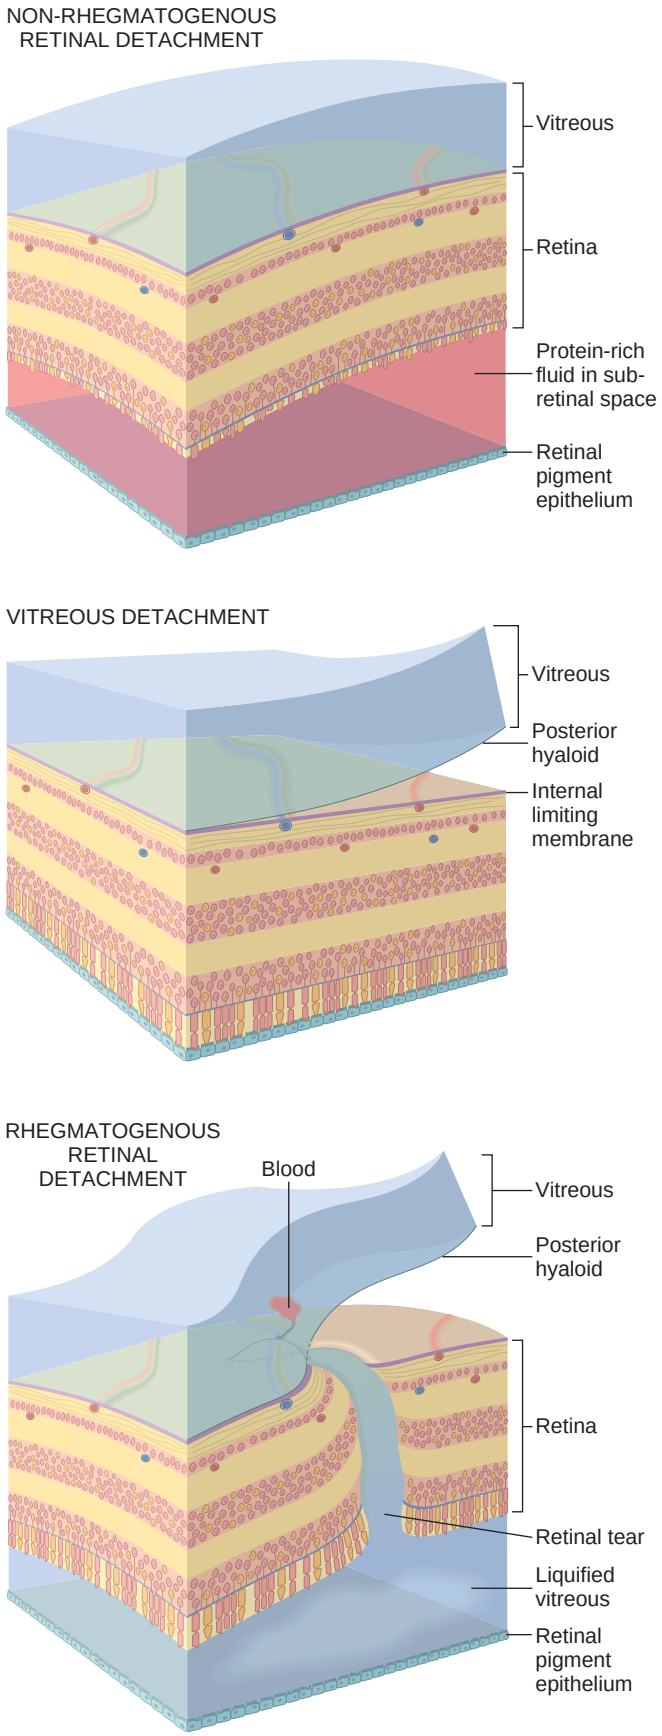

Figure 29.17 Retinal detachment is defined as the separation of the neurosensory retina from the retinal pigment epithelium (RPE). Retinal detachments are classified broadly into nonrhegmatogenous (without a retinal break) and rhegmatogenous (with a retinal break) types. *Top,* In nonrhegmatogenous retinal detachment the subretinal space is filled with protein-rich exudate. Note that the outer segments of the photoreceptors are missing (see Fig. 29.16 for orientation of layers). This indicates a chronic retinal detachment, a finding that can be seen in both nonrhegmatogenous and rhegmatogenous detachments. *Middle,* Posterior vitreous detachment involves the separation of the posterior hyaloid from the internal limiting membrane of the retina and is a normal occurrence in the aging eye. *Bottom,* If during a posterior vitreous detachment the posterior hyaloid does not separate cleanly from the internal limiting membrane of the retina, the vitreous humor will exert traction on the retina, which will be torn at this point. Liquefied vitreous humor seeps through the retinal defect, and the retina is separated from the RPE. The photoreceptor outer segments are intact, illustrating an acute detachment.

The retinal pigment epithelium (RPE), like the retina, is derived embryologically from the primary optic vesicle, an outpouching of the brain. Separation of the neurosensory retina from the RPE defines a *retinal detachment*. The RPE has an important role in the maintenance of the outer segments of the photoreceptors. Disturbances in the RPE–photoreceptor interface are implicated in hereditary retinal degenerations such as *retinitis pigmentosa*.

The adult vitreous humor is avascular. Incomplete regression of fetal vasculature running through the vitreous humor can produce significant pathology as a retrolental mass *(persistent fetal vasculature)*. The vitreous humor can be opacified by hemorrhage from trauma or retinal neovascularization. With age the vitreous humor may liquefy and collapse, creating the visual sensation of "floaters." Also, with aging, the posterior face of the vitreous humor—the posterior hyaloid—may separate from the neurosensory retina *(posterior vitreous detachment)*. The relationship between the posterior hyaloid and the neurosensory retina has a key role in the pathogenesis of retinal neovascularization and in some forms of retinal detachment.

Retinal Detachment

Retinal detachment (separation of the neurosensory retina from the RPE) is broadly classified by etiology based on the presence or absence of a break in the retina. *Rhegmatogenous retinal detachment* is associated with a full-thickness retinal defect. Retinal tears may develop after the vitreous collapses structurally, and the posterior hyaloid exerts traction on points of abnormally strong adhesion to the retinal internal limiting membrane. Liquefied vitreous humor then seeps through the tear and gains access to the potential space between the neurosensory retina and the RPE (Fig. 29.17). Reattachment of the retina to the RPE generally requires relief of vitreous traction through indenting of the sclera by surgical procedures. This can be accomplished by the application of strips of silicon to the surface of the eye (scleral buckling) and possibly by removal of vitreous material (vitrectomy). Rhegmatogenous retinal detachment

may be complicated by *proliferative vitreoretinopathy*, the formation of epiretinal or subretinal membranes by retinal glial cells or RPE cells.

Nonrhegmatogenous retinal detachment (retinal detachment without retinal break) may complicate retinal vascular disorders associated with significant exudation and any condition that damages the RPE and permits fluid to leak from the choroidal circulation under the retina. Retinal detachments associated with choroidal tumors and malignant hypertension are examples of nonrhegmatogenous retinal detachment.

Retinal Vascular Disease

Hypertension

Normally, the thin walls of retinal arterioles permit a direct visualization of the circulating blood by ophthalmoscopy. In retinal arteriolosclerosis the thickened arteriolar wall changes the ophthalmic perception of circulating blood: vessels may appear narrowed, and the color of the blood column may change from bright red to copper and to silver depending on the degree of vascular wall thickness (Fig. 29.18A). Retinal arterioles and veins share a common adventitial sheath. Therefore, in pronounced retinal arteriolosclerosis the arteriole may compress the vein at points where both vessels cross (Fig. 29.18B). Venous stasis distal to arteriolar-venous crossing may precipitate occlusions of the retinal vein branches.

In malignant hypertension, vessels in the retina and choroid may be damaged. Damage to choroidal vessels may produce focal choroidal infarcts, seen clinically as *Elschnig spots*. Damage to the choriocapillaris, the internal layer of the choroidal vasculature, may, in turn, damage the overlying RPE and permit the exudate to accumulate in the potential space between the neurosensory retina and the RPE, thereby producing a retinal detachment. Exudate from damaged retinal arterioles typically accumulates in the outer plexiform layer of the retina (see Fig. 29.18A). The ophthalmoscopic finding of a macular star—a spoke-like arrangement of exudate in the macula in malignant hypertension—results from exudate accumulating in the outer plexiform layer of the macula that is oriented obliquely instead of perpendicular to the retinal surface.

Occlusion of retinal arterioles may produce infarcts of the nerve fiber layer of the retina (axons of the retinal ganglion cell layer populate the nerve fiber layer). Axoplasmic transport in the nerve fiber layer is interrupted at the point of axonal damage, and accumulation of mitochondria at the swollen ends of damaged axons creates the histologic illusion of cells *(cytoid bodies)*. Collections of cytoid bodies populate the nerve fiber layer infarct, seen ophthalmoscopically as "cotton-wool spots" (Fig. 29.19). Although nerve fiber layer infarcts are described here in the context of hypertension, they may be detected in a variety of retinal occlusive vasculopathies. For example, retinal nerve fiber layer infarcts may develop in individuals with AIDS due to a retinal vasculopathy that is similar to the brain vasculopathy that may develop in this condition.

Diabetes Mellitus

The eye is profoundly affected by diabetes mellitus. The effects of hyperglycemia on the lens and iris have already

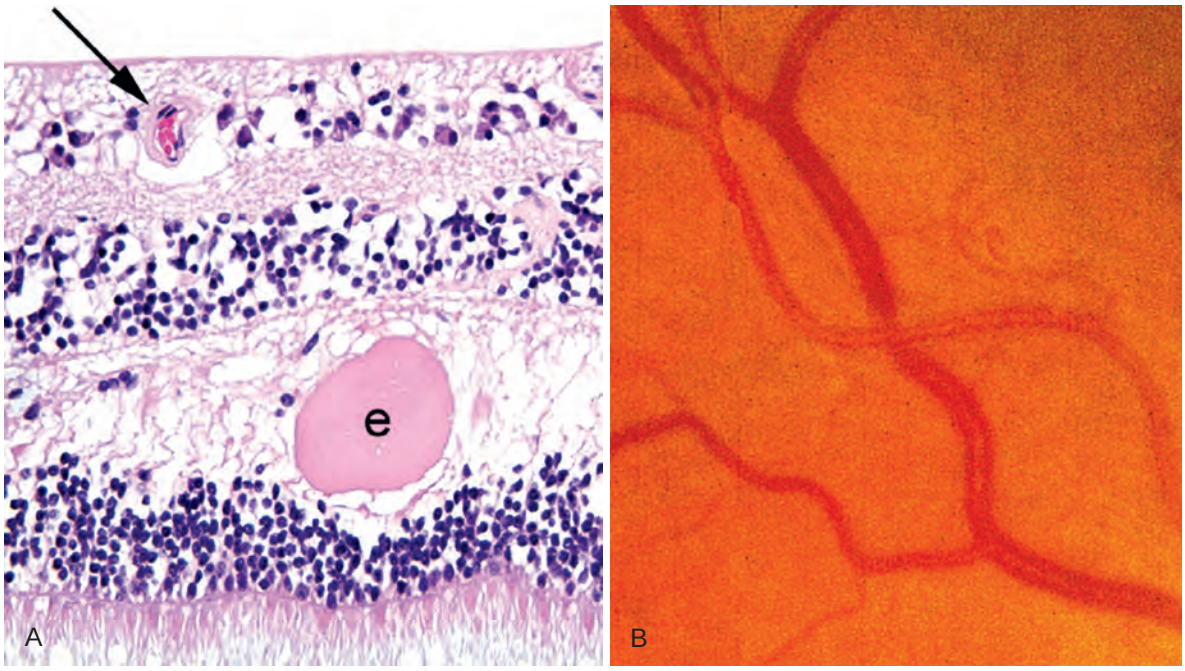

Figure 29.18 The retina in hypertension. (A) The wall of the retinal arteriole *(arrow)* is thick. Note the exudate *(e)* in the retinal outer plexiform layer. (B) The fundus in hypertension. The diameter of the arterioles is reduced, and the color of the blood column appears to be less saturated (copper wire–like). If the wall of the vessel were thicker still, the degree of red color would diminish such that the vessels might appear clinically to have a "silver wire" appearance. In this fundus photograph, note that the vein is compressed where the sclerotic arteriole crosses over it. (B, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.)

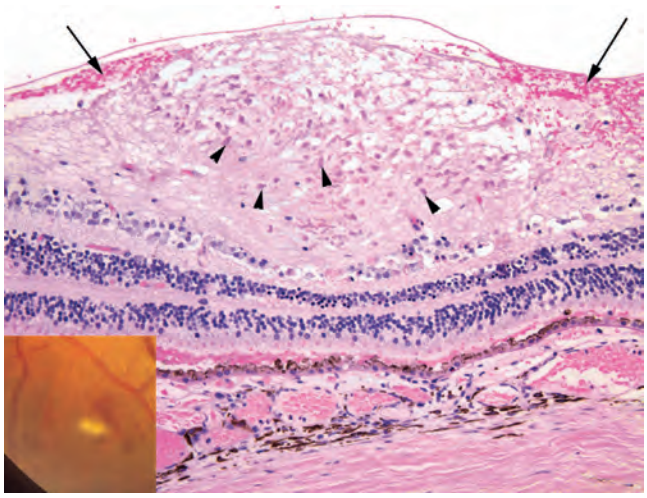

Figure 29.19 Nerve fiber layer infarct. A "cotton-wool spot" is illustrated in the inset, adjacent to a flame-shaped (nerve fiber layer) hemorrhage. The histology of a cotton-wool spot—an infarct of the nerve fiber layer of the retina—is illustrated in the photomicrograph. A focal swelling of the nerve fiber layer is occupied by numerous red to pink cytoid bodies *(arrowheads)*. Hemorrhage *(arrows)* surrounding the nerve fiber layer infarct as illustrated here is a variable and inconsistent finding. (Fundus photograph, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.)

been mentioned. Thickening of the basement membrane of the epithelium of the pars plicata of the ciliary body is a reliable histologic marker of diabetes mellitus in the eye (Fig. 29.20) and is reminiscent of similar changes in the glomerular mesangium. This discussion focuses on the retinal microangiopathy associated with diabetes mellitus, a prototype for the consideration of other retinal microangiopathies.

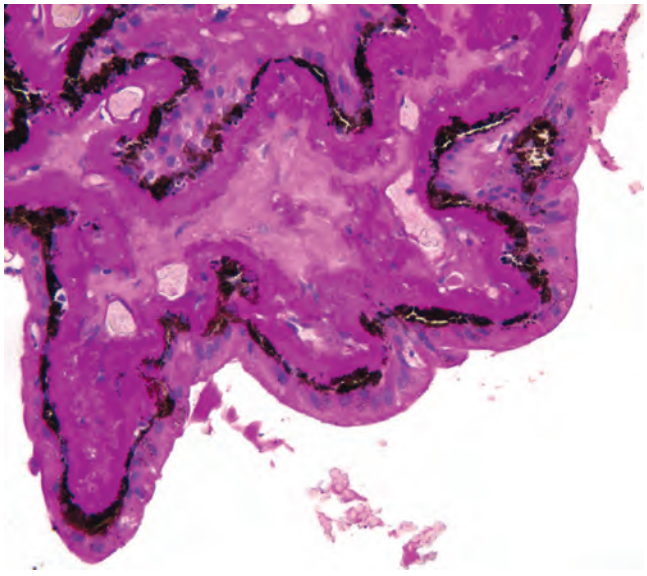

Figure 29.20 The ciliary body in chronic diabetes mellitus, periodic acid–Schiff stain. Note the massive thickening of the basement membrane of the ciliary body epithelia, reminiscent of changes in the mesangium of the renal glomerulus.

MORPHOLOGY

The retinal vasculopathy of diabetes mellitus can be classified into **nonproliferative** and **proliferative diabetic retinopathy.**

Nonproliferative diabetic retinopathy includes a spectrum of changes resulting from structural and functional abnormalities of retinal vessels (i.e., confined beneath the internal limiting membrane of the retina). As with diabetic microangiopathy in general, the **basement membrane of retinal blood vessels is thickened.** In addition, the number of pericytes relative to endothelial cells diminishes. **Microaneurysms** are an important manifestation of diabetic microangiopathy. They are typically smaller than the resolution of direct ophthalmoscopes, and findings customarily described as microaneurysms by ophthalmoscopy may in fact be retinal microhemorrhages. Structural changes in the retinal microcirculation have been associated with a physiologic breakdown in the blood-retinal barrier. Recall that VEGF was initially called vascular permeability factor. Thus, the retinal microcirculation in diabetics may be exceptionally leaky, giving rise to **macular edema,** a common cause of visual loss in these patients. The vascular changes may also produce **exudates** that accumulate in the outer plexiform layer. Although the retinal microcirculation is often hyperpermeable, it is also subject to the effects of micro-occlusion. Both vascular incompetence and vascular micro-occlusions can be visualized clinically after intravenous injection of fluorescein. Nonperfusion of the retina due to the microcirculatory change described earlier is associated with upregulation of VEGF and intraretinal angiogenesis (located beneath the internal limiting membrane of the retina).

Proliferative diabetic retinopathy is defined by the appearance of new vessels sprouting on the surface of either the optic nerve head or the surface of the retina (Fig. 29.21C). The term "retinal neovascularization" is applied only when the newly formed vessels breach the internal limiting membrane of the retina. The quantity and location of retinal neovascularization guide the ophthalmologist in the treatment of proliferative diabetic retinopathy. The web of newly formed vessels is referred to as a neovascular membrane. It is composed of angiogenic vessels with or without a substantial supportive fibrous or glial stroma (Fig. 29.21B).

If the vitreous humor has not detached and the posterior hyaloid is intact, neovascular membranes extend along the potential plane between the retinal internal limiting membrane and the posterior hyaloid. If vitreous humor later separates from the internal limiting membrane of the retina **(posterior vitreous detachment),** there may be massive hemorrhage from the disrupted neovascular membrane. In addition, scarring associated with the organization of the retinal neovascular membrane may wrinkle the retina, disrupting the orientation of retinal photoreceptors and producing visual distortion, and may exert traction on the retina, separating it from the RPE (retinal detachment). **Traction retinal detachment** may begin as a nonrhegmatogenous detachment, but severe traction may tear the retina, producing a traction rhegmatogenous detachment.

Retinal neovascularization may be accompanied by the development of a neovascular membrane on the iris surface, presumably secondary to increased levels of VEGF in the aqueous humor. Contraction of the iris neovascular membrane may lead to adhesions between the iris and trabecular meshwork (anterior synechiae), thus occluding a major pathway for aqueous outflow and thereby contributing to elevation of the intraocular pressure **(neovascular glaucoma).**

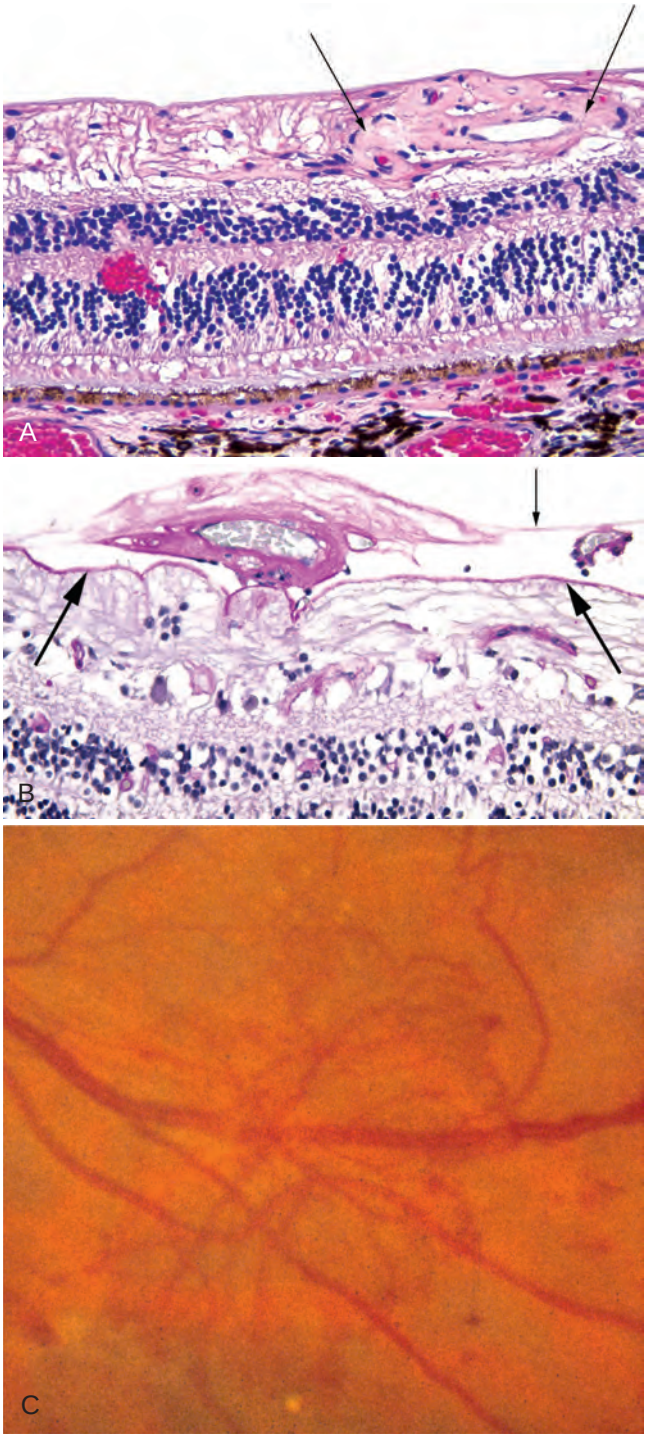

Figure 29.21 The retina in diabetes mellitus (see Fig. 29.16 for a schematic of retinal structure). (A) A tangle of abnormal vessels lies just beneath the internal limiting membrane of the retina on the right half of the photomicrograph *(between arrows)*. This is an example of intraretinal angiogenesis known as intraretinal microangiopathy (IRMA). Note the retinal hemorrhage in the outer plexiform layer in the left half. The ganglion cell layer and the nerve fiber layer—the axons of the ganglion cells—are absent. The rarefied space beneath internal limiting membrane to the left of the focus of IRMA consists largely of elements of retinal glial (Müller) cells. Absence of the ganglion cell and nerve fiber layers is a hallmark of glaucoma. The chronic diabetes mellitus in this individual was complicated by iris neovascularization and secondary angle-closure glaucoma (neovascular glaucoma). (B) In this section stained by periodic acid–Schiff, the internal limiting membrane is indicated by the *thick arrows*, and the posterior hyaloid of the vitreous is indicated by the *thin arrow*. In the potential space between these two landmarks, the vessels to the left of the *thin arrow* are invested with a fibrous-glial stroma and would appear ophthalmoscopically as a white neovascular membrane. The thin-walled vessel to the right of the *thin arrow* is not invested with connective tissue. A posterior vitreous detachment in an eye such as this might exert traction on these new vessels and precipitate a massive vitreous hemorrhage. (C) Ophthalmoscopic view of retinal neovascularization (known clinically as neovascularization "elsewhere" in contrast to neovascularization of the optic disc) creating a neovascular membrane.

Ablating nonperfused retina by laser photocoagulation or cryopexy triggers regression of both retinal and iris neovascularization, emphasizing the central role that retinal hypoxia has in these disorders. More recently, the injection of VEGF inhibitors into the vitreous has been used to treat diabetic macular edema and retinal neovascularization, a successful example of how knowledge of the molecular pathogenesis of a condition may evolve into a successful therapeutic strategy.

Retinopathy of Prematurity (Retrolental Fibroplasia)

At term, the temporal (lateral) aspect of the retinal periphery is incompletely vascularized, whereas the medial aspect is vascularized. In premature or low-birth-weight infants treated with oxygen, immature retinal vessels in the temporal retinal periphery constrict, rendering the retinal tissue distal to this zone ischemic. Retinal ischemia may result in upregulation of proangiogenic factors such as VEGF and lead to retinal angiogenesis. Contraction of the resulting peripheral retinal neovascular membrane may "drag" the temporal aspect of the retina toward the peripheral zone, displacing the macula (situated temporal to the optic nerve) laterally. Neovascular membrane contraction may create sufficient force to cause retinal detachment. The use of VEGF inhibition in this condition is under investigation.

Sickle Retinopathy, Retinal Vasculitis, and Radiation Retinopathy

Retinopathy affecting individuals with sickle hemoglobinopathies (Chapter 14) has been divided into two types that roughly parallel those used for diabetic retinopathy: nonproliferative (intraretinal angiopathic changes) and proliferative (retinal neovascularization). The final common pathway in both types is vascular occlusion. Low oxygen tension within the blood vessels in the retinal periphery results in red cell sickling and microvascular occlusions. In the nonproliferative form (which occurs in individuals with hemoglobin SS and SC genotypes), vascular occlusions are thought to contribute to preretinal, intraretinal, and subretinal hemorrhages. The resolution of these hemorrhages may give rise to several ophthalmoscopically visible changes, known as *salmon patches, iridescent spots,* and *black sunburst lesions.*

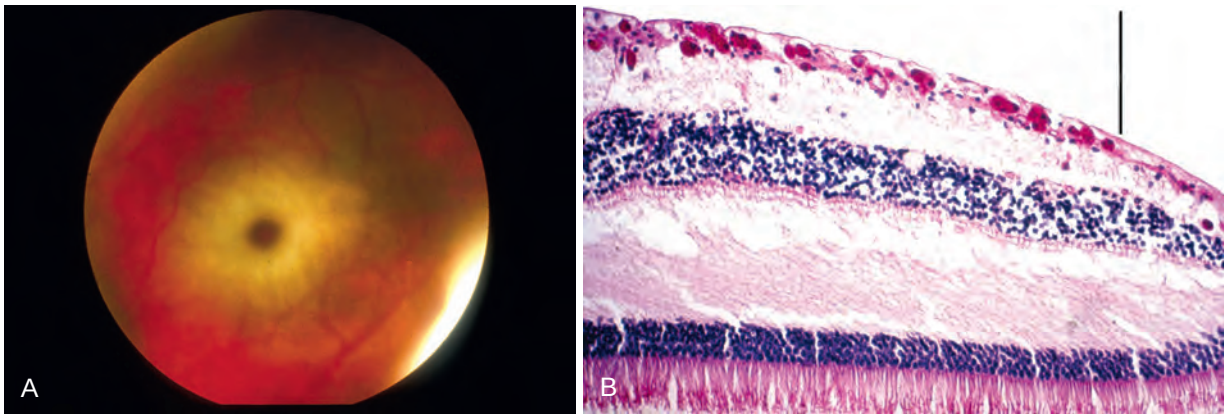

Figure 29.22 Cherry-red spot in Tay-Sachs disease. (A) Fundus photograph of the cherry-red spot in Tay-Sachs disease. (B) Photomicrograph of the macula in an individual with Tay-Sachs disease, stained with periodic acid–Schiff to highlight the accumulation of ganglioside material in the retinal ganglion cells. The presence of ganglion cells filled with gangliosides outside the fovea blocks the transmission of the normal orange-red color of the choroid, but absence of ganglion cells within the fovea (to the right of the *vertical bar*) permits the normal orange-red color to be visualized, accounting for the so-called cherry-red spot. (A, Courtesy Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.; B, from the teaching collection of the Armed Forces Institute of Pathology.)

Organization of pre-retinal hemorrhage may result in retinal traction and retinal detachment. Vascular occlusions may also contribute to angiogenesis secondary to upregulation of both VEGF and basic fibroblast growth factor. This can give rise to areas of florid neovascularization in the periphery of the retina, described clinically as "sea-fans."

Neovascularization also occurs in a variety of other clinical settings such as peripheral retinal vasculitis and in irradiation used to treat intraocular tumors. The feature common to these conditions is damage to retinal vessels, producing zones of retinal ischemia that trigger retinal angiogenesis and its complications hemorrhage and traction, which, in turn, may cause detachment.

Retinal Artery and Vein Occlusions

The central retinal artery or its branches can be occluded by disorders that affect the vessels in general. For example, the lumen of the central retinal artery can be narrowed significantly by atherosclerosis, thus predisposing to thrombosis. Emboli to the central retinal artery can originate from thrombi in the heart or from ulcerated atheromatous plaques in the carotid arteries. Fragments of atherosclerotic plaques can lodge within the retinal circulation *(Hollenhorst plaques)*. Total occlusion of a branch of retinal artery can produce a segmental infarct of the retina. With sudden cessation of blood supply, the retina (an embryologic derivative of brain tissue) swells acutely and becomes optically opaque. By ophthalmoscopy the fundus in the affected area appears white instead of red or orange because the retinal opacity blocks the view of the richly vascular choroid.

Total occlusion of the central retinal artery can produce a diffuse infarct of the retina. Following an acute occlusion, the retina appears relatively opaque by ophthalmoscopy. The fovea and foveola are physiologically thin; therefore, the normal orange-red of the choroid is not only visible but also highlighted by the surrounding opaque retina—the origin of the *cherry-red spot* of the central retinal artery occlusion. Cherry-red spots can also be seen in rare storage diseases such as *Tay-Sachs* and *Niemann-Pick* diseases because of the structural organization of the retina. The storage material accumulates in retinal ganglion cells: the ganglion cell layer of the macula surrounding the fovea is thick, but there are no ganglion cells in the center of the macula, the fovea. Thus, the fovea is relatively transparent to the underlying choroidal vasculature but is rimmed by relatively opaque retina, the result of storage material accumulating in the perifoveal macular ganglion cells (Fig. 29.22).

Retinal vein occlusion may occur with or without ischemia. In ischemic retinal vein occlusion, VEGF and other proangiogenic factors are upregulated in the retina, leading to neovascularization of the retina and surface of the optic nerve head as well as neovascularization of the iris and subsequent angle-closure glaucoma. Nonischemic retinal vein occlusion may be complicated by hemorrhages, exudates, and macular edema.

Age-Related Macular Degeneration (AMD)

AMD results from damage to the macula, which is required for central vision. It occurs in two forms, dry and wet, that are distinguished by the presence of neoangiogenesis in the wet form and its absence in the dry form. From the name of this disorder, it is clear that advancing age is a risk factor. The cumulative incidence of AMD in individuals 75 years of age and older is 8%, and with increasing longevity AMD is becoming a major health problem.

Atrophic or "dry" AMD is characterized ophthalmoscopically by diffuse or discrete deposits in the Bruch membrane *(drusen)* and geographic atrophy of the RPE. Loss of vision may be severe in these individuals. The oral consumption of zinc and of vitamins with antioxidant properties may be associated with a slowing of the progression to AMD. There is currently no effective treatment for "dry" or atrophic AMD; a regenerative approach to replacing diseased RPE cells with stem cells is under investigation.

Neovascular or "wet" AMD is characterized by *choroidal neovascularization*, defined by the presence of vessels that presumably originate from the choriocapillaris and penetrate through the Bruch membrane beneath the RPE (Fig. 29.23). This neovascular membrane may also penetrate the RPE and

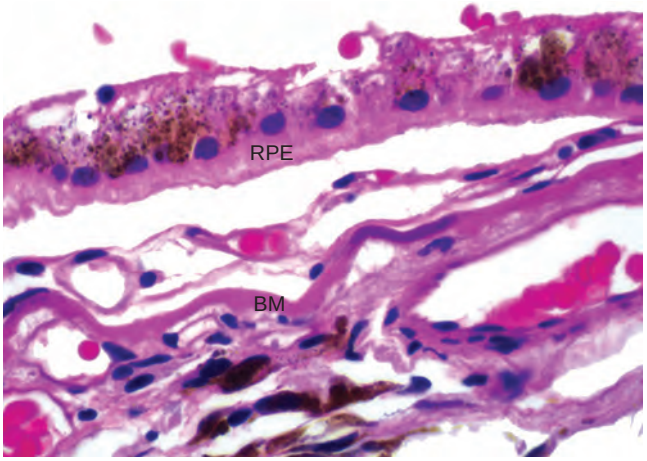

Figure 29.23 "Wet" age-related macular degeneration. A neovascular membrane is positioned between the retinal pigment epithelium *(RPE)* and Bruch membrane *(BM)*. Note the blue discoloration of BM to the right of the label, indicating focal calcification.

become situated directly beneath the neurosensory retina. The vessels in this membrane may leak, and the exuded blood may be organized by RPE cells into macular scars. Occasionally, these vessels are the source of hemorrhage, leading to the localized suffusion of blood that may be mistaken clinically for an intraocular neoplasm, or give rise to diffuse vitreous hemorrhage. Currently the mainstay of treatment for neovascular AMD is the injection of VEGF antagonists into the vitreous of the affected eye. Photodynamic therapy is also being evaluated for effectiveness.

Choroidal neovascular membranes can develop in diverse conditions that are unrelated to age, such as pathologic myopia (Fuchs spot), following disruption of the Bruch membrane (due to trauma or other causes), or an immunologic response to systemic histoplasmosis (presumed ocular histoplasmosis syndrome).

To understand the pathogenesis of AMD it is important to appreciate the existence of a structural and functional unit composed of the RPE, Bruch membrane (which contains the basement membrane of the RPE), and the innermost layer of the choroidal vasculature, the choriocapillaris. Disturbance in any component of this "unit" affects the health of the overlying photoreceptors, producing visual loss.

Attention is now focused on the roles of several genes, especially *CFH* (complement factor H) and other complement regulatory genes in the pathogenesis of this condition. The complement regulatory gene variants that are associated with AMD all appear to decrease their function, implying that AMD may stem from an excess of complement activity. Environmental exposures such as cigarette smoking may also increase risk of AMD, especially in genetically predisposed individuals.

Other Retinal Degenerations

Retinitis Pigmentosa

Retinitis pigmentosa is an inherited condition resulting from mutations that affect rods and cones or RPE. It can cause varying degrees of visual impairment including, in some cases, total blindness. The term *"retinitis" pigmentosa* is an unfortunate relic of the time when these disorders were incorrectly presumed to be inflammatory. They may be inherited as X-linked recessive, autosomal recessive, or autosomal dominant (the age of onset correlates with the inheritance pattern, with autosomal dominant retinitis pigmentosa appearing later in life). Retinitis pigmentosa may be part of a syndrome, such as the *Bardet-Biedl syndrome, Usher syndrome,* or *Refsum disease,* or may develop in isolation (nonsyndromic retinitis pigmentosa).

Retinitis pigmentosa is linked to mutations affecting *RHO, USH2A, RGPR,* and *EYS* genes; they regulate the functions of either the photoreceptor cells or the RPE. *Typically, both rods and cones are lost to apoptosis,* though in varying proportions. Loss of rods may lead to early night blindness and constricted visual fields. As cones are lost, central visual acuity may be affected. Clinically, retinal atrophy is accompanied by constriction of retinal vessels and optic nerve head atrophy ("waxy pallor" of the optic disc) and the accumulation of retinal pigment around blood vessels, thus accounting for the "pigmentosa" in the disease name. The electroretinogram reveals abnormalities characteristic of this disease.

Retinitis

A variety of pathogens can contribute to the development of infectious retinitis. For example, *Candida* may disseminate to the retina hematogenously, especially in the setting of intravenous drug abuse or in systemic candidemia from other causes. Hematogenous dissemination of pathogens to the retina typically results in multiple retinal abscesses. As was mentioned previously, cytomegalovirus retinitis is an important cause of visual morbidity in immunocompromised individuals, especially those with AIDS.

Retinal Neoplasms

Retinoblastoma

Retinoblastoma is the most common primary intraocular malignancy of children. The molecular genetics of retinoblastoma are discussed in detail in Chapter 7. Although the name retinoblastoma might suggest origin from a primitive retinal cell that is capable of differentiation into both glial and neuronal cells, it is now clear that the cell of origin of retinoblastoma is a neuronal progenitor. Recall that in approximately 40% of cases, retinoblastoma occurs in individuals who inherit a germline mutation of one *RB* allele. Retinoblastoma arises when the retinal progenitor suffers a second, somatic mutation and the *RB* gene function is lost. In the sporadic cases, both *RB* alleles are lost by somatic mutations. Retinoblastomas arising in those with germline mutations are often bilateral. In addition, they may be associated with pinealoblastoma ("trilateral" retinoblastoma), which is associated with a dismal outcome.

MORPHOLOGY

The pathology of retinoblastoma, both hereditary and sporadic types, is identical. Tumors may contain both undifferentiated and

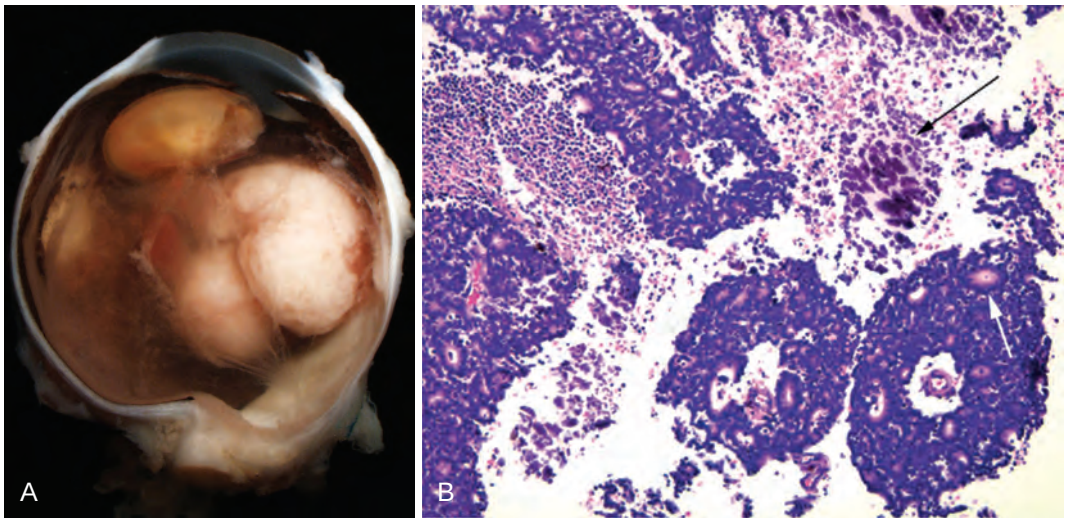

Figure 29.24 Retinoblastoma. (A) Gross photograph of retinoblastoma. (B) Tumor cells appear viable when in proximity to blood vessels, but necrosis is seen as the distance from the vessel increases. Dystrophic calcification *(black arrow)* is present in the zones of tumor necrosis. Flexner-Wintersteiner rosettes—arrangements of a single layer of tumor cells around an apparent "lumen"—are seen throughout the tumor, and one such rosette is indicated by the *white arrow*.

differentiated elements. The former appear as collections of small, round cells with hyperchromatic nuclei. In well-differentiated tumors there are **Flexner-Wintersteiner rosettes** and fleurettes reflecting photoreceptor differentiation. It should be noted, however, that the degree of tumor differentiation does not appear to be associated with the prognosis. As seen in Fig. 29.24, viable tumor cells are found encircling tumor blood vessels with zones of necrosis typically found in relatively avascular areas, illustrating the dependence of retinoblastoma on its blood supply. Focal zones of dystrophic calcification are characteristic of retinoblastoma.

In an effort to preserve vision and eradicate the tumor, many ophthalmic oncologists now attempt to reduce tumor burden by administration of chemotherapy, including selective delivery of the drug to the eye through the ophthalmic artery; after chemoreduction, tumors may be obliterated by laser treatment or cryopexy. Retinoblastoma tends to spread to the brain and bone marrow and seldom disseminates to the lungs. Prognosis is adversely affected by extraocular extension and invasion along the optic nerve and by choroidal invasion. A variant of retinoblastoma—retinocytoma or retinoma—has been reported and appears to be a premalignant lesion. The appearance of retinoblastoma in one eye and retinocytoma in the other eye is characteristic of heritable retinoblastoma.

Retinal Lymphoma

Primary retinal lymphoma is an aggressive tumor that characteristically involves the two retinal layers derived from brain, the neurosensory retina and the RPE. Primary intraocular lymphoma tends to occur in older individuals and may mimic uveitis clinically. Most are diffuse large B-cell lymphomas (Chapter 13). Spread to the brain commonly occurs via the optic nerve. The diagnosis depends on a demonstration of lymphoma cells in vitreous aspirates.

KEY CONCEPTS

- Retinal detachment, a separation of the neurosensory retina from the RPE, may be the consequence of a break in the retina (rhegmatogenous retinal detachment) or may develop without a retinal break because of pathology within or beneath the retina (nonrhegmatogenous retinal detachment).
- The clinical appearance of the retina by ophthalmoscopy can be linked to specific pathologic changes: the change in caliber and color of retinal blood vessels may reflect varying degrees of arteriolosclerosis, and the location of hemorrhages and exudates in the retina is related to their locations within the retinal layers.
- Several major causes of blindness result from pathologic intraocular angiogenesis including proliferative diabetic retinopathy and exudative (wet) age-related macular degeneration, among many other conditions. VEGF antagonists may prevent visual loss in many of these conditions.
- Retinoblastoma is the most common primary intraocular tumor of children.
- Primary retinal lymphoma is an aggressive tumor that often involves the brain as well.

OPTIC NERVE

As a sensory tract of the central nervous system, the optic nerve is surrounded by meninges, and cerebrospinal fluid circulates around the nerve. The pathology of the optic nerve is similar to the pathology of the brain. For example, the most common primary neoplasms of the optic nerve are glioma (typically pilocytic astrocytomas) and meningioma.

Anterior Ischemic Optic Neuropathy

There are striking similarities between stroke and a condition known in ophthalmic terminology as anterior ischemic

optic neuropathy (AION). As used clinically, the term AION includes a spectrum of injuries to the optic nerve varying from ischemia to infarction. Thus, transient partial interruptions in blood flow to the optic nerve can produce episodes of transient loss of vision, whereas total interruption in blood flow can give rise to an optic nerve infarct which may be segmental or total. Zones of relative ischemia may surround segmental infarcts of the optic nerve. Optic nerve function in these poorly perfused but not infarcted zones may recover. The optic nerve does not regenerate, and visual loss from infarction is permanent.

Interruption in the blood supply to the optic nerve can result from inflammation of the vessels that supply the optic nerve or from embolic or thrombotic events. Bilateral total infarcts of the optic nerve resulting in total blindness have been reported in temporal arteritis, adding urgency to the treatment of this condition with high doses of corticosteroids.

Papilledema

Edema of the head of the optic nerve may develop as a consequence of compression of the nerve (as in a primary neoplasm of the optic nerve when swelling of the nerve head produces unilateral disc edema) or from elevations of cerebrospinal fluid pressure surrounding the nerve (resulting typically in bilateral disc edema). The concentric increase in pressure encircling the nerve contributes to venous stasis and also interferes with axoplasmic transport, leading to nerve head swelling. Swelling of the optic nerve head in elevated intracranial pressure is bilateral and is commonly termed *papilledema.* Typically, acute papilledema from increased intracranial pressure is not associated with visual loss. Ophthalmoscopically, the optic nerve head is swollen and hyperemic; by contrast, the optic nerve head in the relatively acute phases of anterior ischemic optic neuropathy appears swollen and pale because of decreased nerve perfusion (Fig. 29.25). In papilledema secondary to increased intracranial pressure, the optic nerve may remain congested for a prolonged period of time.

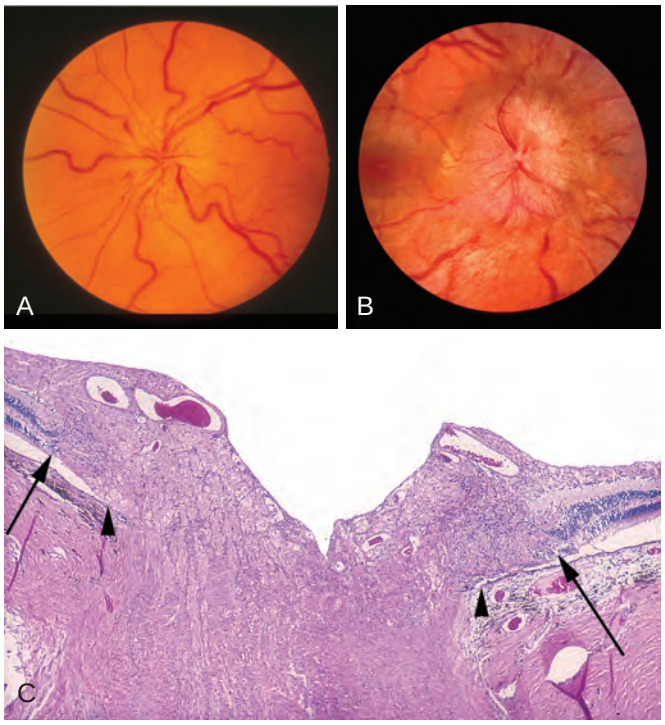

Figure 29.25 The optic nerve in anterior ischemic optic neuropathy (AION) and papilledema. (A) In the acute phases of AION the optic nerve may be swollen, but it is relatively pale because of decreased perfusion. (B) In papilledema secondary to increased intracranial pressure, the optic nerve is typically swollen and hyperemic. (C) Normally, the termination of Bruch membrane *(arrowheads)* is aligned with the beginning of the neurosensory retina, as indicated by the presence of stratified nuclei *(arrows),* but in papilledema the optic nerve is swollen, and the retina is displaced laterally. This is the histologic explanation for the blurred margins of the optic nerve head seen clinically in this condition. (A and B, Courtesy Dr. Sohan S. Hayreh, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, Ia.; C, from the teaching collection of the Armed Forces Institute of Pathology.)

Glaucomatous Optic Nerve Damage

As discussed, the majority of individuals with glaucoma have elevated intraocular pressure. However, there is a small group that develops the visual field and optic nerve changes typical of glaucoma with normal intraocular pressure—so-called normal-tension glaucoma. Conversely, some individuals with elevated intraocular pressure who are followed over long periods of time never develop visual field changes or optic nerve cupping. Therefore, it is clear that there is a spectrum of neuronal susceptibility to the effects of elevated intraocular pressure. Considerable research is now directed toward understanding mechanisms by which the optic nerve axons may be protected from injury.

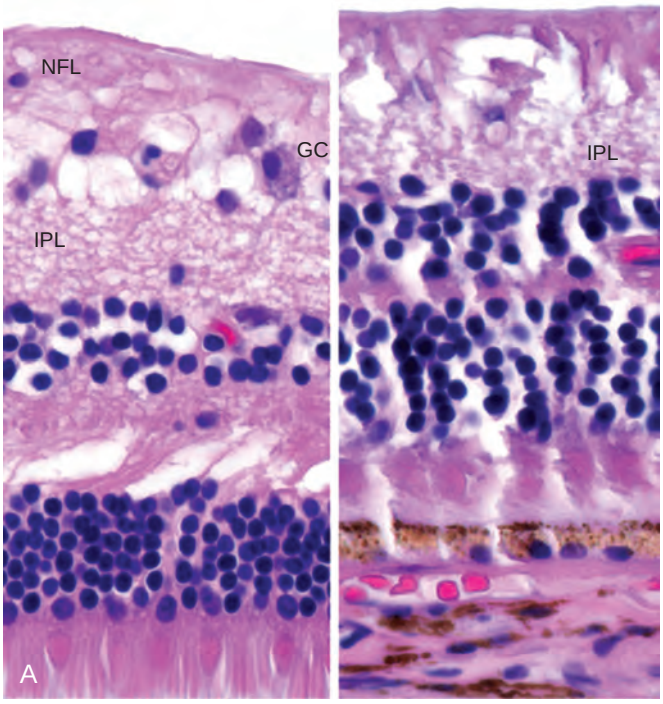
MORPHOLOGY

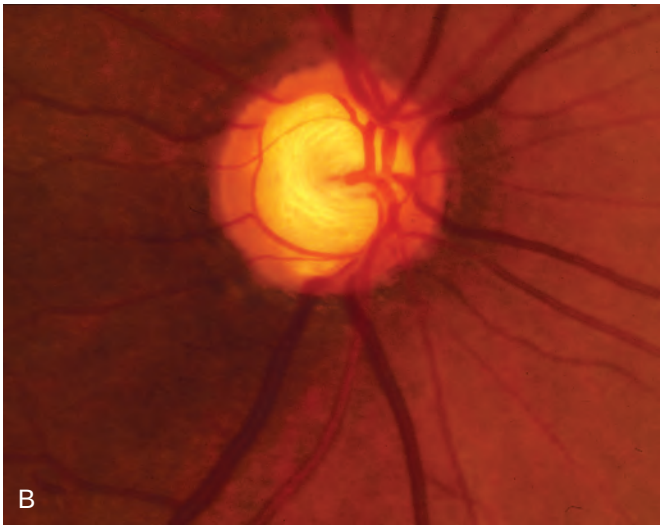
Characteristically, there is a diffuse loss of ganglion cells and thinning of the retinal nerve fiber layer (Fig. 29.26), which can be measured by optical coherence tomography. In advanced cases, the optic nerve is both cupped and atrophic, a combination unique to glaucoma. Elevated intraocular pressure in infants and children can lead to diffuse enlargement of the eye **(buphthalmos)** or enlargement of the cornea **(megalocornea).** After the eye reaches its adult size, prolonged elevation of intraocular pressure can lead to focal thinning of the sclera, and uveal tissue may line ectatic sclera **(staphyloma).**

Other Optic Neuropathies

Optic neuropathy may be inherited or may be secondary to nutritional deficiencies or toxins such as methanol. Individuals may suffer severe visual compromise. If the nerve fibers that originate from the macula are affected, then central visual acuity is lost.

Leber hereditary optic neuropathy results from inheritance of mitochondrial gene mutations (Chapter 5). Since neuronal health is dependent on axoplasmic transport of mitochondria, mitochondrial dysfunctions give rise to neurologic disorders including optic neuropathy. Leber optic neuropathy shows maternal inheritance pattern typical of mitochondrial gene mutations. Males are affected far more commonly than





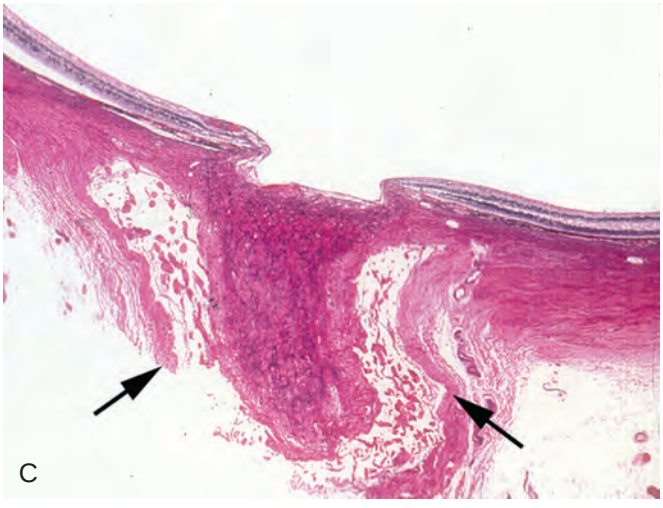


Figure 29.26 The retina and optic nerve in glaucoma. (A) *Left panel,* normal retina; *right panel,* the retina in long-standing glaucoma (same magnification). The full thickness of the glaucomatous retina is captured *(right),* a reflection of the thinning of the retina in glaucoma. In the glaucomatous retina, the areas corresponding to the nerve fiber layer *(NFL)* and ganglion cell layer *(GC)* are atrophic; the inner plexiform layer *(IPL)* is labeled for reference. Note also that the outer nuclear layer of the glaucomatous retina is aligned with the inner nuclear layer of the normal retina due to the thinning of the retina in glaucoma. See Fig. 29.16 for orientation. (B) Glaucomatous optic nerve cupping results in part from loss of retinal ganglion cells, the axons of which populate the optic nerve. (C) The *arrows* point to the dura of the optic nerve. Notice the wide subdural space, a result of atrophy of the optic nerve. There is a striking degree of cupping on the surface of the nerve as a consequence of long-standing glaucoma.

females. The usual age of onset is between 10 and 30 years. It begins with clouding of vision that may progress to total loss of vision.

Optic Neuritis

Many unrelated conditions have historically been grouped under the heading of optic neuritis. Unfortunately, the term itself suggests optic nerve inflammation, which might not accurately describe the pathophysiologic changes. In common clinical usage the term *optic neuritis* is used to describe a loss of vision secondary to demyelinization of the optic nerve. One of the most important causes of optic neuritis is multiple sclerosis (Chapter 28). Indeed, optic neuritis may be the first manifestation of this disease. The 10-year risk of developing multiple sclerosis after the first attack of optic neuritis increases if the affected person has concomitant evidence of brain lesions as detected by magnetic resonance imaging. Individuals with a single episode of optic nerve demyelinization may recover vision and remain disease-free.

KEY CONCEPTS

- The term "anterior ischemic optic neuropathy" refers to a spectrum of ischemic injuries to the optic nerve varying from transient ischemia to infarction.
- Bilateral swelling of the optic nerve head known as papilledema may develop as a consequence of elevated cerebrospinal fluid pressure and stasis of axoplasmic transport within the optic nerve. Unilateral optic nerve head swelling may result from compression of the optic nerve such as in primary tumors of the nerve.
- In chronic glaucoma, the optic nerve may atrophy and the cup on the surface of the nerve may enlarge and deepen.
- Optic neuropathy may be inherited (as in Leber hereditary optic neuropathy) or may result from nutritional deficiencies or toxins such as methanol.

THE END-STAGE EYE: PHTHISIS BULBI

Trauma, intraocular inflammation, chronic retinal detachment, and many other conditions can give rise to an eye that is both small (atrophic) and internally disorganized: phthisis bulbi. Congenitally small eyes—hypoplastic or microphthalmic eyes—are generally not disorganized internally. Phthisical eyes typically show the following changes: the presence of exudate or blood between the ciliary body and sclera and the choroid and sclera *(ciliochoroidal effusion);* the presence of a membrane extending across the eye from one aspect of the ciliary body to the other *(cyclitic membrane);* chronic retinal detachment; optic nerve atrophy; the presence of intraocular bone, which is thought by many to originate from osseous metaplasia of the RPE; and a thickened sclera, especially posteriorly. Ciliochoroidal effusion is typically associated with the physiologic state of low intraocular pressure *(hypotony)*. The normal pull of the extraocular muscles on a hypotonous eye may render the appearance of the eye as square rather than round.
