The gold standards for diagnosis of infections are identification from culture, serology, and molecular techniques, depending on the organism in question. Some infectious agents or their products can be directly observed in hematoxylin and eosin–stained sections (e.g., the inclusion bodies formed by CMV and HSV; bacterial clumps, which usually stain blue). Many infectious agents, however, are best visualized by special stains that identify organisms on the basis of particular characteristics of their cell wall or coat or by staining with specific antibodies (Table 8.9). Organisms are typically easiest to identify at the advancing edge of a

Table 8.9 Special Techniques for Diagnosing Infectious Agents

Techniques	Infectious Agents
Gram stain	Most bacteria

lesion rather than at its center, particularly if there is necrosis. Acute infections can be diagnosed serologically by detecting pathogen-specific antibodies in the serum. The presence of specific IgM antibody shortly after the onset of symptoms is diagnostic. Alternatively, specific antibody titers can be measured during the early infection and again 4 to 6 weeks later; a fourfold rise in titer is considered diagnostic.

Nucleic acid amplification tests, such as PCR and transcription-mediated amplification, are common for rapid identification of microbes. These molecular diagnostic assays have become routine for diagnosis of gonorrhea, chlamydial infection, tuberculosis, and herpes encephalitis. In some cases, molecular assays are much more sensitive than conventional testing, for example for detection of HSV in CSF or for Chlamydia in urine or genital swabs. Multiplex PCR panels for detection of over 20 pathogens are now in clinical use for detection of pathogens in stool, respiratory samples, and cerebrospinal fluid, as a well as positive blood culture broths. In people infected with HIV, HBC, or HCV, quantification of viral RNA is an important guide to management of ART. High-throughput or next-generation sequencing methods, most often following PCR of the 16S rDNA gene for bacteria or the ribosomal internal transcribed spacer (ITS) region for fungi, allow rapid sequencing of large numbers of DNA molecules. Next-generation sequencing can be used to detect bacteria, viruses, parasites, or fungi directly in patient specimens. This method currently has limited clinical application, but is likely to become increasingly important and common in the future.

CHAPTER 9

Environmental and Nutritional Diseases

CHAPTER CONTENTS

Many diseases are caused or influenced by environmental factors. Broadly defined, the term *environment* encompasses the various indoor, outdoor, and occupational settings in which human beings live and work. In each of these settings, the air people breathe, the food and water they consume, and the toxic agents they are exposed to are major determinants of health. The environmental factors that influence our health pertain to individual behavior ("personal environment") and include tobacco use, alcohol ingestion, recreational drug consumption, diet, and the like, or the external (ambient and workplace) environment. In general, in higher income countries personal behavior has a larger effect on health than the ambient environment, but new threats related to global warming (described later) may change this equation.

The term *environmental disease* refers to conditions caused by exposure to chemical or physical agents in the ambient, workplace, and personal environment, including diseases of nutritional origin. The International Labour Organization estimates that work-related injuries and illnesses kill approximately 2.3 million people per year globally (more deaths than are caused by road accidents and wars combined). In the United States in 2018, there were nearly 3 million occupational injuries and illnesses. Disease related to malnutrition is even more pervasive. In 2019, it was estimated that 795 million people were malnourished—one in every nine persons worldwide. Children are disproportionately affected by undernutrition, which accounts for approximately 50% of childhood mortality worldwide. Estimating the burden of disease in the general population caused by nonoccupational exposures to toxic agents is complicated by the diversity of agents and difficulties in determining the extent and duration of exposures. But whatever the precise numbers, it is clear that environmental diseases are major causes of disability and suffering and constitute a heavy financial burden, particularly in low income countries.

In this chapter, we first consider the emerging problem of the health effects of climate change. We then discuss the mechanisms of toxicity of chemical and physical agents and address specific environmental disorders, including those of nutritional origin.

HEALTH EFFECTS OF CLIMATE CHANGE

Without immediate action, climate change stands to become the preeminent global cause of environmental disease in the 21st century and beyond. Global temperature measurements show that the earth has warmed significantly since the early 20th century and especially since the mid-1960s. Record-breaking global temperatures have become common, and the 5 years from 2014 to 2018 have been the warmest since 1880. During 2018, the global land temperature was 1.1°C warmer than the 20th century average. Mean global ocean temperatures also continue to warm, with the annual average temperature in 2018 being 0.66°C warmer than the 20th century average.

The rising atmospheric and oceanic temperatures have led to a large number of effects that include changes in storm frequency, drought, and flood, as well as large-scale ice losses in Greenland, Antarctica, and the vast majority of the other glaciated regions on earth, as well as dramatic thinning or disappearance of Arctic Ocean sea ice. The melting of land-based glacial ice and the thermal expansion of the warming oceans has produced approximately 13–20 cm of global average sea level rise since 1900, and the sea level currently is rising at a global average rate of 3.5 ± 0.4 mm/year.

Although politicians quibble, among scientists there is a general acceptance that climate change is in large part man-made. The culprit is the rising atmospheric level of greenhouse gases, particularly carbon dioxide (CO_2) released through the burning of fossil fuels (Fig. 9.1A), ozone (an important air pollutant, discussed later), and methane. These gases, along with water vapor, produce the so-called greenhouse effect by absorbing energy radiated from Earth's surface that otherwise would be lost into space. The annual average level of atmospheric CO_2 (about 410 ppm) in 2019 was higher than at any point in approximately 650,000 years and, without changes in human behavior, is expected to increase to 500 to 1200 ppm by the end of this century—levels not experienced for tens of millions of years. This increase stems not only from increased CO_2 production but also from deforestation and the attendant decrease in carbon fixation by plants. Depending on the computer model used, increased levels of greenhouse gases are projected to cause the global temperature to rise by 2°C to 5°C by the year 2100 (Fig. 9.1B).

The health consequences of climate change will depend on its extent and rapidity, the severity of the ensuing consequences, and humankind's ability to mitigate the damaging effects. The World Health Organization (WHO) estimates that approximately 250,000 deaths would occur annually between 2030 and 2050 as a consequence of climate change. This number does not include morbidity and disruption of health services from extreme changes in weather. Even in the best-case scenario, however, climate change is expected to have a serious negative impact on human health by increasing the incidence of a number of diseases including the following:

- *Cardiovascular, cerebrovascular, and respiratory diseases,* all of which will be exacerbated by heat waves and air pollution.

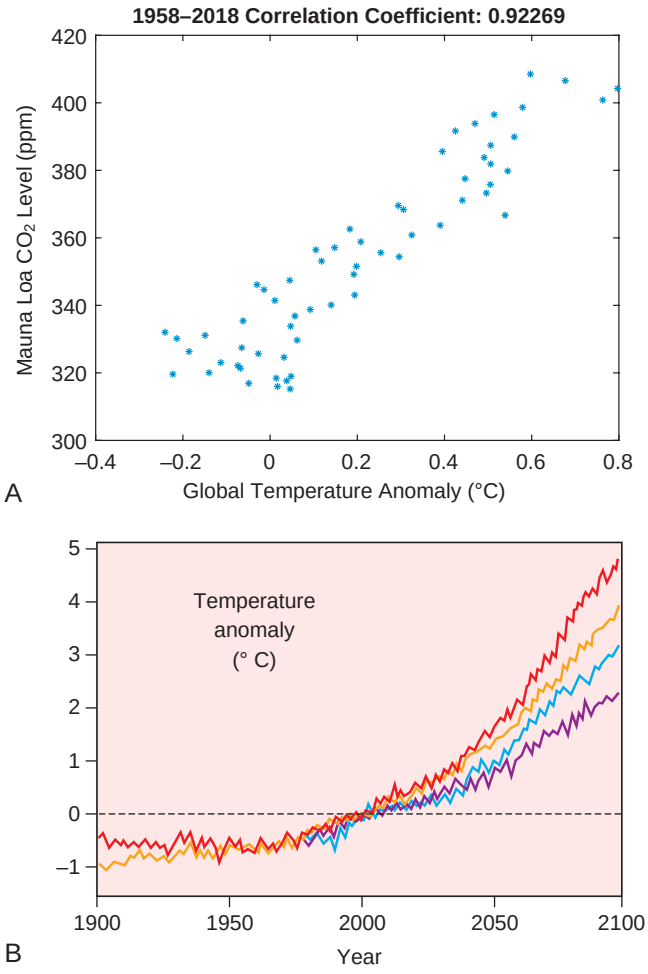

Figure 9.1 Climate change, past and future. (A) Correlation of carbon dioxide *(CO_2)* levels measured at the Mauna Loa Observatory in Hawaii with average global temperature trends over the past 60 years. Global temperature in any given year was deduced at the Hadley Center (United Kingdom) from measurements taken at more than 3000 weather stations located around the globe. (B) Predicted temperature increases during the 21st century. Different computer models plot anticipated rises in global temperatures of 2°C to 5°C by the year 2100. (A, Courtesy Dr. Richard Aster, Department of Geophysics, Colorado State University, Fort Collins, Colo.)

- *Gastroenteritis,* cholera, and other foodborne and waterborne infectious diseases, caused by contamination as a consequence of floods and disruption of clean water supplies and sewage treatment after heavy rains and other environmental disasters.
- *Vector-borne infectious diseases* such as malaria and dengue fever resulting from changes in vector number and geographic distribution related to increased temperatures, crop failures, and more extreme weather variation (e.g., more frequent and severe El Niño events).
- *Malnutrition,* caused by changes in local climate that disrupt crop production. Such changes are anticipated to be most severe in tropical locations, in which average temperatures may already be near or above crop tolerance levels; it is estimated that by 2080, agricultural productivity may decline by 10% to 25% in some low income countries as a consequence of climate change.

Beyond these disease-specific effects, it is estimated that the melting of glacial ice, particularly in Greenland and other parts of the Northern Hemisphere, combined with the thermal expansion of warming oceans will raise sea levels by 2 to 6 feet by 2100. Approximately 10% of the world's population—roughly 600 million people—live in low-lying areas that are at risk for flooding even if the rise in ocean levels is at the low end of these estimates. For example, a rise in sea level by 1.5 feet will submerge 70% of the land mass of the Maldive islands, while a 3-foot rise will inundate 100% of all of the islands, changes in sea level that are projected to occur by 2100. The resulting displacement of people will disrupt lives and commerce, creating conditions ripe for political unrest, war, and poverty—the "vectors" of malnutrition, sickness, and death.

Worldwide recognition of the potentially catastrophic effects of climate change led in late 2015 to a historic meeting of 196 countries in Paris, France, at which the participating countries agreed to the following objective: To hold the increase in the global average temperature to well below 2°C above preindustrial levels and to pursue efforts to limit the temperature increase to 1.5°C above preindustrial levels, recognizing that this would significantly reduce the risks and impacts of climate change. However, in 2017 the United States decided to withdraw from this agreement as of 2020, leading to uncertainty about the world's ability to meet the goals established in the Paris accord.

TOXICITY OF CHEMICAL AND PHYSICAL AGENTS

***Toxicology* is defined as the science of poisons. It studies the distribution, effects, and mechanisms of action of toxic agents.** More broadly, it also includes the study of the effects of physical agents such as radiation and heat. Of the approximately 100,000 chemicals in commercial use in the United States, only a small proportion has been tested experimentally for health effects. Several agencies in the United States set permissible levels of exposure to known environmental hazards (e.g., the maximum level of carbon monoxide [CO] in air that is noninjurious or the tolerable levels of radiation that are "safe"). Factors such as the complex interaction between various pollutants and the age, genetic predisposition, and different tissue sensitivities of exposed persons create wide variations in individual sensitivity to toxic agents, limiting the value of establishing "safe levels" for entire populations. Nevertheless, such cutoffs are useful for comparative studies of the effects of agents between specific populations and for estimating risk of disease in heavily exposed individuals.

We now consider some basic principles relevant to the effects of toxic chemicals and drugs.

- The *definition of a poison* is not straightforward. It is basically a quantitative concept that depends on dosage. The quote from Paracelsus in the 16th century that "all substances are poisons; the right dosage differentiates a poison from a remedy" is still valid today, given the number of pharmaceutical drugs with potentially harmful effects.
- *Xenobiotics* are exogenous chemicals in the environment in air, water, food, and soil that may be absorbed into the body through inhalation, ingestion, and skin contact (Fig. 9.2).
- Chemicals may be excreted in urine or feces; eliminated in expired air; or accumulate in bone, fat, brain, or other tissues.
- Chemicals may act at the site of entry or at other sites following transport through the blood.
- *Most solvents and drugs are lipophilic,* which facilitates their transport in the blood by lipoproteins and their penetration through the plasma membrane into cells.
- Most solvents, drugs, and xenobiotics are metabolized to form inactive water-soluble products (detoxification) or are activated to form toxic metabolites. The reactions

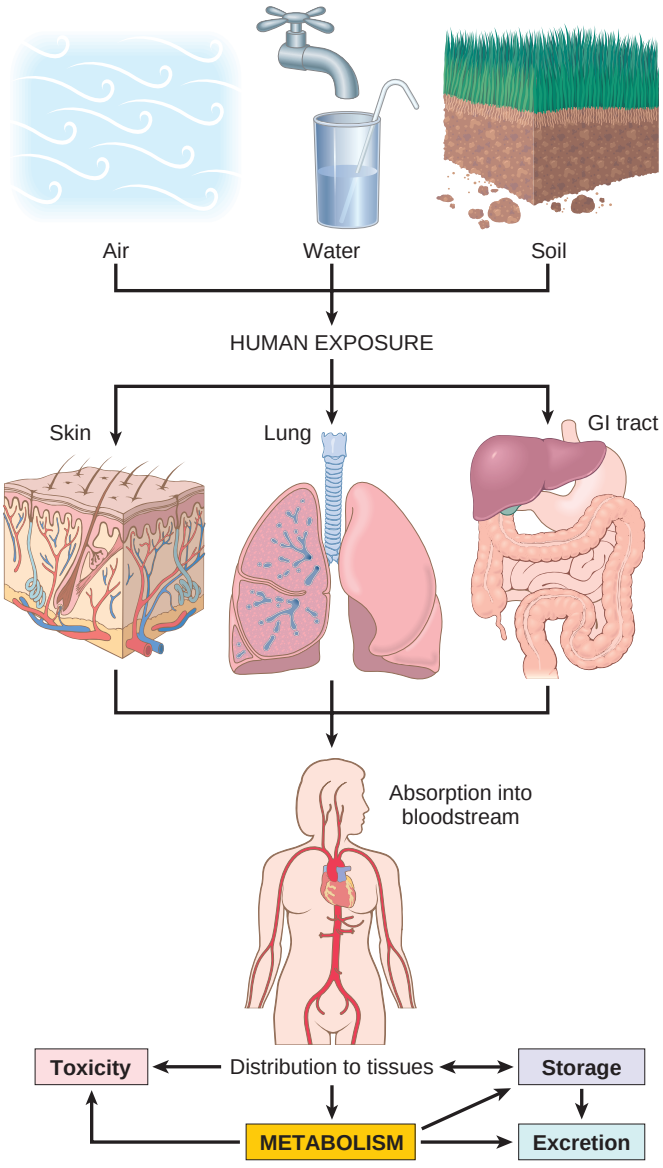

Figure 9.2 Human exposure to pollutants. Pollutants in the air, water, and soil are absorbed through the lungs, gastrointestinal *(GI)* tract, and skin. In the body they may act at the site of absorption, but are generally transported through the bloodstream to various organs where they may be stored or metabolized. Xenobiotics may be metabolized to water-soluble compounds that are excreted or to toxic metabolites, a process referred to as activation.

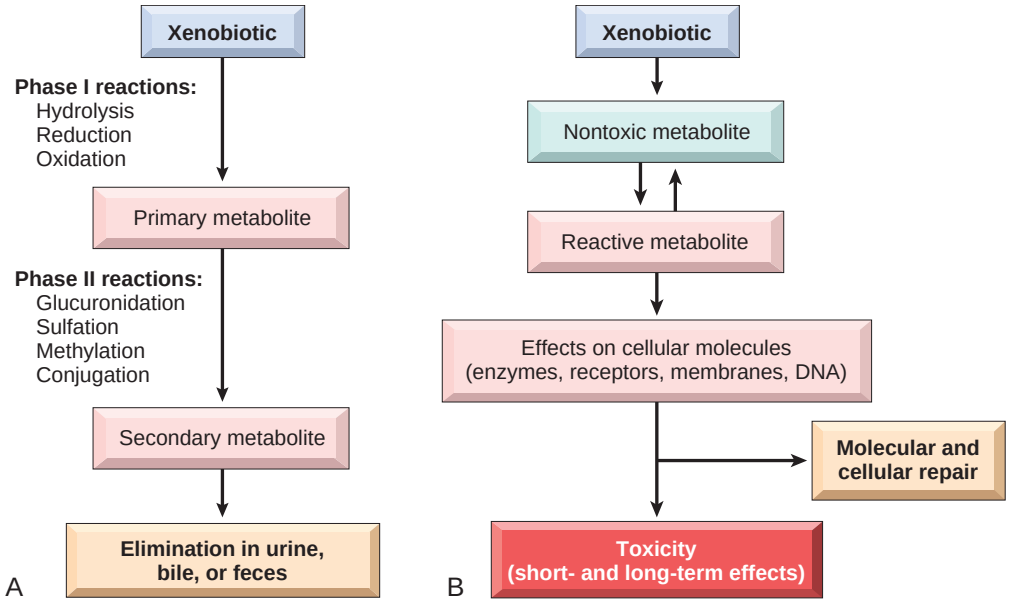

Figure 9.3 Xenobiotic metabolism. (A) Xenobiotics can be metabolized to nontoxic metabolites and eliminated from the body (detoxification). (B) Xenobiotic metabolism may also result in the formation of a reactive metabolite that is toxic to cellular components. If repair is not effective, short-term and long-term effects develop. (Based on Hodgson E: *A textbook of modern toxicology,* ed 3, Hoboken, NJ, 2004, Wiley.)

that metabolize xenobiotics into nontoxic products or that activate xenobiotics to generate toxic compounds (Figs. 9.2 and 9.3) occur in two phases. In phase I reactions, chemicals undergo hydrolysis, oxidation, or reduction. Products of phase I reactions are often metabolized into water-soluble compounds through phase II reactions, which include glucuronidation, sulfation, methylation, and conjugation with glutathione (GSH). Water-soluble compounds are readily excreted.

- The most important catalyst of phase I reactions is the cytochrome P-450 enzyme system. Cytochrome P-450 enzymes (CYPs) are a large family of heme-containing enzymes, each with preferred substrate specificities. These enzymes are primarily expressed in hepatocytes, in which they localize to the endoplasmic reticulum, but can also be found in skin, lungs, gastrointestinal mucosa, and other organs. **The P-450 system catalyzes reactions that either detoxify xenobiotics or, less commonly, convert xenobiotics into active compounds that cause cellular injury.** Both types of reactions may produce, as a by-product, reactive oxygen species (ROS), which can cause cellular damage (Chapter 2). Examples of metabolic activation of chemicals through CYPs are the production of the toxic trichloromethyl free radical from carbon tetrachloride in the liver and the generation of a DNA-binding metabolite from benzo[*a*]pyrene, a carcinogen present in cigarette smoke, in the lung. CYPs participate in the metabolism of alcohol (discussed later) and a large number of common therapeutic drugs, such as acetaminophen, barbiturates, warfarin, and anticonvulsants.

There is great variation in the activity of CYPs among individuals. The variation may be a consequence of genetic polymorphisms in specific CYPs, but more commonly it is due to exposure to drugs or chemicals that induce or diminish CYP activity. Known CYP inducers include environmental chemicals, drugs, smoking, alcohol, and hormones. In contrast, fasting or starvation can decrease CYP activity. Inducers of CYP act by binding to specific nuclear receptors, which then heterodimerize with the *retinoic X receptor (RXR)* to form a transcriptional activation complex that associates with promoter elements located in the 5′-flanking region of CYP genes. Nuclear receptors participating in CYP induction include the aryl hydrocarbon receptor, the peroxisome proliferator-activated receptors *(PPARs),* and two orphan nuclear receptors, constitutive androstane receptor (CAR) and pregnane X receptor (PXR).

This brief overview of the general mechanisms of toxicity provides the background for the discussion of environmental diseases presented in this chapter.

ENVIRONMENTAL POLLUTION

Air Pollution

Air pollution is a significant cause of morbidity and mortality worldwide, particularly among at-risk individuals with preexisting pulmonary or cardiac disease. Air is precious to life, but can also carry many potential causes of disease. Airborne microorganisms have long been major causes of morbidity and mortality, especially in low income countries. More widespread are airborne chemical and particulate pollutants, especially in high income nations. Here we consider these hazards in outdoor and indoor air.

Outdoor Air Pollution

The ambient air in industrialized nations is contaminated with an unsavory mixture of gaseous and particulate pollutants, more heavily in cities and in proximity to heavy industry. In the United States, the Environmental Protection Agency monitors and sets allowable upper limits for six

pollutants: sulfur dioxide, CO, ozone, nitrogen dioxide, lead, and particulate matter. Collectively, these agents produce the well-known *smog* (smoke and fog) that sometimes stifles large cities such as Beijing, Los Angeles, Houston, Cairo, New Delhi, Mexico City, and São Paulo. It may seem that air pollution is a modern phenomenon, but this is hardly the case. John Evelyn wrote in 1661 that inhabitants of London suffered from "Catharrs, Phthisicks and Consumptions" (bronchitis, pneumonia, and tuberculosis) and breathed "nothing but an impure and thick mist, accompanied by a fuliginous and filthy vapour, which renders them obnoxious to a thousand inconveniences, corrupting the lungs, and disordering the entire habit of their bodies." The first environmental control law, proclaimed by Edward I in 1306, was straightforward in its simplicity: "whoever should be found guilty of burning coal shall suffer the loss of his head." What has changed in modern times is the nature and sources of air pollutants and the types of regulations that control their emission.

Although the lungs bear the brunt of the adverse consequences, air pollutants can affect many organ systems. Except for some comments on smoking, pollutant-caused lung diseases are discussed in Chapter 15. Major health effects of outdoor pollutants are summarized in Table 9.1. Ozone, sulfur dioxide, particulates, and CO are discussed here.

Ozone (O_3) is produced by interaction of ultraviolet (UV) radiation and oxygen (O_2) in the stratosphere and naturally accumulates in the so-called ozone layer 10 to 30 miles above the earth's surface. This layer protects life on earth by absorbing the most dangerous UV radiation emitted by the sun. In 1985, it was discovered that ozone was nearly completely depleted over Antarctica and was thinned elsewhere, a dire effect stemming from the widespread use of chlorofluorocarbon gases in air conditioners and refrigerators and as aerosol propellants. When released into the atmosphere, these gases drift up into the stratosphere and participate in chemical reactions that destroy ozone. Due to prevailing stratospheric air currents, the resulting depletion is most profound in polar regions, particularly over Antarctica during the winter months. Recognition of the problem led in 1987 to the Montreal Protocol, international agreements that call for a complete phase-out of chlorofluorocarbon use by 2020 in higher income countries and by 2040 in lower income countries. Decreased use of chlorofluorocarbons over the past 30 years has reduced the size of the yearly ozone "hole" over Antarctica, indicating that this global environmental challenge is being met successfully.

Table 9.1 Health Effects of Outdoor Air Pollutants

Pollutant	Populations at Risk	Effects
Ozone	Healthy adults and children	Decreased lung function Increased airway reactivity Lung inflammation
	Athletes, outdoor workers	Decreased exercise capacity
	Asthmatics	Increased hospitalizations
Nitrogen dioxide	Healthy adults	Increased airway reactivity
	Asthmatics	Decreased lung function
	Children	Increased respiratory infections
Sulfur dioxide	Healthy adults	Increased respiratory symptoms
	Individuals with chronic lung disease	Increased mortality
	Asthmatics	Increased hospitalization Decreased lung function
Acid aerosols	Healthy adults	Altered mucociliary clearance
	Children	Increased respiratory infections
	Asthmatics	Decreased lung function Increased hospitalizations
Particulates	Children	Increased respiratory infections
	Individuals with chronic lung or heart disease	Decreased lung function
	Asthmatics	Excess mortality Increased attacks

From Bascom R, et al: Health effects of outdoor air pollution, *Am J Respir Crit Care Med* 153:477, 1996.

In contrast to the "good" ozone in the stratosphere, ozone that accumulates in the lower atmosphere (ground-level ozone) is one of the most pernicious air pollutants. Ground-level ozone is a gas formed by the reaction of nitrogen oxides and volatile organic compounds in the presence of sunlight. These chemicals are released by industrial emissions and motor vehicle exhaust. Ozone toxicity is in large part mediated by the production of free radicals, which injure epithelial cells along the respiratory tract and type I alveolar cells and cause the release of inflammatory mediators. Healthy individuals exposed to ozone experience upper respiratory tract inflammation and mild symptoms (decreased lung function and chest discomfort), but exposure is much more dangerous for people with asthma or emphysema.

To make matters worse, ozone often combines with other agents such as sulfur dioxide and particulates to create a veritable "witches' brew" of pollutants. Sulfur dioxide is produced by power plants burning coal and oil, from copper smelting, and as a by-product of paper mills. Released into the air, it may be converted into sulfuric acid and sulfuric trioxide, which cause a burning sensation in the nose and throat, difficulty in breathing, and asthma attacks in susceptible individuals.

Particulate matter (known as "soot") is a particularly important cause of morbidity and mortality related to pulmonary inflammation and secondary cardiovascular effects. Based on studies of large cities in the United States, it is estimated that there is a 0.5% increase in overall daily mortality for every 10 mg/m^3 increase in 10-µm particles in outdoor air, mainly due to exacerbations of pulmonary and cardiac disease. Particulates are emitted by coal- and oil-fired power plants, by industrial processes burning these fuels, and by diesel exhaust. Although the particles have not been well characterized chemically or physically, fine or ultrafine particles less than 10 µm in diameter are the most harmful. They are readily inhaled into the alveoli, where they are phagocytosed by macrophages and neutrophils, which respond by releasing a number of inflammatory mediators. In contrast, particles that are greater than 10 µm in diameter are of lesser consequence because they are generally removed in the nose or trapped by the mucociliary epithelium of the airways.

CO is a systemic asphyxiant that is an important cause of accidental and suicidal death. CO is a nonirritating, colorless, tasteless, odorless gas that is produced during any process that results in the incomplete oxidation of hydrocarbons. From the standpoint of human health, the most important environmental source of CO is the burning of carbonaceous materials, as occurs in automotive engines, furnaces, and cigarettes. CO is short-lived in the atmosphere, being rapidly oxidized to CO_2; thus elevated levels in ambient air are transient and occur only in close proximity to sources of CO. Chronic poisoning may occur in individuals working in environments such as tunnels, underground garages, and highway toll booths with high exposures to automobile fumes. Of greater concern is acute toxicity. In a small, closed garage, the average running car can produce sufficient CO to induce coma or death within 5 minutes, and CO concentrations can also rapidly rise to toxic levels with improper use of gasoline-powered generators (e.g., during power outages) or following mine fires. CO kills in part by inducing central nervous system (CNS) depression, which appears so insidiously that victims are often unaware of their plight. Hemoglobin has 200-fold greater affinity for CO than for oxygen, and the resultant carboxyhemoglobin cannot carry O_2. Systemic hypoxia develops when the hemoglobin is 20% to 30% saturated with CO; unconsciousness and death are likely with 60% to 70% saturation.

MORPHOLOGY

Chronic poisoning by CO develops because carboxyhemoglobin, once formed, is remarkably stable. Even with low-level, but persistent, exposure to CO, carboxyhemoglobin may rise to life-threatening levels in the blood. The slowly developing hypoxia can insidiously evoke widespread ischemic changes in the CNS; these are particularly marked in the basal ganglia and lenticular nuclei. With cessation of exposure to CO, the patient usually recovers, but there may be permanent neurologic sequelae, such as impairment of memory, vision, hearing, and speech. The diagnosis is made by measuring carboxyhemoglobin levels in the blood.

Acute poisoning by CO is generally a consequence of accidental exposure or suicide attempt. In light-skinned individuals, **acute poisoning is marked by a characteristic generalized cherry-red color of the skin and mucous membranes,** which results from high levels of carboxyhemoglobin. This effect of CO on coloration may result in a failure to recognize the oxygen-starved state of the victim (and is used by the meat industry in the United States to keep meat appearing fresh—caveat emptor!). If death occurs rapidly, morphologic changes may not be present; with longer survival, the brain may be slightly edematous, with punctate hemorrhages and hypoxia-induced neuronal changes. The morphologic changes are not specific and stem from systemic hypoxia.

Indoor Air Pollution

As we increasingly "button up" our homes to exclude the environment, the potential for pollution of the indoor air increases. The most common pollutant is tobacco smoke (discussed later), but additional offenders are CO, nitrogen dioxide (both already mentioned as outdoor pollutants), and asbestos (Chapter 15). Volatile substances containing polycyclic aromatic hydrocarbons generated by cooking oils and coal burning are important indoor pollutants in lower income parts of the world, particularly parts of Asia. Only a few comments about other agents are made here.

- *Smoke from burning of organic materials,* containing various oxides of nitrogen and carbon particulates, is an irritant that predisposes exposed persons to lung infections and may contain carcinogenic polycyclic hydrocarbons. It is estimated that one-third of the world's people burn carbon-containing material such as wood, dung, or charcoal in their homes for cooking, heating, and light.
- *Bioaerosols* range from microbiologic agents capable of causing infectious diseases such as legionnaires' disease, viral pneumonia, and the common cold to less threatening but nonetheless distressing allergens derived from pet dander, dust mites, fungi, and molds that are variously responsible for rhinitis, eye irritation, and asthma.
- *Radon,* a radioactive gas derived from uranium widely present in soil and in homes, can cause lung cancer in uranium miners. It is also suspected that low-level chronic exposures in the home increase lung cancer risk, particularly in those who smoke tobacco. Radon is the number one cause of lung cancer among nonsmokers, according to EPA estimates. Overall, radon is the second leading cause of lung cancer. Radon is responsible for about 21,000 lung cancer deaths every year. About 2,900 of these deaths occur among people who have never smoked.
- *Formaldehyde* is used in the manufacture of building materials (e.g., cabinetry, furniture, adhesives) and may accumulate in the air in poorly ventilated housing. At concentrations of 0.1 ppm or higher, it causes breathing difficulties and a burning sensation in the eyes and throat and can trigger asthma attacks. Formaldehyde is classified as a carcinogen for humans and animals.
- The so-called *sick building syndrome* remains an elusive problem; it may be a consequence of exposure to one or more indoor pollutants, possibly due to poor ventilation.

KEY CONCEPTS

ENVIRONMENTAL DISEASES AND ENVIRONMENTAL POLLUTION

- Environmental diseases are conditions caused by exposure to chemical or physical agents in the ambient, workplace, and personal environments.
- Exogenous chemicals known as xenobiotics enter the body through inhalation, ingestion, and skin contact and can either be eliminated or accumulate in fat, bone, brain, and other tissues.
- Xenobiotics can be converted into nontoxic products or activated to generate toxic compounds through a two-phase reaction process that involves the cytochrome P-450 system.
- The most common and important air pollutants are ozone (which in combination with oxides and particulate matter forms smog), sulfur dioxide, acid aerosols, and particles less than 10 μm in diameter.
- CO poisoning is an important cause of death from accidents and suicide; it binds hemoglobin with high affinity, leading to systemic asphyxiation associated with CNS depression.
- A variety of pollutants including smoke, bioaerosols, radon, and formaldehyde may accumulate in indoor air and cause disease.

Metals as Environmental Pollutants

Lead, mercury, arsenic, and cadmium are the heavy metals most commonly associated with harmful effects in humans.

Lead

Lead is a readily absorbed metal that binds to sulfhydryl groups in proteins and interferes with calcium metabolism, effects that lead to hematologic, skeletal, neurologic, gastrointestinal, and renal toxicities. Lead exposure may occur through contaminated air, food, and water. For most of the 20th century the major sources of lead in the environment were lead-containing house paints and gasoline. Although limits have been set for the amounts of lead contained in residential paints and use of leaded gasoline in road vehicles was banned in the United States in 1996, lead contamination remains an important health hazard, particularly for children. There are many sources of lead in the environment such as from mining, foundries, batteries, and spray painting that constitute occupational hazards. However, flaking lead paint in older houses and soil contamination pose major hazards to youngsters. Blood levels of lead in children living in older homes containing lead-based paint or lead-contaminated dust often exceed 5 µg/dL, the level at which the Centers for Disease Control and Prevention (CDC) recommends that measures be taken to limit further exposure. A dramatic case of lead contamination of drinking water occurred in Flint, Michigan, in 2014–2016. The Flint water crisis occurred when the source of water supply to the city was changed from Lake Huron to the Flint River. Because water from the Flint River had a higher chloride concentration than the lake waters, it leached lead from century-old lead pipes. This caused an increase in lead levels in tap water above the acceptable limit of 15 parts per billion (ppb) in about 25% of the homes and in some cases as high as 13,200 ppb. As a result, 6000 to 12,000 residents developed very high lead levels in their blood. Ingested lead is particularly harmful to children because they absorb more than 50% of lead from food, whereas adults absorb approximately 15%. A more permeable blood–brain barrier in children creates a high susceptibility to brain damage. The main clinical features of lead poisoning in children and adults are shown in Figs. 9.4 and 9.5.

Most absorbed lead (80% to 85%) is taken up into developing teeth and into bone, where it competes with calcium, binds phosphates, and has a half-life of 20 to 30 years. About 5% to 10% of the absorbed lead remains in the blood, and the remainder is distributed throughout soft tissues. Excess lead is toxic to nervous tissues in adults and children; peripheral neuropathies predominate in adults, whereas central effects are more common in children. The effects of chronic lead exposure in children may be subtle, producing mild dysfunction, including reduced IQ, learning disabilities, and delayed psychomotor development. At higher doses, however, the results can be devastating, taking the form of blindness, psychoses, seizures, coma, and even death. Lead-induced peripheral neuropathies in adults generally remit with the elimination of exposure, but both peripheral nervous system and CNS abnormalities in children usually are irreversible.

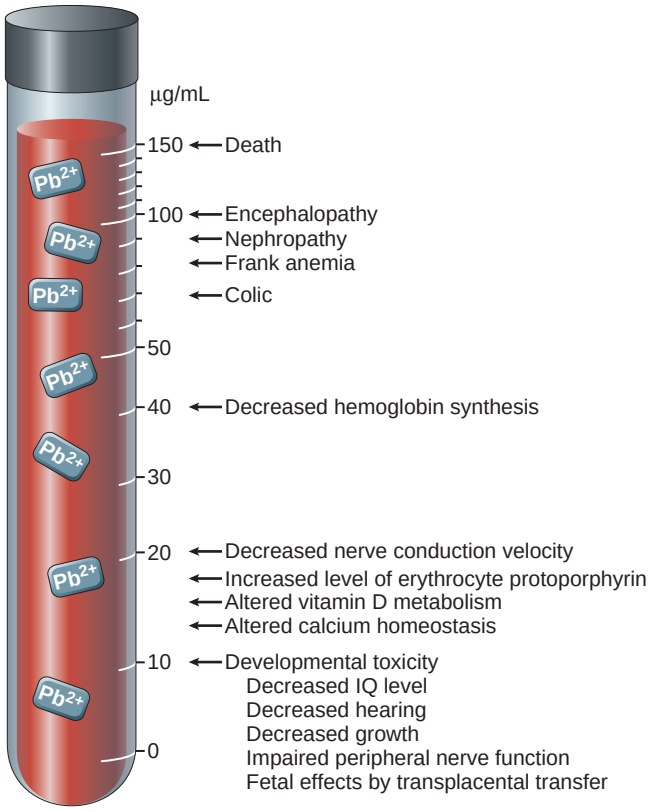

Figure 9.4 Effects of lead poisoning in children related to blood levels. (Modified from Bellinger DC, Bellinger AM: Childhood lead poisoning: the tortuous path from science to policy, *J Clin Invest* 116:853; 2006.)

Lead also affects many other tissues. Excess lead interferes with the normal remodeling of calcified cartilage and primary bone trabeculae in the epiphyses in children, causing increased bone density detected as radiodense lead lines (Fig. 9.6). Lead lines of a different sort also may occur in the gums, where excess lead stimulates hyperpigmentation. Lead inhibits the healing of fractures by increasing chondrogenesis and delaying cartilage mineralization. Excretion of lead occurs by way of the kidneys, and acute exposures may cause damage to proximal tubules.

Lead has a high affinity for sulfhydryl groups and interferes with two enzymes involved in heme synthesis: delta-aminolevulinic acid dehydratase and ferrochelatase. Iron incorporation into heme is impaired, leading to *microcytosis* (small red cells) and anemia. Lead also inhibits sodium- and potassium-dependent adenosine triphosphatases (ATPases) in cell membranes, an effect that may increase the fragility of red cells, causing hemolysis. The diagnosis of lead poisoning requires constant vigilance. It may be suspected on the basis of neurologic changes in children or unexplained microcytic anemia with basophilic stippling in red cells in adults and children. Elevated blood lead and red cell free protoporphyrin levels (greater than 50 µg/dL) or, alternatively, zinc protoporphyrin levels, are required for definitive diagnosis. In milder cases of lead exposure, anemia may be the only abnormality.

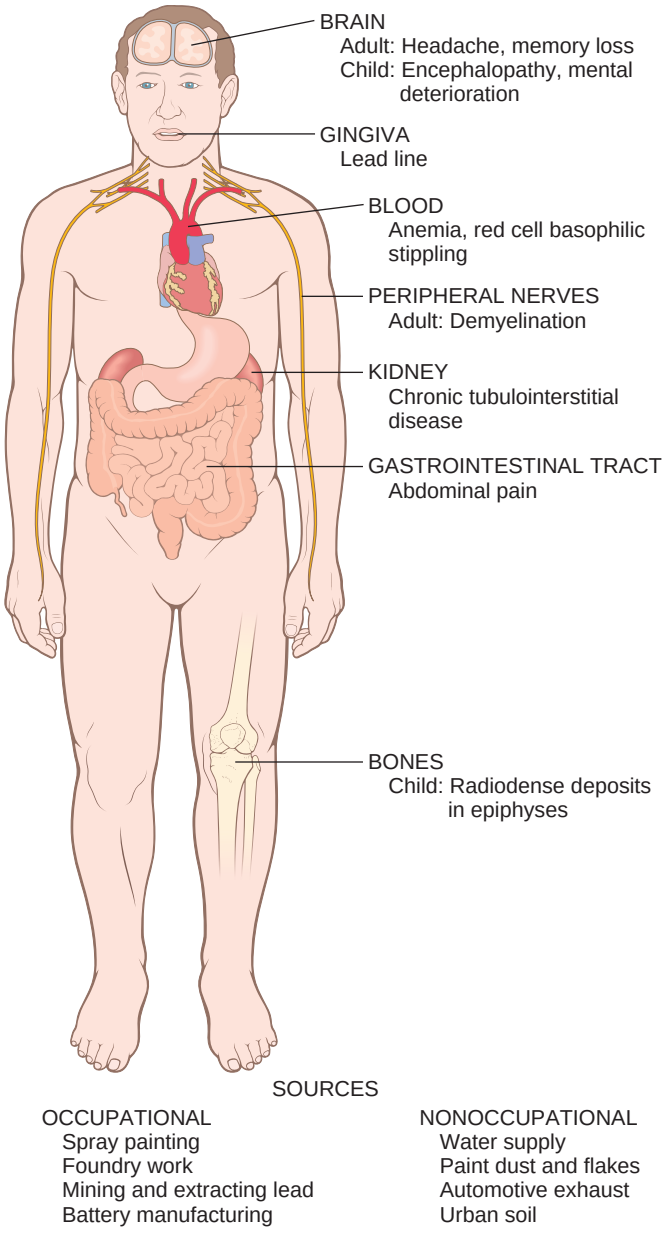

Figure 9.5 Pathologic features of lead poisoning in adults.

MORPHOLOGY

The major anatomic targets of lead toxicity are the bone marrow and blood, nervous system, gastrointestinal tract, and kidneys (see Fig. 9.5).

Blood and marrow changes occur fairly rapidly and are characteristic. The inhibition of ferrochelatase by lead may result in the appearance of a few **ring sideroblasts,** red cell precursors with iron-laden mitochondria that are detected with a Prussian blue stain. In the peripheral blood the defect in hemoglobin synthesis appears as a **microcytic, hypochromic anemia** that is often accompanied by mild **hemolysis.** Even more distinctive is a **punctate basophilic stippling of the red cells.**

Brain damage is prone to occur in children. In young children, sensory, motor, intellectual, and psychologic have been described. Lead toxicity in a pregnant woman may impair brain development in the fetus. The anatomic changes underlying the subtle functional deficits are ill-defined, but there is concern that these defects may be permanent. At the more severe end of the spectrum there is marked brain edema, demyelination of the cerebral and cerebellar white matter, and necrosis of cortical neurons accompanied by diffuse astrocytic proliferation. In adults the CNS is less often affected, but frequently **a peripheral demyelinating neuropathy** appears, typically involving the motor nerves of the most commonly used muscles. Thus the extensor muscles of the wrist and fingers are often the first to be affected (causing wristdrop), followed by paralysis of the peroneal muscles (causing footdrop).

The **gastrointestinal tract** is also a major source of clinical manifestations. Lead colic is characterized by severe, poorly localized abdominal pain.

Kidneys may develop proximal tubular damage associated with intranuclear inclusions consisting of protein aggregates. Chronic renal damage leads eventually to interstitial fibrosis and renal failure. Decreases in uric acid excretion can lead to gout (saturnine gout).

Mercury

Like lead, mercury binds to sulfhydryl groups in certain proteins with high affinity, leading to damage in the CNS and the kidney. Mercury has had many uses throughout history, for example, as a pigment in cave paintings, a cosmetic, a remedy for syphilis, and a component of diuretics. Alchemists tried (without much success) to produce gold from mercury.

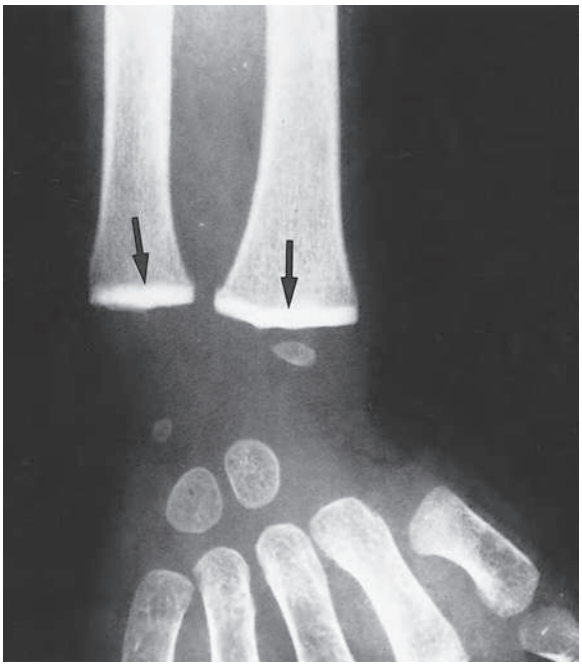

Figure 9.6 Lead poisoning. Impaired remodeling of calcified cartilage in the epiphyses *(arrows)* of the wrist has caused a marked increase in their radiodensity so that they are as radiopaque as the cortical bone. (Courtesy Dr. G. W. Dietz, Department of Radiology, University of Texas Southwestern Medical School, Dallas, Tex.)

Poisoning from inhalation of mercury vapors has long been recognized and is associated with tremor, gingivitis, and bizarre behavior, such as that displayed by the Mad Hatter in *Alice in Wonderland*. There are three forms of mercury: metallic mercury (also referred to as elemental mercury), inorganic mercury compounds (mostly mercuric chloride), and organic mercury (mostly methyl mercury). Today, the main sources of exposure to mercury are contaminated fish (methyl mercury) and mercury vapors released from metallic mercury in dental amalgams, a possible occupational hazard for dental workers. In some areas of the world, mercury used in gold mining has contaminated rivers and streams.

Inorganic mercury from the natural degassing of the earth's crust or from industrial contamination is converted to organic compounds such as methyl mercury by bacteria. Methyl mercury enters the food chain, and in carnivorous fish such as swordfish, shark, and bluefish, mercury levels may be 1 million times higher than in the surrounding water. Almost 90% of ingested methyl mercury is absorbed in the gastrointestinal tract. The consumption of fish contaminated by the release of methyl mercury from industrial sources in Minamata Bay and the Agano River in Japan caused widespread mortality and morbidity. Acute exposure through consumption of bread made from grain treated with a methyl mercury–based fungicide in Iraq in 1971 resulted in hundreds of deaths and thousands of hospitalizations. The medical disorders associated with the Minamata episode became known as *Minamata disease* and include cerebral palsy, deafness, blindness, intellectual disability, and major CNS defects in children exposed in utero. The lipid solubility of methyl mercury and metallic mercury facilitates their accumulation in the brain, disturbing neuromotor, cognitive, and behavioral functions. Intracellular GSH, by acting as a sulfhydryl donor, is the main protective mechanism against mercury-induced CNS and kidney damage.

Mercury continues to be released into the environment by power plants and other industrial sources, and there are serious concerns about the effects of chronic low-level exposure to methyl mercury in the food supply. To protect against potential fetal brain damage, the CDC has recommended that pregnant women avoid consumption of fish known to contain high levels of mercury. Ingested mercury can injure the gut and cause ulcerations and bloody diarrhea. In the kidneys, mercury can cause acute tubular necrosis and renal failure. Chronic exposure can cause nephrotic syndrome.

Arsenic

Arsenic salts interfere with several aspects of cellular metabolism, leading to toxicities that are most prominent in the gastrointestinal tract, nervous system, skin, and heart. Arsenic was the poison of choice in Renaissance Italy, with members of the Borgia and Medici families being highly skilled practitioners of the art of its use. Because of its favored use as an instrument of assassination among royal families, arsenic has been called "the poison of kings and the king of poisons." Deliberate poisoning is rare today, but unintentional exposure to arsenic is an important health problem in many areas of the world. Arsenic is found naturally in soils and water and is used in products such as wood preservers and herbicides and other agricultural products. It may be released into the environment from mines and smelting industries. Arsenic is present in Chinese and Indian herbal medicine, and high concentrations of inorganic arsenic are present in groundwater in countries such as Bangladesh, Chile, and China. It is estimated that 40 million people in Bangladesh drink water contaminated with arsenic, constituting one of the greatest environmental cancer risks yet uncovered.

The most toxic forms of arsenic are the trivalent compounds arsenic trioxide, sodium arsenite, and arsenic trichloride. If ingested in large quantities, arsenic causes acute gastrointestinal, cardiovascular, and CNS toxicities that are often fatal. These effects may be attributed in part to interference with mitochondrial oxidative phosphorylation, since trivalent arsenic can replace the phosphates in ATP. However, arsenic also has pleiotropic effects on the activity of a number of other enzymes and ion channels, and these too may contribute to certain toxicities.

- *Neurologic effects* usually occur 2 to 8 weeks after exposure and consist of a sensorimotor neuropathy that causes paresthesias, numbness, and pain.
- *Cardiovascular effects* include hypertension and prolonged Q-Tc interval with ventricular arrhythmias.
- *Skin changes* consisting of hyperpigmentation and hyperkeratosis occur with chronic exposure.
- *Increased risk for the development of cancers is* the most serious consequence of chronic exposure, particularly of the lung, bladder, and skin. Arsenic-induced skin tumors differ from those induced by sunlight; they are often multiple and usually appear on the palms and soles. The mechanisms of arsenic carcinogenesis in skin and lung have not been elucidated but may involve defects in nucleotide excision repair mechanisms that protect against DNA damage.

Cadmium

Cadmium is preferentially toxic to the kidneys and the lungs through uncertain mechanisms that may involve increased production of ROS. In contrast to the other metals discussed in this section, cadmium toxicity is a relatively modern problem. It is an occupational and environmental pollutant generated by mining, electroplating, and production of nickel-cadmium batteries, which are usually disposed of as household waste. Cadmium can contaminate the soil and plants directly or through fertilizers and irrigation water. Food is the most important source of cadmium exposure for the general population. Its toxic effects require its uptake into cells via transporters such as ZIP8, which normally serves as a transporter for zinc.

The principal toxic effects of excess cadmium are a form of obstructive lung disease caused by necrosis of alveolar epithelial cells and renal tubular damage that may progress to end-stage renal disease. Cadmium exposure can also cause skeletal abnormalities associated with calcium loss. Cadmium-containing water used to irrigate rice fields in Japan caused a disease in postmenopausal women known as *itai-itai* ("ouch-ouch"), a combination of osteoporosis and osteomalacia associated with renal disease. Cadmium exposure is also associated with an elevated risk of lung cancer, which has been demonstrated in workers exposed occupationally and in populations living near zinc

smelters. Cadmium is not directly genotoxic and most likely produces DNA damage through the generation of ROS (Chapter 2).

KEY CONCEPTS

TOXIC EFFECTS OF HEAVY METALS

- Lead, mercury, arsenic, and cadmium are the heavy metals most commonly associated with toxic effects in humans.
- Children absorb more ingested lead than adults; the main source of exposure for children is lead-containing paint in older housing and lead-containing drinking water.
- Excess lead causes CNS defects in children and peripheral neuropathy in adults. It also interferes with the remodeling of cartilage and causes anemia by interfering with hemoglobin synthesis.
- The major source of exposure to mercury is contaminated fish. The developing brain is highly sensitive to methyl mercury, which accumulates in the CNS.
- Exposure of the fetus to high levels of mercury in utero may lead to Minamata disease, characterized by cerebral palsy, deafness, and blindness.
- Arsenic is naturally found in soil and water and is a component of some wood preservatives and herbicides. Excess arsenic interferes with mitochondrial oxidative phosphorylation and the function of a variety of proteins. It causes toxic effects in the gastrointestinal tract, CNS, and cardiovascular system; long-term exposure causes skin lesions and carcinomas.
- Cadmium from nickel-cadmium batteries and chemical fertilizers can contaminate soil. Excess cadmium causes obstructive lung disease and kidney damage.

OCCUPATIONAL HEALTH RISKS: INDUSTRIAL AND AGRICULTURAL EXPOSURES

More than 10 million occupational injuries occur annually in the United States, and approximately 65,000 people die as a consequence of occupational injuries and illnesses. About 10% of these deaths occur due to falls and other traumatic injuries, while the remainder are secondary to toxic exposures that lead to cancer, lung disease, and other potentially fatal conditions. Industrial exposures to toxic agents are as varied as the industries themselves. They range from merely annoying irritations of respiratory airways by formaldehyde or ammonia fumes to lung cancers arising from exposure to asbestos, arsenic, or uranium. Human diseases associated with occupational exposures are listed in Table 9.2. In addition to toxic metals (already discussed), other important agents that contribute to environmental diseases include the following:

- *Organic solvents* are widely used in huge quantities worldwide. Some, such as *chloroform* and *carbon tetrachloride,* are found in degreasing and dry cleaning agents and paint removers. Acute exposure to high levels of these agents can cause dizziness and confusion, CNS depression, and even coma. Lower levels may cause liver and kidney toxicity. Occupational exposure to *benzene* and *1,3-butadiene* increases the risk of leukemia. Benzene is oxidized to an epoxide through hepatic CYP2E1, a component of the P-450 enzyme system already mentioned. The epoxide and other metabolites disrupt progenitor cell differentiation

Table 9.2 Human Diseases Associated With Occupational Exposures

Organ/System	Effect	Toxicant
Cardiovascular system	Heart disease	Carbon monoxide, lead, solvents, cobalt, cadmium
Respiratory system	Nasal cancer	Isopropyl alcohol, wood dust
	Lung cancer	Radon, asbestos, silica, bis(chloromethyl) ether, nickel, arsenic, chromium, mustard gas, uranium
	Chronic obstructive pulmonary disease	Grain dust, coal dust, cadmium
	Hypersensitivity	Beryllium, isocyanates
	Irritation	Ammonia, sulfur oxides, formaldehyde
	Fibrosis	Silica, asbestos, cobalt
Nervous system	Peripheral neuropathies	Solvents, acrylamide, methyl chloride, mercury, lead, arsenic, DDT
	Ataxic gait	Chlordane, toluene, acrylamide, mercury
	CNS depression	Alcohols, ketones, aldehydes, solvents
	Cataracts	Ultraviolet radiation
Urinary system	Renal toxicity	Mercury, lead, glycol ethers, solvents
	Bladder cancer	Naphthylamines, 4-aminobiphenyl, benzidine, rubber products
Reproductive system	Male infertility	Lead, phthalate plasticizers, cadmium
	Female infertility	Lead, mercury
	Stillbirths	Lead, mercury
	Teratogenesis	Mercury, polychlorinated biphenyls
Hematopoietic system	Leukemia	Benzene
Skin	Folliculitis and acneiform dermatosis	Polychlorinated biphenyls, dioxins, herbicides
	Cancer	Ultraviolet radiation
Gastrointestinal tract	Liver angiosarcoma	Vinyl chloride

CNS, Central nervous system; *DDT,* dichlorodiphenyltrichloroethane.

Data from Leigh JP, et al: Occupational injury and illness in the United States. Estimates of costs, morbidity, and mortality, *Arch Intern Med* 157:1557, 1997; Mitchell FL: Hazardous waste. In Rom WN, editor: *Environmental and Occupational Medicine,* ed 2, Boston, 1992, Little, Brown, p 1275; and Levi PE: Classes of toxic chemicals. In Hodgson E, Levi PE, editors: *A Textbook of Modern Toxicology,* Stamford, Conn, 1997, Appleton & Lange, p 229.

in the bone marrow and may lead to marrow aplasia and acute myeloid leukemia.

- *Polycyclic hydrocarbons* are released during the combustion of coal and gas, particularly at the high temperatures used in steel foundries, and also are present in tar and soot. (Pott identified soot as the cause of scrotal cancers in chimney sweeps in 1775, as mentioned in Chapter 7). Polycyclic hydrocarbons are among the most potent carcinogens, and industrial exposures have been implicated in the causation of lung and bladder cancer.
- *Organochlorines* (and halogenated organic compounds in general) are synthetic products that resist degradation and are lipophilic. Organochlorines used as pesticides are *dichlorodiphenyltrichloroethane (DDT)* and its metabolites and agents such as lindane, aldrin, and dieldrin. Nonpesticide organochlorines include *polychlorinated biphenyls (PCBs)* and *dioxin* (2,3,7,8-tetrachlorodibenzo-*p*-dioxin [TCDD]). DDT was banned in the United States in 1973. Acute DDT poisoning in humans causes neurologic toxicity. Most organochlorines are endocrine disruptors and have antiestrogenic or antiandrogenic activity in laboratory animals, but long-term health effects in humans have not been firmly established.
- *Nonpesticide organochlorines* include *PCBs* and *dioxin* (TCDD). Dioxins and PCBs can cause skin disorders such as folliculitis and acneiform dermatosis known as chloracne, which consists of acne, cyst formation, hyperpigmentation, and hyperkeratosis, generally around the face and behind the ears. It can be accompanied by abnormalities in the liver and CNS. Because PCBs induce the P-450 enzyme system, workers exposed to these substances may show altered drug metabolism. Environmental disasters in Japan and China in the late 1960s caused by the consumption of rice oil contaminated by PCBs poisoned about 2000 people in each episode. The primary manifestations of the disease (yusho in Japan, yu-cheng in China) were chloracne and hyperpigmentation of the skin and nails.
- *Bisphenol A* (BPA) is used in the synthesis of polycarbonate food and water containers and of epoxy resins that line almost all food bottles and cans; as a result, exposure to BPA is virtually ubiquitous in humans. BPA has long been known as a potential endocrine disruptor. Several large retrospective studies have linked elevated urinary BPA levels to heart disease in adult populations. In addition, infants who drink from BPA-containing containers may be particularly susceptible to the endocrine effects of BPA. In 2010, Canada was the first country to list BPA as a toxic substance, and the largest makers of baby bottles and "sippy" cups have stopped using BPA in the manufacturing process. The extent of the human health risks associated with BPA remains uncertain.
- *Vinyl chloride,* used in the synthesis of polyvinyl resins, can cause angiosarcoma of the liver, a rare type of liver tumor.
- Inhalation of *mineral dusts* causes chronic, nonneoplastic lung diseases called *pneumoconioses.* This group of disorders includes diseases induced by organic and inorganic particulates as well as chemical fume- and vapor-induced nonneoplastic lung diseases. The most common pneumoconioses are caused by exposures to coal dust (in mining of hard coal), silica (in sandblasting and stone cutting), asbestos (in mining, fabrication, and insulation work), and beryllium (in mining and fabrication). Exposure to these agents nearly always occurs in the workplace. The increased risk of cancer as a result of asbestos exposure, however, extends to family members of asbestos workers and to other persons exposed outside the workplace. Pneumoconioses and their pathogenesis are discussed in Chapter 13.

Effects of Tobacco

Smoking is the most readily preventable cause of death in humans. The main culprit is cigarette smoking, but smokeless tobacco (e.g., snuff, chewing tobacco) is also harmful to health and an important cause of oral cancer. The use of tobacco products not only creates personal risks, but passive tobacco inhalation from the environment *(second-hand smoke)* can cause lung cancer in nonsmokers. More than 20 million US residents have died of smoking-related diseases since the 1964 Surgeon General's report on the adverse effects of smoking. Of these, almost 2.5 million died as a result of inhalation of second-hand smoke. More than 10 times as many people in the United States have died as a result of cigarette smoking than have died in all the wars fought by the United States in its entire history. Annually, tobacco is responsible for more than 400,000 deaths in the United States, one-third of these due to lung cancer. Indeed, tobacco is the leading exogenous cause of human cancers, including 90% of lung cancers.

Worldwide, two-thirds of smokers live in 10 countries, led by China, which accounts for nearly 30%, and India with about 10%, followed by Indonesia, Russia, the United States, Japan, Brazil, Bangladesh, Germany, and Turkey.

From 1998 to 2007 in the United States, the incidence of smoking declined modestly, but this trend failed to continue, and approximately 20% of adults remain smokers. More disturbing, the world's most populous country, China, has become the world's largest producer and consumer of cigarettes. China has approximately 350 million smokers who in aggregate consume about 33% of all cigarettes smoked worldwide. It is estimated that more than 1 million people in China die each year of smoking-related diseases; this rate is projected to rise to 8 million deaths each year by 2050. Worldwide, cigarette smoking causes more than 4 million deaths annually, mostly from cardiovascular disease, various types of cancers, and chronic respiratory problems. These figures are expected to rise to 8 million tobacco-related deaths by 2020, the major increase occurring in lower income countries. Of people alive today, an estimated 500 million will die of tobacco-related illnesses.

Tobacco reduces overall survival through dose-dependent effects that are often expressed as pack-years, the average number of cigarette packs smoked each day multiplied by the number of years of smoking. The cumulative effects of smoking over time are striking. For instance, while about 75% of nonsmokers are alive at age 70, only about 50% of smokers survive to that age (Fig. 9.7). The only good news is that cessation of smoking greatly reduces, within 5 years, overall mortality and the risk of death from cardiovascular diseases. Lung cancer mortality decreases by 21% within 5 years, but the excess risk persists for 30 years.

The number of potentially noxious chemicals in tobacco smoke is extraordinary. Tobacco smoke contains a complex

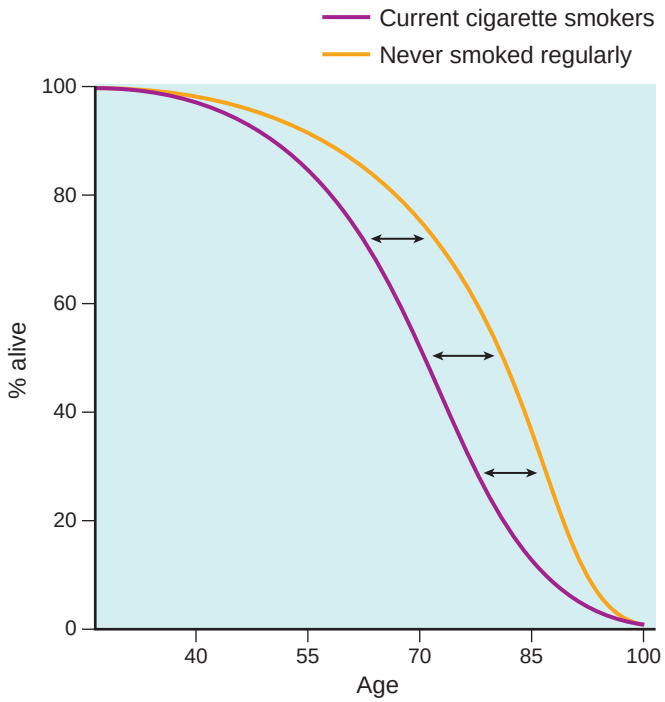

Figure 9.7 Effects of smoking on survival. The study compared age-specific death rates for current cigarette smokers with death rates of individuals who never smoked regularly (British Doctors Study). Measured at age 75, the difference in survival between smokers and nonsmokers is 7.5 years. (Modified from Stewart BW, Kleihues P, editors: *World Cancer Report,* Lyon, 2003, IARC Press.)

mixture of 7000 chemicals, more than 60 of which have been identified as carcinogens. Table 9.3 provides only a partial list and includes various types of injuries produced by these agents.

Nicotine, an alkaloid present in tobacco leaves, is strongly addictive. Nicotine binds to nicotinic acetylcholine receptors in the brain, and stimulates the release of catecholamines from sympathetic neurons. This activity is responsible for the acute effects of smoking, such as the increase in heart rate and blood pressure and the elevation in cardiac contractility and output. Recent studies indicate that in addition to being addictive, nicotine has other untoward effects. These include effects on the fetus, as nicotine, exposure affects fetal brain development and contributes to preterm birth and still birth.

Table 9.3 Effects of Selected Tobacco Smoke Constituents

Substance	Effect
Tar	Carcinogenesis
Polycyclic aromatic hydrocarbons	Carcinogenesis
Nicotine	Ganglionic stimulation and depression; tumor promotion
Phenol	Tumor promotion; mucosal irritation
Benzo[*a*]pyrene	Carcinogenesis
Carbon monoxide	Impaired oxygen transport and utilization
Formaldehyde	Toxicity to cilia; mucosal irritation
Nitrogen oxides	Toxicity to cilia; mucosal irritation
Nitrosamine	Carcinogenesis

Table 9.4 Suspected Organ-Specific Carcinogens in Tobacco Smoke

Organ	Carcinogen
Lung, larynx	Polycyclic aromatic hydrocarbons 4-(Methylnitrosoamino)-1-(3-pyridyl)-1-butanone (NNK) Polonium 210
Esophagus	*N*′-Nitrosonornicotine (NNN)
Pancreas	NNK
Bladder	4-Aminobiphenyl, 2-naphthylamine
Oral cavity (smoking)	Polycyclic aromatic hydrocarbons, NNK, NNN
Oral cavity (snuff)	NNK, NNN, polonium 210

Data from Szczesny LB, Holbrook JH: Cigarette smoking. In Rom WH, editor: *Environmental and Occupational Medicine,* ed 2, Boston, 1992, Little, Brown, p 1211.

Smoking and Lung Cancer. Agents in smoke have a direct irritant effect on the tracheobronchial mucosa, producing increased mucus production (bronchitis). Components of cigarette smoke, particularly polycyclic hydrocarbons and nitrosamines (Table 9.4), are potent carcinogens in animals and are directly involved in the development of lung cancer in humans. CYPs (cytochrome P-450 phase I enzymes) and phase II enzymes increase the water solubility of the carcinogens, facilitating their excretion. However, some intermediates produced by CYPs are electrophilic and form DNA adducts that are repaired by error-prone mechanisms, leading to potentially oncogenic mutations (Chapter 7). Most tellingly, deep sequencing of the genomes of lung cancers that occur in smokers has revealed the presence of thousands of mutations of a type that is produced by carcinogens in tobacco smoke in experimental settings. The risk of developing lung cancer is related to the number of pack-years or cigarettes smoked per day (Fig. 9.8). Moreover, smoking increases the risk of other carcinogenic influences. Witness the 10-fold higher incidence of lung carcinomas in asbestos workers and uranium miners who smoke over those who do not smoke and the interaction between tobacco consumption and alcohol in the development of oral and laryngeal cancers (Fig. 9.9).

Smoking and Other Diseases. In addition to lung cancer, smoking is linked to many other malignant and nonmalignant disorders that affect numerous organ systems (Fig. 9.10).

- Cigarette smoking is associated with *cancers of the esophagus, pancreas, bladder, kidney, cervix,* and *bone marrow*. To this list, the latest report of the US Surgeon General has added *carcinomas of the liver and colon;* the latter is the second most common cause of cancer deaths.
- *The toll taken by nonmalignant conditions* associated with smoking is even more terrible. Agents in smoke have a direct irritant effect on the tracheobronchial mucosa, producing inflammation and increased mucus production (bronchitis). Cigarette smoke also causes the recruitment of leukocytes to the lung, with increased local elastase production and subsequent injury to lung tissue, leading

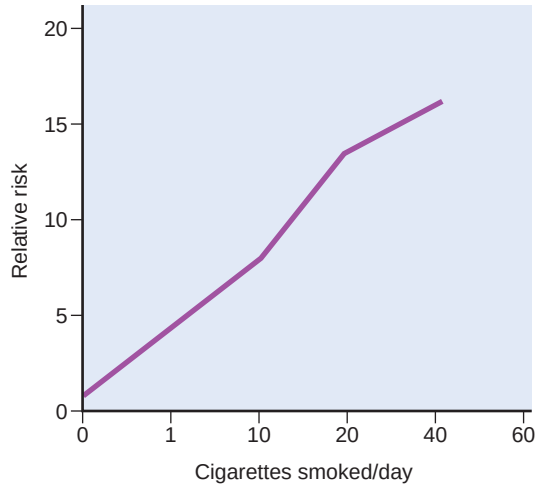

Figure 9.8 The risk of lung cancer is determined by the number of cigarettes smoked. (Modified from Stewart BW, Kleihues P, editors: *World Cancer Report,* Lyon, 2003, IARC Press.)

to emphysema, chronic bronchitis, and chronic obstructive pulmonary disease, conditions that are discussed in Chapter 15. Smoking exacerbates asthma and increases the risk for pulmonary tuberculosis.

- *Cigarette smoking is strongly linked to the development of atherosclerosis* and its major complications, myocardial infarction and stroke. The causal mechanisms probably relate to several factors including increased platelet aggregation, decreased myocardial oxygen supply

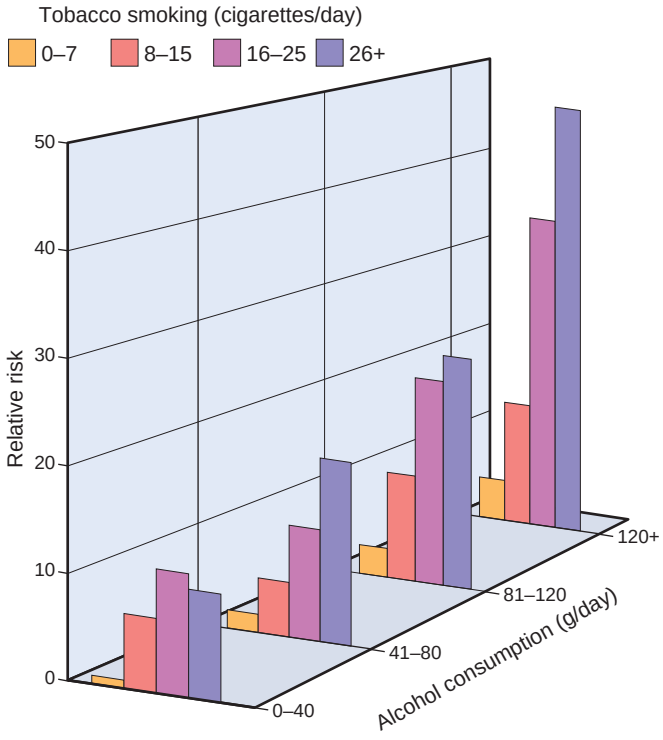

Figure 9.9 Multiplicative increase in the risk of laryngeal cancer from the interaction between cigarette smoking and alcohol consumption. (Modified from Stewart BW, Kleihues P, editors: *World Cancer Report,* Lyon, 2003, IARC Press.)

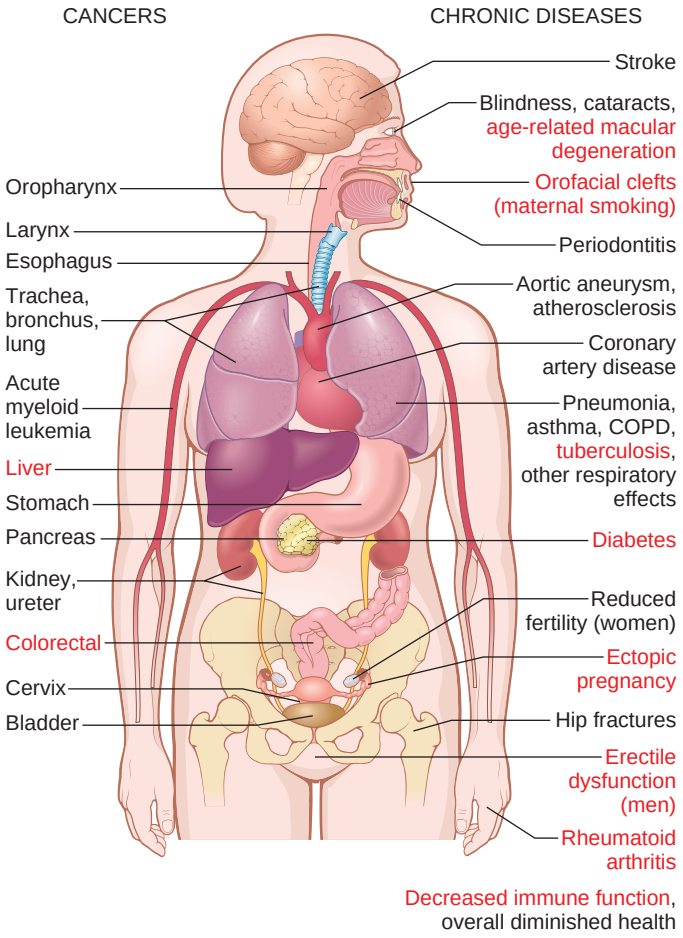

Figure 9.10 Health consequences causally linked to smoking. Items in red are new diseases added in the 2016 report from the Surgeon General (US Department of Health and Human Services. The Health Consequences of Smoking—50 Years of Progress: A Report of the Surgeon General. Atlanta, Ga, 2016, US Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health). *COPD,* Chronic obstructive pulmonary disease.

(because of significant lung disease coupled with the hypoxia related to the CO content of cigarette smoke) accompanied by increased myocardial oxygen demand and a decreased threshold for ventricular fibrillation. Smoking has a multiplicative effect on the incidence of myocardial infarction when combined with hypertension and hypercholesterolemia.

- *Smoking also harms the developing fetus.* Maternal smoking increases the risk of spontaneous abortions and preterm births and results in *intrauterine growth retardation* (Chapter 10). Birth weights of infants born to mothers who stopped smoking before pregnancy are, however, normal.
- The latest US Surgeon General's report has added several new diseases to the previously known list of smoking-associated diseases (Fig. 9.10). *Smoking increases the risk of type 2 diabetes, rheumatoid arthritis, age-related macular degeneration, ectopic pregnancy, and erectile dysfunction.*
- Exposure to environmental tobacco smoke *(passive smoke inhalation)* is associated with some of the same detrimental

effects that result from active smoking. It is estimated that the relative risk of lung cancer in nonsmokers exposed to environmental smoke is about 1.3 times higher than that of nonsmokers who are not exposed to smoke. In the United States, approximately 3000 lung cancer deaths in nonsmokers older than 35 years can be attributed each year to environmental tobacco smoke. Even more striking is the increased risk of coronary atherosclerosis and fatal myocardial infarction. Studies report that every year 30,000 to 60,000 cardiac deaths in the United States are associated with exposure to passive smoke. Children living in a household with an adult who smokes have an increased frequency of respiratory illnesses such as asthma. Passive smoke inhalation in nonsmokers can be estimated by measuring the blood levels of cotinine, a metabolite of nicotine. In the United States, median cotinine levels in nonsmokers have decreased by more than 60% since around 2000 because of the adoption of nonsmoking policies in public places. However, passive exposure to tobacco smoke in the home remains a major public health concern, particularly for children. It is clear that the transient pleasure of smoking comes with a heavy long-term price.

- *Electronic cigarettes* (e-cigarettes), devices that simulate cigarette smoking by delivering vaporized nicotine and flavorings, are rising in popularity. The use of flavored e-cigarettes, called "vaping," has been on the increase in recent years, especially among young adults. While for several years after the introduction of e-cigarettes no significant untoward effects were recorded, starting in the summer of 2019 an outbreak of vaping-associated acute lung injury occurred in the United States. By the end of 2019 close to 2000 cases had been reported to the CDC, with 42 fatalities. The pathogenesis of this outbreak is under intense investigations.

KEY CONCEPTS

HEALTH EFFECTS OF TOBACCO

- Smoking is the most prevalent preventable cause of human death.
- Tobacco smoke contains more than 7000 compounds. Among these are nicotine, which is responsible for tobacco addiction, and potent carcinogens—mainly, polycyclic aromatic hydrocarbons, nitrosamines, and aromatic amines. Nicotine also has other adverse effects, particularly on fetal development, and is associated with preterm birth and stillbirth.
- Approximately 90% of lung cancers occur in smokers. Smoking is also associated with an increased risk of cancers of the oral cavity, larynx, esophagus, stomach, bladder, and kidney, some forms of leukemia, as well as liver and colorectal cancer. Cessation of smoking reduces the risk of lung cancer.
- Smokeless tobacco use is an important cause of oral cancers. Tobacco consumption interacts with alcohol in multiplying the risk of oral, laryngeal, and esophageal cancer and increases the risk of lung cancers from occupational exposures to asbestos, uranium, and other agents.
- Tobacco use is an important risk factor for development of atherosclerosis and myocardial infarction, peripheral vascular disease, and cerebrovascular disease. In the lungs, in addition to cancer, it predisposes to emphysema, chronic bronchitis, and chronic obstructive pulmonary disease.
- Maternal smoking increases the risk of spontaneous abortion, premature birth, and intrauterine growth retardation.

EFFECTS OF ALCOHOL

Ethanol consumption in moderate amounts is generally not injurious (and may even protect against some disorders), but in excessive amounts alcohol causes serious physical and psychologic damage. In this section, we describe alcohol metabolism and the major health consequences associated with alcohol abuse.

Despite all the attention given to illicit drugs such as cocaine and opiates, alcohol abuse is a far more widespread hazard and claims many more lives. According to a 2017 survey conducted by the National Institute on Alcohol Abuse and Alcoholism, 60% of the people reported using alcohol in the previous month. Even more worrisome is the fact that 14 million of adults (over 18 years of age) suffer from alcohol abuse disorder (AUD) in the United States (5.7% of this age group). AUD is a chronic relapsing brain disease characterized by an impaired ability to stop or control alcohol use despite adverse social, occupational, or health consequences. It is estimated that alcohol consumption is responsible for more than 80,000 deaths annually. More than 50% of these deaths result from accidents caused by drunken driving and alcohol-related homicides and suicides, and about 15,000 annual deaths are a consequence of cirrhosis of the liver. Worldwide, alcohol accounts for approximately 3.3 million deaths per year (5.9% of all deaths).

After consumption, ethanol is absorbed unaltered in the stomach and small intestine and then distributes throughout the body in direct proportion to the blood level. Less than 10% is excreted unchanged in the urine, sweat, and breath. The amount exhaled is proportional to the blood level and forms the basis for the breath test used by law enforcement agencies. A concentration of 80 mg/dL in the blood constitutes the legal definition of drunk driving in most states. For an average individual, this alcohol concentration is reached after consumption of three standard drinks, about three (12 ounce) bottles of beer, 15 oz of wine, or 4 to 5 oz of 80-proof distilled spirits. Drowsiness occurs at 200 mg/dL, stupor at 300 mg/dL, and coma, with possible respiratory arrest, at higher levels. The rate of metabolism affects the blood alcohol level. Chronic alcoholics develop tolerance to alcohol. They metabolize alcohol at a higher rate than normal and hence show lower peak levels of alcohol than average for the same about of alcohol consumed. Most of the alcohol in the blood is metabolized to acetaldehyde in the liver by three enzyme systems: alcohol dehydrogenase, cytochrome P-450 isoenzymes, and catalase (Fig. 9.11). Of these, the main enzyme involved in alcohol metabolism is alcohol dehydrogenase, located in the cytosol of hepatocytes. At high blood alcohol levels, however, the microsomal ethanol-oxidizing system also plays an important role. This

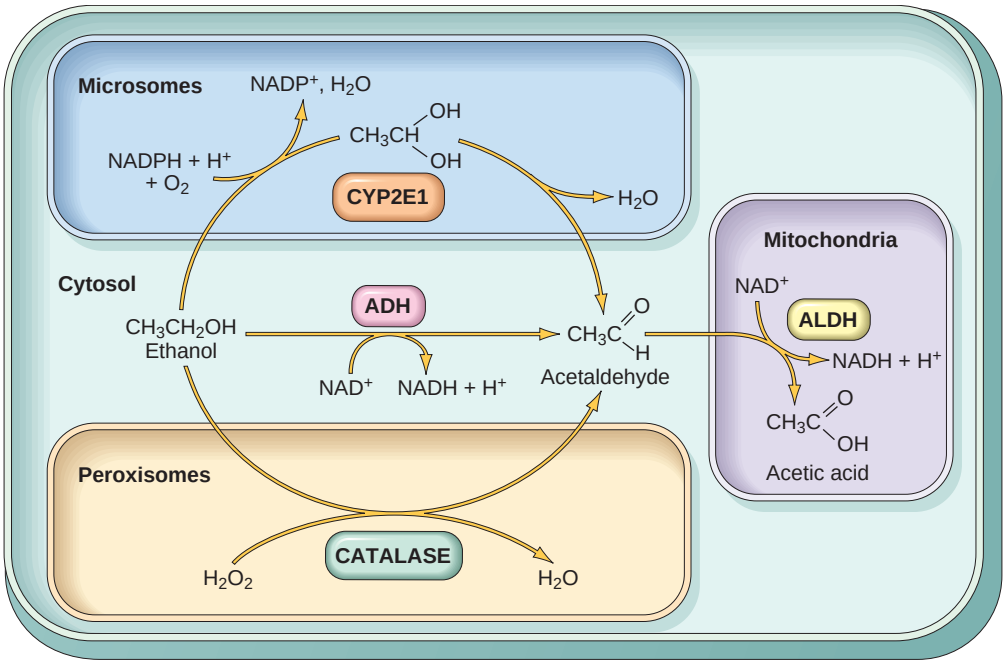

Figure 9.11 Metabolism of ethanol: oxidation of ethanol to acetaldehyde by three different routes and the generation of acetic acid. Note that oxidation by alcohol dehydrogenase *(ADH)* takes place in the cytosol; the cytochrome P-450 system and its CYP2E1 isoform are located in the endoplasmic reticulum (microsomes), and catalase is located in peroxisomes. Oxidation of acetaldehyde by aldehyde dehydrogenase *(ALDH)* occurs in mitochondria. ADH oxidation is the most important route; catalase is involved in only 5% of ethanol metabolism. Oxidation through CYPs may also generate reactive oxygen species (not shown). (From Parkinson A: Biotransformation of xenobiotics. In Klassen CD, editor: *Casarett and Doull's Toxicology: The Basic Science of Poisons*, ed 6, New York, 2001, McGraw-Hill, p 133.)

system involves cytochrome P-450 enzymes, particularly the CYP2E1 isoform, located in the smooth endoplasmic reticulum. Induction of P-450 enzymes by alcohol explains the increased susceptibility of alcoholics to other compounds metabolized by the same enzyme system, which include drugs (acetaminophen, cocaine), anesthetics, carcinogens, and industrial solvents. Of note, however, when alcohol is present in the blood at high concentrations, it competes with other CYP2E1 substrates and may delay the catabolism of other drugs, thereby potentiating their effects. Catalase is of minor importance, being responsible for only about 5% of alcohol metabolism. Acetaldehyde produced by these systems is in turn converted by acetaldehyde dehydrogenase to acetate, which is used in the mitochondrial respiratory chain or in lipid synthesis.

Several toxic effects result from ethanol metabolism. Listed here are only the most important of these.

- *Acetaldehyde,* the direct product of alcohol oxidation, has many toxic effects and is responsible for some of the acute effects of alcohol. The efficiency of alcohol metabolism varies among populations, depending on the expression levels of alcohol dehydrogenase and aldehyde dehydrogenase, as well as the presence of genetic variants that alter enzyme activity. About 50% of Asians have very low aldehyde dehydrogenase activity due to the substitution of lysine for glutamine at residue 487 (the normal allele is termed ALDH2*1, and the inactive variant is designated as ALDH2*2). The ALDH2*2 protein has dominant-negative activity, such that even one copy of the ALDH2*2 allele reduces enzyme activity significantly. Individuals homozygous for the ALDH2*2 allele are completely unable to oxidize acetaldehyde and cannot tolerate alcohol, experiencing nausea, flushing, tachycardia, and hyperventilation after its ingestion.
- *Alcohol oxidation* by alcohol dehydrogenase causes the reduction of nicotinamide adenine dinucleotide (NAD) to NADH, with a consequent decrease in NAD and increase in NADH. NAD is required for fatty acid oxidation in the liver and for the conversion of lactate into pyruvate. Its deficiency is a main cause of the accumulation of fat in the liver of alcoholics. The increase in the NADH/NAD ratio in alcoholics also causes lactic acidosis.
- *ROS generation*. Metabolism of ethanol in the liver by CYP2E1 produces ROS, which cause lipid peroxidation of hepatocyte membranes. Alcohol also provokes the release of endotoxin (lipopolysaccharide) from gram-negative bacteria in the intestinal flora, which stimulates the production of tumor necrosis factor (TNF) and other cytokines from macrophages and Kupffer cells, leading to hepatic injury.

The adverse effects of ethanol can be classified as acute or chronic.

***Acute alcoholism* exerts its effects mainly on the CNS, but it may induce hepatic and gastric changes that are reversible if alcohol consumption is discontinued.** Even with moderate intake of alcohol, multiple fat droplets accumulate in the cytoplasm of hepatocytes (fatty change or hepatic steatosis). The gastric changes are acute gastritis and ulceration. In the CNS, alcohol is a depressant, first affecting subcortical structures (probably the high brain stem

reticular formation) that modulate cerebral cortical activity. Consequently, there is stimulation and disordered cortical, motor, and intellectual behavior. At progressively higher blood levels, cortical neurons and then lower medullary centers are depressed, including those that regulate respiration. Respiratory arrest may follow.

***Chronic alcoholism* affects not only the liver and stomach, but virtually all other organs and tissues as well.** Chronic alcoholics suffer significant morbidity and have a shortened lifespan, related principally to damage to the liver, gastrointestinal tract, CNS, cardiovascular system, and pancreas.

- The *liver* is the main site of chronic injury. In addition to fatty change mentioned above, chronic alcoholism causes alcoholic hepatitis and cirrhosis, as described in Chapter 18. Cirrhosis is associated with portal hypertension and an increased risk for the development of hepatocellular carcinoma.
- In the *gastrointestinal tract,* chronic alcoholism can cause massive bleeding from gastritis, gastric ulcer, or esophageal varices (associated with cirrhosis), which may be fatal.
- *Neurologic effects.* Thiamine (vitamin B_1) deficiency is common in chronic alcoholics; the principal lesions resulting from this deficiency are peripheral neuropathies and Wernicke-Korsakoff syndrome (see Table 9.9 later and Chapter 28); cerebral atrophy, cerebellar degeneration, and optic neuropathy may also occur.
- *Cardiovascular effects*. Alcohol has diverse effects on the cardiovascular system. Injury to the myocardium may produce dilated congestive cardiomyopathy (alcoholic cardiomyopathy, discussed in Chapter 12). Chronic alcoholism is also associated with an increased incidence of hypertension, and heavy alcohol consumption, with attendant liver injury, results in decreased levels of high-density lipoprotein (HDL), increasing the likelihood of coronary heart disease.
- *Pancreatitis*. Excessive alcohol intake increases the risk of acute and chronic pancreatitis (Chapter 19).
- *Fetus.* The use of ethanol during pregnancy can cause fetal alcohol syndrome, which is marked by microcephaly, growth retardation, and facial abnormalities in the newborn and reduction in mental functions as the child grows older. It is difficult to establish the minimal amount of alcohol consumption that can cause fetal alcohol syndrome, but consumption during the first trimester of pregnancy is particularly harmful.
- *Carcinogenesis*. Chronic alcohol consumption is associated with an increased incidence of cancer of the oral cavity, esophagus, and liver. In women, low to moderate intake (12 oz beer or 5 oz of wine) incurs a slightly higher risk of breast cancer. Acetaldehyde is considered to be the main agent associated with alcohol-induced laryngeal and esophageal cancer, and acetaldehyde-DNA adducts have been detected in some tumors from these tissues. Individuals with one copy of the ALDH2*2 aldehyde dehydrogenase allele who drink are at a higher risk for developing cancer of the esophagus. As mentioned earlier, alcohol and cigarette smoke synergize in the causation of various cancers.
- *Malnutrition.* Ethanol is a substantial source of energy (empty calories). Chronic alcoholism leads to malnutrition and nutritional deficiencies, particularly of the B vitamins.

Not all is gloom and doom, however. Moderate amounts of alcohol (about 20 to 30 g/day, corresponding to approximately 250 mL of wine) appear to be protective against coronary heart disease. Possible mechanisms include increase in HDL levels, inhibition of platelet aggregation, and lowering of fibrinogen levels. It seems that the old saying is true, at least with respect to alcohol—all things in moderation!

KEY CONCEPTS

ALCOHOL—METABOLISM AND HEALTH EFFECTS

- Acute alcohol abuse causes drowsiness at blood levels of approximately 200 mg/dL. Stupor and coma develop at higher levels.
- Alcohol is oxidized to acetaldehyde in the liver by alcohol dehydrogenase, by the cytochrome P-450 system, and by catalase, which is of minor importance. Diminished ability to metabolize acetaldehyde is associated with acute toxicity and an increased risk of certain cancers.
- Alcohol oxidation by alcohol dehydrogenase depletes NAD, leading to accumulation of fat in the liver and metabolic acidosis.
- The main effects of chronic alcoholism are fatty liver, alcoholic hepatitis, and cirrhosis, which leads to portal hypertension and increases the risk for development of hepatocellular carcinoma.
- Chronic alcoholism can cause bleeding from gastritis and gastric ulcers, peripheral neuropathy associated with thiamine deficiency, alcoholic cardiomyopathy, and acute and chronic pancreatitis.
- Chronic alcoholism is a major risk factor for cancers of the oral cavity, larynx, and esophagus. The risk is greatly increased by concurrent smoking or use of smokeless tobacco.

INJURY BY THERAPEUTIC DRUGS AND DRUGS OF ABUSE

Injury by Therapeutic Drugs (Adverse Drug Reactions)

Adverse drug reactions refer to untoward effects of drugs that are given in conventional therapeutic settings. These reactions are extremely common in the practice of medicine, affecting almost 7% of patients admitted to the hospitals, with a 0.32% fatality rate (accounting for 106,000 deaths annually). An exotic, but easily seen example is discoloration of the skin caused by accumulation of an oxidized metabolite of the antibiotic minocycline (Fig. 9.12). Much more common are drug reactions that are due to direct actions of the drug or to immunologically based hypersensitivity reactions. Drug-induced hypersensitivity reactions most commonly manifest as skin rashes, but they may also mimic autoimmune disorders such as systemic lupus erythematosus (Chapter 6) or take the form of hemolytic anemia or immune thrombocytopenia (Chapter 13).

Older adults (above 65 years) are much more likely to suffer from adverse drug reactions. Table 9.5 lists common pathologic findings in adverse drug reactions and the drugs

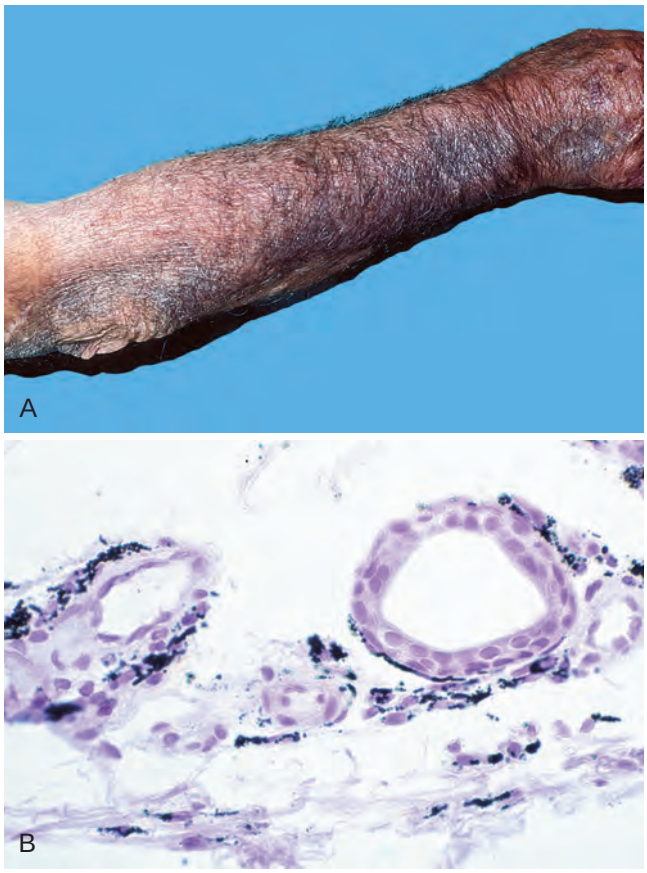

Figure 9.12 Adverse drug reaction. Skin pigmentation caused by minocycline, a long-acting tetracycline derivative. (A) Diffuse blue-gray pigmentation of the forearm. (B) Deposition of drug metabolite/iron/melanin pigment particles in the dermis. (Courtesy Dr. Zsolt Argenyi, Department of Pathology, University of Washington, Seattle, Wash.)

most frequently involved. Many of the drugs that produce adverse reactions, such as antineoplastic agents, are highly potent, and the adverse reactions are accepted risks of treatment. In this section, adverse reactions to commonly used drugs are examined, first discussing the unwelcome effects of anticoagulants, menopausal hormone therapy (MHT), and oral contraceptives (OCs) and then discussing the effects of acetaminophen and aspirin.

Anticoagulants

The two drugs that most frequently cause adverse reactions reported to the US Food and Drug Administration are the oral anticoagulants warfarin and dabigatran. Warfarin is an antagonist of vitamin K, and dabigatran is a direct inhibitor of thrombin. The principal complications associated with both of these medications are bleeding, which can be fatal, and thrombotic complications such as embolic stroke stemming from undertreatment. Warfarin is inexpensive, and its effects are easy to monitor, but many drugs and foods rich in vitamin K either interfere with its metabolism or abrogate its function. As a result, maintaining anticoagulation in a relatively safe therapeutic range can be problematic. Pharmacologic interactions of drugs with dabigatran metabolism have not been described, but many bleeding complications nevertheless occur. It is primarily used to prevent thromboembolism in patients with atrial fibrillation who are at high risk for thrombotic stroke.

Menopausal Hormone Therapy

The most common type of MHT (previously referred to as hormone replacement therapy) consists of the administration of estrogens together with a progestagen. Because of the risk of uterine cancer, therapy with estrogen alone is used only in hysterectomized women. Initially used to counteract

Table 9.5 Common Adverse Drug Reactions and Their Agents

Reaction	Major Offenders
Bone Marrow and Blood Cells[a]	
Granulocytopenia, aplastic anemia, pancytopenia	Antineoplastic agents, immunosuppressives, chloramphenicol
Hemolytic anemia, thrombocytopenia	Penicillin, methyldopa, quinidine, heparin
Cutaneous	
Urticaria, macules, papules, vesicles, petechiae, exfoliative dermatitis, fixed drug eruptions, abnormal pigmentation	Antineoplastic agents, sulfonamides, hydantoins, some antibiotics, and many other agents
Cardiac	
Arrhythmias	Theophylline, hydantoins, digoxin
Cardiomyopathy	Doxorubicin, daunorubicin
Renal	
Glomerulonephritis	Penicillamine
Acute tubular necrosis	Aminoglycoside antibiotics, cyclosporin, amphotericin B
Tubulointerstitial disease with papillary necrosis	Phenacetin, salicylates
Pulmonary	
Asthma	Salicylates
Acute pneumonitis	Nitrofurantoin
Interstitial fibrosis	Busulfan, nitrofurantoin, bleomycin
Hepatic	
Fatty change	Tetracycline
Diffuse hepatocellular damage	Halothane, isoniazid, acetaminophen
Cholestasis	Chlorpromazine, estrogens, contraceptive agents
Systemic	
Anaphylaxis	Penicillin
Lupus erythematosus syndrome (drug-induced lupus)	Hydralazine, procainamide
Bleeding	Warfarin, dabigatran
Central Nervous System	
Tinnitus and dizziness	Salicylates
Acute dystonic reactions and parkinsonian syndrome	Phenothiazine antipsychotics
Respiratory depression	Sedatives

[a]Affected in almost half of all drug-related deaths.

hot flashes and other symptoms of menopause, early clinical studies suggested that MHT use in postmenopausal women could prevent or slow the progression of osteoporosis (Chapter 26) and reduce the likelihood of myocardial infarction. However, subsequent randomized clinical trials have produced decidedly mixed results. In 2002, the Women's Health Initiative stunned the medical community by reporting that a large prospective placebo-controlled trial failed to find support for some of the presumed beneficial effects of the therapy. This study involved approximately 17,000 women who were taking a combination of estrogen (conjugated equine estrogens) and a synthetic progestin (medroxyprogesterone acetate). Although MHT did reduce the number of fractures in women on treatment, researchers also reported that after 5 years of treatment, combination MHT increased the risk of breast cancer (Chapter 23), stroke, and venous thromboembolism (VTE) and had no effect on the incidence of coronary heart disease. The shock waves produced by these findings led to a drastic decrease in the use of MHT, from 22% to 4.7% in 2010, which was accompanied by an apparent drop in the incidence of newly diagnosed breast cancers. But during the past few years there has been a reappraisal of the risks and benefits of MHT. These newer analyses showed that **MHT effects depend on the type of hormone therapy regimen used (combination estrogen-progestin versus estrogen alone); the age and risk factor status of the woman at the start of treatment; the duration of the treatment; and possibly the hormone dose, formulation, and route of administration.** The current risk/benefit consensus can be summarized as follows:

- *Combination estrogen-progestin increases the risk of breast cancer* after a median time of 5 to 6 years. By contrast, estrogen alone in women with hysterectomy is associated with a borderline reduction in risk of breast cancer. There is no increase in the risk for ovarian cancer.
- *MHT may have a protective effect on the development of atherosclerosis and coronary disease in women younger than age 60 years,* but there is no protection in women who started MHT at an older age. These data support the notion that there may be a critical therapeutic window for MHT effects on the cardiovascular system. Protective effects in younger women depend in part on the response of estrogen receptors in healthy vascular endothelium. However, MHT should not be used for prevention of cardiovascular disease or other chronic diseases.
- *MHT increases the risk of stroke and VTE including deep vein thrombosis and pulmonary embolism.* The increase in VTE is more pronounced during the first 2 years of treatment and in women who have other risk factors, such as immobilization and hypercoagulable states caused by prothrombin or factor V Leiden mutations (Chapter 4). The risks of VTE and stroke appear to be lower with transdermal than oral routes of estrogen. The effect of route of administration continues to be studied.

As can be appreciated from these associations, assessment of risks and benefits when considering the use of MHT in women is complex. The current feeling is that these agents have a role in the management of menopausal symptoms in early menopause but should not be used long term for chronic disease prevention.

Oral Contraceptives

Worldwide, millions of women use hormonal contraception. OCs nearly always contain a synthetic estradiol and a variable amount of a progestin, but some preparations contain only progestins. They act by inhibiting ovulation or preventing implantation. Currently prescribed OCs contain a much smaller amount of estrogens (as little as 20 μg of ethinyl estradiol) than the earliest formulations and are associated with fewer side effects. Transdermal and implantable formulations have also become available. Hence the results of epidemiologic studies should be interpreted in the context of the dosage and the delivery system. Nevertheless, there is good evidence to support the following conclusions.

- *Breast carcinoma.* The prevailing opinion is that OCs do not increase breast cancer risk.
- *Endometrial cancer and ovarian cancers.* OCs have a protective effect against these tumors that may last for decades following cessation of OC use.
- *Cervical cancer.* OCs may increase risk of cervical carcinomas in women infected with human papillomavirus.
- *Thromboembolism.* Most studies indicate that OCs including the newer low-dose (less than 50 μg of estrogen) preparations are associated with a twofold to fourfold increased risk of venous thrombosis and pulmonary thromboembolism due to a hypercoagulable state induced by elevated hepatic synthesis of coagulation factors. This risk may be even higher with newer third-generation OCs that contain synthetic progestins, particularly in women who are carriers of the factor V Leiden mutation. To put this complication into context, however, the risk of thromboembolism associated with OC use is two to six times lower than the risk of thromboembolism associated with pregnancy.
- *Cardiovascular disease.* There is considerable uncertainty about the risk of atherosclerosis and myocardial infarction in users of OCs. It seems that OCs do not increase the risk of coronary artery disease in women younger than 30 years or in older women who are nonsmokers, but the risk does approximately double in women older than 35 years who smoke.
- *Hepatic adenoma.* There is a well-defined association between the use of OCs and this rare benign hepatic tumor, especially in older women who have used OCs for prolonged periods.

Ultimately, the pros and cons of OCs must be viewed in the context of their wide applicability and acceptance as a form of contraception.

Acetaminophen

Acetaminophen is the most commonly used analgesic in the United States. It is present in more than 300 products, alone or in combination with other agents. In the United States, it is the cause of about 50% of cases of acute liver failure, with 30% mortality. Intentional overdose (attempted suicide) is the most common cause of acetaminophen toxicity in Great Britain, but unintentional overdose is the most frequent cause in the United States, representing almost 50% of the total intoxication cases.

At therapeutic doses, about 95% of acetaminophen undergoes detoxification in the liver by phase II enzymes and is excreted in the urine as glucuronate or sulfate conjugates

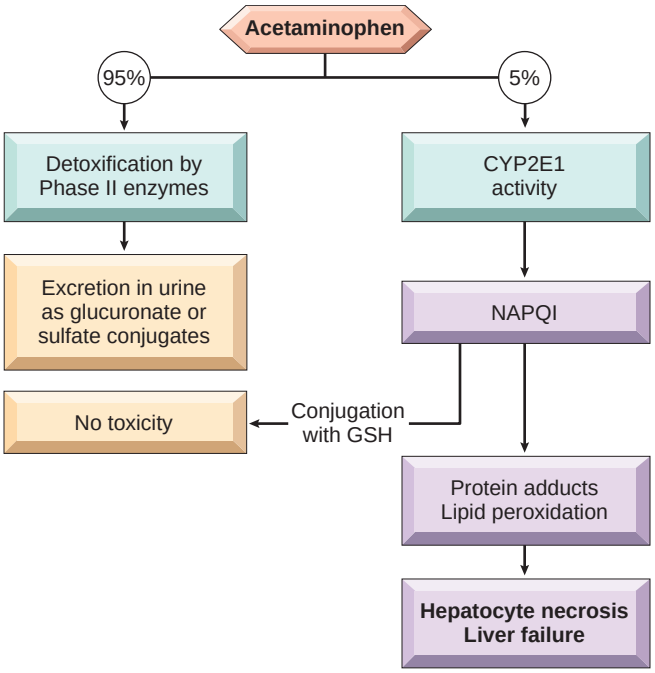

Figure 9.13 Acetaminophen metabolism and toxicity. See text for details. *GSH*, Glutathione; *NAPQI*, NAPQI, *N*-acetyl-*p*-benzoquinoneimine. (Courtesy Dr. Xavier Vaquero, Department of Pathology, University of Washington, Seattle, Wash.)

(Fig. 9.13). About 5% or less is metabolized through the activity of CYPs (primarily CYP2E) to NAPQI (*N*-acetyl-*p*-benzoquinoneimine), a highly reactive metabolite. NAPQI is normally conjugated with GSH, but when acetaminophen is taken in large doses, unconjugated NAPQI accumulates and causes hepatocellular injury, leading to centrilobular necrosis that may progress to liver failure. The injury produced by NAPQI involves two mechanisms: (1) covalent binding to hepatic proteins, which causes damage to cellular membranes and mitochondrial dysfunction, and (2) depletion of GSH, making hepatocytes more susceptible to ROS-induced injury. Because alcohol induces CYP2E in the liver, toxicity can occur at lower doses in chronic alcoholics.

The window between the usual dose (0.5 g) and the toxic dose (15 to 25 g) is large, and the drug is ordinarily very safe. Toxicity begins with nausea, vomiting, diarrhea, and sometimes shock, followed in a few days by evidence of jaundice. Overdose of acetaminophen can be treated in its early stages (within 12 hours) by administration of *N*-acetylcysteine, which restores GSH levels. In serious overdose, liver failure ensues, starting with centrilobular necrosis that may extend to entire lobules; in such circumstances liver transplantation is the only hope for survival. Some patients also show evidence of concurrent renal damage.

Aspirin (Acetylsalicylic Acid)

Aspirin overdose may result from accidental ingestion of a large number of tablets by young children; in adults, overdose is frequently suicidal. Much less commonly, salicylate poisoning is caused by the excessive use of ointments containing oil of wintergreen (methyl salicylate). Acute salicylate overdose causes alkalosis as a consequence of the stimulation of the respiratory center in the medulla. This is followed by metabolic acidosis and accumulation of pyruvate and lactate, caused by uncoupling of oxidative phosphorylation and inhibition of the Krebs cycle. Metabolic acidosis enhances the formation of nonionized forms of salicylates, which diffuse into the brain and produce effects ranging from nausea to coma. Ingestion of 2 to 4 g by children or 10 to 30 g by adults may be fatal, but survival has been reported after ingestion of doses five times larger.

Chronic aspirin toxicity (salicylism) may develop in persons who take 3 g or more daily for long periods of time for treatment of chronic pain or inflammatory conditions. Chronic salicylism is manifested by headaches, dizziness, ringing in the ears (tinnitus), hearing impairment, mental confusion, drowsiness, nausea, vomiting, and diarrhea. The CNS changes may progress to convulsions and coma. The morphologic consequences of chronic salicylism are varied. Most often there is an acute erosive gastritis (Chapter 17), which may produce gastrointestinal bleeding and lead to gastric ulceration. A bleeding tendency may appear concurrently with chronic toxicity because aspirin acetylates platelet cyclooxygenase and irreversibly blocks the production of thromboxane A_2, an activator of platelet aggregation. Petechial hemorrhages may appear in the skin and internal viscera, and bleeding from gastric ulcerations may be exacerbated by the clotting defect. With the recognition of gastric ulceration and bleeding as an important complication of ingestion of large doses of aspirin, chronic toxicity is now quite uncommon.

Proprietary analgesic mixtures of aspirin and phenacetin or its active metabolite, acetaminophen, when taken over several years, can cause tubulointerstitial nephritis with renal papillary necrosis, referred to as analgesic nephropathy (Chapter 20).

Injury by Nontherapeutic Agents (Drug Abuse)

Drug abuse generally involves the repeated or chronic use of mind-altering substances, beyond therapeutic or social norms, and may lead to drug addiction and overdose, both serious public health problems. According to the 2019 United Nations Office on Drugs and Crime report, it is estimated that about 275 million people worldwide, which is roughly 5.6% of the global population aged 15 to 64 years, used drugs at least once during 2016. Approximately, 450,000 people died in 2015 as a result of drug use. Of those deaths, 167,750 were a direct result of drug use disorders, in most cases involving opioids. Common drugs of abuse are listed in Table 9.6. Considered here are cocaine, opioids, amphetamines, and marijuana, among others.

Cocaine

According to the United Nations World Drug Report 2016, globally, there were 18 million users of cocaine in 2016. Of these, 5.1 million users were in North America, representing 1.4% of the population over 14 years of age.

Cocaine is extracted from the leaves of the coca plant and is usually prepared as a water-soluble powder, cocaine hydrochloride. Cocaine sold on the street is liberally diluted with talcum powder, lactose, or other look-alikes. It can be snorted or dissolved in water and injected subcutaneously or intravenously. Crystallization of the pure alkaloid yields nuggets of crack, so called because of the cracking or popping

Table 9.6 Common Drugs of Abuse

Class	Molecular Target	Example
Opioid narcotics	Mu opioid receptor (agonist)	Heroin, hydromorphone (Dilaudid) Oxycodone (OxyContin) Methadone (Dolophine) Meperidine (Demerol)
Sedative-hypnotics	$GABA_A$ receptor (agonist)	Barbiturates Ethanol Methaqualone (Quaalude) Glutethimide (Doriden) Ethchlorvynol (Placidyl)
Psychomotor stimulants	Dopamine transporter (antagonist) Serotonin receptors (toxicity)	Cocaine Amphetamines 3,4-Methylenedioxymethamphetamine (MDMA, Ecstasy)
Phencyclidine-like drugs	NMDA glutamate receptor channel (antagonist)	Phencyclidine (PCP, angel dust) Ketamine
Cannabinoids	CB1 cannabinoid receptors (agonist)	Marijuana Hashish
Hallucinogens	Serotonin 5-HT_2 receptors (agonist)	Lysergic acid diethylamide (LSD) Mescaline Psilocybin

GABA, γ-Aminobutyric acid; *5-HT_2*, 5-hydroxytryptamine; *NMDA*, *N*-methyl D-aspartate.

From Hyman SE: A 28-year-old man addicted to cocaine, *JAMA* 286:2586, 2001.

sound it makes when heated to produce vapors that are inhaled. The pharmacologic actions of cocaine and crack are identical, but crack is far more potent.

Cocaine produces intense euphoria and neurologic stimulation, making it one of the most addictive drugs. Experimental animals will press a lever more than 1000 times and forgo food and drink to obtain it. In the cocaine user, although physical dependence generally does not occur, the psychologic withdrawal is profound and can be extremely difficult to treat. Intense cravings are particularly severe in the first several months after abstinence and can recur for years. **Cocaine facilitates neurotransmission both in the CNS, where it blocks the reuptake of dopamine, and at adrenergic nerve endings, where it blocks the reuptake of both epinephrine and norepinephrine while stimulating the presynaptic release of norepinephrine.** The euphoria is due to its enhancement of brain dopamine activity, especially in the so-called mesolimbic dopamine reward pathway.

The acute and chronic effects of cocaine on various organ systems are as follows.

- *Cardiovascular effects*. The most serious cardiac effects of cocaine relate to its sympathomimetic activity resulting from blockade of reuptake of both epinephrine and norepinephrine at adrenergic nerve endings (Fig. 9.14). The net effect is the accumulation of these two neurotransmitters in synapses, resulting in excess stimulation, manifested by tachycardia, hypertension, and peripheral vasoconstriction. Cocaine may also induce myocardial ischemia by causing coronary artery vasoconstriction and by enhancing platelet aggregation and thrombus formation. These dual effects of cocaine increase myocardial oxygen demand and decrease coronary blood flow, setting the stage for myocardial ischemia and possible myocardial infarction. Cocaine can also precipitate lethal arrhythmias by enhanced sympathetic activity as well as by disrupting normal ion (K^+, Ca^{2+}, Na^+) transport in the myocardium. These toxic effects are not necessarily dose related, and a fatal event may occur in a first-time user with what is a typical mood-altering dose. They may also be potentiated by cigarette smoking, which increases the likelihood of cocaine-induced coronary vasospasm.
- *CNS*. The most common acute effects on the CNS are hyperpyrexia (thought to be caused by aberrations of the dopaminergic pathways that control body temperature) and seizures.
- *Effects on pregnancy*. In pregnant women, cocaine may cause acute decreases in blood flow to the placenta, resulting in fetal hypoxia and spontaneous abortion. Neurologic development may be impaired in the fetus of a pregnant woman who is a chronic drug user.
- *Other effects*. Chronic cocaine use may cause (1) perforation of the nasal septum in snorters, (2) decreased lung diffusing capacity in those who inhale the smoke, and (3) dilated cardiomyopathy.

Opioids and Opiates

According to the 2019 United Nations Office on Drugs and Crime report, in 2016 there were 19 million users of opiates (e.g., morphine and codeine, derived from poppy plants) and 34 million users of opioids (natural and synthetic). Opioid drugs of abuse include prescription drugs such as oxycodone, hydrocodone, fentanyl, tramadol, and methadone. With a death toll of 49,000 from opioid overdoses in 2016, the problem is of epidemic proportions in North America. Of these deaths, 40% were from prescription opioids.

Heroin is a street drug derived from the poppy plant that is closely related to morphine. Use of heroin is even more harmful than cocaine use. As sold on the street, it is cut (diluted) with an agent (often talc or quinine); thus the size of the dose is not only variable but also usually unknown to the buyer. Heroin, along with any contaminating substances, is usually self-administered intravenously or subcutaneously. The effects on the CNS are varied and include euphoria, hallucinations, somnolence, and sedation. Heroin has a wide range of other adverse physical effects related to (1) the pharmacologic action of the agent, (2) reactions to the

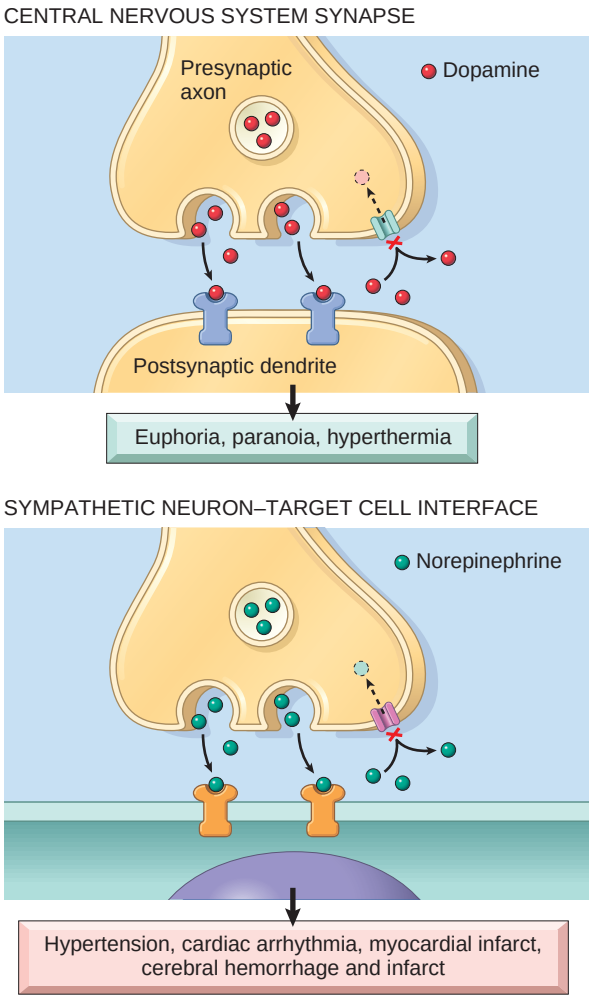

Figure 9.14 Effect of cocaine on neurotransmission. The drug inhibits reuptake of the neurotransmitters dopamine and norepinephrine in the central and peripheral nervous systems.

cutting agents or contaminants, (3) hypersensitivity reactions to the drug or its adulterants (quinine itself has neurologic, renal, and auditory toxicity), and (4) diseases contracted incident to the use of contaminated needles. Some of the most important adverse effects of heroin follow.

- *Sudden death.* Sudden death, usually related to overdose, is an ever-present risk because drug purity is generally unknown (ranging from 2% to 90%). The yearly mortality among heroin users in the United States is estimated to be between 1% and 3%. Addition of very potent synthetic opioids such as fentanyl and carfentanil to heroin, a common practice among dealers, greatly increases the chances of fatal overdose. Sudden death can also occur if heroin is taken after tolerance for the drug, built up over time, is lost (as during a period of incarceration). The mechanisms of death include profound respiratory depression, arrhythmia and cardiac arrest, and severe pulmonary edema.
- *Pulmonary injury.* Pulmonary complications include moderate to severe edema, septic embolism from endocarditis, lung abscess, opportunistic infections, and foreign-body granulomas from talc and other adulterants. Although granulomas occur principally in the lung, they are sometimes found in the mononuclear phagocyte system, particularly in the spleen, liver, and lymph nodes that drain the upper extremities. Examination under polarized light often highlights trapped talc crystals, sometimes enclosed within foreign-body giant cells.
- *Infections.* Infectious complications are common. The four sites most commonly affected are the skin and subcutaneous tissue, heart valves, liver, and lungs. In a series of addicted patients admitted to the hospital, more than 10% had endocarditis, which often takes a distinctive form involving right-sided heart valves, particularly the tricuspid. Most cases are caused by *Staphylococcus aureus,* but fungi and a multitude of other organisms have also been implicated. Viral hepatitis is the most common infection among addicted persons and is acquired by the sharing of dirty needles. In the United States, this practice has also led to a very high incidence of human immunodeficiency virus (HIV) infection in intravenous drug users.
- *Skin.* Cutaneous lesions are probably the most frequent telltale sign of heroin addiction. Acute changes include abscesses, cellulitis, and ulcerations due to subcutaneous injections. Scarring at injection sites, hyperpigmentation over commonly used veins, and thrombosed veins are the usual sequelae of repeated intravenous inoculations.
- *Kidneys.* Kidney disease is a relatively common hazard. The two forms most frequently encountered are amyloidosis (generally secondary to skin infections) and focal and segmental glomerulosclerosis; both induce proteinuria and nephrotic syndrome.

Use of oxycodone, an oral opioid available by prescription for treatment of pain, has increased sharply in recent years in the United States. According to the National Institute on Drug Abuse, approximately 5% of high school seniors took oxycodone in 2010, sometimes with tragic results due to the potent respiratory suppressant effect of the drug. The overall number of yearly fatalities attributed to abuse of prescription opiates in the United States rose from approximately 3000 in 1999 to approximately 49,000 in 2017. Most of this increase is attributable to abuse of oxycodone, which has surpassed heroin as the leading cause of opiate-related death in the United States.

Amphetamines and Related Drugs

Methamphetamine. This addictive drug, known as "speed" or "meth," is closely related to amphetamine but has stronger effects in the CNS. Methamphetamine use rose rapidly in the United States in the early 2000s, peaking in the year 2005, but has fallen steadily since that time. According to national surveys, use of methamphetamine fell to approximately 560,000 users in 2017, a decrease of more than 50% since 2006. Methamphetamine acts by releasing dopamine in the brain, which inhibits presynaptic neurotransmission at corticostriatal synapses, slowing glutamate release. Methamphetamine produces a feeling of euphoria, which is followed by a "crash." Long-term use leads to violent behaviors, confusion, and psychosis marked by paranoia and hallucinations.

Marijuana

It is estimated that worldwide 192 million people used marijuana (or "pot") in 2017, making it far and away the most widely used illicit drug globally. Several states in the United States have legalized the recreational use of marijuana

in 2018, and more appear poised to follow; thus, its status as an illicit drug is undergoing reevaluation.

Marijuana is made from the leaves of the *Cannabis sativa* plant, which contain the psychoactive substance Δ^9-tetrahydrocannabinol (THC). About 5% to 10% of THC is absorbed when it is smoked in a hand-rolled cigarette ("joint"). Marijuana use causes euphoria and a sense of relaxation. In many people it causes a heightened sensory perception (e.g., brighter colors), laughter, altered perception of time, and increased appetite. Among the beneficial effects of marijuana is its potential use to treat nausea secondary to cancer chemotherapy and as an agent capable of decreasing pain in some chronic conditions that are otherwise difficult to treat. The functional and organic CNS consequences of marijuana smoking have received the most scrutiny. Its use distorts sensory perception and impairs motor coordination, but these acute effects generally clear in 4 to 5 hours. With continued use these changes may progress to cognitive and psychomotor impairments, such as inability to judge time, speed, and distance, a potential cause of automobile accidents. Marijuana increases the heart rate and sometimes blood pressure, and it may cause angina in a person with coronary artery disease.

The respiratory system is also affected by chronic marijuana smoking; laryngitis, pharyngitis, bronchitis, cough and hoarseness, and asthma-like symptoms all have been described, along with mild but significant airway obstruction. Marijuana cigarettes contain a large number of carcinogens that are also present in tobacco. Smoking a marijuana cigarette, compared with a tobacco cigarette, is associated with a threefold increase in the amount of tar inhaled and retained in the lungs, presumably because of the larger puff volume, deeper inhalation, and longer breath holding. With the advent of e-cigarettes and vaping, an increasing number of users are inhaling aerosolized THC, a practice that has been associated with severe lung injury in some users, possibly due to the presence of adulterants. Paradoxically, some heavy users develop cannabis hyperemesis syndrome, marked by intractable nausea and vomiting that only remits with cessation of use.

Whether marijuana causes physical dependence and addiction remains controversial. According to the 2018 report from the US National Institute on Drug Abuse, chronic use of marijuana, especially if the exposure started during adolescence, gives rise to marijuana use disorder. Dependence in such individuals is manifested by withdrawal symptoms such as mood and sleep difficulties that may last up to 2 weeks when not taking the drug. A small subset of those who develop dependence may become addicted—individuals who cannot stop using the drug even though it interferes with many aspects of their life. The exact number of people who become addicted is uncertain since epidemiologic studies have not used uniform criteria to define addiction to marijuana.

Other Drugs

The variety of drugs that have been tried by individuals seeking "new experiences" (highs, lows, "out-of-body experiences") are legion. These drugs include various stimulants, depressants, analgesics, and hallucinogens (Table 9.6). Among these are 1-(1-phenylcyclohexyl) piperidine (PCP), or phencyclidine, and ketamine (related anesthetic agents); lysergic acid diethylamide (LSD), the most potent hallucinogen known; Ecstasy (3,4-methylenedioxymethamphetamine [MDMA]); and "bath salts," synthetic cathinones that are chemically related to khat, a widely used stimulant in East Africa. Not much is known about the long-term deleterious effects of any of these agents. Acutely, LSD has unpredictable effects on mood, affect, and thought, sometimes leading to bizarre and dangerous behaviors. Chronic use of Ecstasy may deplete the CNS of serotonin, potentially leading to sleep disorders, depression, anxiety, and aggressive behavior.

On the other hand, therapeutic uses for psychoactive drugs are emerging. Ketamine derivatives taken in low doses have recently been approved for treatment of severe depression, and clinical trials exploring the use of hallucinogens as treatment for psychiatric conditions such as post-traumatic stress disorder are ongoing.

KEY CONCEPTS

DRUG INJURY

- Drug injury may be caused by therapeutic drugs (adverse drug reactions) or nontherapeutic agents (drug abuse).
- Antineoplastic agents, anticoagulants, MHT preparations and OCs, acetaminophen, and aspirin are among the therapeutic drugs involved most frequently.
- MHT increases the risk of endometrial and breast cancers and thromboembolism and does not appear to protect against ischemic heart disease in women over 60 years of age. OCs have a protective effect against endometrial and ovarian cancer but increase the risk of thromboembolism and hepatic adenoma.
- Overdose of acetaminophen may cause centrilobular liver necrosis, leading to liver failure. Early treatment with agents that restore GSH levels may limit toxicity. Aspirin produces gastric ulceration and blocks the production of thromboxane A_2 in platelets, which may produce bleeding.
- The common drugs of abuse include sedative-hypnotics (barbiturates, ethanol), psychomotor stimulants (cocaine, methamphetamine, Ecstasy), opioid narcotics (heroin, oxycodone), hallucinogens, and cannabinoids (marijuana).

INJURY BY PHYSICAL AGENTS

Injury induced by physical agents is divided into the following categories: mechanical trauma, thermal injury, electrical injury, and injury produced by ionizing radiation. Each type is considered separately.

Mechanical Trauma

Mechanical forces may inflict a variety of forms of damage. The type of injury depends on the shape of the colliding object, the amount of energy discharged at impact, and the tissues or organs that bear the impact. Bone and head injuries result in unique damage and are discussed elsewhere (Chapters 26 and 28). All soft tissues react similarly to mechanical forces, and the patterns of injury can be divided into abrasions, contusions, lacerations, incised wounds, and puncture wounds. This is just a small sampling of the various forms of trauma encountered by forensic pathologists, who deal with wounds produced by shooting, stabbing, blunt

force, traffic accidents, and other causes. In addition to morphologic analyses, forensic pathology now includes molecular methods for identity testing and sophisticated methods to detect the presence of foreign substances. Details about the practice of forensic pathology can be found in specialized textbooks.

Thermal Injury

Both excessive heat and excessive cold are important causes of injury. Burns are the most common cause of thermal injury and are discussed first; a brief discussion of hyperthermia and hypothermia follows.

Thermal Burns

In the United States, approximately 450,000 persons per year receive medical treatment for burn injuries. Eighty percent of burns are caused by fire or by scalding, the latter being a major cause of injury in children. It is estimated that approximately 3500 persons die each year as a consequence of injuries caused by fire and smoke inhalation, mostly originating in homes. Since the 1970s, marked decreases have been seen in both mortality rates and the length of hospitalizations of burn patients. In recent years there were approximately 45,000 hospitalizations per year for burns; among patients treated in specialized burn centers (about 55% of those hospitalized), the survival rate was more than 95%, a remarkable testimony to improvements in the care of patients with severe burns. These improvements have been achieved by a better understanding of the systemic effects of extensive burns, the prevention of wound infection, and the use of treatments that promote the healing of skin surfaces.

The clinical significance of a burn injury depends on the following factors:

- *Depth* of the burns
- *Percentage* of body surface involved
- *Internal injuries* caused by the inhalation of hot and toxic fumes
- *Promptness and efficacy of therapy,* especially fluid and electrolyte management and prevention or control of wound infections

Burns used to be classified as first degree to fourth degree, according to the depth of the injury (first-degree burns being the most superficial), but are now classified as superficial, partial-thickness, and full-thickness.

- *Superficial burns* (formerly known as *first-degree burns*) are confined to the epidermis.
- *Partial-thickness burns* (formerly known as *second-degree burns*) involve injury to the dermis.
- *Full-thickness burns* (formerly known as *third-degree burns*) extend to the subcutaneous tissue. Full-thickness burns may also involve damage to underlying muscle tissue underneath the subcutaneous tissue (these were known formerly as fourth-degree burns).

Shock, sepsis, and respiratory insufficiency are the greatest threats to life in burn patients. Particularly in burns of more than 20% of the body surface, there is a rapid (within hours) shift of body fluids into the interstitial compartments throughout the body due to the *systemic inflammatory response syndrome,* leading to shock (Chapter 4). Because of widespread vascular leakiness, generalized edema, including pulmonary edema, can be severe. An important pathophysiologic effect of burns is the development of a hypermetabolic state associated with excess heat loss and an increased need for nutritional support. It is estimated that when more than 40% of the body surface is burned, the resting metabolic rate doubles.

The burn site is ideal for the growth of microorganisms; the serum and debris provide nutrients and the burn injury compromises blood flow, blocking effective inflammatory responses. As a result, virtually all burns become colonized with bacteria. Infections are defined by the presence of greater than 10^5 bacteria per gram of tissue, and invasive local infection is defined by the presence of greater than 10^5 bacteria per gram in unburned adjacent tissue. The most common offender is the opportunist *Pseudomonas aeruginosa,* but antibiotic-resistant strains of other common hospital-acquired bacteria, such as methicillin-resistant *S. aureus,* and fungi, particularly *Candida* species, may also be involved. Furthermore, systemic inflammatory response syndrome may impair or dysregulate both innate and adaptive immune responses (Chapter 4). Direct bacteremic spread and release of toxic substances such as endotoxin from the local site may also have dire consequences. Pneumonia or septic shock with renal failure and/or acute respiratory distress syndrome (Chapter 15) are the most common serious sequelae.

Organ system failure resulting from burn sepsis has greatly diminished during the past 30 years because of the introduction of techniques for early excision and grafting of the burn wound. Removal of the burn wound decreases infection and reduces the need for reconstructive surgery. Grafting is done with split-thickness skin grafts; dermal substitutes, which serve as a bed for cell repopulation, may be used in large full-thickness burns.

Injury to the airways and lungs may develop within 24 to 48 hours after the burn and may result from the direct effect of heat on the mouth, nose, and upper airways or from the inhalation of heated air and noxious gases in the smoke. Water-soluble gases, such as chlorine, sulfur oxides, and ammonia, may react with water to form acids or alkalis, particularly in the upper airways, producing inflammation and swelling, which may lead to partial or complete airway obstruction. Lipid-soluble gases, such as nitrous oxide and products of burning plastics, are more likely to reach deeper airways, producing pneumonitis.

In burn survivors the development of hypertrophic scars, both at the site of the original burn and at donor graft sites, and itching may become long-term, difficult-to-treat problems. Hypertrophic scarring is a common complication of burn injury marked by excessive deposition of collagen in the healing wound bed; its etiology is not well understood.

MORPHOLOGY

Grossly, full-thickness burns are white or charred, dry, and painless (because of destruction of nerve endings), whereas, depending on the depth, partial-thickness burns are pink or mottled with blisters and are painful. Histologically, devitalized tissue reveals coagulative necrosis, adjacent to vital tissue that quickly accumulates inflammatory cells and marked exudation.

Hyperthermia

Prolonged exposure to elevated ambient temperatures can result in heat cramps, heat exhaustion, and heat stroke.

- *Heat cramps* result from loss of electrolytes via sweating. Cramping of voluntary muscles, usually in association with vigorous exercise, is the hallmark. Heat-dissipating mechanisms are able to maintain normal core body temperature.
- *Heat exhaustion* is probably the most common hyperthermic syndrome. Its onset is sudden, with prostration and collapse, and it results from a failure of the cardiovascular system to compensate for hypovolemia caused by dehydration. After a period of collapse, which is usually brief, equilibrium is spontaneously reestablished if the victim is able to rehydrate.
- *Heat stroke* is associated with high ambient temperatures, high humidity, and exertion. Older adults, individuals undergoing intense physical stress (including young athletes and military recruits), and persons with cardiovascular disease are at particularly high risk for heat stroke. Thermoregulatory mechanisms fail, sweating ceases, and the core body temperature rises to more than 40°C, leading to multiorgan dysfunction that can be rapidly fatal. The hyperthermia is accompanied by marked generalized vasodilation, with peripheral pooling of blood and a decreased effective circulating blood volume. Hyperkalemia, tachycardia, arrhythmias, and other systemic effects are common. Particularly important, however, are sustained contractions of skeletal muscle that can exacerbate the hyperthermia and lead to muscle necrosis (rhabdomyolysis). These phenomena appear to stem from nitrosylation of ryanodine receptor 1 (RYR1), which is located in the sarcoplasmic reticulum of skeletal muscle. RYR1 regulates the release of calcium from the sarcoplasm. Heat stroke deranges RYR1 function and allows calcium to leak into the cytoplasm, where it stimulates muscle contraction and heat production.
- *Malignant hyperthermia,* despite the name, is not caused by exposure to high temperatures. It is a genetic condition resulting from mutations in genes such as *RYR1* that control calcium levels in skeletal muscle cells. In affected individuals, exposure to certain anesthetics during surgery triggers a rapid rise in calcium levels in skeletal muscle, leading to muscle rigidity and increased heat production. The resulting hyperthermia has a mortality rate of approximately 80% if untreated, but this falls to less than 5% if the condition is recognized and muscle relaxants are administered promptly.

Hypothermia

Prolonged exposure to low ambient temperature leads to hypothermia, a condition seen all too frequently in homeless persons. High humidity and wet clothing, sometimes exacerbated by dilation of superficial blood vessels due to ingestion of alcohol, hasten the lowering of body temperature. At a body temperature of about 90°F, loss of consciousness occurs, followed by bradycardia and atrial fibrillation at lower core temperatures.

Hypothermia causes injury by two mechanisms:

- *Direct effects* are probably mediated by physical disruptions within cells by high salt concentrations caused by the crystallization of intracellular and extracellular water (frostbite).
- *Indirect effects* result from circulatory changes, which vary depending on the rate and duration of the temperature drop. Slow chilling may induce vasoconstriction and increase vascular permeability, leading to edema and hypoxia. Such changes are typical of trench foot. This condition developed in soldiers who spent long periods of time in waterlogged trenches during World War I (1914–1918), frequently causing gangrene that necessitated amputation. With sudden, persistent chilling, the vasoconstriction and increased viscosity of the blood in the local area may cause ischemic injury and degenerative changes in peripheral nerves. In this situation, vascular injury and edema become evident only after the temperature begins to return to normal. However, if the period of ischemia is prolonged, hypoxic changes and infarction of the affected tissues (e.g., gangrene of toes or feet) may result.

Electrical Injury

Electrical injuries, which are often fatal, can arise from contact with low-voltage currents (i.e., in the home and workplace) or high-voltage currents carried by high-power lines or produced by lightning. Injuries are of two types: (1) burns and (2) ventricular fibrillation or cardiac and respiratory center failure, resulting from disruption of nerve impulse conduction. The type of injury and the severity and extent of burns depend on the strength (amperage), duration, and path of the electric current within the body.

Voltage in the household and workplace (120 or 220 V) is high enough that with low resistance at the site of contact (as when the skin is wet), sufficient current can pass through the body to cause serious injury, including ventricular fibrillation. If the current flow is sustained, it may generate enough heat to produce burns at the site of entry and exit as well as in internal organs. An important characteristic of alternating current, the type supplied to most homes, is that it induces tetanic muscle spasm, so that when a live wire or switch is grasped, irreversible clutching is likely to occur, prolonging the period of current flow. This results in a greater likelihood of developing extensive electrical burns and, in some cases, spasm of the chest wall muscles, producing death from asphyxia. Currents generated from high-voltage sources cause similar damage; however, because of the large current flows generated, these are more likely to produce paralysis of medullary centers and extensive burns. Lightning is a classic cause of high-voltage electrical injury.

Injury Produced by Ionizing Radiation

Radiation is energy that travels in the form of waves or high-speed particles. Radiation has a wide range of energies that span the electromagnetic spectrum; it can be divided into nonionizing and ionizing radiation. The energy of nonionizing radiation such as UV and infrared light, microwave, and sound waves, can move atoms in a molecule or cause them to vibrate but is not sufficient to displace bound electrons from atoms. By contrast, ionizing radiation has sufficient energy to remove tightly bound electrons.

Collision of electrons with other molecules releases electrons in a reaction cascade, referred to as ionization. The main sources of ionizing radiation are (1) x-rays and gamma rays (electromagnetic waves of very high frequencies), (2) high-energy neutrons, alpha particles (composed of two protons and two neutrons), and (3) beta particles, which are essentially electrons. At equivalent amounts of energy, alpha particles induce heavy damage in a restricted area, whereas x-rays and gamma rays dissipate energy over a longer, deeper course and produce considerably less damage per unit of tissue. About 50% of the total dose of ionizing radiation received by the US population is human-made, mostly originating from medical devices and radioisotopes. In fact, the exposure of patients to ionizing radiation during radiologic imaging tests roughly doubled between the early 1980s and 2006, mainly because of much more widespread use of computed tomography (CT) scans.

Ionizing radiation is a double-edged sword. It is indispensable in medical practice, being used in the treatment of cancer, in diagnostic imaging, and in therapeutic or diagnostic radioisotopes, but it also produces adverse short-term and long-term effects such as fibrosis, mutagenesis, carcinogenesis, and teratogenesis.

Radiation Units. Several somewhat confusing terms are used to describe radiation dose, which can be quantified according to the amount of radiation emitted by a source, the amount of radiation that is absorbed by a person, and the biologic effect of the radiation. Commonly used terms are as follows:

- *Curie* (Ci) represents the disintegrations per second of a radionuclide (radioisotope); 1 Ci is equal to 3.7×10^{10} disintegrations per second. This is an expression of the amount of radiation emitted by a source.
- *Gray* (Gy) is a unit that expresses the energy absorbed by the target tissue per unit mass; 1 Gy corresponds to absorption of 10^4 erg/g of tissue. A centigray (cGy), which is the absorption of 100 erg/g of tissue, is equivalent to 100 Rad (radiation absorbed dose), abbreviated as R. The cGy terminology has now replaced the Rad in medical practice.
- *Sievert* (Sv) is a unit of equivalent dose that depends on the biologic rather than the physical effects of radiation (it replaced a unit called Rem). For the same absorbed dose, various types of radiation produce different amounts of damage. The equivalent dose controls for this variation and thereby provides a uniform measure of biologic dose. The equivalent dose (expressed in *Sieverts*) corresponds to the absorbed dose (expressed in Grays) multiplied by the relative biologic effectiveness of the radiation. The relative biologic effectiveness depends on the type of radiation, the type and volume of the exposed tissue, the duration of the exposure, and some other biologic factors (discussed next). The effective dose of x-rays in radiographs and CT is commonly expressed in milliSieverts (mSv). For x-radiation, 1 mSv = 1 mGy.

Main Determinants of Biologic Effects of Ionizing Radiation. In addition to the physical properties of radiation, its biologic effects depend heavily on the following factors.

- *Rate of delivery* significantly modifies the biologic effect. Although the effect of radiant energy is cumulative, divided doses may allow cells to repair some of the damage between exposures. Thus, fractionated doses of radiant energy have a cumulative effect only to the extent that repair during the "recovery" intervals is incomplete. Radiation therapy of tumors exploits the general capability of normal cells to repair themselves and recover more rapidly than tumor cells and thus not sustain as much cumulative radiation damage.
- *Field size* has a great influence on the consequences of irradiation. The body can sustain relatively high doses of radiation when delivered to small, carefully shielded fields, whereas smaller doses delivered to larger fields may be lethal.
- *Cell proliferation.* Because ionizing radiation damages DNA, rapidly dividing cells are more vulnerable to injury than quiescent cells (Fig. 9.15). Except at extremely high doses that impair DNA transcription, irradiation does not kill nondividing cells, such as neurons and muscle cells. However, as discussed in Chapter 7, in dividing cells DNA damage is detected by sensors that produce signals leading to the upregulation of p53, the "guardian of the genome." p53 in turn upregulates the expression of genes that initially lead to cell cycle arrest and, if the DNA damage is too great to be repaired, genes that cause cell death through apoptosis. Understandably, therefore, tissues with a high rate of cell division, such as gonads, bone marrow, lymphoid tissue, and the mucosa of the gastrointestinal tract, are extremely vulnerable to radiation, and the injury is manifested early after exposure.
- *Oxygen effects and hypoxia*. The production of ROS from reactions with free radicals generated by radiolysis of

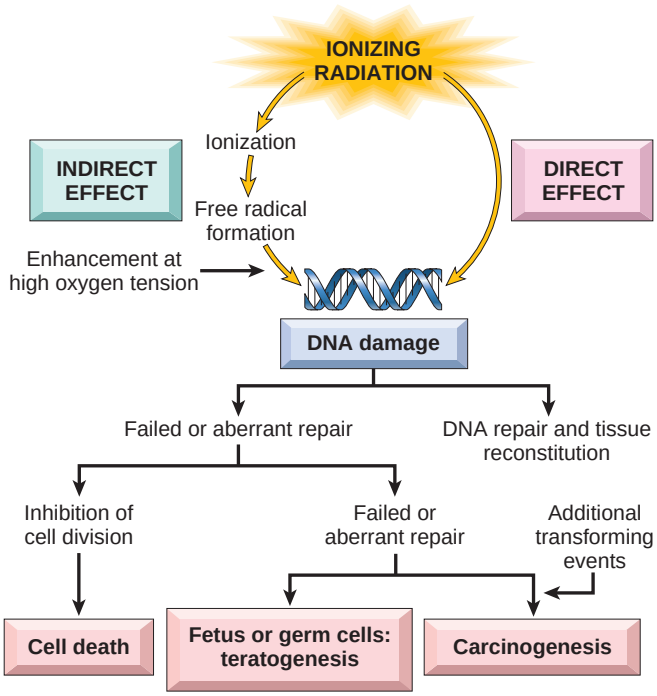

Figure 9.15 Effects of ionizing radiation on DNA and its consequences. The effects on DNA can be direct, or, more importantly, indirect, through free radical formation.

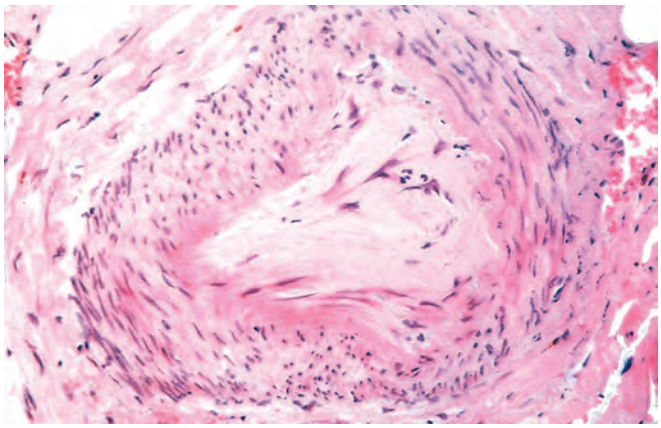

Figure 9.16 Radiation-induced chronic vascular injury with subintimal fibrosis occluding the lumen. (American Registry of Pathology © 1990.)

water is the major mechanism by which DNA is damaged by ionizing radiation. Poorly vascularized tissues with low oxygenation, such as the center of rapidly growing tumors, are generally less sensitive to radiation therapy than nonhypoxic tissues.

- *Vascular damage*. Damage to endothelial cells, which are moderately sensitive to radiation, may cause narrowing or occlusion of blood vessels leading to impaired healing, fibrosis, and chronic ischemic atrophy. These changes may appear months or years after exposure (Fig. 9.16).

Fig. 9.17 shows the overall consequences of radiation exposure. These consequences vary according to the dose of radiation and type of exposure. Table 9.7 lists the estimated threshold doses for acute effects of radiation aimed at specific organs; Table 9.8 lists the syndromes caused by exposure to various doses of total-body radiation.

MORPHOLOGY

Cells surviving radiant energy damage show a wide range of structural **changes in chromosomes** that are related to double-stranded DNA breaks including deletions, translocations, and fragmentation. The mitotic spindle often becomes disorderly, and polyploidy and aneuploidy may be encountered. **Nuclear swelling** and condensation and clumping of chromatin may appear; disruption of the nuclear membrane may also be noted. Apoptosis may occur. Several **abnormal nuclear morphologies** may be seen. Giant cells with pleomorphic nuclei or more than one nucleus may appear and persist for years after exposure. At extremely high doses of radiant energy, indicators of cell death, such as nuclear pyknosis and lysis, appear quickly.

In addition to affecting DNA and nuclei, radiant energy may induce a variety of **cytoplasmic changes** including swelling, mitochondrial distortion, and degeneration of the endoplasmic reticulum. Plasma membrane breaks and focal defects may be seen. The histologic constellation of cellular pleomorphism, giant-cell formation, conformational changes in nuclei, and abnormal mitotic figures creates a more than passing similarity between radiation-injured cells and cancer cells, a problem that plagues the pathologist

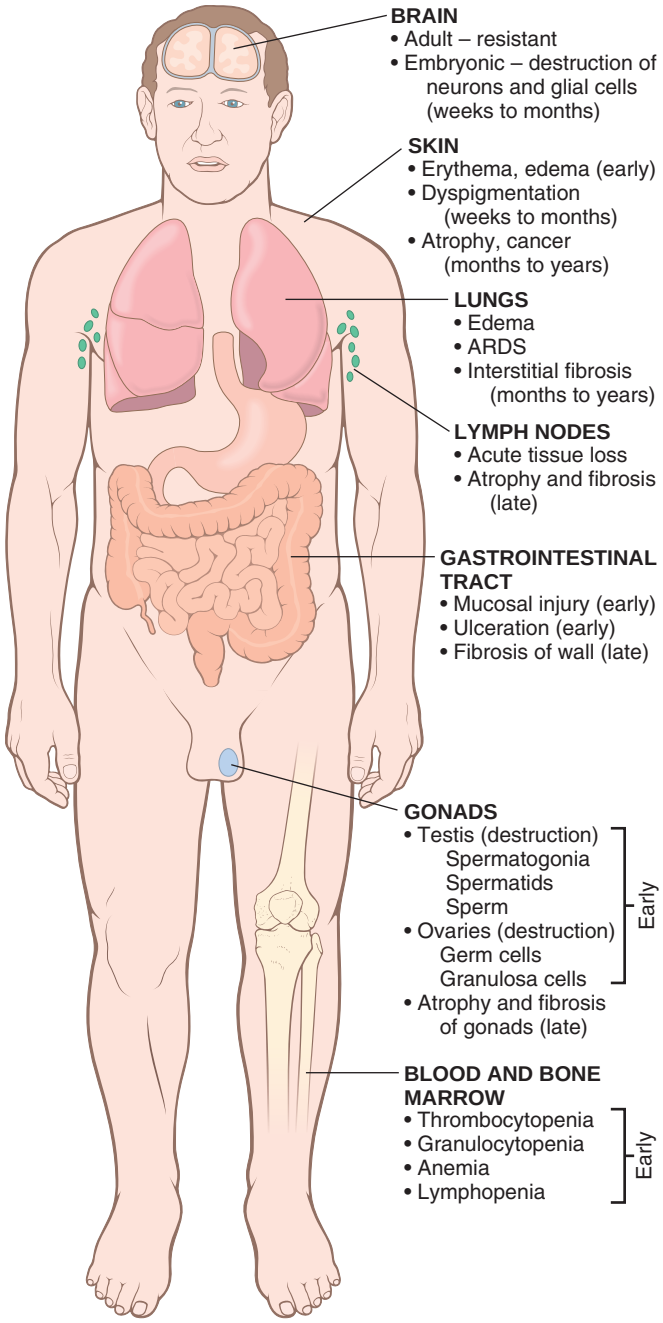

Figure 9.17 Overview of the major morphologic consequences of radiation injury. Early changes occur in hours to weeks; late changes occur in months to years. *ARDS*, Acute respiratory distress syndrome.

Table 9.7 Estimated Threshold Doses for Acute Radiation Effects on Specific Organs

Health Effect	Organ	Dose (Sv)
Temporary sterility	Testes	0.15
Depression of hematopoiesis	Bone marrow	0.50
Reversible skin effects (e.g., erythema)	Skin	1–2
Permanent sterility	Ovaries	2.5–6
Temporary hair loss	Skin	3–5
Permanent sterility	Testis	3.5
Cataract	Lens of eye	5

Table 9.8 Effects of Total-Body Ionizing Radiation

	0–1 Sv	1–2 Sv	2–10 Sv	10–20 Sv	>50 Sv
Main site of injury	None	Lymphocytes	Bone marrow	Small bowel	Brain
Main signs and symptoms	None	Moderate granulocytopenia, lymphopenia	Leukopenia, hemorrhage, hair loss, vomiting	Diarrhea, fever, electrolyte imbalance, vomiting	Ataxia, coma, convulsions, vomiting
Time of development	—	1 day to 1 week	2 to 6 weeks	5 to 14 days	1 to 4 hours
Lethality	None	None	Variable (0%–80%)	100%	100%

when evaluating irradiated tissues for the possible persistence of tumor cells.

Vascular changes and interstitial fibrosis are also prominent in irradiated tissues (Fig. 9.18). During the immediate postirradiation period, vessels may show only dilation. With time or with higher doses, a variety of degenerative changes appear, including endothelial cell swelling and vacuolation, or even necrosis and dissolution of the walls of small vessels such as capillaries and venules. Affected vessels may rupture or thrombose. Still later, endothelial cell proliferation and collagenous hyalinization and thickening of the intima are seen in irradiated vessels, resulting in marked narrowing or even obliteration of the vascular lumens. At this time, an increase in interstitial collagen in the irradiated field usually becomes evident, leading to scarring and contractions.

Total-Body Irradiation. Exposure of large areas of the body to even very small doses of radiation may have devastating effects. Doses below 1 Sv produce minimal symptoms, if any. However, higher levels of exposure cause health effects known as acute radiation syndromes, which at progressively higher doses involve the hematopoietic, gastrointestinal, and central nervous systems. The syndromes associated with total-body exposure to ionizing radiation are presented in Table 9.8.

Acute Effects on Hematopoietic and Lymphoid Systems. The hematopoietic and lymphoid systems are extremely susceptible to radiation injury and deserve special mention. With high dose levels and large exposure fields, severe lymphopenia appears within hours along with shrinkage of the lymph nodes and spleen. Radiation kills lymphocytes directly, both in the circulation and in tissues (nodes, spleen, thymus, gut). With sublethal doses of radiation, regeneration from viable precursors is prompt, leading to restoration of a normal blood lymphocyte count within weeks to months. Hematopoietic precursors in the bone marrow are also quite sensitive to radiant energy, which produces a dose-dependent marrow aplasia. The acute effects of marrow irradiation on peripheral blood counts reflect the kinetics of turnover of the formed elements, the granulocytes, platelets, and red cells, which have half-lives of less than a day (granulocytes), 10 days (platelets), and 120 days (red cells). After a brief rise in the circulating neutrophil count, neutropenia appears within several days. Neutrophil counts reach their nadir, often at counts near zero, during the second week. If the patient survives, recovery of a normal granulocyte count may require 2 to 3 months.

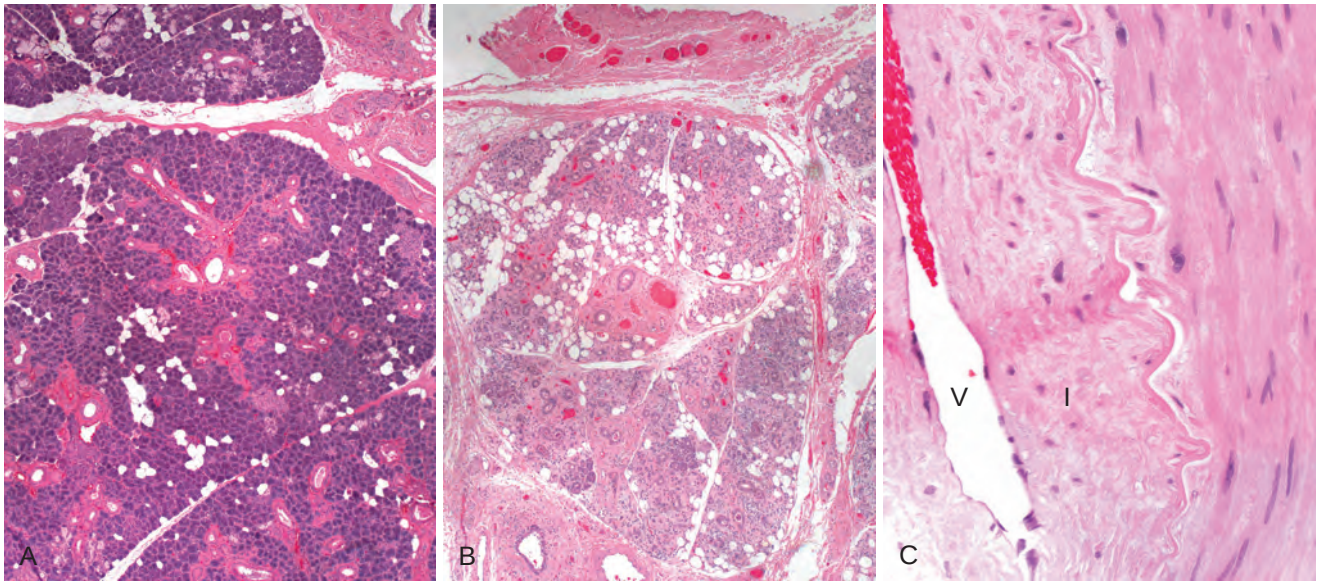

Figure 9.18 Fibrosis and vascular changes in salivary glands produced by radiation therapy of the neck region. (A) Normal salivary gland. (B) Fibrosis caused by radiation. (C) Fibrosis and vascular changes consisting of fibrointimal thickening and arteriolar sclerosis. *I*, Thickened intima; *V*, vessel lumen. (Courtesy Dr. Melissa Upton, Department of Pathology, University of Washington, Seattle, Wash.)

Thrombocytopenia appears by the end of the first week, with the platelet count nadir occurring somewhat later than that of granulocytes; recovery is similarly delayed. Anemia appears after 2 to 3 weeks and may persist for months. Understandably, higher doses of radiation produce more severe cytopenias and more prolonged periods of recovery. Very high doses kill hematopoietic stem cells and induce permanent aplasia (aplastic anemia) marked by a failure of blood count recovery, whereas with lower doses the aplasia is transient.

Fibrosis. A common consequence of radiation therapy for cancer is the development of fibrosis in the tissues included in the irradiated field (see Fig. 9.18). Fibrosis may occur weeks or months after irradiation as a consequence of the replacement of dead parenchymal cells by connective tissue, leading to the formation of scars and adhesions. Vascular damage, the death of tissue stem cells, and the release of cytokines and chemokines that promote inflammation and fibroblast activation are the main contributors to the development of radiation-induced fibrosis (Figs. 9.19 and 9.20). Common sites of fibrosis after radiation treatment are the lungs, the salivary glands after radiation therapy for head and neck cancers, and colorectal and pelvic areas after treatment for cancer of the prostate, rectum, or cervix.

DNA Damage and Carcinogenesis. Ionizing radiation can cause multiple types of DNA damage including single-base damage, single- and double-stranded breaks (DSBs), and DNA-protein cross-links. In surviving cells, simple defects may be repaired by various enzyme systems present in most mammalian cells. The most serious damage to DNA consists of DSBs. Two types of mechanisms can repair DSBs in mammalian cells: homologous recombination and nonhomologous end joining (NHEJ), with NHEJ being the most common repair pathway. DNA repair through NHEJ often produces mutations including short deletions or duplications or gross chromosomal aberrations such as translocations and inversions. If the replication of cells containing DSBs is not stopped by cell cycle checkpoint controls (Chapters 1 and 7), cells with chromosomal damage persist and may initiate carcinogenesis many years later.

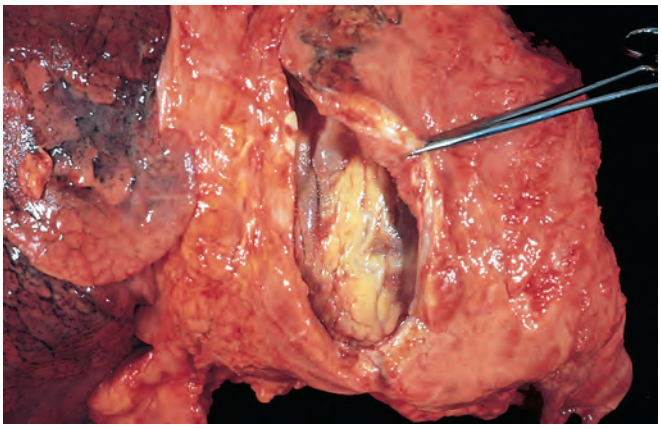

Figure 9.20 Extensive mediastinal fibrosis after radiotherapy for carcinoma of the lung. Note the markedly thickened pericardium. (From the Collection of the Department Pathology, Southwestern Medical School, Dallas, Tex.)

Cancer Risks From Exposures to Radiation. Any cell capable of division that has sustained a mutation has the potential to become cancerous. Thus, an increased incidence of neoplasms may occur in any organ after exposure to ionizing radiation. The level of radiation required to increase the risk of cancer development is difficult to determine, but there is little doubt that acute or prolonged exposures that result in doses of greater than 100 mSv cause serious consequences, including cancer. Proof of this risk is found in the increased incidence of leukemias and solid tumors in several organs (e.g., thyroid, breast, and lungs) in survivors of the atomic bombings of Hiroshima and Nagasaki; the high number of thyroid cancers in survivors of the Chernobyl accident; the high incidence of thyroid tumors and the elevated frequency of leukemias and birth defects in inhabitants of the Marshall Islands exposed to nuclear fallout; and the development of second cancers, such as acute myeloid leukemia, myelodysplastic syndrome, and solid tumors, in individuals who received radiation therapy for cancers such as Hodgkin lymphoma. The long-term cancer risks caused by radiation exposures in the range of 5 to 100 mSv are much more difficult to establish because accurate measurements of risks require large population groups ranging from 50,000 to 5 million people. Nevertheless, for x-rays and gamma rays there is good evidence for a statistically significant increase in the risk of cancer at acute doses of greater than 50 mSv and reasonable evidence for acute doses of greater than 5 mSv; as a point of reference, a single posteroanterior chest radiograph, a lateral chest film chest radiograph, and a CT scan of the chest deliver effective doses to the lungs of 0.01 mSv, 0.15 mSv, and 10 mSv. It is believed that the risk of secondary cancers following irradiation is greatest in children. This is based in part on a recent large-scale epidemiologic study showing that children who receive at least two CT scans have very small but measurable increased risks for leukemia and malignant brain tumors and on older studies showing that radiation therapy to the chest is particularly likely to produce breast cancers when administered to adolescent females.

Increased risk of cancer development may also be associated with occupational exposures. Radon gas is a ubiquitous product of the spontaneous decay of uranium. Its carcinogenic effects are largely attributable to two decay products, polonium 214 and polonium 218 (or "radon daughters"), which emit alpha particles. Polonium 214 and polonium 218 produced from inhaled radon tend to deposit in the lung, and chronic exposure in uranium miners may give rise to lung carcinomas. Risks are also present in homes in which the levels of radon are very high, comparable to those found in mines. It is suspected that lower levels of household radon may also contribute to lung cancer development, particularly in those who also smoke tobacco.

KEY CONCEPTS

RADIATION INJURY

- Ionizing radiation may injure cells directly or indirectly by generating free radicals from water or molecular oxygen.
- Ionizing radiation damages DNA; therefore rapidly dividing cells such as germ cells and those in the bone marrow and gastrointestinal tract are very sensitive to radiation injury.
- DNA damage that is not adequately repaired may result in mutations that predispose affected cells to neoplastic transformation.
- Ionizing radiation may cause vascular damage and sclerosis, resulting in ischemic necrosis of parenchymal cells and their replacement by fibrous tissue.

NUTRITIONAL DISEASES

Malnutrition is a consequence of inadequate intake of proteins and calories or deficiencies in the digestion or absorption of proteins resulting in the loss of fat and muscle mass, weight loss, and generalized weakness. Millions of people in lower income nations are malnourished or living on the cruel edge of starvation. In the higher income world and, more recently, also in some lower income countries, obesity has become a major public health problem due to its association with diseases such as diabetes, atherosclerosis, and cancer.

The sections that follow barely skim the surface of nutritional disorders. Particular attention is devoted to childhood malnutrition, anorexia nervosa and bulimia, deficiencies of vitamins and trace minerals, obesity, and the relationships of diet to cancer and atherosclerosis. Other nutrients and nutritional issues are discussed in the context of specific diseases.

Dietary Insufficiency

An appropriate diet should provide (1) sufficient energy, in the form of carbohydrates, fats, and proteins, for the body's daily metabolic needs; (2) amino acids and fatty acids to be used as building blocks for synthesis of proteins and lipids; and (3) vitamins and minerals, which function as coenzymes or hormones in vital metabolic pathways or, as in the case of calcium and phosphate, as important structural components. In *primary malnutrition,* one or all of these components are missing from the diet. By contrast, *secondary malnutrition* results from malabsorption, impaired utilization or storage, excess loss, or increased need for nutrients.

There are several conditions that may lead to primary or secondary malnutrition.

- *Poverty.* Homeless persons, aged individuals, and children of the poor often suffer from severe malnutrition as well as trace nutrient deficiencies. In lower income countries, poverty, crop failures, livestock deaths, and drought, often in times of war and political upheaval, create the setting for the malnourishment of children and adults.
- *Acute and chronic illnesses*. The basal metabolic rate rises in many illnesses, resulting in increased daily requirements for all nutrients. Failure to recognize these nutritional needs may delay recovery. Malnutrition is often present in patients with wasting diseases, such as advanced cancers and AIDS that are complicated by cachexia (Chapter 7).
- *Chronic alcoholism*. Alcoholic persons may sometimes suffer from malnutrition but more frequently have deficiencies of vitamins, especially thiamine, pyridoxine, folate, and vitamin A, as a result of poor diet, defective gastrointestinal absorption, abnormal nutrient utilization and storage, increased metabolic needs, and an increased rate of loss. A failure to recognize the likelihood of thiamine deficiency in persons with chronic alcoholism may result in irreversible brain damage (e.g., *Wernicke encephalopathy* and *Korsakoff psychosis,* discussed in Chapter 28).
- *Ignorance and failure of diet supplementation.* Even the affluent may fail to recognize that infants, adolescents, and pregnant women have increased nutritional needs. Ignorance about the nutritional content of foods is also a contributing factor. Some examples are iron deficiency in infants fed exclusively artificial milk diets; thiamine deficiency in diets in which polished rice is the mainstay; and lack of iodine from food and water in regions removed from the oceans, unless supplementation is provided.
- *Self-imposed dietary restriction.* Anorexia nervosa, bulimia, and less overt eating disorders affect individuals who are concerned about body image and are obsessed with body weight (anorexia and bulimia are discussed later).
- *Other causes.* Additional causes of malnutrition include gastrointestinal diseases and malabsorption syndromes, genetic diseases, specific drug therapies (which block uptake or utilization of particular nutrients), and inadequate total parenteral nutrition.

Severe Acute Malnutrition

The WHO defines severe acute malnutrition (SAM) as a state characterized by a weight for height ratio that is 3 standard deviations below the normal range. Worldwide about 50 million children are affected by SAM. It is common in low income countries, where as many as 25% of children may be affected and where it is a major contributor to the high death rates among the very young. In addition to loss of life, wars also exact a heavy toll on refugees who live in abject poverty. In recent years, camps set up for refugees from Syria, as many as 20% of the children are severely or moderately malnourished.

Figure 9.21 Childhood malnutrition. (A) Marasmus. Note the loss of muscle mass and subcutaneous fat; the head appears to be too large for the emaciated body. (B) Kwashiorkor. The infant shows generalized edema, seen as ascites and puffiness of the face, hands, and legs. (A, From Clinic Barak, Reisebericht, Kenya.)

SAM, previously called protein energy malnutrition (PEM), manifests as a spectrum of clinical syndromes, all resulting from a dietary intake of protein and calories that is inadequate to meet the body's needs. At two ends of SAM are *marasmus* and *kwashiorkor*. It should be noted that from a functional standpoint, there are two protein compartments in the body: the somatic compartment, represented by proteins in skeletal muscles, and the visceral compartment, represented by protein stores in the visceral organs, primarily the liver. These two compartments are regulated differently, as detailed subsequently. The somatic compartment is affected more severely in marasmus, and the visceral compartment is depleted more severely in kwashiorkor. Clinical assessment of undernutrition is discussed next, followed by descriptions of marasmus and kwashiorkor.

The diagnosis of SAM is obvious in its most severe forms. In mild to moderate forms, the usual approach is to compare the body weight for a given height against standard tables; other helpful parameters are fat stores, muscle mass, and levels of certain serum proteins. With a loss of fat, measured skinfold thickness (which includes skin and subcutaneous tissue) is reduced. If the somatic protein compartment is catabolized, the resultant reduction in muscle mass is reflected by reduced circumference of the midarm. Measurement of serum proteins (albumin, transferrin, and others) provides an estimate of the adequacy of the visceral protein compartment. Recent studies suggest a role for the gut microbiome in the pathogenesis of SAM. There is a substantial difference in the microbial flora of children with SAM when compared with the gut microbiome of normal children. It seems that the alterations in the microbiome are not merely the consequences of SAM but play a role in their causation. The most compelling evidence for this notion comes from fecal transplants from children with SAM into germ-free mice. Malnutrition was induced in host mice by fecal transplants from affected but not well-nourished children.

Marasmus. **Marasmus develops when the diet is severely lacking in calories** (Fig. 9.21A). A child is considered to have marasmus when weight falls to 60% of normal for sex, height, and age. A marasmic child suffers growth retardation and loss of muscle mass as a result of catabolism and depletion of the somatic protein compartment. This seems to be an adaptive response that provides the body with amino acids as a source of energy. Of interest, the visceral protein compartment, which presumably is more critical for survival, is depleted only marginally, so serum albumin levels are either normal or only slightly reduced. In addition to muscle proteins, subcutaneous fat is also mobilized and used as fuel. Leptin (discussed later under "Obesity") production is low, which may stimulate the hypothalamic-pituitary-adrenal axis to produce high levels of cortisol that contribute to lipolysis. Due to losses of muscle and subcutaneous fat, the extremities are emaciated; by comparison, the head appears too large for the body. Anemia and manifestations of multivitamin deficiencies are present, and there is evidence of immune deficiency, particularly of T-cell–mediated immunity. Hence, concurrent infections are usually present, which impose additional stress on a weakened body.

Kwashiorkor. **Kwashiorkor occurs when protein deprivation is relatively greater than the reduction in total calories** (Fig. 9.21B). This is the most common form of SAM seen in African children, who have been weaned too early and subsequently fed, almost exclusively, a carbohydrate diet (the name kwashiorkor, from the Ga language in Ghana, describes the illness in a young child that appears after the

arrival of another baby). The prevalence of kwashiorkor also is high in lower income countries of Southeast Asia. Less severe forms occur worldwide in persons with chronic diarrheal states, in which protein is not absorbed, or in persons with chronic protein loss (e.g., protein-losing enteropathies, the nephrotic syndrome, or the aftermath of extensive burns). Rare cases of kwashiorkor resulting from fad diets or replacement of milk by rice-based beverages have been reported in the United States.

In kwashiorkor, unlike in marasmus, marked protein deprivation is associated with severe loss of the visceral protein compartment, and the resultant hypoalbuminemia gives rise to generalized or dependent edema (see Fig. 9.21). The weight of children with severe kwashiorkor typically is 60% to 80% of normal. However, the true loss of weight is masked by the increased fluid retention (edema). In further contrast with marasmus, there is relative sparing of subcutaneous fat and muscle mass. The modest loss of these compartments may also be masked by edema.

Children with kwashiorkor have characteristic skin lesions with alternating zones of hyperpigmentation, desquamation, and hypopigmentation, giving a "flaky paint" appearance. Hair changes include loss of color or alternating bands of pale and darker color, straightening, fine texture, and loss of firm attachment to the scalp. Other features that distinguish kwashiorkor from marasmus include an enlarged, fatty liver (resulting from reduced synthesis of the carrier protein component of lipoproteins) and the development of apathy, listlessness, and loss of appetite. Like marasmus, vitamin deficiencies are likely to be present, as are defects in immunity and secondary infections, which produce inflammation and a catabolic state that aggravates the malnutrition. As already mentioned, marasmus and kwashiorkor represent two ends of a spectrum, and considerable overlap exists.

Malnutrition in the Upper Income World. In the United States, secondary malnutrition often develops in chronically ill, older, and bedridden patients. It is estimated that more than 50% of older residents in nursing homes in the United States are malnourished. The most obvious signs of secondary malnutrition include (1) depletion of subcutaneous fat in the arms, chest wall, shoulders, or metacarpal regions; (2) wasting of the quadriceps and deltoid muscles; and (3) ankle or sacral edema. Bedridden or hospitalized malnourished patients have an increased risk of infection, sepsis, impaired wound healing, and death after surgery.

MORPHOLOGY

The main anatomic changes in SAM are (1) growth failure; (2) peripheral edema in kwashiorkor; and (3) loss of body fat and atrophy of muscle, more marked in marasmus.

The **liver** in kwashiorkor, but not in marasmus, is enlarged and fatty; superimposed cirrhosis is rare. In kwashiorkor (rarely in marasmus) the **small bowel** shows a decrease in mitotic cells in the crypts of the glands, associated with mucosal atrophy and loss of villi and microvilli. In such cases concurrent loss of small intestinal enzymes occurs, most often manifested as disaccharidase deficiency. Hence infants with kwashiorkor initially may not respond well to full-strength, milk-based diets. With treatment, the mucosal changes are reversible.

The **bone marrow** in both kwashiorkor and marasmus may be hypoplastic, mainly as a result of decreased numbers of red cell precursors. The peripheral blood commonly reveals mild to moderate anemia, which is often multifactorial in origin; nutritional deficiencies of iron, folate, and protein, as well as the suppressive effects of infection (anemia of chronic inflammation) may all contribute. Depending on the predominant factor, the red cells may be microcytic, normocytic, or macrocytic.

The **brain** in infants who are born to malnourished mothers and who suffer SAM during the first 1 or 2 years of life has been reported by some to show cerebral atrophy, a reduced number of neurons, and impaired myelinization of white matter.

Many other changes may be present including (1) thymic and lymphoid atrophy (more marked in kwashiorkor than in marasmus); (2) anatomic alterations induced by intercurrent infections, particularly with all manner of endemic worms and other parasites; and (3) deficiencies of other required nutrients such as iodine and vitamins.

Cachexia. Secondary malnutrition is a common complication in patients with acquired immunodeficiency syndrome (AIDS) or advanced cancers, and in these settings it is known as cachexia. Because of its common association with cancer, cachexia is discussed in Chapter 7.

Anorexia Nervosa and Bulimia

Anorexia nervosa is self-induced starvation, resulting in marked weight loss; bulimia is a condition in which the patient binges on food and then induces vomiting. Anorexia nervosa has the highest death rate of any psychiatric disorder. Bulimia is more common than anorexia nervosa and generally has a better prognosis; it is estimated to occur in 1% to 2% of women and 0.1% of men, with an average onset at 20 years of age. These eating disorders occur primarily in previously healthy young women who have developed an obsession with body image and thinness. The neurobiologic underpinnings of these diseases are unknown, but it has been suggested that altered serotonin metabolism may be an important component.

The clinical findings in anorexia nervosa are generally similar to those in SAM. In addition, effects on the endocrine system are prominent. *Amenorrhea,* resulting from decreased secretion of gonadotropin-releasing hormone and (as a result) luteinizing hormone and follicle-stimulating hormone, is so common that its presence is considered a diagnostic feature. Other common findings related to *decreased thyroid hormone release* include cold intolerance, bradycardia, constipation, and changes in the skin and hair. In addition, dehydration and electrolyte abnormalities are frequently present. The skin becomes dry and scaly. Increased fat in the marrow (paradoxically, since fat is decreased elsewhere) associated with a peculiar deposition of mucinous matrix material that is referred to as *gelatinous transformation* is virtually pathognomonic for anorexia nervosa (Fig. 9.22). The bone density is decreased, most likely because of low estrogen levels, mimicking the postmenopausal acceleration of osteoporosis. Anemia, lymphopenia, and hypoalbuminemia may

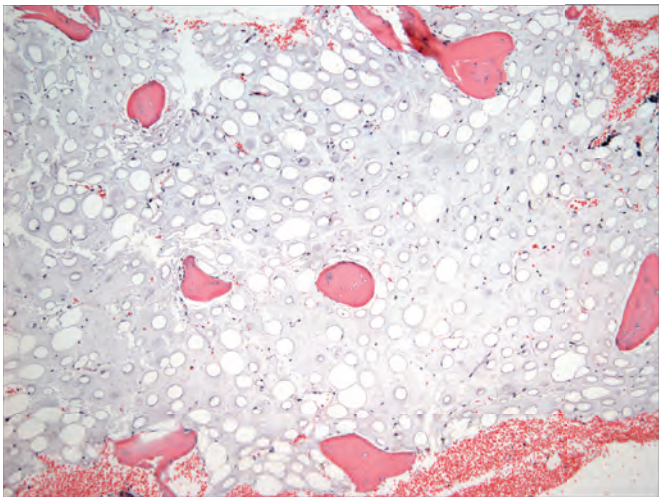

Figure 9.22 Anorexia nervosa. Increased fat in the marrow associated with deposition of mucinous matrix material (gelatinous transformation) is pathognomonic of this disease.

be present. A major complication of anorexia nervosa (and bulimia) is an increased susceptibility to *cardiac arrhythmia* and *sudden death,* resulting from hypokalemia.

In bulimia, *binge eating* is the norm. Large amounts of food, principally carbohydrates, are ingested, followed by induced vomiting. Although menstrual irregularities are common, amenorrhea occurs in less than 50% of bulimic patients because weight and gonadotropin levels remain near normal. The major medical complications relate to frequent vomiting and the chronic use of laxatives and diuretics. They include (1) electrolyte imbalances (hypokalemia), which predispose the patient to cardiac arrhythmias; (2) pulmonary aspiration of gastric contents; and (3) esophageal and gastric rupture. Nevertheless, there are no specific signs or symptoms; thus the diagnosis of bulimia relies on a comprehensive psychologic assessment.

Vitamin Deficiencies

Thirteen vitamins are necessary for health; vitamins A, D, E, and K are fat-soluble, and all others are water-soluble. The distinction between fat-soluble and water-soluble vitamins is important. Fat-soluble vitamins are more readily stored in the body, but they may be poorly absorbed in fat malabsorption disorders, caused by disturbances of digestive functions (Chapter 17). Certain vitamins can be synthesized endogenously—vitamin D from precursor steroids; vitamin K and biotin by the intestinal microflora; and niacin from tryptophan, an essential amino acid. Notwithstanding this endogenous synthesis, a dietary supply of all vitamins is essential for health.

A deficiency of vitamins may be primary (dietary in origin) or secondary to disturbances in intestinal absorption, transport in the blood, tissue storage, or metabolic conversion. In the following sections, vitamins A, D, and C are presented in some detail because of their wide-ranging activities and the morphologic changes of deficient states. This is followed by presentation in tabular form of the main consequences of deficiencies of the remaining vitamins (E, K, and the B complex) and some essential minerals. However, it should be emphasized that deficiency of a single vitamin is uncommon, and that single or multiple vitamin deficiencies may be associated with SAM.

Vitamin A

The major functions of vitamin A are maintenance of normal vision, regulation of cell growth and differentiation, and regulation of lipid metabolism. Vitamin A is the name given to a group of related compounds that include *retinol*, *retinal*, and *retinoic acid*, which have similar biologic activities. The generic term *retinoids* encompasses vitamin A in its various forms and both natural and synthetic chemicals that are structurally related to vitamin A, but may not necessarily have vitamin A–like biologic activity. Animal-derived foods such as liver, fish, eggs, milk, and butter are important dietary sources of preformed vitamin A. Yellow and leafy green vegetables such as carrots, squash, and spinach supply large amounts of carotenoids, provitamins that can be metabolized to active vitamin A in the body. Carotenoids contribute approximately 30% of the vitamin A in human diets; the most important of these is β-carotene, which is efficiently converted to vitamin A. The Recommended Dietary Allowance for vitamin A is expressed in retinol equivalents, to take into account both preformed vitamin A and β-carotene.

Vitamin A is a fat-soluble vitamin, and its absorption requires bile, pancreatic enzymes, and some level of antioxidant activity in the food. Retinol (generally ingested as retinol ester) and β-carotene are absorbed in the intestine, where β-carotene is also converted to retinol (Fig. 9.23). Retinol is then transported in chylomicrons to the liver for esterification and storage. Uptake in liver cells takes place through the apolipoprotein E receptor. More than 90% of the body's vitamin A reserves are stored in the liver, predominantly in the perisinusoidal stellate (Ito) cells. In healthy persons who consume an adequate diet, these reserves are sufficient to meet the body's demands for at least 6 months. Retinol esters stored in the liver can be mobilized; before release, retinol binds to a specific retinol-binding protein (RBP), synthesized in the liver. The uptake of retinol/RBP in peripheral tissues is dependent on cell surface receptors specific for RBP. Once taken up into peripheral tissues, retinol may also be stored as retinol ester or may be oxidized to form retinoic acid, which has important effects on epithelial differentiation and growth.

Function. In humans, the main functions of vitamin A are the following:

- *Maintenance of normal vision.* The visual process involves four forms of vitamin A–containing pigments: rhodopsin in the rods, the most light-sensitive pigment and therefore important in reduced light, and three iodopsins in cone cells, each responsive to specific colors in bright light. The synthesis of rhodopsin from retinol involves (1) oxidation to all-*trans*-retinal, (2) isomerization to 11-*cis*-retinal, and (3) covalent association with the 7-transmembrane rod protein opsin to form rhodopsin. A photon of light causes the isomerization of 11-*cis*-retinal to all-*trans*-retinal, which dissociates from rhodopsin. This induces a conformational change in opsin, triggering a series of downstream events that generate a nerve impulse, which is transmitted

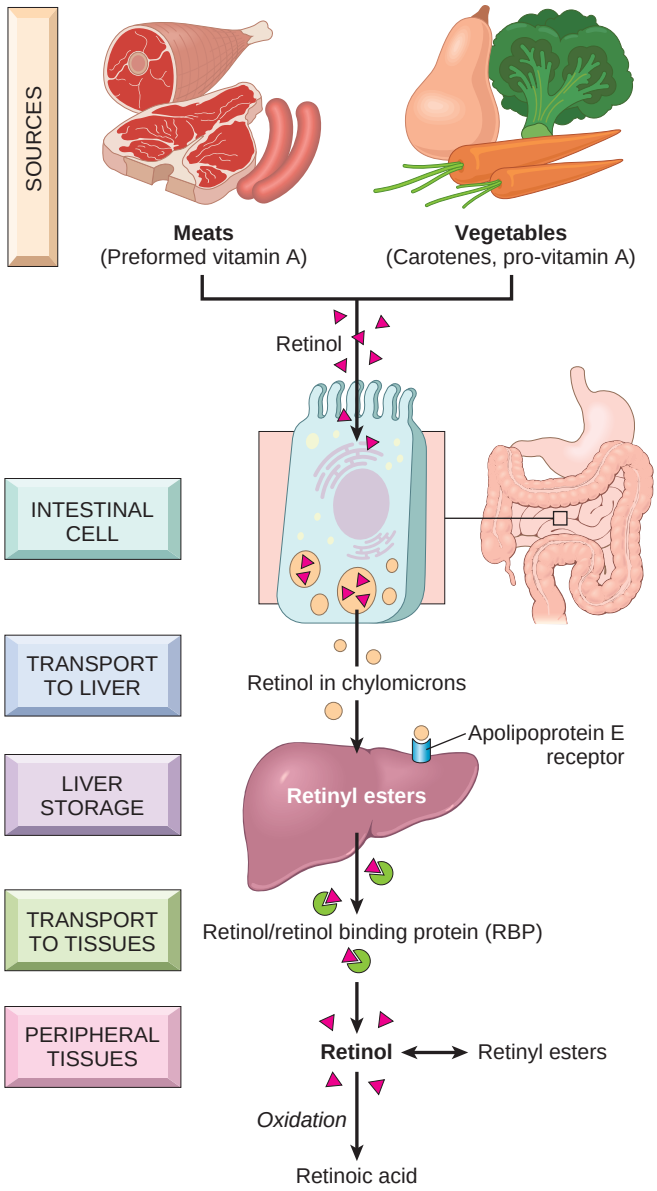

Figure 9.23 Vitamin A metabolism.

via neurons from the retina to the brain. During dark adaptation, some of the all-*trans*-retinal is reconverted to 11-*cis*-retinal, but most is reduced to retinol and lost to the retina, dictating the need for continuous supply.

- *Cell growth and differentiation.* Vitamin A and retinoids play an important role in the orderly differentiation of mucus-secreting epithelium; when a deficiency state exists, the epithelium undergoes squamous metaplasia, differentiating into a keratinizing epithelium. Activation of retinoic acid receptors (RARs) by their ligands causes the release of corepressors and the obligatory formation of heterodimers with another retinoid receptor, *RXR*. Both RAR and RXR have three isoforms, α, β, and γ. The RAR/RXR heterodimers bind to retinoic acid response elements located in the regulatory regions of genes that encode receptors for growth factors, tumor suppressor genes, and secreted proteins. Through these effects, retinoids regulate cell growth and differentiation, cell cycle control, and other biologic responses. All-*trans*-retinoic acid, a potent acid derivative of vitamin A, has the highest affinity for RARs compared with other retinoids.
- *Metabolic effects of retinoids.* The RXR, believed to be activated by 9-*cis*-retinoic acid, can form heterodimers with other nuclear receptors, such as nuclear receptors involved in drug metabolism, peroxisome proliferator-activated receptors (PPARs), and vitamin D receptors. PPARs are key regulators of lipid metabolism including fatty acid oxidation in fat cells and muscle, adipogenesis, and lipoprotein metabolism. The association of RXR and PPARγ thus explains the metabolic effects of retinoids on adipogenesis.
- *Enhancing immunity to infections.* Vitamin A supplementation can reduce morbidity and mortality rates from diarrhea by 15% and 28%, respectively. The effects of vitamin A on infections probably derive in part from its ability to stimulate the immune system through unclear mechanisms. Infections may reduce the bioavailability of vitamin A, possibly by inducing the acute phase response, which appears to inhibit RBP synthesis in the liver. The drop in hepatic RBP causes a decrease in circulating retinol, which reduces the tissue availability of vitamin A. In addition, retinoids, β-carotene, and some related carotenoids function as photoprotective and antioxidant agents.

Retinoids are used clinically in the treatment of skin disorders such as severe acne and certain forms of psoriasis, as well as in the treatment of acute promyelocytic leukemia. As discussed in Chapter 7, all-*trans*-retinoic acid induces the differentiation and subsequent apoptosis of acute promyelocytic leukemia cells through its ability to bind to a PML-RARα fusion protein that characterizes this form of cancer. A different isomer, 13-*cis*-retinoic acid, has been used with some success in the treatment of childhood neuroblastoma.

Vitamin A Deficiency. Vitamin A deficiency occurs worldwide either as a consequence of primary malnutrition or secondary to conditions that cause malabsorption of fats. In children, stores of vitamin A are depleted by infections, and the absorption of the vitamin is poor in newborn infants. Adult patients with malabsorption syndromes such as celiac disease, Crohn disease and colitis may develop vitamin A deficiency in conjunction with depletion of other fat-soluble vitamins. Bariatric surgery and, in older persons, continuous use of mineral oil as a laxative may lead to deficiency. The pathologic effects of vitamin A deficiency are summarized in Fig. 9.24.

As already discussed, vitamin A is a component of rhodopsin and other visual pigments. Not surprisingly, one of the earliest manifestations of vitamin A deficiency is impaired vision, particularly in reduced light (night blindness). Other effects of deficiency are related to the role of vitamin A in regulating the differentiation of epithelial cells. Persistent deficiency gives rise to epithelial metaplasia and keratinization. The most devastating changes occur in the eyes and are referred to as xerophthalmia (dry eye). First, there is dryness of the conjunctiva (xerosis conjunctivae) as the normal lacrimal and mucus-secreting epithelium is replaced by keratinized epithelium. This is followed by a

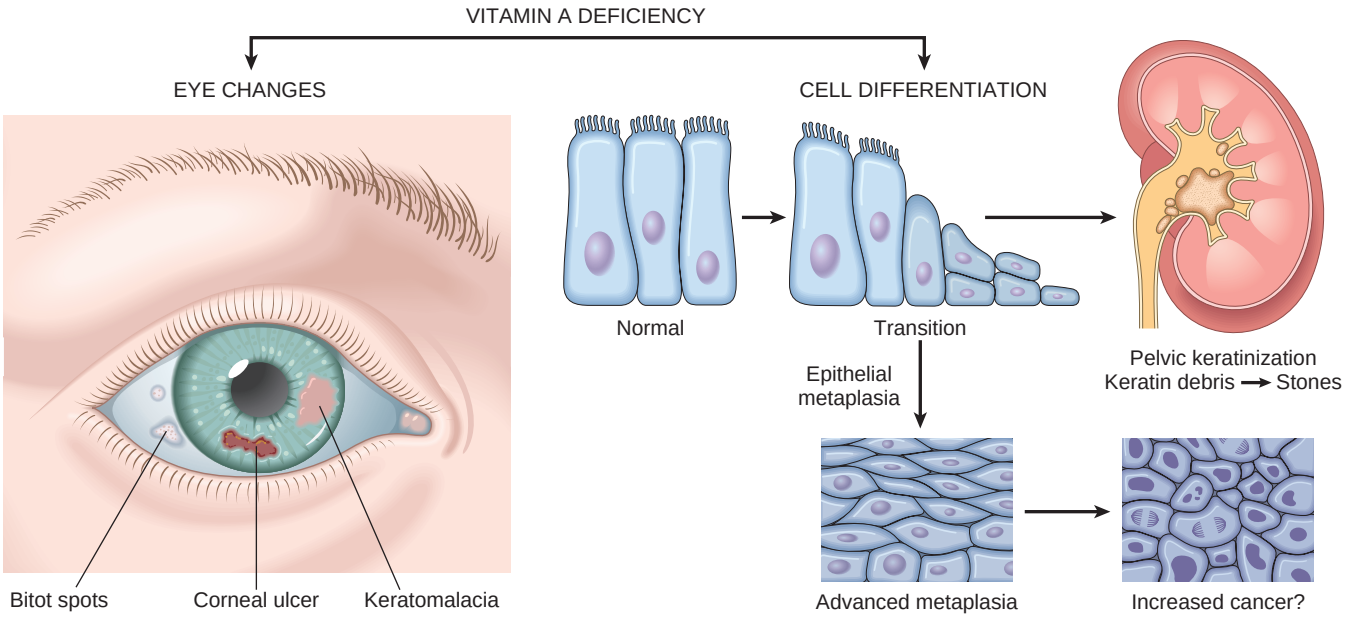

Figure 9.24 Vitamin A deficiency, its major consequences in the eye and in the production of keratinizing metaplasia of specialized epithelial surfaces, and its possible role in epithelial metaplasia. Not depicted are night blindness and immune deficiency.

buildup of keratin debris in small opaque plaques *(Bitot spots)* that progresses to erosion of the roughened corneal surface, softening and destruction of the cornea (keratomalacia), and blindness.

In addition to the ocular epithelium, the epithelium lining the upper respiratory passage and urinary tract also undergoes squamous metaplasia. Loss of the mucociliary epithelium of the airways predisposes to secondary pulmonary infections, and desquamation of keratin debris in the urinary tract predisposes to renal and urinary bladder stones. Hyperplasia and hyperkeratinization of the epidermis and plugging of the ducts of the adnexal glands may produce follicular or papular dermatosis. Another serious consequence is immune deficiency, which is responsible for higher mortality rates from common infections such as measles, pneumonia, and infectious diarrhea. In parts of the world where deficiency of vitamin A is prevalent, dietary supplements reduce mortality by 20% to 30%.

Vitamin A Toxicity. Both short-term and long-term excesses of vitamin A may produce toxic manifestations. The consequences of acute hypervitaminosis A were first described by Gerrit de Veer in 1597, a ship's carpenter stranded in the Arctic, who recounted in his diary the serious symptoms that he and other members of the crew developed after eating polar bear liver. With this cautionary tale in mind, the adventurous eater should be aware that acute vitamin A toxicity has also been described in individuals who ingested the livers of whales, sharks, and even tuna.

The symptoms of acute vitamin A toxicity include headache, dizziness, vomiting, stupor, and blurred vision, symptoms that may be confused with those of a brain tumor *(pseudotumor cerebri)*. Chronic toxicity is associated with weight loss, anorexia, nausea, vomiting, and bone and joint pain. Retinoic acid stimulates osteoclast production and activity, leading to increased bone resorption and high risk of fractures. Although synthetic retinoids used for the treatment of acne are not associated with these types of conditions, their use in pregnancy should be avoided because of the well-established teratogenic effects of retinoids.

Vitamin D

The major function of vitamin D is the maintenance of adequate plasma levels of calcium and phosphorus to support metabolic functions, bone mineralization, and neuromuscular transmission. Vitamin D is a fat-soluble vitamin required for the prevention of bone diseases known as *rickets* (in children whose epiphyses have not already closed) and *osteomalacia* (in adults), as well as *hypocalcemic tetany*. With respect to tetany, vitamin D maintains the correct concentration of ionized calcium in the extracellular fluid compartment. When deficiency develops, the drop in ionized calcium in the extracellular fluid results in continuous excitation of muscle (tetany). It should be noted, however, that any reduction in the level of serum calcium is usually corrected by increased secretion of parathyroid hormone followed by bone resorption; hence, tetany is quite uncommon. Our attention here is focused on the function of vitamin D in the regulation of serum calcium levels.

Metabolism of Vitamin D. **The major source of vitamin D for humans is its endogenous synthesis from a precursor, 7-dehydrocholesterol, in a photochemical reaction that requires solar or artificial UV light in the range of 290 to 315 nm (UVB radiation).** This reaction results in the synthesis of *cholecalciferol,* known as *vitamin* D_3. Herein, the term vitamin D is used to refer to this compound. Under usual conditions of sun exposure, about 90% of the required vitamin D is endogenously synthesized by the skin. However, individuals with dark skin generally have a lower level of vitamin D production because of melanin pigmentation. Dietary sources, such as deep-sea fish, plants, and grains, contribute the remaining required vitamin D and depend

on adequate intestinal fat absorption. In plants, vitamin D is present in a precursor form (ergosterol), which is converted to vitamin D in the body.

The main steps of vitamin D metabolism are summarized as follows:

1. Photochemical synthesis of vitamin D from 7-dehydrocholesterol in the skin and absorption of vitamin D from foods and supplements in the gut
2. Binding of vitamin D from both of these sources to plasma α_1-globulin (D-binding protein [DBP]) and transport into the liver
3. Conversion of vitamin D into 25-hydroxycholecalciferol (25-OH-D) in the liver, through the action of 25-hydroxylases, including CYP27A1 and other CYPs
4. Conversion of 25-OH-D into 1,25-dihydroxyvitamin D [$1\alpha,25(OH)_2D_3$], the most active form of vitamin D, by the enzyme 1α-hydroxylase in the kidney

The production of 1,25-dihydroxyvitamin D in the kidney is regulated by three main mechanisms (Fig. 9.25).

- *Hypocalcemia stimulates secretion of parathyroid hormone (PTH),* which in turn augments the conversion of

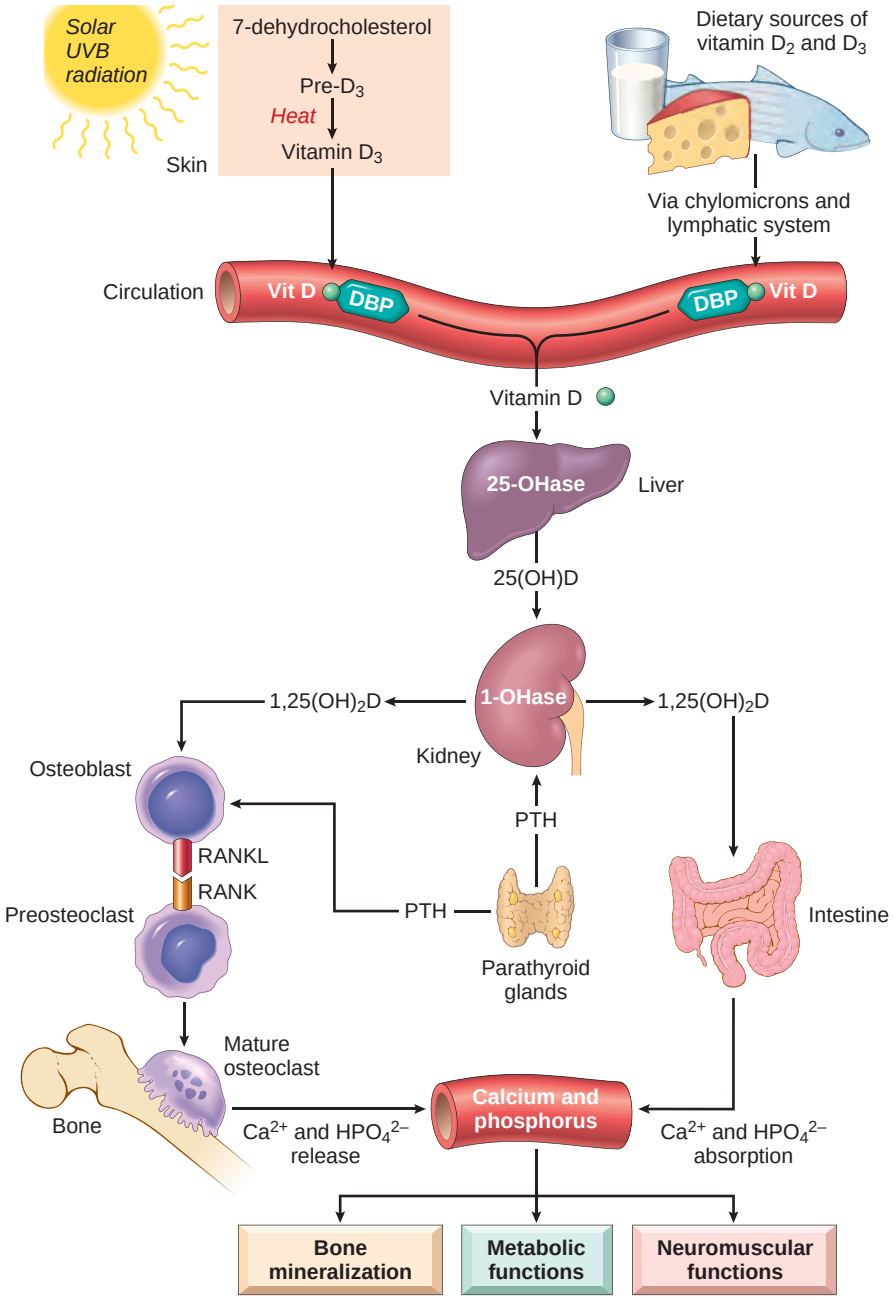

Figure 9.25 Vitamin D metabolism. Vitamin D is produced from 7-dehydrocholesterol in the skin or is ingested in the diet. It is converted in the liver into 25(OH)D and in the kidney into 1,25-dihydroxyvitamin D (*1,25(OH)$_2$D*), the active form of the vitamin. 1,25(OH)$_2$D stimulates the expression of RANKL, an important regulator of osteoclast maturation and function, on osteoblasts and enhances the intestinal absorption of calcium and phosphorus. *DBP,* Vitamin D–binding protein (α_1-globulin).

25-OH-D into 1,25-dihydroxyvitamin D by upregulating the expression of 1α-hydroxylase.
- *Hypophosphatemia also upregulates 1α-hydroxylase expression,* increasing the production of 1,25-dihydroxyvitamin D.
- *Through a feedback mechanism,* increased levels of 1,25-dihydroxyvitamin D downregulate its own synthesis through inhibition of 1α-hydroxylase activity.

Functions. Like retinoids and steroid hormones, 1,25-dihydroxyvitamin D acts by binding to a high-affinity nuclear receptor (vitamin D receptor), which associates with the already mentioned RXR. This heterodimeric complex binds to vitamin D response elements located in the regulatory sequences of vitamin D target genes. The receptors for 1,25-dihydroxyvitamin D are present in most cells of the body. In the small intestine, bones, and kidneys, signals transduced via these receptors regulate plasma levels of calcium and phosphorus. Beyond its role on skeletal homeostasis, vitamin D has immunomodulatory and antiproliferative effects. 1,25-Dihydroxyvitamin D also appears to act through mechanisms that do not require the transcription of target genes. These alternative mechanisms involve the binding of 1,25-dihydroxyvitamin D to a membrane-associated vitamin D receptor (mVDR), leading to the activation of protein kinase C and opening of calcium channels.

Effects of Vitamin D on Calcium and Phosphorus Homeostasis. The main functions of 1,25-dihydroxyvitamin D on calcium and phosphorus homeostasis are the following:
- *Stimulation of intestinal calcium absorption.* 1,25-Dihydroxyvitamin D stimulates intestinal absorption of calcium in the duodenum through the interaction of 1,25-dihydroxyvitamin D with nuclear vitamin D receptor and the formation of a complex with RXR. The complex binds to vitamin D response elements and activates the transcription of TRPV6 (a member of the transient receptor potential vanilloid family), which encodes a critical calcium transport channel.
- *Stimulation of calcium reabsorption in the kidney.* 1,25-Dihydroxyvitamin D increases calcium influx in distal tubules of the kidney through the increased expression of TRPV5, another member of the transient receptor potential vanilloid family. TRPV5 expression is also regulated by PTH in response to hypocalcemia.
- *Interaction with PTH in the regulation of blood calcium.* Vitamin D maintains calcium and phosphorus at supersaturated levels in the plasma. The parathyroid glands have a key role in the regulation of extracellular calcium concentrations. These glands have a calcium receptor that senses even small changes in blood calcium concentrations. In addition to their effects on calcium absorption in the intestine and kidneys already described, both 1,25-dihydroxyvitamin D and PTH enhance the expression of RANKL (receptor activator of NF-κB ligand) on osteoblasts. RANKL binds to its receptor (RANK) located in preosteoclasts, thereby inducing the differentiation of these cells into mature osteoclasts (Chapter 26). Through the secretion of hydrochloric acid and activation of proteases such as cathepsin K, osteoclasts dissolve bone and release calcium and phosphorus into the circulation.
- *Mineralization of bone.* Vitamin D contributes to the mineralization of osteoid matrix and epiphyseal cartilage in both flat and long bones. It stimulates osteoblasts to synthesize the calcium-binding protein osteocalcin, which is involved in the deposition of calcium during bone development. Flat bones develop by intramembranous bone formation, in which mesenchymal cells differentiate directly into osteoblasts, which synthesize the collagenous osteoid matrix on which calcium is deposited. Long bones develop by endochondral ossification, through which growing cartilage at the epiphyseal plates is provisionally mineralized and then progressively resorbed and replaced by osteoid matrix that is mineralized to create bone (Fig. 9.26A).

When *hypocalcemia* occurs due to vitamin D deficiency (Fig. 9.27), PTH production is elevated, causing (1) activation of renal 1α-hydroxylase, increasing the amount of active vitamin D and calcium absorption; (2) increased resorption of calcium from bone by osteoclasts; (3) decreased renal calcium excretion; and (4) increased renal excretion of phosphate. Although a normal serum level of calcium may be restored, hypophosphatemia persists, impairing the mineralization of bone. Increased production of FGF-23 may be responsible for tumor-induced osteomalacia and some forms of hypophosphatemic rickets.

Deficiency States. The normal reference range for circulating 25-(OH)-D is 20 to 100 ng/mL; concentrations of less than 20 ng/mL constitute vitamin D deficiency.

Rickets in growing children and osteomalacia in adults are skeletal diseases with worldwide distributions. They may result from diets deficient in calcium and vitamin D, but an equally important cause of vitamin D deficiency is limited exposure to sunlight. This most often affects inhabitants of northern latitudes, but can even be a problem in tropical countries, in heavily veiled women, and in children born to mothers who have frequent pregnancies followed by lactation. In all of these situations, vitamin D deficiency can be prevented by a diet high in fish oils. Other, less common causes of rickets and osteomalacia include renal disorders causing decreased synthesis of 1,25-dihydroxyvitamin D, phosphate depletion, malabsorption disorders, and some rare inherited disorders. Although rickets and osteomalacia rarely occur outside high-risk groups, milder forms of vitamin D deficiency leading to an increased risk of bone loss and hip fractures are quite common in older adults in the United States and Europe. Some genetically determined variants of the vitamin D receptors are also associated with accelerated loss of bone minerals during aging and certain familial forms of osteoporosis (Chapter 26).

MORPHOLOGY

Vitamin D deficiency in both rickets and osteomalacia results in an **excess of unmineralized matrix.** The following sequence ensues in rickets:
- Overgrowth of epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to mature and disintegrate
- Persistence of distorted, irregular masses of cartilage that project into the marrow cavity

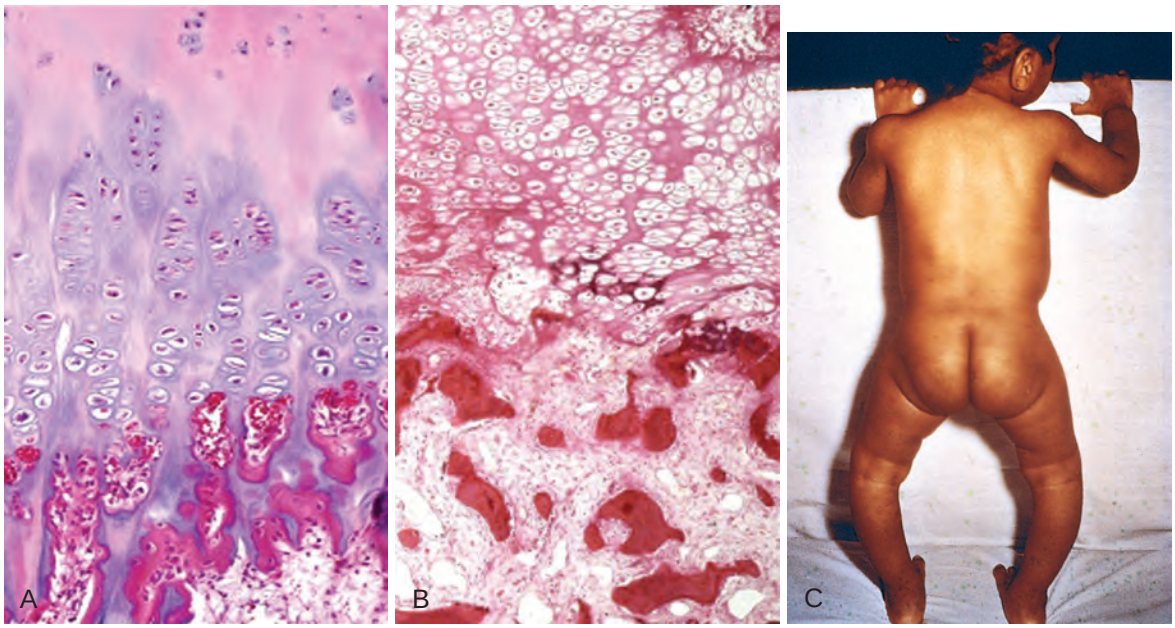

Figure 9.26 Rickets. (A) Normal costochondral junction of a young child illustrating formation of cartilage palisades and orderly transition from cartilage to new bone. (B) Detail of a rachitic costochondral junction in which the palisades of cartilage is lost. Darker trabeculae are well-formed bone; paler trabeculae consist of uncalcified osteoid. (C) Rickets: note bowing of legs due to formation of poorly mineralized bones. (B, Courtesy Dr. Andrew E. Rosenberg, Massachusetts General Hospital, Boston, Mass.)

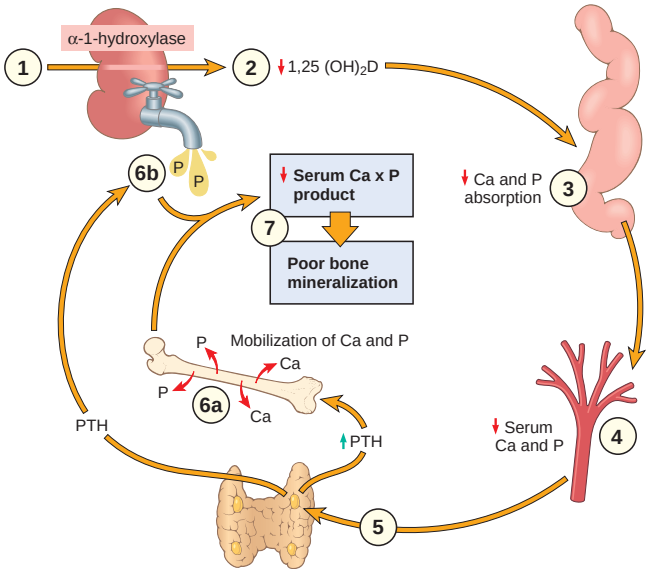

Figure 9.27 Vitamin D deficiency. There is inadequate substrate for renal 1α-hydroxylase *(1)*, yielding a deficiency of $1,25(OH)_2D$ *(2)*, and deficient absorption of calcium *(Ca)* and phosphorus *(P)* from the gut *(3)*, with consequently depressed serum levels of both *(4)*. The hypocalcemia activates the parathyroid glands *(5)*, causing mobilization of calcium and phosphorus from bone *(6a)*. Simultaneously, the parathyroid hormone *(PTH)* induces wasting of phosphate in the urine *(6b)* and calcium retention. As a result, the serum levels of calcium are normal or nearly normal, but phosphate levels are low; hence mineralization is impaired *(7)*.

- Deposition of osteoid matrix on inadequately mineralized cartilaginous remnants
- Disruption of the orderly replacement of cartilage by osteoid matrix, with enlargement and lateral expansion of the osteochondral junction (see Fig. 9.26B)
- Abnormal overgrowth of capillaries and fibroblasts in the disorganized zone resulting from microfractures and stresses on the inadequately mineralized, weak, poorly formed bone
- Deformation of the skeleton due to the loss of structural rigidity of the developing bones

The gross skeletal changes in rickets depend on the severity and duration of the process and, in particular, the stresses to which individual bones are subjected. During the nonambulatory stage of infancy, the head and chest sustain the greatest stresses. The softened occipital bones may become flattened, and the parietal bones can be buckled inward by pressure; with the release of the pressure, elastic recoil snaps the bones back into their original positions **(craniotabes).** An excess of osteoid produces **frontal bossing** and a **squared appearance to the head**. Deformation of the chest results from overgrowth of cartilage or osteoid tissue at the costochondral junction, producing the **rachitic rosary.** The weakened metaphyseal areas of the ribs are subject to the pull of the respiratory muscles and thus bend inward, creating anterior protrusion of the sternum **(pigeon breast deformity).** When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and tibia, causing **lumbar lordosis** and **bowing of the legs** (see Fig. 9.26C).

In adults with **osteomalacia,** the lack of vitamin D deranges the normal bone remodeling that occurs throughout life. The newly formed osteoid matrix laid down by osteoblasts is inadequately mineralized, thus producing the excess of persistent osteoid that is characteristic of osteomalacia. Although the contours of the bone are not affected, the bone is weak and vulnerable to

gross fractures or microfractures, which are most likely to affect vertebral bodies and femoral necks. The unmineralized osteoid appears as a thickened layer of matrix (which stains pink in hematoxylin and eosin preparations) arranged about the more basophilic, normally mineralized trabeculae.

Nonskeletal Effects of Vitamin D. As mentioned earlier, the vitamin D receptor is present in various cells and tissues that do not participate in calcium and phosphorus homeostasis. In addition, macrophages, keratinocytes, and tissues such as breast, prostate, and colon can produce 1,25-dihydroxyvitamin D. Within macrophages, synthesis of 1,25-dihydroxyvitamin D occurs through the activity of CYP27B located in the mitochondria. It appears that pathogen-induced activation of Toll-like receptors in macrophages causes increased expression of vitamin D receptor and CYP27B, leading to local synthesis of 1,25-dihydroxyvitamin D and activation of vitamin D–dependent gene expression in macrophages and other neighboring immune cells. The net effect of this altered gene expression on the immune response remains to be determined, however, and clinical trials have failed to demonstrate beneficial effects of vitamin D supplements on the course of respiratory infections, including tuberculosis.

Vitamin D Toxicity. Prolonged exposure to normal sunlight does not produce an excess of vitamin D, but megadoses of orally administered vitamin can lead to hypervitaminosis. In children, hypervitaminosis D may take the form of metastatic calcifications of soft tissues such as the kidney; in adults, it causes bone pain and hypercalcemia. The toxic potential of this vitamin is so great that in sufficiently large doses it is a potent rodenticide.

Vitamin C (Ascorbic Acid)

A deficiency of water-soluble vitamin C leads to the development of *scurvy*, characterized principally by bone disease in growing children and by hemorrhages and healing defects in both children and adults. Sailors of the British Royal Navy were nicknamed "limeys" because at the end of the 18th century the Navy began to provide lime and lemon juice (rich sources of vitamin C) to sailors to prevent scurvy during their long sojourn at sea. It was not until 1932 that ascorbic acid was identified and synthesized. Ascorbic acid is not synthesized endogenously in humans; therefore we are entirely dependent on the diet for this nutrient. Vitamin C is present in milk and some animal products (liver, fish) and is abundant in a variety of fruits and vegetables. All but the most restricted diets provide adequate amounts of vitamin C.

Function. Ascorbic acid has many functions affecting a variety of processes:

- *Collagen synthesis*. The best-established function of vitamin C is the *activation of prolyl and lysyl hydroxylases* from inactive precursors, providing for *hydroxylation of procollagen*. Inadequately hydroxylated procollagen cannot acquire a stable helical configuration, so it is poorly secreted from the fibroblast. Those molecules that are secreted are inadequately cross-linked, lack tensile strength, and are more soluble and vulnerable to enzymatic degradation. Collagen, which normally has the highest content of hydroxyproline of any polypeptide, is most affected, particularly in blood vessels, accounting for the predisposition to hemorrhages in scurvy.
- *Neurotransmitter synthesis*. Synthesis of norepinephrine requires hydroxylation of dopamine, a step that requires vitamin C.
- *Antioxidant functions.*
- *Modulating the immune response.*

The effect on the latter two has formed the basis of clinical trials based on supplementation of vitamin C in sepsis.

Deficiency States. Consequences of vitamin C deficiency (scurvy) are illustrated in Fig. 9.28. Because of the abundance

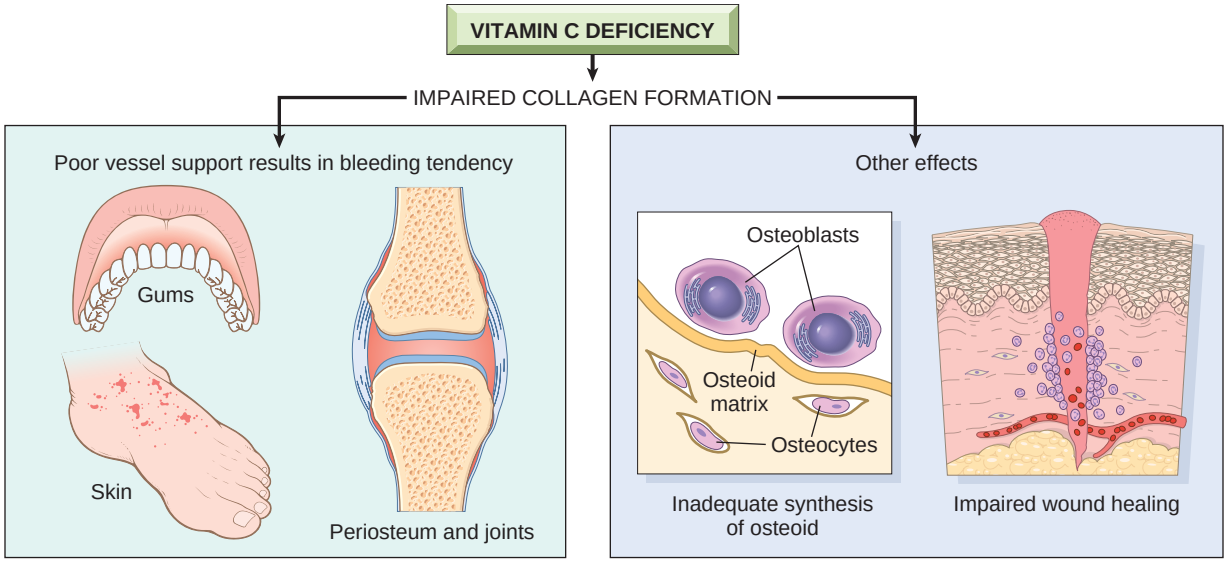

Figure 9.28 Major consequences of vitamin C deficiency caused by impaired formation of collagen.

of ascorbic acid in many foods, scurvy has ceased to be a global problem. It is sometimes encountered even in affluent populations as a secondary deficiency, particularly among older individuals, persons who live alone, and chronic alcoholics, groups that often have erratic and inadequate eating patterns. Occasionally, scurvy occurs in patients undergoing peritoneal dialysis and hemodialysis and in food faddists. The condition also sometimes appears in infants who are maintained on formulas of evaporated milk without supplementation of vitamin C.

Vitamin C Excess. The popular notion that megadoses of vitamin C protect against the common cold, or at least allay the symptoms, has not been borne out by controlled clinical studies. Such slight relief as may be experienced is probably due to the mild antihistamine action of ascorbic acid. Similarly, there is no evidence that large doses of vitamin C protect against cancer development. The physiologic availability of excess vitamin C is limited due to its inherent instability, poor intestinal absorption, and rapid urinary excretion. Fortunately, toxicities related to high doses of vitamin C are rare, consisting of possible iron overload (due to increased absorption), hemolytic anemia in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 14), and calcium oxalate kidney stones.

Other vitamins and some essential minerals are listed and briefly described in Tables 9.9 and 9.10 and are discussed in other chapters.

KEY CONCEPTS

NUTRITIONAL DISEASES

- SAM is a common cause of childhood deaths in low income countries. The two main primary forms of SAM syndromes are marasmus and kwashiorkor. Secondary malnutrition occurs in the chronically ill and in patients with advanced cancer (as a result of cachexia).
- Kwashiorkor is characterized by hypoalbuminemia, generalized edema, fatty liver, skin changes, and defects in immunity. It is caused by diets low in protein but normal in calories.
- Marasmus is characterized by emaciation resulting from loss of muscle mass and fat with relative preservation of serum albumin. It is caused by diets severely lacking in both protein and nonprotein calories.
- Anorexia nervosa is self-induced starvation; it is characterized by amenorrhea and multiple manifestations of low thyroid hormone levels. Bulimia is a condition in which food binges alternate with induced vomiting.
- Vitamins A and D are fat-soluble vitamins with a wide range of activities. Vitamin A is required for vision, epithelial differentiation, and immune function. Vitamin D is a key regulator of calcium and phosphate homeostasis.
- Vitamin C and members of the vitamin B family are water-soluble. Vitamin C is needed for collagen synthesis and collagen cross-linking and tensile strength. B vitamins have diverse roles in cellular metabolism.

Table 9.9 Vitamins: Major Functions and Deficiency Syndromes

Vitamin	Functions	Deficiency Syndromes
Fat-Soluble		
Vitamin A	A component of visual pigment Maintenance of specialized epithelia Maintenance of resistance to infection	Night blindness, xerophthalmia, blindness Squamous metaplasia Vulnerability to infection, particularly measles
Vitamin D	Facilitates intestinal absorption of calcium and phosphorus and mineralization of bone	Rickets in children Osteomalacia in adults
Vitamin E	Major antioxidant; scavenges free radicals	Spinocerebellar degeneration, hemolytic anemia
Vitamin K	Cofactor in hepatic carboxylation of procoagulants—factors II (prothrombin), VII, IX, and X and protein C and protein S	Bleeding diathesis (Chapter 14)
Water-Soluble		
Vitamin B_1 (thiamine)	As pyrophosphate, is coenzyme in decarboxylation reactions	Dry and wet beriberi, Wernicke syndrome, Korsakoff syndrome (Chapter 28)
Vitamin B_2 (riboflavin)	Converted to coenzymes flavin mononucleotide and flavin adenine dinucleotide, cofactors for many enzymes in intermediary metabolism	Ariboflavinosis, cheilosis, stomatitis, glossitis, dermatitis, corneal vascularization
Niacin	Incorporated into nicotinamide adenine dinucleotide (NAD) and NAD phosphate, involved in a variety of redox reactions	Pellagra—"three Ds": dementia, dermatitis, diarrhea
Vitamin B_6 (pyridoxine)	Derivatives serve as coenzymes in many intermediary reactions	Cheilosis, glossitis, dermatitis, peripheral neuropathy (Chapter 28) Maintenance of myelinization of spinal cord tracts
Vitamin B_{12}	Required for normal folate metabolism and DNA synthesis	Megaloblastic pernicious anemia and degeneration of posterolateral spinal cord tracts (Chapter 14)
Vitamin C	Serves in many oxidation-reduction (redox) reactions and hydroxylation of collagen	Scurvy
Folate	Essential for transfer and use of one-carbon units in DNA synthesis	Megaloblastic anemia, neural tube defects (Chapter 14)
Pantothenic acid	Incorporated in coenzyme A	No nonexperimental syndrome recognized
Biotin	Cofactor in carboxylation reactions	No clearly defined clinical syndrome

Table 9.10 Selected Trace Elements and Deficiency Syndromes

Element	Function	Basis of Deficiency	Clinical Features
Zinc	Component of enzymes, principally oxidases	Inadequate supplementation in artificial diets Interference with absorption by other dietary constituents Inborn error of metabolism	Rash around eyes, mouth, nose, and anus called acrodermatitis enteropathica Anorexia and diarrhea Growth retardation in children Depressed mental function Depressed wound healing and immune response Impaired night vision Infertility
Iron	Essential component of hemoglobin as well as several iron-containing metalloenzymes	Inadequate diet Chronic blood loss	Hypochromic microcytic anemia (Chapter 14)
Iodine	Component of thyroid hormone	Inadequate supply in food and water	Goiter and hypothyroidism (Chapter 24)
Copper	Component of cytochrome *c* oxidase, dopamine β-hydroxylase, tyrosinase, lysyl oxidase, and unknown enzymes involved in cross-linking collagen	Inadequate supplementation in artificial diet Interference with absorption	Muscle weakness Neurologic defects Abnormal collagen cross-linking
Fluoride	Mechanism unknown	Inadequate supply in soil and water Inadequate supplementation	Dental caries (Chapter 16)
Selenium	Component of glutathione peroxidase Antioxidant with vitamin E	Inadequate amounts in soil and water	Myopathy Cardiomyopathy (Keshan disease)

Obesity

Obesity is defined as an accumulation of adipose tissue that is of sufficient magnitude to impair health. How does one measure fat accumulation? Several high-tech methods have been devised, but for practical purposes the *body mass index* (BMI) is most commonly used. BMI is calculated as (weight in kilograms)/(height in meters)^2, or kg/m^2. The normal BMI range is 18.5 to 25 kg/m^2, although the range differs for different countries due to differences in ethnicity and genetic backgrounds. Individuals with BMI greater than 30 kg/m^2 are classified as obese; individuals with BMI between 25 kg/m^2 and 30 kg/m^2 are considered overweight. Unless otherwise noted, the term obesity herein applies to both truly obese and overweight individuals.

Obesity is associated with several of the most important diseases of humans, including type 2 diabetes, dyslipidemia, cardiovascular disease, hypertension, and cancer. The strength of this association is affected not only by the quantity of excess fat but also by its distribution. Central, or visceral, obesity, in which excess fat accumulates preferentially in the trunk and in the abdominal cavity (in the mesentery and around viscera), is associated with a much higher risk for several diseases than is excess accumulation of subcutaneous fat.

Obesity is a major public health problem in higher income countries and an emerging health problem in lower income nations, such as India. According to the WHO, >1.9 billion adults were estimated to be overweight or obese globally in 2015, of which 650 million were obese. In the United States, obesity has reached epidemic proportions. In 2016 the prevalence of obesity in men was 37.9%, and the prevalence of obesity in women was 41.1%. Equally troubling is the prevalence of obesity in children and adolescents, approximately one-third of whom are obese. The increase in obesity in the United States has been associated with the higher caloric content of the diet, mostly caused by increased consumption of refined sugars, sweetened beverages, and vegetable oils.

The etiology of obesity is complex and incompletely understood. Genetic, environmental, and psychologic factors are involved. However, simply put, obesity is a disorder of energy homeostasis. **The two sides of the energy equation, intake and expenditure, are finely regulated by neural and hormonal mechanisms so that body weight is maintained within a narrow range for many years.** Apparently, this fine balance is controlled by an internal set-point, or "lipostat," that senses the quantity of energy stores (adipose tissue) and appropriately regulates food intake as well as energy expenditure. The hypothalamus is the master regulator of energy homeostasis. It receives inputs from the periphery about the state of energy stores; if they are inadequate, it triggers anabolic circuits, and if they are adequate, catabolic circuits are activated. The effect of the anabolic circuits is to increase intake of food and reduce energy expenditure, whereas catabolic circuits reduce food intake and increase energy expenditure. The neurohumoral mechanisms that regulate energy balance can be subdivided into three components (Figs. 9.29 and 9.30).

- The *peripheral or afferent system* generates signals from various sites. Its main components are leptin produced by fat cells, ghrelin from the stomach, peptide YY (PYY) and glucagon-like peptide 1 (GLP-1) from the ileum and colon, and insulin from the pancreas. The afferent systems provide signals to the central processing system in the brain.
- *The central processing system resides in the arcuate nucleus of the hypothalamus* where neurohumoral peripheral signals are integrated to generate efferent signals. Two sets of neurons participate in central processing (see Fig. 9.30).
  - A pair of first-order neurons: (1) pro-opiomelanocortin *(POMC)* and cocaine and amphetamine-regulated transcript *(CART)* neurons and (2) neurons containing neuropeptide Y *(NPY)* and agouti-related peptide

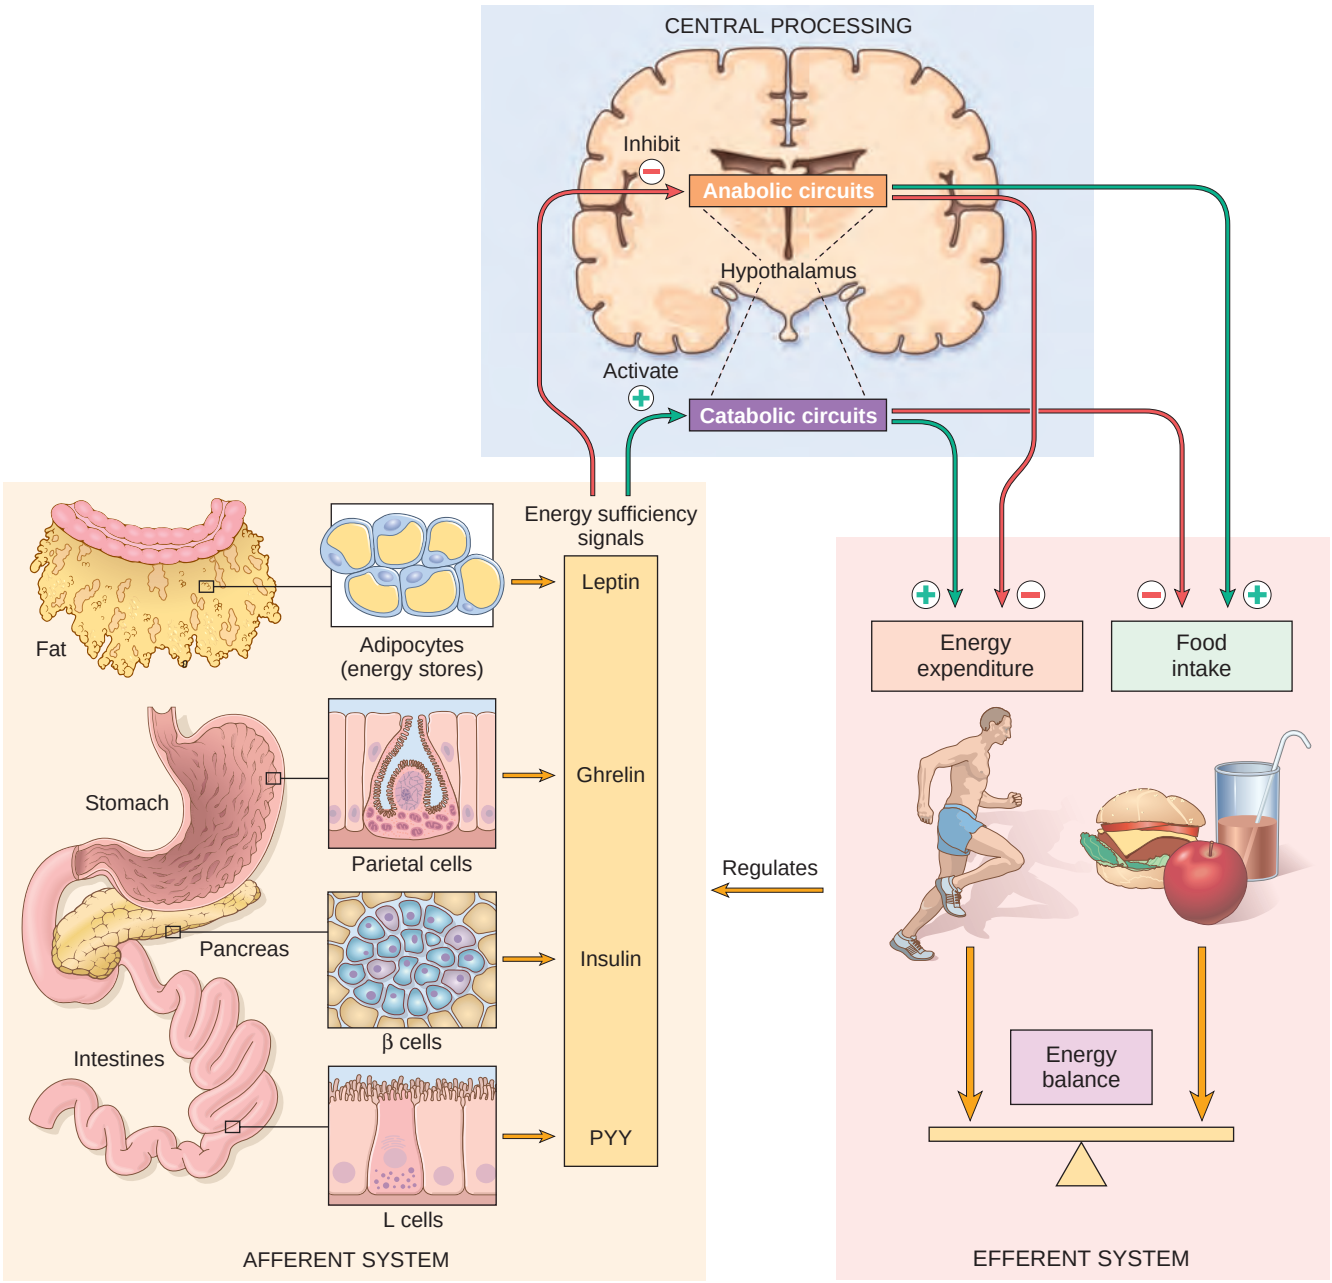

Figure 9.29 Energy balance regulatory circuitry. When sufficient energy is stored in adipose tissue and the individual is well fed, afferent signals (insulin, leptin, ghrelin, peptide YY) are delivered to the central neuronal processing units in the hypothalamus. Here these signals inhibit anabolic circuits and activate catabolic circuits. The effector arms of these central circuits then influence energy balance by inhibiting food intake and promoting energy expenditure. This in turn reduces the energy stores, and energy sufficiency signals are blunted. Conversely, when energy stores are low, the anabolic circuits take over, at the expense of catabolic circuits, to generate energy stores in the form of adipose tissue.

(AgRP). These first-order neurons communicate with second-order neurons.

- A pair of second-order neurons: (1) neurons that bear melanocortin receptors 3 and 4 (MC3/4R) and receive signals from first-order *POMC/CART* neurons and (2) neurons that bear Y1 and Y5 receptors and receive signals from first-order *NPY/AgRP* neurons.

- The *efferent system* consists of signals generated by second-order neurons and is organized along two pathways, catabolic (downstream of MC3/4R) and anabolic (downstream of Y1 and Y5 receptors) that control food intake and energy expenditure. In addition to these circuits (within the hypothalamus), the hypothalamic nuclei also communicate with forebrain and midbrain centers that control the autonomic nervous system.

With this background on the organization of the hypothalamic centers that regulate energy balance, we can now discuss how they function. Upon nutrient intake, POMC is cleaved from *POMC/CART* neurons and gives rise to α-melanocyte–stimulating hormone (MSH), which activates MC3/4R receptors in second-order neurons. These

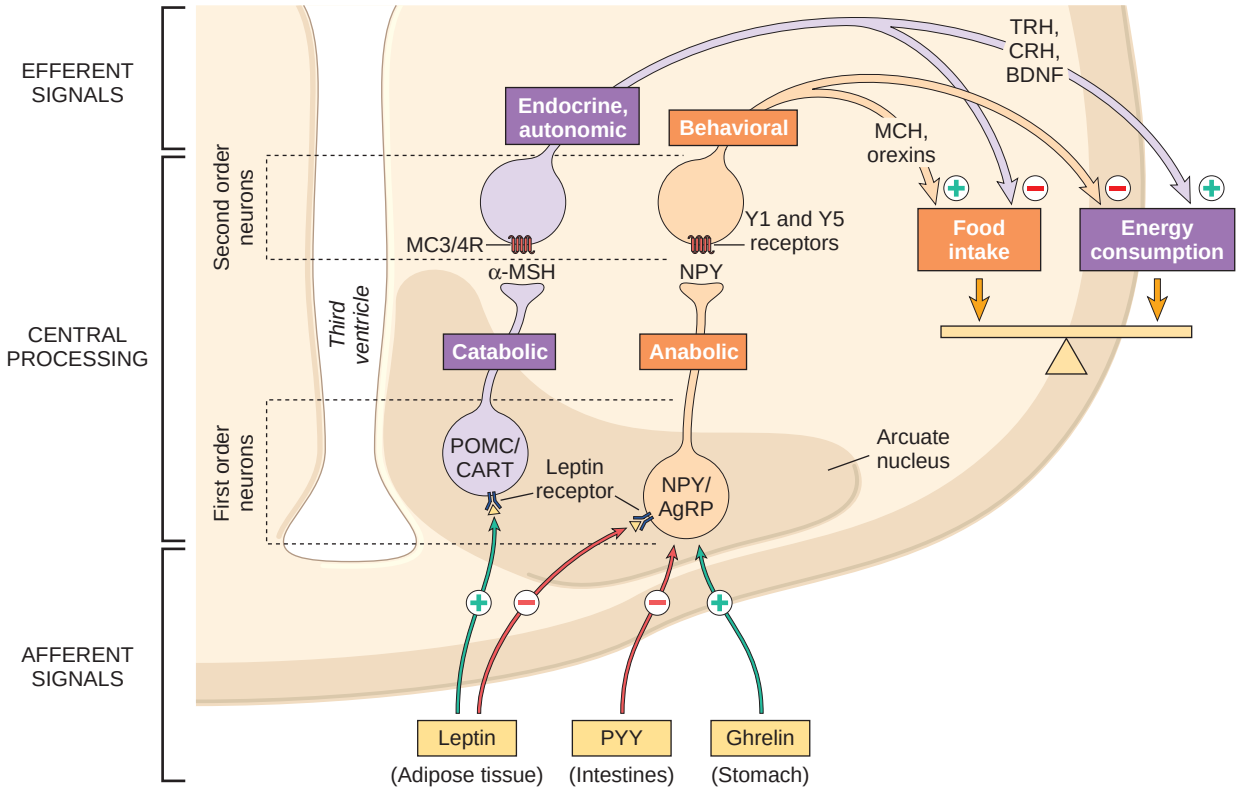

Figure 9.30 Neurohumoral circuits in the hypothalamus that regulate energy balance. Shown are POMC/CART anorexigenic neurons and NPY/AgRP orexigenic neurons in the arcuate nucleus of the hypothalamus and their pathways. See text for details. *BDNF,* Brain-derived neurotrophic factor; *CRH,* corticotropin-releasing hormone; *TRH,* thyroid-releasing hormone; *MCH,* melanin-concentrating hormone; *PYY,* peptide YY.

second-order neurons are responsible for reducing food intake and increasing energy expenditure by producing brain-derived neurotrophic factor (BDNF), thyroid-releasing hormone (TSH), and corticotropin-releasing hormone (CRH). By contrast, fasting activates the NPY/AgRP neurons to release NPY, which activates Y1and Y5 receptors in second-order neurons. These second-order neurons are responsible for increasing food intake by producing melanin-concentrating hormone (MCH) and orexin, and for reducing energy expenditure by downregulation of sympathetic output. NPY/AgRP neurons also directly inhibit POMC/CART neurons, thus blunting their anorexigenic effect.

To summarize, NPY/AgRP neurons may be thought of as the gas pedals for appetite, whereas POMC/CART neurons represent the brake pedal. The orderly functioning of these two pedals maintains energy homeostasis.

Discussed next are three important components of the afferent system, which regulates appetite and satiety: leptin, gut hormones, and adiponectin, which regulates energy consumption.

Leptin. **Leptin is secreted by fat cells, and its output is regulated by the adequacy of fat stores.** BMI and body fat stores are directly related to leptin secretion. With abundant adipose tissue, leptin secretion is stimulated and it crosses the blood–brain barrier and travels to the hypothalamus, where it reduces food intake by stimulating POMC/CART neurons and inhibiting NPY/AgRP neurons. The opposite sequence of events occurs when there are inadequate stores of body fat: leptin secretion is diminished, and food intake is increased. In persons of stable weight, the activities of these pathways are balanced.

Leptin regulates not only food intake but also energy expenditure through a distinct set of pathways. Thus an abundance of leptin stimulates physical activity, heat production, and energy expenditure. The neurohumoral mediators of leptin-induced energy expenditure are less well defined. *Thermogenesis,* an important catabolic effect mediated by leptin, is controlled in part by hypothalamic signals that increase the release of norepinephrine from sympathetic nerve endings in adipose tissue.

The central role of leptin in energy homeostasis is underscored by the study of mutations affecting components of the leptin pathway in mice and in humans. Mice with mutations that disable the leptin gene or its receptor fail to sense the adequacy of fat stores, so they behave as if they are undernourished, eating ravenously and becoming massively obese. As in mice, mutations of the leptin gene or receptor in humans, although rare, cause massive obesity. More common are mutations in the melanocortin receptor 4 gene *(MC4R),* found in 4% to 5% of patients with massive obesity. These monogenic traits confirm the importance of leptin signaling in the control of body weight, and it is possible that other genetic or acquired defects in the leptin pathway play a role in the more common forms of obesity. In keeping with this notion, the anorexigenic response of leptin is blunted in states of obesity despite high levels of circulating leptin (leptin resistance). Furthermore, injections of leptin in obese humans fail to affect food intake and

energy expenditure, dashing initial enthusiasm of leptin therapy for obesity.

In closing it should be noted that although our discussion has centered on the actions of leptin, there is increasing evidence that insulin, like leptin, exerts anorexigenic responses. Both POMC/CART and NPY/AgRP neurons express insulin receptors. However, while insulin can mimic the actions of leptin, most of the evidence suggests the primacy of leptin in the regulation of energy homeostasis.

Adiponectin. **Adiponectin, produced in the adipose tissue, has been called a "fat-burning molecule,"** as it stimulates fatty acid oxidation in skeletal muscle, thereby reducing fatty acid levels. Evidence suggests that excess fatty acids can cross the blood–brain barrier and enter the hypothalamus, where they are sensed by microglial cells. These cells respond by releasing inflammatory factors that appear to act on hypothalamic neurons to cause leptin resistance, thereby blunting its antiadiposity signals. Because of its actions on reducing fatty acids by promoting their oxidation, adiponectin is called the "guardian angel against obesity." Adiponectin also decreases glucose production in the liver and increases insulin sensitivity, protecting against the metabolic syndrome. In addition to its metabolic effects, adiponectin has antiinflammatory, antiatherogenic, antiproliferative, and cardioprotective effects. Its serum levels are lower in obese than in lean individuals. These effects contribute to obesity-associated insulin resistance, type 2 diabetes, and nonalcoholic fatty liver disease (Chapter 18).

Adiponectin binds to two receptors, AdipoR1 and AdipoR2. These receptors are found in many tissues, including the brain, but AdipoR1 and AdipoR2 are most highly expressed in skeletal muscle and liver, respectively. Binding of adiponectin to its receptors triggers signals that activate cyclic adenosine monophosphate (cAMP)–dependent protein kinase (protein kinase A), which in turn phosphorylates and inactivates acetyl coenzyme A carboxylase, a key enzyme required for fatty acid synthesis.

Gut Hormones. Gut peptides act as short-term meal initiators and terminators. They include ghrelin, PYY, and GLP-1 (glucagon-like peptide-1), among others. *Ghrelin* is produced in the stomach and is the only known gut hormone that increases food intake (orexigenic effect). Its injection in rodents elicits voracious feeding, even after repeated administration. Long-term injections cause weight gain, by increasing caloric intake and reducing energy utilization. Ghrelin acts centrally by activating orexigenic NPY/AgRP neurons.

Ghrelin levels normally rise before meals and fall 1 to 2 hours afterward, but this drop is attenuated in obese persons. Ghrelin levels are lower in obese individuals compared with normal-weight individuals, and levels increase with a reduction in obesity. Interestingly, the rise in ghrelin levels is much reduced in individuals in whom gastric bypass surgery is performed for the treatment of obesity, suggesting that the beneficial effects of such surgery may be in part due to a reduced surface of gastric mucosa that is exposed to food.

PYY and GLP-1 are secreted from endocrine cells in the ileum and colon. Plasma levels of PYY and GLP-1 are low during fasting and increase shortly after food intake. Both PYY and GLP-1 act centrally through NPY/AgRP neurons in the hypothalamus, causing a decrease in food intake. Because of the anorexigenic effect of GLP-1, agonists of GLP-1 receptor have recently been approved for treatment of obesity and type 2 diabetes since in addition to reducing food intake, GLP-1 enhances glucose-dependent insulin secretion.

Adipose Tissue. It has been known for quite some time that there are two types of adipose tissues: white adipose tissue (WAT) and brown adipose tissue (BAT). BAT has the unique property of expending energy by nonshivering thermogenesis. BAT functions by uncoupling energy production from energy storage and converting the energy produced into heat. BAT is abundant in newborns and is located primarily in interscapular and supraclavicular areas. Lesser amounts are present around kidneys, aorta, heart, pancreas, and trachea. Until recently, it was thought that BAT is lost in adults. However, recent imaging studies have revealed that some BAT is preserved in adolescents and adults. Much effort is now focused on how BAT can be preserved in adulthood and activated to burn energy.

In addition to leptin and adiponectin, white adipose tissue produces cytokines such as TNF, IL-6, IL-1, and IL-18; chemokines; and steroid hormones. The increased production of cytokines and chemokines by adipose tissue in obese patients creates a chronic proinflammatory state marked by high levels of circulating C-reactive protein (CRP). This relationship may be more than a one-way street, as emerging evidence suggests that immune cells, particularly tissue macrophages, have important roles in regulating adipocyte function.

It is now evident that through this panoply of mediators, adipose tissue participates in the control of energy balance and energy metabolism, functioning as a link between lipid metabolism, nutrition, and inflammatory responses. Thus the adipocyte, which was relegated to an obscure and passive role as the "Cinderella of cells of metabolism," is now "the belle of the ball" at the forefront of metabolic research.

Role of the Gut Microbiome. An interesting series of observations in mice suggest that the gut microbiome may be involved in the development of obesity. In support of this notion is the finding that the profiles of gut microbiota differ between genetically obese mice and their lean littermates. The microbiome of genetically obese mice can harvest much more energy from food compared with that of lean mice. Colonization of the gut of germ-free mice by microbiota from obese mice (but not microbiota from lean mice) is associated with increased body weight. The relevance of the mouse models to human obesity is tantalizing but remains to be proven. Differences between the gut microbiome of obese and lean humans have also been reported. Whether this difference is causal or just an association is unclear.

Clinical Consequences of Obesity

Obesity, particularly central obesity, is associated with an increase in all-cause mortality and is a known risk factor for a number of conditions including type 2 diabetes, cardiovascular disease, and cancer (Fig. 9.31). Central obesity also stands at the center of a cluster of alterations known

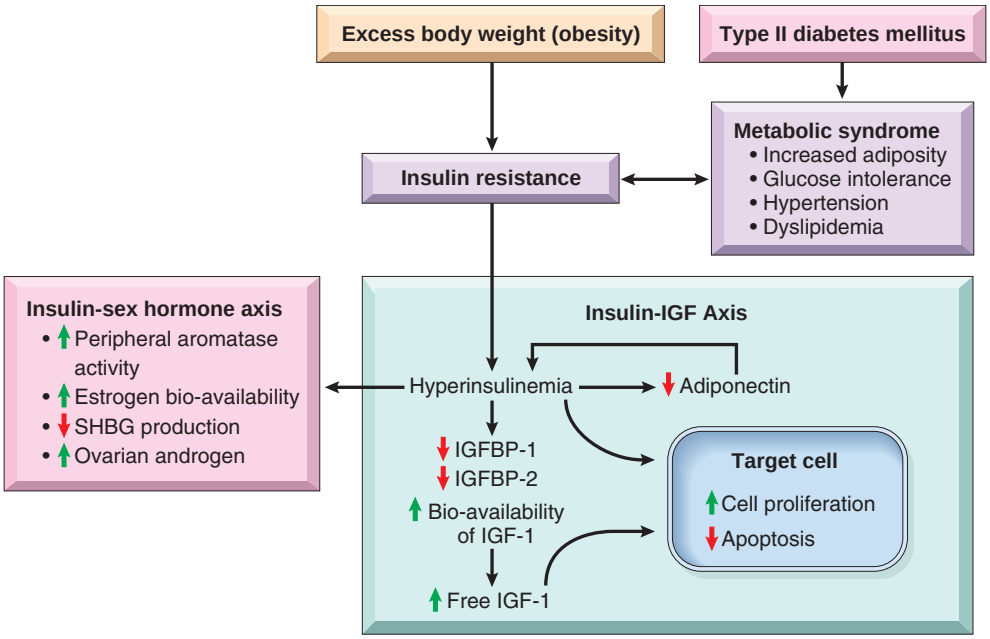

Figure 9.31 Obesity, metabolic syndrome, and cancer. Excessive weight and obesity are precursors of the metabolic syndrome, which is associated with insulin resistance, type 2 diabetes, and hormonal changes. Increases in insulin and insulin-like growth factor-1 stimulate cell proliferation and inhibit apoptosis and may contribute to tumor development. *IGF,* Insulin-like growth factor; *IGFBP,* insulin-like growth factor–binding protein; *SHBG,* sex hormone–binding globulin. (Modified from Renehan AG, et al: and cancer. Obesity and excessive weight: the role of the insulin-IGF axis, *Trends Endocrinol Metab* 17:328, 2006.)

as the *metabolic syndrome,* characterized by abnormalities of glucose and lipid metabolism coupled with hypertension and evidence of a systemic proinflammatory state. This seems to be caused by activation of the inflammasome by free fatty acids and excess levels of lipids in cells and tissue. This in turn stimulates secretion of IL-1, which induces systemic inflammation. The following associations are worthy of note.

- *Obesity is associated with insulin resistance and hyperinsulinemia,* important features of type 2 diabetes (Chapter 24). Inflammation induced by IL-1 and other factors likely contributes to insulin resistance. Excess insulin, in turn, may play a role in the retention of sodium, expansion of blood volume, production of excess norepinephrine, and smooth muscle proliferation that are the hallmarks of hypertension. Whatever the mechanism, the risk of developing hypertension among previously normotensive persons increases proportionately with weight.
- *Obese persons generally have hypertriglyceridemia and low HDL cholesterol levels,* factors that increase the risk of coronary artery disease. The risk of coronary heart disease is compounded by the existence of comorbid conditions including diabetes, hypertension, and dyslipidemia.
- *Nonalcoholic fatty liver disease* is commonly associated with obesity and type 2 diabetes. It can progress to fibrosis and cirrhosis (Chapter 18).
- *Cholelithiasis (gallstones)* is six times more common in obese than in lean subjects. The obesity-associated increase in total body cholesterol and cholesterol turnover leads to elevated biliary excretion of cholesterol in the bile, which in turn predisposes affected persons to the formation of cholesterol-rich gallstones (Chapter 18).
- *Obstructive sleep apnea* and consequent right-sided heart failure is strongly associated with obesity. Hypoventilation syndrome is a constellation of respiratory abnormalities in very obese persons. It has been called the pickwickian syndrome, after the fat lad who was constantly falling asleep in Charles Dickens' novel *The Pickwick Papers.*
- *Marked adiposity is a predisposing factor for the development of degenerative joint disease (osteoarthritis).* This form of arthritis, which typically appears in older persons, is attributed in large part to the cumulative effects of wear and tear on joints. The greater the body burdens of fat, the greater the trauma to joints with the passage of time.
- *Markers of inflammation, such as CRP and proinflammatory cytokines like TNF, are often elevated in obese persons, in particular people with central obesity.* The basis for the inflammation is uncertain; both a direct proinflammatory effect of excess circulating lipids and increased release of cytokines from fat-laden adipocytes have been proposed. Whatever the cause, it is thought that chronic inflammation may contribute to many of the complications of obesity including insulin resistance, metabolic abnormalities, thrombosis, cardiovascular disease, and cancer.

Obesity and Cancer

There is an increased incidence of certain cancers in overweight people, including cancers of the esophagus, thyroid, colon, and kidney in men and cancers of the esophagus, endometrium, gallbladder, and kidney in women. Though the "risk" associated with obesity is modest, because of the prevalence of obesity in the population, it is associated with approximately 40% of all cancers in the United States, somewhat more in women than in men. The underlying mechanisms are unknown and are likely to be multiple.

- *Elevated insulin levels.* Insulin resistance leads to hyperinsulinemia, which includes multiple effects that may

directly or indirectly contribute to cancer (see Fig. 9.31). For example, hyperinsulinemia causes a rise in levels of free insulin-like growth factor 1 (IGF-1). IGF-1 is a mitogen, and its receptor, IGFR-1, is highly expressed in many human cancers. IGFR-1 activates the RAS and PI3K/AKT pathways, which promote the growth of both normal and neoplastic cells (Chapter 7).

- Obesity has effects on *steroid hormones* that regulate cell growth and differentiation in the breast, uterus, and other tissues. Specifically, obesity increases the synthesis of estrogen from androgen precursors, increases androgen synthesis in ovaries and adrenals, and enhances estrogen availability in obese persons by inhibiting the production of sex hormone–binding globulin (SHBG) in the liver.
- As discussed earlier, *adiponectin* secretion from adipose tissue is reduced in obese individuals. Adiponectin suppresses cell proliferation and promotes apoptosis. It does so in part by promoting the actions of p53 and p21. In obese individuals these antineoplastic actions of adiponectin may be compromised.
- The *proinflammatory state* that is associated with obesity may itself be carcinogenic through mechanisms discussed in Chapter 7.

KEY CONCEPTS

OBESITY

- Obesity is a disorder of energy regulation. It increases the risk for a number of important conditions such as insulin resistance, type 2 diabetes, hypertension, and hypertriglyceridemia, which are associated with coronary artery disease, certain cancers, nonalcoholic fatty liver disease, and gallstones.
- The regulation of energy balance has three main components: (1) afferent signals provided mostly by insulin, leptin, ghrelin, GLP-1, and peptide YY; (2) the central hypothalamic system, which integrates afferent signals and triggers the efferent signals; and (3) efferent signals, which control energy balance.
- Leptin plays a key role in energy balance. Its output from adipose tissues is increased by the abundance of fat stores. Leptin binding to its receptors in the hypothalamus decreases appetite and increases energy consumption by stimulating POMC/CART neurons and inhibiting NPY/AgRP neurons.

Diet and Cancer

As you will recall from Chapter 7, the incidence of specific cancers varies as much as 100-fold in different geographic areas. It is well known that differences in incidence of various cancers are not fixed and can be modified by environmental factors including changes in diet. For instance, the incidence of colon cancer in Japanese men and women 55 to 60 years of age was negligible about 50 years ago, but it is now higher than that in men of the same age in the United Kingdom. Studies have also shown a progressive increase in colon cancers in Japanese populations as they moved from Japan to Hawaii and from there to the continental United States. Nevertheless, despite extensive experimental and epidemiologic research, relatively few mechanisms that link diets and specific types of cancer have been established.

With respect to carcinogenesis, three aspects of the diet are of major concern: (1) the content of exogenous carcinogens, (2) the endogenous synthesis of carcinogens from dietary components, and (3) the lack of protective factors.

- Regarding exogenous substances, *aflatoxin* is involved in the development of hepatocellular carcinomas in parts of Asia and Africa, generally in cooperation with hepatitis B virus. Exposure to aflatoxin causes a specific mutation in codon 249 of the *TP53* gene; when found in hepatocellular carcinomas, this mutation serves as a molecular signature for aflatoxin exposure. Debate continues about the carcinogenicity of food additives, artificial sweeteners, and contaminating pesticides.
- The concern about endogenous synthesis of carcinogens or enhancers of carcinogenicity from components of the diet relates principally to gastric carcinomas. *Nitrosamines and nitrosamides* are implicated in the generation of these tumors, as they have been clearly shown to induce gastric cancer in animals. These compounds can be formed in the body from nitrites and amines or amides derived from digested proteins. Sources of nitrites include sodium nitrite added to foods as a preservative, and nitrates, present in common vegetables, which are reduced in the gut by bacterial flora. There is, then, the potential for endogenous production of carcinogenic agents from dietary components, which might well have an effect on the stomach.
- *High animal fat intake combined with low fiber intake has been implicated in the causation of colon cancer.* It has been estimated that doubling the average level of total fiber consumption to about 40 g/day per person in most populations decreases the risk of colon cancer by 50%. The most plausible explanation for this association is that high fat intake increases the level of bile acids in the gut, which in turn modifies intestinal flora, favoring the growth of microaerophilic bacteria. Bile acid metabolites produced by these bacteria may function as carcinogens. The *protective effect of a high-fiber diet* might relate to (1) increased stool bulk and decreased transit time, which decreases the exposure of mucosa to putative offenders, and (2) the capacity of certain fibers to bind carcinogens and thereby protect the mucosa. However, attempts to document these theories in clinical and experimental studies have not generated consistent results.
- *Vitamins C and E, β-carotene, and selenium* have been assumed to have anticarcinogenic effects because of their antioxidant properties. However, thus far there is no convincing evidence that these antioxidants act as chemopreventive agents. As discussed earlier in this chapter, retinoids are effective agents in the therapy of acute promyelocytic leukemia, and associations between low levels of vitamin D and cancer of the colon, prostate, and breast have been reported.

On one hand, despite many tantalizing trends and proclamations by diet gurus, thus far there is no definitive proof that a particular diet can cause or prevent cancer. On the other hand, given the relationships between obesity and cancer development, prevention of obesity through the consumption of a healthy diet is a commonsense measure that goes a long way in preserving good health.

Diet and Systemic Diseases

The problems of undernutrition and overnutrition, as well as specific nutrient deficiencies, have been discussed; however, the composition of the diet, even in the absence of any of these problems, may make a significant contribution to the causation and progression of a number of diseases. A few examples suffice here.

Currently, one of the most important and controversial issues is the contribution of diet to atherogenesis. The central question is whether dietary modification—specifically, reduction in the consumption of foods high in cholesterol and saturated animal fats (e.g., eggs, butter, beef)—can reduce serum cholesterol levels and prevent or retard the development of atherosclerosis (of most importance, coronary heart disease) in people with no previous episode of cardiovascular disease. This is called primary prevention. We know some, but not all, the answers. The average adult in the United States consumes a large amount of fat and cholesterol daily, with a ratio of saturated fatty acids to polyunsaturated fatty acids of about 3:1. Lowering the level of saturates to the level of the polyunsaturates causes a 10% to 15% reduction in serum cholesterol within a few weeks. Vegetable oils (e.g., corn and safflower oils) and fish oils contain polyunsaturated fatty acids and are good sources of such cholesterol-lowering lipids. Fish oil fatty acids belonging to the omega-3, or *n-3,* family have more double bonds than the omega-6, or *n-6,* fatty acids found in vegetable oils. A corollary of this idea is that supplementation of diet with fish oils might protect against atherosclerosis. However, a recent large meta-analysis of 79 randomized controlled trials showed that dietary supplements of omega-3 fatty acids or consumption of oily fish had little or no effect on cardiovascular disease (ischemic heart disease, stroke).

Other specific effects of diet on disease have been recognized:

- Restricting sodium intake reduces hypertension.
- Dietary fiber, or roughage, resulting in increased fecal bulk, is thought by some investigators to provide a preventive effect against diverticulosis of the colon.
- Caloric restriction has been convincingly demonstrated to increase lifespan in experimental animals, including monkeys. The basis for this striking observation is not clear (Chapter 2), and the degree of calorie restriction that is needed to prolong life is so great that one can question if such a life is worth living. Perhaps by understanding the underlying mechanism, we may some day be able to have our cake and eat it, too.
- Even lowly garlic has been touted to protect against heart disease (and also against devils, werewolves, vampires, and, alas, kisses), although research has yet to prove this effect unequivocally. Of these, the effect on kisses is the best established!

CHAPTER 10

Diseases of Infancy and Childhood[a]

Aliya N. Husain • Selene C. Koo

CHAPTER CONTENTS

Children are not merely little adults, and their diseases are not merely variants of adult diseases. Many childhood conditions are unique to, or at least take distinctive forms in, this stage of life and so are discussed separately in this chapter. Diseases originating in the perinatal period are important in that they account for significant morbidity and mortality. The chances for survival of infants improve with each passing week. The infant mortality rate in the United States has shown a decline from a level of 20 deaths per 1000 live births in 1970 to 5.8 in 2014. Although the death rate has continued to decline for all infants, African Americans continue to have an infant mortality rate more than twice (11 deaths per 1000 live births) that of American whites (4.9 deaths). Worldwide, infant mortality rates vary widely, from as low as 1.8 deaths per 1000 live births in Slovenia, to as high as 110.6 deaths in Afghanistan. Rather dismayingly, the United States ranks thirtieth in infant mortality rate among high income nations in the Western hemisphere.

Each stage of development of the infant and child is prey to a somewhat different group of disorders: (1) the neonatal period (the first 4 weeks of life), (2) infancy (the first year of life), (3) 1 to 4 years of age, and (4) 5 to 14 years of age.

Congenital anomalies, prematurity and low birth weight, sudden infant death syndrome, and maternal complications and injuries represent the leading causes of death in the first 12 months of life. Once the infant survives the first year of life, the outlook brightens measurably. In the next two age groups—1 to 4 years and 5 to 9 years—unintentional injuries resulting from accidents are the leading cause of death. Among the natural diseases, in order of importance, congenital anomalies and malignant neoplasms assume major significance. In the 10- to 14-year age group, accidents, malignancies, suicide, homicide, and congenital malformations are the leading causes of death.

The following discussion looks at specific conditions encountered during the various stages of infant and child development.

[a]The prior contributions of Dr. Anirban Maitra to this chapter are gratefully acknowledged.

CONGENITAL ANOMALIES

Congenital anomalies are anatomic defects that are present at birth, but some, such as cardiac defects and renal anomalies, may not become clinically apparent until years later. The term *congenital* means "born with," but it does not imply or exclude a genetic basis for the birth defect. It is estimated that about 120,000 (1 in 33) babies are born with a birth defect each year in the United States. In a sense, anomalies found in live-born infants represent the less serious developmental failures in embryogenesis as they are compatible with live birth. Perhaps 20% of fertilized ova are so anomalous that they are blighted at early stages. Others may be compatible with early fetal development, only to

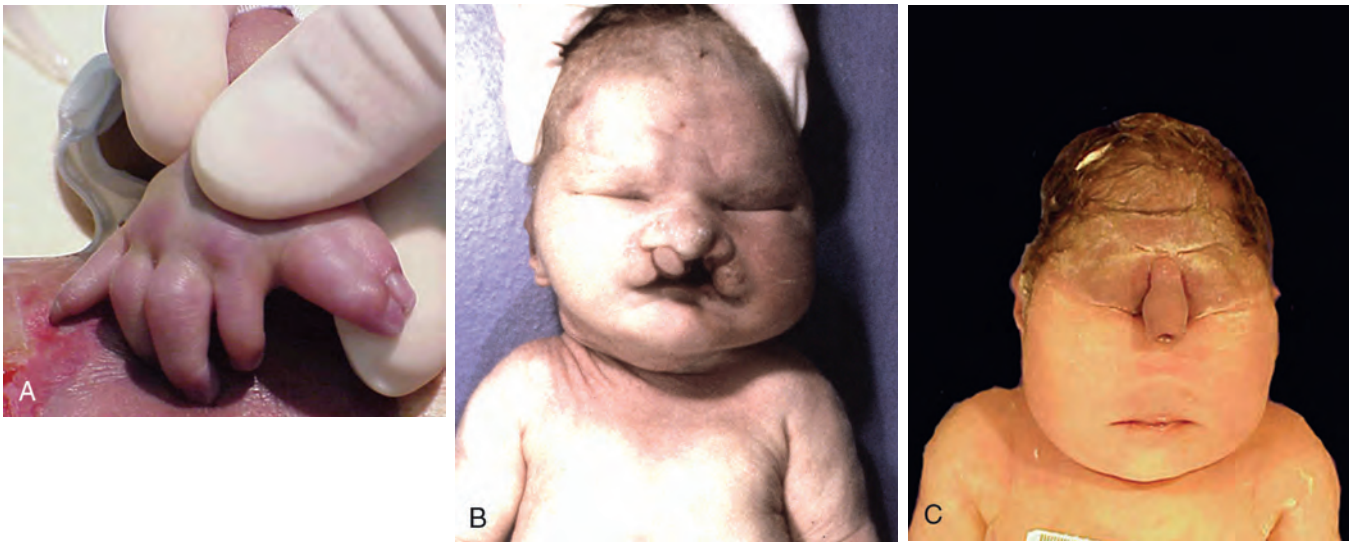

Figure 10.1 Examples of malformations. (A) *Polydactyly* (one or more extra digits) and *syndactyly* (fusion of digits) have little functional consequence when they occur in isolation. Similarly, *cleft lip* (B), with or without associated *cleft palate*, is compatible with life when it occurs as an isolated anomaly; in the present case, however, this neonate had an underlying *malformation syndrome* (trisomy 13) and died of severe cardiac defects. (C) The stillbirth illustrated represents a severe and essentially lethal malformation, wherein the midface structures are fused or ill-formed; in almost all cases, this degree of external dysmorphogenesis is associated with severe internal anomalies such as maldevelopment of the brain and cardiac defects. (A and C, Courtesy Dr. Reade Quinton; B, Courtesy Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.)

lead to spontaneous abortion. Less severe anomalies allow more prolonged intrauterine survival, with some disorders terminating in stillbirth and those still less significant permitting live birth despite the handicaps imposed.

Definitions

The process of morphogenesis (organ and tissue development) can be impaired by a variety of different errors.

- ***Malformations*** **represent primary errors of morphogenesis, in which there is an intrinsically abnormal developmental process** (Fig. 10.1). Malformations can be the result of a single gene or chromosomal defect, but are more commonly multifactorial in origin. Developmental anomalies may present in several patterns. Some, such as congenital heart defects and anencephaly (absence of part or all of the brain), involve single body systems, whereas in other cases multiple malformations involving many organs may coexist.
- ***Disruptions*** **result from secondary destruction of an organ or body region that was previously normal in development**; thus, in contrast with malformations, disruptions arise from an extrinsic disturbance in morphogenesis. Amniotic bands, denoting rupture of amnion with resultant formation of "bands" that encircle, compress, or attach to parts of the developing fetus, are the classic example of a disruption (Fig. 10.2). A variety of environmental agents may cause disruptions (see later). Disruptions are not heritable, hence they are not associated with increased risk of recurrence in subsequent pregnancies.
- ***Deformations*****, like disruptions, represent an extrinsic disturbance of development rather than an intrinsic error of morphogenesis.** Deformations are common problems, affecting approximately 2% of newborn infants to varying degrees. Fundamental to the pathogenesis of deformations is localized or generalized compression of the growing fetus by abnormal biomechanical forces, leading eventually to a variety of structural abnormalities. The most common underlying factor responsible for deformations is uterine constraint. Between 35 and 38 weeks of gestation, rapid increase in the size of the fetus outpaces the growth of the uterus, and the relative amount of amniotic fluid (which normally acts as a cushion) decreases. Thus, even the normal fetus is subjected to some degree of uterine constraint. Several factors increase

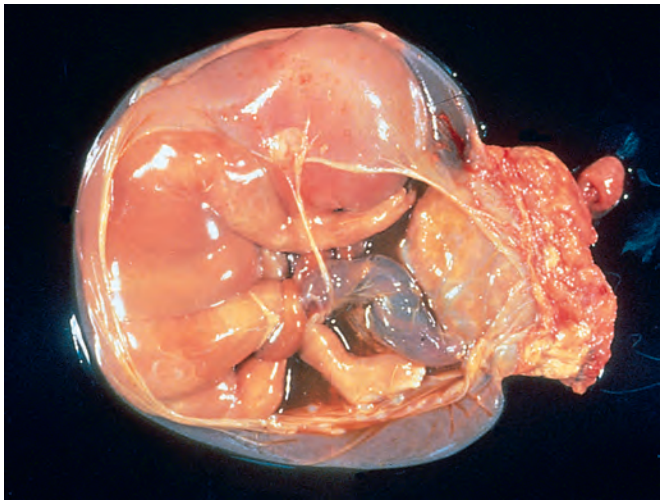

Figure 10.2 Disruption of morphogenesis by an amniotic band. Note the placenta at the right of the diagram and the band of amnion extending from the top portion of the amniotic sac to encircle the leg of the fetus. (Courtesy Dr. Theonia Boyd, Boston Children's Hospital, Boston, Mass.)

the likelihood of excessive compression of the fetus resulting in deformations. Maternal factors include first pregnancy, small uterus, malformed (e.g., bicornuate) uterus, and leiomyomas. Fetal or placental factors include oligohydramnios, multiple fetuses, and abnormal fetal presentation. For example, clubfeet can occur as a component of Potter sequence, described later.

- **A *sequence* is a cascade of anomalies triggered by one initiating aberration.** Approximately one-half the time, congenital anomalies occur singly; in the remaining cases, multiple congenital anomalies are recognized. In some instances, the constellation of anomalies may be explained by a single localized aberration in organogenesis (malformation, disruption, or deformation) that sets into motion secondary effects in other organs. A good example is the *oligohydramnios* (or *Potter*) *sequence* (Fig. 10.3). Oligohydramnios (decreased amniotic fluid) may be caused by a variety of unrelated maternal, placental, or fetal abnormalities. The most common cause of oligohydramnios is chronic leakage of amniotic fluid due to rupture of fetal membranes. Other causes include renal agenesis and urinary tract obstruction in the fetus (because fetal urine is a major constituent of amniotic fluid), and uteroplacental insufficiency resulting from maternal hypertension or severe preeclampsia. The fetal compression associated with significant oligohydramnios, in turn, results in a classic phenotype in the newborn infant, including flattened facies, positional abnormalities of the hands, and clubfeet (Fig. 10.4). The hips may be dislocated. Growth of the chest wall and the contained lungs is also compromised so that the lungs are frequently hypoplastic, and may cause fetal demise. Nodules in the amnion *(amnion nodosum)* are frequently present.
- **A *malformation syndrome* is a constellation of congenital anomalies**, believed to be pathologically related, that, in contrast to a sequence, cannot be explained on the basis of a single, localized, initiating defect. Syndromes are most often caused by a single etiologic agent, such as a viral infection or specific chromosomal abnormality, which simultaneously affects several tissues.

In addition to the aforementioned general definitions, a few organ-specific terms should be defined. *Agenesis* refers to the complete absence of an organ and its associated primordium. A closely related term, *aplasia,* also refers to the absence of an organ but one that occurs due to failure of growth of the existing primordium. *Atresia* describes the absence of an opening, usually of a hollow visceral organ, such as the trachea or intestine. *Hypoplasia* refers to incomplete development or decreased size of an organ with decreased numbers of cells, whereas *hyperplasia* refers to the converse, that is, the enlargement of an organ due to increased numbers of cells. An abnormality in an organ or a tissue as a result of an increase or a decrease in the size (rather than the number) of individual cells defines hypertrophy or hypotrophy, respectively. Finally, *dysplasia* in the context of malformations (versus *neoplasia*) describes an abnormal organization of cells.

Figure 10.4 Infant with oligohydramnios sequence. Note the flattened facial features and deformed right foot (talipes equinovarus).

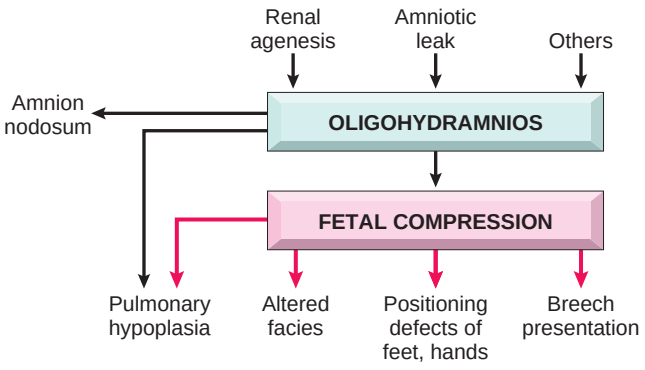

Figure 10.3 Schematic diagram of the pathogenesis of the oligohydramnios sequence.

Causes of Anomalies

Although we are learning a great deal about the molecular bases of some congenital anomalies, the exact cause remains unknown in 40% to 60% of cases. The era of molecular medicine promises to bring additional insights into the mechanisms by which malformations occur. The common known causes of congenital anomalies can be grouped into three major categories: genetic, environmental, and multifactorial (Table 10.1).

Genetic causes of malformations include all of the previously discussed mechanisms of genetic disease (Chapter 5). Virtually all chromosomal syndromes are associated with congenital malformations. Examples include Down syndrome and other trisomies, Turner syndrome, and Klinefelter syndrome. Most chromosomal disorders arise during gametogenesis and hence are not familial. Single-gene

Table 10.1 Causes of Congenital Anomalies in Live-Born Infants

Cause	Frequency (%)
Genetic	
Chromosomal aberrations	10–15
Mendelian inheritance	2–10
Environmental	
Maternal/placental infections Rubella Toxoplasmosis Syphilis Cytomegalovirus Human immunodeficiency virus	2–3
Maternal disease states Diabetes Phenylketonuria Endocrinopathies, including severe obesity	6–8
Drugs and chemicals Alcohol, smoking Folic acid antagonists Androgens Phenytoin Thalidomide Warfarin 13-*cis*-retinoic acid Others	1
Irradiation	1
Multifactorial	20–25
Unknown	40–60

Modified from Stevenson RE, Hall JG, Everman DB, Solomon B, editors: *Human Malformations and Related Anomalies*, ed 3, New York, 2016, Oxford University Press, p 12.

mutations, characterized by Mendelian inheritance, may underlie some major malformations. For example, holoprosencephaly is the most common developmental defect of the forebrain and midface in humans; the Hedgehog signaling pathway plays a critical role in the morphogenesis of these structures, and loss-of-function mutations of individual components within this pathway are reported in families with a history of recurrent holoprosencephaly.

Environmental influences, such as viral infections, drugs, and maternal irradiation, may cause fetal anomalies. Among the viral infections listed in Table 10.1, rubella was a major scourge of the nineteenth and early twentieth centuries. Fortunately, maternal rubella and the resultant *rubella embryopathy* have been virtually eliminated in high income countries as a result of maternal rubella vaccination. A variety of drugs and chemicals have been suspected to be teratogenic, but perhaps less than 1% of congenital malformations are caused by these agents. The list includes thalidomide, alcohol, anticonvulsants, warfarin (oral anticoagulant), and 13-*cis*-retinoic acid, which is used in the treatment of severe acne. For example, thalidomide, once used as a tranquilizer in Europe, causes an extremely high incidence (50% to 80%) of limb malformations. Alcohol, when consumed even in modest amounts during pregnancy, is an important environmental teratogen. Affected infants show prenatal and postnatal growth restriction, facial anomalies (microcephaly, short palpebral fissures, maxillary hypoplasia), and psychomotor disturbances. These in combination are labeled the *fetal alcohol syndrome* (also discussed in Chapter 9). Although cigarette smoke–derived nicotine has not been convincingly demonstrated to be a teratogen, there is a high incidence of spontaneous abortion, premature labor, and placental abnormalities in pregnant women who smoke, babies born to mothers who smoke often have a low birth weight and may be prone to sudden infant death syndrome (discussed later). In light of these findings, it is best to avoid nicotine exposure altogether during pregnancy. Among maternal conditions listed in Table 10.1, diabetes mellitus is a common entity, and despite advances in antenatal obstetric monitoring and glucose control, the incidence of major malformations in infants of diabetic mothers stands between 6% and 10% in most series. Maternal hyperglycemia-induced fetal hyperinsulinemia results in fetal macrosomia (organomegaly and increased body fat and muscle mass); cardiac anomalies, neural tube defects, and other central nervous system (CNS) malformations are some of the major anomalies seen in *diabetic embryopathy*.

Multifactorial inheritance, which implies the interaction of environmental influences with two or more genes of small effect, is the most common genetic etiology of congenital malformations. Examples include relatively common malformations such as cleft lip, cleft palate, and neural tube defects. The dramatic reduction in incidence of neural tube defects by periconceptional intake of folic acid is one case where understanding the environmental stimuli has prevented development of multifactorial malformations even though contributing genes have not been eliminated.

Pathogenesis

The pathogenesis of congenital anomalies is complex and still poorly understood, but two general principles of developmental pathology are relevant regardless of the etiologic agent.

1. The timing of the prenatal teratogenic insult has an important impact on the occurrence and the type of anomaly produced (Fig. 10.5). The intrauterine development of humans can be divided into two phases: (1) the early embryonic period occupying the first 9 weeks of pregnancy and (2) the fetal period terminating at birth.
   - In the *early embryonic period* (first 3 weeks after fertilization), an injurious agent damages either enough cells to cause death and abortion or only a few cells, presumably allowing the embryo to recover without developing defects. **Between the third and the ninth weeks, the embryo is extremely susceptible to teratogenesis;** peak sensitivity occurs between the fourth and the fifth weeks. During this period, organs are being crafted out of the germ cell layers.
   - The *fetal period* that follows organogenesis is marked chiefly by further growth and maturation of the organs, with greatly reduced susceptibility to teratogenic agents. Instead, the fetus is susceptible to growth restriction or injury to already formed organs. Thus a given agent may produce different anomalies if exposure occurs at different times of gestation.
2. The interplay between environmental teratogens and intrinsic genetic defects is exemplified by the fact that features of dysmorphogenesis caused by environmental insults can often be recapitulated by genetic defects in

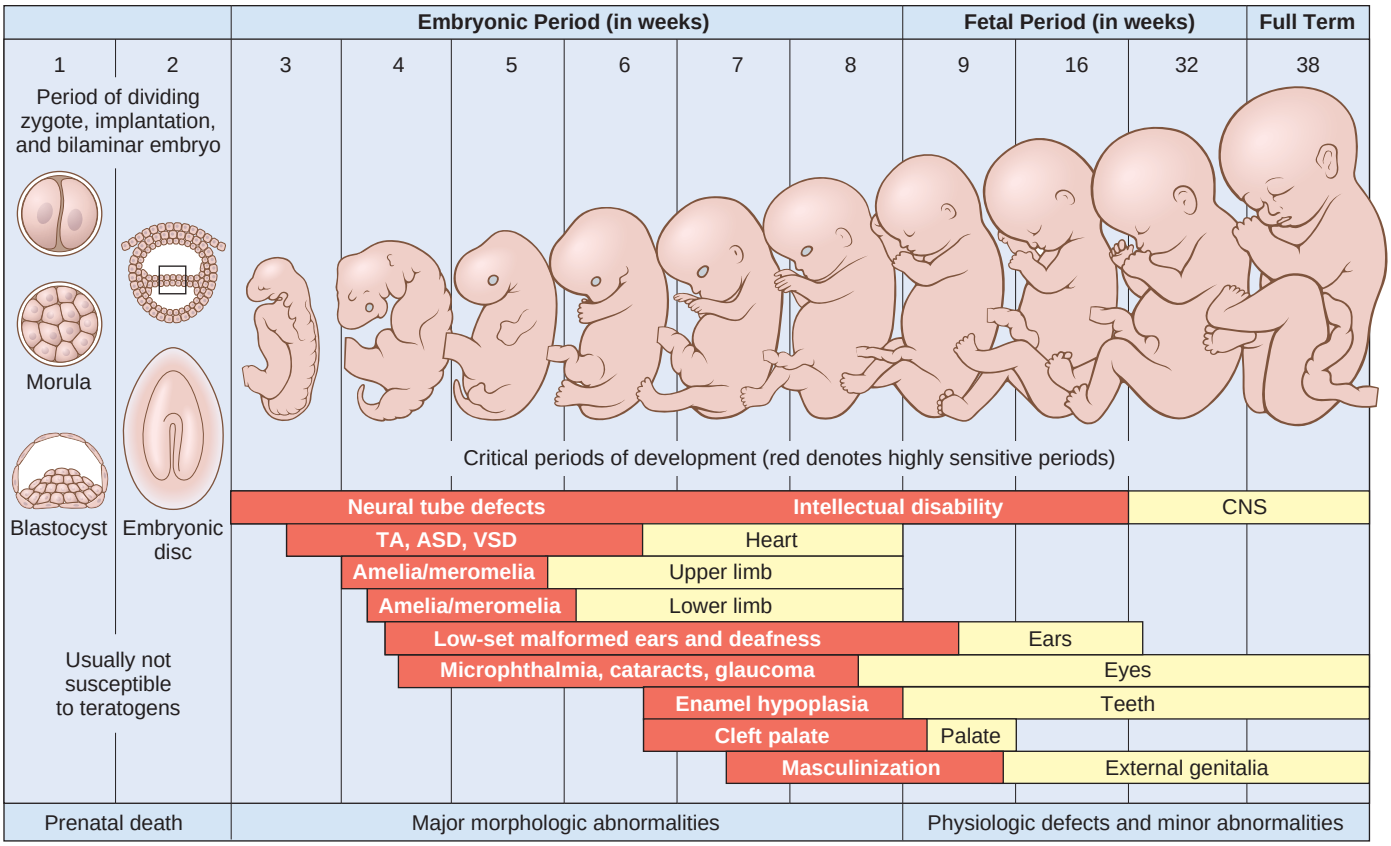

Figure 10.5 Critical periods of development for various organ systems and the resultant malformations. (Modified and redrawn from Moore KL: *The Developing Human,* ed 10, Philadelphia, 2016, WB Saunders, p 474.)

the pathways targeted by these teratogens. This is illustrated by the following representative examples.

- *Cyclopamine* is a plant teratogen contained in the corn lily; pregnant sheep who feed on this plant give birth to lambs with severe craniofacial abnormalities including holoprosencephaly and "cyclopia" (single fused eye, hence the origin of the moniker cyclopamine). This compound is an inhibitor of Hedgehog signaling in the embryo, and, as stated earlier, mutations of Hedgehog genes are present in subsets of patients with holoprosencephaly.
- *Valproic acid* is an antiepileptic and a recognized teratogen during pregnancy. Valproic acid disrupts expression of a family of highly conserved developmentally critical transcription factors known as *homeobox* (HOX) proteins. In vertebrates, HOX proteins have been implicated in the patterning of limbs, vertebrae, and craniofacial structures. Not surprisingly, mutations in the *HOX* family of genes are responsible for congenital anomalies that mimic features observed in valproic acid embryopathy.
- The vitamin A (retinol) derivative *all-trans-retinoic acid* is essential for normal development and differentiation, and its absence during embryogenesis results in a constellation of malformations affecting multiple organ systems, including the eyes, genitourinary system, cardiovascular system, diaphragm, and lungs (see Chapter 9 for effects of vitamin A deficiency in the postnatal period). Conversely, excessive exposure to retinoic acid is also teratogenic. Infants born to mothers treated with retinoic acid for severe acne have a predictable phenotype (retinoic acid embryopathy) including CNS, cardiac, and craniofacial defects, such as cleft lip and cleft palate. The latter may stem from retinoic acid–mediated deregulation of components of the transforming growth factor-β (TGF-β) signaling pathway, which is involved in palatogenesis. Mice with knockout of the *Tgfb3* gene uniformly develop cleft palate, once again illustrating the functional relationship between teratogenic exposure and signaling pathways in the causation of congenital anomalies.

PREMATURITY AND FETAL GROWTH RESTRICTION

Prematurity, defined by a gestational age less than 37 weeks, is the second most common cause of neonatal mortality, behind only congenital anomalies. The Centers for Disease Control and Prevention (CDC; cdc.gov/reproductivehealth) report that in 2016, preterm birth affected about 1 in 10 infants born in the United States. Preterm birth rates decreased from 2007 to 2014 due, in part, to declines in the number of births to teens and young mothers; however, the rate among African-American women (14%) remains greater than that in white women (9%). The major risk factors for prematurity include the following:

- *Preterm premature rupture of membranes* (PPROM): PPROM complicates about 3% of all pregnancies and is responsible for as many as one-third of all preterm deliveries. Rupture of membranes (ROM) before the onset of labor can be spontaneous or induced. PPROM refers to spontaneous ROM occurring *before* 37 weeks of gestation (hence the annotation "preterm"). In contrast, PROM refers to spontaneous ROM occurring *after* 37 weeks of gestation. This distinction is important because after 37 weeks the associated risk to the fetus is considerably decreased. Several clinical risk factors have been identified for PPROM, including a prior history of preterm delivery, preterm labor and/or vaginal bleeding during the current pregnancy, maternal smoking, low socioeconomic status, and poor maternal nutrition. The fetal and maternal outcome after PPROM depends on the gestational age of the fetus (second-trimester PPROM has a dismal prognosis) and the effective prophylaxis of infections in the exposed amniotic cavity.
- *Intrauterine infection:* This is a major cause of preterm labor with and without intact membranes. Intrauterine infection is present in approximately 25% of all preterm births, and the earlier the gestational age at delivery, the higher the frequency of intra-amniotic infection. The histologic correlates of intrauterine infection are inflammation of the placental membranes (chorioamnionitis) and inflammation of the fetal umbilical cord (funisitis). The most common microorganisms implicated in intrauterine infections leading to preterm labor are *Ureaplasma urealyticum, Mycoplasma hominis, Gardnerella vaginalis* (the dominant organism found in "bacterial vaginosis," a polymicrobial infection), *Trichomonas,* gonorrhea, and *Chlamydia.* In low income countries, malaria and HIV are significant contributors to the burden of preterm labor and prematurity. Recent studies have begun to elucidate the molecular mechanisms of inflammation-induced preterm labor. Endogenous Toll-like receptors (TLRs), which bind bacterial components as natural ligands (Chapter 6), have emerged as key players in this process. It is postulated that signals produced by TLR engagement deregulate prostaglandin expression, which, in turn, induces uterine smooth muscle contractions.
- *Uterine, cervical, and placental structural abnormalities:* Uterine distortion (e.g., uterine fibroids), compromised structural support of the cervix ("cervical incompetence"), placenta previa, and abruptio placentae (Chapter 22) are associated with an increased risk of prematurity.
- *Multiple gestation* (twin pregnancy)

The hazards of prematurity are manifold for the newborn and may give rise to one or more of the following:

- *Neonatal respiratory distress syndrome,* also known as *hyaline membrane disease*
- *Necrotizing enterocolitis (NEC)*
- *Sepsis*
- *Intraventricular and germinal matrix hemorrhage*

Fetal Growth Restriction

Although preterm infants have low birth weights, it is usually appropriate once adjusted for their gestational age. In contrast, as many as one-third of infants who weigh less than 2500 g are born at term and are therefore undergrown rather than immature. These small-for-gestational-age (SGA) infants suffer from fetal growth restriction (FGR),which may result from maternal, fetal, or placental abnormalities, although in many cases the specific cause is unknown.

Maternal Abnormalities

By far the most common factors associated with SGA infants are maternal conditions that result in decreased placental blood flow. Vascular diseases such as preeclampsia (toxemia of pregnancy) and chronic hypertension are often the underlying cause. The list of other maternal conditions associated with SGA infants is long, but some of the avoidable factors worth mentioning are maternal narcotic abuse, alcohol intake, and heavy cigarette smoking. Drugs causing FGR include both classic teratogens, such as chemotherapeutic agents, and some commonly administered therapeutic agents, such as phenytoin (Dilantin). Maternal malnutrition (in particular, prolonged hypoglycemia) may also affect fetal growth.

Fetal Abnormalities

Fetal influences are those that intrinsically reduce growth potential of the fetus despite an adequate supply of nutrients from the mother. Prominent among such fetal conditions are chromosomal disorders, congenital anomalies, and congenital infections. Chromosomal abnormalities may be detected in up to 17% of fetuses sampled for FGR and in up to 66% of fetuses with documented ultrasonographic malformations. Among the first group, the abnormalities include triploidy (7%), trisomy 18 (6%), trisomy 21 (1%), trisomy 13 (1%), and a variety of deletions and translocations (2%). Fetal infection should be considered in all infants with FGR. Those most commonly responsible for FGR are the TORCH group of infections (*t*oxoplasmosis, *o*ther viruses and bacteria such as syphilis, *r*ubella, *c*ytomegalovirus, and *h*erpesvirus). Infants who are SGA because of fetal factors usually have symmetric growth restriction (also referred to as proportionate FGR), meaning that all organ systems are similarly affected.

Placental Abnormalities

During the third trimester of pregnancy, vigorous fetal growth places particularly heavy demands on the uteroplacental blood supply. Therefore, the adequacy of placental growth in the preceding midtrimester is extremely important, and uteroplacental insufficiency is an important cause of growth restriction. This insufficiency may result from umbilical-placental vascular anomalies (such as single umbilical artery and abnormal cord insertion), placental abruption, placenta previa, placental thrombosis and infarction, chronic villitis of unknown etiology, placental infection, or multiple gestations (Chapter 22). In some cases the placenta (and the baby) may be small without any detectable underlying cause. Placental causes of FGR tend to result in asymmetric (or disproportionate) growth restriction of the fetus with relative sparing of the brain. Physiologically, this general type of FGR is viewed as a down-regulation of growth in the latter half of gestation because of limited availability of nutrients or oxygen.

The SGA infant faces a difficult course, not only during the struggle for survival in the perinatal period, but also in

childhood and adult life. Depending on the underlying cause of FGR and, to a lesser extent, the degree of prematurity, there is a significant risk of morbidity in the form of a major handicap such as cerebral dysfunction, learning disability, or hearing and visual impairment.

Neonatal Respiratory Distress Syndrome

There are many causes of respiratory distress in the newborn. The most common cause is neonatal respiratory distress syndrome (RDS), also known as hyaline membrane disease because of the deposition of a layer of hyaline proteinaceous material in the peripheral airspaces of infants who succumb to this condition. Others include excessive sedation of the mother, fetal head injury during delivery, aspiration of blood or amniotic fluid, and intrauterine hypoxia brought about by coiling of the umbilical cord about the neck. The incidence of RDS increases with decreasing gestational age, being 1% at 37 weeks, 10.5% at 34 weeks, and 93% in extremely preterm infants (28 weeks or below).

Pathogenesis

The fundamental defect in RDS is pulmonary immaturity and deficiency of surfactant. As described in Chapter 15, surfactant consists predominantly of dipalmitoyl phosphatidylcholine (lecithin), smaller amounts of phosphatidylglycerol, and two groups of surfactant-associated proteins. The first group is composed of hydrophilic glycoproteins SP-A and SP-D, which play a role in pulmonary host defense (innate immunity). The second group consists of hydrophobic surfactant proteins SP-B and SP-C, which, in concert with the surfactant lipids, are involved in the reduction of surface tension at the air-liquid barrier in the alveoli of the lung. With reduced surface tension in the alveoli, less pressure is required to keep them patent and hence aerated. The importance of surfactant proteins in normal lung function can be gauged by the occurrence of severe respiratory failure in neonates with congenital deficiency of surfactant caused by mutations in the *SFTPB* or *SFTPC* genes.

Surfactant production by type II alveolar cells is accelerated after the 35th week of gestation in the fetus. At birth, the first breath of life requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain up to 40% of the residual air volume after the first breath; thus, subsequent breaths require far lower inspiratory pressures. With a deficiency of surfactant, the lungs collapse with each successive breath, so infants must work as hard with each successive breath as they did with the first. The problem of stiff atelectatic lungs is compounded by the soft thoracic wall that is pulled in as the diaphragm descends. Progressive atelectasis and reduced lung compliance then lead to a chain of events as depicted in Fig. 10.6, resulting in protein-rich, fibrin-rich exudation into the alveolar spaces with the formation of hyaline membranes. The fibrin-hyaline membranes are barriers to gas exchange, leading to carbon dioxide retention and hypoxemia. The hypoxemia itself further impairs surfactant synthesis, and a vicious cycle ensues.

Surfactant synthesis is modulated by a variety of hormones and growth factors, including cortisol, insulin, prolactin, thyroxine, and TGF-β. The role of glucocorticoids is particularly important. Conditions associated with intrauterine stress and FGR that increase corticosteroid release lower the risk of developing RDS. Surfactant synthesis can be suppressed by the compensatory high blood levels of insulin in infants of diabetic mothers, which counteracts the effects of steroids. This may explain, in part, why infants of diabetic mothers have a higher risk of developing RDS. Labor is known to increase surfactant synthesis; hence, cesarean delivery before the onset of labor may increase the risk of RDS.

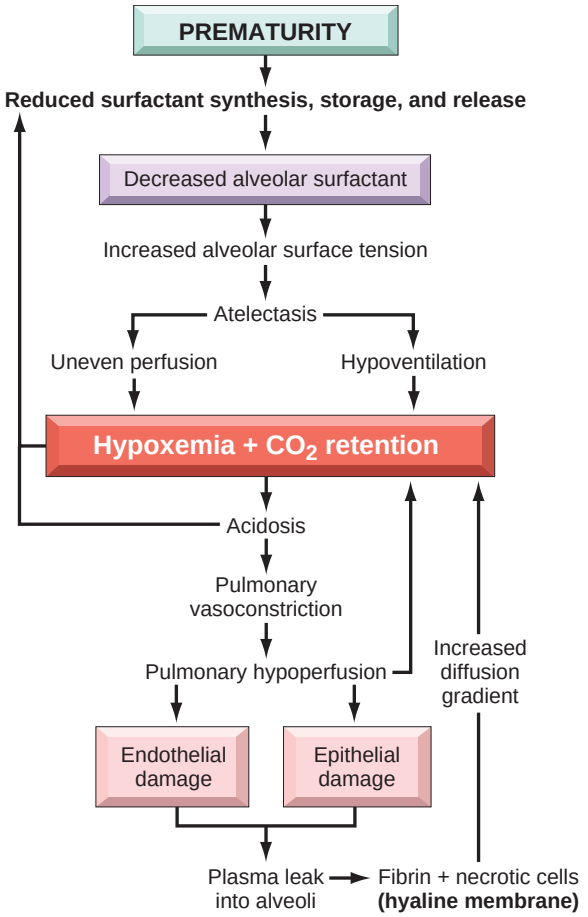

Figure 10.6 Schematic outline of the pathophysiology of respiratory distress syndrome (see text).

MORPHOLOGY

The lungs are distinctive on gross examination. Though of normal size, they are solid, airless, and reddish purple, similar to the color of the liver, and they usually sink in water, indicating the relative absence of entrapped air. Microscopically, alveoli are poorly developed, and those that are present are collapsed (Fig. 10.7). When the infant dies early in the course of the disease, necrotic cellular debris can be seen in the terminal bronchioles and alveolar ducts. The necrotic material becomes incorporated within **eosinophilic hyaline membranes** lining the respiratory bronchioles, alveolar ducts, and alveoli. The membranes are largely made up of fibrin admixed with cell debris derived chiefly from necrotic type II pneumocytes. The sequence of events that leads to the formation of hyaline membranes is depicted in Fig. 10.6.

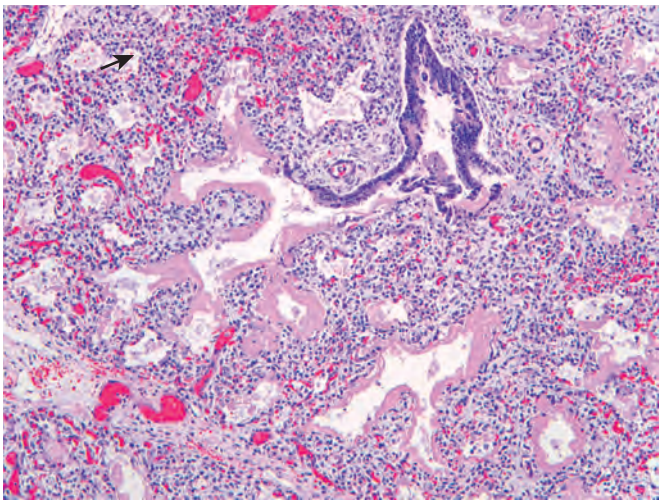

Figure 10.7 Hyaline membrane disease. There are eosinophilic thick hyaline membranes lining the dilated alveoli. Note that the remaining airspaces are lined by cuboidal epithelium *(arrow)*, indicating immaturity of the lung.

There is a remarkable paucity of neutrophilic inflammatory reaction associated with these membranes. The lesions of hyaline membrane disease are never seen in stillborn infants.

In infants who survive more than 48 hours, progressive reparative changes occur in the lungs. The alveolar epithelium proliferates under the surface of the membrane, which may detach into the airspace where it undergoes partial digestion or phagocytosis by macrophages. If it does not detach, fibroblasts grow into the membrane, and it becomes incorporated into the alveolar wall.

Clinical Features

The infant is almost always preterm but has weight appropriate for gestational age, and there are strong but not invariable associations with male gender, maternal diabetes, and cesarean delivery. Resuscitation may be necessary at birth, but usually within a few minutes rhythmic breathing and normal color are reestablished. Soon afterward, often within 30 minutes, breathing becomes more difficult, and within a few hours cyanosis becomes evident in the untreated infant. Fine rales can then be heard over both lung fields. A chest radiograph at this time usually reveals uniform minute reticulogranular densities, producing a so-called ground-glass picture. In the full-blown condition, the respiratory distress persists, cyanosis increases, and even the administration of 80% oxygen by a variety of ventilatory methods fails to improve the situation. If therapy staves off death for the first 3 or 4 days, however, the infant has an excellent chance of recovery.

Currently, the actual clinical course and prognosis for neonatal RDS vary, depending on the maturity and birth weight of the infant and the promptness of institution of therapy. A major thrust in the control of RDS focuses on prevention, either by delaying labor until the fetal lung reaches maturity or by inducing maturation of the lung in the at-risk fetus by use of antenatal steroids. Critical to these objectives is the ability to assess fetal lung maturity accurately. Because pulmonary secretions are discharged into the amniotic fluid, analysis of amniotic fluid phospholipids provides a good estimate of the level of surfactant in the alveolar lining. Prophylactic administration of exogenous surfactant at birth to extremely premature infants (gestational age <28 weeks) has been shown to be very beneficial. Together with newer assisted ventilation techniques, this has resulted in dramatic improvement in pulmonary function, symptom resolution, a shortened course, and markedly reduced mortality. In uncomplicated cases, recovery begins to occur within 3 or 4 days.

Complications of RDS, retrolental fibroplasia (also called retinopathy of prematurity) in the eyes, and bronchopulmonary dysplasia are now less frequent and less severe when they do occur.

- *Retinopathy of prematurity* has a two-phase pathogenesis. During the hyperoxic phase of RDS therapy (phase I), expression of the proangiogenic vascular endothelial growth factor (VEGF) is markedly decreased, causing endothelial cell apoptosis; VEGF levels rebound after return to relatively hypoxic room air ventilation (phase II), inducing retinal vessel proliferation (neovascularization) characteristic of the lesions in the retina (Chapter 29).
- *Bronchopulmonary dysplasia is* characterized by striking decrease in alveolar septation (manifested as large, simplified alveolar structures) and a dysmorphic capillary configuration. Thus, the current view is that bronchopulmonary dysplasia is caused by a potentially reversible impairment in the development of alveolar septation at the so-called "saccular" stage. Multiple factors—hyperoxemia, hyperventilation, prematurity, inflammatory cytokines, and vascular maldevelopment—contribute to bronchopulmonary dysplasia and probably act additively or synergistically to promote injury. The levels of a variety of proinflammatory cytokines (TNF, interleukin-1β [IL-1β], IL-6, and IL-8) are increased in the alveoli of infants who develop bronchopulmonary dysplasia, suggesting a role for these cytokines in arresting pulmonary development. Treatment with mesenchymal stem cells has potential but remains experimental. They act by secreting soluble factors that suppress inflammation and favor repair of the air spaces.

Infants who recover from RDS are also at increased risk for developing a variety of other complications associated with preterm birth; most important among these are patent ductus arteriosus, intraventricular hemorrhage, and necrotizing enterocolitis.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is most common in premature infants, with the incidence of the disease being inversely proportional to the gestational age. It occurs in approximately 1 in 10 very-low-birth-weight infants (<1500 g). Approximately 2500 cases occur annually in the United States.

The pathogenesis of NEC is uncertain but multifactorial. In addition to prematurity, most cases are associated with enteral feeding, suggesting that some postnatal insult (such as introduction of bacteria) sets in motion a cascade of events culminating in tissue destruction. Although infectious agents may play a role in the pathogenesis of NEC, no single bacterial pathogen has been linked to the disease. Perhaps alteration in the microbiome on enteral feeding

plays a role. A large number of inflammatory mediators have been associated with NEC. One particular mediator, platelet activating factor (PAF), has been implicated in increasing mucosal permeability by promoting enterocyte apoptosis and compromising intercellular tight junctions, thus adding "fuel to the fire." Stool and serum samples of infants with NEC demonstrate higher PAF levels than age-matched controls. Ultimately, breakdown of mucosal barrier functions permits transluminal migration of gut bacteria, leading to a vicious cycle of inflammation, mucosal necrosis, and further bacterial entry, eventually culminating in sepsis and shock (Chapter 4).

The clinical course is fairly typical, with the onset of bloody stools, abdominal distention, and development of circulatory collapse. Abdominal radiographs often demonstrate gas within the intestinal wall *(pneumatosis intestinalis)*. When detected early, NEC often can be managed conservatively, but many cases (20% to 60%) require resection of the necrotic segments of bowel. NEC is associated with high perinatal mortality; those who survive often develop post-NEC strictures from fibrosis caused by the healing process. Probiotic therapies are being evaluated for prevention of NEC.

MORPHOLOGY

NEC typically involves the terminal ileum, cecum, and right colon, although any part of the small or large intestine may be involved. The involved segment is distended, friable, and congested, or it can be frankly gangrenous; intestinal perforation with accompanying peritonitis may occur. Microscopically, mucosal or transmural coagulative necrosis, ulceration, bacterial colonization, and submucosal gas bubbles may be seen (Fig. 10.8). Reparative changes, such as the formation of granulation tissue and fibrosis, may begin shortly after the acute episode.

PERINATAL INFECTIONS

In general, fetal and perinatal infections are acquired through one of two primary routes—transcervically (also referred to as ascending) or transplacentally (hematologic). Occasionally, infections occur by a combination of the two routes in that an ascending microorganism infects the endometrium and then invades the fetal bloodstream via the chorionic villi.

Transcervical (Ascending) Infections

Most bacterial and a few viral (e.g., herpes simplex II) infections are acquired by the cervicovaginal route. Such infections may be acquired in utero or around the time of birth. In general, the fetus acquires the infection either by inhaling infected amniotic fluid into the lungs shortly before birth or by passing through an infected birth canal during delivery. As stated earlier, preterm birth is a common and unfortunate consequence of infection. Preterm birth due to infection may be related either to damage and rupture of the amniotic sac as a direct consequence of the inflammation, or to the induction of labor by prostaglandins released from infiltrating neutrophils. Inflammation of the placental membranes and cord are usually seen, but the presence or absence and severity of chorioamnionitis do not necessarily correlate with the severity of the fetal infection. In the fetus infected by inhalation of amniotic fluid, pneumonia, sepsis, and meningitis are the most common sequelae.

Transplacental (Hematologic) Infections

Most parasitic (e.g., *Toxoplasma,* malaria) and viral infections and a few bacterial infections (i.e., *Listeria*, *Treponema*) gain access to the fetal bloodstream transplacentally via the

Figure 10.8 Necrotizing enterocolitis (NEC). (A) Postmortem examination in a severe case of NEC shows the entire small bowel is markedly distended with a perilously thin wall (usually this implies impending perforation). (B) The congested portion of the ileum corresponds to areas of hemorrhagic infarction and transmural necrosis microscopically. Submucosal gas bubbles (pneumatosis intestinalis) can be seen in several areas *(arrows)*.

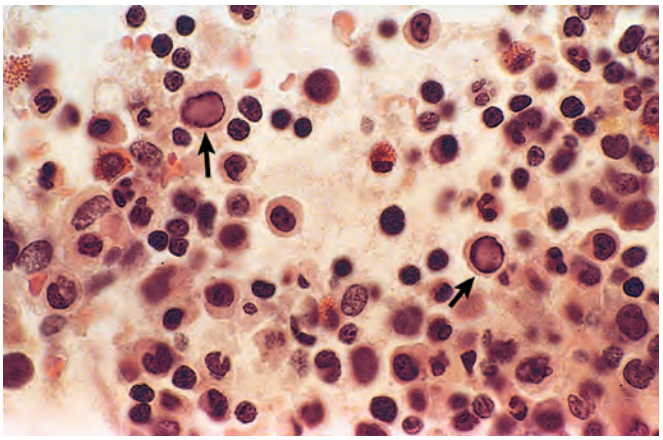

Figure 10.9 Bone marrow from an infant infected with parvovirus B19. The *arrows* indicate two erythroid precursors with large homogeneous intranuclear inclusions and a surrounding peripheral rim of residual chromatin.

chorionic villi. This hematogenous transmission may occur at any time during gestation or occasionally, as may be the case with hepatitis B and HIV, at the time of delivery via maternal-to-fetal transfusion. The clinical manifestations of these infections are highly variable, depending largely on the gestational timing and microorganism involved.

Parvovirus B19, which causes erythema infectiosum or "fifth disease of childhood" in immunocompetent older children, can infect 1% to 5% of seronegative (nonimmune) pregnant women, and the vast majority have a normal pregnancy outcome. Adverse pregnancy outcomes in a minority of intrauterine infections include spontaneous abortion (particularly in the second trimester), stillbirth, hydrops fetalis (see later), and congenital anemia. Parvovirus B19 has a particular tropism for erythroid cells, and diagnostic viral inclusions can be seen in early erythroid progenitors in infected infants (Fig. 10.9).

The *TORCH group of infections* (see earlier) are grouped together because they may evoke similar clinical and pathologic manifestations, including fever, encephalitis, chorioretinitis, hepatosplenomegaly, pneumonitis, myocarditis, hemolytic anemia, and vesicular or hemorrhagic skin lesions. Such infections occurring early in gestation may also cause chronic sequelae in the child, including growth retardation and intellectual disability, cataracts, congenital cardiac anomalies, and bone defects.

Sepsis

Perinatal sepsis can be grouped clinically based on early onset (within the first 7 days of life) versus late onset (from 7 days to 3 months). Most cases of early-onset sepsis are acquired at or shortly before birth and tend to result in clinical signs and symptoms of pneumonia, sepsis, and occasionally meningitis within 4 or 5 days of life. Group B *Streptococcus* is the most common cause of early-onset sepsis as well as early-onset bacterial meningitis. Infections with *Listeria* and *Candida* have longer latent periods between the time of microorganism inoculation and the appearance of clinical symptoms and present as late-onset sepsis.

FETAL HYDROPS

Fetal hydrops refers to the accumulation of edema fluid in the fetus during intrauterine growth. In the past, hemolytic anemia caused by Rh blood group incompatibility between mother and fetus (immune hydrops) was the most common cause, but with the successful prophylaxis of this disorder during pregnancy, nonimmune hydrops is more common. The intrauterine fluid accumulation can be quite variable, from progressive, generalized edema of the fetus (hydrops fetalis), a usually lethal condition, to more localized edema, such as isolated pleural and peritoneal effusions, or postnuchal fluid accumulation (cystic hygroma, see later) that are compatible with life.

Immune Hydrops

Immune hydrops is a hemolytic disease caused by blood group antigen incompatibility between mother and fetus. When the fetus inherits red cell antigenic determinants from the father that are foreign to the mother, a maternal immune reaction may occur. The major antigens known to induce clinically significant immunologic reactions are certain Rh antigens and the ABO blood groups. The reaction occurs in second and subsequent pregnancies in an Rh-negative mother with an Rh-positive father.

Etiology and Pathogenesis

The underlying basis of immune hydrops is the immunization of the mother by blood group antigens on fetal red cells and the free passage of antibodies from the mother through the placenta to the fetus (Fig. 10.10). Fetal red cells may reach the maternal circulation during the last trimester of pregnancy, when the cytotrophoblast is no longer present as a barrier, or during childbirth itself. The mother thus becomes sensitized to the foreign antigen. The initial exposure to Rh antigen evokes the formation of IgM antibodies that unlike IgG antibodies, do not cross the placenta. Thus, Rh disease is uncommon with the first pregnancy. Exposure during a subsequent pregnancy generally leads to a brisk IgG antibody response and the risk of immune hydrops.

Of the numerous antigens included in the Rh system, only the D antigen is a major cause of Rh incompatibility. Several factors influence the immune response to RhD-positive fetal red cells that reach the maternal circulation.

- *Concurrent ABO incompatibility protects the mother against Rh immunization* because the fetal red cells are promptly coated and removed from the maternal circulation by anti-A or anti-B IgM antibodies that do not cross the placenta.
- *The antibody response depends on the dose of immunizing antigen;* hence, hemolytic disease develops only when the mother has experienced a significant transplacental bleed (>1 mL of Rh-positive fetal red cells).

The incidence of maternal Rh isoimmunization has decreased significantly since the use of Rhesus immune globulin (RhIg) containing anti-D antibodies. Administration of RhIg at 28 weeks of gestation and within 72 hours of delivery to Rh-negative mothers significantly decreases the risk for hemolytic disease in Rh-positive neonates and

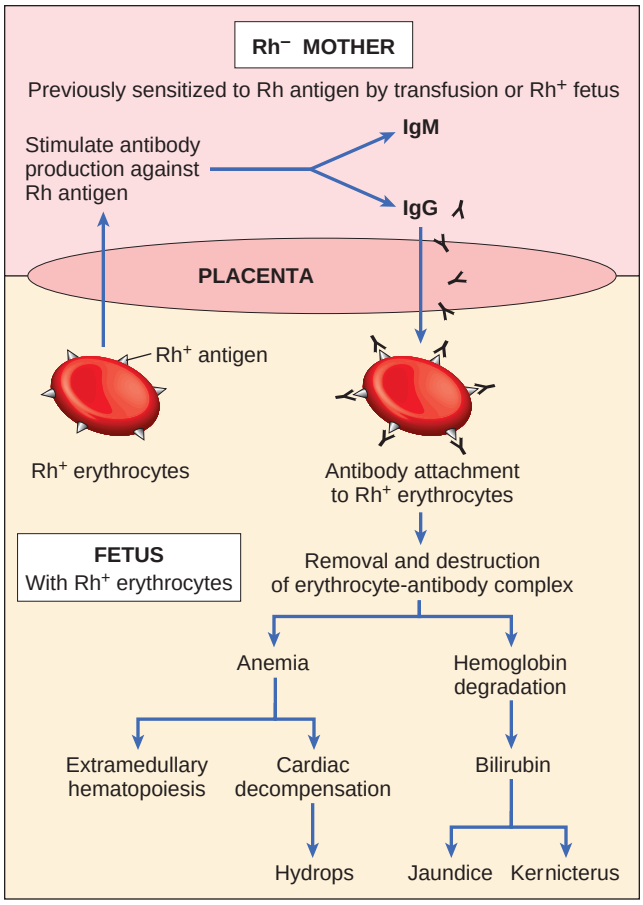

Figure 10.10 Pathogenesis of immune hydrops fetalis (see text).

in subsequent pregnancies; RhIg is also administered following abortions, because these too can lead to immunization. Antenatal identification and management of the at-risk fetus have been greatly facilitated by amniocentesis and chorionic villus and fetal blood sampling. In addition, cloning of the *RHD* gene has resulted in efforts to determine fetal Rh status using maternal serum because it contains fetal DNA. When identified, cases of severe intrauterine hemolysis may be treated by fetal intravascular transfusions via the umbilical cord and early delivery.

The pathogenesis of fetal hemolysis caused by maternal-fetal ABO incompatibility is slightly different from that caused by differences in the Rh antigens. ABO incompatibility occurs in approximately 20% to 25% of pregnancies, but laboratory evidence of hemolytic disease occurs in only 1 in 10 of such infants, and the hemolytic disease is severe enough to require treatment in only 1 in 200 cases. Several factors account for this. First, most anti-A and anti-B antibodies are of the IgM type and hence do not cross the placenta. Second, neonatal red cells express blood group antigens A and B poorly. Third, many cells other than red cells express A and B antigens and thus absorb some of the transferred antibody. ABO hemolytic disease occurs almost exclusively in infants of group A or B who are born of group O mothers. For unknown reasons, certain group O women possess IgG antibodies directed against group A or B antigens (or both) even without prior sensitization. Therefore, the firstborn may be affected. Fortunately, even with transplacentally acquired antibodies, lysis of the infant's red cells is minimal. There is no effective protection against ABO reactions.

There are two consequences of excessive destruction of red cells in the neonate (see Fig. 10.10). The severity of these changes varies considerably, depending on the degree of hemolysis and the maturity of the infant.

- *Anemia* is a direct result of red cell loss. If hemolysis is mild, increased red cell production may suffice to maintain near-normal levels of red cells. However, with more severe hemolysis, progressive anemia develops and may result in hypoxic injury to the heart and liver. Because of liver injury, plasma protein synthesis decreases, and levels of these proteins may drop to as low as 2 to 2.5 mg/dL. Cardiac hypoxia may lead to cardiac decompensation and failure. The combination of reduced plasma oncotic pressure and increased hydrostatic pressure in the circulation (secondary to cardiac failure) results in generalized edema and anasarca, culminating in hydrops fetalis.
- *Jaundice* develops because hemolysis produces unconjugated bilirubin (Chapter 18). Bilirubin also passes through the infant's poorly developed blood-brain barrier. Being water-insoluble, bilirubin blinds to lipids in the brain and can damage the CNS, causing kernicterus (see Fig. 10.13).

Nonimmune Hydrops

The three major causes of nonimmune hydrops include cardiovascular defects, chromosomal anomalies, and fetal anemia. Both structural and functional cardiovascular defects, such as congenital malformations and arrhythmias, may result in intrauterine cardiac failure and hydrops. Among the chromosomal anomalies, 45,X karyotype (Turner syndrome) and trisomies 21 and 18 are associated with fetal hydrops because of the accompanying structural cardiac anomalies. In Turner syndrome, abnormalities of lymphatic drainage from the neck may lead to postnuchal fluid accumulation (cystic hygromas) as well. Fetal anemia, not caused by Rh- or ABO-associated antibodies, can also result in hydrops. In fact, in some parts of the world (e.g., Southeast Asia), severe fetal anemia due to homozygous α-thalassemia, resulting from deletion of all four α-globin genes, is probably the most common cause of nonimmune hydrops (Chapter 14). Transplacental infection by parvovirus B19 is rapidly emerging as an important cause of hydrops (see earlier). The virus gains preferential entry into erythroid precursors (normoblasts), where it replicates, leading to apoptosis of red cell progenitors and isolated red cell aplasia. Parvoviral intranuclear inclusions can be seen within circulating and marrow erythroid precursors (see Fig. 10.9). Approximately 10% of cases of nonimmune hydrops are related to monozygous twin pregnancies and twin-to-twin transfusion occurring through anastomoses between the two circulations. In up to 20% of cases, the cause remains unknown.

MORPHOLOGY

The anatomic findings in fetuses with intrauterine fluid accumulation vary with both the severity of the disease and the underlying etiology. As previously noted, hydrops fetalis represents the most severe and generalized manifestation (Fig. 10.11), and lesser degrees

Figure 10.11 Hydrops fetalis. (A) There is generalized accumulation of fluid in the fetus. (B) Fluid accumulation is particularly prominent in the soft tissues of the neck, and this condition has been termed *cystic hygroma.* Cystic hygromas are characteristically seen, but not limited to, constitutional chromosomal anomalies such as 45,X karyotypes. (Courtesy Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, Tex.)

of edema such as isolated pleural, peritoneal, or postnuchal fluid collections can occur. Accordingly, infants may be stillborn, die within the first few days, or recover completely. The presence of dysmorphic features suggests a chromosomal abnormality; postmortem examination may reveal an underlying cardiac anomaly.

In hydrops associated with fetal anemia, both the fetus and placenta are characteristically pale; in most cases the liver and spleen are enlarged from cardiac failure and congestion. Additionally, the bone marrow demonstrates compensatory hyperplasia of erythroid precursors (parvovirus-associated red cell aplasia being a notable exception), and extramedullary hematopoiesis is present in the liver, spleen, lymph nodes, and possibly other tissues such as the kidneys, lungs, and even the heart (Fig. 10.12). The increased hematopoietic activity accounts for the presence in the peripheral circulation of large numbers of immature red cells, including reticulocytes and erythroblasts **(erythroblastosis fetalis).**

The most serious threat in fetal hydrops is CNS damage, known as **kernicterus** (Fig. 10.13). The affected brain is enlarged and edematous and, when sectioned, has a bright yellow color, particularly the basal ganglia, thalamus, cerebellum, cerebral gray matter, and spinal cord. The precise level of bilirubin that induces kernicterus is unpredictable, but neural damage usually requires a blood bilirubin level greater than 20 mg/dL in term infants; in premature infants this threshold may be considerably lower.

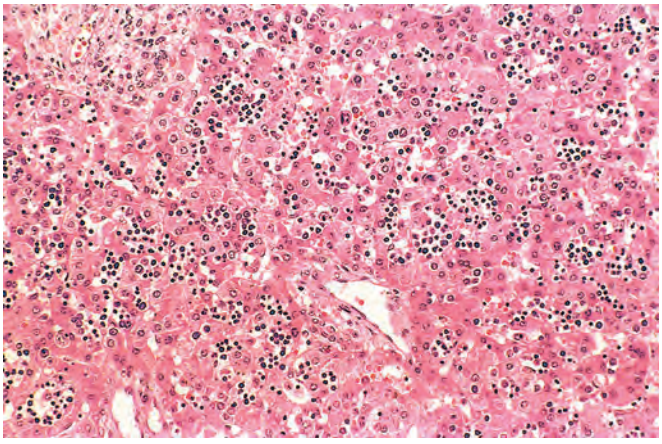

Figure 10.12 Numerous islands of extramedullary hematopoiesis (small blue cells) are scattered among mature hepatocytes in the liver of this infant with nonimmune hydrops fetalis.

Clinical Features

The clinical manifestations of fetal hydrops vary with the severity of the disease and can be inferred from the preceding discussion. Minimally affected infants display pallor, possibly accompanied by hepatosplenomegaly (to which may be added jaundice with more severe hemolytic reactions), whereas the most gravely ill neonates present with intense jaundice, generalized edema, and signs of neurologic injury. These infants may be supported by a variety of measures, including phototherapy (visual light oxidizes toxic unconjugated bilirubin to harmless, readily excreted, water-soluble dipyrroles) and, in severe cases, total exchange transfusion of the infant.

INBORN ERRORS OF METABOLISM AND OTHER GENETIC DISORDERS

Inborn errors of metabolism are genetic disorders that give rise to defects in metabolism. Since Sir Archibald Garrod

Figure 10.13 Kernicterus. Note the yellow discoloration of the brain parenchyma due to bilirubin accumulation, which is most prominent in the basal ganglia deep to the ventricles.

coined the term in 1908, the number of recognized metabolic diseases has increased exponentially. Most inborn errors of metabolism are rare diseases that are generally inherited as autosomal recessive or X-linked traits (Chapter 5). Mitochondrial disorders (Chapter 5) form a distinct entity by themselves. Some of the clinical features that suggest an underlying metabolic disorder in a neonate are listed in Table 10.2. The clinical manifestations of these diseases are generally the result of either abnormal metabolite accumulation or deficiency of the desired product. Three genetic disorders, phenylketonuria (PKU), galactosemia, and cystic fibrosis, are selected for discussion here. PKU and galactosemia are reviewed because their early diagnosis (via neonatal screening programs) is particularly important, and early death or intellectual disability can be prevented with appropriate dietary regimens. Cystic fibrosis is included because it is one of the most common, potentially lethal diseases occurring in individuals of Caucasian descent.

Phenylketonuria

There are several variants of this inborn error of metabolism, which affects 1 in 10,000 live-born Caucasian infants. The most common form, referred to as classic PKU, is quite common in persons of Scandinavian descent and is distinctly uncommon in African-American and Jewish populations.

PKU is an autosomal recessive disorder caused by a severe deficiency of the enzyme phenylalanine hydroxylase (PAH) leading to hyperphenylalaninemia. Affected infants are normal at birth but within a few weeks develop an elevated plasma phenylalanine level, which impairs brain development. Usually by 6 months of life, severe intellectual disability becomes evident; fewer than 4% of untreated phenylketonuric children have IQs greater than 50 or 60. About one-third of these children are never able to walk, and two-thirds cannot talk. Seizures, other neurologic abnormalities, decreased pigmentation of hair and skin, a characteristic musty odor, and eczema often accompany the intellectual disability in untreated children. Hyperphenylalaninemia and the resultant intellectual disability can be avoided by restricting phenylalanine intake early in life. Hence, all states in the United States have adopted screening procedures to detect PKU in the immediate postnatal period.

Many female PKU patients, if treated with dietary restriction early in life, reach childbearing age and are clinically asymptomatic. Most of them have marked hyperphenylalaninemia, because dietary treatment is discontinued after they reach adulthood. Between 75% and 90% of children born to such women have intellectual disability and are microcephalic, and 15% have congenital heart disease, even though the infants themselves are heterozygotes. This syndrome, termed maternal PKU, results from the teratogenic effects of phenylalanine or its metabolites that cross the placenta and affect specific fetal organs during development. The presence and severity of the fetal anomalies directly correlate with the maternal phenylalanine level, so it is imperative that maternal dietary restriction of phenylalanine be initiated before conception and continued throughout pregnancy.

The biochemical abnormality in PKU is an inability to convert phenylalanine into tyrosine. In normal children, less than 50% of the dietary intake of phenylalanine is necessary for protein synthesis. The remainder is converted to tyrosine by the phenylalanine hydroxylase system (Fig. 10.14). When phenylalanine metabolism is blocked because of a lack of functional PAH, minor shunt pathways come into play, yielding several off-pathway metabolites that are

Modified from Barness LA, Gilbert-Barness E: Metabolic diseases. In Gilbert-Barness E, Barness LA, editors: *Potter's Pathology of the Fetus, Infant, and Child,* St, Louis, 2007, Mosby.

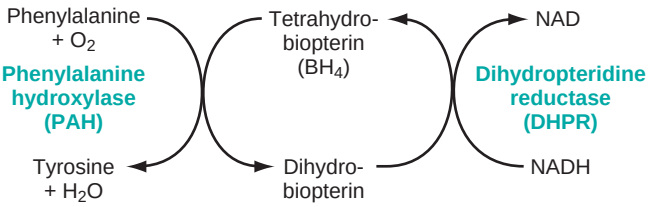

Figure 10.14 The phenylalanine hydroxylase *(PAH)* system. Deficiency of PAH or dihydropteridine reductase *(DHPR)* can give rise to phenylketonuria. *NAD,* Nicotinamide adenine dinucleotide (oxidized); *NADH,* nicotinamide adenine dinucleotide (reduced).

excreted in large amounts in the urine and sweat. These impart a strong musty or mousy odor to affected infants. It is believed that excess phenylalanine or its metabolites contribute to the brain damage in PKU. Concomitant lack of tyrosine (see Fig. 10.14), a precursor of melanin, is responsible for the light color of hair and skin.

At the molecular level, over 500 mutant alleles of the *PAH* gene have been identified. Mutations in both *PAH* alleles are required to develop the disease. Infants with mutations resulting in severely reduced PAH activity present with markedly elevated blood phenylalanine levels and the classic features of PKU, and those with up to 6% residual PAH activity present with milder disease. Some PAH mutations result in only modest elevations of blood phenylalanine levels without associated neurologic damage. This latter condition, referred to as benign hyperphenylalaninemia, is important to recognize because these individuals may have positive screening tests but do not develop the stigmata of classic PKU. Because of the numerous disease-causing alleles of the *PAH* gene, molecular diagnosis is not feasible, and measurement of serum phenylalanine levels is necessary to differentiate benign hyperphenylalaninemia from PKU; the levels in the latter are typically fivefold or more above normal. Once a biochemical diagnosis is established, the specific mutation causing PKU can be determined. With the identification of the mutation, carrier testing of at-risk family members can be performed.

Although 98% of PKU is attributable to mutations in *PAH*, approximately 2% occur due to abnormalities in synthesis or recycling of the cofactor tetrahydrobiopterin (BH_4; see Fig. 10.14). It is clinically important to recognize these variant forms of PKU because they cannot be treated by dietary restriction of phenylalanine.

Galactosemia

Galactosemia is an autosomal recessive disorder of galactose metabolism resulting from accumulation of galactose-1-phosphate in tissues. It affects 1 in 60,000 live-born infants. Normally, lactose, the major carbohydrate of mammalian milk, is split into glucose and galactose in the intestinal microvilli by lactase. Galactose is then converted to glucose in several steps catalyzed by distinct enzymes. Two variants of galactosemia have been identified. In the more common variant, there is a total lack of galactose-1-phosphate uridyl transferase (GALT). The rare variant arises from a deficiency of galactokinase. Because galactokinase deficiency leads to a milder form of the disease that is not associated with intellectual disability, it is not considered in this discussion.

As a result of GALT deficiency, galactose-1-phosphate accumulates in many locations, including the liver, spleen, lens of the eye, kidneys, heart muscle, cerebral cortex, and erythrocytes. Alternative metabolic pathways are activated, leading to the production of galactitol (a polyol metabolite of galactose) and galactonate, an oxidized by-product of excess galactose, both of which also accumulate in the tissues. Long-term toxicity in galactosemia has been variously imputed to these metabolic intermediates. Heterozygotes may have a mild enzyme deficiency and are spared the clinical and pathologic consequences of the homozygous state.

The clinical picture is variable, probably reflecting the heterogeneity of mutations in the *GALT* gene. The liver, eyes, and brain bear the brunt of the damage. The early-to-develop hepatomegaly is due largely to fatty change, but in time widespread scarring that closely resembles the cirrhosis of alcohol abuse may supervene. Opacification of the lens (cataract) develops, probably because the lens absorbs water and swells as galactitol, produced by alternative metabolic pathways, accumulates and increases osmotic pressure. Nonspecific alterations appear in the CNS, including loss of nerve cells, gliosis, and edema, particularly in the dentate nuclei of the cerebellum and the olivary nuclei of the medulla. Similar changes may occur in the cerebral cortex and white matter.

These infants fail to thrive almost from birth. Vomiting and diarrhea appear within a few days of milk ingestion. Jaundice and hepatomegaly usually become evident during the first week of life and may seem to be a continuation of the physiologic jaundice of the newborn. Cataracts develop within a few weeks, and within the first 6 to 12 months of life intellectual disability may be detected. Even in untreated infants, however, the disability is usually not as severe as that seen in PKU. Accumulation of galactose and galactose-1-phosphate in the kidney impairs amino acid transport, resulting in aminoaciduria. There is an increased frequency of fulminant *Escherichia coli* septicemia, possibly arising from depressed neutrophil bactericidal activity. Hemolysis and coagulopathy in the newborn period can occur as well. Newborn screening tests are widely utilized in the United States. They depend on fluorometric assay of GALT enzyme activity on a dried blood spot. A positive screening test must be confirmed by assay of GALT levels in red cells. Antenatal diagnosis is possible by assay of GALT activity in cultured amniotic fluid cells or determination of galactitol level in amniotic fluid supernatant.

Many of the clinical and morphologic changes of galactosemia can be prevented or ameliorated by early removal of galactose from the diet for at least the first 2 years of life. Control instituted soon after birth prevents the cataracts and liver damage and permits almost normal development. Even with dietary restrictions, however, it is now established that older patients are frequently affected by a speech disorder and gonadal failure (especially premature ovarian failure) and, less commonly, ataxia.

Cystic Fibrosis (Mucoviscidosis)

Cystic fibrosis is an inherited disorder of ion transport that affects fluid secretion in exocrine glands and in the epithelial lining of the respiratory, gastrointestinal, and

reproductive tracts. In many individuals this disorder leads to abnormally viscous secretions that obstruct organ passages, resulting in most of the clinical features of this disorder, such as chronic lung disease secondary to recurrent infections, pancreatic insufficiency, steatorrhea, malnutrition, hepatic cirrhosis, intestinal obstruction, and male infertility. These manifestations may appear at any point in life from before birth to much later in childhood or even in adolescence.

Cystic fibrosis is the most common lethal genetic disease that affects Caucasian populations, with an incidence of approximately 1 in 2500 live births. The carrier frequency in the United States is 1 in 20 among Caucasians but significantly lower in African Americans, Asians, and Hispanics. Although cystic fibrosis follows an autosomal recessive transmission pattern, recent data suggest that even heterozygote carriers have a higher incidence of respiratory and pancreatic disease compared with the general population. In addition, despite the classification of cystic fibrosis as a "Mendelian" disorder, there is a wide degree of phenotypic variation that results from three additional factors: diverse mutations in the gene associated with cystic fibrosis, the tissue-specific effects of the encoded gene product, and the influence of modifier genes.

Cystic Fibrosis Gene: Normal Structure and Function

The primary defect in cystic fibrosis is abnormal transport of chloride and bicarbonate ions mediated by an anion channel encoded by the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene on chromosome 7q31.2. The 1480–amino acid polypeptide encoded by *CFTR* has two transmembrane domains (each containing six α-helices), two cytoplasmic nucleotide-binding domains (NBDs), and a regulatory domain (R domain) that contains protein kinase A and C phosphorylation sites (Fig. 10.15). The two transmembrane domains form a channel through which chloride passes. Activation of the CFTR channel is mediated by agonist-induced increases in cyclic adenosine monophosphate (cAMP), which lead to activation of a protein kinase A that phosphorylates the R domain. Adenosine triphosphate (ATP) binding and hydrolysis occurs at the NBD and is essential for opening and closing of the channel pore, which is enhanced by the presence of phosphorylated R domain. Several important facets of CFTR function have emerged in recent years:

- *CFTR regulates multiple ion channels and cellular processes.* Although initially characterized as a chloride-conductance channel, it is now recognized that CFTR can regulate additional ion channels and cellular processes. These include so-called outwardly rectifying chloride channels, inwardly rectifying potassium channels (Kir6.1), the epithelial sodium channel (ENaC), gap junction channels, and cellular processes involved in ATP transport and mucus secretion. Of these, the interaction of CFTR with the ENaC has possibly the most pathophysiologic relevance in cystic fibrosis. The ENaC is situated on the apical surface of epithelial cells and is responsible for sodium uptake from the luminal fluid, rendering the luminal fluid hypotonic. ENaC is inhibited by normally functioning CFTR; hence, in cystic fibrosis, ENaC activity increases, markedly augmenting sodium uptake across the apical membrane. The importance of this phenomenon is discussed later in the context of pulmonary and gastrointestinal pathology in cystic fibrosis. The one exception to this is the human sweat ducts, where ENaC activity decreases as a result of *CFTR* mutations; therefore, hypertonic fluid with high sodium chloride (the *sine qua non* of classic cystic fibrosis) is formed. This is the basis for the "salty" sweat that mothers can often detect in their affected infants.
- *The functions of* CFTR *are tissue-specific; therefore, the impact of a mutation in* CFTR *is also tissue-specific.* The major function of CFTR in the sweat gland ducts is to reabsorb luminal chloride ions and augment sodium reabsorption via the ENaC (see earlier). Therefore, in the sweat ducts, loss of CFTR function leads to decreased reabsorption of sodium chloride and the production of hypertonic sweat (Fig. 10.16). However, in the respiratory and intestinal epithelium, CFTR is one of the most important avenues for active luminal secretion of chloride. At these sites, *CFTR* mutations result in loss or reduction of chloride secretion into the lumen (Fig. 10.16), and active luminal sodium absorption is increased due to loss of inhibition of ENaC activity. These changes in ion distribution result in increased passive water reabsorption from the lumen, lowering the water content of the surface fluid

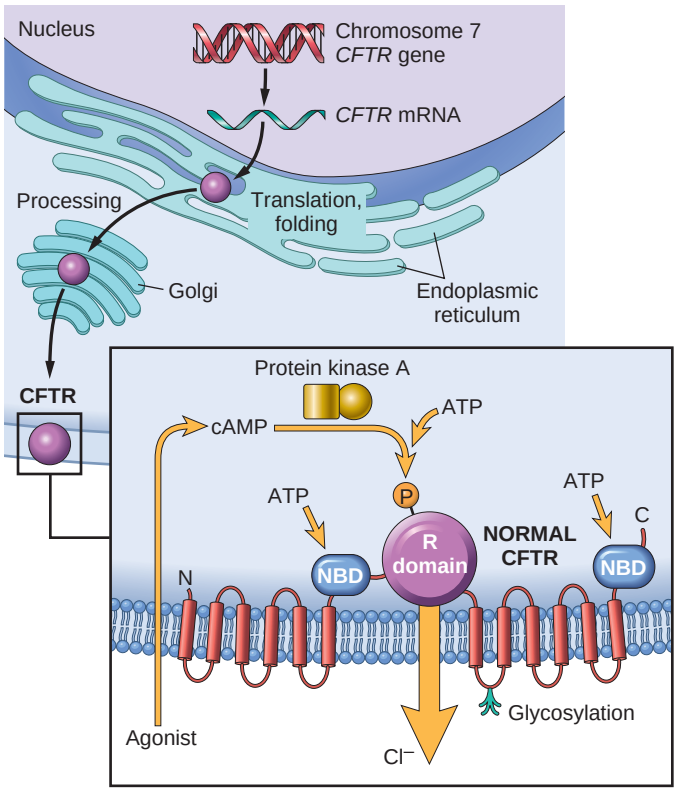

Figure 10.15 *Top*, CFTR from gene to protein. *Bottom*, Normal cystic fibrosis transmembrane conductance regulator (CFTR) structure and activation. CFTR consists of two transmembrane domains, two nucleotide-binding domains (NBDs), and a regulatory R domain. Agonists (e.g., acetylcholine) bind to epithelial cells and increase levels of cyclic adenosine monophosphate (cAMP), which activates protein kinase A; the latter phosphorylates the CFTR R domain using ATP. This results in opening of the chloride ion channel.

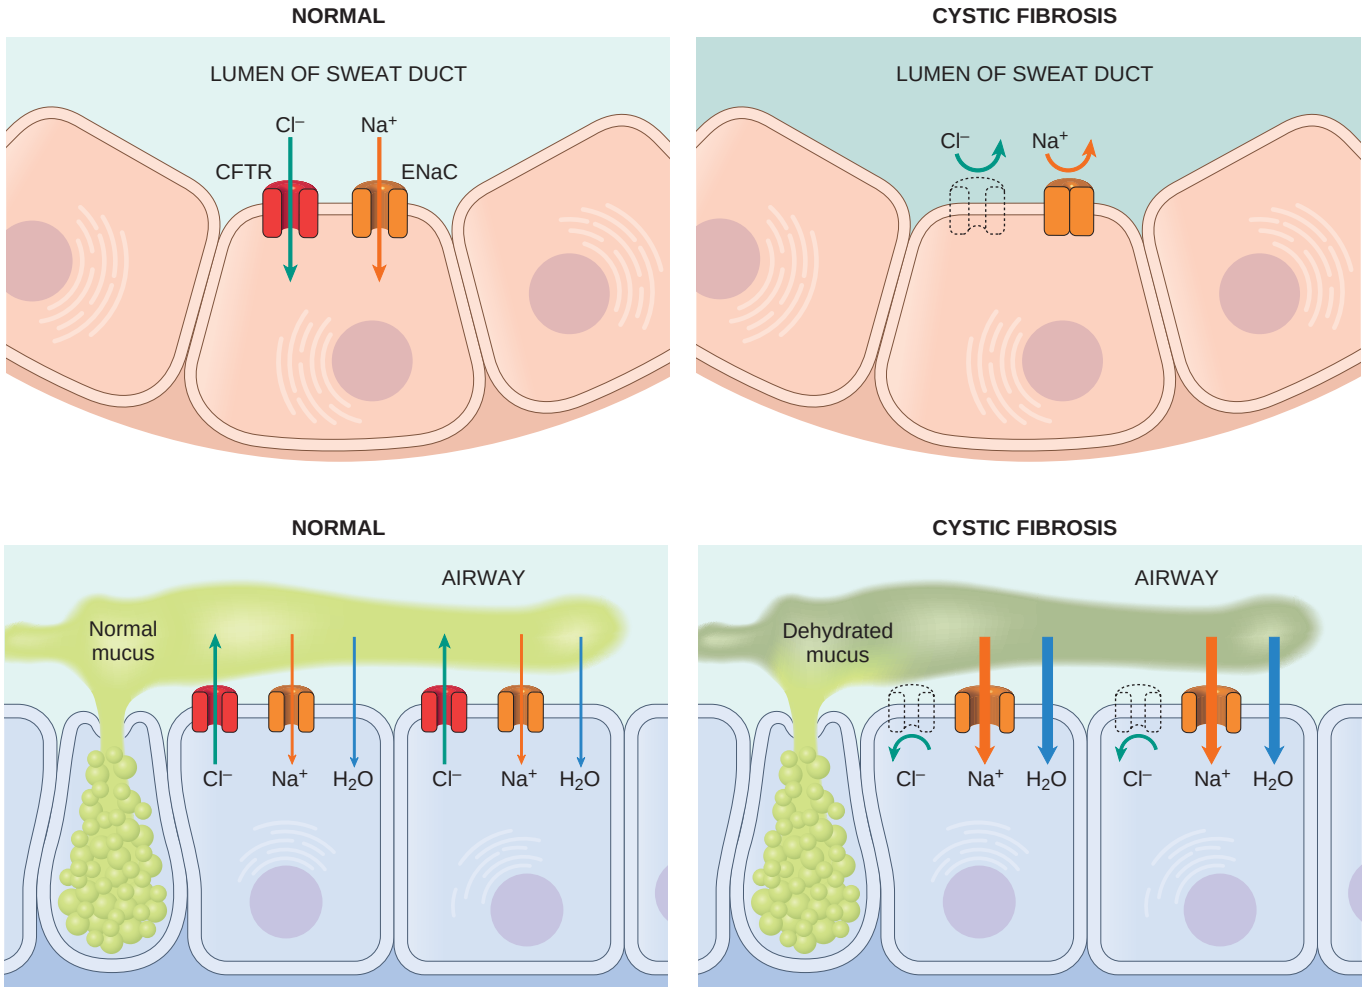

Figure 10.16 CFTR chloride channel defect in the sweat ducts *(top)* causes increased sodium chloride concentration in sweat. In the airway *(bottom)*, patients with cystic fibrosis have decreased chloride secretion and increased sodium and water reabsorption, leading to dehydration of the mucus layer coating epithelial cells, defective mucociliary action, and mucus plugging of airways. *CFTR*, Cystic fibrosis transmembrane conductance regulator; *ENaC*, epithelial sodium channel.

layer coating mucosal cells. Thus, unlike in the sweat ducts, there is no difference in the salt concentration of the surface fluid layer coating respiratory and intestinal mucosal cells in those with cystic fibrosis when compared with normal individuals. Instead, the pathogenesis of respiratory and intestinal complications in cystic fibrosis seems to stem from an isotonic but low-volume surface fluid layer. In the lungs, this dehydration leads to defective mucociliary action and the accumulation of hyperconcentrated, viscid secretions that obstruct the air passages and predispose to recurrent pulmonary infections.

- CFTR *regulates transport of bicarbonate ions.* CFTR plays both a direct and indirect role in regulating bicarbonate transport across the apical epithelial membrane. The anion channel of CFTR is not entirely specific for chloride and has been found to be permeable to bicarbonate as well. In addition, CFTR has reciprocal interactions with the SLC26 family of anion exchangers, which are co-expressed on the apical surface with CFTR. In some *CFTR* mutants, chloride transport is completely or substantially preserved, and bicarbonate transport is markedly abnormal. Normal tissue secretes alkaline fluids; in contrast, fluids that are acidic (due to absence of bicarbonate ions) are secreted by epithelia harboring these mutant *CFTR* alleles. The acidity of secretions results in decreased luminal pH that can lead to a variety of adverse effects such as increased mucin precipitation and plugging of ducts and increased binding of bacteria to plugged mucins. Pancreatic insufficiency, a feature of classic cystic fibrosis, is virtually always present when there are *CFTR* mutations with abnormal bicarbonate conductance.

Cystic Fibrosis Gene: Mutational Spectrum and Genotype-Phenotype Correlation

Since the *CFTR* gene was cloned in 1989, more than 2000 disease-associated mutations have been identified; only five mutations have a relative frequency of 1% or more of disease-causing genotypes. Most of the mutations are missense alterations but frameshift, splicing, and nonsense mutations are also present. The mutations can be grouped into six classes based on their effect on the CFTR protein (Fig. 10.17). Class I to III mutations result in less than 10% residual CFTR activity and are termed "severe" mutations,

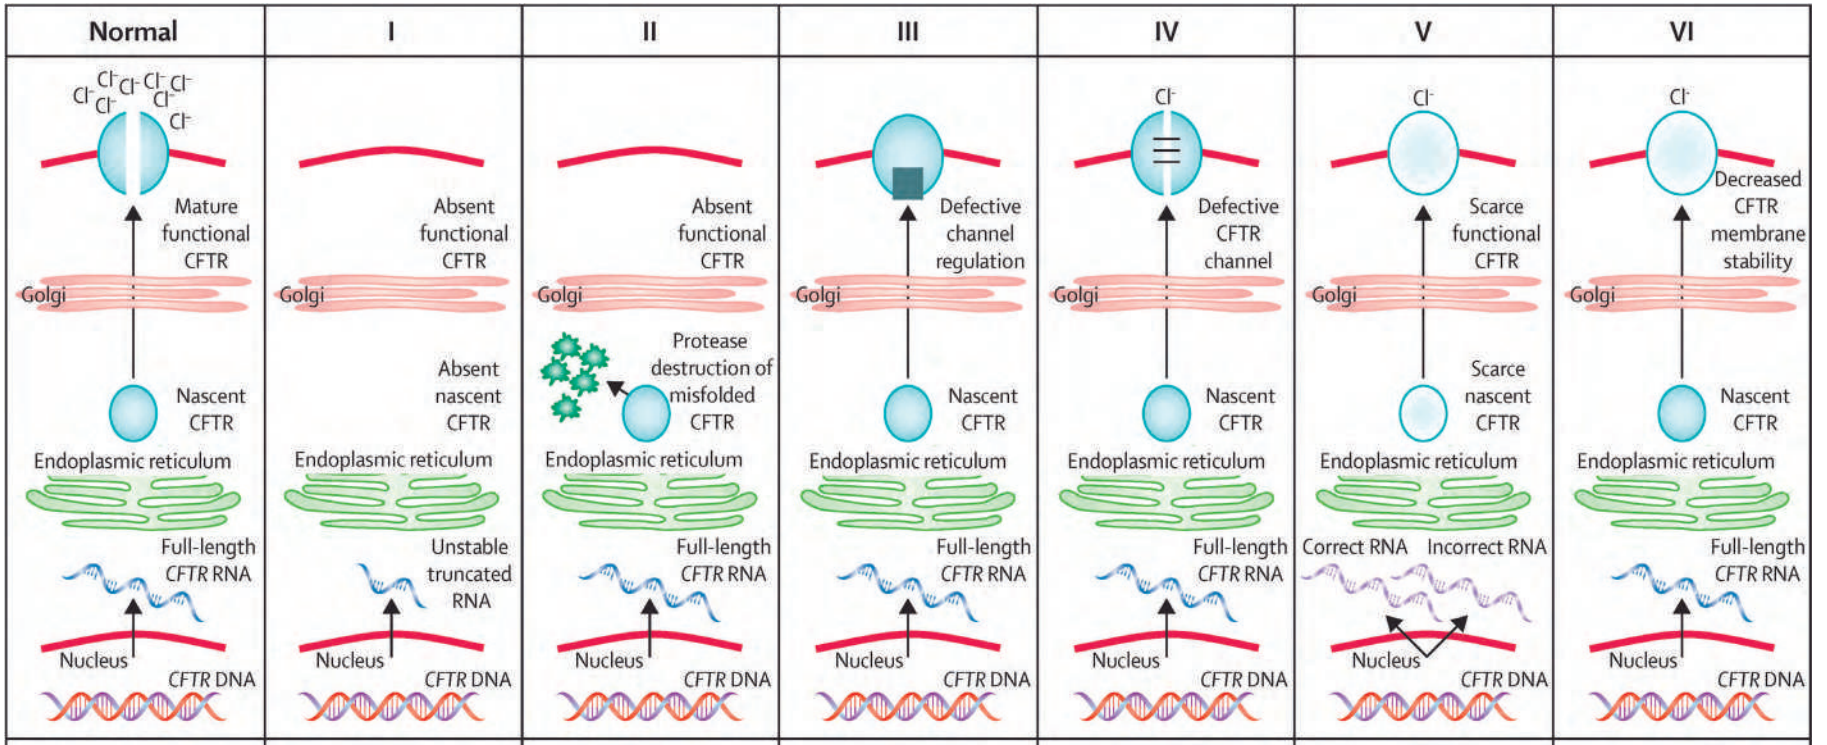

Figure 10.17 Classes of *CFTR* mutations. Mutations in the cystic fibrosis transmembrane conductance regulator *(CFTR)* gene can be divided into six classes. Class I mutations result in no protein production. Class II mutations (including the most prevalent, Phe508del or ΔF508) cause retention of a misfolded protein at the endoplasmic reticulum, and subsequent degradation in the proteasome. Class III mutations affect channel regulation, impairing channel opening (e.g., Gly551Asp). Class IV mutants show reduced conduction—i.e., decreased flow of ions (e.g., Arg117His). Class V mutations cause substantial reduction in mRNA or protein, or both. Class VI mutations cause substantial plasma membrane instability. (Reproduced from Elborn JS: Cystic fibrosis, *Lancet* 388:2519–2531, 2016, from Boyle MP, De Boeck K: A new era in the treatment of cystic fibrosis: correction of the underlying CFTR defect, *Lancet Respir Med* 1:158–163, 2013.)

and class IV to VI mutations result in less than 20% residual CFTR activity and are termed "mild" mutations.

- Class I: *Defective protein synthesis (null mutations).* These mutations result in premature termination of protein translation and are associated with complete lack of CFTR protein at the apical surface of epithelial cells.
- Class II: *Abnormal protein folding, processing, and trafficking (processing mutations).* These mutations result in defective processing of the protein from the endoplasmic reticulum to the Golgi apparatus; the protein does not become fully folded and glycosylated and is instead degraded before it reaches the cell surface. The most common *CFTR* mutation is a class II caused by deletion of three nucleotides coding for phenylalanine at amino acid position 508 (ΔF508). Worldwide, this mutation can be found in approximately 70% of Caucasian cystic fibrosis patients. Class II mutations are associated with near-complete lack of CFTR protein at the apical surface of epithelial cells.
- Class III: *Defective regulation (gating mutations).* Mutations in this class prevent activation of CFTR by abrogating ATP binding and hydrolysis, an essential prerequisite for ion transport (see earlier). Thus, there is a normal amount of CFTR on the apical surface, but it is nonfunctional.
- Class IV: *Decreased conductance (conduction mutations).* These mutations typically occur in the transmembrane domain of *CFTR*, which forms the ionic pore for chloride transport. There is a normal amount of CFTR at the apical membrane, but with reduced chloride conduction.
- Class V: *Reduced abundance (production mutations).* These mutations typically affect intronic splice sites or the *CFTR* promoter, such that there is a reduced amount of normal protein.
- Class VI: *Decreased membrane CFTR stability (instability mutations).* These mutations give rise to fully processed and functional proteins but with greatly reduced membrane stability.

Because cystic fibrosis is an autosomal recessive disease, affected individuals harbor mutations on both alleles. However, the nature of mutations on each of the two alleles can have a remarkable effect on the overall phenotype, as well as on organ-specific manifestations (Fig. 10.18). Thus, two "severe" mutations that produce virtual absence of membrane CFTR function are associated with the classic cystic fibrosis phenotype (pancreatic insufficiency, sinopulmonary infections, and gastrointestinal symptoms), and the presence of a "mild" mutation on one or both alleles results in a less severe phenotype. This general dictum of genotype-phenotype correlation is most consistent for pancreatic disease, wherein the presence of one allele with a "mild" mutation associated with some CFTR activity can prevent the pancreatic insufficiency that is virtually always seen with homozygosity for "severe" mutations. In contrast, genotype-phenotype correlations are far less consistent in pulmonary disease, due to the effect of secondary modifiers (see later). As genetic testing for *CFTR* mutations has expanded, it has become evident that some patients who present with clinical features apparently unrelated to cystic fibrosis may also harbor *CFTR* mutations. These include individuals with idiopathic chronic pancreatitis, late-onset chronic pulmonary disease, idiopathic bronchiectasis, and obstructive azoospermia caused by bilateral absence of the vas deferens (see detailed discussion of individual phenotypes later). Most of these patients do not demonstrate other features of cystic fibrosis, despite the presence of bi-allelic *CFTR* mutations; these patients are classified as having nonclassic or atypical cystic fibrosis. Identifying these individuals is important not only for subsequent management, but also for genetic counseling.

Genetic and Environmental Modifiers

Although cystic fibrosis remains one of the best-known examples of the "one gene, one disease" axiom, there is considerable evidence that genes other than *CFTR* modify the frequency and severity of certain organ-specific manifestations, especially pulmonary manifestations and neonatal meconium ileus. Not surprisingly, polymorphisms in genes whose products modulate neutrophil function in response to bacterial infections act as modifier loci for the severity of pulmonary disease in cystic fibrosis. Examples of such modifier genes include mannose binding lectin 2 *(MBL2)*, transforming growth factor β1 *(TGF-β1)*, and interferon-related developmental regulator 1 *(IFRD1)*. It is postulated that polymorphisms in these genes regulate the

Level of CFTR function	<5%	<10%	<20%	50%
Sinuses	Severe chronic sinusitis	Moderate chronic sinusitis		Increased rate of chronic sinusitis
Lungs	Severe lung disease	Variable lung disease		Increased rate of lung disease
Sweat glands	High sweat chloride	Intermediate sweat chloride		
Pancreas	Pancreatic insufficiency	Pancreatic sufficiency		
Intestines	Meconium ileus	Distal intestinal obstruction syndrome		
Vas deferens	Absent vas deferens			Increased risk of absent vas deferens

Figure 10.18 The many clinical manifestations of mutations in the cystic fibrosis gene, from most severe to asymptomatic. (Modified from Chang EH and Zabner J: Precision genomic medicine in cystic fibrosis, *Clin Transl Sci* 8(5):606–610, 2015.)

resistance of the lungs to exogenous infections with virulent microbes (see later), thus modifying the natural history of cystic fibrosis.

Environmental modifiers may also explain some of the significant phenotypic differences between individuals who share the same *CFTR* genotype. This is best exemplified in pulmonary disease, where *CFTR* genotype-phenotype correlations can be perplexing. As stated earlier, defective mucociliary action because of deficient hydration of the mucus results in an inability to clear bacteria from the airways. *Pseudomonas aeruginosa* species, in particular, colonize the lower respiratory tract, first intermittently and then chronically. Concurrent viral infections predispose to such colonization. The static mucus creates a hypoxic microenvironment in the airway surface fluid, which in turn favors the production of alginate, a mucoid polysaccharide capsule, by the colonizing bacteria. Alginate production permits the formation of a biofilm that protects the bacteria from antibodies and antibiotics, allowing them to evade host defenses and produce a chronic destructive lung disease. Antibody- and cell-mediated immune reactions induced by the organisms result in further pulmonary destruction, but are ineffective against the organism. Approximately 80% of cystic fibrosis patients are colonized by *Pseudomonas aeruginosa* by 20 years of age. Chronic colonization by these bacteria is a significant contributor to the morbidity and mortality of cystic fibrosis.

It is evident, therefore, that in addition to genetic factors (e.g., class of mutation), a plethora of environmental modifiers (e.g., intercurrent and concurrent infections by microorganisms) can influence the severity and progression of lung disease in cystic fibrosis.

MORPHOLOGY

The anatomic changes are highly variable in distribution and severity. In individuals with nonclassic cystic fibrosis, the disease is quite mild and does not seriously disturb their growth and development. In others, the pancreatic involvement is severe and impairs intestinal absorption because of pancreatic insufficiency (Chapter 19), so malabsorption stunts development and postnatal growth. In others, the mucus secretion defect leads to defective mucociliary action, obstruction of bronchi and bronchioles, and crippling fatal pulmonary infections. In all variants, the **sweat glands are morphologically unaffected.**

Pancreatic abnormalities are present in approximately 85% to 90% of patients with cystic fibrosis. In milder cases, there may be only accumulation of mucus in the small ducts with some dilation of the exocrine glands. In more severe cases, usually seen in older children or adolescents, the ducts are completely plugged, causing atrophy of the exocrine glands and progressive fibrosis (Fig. 10.19). Atrophy of the exocrine portion of the pancreas may occur, leaving only islets within a fibrofatty stroma. The loss of pancreatic exocrine secretion impairs fat absorption, and the associated avitaminosis A may contribute to squamous metaplasia of the pancreatic duct lining epithelium, which is already injured by the inspissated mucus secretions. Thick viscid plugs of mucus may also be found in the small intestine of infants. Sometimes these cause small-bowel obstruction, known as **meconium ileus.**

Liver involvement follows the same basic pattern. Bile canaliculi are plugged by mucus material, accompanied by ductular proliferation and portal inflammation. Hepatic **steatosis** is not an uncommon finding in liver biopsies. Over time, **focal biliary cirrhosis** develops in approximately one-third of patients (Chapter 18), which can eventually involve the entire liver, resulting in diffuse hepatic nodularity. Such severe hepatic involvement is encountered in less than 10% of patients.

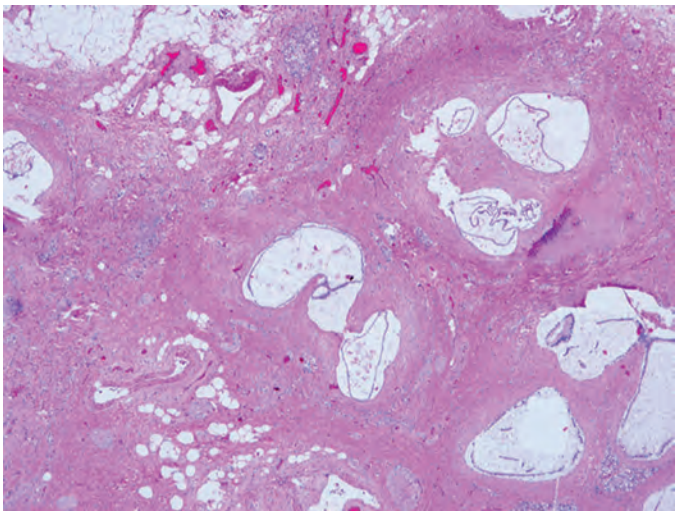

Figure 10.19 End-stage pancreatic disease in cystic fibrosis. The ducts are markedly dilated, and exocrine glands are destroyed and replaced by fibrous tissue.

The **salivary glands** frequently show histologic changes similar to those described in the pancreas: progressive dilation of ducts, squamous metaplasia of the lining epithelium, and glandular atrophy followed by fibrosis.

The **pulmonary changes** are the most serious complications of this disease (Fig. 10.20). These stem from the viscous mucus secretions of the submucosal glands of the respiratory tree, leading to secondary obstruction and infection of the air passages. The bronchioles are often distended with thick mucus associated with marked hyperplasia and hypertrophy of the mucus-secreting cells. Superimposed infections give rise to severe chronic bronchitis and bronchiectasis (Chapter 15). In many instances, lung abscesses develop. *Staphylococcus aureus, Haemophilus influenzae,* and *Pseudomonas aeruginosa* are the three most common organisms responsible for lung infections. As mentioned earlier, a mucoid form of *P. aeruginosa* (alginate-producing) is particularly frequent and causes chronic inflammation. Even more sinister is the increasing frequency of infection with another group of pseudomonads, the *Burkholderia cepacia* complex, which includes at least nine different species; of these, infections with *B. cenocepacia* are the most common in cystic fibrosis patients. This opportunistic bacterium is particularly hardy, and infection with this organism has been associated with fulminant illness ("cepacia syndrome"), longer hospital stays, and increased mortality. Other opportunistic bacterial pathogens include *Stenotrophomonas maltophilia* and nontuberculous mycobacteria; allergic bronchopulmonary aspergillosis also occurs with increased frequency in cystic fibrosis.

Azoospermia and infertility are found in 95% of males who survive to adulthood; **congenital bilateral absence of the vas deferens** is a frequent finding in these patients. In some males, bilateral absence of the vas deferens may be the only feature suggesting an underlying *CFTR* mutation.

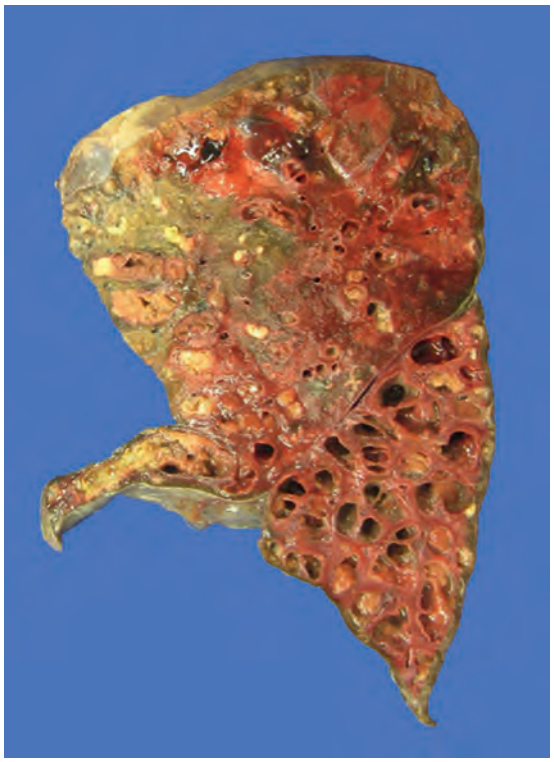

Figure 10.20 Lungs of a patient who died of cystic fibrosis. There is extensive mucus plugging and dilation of the tracheobronchial tree. The pulmonary parenchyma is consolidated by a combination of both secretions and pneumonia—the green color associated with *Pseudomonas* infection.

Clinical Features

Few childhood diseases are as protean as cystic fibrosis in clinical manifestations (Table 10.3; Fig. 10.18). The symptoms are extremely varied and may appear at birth to years later, and involve one organ system or many. Approximately 5% to 10% of cases come to clinical attention at birth or soon after because of meconium ileus. Distal intestinal obstruction can also occur in older individuals, manifesting as recurrent episodes of right lower quadrant pain sometimes associated with a palpable mass of meconium, with or without associated intussusception, in the right iliac fossa.

Exocrine pancreatic insufficiency occurs in the majority (85% to 90%) of patients with cystic fibrosis and is associated with "severe" *CFTR* mutations on *both* alleles (e.g., *ΔF508/ΔF508*), whereas 10% to 15% of patients with one "severe" and one "mild" *CFTR* mutation (e.g., *ΔF508/R117H*) or two "mild" *CFTR* mutations retain enough pancreatic exocrine function so as not to require enzyme supplementation (pancreas-sufficient phenotype). Pancreatic insufficiency is associated with protein and fat malabsorption and increased fecal loss. Manifestations of malabsorption (e.g., large foul-smelling stools, abdominal distention, and poor weight gain) may appear during the first year of life. The faulty fat absorption may induce deficiency of the fat-soluble vitamins, resulting in manifestations of avitaminosis A, D, E, or K. Hypoproteinemia may be severe enough to cause generalized edema. Persistent diarrhea may result in rectal prolapse in up to 10% of children with this disease. The pancreas-sufficient phenotype is usually not associated with other gastrointestinal complications, and, in general, these individuals demonstrate excellent growth and development. A subset of patients with pancreas-sufficient cystic fibrosis have recurrent bouts of pancreatitis associated with acute abdominal pain and occasionally, life-threatening complications. These patients have other features of classic cystic fibrosis, such as pulmonary disease. "Idiopathic" chronic pancreatitis can also occur as an isolated late-onset finding in the absence of other stigmata of cystic fibrosis (Chapter 19); bi-allelic *CFTR* mutations (usually one "mild," one "severe") are demonstrable in the majority of these individuals who have nonclassic or atypical cystic fibrosis. Endocrine pancreatic insufficiency (i.e., diabetes mellitus) occurs in up to 50% of adults with cystic fibrosis and is thought to be caused by severe destruction of pancreatic parenchyma including the islets.

Cardiorespiratory complications, such as persistent lung infections, obstructive pulmonary disease, and cor pulmonale, are the most common cause of death (~80%) in cystic fibrosis

Table 10.3 Clinical Features and Diagnostic Criteria for Cystic Fibrosis

Clinical Features of Cystic Fibrosis
1. Chronic sinopulmonary disease manifested by
a. Persistent colonization/infection with typical cystic fibrosis pathogens, including *Staphylococcus aureus*, nontypeable *Haemophilus influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa, Burkholderia cepacia*
b. Chronic cough and sputum production
c. Persistent chest radiograph abnormalities (e.g., bronchiectasis, atelectasis, infiltrates, hyperinflation)
d. Airway obstruction manifested by wheezing and air trapping
e. Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
f. Digital clubbing
2. Gastrointestinal and nutritional abnormalities, including
a. Intestinal: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
b. Pancreatic: pancreatic insufficiency, recurrent acute pancreatitis, chronic pancreatitis
c. Hepatic: chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis or multilobular cirrhosis, prolonged neonatal jaundice
d. Nutritional: failure to thrive (severe acute malnutrition), hypoproteinemia, edema, complications secondary to fat-soluble vitamin deficiency
3. Salt-loss syndromes: acute salt depletion, chronic metabolic alkalosis
4. Male urogenital abnormalities resulting in obstructive azoospermia (congenital bilateral absence of vas deferens)
Criteria for Diagnosis of Cystic Fibrosis
One or more characteristic phenotypic features, OR a history of cystic fibrosis in a sibling, parent, or child, OR a positive newborn screening test result AND An increased sweat chloride concentration, OR a sweat chloride concentration in the intermediate range AND identification of two disease-causing *CFTR* mutations, OR a sweat chloride concentration in the intermediate range AND demonstration of abnormal epithelial nasal ion transport (nasal potential difference or intestinal current measurement)

Modified with permission from Farrell PM, White TB, Ren CL, et al: Diagnosis of cystic fibrosis: consensus guidelines from the Cystic Fibrosis Foundation, *J Pediatr* 181S:S4–S15, 2017.

patients in the United States. By 18 years of age, 80% of patients with classic cystic fibrosis harbor *P. aeruginosa,* and 3.5% harbor *B. cepacia*. With the indiscriminate use of antibiotic prophylaxis against *Staphylococcus,* there has been an unfortunate resurgence of resistant strains of *Pseudomonas* in many patients. Individuals who carry one "severe" and one "mild" *CFTR* mutation may develop late-onset mild pulmonary disease, another example of nonclassic or atypical cystic fibrosis. Patients with mild pulmonary disease usually have little or no pancreatic disease. Adult-onset "idiopathic" bronchiectasis has been linked to *CFTR* mutations in a subset of cases. Recurrent sinonasal polyps can occur in 10% to 25% of individuals with cystic fibrosis; hence, children who present with this finding should be tested for cystic fibrosis.

Significant *liver disease* occurs late in the natural history of cystic fibrosis and is gaining in clinical importance as life expectancies increase. In fact, after cardiopulmonary and transplantation-related complications, liver disease is the most common cause of death in cystic fibrosis. Most studies suggest that symptomatic or biochemical liver disease has its onset at or around puberty, with a prevalence of approximately 13% to 17%. However, asymptomatic hepatomegaly may be present in up to one-third of individuals. Obstruction of the common bile duct may occur due to stones or sludge; it presents with abdominal pain and the acute onset of jaundice. As previously noted, diffuse biliary cirrhosis develops in less than 10% of individuals with cystic fibrosis.

Approximately 95% of males with cystic fibrosis are infertile as a result of *obstructive azoospermia.* As mentioned earlier, this is most commonly due to congenital bilateral absence of the vas deferens, which is caused in 80% of cases by bi-allelic *CFTR* mutations.

In most cases, the diagnosis of cystic fibrosis is based on persistently elevated sweat electrolyte concentrations (often the mother makes the diagnosis by recognizing her infant's abnormally salty sweat), characteristic clinical findings (sinopulmonary disease and gastrointestinal manifestations), an abnormal newborn screening test, or a family history. The most common newborn screening test is based on measuring the blood level of immunoreactive trypsinogen, which is produced by the pancreas, and elevated levels result from pancreatic injury. A minority of patients with cystic fibrosis, especially those with at least one "mild" *CFTR* mutation, may have a normal or near-normal sweat test (<60 mM). Measurement of nasal transepithelial potential difference in vivo can be a useful adjunct under these circumstances; individuals with cystic fibrosis demonstrate a significantly more negative baseline nasal potential difference than controls. In patients with a positive screening test, suggestive clinical findings, or family history (or more than one of these), genetic analysis is warranted. Sequencing the *CFTR* gene is the gold standard for diagnosis of cystic fibrosis.

There have been major improvements in the management of acute and chronic complications for cystic fibrosis, including more potent antimicrobial therapies, pancreatic enzyme replacement, and bilateral lung transplantation. New treatment modalities for restoring mutant CFTR function are being tested in clinical trials. Based on the molecular defect, three classes of agents are being developed:

- *Potentiators.* These agents keep the "gate" of the CFTR channel open. Hence they are most useful in gating (class III) and conduction (class IV) mutations. They are also helpful for patients with production mutations (class V), by improving the function of reduced amounts of CFTR.
- *Correctors.* These agents assist in proper folding of the CFTR protein, thereby increasing its trafficking to the cell surface. Hence they have the potential to help patients with processing (class II) mutations. These include patients with ΔF508, the most common *CFTR* mutation.
- *Amplifiers.* These agents increase the amount of CFTR protein the cell makes and thus can be useful for patients with production (class V) mutations.

A combination therapy consisting of a "potentiator" agent and a small molecule that is a CFTR "corrector" has been approved for the treatment of patients with two copies of ΔF508, the most common *CFTR* mutation. For treatment of patients with class I nonsense mutations, molecules that allow "ribosomal read-through" of premature stop codons are in the pipeline. Such therapy is also being tested in muscular dystrophies in which stop codons prevent synthesis of dystrophin (Chapter 27). Overall, improvements in the management of cystic fibrosis have extended the median life expectancy to 50 years.

SUDDEN INFANT DEATH SYNDROME

According to the National Institute of Child Health and Human Development, **SIDS is defined as "the sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history."** It is important to emphasize that many cases of sudden death in infancy may have an unexpected anatomic or biochemical basis discernible at autopsy (Table 10.4), and these should not be labeled as SIDS, but rather as sudden unexpected infant death (SUID). The Centers for Disease Control and Prevention estimates that SIDS accounts for approximately one-half of SUID cases in the United States. An aspect of SIDS that is not stressed in the definition is that the infant usually dies while asleep, mostly in the prone or side position, hence the pseudonyms of crib death or cot death.

Epidemiology

As infant deaths due to nutritional problems and infections have come under control in high income countries, SIDS has assumed greater importance, including in the United States. SIDS is the leading cause of death between 1 month and 1 year of age in this country and the fourth leading cause of death overall in infancy, after congenital anomalies, diseases of prematurity and low birth weight, and maternal complications. Mostly because of nationwide "Back to Sleep" (now "Safe to Sleep") campaigns, there has been a significant drop in SIDS-related mortality, from an estimated 120 deaths per 100,000 live births in 1992 to 35 per 100,000 in 2017. This number translates to about 1360 deaths due to SIDS in the United States. Despite the decline in SIDS and SUID in all races and ethnicities, the rate of SUID among

Table 10.4 Risk Factors and Postmortem Findings Associated With Sudden Infant Death Syndrome

Parental
Young maternal age (younger than 20 years of age)
Maternal smoking during pregnancy
Drug abuse in *either* parent, specifically paternal marijuana and maternal opiate, cocaine use
Short intergestational intervals
Late or no prenatal care
Low socioeconomic group
African-American and American Indian ethnicity (? socioeconomic factors)
Infant
Brainstem abnormalities, associated with delayed development of arousal and cardiorespiratory control
Prematurity and/or low birth weight
Male sex
Product of a multiple birth
SIDS in a prior sibling
Antecedent respiratory infections
Germline polymorphisms in autonomic nervous system genes
Environment
Prone or side sleep position
Sleeping on a soft surface
Hyperthermia
Co-sleeping in first 3 months of life
Postmortem Abnormalities Detected in Cases of Sudden Unexpected Infant Death (SUID)[a]
Infections
Viral myocarditis
Bronchopneumonia
Unsuspected congenital anomaly
Congenital aortic stenosis
Anomalous origin of the left coronary artery from the pulmonary artery
Traumatic child abuse
Intentional suffocation (filicide)
Genetic and metabolic defects
Long QT syndrome (*SCN5A* and *KCNQ1* mutations)
Fatty acid oxidation disorders (*MCAD, LCHAD, SCHAD* mutations)
Histiocytoid cardiomyopathy (*MTCYB* mutations)
Abnormal inflammatory responsiveness (partial deletions in *C4a* and *C4b*)

[a]SIDS is not the only cause of SUIDs, but rather is a diagnosis of exclusion. Therefore, performance of an autopsy may often reveal findings that would explain the cause of an SUID. These cases should *not*, strictly speaking, be labeled as "SIDS."

C4, Complement component 4; *KCNQ1*, potassium voltage-gated channel, KQT-like subfamily, member 1; *LCHAD*, long-chain 3-hydroxyacyl coenzyme A dehydrogenase; *MCAD*, medium-chain acyl coenzyme A dehydrogenase; *MTCYB*, mitochondrial cytochrome b; *SCHAD*, short-chain 3-hydroxyacyl coenzyme A dehydrogenase; *SCN5A*, sodium channel, voltage-gated, type V, alpha subunit.

non-Hispanic black (70 per 100,000 live births) and American Indian/Alaskan Native (77 per 100,000 live births) infants was more than double that of non-Hispanic white infants (35 per 100,000 live births) in 2017. SIDS rates for Asian/Pacific Islander and Hispanic infants were much lower than the rate for non-Hispanic white infants. Differences in the prevalence of supine positioning and other sleep environment conditions between racial and ethnic populations may contribute to these disparities. Worldwide, in countries where unexpected infant deaths are diagnosed as SIDS only after postmortem examination, the death rates from SIDS range from 10 per 100,000 live births in the Netherlands to 80 per 100,000 in New Zealand.

Approximately 90% of all SIDS deaths occur during the first 6 months of life, most between 2 and 4 months of age. This narrow window of peak susceptibility is a unique characteristic that is independent of other risk factors (to be described) and the geographic locale. Most infants who die of SIDS die at home, usually during the night after a period of sleep.

MORPHOLOGY

In infants who have died of suspected SIDS, a variety of findings have been reported at postmortem examination. They are usually subtle and of uncertain significance and are not present in all cases. Multiple petechiae are the most common finding (~80% of cases); these are usually present on the thymus, visceral and parietal pleura, and epicardium. Grossly, the lungs are usually congested, and vascular engorgement with or without pulmonary edema is demonstrable microscopically in the majority of cases. These changes possibly represent agonal events, because they are found with comparable frequencies in explained sudden deaths in infancy. Within the upper respiratory system (larynx and trachea), there may be some histologic evidence of recent infection (correlating with the clinical symptoms), although the changes are not sufficiently severe to account for death and should not detract from the diagnosis of SIDS. The CNS demonstrates astrogliosis of the brainstem and cerebellum. Sophisticated morphometric studies have revealed quantitative brainstem abnormalities such as hypoplasia of the arcuate nucleus or a decrease in brainstem neuronal populations in several cases; these observations are not uniform, however. Nonspecific findings include frequent persistence of hepatic extramedullary hematopoiesis and periadrenal brown fat; it is tempting to speculate that these latter findings relate to chronic hypoxemia, retardation of normal development, and chronic stress. Thus, autopsy usually fails to provide a clear cause of death, and this may well be related to the etiologic heterogeneity of SIDS. The importance of a postmortem examination rests in identifying other causes of SUID, such as unsuspected infection, congenital anomaly, or a genetic disorder (see Table 10.4), the presence of any of which would exclude a diagnosis of SIDS; and in ruling out the unfortunate possibility of traumatic child abuse.

Pathogenesis

The circumstances surrounding SIDS have been explored in great detail, and it is generally accepted that it is a multifactorial condition. **A "triple-risk" model of SIDS has been proposed, which postulates the intersection of three overlapping factors: (1) a vulnerable infant, (2) a critical developmental period in homeostatic control, and (3) an exogenous stressor.** According to this model, several factors make the infant vulnerable to sudden death during the critical developmental period (i.e., the first 6 months of life). These vulnerability factors may relate to the parents, infant, or exogenous environmental stressors (see Table 10.4).

Although numerous factors have been proposed to account for a vulnerable infant, the most compelling hypothesis is that SIDS reflects a delayed development of "arousal" and cardiorespiratory control. The brainstem, and in particular the medulla oblongata, plays a critical role in

the body's "arousal" response to noxious stimuli such as episodic hypercarbia, hypoxia, and thermal stress encountered during sleep. The serotonergic (5-HT) system of the medulla is implicated in these "arousal" responses, as well as regulation of other critical homeostatic functions such as respiratory drive, blood pressure, and upper airway reflexes. Abnormalities in serotonin-dependent signaling in the brainstem may be the underlying basis for SIDS in some infants.

Epidemiologic and genetic studies have identified additional vulnerability factors for SIDS in the "triple-risk" model. Infants who are born before term or who are low birth weight are at increased risk, and risk increases with decreasing gestational age or birth weight. Male sex is associated with a slightly greater incidence of SIDS. SIDS in a prior sibling is associated with a fivefold relative risk of recurrence, highlighting the importance of a genetic predisposition; traumatic child abuse must be carefully excluded under these circumstances. Most SIDS babies have an immediate prior history of a mild respiratory tract infection, but no single causative organism has been isolated. These infections may predispose an already vulnerable infant to even greater impairment of cardiorespiratory control and delayed arousal. In this context, laryngeal chemoreceptors have emerged as a putative "missing link" between upper respiratory tract infections, the prone position, and SIDS. When stimulated, these laryngeal chemoreceptors typically elicit an inhibitory cardiorespiratory reflex. Stimulation of the chemoreceptors is augmented by respiratory tract infections, which increase the volume of secretions, and by the prone position, which impairs swallowing and clearing of the airways, even in healthy infants. In a previously vulnerable infant with impaired arousal, the resulting inhibitory cardiorespiratory reflex may prove fatal. Genetic vulnerability factors in the infant include polymorphisms of genes related to serotonergic signaling and autonomic innervation, pointing to the importance of these processes in the pathophysiology of SIDS.

Maternal smoking during pregnancy has consistently emerged as a risk factor in epidemiologic studies of SIDS, with children exposed to in utero nicotine having more than double the risk of SIDS as compared with children born to nonsmokers. Young maternal age, frequent childbirths, and inadequate prenatal care are all risk factors associated with increased incidence of SIDS in the offspring.

Among the potential "environmental stressors," prone or side sleeping positions, sleeping with parents in the first 3 months, sleeping on soft surfaces, and thermal stress are probably the most important modifiable risk factors for SIDS. The prone or side positions predispose an infant to one or more recognized noxious stimuli (hypoxia, hypercarbia, and thermal stress) during sleep. The side position was considered a reliable alternative to the prone sleeping position, but the American Academy of Pediatrics now recognizes the supine sleeping position as the only safe position that reduces the risk of SIDS. This "Back to Sleep" campaign has resulted in substantial reductions in SIDS-related deaths since its inception in 1994.

SIDS is a diagnosis of exclusion, requiring careful examination of the death scene and a complete postmortem examination. The latter can reveal an unsuspected cause of sudden death in as many as 20% or more of "SIDS" babies. Infections (e.g., viral myocarditis or bronchopneumonia) are the most common causes of sudden "unexpected" death, followed by unsuspected congenital anomalies. In part as a result of advancements in molecular diagnostics and knowledge of the human genome, several genetic causes of sudden "unexpected" infant death have emerged (see Table 10.4). For example, fatty acid oxidation disorders, characterized by defects in mitochondrial fatty acid oxidative enzymes, may be responsible for as many as 5% of SUIDs.

TUMORS AND TUMORLIKE LESIONS OF INFANCY AND CHILDHOOD

Only 2% of all malignant tumors occur in infancy and childhood; nonetheless, cancer (including leukemia) accounts for about 16% of deaths in the United States in children between 5 and 14 years of age, and only accidents cause significantly more deaths. Benign tumors are even more common than cancers. Most benign tumors are of little concern, but on occasion they cause serious complications by virtue of their location or size.

It is sometimes difficult to separate, on morphologic grounds, true tumors or neoplasms from tumorlike lesions in the infant and child. In this context, two special categories of tumorlike lesions should be distinguished from true tumors.

- The term *heterotopia* (or *choristoma*) is applied to microscopically normal cells or tissues that are present in abnormal locations. Examples of heterotopias include a rest of pancreatic tissue found in the wall of the stomach or small intestine, or a small mass of adrenal cells found in the kidney, lungs, or ovaries. These heterotopic rests are usually of little significance, but they can be confused clinically with neoplasms. Rarely, they are sites of origin of true neoplasms, producing paradoxes such as an adrenal carcinoma arising in the ovary.
- The term *hamartoma* refers to an excessive, focal overgrowth of cells and tissues native to the organ in which it occurs. Although the cellular elements are mature and identical to those found in the remainder of the organ, they do not reproduce the normal architecture of the surrounding tissue. The line of demarcation between a hamartoma and a benign neoplasm is often unclear because both lesions can be clonal. Hemangiomas, lymphangiomas, rhabdomyomas of the heart, adenomas of the liver, and developmental cysts within the kidneys, lungs, or pancreas are interpreted by some as hamartomas and by others as true neoplasms. Their unequivocally benign histology, however, does not preclude bothersome and rarely life-threatening clinical problems in some cases.

Benign Tumors and Tumorlike Lesions

Virtually any tumor may be encountered in children, but within this wide array hemangiomas, fibrous lesions, and teratomas deserve special mention. You will notice that the most common neoplasms of childhood are soft-tissue tumors of mesenchymal derivation. This contrasts with adults, in whom the most common tumors, benign or malignant, have an epithelial origin. Benign tumors of various tissues are described in greater detail in appropriate chapters; here a

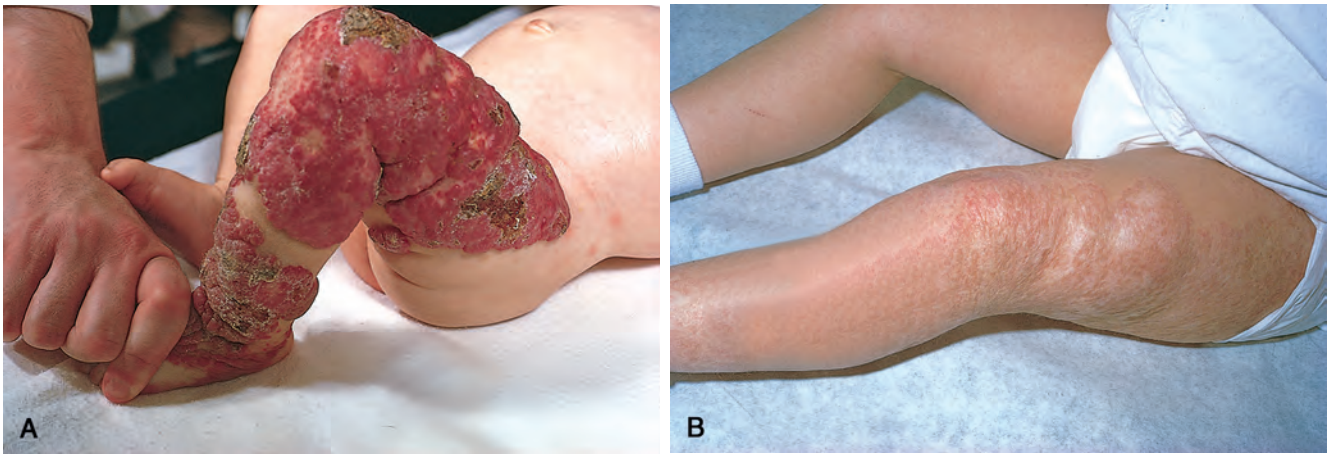

Figure 10.21 Congenital hemangioma at birth (A) and at 2 years of age (B) after spontaneous regression. (Courtesy Dr. Eduardo Yunis, Children's Hospital of Pittsburgh, Pittsburgh, Pa.)

few comments are made about their special features in childhood.

Hemangioma

Hemangiomas are the most common tumors of infancy (Chapter 11). Architecturally, they do not differ from those occurring in adults. Both cavernous and capillary hemangiomas may be encountered, although the latter are often more cellular than in adults, a feature that is deceptively worrisome. In children, most are located in the skin, particularly on the face and scalp, where they produce flat to elevated, irregular, red-blue masses; some of the flat, larger lesions (considered by some to represent vascular ectasias) are referred to as *port-wine stains*. Hemangiomas may enlarge along with the growth of the child, but in many instances they spontaneously regress (Fig. 10.21). In addition to their cosmetic significance, they can represent one facet of the hereditary disorder von Hippel-Lindau disease (Chapter 28). A subset of CNS cavernous hemangiomas can occur in the familial setting; these families harbor mutations in one of three genes (*KRIT1, CCM2,* or *PDCD10*).

Fibrous Tumors

Fibrous tumors occurring in infants and children include sparsely cellular proliferations of spindle-shaped cells (designated as fibromatosis) and richly cellular lesions indistinguishable from fibrosarcomas occurring in adults (designated as congenital-infantile fibrosarcomas). Biologic behavior cannot be predicted based on histology alone; however, despite their histologic similarities with adult fibrosarcomas, the congenital-infantile variants have an excellent prognosis. A characteristic chromosomal translocation, t(12;15)(p13;q25), has been described in congenital-infantile fibrosarcomas, which results in generation of an ETV6-NTRK3 fusion transcript. The normal *ETV6* gene product is a transcription factor, and the *NTRK3* gene product (also known as TRKC) is a tyrosine kinase. Like other tyrosine kinase fusion proteins found in human neoplasms, ETV6-NTRK3 is constitutively active and stimulates signaling through the oncogenic RAS-MAPK and PI3K/AKT pathways (Chapter 7). Among soft-tissue tumors, the *ETV6-NTRK3* fusion transcript is most commonly found in congenital-infantile fibrosarcomas, making it a useful diagnostic marker.

Teratomas

Teratomas illustrate the relationship of histologic maturity to biologic behavior. Teratomas may occur as benign, well-differentiated cystic lesions (mature teratomas), as lesions of indeterminate potential (immature teratomas), or as unequivocally malignant teratomas (usually admixed with another germ cell tumor component such as yolk sac tumor) (Chapter 21). They exhibit two peaks in incidence: the first at approximately 2 years of age and the second in late adolescence or early adulthood. The first peak is congenital neoplasms; the later occurring lesions may also be of prenatal origin but are more slowly growing. Sacrococcygeal teratomas are the most common teratomas of childhood, accounting for 40% or more of cases (Fig. 10.22). They occur with a frequency of 1 in 20,000 to 40,000 live

Figure 10.22 Sacrococcygeal teratoma. Note the size of the lesion compared with that of the stillbirth.

births, and they are four times more common in girls than in boys. Approximately 10% of sacrococcygeal teratomas are associated with congenital anomalies, primarily defects of the hindgut and cloacal region and other midline defects (e.g., meningocele, spina bifida) not believed to result from local effects of the tumor. Approximately 75% of these tumors are mature teratomas, and about 12% are unequivocally malignant and lethal. The remainder are immature teratomas; their malignant potential correlates with the amount of immature tissue, usually immature neuroepithelial elements, that are present. Most benign teratomas are encountered in younger infants (<4 months), whereas children with malignant lesions tend to be somewhat older. Other sites for teratomas in childhood include the testis (Chapter 21), ovary (Chapter 22), and various midline locations, such as the mediastinum, retroperitoneum, and head and neck.

Malignant Tumors

Cancers of infancy and childhood differ biologically and histologically from their counterparts occurring later in life. The main differences, some of which have already been alluded to, include the following:

- Incidence and type of tumor
- Relatively frequent demonstration of a close relationship between abnormal development (teratogenesis) and tumor induction (oncogenesis)
- Prevalence of underlying familial genetic aberrations
- Tendency of fetal and neonatal malignancies to regress or differentiate spontaneously
- Improved survival or cure of many childhood tumors, so that more attention is now being devoted to minimizing the adverse delayed effects of chemotherapy and radiation therapy in survivors, including the development of second malignancies

Incidence and Types

The most frequent childhood cancers arise in the hematopoietic system, nervous tissue (including the central and sympathetic nervous system, adrenal medulla, and retina), soft tissue, bone, and kidney. This is in sharp contrast to adults, in whom the skin, lung, breast, prostate, and colon are the most common sites of tumors.

Neoplasms that exhibit sharp peaks in incidence in children younger than 15 years of age and their approximate age distribution are indicated in Table 10.5. Leukemia alone accounts for more deaths in children under 15 years of age than all of the other tumors combined.

Histologically, many of the malignant nonhematopoietic pediatric neoplasms are unique. In general, they tend to have a more primitive (embryonal) undifferentiated appearance, often characterized by sheets of cells with small round nuclei, and frequently show features of organogenesis specific to the site of tumor origin. Because of this latter characteristic, these tumors are frequently designated by the suffix *-blastoma,* for example, nephroblastoma (Wilms tumor), hepatoblastoma, and neuroblastoma. Because of their primitive histologic appearance, many childhood tumors have been collectively referred to as *small round blue cell tumors.* The differential diagnosis of such tumors includes neuroblastoma, Wilms tumor, lymphoma (Chapter 13), rhabdomyosarcoma (Chapter 26), Ewing sarcoma/primitive neuroectodermal tumor (Chapter 26), medulloblastoma (Chapter 28), and retinoblastoma (Chapter 29). If the anatomic site of origin is known, diagnosis is usually possible on histologic grounds alone. Occasionally, a combination of chromosome analysis, immunoperoxidase stains, or electron microscopy is required. Two of these tumors are discussed here: the neuroblastic tumors, specifically neuroblastoma, and Wilms tumor. The remaining tumors are discussed in their respective organ-specific chapters.

Table 10.5 Common Malignant Neoplasms of Infancy and Childhood

0–4 Years	5–9 Years	10–14 Years
Leukemia	Leukemia	
Retinoblastoma		
Neuroblastoma	Neuroblastoma	
Wilms tumor		Renal cell carcinoma
Hepatoblastoma	Hepatocellular carcinoma	Hepatocellular carcinoma
Soft tissue sarcoma (especially rhabdomyosarcoma)	Soft tissue sarcoma	Soft tissue sarcoma
	Ewing sarcoma	Ewing sarcoma
		Osteogenic sarcoma
Teratoma		
Central nervous system tumors	Central nervous system tumors	
	Lymphoma	Lymphoma, including Hodgkin lymphoma
		Thyroid carcinoma

Neuroblastic Tumors

The term neuroblastic tumor includes tumors of the sympathetic ganglia and adrenal medulla that are derived from primordial neural crest cells populating these sites. Neuroblastoma is the most important member of this family. It is the most common extracranial solid tumor of childhood, and the most frequently diagnosed infant malignancy. The prevalence is about 1 in 7000 live births, and there are approximately 700 cases diagnosed each year in the United States. The median age at diagnosis is 18 months; approximately 40% of cases are diagnosed in infancy. Most neuroblastomas occur sporadically, but 1% to 2% are familial; in such cases the neoplasms may involve both of the adrenals or multiple primary autonomic sites. Germline mutations in the *anaplastic lymphoma kinase (ALK)* gene (Chapter 13) are a major cause of familial predisposition to neuroblastoma. Somatic gain-of-function *ALK* mutations are also observed in approximately 10% of sporadic neuroblastomas.

Despite the remarkable progress made in the therapy of this disease, long-term prognosis for high-risk subsets remains guarded, with 5-year survival in the range of 40%. As will be evident later, age and stage have a remarkable effect on prognosis, and, in general, children younger than 18 months of age tend to have a significantly more favorable prognosis than older individuals with similar disease burdens.

MORPHOLOGY

In childhood, about 40% of neuroblastomas arise in the adrenal medulla. The remainder occur anywhere along the sympathetic chain, with the most common locations being the paravertebral region of the abdomen (25%) and posterior mediastinum (15%). Tumors may arise in numerous other sites, including the pelvis, the neck, and within the brain (cerebral neuroblastomas).

Neuroblastomas range in size from minute nodules (so-called **in situ lesions**) to large masses more than 1 kg in weight. In situ neuroblastomas are reported to occur 40 times more frequently than clinically overt tumors. The great majority of these silent lesions spontaneously regress, leaving only a focus of fibrosis or calcification in the adult; this has led some to question the neoplastic connotation for the in situ lesions.

Some neuroblastomas are sharply demarcated by a fibrous pseudocapsule, but others are far more infiltrative and invade surrounding structures, including the kidneys, renal vein, and vena cava, and envelop the aorta. On transection, they are composed of soft, gray-tan tissue. Larger tumors have areas of necrosis, cystic softening, and hemorrhage. Occasionally, foci of punctate intratumoral calcification can be palpated.

Histologically, classic neuroblastomas are composed of small, primitive-appearing cells with dark nuclei, scant cytoplasm, and poorly defined cell borders growing in solid sheets. Such tumors may be difficult to differentiate morphologically from other small round blue cell tumors. Mitotic activity, nuclear breakdown ("karyorrhexis"), and pleomorphism may be prominent. The background often demonstrates a faintly eosinophilic fibrillary material **(neuropil)** that corresponds to neuritic processes of the primitive neuroblasts. Typically, **Homer-Wright pseudorosettes** can be found in which tumor cells are concentrically arranged about a central space filled with neuropil (Fig. 10.23). Other helpful features include positive immunohistochemical reactions for neuron-specific enolase and the transcription factor PHOX2B. Some neoplasms show signs of maturation that can be spontaneous or therapy-induced. Larger cells having more abundant cytoplasm, large vesicular nuclei, and a prominent nucleolus, representing ganglion cells in various stages of maturation, may be found in tumors admixed with primitive neuroblasts **(ganglioneuroblastoma).** Even better differentiated lesions contain many more large cells resembling mature ganglion cells with few if any residual neuroblasts; such neoplasms merit the designation **ganglioneuroma** (Fig. 10.24). Maturation of neuroblasts into ganglion cells is usually accompanied by the appearance of **Schwann cells.** The origin of Schwann cells in neuroblastoma remains an issue of contention; some investigators believe they represent a reactive population recruited by the tumor cells. However, studies using microdissection techniques have demonstrated that the Schwann cells harbor at least a subset of the same genetic alterations found in neuroblasts, and therefore are a component of the malignant clone. Irrespective of histogenesis, documenting the presence of schwannian stroma is essential, because its presence is associated with a **favorable outcome** (see later).

Metastases, when they develop, appear early and widely. In addition to local infiltration and lymph node spread, there is a pronounced tendency to spread through the bloodstream to the liver, lungs, bone marrow, and bones.

Staging. The International Neuroblastoma Staging System (INSS), which is the most widely used staging scheme worldwide, is detailed in Table 10.6.

Unfortunately, most (60% to 80%) children present with stage 3 or 4 tumors, and only 20% to 40% present with stage 1, 2A, 2B, or 4S neuroblastomas. The staging system is of paramount importance in determining prognosis.

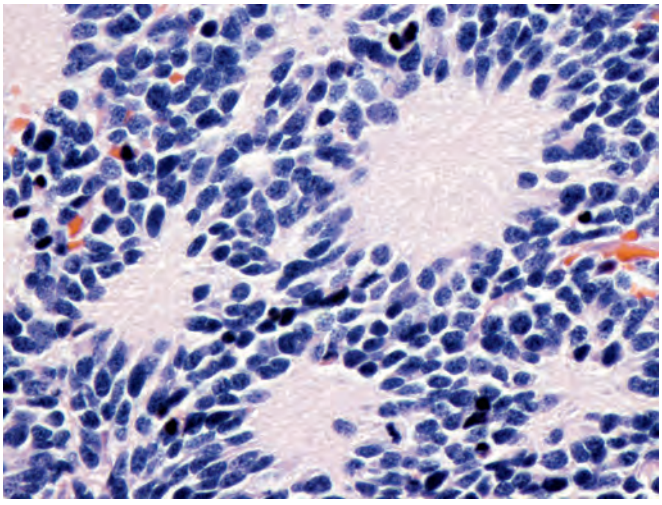

Figure 10.23 Adrenal neuroblastoma. This tumor is composed of small cells embedded in a finely fibrillar matrix (neuropil). Several Homer-Wright pseudorosettes are seen in this image.

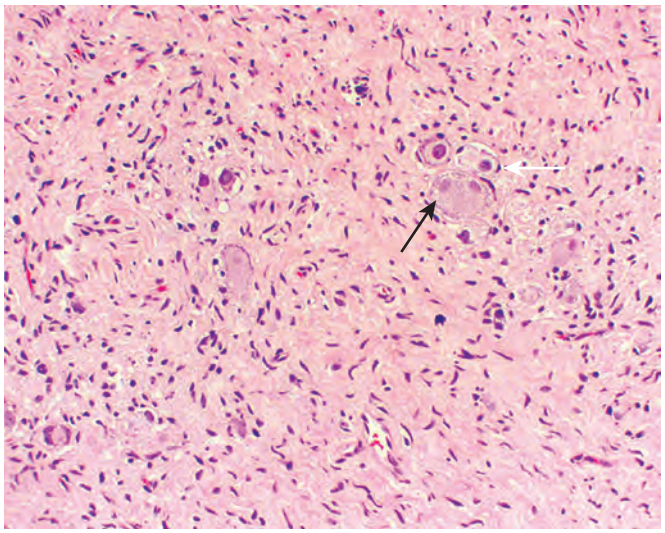

Figure 10.24 Ganglioneuromas are characterized by clusters of large cells with eccentric nuclei, prominent nucleoli, and abundant eosinophilic cytoplasm, representing neoplastic ganglion cells *(arrows)*. Spindle-shaped Schwann cells are present in the background stroma.

Clinical Course and Prognostic Features (Table 10.7)

In young children (younger than 2 years of age), neuroblastomas generally present with large abdominal masses, fever, and possibly weight loss. In older children, they may not come to attention until metastases produce manifestations, such as bone pain, respiratory symptoms, or gastrointestinal

Table 10.6 International Neuroblastoma Staging System

Stage 1	Localized tumor completely excised, with or without microscopic residual disease; representative ipsilateral nonadherent lymph nodes negative for tumor (nodes adherent to the primary tumor may be positive for tumor)
Stage 2A	Localized tumor resected incompletely grossly; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically
Stage 2B	Localized tumor with or without complete gross excision, ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes, which are negative for tumor microscopically
Stage 3	Unresectable unilateral tumor infiltrating across the midline with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement
Stage 4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S)
Stage 4S	Localized primary tumor (as defined for stage 1, 2A, or 2B) with dissemination limited to skin, liver, and/or bone marrow (<10% of nucleated cells are constituted by neoplastic cells; >10% involvement of bone marrow is considered as stage 4); stage 4S limited to infants younger than 1 year of age

S, Special.

Table 10.7 Prognostic Factors in Neuroblastomas

Variable	Favorable	Unfavorable
Stage[a]	Stage 1, 2A, 2B, 4S	Stage 3, 4
Age[a]	<18 months	>18 months
Histology[a]		
Evidence of schwannian stroma and gangliocytic differentiation[b]	Present	Absent
Mitosis-karyorrhexis index[c]	<200/5000 cells	>200/5000 cells
DNA ploidy[a]	Hyperdiploid (whole-chromosome gains)	Near-diploid (segmental chromosome losses; chromothripsis)
MYCN[a]	Not amplified	Amplified
Chromosome 1p loss	Absent	Present
Chromosome 11q loss	Absent	Present
TRKA expression	Present	Absent
TRKB expression	Absent	Present
Mutations of neuritogenesis genes	Absent	Present

[a]Corresponds to the most commonly used parameters in clinical practice for assessment of prognosis and risk stratification.

[b]It is not only the presence but also the amount of schwannian stroma that confer the designation of a favorable histology. At least 50% or more schwannian stroma is required before a neoplasm can be classified as ganglioneuroblastoma or ganglioneuroma.

[c]Mitosis-karyorrhexis index (MKI) is defined as the number of mitotic or karyorrhectic cells per 5000 tumor cells in random foci.

complaints. Neuroblastomas may metastasize widely through the hematogenous and lymphatic systems, particularly to liver, lungs, bones, and bone marrow. Proptosis and ecchymosis may also be present due to spread to the periorbital region, a common metastatic site. In neonates, disseminated neuroblastomas may present with multiple cutaneous metastases that cause deep blue discoloration of the skin (earning the unfortunate designation of "blueberry muffin baby"). About 90% of neuroblastomas, regardless of location, produce catecholamines (similar to the catecholamines associated with pheochromocytomas), which are an important diagnostic feature (i.e., elevated blood levels of catecholamines and elevated urine levels of the metabolites vanillylmandelic acid [VMA] and homovanillic acid [HVA]). Despite the elaboration of catecholamines, hypertension is much less frequent with these neoplasms than with pheochromocytomas (Chapter 24). Ganglioneuromas, unlike their malignant counterparts, tend to produce either asymptomatic mass lesions or symptoms related to compression.

The clinical course of neuroblastomas is extremely variable. Several clinical, histopathologic, molecular, and biochemical factors have been identified that have a bearing on prognosis (see Table 10.7); based on the collection of prognostic factors present in a given patient, they are classified as "low," "intermediate," or "high" risk. With improvements in therapy, long-term survival exceeds 90% of patients in the first two groups, but less than 50% of patients in the high-risk category are long-term survivors. The most pertinent prognostic factors include the following:

- *Tumor stage and patient age at time of diagnosis.* Neuroblastomas at stage 1, 2A, or 2B tend to have an excellent prognosis, irrespective of age ("low" or "intermediate" risk); tumors exhibiting amplification of the *MYCN* oncogene are a notable exception. Infants with localized primary tumors and metastases to the liver, bone marrow, and skin (stage 4S) represent a special subtype, wherein it is not uncommon for the disease to regress spontaneously. The biologic basis of this welcome behavior is not clear. The age of 18 months has emerged as a critical point of dichotomy in terms of prognosis. Children younger than 18 months of age, and especially those in the first year of life, have an excellent prognosis regardless of the stage of the neoplasm. Children older than 18 months of age generally fall into at least the "intermediate" risk category, and those with higher-stage tumors or with unfavorable prognostic features like *MYCN* amplification in the neoplastic cells are considered "high" risk.
- *Tumor morphology.* An age-linked morphologic classification of neuroblastic tumors has been proposed that divides them into favorable and unfavorable histologic subtypes. The specific morphologic features that bear on prognosis are listed in Table 10.7.
- *MYCN amplification status.* Amplification of the *MYCN* proto-oncogene in neuroblastomas markedly impacts the prognosis, particularly in tumors that would otherwise be classified as having a good prognosis. The presence of *MYCN* amplification "bumps" the tumor to the "high"-risk category, irrespective of age, stage, or histology. *MYCN* is located on the distal short arm of chromosome 2 (2p23-p24). Amplification of *MYCN* does not occur at the 2p23-p24 site, but as extrachromosomal double minute chromosomes or homogeneously staining regions on

other chromosomes (Fig. 10.25). *MYCN* amplification is present in about 20% to 30% of primary tumors, most presenting as advanced-stage disease, and the degree of amplification correlates with poorer prognosis. *MYCN* amplification is currently the most important genetic abnormality used in risk stratification of neuroblastic tumors (see later).

- *Ploidy* of the tumor cells correlates with outcome in children younger than 2 years of age but loses its independent prognostic significance in older children. Broadly, neuroblastomas can be divided into two categories: near-diploid and hyperdiploid (whole-chromosome gains), with the latter being associated with a more favorable prognosis.

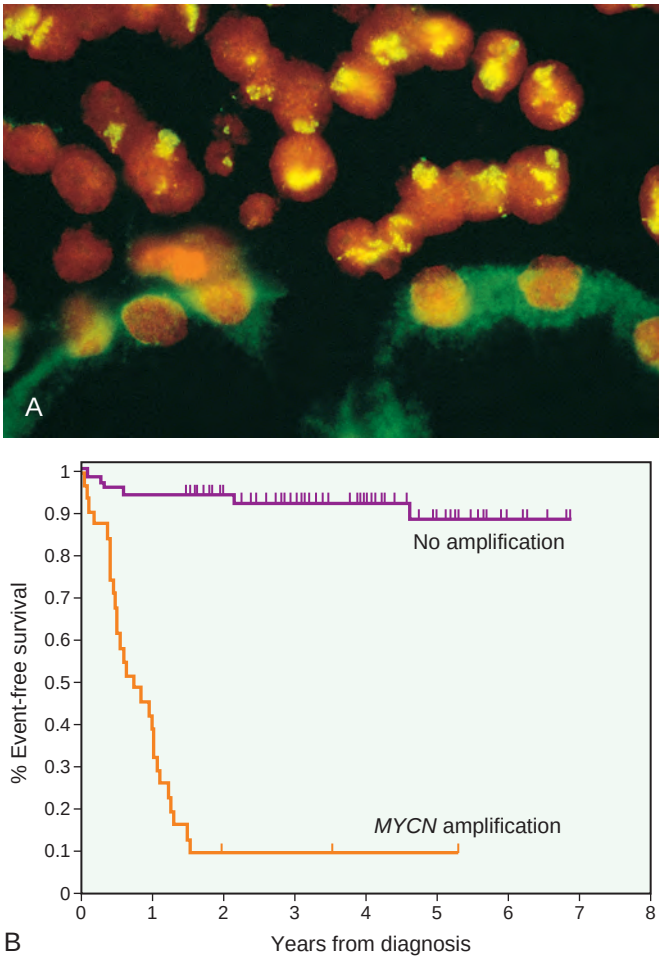

Figure 10.25 (A) Fluorescence in situ hybridization using a fluorescein-labeled cosmid probe for *MYCN* on a tissue section. Note the neuroblastoma cells on the upper half of the photo with large areas of staining *(yellow-green)*; this corresponds to amplified *MYCN* in the form of homogeneously staining regions. Renal tubular epithelial cells in the lower half of the photograph show no nuclear staining and background *(green)* cytoplasmic staining. (B) A Kaplan-Meier survival curve of infants younger than 1 year of age with metastatic neuroblastoma. The 3-year event-free survival of infants whose tumors lacked *MYCN* amplification was 93%, whereas those with tumors that had *MYCN* amplification had only a 10% event-free survival. (A, Courtesy Dr. Timothy Triche, Children's Hospital, Los Angeles, Calif.; B, Reproduced with permission from Brodeur GM: Neuroblastoma: biological insights into a clinical enigma, *Nat Rev Cancer* 3(3):203–216, 2003.)

It is postulated that neuroblastomas with hyperdiploidy have an underlying defect in the mitotic machinery leading to nondisjunction and whole-chromosome gains, but otherwise relatively banal karyotypes. The more aggressive near-diploid tumors harbor generalized genomic instability, with multiple segmental chromosomal aberrations that result in a complex karyotype with adverse prognostic implications. One peculiar form of segmental aberration in aggressive neuroblastomas is called chromothripsis (Chapter 7), which involves localized fragmentation of a chromosome segment followed by random assembly of the fragments. In a subset of neuroblastomas, chromothripsis can result in amplification of *MYCN* or other oncogenes, or losses in tumor suppressor loci.

Although age, stage, histology, *MYCN* status, and DNA ploidy are the "core" criteria used for formal risk stratification and therapeutic decision-making, various segmental chromosomal losses can also have prognostic significance. In particular, hemizygous deletion of the distal short arm of chromosome 1 in the region of band p36, which occurs in 25% to 35% of primary tumors, is strongly correlated with *MYCN* amplification, advanced disease stage, and an increased risk of disease relapse. Hemizygous loss of chromosome 11q is another common deletion event with adverse prognosis but is not correlated with *MYCN* amplification.

Whole-genome sequencing has uncovered alterations in a variety of genes. Some of these alterations have prognostic implications. These include those whose products are involved in neuritogenesis (a process in neuronal differentiation that includes the sprouting of neurites, which later become dendrites and axons). Selected examples of mutated genes in this category include *alpha thalassemia/mental retardation, X linked (ATRX);* genes involving chromatin remodeling, such as *AT-rich interaction domains 1A* and *1B* (*ARID1A* and *ARID1B*); and neurotrophin receptors (*NTRK1, NTRK2,* and *NTRK3*). The impact of these changes on prognosis is under investigation.

Although discussion of the treatment modalities for neuroblastoma is beyond the scope of this book, we mention in passing two promising experimental approaches. The first involves the use of retinoids as an adjunct therapy for inducing the differentiation of neuroblastoma. Recall that the retinoic acid pathway plays a critical role in cellular differentiation during embryogenesis. Secondly, clinical trials are evaluating the utility of small-molecule ALK inhibitors in treating tumors harboring activating *ALK* mutations.

Wilms Tumor

Wilms tumor (nephroblastoma) afflicts approximately 1 in 10,000 children in the United States, making it the most common primary renal tumor of childhood and the fourth most common pediatric malignancy in the United States. The peak incidence for Wilms tumor is between 2 and 5 years of age, and 95% of tumors occur before 10 years of age. Approximately 5% to 10% of Wilms tumors involve both kidneys, either simultaneously (synchronous) or one after the other (metachronous). Bilateral Wilms tumors have

a median age of onset approximately 10 months earlier than tumors restricted to one kidney, and these patients are presumed to harbor a germline mutation in one of the Wilms tumor–predisposing genes (see later). The biology of this tumor illustrates several important aspects of childhood neoplasms, such as the relationship between malformations and neoplasia, the histologic similarities between organogenesis and oncogenesis, the two-hit theory of recessive tumor suppressor genes (Chapter 7), the role of premalignant lesions, and perhaps most importantly, the potential for treatment to affect prognosis and outcome. Improvements in cure rates for Wilms tumor (from as low as 30% a few decades ago to approximately 90% currently) represent one of the greatest successes of pediatric oncology.

Pathogenesis and Genetics

The risk of Wilms tumor is increased with at least three recognizable groups of congenital malformations associated with distinct chromosomal loci. Although Wilms tumors arising in this setting account for no more than 10% of cases, these syndromic tumors have provided important insight into the biology of this neoplasm.

- The first group of patients has the *WAGR syndrome,* characterized by *W*ilms tumor, *a*niridia, *g*enitourinary anomalies, and intellectual disability (formerly called mental retardation). Their lifetime risk of developing Wilms tumor is approximately 33%. Individuals with WAGR syndrome carry constitutional (germline) deletions of 11p13. Studies on these patients led to the identification of the first Wilms tumor–associated gene, *WT1,* and a contiguously deleted autosomal dominant gene for aniridia, *PAX6,* both located on chromosome 11p13. Patients with deletions restricted to *PAX6,* with normal *WT1* function, develop aniridia, but they are not at increased risk for Wilms tumors. The presence of germline *WT1* deletions in WAGR syndrome represents the "first hit"; the development of Wilms tumor in these patients frequently correlates with the occurrence of a nonsense or frameshift mutation in the second *WT1* allele ("second hit").
- A second group of patients at much higher risk for Wilms tumor (~90%) has *Denys-Drash syndrome,* which is characterized by gonadal dysgenesis (male pseudohermaphroditism) and early-onset nephropathy leading to renal failure. The characteristic glomerular lesion in these patients is diffuse mesangial sclerosis (Chapter 20). As in patients with WAGR, these patients also demonstrate germline abnormalities in *WT1.* In patients with Denys-Drash syndrome, however, the genetic abnormality is a dominant-negative missense mutation in the zinc-finger region of the WT1 protein that affects its DNA-binding properties. This mutation interferes with the function of the remaining wild-type allele, yet strangely, it is sufficient only in causing genitourinary abnormalities but not tumorigenesis; Wilms tumors arising in Denys-Drash syndrome demonstrate bi-allelic inactivation of *WT1.* In addition to Wilms tumors, these individuals are also at increased risk for developing germ cell tumors called gonadoblastomas (Chapter 21), almost certainly a consequence of disruption in normal gonadal development.

  WT1 encodes a DNA-binding transcription factor that is expressed within several tissues, including the kidney and gonads, during embryogenesis. The WT1 protein is critical for normal renal and gonadal development. WT1 has multiple binding partners, and the choice of this partner can affect whether WT1 functions as a transcriptional activator or repressor in a given cellular context. Numerous transcriptional targets of WT1 have been identified, including genes encoding glomerular podocyte–specific proteins and proteins involved in induction of renal differentiation. Despite the importance of *WT1* in nephrogenesis and its unequivocal role as a tumor suppressor gene, only about 10% of patients with sporadic (nonsyndromic) Wilms tumors demonstrate *WT1* mutations, suggesting that the majority of these tumors are caused by mutations in other genes.
- A third group with an increased risk of developing Wilms tumor consists of children with *Beckwith-Wiedemann syndrome* (BWS), characterized by enlargement of body organs (organomegaly), macroglossia, hemihypertrophy, omphalocele, and abnormal large cells in the adrenal cortex (adrenal cytomegaly). BWS has served as a model for tumorigenesis associated with genomic imprinting (Chapter 5). The chromosomal region implicated in BWS has been localized to band 11p15.5 (so-called WT2 locus), distal to the *WT1* locus. This region contains multiple genes that are normally expressed from only one of the two parental alleles, with transcriptional silencing (i.e., imprinting) of the other parental homologue by methylation of the promoter region. Unlike WAGR and Denys-Drash syndromes, the genetic basis for BWS is considerably more heterogeneous in that no single 11p15.5 gene is involved in all cases. Moreover, the phenotype of BWS, including the predisposition to tumorigenesis, is influenced by the specific imprinting abnormalities present. One of the genes in the 11p15.5 region—insulin-like growth factor-2 (*IGF2*)—is normally expressed solely from the paternal allele, and the maternal allele is silenced by imprinting. In some Wilms tumors, loss of imprinting (i.e., re-expression of the maternal *IGF2* allele) can be demonstrated, leading to overexpression of the IGF2 protein. In other instances, there is selective deletion of the imprinted maternal allele combined with duplication of the transcriptionally active paternal allele in the tumor (uniparental paternal disomy), which has the identical functional effect of IGF2 overexpression. Because the IGF2 protein is an embryonal growth factor, it could conceivably explain the features of overgrowth associated with BWS as well as the increased risk for Wilms tumors in these patients.

In contrast with syndromic Wilms tumors, the molecular abnormalities underlying sporadic (i.e., nonsyndromic) tumors, which account for 90% of cases overall in children, are only beginning to be elucidated. Some of them are associated with specific histologic features described later. For example, gain-of-function mutations of the gene encoding β-catenin (Chapter 7) have been demonstrated in approximately 10% of sporadic Wilms tumors. Other recurrent mutations occur in genes encoding proteins involved in micro-RNA (miRNA) processing (*DROSHA,*

DGCR8, and *DICER1*); these are seen in 15% to 20% of Wilms tumors with predominantly blastemal histology (see later). It is postulated that aberrations in miRNA processing lead to reduced levels of many mature miRNAs, in particular in the miR-200 family, which is involved in "mesenchymal to epithelial transformation" during renal morphogenesis. The lack of mesenchymal to epithelial transformation likely leads to persistent blastemal "rests" in the kidney (see the following), which evolve into Wilms tumors. Finally, tumors with *TP53* mutations are associated with an especially poor prognosis and often have a distinctive anaplastic histologic appearance, described later.

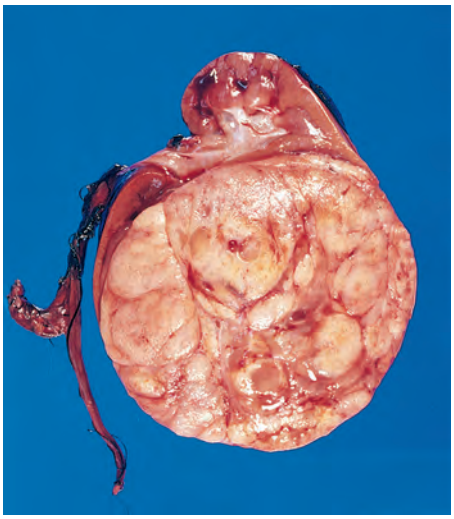

Figure 10.26 Wilms tumor in the lower pole of the kidney with the characteristic tan-to-gray color and well-circumscribed margins.

MORPHOLOGY

Grossly, Wilms tumor tends to present as a large, solitary, well-circumscribed mass. Approximately 10% are either bilateral or multicentric at the time of diagnosis. On cut section, the tumor is soft, homogeneous, and tan to gray with occasional foci of hemorrhage, cyst formation, and necrosis (Fig. 10.26).

Microscopically, Wilms tumors are characterized by recognizable attempts to recapitulate different stages of nephrogenesis. **The classic triphasic combination of blastemal, stromal, and epithelial cell types is observed in the vast majority of lesions,** although the percentage of each component is variable (Fig. 10.27A). Sheets of small blue cells with few distinctive features characterize the blastemal component. Epithelial differentiation is usually in the form of abortive tubules or glomeruli. Stromal cells are usually fibroblastic or myxoid in nature, although skeletal muscle differentiation is not uncommon. Rarely, other heterologous elements are identified, including squamous or mucinous epithelium, smooth muscle, adipose tissue, cartilage, and osteoid and neurogenic tissue. Approximately 5% of tumors have **anaplasia,** defined as the presence of cells with large, hyperchromatic, pleomorphic nuclei and abnormal mitoses (see Fig. 10.27B). The presence of anaplasia correlates with the presence of *TP53* mutations and the emergence of resistance to chemotherapy. Recall that p53 elicits pro-apoptotic signals in response to DNA damage (Chapter 7). The loss of p53 function might explain the relative unresponsiveness of anaplastic cells to cytotoxic chemotherapy.

Nephrogenic rests are putative precursor lesions of Wilms tumors and are seen in the renal parenchyma adjacent to approximately 25% to 40% of unilateral tumors; this frequency rises to nearly 100% in cases of bilateral Wilms tumors. In many instances the nephrogenic rests share genetic alterations with the adjacent Wilms tumor, pointing to their preneoplastic status. The appearance of nephrogenic rests varies from expansile masses that resemble Wilms tumors (hyperplastic rests) to sclerotic rests consisting predominantly of fibrous tissue and occasional admixed immature tubules or glomeruli. It is important to document the presence of nephrogenic rests in the resected specimen, because these patients are at an increased risk of developing Wilms tumors in the contralateral kidney and require frequent and regular surveillance for many years.

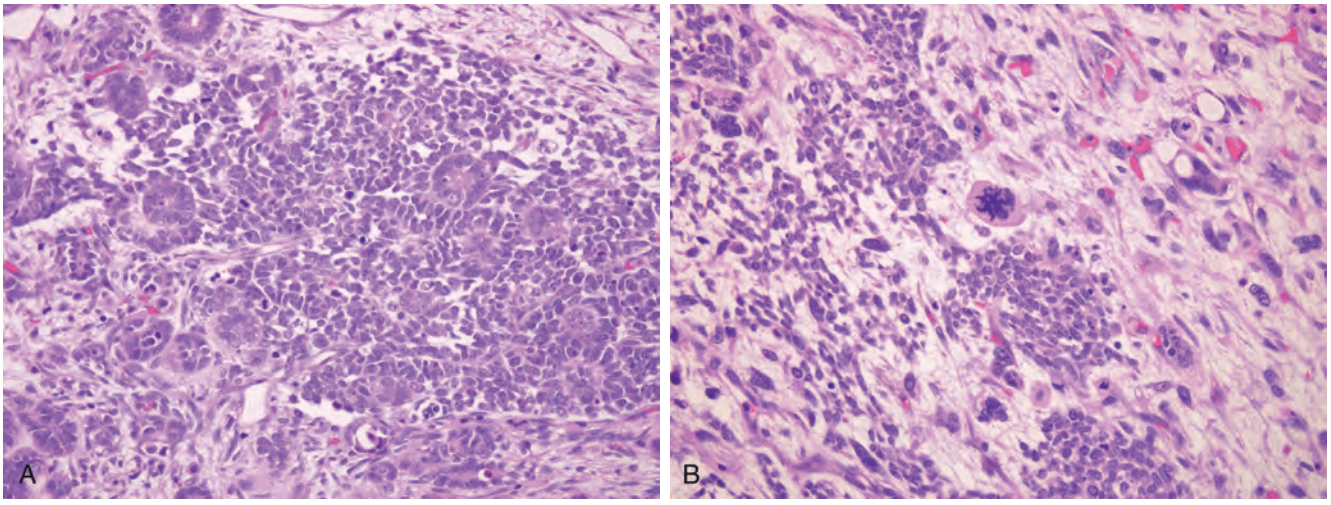

Figure 10.27 (A) Wilms tumor with tightly packed blue cells (blastemal component) and interspersed primitive tubules (epithelial component). Although multiple mitotic figures are seen, none are atypical in this field. (B) Focal anaplasia was present in this Wilms tumor, characterized by cells with hyperchromatic, pleomorphic nuclei, and abnormal mitoses (center).

Clinical Features

Most children with Wilms tumors present with a large abdominal mass that may be unilateral or, when very large, extend across the midline and down into the pelvis. Hematuria, pain in the abdomen after a traumatic incident, intestinal obstruction, and hypertension are other patterns of presentation. In a considerable number of these patients, pulmonary metastases are present at the time of primary diagnosis.

As stated, most patients with Wilms tumor can expect to be cured of their malignancy. Anaplastic histology is perhaps the most critical determinant of adverse prognosis. Even anaplasia restricted to the kidney (i.e., without extrarenal spread) confers an increased risk of recurrence and death, emphasizing the need for accurate identification of this histologic feature. Molecular parameters that correlate with adverse prognosis include loss of heterozygosity of chromosomes 1p and 16q, and gain of chromosome 1q in tumor cells. Along with the increased survival of individuals with Wilms tumor have come reports of an increased risk of developing second primary tumors, including bone and soft tissue sarcomas, leukemia and lymphomas, and breast cancers. Although some of these neoplasms result from the presence of a germline mutation in a cancer predisposition gene, others are a consequence of therapy, most commonly radiation administered to the cancer field. This tragic, albeit uncommon, outcome has mandated that radiation therapy be used judiciously in the treatment of this and other childhood cancers.

CHAPTER 11

Blood Vessels

Richard N. Mitchell • Marc K. Halushka

CHAPTER CONTENTS

Vascular pathology is responsible for more morbidity and mortality than any other category of human disease. Although the most clinically significant lesions involve arteries, venous disorders are not inconsequential. Two principal mechanisms underlie vascular disease:

- *Narrowing (stenosis)* or *complete obstruction* of vessel lumens, either progressively (e.g., by atherosclerosis) or precipitously (e.g., by thrombosis or embolism)
- *Weakening* of vessel walls, leading to dilation or rupture

To better appreciate the pathogenesis of vascular disorders, it is important to first understand the normal vessel structure and function.

VASCULAR STRUCTURE AND FUNCTION

The general architecture and cellular composition of blood vessels are comparable throughout the cardiovascular system. However, structural specializations that reflect distinct functional roles characterize specific kinds of vessels (Fig. 11.1). For example, arterial walls are thicker than corresponding veins at the same level of branching to accommodate pulsatile flow and higher blood pressures. Arterial wall thickness gradually diminishes as the vessels become smaller, but the ratio of wall thickness to lumen diameter increases, allowing these muscular vessels to exert control over blood flow and pressure. Many disorders of the vasculature affect only particular types of vessels and thus have characteristic anatomic distributions. Thus atherosclerosis affects mainly elastic and muscular arteries, hypertension affects small muscular arteries and arterioles, and different varieties of vasculitis characteristically involve only vessels of a certain caliber.

The basic constituents of the walls of blood vessels are endothelial cells (ECs) and smooth muscle cells (SMCs), admixed with a variety of extracellular matrix (ECM) including elastin, collagen, and glycosaminoglycans. The relative amount and configuration of the basic constituents differ along the vasculature owing to local adaptations to mechanical or metabolic needs. In arteries and veins, these constituents are organized into three concentric layers—*intima, media,* and *adventitia,* which are anatomically more distinct in the arteries.

- The *intima* normally consists of a single layer of ECs attached to a basement membrane with a thin underlying

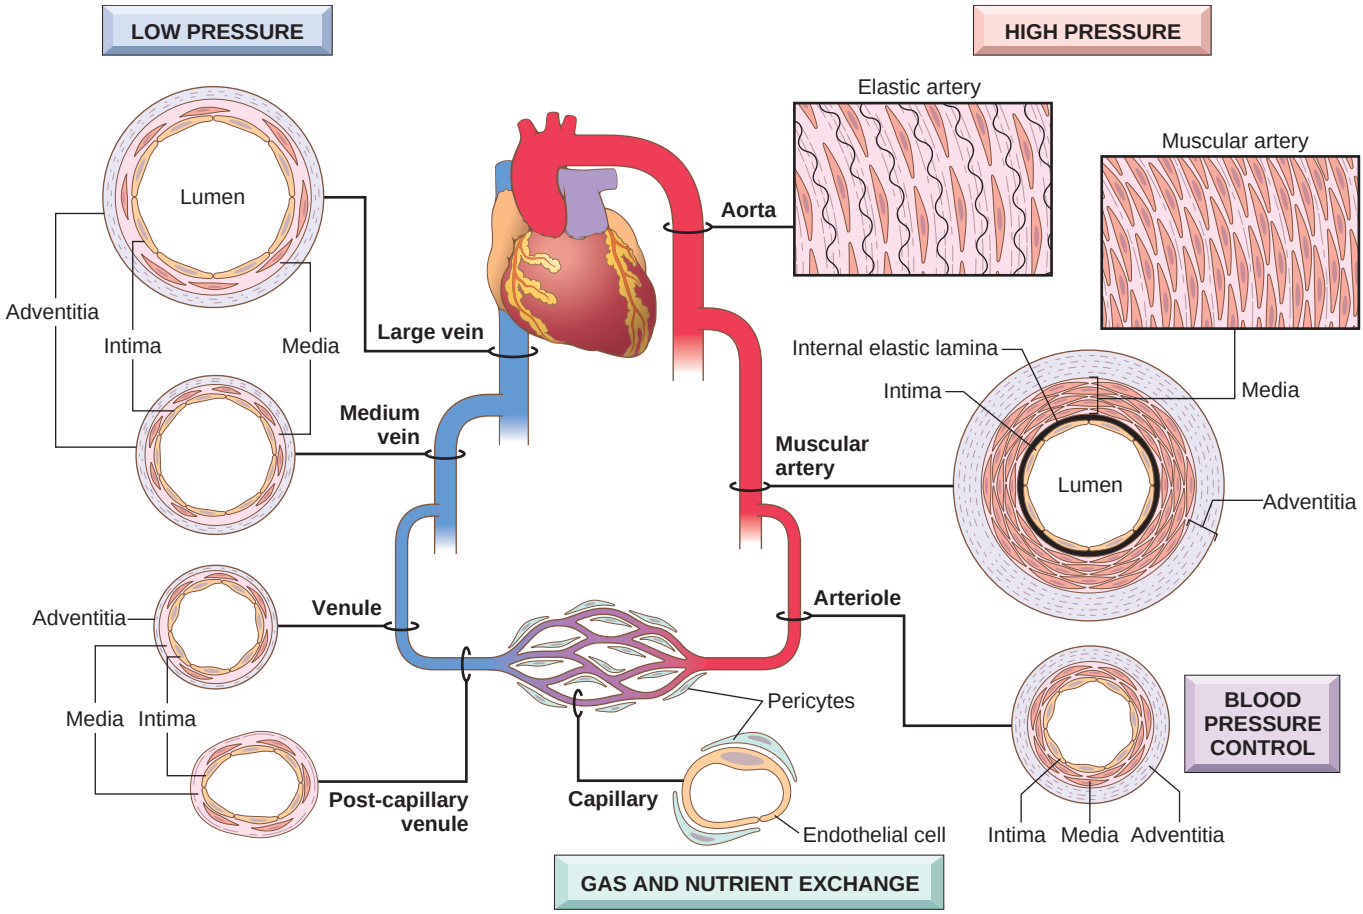

Figure 11.1 Regional specializations of the vasculature. Although the basic organization of the vasculature is constant, the thickness and composition of the various layers differs according to hemodynamic forces and tissue requirements. Thus, the aorta and other elastic arteries have substantial elastic tissue to accommodate high pulsatile forces, with the capacity to recoil and transmit energy into forward blood flow. These vessels have lamellar units that are comprised of repetitions of a layer of elastic fibers, a smooth muscle cell, and intervening extracellular matrix. Purely muscular arteries have elastic fibers only at the intersection of the intima and media or media and adventitia. In comparison, the venous system has relatively poorly developed thinner medial layers that permit greater capacitance, and the capillary wall permits ready diffusion of oxygen and nutrients because it is comprised only of an endothelial cell and sparse encircling pericytes. The different structure and functional attributes also influence the disorders that can affect the various parts of the vascular tree. Thus, loss of aortic elastic tissue will result in aneurysm, while stasis in a dilated venous bed can result in thrombosis.

layer of ECM; the intima is demarcated from the media by the internal elastic lamina.

- The *media* of *elastic arteries* (e.g., the aorta) are arranged in layers of lamellar units of elastin fibers and SMCs akin to tree rings. This high elastin content allows these vessels to expand during systole and recoil during diastole—functionally propelling blood toward the tissues. With aging and the loss of elasticity, the aorta and larger arteries become less compliant; besides transmitting higher pressures into distal tissues, the arteries of older individuals often become progressively tortuous and dilated *(ectatic)*.
  - In *muscular arteries,* the media is composed predominantly of circumferentially oriented SMCs. Arteriolar SMC contraction (vasoconstriction) or relaxation (vasodilation) is regulated by inputs from the autonomic nervous system and local metabolic factors.
  - *Arterioles are the principal points of physiologic resistance to blood flow*. Since the resistance to fluid flow is inversely proportional to the fourth power of the diameter (i.e., halving the diameter increases resistance 16-fold), small decreases in the lumen size of arterioles caused by structural changes or vasoconstriction can have profound effects on blood pressure.
- The *adventitia* lies external to the media and in many arteries is separated from the media by a well-defined external elastic lamina. The adventitia consists of loose connective tissue and can also contain nerve fibers. Diffusion of oxygen and nutrients from the lumen is adequate to sustain thin-walled vessels and the innermost SMCs of all vessels. In large- and medium-sized vessels, however, small arterioles within the adventitia (called *vasa vasorum*—literally, "vessels of the vessels") perfuse the outer half to two-thirds of the media.

As already alluded to, arteries are divided into three types based on their size and structural features: (1) large or elastic arteries including the aorta, the major branches of the aorta (innominate, subclavian, common carotid, and iliac), and pulmonary arteries; (2) medium-sized or muscular arteries comprising smaller branches of the aorta (e.g., coronary and renal arteries); and (3) small arteries (≤2 mm in diameter) and *arterioles* (20 to 100 μm in diameter) within tissues and organs.

Capillaries are slightly smaller (5 μm) than the diameter of a red blood cell (7 to 8 μm); they have an EC lining but no media, although variable numbers of pericytes, cells that resemble SMCs, typically lie just deep to the endothelium. Collectively, capillaries have a huge cross-sectional area and also have a relatively low flow rate. The combination of thin walls and slow flow makes capillaries ideally suited for the exchange of diffusible substances between blood and tissues. Because functionally useful oxygen diffusion is limited to a distance of only approximately 100 μm, the capillary network of most tissues is very rich. Tissues with high metabolic rates such as myocardium and brain have the highest density of capillaries.

Blood from capillary beds flows into *postcapillary venules* and then sequentially through collecting venules and small, medium, and large veins. In most forms of inflammation, vascular leakage and leukocyte exudation occur preferentially from postcapillary venules (Chapter 3).

Relative to arteries at the same level of branching, veins have larger diameters, larger lumens, and thinner and less well-organized walls (see Fig. 11.1). These structural features augment the capacitance of the venous side of the circulation, which on average contains about two-thirds of total blood volume. Reverse flow (due to gravity) is prevented in the extremities by venous valves.

Lymphatics are thin-walled, endothelium-lined channels that drain lymph (water, electrolytes, glucose, fat, proteins, and inflammatory cells) from the interstitium of tissues, eventually reconnecting with the blood stream via the thoracic duct. Lymphatics transport interstitial fluid and inflammatory cells from the periphery to lymph nodes, thereby facilitating antigen presentation and cell activation in the nodal tissues—and enabling continuous monitoring of peripheral tissues for infection. This can be a double-edged sword, however, as these channels can also disseminate disease by transporting microbes or tumor cells to distant sites.

KEY CONCEPTS

VASCULAR STRUCTURE AND FUNCTION

- All vessels except capillaries share a general three-layered architecture consisting of an endothelial-lined intima, surrounding smooth muscle media, and supportive adventitia.
- The SMCs and ECM of arteries, veins, and capillaries vary according to hemodynamic demands (e.g., pressure, pulsatility) and functional requirements.
- The specific composition of the vessel wall at any given site within the vascular tree influences the nature and consequences of pathologic injuries.

VASCULAR ANOMALIES

Although rarely symptomatic, anatomic variants of the usual vascular supply are important to recognize, as the failure to do so may lead to surgical complications and impede attempted therapeutic interventions (e.g., placement of coronary artery stents). Among the other congenital vascular anomalies, four are particularly significant, although not necessarily common.

- *Developmental* or *berry aneurysms* occur in cerebral vessels; when ruptured, these can cause fatal intracerebral hemorrhage (Chapter 28).
- *Arteriovenous fistulas* are direct connections (usually small) between arteries and veins that bypass capillaries. They occur most commonly as developmental defects but can also result from rupture of an arterial aneurysm into the adjacent vein, from penetrating injuries that pierce arteries and veins, or from inflammatory necrosis of adjacent vessels. Surgically generated arteriovenous fistulas provide vascular access for chronic hemodialysis. Like berry aneurysms, arteriovenous fistulas can rupture. Large or multiple arteriovenous fistulas become clinically significant by shunting blood from the arterial to the venous circulations, forcing the heart to pump additional volume and leading to high-output cardiac failure.
- *Fibromuscular dysplasia* is a focal irregular thickening in medium and large muscular arteries including renal, carotid, splanchnic, and vertebral vessels. The cause is unknown. Segments of the vessel wall are focally thickened by a combination of medial and intimal hyperplasia and fibrosis, resulting in luminal stenosis. In the renal arteries, it can be a cause of renovascular hypertension (Chapter 20). Immediately adjacent vessel segments can have markedly attenuated media (on angiography the vessels are said to have a "string of beads" appearance) leading to vascular outpouchings *(aneurysms)* that can rupture.
- *Anomalous coronary artery origin* occurs from a developmental anomaly in which both coronary arteries arise over the same coronary cusp of the aortic valve. Although many of these anomalies are benign, when a coronary vessel passes between the aorta and pulmonary artery it can be squeezed, for example, during exercise, limiting blood flow and resulting in sudden death.

VASCULAR WALL RESPONSE TO INJURY

The integrated functioning of ECs and SMCs impacts physiologic and pathophysiologic responses to hemodynamic and biochemical stimuli. Their function (and dysfunction) are described briefly, followed by discussion of specific vascular disorders.

ECs form a specialized simple squamous epithelium lining for blood vessels. Although ECs throughout the vascular tree share many attributes, populations that line different portions of the vascular tree (large vessels vs. capillaries, arteries vs. veins) have distinct gene expression profiles, behaviors, and morphologic appearances. Thus ECs in liver sinusoids or in renal glomeruli are fenestrated (they have holes, presumably to facilitate filtration), while central nervous system ECs (along with the associated perivascular cells) create an impermeable blood-brain barrier.

ECs are versatile multifunctional cells with a wealth of synthetic and metabolic properties. In the normal state they have several constitutive activities that are critical for vessel homeostasis and circulatory function (Table 11.1). Unless injured or otherwise activated, ECs have a nonthrombogenic surface that maintains blood in a fluid state (Chapter 4). They also modulate medial SMC tone (thereby influencing

Table 11.1 Endothelial Cell Properties and Functions

Property/Function	Mediators/Products
Maintenance of permeability barrier	
Elaboration of anticoagulant, antithrombotic, and fibrinolytic regulators	Prostacyclin Thrombomodulin Heparin-like molecules Plasminogen activator
Elaboration of prothrombotic molecules	Von Willebrand factor Tissue factor Plasminogen activator inhibitor

Modulation of blood flow and vascular reactivity	*Vasoconstrictors:* endothelin, ACE *Vasodilators:* NO, prostacyclin
Regulation of inflammation and immunity	IL-1, IL-6, chemokines Adhesion molecules: VCAM-1, ICAM, E-selectin, P-selectin Histocompatibility antigens
Regulation of cell growth	Growth stimulators: PDGF, CSF, FGF Growth inhibitors: heparin, TGF-β

ACE, Angiotensin-converting enzyme; *CSF*, colony-stimulating factor; *FGF*, fibroblast growth factor; *ICAM*, intercellular adhesion molecule; *IL*, interleukin; *LDL*, low-density lipoprotein; *NO*, nitric oxide; *PDGF*, platelet-derived growth factor; *TGF-β*, transforming growth factor-β; *VCAM*, vascular cell adhesion molecule.

vascular resistance); metabolize hormones such as angiotensin; regulate inflammation; and affect the growth of other cell types, particularly SMCs. Although interendothelial junctions are largely impermeable in normal vessels, vasoactive agents (e.g., histamine) cause contraction of ECs and allow the rapid egress of fluids, electrolytes, and protein; in inflammation, even leukocytes can slip between adjacent ECs (Chapter 3).

ECs can respond to various stimuli by adjusting their steady-state (constitutive) functions and by expressing newly acquired (inducible) properties—a process termed *endothelial activation* (Fig. 11.2). There are numerous inducers of endothelial activation including cytokines and bacterial products, which elicit inflammation and, in severe cases, can promote septic shock (Chapter 4). Additional activators include hemodynamic stresses and lipid products that are critical to the pathogenesis of atherosclerosis (see later) and advanced glycation end-products that are important in the pathogenic sequelae of diabetes (Chapter 24). Viruses, complement components, and hypoxia also activate ECs. Activated ECs, in turn, express adhesion molecules (Chapter 3) and produce cytokines, chemokines, growth factors, vasoactive molecules that result either in vasoconstriction or in vasodilation, induction of major histocompatibility complex molecules, procoagulant and anticoagulant factors, and a variety of other biologically active products. ECs influence the vasoreactivity of the underlying SMCs through the production of both vasodilating (relaxing) factors (e.g., nitric oxide [NO]) and vasoconstrictive factors (e.g., endothelin). Normal EC function is characterized by a balance of these responses.

Endothelial dysfunction refers to an alteration in endothelial phenotype—seen in many different conditions—that is often both proinflammatory and prothrombogenic. It is responsible, at least in part, for the initiation of thrombus formation, atherosclerosis, and the vascular lesions of hypertension and other disorders. Certain forms of endothelial dysfunction are rapid in onset (within minutes), reversible, and independent of new protein synthesis (e.g., EC contraction induced by histamine and other vasoactive mediators that cause gaps in venular endothelium (Chapter 3). Other changes, such as the upregulation of adhesion molecules, involve alterations in gene expression and protein synthesis and may require hours or even days to develop.

Vascular SMCs are the predominant cellular element of the vascular media, playing important roles in normal vascular repair and pathologic processes such as atherosclerosis. SMCs have the capacity to proliferate when appropriately stimulated; they can also synthesize collagen, elastin, and proteoglycans and elaborate growth factors and cytokines. SMCs are also responsible for the vasoconstriction or dilation that occurs in response to physiologic or pharmacologic stimuli.

Intimal Thickening: A Stereotyped Response to Vascular Injury

Vascular injury associated with EC dysfunction or loss stimulates SMC recruitment and proliferation and associated ECM synthesis; the result is intimal thickening that can compromise vascular flow. Healing of injured vessels is analogous to the healing process that occurs in any other damaged tissue (Chapter 3) but has a somewhat unique outcome because the process impacts downstream blood flow. ECs involved in repair can migrate from adjacent uninjured areas into denuded areas or can derive from

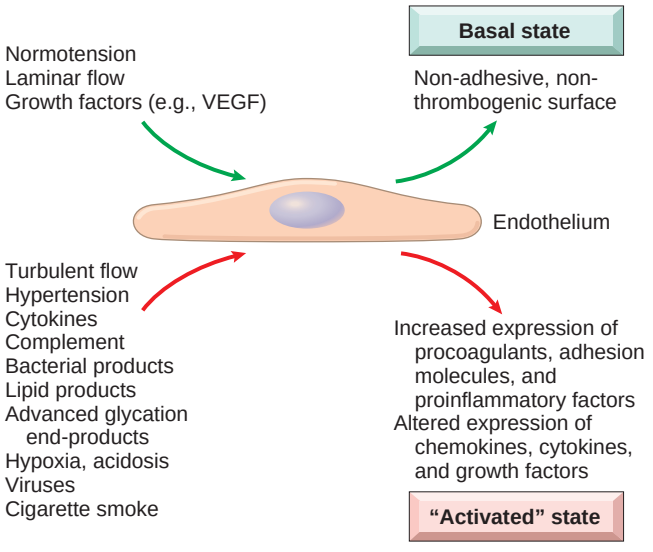

Figure 11.2 Basal and activated endothelial cell states. Normal blood pressure, laminar flow, and stable growth factor levels promote a basal endothelial cell state that maintains a nonthrombotic, nonadhesive surface with appropriate vascular wall smooth muscle tone. Injury or exposure to certain mediators results in endothelial activation, a state where endothelial cells develop a procoagulant surface that can be adhesive for inflammatory cells and express factors that cause smooth muscle contraction and/or proliferation and matrix synthesis. *VEGF*, Vascular endothelial growth factor.

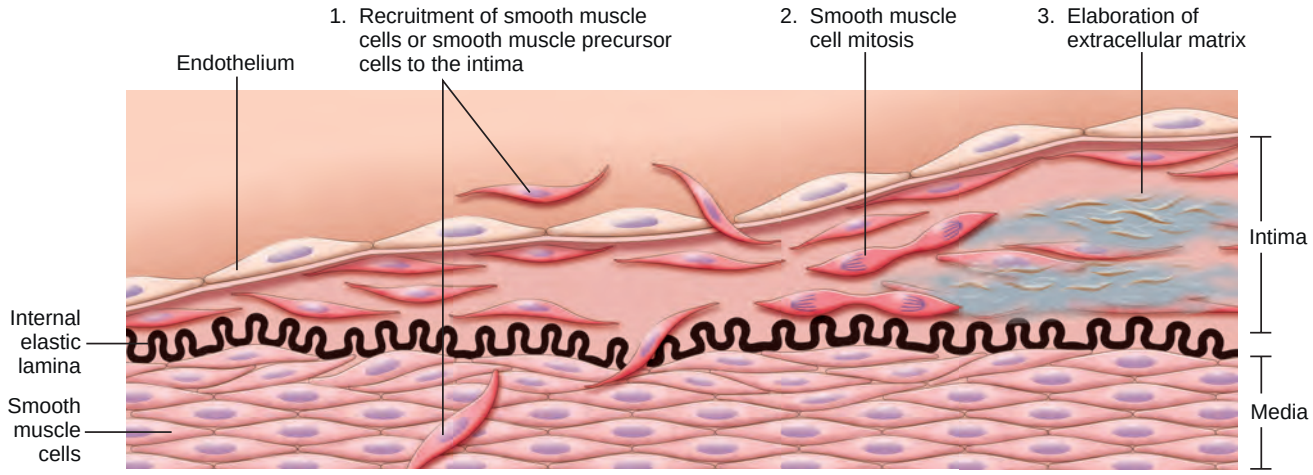

Figure 11.3 Stereotypical response to vascular injury. Schematic diagram of intimal thickening, emphasizing intimal smooth muscle cell migration and proliferation associated with extracellular matrix synthesis. Intimal smooth muscle cells can derive from the underlying media or can be recruited from circulating precursors; the intimal cells are shown in a darker shade to emphasize that they have a proliferative, synthetic, and noncontractile phenotype distinct from medial smooth muscle cells.

circulating precursors. Medial SMCs or circulating smooth muscle precursor cells also migrate into the intima, proliferate, and synthesize ECM in much the same way that fibroblasts fill in a wound (Fig. 11.3). The resulting neointima is typically completely covered by ECs. This neointimal response occurs with any form of vascular damage or dysfunction, regardless of cause. Thus intimal thickening is the stereotypical response of the vessel wall to any insult.

Neointimal SMCs have a phenotype that is distinct from that of medial SMCs. Specifically, neointimal SMCs are more proliferative, with increased biosynthetic capabilities and reduced contractile function. This neointimal SMC behavior is regulated by cytokines and growth factors derived from platelets, ECs, and macrophages, as well as thrombin and activated complement factors. With time and restoration and/or normalization of the EC layer, the neointimal SMCs can return to a nonproliferative state.

KEY CONCEPTS

RESPONSE OF VASCULAR WALL CELLS TO INJURY

- All vessels are lined by endothelium; although all ECs share certain homeostatic properties, ECs in specific vascular beds have special features that allow for tissue-specific functions (e.g., fenestrated ECs in renal glomeruli).
- EC function is tightly regulated in both the basal and activated states. Various physiologic and pathophysiologic stimuli induce endothelial activation and dysfunction that alter the EC phenotype (e.g., procoagulative vs. anticoagulative, proinflammatory vs. antiinflammatory, and nonadhesive vs. adhesive).
- Injury (of almost any type) to the vessel wall results in a stereotyped healing response involving SMC proliferation, ECM deposition, and intimal expansion.
- The recruitment and activation of the SMCs involves signals from cells (e.g., ECs, platelets, and macrophages) as well as mediators derived from coagulation and complement cascades.
- Excessive thickening of the intima can result in luminal stenosis and vascular obstruction.

HYPERTENSIVE VASCULAR DISEASE

Systemic and local tissue blood pressures must be maintained within a narrow range to prevent untoward consequences. Low pressures (hypotension) result in inadequate organ perfusion and can lead to dysfunction or tissue death. Conversely, high pressure (hypertension) can cause end-organ damage and is one of the major risk factors for atherosclerosis (see later).

Like height and weight, blood pressure is a continuously distributed variable. Detrimental effects of blood pressure increase continuously as the pressure rises—no rigidly defined threshold level of blood pressure identifies those who have an increased risk for cardiovascular disease. Both the systolic and the diastolic blood pressure are important in determining risk; specifically, according to the newest guidelines, individuals with diastolic pressures above 80 mm Hg or systolic pressures above 120 mm Hg are considered to have clinically significant hypertension. Approximately 46% of individuals in the general population are therefore hypertensive based on these newer criteria. However, such cutoffs do not reliably assess risk in all patients; for example, when other risk factors such as diabetes are present, lower thresholds are applicable.

Table 11.2 lists the major causes of hypertension. Although the molecular pathways that regulate normal blood pressure are reasonably well understood, the causes of hypertension in most individuals remain largely unknown. A small number of patients (approximately 10%) are said to have *secondary hypertension* resulting from an underlying renal or adrenal disease (e.g., primary aldosteronism, Cushing syndrome, or pheochromocytoma), renal artery stenosis, or other identifiable cause. However, approximately 90% of hypertension is idiopathic—so-called essential hypertension. It seems likely that hypertension is a multifactorial disorder resulting from the cumulative effects of multiple genetic polymorphisms and interacting environmental factors.

The prevalence and vulnerability to complications of hypertension increase with age and are higher among African

Table 11.2 Types and Causes of Hypertension (Systolic and Diastolic)

Psychogenic Increased intracranial pressure Sleep apnea Acute stress, including surgery

Americans. Besides increasing risk of atherosclerosis, hypertension can cause cardiac hypertrophy and heart failure *(hypertensive heart disease)* (Chapter 12), multi-infarct dementia (Chapter 28), aortic dissection (discussed later in this chapter), and renal failure (Chapter 20). Unfortunately, hypertension typically remains asymptomatic until late in its course, and even severely elevated pressures can be clinically silent for years. Left untreated, roughly half of hypertensive patients die of ischemic heart disease or congestive heart failure, and another third die of stroke. Treatment with blood pressure–lowering drugs dramatically reduces the incidence and death rates attributable to all forms of hypertension-related pathology.

A small percentage of hypertensive persons (as much as 5%) show a rapidly rising blood pressure that, if untreated, leads to death within 1 to 2 years. This form of hypertension, called *malignant hypertension,* is characterized by severe pressure elevations (i.e., systolic pressure more than 200 mm Hg, diastolic pressure more than 120 mm Hg), renal failure, and retinal hemorrhages and exudates, with or without papilledema (swelling of the optic nerve that reflects increased intracranial pressures). It can develop in previously normotensive persons but more often is superimposed on preexisting "benign" hypertension.

In this section, we will first briefly outline normal blood pressure homeostasis, followed by a discussion of pathogenic mechanisms that underlie hypertension and a description of hypertension-associated pathologic changes in vessels.

Blood Pressure Regulation

Blood pressure is a function of cardiac output and peripheral vascular resistance, both of which are influenced by multiple genetic and environmental factors (Fig. 11.4). The integration of the various inputs ensures adequate systemic perfusion, despite regional demand differences.

- *Cardiac output* is a function of stroke volume and heart rate. The most important determinant of stroke volume is the filling pressure, which is regulated through sodium homeostasis and its effect on blood volume. Heart rate and myocardial contractility (a second factor affecting stroke volume) are both regulated by the α- and β-adrenergic systems, which also have important effects on vascular tone.
- *Peripheral resistance* is regulated predominantly at the level of the arterioles by neural and hormonal inputs.

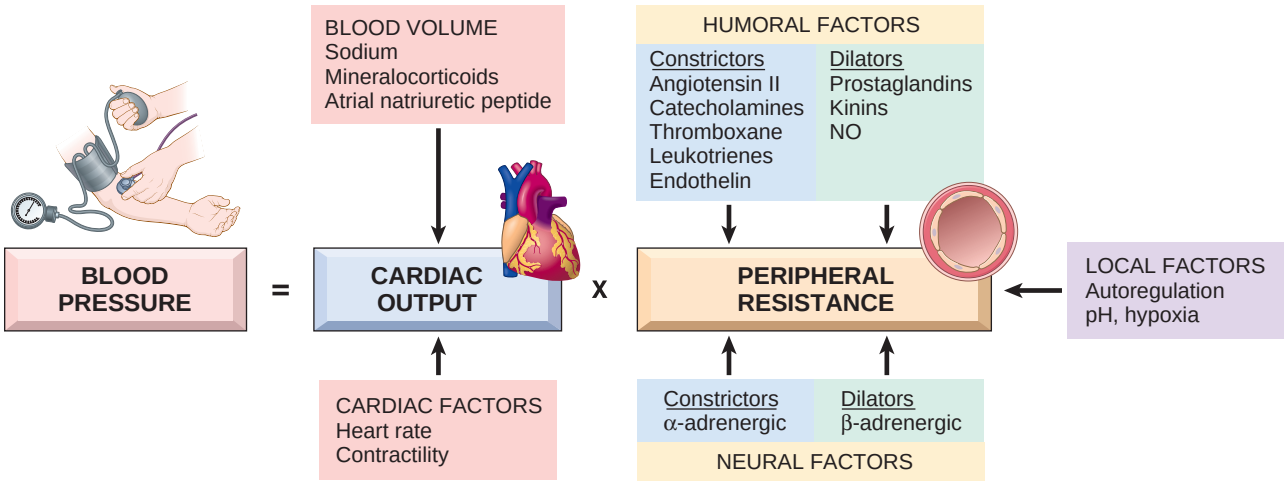

Figure 11.4 Blood pressure regulation. Diverse influences on cardiac output (e.g., blood volume and myocardial contractility) and peripheral resistance (neural, humoral, and local effectors) impact the output blood pressure.

Vascular tone reflects a balance between vasoconstrictors (including angiotensin II, catecholamines, and endothelin) and vasodilators (including kinins, prostaglandins, and NO). Resistance vessels also exhibit autoregulation, whereby increased blood flow induces vasoconstriction to protect tissues against hyperperfusion. Finally, blood pressure is fine-tuned by tissue pH and hypoxia to accommodate local metabolic demands.

Factors released from the kidneys, adrenals, and myocardium interact to influence vascular tone and to regulate blood volume by adjusting sodium balance (Fig. 11.5). The kidneys filter 170 liters of plasma containing 23 moles of salt daily. Thus with a typical diet containing 100 mEq of sodium, 99.5% of the filtered salt must be reabsorbed to maintain total body sodium levels. About 98% of the filtered sodium is reabsorbed by several constitutively active transporters. The small amount of remaining sodium is subject to resorption by the epithelial sodium channel (EnaC), which is tightly regulated by the renin-angiotensin-aldosterone system; it is this pathway that determines net sodium balance.

The kidneys and heart contain cells that sense changes in blood pressure or volume. In response, these cells release circulating effectors that act in concert to maintain normal blood pressure. Kidneys influence peripheral resistance and sodium excretion/retention primarily through the renin-angiotensin-aldosterone system.

- *Renin* is a proteolytic enzyme produced by renal juxtaglomerular cells, which are myoepithelial cells adjacent to the glomerular afferent arterioles. Renin is released in response to low blood pressure in afferent arterioles, elevated levels of circulating catecholamines, or low sodium levels in the distal convoluted renal tubules. The latter occurs when the glomerular filtration rate falls (e.g., when the cardiac output is low), leading to increased sodium resorption by the proximal tubules.
- *Renin cleaves plasma angiotensinogen to angiotensin I, which in turn is converted to angiotensin II by angiotensin-converting enzyme (ACE),* mainly a product of vascular endothelium. Angiotensin II raises blood pressure by (1) inducing vascular contraction, (2) stimulating aldosterone secretion by the adrenal gland, and (3) increasing tubular sodium resorption. Adrenal aldosterone increases blood pressure by its effect on blood volume; aldosterone increases sodium resorption (and thus water) in the distal convoluted tubules, which increases blood volume.
- *The kidney also produces a variety of vascular relaxing substances* (including prostaglandins and NO) that can counterbalance the vasopressor effects of angiotensin.

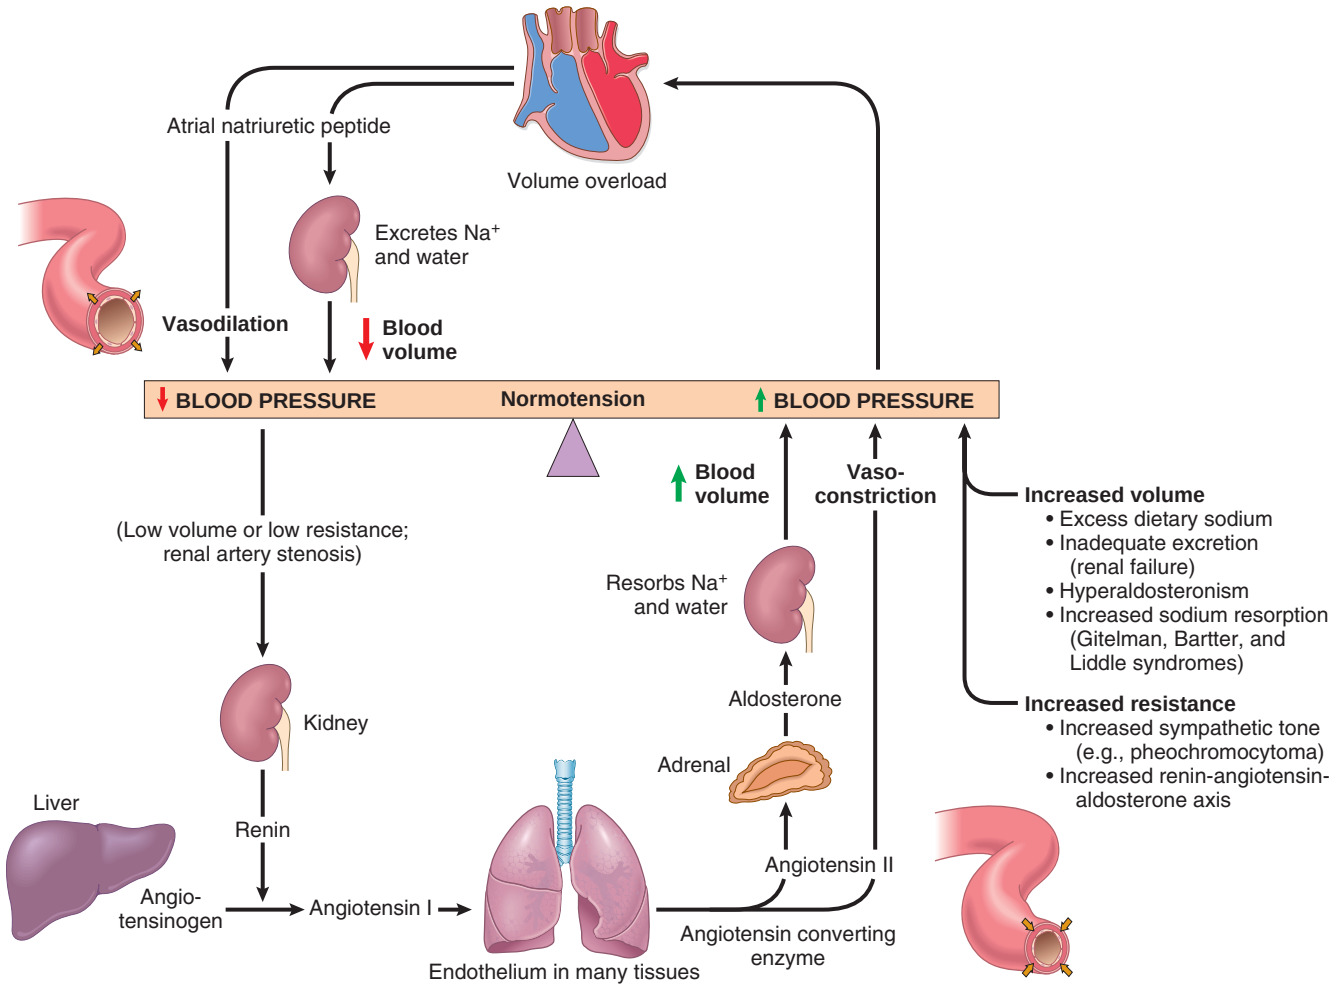

Figure 11.5 Interplay of renin-angiotensin-aldosterone and atrial natriuretic peptide in maintaining blood pressure homeostasis.

Myocardial natriuretic peptides are released from atrial (dominant contributor) and ventricular (minor contributor) myocardium in response to volume expansion; these inhibit sodium resorption in the distal renal tubules, thus leading to sodium excretion and diuresis. They also induce systemic vasodilation.

KEY CONCEPTS

BLOOD PRESSURE REGULATION

- Blood pressure is determined by vascular resistance and cardiac output.
- Vascular resistance is regulated at the level of the arterioles, influenced by neural and hormonal inputs.
- Cardiac output is determined by heart rate and stroke volume, which is strongly influenced by blood volume. Blood volume in turn is regulated mainly by renal sodium excretion or resorption.
- Renin, a major regulator of blood pressure, is secreted by the kidneys in response to decreased blood pressure in afferent arterioles. In turn, renin cleaves angiotensinogen to angiotensin I; subsequent endothelial catabolism produces angiotensin II, which regulates blood pressure by increasing vascular SMC tone and by increasing adrenal aldosterone secretion, thereby increasing renal sodium resorption.

Pathogenesis of Hypertension

The vast majority (90% to 95%) of hypertension is idiopathic, the result of interacting genetic and environmental factors. Even without knowing the specific lesions, it is reasonable to suppose that small changes in renal sodium homeostasis and/or vessel wall tone or structure act in combination to cause essential hypertension (see Fig. 11.5). Most other causes fall under the general rubric of renal disease, including renovascular hypertension (due to renal artery occlusion). Infrequently, hypertension has an underlying endocrine basis.

Mechanisms of Secondary Hypertension. For many of the secondary forms of hypertension, the underlying pathways are reasonably well understood.

- In *renovascular hypertension,* renal artery stenosis causes decreased glomerular flow and pressure in the afferent arteriole of the glomerulus. As already discussed, this induces renin secretion leading to increased blood volume and vascular tone via angiotensin and aldosterone pathways (see Fig. 11.5).
- *Primary hyperaldosteronism* is one of the most common causes of secondary hypertension (Chapter 24). It may be idiopathic or less commonly caused by aldosterone-secreting adrenal adenomas.
- *Single-gene disorders* cause severe but rare forms of hypertension.
  - *Gene defects affecting enzymes involved in aldosterone metabolism (e.g., aldosterone synthase, 11β-hydroxylase, 17α-hydroxylase)* can lead to increased aldosterone secretion with downstream increases in salt and water resorption, plasma volume expansion, and, ultimately, hypertension.
  - *Mutations affecting proteins that influence sodium reabsorption.* For example, the moderately severe form of salt-sensitive hypertension, called Liddle syndrome, is caused by mutations in an epithelial Na^+ channel protein that increase distal tubular reabsorption of sodium in response to aldosterone.

Mechanisms of Essential Hypertension. As mentioned earlier, in the vast majority of cases hypertension results from complex interactions between multiple genetic and environmental influences.

- *Genetic factors* definitely contribute to blood pressure regulation, as shown by comparisons of monozygotic and dizygotic twins and genetically related versus adopted children. Moreover, as noted earlier, several single-gene disorders cause relatively rare forms of hypertension (and hypotension) by altering net sodium reabsorption in the kidney. Large genome-wide association studies point to more than 60 genetic loci in which variants individually contribute minimally to blood pressure levels but in sum have larger effects.
- *Insufficient renal sodium excretion* in the presence of normal arterial pressure may be a key initiating event in essential hypertension and, indeed, a final common pathway for the pathogenesis of hypertension. Insufficient sodium excretion may lead sequentially to an increase in fluid volume, increased cardiac output, and peripheral vasoconstriction, thereby elevating blood pressure. At the higher blood pressure, enough additional sodium is excreted by the kidneys to equal intake and prevent further fluid retention. Thus a new steady state of sodium balance is achieved ("resetting of pressure natriuresis"), but at the expense of an increase in blood pressure.
- *Vasoconstrictive influences,* such as factors that induce vasoconstriction or stimuli that cause structural changes in the vessel wall, can lead to an increase in peripheral resistance and may also play a role in essential hypertension.
- *Environmental factors* such as stress, obesity, smoking, physical inactivity, and heavy salt consumption all are implicated in hypertension. Indeed, the evidence linking dietary sodium intake with the prevalence of hypertension in different populations is particularly impressive.

Vascular Pathology in Hypertension

Hypertension not only accelerates atherogenesis (see later) but also causes degenerative changes in the walls of large and medium arteries that can lead to both aortic dissection and cerebrovascular hemorrhage. Three forms of small vessel disease are hypertension-related (Fig. 11.6).

MORPHOLOGY

Hyaline arteriolosclerosis. Arterioles show homogeneous, pink hyaline thickening with associated luminal narrowing (Fig. 11.6A). These changes reflect both plasma protein leakage across injured ECs and increased SMC matrix synthesis in response to the chronic hemodynamic pressures of hypertension. Although the vessels of older patients (either normotensive or hypertensive) also frequently exhibit hyaline arteriosclerosis, it is more generalized and severe in patients with hypertension and diabetes (Chapter 24). In **nephrosclerosis** due to chronic hypertension, the arteriolar

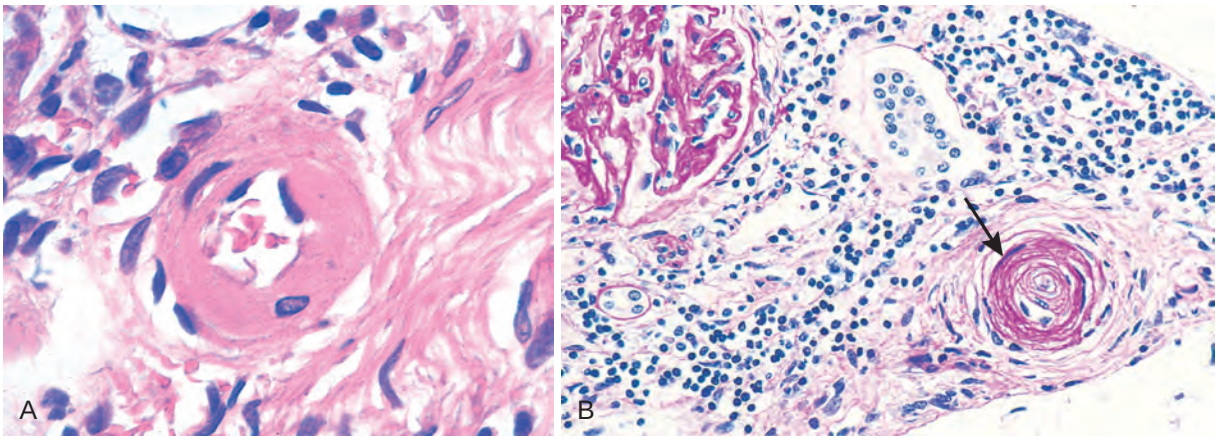

Figure 11.6 Vascular pathology in hypertension. (A) Hyaline arteriolosclerosis. The arteriolar wall is thickened with increased protein deposition (hyalinized), and the lumen is markedly narrowed. (B) Hyperplastic arteriolosclerosis (onion-skinning) causing luminal obliteration *(arrow)* (periodic acid-Schiff stain). (B, Courtesy Helmut Rennke, MD, Brigham and Women's Hospital, Boston, Mass.)

narrowing causes diffuse impairment of renal blood supply and glomerular scarring (Chapter 20).

Hyperplastic arteriolosclerosis. This lesion occurs in severe hypertension; vessels exhibit concentric, **laminated ("onion-skin")** thickening of the walls with luminal narrowing (Fig. 11.6B). The laminations consist of SMCs with thickened, reduplicated basement membrane; in malignant hypertension, they are accompanied by fibrinoid deposits and vessel wall necrosis **(necrotizing arteriolitis)**, particularly in the kidney (Chapter 20).

Pulmonary hypertension can be caused by several entities including left heart failure, congenital heart disease, valve disorders, obstructive or interstitial lung disease, and recurrent thromboemboli. The arterioles in such affected lungs typically show histologic changes ranging from fibrotic intimal thickening to medial hyperplasia. These are described in greater detail in Chapter 15.

KEY CONCEPTS

HYPERTENSION

- Hypertension is a common disorder affecting roughly half of adults in the United States; it is a major risk factor for atherosclerosis, congestive heart failure, and renal failure.
- Essential hypertension represents 90% to 95% of cases and is a complex, multifactorial disorder involving both environmental influences and genetic polymorphisms that influence sodium resorption, aldosterone pathways, and the renin-angiotensin-aldosterone system.
- Hypertension is occasionally caused by single-gene disorders or is secondary to diseases of the kidney, adrenal, or other endocrine organs.
- Sustained hypertension requires participation of the kidney, which normally responds to hypertension by eliminating salt and water. In established hypertension, both increased blood volume and increased peripheral resistance contribute to the increased pressure.
- Histologically, hypertension is associated with thickening of arterial walls caused by hyaline deposits and, in severe cases, by proliferation of ECs or SMCs and replication of the basement membrane.

ARTERIOSCLEROSIS

Arteriosclerosis literally means "hardening of the arteries"; it is a generic term for arterial wall thickening and loss of elasticity. There are four general patterns, with different clinical and pathologic consequences.

- *Arteriolosclerosis* affects small arteries and arterioles and may cause downstream ischemic injury. The two anatomic variants, hyaline and hyperplastic, were discussed earlier in relation to hypertension.
- *Mönckeberg medial sclerosis* is characterized by calcifications of the medial walls of muscular arteries, typically starting along the internal elastic membrane. Adults older than age 50 are most commonly affected. The calcifications do not encroach on the vessel lumen and are usually not clinically significant.
- *Fibromuscular intimal hyperplasia* occurs in muscular arteries larger than arterioles. It is driven by inflammation (as in a healed arteritis or transplant-associated arteriopathy; see Chapter 12) or by mechanical injury (e.g., associated with stents or balloon angioplasty; see later) and can be considered as a healing response. The affected vessels can become quite stenotic; indeed, such intimal hyperplasia underlies in-stent restenosis and is the major long-term limitation of solid-organ transplants.
- *Atherosclerosis,* from Greek root words for "gruel" and "hardening," is the most frequent and clinically important pattern and is discussed here.

ATHEROSCLEROSIS

Atherosclerosis underlies the pathogenesis of coronary, cerebral, and peripheral vascular disease and causes more morbidity and mortality (roughly half of all deaths) in the Western world than any other disorder. Because coronary artery disease is an important manifestation of the disease, epidemiologic data related to atherosclerosis mortality typically reflect deaths caused by ischemic heart disease (Chapter 12); indeed, myocardial infarction is responsible for almost a quarter of all deaths in the United

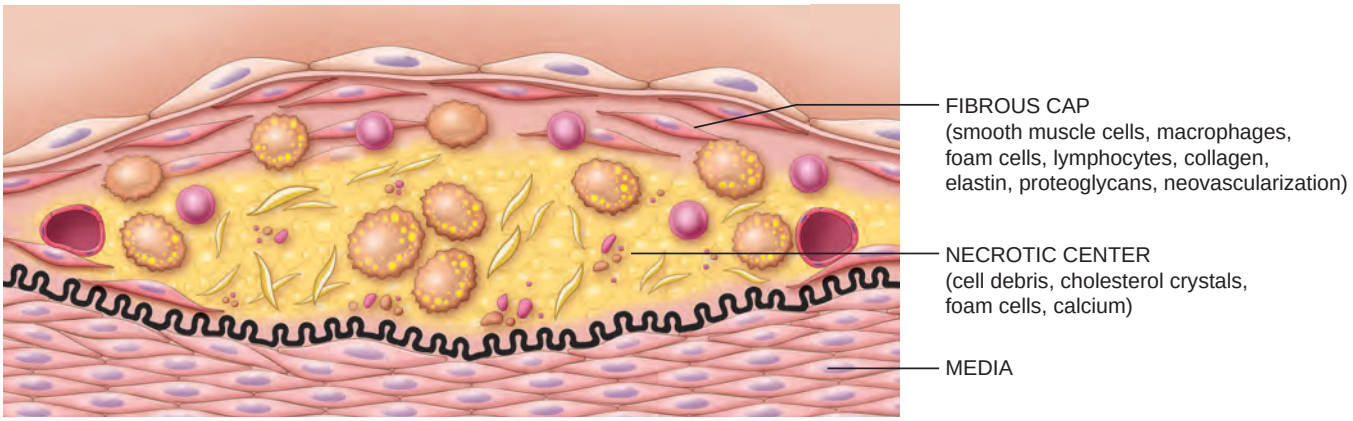

Figure 11.7 Basic structure of an atherosclerotic plaque. Note that atherosclerosis is an intimal-based process with a complex interplay of cells and extracellular materials. Plaques can have secondary effects on the underlying media including a reduction in smooth muscle cells.

States. Significant morbidity and mortality are also caused by aortic and carotid atherosclerotic disease and stroke.

The likelihood of atherosclerosis is determined by the combination of acquired (e.g., cholesterol levels, smoking, hypertension), inherited (e.g., low-density lipoprotein [LDL] receptor gene mutations), and gender- and age-associated risk factors. Acting in concert, they cause intimal lesions called *atheromas* (also called *atheromatous* or *atherosclerotic plaques*) that protrude into vessel lumens. An atheromatous plaque typically consists of a raised lesion with a soft grumous core of lipid (mainly cholesterol and cholesterol esters) covered by a fibrous cap (Fig. 11.7). Besides mechanically obstructing blood flow, atherosclerotic plaques can rupture leading to catastrophic obstructive vascular thrombosis. Atherosclerotic plaques can also increase the diffusion distance from the lumen to the media, leading to ischemic injury and weakening of the vessel wall, changes that can result in aneurysm formation.

Epidemiology. Although atherosclerosis-associated ischemic heart disease is ubiquitous among most developed nations, risk reduction and improved therapies have combined to moderate the associated mortality. At the same time, reduced mortality from infectious diseases and the adoption of Western lifestyles has led to the increased prevalence of ischemic heart disease in low income nations. As a result, the death rate for coronary artery disease in Africa, India, and Southeast Asia now exceeds that in the United States; eastern European countries have rates 3 to 5 times higher than the United States and 7 to 12 times higher than Japan.

Risk Factors

The prevalence and severity of atherosclerosis and ischemic heart disease among individuals and groups are related to a number of risk factors identified through several prospective analyses (e.g., the Framingham Heart Study); some of these are constitutional (and therefore less controllable), but others are acquired or related to specific behaviors and potentially amenable to intervention (Table 11.3). These risk factors typically have greater than additive effects, but treatment (even less than optimal) can mitigate some of the risk (Fig. 11.8).

Constitutional Risk Factors

- *Genetics.* Family history is the most important independent risk factor for atherosclerosis. Certain Mendelian disorders are strongly associated with atherosclerosis (e.g., familial hypercholesterolemia; see Chapter 5), but they account for only a small percentage of cases. The well-established familial predisposition to atherosclerosis and ischemic heart disease is usually polygenic, relating to small effects of many shared alleles common to a family or population.
- *Age is a dominant influence.* The development of atherosclerotic plaque is a progressive process that usually becomes clinically manifest in middle age or later (see later). Thus between ages 40 and 60, the incidence of myocardial infarction increases fivefold. Death rates from ischemic heart disease rise with each decade even into advanced age. Increasingly, however, this age association is being recognized as perhaps more than just the accumulated slings and arrows of vascular injury over the years. Indeed, with aging, there is a tendency for the outgrowth of hematopoietic clones (so-called *clonal hematopoiesis of indeterminate potential [CHIP]*) carrying mutations that confer a proliferative advantage. Many of these affect DNA modifications and transcriptional regulation (e.g., *TET2* encoding an enzyme that converts methylcytosine to 5-hydroxymethylcytosine); as expected, these can ultimately influence the risk of developing hematologic malignancies. Perhaps more remarkable, however, is that such clonal hematopoiesis is even more

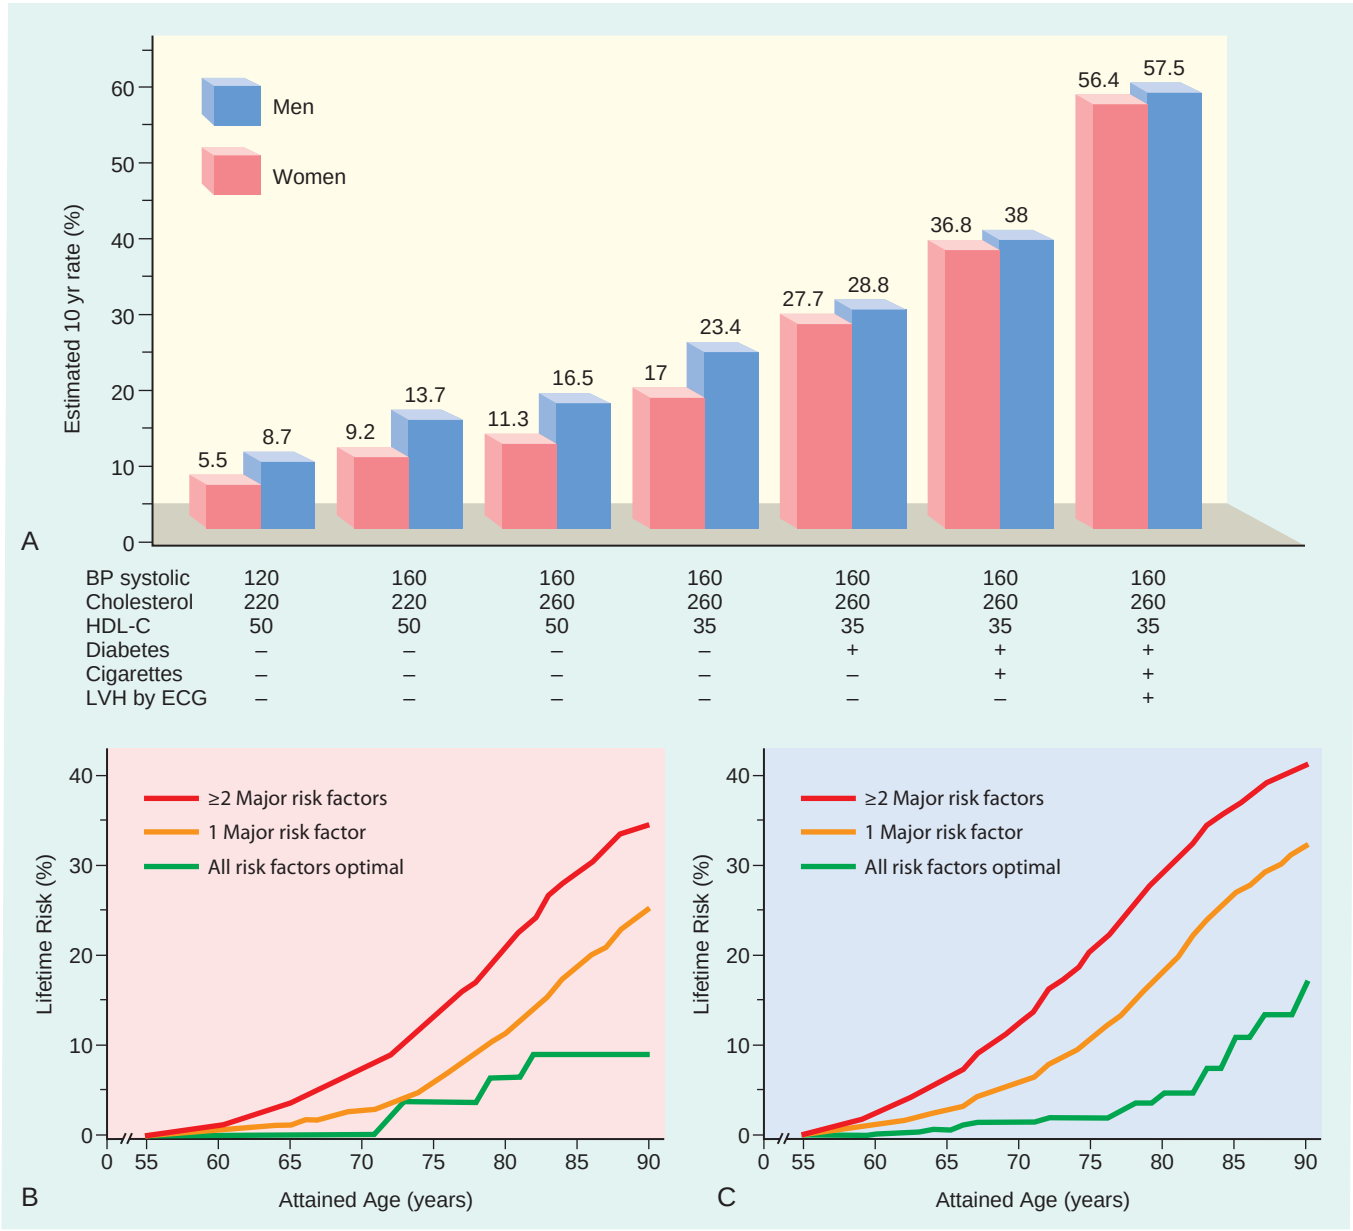

Figure 11.8 Lifetime risk of death from cardiovascular disease. (A) Estimated 10-year risk of coronary artery disease in hypothetical 55-year-old men and women as a function of traditional risk factors (hyperlipidemia, hypertension, smoking, and diabetes). *BP,* Blood pressure; *ECG,* electrocardiogram; *HDL-C,* high-density lipoprotein cholesterol; *LVH,* left ventricular hypertrophy. In women (B) and men (C), one or more risk factors of blood pressure, cholesterol, diabetes, and cigarettes significantly increases the lifetime risk of a cardiovascular event. (A, From O'Donnell CJ, Kannel WB: Cardiovascular risks of hypertension: lessons from observational studies, *J Hypertens Suppl* 16(6):S3–S7, 1998, with permission from Lippincott Williams & Wilkins; B and C, Modified from Berry JD, Dyer A, Cai X, et al: Lifetime risks of cardiovascular disease, *N Eng J Med* 366:321–329, 2012.)

significantly associated with increased all-cause cardiovascular mortality. An explanation is beginning to emerge that the same CHIP mutations that affect cellular proliferation (e.g., *TET2*) can also impact the inflammatory response of mononuclear cells and thereby influence atherogenesis (see also later).

- *Gender.* Premenopausal women are relatively protected against atherosclerosis and its consequences compared with age-matched men. Thus myocardial infarction and other complications of atherosclerosis are uncommon in premenopausal women unless they are otherwise predisposed by diabetes, hyperlipidemia, or severe hypertension. After menopause, however, the incidence of atherosclerosis-related diseases increases and at older ages exceeds that of men. Although a favorable influence of estrogen has been proposed to explain this effect, clinical trials of estrogen replacement did not show any benefit; indeed, postmenopausal estrogen therapy actually increased cardiovascular risk in some older women.

Modifiable Major Risk Factors

- *Hyperlipidemia*—and more specifically hypercholesterolemia—is a major risk factor for atherosclerosis; even in the absence of other risk factors, hypercholesterolemia is sufficient to initiate lesion development. The major component of serum cholesterol associated with increased risk is LDL cholesterol

("bad cholesterol"). LDL is the lipid-cholesterol-protein complex that delivers cholesterol to peripheral tissues; in contrast, high-density lipoprotein (HDL) is the complex that mobilizes cholesterol from the periphery (including atheromas) and transports it to the liver for catabolism and biliary excretion. Higher levels of HDL ("good cholesterol") correlate with reduced risk.

Understandably, dietary and pharmacologic interventions that lower LDL or total serum cholesterol are of considerable interest. Interestingly, approaches that exclusively raise HDL are not effective. Although previously considered important, the contribution of most dietary fats to atherosclerosis is now viewed as minimal. Nevertheless, omega-3 fatty acids (abundant in fish oils) are considered beneficial, whereas trans unsaturated fats produced by artificial hydrogenation of polyunsaturated oils (used in baked goods and margarine) can adversely affect cholesterol profiles. *Statins* are a class of drugs that lower circulating cholesterol levels by inhibiting hydroxymethylglutaryl coenzyme A (HMG CoA) reductase, the rate-limiting enzyme in hepatic cholesterol biosynthesis (Chapter 5). Statins are widely used to lower serum cholesterol levels, lowering rates of myocardial infarctions, arguably one of the most significant success stories of translational research. Interestingly, some of the benefit of the statins may be due to "off-target" effects on reducing inflammation (see also later).

- *Hypertension* can increase the risk of ischemic heart disease by approximately 60% versus normotensive populations. Chronic hypertension is the most common cause of left ventricular hypertrophy, and hence the latter is also a surrogate marker for cardiovascular risk.
- *Cigarette smoking*, and in particular prolonged (years) use, doubles the death rate from ischemic heart disease. Smoking cessation reduces that risk substantially.
- *Diabetes mellitus* induces hypercholesterolemia (Chapter 24) and markedly increases the risk of atherosclerosis. Other factors being equal, the incidence of myocardial infarction is twice as high in diabetics relative to normoglycemic individuals. There is also an increased risk of strokes and a 100-fold increased risk of atherosclerosis-induced gangrene of the lower extremities.

Additional Risk Factors

As many as 20% of all cardiovascular events occur in the absence of major risk factors (e.g., hypertension, hyperlipidemia, smoking, or diabetes). Indeed, more than 75% of cardiovascular events in previously healthy women occur with LDL cholesterol levels below 160 mg/dL (levels generally considered to connote low risk). Clearly, other factors are contributory. Among those that are proven or suspected are the following:

- *Inflammation*. Inflammation is present during all stages of atherogenesis and is intimately linked with atherosclerotic plaque formation and rupture (see later). With the increasing recognition that inflammation plays a significant causal role in ischemic heart disease, assessment of systemic inflammation has become important in overall risk stratification. A number of circulating markers of inflammation correlate with ischemic heart disease, and *C-reactive protein (CRP)* has emerged as one of the most stable and simplest to measure.

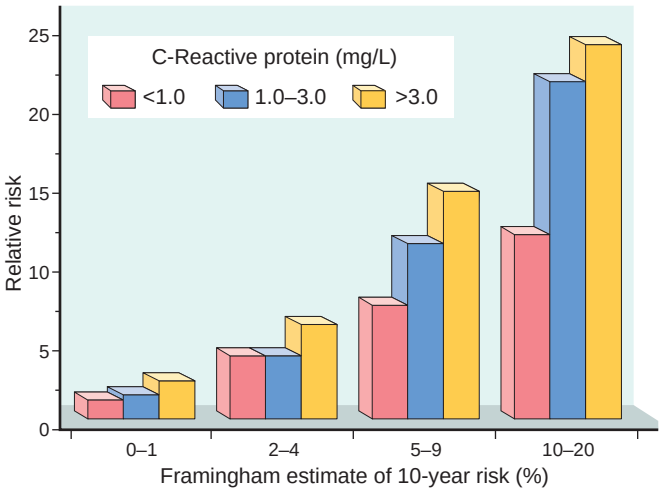

Figure 11.9 C-reactive protein adds prognostic information at all levels of traditional risk identified from the Framingham Heart Study. Relative risk (y-axis) refers to the risk of a cardiovascular event (e.g., myocardial infarction). The x-axis is the 10-year risk of a cardiovascular event derived from the traditional risk factors identified in the Framingham study. In each risk group, C-reactive protein values further stratify the patients. (Data from Ridker PM, et al: Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events, *N Engl J Med* 347:1557, 2002.)

CRP is an acute phase reactant synthesized primarily by the liver. Although CRP does not appear to be causally related to the development of atherosclerosis or its sequelae, it is well established that plasma CRP is a strong, independent marker of risk for myocardial infarction, stroke, peripheral arterial disease, and sudden cardiac death, even among apparently healthy individuals (Fig. 11.9). Accordingly, CRP levels are now incorporated into risk stratification algorithms. Interestingly, CRP levels are also typically lowered in concert with other risk reduction measures including smoking cessation, weight loss, exercise, and statin administration.

- *Hyperhomocysteinemia.* Serum homocysteine levels correlate with coronary atherosclerosis, peripheral vascular disease, stroke, and venous thrombosis. *Homocystinuria,* due to rare inborn errors of metabolism, results in elevated circulating homocysteine (>100 μmol/L) and is associated with premature vascular disease.
- *Metabolic syndrome.* Associated with central obesity (Chapter 9), this entity is characterized by insulin resistance, hypertension, dyslipidemia (elevated LDL and depressed HDL), hypercoagulability, and a proinflammatory state. Dyslipidemia, hyperglycemia, and hypertension all are cardiac risk factors, while the systemic hypercoagulable and proinflammatory state may contribute to endothelial dysfunction and/or thrombosis.
- *Lipoprotein a [Lp(a)]* is an altered form of LDL that contains the apolipoprotein B-100 portion of LDL linked to apolipoprotein A (apo A); Lp(a) levels are associated with coronary and cerebrovascular disease risk, independent of total cholesterol or LDL levels.
- *Factors affecting hemostasis*. Several markers of hemostatic and/or fibrinolytic function (e.g., elevated plasminogen activator inhibitor 1) are potent predictors of risk for

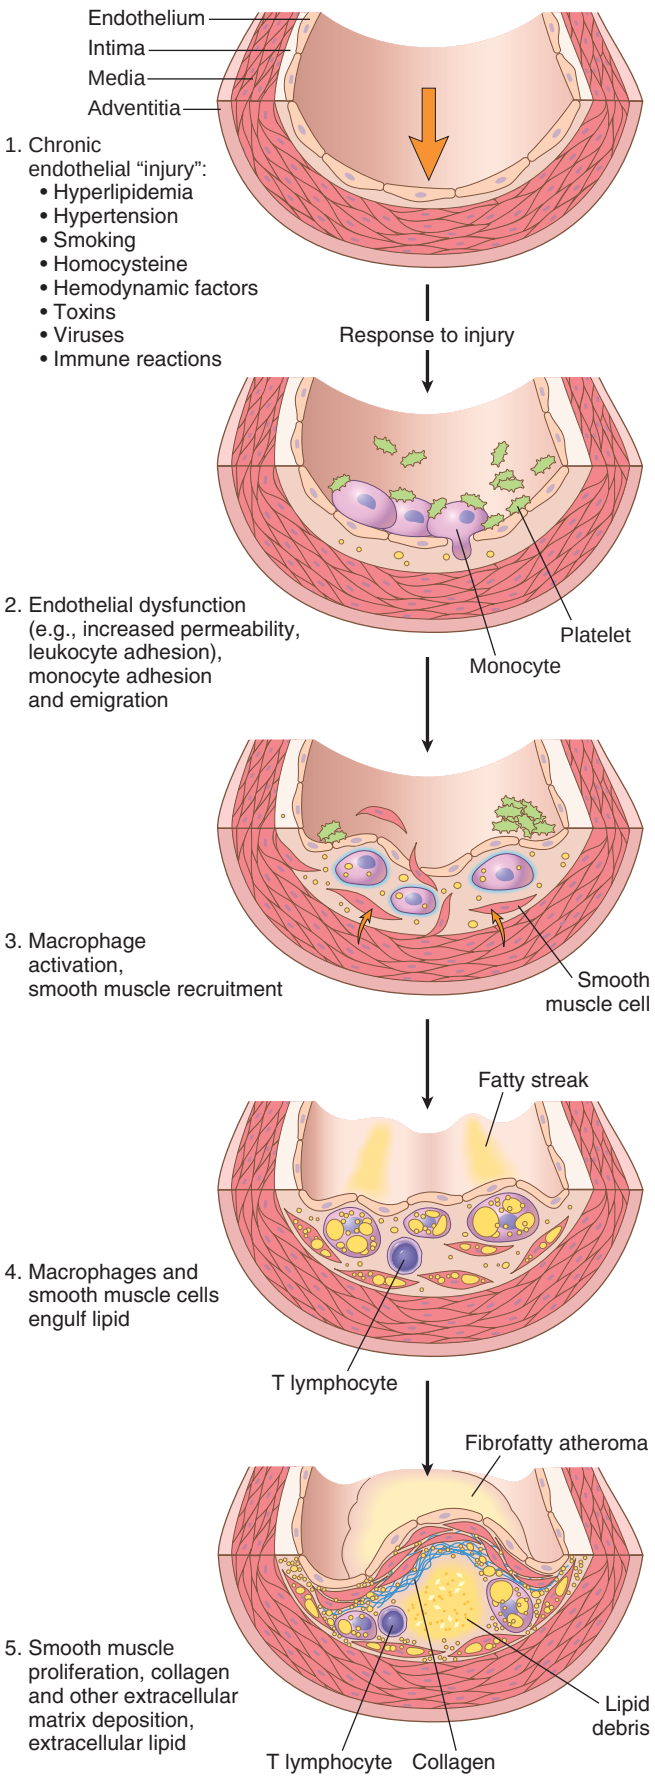

Figure 11.10 Evolution of arterial wall changes in the response to injury hypothesis. *1*, Normal. *2*, Endothelial injury with monocyte and platelet adhesion. *3*, Monocyte and smooth muscle cell migration into the intima, with macrophage activation. *4*, Macrophage and smooth muscle cell uptake of modified lipids, with further activation. *5*, Intimal smooth muscle cell proliferation with extracellular matrix production, forming a well-developed plaque.

major atherosclerotic events including myocardial infarction and stroke. Platelet-derived factors as well as thrombin—through both procoagulant and proinflammatory effects—are increasingly recognized as major contributors to local vascular pathology.

- *Other factors*. Factors associated with a less pronounced and/or difficult to quantitate risk include lack of exercise; competitive, stressful lifestyle (type A personality); and obesity (the last-mentioned also being complicated by hypertension, diabetes, hypertriglyceridemia, and decreased HDL).

Pathogenesis of Atherosclerosis

The clinical importance of atherosclerosis has stimulated enormous interest in understanding the mechanisms that underlie its evolution and complications. The contemporary view of atherogenesis integrates the risk factors previously discussed and is called the "response to injury" hypothesis. **This model views atherosclerosis as a chronic inflammatory and healing response of the arterial wall to endothelial injury. Lesion progression occurs through interaction of modified lipoproteins, macrophages, and T lymphocytes with ECs and SMCs of the arterial wall** (Fig. 11.10). According to this schema, atherosclerosis progresses in the following sequence:

- *Endothelial injury and dysfunction,* causing (among other things) increased vascular permeability, leukocyte adhesion, and thrombosis.
- *Accumulation of lipoproteins* (mainly LDL and its oxidized forms) in the vessel wall.
- *Monocyte adhesion to the endothelium,* followed by migration into the intima and transformation into *macrophages* and *foam cells.*
- *Platelet adhesion.*
- *Factor release* from activated platelets, macrophages, and vascular wall cells, inducing *SMC* recruitment, either from the media or from circulating precursors.
- *SMC proliferation, ECM production, and recruitment of T cells.*
- *Lipid accumulation* both extracellularly and within cells (macrophages and SMCs).
- *Calcification* of ECM and necrotic debris late in the pathogenesis.

We will now discuss the role of these factors in the pathogenesis of atherosclerosis in some detail, starting with endothelial injury.

Endothelial Injury. EC injury is the cornerstone of the response-to-injury hypothesis. Early lesions begin at sites of morphologically intact endothelium that exhibit

features of endothelial dysfunction—increased permeability, enhanced leukocyte adhesion, and altered gene expression. Causes of EC dysfunction include toxins from cigarette smoke, homocysteine, and the local production of inflammatory cytokines. However, the **three most important causes of endothelial dysfunction are hemodynamic disturbances, hypercholesterolemia, and inflammation.**

Hemodynamic Disturbances. The importance of hemodynamic turbulence in atherogenesis is illustrated by the observation that plaques do not occur randomly, but rather tend to locate at the ostia of exiting vessels, branch points, and along the posterior abdominal aorta where flow patterns are disturbed and nonlaminar. This is explained by the fact that laminar nonturbulent flow increases the production of transcription factors and, in particular, Krüppel-like factor-2 (KLF2) that turn on atheroprotective genes and turn off inflammatory gene transcription. Conversely, turbulent, nonlaminar flow drives a repertoire of genetic transcription that makes those sites atheroprone. It is noteworthy that some of the atheroprotective effects of statins also occur through KLF2 upregulation.

Hypercholesterolemia. Lipids are transported in the bloodstream bound to specific apoproteins (forming lipoprotein complexes). *Dyslipoproteinemias* are lipoprotein abnormalities that may be present in the general population (and, indeed, are found in many myocardial infarction survivors). These include (1) increased LDL cholesterol levels, (2) decreased HDL cholesterol levels, and (3) increased levels of the abnormal Lp(a). These may result from mutations in apoproteins or lipoprotein receptors or arise from other underlying disorders that affect circulating lipid levels such as nephrotic syndrome, alcoholism, hypothyroidism, or diabetes mellitus. All of these abnormalities are associated with an increased risk of atherosclerosis.

The evidence implicating hypercholesterolemia in atherogenesis includes the following:

- *The dominant lipids in atheromatous plaques are cholesterol and cholesterol esters.*
- *Genetic defects in lipoprotein uptake and metabolism* that cause hyperlipoproteinemia are associated with accelerated atherosclerosis. Thus familial hypercholesterolemia, caused by mutations affecting the LDL receptors and consequent inadequate hepatic LDL uptake and catabolism (Chapter 5), can precipitate myocardial infarctions before age 20 in those homozygous for the mutation. Similarly, accelerated atherosclerosis occurs in animal models with engineered deficiencies in apolipoproteins or LDL receptors.
- *Epidemiologic analyses* demonstrate a significant correlation between the severity of atherosclerosis and the levels of total plasma cholesterol or LDL.
- *Lowering serum cholesterol* by diet or drugs slows the rate of progression of atherosclerosis, causes regression of some plaques, and reduces the risk of cardiovascular events.

The mechanisms by which hyperlipidemia contributes to atherogenesis include the following:

- *Impaired EC function.* Chronic hyperlipidemia, particularly hypercholesterolemia, can directly impair EC function by increasing local reactive oxygen species production; besides causing membrane and mitochondrial damage, oxygen free radicals accelerate NO decay, dampening its vasodilator activity.
- *Modified LDL.* With chronic hyperlipidemia, lipoproteins accumulate within the intima, where they may aggregate or become oxidized by free radicals produced by inflammatory cells. Such modified LDL is then accumulated by macrophages through a variety of scavenger receptors (distinct from the LDL receptor). Because the modified lipoproteins cannot be completely degraded, chronic ingestion leads to the formation of lipid-filled macrophages called *foam cells;* SMCs can similarly transform into lipid-laden foam cells by ingesting modified lipids through LDL receptor–related proteins. Not only are the modified lipoproteins toxic to ECs, SMCs, and macrophages, but their binding and uptake also stimulate the release of growth factors, cytokines, and chemokines that create a vicious inflammatory cycle of monocyte recruitment and activation. The early lesions containing lipid-filled macrophages are called *fatty streaks.*

Inflammation. **Chronic inflammation contributes to the initiation and progression of atherosclerotic lesions.** It is believed that inflammation is triggered by the accumulation of cholesterol crystals and free fatty acids in macrophages and other cells (Fig. 11.11). These cells sense the presence of abnormal materials via cytosolic innate immune receptors that are components of the inflammasome (Chapter 6). The resulting inflammasome activation leads to the production of the proinflammatory cytokine interleukin (IL)-1, which recruits and activates mononuclear cells including macrophages and T lymphocytes. Such mononuclear cell activation, in turn, leads to local production of cytokines and chemokines that recruit and activate more inflammatory cells. Activated macrophages produce reactive oxygen species that enhance LDL oxidation and elaborate growth factors that drive SMC proliferation. Activated T lymphocytes in the growing intimal lesions elaborate inflammatory cytokines, (e.g., interferon-γ), which, in turn, can activate macrophages as well as ECs and SMCs. Thus many of the lesions of atherosclerosis are attributable to the chronic inflammatory reaction in the vessel wall.

Infection. Although circumstantial evidence has been presented linking atherosclerosis to herpesvirus, cytomegalovirus, and *Chlamydophila pneumoniae,* there is not an established causal role for infection.

Smooth Muscle Proliferation and Matrix Synthesis. Intimal SMC proliferation and ECM deposition convert a fatty streak into a mature atheroma and contribute to the progressive growth of atherosclerotic lesions (see Fig. 11.10). Several growth factors are implicated in SMC proliferation and ECM synthesis, including platelet-derived growth factor (PDGF), released by locally adherent platelets, as well as macrophages, ECs and SMCs; fibroblast growth factor; and transforming growth factor-α (Chapter 1). These factors also stimulate SMCs to synthesize ECM (notably collagen), which stabilizes atherosclerotic plaques. In contrast, activated inflammatory cells in atheromas may increase the breakdown of ECM components resulting in unstable plaques (see later).

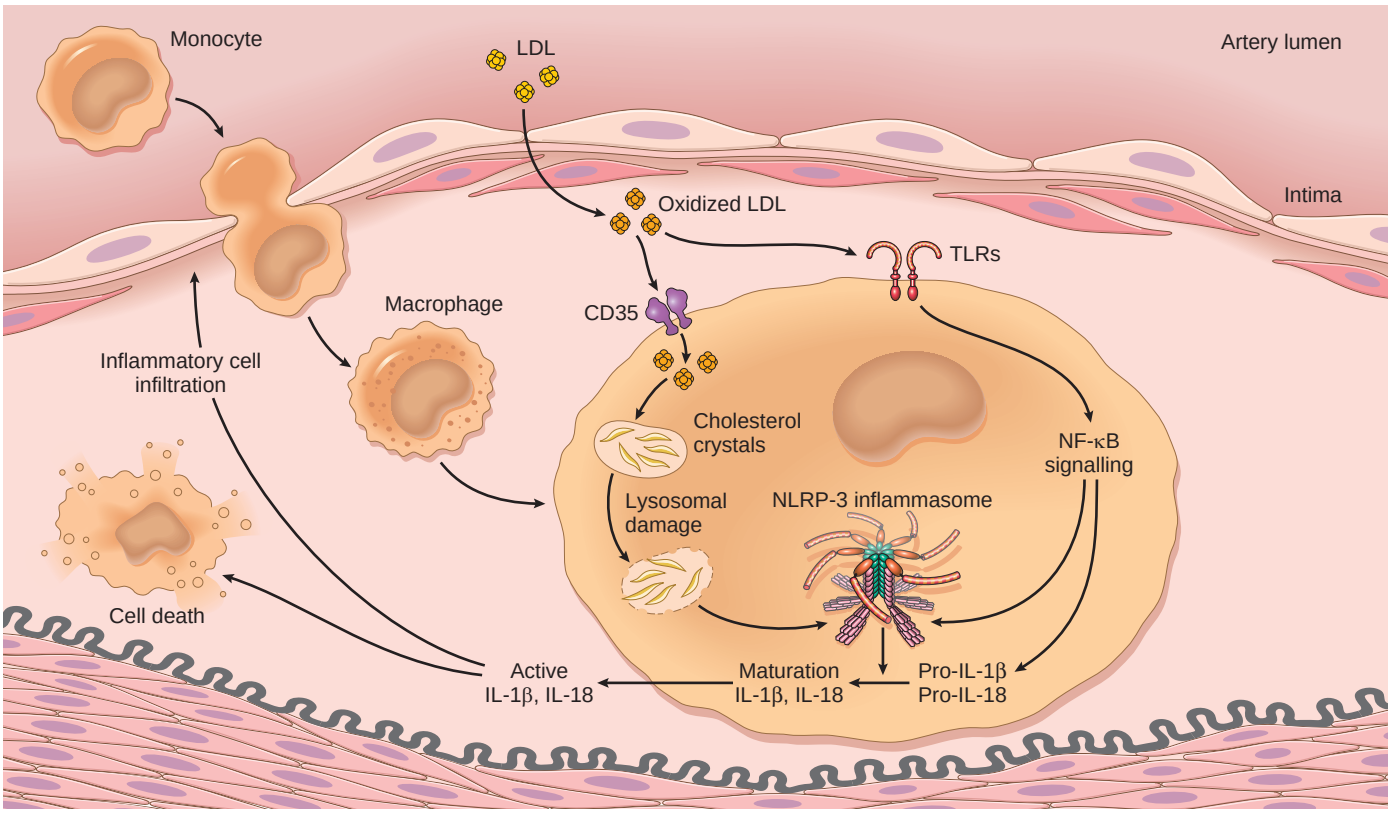

Figure 11.11 The role of cholesterol crystals in inflammasome activation and interleukin-1 production in atherosclerotic plaque. Oxidized low-density lipoprotein *(LDL)* leads to the activation of subendothelial macrophages through toll-like receptor *(TLR)* mediated initiation of downstream *NF-κB* transcription factor activation. The NF-κB complex then induces the production of a variety of proinflammatory mediators, including interleukin precursors and the components of the *NLRP3* inflammasome. Uptake of oxidized LDL and subsequent cholesterol crystallization results in assembly of the precursor components into an active inflammasome complex that proteolytically activates the pro-interleukin-1 beta *(IL-1β)* and interleukin-18 *(IL-18)* molecules. (Modified from Li X, Deroide N, Mallat Z: The role of the inflammasome in cardiovascular disease, *J Mol Med (Berl)* 92:307–319, 2014.)

Overview. Fig. 11.12 summarizes the major pathogenic pathways in atherogenesis, emphasizing the multifactorial nature of the disease. This schematic highlights the concept of atherosclerosis as a chronic inflammatory response—and ultimately an attempt at vascular "healing"—driven by a variety of insults including EC injury, lipid oxidation, lipid accumulation, and inflammation. Atheromas are dynamic lesions consisting of dysfunctional ECs, proliferating SMCs, and admixed T lymphocytes and macrophages. All four cell types are capable of liberating mediators that can influence atherogenesis. Thus at early stages, intimal plaques are little more than aggregates of SMCs, macrophages, and foam cells; death of these cells releases lipids and necrotic debris. With progression, the atheroma is modified by ECM synthesized by SMCs; connective tissue is particularly prominent on the intimal aspect forming a fibrous cap. Lesions typically retain a central core of lipid-laden cells and fatty debris that can become calcified. Although the intimal plaque can initially cause medial remodeling and outward expansion, the growing atherosclerotic plaque—with varying degrees of calcification depending on the nature of the surrounding matrix—eventually encroaches on the vessel lumen and compromises blood flow. The plaque can also compress the underlying media, leading to its degeneration, or can erode or rupture to expose thrombogenic factors resulting in thrombus formation and acute vascular occlusion.

MORPHOLOGY

Fatty streaks. Fatty streaks are composed primarily of lipid-filled foamy macrophages. Beginning as small flat yellow macules, these can eventually coalesce into elongated streaks 1 cm long or longer. The lesions are not particularly raised and do not cause any significant flow disturbance (Fig. 11.13). Although fatty streaks can evolve into plaques, not all are destined to become advanced lesions. Aortas of infants can exhibit fatty streaks, and such lesions are present in virtually all adolescents, even those without known risk factors. That coronary fatty streaks begin to form in adolescence at the same anatomic sites that later tend to develop plaques suggests a temporal evolution of these lesions.

Atherosclerotic plaque. The key processes in atherosclerosis are intimal thickening and lipid accumulation (see Figs. 11.7, 11.10, and 11.12). Atheromatous plaques are yellow-tan and are raised above the surrounding vessel wall; any superimposed thrombus over ulcerated plaques will be red-brown. Plaques vary in size but can coalesce to form larger masses (Fig. 11.14).

Atherosclerotic lesions are patchy and rarely circumferential, usually involving only a portion of any given arterial wall; on cross-section, the lesions therefore appear eccentric (Fig. 11.15A). The focality of atherosclerotic lesions—despite the uniform exposure of vessel walls to such factors as cigarette smoke toxins, elevated LDL, hyperglycemia, etc.—is attributable to the vagaries

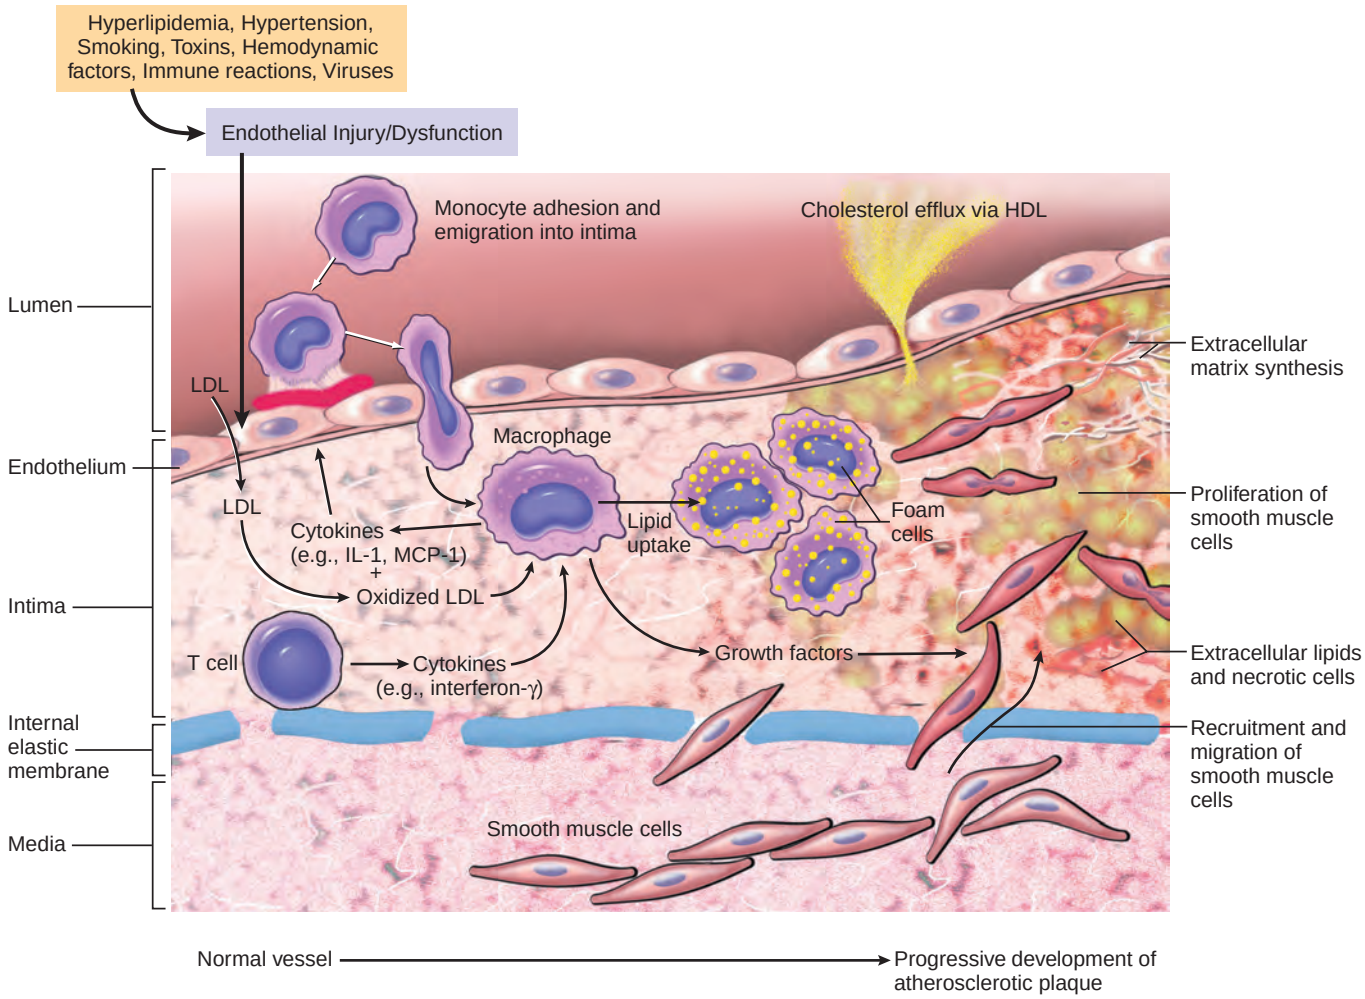

Figure 11.12 Sequence of cellular interactions in atherosclerosis. Hyperlipidemia, hyperglycemia, hypertension, and other influences cause endothelial dysfunction. This results in platelet and monocyte adhesion, with subsequent cytokine and growth factor release leading to smooth muscle cell migration and proliferation. Foam cells in atheromatous plaques derive from macrophages and smooth muscle cells that have accumulated modified lipids (e.g., oxidized and aggregated low-density lipoprotein *[LDL]*) via scavenger and LDL-receptor–related proteins. Extracellular lipid is derived from insudation from the vessel lumen, particularly in the presence of hypercholesterolemia, as well as from degenerating foam cells. Cholesterol accumulation in the plaque reflects an imbalance between influx and efflux; high-density lipoprotein *(HDL)* likely helps clear cholesterol from these accumulations. In response to the elaborated cytokines and chemokines, smooth muscle cells migrate to the intima, proliferate, and produce extracellular matrix including collagen and proteoglycans. *IL-1,* Interleukin-1; *MCP-1,* monocyte chemoattractant protein-1.

Cybulsky, MD, University of Toronto, Toronto, Ontario, Canada).

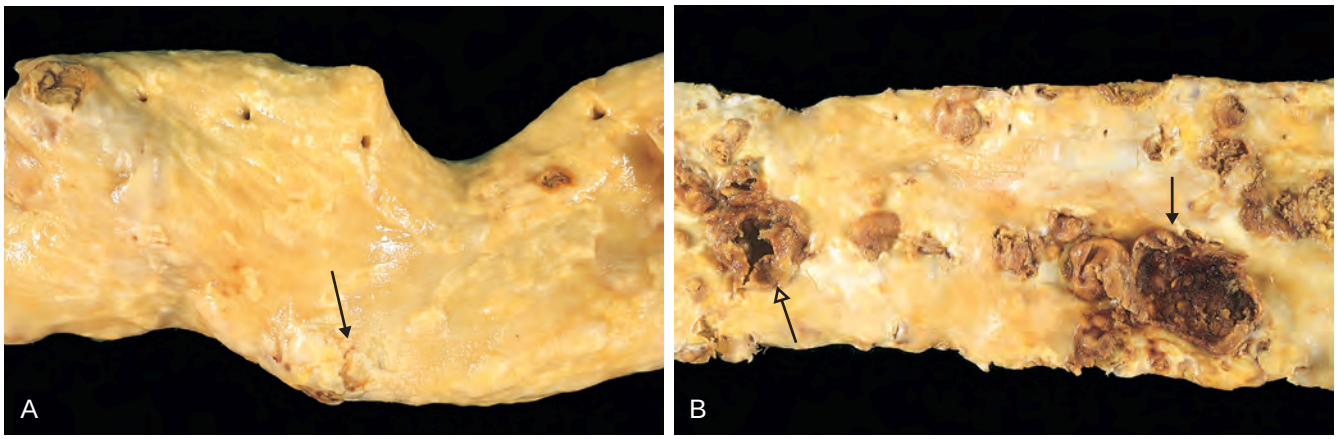

Figure 11.14 Gross views of atherosclerosis in the aorta. (A) Mild atherosclerosis composed of fibrous plaques, one of which is denoted by the *arrow.* (B) Severe disease with diffuse, complicated lesions including an ulcerated plaque *(open arrow)* and a lesion with overlying thrombus *(closed arrow)*.

of vascular hemodynamics. Local flow disturbances, such as nonlaminar flow (turbulence) at branch points, make certain portions of a vessel wall more susceptible to plaque formation. Although initially focal and sparsely distributed, atherosclerotic lesions tend to enlarge over time and become more numerous and broadly distributed. Moreover, in any given vessel, lesions at various stages often coexist.

In descending order, **the most extensively involved vessels are the lower abdominal aorta and iliac arteries, the coronary arteries, the popliteal arteries, the internal carotid arteries, and the vessels of the circle of Willis.** Vessels of the upper extremities are usually relatively spared, as are the mesenteric and renal arteries except at their ostia. Although most individuals tend to have a consistent degree of atherosclerotic burden in the affected vasculature, the severity of disease in one arterial distribution does not necessarily predict severity in another.

Atherosclerotic plaques have four principal components: (1) cells including variable numbers of SMCs, macrophages, and T lymphocytes; (2) ECM including collagen, elastic fibers, and proteoglycans; (3) intracellular and extracellular lipids; and (4) calcifications in later stage plaques (Fig. 11.15B and C). These components occur in varying proportions and configurations in different lesions. Typically, there is a superficial fibrous cap composed of SMCs and relatively dense collagen. Beneath and to the side of the cap (the "shoulder") is a more cellular area containing macrophages, T lymphocytes, and SMCs. Deep to the fibrous cap is a necrotic core containing lipid (primarily cholesterol and cholesterol esters), debris from dead cells, foam cells (lipid-laden macrophages and lipid-laden SMCs), fibrin, thrombus in varying degrees of organization, and other plasma proteins; the cholesterol content is frequently present as crystalline aggregates that are washed out during routine tissue processing

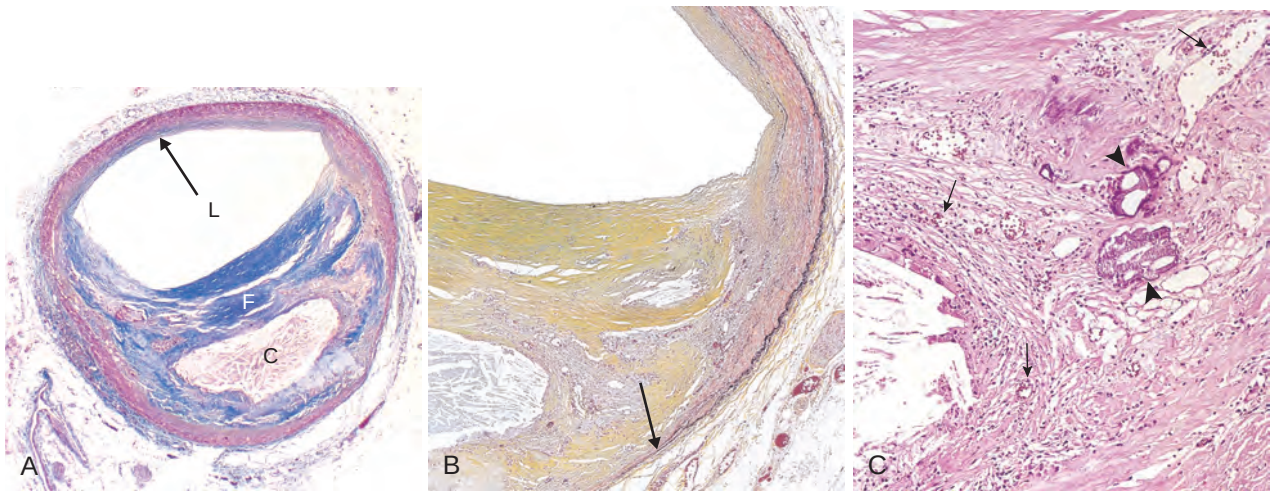

Figure 11.15 Histologic features of atheromatous plaque in the coronary artery. (A) Overall architecture demonstrating fibrous cap *(F)* and a central necrotic core *(C)* containing cholesterol and other lipids. The lumen *(L)* has been moderately compromised. Note that a segment of the wall is plaque-free *(arrow)*; the lesion is therefore "eccentric." In this section, collagen has been stained blue (Masson trichrome stain). (B) Higher power photograph of a section of the plaque shown in (A), stained for elastin (black), demonstrating that the internal and external elastic membranes are attenuated and the media of the artery is thinned under the most advanced plaque *(arrow)*. (C) Higher magnification photomicrograph at the junction of the fibrous cap and core showing scattered inflammatory cells, calcification *(arrowhead)*, and neovascularization *(small arrows)*.

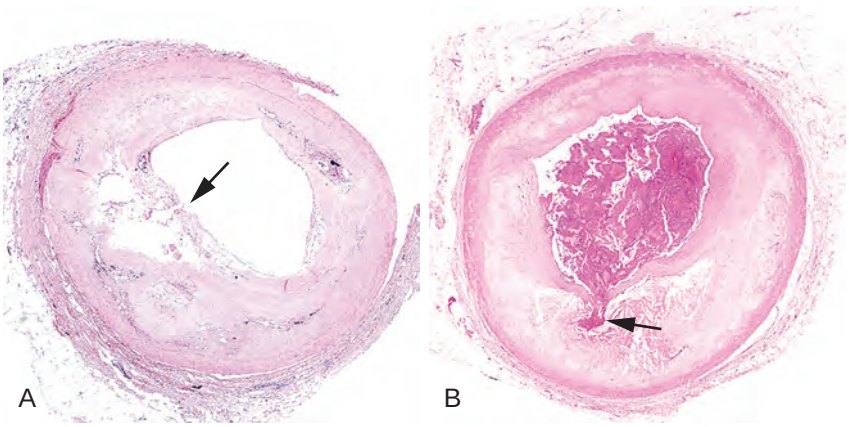

Figure 11.16 Atherosclerotic plaque rupture. (A) Plaque rupture without superimposed thrombus in a patient who died suddenly. (B) Acute coronary thrombosis superimposed on an atherosclerotic plaque with focal disruption of the fibrous cap, triggering fatal myocardial infarction. In both (A) and (B), an *arrow* points to the site of plaque rupture. (B, Reproduced from Schoen FJ: *Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles*, Philadelphia, 1989, WB Saunders, p 61.)

and leave behind only empty "clefts." The periphery of the lesions demonstrate **neovascularization** (proliferating small blood vessels) (Fig. 11.15C). Most atheromas contain abundant lipid, but some plaques ("fibrous plaques") are composed almost exclusively of SMCs and fibrous tissue, which can be heavily calcified.

Plaques generally continue to change and progressively enlarge as a consequence of cell death and degeneration, synthesis and degradation (remodeling) of ECM, organization of any superimposed thrombus, and secondary calcification of phospholipid or necrotic debris (see Fig. 11.15C).

Atherosclerotic plaques are susceptible to clinically important pathologic changes. As discussed further later, the thickness and ECM content of the overlying fibrous cap will impact the stability or fragility of the plaque and its tendency to undergo secondary changes.

- **Rupture, ulceration, or erosion** of the surface of atheromatous plaques exposes the blood stream to highly thrombogenic substances and leads to **thrombosis,** which can partially or completely occlude the vessel lumen (Fig. 11.16). If the patient survives, the thrombus may organize and become incorporated into the growing plaque.
- **Hemorrhage into a plaque.** Rupture of the overlying fibrous cap or of the thin-walled vessels in the areas of neovascularization can cause intraplaque hemorrhage; a contained hematoma may expand the plaque or induce plaque rupture.
- **Atheroembolism.** Plaque rupture can discharge atherosclerotic debris into the blood stream, producing microemboli.
- **Aneurysm formation.** Atherosclerosis-induced pressure or ischemic atrophy of the underlying media, with loss of elastic tissue, causes weakness and potential rupture.

Consequences of Atherosclerotic Disease

Myocardial infarction (heart attack), cerebral infarction (stroke), aortic aneurysms, and peripheral vascular disease (gangrene of the legs) are the major consequences of atherosclerosis. Large elastic arteries (e.g., aorta, carotid, and iliac arteries) and large- and medium-sized muscular arteries (e.g., coronary and popliteal arteries) are the major targets of atherosclerosis. Symptomatic atherosclerotic disease most often involves the arteries supplying the heart, brain, kidneys, and lower extremities. The natural history, principal morphologic features, and main pathogenic events are schematized in Fig. 11.17.

We next describe the features of atherosclerotic lesions that are typically responsible for the clinicopathologic manifestations.

Atherosclerotic Stenosis. In small arteries, atherosclerotic plaques can gradually occlude vessel lumens, compromising blood flow and causing ischemic injury. At early stages of stenosis, outward remodeling of the vessel media tends to preserve the size of the lumen. However, there are limits on the extent of remodeling, and eventually the expanding atheroma impinges on the lumen to such a degree that blood flow is compromised (see Fig. 11.17). *Critical stenosis* is the stage at which the occlusion is sufficiently severe to cause tissue ischemia. In the coronary (and other) circulations, this typically occurs when the occlusion produces a 70% to 75% decrease in luminal cross-sectional area; with this degree of stenosis, chest pain may develop with exertion (so-called *stable angina*; see Chapter 12). Although acute plaque rupture (see later) is the most dangerous consequence, atherosclerosis also takes a toll through chronically diminished arterial perfusion. Mesenteric occlusion and bowel ischemia, sudden cardiac death, chronic ischemic heart disease, ischemic encephalopathy, and intermittent claudication (diminished perfusion of the extremities) all are consequences of flow-limiting stenoses. The effects of vascular occlusion ultimately depend on arterial supply and the metabolic demand of the affected tissue. If stenosis occurs slowly, smaller adjacent vessels can partially compensate by enlarging and creating collateral circulation to perfuse the organ.

Acute Plaque Change. Plaque erosion or rupture is typically promptly followed by partial or complete vascular thrombosis (see Fig. 11.16), resulting in acute tissue infarction (e.g., myocardial or cerebral infarction) (see Fig. 11.17). Plaque changes fall into three general categories:

- *Rupture/fissuring,* exposing highly thrombogenic plaque constituents that activate coagulation and induce thrombosis that is often completely occlusive
- *Erosion/ulceration,* exposing the thrombogenic subendothelial basement membrane to blood, less-frequently inducing fully occlusive thrombosis
- *Hemorrhage into the atheroma,* expanding its volume

It is now recognized that the plaques that are responsible for myocardial infarction and other acute coronary

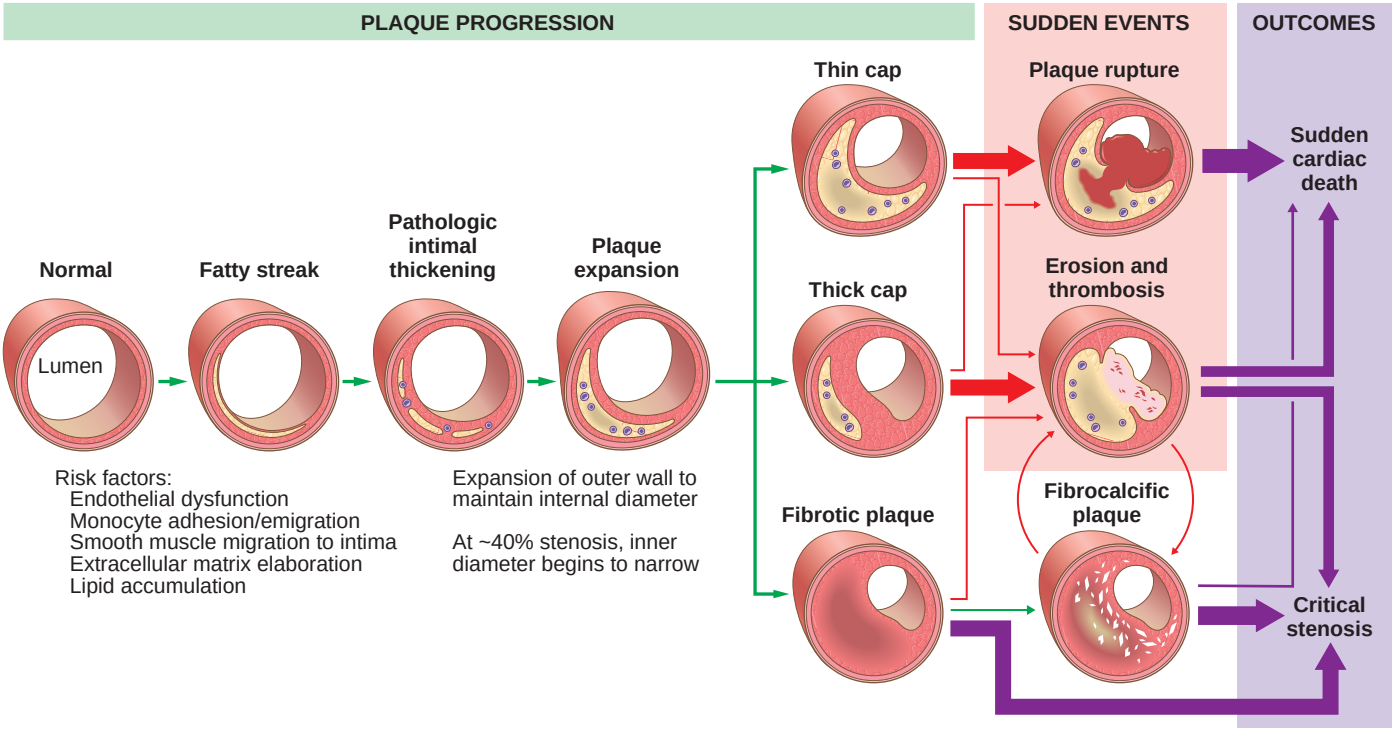

Figure 11.17 Atherosclerotic plaque formation, activities, and outcomes. In a lesion-prone area along with other risk factors, a reversible fatty streak is formed, which can progress to atherosclerosis. Compensatory enlargement initially prevents a reduction of blood flow through the vessel. A plaque can become a thin cap plaque (unstable, vulnerable), a thick cap plaque (stable), or a fibrotic plaque (stable). Thin cap plaques are the most prone to plaque rupture, generally leading to sudden cardiac death. Stable plaques can undergo surface erosion and thrombosis, rapidly expanding the plaque size and leading to more prominent calcifications. This event can lead to sudden cardiac death. Extensive narrowing of the luminal diameter from large plaques generally results in critical stenosis, reducing blood supply to the heart and resulting in angina.

syndromes are often asymptomatic before undergoing a sudden, typically unpredictable change. Thus pathologic and clinical studies show that the majority of plaques that undergo abrupt disruption and coronary occlusion previously showed only mild to moderate noncritical luminal stenosis. Thus a large number of asymptomatic adults may be at risk for a catastrophic coronary event. Although imaging modalities are being developed that could preemptively identify such lesions, it is clear that standard angiographic studies are woefully inadequate to visualize them until after the fact.

Plaques rupture when they are unable to withstand mechanical stresses generated by vascular shear forces. The events that trigger abrupt changes in plaques and subsequent thrombosis are complex and include both intrinsic factors (e.g., plaque structure and composition) and extrinsic elements (e.g., blood pressure, platelet reactivity, and vessel spasm).

The fibrous cap undergoes continuous remodeling that can stabilize the plaque or, conversely, render it more susceptible to rupture. Collagen is the major structural component of the fibrous cap and accounts for its mechanical strength and stability; the balance of collagen synthesis versus degradation affects cap integrity. Thus plaques with thin fibrous caps and active inflammatory cells over a necrotic core are more likely to rupture; these are referred to as "vulnerable plaques" (Fig. 11.18).

Collagen in atherosclerotic plaque is produced primarily by SMCs so that loss of these cells results in a less sturdy cap. Moreover, collagen turnover is controlled by metalloproteinases (MMPs), enzymes elaborated largely by macrophages and SMCs within the atheromatous plaque. Conversely, tissue inhibitors of metalloproteinases (TIMPs) produced by ECs, SMCs, and macrophages modulate MMP activity. In general, plaque inflammation results in a net increase in collagen degradation and reduced collagen synthesis, thereby destabilizing the mechanical integrity of

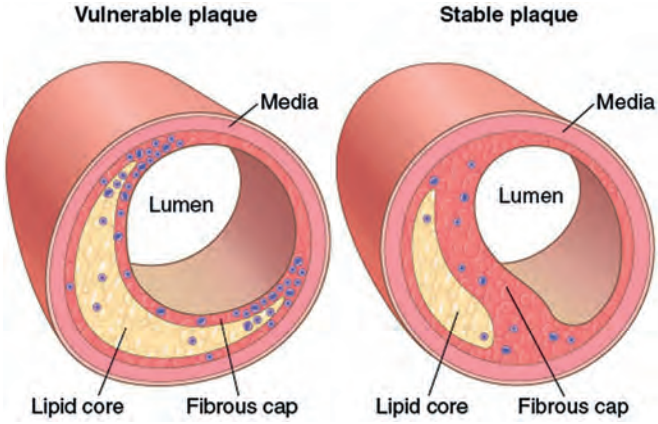

Figure 11.18 Vulnerable and stable atherosclerotic plaque. *Stable plaques* have thickened and densely collagenous fibrous caps with minimal inflammation and underlying atheromatous core. *Vulnerable plaques* have thin fibrous caps, large lipid cores, and increased inflammation. (Modified from Libby P: Molecular bases of the acute coronary syndromes, *Circulation* 91:2844, 1995.)

the fibrous cap (see later). The inflammation induced by cholesterol deposits themselves may contribute to plaque destabilization. Conversely, statins may have a beneficial therapeutic effect not only by reducing circulating cholesterol levels but also by stabilizing plaques through a reduction in plaque inflammation.

Influences extrinsic to plaques also contribute to acute plaque changes. Adrenergic stimulation can increase systemic blood pressure or induce local vasoconstriction, thereby increasing the physical stresses on a given plaque. Indeed, the adrenergic stimulation associated with awakening and rising can cause blood pressure spikes (followed by heightened platelet reactivity) that have been causally linked to the pronounced circadian periodicity for onset of acute myocardial infarction (peaking between 6 a.m. and 12 noon). Intense emotional stress can also contribute to plaque disruption; this is most dramatically illustrated by the uptick in the incidence of sudden death associated with natural or other disasters, such as earthquakes and the September 11, 2001, attack on the World Trade Center.

It is also important to note that not all plaque ruptures result in occlusive thromboses with catastrophic consequences. Indeed, plaque disruption and an ensuing superficial platelet aggregation and thrombosis are probably common, repetitive, and often clinically silent complications of atheroma. Healing of these subclinical plaque disruptions—and organization of their overlying thrombi—is an important mechanism in the growth of atherosclerotic lesions.

Thrombosis, partial or total, associated with a disrupted plaque is a central factor in acute coronary syndromes. In its most serious form, thrombus leads to total occlusion of the affected vessel. In contrast, in other coronary syndromes (Chapter 12), luminal obstruction by the thrombus is incomplete and may even wax and wane with time.

Mural thrombi in a coronary artery can also embolize. Small embolic fragments of thrombus can often be found in the distal intramyocardial circulation or in association with microinfarcts in patients with atherosclerosis who die suddenly. Thrombin and other factors associated with thrombosis are potent activators of SMCs and can thereby contribute to the growth of atherosclerotic lesions.

Vasoconstriction compromises lumen size and, by increasing the local mechanical forces, can potentiate plaque disruption. Vasoconstriction at sites of atheroma may be stimulated by (1) circulating adrenergic agonists, (2) locally released platelet contents, (3) EC dysfunction with impaired secretion of endothelial-derived relaxing factors (NO) relative to contracting factors (endothelin), and (4) mediators released from perivascular inflammatory cells.

KEY CONCEPTS

ATHEROSCLEROSIS

- Atherosclerosis is an intimal-based lesion composed of a fibrous cap and an atheromatous core; the constituents of the plaque include SMCs, ECM, inflammatory cells, calcifications, lipids, and necrotic debris.
- Atherogenesis is driven by an interplay of vessel wall injury and inflammation. The multiple risk factors for atherosclerosis all cause EC dysfunction and influence inflammatory cell and SMC recruitment and stimulation.
- Atherosclerotic plaques develop and generally grow slowly over decades. Stable plaques can produce symptoms related to chronic ischemia by narrowing vessel lumens, whereas unstable plaques can cause dramatic and potentially fatal ischemic complications related to acute plaque rupture, thrombosis, or embolization.
- Stable plaques tend to have a dense fibrous cap, minimal lipid accumulation and little inflammation, whereas "vulnerable" unstable plaques have thin caps, large lipid cores, and relatively dense inflammatory infiltrates.

ANEURYSMS AND DISSECTION

An aneurysm is a localized abnormal dilation of a blood vessel or the heart that may be congenital or acquired (Fig. 11.19). When an aneurysm involves all the layers of an intact (but attenuated) arterial wall or the thinned ventricular wall of the heart, it is called a true aneurysm. Atherosclerotic and congenital vascular aneurysms and ventricular aneurysms that follow transmural myocardial infarctions

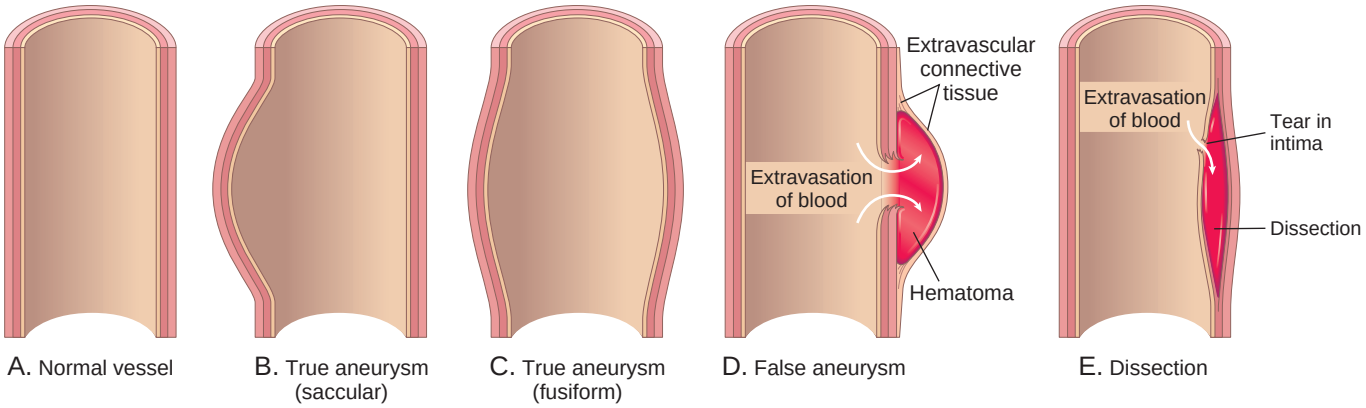

Figure 11.19 Aneurysms. (A) Normal vessel. (B) True aneurysm, saccular type. The wall focally bulges outward and may be attenuated but is otherwise intact. (C) True aneurysm, fusiform type. There is circumferential dilation of the vessel, without rupture. (D) False aneurysm. The wall is ruptured, and there is a collection of blood (hematoma) that is bounded externally by adherent extravascular tissues. (E) Dissection. Blood has entered *(dissected)* the wall of the vessel and separated the layers. Although this is shown as occurring through a tear in the lumen, dissections can also occur by rupture of the vessels of the *vasa vasorum* within the media.

are of this type. In contrast, a false aneurysm (also called a pseudoaneurysm) is a defect in the vascular wall leading to an extravascular hematoma that freely communicates with the intravascular space ("pulsating hematoma"). Examples include a ventricular rupture after myocardial infarction that is contained by a pericardial adhesion or a leak at the sutured junction of a vascular graft with a natural artery. An arterial dissection arises when blood enters a defect in the arterial wall and tunnels through medial or medial-adventitial planes. Dissections are often, but not always, aneurysmal (see later). Both true and false aneurysms as well as dissections can rupture, often with catastrophic consequences.

Descriptively, aneurysms are classified by macroscopic shape and size (see Fig. 11.19). *Saccular aneurysms* are essentially spherical outpouchings (involving only a portion of the vessel wall); in intracranial vessels they generally measure 2 to 20 mm; however, in the aorta they range from 5 to 10 cm in diameter and often contain thrombus. *Fusiform aneurysms* involve diffuse, circumferential dilation of a long vascular segment; they vary in diameter (in the aorta generally from 5 to 10 cm) and can involve extensive portions of the aortic arch, abdominal aorta, or even the iliacs. These types are not specific for any disease or clinical manifestations.

Pathogenesis

To maintain their structural and functional integrity, arterial walls constantly remodel by synthesizing, degrading, and repairing damage to their ECM constituents. Aneurysms can occur when the structure or function of the connective tissue within the vascular wall is compromised. Defects in synthesis or breakdown of connective tissue contribute to the pathobiology of both heritable aneurysmal diseases, as well as the common, sporadic forms of aneurysms. These defects include the following:

- *The intrinsic quality of the vascular wall connective tissue is poor.* Weak vessel walls due to defective type III collagen synthesis are a hallmark of the vascular form of *Ehlers-Danlos syndrome* (Chapter 5).
- *Abnormal transforming growth factor-β (TGF-β) signaling.* Excessive TGF-β activity alters vascular wall remodeling, primarily of the ascending aorta, leading ultimately to diminished ECM content and integrity with aneurysmal dilation. In *Marfan syndrome* (Chapter 5), defective synthesis of the scaffolding protein fibrillin leads to the inability to appropriately sequester endogenously produced TGF-β. In *Loeys-Dietz syndrome,* increased activity in the TGF-β signaling pathway can result from mutations in TGF-β receptors, an intracellular downstream signaling molecule in the TGF-β pathway (SMAD3), and even TGF-β3 itself. Aneurysms in patients with Loeys-Dietz syndrome can rupture at small sizes and are thus considered to follow an "aggressive" course.
- *The balance of collagen degradation and synthesis is altered by inflammation and associated proteases.* Inflammatory cells in the setting of an aortitis or associated with atherosclerosis can be found throughout the aortic wall. Increased MMP production, especially by macrophages, can contribute to aneurysm development by degrading ECM (elastin, collagens, proteoglycans, laminin, fibronectin) in all layers of the wall; decreased expression of TIMPs can also impact ECM degradation. Both processes result in a loss of elastic fibers necessary for recoil in diastole.

Genetic predisposition to aneurysm formation in the setting of inflammatory lesions (e.g., atherosclerosis) may be related to MMP and/or TIMP polymorphisms or to the nature of the local inflammatory response. Indeed, abdominal aortic aneurysms (AAAs) (see later) are associated with shifts in the local cytokine environments toward the production of T helper 2 cytokines (e.g., IL-4 and IL-10) that can drive macrophages to produce increased amounts of elastolytic MMP.

- *The vascular wall is weakened through loss of SMCs or the inappropriate synthesis of noncollagenous or nonelastic ECM.* Ischemia of the inner media occurs when there is atherosclerotic thickening of the intima, increasing the distance that oxygen and nutrients must diffuse. Systemic hypertension can also cause significant narrowing of arterioles of the vasa vasorum (e.g., in the aorta), which causes outer medial ischemia. Tertiary syphilis is another rare cause of aortic aneurysms in which obliterative endarteritis occurs in the vasa vasorum of the thoracic aorta; this engenders medial ischemia that leads to SMC loss, elastic fiber loss, and inadequate or inappropriate ECM synthesis.

All of the above-described processes lead to histopathologic changes in the arterial wall (referred to as medial degeneration) (Fig. 11.20). Although adventitial lymphoplasmacytic

Figure 11.20 Cystic medial degeneration. (A) Cross-section of aortic media from a patient with Marfan syndrome showing marked elastin fragmentation and formation of areas devoid of elastin that resemble cystic spaces but are actually filled with increased amounts of proteoglycans *(asterisks).* (B) Normal media for comparison showing the regular layered pattern of elastic tissue. In both (A) and (B), elastin is stained black.

inflammation can suggest syphilis, and clinical features (e.g., skeletal changes in Marfan syndrome) can suggest a potential genetic underpinning, medial degeneration is a nonspecific finding common to all forms of aortic disease.

The two most important causes of aortic aneurysms are atherosclerosis and hypertension; atherosclerosis is a greater factor in AAAs, while hypertension is the most common etiology associated with ascending aortic aneurysms. Other pathologies and risk factors that weaken vessel walls and lead to aneurysms include advanced age, smoking, trauma, vasculitis (see later), congenital defects (e.g., fibromuscular dysplasia and berry aneurysms typically in the circle of Willis; see Chapter 28), and infections (mycotic aneurysms). Mycotic aneurysms can originate from (1) embolization of a septic embolus, usually as a complication of infective endocarditis; (2) extension of an adjacent suppurative process; or (3) circulating organisms directly infecting the arterial wall.

Abdominal Aortic Aneurysm

Aneurysms occurring as a consequence of atherosclerosis form most commonly in the abdominal aorta and common iliac arteries. A variety of factors discussed earlier collaborate to weaken the media and predispose to aneurysm formation.

AAAs occur more frequently in men and in smokers, rarely developing before age 50. Atherosclerosis is a major cause of AAAs, but other factors clearly contribute, since the incidence is <5% in men older than age 60, despite almost universal abdominal aortic atherosclerosis in that population.

MORPHOLOGY

Usually located between the renal arteries and the bifurcation of the aorta, AAAs can be saccular or fusiform: greater than 3 cm, but often >5.5 cm, in diameter, and up to 25 cm in length (Fig. 11.21). There is severe complicated atherosclerosis with destruction and thinning of the underlying aortic media; the aneurysm frequently contains a bland, poorly organized mural thrombus. AAAs can occasionally affect the renal and superior or inferior mesenteric arteries, either by direct extension or by occluding vessel ostia with mural thrombi. Not infrequently, AAAs will be accompanied by smaller aneurysms of the iliac arteries.

Three AAA variants merit special mention:

- **Inflammatory AAAs** account for 5% to 10% of all AAAs; these typically occur in younger patients who often present with back pain and elevated inflammatory markers (e.g., erythrocyte sedimentation rate). Inflammatory aneurysms are characterized by abundant lymphoplasmacytic inflammation with many macrophages (and even giant cells) associated with dense periaortic scarring that can extend into the anterior retroperitoneum. The cause is a presumed localized immune response to the abdominal aortic wall; remarkably, most cases are not associated with inflammation of other arteries.
- A subset of inflammatory AAAs may be a vascular manifestation of **immunoglobulin G4–related disease (IgG4-RD).** This is a disorder marked by (in most cases) high circulating levels of IgG4, with storiform fibrosis and IgG4-positive infiltrating plasma cells in affected tissues. It may affect a host of organs including the pancreas and thyroid, as well as other vascular sites such as the ascending aorta and heart vessels. There may be retroperitoneal fibrosis with bilateral hydronephrosis. Recognition of this entity is important since it responds well to steroid and anti–B-cell therapies.
- **Mycotic AAAs** are lesions that have become infected by the lodging of circulating microorganisms in the wall. In such cases, suppuration further destroys the media, potentiating rapid dilation and rupture.

Clinical Features

Most cases of AAAs are completely asymptomatic and are discovered incidentally on physical examination as an abdominal mass (often palpably pulsating) that simulates a tumor. The other clinical manifestations of AAAs include:

- *Rupture* into the peritoneal cavity or retroperitoneal tissues with massive, potentially fatal hemorrhage
- *Obstruction* of a branch vessel resulting in downstream tissue ischemic injury; for example, iliac (leg), renal (kidney), mesenteric (gastrointestinal tract), or vertebral arteries (spinal cord)
- *Embolism* from atheroma or mural thrombus
- *Impingement* on an adjacent structure, for example, compression of a ureter or erosion of vertebrae

The risk of rupture is directly related to the size of the aneurysm, varying from nil for AAAs ≤4 cm in diameter to 1% per year for AAAs between 4 and 5 cm, 11% per year for AAAs between 5 and 6 cm, and 25% per year for aneurysms >6 cm. Most aneurysms expand at a rate of 0.2 to 0.3 cm/year, but 20% expand more rapidly. In general, aneurysms ≥5 cm are managed aggressively, either through

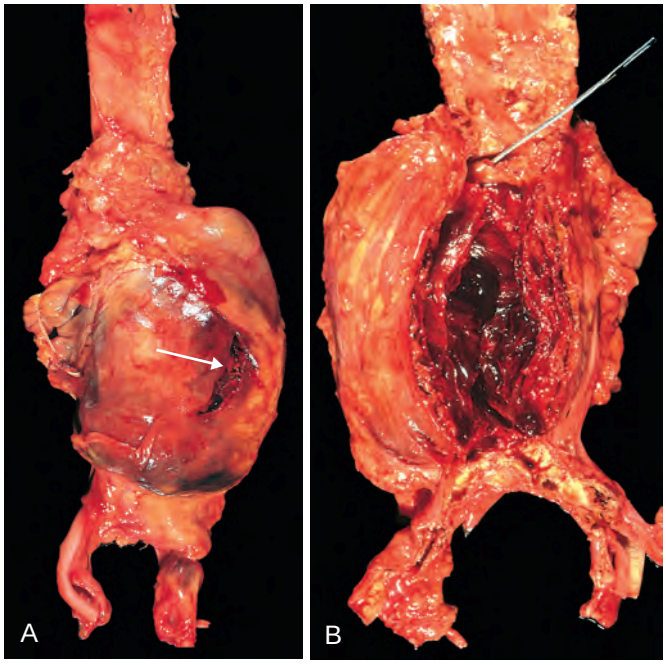

Figure 11.21 Abdominal aortic aneurysm. (A) External view, gross photograph of a large aortic aneurysm that ruptured (rupture site is indicated by the *arrow*). (B) Opened view, with the location of the rupture tract indicated by a probe. The wall of the aneurysm is exceedingly thin, and the lumen is filled by a large quantity of layered but largely unorganized thrombus.

open surgeries involving prosthetic grafts or endovascular approaches through the femoral artery deploying a stent graft (expandable wire frame covered by a cloth sleeve). Timely surgery is critical; operative mortality for unruptured aneurysms is approximately 5%, whereas emergency surgery after rupture carries a mortality rate of more than 50%. It is worth reiterating that because atherosclerosis is a systemic disease, a patient with an AAA is also very likely to have atherosclerosis in other vascular beds and is at a significantly increased risk of ischemic heart disease and stroke.

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms are most commonly associated with hypertension, although other causes such as Marfan syndrome, Loeys-Dietz syndrome, and inflammatory conditions (aortitis) are increasingly recognized. Before dissection or rupture, symptoms can include (1) chest pain from encroachment or erosion into bone, (2) myocardial ischemia from compression of a coronary artery, (3) difficulty swallowing due to compression of the esophagus, (4) hoarseness from irritation of or pressure on the recurrent laryngeal nerves, or (5) respiratory complications from compression of the bronchi; the vast majority cause no symptoms at all until a catastrophic event occurs (see later).

Aortic Dissection

Aortic dissection occurs when blood separates the laminar planes of the media to form a blood-filled channel within the aortic wall (Fig. 11.22). Aortic dissection is generally associated with aortic dilation; it can be disastrous if the dissection then ruptures through the adventitia and hemorrhages into adjacent spaces.

Aortic dissection occurs principally in two groups of patients: (1) men aged 40 to 60 years, with antecedent hypertension (more than 90% of cases) and (2) younger patients with syndromic diseases affecting the aorta (e.g., Marfan syndrome). Dissections can be iatrogenic (e.g., following arterial cannulations during diagnostic catheterization or cardiopulmonary bypass). Pregnancy is also rarely associated with aortic (or other vessel) dissection (roughly 10 to 20 cases per 1 million births), typically occurring during or after the third trimester. It may be related to hormonally induced vascular remodeling and the hemodynamic stresses of the perinatal period. Dissection is unusual in the presence of substantial atherosclerosis or other cause of medial scarring, such as syphilis, presumably because the medial fibrosis inhibits propagation of the dissecting hematoma.

Pathogenesis

Hypertension is the major risk factor for aortic dissection. Aortas of hypertensive patients have medial degenerative changes with SMC loss and altered ECM content. Other dissections occur in the setting of inherited or acquired connective tissue disorders with defective TGF-β signaling or defective ECM synthesis or degradation. However, specific patterns of medial damage are neither a prerequisite for dissection nor a reliable predictor of its occurrence. Regardless of the underlying etiology, the ultimate trigger for the intimal tear and initial intramural aortic hemorrhage is not known in most cases. Nevertheless, once the tear has occurred, blood flow under systemic pressure dissects through the media leading to progression of the hematoma. Accordingly, aggressive pressure-reducing therapy may be effective in limiting an evolving dissection. In some cases, disruption of penetrating vessels of the vasa vasorum can give rise to an intramural hematoma without an intimal tear.

MORPHOLOGY

In most cases of dissection, medial degeneration is present at the site of tear but may not be seen in the area of propagation. These typically feature elastic fiber fragmentation and loss, mucoid ECM accumulation, and SMC attrition (see Fig. 11.20); inflammation is characteristically absent. Dissections can occur in the setting of rather trivial medial degeneration; conversely, marked degenerative changes are frequently seen at autopsies of patients who are completely free from dissection. Thus the relationship of the structural changes to the pathogenesis of dissection is uncertain.

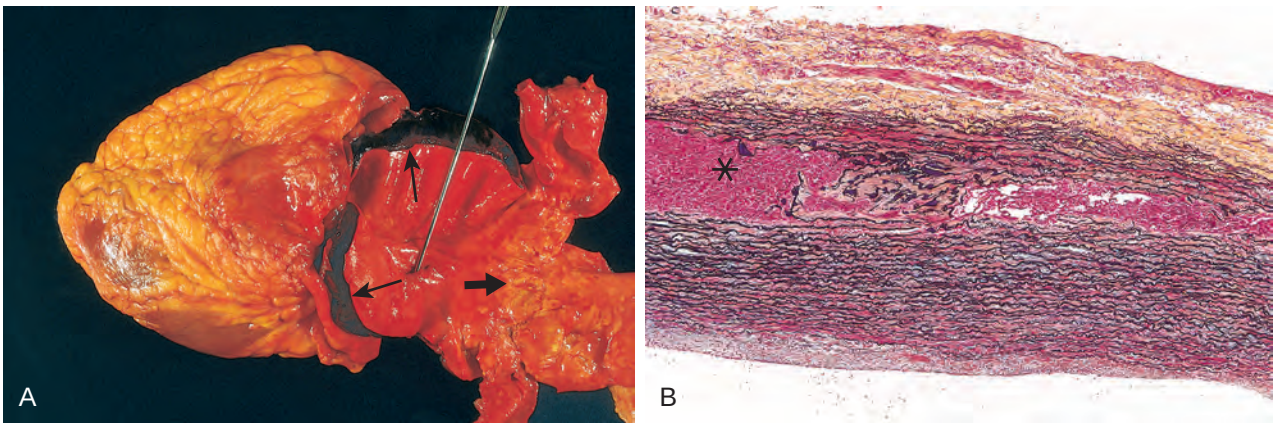

Figure 11.22 Aortic dissection. (A) Gross photograph of an opened aorta with proximal dissection originating from a small, oblique intimal tear *(probe)*, allowing blood to enter the media and creating a retrograde intramural hematoma *(thin arrows)*. Note that the intimal tear has occurred in a region largely free of atherosclerotic plaque and that propagation of the intramural hematoma distally is arrested where atherosclerosis begins *(thick arrow)*. (B) Histologic view of dissection demonstrating an aortic intramural hematoma *(asterisk)*. Aortic elastic layers are black and blood is red (Movat stain).

An aortic dissection usually initiates with an intimal tear. In the vast majority of spontaneous dissections, the tear occurs in the ascending aorta, usually within 10 cm of the aortic valve (see Fig. 11.22A). Such tears are typically transverse with sharp, jagged edges up to 1 to 5 cm in length. The dissection can extend retrograde toward the heart as well as distally, sometimes as far as the iliac and femoral arteries. The dissecting hematoma spreads characteristically between lamellar units of the outer third of the media or between media and adventitial layers (see Fig. 11.22B). It can rupture through the adventitia causing massive hemorrhage (e.g., into the thoracic or abdominal cavities) or cardiac tamponade (hemorrhage into the pericardial sac). In some (fortuitous) instances, the dissecting hematoma reenters the lumen of the aorta through a second distal intimal tear, creating a new false vascular channel ("double-barreled aorta"). This averts a fatal extraaortic hemorrhage, and over time, such false channels can be endothelialized to become recognizable **chronic dissections.**

Traumatic chest injury (e.g., motor vehicle accident, or even extremely vigorous cardiopulmonary resuscitation) can cause intimal tears that originate after the origin of arch vessels at the *ligamentum arteriosum.* In such cases the connective tissue that tethers the aorta and pulmonary vessels in that location can lead to aortic tearing when there is sudden extreme movement of the heart toward the anterior chest wall.

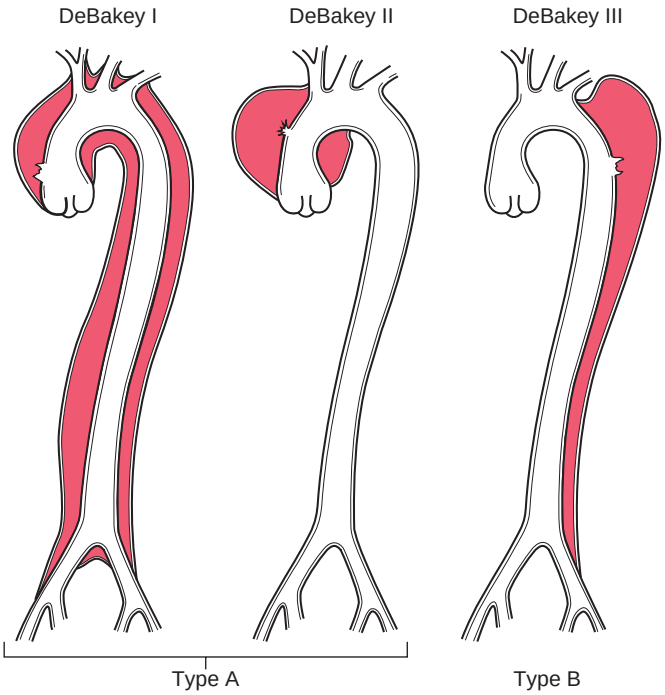

Figure 11.23 Classification of dissections. *Type A* (proximal) involves the ascending aorta, either as part of a more extensive dissection (DeBakey I) or in isolation (Debakey II). *Type B* (distal or Debakey III) dissections arise after the take-off of the great vessels. Type A dissections typically have the most serious complications and greatest mortality.

Clinical Features

The morbidity and mortality associated with dissections depends on which part of the aorta is involved; the most serious complications occur with dissections between the aortic valve and the distal arch. Accordingly, aortic dissections are generally classified into two types (Fig. 11.23):

- *Type A dissections.* These are the more common (and dangerous) *proximal* lesions involving either both the ascending and the descending aorta or the ascending aorta only (types I and II of the DeBakey classification).
- *Type B dissections.* Distal lesions not involving the ascending aorta and usually beginning distal to the subclavian artery (called DeBakey type III).

The classic clinical symptoms of aortic dissection are the sudden onset of excruciating pain, usually beginning in the anterior chest, radiating to the back between the scapulae, and moving downward as the dissection progresses; the pain can be confused with that of myocardial infarction.

The most common cause of death is rupture of the dissection and bleeding into the pericardial, pleural, or peritoneal cavities. Retrograde dissection into the aortic root can also disrupt the aortic valve annulus. Common clinical manifestations include cardiac tamponade and aortic insufficiency. Dissections can also extend into the great arteries of the neck or into the coronary, renal, mesenteric, or iliac arteries, causing vascular obstruction and ischemic consequences such as myocardial infarction; involvement of spinal arteries can cause transverse myelitis.

In type A dissections, rapid diagnosis and institution of intensive antihypertensive therapy coupled with surgical plication of the aortic tear can save 65% to 85% of patients. However, mortality approaches 70% in those who present with hemorrhage or symptoms related to distal ischemia, and the overall 10-year survival is 40% to 88% depending on whether a patient is a surgical candidate and other prognostic factors. Most type B dissections can be managed conservatively; such patients have a short-term 75% survival rate whether they are treated with surgery or antihypertensive medication only.

KEY CONCEPTS

ANEURYSMS AND DISSECTIONS

- Vascular aneurysms are congenital or acquired dilations of the blood vessels that involve the entire thickness of the wall. Complications are related to rupture, thrombosis, and embolization.
- Dissections occur when blood enters the wall of a vessel and dissects through the layers generally between lamellar units. Complications arise due to rupture or obstruction of vessels branching off the aorta.
- Aneurysms and dissections result from structural weakness of the vessel wall caused by aberrant TGF-β signaling, loss of SMCs, and changes in the ECM, which can result from ischemia, genetic defects, or defective matrix remodeling.

VASCULITIS

***Vasculitis* is a general term for vessel wall inflammation with protean manifestations depending on the vascular bed affected** (e.g., central nervous system vs. heart vs. small bowel). Besides the findings referable to the specific tissues involved, the clinical manifestations typically include constitutional signs and symptoms associated with systemic inflammation, such as fever, myalgias, arthralgias, and malaise.

Table 11.4 Primary Forms of Vasculitis

[a]The granulomas of giant cell arteritis are found within the vessel wall as part of the inflammation comprising the vasculitis but need not be present to render the diagnosis. The granulomas of granulomatosis with polyangiitis are larger, spanning between vessels, and associated with areas of tissue necrosis.

ANCA, Antineutrophil cytoplasmic antibody.

From Seidman MA, Mitchell RN: Surgical pathology of small- and medium-sized vessels, *Surg Pathol Clin* 5:435, 2012.

Vessels of any type in virtually any organ can be affected; most vasculitides affect small vessels ranging from arterioles to capillaries to venules. Nevertheless, several vasculitides tend to affect only vessels of a particular size or location. Thus there are entities that primarily affect the aorta and medium-sized arteries, while others principally affect only smaller arterioles. Some 20 primary forms of vasculitis are recognized, and classification schemes attempt (with variable success) to group them according to vessel diameter, role of immune complexes, presence of specific autoantibodies, granuloma formation, organ specificity, and even population demographics (Table 11.4 and Fig. 11.24). As we will see, there is considerable clinical and pathologic overlap among many of them.

The two pathogenic mechanisms of vasculitis are immune-mediated inflammation and direct invasion of vascular walls by infectious pathogens. Infections can also indirectly induce a noninfectious vasculitis, for example, by generating immune complexes or triggering vascular cross-reactivity. In any given patient, it is critical to distinguish between infectious and immunologic mechanisms because immunosuppressive therapy is appropriate for immune-mediated vasculitis but could very well be counterproductive for infectious vasculitides. Physical and chemical injury (e.g., from irradiation, mechanical trauma, and toxins) can also cause vasculitis.

Noninfectious Vasculitis

The main immunologic mechanisms underlying noninfectious vasculitis are:

- *Immune complex deposition*
- *Antineutrophil cytoplasmic antibodies (ANCAs)*
- *Anti-EC antibodies*
- *Autoreactive T cells*

Immune Complex–Associated Vasculitis

This form of vasculitis can be seen in immunologic disorders such as systemic lupus erythematosus (SLE) (Chapter 6) that are associated with autoantibody production. The vascular lesions resemble those found in experimental immune complex–mediated disorders such as the Arthus phenomenon and serum sickness and in many cases contain readily identifiable antibody and complement. Often, however, this type of vasculitis presents a number of diagnostic challenges. Only rarely is the specific antigen responsible for immune complex formation identified. While immune complexes can occasionally be detected in the blood, in most cases it is not clear whether the pathogenic antigen-antibody complexes are deposited from the circulation or form in situ. Indeed, the sensitivity and specificity of circulating immune complex assays in such diseases are extremely low. In many suspected cases, even the antigen-antibody

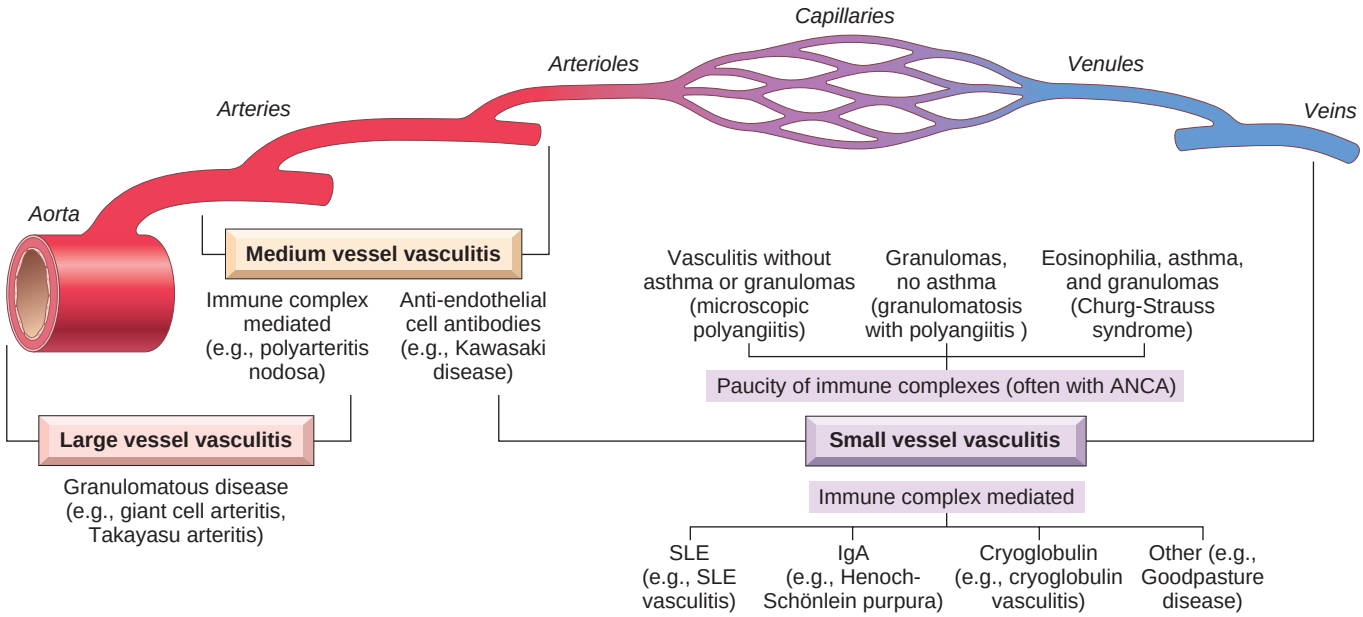

Figure 11.24 Vascular sites typically involved with the more common forms of vasculitis as well as their presumptive etiologies. Note that there is a substantial overlap in distributions. *ANCA*, Antineutrophil cytoplasmic antibody; *SLE*, systemic lupus erythematosus.

deposits are scarce. In such instances the immune complexes have putatively been degraded by the time of biopsy; alternatively, other underlying mechanisms need to be considered for such "pauci-immune" vasculitides.

Immune complex deposition is implicated in the following vasculitides:

- *Drug hypersensitivity vasculitis*. In some cases (e.g., penicillin), drugs act as haptens by binding to serum proteins; other agents are themselves foreign proteins (e.g., streptokinase). Regardless, antibodies directed against the drug-modified proteins or foreign molecules result in immune complex formation. The clinical manifestations can be mild and self-limiting or severe and even fatal; skin lesions are most common. It is always important to consider drug hypersensitivity as a cause of vasculitis since discontinuation of the offending agent usually leads to resolution.
- *Vasculitis secondary to infections*. Antibodies to microbial constituents can form immune complexes that circulate and deposit in vascular lesions. In up to 30% of patients with polyarteritis nodosa (see later), the vasculitis is attributable to immune complexes composed of hepatitis B surface antigen (HBsAg) and anti-HBsAg antibody.

Antineutrophil Cytoplasmic Antibodies

Many patients with vasculitis have circulating antibodies that react with neutrophil cytoplasmic antigens—*ANCAs*. ANCAs are a heterogeneous group of autoantibodies directed against constituents (mainly enzymes) of neutrophil primary granules, monocyte lysosomes, and ECs. ANCAs are very useful diagnostic markers; their titers generally mirror clinical severity, and a rise in titers after periods of quiescence is predictive of disease recurrence. Although a number of ANCAs have been described, two are most important. These were previously grouped according to the intracellular distribution of the target antigens (cytoplasmic [c-ANCA] or perinuclear [p-ANCA]), but are now classified according to their antigen specificity.

- *Anti-proteinase-3 (PR3-ANCA, previously c-ANCA)*. Proteinase-3 (PR3) is a neutrophil azurophilic granule constituent that shares homology with numerous microbial peptides, possibly explaining the generation of PR3-ANCAs. PR3-ANCAs are associated with granulomatosis with polyangiitis (see later).
- *Anti-myeloperoxidase (MPO-ANCA, previously p-ANCA)*. Myeloperoxidase (MPO) is a lysosomal granule constituent involved in oxygen free radical generation (Chapter 3). MPO-ANCAs are induced by several therapeutic agents, particularly propylthiouracil (used to treat hyperthyroidism). MPO-ANCAs are associated with microscopic polyangiitis and Churg-Strauss syndrome (see later).

The close association between ANCA titers and disease activity also suggests a pathogenic role for these antibodies. Of note, ANCAs can directly activate neutrophils, stimulating the release of reactive oxygen species and proteolytic enzymes; in vascular beds, such activation also leads to destructive interactions between inflammatory cells and ECs. While the antigenic targets of ANCA are primarily intracellular (and therefore not usually accessible to circulating antibodies), it is now clear that ANCA antigens (especially PR3) are either constitutively expressed at low levels on the plasma membrane or are translocated to the cell surface in activated and apoptotic leukocytes.

A plausible mechanism for ANCA vasculitis is the following.

- Drugs or cross-reactive microbial antigens induce ANCA formation; alternatively, leukocyte surface expression or release of PR3 and MPO (in the setting of infections) incites ANCA development in a susceptible host.
- Subsequent infection, endotoxin exposure, or inflammatory stimulus elicits cytokines such as tumor necrosis

factor [TNF] that upregulate the surface expression of PR3 and MPO on neutrophils and other cell types.
- ANCAs react with these cytokine-activated cells, causing either direct injury (e.g., to ECs) or further activation (e.g., of neutrophils).
- ANCA-activated neutrophils cause tissue injury by releasing granule contents and reactive oxygen species.

Since the ANCA autoantibodies are directed against cellular constituents and do not form circulating immune complexes, the vascular lesions do not typically contain demonstrable antibody and complement. Thus ANCA-associated vasculitides are often described as pauci-immune.

Anti–Endothelial Cell Antibodies

Antibodies to ECs, perhaps induced by defects in immune regulation, may predispose to certain vasculitides, for example, Kawasaki disease (see later).

We will now briefly present several of the best-characterized and generally recognized vasculitides, reemphasizing that there is substantial overlap among the different entities. Moreover, it should be kept in mind that some patients with vasculitis do not have a classic constellation of findings that allows them to be neatly pigeon-holed into one specific diagnosis.

Giant Cell (Temporal) Arteritis

Giant cell (temporal) arteritis is a chronic, classically granulomatous inflammation of large- to small-sized arteries that principally affects arteries in the head. It is the most common form of vasculitis among elderly adults in the United States and Europe. The temporal arteries are not particularly vulnerable, but their name is attached to the disorder since they are the most readily biopsied in making the diagnosis. Vertebral and ophthalmic arteries, as well as the aorta *(giant cell aortitis)*, also can be involved. Because ophthalmic artery involvement can lead to sudden and permanent blindness, affected persons must be diagnosed and treated promptly.

Pathogenesis

Giant cell arteritis likely occurs as a result of a T cell–mediated immune response to an as yet uncharacterized vessel wall antigen. Proinflammatory cytokines (especially TNF) and anti-EC antibodies also contribute. The characteristic granulomatous inflammation, an association with certain major histocompatibility complex (MHC) class II haplotypes, and the excellent therapeutic response to steroids all strongly support an immune etiology. The predilection for vessels of the head remains unexplained, although one hypothesis is that vessels in various parts of the body develop from distinct anlagen and may therefore express unique antigens.

MORPHOLOGY

Involved arterial segments develop **intimal thickening** (with occasional thromboses) **that reduces the luminal diameter.** Classic lesions exhibit medial **granulomatous inflammation** centered on the internal elastic membrane with **elastic lamina fragmentation;** there is an infiltrate of T cells (CD4+ > CD8+) and macrophages. Although multinucleated giant cells are seen in approximately 75% of adequately biopsied specimens (Fig. 11.25), granulomas and giant cells can be rare or absent. Inflammatory

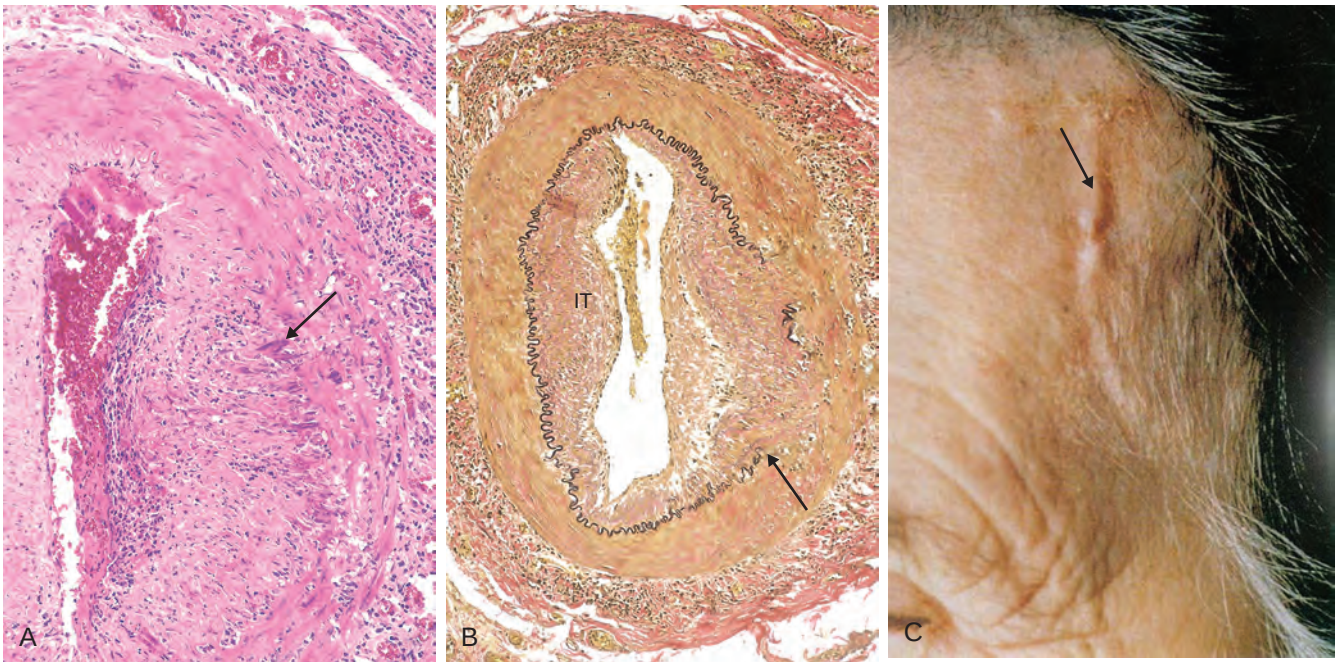

Figure 11.25 Giant cell (temporal) arteritis. (A) Hematoxylin-and-eosin stain of section of temporal artery showing giant cells at the degenerated internal elastic membrane in active arteritis *(arrow)*. (B) Elastic tissue stain demonstrating focal destruction of internal elastic membrane *(arrow)* and intimal thickening *(IT)* characteristic of long-standing or healed arteritis. (C) The temporal artery of a patient with classic giant cell arteritis shows a thickened, nodular, and tender segment of a vessel on the surface of head *(arrow)*. (C, From Salvarani C, et al. Polymyalgia rheumatica and giant-cell arteritis, *N Engl J Med* 347:261, 2002.)

lesions are only focally distributed along the vessel, and segments of relatively normal artery may be interposed. The healed stage is marked by medial attenuation and scarring with intimal thickening, fragmentation of greater than 30% of the circumference of the internal elastic lamina, and adventitial fibrosis.

Clinical Features

Temporal arteritis is rare before age 50. Symptoms may be only vague and constitutional—fever, fatigue, weight loss—or may involve facial pain or headache, most intense along the course of the superficial temporal artery, which can be painful to palpation. Ocular symptoms (associated with involvement of the ophthalmic artery) abruptly appear in about 50% of patients; these range from diplopia to complete vision loss. Diagnosis depends on biopsy and histologic confirmation. However, because giant cell arteritis can be extremely focal within an artery, adequate biopsy requires at least a 1-cm segment; even then, a negative biopsy result does not exclude the diagnosis. Corticosteroids or anti-TNF therapies are typically effective.

Takayasu Arteritis

Takayasu arteritis is a granulomatous vasculitis of medium and larger arteries characterized principally by ocular disturbances and marked weakening of the pulses in the upper extremities (hence the name *pulseless disease*). Takayasu arteritis manifests with transmural fibrous thickening of the aorta—particularly the aortic arch and great vessels—with severe luminal narrowing of the major branch vessels (Fig. 11.26). Takayasu aortitis shares many attributes with giant cell aortitis, including clinical features and histology; indeed, the distinction is typically made based on the age of the patient. Those over 50 years of age are designated as giant cell aortitis, while those under 50 are designated as Takayasu aortitis. Although traditionally associated with the Japanese population and a subset of human leukocyte antigen haplotypes, Takayasu aortitis has a global distribution. An autoimmune etiology is likely.

MORPHOLOGY

Takayasu arteritis classically involves the aortic arch. In a third of patients, it also affects the remainder of the aorta and its branches, with **pulmonary artery** involvement in half of cases; **coronary and renal arteries** may be similarly affected. There is irregular thickening of the vessel wall with intimal hyperplasia; when the aortic arch is involved, the great vessel lumens can be markedly narrowed or even obliterated (Fig. 11.26A and B). Such narrowing explains the weakness of the peripheral pulses. Histologically the changes range from adventitial mononuclear infiltrates with perivascular cuffing of the vasa vasorum to intense mononuclear inflammation in the media. Granulomatous inflammation, replete with giant cells and patchy medial necrosis, is also seen. The histology (Fig. 11.26C) is essentially indistinguishable from giant cell (temporal) arteritis. As the disease progresses, collagenous scarring, with admixed chronic inflammatory infiltrates, occurs in all three layers of the vessel wall. Occasionally, aortic root involvement causes dilation and aortic valve insufficiency.

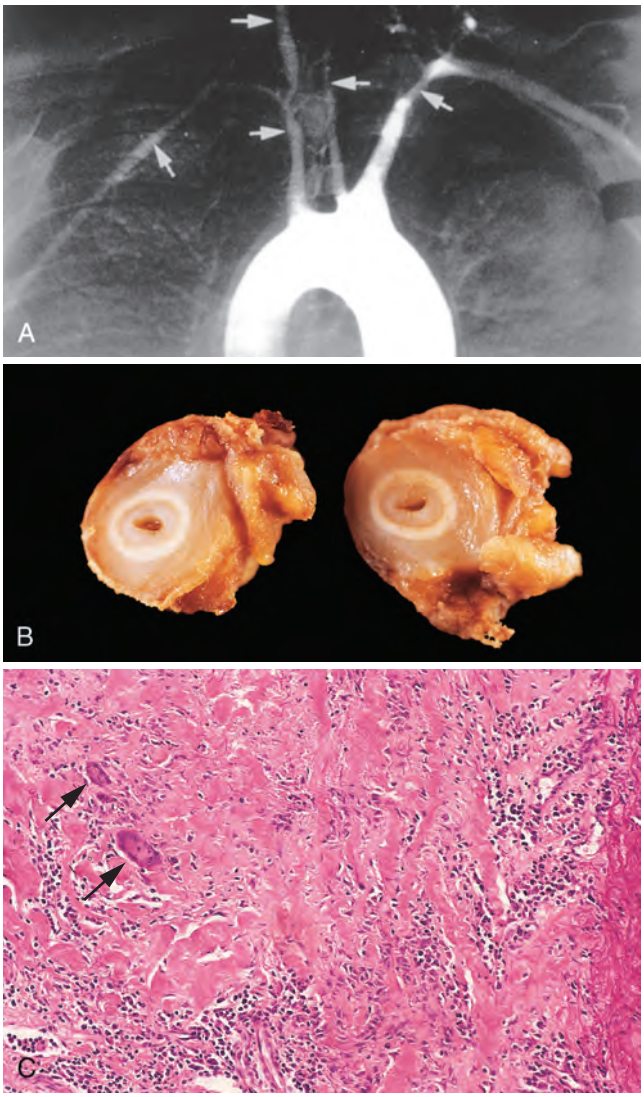

Figure 11.26 Takayasu arteritis. (A) Aortic arch angiogram showing narrowing of brachiocephalic, carotid, and subclavian arteries *(arrows)*. (B) Gross photograph of two cross-sections of the right carotid artery taken at autopsy of the patient shown in (A) demonstrating marked intimal thickening and adventitial fibrosis with minimal residual lumen. (C) Histologic appearance in active Takayasu aortitis illustrating destruction and fibrosis of the arterial media associated with mononuclear infiltrates and inflammatory giant cells *(arrows)*.

Clinical Features

Initial symptoms are usually nonspecific, including fatigue, weight loss, and fever. With progression, vascular symptoms appear and dominate the clinical picture, including reduced blood pressure and weaker pulses in the upper extremities; ocular disturbances, including visual defects, retinal hemorrhages, and total blindness; and neurologic deficits. Involvement of the more distal aorta may lead to claudication of the legs; pulmonary artery involvement can cause pulmonary hypertension. Narrowing of the coronary ostia may lead to myocardial infarction, and involvement of the renal arteries leads to systemic hypertension in roughly half of patients. The course of the disease is variable. In some patients there is rapid progression, while others enter a quiescent stage at 1 to 2 years, permitting long-term survival, albeit with visual or neurologic deficits.

Polyarteritis Nodosa (PAN)

PAN is a systemic vasculitis of small- or medium-sized muscular arteries that typically affects renal and visceral vessels but spares the pulmonary circulation. There is no association with ANCAs, but a third of patients with PAN have chronic hepatitis B, which leads to the formation of HBsAg-HbsAb complexes that deposit in affected vessels. The cause remains unknown in the majority of cases. Clinical manifestations result from ischemia and infarction of affected tissues and organs.

MORPHOLOGY

PAN is associated with segmental transmural necrotizing inflammation of small- to medium-sized arteries, often with superimposed aneurysms and/or thrombosis. Kidney, heart, liver, and gastrointestinal tract vessels are involved in descending order of frequency. Lesions usually involve only part of the vessel circumference with a predilection for branch points. Impaired perfusion of parenchyma distal to the lesions results in ulcerations, infarcts, ischemic atrophy, or hemorrhage.

During the acute phase, there is transmural inflammation of the arterial wall with a mixed infiltrate of neutrophils, eosinophils, and mononuclear cells, frequently accompanied by **fibrinoid necrosis and luminal thrombosis** (Fig. 11.27). Older lesions show fibrous thickening of the vessel wall extending into the adventitia. Characteristically, all stages of activity (from early to late) coexist in different vessels or even within the same vessel, suggesting ongoing injury.

Clinical Features

PAN is primarily a disease of young adults but can occur in all age groups. The course is frequently remitting and episodic, with long symptom-free intervals. Because the vascular involvement is widely scattered, the clinical signs and symptoms of PAN can be quite variable. Typical presentation involves some combination of rapidly accelerating hypertension due to renal artery involvement; abdominal pain and bloody stools caused by vascular gastrointestinal lesions; diffuse myalgias; and peripheral neuritis, predominantly affecting motor nerves. Renal involvement is often a major cause of mortality. Untreated, PAN is typically fatal; however, immunosuppression can yield remissions or cure in 90% of cases.

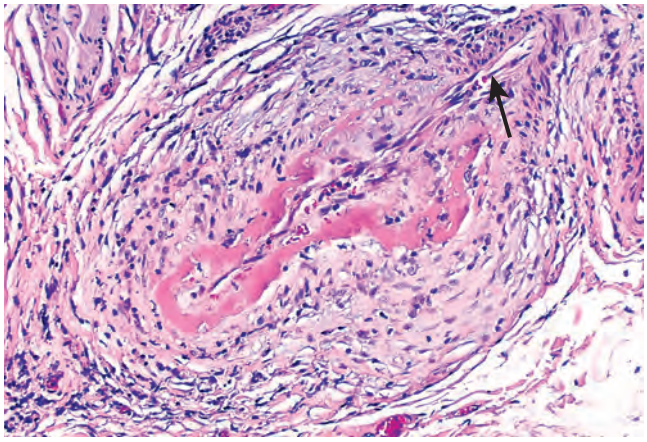

Figure 11.27 Polyarteritis nodosa. There is segmental fibrinoid necrosis and thrombotic occlusion of the lumen of this small artery. Note that part of the vessel wall at the upper right *(arrow)* is uninvolved. (Courtesy Sidney Murphree, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Kawasaki Disease

Kawasaki disease is an acute, febrile, usually self-limited illness of infancy and childhood associated with large- to medium-sized vessel arteritis; 80% of the patients are younger than 4 years of age. Its clinical significance stems from the involvement of coronary arteries. Coronary arteritis can result in aneurysms that rupture or thrombose, causing myocardial infarction. Originally described in Japan, the disease is now recognized in the United States and elsewhere.

In genetically susceptible persons, a variety of infectious agents (mostly viral) have been posited to trigger the disease. The vasculitis may result from a delayed-type hypersensitivity response directed against cross-reactive or newly uncovered vascular antigens. Subsequent cytokine production and polyclonal B-cell activation result in autoantibodies to ECs and SMCs that precipitate the vasculitis.

MORPHOLOGY

Kawasaki disease vasculitis resembles that seen in PAN. There is a dense transmural inflammatory infiltrate, although the fibrinoid necrosis is usually less prominent than in PAN. The acute vasculitis typically subsides spontaneously or in response to treatment, but aneurysm formation due to wall damage can appear. As with other arteritides, healed lesions can also exhibit obstructive intimal thickening. Pathologic changes outside the cardiovascular system are rarely significant.

Clinical Features

Kawasaki disease typically presents with conjunctival and oral erythema and blistering, edema of the hands and feet, erythema of the palms and soles, a desquamative rash, and cervical lymph node enlargement (hence its other name, *mucocutaneous lymph node syndrome*). Approximately 20% of untreated patients develop cardiovascular sequelae, ranging from asymptomatic coronary arteritis, to coronary artery ectasia, to giant coronary artery aneurysms (7 to 8 mm); the last-mentioned are associated with rupture, thrombosis, myocardial infarction, or sudden death. With intravenous immunoglobulin therapy and aspirin, the rate of symptomatic coronary artery disease is less than 4%.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing vasculitis that generally affects capillaries as well as small arterioles and venules. Unlike PAN, all lesions of microscopic polyangiitis tend to be of the same age in any given patient, suggesting a single episode of antibody or immune complex deposition. It is also called hypersensitivity vasculitis or *leukocytoclastic vasculitis.* The skin, mucous membranes, lungs, brain, heart, gastrointestinal tract, kidneys, and muscle all can be

involved; necrotizing glomerulonephritis (90% of patients) and pulmonary capillaritis are particularly common. Microscopic angiitis can be a feature of a number of immune disorders (e.g., Henoch-Schönlein purpura, essential mixed cryoglobulinemia, and vasculitis associated with connective tissue disorders).

Pathogenesis

In some cases, antibody responses to antigens such as drugs (e.g., penicillin), microorganisms (e.g., streptococci), heterologous proteins, or tumor proteins have been implicated. These can either lead to immune complex deposition or trigger secondary immune responses (e.g., development of ANCAs) that are pathogenic. Indeed, most cases are associated with MPO-ANCA. Recruitment and activation of neutrophils within affected vascular beds is likely responsible for the disease manifestations.

MORPHOLOGY

Microscopic polyangiitis is characterized by **segmental fibrinoid necrosis of the media** with focal transmural necrotizing lesions; granulomatous inflammation is absent. These lesions morphologically resemble PAN but typically spare medium-sized and larger arteries; consequently, macroscopic infarcts are uncommon. In some areas (typically postcapillary venules), only infiltrating and fragmenting neutrophils are seen, giving rise to the term **leukocytoclastic vasculitis** (Fig. 11.28A). Although immunoglobulins and complement components can be demonstrated in early skin lesions, little or no immunoglobulin can be seen in most lesions (so-called pauci-immune injury).

Clinical Features

Depending on the vascular bed involved, major clinical features include hemoptysis, hematuria and proteinuria, bowel pain or bleeding, muscle pain or weakness, and palpable cutaneous purpura. With the exception of those who develop widespread renal or brain involvement, immunosuppression induces remission and markedly improves long-term survival.

Granulomatosis With Polyangiitis (GPA)

Previously called Wegener granulomatosis, GPA is a necrotizing vasculitis characterized by a triad of:

- *Acute necrotizing granulomas* of the upper respiratory tract (ear, nose, sinuses, throat) or the lower respiratory tract (lung) or both
- *Necrotizing or granulomatous vasculitis* affecting small- to medium-sized vessels (e.g., capillaries, venules, arterioles, and arteries), most prominent in the lungs and upper airways but affecting other sites as well
- *Focal necrotizing, often crescentic, glomerulonephritis*

"Limited" forms of GPA may be restricted to the respiratory tract. Conversely, a widespread form of the disease can affect eyes, skin, and other organs, notably the heart; clinically, widespread GPA resembles PAN except that there is also respiratory involvement.

Pathogenesis

GPA likely represents a form of T cell–mediated hypersensitivity response to normally "innocuous" inhaled microbial or other environmental agents. Such a pathogenesis is supported by the presence of granulomas and a dramatic response to immunosuppressive therapy. PR3-ANCAs are also present in up to 95% of cases; they are a useful marker of disease activity and may participate in disease pathogenesis. Following immunosuppression treatment, PR3-ANCA titers fall dramatically; subsequent rising titers are predictive of relapse.

MORPHOLOGY

Upper respiratory tract lesions range from inflammatory sinusitis with mucosal granulomas to ulcerative lesions of the nose, palate, or pharynx, rimmed by **granulomas with geographic patterns of central necrosis and accompanying vasculitis** (Fig. 11.28B). The necrotizing granulomas are surrounded by a zone of proliferating fibroblasts with giant cells and leukocyte infiltrate, reminiscent

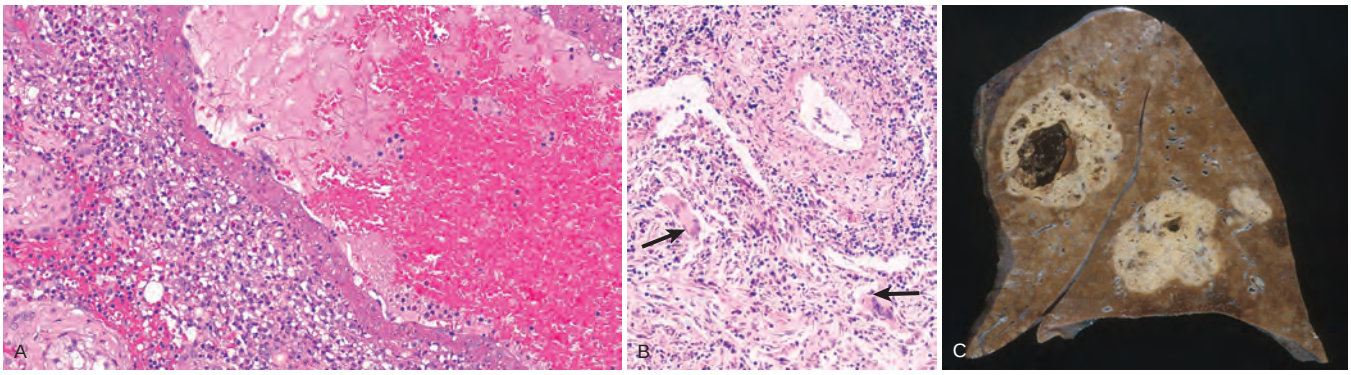

Figure 11.28 Antineutrophil cytoplasmic antibody–associated small vessel vasculitis. (A) Leukocytoclastic vasculitis (microscopic polyangiitis) with fragmentation of neutrophils in and around blood vessel walls. (B and C) Granulomatosis with polyangiitis. (B) Vasculitis of a small artery with adjacent granulomatous inflammation including epithelioid cells and giant cells *(arrows)*. (C) Gross photo from the lung of a patient with fatal granulomatosis with polyangiitis demonstrating large, nodular, centrally cavitating lesions. (A, Courtesy Michael A. Seidman, MD, PhD, Laboratory Medicine Program, University Health Network, Toronto, Canada; C, courtesy Sidney Murphree, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

of mycobacterial or fungal infections. Multiple granulomata can coalesce to produce radiographically visible nodules that can also cavitate; late-stage disease may be marked by extensive necrotizing granulomatous involvement of the parenchyma (Fig. 11.28C), and alveolar hemorrhage may be prominent. Lesions may ultimately undergo progressive fibrosis and organization.

Renal lesions range from mild, focal glomerular necrosis with isolated capillary loop thrombosis **(focal and segmental necrotizing glomerulonephritis)** to more advanced glomerular lesions with diffuse necrosis with parietal cell proliferation resulting in crescent formation **(crescentic glomerulonephritis)**.

Clinical Features

Males are affected more often than females, at an average age of about 40 years. Classic features include bilateral pneumonitis with nodules and cavitary lesions (95%), chronic sinusitis (90%), mucosal ulcerations of the nasopharynx (75%), and renal disease (80%). Rashes, myalgias, articular involvement, neuritis, and fever can also occur. Left untreated, the disease is usually rapidly fatal with 80% mortality within 1 year. Treatment with steroids, cyclophosphamide, TNF antagonists, and anti–B-cell antibodies, have turned GPA into a chronic relapsing and remitting disease.

Churg-Strauss Syndrome

Churg-Strauss syndrome (also called *allergic granulomatosis and angiitis*) is a small-vessel necrotizing vasculitis classically associated with asthma, allergic rhinitis, lung infiltrates, peripheral eosinophilia, extravascular necrotizing granulomas, and a striking eosinophilic infiltration of vessels and tissues.

Cutaneous involvement (with palpable purpura), gastrointestinal bleeding, and renal disease (primarily as focal and segmental glomerulosclerosis) are the major associations. Cytotoxicity produced by the myocardial eosinophilic infiltrates often leads to cardiomyopathy; cardiac involvement is seen in 60% of patients and is a major cause of morbidity and death.

Churg-Strauss syndrome is likely a consequence of hyperresponsiveness to some normally innocuous allergic stimulus. MPO-ANCAs are present in a minority of cases, suggesting that the disorder is pathogenically heterogeneous. The vascular lesions differ from those of PAN or microscopic polyangiitis by virtue of the presence of both granulomas and eosinophils.

Thromboangiitis Obliterans (Buerger Disease)

Thromboangiitis obliterans is characterized by segmental, thrombosing, acute and chronic inflammation of medium- and small-sized arteries, especially the tibial and radial arteries, that often leads to vascular insufficiency, typically of the extremities. It occurs almost exclusively in heavy cigarette smokers, usually before the age of 35.

Pathogenesis

The strong relationship with cigarette use involves either direct idiosyncratic EC toxicity caused by some tobacco component or an immune response to the same agents that have modified host vascular wall proteins. Most patients with Buerger disease have hypersensitivity to intradermally injected tobacco extracts, and their vessels exhibit impaired endothelium-dependent vasodilation when challenged with acetylcholine. There is an increased prevalence in certain ethnic groups (Israeli, Indian subcontinent, Japanese) and an association with certain MHC haplotypes.

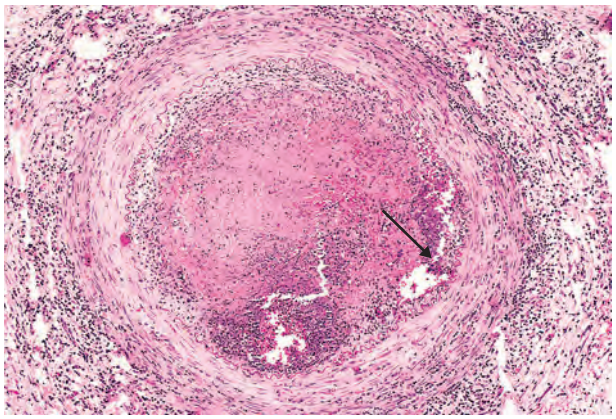

Figure 11.29 Thromboangiitis obliterans (Buerger disease). The lumen is occluded by a thrombus containing abscesses *(arrow)*, and the vessel wall is infiltrated with leukocytes.

MORPHOLOGY

Affected vessels of thombangitis obliterans show acute and chronic inflammation, accompanied by luminal thrombosis. The thrombus can contain small **microabscesses** composed of neutrophils surrounded by granulomatous inflammation (Fig. 11.29); the thrombus may eventually organize and recanalize. The inflammatory process extends into contiguous veins and nerves (rare with other forms of vasculitis), and with time all three structures can be encased in fibrous tissue.

Clinical Features

Early manifestations include Raynaud phenomenon (see later), instep foot pain induced by exercise (instep claudication), and a superficial nodular phlebitis (venous inflammation). The vascular insufficiency of Buerger disease tends to be accompanied by severe pain—even at rest—undoubtedly due to the neural involvement. Chronic extremity ulcerations can develop, progressing over time (occasionally precipitously) to frank gangrene. Smoking abstinence in the early stages of the disease can often ameliorate further attacks; however, once established, the vascular lesions do not respond to smoking abstinence.

Vasculitis Associated With Other Noninfectious Disorders

Vasculitis resembling hypersensitivity angiitis or classic PAN can sometimes be associated with other disorders, such as rheumatoid arthritis; systemic lupus erythematosus; malignancy; or systemic illnesses, such as mixed cryoglobulinemia, antiphospholipid antibody syndrome, and Henoch-Schönlein purpura. Rheumatoid vasculitis occurs predominantly in the setting of long-standing, severe rheumatoid arthritis and usually affects small- and medium-sized arteries,

leading to visceral infarction; it may also cause a clinically significant aortitis. Identifying the underlying pathology has therapeutic significance. For example, although classic immune complex lupus vasculitis and antiphospholipid antibody syndrome can be morphologically and clinically similar, antiinflammatory therapy is required in the former, and aggressive anticoagulant therapy is indicated in the latter.

Infectious Vasculitis

Arteritis can be caused by the direct invasion of infectious agents, usually bacteria or fungi, and in particular *Aspergillus* and *Mucor* species. Vascular invasion can be part of a localized tissue infection (e.g., bacterial pneumonia or adjacent to abscesses) or, less commonly, can arise from hematogenous spread of microorganisms during septicemia or embolization from infective endocarditis.

Vascular infections can weaken arterial walls and culminate in mycotic aneurysms (see earlier) or can induce thrombosis and downstream infarction. Thus inflammation-induced thrombosis of meningeal vessels in bacterial meningitis can eventually give rise to infarction of the underlying brain.

KEY CONCEPTS

VASCULITIS

- Vasculitis is defined as inflammation of vessel walls; it is frequently associated with systemic manifestations (including fever, malaise, myalgias, and arthralgias) and organ dysfunction that depends on the pattern of vascular involvement.
- Vasculitis most commonly has an immunologic basis resulting from immune complex deposition, ANCAs, or anti-EC antibodies. Less commonly it is caused by infections.
- Different forms of vasculitis tend to specifically affect vessels of a particular caliber and location (see Fig. 11.24 and Table 11.4).

DISORDERS OF BLOOD VESSEL HYPERREACTIVITY

Several disorders are characterized by inappropriate or excessive blood vessel vasoconstriction.

Raynaud Phenomenon

Raynaud phenomenon results from exaggerated vasoconstriction of arteries and arterioles in responses to cold or emotion. It most commonly affects the extremities, particularly the fingers and toes, but also occasionally the nose, earlobes, or lips. The restricted blood flow induces paroxysmal pallor and even cyanosis in severe cases; involved digits classically show "red, white, and blue" color changes from most proximal to most distal, correlating with proximal vasodilation, central vasoconstriction, and more distal cyanosis (Fig. 11.30). Raynaud phenomenon can be a primary entity or secondary to other disorders.

- *Primary Raynaud phenomenon* affects 3% to 5% of the general population and occurs most often in young women. It tends to symmetrically affect the extremities, and the severity and extent of involvement typically does not progress. It results from intrinsic hyperreactivity of medial SMCs. Structural changes in the arterial walls are absent except in long-standing disease, when intimal thickening can develop. The course is usually benign, but chronicity can lead to atrophy of the skin, subcutaneous tissues, and muscles. Ulceration and ischemic gangrene are rare.
- *Secondary Raynaud phenomenon* refers to vascular insufficiency due to arterial disease caused by other entities, including SLE, scleroderma, Buerger disease, or even atherosclerosis. Clinically, secondary Raynaud phenomenon tends to have asymmetric involvement of the extremities and progressively worsens (extent and severity) over time.

Since Raynaud phenomenon may be the first manifestation of immune-mediated vasculitides, any patient with new

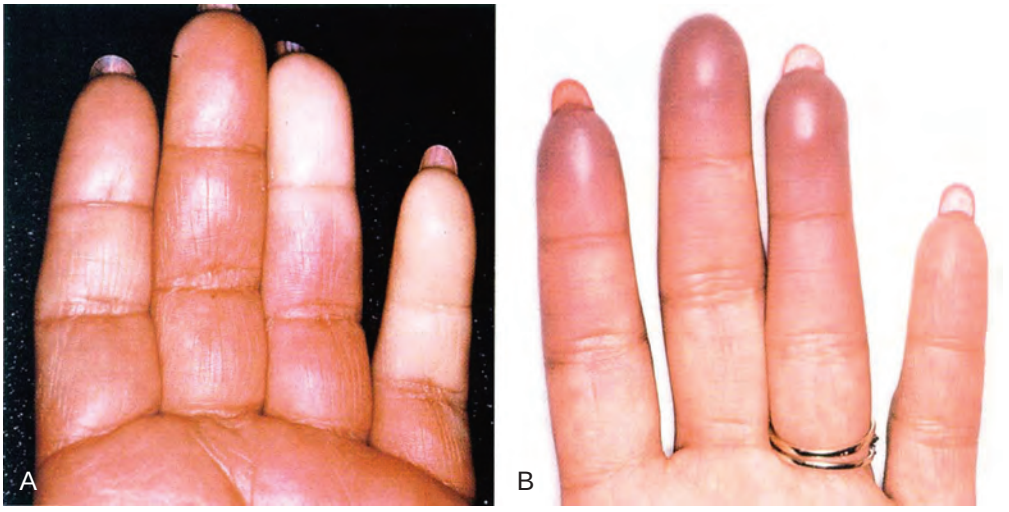

Figure 11.30 Raynaud phenomenon. (A) Sharply demarcated pallor of the distal fingers resulting from the closure of digital arteries. (B) Cyanosis of the fingertips. (Reproduced from Salvarani C, et al: Polymyalgia rheumatica and giant-cell arteritis, *N Engl J Med* 347:261, 2002.)

symptoms should be evaluated. Of these, some 10% will eventually manifest an underlying disorder.

Myocardial Vessel Vasospasm

Excessive constriction of arteries or arterioles may cause ischemia, and persistent vasospasm can even cause myocardial infarction. In addition to intrinsic hyperreactivity of medial SMCs, as described for primary Raynaud disease (see earlier), high levels of vasoactive mediators can precipitate prolonged vascular contraction. Such agents can be endogenous (e.g., epinephrine released by pheochromocytomas) or exogenous (cocaine or phenylephrine). Elevated thyroid hormone causes a similar effect by increasing the sensitivity of vessels to circulating catecholamines, while autoantibodies and T cells in scleroderma (Chapter 6) can cause vascular instability and vasospasm. Extreme psychological stress and the attendant release of catecholamines can lead to pathologic vasospasm.

When vasospasm of cardiac arterial or arteriolar beds (so-called cardiac Raynaud) is of sufficient duration (20 to 30 minutes), myocardial infarction or sudden cardiac death may occur.

VEINS AND LYMPHATICS

Varicose veins and phlebothrombosis/thrombophlebitis together account for at least 90% of clinical venous disease.

Varicose Veins

Varicose veins are abnormally dilated, tortuous veins produced by prolonged, increased intraluminal pressure with vessel dilation and incompetence of the venous valves. The superficial veins of the upper and lower leg are commonly involved because venous pressures in these sites can be markedly elevated (up to 10 times normal) by prolonged dependent posture. Up to 20% of men and a third of women develop lower extremity varicose veins. Obesity increases the risk, and the higher incidence in women probably reflects the prolonged elevation in venous pressure caused by compression of the inferior vena cava by the gravid uterus during pregnancy. A familial predilection to varicose veins reflects defective venous wall development.

Clinical Features

Incompetence of the venous valves leads to stasis, congestion, edema, pain, and thrombosis. Secondary tissue ischemia results from chronic venous congestion and poor vessel drainage leading to stasis dermatitis (also called "brawny induration"; the brawny color comes from the hemolysis of extravasated red cells) and ulcerations; poor wound healing and superimposed infections are common additional complications. Notably, embolism from these superficial veins is very rare, as opposed to the relatively frequent thromboembolism that arises from thrombosed deep veins (see later and Chapter 4).

Varicosities in two other sites also deserve mention:

- *Esophageal varices.* Liver cirrhosis (less frequently, portal vein obstruction or hepatic vein thrombosis) causes portal vein hypertension (Chapter 18). Portal hypertension leads to the opening of portosystemic shunts that increase blood flow into veins at the gastroesophageal junction (forming esophageal varices), rectum (forming hemorrhoids), and periumbilical veins of the abdominal wall (forming a caput medusa). Esophageal varices are the most important since their rupture can lead to massive (even fatal) upper gastrointestinal hemorrhage.
- *Hemorrhoids* can also result from primary varicose dilation of the venous plexus at the anorectal junction (e.g., through prolonged pelvic vascular congestion due to pregnancy or straining to defecate). Hemorrhoids are uncomfortable and may be a source of bleeding; they can also thrombose and are prone to painful ulceration.

Thrombophlebitis and Phlebothrombosis

Thrombophlebitis and phlebothrombosis are largely interchangeable designations for venous thrombosis and inflammation; deep leg veins account for more than 90% of cases. The periprostatic venous plexus in males and the pelvic venous plexus in females are additional sites, as are the large veins in the skull and the dural sinuses (especially in the setting of infection or inflammation). Portal vein thrombosis can occur in association with peritoneal infections (peritonitis, appendicitis, salpingitis, and pelvic abscesses), as well as certain thrombophilic conditions associated with platelet hyperactivity (e.g., polycythemia vera) (Chapter 14).

Decreased blood flow in the setting of prolonged immobilization is the most common cause of lower extremity *deep venous thrombosis (DVT).* This can occur with extended bed rest or sitting during long airplane or automobile excursions; the postoperative state can also precipitate DVT, and congestive heart failure, pregnancy, oral contraceptive use, malignancy, and obesity all constitute additional risk factors.

Systemic hypercoagulability, including genetic hypercoagulability syndromes (Chapter 4), can also contribute to thrombophlebitis. In patients with cancer, particularly adenocarcinomas, hypercoagulability occurs as a paraneoplastic syndrome related to tumor elaboration of procoagulant factors (Chapter 7). In this setting, venous thromboses classically appear in one location, disappear, and then occur in another site—so-called migratory thrombophlebitis *(Trousseau syndrome).*

Thrombi in the legs tend to produce few, if any, reliable signs or symptoms. Indeed, local manifestations including vein dilation, edema, cyanosis, heat, erythema, or pain may be entirely absent, especially in bedridden patients. In some cases, pain can be elicited by pressure over affected veins, squeezing the calf muscles, or forced dorsiflexion of the foot *(Homan sign)*; absence of these findings does not exclude a diagnosis of DVT.

Pulmonary embolism is a serious clinical complication of *DVT* (Chapter 4), resulting from fragmentation or detachment of the venous thrombus. In many cases the first manifestation of thrombophlebitis is a pulmonary embolus. Depending on the size and number of emboli, the outcome can range from no symptoms to death.

Superior and Inferior Vena Caval Syndromes

The superior vena caval syndrome is usually caused by neoplasms that compress or invade the superior vena cava (e.g., bronchogenic carcinoma or mediastinal lymphoma).

The resulting obstruction produces a characteristic clinical complex including marked dilation of the veins of the head, neck, and arms with cyanosis. Pulmonary vessels can also be compressed, inducing respiratory distress.

The inferior vena caval syndrome can be caused by neoplasms that compress or invade the inferior vena cava (IVC) or by thrombosis of the hepatic, renal, or lower extremity veins that propagates cephalad. Certain neoplasms—particularly hepatocellular carcinoma and renal cell carcinoma—show a striking tendency to grow within veins, and these can ultimately occlude the IVC. IVC obstruction induces marked lower extremity edema, distention of the superficial collateral veins of the lower abdomen, and—with renal vein involvement—massive proteinuria.

Lymphangitis and Lymphedema

Although primary disorders of lymphatic vessels are extremely uncommon, secondary processes frequently develop in association with inflammation or malignancies.

Lymphangitis represents acute inflammation caused by the spread of bacterial infections into lymphatics; group A β-hemolytic streptococcus is the most common agent. Affected lymphatics are dilated and filled with an exudate of neutrophils and monocytes; the infiltrates can extend through the vessel wall and, in severe cases, can produce cellulitis or focal abscesses. Lymphangitis is manifested by red, painful subcutaneous streaks (the inflamed lymphatics), with painful enlargement of the draining lymph nodes (lymphadenitis). If bacteria are not successfully contained within the lymph nodes, subsequent escape into the venous circulation can result in bacteremia or sepsis.

Primary lymphedema can occur as an isolated congenital defect (simple congenital lymphedema) or as the familial *Milroy disease (heredofamilial congenital lymphedema)*, which results in lymphatic agenesis or hypoplasia. Secondary or obstructive lymphedema stems from blockage of previously normal lymphatics, including:

- *Tumors* obstructing lymphatic channels or the regional lymph nodes
- *Surgical procedures* that sever lymphatic connections (e.g., axillary lymph node resection in a radical mastectomy)
- *Postradiation fibrosis*
- *Filariasis*
- *Postinflammatory thrombosis and scarring*

Regardless of the cause, lymphedema increases the hydrostatic pressure in the lymphatics distal to the obstruction and causes edema. Chronic edema, in turn, can lead to ECM deposition and fibrosis, producing brawny induration or a *peau d'orange* (orange peel) appearance of the overlying skin. Eventually inadequate tissue perfusion can lead to skin ulceration. Rupture of dilated lymphatics (e.g., secondary to obstruction from a tumor or following surgical injury) leads to milky accumulations of lymph designated as chylous ascites (abdomen), chylothorax, and chylopericardium.

VASCULAR TUMORS

Tumors of blood vessels and lymphatics constitute a spectrum from benign hemangiomas (extremely common) to locally aggressive neoplasms that rarely metastasize, to rare, highly malignant angiosarcomas (Table 11.5).

Table 11.5 Classification of Vascular Tumors and Tumor-Like Conditions

Benign Neoplasms, Developmental and Acquired Conditions
Hemangioma
Capillary hemangioma
Cavernous hemangioma
Pyogenic granuloma
Lymphangioma
Simple (capillary) lymphangioma
Cavernous lymphangioma (cystic hygroma)
Glomus tumor
Vascular ectasias
Nevus flammeus
Spider telangiectasia (arterial spider)
Hereditary hemorrhagic telangiectasis (Osler-Weber-Rendu disease)
Reactive vascular proliferations
Bacillary angiomatosis
Intermediate-Grade Neoplasms
Kaposi sarcoma
Hemangioendothelioma
Malignant Neoplasms
Angiosarcoma
Hemangiopericytoma

Vascular neoplasms arise either from endothelium (e.g., hemangioma, lymphangioma, angiosarcoma) or from cells that support or surround blood vessels (e.g., glomus tumor). Primary tumors of large vessels (aorta, pulmonary artery, and vena cava) are mostly sarcomas. Although a benign well-differentiated hemangioma is not usually confused with an anaplastic angiosarcoma, the distinction between benign and malignant can occasionally be difficult. Congenital or developmental malformations and nonneoplastic reactive vascular proliferations (e.g., *bacillary angiomatosis*) can also present as tumor-like lesions that can be diagnostically challenging. In general, benign and malignant vascular neoplasms can be distinguished by the following features.

- *Benign tumors* usually contain obvious vascular channels filled with blood cells (lymphatics will be filled with lymph), lined by a monolayer of normal-appearing ECs.
- *Malignant tumors* are more solidly cellular and more proliferative and exhibit cytologic atypia; they usually do not form well-organized vessels. The endothelial derivation of such neoplastic proliferations may require immunohistochemical detection of EC-specific markers such as CD31 or von Willebrand factor.

Benign Tumors and Tumor-Like Conditions

Vascular Ectasias. *Ectasia* is a generic term for any local dilation of a structure, while *telangiectasia* is used to describe a permanent dilation of preexisting small vessels (capillaries, venules, and arterioles, usually in the skin or mucous membranes) that forms a discrete red lesion. These can be congenital or acquired and are not true neoplasms.

- *Nevus flammeus* (a "birthmark"), the most common form of vascular ectasia, is a light pink to deep purple flat lesion on the head or neck composed of dilated vessels. Most ultimately regress spontaneously.
- The so-called *port wine stain* is a type of nevus flammeus that tends to grow during childhood, thickening the associated skin surface, and persisting over time (perhaps the most well-known example is that on the forehead of the former Soviet President Mikhail Gorbachev). Such lesions in the distribution of the trigeminal nerve can be associated with *Sturge-Weber syndrome* (also called encephalotrigeminal angiomatosis). This uncommon congenital disorder is associated with facial port wine nevi, ipsilateral venous angiomas in the cortical leptomeninges, intellectual disability, seizures, hemiplegia, and skull radiopacities. A large facial telangiectasia in a child with intellectual deficiency may indicate the presence of additional vascular malformations. The majority of cases of port wine stains (including those associated with Sturge-Weber syndrome) are caused by a somatic single-nucleotide missense mutation in GNAQ (the alpha subunit of heterotrimeric transmembrane signaling molecule).
- *Spider telangiectasias* are nonneoplastic vascular malformations grossly resembling a spider. These manifest as radial, often pulsatile lesions composed of dilated subcutaneous arteries or arterioles (resembling spider legs) about a central core (resembling a spider's body) that blanch with pressure. These commonly occur on the face, neck, or upper chest and are most frequently associated with hyperestrogenic states (e.g., in pregnant women or patients with cirrhosis).
- *Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease)* is an autosomal dominant disorder caused by mutations in genes that encode components of the TGF-β signaling pathway in ECs. The telangiectasias are malformations composed of dilated capillaries and veins that are present at birth. They are widely distributed over the skin and oral mucous membranes, as well as in the respiratory, gastrointestinal, and urinary tracts. The lesions can spontaneously rupture, causing serious epistaxis (nosebleed), gastrointestinal bleeding, or hematuria.

Hemangiomas. Hemangiomas are very common tumors composed of blood-filled vessels (Fig. 11.31); they constitute 7% of all benign tumors of infancy and childhood. Most are present from birth and initially increase in size, but many eventually regress spontaneously. While hemangiomas are typically confined to the head, neck, and thoracic skin, they can also arise internally and can occasionally be more extensive *(angiomatosis)*. Nearly one-third of internal lesions occur in the liver. Malignant transformation is rare. Several histologic and clinical variants have been described.

- *Capillary hemangiomas* are the most common type; these occur in the skin, subcutaneous tissues, and mucous

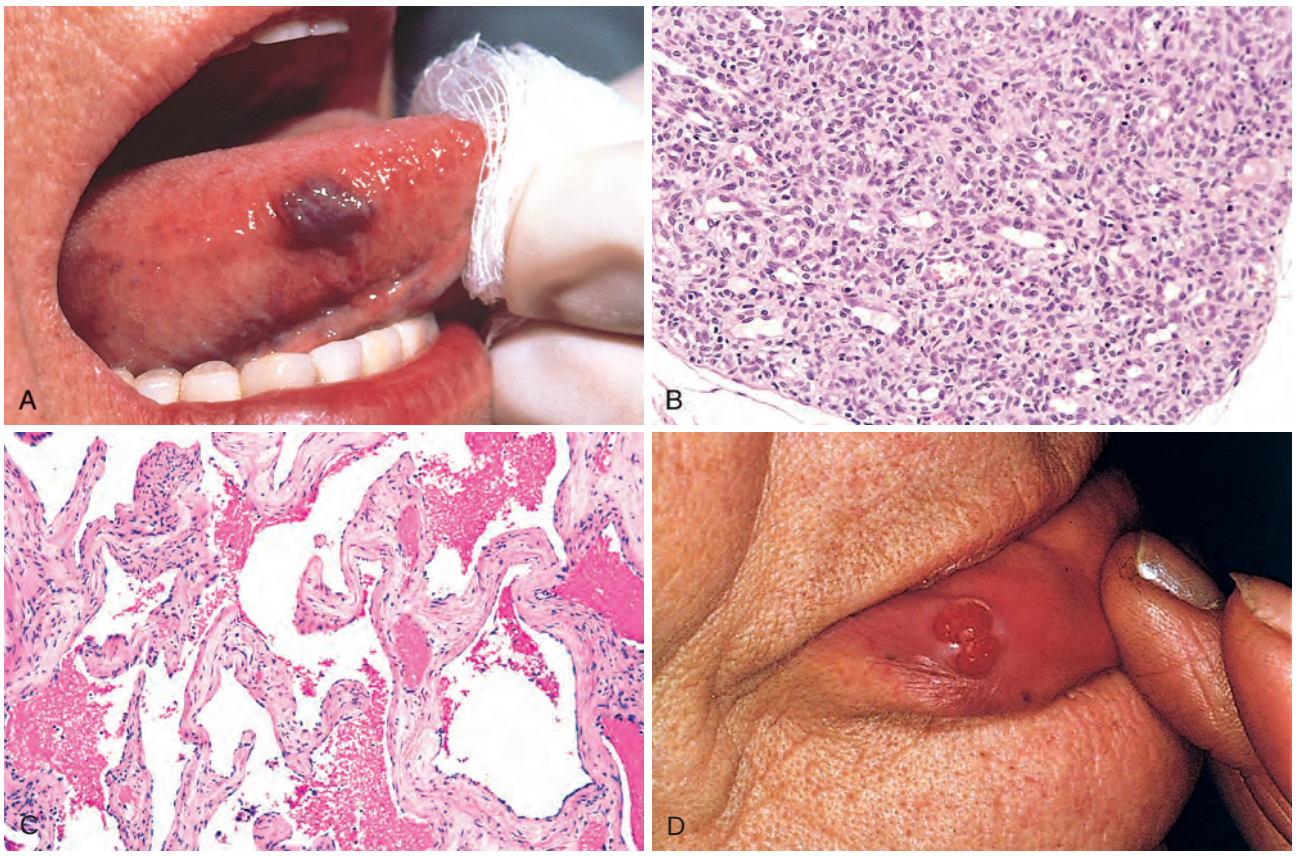

Figure 11.31 Hemangiomas. (A) Hemangioma of the tongue. (B) Histology of juvenile capillary hemangioma. (C) Histology of cavernous hemangioma. (D) Pyogenic granuloma of the lip. (A and D, Courtesy John Sexton, MD, Beth Israel Hospital, Boston, Mass.; B, courtesy Christopher D. M. Fletcher, MD, Brigham and Women's Hospital, Boston, Mass.; and C, courtesy Thomas Rogers, MD, University of Texas Southwestern Medical School, Dallas, Tex.)

membranes of the oral cavities and lips, as well as in the liver, spleen, and kidneys (Fig. 11.31A). Histologically, they are composed of thin-walled capillaries with scant stroma (Fig. 11.31B).

- *Juvenile hemangiomas* (so-called strawberry-type hemangiomas) of the newborn skin are extremely common (1 in 200 births) and can be multiple. These grow rapidly for a few months, but then fade by 1 to 3 years of age and completely regress by age 7 in most cases.
- *Cavernous hemangiomas* are composed of large, dilated vascular channels. In contradistinction to capillary hemangiomas, cavernous hemangiomas are more infiltrative, frequently involve deep structures, and do not spontaneously regress. Moreover, cavernous hemangiomas detected by imaging studies may be difficult to distinguish from their malignant counterparts. On histologic examination, the mass is sharply delineated but unencapsulated and composed of large, cavernous blood-filled vascular spaces, separated by connective tissue stroma (Fig. 11.31C). Intravascular thrombosis with associated dystrophic calcification is common. They can be locally destructive, but more often are of little clinical significance outside of a cosmetic disfigurement or their vulnerability to traumatic ulceration and bleeding. Brain hemangiomas are problematic, as they can cause symptoms related to compression of adjacent tissue or rupture. Cavernous hemangiomas are one component of *von Hippel-Lindau disease* (Chapter 28), in which vascular lesions are commonly found in the cerebellum, brain stem, retina, pancreas, and liver.
- *Pyogenic granulomas* are capillary hemangiomas that present as rapidly growing red pedunculated lesions on the skin, gingiva, or oral mucosa. They bleed easily and are often ulcerated (Fig. 11.31D). Roughly a quarter of lesions develop after trauma, reaching a size of 1 to 2 cm within a few weeks. Curettage and cautery is usually curative. Pregnancy tumor (granuloma gravidarum) is a pyogenic granuloma that occurs infrequently (1% of patients) in the gingiva of pregnant women. These lesions may spontaneously regress (especially after pregnancy) or undergo fibrosis, but occasionally require surgical excision.

Lymphangiomas. Lymphangiomas are the benign lymphatic counterparts of hemangiomas.

- *Simple (capillary) lymphangiomas* are slightly elevated or sometimes pedunculated lesions up to 1 to 2 cm in diameter that occur predominantly in the head, neck, and axillary subcutaneous tissues. Histologically, lymphangiomas exhibit networks of endothelium-lined spaces that can be distinguished from capillary channels by lymphatic endothelial markers (e.g., VEGFR-3, LYVE-1, and others) or by the absence of erythrocytes.
- *Cavernous lymphangiomas (cystic hygromas)* are typically found in the neck or axilla of children and more rarely in the retroperitoneum. Cavernous lymphangiomas can occasionally be enormous (up to 15 cm), filling the axilla or producing gross deformities about the neck; cavernous lymphangiomas of the neck are common in *Turner syndrome*. The lesions are composed of massively dilated lymphatic spaces lined by ECs and separated by intervening connective tissue stroma containing lymphoid aggregates. The tumor margins are indistinct and unencapsulated, making resection difficult.

Glomus Tumor (Glomangioma). Glomus tumors are benign but exquisitely painful tumors arising from modified SMCs of the glomus bodies, arteriovenous structures involved in thermoregulation. Although they may superficially resemble hemangiomas, glomangiomas arise from SMCs rather than ECs. They are most commonly found in the distal portion of the digits, especially under the fingernails. Excision is curative.

Bacillary Angiomatosis. *Bacillary angiomatosis* is a vascular proliferation in immunocompromised hosts (e.g., patients with acquired immunodeficiency syndrome [AIDS]) caused by opportunistic bacilli of the *Bartonella* family. Lesions can involve the skin, bone, brain, and other organs. Two species are implicated.

- *Bartonella henselae,* whose principal reservoir is the domestic cat, causes *cat-scratch disease* (a necrotizing granulomatous disorder of lymph nodes) in immunocompetent hosts.
- *Bartonella quintana* is transmitted by human body lice; this microbe was the cause of trench fever in World War I.

MORPHOLOGY

Skin lesions are red papules and nodules or rounded subcutaneous masses; histologically, there is capillary proliferation with prominent epithelioid ECs exhibiting nuclear atypia and mitoses, with scattered stromal neutrophils and causal bacteria (Fig. 11.32).

The bacteria induce host tissues to produce hypoxia-inducible factor-1α (HIF-1α), which, in turn, drives vascular endothelial growth factor (VEGF) production and ultimately vascular proliferation. The infections (and lesions) are cleared by antibiotics.

Intermediate-Grade (Borderline) Tumors

Kaposi Sarcoma. **Kaposi sarcoma (KS) is a vascular neoplasm caused by human herpesvirus 8 (HHV8, also known as Kaposi sarcoma herpesvirus).** Although it occurs in a number of contexts, it is by far most common in patients with AIDS; indeed, its presence is used as a criterion for diagnosis of AIDS. Based on population demographics and risk factors, KS is categorized into four forms:

- *Classic KS* is a disorder of older men of Mediterranean, Middle Eastern, or Eastern European descent (especially Ashkenazic Jews); it is uncommon in the United States. It can be associated with malignancy or altered immunity, but it is not associated with human immunodeficiency virus (HIV) infection. Classic KS manifests as multiple red-purple skin plaques or nodules, usually in the distal lower extremities; these progressively increase in size and number and spread proximally. Although persistent, the tumors are typically asymptomatic and remain localized to the skin and subcutaneous tissue.
- *Endemic African KS* typically occurs in HIV-seronegative individuals younger than age 40 years and can follow an indolent or aggressive course; it involves lymph nodes much more frequently than the classic variant. In combination with AIDS-associated KS (see later), KS is one of the

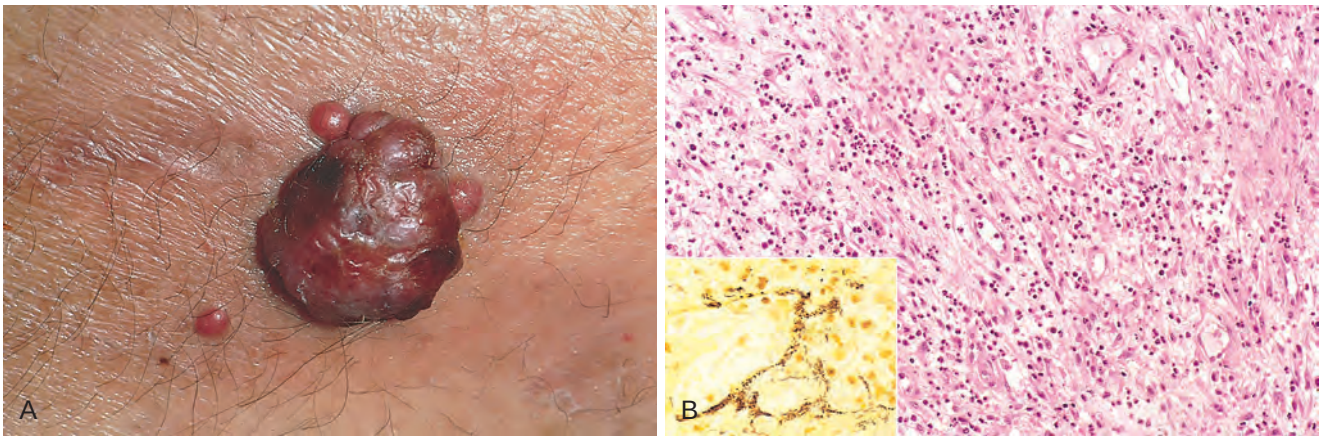

Figure 11.32 Bacillary angiomatosis. (A) Characteristic cutaneous lesion. (B) Histologic appearance with acute neutrophilic inflammation and vascular (capillary) proliferation. *Inset,* Modified silver (Warthin-Starry) stain demonstrates clusters of tangled bacilli (black). (A, Courtesy Richard Johnson, MD, Beth Israel Deaconess Medical Center, Boston, Mass.; B and *inset,* courtesy Scott Granter, MD, Brigham and Women's Hospital, Boston, Mass.)

more common tumors in central Africa. A particularly severe form, with prominent lymph node and visceral involvement, occurs in prepubertal children; the prognosis is poor, with almost 100% mortality within 3 years.

- *Transplant-associated KS* occurs in solid-organ transplant recipients receiving T-cell immunosuppression; the risk can be 100-fold greater than for immunocompetent patients. Transplant-associated KS typically follows an aggressive course involving lymph nodes, mucosa, and viscera; cutaneous lesions may be absent. Lesions can regress as immunosuppression is reduced, but at the risk of organ rejection.
- *AIDS-associated (epidemic) KS* is an AIDS-defining illness; worldwide, it represents the most common HIV-related malignancy. Although the incidence of KS has fallen more than 80% with the advent of aggressive antiretroviral therapies, it still occurs in HIV-infected individuals 300-fold more commonly than in transplant recipients and 1000-fold greater than in the general population. AIDS-associated KS often involves lymph nodes and disseminates widely to viscera early in its course; most patients eventually die of opportunistic infections rather than KS.

Pathogenesis

Virtually all KS lesions are infected by *HHV8.* Like Epstein-Barr virus, HHV8 is a γ-herpesvirus. It is transmitted sexually and potentially via oral secretions and cutaneous exposures (of note, the prevalence of endemic African KS is inversely related to the wearing of shoes). HHV8 and altered T-cell immunity are likely required for KS development; in elderly adults, diminished T-cell immunity may be related to aging. Acquired somatic mutations in the cells of origin also contribute to tumor development and progression.

HHV8 causes lytic and latent infections in ECs, both of which contribute to KS pathogenesis. A virally encoded G protein induces VEGF production, stimulating endothelial growth; in addition, cytokines produced by inflammatory cells recruited to sites of lytic infection create a local proliferative milieu. In latently infected cells, HHV8 encoded proteins disrupt normal cellular proliferation controls (e.g., through synthesis of a viral homologue of cyclin D) and prevent apoptosis by inhibiting p53. Thus the local inflammatory environment favors cellular proliferation, and latently infected cells have a growth advantage. In its early stages, only a few cells are HHV8-infected, but with time, virtually all of the proliferating cells carry the virus. Molecular pathogenesis is discussed in more detail in Chapter 6 along with HIV infections.

MORPHOLOGY

In **classic KS** (and sometimes in other variants), the cutaneous lesions progress through three stages:

- **Patches** are red-purple macules (Fig. 11.33A). Histology shows dilated irregular EC-lined vascular spaces with interspersed lymphocytes, plasma cells, and macrophages (sometimes containing hemosiderin). The lesions can be difficult to distinguish from granulation tissue.
- With time, lesions become larger, violaceous, **raised plaques** (see Fig. 11.33A) composed of dermal accumulations of dilated, jagged vascular channels lined and surrounded by plump spindle cells. Scattered between the vascular channels are extravasated erythrocytes, hemosiderin-laden macrophages, and other mononuclear inflammatory cells.
- Eventually, lesions become **nodular** and more distinctly neoplastic. These lesions are composed of sheets of plump, proliferating spindle cells, mostly in the dermis or subcutaneous tissues (Fig. 11.33B), containing small vessels and slitlike spaces with red cells. Marked hemorrhage, hemosiderin pigment, and mononuclear inflammation are present; mitotic figures are common, as are round, pink, cytoplasmic globules representing degenerating erythrocytes within phagolysosomes. The nodular stage often heralds lymph node and visceral involvement.

Clinical Features

The course of KS varies widely and is significantly influenced by the clinical setting. Most primary HHV8 infections are asymptomatic. Classic KS is—at least initially—largely restricted to the skin, and surgical resection is usually adequate for an excellent prognosis. Radiation can be used for multiple lesions in a restricted area, and chemotherapy yields satisfactory results for more disseminated disease

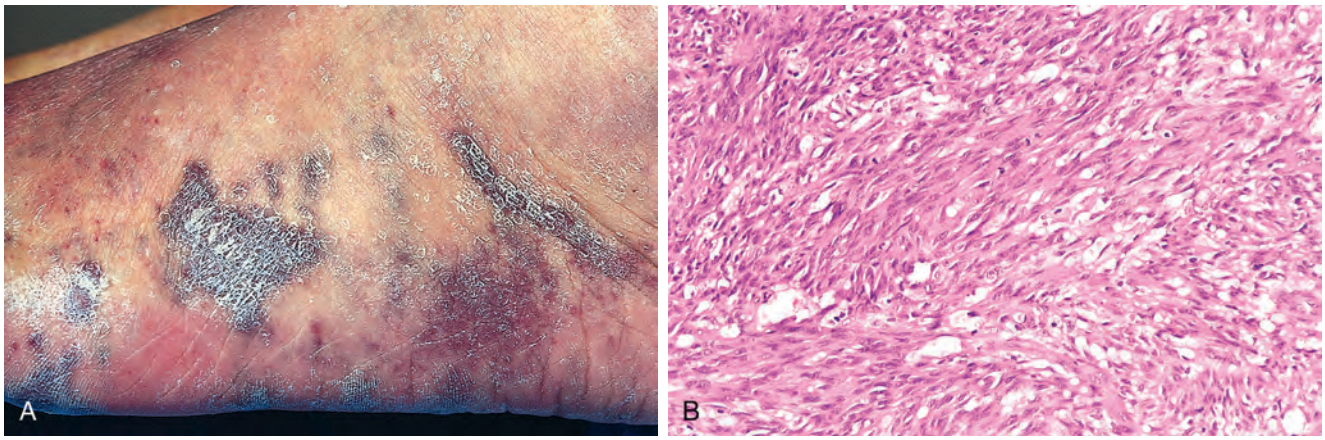

Figure 11.33 Kaposi sarcoma. (A) Gross photograph illustrating coalescent red-purple macules and plaques of the skin. (B) Histologic appearance of the nodular stage of Kaposi sarcoma, demonstrating sheets of plump, proliferating spindle cells. (B, Courtesy Christopher D. M. Fletcher, MD, Brigham and Women's Hospital, Boston, Mass.)

including nodal involvement. In immunosuppression-associated KS, withdrawal of immunosuppression (perhaps with adjunct chemotherapy or radiotherapy) is often effective. For AIDS-associated KS, HIV antiretroviral therapy is generally beneficial, with or without additional therapy. Interferon-γ and angiogenesis inhibitors also have proved variably effective, while newer strategies aimed at specific kinases downstream of VEGF receptors show promise.

Hemangioendothelioma. Hemangioendotheliomas comprise a spectrum of borderline vascular neoplasms with clinical behaviors intermediate between benign, well-differentiated hemangiomas and frankly anaplastic angiosarcomas.

Epithelioid hemangioendothelioma is a tumor of adults occurring around medium- and large-sized veins. Well-defined vascular channels are inconspicuous, and neoplastic cells are plump and often cuboidal (resembling epithelial cells). The clinical behavior is extremely variable; most are cured by excision, but up to 40% recur, 20% to 30% eventually metastasize, and 15% of patients will die of their tumor.

Malignant Tumors

Angiosarcoma. Angiosarcomas are malignant endothelial neoplasms (Fig. 11.34) with histology varying from highly differentiated tumors that resemble hemangiomas to profoundly anaplastic lesions. Older adults, males and females, are more commonly affected; angiosarcomas occur at any site, but most often involve skin, soft tissue, breast, and liver.

Angiosarcomas can also arise in the setting of lymphedema, classically in the ipsilateral upper extremity several years after radical mastectomy for breast cancer (i.e., after lymph node resection and/or radiation); in such cases the tumor presumably arises from lymphatic vessels *(lymphangiosarcoma).* Angiosarcomas have also been induced by radiation and are rarely associated with prolonged insertion of foreign material (e.g., prosthetic devices).

Hepatic angiosarcomas are associated with a variety of carcinogenic exposures including arsenic (e.g., in pesticides), Thorotrast (a radioactive contrast agent formerly used for radiologic imaging), and polyvinyl chloride (one of the best-known examples of human chemical carcinogenesis). All of these agents have long latencies between initial exposure and eventual tumor development.

Angiosarcomas are locally invasive and can readily metastasize, with 5-year survival rates of approximately 30%.

MORPHOLOGY

Cutaneous angiosarcomas can begin as multiple, deceptively small and asymptomatic red papules or nodules. More advanced lesions are large, fleshy masses of red-tan to gray-white tissue with margins blurring imperceptibly into surrounding structures (Fig. 11.34A). Necrosis and hemorrhage are common.

Microscopically, **all degrees of differentiation can be seen,** from plump, atypical ECs forming vascular channels (Fig. 11.34B) to wildly undifferentiated tumors with no discernible blood vessels. The endothelial origin of these tumors can be demonstrated by immunohistochemical staining for CD31 or von Willebrand factor (Fig. 11.34C).

KEY CONCEPTS

VASCULAR TUMORS

- Vascular ectasias are not neoplasms, but rather dilations of existing vessels.
- Vessel neoplasms can derive from either blood vessels or lymphatics and can be composed of ECs (hemangioma, lymphangioma, angiosarcoma) or other components of vascular wall cells (glomus tumor).
- Most vascular tumors are benign (e.g., hemangiomas); some have an intermediate, locally aggressive behavior (e.g., Kaposi sarcoma); and others are highly malignant (e.g., angiosarcoma).
- Benign tumors typically form obvious vascular channels lined by normal-appearing ECs. Malignant tumors are more often solid and cellular, exhibit cytologic atypia, and lack well-defined vessels.

(C) Immunohistochemical staining for the endothelial cell marker CD31 demonstrating the endothelial nature of the tumor cells.

PATHOLOGY OF VASCULAR INTERVENTION

The morphologic changes that occur in vessels following therapeutic intervention (e.g., stenting or bypass surgery) largely recapitulate the changes that occur in the setting of any vascular insult. Local trauma or thrombosis (e.g., due to a stent) or abnormal mechanical forces (e.g., a saphenous vein inserted into the arterial circulation as a coronary artery bypass graft) all induce the same stereotypical healing responses—fibromuscular intimal hyperplastic lesions composed of SMCs and ECM. Thus, just as with several risk factors for atherosclerosis, interventions that injure the endothelium also tend to induce intimal thickening by recruiting SMCs and promoting ECM deposition.

Endovascular Stenting

Arterial stenoses (especially those in coronary arteries) can be dilated by transiently inflating a balloon catheter to pressures sufficient to rupture the occluding plaque *(balloon angioplasty)*. Although most patients improve symptomatically following angioplasty alone, abrupt reclosure frequently occurs due to luminal compression caused by angioplasty-induced vascular dissection, by vessel wall spasm, or by thrombosis. Thus more than 95% of endovascular coronary procedures now involve both angioplasty and concurrent *coronary stent* placement.

Coronary stents are expandable tubes of metallic mesh. They provide a larger and more regular lumen, "tack down" the intimal flaps and dissections that occur during angioplasty, and mechanically limit vascular spasm. Nevertheless, due to endothelial injury, thrombosis is an important immediate post-stenting complication, and patients must receive potent antithrombotic agents (primarily platelet antagonists) to prevent acute catastrophic thrombotic occlusions. The long-term success of angioplasty is limited by the development of proliferative in-stent restenosis. This intimal thickening is due to SMC ingrowth, proliferation, and ECM synthesis, all driven by the initial vascular wall injury; it can cause clinically significant luminal occlusion in up to a third of patients within 6 to 12 months of stenting (Fig. 11.35).

The newest generation of *drug-eluting stents* is designed to avoid this complication by leaching antiproliferative drugs (e.g., paclitaxel or sirolimus) into the adjacent vessel wall to block SMC activation. Although the duration of drug elution is short (on the order of days to weeks), these drug-eluting stents nevertheless reduce the incidence of restenosis at 1 year by 50% to 80%. However, because of the antiproliferative effect of the drug-eluting stents, the time to reendothelialization is prolonged, and patients require extended courses of anticoagulation to prevent stent thrombosis.

Vascular Replacement

Synthetic or autologous vascular grafts can be used to replace damaged vessels or bypass diseased arteries. Large-bore (12- to 18-mm) synthetic conduits function well in high-flow locations such as the aorta; unfortunately, small-diameter artificial grafts (≤8 mm in diameter) generally fail as a result of early thrombosis or late intimal hyperplasia, the latter at the junction of the graft with the native vasculature (Fig. 11.36).

Consequently, when small-bore vessel replacement is required (e.g., in the >400,000 coronary bypass surgeries performed annually), the grafts are fashioned from saphenous

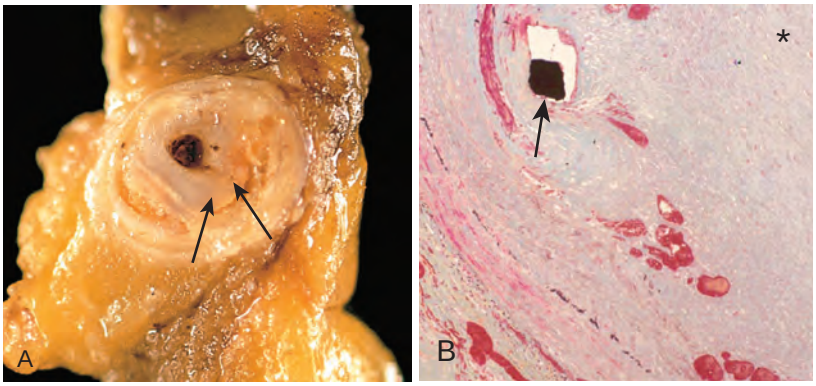

Figure 11.35 Restenosis after angioplasty and stenting. (A) Gross view demonstrating residual yellow atherosclerotic plaque *(arrows)* and a new, tan-white concentric intimal lesion inside of that plaque. (B) Histologic view shows a thickened neointima separating and overlying the stent wires (black diamond indicated by the *arrow*), which encroaches on the lumen (indicated by the *asterisk*); Movat stain with matrix staining gray-green. (B, Reproduced from Schoen FJ, Edwards WD: Pathology of cardiovascular interventions, including endovascular therapies, revascularization, vascular replacement, cardiac assist/replacement, arrhythmia control, and repaired congenital heart disease. veins (taken from the patient's own leg) or left internal mammary arteries. The long-term patency of saphenous vein grafts averages only 50% at 10 years; grafts occlude due to thrombosis (typically early), intimal thickening (months to years postoperatively), and vein graft atherosclerosis—sometimes with superimposed plaque rupture, thrombosis, or aneurysms. By contrast, more than 90% of internal mammary artery grafts, which can be used only to bypass the left anterior descending artery, are patent at 10 years.

CHAPTER 12

The Heart

Richard N. Mitchell • Andrew J. Connolly

CHAPTER CONTENTS

The human heart is a remarkably efficient, durable, and reliable pump, propelling more than 7500 L of blood through the body each day, and beating more than 40 million times a year—the wellspring for tissue oxygenation, nutrition, and waste removal. In utero, the heart and vasculature are the first fully functional organ system (at roughly 8 weeks of gestation). Without a vascular supply and a beating heart, further development cannot occur and fetal demise is inevitable. When the heart fails postnatally, the results are equally catastrophic. Cardiovascular disease (including coronary artery disease [CAD], stroke, and peripheral vascular disease) is the number-one cause of worldwide mortality. In the United States alone, cardiovascular disease accounts for roughly 1 in 4 of all deaths, totaling about 610,000 individuals each year—greater than the number of deaths caused by all forms of cancer combined.

This chapter begins with a brief review of the normal heart because most cardiac diseases manifest as structural and/or functional changes in one or more cardiac components. General principles underlying cardiac hypertrophy and failure—common end points of several of the different forms of heart disease—are also discussed, before exploring the major categories of cardiac disease: congenital heart abnormalities, ischemic heart disease (IHD), hypertensive heart disease, diseases of the cardiac valves, and primary myocardial disorders. The chapter concludes with a few comments about pericardial diseases and cardiac neoplasms, as well as cardiac transplantation and devices.

CARDIAC STRUCTURE AND SPECIALIZATIONS

Heart weight varies with body habitus, averaging approximately 0.4% to 0.5% of body weight (250 to 320 g in the average adult female and 300 to 360 g in the average adult male). Increased heart weight or ventricular thickness indicates hypertrophy, and an enlarged chamber size implies dilation; both reflect compensatory changes in response to volume and/or pressure overloads (see later). Increased cardiac weight or size (or both)—resulting from hypertrophy and/or dilation—is called cardiomegaly.

Myocardium

The pumping function of the heart occurs through coordinated contraction (during systole) and relaxation (during diastole) of cardiac myocytes (the myocardium). Left ventricular myocytes are arranged in a spiral circumferential orientation to generate vigorous coordinated waves of contraction spreading from the cardiac apex to the base of the heart. In contrast, right ventricular myocytes have a less structured organization, generating overall less robust contractile forces. Contraction is achieved by shortening of serial contractile elements (sarcomeres) within parallel myofibrils. Although the heart is primarily a pump, it is worth remembering that it also has other functions (e.g., endocrine). For example, atrial cardiomyocytes have cytoplasmic storage granules that contain atrial natriuretic peptide, and ventricular myocytes contain B-type natriuretic peptide. Both of these are protein hormones that are released in response to increased stretch; they both promote arterial vasodilation and stimulate renal salt and water elimination (natriuresis and diuresis).

Valves

The four cardiac valves—tricuspid, pulmonary, mitral, and aortic—maintain unidirectional blood flow. Valve function depends on the mobility, pliability, and structural integrity of the leaflets of the atrioventricular valves (tricuspid and mitral) or cusps of the semilunar valves (aortic and pulmonary).

The function of the semilunar valves depends on the integrity and coordinated movements of the cuspal attachments. Thus, dilation of the aortic root can result in valvular regurgitation. In contrast, the competence of the atrioventricular valves depends on the proper function not only of the leaflets but also the tendinous cords and the attached papillary muscles of the ventricular wall. Left ventricular dilation, a ruptured cord, or papillary muscle dysfunction can all interfere with mitral valve closure, causing valvular insufficiency.

Cardiac valves are lined by endothelium and share a similar, trilayered architecture:

- *Fibrosa layer.* A dense collagenous layer at the outflow surface, connected to the valvular supporting structures and providing mechanical integrity
- *Spongiosa layer.* A central core of loose connective tissue
- *Ventricularis or atrialis layer* (depending on which chamber it faces). A layer rich in elastin on the inflow surface, providing leaflet recoil

Because they are thin enough to be nourished by diffusion from the blood, normal leaflets and cusps have only scant blood vessels limited to the proximal portion of the valve. Valve endothelium also does not express ABO or histocompatibility antigens, so cryopreserved valvular tissues can be transplanted with relative impunity.

Conduction System

Coordinated contraction of the cardiac muscle depends on the initiation and rapid propagation of electrical impulses—accomplished through specialized myocytes in the conduction system. The frequency of electrical impulses is sensitive to neural inputs (e.g., vagal stimulation), extrinsic adrenergic agents (e.g., circulating adrenaline), hypoxia, and potassium concentration (i.e., hyperkalemia can block signal transmission altogether).

The components of the conduction system include the following:

- *Sinoatrial (SA) node* pacemaker, at the junction of the right atrial appendage and superior vena cava
- *Atrioventricular (AV) node,* located in the right atrium along the interatrial septum
- *Bundle of His (AV bundle),* connecting the right atrium to the ventricular septum
- *Right and left bundle branch divisions* that stimulate their respective ventricles via further arborization into the *Purkinje network*

The cells of the cardiac conduction system depolarize spontaneously, potentially enabling all of them to function as cardiac pacemakers. Because the normal rate of spontaneous depolarization in the SA node (60 to 100 beats/min) is faster than the other components, it normally sets the pace. However, if nodal tissues become dysfunctional, other cells in the conduction system can take over, generating, for example, a junctional escape rhythm (usually at a much slower rhythm). The AV node has a gatekeeper function; by delaying the transmission of signals from the atria to the ventricles, it ensures that atrial contraction precedes ventricular systole.

Blood Supply

Cardiac myocytes rely almost exclusively on oxidative phosphorylation for their energy needs. Besides a high density of mitochondria (20% to 30% of myocyte volume), myocardial energy generation also requires a constant supply of oxygenated blood—rendering myocardium extremely vulnerable to ischemia. Nutrients and oxygen are delivered via the coronary arteries, with ostia immediately distal to the aortic valve. These initially course along the external surface of the heart (epicardial coronary arteries) and then penetrate the myocardium (intramural arteries), subsequently branching into arterioles, and forming a rich arborizing vascular network so that each myocyte contacts roughly three capillaries.

The right and left coronary arteries function as end arteries, although anatomically most hearts have numerous intercoronary anastomoses (connections called collateral circulation). Blood flow to the myocardium occurs during ventricular diastole, after closure of the aortic valve, and

when the microcirculation is not compressed by cardiac contraction. At rest, diastole comprises approximately two-thirds of the cardiac cycle; with tachycardia (increased heart rate), the relative duration of diastole also shortens, thus potentially compromising cardiac perfusion.

Cardiac Regeneration

There is considerable interest in exploring the possibility of replacing damaged myocardium by inducing cardiac regeneration in vivo or implanting stem cell–derived cardiac cells. Although cardiac regeneration in metazoans such as newts and zebrafish is well described, the myocardium of mammals has a very low replicative potential after fetal and neonatal life, averaging less than 1% cardiomyocyte turnover per year in adult humans. Increasing evidence, however, indicates that cardiomyocyte proliferation can be augmented in mice. The potential for stimulating cardiac regeneration in vivo in humans is tantalizing because it could facilitate recovery of myocardial function after a host of injurious stimuli. Another area of vigorous investigation is ex vivo expansion and subsequent administration of stem cell–derived myocardial cells into areas of myocardial injury. Unfortunately, results thus far have been less than exciting. Implanted cells may show some cardiomyocyte differentiation, but the durability of this benefit has been limited, and they do not contribute significantly to the restoration of contractile force; moreover, failure to successfully integrate these cells into the conduction pathways of the host heart carries the very real risk of autonomous arrhythmic foci.

Effects of Aging on the Heart

Most forms of heart disease become more prevalent with each advancing decade. Consequently, as the average populations in high income countries get progressively older, aging-associated changes in the cardiovascular system become ever more significant (Table 12.1).

The size of the left ventricular cavity, particularly in the base-to-apex dimension, is reduced in later life; this volume change is exacerbated by systemic hypertension as the basal ventricular septum protrudes into the left ventricular outflow tract (so-called sigmoid septum). Compared with younger myocardium, the "elderly" heart typically has fewer myocytes (due to degenerative attrition) and increased connective tissue; octogenarians (and older) also frequently have deposition of extracellular amyloid (most often poorly catabolized transthyretin; Chapter 6) that stiffens the heart and reduces diastolic filling. Valvular aging changes are major contributors to significant valvular disease (see later), and progressive atherosclerosis, with a strong aging component (Chapter 11), is the major cause of IHD.

Table 12.1 Changes in the Aging Heart

Chambers
Increased left atrial cavity size
Decreased left ventricular cavity size
Sigmoid-shaped ventricular septum
Valves
Aortic valve calcific deposits
Mitral valve annular calcific deposits
Fibrous thickening of leaflets
Buckling of mitral leaflets toward the left atrium
Lambl excrescences
Epicardial Coronary Arteries
Tortuosity
Diminished compliance
Calcific deposits
Atherosclerotic plaque
Myocardium
Decreased mass
Increased subepicardial fat
Brown atrophy
Lipofuscin deposition
Basophilic degeneration
Amyloid deposits
Aorta
Dilated ascending aorta with rightward shift
Elongated (tortuous) thoracic aorta
Sinotubular junction calcific deposits
Elastic fragmentation and collagen accumulation
Atherosclerotic plaque

OVERVIEW OF CARDIAC PATHOPHYSIOLOGY

Although a host of diseases can affect the cardiovascular system, the pathophysiologic pathways that result in a "broken" heart distill down to six principal mechanisms:

- *Failure of the pump.* In the most common situation, the cardiac muscle contracts weakly and the chambers cannot empty properly—so-called systolic dysfunction. In some cases, the myocardium cannot relax sufficiently to permit ventricular filling, resulting in diastolic dysfunction.
- *Obstruction to flow.* Lesions that prevent valve opening (e.g., calcific aortic valve stenosis) or cause increased ventricular chamber pressures (e.g., systemic hypertension or aortic coarctation) can overwork the myocardium, which has to pump against the obstruction.
- *Regurgitant flow.* Valve pathology that allows backward flow of blood results in increased volume workload and may overwhelm the pumping capacity of the affected chambers.
- *Shunted flow.* Defects (congenital or acquired) that divert blood inappropriately from one chamber to another, or from one vessel to another, lead to pressure and volume overloads.
- *Disorders of cardiac conduction.* Uncoordinated cardiac impulses or blocked conduction pathways can cause arrhythmias that slow contractions or prevent effective pumping altogether.
- *Rupture of the heart or major vessel.* Loss of circulatory continuity (e.g., a gunshot wound through the thoracic aorta) may lead to massive blood loss, hypotensive shock, and death.

Most cardiovascular disease results from a complex interplay of genetics and environmental factors; these can disrupt signaling pathways that control morphogenesis,

affect myocyte survival after injury, or affect contractility or electrical conduction in the face of biomechanical stressors. Indeed, the pathogenesis of many congenital heart defects involves an underlying genetic abnormality whose expression is modified by environmental factors (see later). Moreover, genes that control the development of the heart may also regulate the response to various forms of injury including aging. Subtle polymorphisms can significantly affect the risk of many forms of heart disease, and, as discussed later, a number of adult-onset heart disorders have a fundamentally genetic basis. Thus, cardiovascular genetics provides an important window on the pathogenesis of heart disease, and molecular diagnoses are increasingly a critical part of its classification.

HEART FAILURE

Heart failure, often called congestive heart failure (CHF), is a common, usually progressive condition with a poor prognosis. Each year in the United States, CHF affects more than 5 million individuals (approximately 2% of the population), necessitating more than 1 million hospitalizations, and contributing to the death of nearly 300,000 people. Roughly one-half of patients die within 5 years of receiving a diagnosis of CHF, and 1 in 9 deaths in the United States include heart failure as a contributory cause.

Heart failure is defined as the condition in which a heart cannot pump blood to adequately meet the metabolic demands of peripheral tissues, or can do so only at elevated filling pressures. It is the common end stage of many forms of chronic heart disease, often emerging insidiously from the cumulative effects of chronic work overload (e.g., in valve disease or hypertension) or IHD (e.g., after myocardial infarction [MI] with heart damage). However, acute hemodynamic stresses, such as fluid overload, abrupt valvular dysfunction, or myocardial infarction, can all precipitate sudden CHF.

When cardiac workload increases or cardiac function is compromised, several physiologic mechanisms swing into action, and can at least initially maintain arterial pressure and organ perfusion:

- *Frank-Starling mechanism:* Increased filling volumes dilate the heart, thereby increasing actin-myosin cross-bridge formation, and enhancing contractility and stroke volume.
- *Activation of neurohumoral systems:* These augment heart function and/or regulate filling volumes and pressures (and many of the therapies for CHF affect these systems when they become maladaptive).
  - *Release of norepinephrine* by adrenergic nerves of the autonomic nervous system, elevating heart rate, augmenting myocardial contractility and increasing vascular resistance
  - *Activation of the renin-angiotensin-aldosterone system,* promoting water and salt retention (augmenting circulatory volume) and increasing vascular tone
  - *Release of atrial natriuretic peptide,* counterbalancing the renin-angiotensin-aldosterone system through diuresis and vascular smooth muscle relaxation
- *Myocardial adaptations*: In many pathologic states, heart failure is preceded by cardiac hypertrophy, a compensatory response to increased mechanical work. Ventricular remodeling is the general term applied to the collective molecular, cellular, and structural changes that occur in response to injury or altered ventricular loading.

Although such adaptive mechanisms can potentially maintain adequate cardiac output in the face of acute perturbations, their capacity to do so may ultimately be overwhelmed. Heart failure can result from progressive deterioration of myocardial contractile function (systolic dysfunction)—reflected as a decrease in ejection fraction (EF, the percentage of blood volume ejected from the ventricle during systole; normal is approximately 45% to 65%). Reduction in EF can occur with ischemic injury, inadequate adaptation to pressure or volume overload due to hypertension or valvular disease, or ventricular dilation. Increasingly, heart failure is recognized as resulting from an inability of the heart chamber to expand and fill sufficiently during diastole (diastolic dysfunction), for example, due to left ventricular hypertrophy, myocardial fibrosis, constrictive pericarditis, or amyloid deposition.

Cardiac Hypertrophy: Pathophysiology and Progression to Heart Failure

Sustained increase in mechanical work of either ventricle due to pressure overload, volume overload, or trophic signals (e.g., those mediated through the activation of β-adrenergic receptors) causes myocytes to increase in size (cellular hypertrophy); cumulatively, this increases the size and weight of the heart (Fig. 12.1). Hypertrophy requires increased protein synthesis to form additional sarcomeres, as well as increasing the numbers of mitochondria. Hypertrophic myocytes also have multiple or enlarged nuclei, attributable to increased DNA ploidy resulting from DNA replication in the absence of cell division.

The pattern of hypertrophy reflects the nature of the stimulus.

- In *pressure-overload hypertrophy* (e.g., due to hypertension or aortic stenosis), new sarcomeres are predominantly assembled in parallel to the long axes of cells, expanding the cross-sectional area of myocytes in ventricles and causing a concentric increase in wall thickness.
- In contrast, *volume-overload hypertrophy* (e.g., due to valvular regurgitation) is characterized by new sarcomeres being assembled in series within existing sarcomeres, leading primarily to ventricular dilation. As a result, in dilation due to volume overload, or dilation that accompanies failure of a previously pressure overloaded heart, the wall thickness may be increased, normal, or less than normal. Consequently, heart weight, rather than wall thickness, is the best measure of hypertrophy in dilated hearts.

Heart disease can lead to dramatic levels of cardiac hypertrophy. Patients with systemic hypertension, IHD, aortic stenosis, mitral regurgitation, or dilated cardiomyopathy frequently have heart weights double or triple the average, and aortic regurgitation or hypertrophic cardiomyopathy can produce heart weights threefold to fourfold greater than normal.

Important changes at the tissue and cell level occur with cardiac hypertrophy. Significantly, myocyte hypertrophy

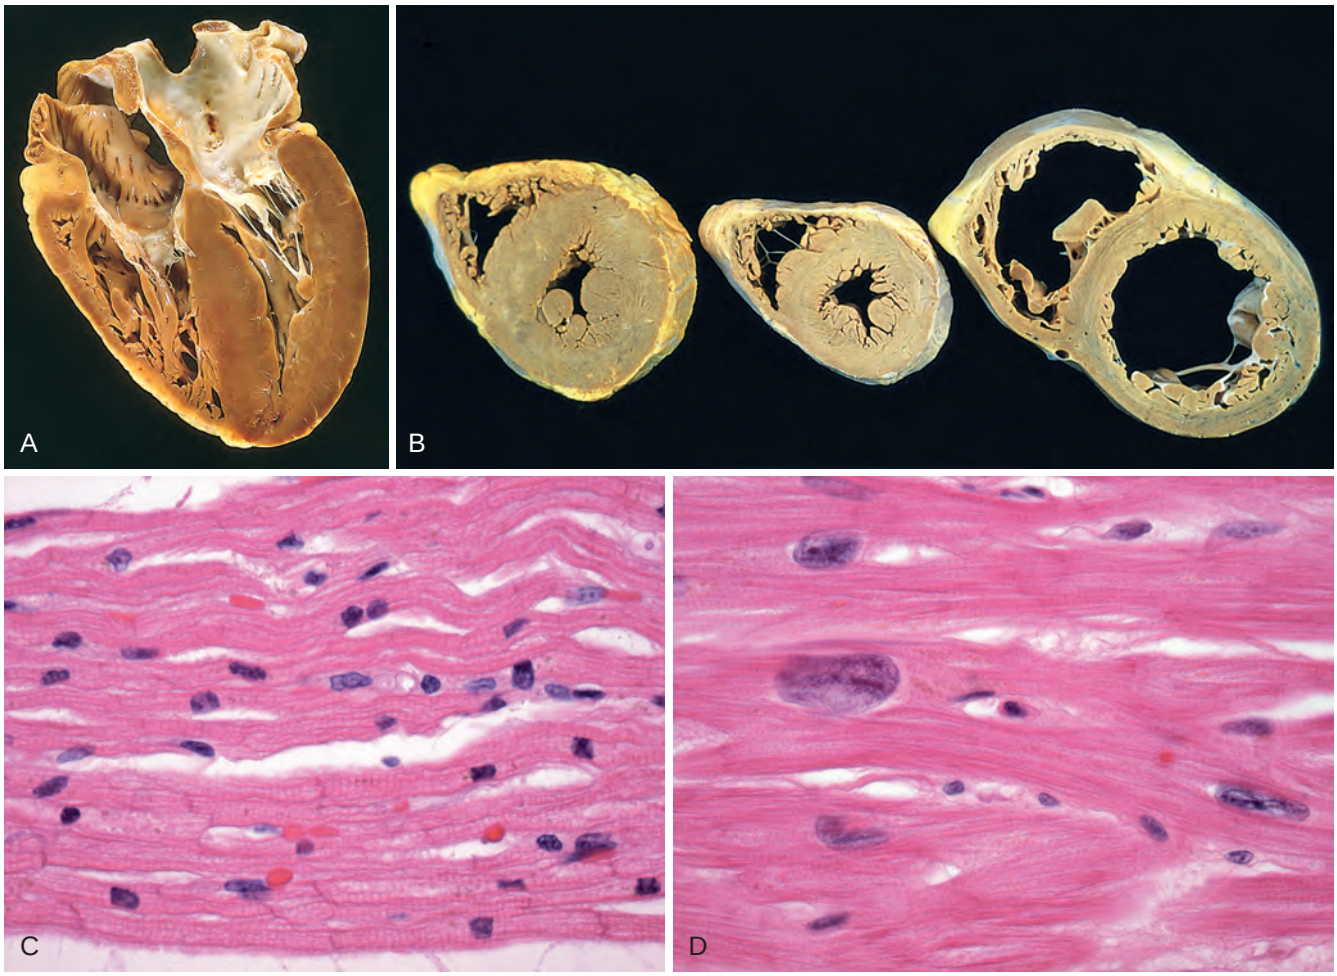

Figure 12.1 Left ventricular hypertrophy. (A) Pressure hypertrophy due to left ventricular outflow obstruction. The left ventricle is on the lower right in this apical four-chamber view of the heart. (B) Left ventricular hypertrophy with and without dilation, viewed in transverse heart sections. Compared with a normal heart *(center)*, the pressure-hypertrophied hearts *(left and in A)* have increased mass and a thick left ventricular wall, and the hypertrophied, dilated heart *(right)* has increased mass and an apparently normal wall thickness. (C) Normal myocardium. (D) Hypertrophied myocardium (C and D are photomicrographs at the same magnification). Note the increases in both cell size and nuclear size in the hypertrophied myocytes, and the interstitial cells remain small. (A and B, Reproduced with permission from Edwards WD: Cardiac anatomy and examination of cardiac specimens. In Emmanouilides GC, et al., editors: *Moss and Adams Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adults*, ed 5, Philadelphia, 1995, Williams & Wilkins, p 86.)

is not accompanied by a proportional increase in capillary numbers. As a result, the supply of oxygen and nutrients to the hypertrophied heart, particularly one undergoing pressure-overload hypertrophy, is more tenuous than in the normal heart. At the same time, cardiac hypertrophy is associated with heightened metabolic demands due to increases in mass, heart rate, and contractility (inotropic state, or force of contraction), all of which increase cardiac oxygen consumption. As a result of these changes, the hypertrophied heart is vulnerable to ischemia-related decompensation, which can evolve to cardiac failure. Adding insult to injury, hypertrophy is also typically accompanied by deposition of fibrous tissue (interstitial fibrosis), causing increased resistance to diastolic filling.

Molecular changes in hypertrophied cardiomyocytes include the expression of immediate-early genes (e.g., *FOS, JUN, MYC,* and *EGR1*) (Chapter 2) putatively driving cellular growth and altered protein expression; with prolonged hemodynamic overload, myocytes can even express genes usually only seen during fetal cardiac development (including fetal forms of myosin, natriuretic peptides, and collagen).

The proposed sequence of initially adaptive—and later harmful—events in response to increased cardiac work is summarized in Fig. 12.2. As illustrated, heart failure eventually supervenes. The degree of anatomic abnormality does not always reflect the severity of dysfunction; indeed, the gross appearance of the "failing heart" does not adequately convey the underlying structural, biochemical, and molecular basis for myocardial contractile failure. The hearts of patients with CHF are generally heavy and dilated, but can be relatively thin-walled, and histologically they exhibit variable degrees of myocyte hypertrophy. Loss of myocardial mass in the setting of infarction leads to work-related hypertrophy of the surrounding viable myocardium. In valvular heart disease, the increased pressure or volume overloads the myocardium globally. Increased heart mass owing to disease

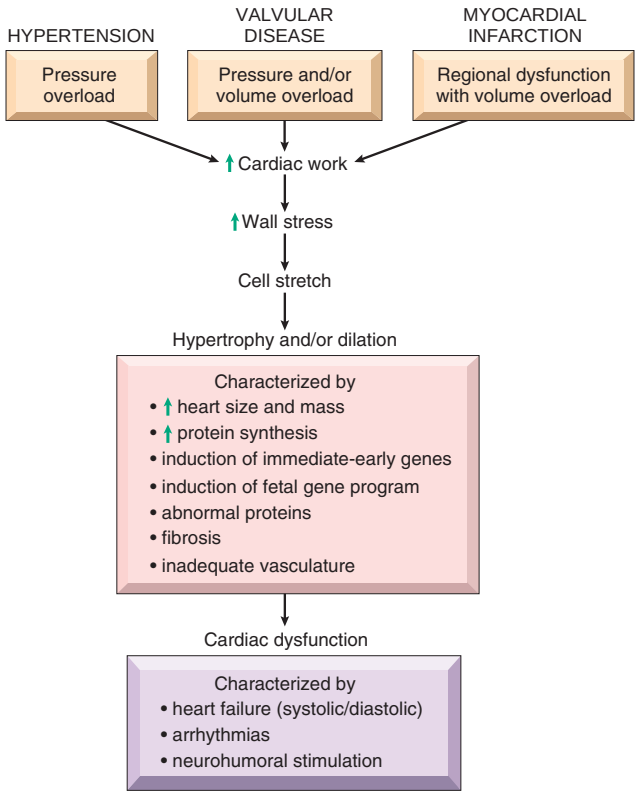

Figure 12.2 Schematic representation of the causes and consequences of cardiac hypertrophy.

is correlated with excess cardiac mortality and morbidity; indeed, cardiomegaly is an independent risk factor for sudden death.

In contrast to the pathologic hypertrophy associated with persistent mechanical stressors, regular exercise can promote potentially beneficial physiologic hypertrophy. Aerobic exercise (e.g., long-distance running) tends to be associated with volume-load hypertrophy accompanied by increases in capillary density (unlike other forms of hypertrophy); regular aerobic activity also decreases the resting heart rate and blood pressure—effects that are all beneficial. In comparison, purely static exercise (e.g., weight lifting) induces mild pressure hypertrophy (e.g., secondary to recurring Valsalva maneuvers) and less beneficial remodeling.

Whatever its basis, CHF is characterized by variable degrees of decreased cardiac output and tissue perfusion (forward failure), as well as pooling of blood in the venous capacitance system (backward failure); the latter may cause pulmonary edema, peripheral edema, or both. As a result, many of the significant clinical features and morphologic changes noted in CHF are actually secondary to disorders induced by hypoxia and congestion in noncardiac peripheral tissues.

The cardiovascular system is a closed circuit. Thus, although left-sided and right-sided failure can occur independently, failure of one side (particularly the left) often produces excessive strain on the other, terminating in global heart failure. Despite this interdependence, it is easiest to understand the pathology of heart failure by considering right- and left-sided heart failure separately.

Left-Sided Heart Failure

Left-sided heart failure is most often caused by the following:

- IHD
- Hypertension
- Aortic and mitral valvular diseases
- Primary myocardial diseases

The clinical and morphologic effects of left-sided CHF are a consequence of passive congestion (blood backing up in the pulmonary circulation), stasis of blood in the left-sided chambers, and inadequate perfusion of downstream tissues leading to organ dysfunction.

MORPHOLOGY

Heart. The findings depend on the disease process, ranging from myocardial infarcts, to stenotic or regurgitant valves, to intrinsic myocardial pathology. Except for failure caused by mitral valve stenosis or unusual restrictive cardiomyopathies (described later), the left ventricle is usually hypertrophied and often dilated, sometimes massively. Left ventricular diastolic dysfunction or dilation with mitral valve incompetence causes secondary dilation of the left atrium, increasing the risk of atrial fibrillation. This in turn results in stasis of blood, particularly in the atrial appendage, which is a common site of thrombus formation. The microscopic changes in the failing heart are nonspecific: variable degrees of myocyte hypertrophy and interstitial fibrosis.

Lungs. Pulmonary congestion and **edema** produce heavy, wet lungs, as described elsewhere (Chapters 4 and 15). Pulmonary changes—from mildest to most severe—include (1) perivascular and interstitial edema, particularly in the interlobular septa, (2) progressive edematous widening of alveolar septa, and (3) accumulation of edema fluid in the alveolar spaces. Extravasated red cells and plasma proteins in the alveoli are phagocytosed and digested by macrophages; the accumulated iron is stored as hemosiderin. These hemosiderin-laden macrophages (also known as **heart failure cells**) are telltale signs of previous episodes of pulmonary edema. Pleural effusions (typically serous) arise from elevated pleural capillary and lymphatic pressure and the resultant transudation of fluid into the pleural cavities.

Early left-sided heart failure symptoms are related to pulmonary congestion and edema. Initially, cough and dyspnea (breathlessness) may occur only with exertion. As CHF progresses, worsening pulmonary edema may cause orthopnea (dyspnea when supine, relieved by sitting or standing) or paroxysmal nocturnal dyspnea (dyspnea usually occurring at night that is so severe that it induces a feeling of suffocation). Dyspnea at rest may follow. The respiratory symptoms are characteristically associated with fine rales at the lung bases, caused when edematous pulmonary alveoli snap open during inspiration. Other manifestations of left ventricular failure include an enlarged heart (cardiomegaly, apparent on imaging), tachycardia, a third heart sound due to volume overload (S3), or a fourth heart sound (S4) due to increased myocardial stiffness. If heart failure is associated with progressive ventricular dilation, the papillary muscles are displaced outward, causing mitral regurgitation. Subsequent chronic dilation of the left atrium can cause atrial

fibrillation, and such uncoordinated, chaotic atrial contractions reduce the atrial contribution to ventricular filling, thus reducing the ventricular stroke volume.

In moderate CHF, a reduced ejection fraction leads to diminished renal perfusion, causing activation of the renin-angiotensin-aldosterone system as a compensatory mechanism to correct the "perceived" hypotension. This leads to salt and water retention, with expansion of the interstitial and intravascular fluid volumes (Chapters 4 and 11) exacerbating the ongoing pulmonary edema. If the hypoperfusion of the kidney becomes sufficiently severe, impaired excretion of nitrogenous products may cause azotemia (called prerenal azotemia; Chapter 20). In far-advanced CHF, cerebral hypoperfusion can give rise to hypoxic encephalopathy (Chapter 28), with irritability, loss of attention span, and restlessness that can progress to stupor and coma with ischemic cerebral injury.

Left-sided heart failure can be divided into systolic and diastolic failure:

- *Systolic failure* is defined by insufficient ejection fraction (pump failure) and can be caused by any of the many disorders that damage or derange the contractile function of the left ventricle.
- In *diastolic failure,* the left ventricle is abnormally stiff and cannot relax during diastole. Thus, although cardiac function is relatively preserved at rest, the heart is unable to increase its output in response to increases in the metabolic demands of peripheral tissues (e.g., during exercise). Moreover, because the left ventricle cannot expand normally, any increase in filling pressure is immediately transferred back into the pulmonary circulation, producing pulmonary edema. Hypertension is the most common underlying etiology; diabetes mellitus, obesity, and bilateral renal artery stenosis can also be causal. Reduced left ventricular relaxation may stem from myocardial fibrosis (e.g., in cardiomyopathies and IHD) or infiltrative disorders associated with restrictive cardiomyopathies (e.g., cardiac amyloidosis). Diastolic failure may appear in older patients without any known predisposing factors, possibly as an exaggeration of the normal stiffening of the heart with age. Constrictive pericarditis (discussed later) can also limit myocardial relaxation and therefore mimics primary diastolic dysfunction.

Right-Sided Heart Failure

Right-sided heart failure is most commonly caused by left-sided heart failure, as any increase in pressure in the pulmonary circulation from left-sided failure inevitably burdens the right side of the heart. Consequently, the causes of right-sided heart failure include all the etiologies for left-sided heart failure. Isolated right-sided heart failure is infrequent and typically occurs in patients with one of a variety of disorders affecting the lungs; hence it is often referred to as cor pulmonale. Besides parenchymal lung diseases, cor pulmonale can also arise secondary to disorders that affect the pulmonary vasculature, for example, primary pulmonary hypertension (Chapter 15), recurrent pulmonary thromboembolism (Chapter 4), or conditions that cause pulmonary vasoconstriction (obstructive sleep apnea, altitude sickness). The common feature of these disorders is pulmonary hypertension (discussed later), which results in hypertrophy and dilation of the right side of the heart. In extreme cases, leftward bulging of the interventricular septum can even cause left ventricular dysfunction. The major morphologic and clinical effects of primary right-sided heart failure differ from those of left-sided heart failure in that pulmonary congestion is minimal while engorgement of the systemic and portal venous systems is pronounced.

MORPHOLOGY

Heart. As in left-heart failure, the cardiac morphology varies with cause. Rarely, structural defects such as tricuspid or pulmonary valvular abnormalities or endocardial fibrosis (as in carcinoid heart disease) may be present. However, because isolated right heart failure is most often caused by lung disease, most cases exhibit only hypertrophy and dilation of the right atrium and ventricle.

Liver and Portal System. Congestion of the hepatic and portal vessels may produce pathologic changes in the liver, the spleen, and the gastrointestinal tract. The liver is usually increased in size and weight **(congestive hepatomegaly)** caused by **passive congestion,** greatest around the central veins (Chapter 4). Grossly, this is reflected as congested red-brown pericentral zones, with relatively normal-colored tan periportal regions, producing the characteristic "nutmeg liver" appearance (Chapter 4). In some instances, especially when left-sided heart failure with hypoperfusion is also present, severe centrilobular hypoxia produces **centrilobular necrosis.** With longstanding severe right-sided heart failure, the central areas can become fibrotic, eventually culminating in **cardiac cirrhosis** (Chapter 18). Portal venous hypertension also causes enlargement of the spleen with platelet sequestration **(congestive splenomegaly)** and can also contribute to chronic congestion and edema of the bowel wall. The latter may be sufficiently severe as to interfere with nutrient (and/or drug) absorption.

Pleural, Pericardial, and Peritoneal Spaces. Systemic venous congestion can lead to fluid accumulation **(effusions)** in the pleural, pericardial, or peritoneal spaces (a peritoneal effusion is also called **ascites**). Large pleural effusions can impact lung inflation, causing atelectasis, and substantial ascites can also limit diaphragmatic excursion, causing dyspnea on a purely mechanical basis.

Subcutaneous Tissues. Edema of the peripheral and dependent portions of the body, especially foot/ankle (pedal) and pretibial edema, is a hallmark of right-sided heart failure. In chronically bedridden patients, presacral edema may predominate. Generalized massive edema **(anasarca)** can also occur.

The kidney and the brain are also prominently affected in right-sided heart failure. Renal congestion is more marked with right-sided than with left-sided heart failure, leading to greater fluid retention and peripheral edema, and more pronounced azotemia. Venous congestion and hypoxia of the central nervous system can also produce deficits of mental function akin to those seen in left-sided heart failure with poor systemic perfusion.

Although we have discussed right and left heart failure separately, it is again worth emphasizing that in many cases of chronic cardiac decompensation, patients with biventricular CHF have symptoms reflecting both right-sided and left-sided heart failure. Besides a careful history and physical

examination, serum levels of B-type (or brain) natriuretic factor (BNP) have become a popular tool to quantitatively assess the extent of CHF. Recall that BNP is released by ventricular cardiomyocytes during increased wall stress; a low value has a high negative predictive value for CHF. Echocardiography is also an extremely valuable tool in following patients with CHF, providing a measure of ejection fraction, wall motion, valvular function, and possible mural thrombosis.

Treatment for CHF is initially focused on correcting any underlying cause, for example, a valvular defect or inadequate cardiac perfusion. Beyond that, the clinical approach includes salt restriction or pharmacologic agents that variously reduce volume overload (e.g., diuretics), increase myocardial contractility (so-called positive inotropes), or reduce afterload (via adrenergic blockade or inhibitors of angiotensin-converting enzymes [ACE]). Although many of these medications provide benefit through effects on neurohumoral pathways, ACE inhibitors also limit myocyte hypertrophy and cardiac remodeling. Although cardiac resynchronization therapy (exogenous pacing of both the right and left ventricles) and mechanical ventricular assist devices (VADs, discussed later) have also been added to the cardiologist's armamentarium, CHF remains a serious cause of human morbidity and mortality.

KEY CONCEPTS

HEART FAILURE

- Heart failure occurs when the heart is unable to provide adequate perfusion to meet the metabolic requirements of peripheral tissues; inadequate cardiac output is usually accompanied by increased congestion of the venous circulation.
- Left-sided heart failure is most commonly due to IHD, systemic hypertension, mitral or aortic valve disease, and primary diseases of the myocardium; symptoms are mainly a consequence of pulmonary congestion and edema, although systemic hypoperfusion can cause secondary renal and cerebral dysfunction.
- Right-sided heart failure is most often due to left heart failure, and less commonly to primary pulmonary disorders; symptoms are chiefly related to peripheral edema and visceral congestion.

CARDIAC DEVELOPMENT

The heart is a mechanical organ that generates pulsatile blood within just 3 weeks after fertilization. It is therefore likely that hemodynamic forces play an important role in cardiac development, just as they influence adaptations in the adult heart such as hypertrophy and dilation.

The diverse malformations seen in congenital heart disease (CHD) are caused by errors that occur during the complex migration and folding that constitutes cardiac morphogenesis. Derived from cells in the lateral mesoderm, the earliest cardiac precursors move to the midline in two migratory waves (called the first and second heart fields) within the first 15 days of fetal development. Although these are multipotent progenitor cells that can produce all of the major cell types of the heart (endocardium, myocardium, and smooth muscle cells), they rapidly assume distinct fates; cells in the first wave largely populate the developing left ventricle, whereas those in the second wave become the outflow tract, right ventricle, and most of the atria. Thus, defects in one or the other anlage can explain some of the CHDs involving discrete structures. By day 20 of development, the nascent heart has become a beating tube, which begins to form the basic heart chambers roughly 8 days later. At about the same time, (1) neural crest–derived cells migrate into the outflow tract, where they participate in the septation of the aortic and pulmonic outflow tracts and the formation of the aortic arch; and (2) interstitial connective tissue expands to become definitive endocardial cushions that will become the future atrioventricular canals and outflow tracts. By day 50, further septation of the ventricles, atria, and atrioventricular valves produces a four-chambered heart.

Proper orchestration of these remarkable transformations depends on a network of transcription factors that are regulated by a number of signaling pathways, particularly the Wnt, hedgehog, vascular endothelial growth factor (VEGF), bone morphogenetic protein, transforming growth factor-β (TGF-β), fibroblast growth factor, and Notch pathways (Chapter 1). It is not too surprising then that many of the inherited defects that affect heart development involve genes that encode transcription factors; these typically cause partial loss of function and are autosomal dominant (discussed later). In addition, specific micro-RNAs play critical roles in cardiac development by coordinating patterns and levels of transcription factor expression.

CONGENITAL HEART DISEASE

CHD refers to abnormalities of the heart or great vessels that are present at birth. Most CHD arises from faulty embryogenesis during gestational weeks 3 to 8, when major cardiovascular structures form and begin to function. The most severe anomalies preclude intrauterine survival, and significant heart malformations are common among stillborn infants. On the other hand, circumscribed defects affecting discrete regions of the heart or individual chambers can be compatible with live birth. In this latter category are the following:

- *Septal defects,* or "holes in the heart," including atrial septal defects (ASDs) or ventricular septal defects (VSDs)
- *Stenotic lesions,* either at the level of valves, or the entire cardiac chamber as in hypoplastic left heart syndrome
- *Outflow tract anomalies* including inappropriate routing of the great vessels from the ventricles, or anomalous coronary arteries

Such "tolerated" forms of CHD usually produce clinically important manifestations only after birth—uncovered by the transition from fetal to perinatal circulation; roughly one-half will be diagnosed in the first year of life, although some milder forms may not be discovered until adulthood (e.g., ASD).

Incidence

The incidence of CHD depends on what is counted as a defect. Thus, if echocardiography is performed routinely on neonates, small muscular VSDs or ASDs are detected in over 5% of live births. However, these typically close

Table 12.2 Frequencies of Congenital Cardiac Malformations[a]

Malformation	Incidence per Million Live Births	%
Ventricular septal defect	4482	42

Data from: Hoffman JI, Kaplan S: The incidence of congenital heart disease, *J Am Coll Cardiol* 39(12):1890–1900, 2002.

spontaneously in the first year of life, and they probably should not be tallied with the burden of CHD. Similarly, bicuspid aortic valve—with an incidence of 1% to 2%—clearly persists beyond infancy, but often has modest manifestations and may not become evident until late adulthood. If the accounting is restricted to more serious defects, the worldwide incidence of congenital cardiovascular malformations is slightly less than 1%—still ranking CHD among the most prevalent birth defects. Twelve disorders account for about 85% of cases; their frequencies are listed in Table 12.2.

The number of individuals who survive into adulthood with CHD is increasing rapidly and is estimated at nearly 1.5 million people in the United States alone. Many have benefited from surgical advances that increasingly permit early postnatal repair of structural defects. In some cases, however, surgical intervention fails to restore complete normalcy; patients may have already sustained pulmonary or myocardial changes that are no longer reversible, or conversely, may suffer from arrhythmias due to surgical scarring. Other factors that impact the long-term outcome include complications associated with the use of prosthetic materials and devices (e.g., substitute valves or myocardial patches), and the cardiovascular stressors associated with childbearing that may tip a repaired heart into failure.

Etiology and Pathogenesis

Environmental exposures (e.g., congenital rubella infection, teratogens—including some therapeutic drugs, and gestational diabetes) and genetic factors are the best characterized causes but still account for a minority of CHD cases. Nutritional factors can also influence risk; folate supplementation during early pregnancy reduces CHD incidence.

Genetic factors include specific loci implicated in familial forms of CHD and certain chromosomal abnormalities (e.g., trisomies 13, 15, 18, and 21, and monosomy X/Turner syndrome). Indeed, the most common known genetic cause of CHD is trisomy 21 (Down syndrome); roughly 40% of patients with Down syndrome have one or more heart defects, most often affecting structures derived from the second migratory wave of cells (e.g., the atrioventricular septae). The mechanisms by which aneuploidy causes CHD likely involve the dysregulated expression of multiple genes.

A notable example of a small chromosomal lesion causing CHD is deletion of chromosome 22q11.2, occurring in patients with DiGeorge syndrome. In this syndrome, the fourth branchial arch and the derivatives of the third and fourth pharyngeal pouches (which contribute to the formation of the thymus, parathyroid glands, and heart) develop abnormally. Of the 30 or so genes present on this chromosome segment, deletion of the *TBX1* transcription factor gene is probably the culprit lesion. TBX1 regulates neural crest migration, as well as the expansion of cardiac progenitors in the second migratory wave. Interestingly, deletions in this region are also associated with mental illness, including schizophrenia.

In the case of single-gene mutations, the affected genes encode proteins belonging to several different functional classes (Table 12.3); as mentioned earlier, many of these involve transcription factors. Because affected patients are heterozygous for such mutations, it follows that a 50% reduction in the activity of these factors (or even less) may

Table 12.3 Selected Examples of Gene Defects Associated With Congenital Heart Disease[a]

Disorder	Gene(s)	Gene Product Function
Nonsyndromic		
ASD or conduction defects	*NKX2.5*	Transcription factor
ASD or VSD	*GATA4*	Transcription factor
Tetralogy of Fallot	*ZFPM2 or NKX2.5*	Transcription factors
Syndromic[b]		
Alagille syndrome—pulmonary artery stenosis or tetralogy of Fallot	*JAG1 or NOTCH2*	Signaling proteins or receptors
Char syndrome—PDA	*TFAP2B*	Transcription factor
CHARGE syndrome—ASD, VSD, PDA, or hypoplastic right side of the heart	*CHD7*	Helicase-binding protein
DiGeorge syndrome—ASD, VSD, or outflow tract obstruction	*TBX1*	Transcription factor
Holt-Oram syndrome—ASD, VSD, or conduction defect	*TBX5*	Transcription factor
Noonan syndrome—pulmonary valve stenosis, VSD, or hypertrophic cardiomyopathy	*PTPN11, KRAS, SOS1*	Signaling proteins

ASD, Atrial septal defect; *CHARGE*, posterior coloboma, heart defect, choanal atresia, retardation, genital and ear anomalies; *PDA*, patent ductus arteriosus; *VSD*, ventricular septal defect.

[a]Different mutations can cause the same phenotype, and mutations in some genes can cause multiple phenotypes (e.g., *NKX2.5*). Many of these congenital lesions also can occur sporadically, without specific genetic mutation.

[b]Only the cardiac manifestations of the syndrome are listed; the other skeletal, facial, neurologic, and visceral changes are not.

be sufficient to derange cardiac development. Even relatively minor decrements in activity of particular genes can result in significant defects. Thus, transient environmental stresses during the first trimester of pregnancy that alter the synthesis or activity of these same genes can conceivably lead to acquired defects that mimic those produced by heritable mutations. In addition, many of the transcription factors interact in large protein complexes, providing a rationale for why mutations in any one of several genes can produce similar defects. Thus, GATA4, TBX5, and NKX2-5, three transcription factors that are mutated in some patients with atrial and ventricular septal defects, all bind to one another and co-regulate the expression of target genes required for proper cardiac development.

Other single-gene mutations can alter structural proteins or affect signaling pathway molecules. Thus, mutations in genes encoding various components of the Notch pathway (Chapter 1) are associated with a variety of congenital heart defects, including bicuspid aortic valve (*NOTCH1*, discussed later) and tetralogy of Fallot (*JAG1* and *NOTCH2*). As described in Chapter 5 and 11, fibrillin mutations underlie Marfan syndrome—associated with valvular defects and aortic aneurysms. Although fibrillin is an important structural protein in the extracellular matrix (ECM), it is also an important negative regulator of TGF-β signaling, and hyperactive TGF-β signaling contributes to the cardiovascular abnormalities in Marfan syndrome and the related Loeys-Dietz syndrome.

Despite these advances, our understanding of the mechanisms underlying CHD remains rudimentary; the precise cause is unknown in almost 90% of cases. Most affected patients have no identifiable genetic risk, and even in those that do, the nature and severity of the defect are highly variable. It is likely that most forms of CHD arise by interactions of environmental factors with multiple genes. Guidelines for genetic testing are complex and evolving but suggest that genetic testing may be useful in patients with a broader noncardiac syndrome or a family history of CHD.

Clinical Features

Most of the various structural anomalies in CHD can be organized into three major categories according to the major functional abnormalities they cause:

- *Left-to-right shunt*
- *Right-to-left shunt*
- *Obstruction*

A shunt is an abnormal communication between chambers or blood vessels. Abnormal channels permit blood flow down pressure gradients from the left (systemic) side to the right (pulmonary) side of the circulation or vice versa. When blood from the right side of the circulation flows directly into the left side (right-to-left shunt), hypoxemia and *cyanosis* (a dusky blueness of the skin and mucous membranes) result because the pulmonary circulation is bypassed and poorly oxygenated venous blood shunts directly into the systemic arterial supply. In addition, right-to-left shunts can allow emboli from the peripheral veins to bypass the lungs and directly enter the systemic circulation (paradoxical embolism). Severe, long-standing hypoxia/cyanosis also causes increased numbers of circulating red blood cells (polycythemia), as well as a peculiar distal blunting and enlargement ("clubbing") of the tips of the fingers and toes that can include bony changes (called hypertrophic osteoarthropathy). The most important causes of right-to-left shunts are tetralogy of Fallot (TOF), transposition of the great arteries (TGA), persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection.

In contrast, left-to-right shunts (e.g., ASD, VSD, and patent ductus arteriosus [PDA]) increase pulmonary blood flow but are not initially associated with cyanosis. However, left-to-right shunts chronically elevate both volume and pressure in the normally low-pressure, low-resistance pulmonary circulation. To maintain relatively normal distal pulmonary capillary and venous pressures, the muscular pulmonary arteries (<1 mm in diameter) initially respond by undergoing medial hypertrophy and vasoconstriction. However, prolonged pulmonary arterial vasoconstriction stimulates the development of irreversible obstructive intimal lesions analogous to the arteriolar changes seen in systemic hypertension; pulmonary arteries can even develop frank atherosclerotic lesions (Chapter 11). The right ventricle also responds to the pulmonary vascular changes by undergoing progressive hypertrophy. Eventually, pulmonary vascular resistance approaches systemic levels, and the original left-to-right shunt becomes a right-to-left shunt that introduces poorly oxygenated blood into the systemic circulation *(Eisenmenger syndrome)*.

Once irreversible pulmonary hypertension develops, the structural defects of CHD are considered irreparable; subsequent right heart failure can lead to the patient's death unless combined heart-lung transplantation can be performed. This provides the rationale for early intervention to close significant left-to-right shunts.

Obstructive CHD occurs when there is abnormal narrowing of chambers, valves, or blood vessels; these include coarctation of the aorta, aortic valvular stenosis, and pulmonary valvular stenosis. A complete obstruction is called an atresia. In some disorders (e.g., TOF), an obstruction (pulmonary stenosis) and a shunt (right-to-left through a VSD) are both present.

The altered hemodynamics of CHD usually cause cardiac dilation or hypertrophy (or both). However, some defects induce a decrease in the volume and muscle mass of a cardiac chamber; this is called hypoplasia if it occurs before birth and atrophy if it develops postnatally.

Left-to-Right Shunts

Left-to-right shunts are the most common CHD; these include ASD, VSD, and PDA (Fig. 12.3). ASDs typically increase only right ventricular and pulmonary outflow volumes, and VSDs and PDA cause both increased pulmonary blood flow and pressure. Depending on their size and location, manifestations of these shunts range in severity from no symptoms at all to fulminant heart failure.

Atrial Septal Defect

ASDs are abnormal, fixed openings in the atrial septum caused by incomplete tissue formation that allows communication of blood between the left and right atria; ASDs are usually asymptomatic until adulthood (see Table 12.2 and Fig. 12.3*A*). ASD should not be confused with patent foramen ovale (PFO; see later), which represents the postnatal

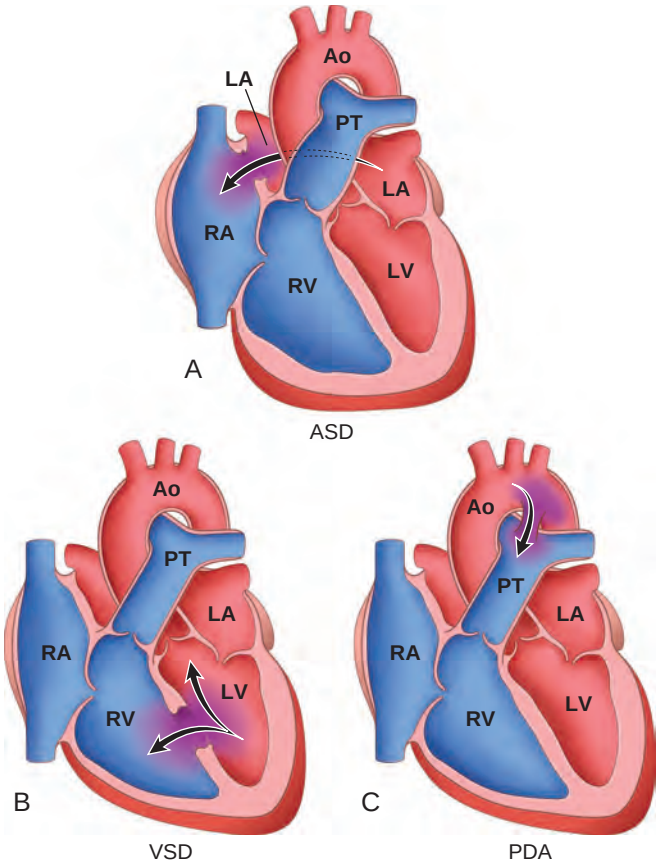

Figure 12.3 Common congenital left-to-right shunts (*arrows* indicate the direction of blood flow). (A) Atrial septal defect *(ASD).* (B) Ventricular septal defect *(VSD).* With VSD, the shunt is left-to-right, and the pressures are the same in both ventricles. Pressure hypertrophy of the right ventricle and volume hypertrophy of the left ventricle are generally present. (C) Patent ductus arteriosus *(PDA). failure to close a foramen (channel) that is part of normal development. A brief summary of the developmental stages of the atrial septum follows:

- The septum primum is a crescent-shaped membranous ingrowth that sits posteriorly between the right and left atria and partially separates them; the remaining transient anterior opening, called the *ostium primum,* allows movement of blood from the right to left atrium during early fetal development.
- Before the growing septum primum completely obliterates the ostium primum, it develops a second posterior opening called the ostium secundum.
- The septum secundum is a subsequent membranous ingrowth located to the right and anterior of the septum primum.
- The septum secundum grows to cover the ostium secundum, leaving only a small channel called the foramen ovale that is continuous with the ostium secundum—the foramen ovale/ostium secundum permits continued right-to-left shunting of blood during intrauterine development.

This flap of septum secundum tissue opens and closes in response to pressure gradients between the left and right atria; the valve opens only when the pressure is greater in the right atrium. In fetal life, the lungs are nonfunctional, and the pressure in the pulmonary circulation is greater than that of the systemic circulation; thus, the right atrium is under higher pressures than the left atrium, and the valve of the foramen ovale is normally open. At birth, with lung expansion, the pulmonary vascular pressures drop, and the right atrial pressures fall below those in the left atrium. As a result, the valve of the foramen ovale closes—and is usually permanently sealed before adulthood (see later).

MORPHOLOGY

ASDs are classified according to their location. **Secundum ASD** (90% of all ASDs) result from a deficient septum secundum formation near the center of the atrial septum. These are usually not associated with other anomalies, may be of any size, and can be multiple or fenestrated. **Primum anomalies** (5% of ASD) occur adjacent to the AV valves and are often associated with AV valve abnormalities and/or a VSD. **Sinus venosus defects** (5%) are located near the entrance of the superior vena cava and can be associated with anomalous pulmonary venous return to the right atrium.

Clinical Features

ASDs are usually asymptomatic until adulthood. Although VSDs are more common, most close spontaneously. Consequently, ASDs—which are less likely to close spontaneously—are the most common defects to be diagnosed in adults. ASDs result in a left-to-right shunt, largely because pulmonary vascular resistance is considerably less than systemic vascular resistance and because the compliance (distensibility) of the right ventricle is much greater than that of the left. The resulting pulmonary flow volumes may be two to eight times normal. A murmur is often present as a result of excessive flow through the pulmonary valve and/or through the ASD. Despite the right-sided volume overload, ASDs are generally well tolerated and usually do not become symptomatic before 30 years of age; irreversible pulmonary hypertension is unusual.

Surgical or intravascular ASD closure is performed to preempt the development of heart failure, paradoxical embolization, and irreversible pulmonary vascular disease. Mortality is low, and postoperative survival is comparable to that for an unaffected population.

Patent Foramen Ovale

The foramen ovale closes permanently in approximately 80% of people by 2 years of age. However, in the remaining 20%, the unsealed flap can open if right-sided pressures become elevated. Thus, sustained pulmonary hypertension or even transient increases in right-sided pressures (e.g., during a bowel movement, coughing, or sneezing) can produce brief periods of right-to-left shunting, with the possibility of paradoxical embolism.

Ventricular Septal Defect

VSDs are incomplete closures of the ventricular septum, allowing free communication of blood between the left to right ventricles; they are the most common form of CHD (see Table 12.2 and Fig. 12.3*B*).

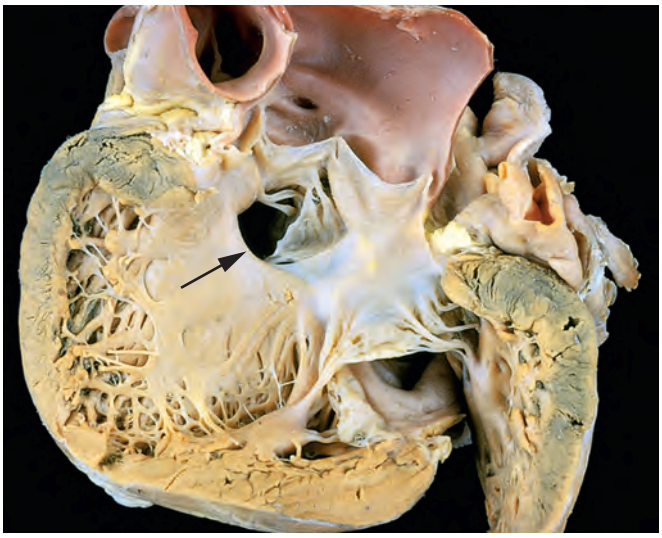

Figure 12.4 A membranous type ventricular septal defect *(arrow)* just proximal to the aortic valve. (Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn.)

MORPHOLOGY

VSDs are classified according to their location and magnitude. About 90% occur in the region of the membranous interventricular septum (**membranous VSD**; Fig. 12.4), and the majority are 2 to 3 cm in diameter. The remaining 10% occur below the pulmonary valve **(infundibular VSD)** or within the muscular septum. Although most VSDs are single, those in the muscular septum may be multiple.

Clinical Features

Most VSDs that clinically manifest in the pediatric age group are associated with other congenital cardiac anomalies such as TOF; only 20% to 30% are isolated. Conversely, if a VSD is first detected only in an adult, it is usually an isolated defect. The functional consequences of a VSD depend on the size of the defect and whether there are associated right-sided malformations. Thus, large VSDs cause difficulties virtually from birth; smaller lesions are generally well tolerated for years and may not be recognized until much later in life. Moreover, approximately 50% of small muscular VSDs close spontaneously. Large defects are usually membranous or infundibular, and they generally cause significant left-to-right shunting, leading to early right ventricular hypertrophy and pulmonary hypertension. Over time, large unclosed VSDs almost universally lead to irreversible pulmonary vascular disease, ultimately resulting in shunt reversal and cyanosis. Surgical or catheter-based closure of asymptomatic VSD is generally delayed beyond infancy, in hope of spontaneous closure. Early correction, however, must be performed for large defects to prevent the development of irreversible obstructive pulmonary vascular disease.

Patent Ductus Arteriosus

The ductus arteriosus arises from the pulmonary artery and joins the aorta just distal to the origin of the left subclavian artery. During intrauterine life, it permits blood flow from the pulmonary artery to the aorta, thereby bypassing the unoxygenated lungs. In healthy term infants, the ductus constricts and is functionally closed within 1 to 2 days of birth; this occurs in response to increased arterial oxygenation, decreased pulmonary vascular resistance, and declining local levels of prostaglandin E_2. Complete structural obliteration occurs within the first few months of extrauterine life leaving behind the ligamentum arteriosum. Ductal closure is often delayed (or even absent) in infants with hypoxia (due to respiratory distress or heart disease) or when other congenital defects are present, particularly VSDs that increase pulmonary vascular pressures. PDAs account for about 7% of cases of CHD (see Table 12.2 and Fig. 12.3C), and 90% of these are isolated defects.

PDA produces a characteristic, continuous, harsh "machinery-like" murmur. The clinical impact of a PDA depends on its diameter and the cardiovascular status of the individual. PDA is usually asymptomatic at birth, and a narrow PDA may have no effect on the child's growth and development. Because the shunt is initially left-to-right, there is no cyanosis. However, with large shunts, the additional volume and pressure overloads eventually produce obstructive changes in small pulmonary arteries, leading to reversal of flow and its associated consequences. In general, isolated PDA should be closed as early in life as is feasible; therapy includes prostaglandin synthesis inhibitors and possibly percutaneous or surgical interventions. Conversely, preservation of ductal patency (by administering prostaglandin E1) may be life-saving for infants with various congenital malformations that obstruct the pulmonary or systemic outflow tracts. In CHD with aortic valve or pulmonary valve atresia, for example, a PDA may provide the entire systemic blood flow or pulmonary blood flow, respectively.

Right-to-Left Shunts

The diseases in this group cause cyanosis early in postnatal life (cyanotic CHD). TOF, the most common in this group, and TGA are illustrated schematically in Fig. 12.5. The others include persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection. Note that the names of all of these conditions start with a *T*.

Tetralogy of Fallot

The four cardinal features of TOF are (1) VSD, (2) obstruction of the right ventricular outflow tract (subpulmonic stenosis), (3) an aorta that overrides the VSD, and (4) right ventricular hypertrophy (see Fig. 12.5A). The first three features result embryologically from anterosuperior displacement of the infundibular septum, and the right ventricular hypertrophy is a secondary consequence of the pressure overload.

MORPHOLOGY

The heart is typically enlarged and is classically "boot-shaped" due to marked right ventricular hypertrophy. The VSD is usually large with the aortic valve at the superior border, thereby overriding the defect and both ventricular chambers. The obstruction to right ventricular outflow is most often due to narrowing of the infundibulum (subpulmonic stenosis) but can be accompanied

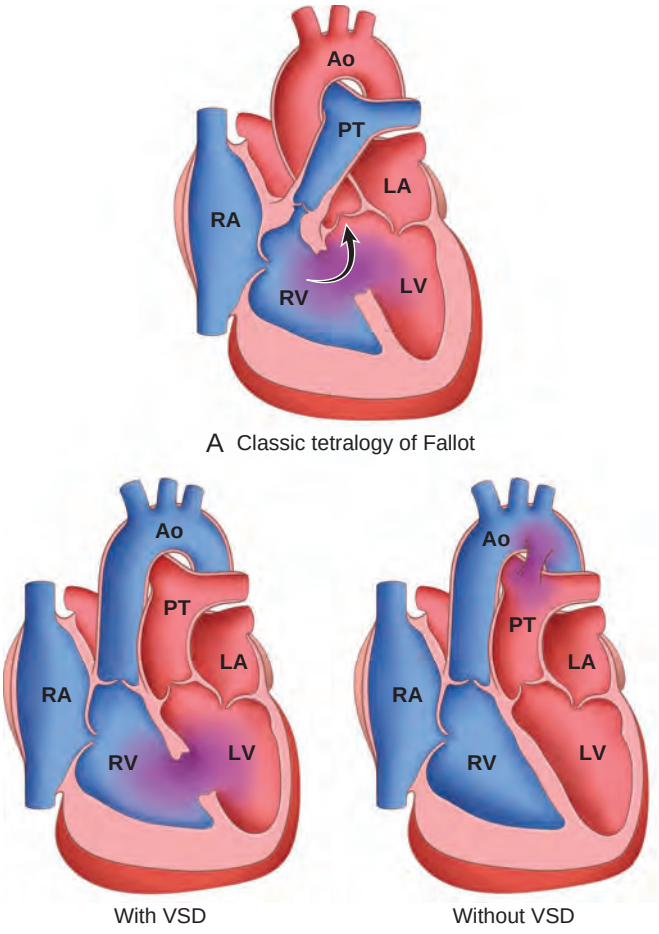

Figure 12.5 Common congenital right-to-left shunts (cyanotic congenital heart disease). (A) Tetralogy of Fallot. The direction of shunting across the ventricular septal defect *(VSD)* depends on the degree of the subpulmonic stenosis; when severe, a right-to-left shunt results *(arrow)*. (B) Dextro-transposition of the great arteries with and without VSD. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PT,* pulmonary trunk; *RA,* right atrium; *RV,* right ventricle.

by pulmonary valvular stenosis. Sometimes there is complete atresia of the pulmonary valve and variable portions of the pulmonary arteries, such that blood flow through a PDA, dilated bronchial arteries, or both, is necessary for survival. Aortic valve insufficiency or an ASD may also be present; a right aortic arch is present in about 25% of cases.

Clinical Features

Depending on the severity of the subpulmonic stenosis, untreated TOF can be tolerated into adulthood; 10% of unoperated individuals are alive at 20 years of age, and 3% survive for 40 years. If the subpulmonic stenosis is mild, the abnormality resembles an isolated VSD, and the shunt may be left-to-right, without cyanosis (so-called pink tetralogy). With more severe right ventricular outflow obstruction, right-sided pressures approach or exceed left-sided pressures, and right-to-left shunting develops, producing cyanosis (classic TOF). Most infants with TOF are cyanotic at birth or soon thereafter. The more severe the subpulmonic stenosis, the more hypoplastic are the pulmonary arteries (i.e., smaller and thinner-walled) and the larger is the overriding aorta. As the child grows and the heart increases in size, the pulmonic orifice does not expand proportionally, making the obstruction progressively worse. The subpulmonic stenosis, however, protects the pulmonary vasculature from pressure overload, and right ventricular failure is rare because the right ventricle is decompressed by the shunting of blood into the left ventricle and aorta. Complete surgical repair is possible but becomes complicated for individuals with pulmonary atresia and dilated bronchial arteries.

Transposition of the Great Arteries

TGA produces ventriculoarterial discordance (the ventricle outflow going to the wrong outflow vessel). In the more common variant (dextro-TGA or d-TGA), the aorta arises from the right ventricle, and the pulmonary artery emanates from the left ventricle (ventriculoarterial discordance; Fig. 12.5B and Fig. 12.6). The atrium-to-ventricle connections are normal (concordant), with the right atrium joining the right ventricle and the left atrium emptying into the left ventricle. The embryologic defect in complete TGA stems from abnormal formation of the spiraling truncal and aortopulmonary septae. The result is separation of the systemic and pulmonary circulations, a condition incompatible with postnatal life unless a shunt exists for adequate mixing of blood.

The outlook for infants with d-TGA depends on the degree of blood "mixing," the magnitude of tissue hypoxia, and the ability of the right ventricle to maintain the systemic circulation. Patients with d-TGA and a VSD (approximately 35%) often have a stable shunt. However, dependence on a patent foramen ovale or ductus arteriosus for blood mixing (approximately 65%) is problematic. These systemic-to-pulmonary connections tend to close early and thus require intervention to create a new shunt within the first few days of life (e.g., balloon atrial septostomy). With time, right

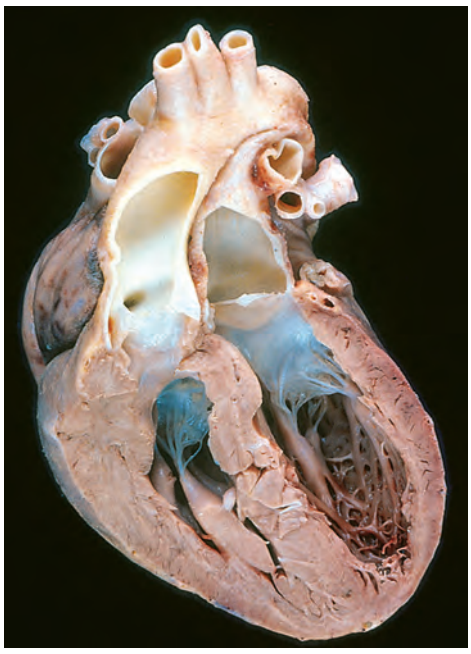

Figure 12.6 Dextro-transposition of the great arteries. (Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn.)

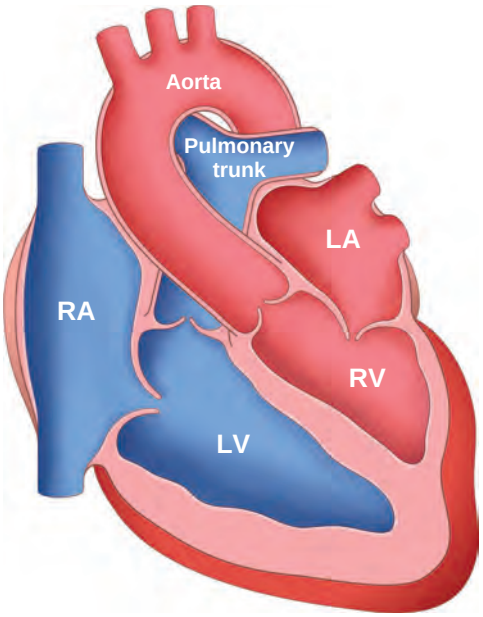

Figure 12.7 Schematic for "congenitally corrected" levo-transposition of the great arteries. The right atrium *(RA)* flows to the morphologic left ventricle *(LV)*, which connects to the pulmonary arteries; the left atrium *(LA)* connects to the morphologic right ventricle *(RV)*, which empties into the aorta, which is anomalously anterior and to the left. This congenital malformation may be well-tolerated, presenting only relatively late in adulthood with decompensation of the morphologic right ventricle.

ventricular hypertrophy becomes prominent because this chamber is functioning as the systemic ventricle. Concurrently, the left ventricle becomes thin-walled (atrophic) as it supports the low-resistance pulmonary circulation. Without surgery, most patients die within months. However, improved early surgical intervention, typically with an arterial switch operation, allows many patients with d-TGA to survive into adulthood.

In the less common levo-TGA (l-TGA, also commonly referred to as "congenitally corrected" TGA), the right atrium connects to a ventricle with the internal morphology of a left ventricle (atrioventricular discordance), which in turn empties into the pulmonary arteries (ventriculoarterial discordance); at the same time, the left atrium connects to a morphologic right ventricle, which empties into the aorta (Fig. 12.7). l-TGA does not lead to cyanosis and indeed can be entirely asymptomatic, being diagnosed in adulthood only during a workup for other cardiac issues. Nevertheless, l-TGA will result in hypertrophy of the morphologic right ventricle and eventually can cause heart failure; it is also often associated with other CHD such as VSD, ASD, and patent foramen ovale.

Tricuspid Atresia

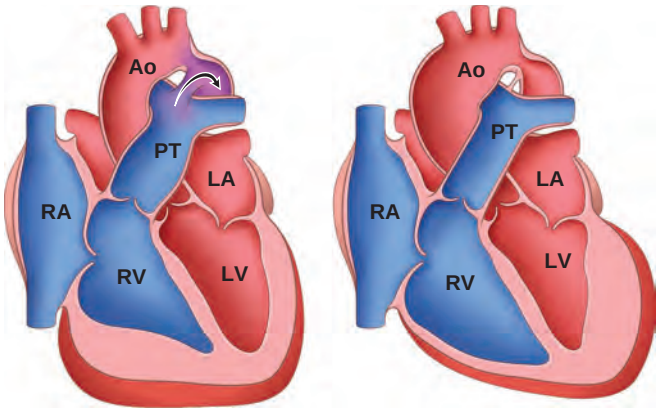
Tricuspid atresia represents complete occlusion of the tricuspid valve orifice. It results embryologically from unequal division of the AV canal; thus, the mitral valve is larger than normal, and there is right ventricular underdevelopment (hypoplasia). The circulation can be maintained by right-to-left shunting through an interatrial communication (ASD or patent foramen ovale), in addition to a VSD that connects the left ventricle and the pulmonary artery arising from the hypoplastic right ventricle. Cyanosis is present virtually from birth, and there is a high early mortality.

Obstructive Lesions

Congenital obstruction to blood flow can occur at the level of the heart valves or within a great vessel. Common examples include aortic or pulmonary valve stenosis or atresia, and coarctation of the aorta. Obstruction can also occur within a chamber, as with subpulmonic stenosis in TOF.

Coarctation of the Aorta

Coarctation (narrowing, constriction) of the aorta ranks high in frequency among the common structural anomalies. It is twice as common in males as in females; interestingly, females with Turner syndrome are also frequently affected (Chapter 5). There are two classic forms: (1) an "infantile" form—often symptomatic in early childhood—with tubular hypoplasia of the aortic arch proximal to a PDA, and (2) an "adult" form with a discrete ridgelike infolding of the aorta just opposite the closed ductus arteriosus (ligamentum arteriosum) distal to the arch vessels (Fig. 12.8). Encroachment



A Coarctation of aorta

Figure 12.8 (A) Schematic of aortic coarctation with and without patent ductus arteriosus *(PDA)*. (B) Coarctation of the aorta, postductal type. The coarctation is a segmental narrowing of the aorta *(arrow)*. Such lesions typically manifest later in life than preductal coarctations. The dilated ascending aorta and major branch vessels are to the left of the coarctation. The lower extremities are perfused predominantly by way of dilated, tortuous collateral channels. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PT*, pulmonary trunk; *RA*, right atrium; *RV*, right ventricle; *PDA*, patent ductus arteriosus. (A, Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn. B, Courtesy Sid Murphree, MD, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

on the aortic lumen is variable, sometimes leaving only a small channel and at other times producing only minimal narrowing. Although coarctation of the aorta may occur as a solitary defect, in 50% of cases it is accompanied by a bicuspid aortic valve and may also be associated with congenital aortic stenosis, ASD, VSD, mitral regurgitation, or berry aneurysms of the circle of Willis.

MORPHOLOGY

Preductal coarctation is characterized by circumferential narrowing of the aortic segment between the left subclavian artery and the ductus arteriosus; the ductus typically is patent and is the main source of (unoxygenated) blood delivered to the distal aorta. The pulmonary trunk is dilated to accommodate the increased blood flow; because the right side of the heart now perfuses the body distal to the narrowed segment ("coarct"), the right ventricle typically is hypertrophied.

In the more common **"adult" postductal coarctation,** the aorta is sharply constricted by a tissue ridge adjacent to the nonpatent ligamentum arteriosum (see Fig. 12.8B). The constricted segment is made up of smooth muscle and elastic fibers derived from the aortic media. Proximal to the coarctation, the aortic arch and its branch vessels are dilated and the left ventricle is hypertrophied.

Clinical Features

Clinical manifestations depend on the severity of the narrowing and the patency of the ductus arteriosus. Coarctation of the aorta with a PDA usually manifests early in life; indeed, it may cause signs and symptoms immediately after birth. In such cases, the delivery of unsaturated blood through the PDA produces cyanosis localized to the lower half of the body. Many such infants do not survive the neonatal period without surgical or catheter-based intervention to occlude the PDA.

The outlook is different with coarctation of the aorta without a PDA, unless the aortic constriction is severe. Most children are asymptomatic, and the disease may go unrecognized until well into adult life. Typically there is hypertension in the upper extremities with weak pulses and hypotension in the lower extremities, associated with manifestations of arterial insufficiency (i.e., claudication and coldness). Particularly characteristic is the development of collateral circulation between the pre-coarctation and post-coarctation arteries through enlarged intercostal and internal mammary arteries, often producing radiographically visible erosions ("notching") of the undersurfaces of the ribs.

With significant coarctations, murmurs are present throughout systole; sometimes a vibratory "thrill" is also present. The long-standing pressure overload leads to concentric left ventricular hypertrophy. With uncomplicated coarctation of the aorta, surgical resection and end-to-end anastomosis or replacement of the affected aortic segment by a prosthetic graft yields excellent results.

Pulmonary Stenosis and Atresia

Pulmonary stenosis or atresia is a relatively frequent malformation leading to obstruction at the level of the pulmonary valve. This can be mild to severe; the lesion can also be isolated or part of a more complex anomaly—either TOF or TGA. Right ventricular hypertrophy typically develops, and there is sometimes poststenotic dilation of the pulmonary artery due to injury of the wall by high-pressure jets through the stenotic valve. With coexistent subpulmonic stenosis (as in TOF), the pulmonary trunk is not dilated and may in fact be hypoplastic. When the valve is entirely atretic, there is no communication between the right ventricle and lungs. In such cases, the anomaly is associated with a hypoplastic right ventricle and an ASD; blood reaches the lungs through a PDA. Mild stenosis may be asymptomatic and compatible with long life, whereas symptomatic cases require surgical correction. When the RV is severely hypoplastic, blood can be surgically routed directly from the vena cavae to the pulmonary artery, bypassing the right side of the heart.

Aortic Stenosis and Atresia

Congenital narrowing and obstruction of the aortic valve can occur at three locations: valvular, subvalvular, and supravalvular. Congenital aortic valve stenosis is an isolated lesion in 80% of cases. With valvular aortic stenosis, the cusps may be hypoplastic (small), dysplastic (thickened, nodular), or abnormal in number (usually with one or no commissures). In severe congenital aortic stenosis or atresia, obstruction of the left ventricular outflow tract leads to hypoplasia of the left ventricle and ascending aorta, sometimes accompanied by dense, porcelain-like left ventricular endocardial fibroelastosis; the ductus arteriosus must be patent to allow blood flow to the aorta and coronary arteries. The constellation of findings is called hypoplastic left heart syndrome, and unless PDA patency is preserved, duct closure in the first week of life is generally lethal. Affected patients require surgeries that allow the right ventricle to become the pump for the systemic circulation, with the lungs perfused from either a parallel right ventricular conduit or passively from the venae cavae.

Subaortic stenosis is caused by a thickened ring or collar of dense endocardial fibrous tissue below the level of the cusps. Supravalvular aortic stenosis is a congenital aortic dysplasia with thickening and constriction of the ascending aortic wall. Elastin gene mutations can cause supravalvular stenosis by disrupting elastin–smooth muscle cell interactions during aortic morphogenesis. Subaortic stenosis is usually associated with a prominent systolic murmur and sometimes a thrill. Pressure hypertrophy of the left ventricle develops as a consequence of the obstruction to blood flow; unless very severe, the stenosis is generally well-tolerated, although left ventricular hypertrophy still carries a risk of sudden cardiac death.

KEY CONCEPTS

CONGENITAL HEART DISEASE

- CHD represents defects of cardiac chambers or the great vessels; these typically either result in shunting of blood between the right and left circulation or cause outflow obstruction. Lesions range from relatively asymptomatic to rapidly fatal. Environmental and genetic causes both contribute, and the manifestations depend on the timing of the environmental insult and which step in cardiac development is affected.

- Left-to-right shunts are most common and are typically associated with ASD, VSD, or PDA. These lesions result in chronic right-sided pressure and volume overloads that eventually cause pulmonary hypertension with reversal of flow and right-to-left shunts with cyanosis (Eisenmenger syndrome).
- Right-to-left shunts are most commonly caused by TOF or TGA. These are cyanotic lesions from the outset and are associated with polycythemia, peripheral cyanosis effects, and paradoxical emboli.
- Obstructive lesions include valve stenoses and aortic coarctation; the clinical severity of the lesion depends on the degree of stenosis and the patency of the ductus arteriosus.

ISCHEMIC HEART DISEASE

IHD represents a group of related entities resulting from myocardial ischemia—an imbalance between myocardial supply (perfusion) and cardiac demand for oxygenated blood. Ischemia not only limits tissue oxygenation (and thus ATP generation), but also reduces the availability of nutrients and the removal of metabolic wastes (Chapter 2). Thus, cardiac ischemia is generally less well tolerated than hypoxemia per se, such as may occur with severe anemia, cyanotic heart disease, or advanced lung disease.

In more than 90% of cases, myocardial ischemia results from reduced blood flow due to obstructive atherosclerotic lesions in the epicardial coronary arteries; consequently, IHD is frequently referred to as coronary artery disease (CAD). In most cases, there is a long period (up to decades) of silent, slow progression of coronary lesions before the sudden onset of symptoms. Thus, IHD is often the late manifestation of coronary atherosclerosis that began during childhood or adolescence (Chapter 11).

IHD can declare itself through one or more of the following clinical presentations:

- *Myocardial infarction (MI),* in which ischemia causes frank cardiac necrosis
- *Angina pectoris* (literally "chest pain"), in which ischemia is not severe enough to cause infarction, but the symptoms nevertheless portend infarction risk
- *Chronic IHD* with heart failure
- *Sudden cardiac death (SCD)*

In addition to coronary atherosclerosis, myocardial ischemia can be caused by coronary emboli, myocardial vessel inflammation, or vascular spasm. Moreover, otherwise modest coronary artery occlusions may become consequential in the setting of increased cardiac energy demand (e.g., myocardial hypertrophy or increased heart rate), hypoxemia, or systemic hypotension (e.g., shock). Some conditions can have multiple deleterious effects. Thus, tachycardia increases oxygen demand (because of more contractions per unit time) while decreasing functional supply (by decreasing the relative time spent in diastole, when cardiac perfusion occurs).

Epidemiology

IHD is the single largest cause of mortality worldwide, accounting for over 12% of global deaths; in the industrialized nations, this amounts to over 7.5 million casualties each year. Even in low income countries, advances in the treatment and prevention of infectious diseases, and the increasing adoption of westernized diets is accelerating IHD incidence; it is predicted soon to become the leading cause of mortality there as well.

At the same time, there is cause for optimism; since peaking in the mid-1960s, the overall death rate from IHD has fallen in the United States by over 50%. This remarkable improvement can be attributed to the following:

- *Prevention,* achieved by modifying important risk factors, such as smoking, level of blood cholesterol, and hypertension. Additional risk reduction can occur through weight loss, exercise, and maintaining good glycemic control in diabetic patients.
- *Diagnostic and therapeutic advances,* allowing earlier and more effective treatments. The latter include cholesterol- (and inflammation-) lowering drugs such as statins, thrombolysis for acute coronary occlusions, better medical management after MI, coronary angioplasty and stenting, coronary artery bypass graft (CABG) surgery, and improved therapies for heart failure and arrhythmias using left VADs, implantable defibrillators, and cardiac resynchronization approaches. Even a simple daily prophylactic aspirin can have therapeutic benefit.

Continuing this encouraging trend will be challenging, particularly in view of the increased longevity of "baby boomers" (which will lead to a doubling of individuals older than 65 years of age by 2050), and the "obesity epidemic." New therapeutic advances will depend on understanding the genetic determinants of coronary atherosclerosis and IHD. Thus, the observation that MIs occur in only a fraction of individuals with coronary disease suggests that simple control of atherosclerotic risk factors is only part of the story.

Pathogenesis

The dominant cause of IHD syndromes is insufficient coronary perfusion relative to myocardial demand; in the vast majority of cases, this is due to either of the following:

- *Chronic,* progressive atherosclerotic narrowing of the epicardial coronary arteries
- Variable degrees of superimposed *acute* plaque change, thrombosis, and vasospasm.

The individual elements and their interactions are discussed next.

Chronic Vascular Occlusion

More than 90% of patients with IHD have atherosclerosis involving one or more of the epicardial coronary arteries (Chapter 11). A fixed lesion obstructing greater than 70% of vascular cross-sectional area (so called "critical stenosis") is typically cited as the threshold for symptomatic ischemia precipitated by exercise (characteristically manifesting as exertional angina). With this degree of obstruction, compensatory coronary arterial vasodilation is no longer sufficient to meet even moderate increases in myocardial demand. Obstruction of 90% of the cross-sectional area of the lumen generally leads to inadequate coronary blood flow, even at rest. Slowly developing obstructions induce the formation

of collateral circulation that can mitigate the effects of even high-grade stenoses by allowing alternate channels to perfuse at-risk myocardium. Consequently, rather than just assessing the extent of local vascular stenosis, measurements of coronary flow across the stenosis (flow reserves) provide a better assessment of the consequences of fixed coronary artery occlusions, particularly when multifocal.

Although only a single major coronary epicardial vessel may be affected, two or all three—the left anterior descending (LAD), left circumflex (LCX), and right coronary artery (RCA)—are often involved simultaneously by obstructive atherosclerosis. Clinically significant plaques can be located anywhere along the course of the vessels, although they tend to predominate within the first several centimeters of the LAD and LCX. Sometimes the major epicardial branches are also involved (i.e., LAD diagonal branches, LCX obtuse marginal branches, or posterior descending branch of the RCA), but atherosclerosis of the intramyocardial (penetrating) branches is rare. Thus, most atherosclerotic stenoses can be accessed by coronary catheterization.

Acute Plaque Change

The risk of an individual developing clinically important IHD depends in part on the number, distribution, structure, and degree of obstruction by atheromatous plaques. However, the varied clinical manifestations of IHD cannot be explained by the anatomic disease burden and fixed stenoses alone. This is particularly true for the so-called acute coronary syndromes, namely when unstable angina, acute MI, and sudden death are caused abruptly by acute plaque changes. These acute coronary syndromes are typically initiated by an unpredictable and sudden conversion of a stable atherosclerotic plaque to an unstable and potentially life-threatening atherothrombotic lesion through rupture, superficial erosion, ulceration, fissuring, or deep hemorrhage (collectively called acute plaque change) (Chapter 11). In most instances, acute plaque changes—typically associated with intralesional inflammation—precipitate the formation of a superimposed thrombus that partially or completely occludes the artery. It remains to be seen whether aggressive anti-inflammatory regimens are a means to reduce such acute coronary events.

Consequences of Myocardial Ischemia

- *Stable angina* results from increases in myocardial oxygen demand that outstrip the ability of coronary arteries with fixed stenoses to increase oxygen delivery; it is usually not associated with plaque disruption.
- *Unstable angina* is caused by acute plaque change that results in thrombosis and/or vasoconstriction, and leads to incomplete or transient reductions in coronary blood flow. In some cases, microinfarcts can occur distal to disrupted plaques due to thromboemboli.
- *MI* is often the result of acute plaque change that induces an abrupt thrombotic occlusion, resulting in myocardial necrosis.
- *Sudden cardiac death* may be caused by regional myocardial ischemia that induces a fatal ventricular arrhythmia. This can result from a fixed stenosis or acute plaque change.

Each of these important syndromes is discussed in detail next, followed by an examination of the important myocardial consequences.

Angina Pectoris

Angina pectoris is characterized by paroxysmal and usually recurrent attacks of substernal or precordial chest discomfort caused by transient (15 seconds to 15 minutes) myocardial ischemia that is insufficient to induce myocyte necrosis. The anginal pain is a consequence of the ischemia-induced release of adenosine, bradykinin, and other molecules that stimulate sympathetic and vagal afferent nerves. Three overlapping patterns of angina pectoris are recognized, caused by varying combinations of decreased perfusion, increased demand, and coronary arterial pathology. Importantly, not all ischemic events are perceived by patients; silent ischemia is particularly common in the geriatric population and in the setting of diabetic neuropathy.

- *Stable (typical) angina* is the most common form of angina; it is caused by an imbalance in coronary perfusion (due to chronic stenosing coronary atherosclerosis) relative to myocardial demand. Stable angina does not occur at rest, but in a given patient can be reliably induced by activities that increase the energy requirements of the heart, including physical activity, emotional excitement, or psychological stress. Angina pectoris is classically described as a crushing or squeezing substernal sensation that can radiate down the left arm or to the left jaw *(referred pain)*. The pain is usually relieved by rest (decreasing demand) or by administering vasodilators, such as nitroglycerin and calcium channel blockers (thereby increasing perfusion).
- *Prinzmetal variant angina* is an uncommon form of episodic myocardial ischemia caused by coronary artery spasm. Although individuals with Prinzmetal variant angina can also have significant coronary atherosclerosis, the anginal attacks are unrelated to physical activity, heart rate, or blood pressure, and can occur at rest. Prinzmetal angina generally responds promptly to vasodilators.
- *Unstable* or *crescendo angina* refers to a pattern of increasingly frequent, prolonged (>20 min), or severe angina, precipitated by progressively lower levels of physical activity or even occurring at rest. Unstable angina is associated with plaque disruption and superimposed thrombosis, distal embolization of the thrombus, and/or vasospasm; it is an important harbinger of MI, potentially portending complete vascular occlusion.

Myocardial Infarction

MI, also commonly referred to as "heart attack," is the death of cardiac muscle due to prolonged ischemia. Roughly 1.5 million individuals in the United States suffer an MI each year, causing approximately 610,000 deaths annually. The major underlying cause of IHD is atherosclerosis; although MIs can occur at virtually any age, 10% of MIs occur in people younger than 40 years of age, and 45% occur in people younger than 65 years of age. Nevertheless, the frequency rises progressively with increasing age and with increasing atherosclerotic risk factors (Chapter 11). Through middle age, male gender increases the relative risk of MI; indeed, women are generally protected against MI during their reproductive years. However, postmenopausal decline in estrogen production is usually associated with accelerated CAD, and IHD is the most common cause of death in older

women. Unfortunately, postmenopausal hormonal replacement therapy has not been shown to be protective, and in fact, in some cases, may be detrimental.

Pathogenesis

Coronary Arterial Occlusion. The following sequence of events likely underlies most MIs (see Chapter 11 for additional details):

- An atheromatous plaque is eroded or suddenly disrupted by endothelial injury, intraplaque hemorrhage, or mechanical forces, exposing subendothelial collagen and necrotic plaque contents to the blood.
- Platelets adhere, aggregate, and are activated, releasing thromboxane A_2, adenosine diphosphate (ADP), and serotonin—causing further platelet aggregation and vasospasm (Chapter 4).
- Activation of coagulation by tissue factor and other mechanisms adds to the growing thrombus.
- Within minutes, the thrombus can evolve to completely occlude the coronary artery lumen.

The evidence for this scenario derives from autopsy studies of patients dying of acute MI, as well as imaging studies demonstrating a high frequency of thrombotic occlusion early after MI; interestingly, comparison to prior angiograms shows that these thrombi are usually at a site that did not previously have a critical (>70%) fixed stenosis. Typically, when angiography is performed within 4 hours of the onset of MI, it demonstrates coronary thrombosis in almost 90% of cases. However, when angiography is performed 12 to 24 hours after onset of symptoms, evidence of thrombosis is seen in only 60% of patients, even without intervention. Thus, at least some occlusions clear spontaneously through lysis of the thrombus or relaxation of spasm. This sequence of events in a typical MI also has therapeutic implications: early thrombolysis and/or angioplasty can be highly successful in limiting the extent of myocardial necrosis.

In approximately 10% of cases, MI occurs in the absence of the typical coronary atherothrombosis. In such situations, other mechanisms may be responsible for the reduced coronary blood flow:

- *Vasospasm* with or without coronary atherosclerosis, perhaps in association with platelet aggregation or due to drug ingestion (e.g., cocaine or ephedrine).
- *Emboli* from the left atrium in association with atrial fibrillation, a left-sided mural thrombus, vegetations of infective endocarditis (IE), intracardiac prosthetic material, or paradoxical emboli from the right side of the heart or the peripheral veins traversing a patent foramen ovale and into the coronary arteries
- *Uncommon causes* of MI without atherothrombosis include disorders of small intramural coronary vessels (e.g., vasculitis), hematologic abnormalities (e.g., sickle cell disease), amyloid deposition in vascular walls, vascular dissection, marked hypertrophy (e.g., due to aortic stenosis), lowered systemic blood pressure (e.g., shock), or inadequate myocardial "protection" during cardiac surgery.

Myocardial Response. Coronary arterial obstruction diminishes blood flow to a region of myocardium, causing ischemia, rapid myocardial dysfunction, and eventually—with prolonged vascular compromise—myocyte death. The anatomic region supplied by that artery is referred to as the area at risk. The outcome depends predominantly on the severity and duration of flow deprivation (Fig. 12.9).

The early biochemical consequence of myocardial ischemia is the cessation of aerobic metabolism within seconds, leading to inadequate production of high-energy phosphates (e.g., creatine phosphate and adenosine triphosphate) and accumulation of potentially noxious metabolites (e.g., lactic acid) (see Fig. 12.9A). Because of the exquisite dependence of myocardial function on oxygen and nutrients, myocardial contractility ceases within a minute or so of the onset of severe ischemia. Such loss of function contributes to decreased systolic function long before myocyte death occurs.

As detailed in Chapter 2, ultrastructural changes (including myofibrillar relaxation, glycogen depletion, cell and mitochondrial swelling) also develop within a few minutes

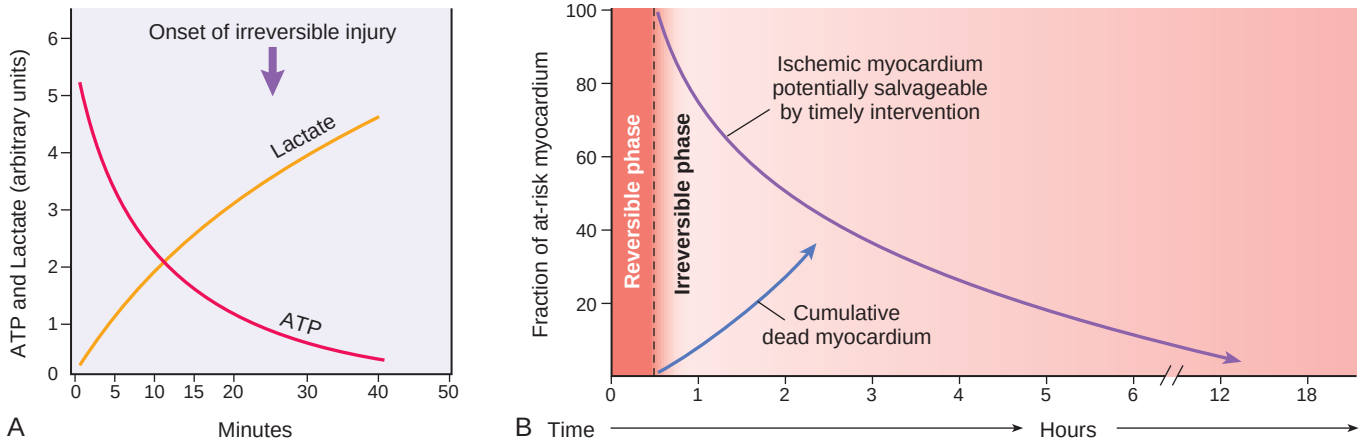


Figure 12.9 Temporal sequence of early biochemical findings and progression of cardiomyocyte necrosis after onset of severe myocardial ischemia. (A) Early changes include loss of adenosine triphosphate (ATP) and accumulation of lactate. (B) For approximately 30 minutes after the onset of even the most severe ischemia, myocardial injury is potentially reversible. Thereafter, progressive loss of viability occurs that becomes complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early and are progressively lost when reperfusion is delayed. (Originally modified with permission from Antman E: Acute myocardial infarction. In Braunwald E, et al., editors: *Heart Disease: a Textbook of Cardiovascular Medicine*, ed 6, Philadelphia, 2001, WB Saunders, pp 1114–1231.)

of the onset of ischemia. Nevertheless, these early manifestations of ischemic injury are potentially reversible. Indeed, experimental and clinical evidence shows that only severe ischemia (blood flow 10% or less of normal) lasting 20 to 30 minutes or longer leads to irreversible damage (necrosis) of cardiac myocytes. This delay in the onset of permanent myocardial injury provides the rationale for rapid diagnosis in acute MI—to permit early coronary intervention to establish reperfusion and salvage as much "at risk" myocardium as possible.

The earliest detectable feature of myocyte necrosis is disruption of the integrity of the sarcolemmal membrane, allowing intracellular macromolecules to leak out of necrotic cells into the cardiac interstitium and ultimately into the microvasculature and lymphatics. This escape of intracellular myocardial proteins into the circulation forms the basis for blood tests that can sensitively detect irreversible myocyte damage, and are important for managing MI (see later). With prolonged severe ischemia, injury to the microvasculature follows injury to the cardiac myocytes. The temporal progression of these events is summarized in Table 12.4.

Table 12.4 Approximate Time of Onset of Key Events in Ischemic Cardiac Myocytes

Feature	Time
Onset of ATP depletion	Seconds
Loss of contractility	<2 minutes
ATP reduced to 50% of normal to 10% of normal	 10 minutes 40 minutes
Irreversible cell injury	20–40 minutes
Microvascular injury	>1 hour

ATP, Adenosine triphosphate.

The progression of ischemic necrosis in the myocardium is summarized in Fig. 12.10. Irreversible injury of ischemic myocytes first occurs in the subendocardial zone. This region is especially susceptible to ischemia because it is the last area to receive blood delivered by the epicardial vessels, and also because it is exposed to relatively high intramural

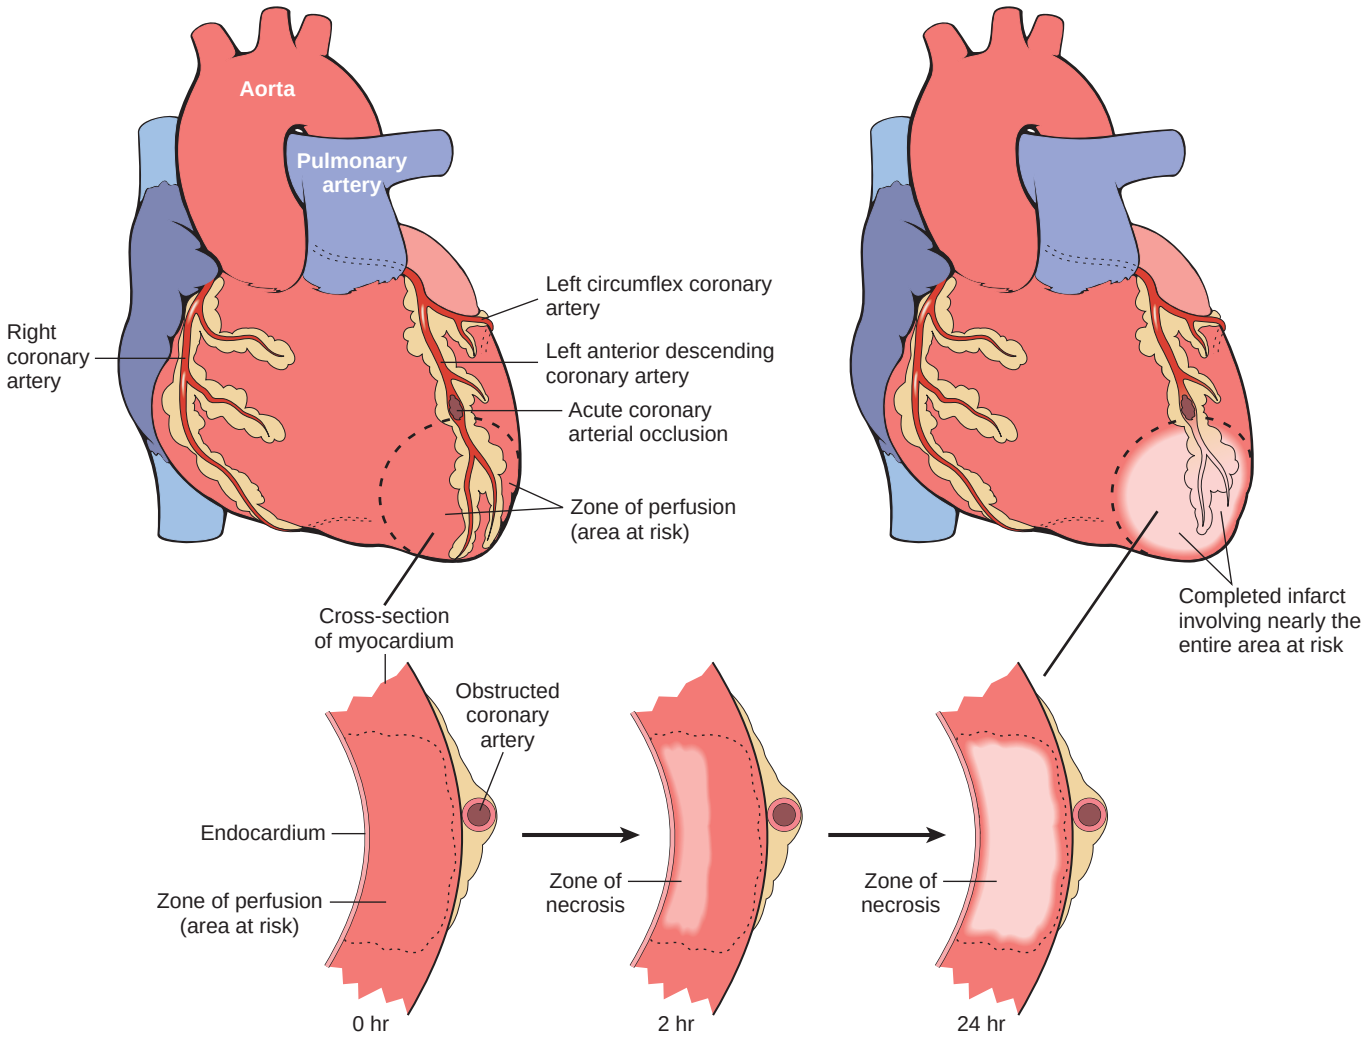

Figure 12.10 Progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. The area that depends on the occluded vessel for perfusion is the "at risk" myocardium *(shaded)*. Note that a very narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because oxygen and nutrition can be provided by diffusion from the ventricle.

pressures, which act to impede the inflow of blood. With more prolonged ischemia, a wavefront of cell death moves through other regions of the myocardium, driven by progressive tissue edema and myocardial-derived reactive oxygen species and inflammatory mediators.

The location, size, and specific morphologic features of an acute MI depend on the following:

- The *location, severity, and rate of development of coronary obstructions* due to atherosclerosis and thromboses
- The *size of the vascular bed* perfused by the obstructed vessels
- The *duration* of the occlusion
- The *metabolic and oxygen needs* of the myocardium at risk
- The extent of *vascular collateralization*
- The presence, site, and severity of coronary *arterial spasm*
- *Other factors,* such as heart rate, cardiac rhythm, and blood oxygenation

An infarct usually achieves its full extent within 3 to 6 hours; in the absence of intervention, an infarct caused by occlusion of an epicardial vessel can involve the entire wall thickness (transmural infarct). Clinical intervention within this critical window of time can lessen the size of the infarct within the territory at risk.

Patterns of Infarction. The distribution of myocardial necrosis correlates with the location and cause of the decreased perfusion (Fig. 12.11).

Knowledge of the areas of myocardium perfused by the major coronary arteries allows correlation of specific vascular obstructions with their corresponding areas of MI. Typically, the LAD branch of the left coronary artery supplies most of the apex of the heart, the anterior wall of the left ventricle, and the anterior two-thirds of the ventricular septum. By convention, the coronary artery—either RCA or LCX—that perfuses the posterior third of the septum is called "dominant" (even though the LAD and LCX collectively perfuse the majority of the left ventricular myocardium). In a right dominant circulation (present in approximately 80% of individuals), the RCA supplies the entire right ventricular free wall, the posterobasal wall of the left ventricle, and the posterior third of the ventricular septum, and the LCX generally perfuses only the lateral wall of the left ventricle. Thus, RCA occlusions can potentially lead to left ventricular damage.

Although most hearts have numerous intercoronary anastomoses (collateral circulation), relatively little blood normally courses through these. However, when a coronary artery is progressively narrowed over time, blood flows via the collaterals from the high- to the low-pressure circulation causing the channels to enlarge. Through such progressive dilation and growth of collaterals, stimulated by ischemia, blood flow is provided to areas of myocardium that would otherwise be deprived of adequate perfusion. Indeed, in the setting of extensive collateralization, the normal epicardial perfusion territories may be so expanded that subsequent occlusion leads to infarction in paradoxical distributions.

Transmural infarctions occur when there is occlusion of an epicardial vessel (in the absence of any therapeutic intervention)—the necrosis involves virtually the full thickness of the ventricular wall in the distribution of the affected coronary. This pattern of infarction is usually associated with a combination of chronic coronary atherosclerosis, acute

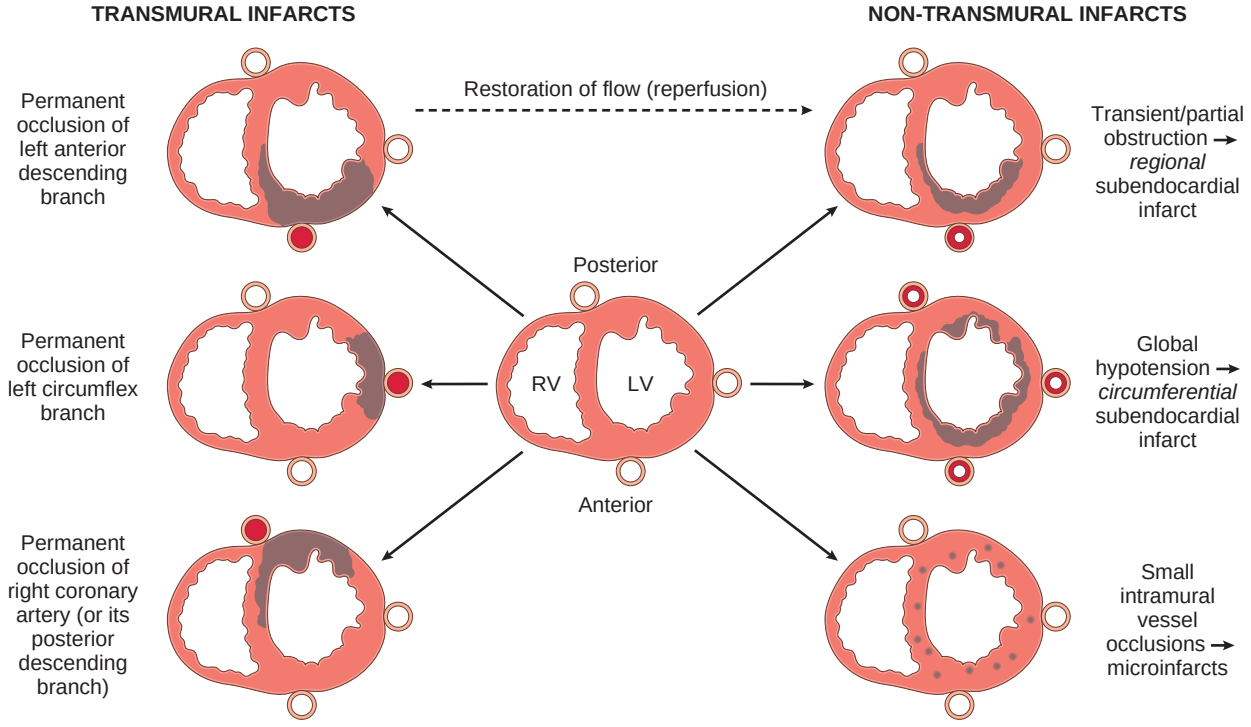

Figure 12.11 Distribution of myocardial ischemic necrosis correlates with the location and nature of decreased perfusion. *Left,* the positions of transmural acute infarcts resulting from occlusions of the major coronary arteries; *top to bottom,* left anterior descending, left circumflex, and right coronary arteries. *Right,* the types of infarcts that result from a partial or transient occlusion, global hypotension, or intramural small vessel occlusions.

plaque change, and superimposed thrombosis (discussed earlier).

Subendocardial (nontransmural) infarctions can occur as a result of a plaque disruption followed by a coronary thrombus that becomes lysed (therapeutically or spontaneously) before myocardial necrosis extends across the full thickness of the wall. Subendocardial infarcts can also result from prolonged, severe reduction in systemic blood pressure, as in shock superimposed on chronic, otherwise noncritical, coronary stenoses. In the subendocardial infarcts that occur as a result of global hypotension, myocardial damage is often circumferential, rather than being limited to the distribution of a single major coronary artery.

Multifocal microinfarction refers to a pattern that is seen when there is pathology involving only smaller intramural vessels. It can occur in the setting of microembolization, vasculitis, or vascular spasm, for example, due to endogenous catecholamines (epinephrine) or drugs (cocaine or ephedrine). Elevated levels of catecholamines also increase heart rate and myocardial contractility, exacerbating ischemia caused by the vasospasm. The outcome of such vasospasm can be sudden cardiac death (usually caused by a fatal arrhythmia) or an ischemic dilated cardiomyopathy (discussed later).

MORPHOLOGY

The temporal evolution of the morphologic changes in acute MI and subsequent healing are summarized in Table 12.5.

Nearly all transmural infarcts involve at least a portion of the left ventricle (comprising the free wall and ventricular septum); they encompass nearly the entire perfusion zone of the occluded coronary artery save for a narrow rim (approximately 0.1 mm) of viable subendocardial myocardium that is preserved by diffusion of oxygen and nutrients from the ventricular lumen.

The frequencies of involvement of each of the three main arterial trunks and the corresponding sites of myocardial lesions resulting in infarction (in the typical right dominant heart) are as follows (left side of Fig. 12.11):

- Left anterior descending coronary artery (40% to 50%): infarcts involving the anterior wall of left ventricle near the apex; the anterior portion of ventricular septum; and the apex circumferentially
- Right coronary artery (30% to 40%): infarcts involving the inferior/posterior wall of the left ventricle; posterior portion of ventricular septum; and the inferior/posterior right ventricular free wall in some cases
- Left circumflex coronary artery (15% to 20%): infarcts involving the lateral wall of the left ventricle except at the apex

Other locations of critical coronary arterial lesions causing infarcts are sometimes encountered, such as the left main coronary artery, the secondary (diagonal) branches of the left anterior descending coronary artery, or the marginal branches of the left circumflex coronary artery. Of MIs caused by a right coronary obstruction, 15% to 30% extend from the posterior free wall of the septal portion of the left ventricle into the adjacent right ventricular wall. Isolated infarction of the right ventricle is unusual (only 1% to 3% of cases), as is infarction of the atria.

The gross and microscopic appearance of an infarct depends on the interval of time between the MI and death. Damaged myocardium undergoes a progressive sequence of morphologic changes involving typical ischemic coagulative necrosis, the predominant mechanism of cell death in MI (although apoptosis

Table 12.5 Evolution of Morphologic Changes in Myocardial Infarction

Time	Gross Features	Light Microscope	Electron Microscope
Reversible Injury			
0–½ hour	None	None	Relaxation of myofibrils; glycogen loss; mitochondrial swelling
Irreversible Injury			
½–4 hours	None	Usually none; variable waviness of fibers at border	Sarcolemmal disruption; mitochondrial amorphous densities
4–12 hours	Dark mottling (occasional)	Early coagulative necrosis; edema; hemorrhage	
12–24 hours	Dark mottling	Ongoing coagulative necrosis; pyknosis of nuclei; myocyte hypereosinophilia; marginal contraction band necrosis; early neutrophilic infiltrate	
1–3 days	Mottling with yellow-tan infarct center	Coagulative necrosis, with loss of nuclei and striations; brisk interstitial infiltrate of neutrophils	
3–7 days	Hyperemic border; central yellow-tan softening	Beginning disintegration of dead myofibers, with dying neutrophils; early phagocytosis of dead cells by macrophages at infarct border	
7–10 days	Maximally yellow-tan and soft, with depressed red-tan margins	Well-developed phagocytosis of dead cells; granulation tissue at margins	
10–14 days	Red-gray depressed infarct borders	Well-established granulation tissue with new blood vessels and collagen deposition	
2–8 weeks	Gray-white scar, progressive from border toward core of infarct	Increased collagen deposition, with decreased cellularity	
>2 months	Scarring complete	Dense collagenous scar	

can also occur); this is followed by stereotypical inflammation and repair that parallels responses to injury in other tissues (Chapter 2).

Early morphologic recognition of acute MI can be difficult, particularly when death occurs within only a few hours of symptom onset. MIs less than 12 hours old are usually not apparent on gross examination alone; however, if the infarct preceded death by at least 2 to 3 hours, it is possible to highlight the area of necrosis by immersion of tissue slices in a solution of **triphenyltetrazolium chloride.** This gross histochemical stain imparts a brick-red color to intact, noninfarcted myocardium with preserved lactate dehydrogenase activity. Because dehydrogenases leak out through the damaged membranes of dead cells, an infarct appears as an unstained pale zone (Fig. 12.12). By 12 to 24 hours after infarction, an MI can usually be identified grossly as a reddish-blue area of discoloration caused by congestion and extravasated blood. By 3 to 7 days, it is rimmed by a hyperemic zone of highly vascularized early wound healing **(granulation tissue).** Thereafter, the infarct becomes progressively more sharply defined, yellow-tan, and soft. Over the succeeding weeks, the injured region evolves to a fibrous scar.

The histopathologic changes also proceed in a fairly predictable sequence (Fig. 12.13). The typical changes of coagulative necrosis become detectable in the first 6 to 12 hours. "Wavy fibers" may

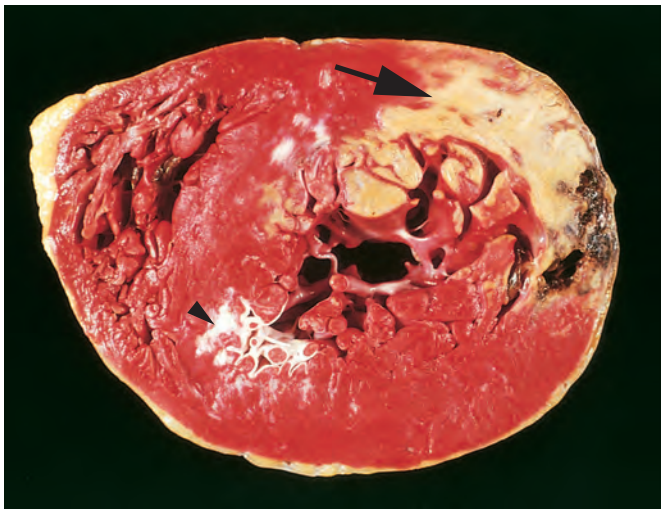

Figure 12.12 Acute myocardial infarct, predominantly of the posterolateral left ventricle, demonstrated histochemically by a lack of staining by triphenyltetrazolium chloride in areas of necrosis *(arrow)*. The staining defect is due to the lactate dehydrogenase leakage that follows cell death. Note the myocardial hemorrhage at one edge of the infarct that was associated with cardiac rupture, and the anterior scar *(arrowhead),* indicative of an old infarct. The specimen is oriented with the posterior wall at the top.

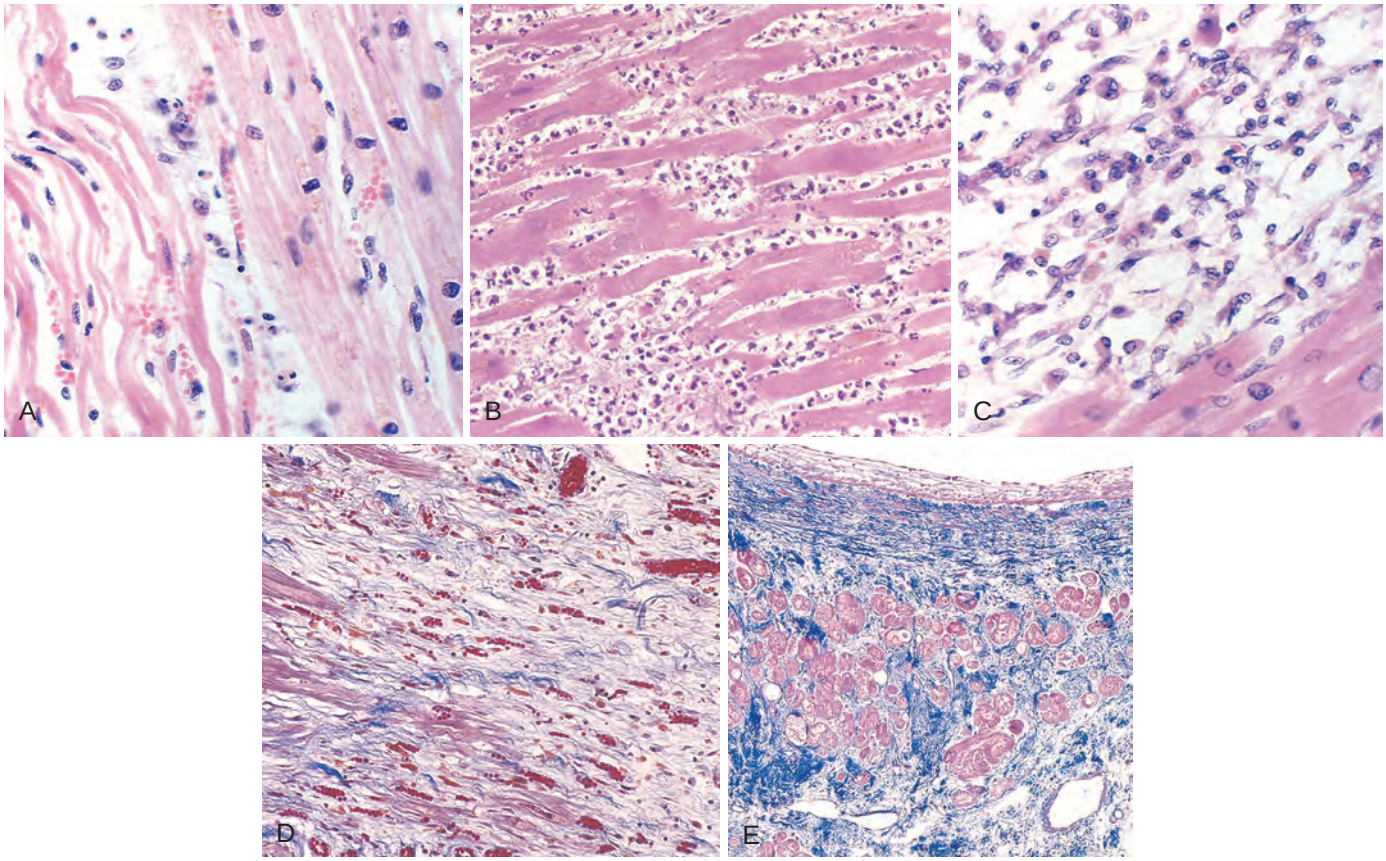

Figure 12.13 Microscopic features of myocardial infarction and its repair. (A) One-day-old infarct showing coagulative necrosis and wavy fibers (elongated and narrow, as compared with adjacent normal fibers at *right*). Widened spaces between the dead fibers contain edema fluid and scattered neutrophils. (B) Dense polymorphonuclear leukocytic infiltrate in an acute myocardial infarction that is 3 to 4 days old. (C) Removal of necrotic myocytes by phagocytosis (approximately 7 to 10 days). (D) Granulation tissue characterized by loose collagen and abundant capillaries. E, Healed myocardial infarct in which the necrotic tissue has been replaced by a dense collagenous scar. The residual cardiac muscle cells show evidence of compensatory hypertrophy. D and E are stained with Masson's trichrome, rendering collagenous connective tissue a deep blue color; note the accumulation of extracellular matrix (density of blue stain) between the early granulation tissue and the subsequent dense scar.

be present at the periphery of the infarct, resulting from the contractions of viable myocardium that cause the stretching and buckling of adjacent, noncontractile dead fibers. An additional sublethal ischemic change may be seen in the margins of infarcts: this so-called **myocyte vacuolization** reflects intracellular accumulations of salt and water within the sarcoplasmic reticulum, and marks myocytes that are viable but poorly contractile.

Necrotic myocardium elicits acute inflammation (typically most prominent 1 to 3 days after MI), followed by a wave of macrophages that remove necrotic myocytes and neutrophil fragments (most pronounced 3 to 7 days after MI). The infarcted zone is progressively replaced by granulation tissue (most prominent 7 to 10 days after MI), which in turn forms the provisional scaffolding on which dense collagenous scar forms; because cardiac myocytes are terminally differentiated cells, no cardiomyocyte proliferation is seen. In most instances, scarring is well advanced by the end of the sixth week, but the efficiency of repair depends on the size of the original lesion and the ability of the host tissues to heal. Healing requires the migration of inflammatory cells and ingrowth of new vessels from the infarct margins. Thus, an MI heals from its borders toward the center, and a large infarct may not heal as fast or as completely as a small one. Moreover, malnutrition, poor vasculature, or exogenous anti-inflammatory steroids can impede effective infarct scarring (Chapter 3). Once an MI is completely healed, it is impossible to distinguish its age: whether present for 8 weeks or 10 years, fibrous scars look the same.

The following discussion considers the changes that result from interventions that can limit infarct size by salvaging myocardium that is not yet necrotic.

Infarct Modification by Reperfusion. The therapeutic goal in acute MI is to salvage the maximal amount of ischemic myocardium; this is accomplished by restoration of tissue perfusion as quickly as possible (hence the adage "time is myocardium"). Such reperfusion is achieved by thrombolysis (dissolution of thrombus by tissue plasminogen activator), angioplasty, or coronary arterial bypass graft. Unfortunately, although preservation of viable (but at-risk) heart can improve both short- and long-term outcomes, reperfusion is not an unalloyed blessing. Indeed, late restoration of blood flow into ischemic tissues can be associated with arrhythmias, and can incite greater local damage than might otherwise have occurred—so-called reperfusion injury.

The effects of reperfusion on myocardial viability and function are summarized in Fig. 12.14. Although the clinical significance of myocardial reperfusion injury is debated, it has been estimated that up to 50% (or more) of the ultimate infarct size can be attributed to its effects. To date, clinical trials to prevent reperfusion injury have not been fruitful, but this remains an active area of investigation. Factors that contribute to reperfusion injury include the following:

- *Mitochondrial dysfunction:* Ischemia alters the mitochondrial membrane permeability, which allows proteins to move into the mitochondria. This leads to swelling and rupture of the outer membrane, releasing mitochondrial contents that promote apoptosis.
- *Myocyte hypercontracture:* During periods of ischemia, the intracellular levels of calcium are increased as a result of impaired calcium cycling and sarcolemmal damage. After reperfusion, the contraction of myofibrils is augmented and uncontrolled, causing cytoskeletal damage and cell death.
- *Free radicals* including superoxide anion (•O2), hydrogen peroxide (H_2O_2), hypochlorous acid (HOCl), nitric oxide–derived peroxynitrite, and hydroxyl radicals (•OH) are produced within minutes of reperfusion and cause damage to the myocytes by altering membrane proteins and phospholipids.
- *Leukocyte aggregation,* which may occlude the microvasculature and contribute to the "no-reflow" phenomenon. Further, leukocytes elaborate proteases and elastases that cause cell death.
- *Platelet and complement activation* also contribute to microvascular injury. Complement activation is thought to play a role in the no-reflow phenomenon by injuring the endothelium.

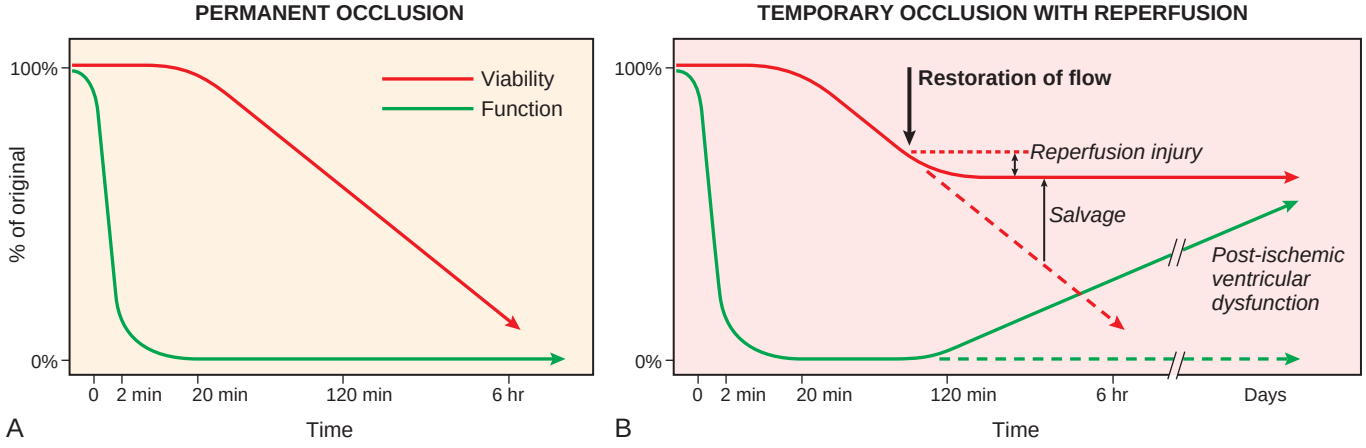

Figure 12.14 Effects of reperfusion on myocardial viability and function. After coronary occlusion, contractile function is lost within 2 minutes, and viability begins to diminish after approximately 20 minutes. If perfusion is not restored (A), then nearly all myocardium in the affected region suffers death. (B) If flow is restored, then some necrosis is prevented, myocardium is salvaged, and at least some function can return. The earlier reperfusion occurs, the greater the degree of salvage. However, the process of reperfusion itself may induce some damage (reperfusion injury), and return of function of salvaged myocardium may be delayed for hours to days (postischemic ventricular dysfunction or stunning).

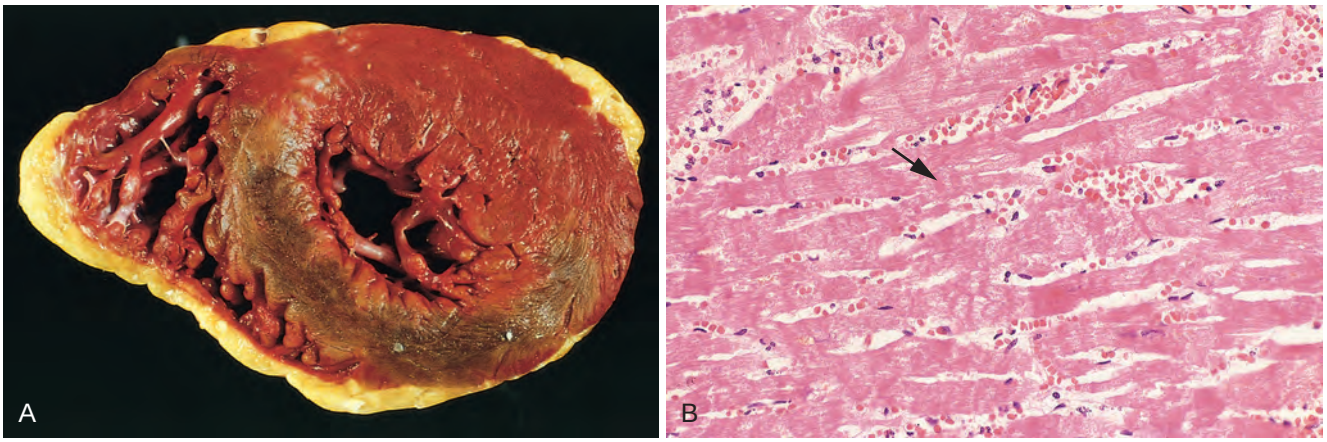

Figure 12.15 Consequences of myocardial ischemia followed by reperfusion. Gross (A) and microscopic (B) appearance of myocardium modified by reperfusion. (A) Large, densely hemorrhagic, anterior wall acute myocardial infarction in a patient with left anterior descending artery thrombus treated with streptokinase, a fibrinolytic agent (slice is stained with triphenyl tetrazolium chloride; see Fig. 12.12). Specimen oriented with posterior wall at top. (B) Myocardial necrosis with hemorrhage and contraction bands, visible as dark bands spanning some myofibers *(arrow)*.

The typical appearance of reperfused myocardium in the setting of an acute MI is shown in Fig. 12.15. Such infarcts typically are hemorrhagic as a consequence of vascular injury and leakiness. Microscopically, irreversibly damaged myocytes after reperfusion develop contraction band necrosis; in this pathologic process, intense eosinophilic bands of hypercontracted sarcomeres are created by an influx of calcium across plasma membranes that heightens actin-myosin interactions. In the absence of ATP, the sarcomeres cannot relax and get stuck in an agonal tetanic state. Thus, although reperfusion can salvage reversibly injured cells, it also alters the morphology of irreversibly injured cells.

The biochemical abnormalities (and their functional consequences) may also persist for days to weeks in reperfused myocytes. Such changes are thought to underlie a phenomenon referred to as stunned myocardium, a state of prolonged contractile dysfunction induced by short-term ischemia that usually recovers after several days. Myocardium that is subjected to chronic, sublethal ischemia can also enter into a state of lowered metabolism and function called hibernation. Subsequent revascularization (e.g., by CABG surgery, angioplasty, or stenting) often restores normal function to such hibernating myocardium.

Clinical Features

MI is diagnosed by clinical symptoms, laboratory tests for the presence of myocardial proteins in the plasma, and characteristic electrocardiographic changes. Patients with MI classically present with prolonged (more than 30 minutes) chest pain described as crushing, stabbing, or squeezing, associated with a rapid, weak pulse. Profuse sweating (diaphoresis), and nausea and vomiting are common and can suggest involvement of the posterior-inferior ventricle with secondary vagal stimulation. Dyspnea due to impaired contractility of the ischemic myocardium and the resultant pulmonary congestion and edema is a frequent symptom. However, in as many as 25% of patients the onset is entirely asymptomatic (e.g., in the setting of diabetic neuropathy), and the disease is discovered only by electrocardiographic changes or laboratory tests that show evidence of myocardial damage (see later).

Owing to the characteristic electrocardiographic changes resulting from myocardial ischemia or necrosis in various distributions, a transmural infarct is sometimes referred to as an ST-elevation myocardial infarct (STEMI) and a subendocardial infarct as a non–ST-elevation infarct (NSTEMI). Depending on the extent and location of the vascular involvement, microinfarctions show nonspecific changes or can even be electrocardiographically silent.

The laboratory evaluation of MI is based on measuring the blood levels of proteins that leak out of irreversibly damaged myocytes; previously, this involved measurement of the MB fraction of creatine kinase (CK-MB). Currently, the most clinically useful biomarkers of myocardial damage are cardiac-specific troponins T and I (cTnT and cTnI), proteins that normally regulate calcium-mediated contraction of cardiac muscle (Fig. 12.16). The diagnosis of myocardial injury is established when blood levels of troponin are elevated above threshold levels; the tempo and magnitude of appearance of these serum markers after MI depends on several factors, including the volume of damaged myocardium, blood flow and lymphatic drainage in the area of the infarct, and the rate of elimination of the marker from the blood. Cardiac troponins begin to rise in 2 to 4 hours and peak at 24 to 48 hours after an acute infarct. With reperfusion, troponin levels may be higher and peak earlier owing to more rapid washout of the marker from the necrotic tissue.

Significant acute elevation in serum troponin can also be seen in other conditions that cause death of cardiac myocytes, such as myocarditis and myocardial trauma. On the other hand, low-level serum troponin elevation ("troponin leak") can occur in a host of other conditions, including congestive heart failure, pulmonary embolus, renal failure, and sepsis. These elevations do not usually follow the same abrupt-injury time course, so serial measurements may be helpful in distinguishing different etiologies.

Recommended initial therapies for acute MI make sense based on the pathophysiologic features discussed earlier and include the following:

- *Oxygen supplementation* to improve blood oxygen saturation for patients with hypoxia or respiratory distress
- *Nitrates* to induce vasodilation and reverse vasospasm

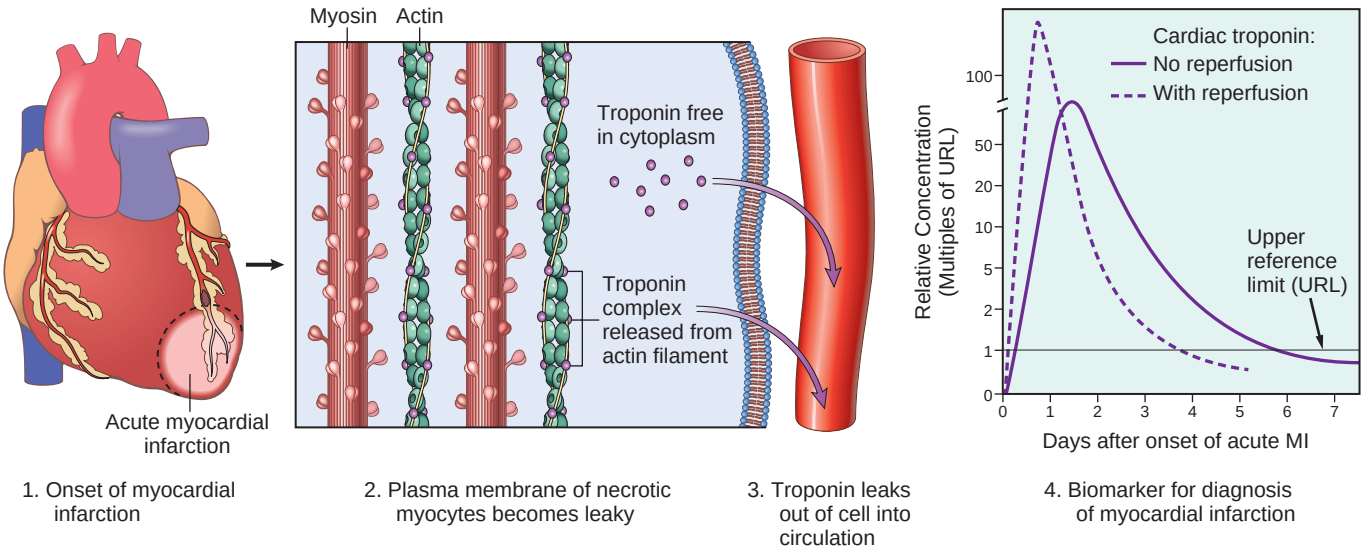

Figure 12.16 Release of myocyte proteins in myocardial infarction. Troponin I or troponin T are now most routinely used as diagnostic biomarkers of myocyte injury.

- *Antiplatelet agents* such as aspirin, ADP receptor inhibitors, and GPIIb/IIIa inhibitors
- *Anticoagulant therapy* with unfractionated heparin, low-molecular-weight heparin, direct thrombin inhibitors, and/or factor Xa inhibitors to prevent coronary artery thrombus propagation
- *Beta blockers* to decrease myocardial oxygen demand and to reduce the risk of arrhythmias, unless contraindicated such as in heart failure
- *Prompt reperfusion* to salvage myocardium, by either fibrinolytic medications or transcatheter interventions
- *Improve myocardial oxygen supply versus demand* by management of other factors, such as anxiety, ischemic pain, abnormal hemodynamics, anemia, and respiratory disorders
- *Early arrhythmia monitoring* and management

Consequences and Complications of Myocardial Infarction

Extraordinary progress has been made in improving patient outcomes after acute MI. The overall in-hospital death rate for MI is approximately 7% to 8%, with STEMI patients experiencing slightly higher mortality (10%) than NSTEMI patients (6%). Unfortunately, mortality for out-of-hospital MIs is substantially worse: one-third of patients who are unfortunate enough to suffer a STEMI at home will die, usually of an arrhythmia within 1 hour of symptom onset and before they can receive medical attention. Such statistics make the rising rate of CAD in countries with limited hospital facilities all the more worrisome.

Nearly three-fourths of patients experience one or more of the following complications after an acute MI (Fig. 12.17):

- *Contractile dysfunction.* In general, MIs affect left ventricular pump function in proportion to the volume of damage. In most cases, there is some degree of left ventricular failure manifested as hypotension, pulmonary congestion, and pulmonary edema. Severe "pump failure" *(cardiogenic shock)* occurs in roughly 10% of patients with transmural MIs and typically is associated with infarcts that damage 40% or more of the left ventricle.
- *Papillary muscle dysfunction.* Although papillary muscles rupture infrequently after MI, they often are dysfunctional and can be poorly contractile as a result of ischemia, leading to postinfarct mitral regurgitation. Much later, papillary muscle fibrosis and shortening, or global ventricular dilation also can cause mitral regurgitation.
- *Right ventricular infarction.* Although isolated right ventricular infarction occurs in only 1% to 3% of MIs, the right ventricle is affected by RCA occlusions leading to posterior septal or left ventricular infarction. In either case, right-sided heart failure is a common outcome, leading to pooling of blood in the venous circulation and systemic hypotension.
- *Myocardial rupture.* Rupture complicates only 1% to 5% of MIs, but is frequently fatal when it occurs. Left ventricular free wall rupture is most common, usually resulting in rapidly fatal hemopericardium and cardiac tamponade (see Fig. 12.17A). Ventricular septal rupture creates a VSD with left-to-right shunting (see Fig. 12.17B), and papillary muscle rupture leads to severe mitral regurgitation (see Fig. 12.17C). Rupture occurs most commonly within 3 to 7 days after infarction—the time in the healing process when lysis of necrotic myocardium is maximal and when much of the infarct has been converted to soft, friable granulation tissue. Risk factors for free wall rupture include age older than 60 years, anterior or lateral wall infarctions, female gender, lack of left ventricular hypertrophy, and first MI (because scarring associated with prior MIs tends to limit the risk for myocardial tearing).
- *Arrhythmias.* MIs lead to myocardial irritability and conduction disturbances that can cause sudden death. Approximately 90% of patients develop some form of rhythm disturbance, with the incidence being higher in STEMIs versus NSTEMIs. MI-associated arrhythmias include heart block of variable degree (including asystole),

Edwards, MD, Mayo Clinic, Rochester, Minn.)

bradycardia, supraventricular tachyarrhythmias, ventricular premature contractions or ventricular tachycardia, and ventricular fibrillation. The risk for serious arrhythmias (e.g., ventricular fibrillation) is greatest in the first hour and declines thereafter.

- *Pericarditis.* Transmural MIs can elicit a fibrinohemorrhagic pericarditis; this is an epicardial manifestation of the underlying myocardial inflammation (see Fig. 12.17D). Heralded by anterior chest pain and a pericardial friction rub, pericarditis typically appears 2 to 3 days after infarction and then gradually resolves over the next few days. Extensive infarcts or severe pericardial inflammation occasionally can lead to large effusions or can organize to form dense adhesions that eventually manifest as a constrictive lesion. Rarely patients can develop an intense pericarditis weeks after MI *(Dressler syndrome)* due to formation of antibodies against damaged myocardium.
- *Chamber dilation.* Because of the weakening of necrotic muscle, there may be disproportionate stretching, thinning, and dilation of the infarcted region (especially with anteroseptal infarcts).
- *Mural thrombus.* With any infarct, the combination of attenuated myocardial contractility (causing stasis), chamber dilation, and endocardial damage (causing a thrombogenic surface) can foster mural thrombosis (see Fig. 12.17E), potentially leading to left-sided thromboembolism.
- *Ventricular aneurysm.* A late complication, aneurysms of the ventricle most commonly result from a large transmural anteroseptal infarct that heals with the formation of a thinned wall of scar tissue (see Fig. 12.17F). Although ventricular aneurysms frequently give rise to formation of mural thrombi, arrhythmias, and heart failure, they do not rupture.
- *Progressive heart failure.* This is discussed in the Chronic Ischemic Heart Disease section later in this chapter.

The risk of postinfarct complications and the prognosis of the patient depend primarily on the infarct size, location, and fraction of the wall thickness involved (subendocardial or transmural). Thus, large transmural infarcts yield a higher probability of cardiogenic shock, arrhythmias, and late CHF. Patients with anterior transmural infarcts are at greatest risk for free-wall rupture, expansion, mural thrombi, and aneurysm. In contrast, posterior transmural infarcts are more likely to be complicated by conduction blocks, right ventricular involvement, or both; when acute VSDs occur in this area they are more difficult to manage. Moreover, female gender, age older than 70 years, diabetes mellitus and previous MI are poor prognostic factors in patients with ST

elevation myocardial infarcts. With subendocardial infarcts, only rarely do pericarditis, rupture, and aneurysm occur.

In addition to the sequence of repair in the infarcted tissues described earlier, the noninfarcted segments of the ventricle undergo hypertrophy and dilation; collectively, these changes are termed ventricular remodeling. The compensatory hypertrophy of noninfarcted myocardium is initially hemodynamically beneficial. However, this adaptive effect may be overwhelmed by ventricular dilation (with or without ventricular aneurysm) and increased oxygen demand, which can exacerbate ischemia and depress cardiac function. There may also be changes in ventricular shape and stiffening of the ventricle due to scar formation and hypertrophy that further diminish cardiac output. Some of these deleterious effects appear to be reduced by ACE inhibitors, which lessen the ventricular remodeling that can occur after infarction.

Long-term prognosis after MI depends on many factors, the most important of which are the residual left ventricular function and the extent of any vascular obstructions in vessels that perfuse the remaining viable myocardium. The overall total mortality within the first year can be as high as 30%; thereafter, each passing year is associated with an additional 3% to 4% mortality among survivors. Infarct prevention (through control of risk factors) in individuals who have never experienced MI (primary prevention) and prevention of reinfarction in MI survivors (secondary prevention) are important strategies that have received much attention and achieved considerable success.

The relationship of the causes, pathophysiology, and consequences of MI are summarized in Fig. 12.18, including the possible outcomes of chronic IHD and sudden death, discussed later.

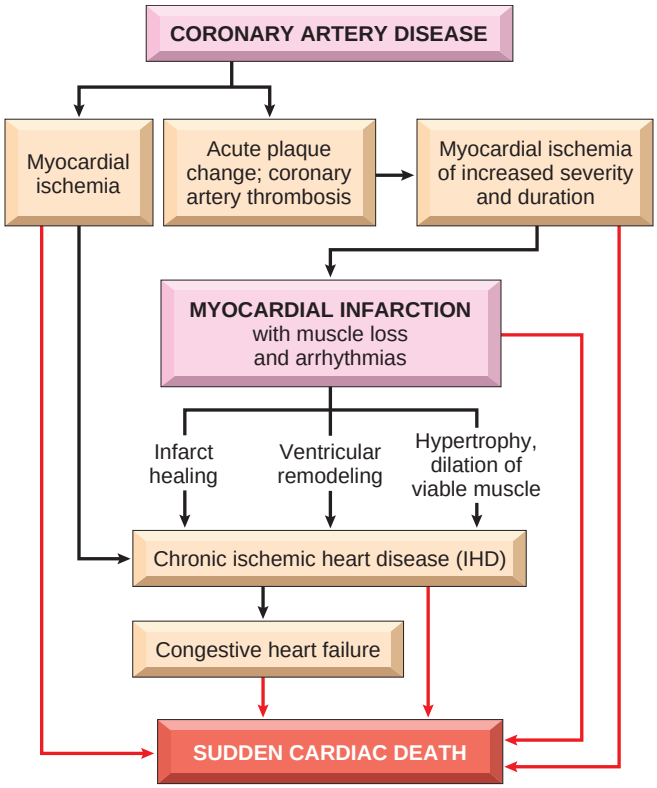

Figure 12.18 Schematic for the causes and outcomes of ischemic heart disease *(IHD)*, showing the interrelationships among coronary artery disease, acute plaque change, myocardial ischemia, myocardial infarction, chronic IHD, congestive heart failure, and sudden cardiac death.

Chronic Ischemic Heart Disease

The designation chronic IHD (often called ischemic cardiomyopathy by clinicians) is used here to describe progressive congestive heart failure as a consequence of accumulated ischemic myocardial damage and/or inadequate compensatory responses. In most instances, there has been a prior MI and sometimes previous coronary arterial interventions and/or bypass surgery. Chronic IHD usually appears postinfarction due to the functional decompensation of hypertrophied noninfarcted myocardium (see earlier discussion of cardiac hypertrophy). However, in other cases severe obstructive CAD may present as chronic congestive heart failure in the absence of prior infarction. Patients with chronic IHD account for almost 50% of cardiac transplant recipients.

MORPHOLOGY

Patients with chronic IHD have cardiomegaly, with left ventricular hypertrophy and dilation. Invariably there is some degree of stenotic coronary atherosclerosis. Discrete scars representing healed infarcts are usually present. The mural endocardium often has patchy fibrous thickenings (due to abnormal wall shear forces), and mural thrombi may be present. Microscopic findings include myocardial hypertrophy, diffuse subendocardial myocyte vacuolization, and interstitial fibrosis.

KEY CONCEPTS

ISCHEMIC HEART DISEASE

- The vast majority of IHD is due to coronary artery atherosclerosis. Vasospasm, vasculitis, or embolism are less common causes.
- Cardiac ischemia results from a mismatch in coronary supply and myocardial demand, and it presents as different, albeit overlapping, syndromes:
  - Angina pectoris is chest pain on exertion due to inadequate perfusion, and is typically due to atherosclerotic disease with greater than 70% fixed stenosis (so-called critical stenosis).
  - Unstable angina results from a small fissure or rupture of atherosclerotic plaque triggering platelet aggregation, vasoconstriction, and formation of a mural thrombus that needs not necessarily be occlusive. Chest pain may occur, even at rest or with minimal exertion.
  - Acute MI typically results from acute thromboses after plaque disruption; most occur in plaques that did not previously exhibit critical stenosis.
  - Chronic IHD is progressive heart failure due to ischemic injury, either from prior infarctions or chronic low-grade ischemia.
- Myocardial ischemia leads to loss of function within 1 to 2 minutes but causes necrosis only after 20 to 30 minutes. MI is diagnosed based on symptoms, electrocardiographic changes, and measurement of serum troponins. Gross and histologic changes of infarction require hours to days to develop.

- Infarction can be modified by therapeutic intervention (e.g., thrombolysis or stenting), which salvages myocardium at risk, but potentially induces reperfusion-related injury.
- Complications of infarction include: ventricular rupture, papillary muscle rupture, aneurysm formation, mural thrombus, arrhythmia, pericarditis, and CHF.

ARRHYTHMIAS

Abnormalities in myocardial conduction can be sustained or sporadic (paroxysmal). Aberrant rhythms can be initiated anywhere in the conduction system, from SA node down to the level of an individual myocyte; they are typically designated as originating from the atrium (supraventricular) or within the ventricular myocardium. Arrhythmias can manifest as tachycardia (fast heart rate), bradycardia (slow heart rate), an irregular rhythm with normal ventricular contraction, chaotic depolarization without functional ventricular contraction (ventricular fibrillation), or no electrical activity at all (asystole). Patients may be unaware of a rhythm disorder, or may note a "racing heart" or palpitations (irregular rhythm); loss of adequate cardiac output due to sustained arrhythmia can produce lightheadedness (near syncope), loss of consciousness (syncope), or sudden cardiac death (see later).

Ischemic injury is a common cause of rhythm disorders, either through direct damage or through the dilation of heart chambers that alters conduction system firing.

- *Sick sinus syndrome.* If the SA node is damaged, other fibers or even the AV node can take over pacemaker function, albeit at a much slower intrinsic rate (causing bradycardia).
- *Atrial fibrillation.* If the atrial myocytes become "irritable" and depolarize independently and sporadically (as occurs with atrial dilation), the signals are variably transmitted through the AV node, leading to the random "irregularly irregular" heart rate.
- *Heart block.* If the AV node is dysfunctional, varying degrees of heart block occur, ranging from simple prolongation of the P-R interval on electrocardiogram (first-degree heart block), to intermittent transmission of the signal (second-degree heart block), to complete failure (third-degree heart block).

As discussed earlier, coordinated cardiac contraction depends on the orderly transmission of electrical currents from myocyte to myocyte via gap junctions. Thus, abnormalities in the structure or spatial distribution of gap junctions, which are seen in a variety of disorders (e.g., IHD and dilated cardiomyopathies), can cause arrhythmias. Ischemia, myocyte hypertrophy, and inflammation (e.g., myocarditis or sarcoidosis) also promote increased "irritability" that leads to spontaneous aberrant myocyte depolarization; because of the electrical interconnection of myocytes, such random events can cause inappropriate firing of adjacent cells and create abnormal electrical circuits (so-called reentry circuits) that lead to ventricular tachycardia, which may progress to fatal ventricular fibrillation. Likewise, deposition of nonconducting material (e.g., amyloid) and even small areas of fibrosis can disrupt myocyte-to-myocyte signaling, again sowing the seeds for development of reentry circuits that can give rise to potentially fatal arrhythmias.

Heritable conditions associated with arrhythmias are important to recognize because they may alert physicians to the need for intervention to prevent sudden cardiac death (discussed later) in the proband and their family members. Some of these disorders are associated with recognizable anatomic abnormalities (e.g., congenital anomalies, hypertrophic cardiomyopathy, mitral valve prolapse). However, other heritable disorders precipitate arrhythmias and sudden death in the absence of structural cardiac pathology (so-called primary electrical disorders). These syndromes can only be diagnosed by genetic testing, which is performed in those with a positive family history or an unexplained nonlethal arrhythmia.

Channelopathies are the most important of the primary electrical abnormalities of the heart that predispose to arrhythmias (Table 12.6). Channelopathies are caused by mutations in genes that are required for normal ion channel function. These disorders (mostly with autosomal dominant inheritance) either involve genes that encode the structural components of ion channels (including Na^+, K^+, and Ca^+ channels) or accessory proteins that are essential for normal channel function. Ion channels are responsible for conducting the electrical currents that mediate contraction of the heart, and it is thus not surprising that defects in these channels may provoke arrhythmias. The prototype is the *long QT syndrome,* characterized by prolongation of the QT segment in ECGs with susceptibility to serious ventricular arrhythmias. Ion channels are needed for the normal function of

Table 12.6 Selected Examples of Causal Genes in Inherited Arrhythmogenic Diseases[a]

Disorder	Gene	Function
Long QT syndrome[b]	*KCNQ1*	K^+ channel (LOF)
	KCNH2	K^+ channel (LOF)
	SCN5A	Na^+ channel (GOF)
	CAV3	Caveolin, Na^+current (GOF)
Short QT syndrome[b]	*KCNQ1*	K^+ channel (GOF)
	KCNH2	K^+ channel (GOF)
Brugada syndrome[b]	*SCN5A*	Na^+ channel (LOF)
	CACNB2b	Ca^{++} channel (LOF)
	SCN1b	Na^+ channel (LOF)[a]
CPVT syndrome[b]	*RYR2*	Diastolic Ca^{++} release (GOF)
	CASQ2	Diastolic Ca^{++} release (LOF)

LOF, Loss-of-function mutations; *GOF,* gain-of-function mutations; *CPVT,* catecholaminergic polymorphic ventricular tachycardia.

[a]Different mutations can cause the same general syndrome, and mutations in some genes can cause multiple different phenotypes; thus, loss-of-function (LOF) mutations may cause long QT intervals, whereas gain-of-function (GOF) mutations result in short repolarization intervals.

[b]*Long QT syndrome* manifests as arrhythmias associated with excessive prolongation of the cardiac repolarization; patients often present with stress-induced syncope or sudden cardiac death (SCD), and some forms are associated with swimming. *Short QT syndrome* patients have arrhythmias associated with abbreviated repolarization intervals; they can present with palpitations, syncope, and SCD. *Brugada syndrome* manifests as ECG abnormalities (ST segment elevations and right bundle branch block) in the absence of structural heart disease; patients classically present with syncope or SCD during rest or sleep, or after large meals. *CPVT* does not have characteristic ECG changes; patients often present in childhood with life-threatening arrhythmias due to adrenergic stimulation (stress-related).

Modified from Cerrone M, Priori SG: Genetics of sudden death: focus on inherited channelopathies, *Eur Heart J* 32(17), 2109–2118, 2011.

many tissues, and certain channelopathies are also associated with skeletal muscle disorders and diabetes. Nevertheless, the most common channelopathies are isolated disorders of the heart, and their most feared consequence is sudden cardiac death (discussed in the next section).

Sudden Cardiac Death

SCD is most commonly defined as unexpected death from cardiac causes, either without symptoms or within 1 to 24 hours of symptom onset (different authors use different criteria); this happens in some 180,000 to 450,000 individuals each year in the United States alone. **The mechanism of SCD is most often a lethal arrhythmia (e.g., asystole or ventricular fibrillation).** Although ischemic injury (and other pathologies) can directly affect the major components of the conduction system, most cases of fatal arrhythmia are triggered by electrical irritability of myocardium distant from the major elements of the conduction system.

CAD is the leading cause of SCD, responsible for the majority of cases; unfortunately, SCD can be the first manifestation of IHD. In such cases, there is typically only chronic severe atherosclerotic disease with fixed critical stenoses; acute plaque disruption is found in only 10% to 20% of cases, and 80% to 90% of patients who suffer SCD but are successfully resuscitated do not show any enzymatic or ECG evidence of myocardial necrosis. Healed remote MIs are present in about 40%, and subendocardial myocyte vacuolization indicative of severe chronic ischemia is a common feature. With the decrease of prevalence of IHD in high income countries, SCD is increasingly being seen in individuals with hearts that are hypertrophic and fibrotic (from hypertension, obesity, substance abuse, etc.) without IHD.

With younger victims, nonatherosclerotic causes are more common etiologies for SCD:

- *Cardiac conduction abnormalities,* hereditary or acquired
- *Dilated* or *hypertrophic cardiomyopathy*
- *Congenital coronary arterial abnormalities*
- *Myocarditis*
- *Mitral valve prolapse*
- *Pulmonary hypertension*
- *Other miscellaneous causes,* such as pericardial tamponade, pulmonary embolism, systemic metabolic and hemodynamic alterations, catecholamines, and drugs of abuse, particularly cocaine and methamphetamine.

The prognosis of patients vulnerable to SCD is markedly improved by pharmaceutical intervention, and particularly by implantation of automatic cardioverter defibrillators that can sense and electrically counteract episodes of ventricular fibrillation.

KEY CONCEPTS

ARRHYTHMIAS

- Arrhythmias can be caused by ischemic or structural changes in the conduction system or by intrinsic myocyte electrical instability. In structurally normal hearts, arrhythmias are often due to mutations in ion channels that cause aberrant repolarization or depolarization.
- SCD typically results from ventricular fibrillation and is most frequently a consequence of CAD. Myocardial irritability typically results from nonlethal ischemia or from preexisting fibrosis from previous myocardial injury. SCD is less often due to acute plaque rupture with thrombosis that induces a rapidly fatal arrhythmia.

HYPERTENSIVE HEART DISEASE

Hypertensive heart disease (HHD) is a consequence of the increased demands placed on the heart by hypertension, causing pressure overload and ventricular hypertrophy. Although most commonly seen in the left heart as the result of systemic hypertension, pulmonary hypertension can cause right-sided HHD, or cor pulmonale.

Systemic (Left-Sided) Hypertensive Heart Disease

Hypertrophy of the heart is an adaptive response to the pressure overload of chronic hypertension. However, such compensatory changes may be ultimately maladaptive and can lead to myocardial dysfunction, myocardial "demand" ischemia, cardiac dilation, CHF, and in some cases sudden death.

The minimal pathologic criteria for the diagnosis of systemic HHD are the following: (1) left ventricular hypertrophy (usually concentric) in the absence of other cardiovascular pathology and (2) a clinical history or pathologic evidence of hypertension in other organs (e.g., kidney). The Framingham Study established unequivocally that even mild hypertension (levels only slightly above 140/90 mm Hg)—if sufficiently prolonged—induces left ventricular hypertrophy; some 30% of the population of the United States suffers from hypertension of at least this degree. More recently, the criteria for diagnosing hypertension were changed; according to the newest guidelines, diastolic pressures above 80 mm Hg, or systolic pressures above 120 mm Hg constitute clinically significant elevations in blood pressure. On that basis, almost one-half of individuals in the general population (!!) are hypertensive. The pathogenesis of hypertension is discussed in Chapter 11.

MORPHOLOGY

Hypertension induces left ventricular pressure overload hypertrophy, initially without ventricular dilation. As a result, the left ventricular wall thickening increases the weight of the heart disproportionately to the increase in overall cardiac size (Fig. 12.19A). The heart weight may exceed 500 g, and the left ventricular wall thickness may exceed 2.0 cm. Over time, the increased thickness of the left ventricular wall, associated with increased interstitial connective tissue, imparts a stiffness that impairs diastolic filling, often leading to left atrial enlargement.

Microscopically, the earliest change of systemic HHD is an increase in the transverse diameter of myocytes, which may be difficult to appreciate on routine microscopy. At a more advanced stage, variable degrees of cellular and nuclear enlargement become apparent, often accompanied by perivascular and interstitial fibrosis.

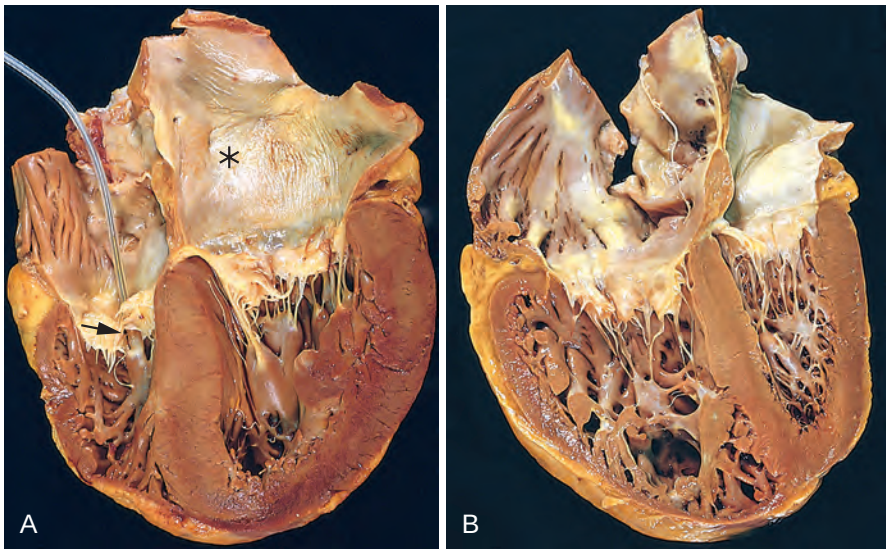

Figure 12.19 Hypertensive heart disease, systemic and pulmonary. (A) Systemic (left-sided) hypertensive heart disease. There is marked concentric thickening of the left ventricular wall causing reduction in lumen size. The left ventricle and left atrium *(asterisk)* are on the *right* in this apical four-chamber view of the heart. A pacemaker is present in the right ventricle *(arrow)*. (B) Pulmonary (right-sided) hypertensive heart disease (cor pulmonale). The right ventricle is markedly dilated and has a thickened free wall and hypertrophied trabeculae (apical four-chamber view of heart, right ventricle on left). The shape of the left ventricle *(to the right)* has been distorted by the enlarged right ventricle.

Compensated systemic HHD may be asymptomatic, producing only electrocardiographic or echocardiographic evidence of left ventricular enlargement. In many patients, systemic HHD comes to attention because of new atrial fibrillation induced by left atrial enlargement, or by progressive CHF. Depending on the severity, duration, and underlying basis of the hypertension, and on the adequacy of therapeutic control, the patient may (1) enjoy normal longevity and die of unrelated causes, (2) develop IHD due to both the potentiating effects of hypertension on coronary atherosclerosis and the ischemia induced by increased oxygen demand from the hypertrophic muscle, (3) suffer renal damage or cerebrovascular stroke as direct effects of hypertension, or (4) experience progressive heart failure or SCD. Effective control of hypertension can prevent cardiac hypertrophy and can even lead to its regression; with normalization of blood pressure, the associated risks of HHD are diminished.

Pulmonary (Right-Sided) Hypertensive Heart Disease (Cor Pulmonale)

Normally, because the pulmonary vasculature is the low-pressure side of the circulation, the right ventricle has a thinner and more compliant wall than the left ventricle. Isolated pulmonary HHD, or cor pulmonale, stems from right ventricular pressure overload. Chronic cor pulmonale is characterized by right ventricular hypertrophy, dilation, and potentially right-sided failure. Typical causes of chronic cor pulmonale are disorders of the lungs, especially chronic parenchymal diseases such as emphysema, and primary pulmonary hypertension (Table 12.7; see also Chapter 15). Acute cor pulmonale can follow massive pulmonary embolism. Nevertheless, it should also be remembered that pulmonary hypertension most commonly occurs as a complication of left-sided heart disease.

MORPHOLOGY

In acute cor pulmonale there is marked dilation of the right ventricle without hypertrophy. On cross-section, the normal crescent shape of the right ventricle chamber is transformed to a dilated ovoid. In chronic cor pulmonale, the right ventricular wall thickens, sometimes up to 1.0 cm or more (see Fig. 12.19B). More subtle right ventricular hypertrophy may take the form of thickening of the muscle bundles in the outflow tract, immediately

Chronic altitude sickness
Obstruction of major airways
Idiopathic alveolar hypoventilation

below the pulmonary valve, or thickening of the moderator band, the muscle bundle that connects the ventricular septum to the anterior right ventricular papillary muscle. Sometimes, the hypertrophied right ventricle compresses the left ventricular chamber or leads to regurgitation and fibrous thickening of the tricuspid valve.

KEY CONCEPTS

HYPERTENSIVE HEART DISEASE

- HHD can affect either the left ventricle or the right ventricle; the latter is called cor pulmonale. Elevated pressures induce myocyte hypertrophy and interstitial fibrosis that increases wall thickness and myocardial stiffness.
- The chronic pressure overload of systemic hypertension causes left ventricular concentric hypertrophy, often associated with left atrial dilation due to impaired diastolic filling of the ventricle. Persistently elevated pressure overload can cause ventricular failure with dilation.
- Cor pulmonale results from pulmonary hypertension due to primary lung parenchymal or vascular disorders. There is commonly right ventricular and right atrial hypertrophy; right ventricular and atrial dilation can occur.

VALVULAR HEART DISEASE

Valvular disease can come to clinical attention due to stenosis, insufficiency (synonyms: regurgitation or incompetence), or both.

- *Stenosis* is the failure of a valve to open completely, obstructing forward flow. Acquired valvular stenosis is almost always due to a primary leaflet abnormality and is virtually always a chronic process (e.g., calcification or valve scarring).
- *Insufficiency* results from failure of a valve to close completely, thereby allowing regurgitation (backflow) of blood. Valvular insufficiency can result from either intrinsic disease of the valve leaflets (e.g., endocarditis) or disruption of the supporting structures (e.g., the aorta, mitral annulus, tendinous cords, papillary muscles, or ventricular free wall) without primary leaflet injury. It can appear abruptly, as with chordal rupture, or insidiously as a consequence of leaflet scarring and retraction.

Stenosis or insufficiency can occur alone or together in the same valve. Valvular disease can involve only one valve (the mitral valve being the most common target) or more than one valve. Abnormal flow through diseased valves typically produces abnormal heart sounds called murmurs; severe lesions can even be externally palpated as thrills. Depending on the valve involved, murmurs are best heard at different locations on the chest wall; moreover, the nature (regurgitation versus stenosis) and severity of the valvular disease determines the quality and timing of the murmur (e.g., harsh systolic or soft diastolic murmurs).

The clinical consequences of valve dysfunction vary depending on the valve involved, the degree of impairment, the tempo of disease onset, and the rate and quality of compensatory mechanisms. For example, sudden destruction of an aortic valve cusp by infection (infectious endocarditis; see later) can cause acute, massive, and rapidly fatal aortic regurgitation. In contrast, rheumatic mitral stenosis typically develops indolently over years, and its clinical effects can be well tolerated for extended periods. Certain conditions can complicate valvular heart disease by increasing the demands on the heart; for example, the increased output demands of pregnancy can exacerbate valve disease and lead to unfavorable maternal or fetal outcomes. Valvular stenosis or insufficiency often produces secondary changes, both proximal and distal to the affected valve, particularly in the myocardium. Generally, valvular stenosis leads to pressure overload cardiac hypertrophy, whereas valvular insufficiency leads to volume overload; both situations can culminate in heart failure. In addition, the ejection of blood through narrowed stenotic valves can produce high speed "jets" of blood that injure the endothelium or endocardium where they impact.

Valvular abnormalities can be congenital (discussed earlier) or acquired. Acquired valvular stenosis is almost always a consequence of a remote or chronic injury of the valve leaflets that declares itself clinically only after many years. In contrast, acquired valvular insufficiency can result from intrinsic disease of the valve leaflets or damage to or distortion of the supporting structures (e.g., the aorta, mitral annulus, tendinous cords, papillary muscles, ventricular free wall).

The causes of acquired heart valve diseases are summarized in Table 12.8. The most frequent causes of the major valvular lesions are as follows:

- *Aortic stenosis:* calcification and sclerosis of anatomically normal or congenitally bicuspid aortic valves
- *Aortic insufficiency:* dilation of the ascending aorta, often secondary to hypertension and/or aging
- *Mitral stenosis:* rheumatic heart disease (RHD)
- *Mitral insufficiency:* myxomatous degeneration (MVP), or left ventricular dilation due to ischemic or nonischemic heart failure

Calcific Valvular Degeneration

Heart valves are subjected to high levels of repetitive mechanical stress, particularly at the hinge points of the leaflets; this is a consequence of (1) millions of cardiac contractions per year, (2) substantial tissue deformations during each contraction, and (3) transvalvular pressure gradients in the closed phase of each contraction of approximately 120 mm Hg for the mitral and 80 mm Hg for the aortic valve. It is therefore not surprising that these delicate structures can suffer cumulative damage and calcification that lead to clinically important dysfunction.

Calcific Aortic Stenosis

The most common of all valvular abnormalities, calcific aortic stenosis is usually the consequence of age-associated "wear and tear" of either anatomically normal valves or congenitally bicuspid valves (found in approximately 1% of the population). The prevalence of aortic stenosis is estimated at 2% and is increasing as the general population ages. Aortic stenosis of previously normal valves (termed degenerative calcific aortic stenosis) usually comes to clinical attention in the seventh to ninth decades of life, whereas

stenotic bicuspid valves tend to become clinically significant one to two decades earlier.

Aortic valve calcification is likely a consequence of recurrent chronic injury due to hyperlipidemia, hypertension, inflammation, and other factors similar to those implicated in atherosclerosis. The chronic progressive injury leads to valvular degeneration and incites the deposition of hydroxyapatite (the same calcium salt found in bone). Although this model provides a good starting point for understanding calcific degeneration, it is increasingly clear that the valve injury of calcific aortic stenosis differs in some important respects from atherosclerosis. Most notably, the abnormal valves contain cells resembling osteoblasts that synthesize bone matrix proteins and promote the deposition of calcium salts. Moreover, interventions that improve atherosclerotic risk (e.g., statins) do not appear to significantly prevent valvular calcific degeneration. Bicuspid valves incur greater mechanical stress than normal tricuspid valves, which may explain their accelerated stenosis.

MORPHOLOGY

The gross morphologic hallmark of nonrheumatic, calcific aortic stenosis (involving either tricuspid or bicuspid valves) is mounded calcified masses on the outflow surfaces of the cusps that ultimately prevent cuspal opening. The free edges of the cusps are usually not involved (Fig. 12.20A). Microscopically, the layered architecture of the valve is largely preserved. The calcific process begins in the valvular fibrosa on the outflow surface of the valve, at the points of maximal cusp flexion (near the margins of attachment). Inflammation is variable, and metaplastic bone can be seen. In aortic stenosis, the functional valve area is decreased by large nodular calcific deposits that can eventually cause measurable outflow obstruction; this subjects the left ventricular myocardium to progressively increasing pressure overload. In contrast with rheumatic (and congenital) aortic stenosis (see Fig. 12.22E), commissural fusion is not usually seen.

Clinical Features

In calcific aortic stenosis (superimposed on a previously normal or bicuspid aortic valve), the obstruction to left ventricular outflow leads to gradual narrowing of the valve orifice (valve area approximately 0.5 to 1 cm^2 in severe aortic stenosis; normal is approximately 4 cm^2) and an increasing pressure gradient across the calcified valve. Left ventricular pressures rise to 200 mm Hg or more in such instances, producing concentric left ventricular (pressure overload) hypertrophy. The hypertrophied myocardium tends to be ischemic (as a result of diminished microcirculatory perfusion, often complicated by coronary atherosclerosis), and angina pectoris may occur. Both systolic and diastolic myocardial function may be impaired; eventually, cardiac decompensation and CHF can ensue. The onset of symptoms (angina, CHF, or syncope) in aortic stenosis heralds cardiac

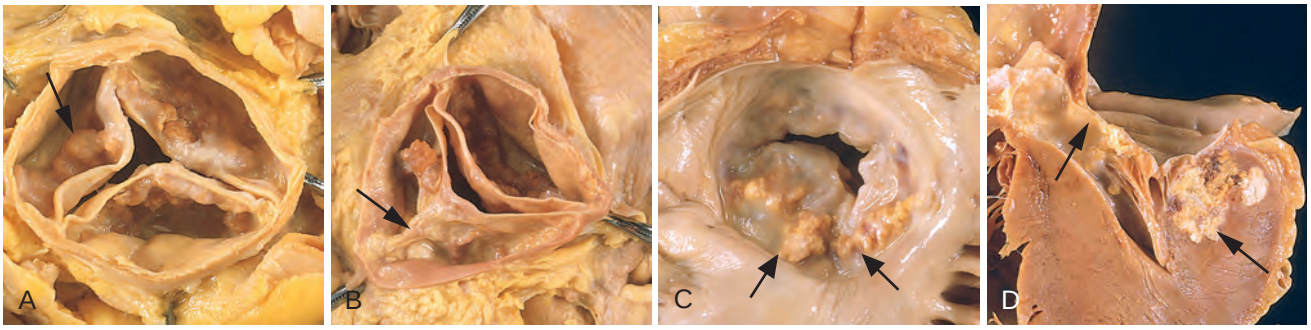

Figure 12.20 Calcific valvular degeneration. (A) Calcific aortic stenosis of a previously normal valve (viewed from aortic aspect). Nodular masses of calcium are heaped up within the sinuses of Valsalva *(arrow)*. Note that the commissures are not fused, as occurs with postrheumatic aortic valve stenosis (see Fig. 12.22E). (B) Calcific aortic stenosis of a congenitally bicuspid valve. One cusp has a partial fusion at its center, called a raphe *(arrow)*. (C and D) Mitral annular calcification, with calcific nodules at the base (attachment margin) of the anterior mitral leaflet *(arrows)*. (C) Left atrial view. (D) Cut section of myocardium showing the lateral wall with dense calcification that extends into the underlying myocardium *(arrow)*.

decompensation and carries an extremely poor prognosis. If untreated, most patients with aortic stenosis will die within 5 years of developing angina, within 3 years of developing syncope, and within 2 years of CHF onset. Treatment requires surgical valve replacement, as medical therapy is ineffective in severe symptomatic aortic stenosis.

Calcific Stenosis of Congenitally Bicuspid Aortic Valve

Bicuspid aortic valve (BAV) is a developmental abnormality with prevalence in the population of approximately 1%; calcified BAV comprises approximately 50% of cases of aortic stenosis in adults. Some cases of BAV show familial clustering, often with associated aortic or left ventricular outflow tract malformations. Loss-of-function mutations in *NOTCH1* (mapping to chromosome 9q34.3) have been specifically associated with BAV in a few families.

In a congenitally bicuspid aortic valve, there are only two functional cusps, usually of unequal size, with the larger cusp having a midline raphe, resulting from incomplete commissural separation during development; less frequently, the cusps are of equal size and the raphe is absent. The raphe is frequently a major site of calcific deposits (see Fig. 12.20B).

Although BAV is usually asymptomatic early in life, the onset of calcific degeneration heralds a clinical course similar to that described earlier for calcific aortic stenosis. Other bicuspid valve complications include aortic regurgitation and infective endocarditis. Interestingly, structural abnormalities of the aortic wall also commonly accompany BAV, even when the valve is hemodynamically normal, and this may potentiate aortic dilation or aortic dissection.

Mitral Annular Calcification

As opposed to the predominantly cuspal involvement in aortic valve calcification, degenerative calcific deposits in the mitral valve typically develop in the fibrous annulus. Grossly, these appear as irregular, stony hard, occasionally ulcerated nodules (2 to 5 mm in thickness) at the base of the leaflets (see Fig. 12.20C, D). Mitral annular calcification usually does not affect valvular function. However, in exceptional cases it can lead to the following:

- *Regurgitation* by interfering with physiologic contraction of the valve ring
- *Stenosis* by impairing opening of the mitral leaflets
- *Arrhythmias* and occasionally sudden death by penetration of calcium deposits to a depth sufficient to impinge on the atrioventricular conduction system

Because calcific nodules may also provide a site for thrombus formation, patients with mitral annular calcification have a mildly increased risk of embolic stroke, and the calcific nodules can become a nidus for infective endocarditis. Mitral annular calcification increases with age and is more common in women and individuals with mitral valve prolapse (see later).

Mitral Valve Prolapse (Myxomatous Degeneration of the Mitral Valve)

In mitral valve prolapse (MVP), one or both mitral valve leaflets are "floppy" and protrude into the left atrium during systole. MVP affects approximately 2% to 3% of adults in the United States and is more common in women; it is most often an incidental finding on physical examination, but may lead to serious complications in a small minority of affected individuals.

Pathogenesis

The etiologic basis for the changes that weaken the valve leaflets and associated structures is unknown in most cases. Uncommonly, MVP is associated with heritable disorders of connective tissue including Marfan syndrome, caused by fibrillin-1 *(FBN1)* mutations that alter cell-matrix interactions and dysregulate TGF-β signaling (Chapter 5). Interestingly, mice with mutated *FBN1* develop a form of MVP that is prevented by TGF-β inhibitors, indicating that excess TGF-β activity can cause the characteristic structural laxity and myxomatous changes.

MORPHOLOGY

The characteristic anatomic change in MVP is ballooning (hooding) of the mitral leaflets (Fig. 12.21A–C). The affected leaflets are often enlarged, redundant, thick, and rubbery. The associated tendinous cords may be elongated, thinned, or even ruptured, and the annulus may be dilated. The tricuspid, aortic, or pulmonary valves may also be affected. The key histologic change in the tissue is marked **myxomatous degeneration** of the spongiosa layer, reflected by increased deposition of a highly sulfated hydrophilic matrix (see Fig. 12.21E); the collagenous fibrosa layer of the valve is also attenuated, affecting the structural integrity of the leaflet. Secondary changes reflect the stresses and tissue injury incident to the billowing leaflets: (1) fibrous thickening of the valve leaflets, particularly where they rub against each other; (2) linear fibrous thickening of the left ventricular endocardial surface where the abnormally long cords snap or rub against it; (3) thickening of the mural endocardium of the left ventricle or atrium as a consequence of friction-induced injury induced by the prolapsing, hypermobile leaflets; (4) thrombi on the atrial surfaces of the leaflets or the atrial walls (Fig. 12.21B); and (5) focal calcifications at the base of the posterior mitral leaflet (Fig. 12.21C). Notably, mitral valve myxomatous degeneration can also occur as a secondary consequence of regurgitation of other etiologies (e.g., ischemic dysfunction).

Clinical Features

Most individuals diagnosed with MVP are asymptomatic; in such cases, the condition is discovered incidentally by auscultation of mid-systolic clicks, caused by abrupt tension on the redundant valve leaflets and chordae tendineae as the valve attempts to close; there may or may not be an associated regurgitant murmur. The diagnosis is confirmed by echocardiography. A minority of patients have chest pain mimicking angina (although not exertional in nature), and a subset has dyspnea, presumably related to valvular insufficiency. Although the great majority of persons with MVP have no untoward effects, approximately 3% develop one of four serious complications: (1) infective endocarditis; (2) mitral insufficiency, sometimes with chordal rupture; (3) stroke or other systemic infarct, resulting from embolism of leaflet thrombi; or (4) arrhythmias, both ventricular and atrial. Rarely, MVP is the only finding in sudden cardiac

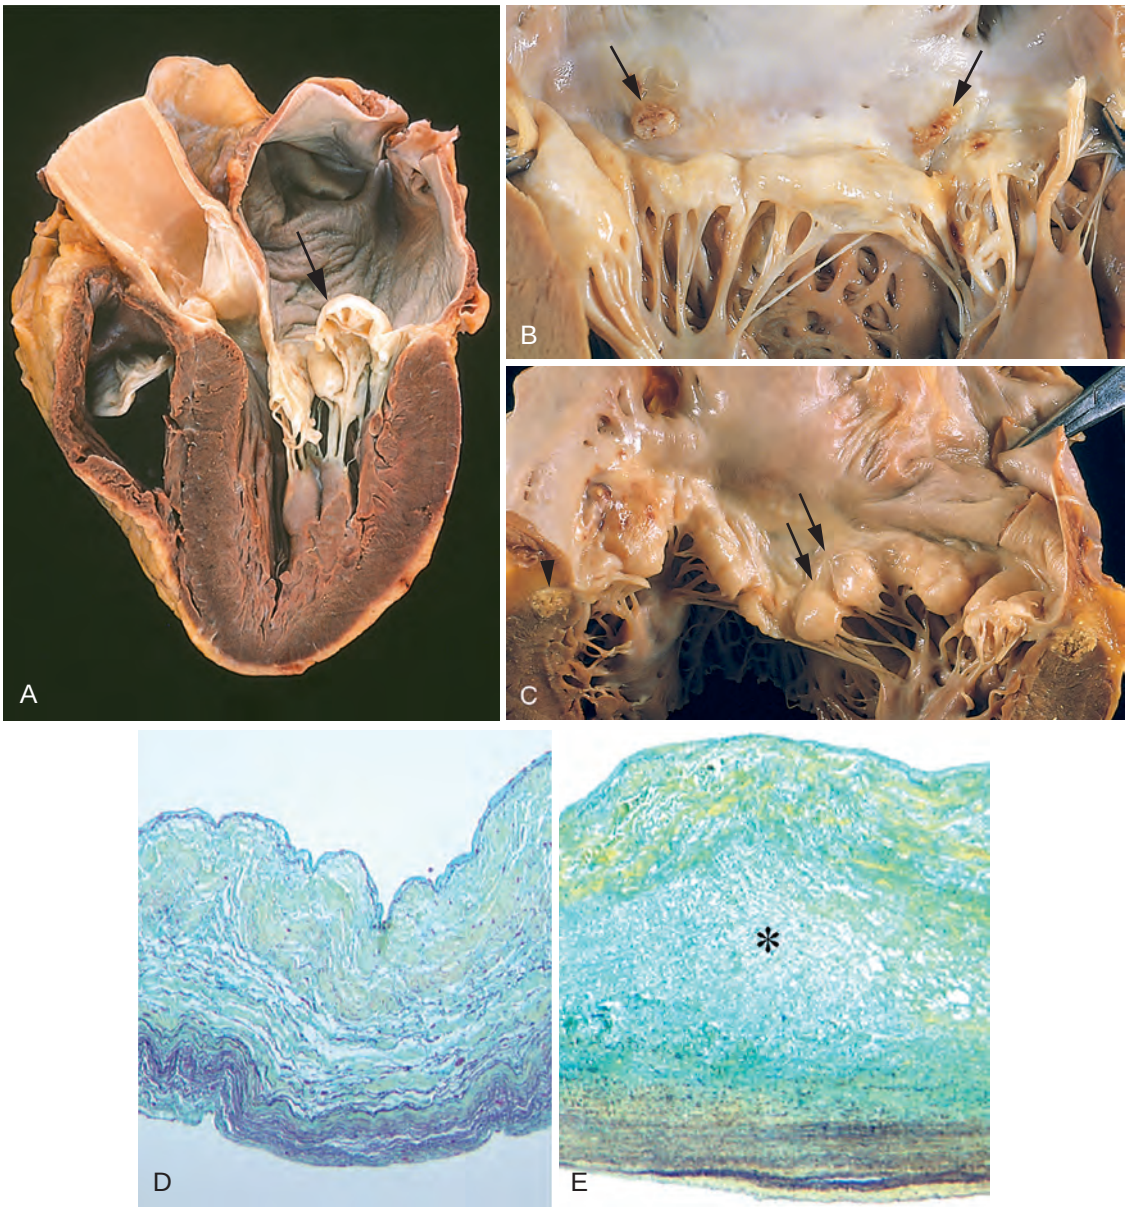

Figure 12.21 Myxomatous degeneration of the mitral valve. (A) Long axis view (left ventricle is on the *right*) demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium *(arrow)*. (B) Opened valve, showing pronounced hooding of the posterior mitral leaflet with thrombotic plaques at sites of leaflet-left atrium contact *(arrows)*. (C) Opened valve with pronounced hooding *(double arrows)* in a patient who died suddenly. Note also mitral annular calcification on the left side *(arrowhead)*. Normal heart valve (D) and myxomatous mitral valve (E). In myxomatous valves, collagen in the fibrosa layer is loose and disorganized, proteoglycan deposition *(asterisk)* in the central spongiosa layer is markedly expanded, and elastin in the atrialis layer is disorganized. (A, Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, Minn; D and E, Movat pentachrome stain, in which collagen is yellow, elastin is black, and proteoglycans are blue). From Rabkin E, et al: Activated interstitial myofibroblasts express catabolic enzymes and mediate matrix remodeling in myxomatous heart valves, *Circulation* 104:2525–2532, 2001.)

death. Valve repair or replacement surgery can be done for symptomatic patients or those with increased risk for significant complications.

Rheumatic Fever and Rheumatic Heart Disease

Rheumatic fever (RF) is an acute, immunologically mediated, multisystem inflammatory disease classically occurring a few weeks after group A streptococcal pharyngitis; occasionally, RF can follow streptococcal infections at other sites, such as the skin. Acute rheumatic carditis is a common manifestation of active RF and may progress over time to chronic rheumatic heart disease (RHD).

RHD is characterized principally by deforming fibrotic valvular disease, particularly involving the mitral valve; indeed, RHD is virtually the only cause of mitral stenosis. The incidence and mortality rate of RF and RHD have declined remarkably in many parts of the world over the past century, as a result of improved sanitation, and rapid diagnosis and treatment of streptococcal pharyngitis.

Nevertheless, in low income countries, and in many crowded, economically depressed urban areas, RHD remains an important public health problem.

Pathogenesis

Acute rheumatic fever results from host immune responses to group A streptococcal antigens that cross-react with host proteins. The characteristic 2- to 3-week delay in symptom onset after infection is explained by the time needed to generate an immune response; In particular, antibodies and CD4+ T cells directed against streptococcal M proteins can also in some cases recognize cardiac self antigens. Antibody binding can activate complement, as well as recruit Fc-receptor–bearing cells (neutrophils and macrophages); cytokine production by the stimulated T cells leads to macrophage activation (e.g., within Aschoff bodies). Damage to heart tissue may thus be caused by a combination of antibody- and T cell–mediated reactions (Chapter 6). In keeping with an immunologic basis of RHD, streptococci are completely absent from the lesions. Because only a small minority of infected patients develop rheumatic fever (estimated at 3%), a genetic susceptibility is likely to influence the development of the cross-reactive immune responses. The chronic fibrotic lesions are the predictable consequence of healing and scarring associated with the resolution of the acute inflammation.

MORPHOLOGY

Key pathologic features of acute RF and chronic RHD are shown in Fig. 12.22. During acute RF, focal inflammatory lesions are found in various tissues. Distinctive lesions in the heart—called **Aschoff bodies**—are composed of foci of T lymphocytes, occasional plasma cells, and plump activated macrophages called **Anitschkow cells.** These macrophages have abundant cytoplasm and central round-to-ovoid nuclei (occasionally binucleate) in which the chromatin condenses into a central, slender, wavy ribbon (hence the designation "caterpillar cells").

During acute RF, diffuse inflammation and Aschoff bodies may be found in any of the three layers of the heart, resulting in pericarditis, myocarditis, or endocarditis **(pancarditis).**

Inflammation of the endocardium and the left-sided valves typically results in fibrinoid necrosis within the cusps or tendinous

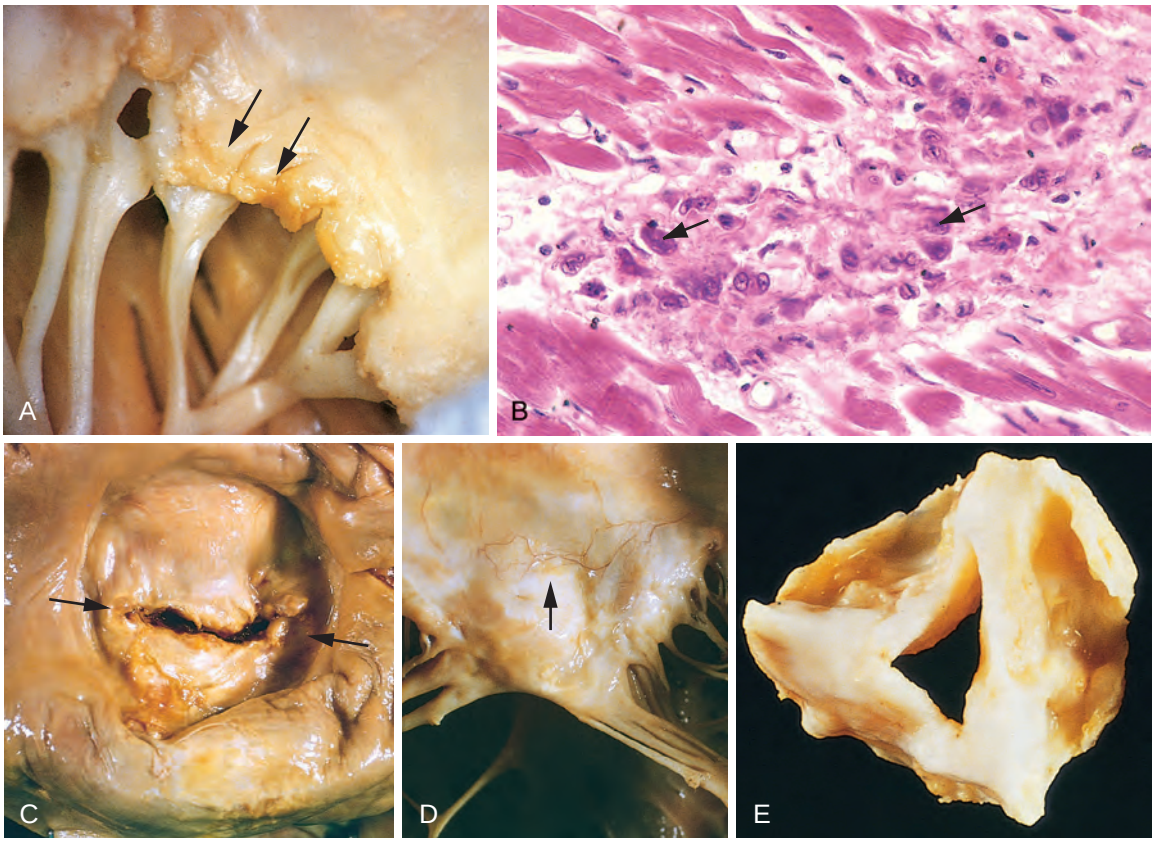

Figure 12.22 Acute and chronic rheumatic heart disease. (A) Acute rheumatic mitral valvulitis superimposed on chronic rheumatic heart disease. Small vegetations (verrucae) are visible along the line of closure of the mitral valve leaflet *(arrows)*. Previous episodes of rheumatic valvulitis have caused fibrous thickening and fusion of the chordae tendineae. (B) Microscopic appearance of an Aschoff body in a patient with acute rheumatic carditis. The myocardium exhibits a circumscribed nodule of mixed mononuclear inflammatory cells with associated necrosis; within the inflammation, large activated macrophages show prominent nucleoli, as well as chromatin condensed into long, wavy ribbons (caterpillar cells; *arrows*). (C and D) Mitral stenosis with diffuse fibrous thickening and distortion of the valve leaflets and commissural fusion (*arrows,* C), and thickening of the chordae tendineae (D). Note the neovascularization of the anterior mitral leaflet (*arrow,* D). (E) Surgically resected specimen of rheumatic aortic stenosis, demonstrating thickening and distortion of the cusps with commissural fusion. (E, Reproduced from Schoen FJ, St. John-Sutton M: Contemporary issues in the pathology of valvular heart disease, *Hum Pathol* 18:568, 1967.)

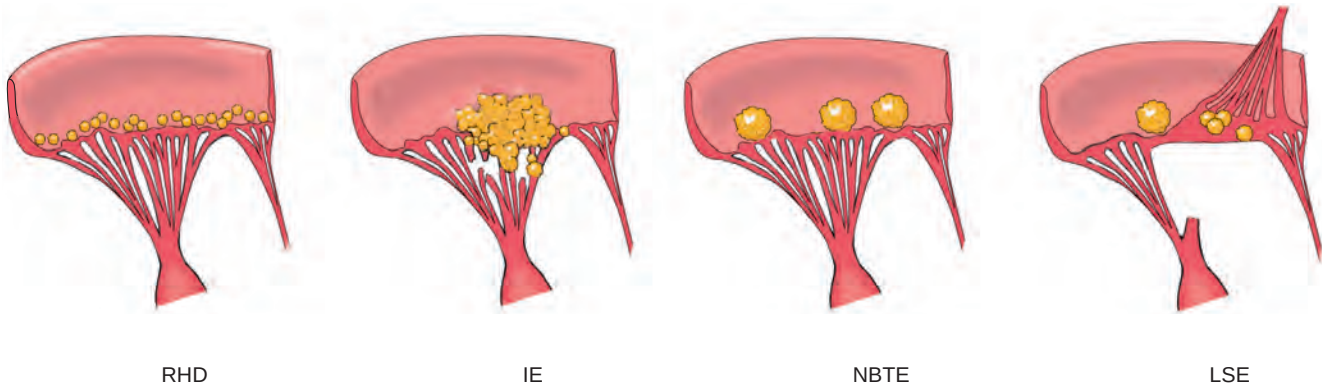

Figure 12.23 Comparison of the four major forms of vegetative endocarditis. The rheumatic fever phase of rheumatic heart disease *(RHD)* is marked by small, warty vegetations along the lines of closure of the valve leaflets. Infective endocarditis *(IE)* is characterized by large, irregular masses on the valve cusps that can extend onto the chordae (see Fig. 12.24A). Nonbacterial thrombotic endocarditis *(NBTE)* typically exhibits small, bland vegetations, usually attached at the line of closure. One or many may be present (see Fig. 12.25). Libman-Sacks endocarditis *(LSE)* has small- or medium-sized vegetations on either or both sides of the valve leaflets.

cords. Overlying these necrotic foci and along the lines of closure are small (1 to 2 mm) vegetations, called **verrucae.** Thus, RHD is one of the forms of vegetative valve disease, each of which exhibit their own characteristic morphologic features (Fig. 12.23). Subendocardial lesions, perhaps exacerbated by regurgitant jets, can induce irregular thickenings called **MacCallum plaques,** usually in the left atrium.

The cardinal anatomic changes of the mitral valve in chronic RHD are **leaflet thickening, commissural fusion and shortening, and thickening and fusion of the tendinous cords** (see Fig. 12.22D). The mitral valve is virtually always involved in chronic RHD; it is affected in isolation in roughly two-thirds of cases, and along with the aortic valve in another 25%. Tricuspid valve involvement is infrequent, and the pulmonary valve is only rarely affected.

In rheumatic mitral stenosis, calcification and fibrous bridging across the valvular commissures create "fish mouth" stenoses (see Fig. 12.22C). With tight mitral stenosis, the left atrium progressively dilates and may harbor mural thrombi that can embolize. Long-standing congestive changes in the lungs may induce pulmonary vascular and parenchymal changes; over time, these can lead to right ventricular hypertrophy. The left ventricle is largely unaffected by isolated pure mitral stenosis. Microscopically, valves show organization of the acute inflammation, with postinflammatory neovascularization and transmural fibrosis that obliterate the leaflet architecture. Aschoff bodies are rarely seen in surgical specimens or autopsy tissue from patients with chronic RHD, because of the long intervals between the initial insult and the development of the chronic deformity.

Clinical Features

RF is characterized by a constellation of major manifestations:

- *Migratory polyarthritis* of the large joints
- *Pancarditis* (myocarditis, pericarditis, or endocarditis)
- *Subcutaneous nodules* (typically on extensor surfaces of extremities)
- *Erythema marginatum,* an irregular circinate skin rash
- *Sydenham chorea,* a neurologic disorder with involuntary rapid movements

The diagnosis is established in accordance with the revised Jones criteria: evidence of a preceding group A streptococcal infection, and the presence of two major manifestations, or one major and two minor manifestations (nonspecific signs and symptoms that include fever, arthralgia, or elevated blood levels of acute-phase reactants); notably, these criteria are evolving and are applied differently in low- and high-risk settings.

Acute RF typically appears 10 days to 6 weeks after a group A streptococcal infection in about 3% of patients. It occurs most often in children between 5 and 15 years of age, but first attacks can occur in middle to later life. Although pharyngeal cultures for streptococci are negative by the time the illness begins, antibodies to one or more streptococcal enzymes, such as streptolysin O and DNase B, can be detected in the sera of most patients with RF. The predominant clinical manifestations are carditis and arthritis, the latter more common in adults than in children. Arthritis typically begins with migratory polyarthritis (accompanied by fever) in which one large joint after another becomes painful and swollen for a period of days and then subsides spontaneously, leaving no residual disability. Clinical features related to acute carditis include pericardial friction rubs, tachycardia, and arrhythmias. Myocarditis can cause cardiac dilation that may culminate in functional mitral valve insufficiency or even heart failure. Approximately 1% of affected individuals die of fulminant RF involvement of the heart.

After an initial attack, there is increased vulnerability to reactivation of the disease with subsequent pharyngeal infections, and the same manifestations are likely to appear with each recurrent attack. Damage to the valves is cumulative. Turbulence induced by ongoing valvular deformities leads to additional fibrosis. This is a prime example of a common theme in valvular heart disease in which the consequences of valve pathology may contribute to progression of that valve pathology in a positive feedback loop.

Clinical manifestations of RHD appear years or even decades after the initial episode of RF and depend on which valves are involved. In addition to cardiac murmurs, cardiac hypertrophy and dilation, and heart failure, individuals with chronic RHD may suffer from arrhythmias (particularly atrial fibrillation in the setting of mitral stenosis),

thromboembolic complications, and infective endocarditis (see later). The long-term prognosis is highly variable. Surgical repair or replacement of diseased valves has greatly improved the outlook for persons with RHD.

Infective Endocarditis (IE)

IE is a microbial infection of the heart valves or the mural endocardium that leads to the formation of vegetations composed of thrombotic debris and organisms, often associated with destruction of the underlying cardiac tissues. The aorta, aneurysms, other blood vessels, and prosthetic devices can also become infected. Although fungi and other classes of microorganisms can be responsible, most infections are bacterial (bacterial endocarditis). Prompt diagnosis, identification of the offending agent, and effective treatment of IE is important in limiting morbidity and mortality.

Traditionally, IE has been classified on clinical grounds into acute and subacute forms based on severity and tempo (reflecting microbial virulence), and whether there is underlying valvular pathology. Thus, acute IE is typically caused by infection of a previously normal heart valve by a highly virulent organism (e.g., *Staphylococcus aureus*) that rapidly produces destructive lesions. These infections may be difficult to cure with antibiotics alone and often require surgery; despite appropriate treatment, there can be substantial morbidity and even mortality. In contrast, subacute IE is characterized by organisms with lower virulence (e.g., viridans streptococci) that cause insidious infections of deformed valves with overall less destruction. In such cases the disease may pursue a protracted course of weeks to months, and cures can often be achieved with antibiotics alone. Of note, a clear delineation between acute and subacute endocarditis does not always exist, and many cases fall somewhere along the spectrum between the two forms.

Pathogenesis

Although highly virulent organisms can infect previously normal valves, a variety of cardiac abnormalities increase the risk of developing IE. RHD with valvular scarring has historically been the major antecedent disorder; as RHD becomes less common, it has been supplanted by mitral valve prolapse, degenerative calcific valvular stenosis, bicuspid aortic valve (whether calcified or not), artificial (prosthetic) valves, and congenital defects.

Endocarditis of native but previously damaged or otherwise abnormal valves is caused most commonly (50% to 60% of cases) by *Streptococcus viridans,* a normal component of the oral cavity flora. In contrast, more virulent *S. aureus* organisms commonly found on the skin can infect either healthy or deformed valves and are responsible for 20% to 30% of cases overall; notably, *S. aureus* is the major offender in IE among intravenous drug abusers. Other bacterial causes include enterococci and the so-called HACEK group (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella*), all commensals in the oral cavity. More rarely, Gram-negative bacilli and fungi can be involved. Prosthetic valve endocarditis occurring in the 1 to 2 months after surgical implantation is typically caused by skin flora (*S. aureus* and *S. epidermidis*); prosthetic valve infections 1 year or more after surgery tend to be streptococci and *S. aureus* (see later discussion of prosthetic valves). In about 10% of all cases of endocarditis, no organism can be isolated from the blood ("culture-negative" endocarditis); reasons include prior antibiotic therapy, difficulties in isolating the offending agent, or because deeply embedded organisms within the enlarging vegetation are not released into the blood.

Foremost among the factors predisposing to endocarditis are those that cause microorganism seeding into the bloodstream (bacteremia or fungemia). The source may be an obvious infection elsewhere, a dental or surgical procedure, a contaminated needle shared by intravenous drug users, or seemingly trivial breaks in the epithelial barriers of the gut, oral cavity, or skin. In patients with valve abnormalities, or with known bacteremia, IE risk can be lowered by antibiotic prophylaxis.

MORPHOLOGY

Vegetations on heart valves are the classic hallmark of IE; these are friable, bulky, potentially destructive lesions containing fibrin, inflammatory cells, and bacteria or other organisms (Figs. 12.23 and 12.24). The aortic and mitral valves are the most common

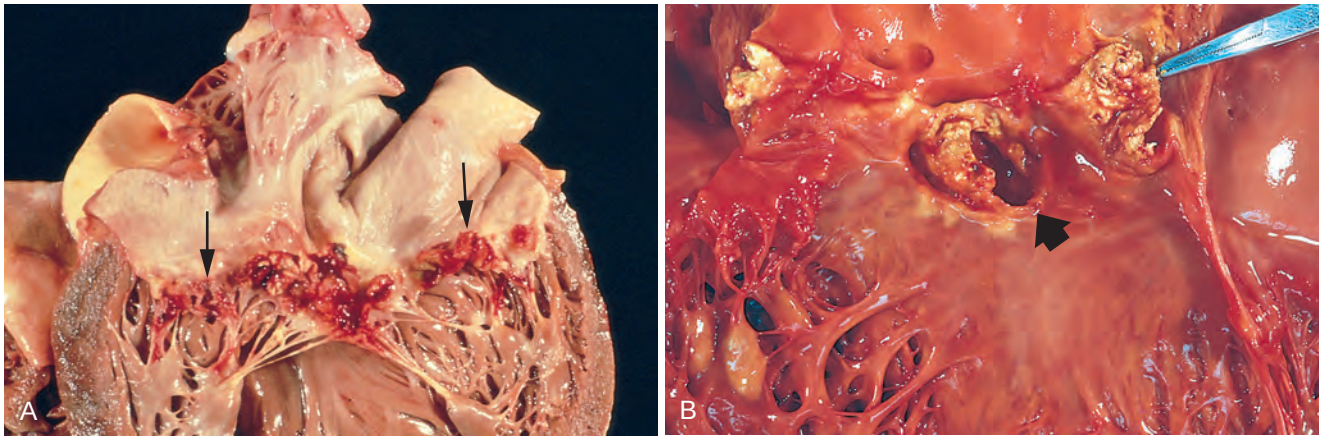

Figure 12.24 Infective (bacterial) endocarditis. (A) Endocarditis of mitral valve (subacute, caused by *Streptococcus viridans*). The large, friable vegetations are denoted by *arrows*. (B) Acute endocarditis of congenitally bicuspid aortic valve (caused by *Staphylococcus aureus*) with extensive cuspal destruction and ring abscess *(arrow)*.

sites of infection, although the valves of the right heart may also be involved, particularly in intravenous drug abusers. Vegetations can be single or multiple and may involve more than one valve; they can occasionally erode into the underlying myocardium and produce an abscess (ring abscess; see Fig. 12.24B). Vegetations are prone to embolization; because the embolic fragments often contain virulent organisms, abscesses frequently develop where they lodge, leading to sequelae such as septic infarcts or mycotic aneurysms.

The vegetations of subacute endocarditis are associated with less valvular destruction than those of acute endocarditis, although the distinction can be subtle. Microscopically, the vegetations of subacute IE typically exhibit granulation tissue at their bases indicative of healing. With time, fibrosis, calcification, and a chronic inflammatory infiltrate can develop.

Clinical Features

Acute endocarditis has a stormy onset with rapid onset of fever, chills, weakness, and lassitude. Although fever is the most consistent sign of IE, it can be slight or absent, particularly in older adults, and the only manifestations may be nonspecific fatigue, weight loss, and a flulike syndrome. Murmurs are present in the majority of patients with left-sided IE, either from a new valvular defect or from a preexisting abnormality. The modified Duke criteria (Table 12.9) facilitate diagnosis of individuals with suspected IE by taking into account predisposing factors, physical findings, blood culture results, echocardiographic findings, and laboratory information.

Complications of IE generally begin within the first few weeks of onset and can include glomerular antigen-antibody complex deposition causing glomerulonephritis (Chapter 20). Sepsis, arrhythmias (suggesting invasion into underlying myocardium and conduction system), and systemic embolization bode particularly ill for the patient. Left untreated, IE generally is fatal. However, with appropriate long-term (6 weeks or more) antibiotic therapy and/or valve replacement, mortality is reduced. For infections involving low-virulence organisms (e.g., *S. viridans*), the cure rate is 98%, and for enterococci and *S. aureus* infections, cure rates range from 60% to 90%; however, with infections due to gram-negative bacilli or fungi, one-half of the patients ultimately succumb. The cure rate for endocarditis arising on prosthetic valves is uniformly worse, and valve replacement is commonly required.

Earlier diagnosis and effective treatment has nearly eliminated some previously common clinical manifestations of long-standing IE—for example, microthromboemboli (manifest as splinter or subungual hemorrhages), erythematous or hemorrhagic nontender lesions on the palms or soles (Janeway lesions), subcutaneous nodules in the pulp of the digits (Osler nodes), and retinal hemorrhages in the eyes (Roth spots).

Noninfected Vegetations

Noninfected (sterile) vegetations occur in nonbacterial thrombotic endocarditis (NBTE) and the endocarditis of systemic lupus erythematosus (SLE).

Table 12.9 Diagnostic Criteria for Infective Endocarditis[a]

Pathologic Criteria
Microorganisms, demonstrated by culture or histologic examination, in a vegetation, embolus from a vegetation, or intracardiac abscess
Histologic confirmation of active endocarditis in a vegetation or intracardiac abscess
Clinical Criteria
Major
Blood culture(s) positive for a characteristic organism or persistently positive for an unusual organism
Echocardiographic identification of a valve-related or implant-related oscillating mass or abscess, or partial separation of artificial valve
New valvular regurgitation
Minor
Predisposing heart lesion or intravenous drug use
Fever
Vascular lesions, including major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions[b]
Immunological phenomena, including glomerulonephritis, Osler nodes,[c] Roth spots,[d] and rheumatoid factor
Microbiologic evidence, including a single culture positive for an unusual organism

[a]Diagnosis by these guidelines, often called the Modified Duke Criteria, requires either pathologic or clinical criteria; if clinical criteria are used, 2 major, 1 major + 3 minor, or 5 minor criteria are required for definitive diagnosis. "Possible" infective endocarditis diagnosis requires either 1 major +1 minor, or 3 minor.

[b]Janeway lesions are small erythematous or hemorrhagic, macular, nontender lesions on the palms and soles and are the consequence of septic embolic events.

[c]Osler nodes are small, tender subcutaneous nodules that develop in the pulp of the digits or occasionally more proximally in the fingers and persist for hours to several days.

[d]Roth spots are oval retinal hemorrhages with pale centers.

Modified from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis, *Clin Infect Dis* 30(4):633–638, 2000; Baddour LM: Cardiovascular infections. In Mann D, et al., editors: *Braunwald's Heart Disease. a Textbook of Cardiovascular Medicine*, ed 10, Philadelphia, 2015, WB Saunders, p 1524.

Nonbacterial Thrombotic Endocarditis (NBTE)

NBTE is characterized by the deposition of small (1 to 5 mm) sterile thrombi on the leaflets of the cardiac valves (Figs. 12.23 and 12.25). Histologically, these are bland thrombi, loosely attached to the underlying valve; the vegetations are nondestructive and do not elicit any inflammatory reaction. Although the local effect of the vegetations is usually trivial, they can be the source of systemic emboli that produce significant infarcts in the brain, heart, or elsewhere.

NBTE is often encountered in debilitated patients, such as those with cancer or sepsis—hence the previous term marantic endocarditis (root word *marasmus,* relating to malnutrition). Valvular damage is not a prerequisite for NBTE; indeed, the condition usually occurs on previously normal valves. Rather, hypercoagulable states are the usual precursor to NBTE; such conditions include chronic disseminated intravascular coagulation, hyperestrogenic states, and those associated with underlying malignancy, particularly mucinous adenocarcinomas. The latter association is likely related to the procoagulant effects of tumor-derived mucin or tissue factor that can also cause migratory thrombophlebitis (*Trousseau syndrome,* Chapter 4). Endocardial trauma, as from an indwelling catheter, is another well-recognized predisposing condition.

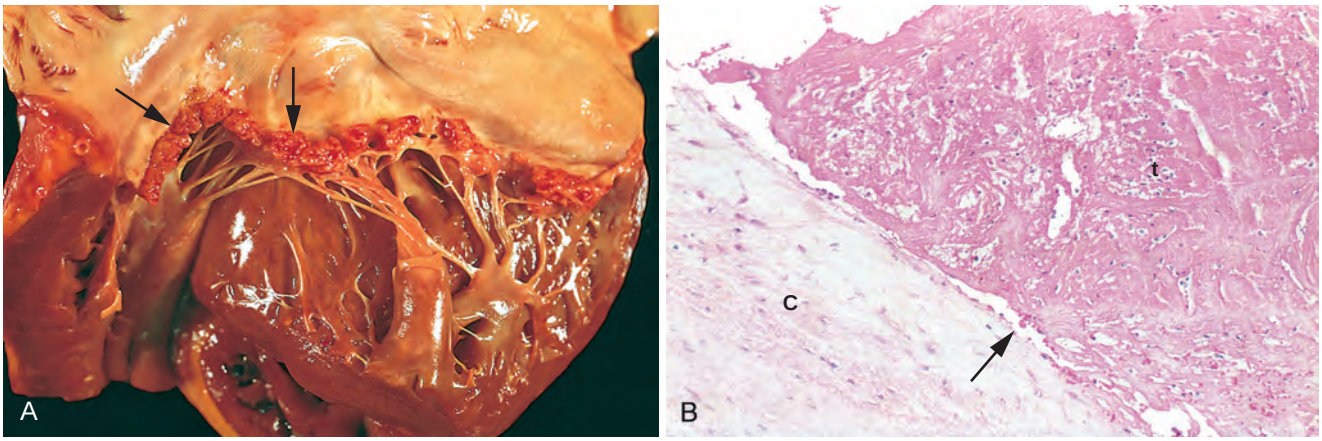

Figure 12.25 Nonbacterial thrombotic endocarditis (NBTE). (A) Nearly complete row of thrombotic vegetations along the line of closure of the mitral valve leaflets *(arrows)*. (B) Photomicrograph of NBTE, showing bland thrombus, with virtually no inflammation in the valve cusp *(c)* or the thrombotic deposit *(t)*. The thrombus is only loosely attached to the cusp *(arrow)*.

Endocarditis of Systemic Lupus Erythematosus (Libman-Sacks Disease)

Small (1 to 4 mm), sterile vegetations in the setting of systemic lupus erythematosus are termed Libman-Sacks endocarditis. The lesions develop as a consequence of immune complex deposition, with activation of complement and recruitment of Fc-receptor–bearing cells; histologically, there is an intense valvulitis and fibrinoid necrosis of the valve substance. The vegetations can occur anywhere on the valve surface, on the chordae, or even on the atrial or ventricular endocardium (see Fig. 12.23). Persistent injury can eventually result in valvular scarring and leaflet fusion, analogous to that seen in RHD. Similar lesions can occur in the antiphospholipid antibody syndrome (Chapter 4).

Carcinoid Heart Disease

The carcinoid syndrome refers to a systemic disorder marked by flushing, diarrhea, dermatitis, and bronchoconstriction that is caused by bioactive compounds such as serotonin released by carcinoid tumors (Chapter 17). Carcinoid heart disease refers to the cardiac manifestations caused by the bioactive compounds and occurs in roughly one-half of the patients in whom the systemic syndrome develops. Cardiac lesions do not typically occur until there is a massive hepatic metastatic burden, because the liver normally catabolizes circulating mediators before they can affect the heart. Classically, endocardium and valves of the right heart are primarily affected because they are the first cardiac tissues bathed by the mediators released by gastrointestinal carcinoid tumors. The left side of the heart is afforded some measure of protection because the pulmonary vascular bed degrades the mediators. However, left heart carcinoid lesions can occur in the setting of atrial or septal defects and right-to-left flow, or they can be induced by primary pulmonary carcinoid tumors.

Pathogenesis

The mediators elaborated by carcinoid tumors include serotonin (5-hydroxytryptamine), kallikrein, bradykinin, histamine, prostaglandins, and tachykinins. Although it is not clear which of these is causal, plasma levels of serotonin and urinary excretion of the serotonin metabolite 5-hydroxyindoleacetic acid correlate with the severity of the cardiac lesions. The valvular plaques in carcinoid syndrome are also similar to lesions that occured in patients taking fenfluramine (an appetite suppressant, no longer marketed) or ergot alkaloids (used previously for migraine headaches); interestingly, these agents affect systemic serotonin metabolism. Similarly, left-sided plaques have been reported after methysergide or ergotamine therapy for migraines; notably, these drugs are metabolized to serotonin as they pass through the pulmonary vasculature.

MORPHOLOGY

The cardiovascular lesions associated with the carcinoid syndrome are distinctive, glistening white intimal plaquelike thickenings of the endocardial surfaces of the cardiac chambers and valve leaflets (Fig. 12.26). The lesions are composed of smooth muscle cells and sparse collagen fibers embedded in an acid mucopolysaccharide-rich matrix material. Underlying structures are intact. With right-sided involvement, typical findings are tricuspid insufficiency and pulmonary stenosis.

Complications of Prosthetic Valves

Although prosthetic heart valves are less-than-perfect substitutes for the native tissues, their introduction has radically altered the prognosis for patients with valve disease. Two types of prosthetic valves are currently used, each with its own advantages and disadvantages:

- *Mechanical valves*. These consist of different configurations of rigid nonphysiologic material, such as caged balls, tilting disks, or hinged semicircular flaps (bileaflet tilting disk valves).
- *Tissue valves (bioprostheses)*. Porcine aortic valves or bovine pericardium are preserved in a dilute glutaraldehyde solution and then mounted on a prosthetic frame. Alternatively, frozen human valves from deceased donors

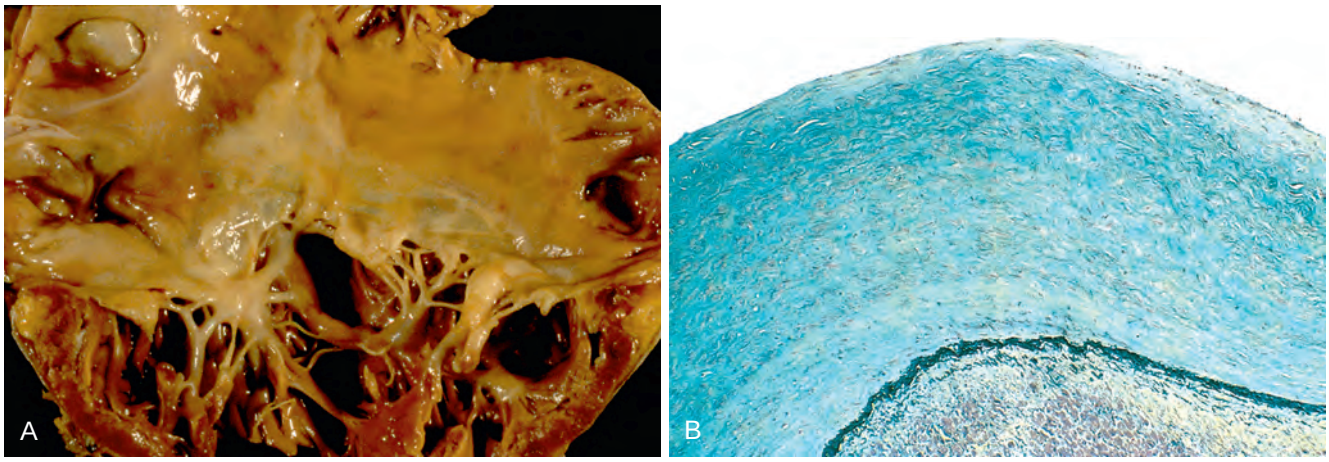

Figure 12.26 Carcinoid heart disease. (A) Characteristic endocardial fibrotic lesion involving the right ventricle and tricuspid valve. (B) Microscopic appearance of carcinoid heart disease with endocardial thickening. Movat stain shows myocardial elastic tissue *(black)* underlying the acid mucopolysaccharide-rich lesion *(blue-green)*. The underlying myocardium is unaffected.

(called cryopreserved "homografts") can also be used. Increasingly—especially in patients who are not good "open" surgical candidates—bioprosthetic valves are deployed by catheter-based approaches (transcatheter aortic valve replacement or TAVR) wedging the new valve into the outflow tract without resecting the original diseased valve. Tissue valves are flexible and function similarly to natural semilunar valves. However, the chemical treatment of the animal valves cross-links the valvular proteins, especially collagen, and renders the tissue nonviable. Similarly, the freezing and thawing of human homografts may also render them largely nonviable.

Approximately 60% of substitute valve recipients develop a serious prosthesis-related problem within 10 years after the surgery. The complications that occur depend on which type of valve has been implanted (Table 12.10 and Fig. 12.27).

- *Thromboembolism* is the major consideration with mechanical valves (see Fig. 12.27A); this may take the form of either thrombotic occlusion of the prosthesis or emboli released from thrombi formed on the valve. Because blood flow in all mechanical devices is nonlaminar, foci of turbulence and stasis are produced by prostheses that

Table 12.10 Complications of Cardiac Valve Prostheses

Thrombosis/thromboembolism
Anticoagulant-related hemorrhage
Prosthetic valve endocarditis
Structural deterioration (intrinsic)
Wear, fracture, poppet failure in ball valves, cuspal tear, calcification
Other forms of dysfunction
Inadequate healing (paravalvular leak), exuberant healing (obstruction), hemolysis

predispose to thrombus formation. The risk of such complications necessitates long-term anticoagulation in all individuals with mechanical valves, with the attendant risk of hemorrhagic stroke or other forms of serious bleeding.

- *Structural deterioration* rarely causes failure of any of the mechanical valves in current use. However, virtually all bioprostheses eventually become incompetent due to calcification and/or tearing (see Fig. 12.27B).
- *Infective endocarditis* is a potentially serious complication of any valve replacement. The vegetations of prosthetic valve endocarditis are usually located at the prosthesis-tissue interface, and they often cause the formation of a ring abscess, which can eventually lead to a paravalvular regurgitant blood leak. In addition, vegetations may directly involve the tissue of bioprosthetic valvular cusps.
- *Other complications* include paravalvular leak due to inadequate healing, obstruction due to overgrowth of fibrous tissue during healing, valve-orifice disproportion—where the effective valve area is too small for the needs of the patient, leading to a relative stenosis—or intravascular hemolysis due to high shear forces.

KEY CONCEPTS

VALVULAR HEART DISEASE

- Valve pathology can lead to occlusion (stenosis) and/or regurgitation (insufficiency); acquired aortic and mitral valve stenoses account for approximately two-thirds of all valve disease; much of the remainder is mitral regurgitation.
- Valve calcification is a degenerative process that typically results in stenosis.
- Abnormal matrix synthesis and turnover result in myxomatous degeneration and insufficiency.
- Inflammatory valve diseases lead to postinflammatory scarring. RHD results from anti-streptococcal antibodies and T cells that cross-react with cardiac tissues; it most commonly affects the mitral valve and is responsible for 99% of acquired mitral stenoses.
- IE can be aggressive and rapidly destroy normal valves (acute IE), or can be indolent and minimally destructive of previously abnormal valves (subacute IE). Systemic embolization can produce septic infarcts.
- NBTE occurs on previously normal valves due to hypercoagulable states; embolization is an important complication.
- Mechanical prosthetic valves have thrombotic or hemorrhagic complications related to the nonlaminar flow of blood and the need for chronic anticoagulation. Bioprosthetic valves are nonviable and are therefore susceptible to long-term calcification and/or degeneration with tearing. Both types of valves have an increased risk of developing endocarditis relative to native valves.

CARDIOMYOPATHIES

The term cardiomyopathy (literally, heart muscle disease) has been historically applied to any cardiac dysfunction. Technically, that is not incorrect; the major heart disease categories already discussed—ischemic, valvular, hypertensive, or congenital—do cause "heart muscle disease." However, these major categories of cardiac diseases cause heart failure as predictable secondary consequences of other forms of cardiac dysfunctions—e.g., loss of pump function due to MI, or volume-pressure overloads due to an incompetent valve; in Table 12.11 these are referred to as secondary myocardial dysfunction. To distinguish these forms of "heart disease" from those associated with innate "primary" myocardial dysfunction, a more nuanced definition of cardiomyopathy has emerged. Thus, stimulated by the recognition of new phenotypes and the advent of more sophisticated molecular characterization—an expert panel has suggested: "Cardiomyopathies are a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic. Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure-related disability."

There are two major groups of cardiomyopathies:

- *Primary cardiomyopathies* involve predominantly the heart. They may be genetic or acquired (e.g., viral myocarditis, anthracycline cardiotoxic).
- *Secondary cardiomyopathies* have myocardial involvement as a component of a systemic or multiorgan disorder (e.g. hemochromatosis, amyloidosis).

Table 12.11 Cardiomyopathies: Functional Patterns and Causes

Functional Pattern	Left Ventricular Ejection Fraction[a]	Mechanisms of Heart Failure	Causes	Secondary Myocardial Dysfunction (Mimicking Cardiomyopathy)
Dilated	<40%	Impairment of contractility (systolic dysfunction)	Genetic; alcohol; peripartum; myocarditis; hemochromatosis; chronic anemia; anthracycline medications; sarcoidosis; idiopathic	Ischemic heart disease; valvular heart disease; hypertensive heart disease; congenital heart disease
Hypertrophic	50%–80%	Impairment of compliance (diastolic dysfunction)	Genetic; Friedreich ataxia; storage diseases; infants of diabetic mothers	Hypertensive heart disease; aortic stenosis
Restrictive	45%–90%	Impairment of compliance (diastolic dysfunction)	Amyloidosis; radiation-induced fibrosis; idiopathic	Pericardial constriction

[a]Range of normal values is approximately 50% to 65%.

A major advance in our understanding of the pathogenesis of cardiomyopathies stems from the accelerating identification of underlying genetic causes, including mutations in myocardial proteins involved in energy generation, contraction, cell-to-cell contacts, or connecting cytoskeleton to the extracellular matrix. These, in turn, lead to abnormal contraction or relaxation, or to dysregulated ion transport that can cause arrhythmias.

Cardiomyopathies can be classified according to a variety of criteria, including the underlying genetic basis of dysfunction; we have already discussed a number of the arrhythmia-inducing channelopathies. Here, we will confine our discussion to disorders that produce anatomic abnormalities falling into one of three distinct pathologic patterns (Fig. 12.28 and Table 12.11):

- *Dilated cardiomyopathy (DCM)* (including arrhythmogenic cardiomyopathy)
- *Hypertrophic cardiomyopathy*
- *Restrictive cardiomyopathy*

Among the three major patterns, DCM is most common (90% of cases), and restrictive cardiomyopathy is the least frequent. Within each pattern, there is a spectrum of clinical severity, and in some cases clinical features overlap among the groups. In addition, each of these patterns is associated with a specific identifiable cause or idiopathic; although many cases of DCM were previously labeled "idiopathic," the majority of these can now be assigned a genetic, toxic, or infectious etiology (Tables 12.11 and 12.12).

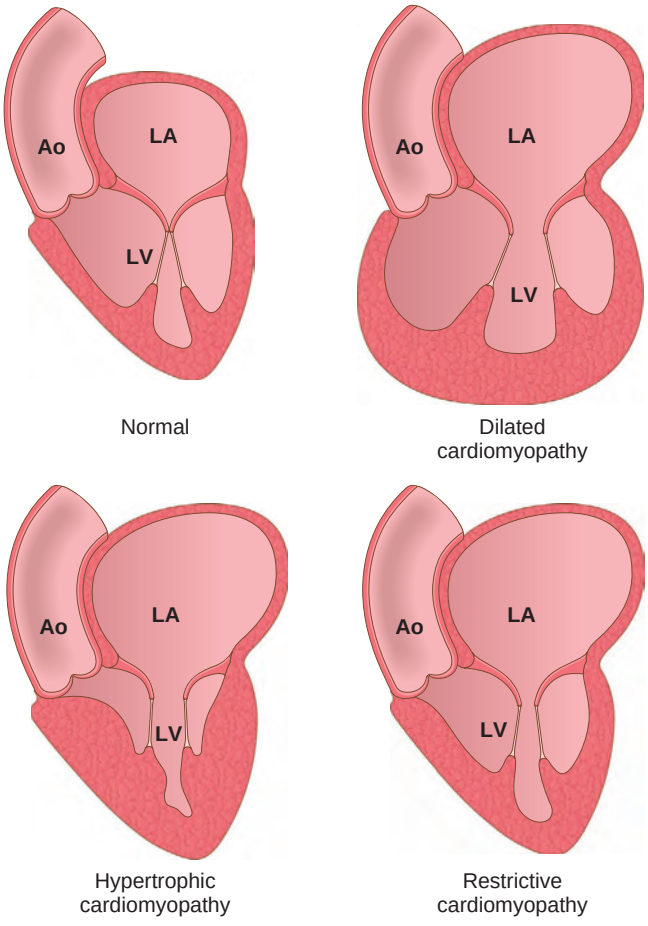

Figure 12.28 The three major morphologic patterns of cardiomyopathy. Dilated cardiomyopathy leads primarily to systolic dysfunction, whereas restrictive and hypertrophic cardiomyopathies result in diastolic dysfunction. Note the changes in atrial and/or ventricular wall thickness. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle.

Dilated Cardiomyopathy (DCM)

DCM is characterized morphologically and functionally by progressive cardiac dilation and contractile (systolic) dysfunction, usually with concomitant hypertrophy. Many cases are familial, but the DCM phenotype can result from diverse causes, both primary and secondary.

Pathogenesis

Several different pathways can lead to DCM (Fig. 12.29). Identifying which may be causal in any given case is often

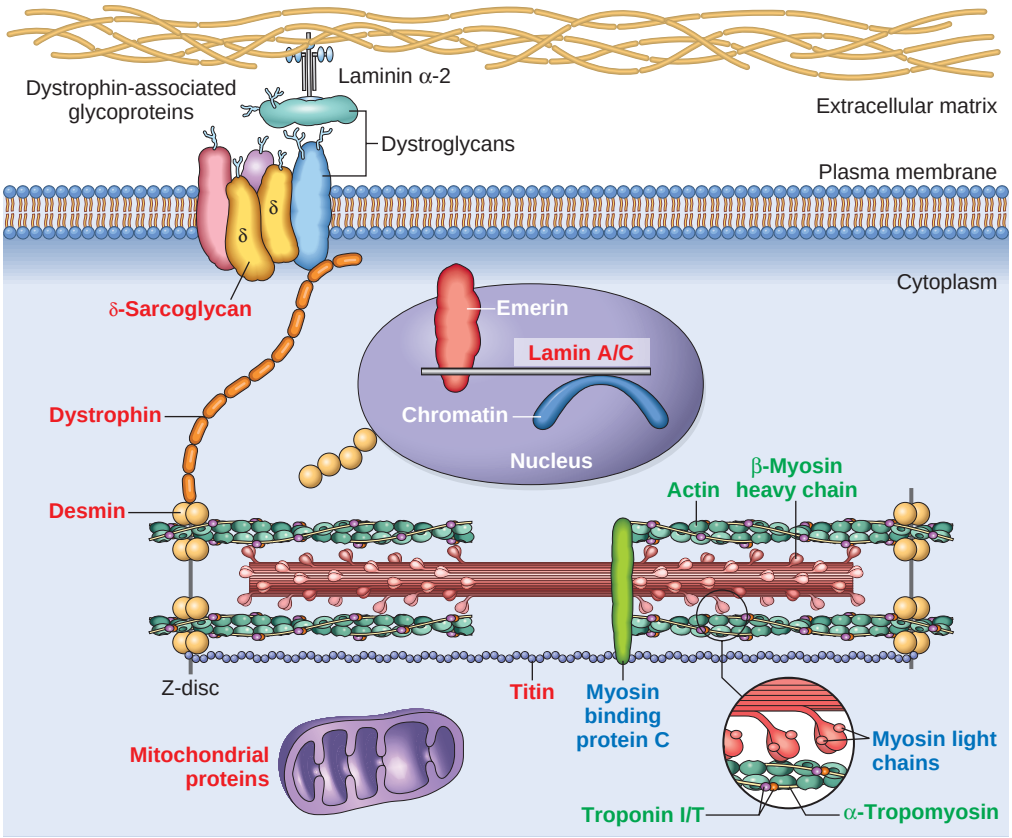

Figure 12.29 Schematic of a myocyte, showing key proteins mutated in dilated cardiomyopathy *(red labels)*, hypertrophic cardiomyopathy *(blue labels)*, or both *(green labels)*. Mutations in titin (the largest known human protein at approximately 30,000 amino acids) account for approximately 20% of all dilated cardiomyopathy. Titin spans the sarcomere and connects the Z and M bands, thereby limiting the passive range of motion of the sarcomere as it is stretched. Titin also functions like a molecular spring, with domains that unfold when the protein is stretched and refold when the tension is removed, thereby affecting the passive elasticity of striated muscle.

frustrating, because diagnosis is only made after the patient has developed end-stage heart failure; very simply, the heart is nonspecifically dilated and poorly contractile. The clinical evaluation at that point is done to exclude ischemic, valvular, hypertensive, or congenital causes; once they have been ruled out, a diagnosis of primary dilated cardiomyopathy can be suggested. Although an exhaustive evaluation may not be able to pinpoint a specific etiology ("idiopathic DCM"), familial (genetic) forms of DCM are increasingly recognized, and the final pathology can also result from a host of myocardial insults:

- *Genetic Influences.* DCM is probably familial in up to 50% of cases, caused by mutations in a diverse group of more than 20 genes encoding proteins involved in the cytoskeleton, sarcolemma, and nuclear envelope (e.g., lamin A/C). In particular, truncation mutations in *TTN,* a gene that encodes titin (so-called because it is the largest protein expressed in humans), may account for approximately 10% to 20% of all cases of DCM (Fig. 12.30). In the genetic forms of DCM, autosomal dominant inheritance is the predominant pattern, although there is often variable penetrance even within the same families, suggesting that the progression to DCM can be multifactorial.

  X-linked, autosomal recessive, and mitochondrial inheritance of DCM are less common. In some families, mitochondrial gene deletions affect oxidative phosphorylation; in others, there are mutations in genes encoding enzymes involved in fatty acid β-oxidation. Mitochondrial defects typically manifest in the pediatric population, whereas X-linked DCM typically presents after puberty and into early adulthood. X-linked cardiomyopathy can also be associated with mutations affecting the membrane-associated dystrophin protein that couples cytoskeleton to the extracellular matrix (recall that dystrophin is mutated in the most common skeletal myopathies, Duchenne and Becker muscular dystrophies; Chapter 27); some dystrophin gene mutations have DCM as the primary clinical feature. Interestingly, and probably resulting from the common developmental origin of contractile myocytes and conduction elements, congenital abnormalities of conduction may also be associated with DCM.
- *Myocarditis.* Sequential endomyocardial biopsies have documented progression from myocarditis to DCM. In other studies, the detection of the genetic fingerprints of coxsackie B and other viruses within myocardium of patients with DCM suggests that viral myocarditis can be causal (see later discussion).
- *Alcohol and other toxins.* Alcohol abuse is strongly associated with the development of DCM, raising the possibility that ethanol toxicity (Chapter 9) or a secondary nutritional disturbance can underlie myocardial injury. Alcohol or its metabolites (especially acetaldehyde) have a direct toxic effect on the myocardium. Moreover, chronic alcoholism may be associated with thiamine deficiency,

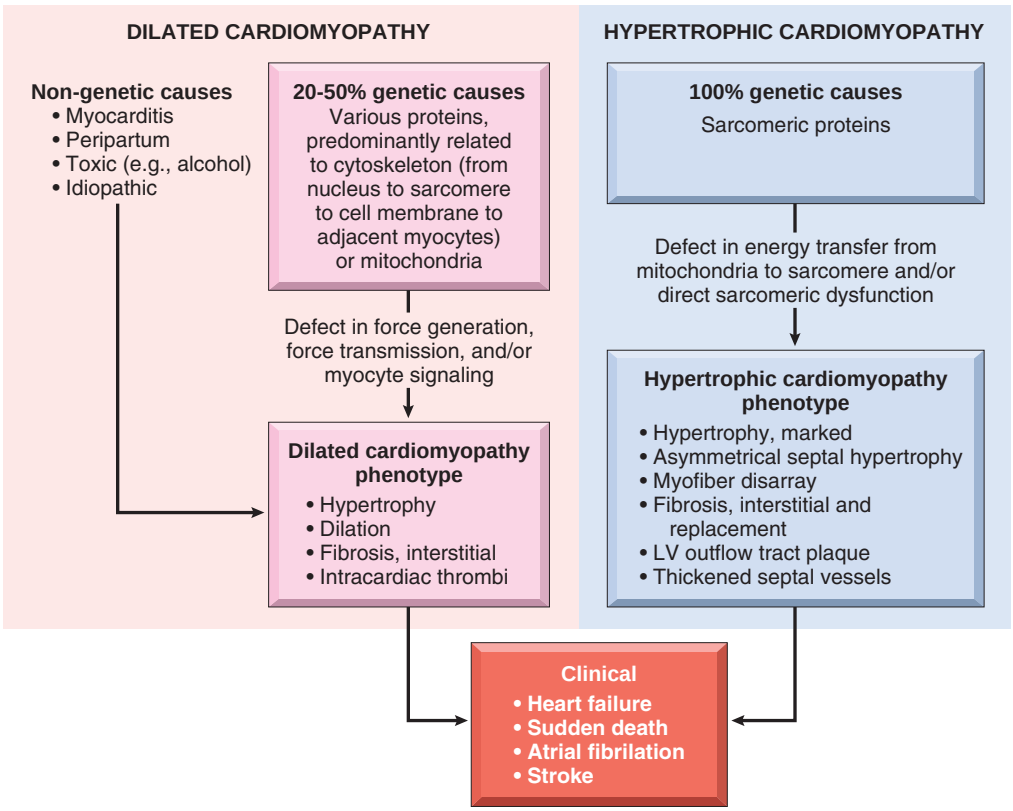

Figure 12.30 Causes and consequences of dilated and hypertrophic cardiomyopathy. Some dilated cardiomyopathies and virtually all hypertrophic cardiomyopathies are genetic in origin. The genetic causes of dilated cardiomyopathy involve mutations in any of a wide range of genes. They encode proteins predominantly of the cytoskeleton, but also the sarcomere, mitochondria, and nuclear envelope. In contrast, all of the mutated genes that cause hypertrophic cardiomyopathy encode proteins of the sarcomere. Although these two forms of cardiomyopathy differ greatly in subcellular basis and morphologic phenotypes, they share a common set of clinical complications. *LV,* left ventricle.

which can lead to beriberi heart disease (a form of DCM). Nevertheless, no morphologic features serve to distinguish alcoholic cardiomyopathy from DCM of other causes. Cobalt is an example of a heavy metal with cardiotoxicity and has caused DCM in the setting of inadvertent tainting (e.g., in beer production). Cardiotoxic drugs used for chemotherapy (discussed later) are also important causes of DCM.

- *Childbirth.* Peripartum cardiomyopathy can occur late in pregnancy or up to 5 months postpartum; the mechanism is probably multifactorial, including contributions from genetic susceptibility, pregnancy-associated hypertension, volume overload, nutritional deficiency, and/or other subtle metabolic derangements. In mouse models, DCM can also be induced by increased levels of circulating antiangiogenic mediators including vascular endothelial growth factor inhibitors (e.g., sFLT1, as occurs with preeclampsia) or antiangiogenic cleavage products of the hormone prolactin (which rises late in pregnancy). Thus, in pregnant women with a particular genetic predisposition, elevated antiangiogenic molecules can potentially lead to a microvascular angiogenic imbalance (microvascular loss in excess of angiogenesis), ultimately resulting in functional ischemic injury.
- *Iron overload* in the heart can result from either hereditary hemochromatosis (Chapter 18) or from multiple transfusions. DCM is the most common manifestation of such iron excess, and it may be caused by interference with metal-dependent enzyme systems or by injury from iron-mediated production of reactive oxygen species.
- *Supraphysiologic stress* can also result in DCM. This can happen with persistent tachycardia, hyperthyroidism, or even during development, as in the fetuses of insulin-dependent diabetic mothers. Excess catecholamines, in particular, cause multifocal myocardial contraction band necrosis that can eventually progress to DCM. This can happen in individuals with pheochromocytomas, tumors that elaborate epinephrine (Chapter 24); use of cocaine or vasopressor agents such as dopamine can have similar consequences. Such "catecholamine effect" also occurs in the setting of intense autonomic stimulation, for example, secondary to intracranial lesions or emotional duress. *Takotsubo cardiomyopathy* is an entity characterized by left ventricular contractile dysfunction after extreme psychological stress (thus also called broken heart syndrome); affected myocardium may be stunned or show contraction band necrosis. For unclear reasons, the left ventricular apex is most often affected, leading to "apical ballooning" that resembles a *takotsubo,* Japanese for "fishing pot for trapping octopus" (hence, the name). The mechanism of catecholamine cardiotoxicity is uncertain but likely relates either to direct myocyte toxicity due to calcium overload or to focal vasoconstriction in the coronary arterial macro- or microcirculation in the face of an increased heart rate.

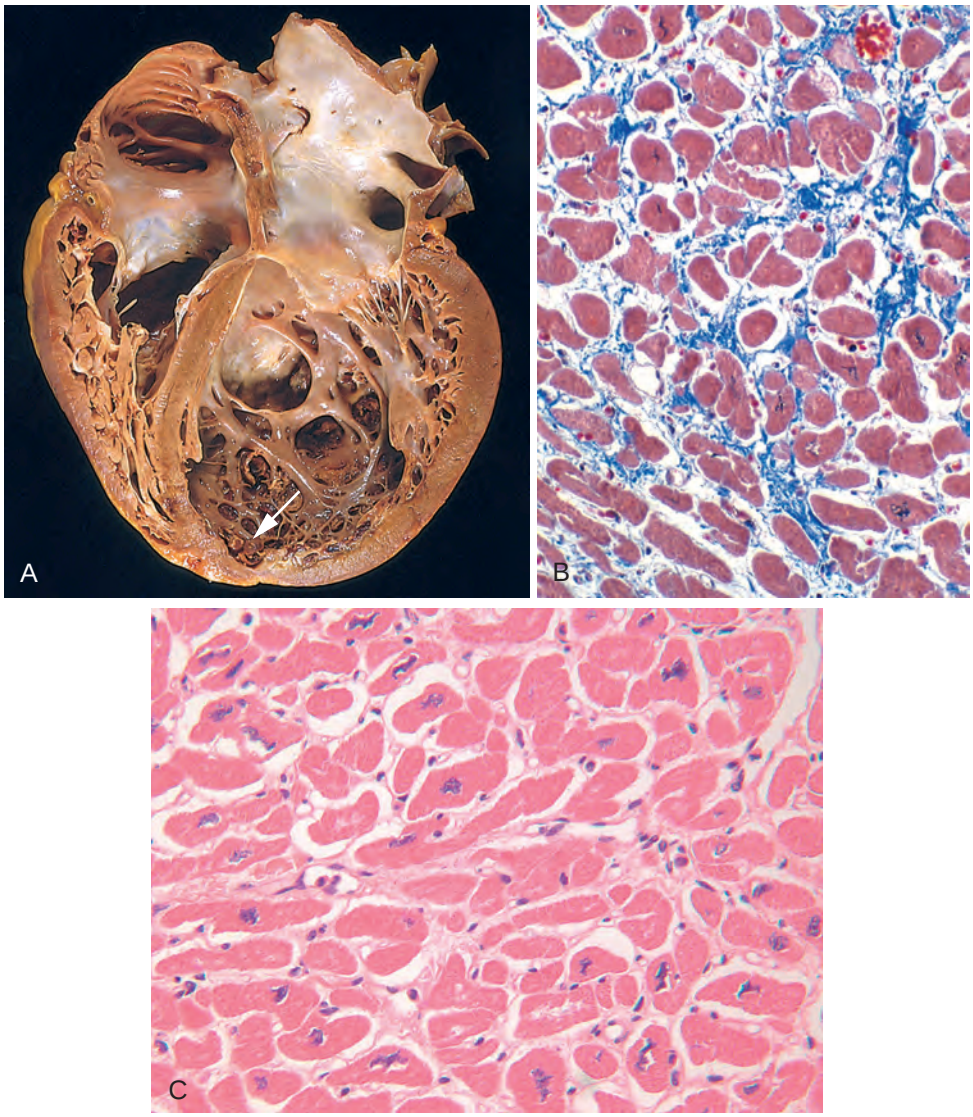

Figure 12.31 Dilated cardiomyopathy. (A) Four-chamber dilatation and hypertrophy are evident. There is a mural thrombus *(arrow)* at the apex of the left ventricle (seen on the right in this apical four-chamber view). The coronary arteries were patent. (B) Histologic section demonstrating variable myocyte hypertrophy and interstitial fibrosis (collagen is highlighted as blue in this Masson trichrome stain). (C) Histologic appearance of the enlarged, bizarre, hyperchromatic nuclei (likened to "Ninja stars") that are seen in greater numbers in patients with dilated cardiomyopathy caused by titin-truncating mutations.

MORPHOLOGY

In the DCM phenotype, the heart is typically enlarged, heavy (often weighing two to three times normal), and flabby, due to dilation of all chambers (Fig. 12.31). Mural thrombi can result from relative stasis of the blood in poorly contractile chambers and may be a source of thromboemboli. To be considered DCM, the heart should have no primary valvular alterations; if mitral (or tricuspid) regurgitation is present, it results from left (or right) ventricular chamber dilation (functional regurgitation). Either the coronary arteries are free from significant narrowing or the obstructions present are insufficient to explain the degree of cardiac dysfunction.

The histologic abnormalities in DCM are nonspecific and usually do not point to a specific etiology (see Fig. 12.31B). Moreover, the severity of morphologic changes may not reflect either the degree of dysfunction or the patient's prognosis.

Interstitial and endocardial fibrosis of variable degree is present, and small subendocardial scars may replace individual cells or groups of cells, probably reflecting healing of previous ischemic necrosis of myocytes caused by hypertrophy-induced imbalance between perfusion and demand. Most muscle cells are hypertrophied with enlarged nuclei, but some are attenuated, stretched, and irregular. In DCM caused by truncating mutations in the titin gene, myocytes may exhibit hyperchromatic, highly distorted "Ninja star"-like nuclei (see Fig. 12.31C); although these can be a nonspecific finding, identifying them in greater than or equal to 5% of myocytes is highly suggestive of a titin-truncation mutation.

Clinical Features

The fundamental defect in DCM is ineffective contraction. Thus, in end-stage DCM, the cardiac ejection fraction typically is less than 25% (normal is 50% to 65%). DCM can

occur at any age, including in childhood, but it most commonly affects individuals between 20 and 50 years of age. It presents with slowly progressive signs and symptoms of CHF including dyspnea, easy fatigability, and poor exertional capacity. Secondary mitral regurgitation and abnormal cardiac rhythms are common, and embolism from intracardiac thrombi can occur. Death usually results from progressive cardiac failure or arrhythmia, and it can occur suddenly. Although the annual mortality is high (10% to 50%), some severely affected patients respond well to pharmacologic or electrical resynchronization (biventricular pacing) therapies. Cardiac transplantation is also increasingly performed, and long-term ventricular assist can be beneficial. Interestingly, in some patients, relatively short-term mechanical cardiac support can induce durable improvement of cardiac function.

Arrhythmogenic Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy is an autosomal dominant disorder that classically manifests with right-sided heart failure and rhythm disturbances, which can cause sudden cardiac death. Left-sided involvement with left-sided heart failure can also occur. Classically, the right ventricular wall is severely attenuated due to loss of myocytes, accompanied by massive fatty infiltration and focal fibrosis (Fig. 12.32). Although mononuclear inflammation may be present around degenerating cardiomyocytes, arrhythmogenic cardiomyopathy is not considered an inflammatory cardiomyopathy. Classical arrhythmogenic cardiomyopathy has an autosomal dominant inheritance with a variable penetrance; many of the causal mutations involve genes encoding desmosomal junctional proteins at the intercalated disk (e.g., plakoglobin) as well as proteins that interact with the desmosome (e.g., the intermediate filament desmin). Naxos syndrome is a disorder characterized by arrhythmogenic cardiomyopathy and hyperkeratosis of plantar and palmar skin surfaces, and is also associated with plakoglobin mutations.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a common (1 in 500 prevalence), clinically heterogeneous, genetic disorder characterized by myocardial hypertrophy, poorly compliant left ventricular myocardium leading to abnormal diastolic filling, and (in about one-third of cases) intermittent ventricular outflow obstruction. It is the leading cause of left ventricular hypertrophy unexplained by other clinical or pathologic causes. The heart is thick-walled, heavy, and hypercontracting, in striking contrast to the flabby, hypocontracting heart of DCM. HCM causes primarily diastolic dysfunction; systolic function is usually preserved. The two most common diseases that must be distinguished clinically from HCM are deposition diseases (e.g., amyloidosis, Fabry disease) and hypertensive heart disease coupled with age-related subaortic septal hypertrophy (see earlier discussion under Hypertensive Heart Disease in this chapter). Occasionally, valvular or congenital subvalvular aortic stenosis can also mimic HCM.

Pathogenesis

In most cases, the pattern of transmission is autosomal dominant with variable penetrance. **HCM is most commonly caused by mutations in any one of several genes that encode sarcomeric proteins;** there are more than 400 different known mutations in nine different genes, most being missense mutations. Mutations causing HCM are found most commonly in the genes encoding myosin-binding protein C *(MYBP-C)* or β-myosin heavy chain *(β-MHC/MYH7),* followed by the genes coding for cardiac TnI, TnT, and α-tropomyosin; overall, these account for 70% to 80% of all cases. Different affected families can have distinct mutations involving the same protein; thus, over 50 different *β-MHC* mutations can cause HCM. The prognosis of HCM varies widely and correlates strongly with specific mutations.

As mentioned earlier, HCM is a disease caused by mutations in proteins of the sarcomere. Although the precise mechanism by which these mutations cause HCM is unclear,

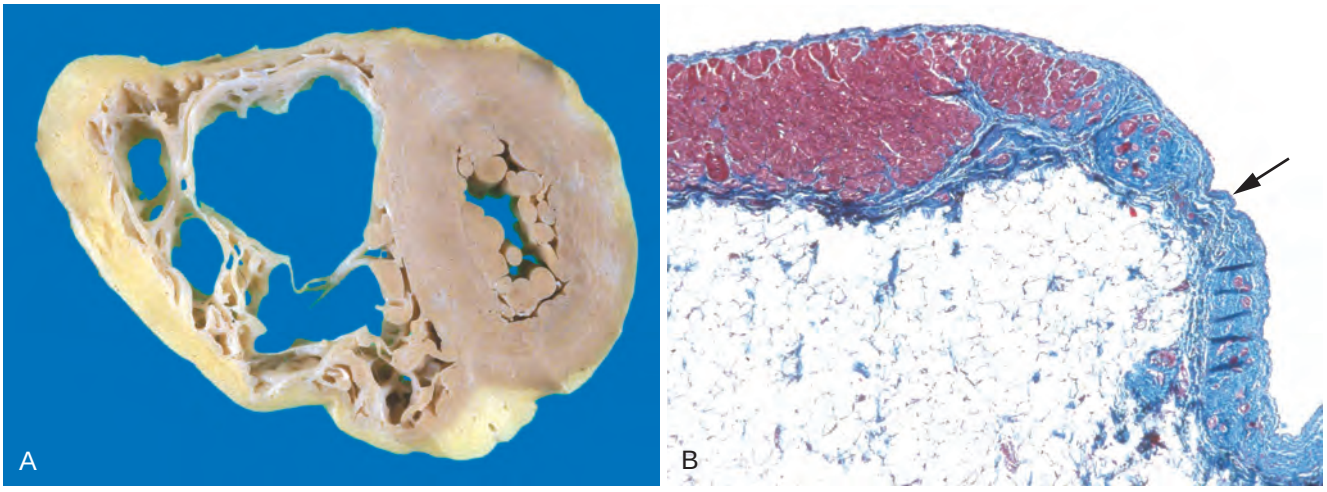

Figure 12.32 Arrhythmogenic cardiomyopathy. (A) Gross photograph, showing dilation of the right ventricle and near-transmural replacement of the right ventricular free-wall by fat and fibrosis. The left ventricle has a virtually normal configuration in this case, but can also be involved by the disease process. (B) Histologic section of the right ventricular free wall, demonstrating replacement of myocardium *(red)* by fibrosis *(blue, arrow)* and fat (Masson trichrome stain).

current evidence suggests that it arises from defective energy transfer from its source of generation (mitochondria) to its site of use (sarcomeres). In contrast, DCM is mostly associated with abnormalities of cytoskeletal proteins (see Fig. 12.30) and can be conceptualized as a disease of abnormal force generation, force transmission, or myocyte signaling. To complicate matters, mutations in certain genes (highlighted in Fig. 12.30) can give rise to either HCM or DCM, depending on the site and nature of the mutation. Genetic testing in cardiomyopathies is still hindered by the large number of genetic "variants of unknown significance," so genetic screening of family members of affected probands must be interpreted within the clinical context.

MORPHOLOGY

The essential feature of HCM is **massive myocardial hypertrophy, usually without ventricular dilation** (Fig. 12.33). The classic pattern involves disproportionate thickening of the ventricular septum relative to the left ventricle free wall, termed **asymmetric septal hypertrophy.** In about 10% of cases, the hypertrophy is concentric and symmetrical. On longitudinal sectioning, the normally round-to-ovoid left ventricular cavity may be compressed into a "banana-like" configuration by bulging of the ventricular septum into the lumen (see Fig. 12.33A). Although marked hypertrophy can involve the entire septum, it is usually most prominent in the subaortic region; the left ventricular outflow tract often exhibits a fibrous endocardial plaque and thickening of the anterior mitral leaflet. Both findings result from contact of the anterior mitral leaflet with the septum during ventricular systole; they correlate with the echocardiographic "systolic anterior motion" of the anterior leaflet, with functional left ventricular outflow tract obstruction during systole.

The most important histologic features of HCM myocardium are (1) massive myocyte hypertrophy, with transverse myocyte diameters frequently greater than 40 μm (normal is approximately 15 μm); (2) haphazard disarray of bundles of myocytes, individual myocytes, and contractile elements in sarcomeres within cells (termed ***myofiber disarray***); (3) fibrotic narrowing of small intramural arteries; and (4) interstitial and replacement fibrosis (see Fig. 12.33B).

Clinical Features

HCM is characterized by reduced stroke volume due to impaired diastolic filling—a consequence of a reduced chamber size, as well as the reduced compliance of the massively hypertrophied left ventricle. In addition, approximately 25% of patients with HCM have dynamic obstruction to the left ventricular outflow as the anterior mitral leaflet moves toward the ventricular septum during systole. The compromised cardiac output in conjunction with a secondary increase in pulmonary venous pressure explains the exertional dyspnea seen in these patients. Auscultation discloses a harsh systolic ejection murmur caused by the ventricular outflow obstruction. Because of the massive hypertrophy, high left ventricular chamber pressure, and frequently thick-walled intramural arteries, focal myocardial ischemia commonly results, even in the absence of concomitant epicardial CAD. Major clinical problems in HCM are atrial fibrillation, mural thrombus formation leading to embolization and possible stroke, intractable cardiac failure, ventricular arrhythmias, and, not infrequently, sudden death, especially with certain mutations. Indeed, HCM is one of the most common causes of sudden, otherwise unexplained death in young athletes.

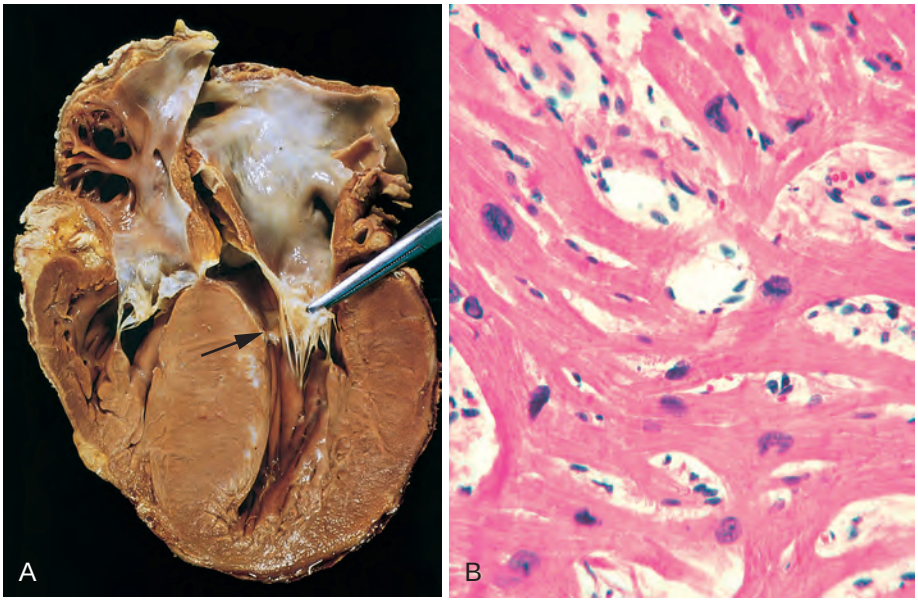

Figure 12.33 Hypertrophic cardiomyopathy with asymmetric septal hypertrophy. (A) The septal muscle bulges into the left ventricular outflow tract, and the left atrium is enlarged. The anterior mitral leaflet has been reflected away from the septum to reveal a fibrous endocardial plaque *(arrow)* (see text). (B) Histologic appearance demonstrating myocyte disarray, extreme hypertrophy, and exaggerated myocyte branching, as well as the characteristic interstitial fibrosis.

The natural history of HCM is highly variable. Most patients can be helped by pharmacologic intervention (e.g., β-adrenergic blockade) to decrease heart rate and contractility. Implantable cardioverter defibrillators are warranted for HCM patients at risk for ventricular arrhythmias. Some benefit can also be gained by reducing the septal myocardial mass, thus relieving the outflow tract obstruction. This can be achieved either by surgical excision of muscle or by carefully controlled septal infarction through a catheter-based infusion of alcohol.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy is characterized by a primary decrease in ventricular compliance, resulting in impaired ventricular diastolic filling. Because the contractile (systolic) function of the left ventricle is usually unaffected, the functional abnormality can be confused with that of constrictive pericarditis or HCM. Restrictive cardiomyopathy can be idiopathic or associated with distinct disorders that affect the myocardium, principally amyloidosis (described later), sarcoidosis, radiation-induced fibrosis, metastatic tumors, or the accumulation of metabolites from inborn errors of metabolism.

The gross morphologic features are somewhat nonspecific; although bi-atrial dilation is commonly observed due to restricted ventricular filling and pressure overloads, the ventricles are of approximately normal size (or slightly enlarged), the cavities are not dilated, and the myocardium is largely unremarkable. Microscopically, there can be patchy or diffuse interstitial fibrosis, varying from minimal to extensive. Cardiac imaging is increasingly used to characterize myocardial "infiltrates," and endomyocardial biopsy can occasionally suggest a specific etiology.

Three other restrictive conditions merit brief mention.

- *Endomyocardial fibrosis* is principally a disease of children and young adults in Africa and other tropical areas, characterized by fibrosis of the ventricular endocardium and subendocardium that extends from the apex upward, often eventually involving the tricuspid and mitral valves. The fibrous tissue markedly diminishes the volume and compliance of affected chambers and so causes a restrictive functional defect. Ventricular mural thrombi sometimes develop, and indeed much of the endocardial fibrosis may result from thrombus organization. Endomyocardial fibrosis is linked to nutritional deficiencies and/or inflammation related to parasitic infections (e.g., hypereosinophilia); worldwide, it is the most common form of restrictive cardiomyopathy.
- *Loeffler endomyocarditis* also results in endomyocardial fibrosis, typically with large mural thrombi, and an overall morphology similar to the tropical disease. However, in addition to the cardiac changes, there is often a peripheral eosinophilia and eosinophilic infiltrates in multiple organs, including the heart. The release of toxic products of eosinophils, especially major basic protein, probably causes endomyocardial necrosis, followed by scarring of the necrotic area, layering of the endocardium by thrombus, and finally organization of the thrombus. Many patients with Loeffler endomyocarditis have a myeloproliferative disorder associated with chromosomal rearrangements involving either the platelet-derived growth factor receptor *(PDGFR)-α* or *-β* genes (Chapter 13). These rearrangements produce fusion genes that encode constitutively active PDGFR tyrosine kinases. Treatment of such patients with tyrosine kinase inhibitors has resulted in hematologic remissions and resolution of the endomyocardial lesions.
- *Endocardial fibroelastosis* is an uncommon heart disease characterized by fibroelastic thickening that typically involves the left ventricular endocardium. It is most common in the first 2 years of life; in one-third of cases, it is accompanied by aortic valve obstruction or other congenital cardiac anomalies. Endocardial fibroelastosis may actually represent a common morphologic end-point of several different insults including viral infections (e.g., intrauterine exposure to mumps) or mutations in the gene for tafazzin, which affects mitochondrial inner membrane integrity. Diffuse involvement may be responsible for rapid and progressive cardiac decompensation and death.

Amyloidosis

Amyloidosis is an important form of restrictive cardiomyopathy resulting from the extracellular accumulation of protein fibrils that form insoluble β-pleated sheets (Chapter 6). Cardiac amyloidosis can appear as a consequence of systemic amyloidosis (e.g., due to myeloma or inflammation-associated amyloid) or can be restricted to the heart, particularly in the aged (senile cardiac amyloidosis). Cardiac amyloidosis characteristically occurs in individuals 70 years of age and older, and it has a far better prognosis than systemic amyloidosis; the amyloid deposits are largely composed of transthyretin, a normal serum protein synthesized in the liver that transports thyroxine and retinol-binding protein. Mutant forms of transthyretin can accelerate the cardiac amyloid deposition; 4% of African Americans have a transthyretin mutation substituting isoleucine for valine at position 122 that produces a particularly amyloidogenic protein that is responsible for autosomal dominant familial transthyretin amyloidosis.

Cardiac amyloidosis most frequently produces a restrictive cardiomyopathy, but it can also be asymptomatic, manifest as dilation or arrhythmias, or mimic ischemic or valvular disease. The varied presentations depend on the predominant location of the deposits, for example, interstitium, conduction system, coronary vasculature, or valves.

MORPHOLOGY

In cardiac amyloidosis, the heart varies in consistency from normal to firm and rubbery. The chambers are usually of normal size but can be dilated and have thickened walls. Small, semitranslucent nodules resembling drips of wax may be seen on the atrial endocardial surface, particularly on the left. Histologically, hyaline eosinophilic deposits of amyloid may be found in the interstitium, conduction tissue, valves, endocardium, pericardium, and small intramural coronary arteries (Fig. 12.34). Amyloid accumulations can be distinguished from other deposits by special stains such as Congo red or sulfated Alcian blue; the former produces classic apple-green birefringence when viewed under polarized light (see Fig. 12.34B). Intramural arteries and arterioles may have sufficient amyloid in their walls to compress and occlude their lumens, inducing myocardial ischemia ("small-vessel disease").

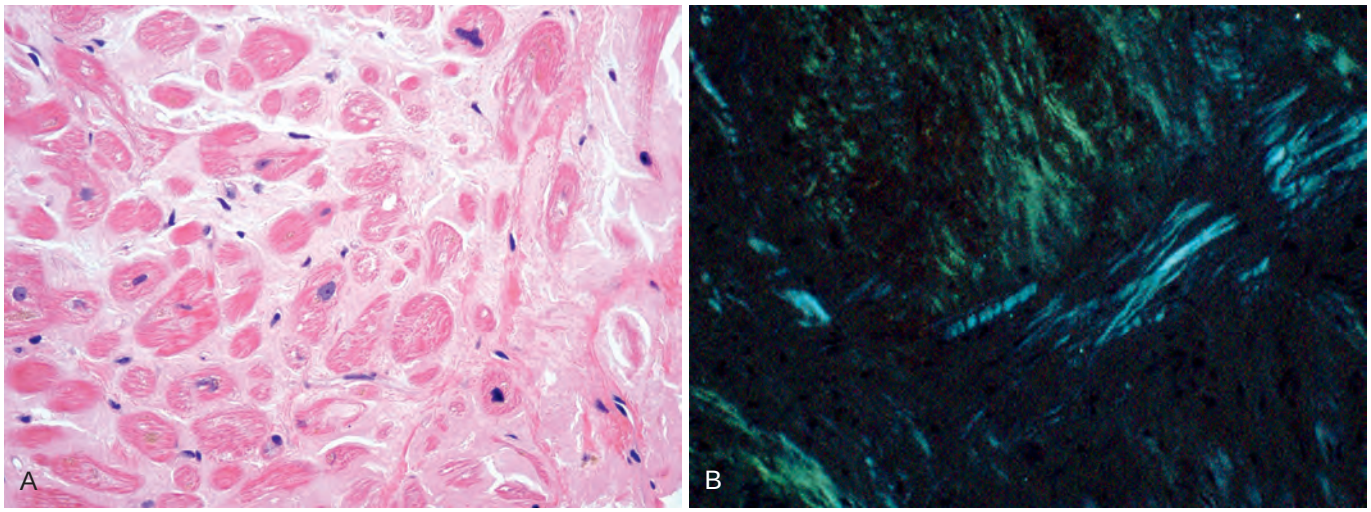

Figure 12.34 Cardiac amyloidosis. (A) Hematoxylin and eosin stain, showing amyloid appearing as amorphous pink material around myocytes. (B) Congo red stain viewed under polarized light, in which amyloid shows characteristic apple-green birefringence (compared with collagen, pale blue).

Myocarditis

Myocarditis is a diverse group of pathologic entities in which infectious microorganisms and/or a primary inflammatory process cause myocardial injury. Myocarditis should be distinguished from conditions such as IHD, in which myocardial inflammation is secondary to other causes.

Pathogenesis

In the United States, viral infections are the most common cause of myocarditis. Coxsackie viruses A and B and other enteroviruses probably account for most of the cases. Other less common etiologic agents include cytomegalovirus, HIV, and influenza (Table 12.13). In some (but not all) cases, the offending agent can be implicated by serologic studies or by identifying viral nucleic acid sequences in myocardial biopsies. Depending on the pathogen and the host, viruses can potentially cause myocardial injury either as a direct cytopathic effect, or by eliciting a destructive immune response. Inflammatory cytokines produced in response to myocardial injury can also cause myocardial dysfunction that is out of proportion to the degree of actual myocyte damage.

Nonviral agents are also important causes of infectious myocarditis, particularly the protozoan *Trypanosoma cruzi,* the agent of Chagas disease. Chagas disease is endemic in some regions of South America, with myocardial involvement in most infected individuals. About 10% of patients die during an acute attack; others develop a chronic immune-mediated myocarditis that may progress to cardiac insufficiency in 10 to 20 years. Trichinosis *(Trichinella spiralis)* is the most common helminthic disease associated with myocarditis. Parasitic diseases, including toxoplasmosis, and bacterial infections such as Lyme disease and diphtheria, can also cause myocarditis. In the case of diphtheritic myocarditis, the myocardial injury is a consequence of diphtheria toxin release by *Corynebacterium diphtheriae* (Chapter 8). Myocarditis occurs in approximately 5% of patients with Lyme disease, a systemic illness caused by the bacterial spirochete *Borrelia burgdorferi* (Chapter 8); it manifests primarily as a self-limited conduction system disorder that may require a temporary pacemaker. AIDS-associated myocarditis may reflect inflammation and myocyte damage without a clear etiologic agent, or a myocarditis attributable directly to HIV or to an opportunistic pathogen.

There are also noninfectious causes of myocarditis. Broadly speaking they are either immunologically mediated (hypersensitivity myocarditis) or idiopathic conditions with distinctive morphology (giant cell myocarditis) suspected to be of immunologic origin (see Table 12.13). More recently, immune checkpoint inhibitiors administered for treatment of cancer have occasionally led to an (often fatal) lymphocytic myocarditis.

Table 12.13 Major Causes of Myocarditis

Infections
Viruses (e.g., coxsackievirus, echovirus, influenza, HIV, cytomegalovirus)

HIV, Human immunodeficiency virus.

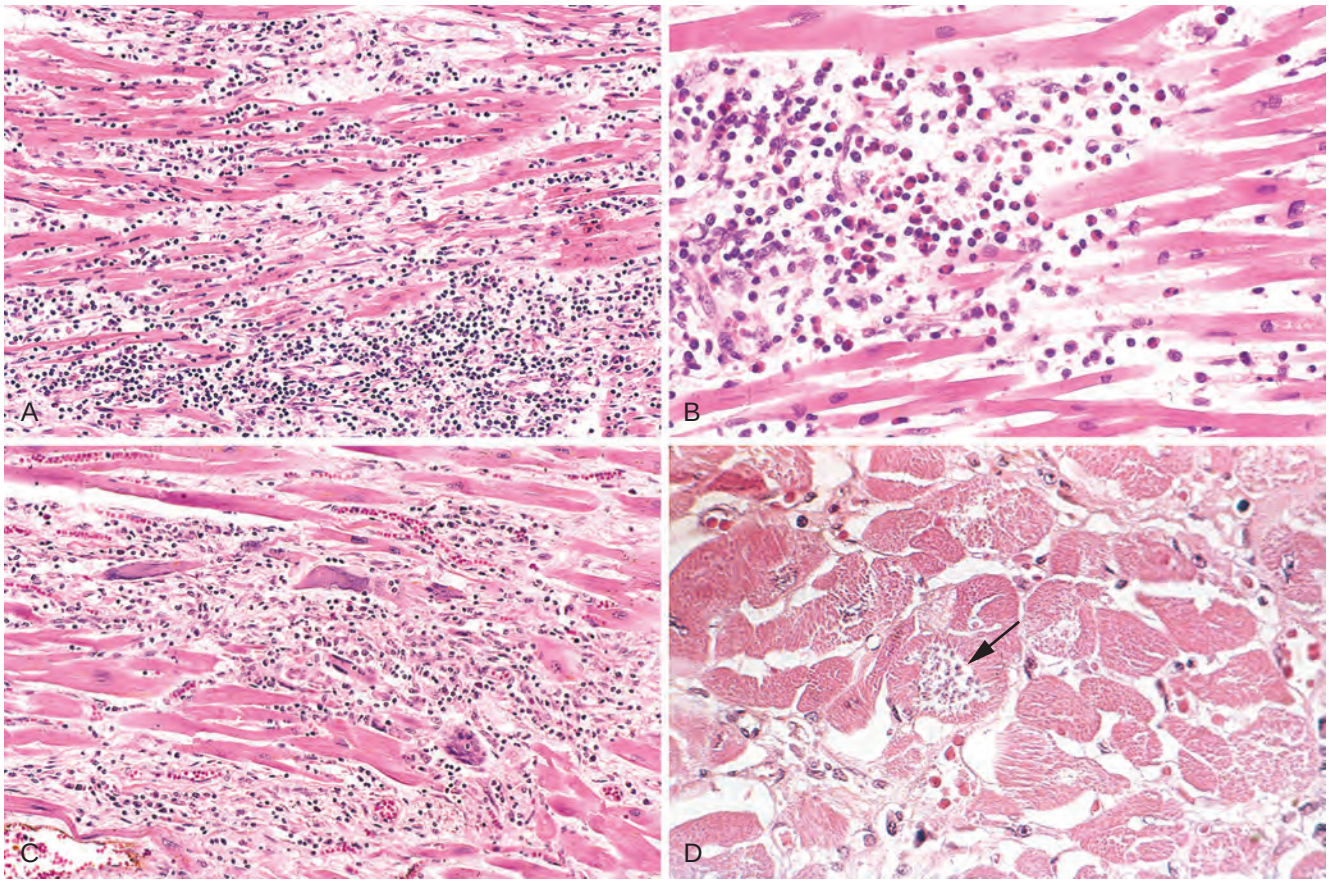

Figure 12.35 Myocarditis. (A) Lymphocytic myocarditis, associated with myocyte injury. (B) Hypersensitivity myocarditis, characterized by interstitial inflammatory infiltrate composed largely of eosinophils and mononuclear inflammatory cells, predominantly localized to perivascular and expanded interstitial spaces. (C) Giant-cell myocarditis, with mononuclear inflammatory infiltrate containing lymphocytes and macrophages, extensive loss of muscle, and multinucleated giant cells (fused macrophages). (D) The myocarditis of Chagas disease. A myofiber distended with trypanosomes *(arrow)* is present along with individual myofiber necrosis, and modest amounts of inflammation.

MORPHOLOGY

Grossly, the heart in myocarditis may appear normal or dilated; some hypertrophy may be present depending on disease duration. In advanced stages, the ventricular myocardium is flabby and often mottled by either pale foci or minute hemorrhagic lesions. Mural thrombi may be present.

Active myocarditis is characterized by an interstitial inflammatory infiltrate associated with degenerating or apoptotic myocytes (Fig. 12.35); larger zones of myocyte drop-out or necrosis with interstitial edema may reflect vascular injury with secondary ischemic damage. A diffuse, mononuclear, predominantly lymphocytic infiltrate is most common (see Fig. 12.35A). Although endomyocardial biopsies can be diagnostic, they can be spuriously negative because inflammation of the myocardium is patchy. If the patient survives the acute phase of myocarditis, the inflammatory lesions either resolve, leaving no residual changes, or heal by progressive fibrosis.

Hypersensitivity myocarditis is characterized by perivascular infiltrates composed of lymphocytes, macrophages, and a high proportion of eosinophils (see Fig. 12.35B). A morphologically distinctive form of myocarditis, called **giant-cell myocarditis,** is characterized by a widespread inflammatory cellular infiltrate containing multinucleate giant cells (fused macrophages) interspersed with lymphocytes, eosinophils, plasma cells, and macrophages. Focal to frequently extensive myocyte damage is present (see Fig. 12.35C). This variant likely represents the fulminant end of the myocarditis spectrum and carries a poor prognosis.

The myocarditis of **Chagas disease** is distinctive by virtue of the parasitization of scattered myofibers by trypanosomes accompanied by a mixed inflammatory infiltrate of neutrophils, lymphocytes, macrophages, and occasional eosinophils (see Fig. 12.35D).

Clinical Features

The clinical spectrum of myocarditis is broad. At one end, the disease is entirely asymptomatic, and patients can expect a complete recovery without sequelae; at the other extreme is the precipitous onset of heart failure or arrhythmias, occasionally followed by sudden death. Between these extremes are various levels of symptomatology, including fatigue, dyspnea, palpitations, precordial discomfort, and fever. The clinical features of myocarditis can mimic those of acute MI. As noted previously, patients can develop DCM as a late complication of myocarditis.

Other Causes of Myocardial Disease

Cardiotoxic Drugs

Cardiac complications of cytotoxic cancer therapies are an important clinical problem. Cardiotoxicity may be associated with many different conventional chemotherapeutic agents, as well as tyrosine kinase inhibitors. The anthracyclines doxorubicin and daunorubicin are the chemotherapeutic agents most often associated with toxic myocardial injury; they cause DCM with heart failure by direct damage to cardiomyocytes. Anthracycline toxicity is dose-dependent, with the cardiotoxicity risk increasing when cumulative lifetime doses exceed 250 mg/m^2.

Many other therapeutic agents, including lithium, phenothiazines, and chloroquine can idiosyncratically induce myocardial injury and sometimes sudden death. Common findings in affected myocardium include myofiber swelling, cytoplasmic vacuolization, and fatty change. Discontinuing the offending agent often leads to prompt resolution, without apparent sequelae. Occasionally, however, more extensive damage produces myocyte death that can evolve to a DCM.

Radiation

Radiation therapy to the thorax can cause free radical damage that in turn can lead to fibrosis of any of the cardiac structures; manifestations include accelerated atherosclerosis, valvular stenosis, pericardial constriction, and/or a restrictive cardiomyopathy due to interstitial fibrosis.

KEY CONCEPTS

CARDIOMYOPATHY

- Cardiomyopathies are intrinsic cardiac muscle diseases that may be genetic (idiopathic) or due to well-defined causes.
- There are three general pathophysiologic categories of cardiomyopathy: dilated (90%), hypertrophic, and restrictive (least common).
- DCM results in systolic (contractile) dysfunction. Causes include myocarditis, toxic exposures (e.g., alcohol), and pregnancy. In up to 50% of cases, genetic mutations are causal, with titin truncation mutations representing up to 20% of cases of DCM.
- HCM results in diastolic (relaxation) dysfunction. Virtually all cases are due to autosomal dominant mutations in the proteins comprising the contractile apparatus.
- Restrictive cardiomyopathy results in a stiff, noncompliant myocardium and can be due to deposition (e.g., amyloid), increased interstitial fibrosis (e.g., due to radiation), or endomyocardial scarring.
- Myocarditis is myocardial damage caused by inflammatory infiltrates secondary to infections or immune reactions. Viral infections are the most common causes in the United States. Clinically, myocarditis can be asymptomatic, give rise to acute heart failure, or evolve into DCM.

PERICARDIAL DISEASE

The most important pericardial disorders involve fluid accumulation, inflammation, fibrous constriction, or some combination of these processes, often in association with other cardiac pathology or a systemic disease.

Pericardial Effusion and Hemopericardium

Normally, the pericardial sac contains less than 50 mL of thin, clear, straw-colored fluid. Under various circumstances, the parietal pericardium may be distended by serous fluid (pericardial effusion), blood (hemopericardium), or pus (purulent pericarditis). With long-standing cardiac enlargement or with slowly accumulating fluid, the pericardium has time to remodel to accommodate the larger volume. This permits a slowly accumulating pericardial effusion to become quite substantial without restricting cardiac function. Thus, with chronic effusions of less than 500 mL in volume, the only clinical significance is a characteristic globular enlargement of the heart shadow on chest radiographs. In contrast, rapidly developing fluid collections of as little as 200 to 300 mL—e.g., due to hemopericardium caused by a ruptured MI or aortic dissection—can produce clinically devastating compression of the thin-walled atria and venae cavae, or the ventricles themselves; cardiac filling is thereby compromised, producing fatal cardiac tamponade.

Pericarditis

Pericardial inflammation can occur secondary to a variety of cardiac, thoracic, or systemic disorders, metastases from remote neoplasms, or cardiac surgical procedures. The major causes of pericarditis are listed in Table 12.14. Most evoke an acute pericarditis, but a few, such as tuberculosis and fungi, produce only chronic reactions.

Acute Pericarditis

Serous pericarditis is characteristically produced by noninfectious inflammatory diseases, including rheumatic fever, SLE, and scleroderma, as well as tumors and uremia. An infection in the tissues contiguous to the pericardium—for example, a bacterial pleuritis—may incite sufficient irritation of the parietal pericardial serosa to cause a sterile serous effusion that can progress to serofibrinous pericarditis and

ultimately to a frank suppurative reaction. In some cases, a well-defined viral infection elsewhere—upper respiratory tract, lung, parotid gland—antedates the pericarditis and serves as the primary focus of infection. Infrequently, usually in young adults, a viral pericarditis occurs as an apparent primary infection that may be accompanied by myocarditis (myopericarditis). Tumors can cause a serous pericarditis by lymphatic invasion or direct contiguous extension into the pericardium. Histologically, serous pericarditis elicits a mild inflammatory infiltrate in the epipericardial fat consisting predominantly of lymphocytes; tumor-associated pericarditis may also exhibit neoplastic cells. Organization into fibrous adhesions rarely occurs.

Fibrinous and serofibrinous pericarditis are the most frequent types of pericarditis; these are composed of serous fluid variably admixed with a fibrinous exudate. Common causes include acute MI (see Fig. 12.17D), postinfarction (Dressler) syndrome (an autoimmune response appearing weeks after an MI), uremia, rheumatic fever, SLE, and trauma. A fibrinous reaction also follows routine cardiac surgery. Radiation used to treat breast, lung, or mediastinal neoplasms can cause pericarditis, pericardial effusion, and chronic pericardial disorders.

Symptoms of fibrinous pericarditis characteristically include pain (sharp, pleuritic, and position dependent) and fever; congestive failure may also be present. A loud pericardial friction rub is the most striking clinical finding. However, the collection of serous fluid can actually prevent rubbing by separating the two layers of the pericardium.

Purulent or suppurative pericarditis reflects an active infection caused by microbial invasion of the pericardial space; this can occur through the following:

- *Direct extension* from neighboring infections, such as an empyema of the pleural cavity, lobar pneumonia, mediastinal infections, or extension of a ring abscess through the myocardium or aortic root
- *Seeding from the blood*
- *Lymphatic extension*
- *Direct introduction* during cardiotomy

The exudate ranges from a thin cloudy fluid to frank pus up to 500 mL in volume, and tuberculous pericarditis can exhibit foci of caseation. The serosal surfaces are reddened, granular, and coated with the exudate (Fig. 12.36). Microscopically there is an acute inflammatory reaction, which sometimes extends into surrounding structures (mediastinopericarditis). Complete resolution is infrequent, and organization by scarring is the usual outcome. The intense inflammatory response and the subsequent scarring frequently produce constrictive pericarditis (see later). Clinical findings in the active phase resemble those seen in fibrinous pericarditis, although the frank infection leads to more marked systemic symptoms including spiking fevers and rigors.

Hemorrhagic pericarditis has an exudate composed of blood mixed with a fibrinous or suppurative effusion. It is most commonly caused by the spread of a malignant neoplasm to the pericardial space; cytologic examination of fluid removed through a pericardial tap often reveals neoplastic cells. Hemorrhagic pericarditis can also be found in bacterial infections, in persons with an underlying bleeding diathesis, and in tuberculosis. Hemorrhagic pericarditis often follows cardiac surgery and is occasionally responsible for significant blood loss or even tamponade, requiring reoperation. The clinical significance is similar to that of fibrinous or suppurative pericarditis.

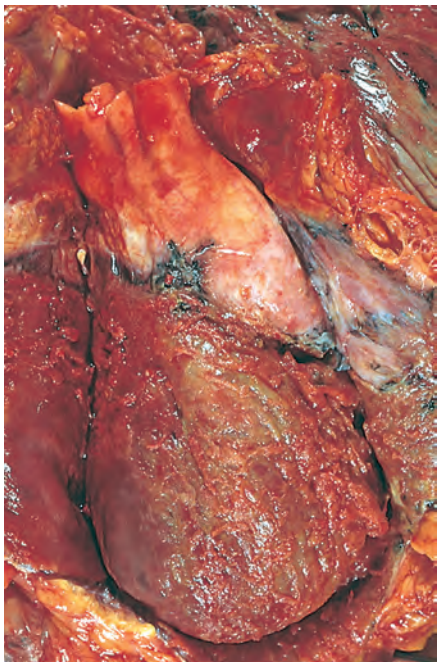

Figure 12.36 Acute suppurative pericarditis arising from direct extension of an adjacent pneumonia. Extensive purulent exudate is evident.

Chronic or Healed Pericarditis

Organization of pericardial inflammation may produce unobtrusive plaquelike fibrous thickenings of the serosal membranes ("soldiers' plaque") or thin, delicate adhesions that rarely cause impairment of cardiac function. In other cases, fibrosis in the form of meshlike stringy adhesions can largely obliterate the virtual space in the pericardial sac (adhesive pericarditis); in most instances, this has no effect on cardiac function. Two forms are worthy of some discussion.

- *Adhesive mediastinopericarditis* may follow infectious pericarditis, previous cardiac surgery, or mediastinal irradiation. The pericardial sac is obliterated, and adherence of the external aspect of the parietal layer to surrounding structures strains cardiac function. With each systolic contraction, the heart pulls not only against the parietal pericardium but also against the attached surrounding structures. Systolic retraction of the rib cage and diaphragm and pulsus paradoxus may be observed. The increased workload occasionally causes significant cardiac hypertrophy and dilation.
- In *constrictive pericarditis,* the heart is encased in a dense, fibrous, or fibrocalcific scar that limits diastolic expansion and cardiac output, features that mimic a restrictive cardiomyopathy. A prior history of pericarditis may or may not be present. The fibrous scar can be up to 1 centimeter in thickness, obliterating the pericardial space and sometimes calcifying; in extreme cases, it can resemble a plaster mold (concretio cordis). Because of the dense enclosing scar, cardiac hypertrophy and dilation

cannot occur. Cardiac output may be reduced at rest, but more importantly the heart has little if any capacity to increase its output in response to increased systemic demands. Signs of constrictive pericarditis include distant or muffled heart sounds, elevated jugular venous pressure, and peripheral edema. Treatment consists of surgical resection of the shell of constricting fibrous tissue (pericardiectomy).

TUMORS OF THE HEART

Primary Cardiac Tumors

Primary cardiac tumors are uncommon; moreover, most are (fortunately) benign. The five most common tumors have no malignant potential and account for almost 90% of all primary heart tumors. In descending order of frequency (combined pediatric and adult populations), these are myxomas, fibromas, lipomas, papillary fibroelastomas, and rhabdomyomas.

Primary malignant tumors of the heart are exceedingly rare, and usually are either an angiosarcoma or a sarcoma with poor differentiation and *MDM2* oncogene amplification. These and other sarcomas of the heart are not clinically or morphologically distinctive from sarcomas arising in other locations.

Fibromas and lipomas resemble their counterparts elsewhere; only the myxomas, papillary fibroelastomas, and rhabdomyomas merit further mention here.

Myxomas are the most common primary tumor of the adult heart (Fig. 12.37). These are benign neoplasms arising from primitive multipotent mesenchymal cells. Although sporadic myxomas do not show consistent genetic alterations, familial syndromes associated with myxomas have activating mutations in the *GNAS1* gene, encoding a subunit of G protein (Gsα) (in association with McCune-Albright syndrome) or null mutations in *PRKAR1A,* encoding a regulatory subunit of a cyclic-AMP–dependent protein kinase (Carney complex). About 90% of myxomas arise in the atria, with a left-to-right ratio of approximately 4:1.

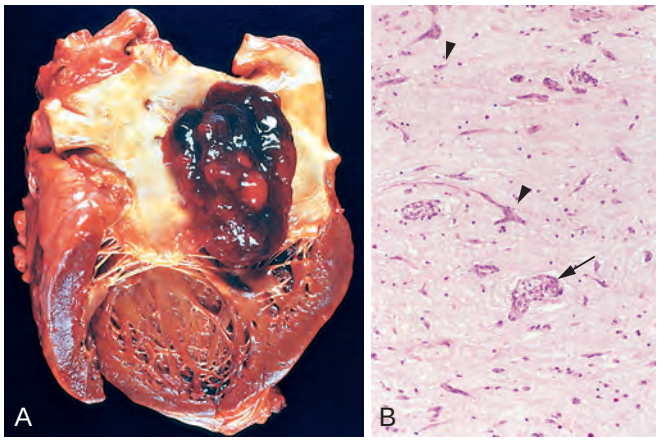

Figure 12.37 Atrial myxoma. (A) A large sessile lesion arises from the region of the fossa ovalis and extends into the mitral valve orifice. (B) Abundant amorphous extracellular matrix contains scattered multinucleate myxoma cells *(arrowheads)* in various groupings, including abnormal vessel-like formations *(arrow)*.

MORPHOLOGY

The tumors are usually single, but can rarely be multiple. The region of the fossa ovalis in the atrial septum is the favored site of origin. Myxomas range from small (<1 cm) to large (≥10 cm) and can be sessile or pedunculated lesions (see Fig. 12.37A). They vary from globular hard masses mottled with hemorrhage to soft, translucent, papillary, or villous lesions having a gelatinous appearance. The pedunculated form is often sufficiently mobile to move during systole into the atrioventricular valve opening, causing intermittent obstruction that may be position-dependent.

Histologically, myxomas are composed of stellate or globular myxoma cells embedded within an abundant acid mucopolysaccharide ground substance (see Fig. 12.37B). Peculiar vessel-like or glandlike structures are characteristic. Hemorrhage and mononuclear inflammation are usually present.

The major clinical manifestations are due to valvular "ball-valve" obstruction, embolization, or a syndrome of constitutional symptoms, such as fever and malaise. Sometimes fragmentation and systemic embolization calls attention to these lesions. Constitutional symptoms are probably due to the elaboration by some myxomas of the cytokine interleukin-6, a major mediator of the acute-phase response. Echocardiography provides the opportunity to identify these masses noninvasively. Surgical removal is usually curative; rarely, presumably with incomplete excision, the neoplasm can recur months to years later.

Papillary fibroelastomas are curious, sea-anemone–shaped endocardial tumors; they are usually incidental but can embolize and thereby become clinically important. Clonal cytogenetic abnormalities have been reported, suggesting that fibroelastomas are benign neoplasms. They resemble the much smaller, usually trivial, Lambl excrescences that project from sites of valve apposition.

MORPHOLOGY

Papillary fibroelastomas are usually (>80%) located on valves, particularly the ventricular surfaces of semilunar valves and the atrial surfaces of atrioventricular valves. Each lesion, typically 1 to 2 cm in diameter, consists of a distinctive cluster of hairlike projections up to 1 cm in length. Histologically, the projections are covered by a surface endothelium surrounding a core of myxoid connective tissue with abundant mucopolysaccharide matrix and elastic fibers.

Rhabdomyomas are the most frequent primary tumor of the pediatric heart; they are commonly discovered in the first years of life during an evaluation for a valve or other flow obstruction. Approximately one-half of cardiac rhabdomyomas are due to sporadic mutations; the other 50% of cases are associated with tuberous sclerosis (Chapter 28), with mutations in the tuberous sclerosis complex *TSC1* or *TSC2* tumor suppressor genes. The TSC1 and TSC2 proteins (hamartin and tuberin, respectively) function in a complex that inhibits the activity of the mammalian target of rapamycin (mTOR), a kinase that stimulates cell growth and regulates cell size. TSC1 or TSC2 expression is often absent in tuberous sclerosis–associated rhabdomyomas, providing a mechanism

for myocyte overgrowth. Because rhabdomyomas often regress spontaneously, they may be considered as hamartomas rather than true neoplasms.

MORPHOLOGY

Rhabdomyomas are gray-white myocardial masses that can be small or up to several centimeters in diameter. They are usually multiple and involve the ventricles preferentially, protruding into the lumen. Microscopically, they are composed of bizarre, markedly enlarged myocytes with large collections of glycogen. Routine histologic processing removes the glycogen and artifactually reduces the abundant cytoplasm to thin strands that stretch from the nucleus to the surface membrane, an appearance referred to as "spider" cells.

Metastatic Neoplasms

Metastatic tumors to the heart occur in roughly 5% of patients dying of cancer; the most frequent are lung and breast carcinomas, melanomas, leukemias, and lymphomas. Metastases can reach the heart and pericardium by retrograde lymphatic extension from the mediastinum (mostly carcinomas), by hematogenous seeding (many tumors), by direct contiguous extension (of intrathoracic tumors), or by venous extension (tumors of the kidney or liver). Clinical symptoms are most often associated with pericardial spread, which can cause symptomatic pericardial effusions or a mass-effect that is sufficient to restrict cardiac filling. Myocardial metastases are usually clinically silent or have nonspecific features, such as a generalized defect in ventricular contractility or compliance; occasionally they may cause arrhythmias. Bronchogenic carcinoma or malignant lymphoma can infiltrate the mediastinum extensively, causing encasement, compression, or invasion of the superior vena cava with resultant obstruction to blood coming from the head and upper extremities (superior vena cava syndrome). Renal cell carcinoma often invades the renal vein and can grow as a continuous column of tumor up the inferior vena cava lumen and into the right atrium, blocking venous return to the heart.

CARDIAC TRANSPLANTATION

Cardiac transplantation is performed for severe, intractable heart failure of diverse causes—most commonly DCM and IHD; over 3500 per year are performed worldwide. Three factors are primarily responsible for the dramatic improvement in allograft outcomes since the first transplant in 1967: (1) more effective immunosuppressive therapy (including the use of calcineurin inhibitors, mTOR inhibitors, glucocorticoids, and other agents), (2) careful selection of candidates, and (3) early histopathologic diagnosis of acute allograft rejection by endomyocardial biopsy.

Of the major complications, allograft rejection is the primary problem requiring surveillance; routine endomyocardial biopsy is the only reliable means of diagnosing acute cardiac rejection before substantial myocardial damage has occurred and at a stage that is reversible in the majority of instances.

Classic cellular rejection is characterized by interstitial lymphocytic inflammation with associated myocyte damage; the histology resembles myocarditis (Fig. 12.38A). There may also be interstitial edema due to vascular injury, and local cytokine elaboration can affect myocardial contractility without necessarily eliciting myocyte damage.

Increasingly, antibody-mediated rejection is also recognized as a mechanism of injury; donor-specific antibodies directed against major histocompatibility complex proteins lead to complement activation and the recruitment of Fc-receptor–bearing cells. These donor-specific antibodies cause allograft compromise by inducing endothelial cell injury leading to microvascular damage with thrombosis. Antibody-mediated rejection shows mild perivascular edema and scattered adherent intravascular inflammatory cells; it is often confirmed by immunohistochemical staining for complement fragment C4d, a long-lived catabolite that is released during complement cascade activation (see Fig. 12.38B and C).

Mild rejection may resolve spontaneously, and prompt recognition of more severe episodes allows successful treatment by augmenting baseline levels of immunosuppression; occasionally aggressive anti–T cell or anti–B cell immunotherapy, with or without plasmapheresis, may be necessary.

Allograft vasculopathy is the single most important long-term limitation for cardiac transplantation. It is a late, progressive, diffusely stenosing intimal proliferation in allograft blood vessels, predominantly in the coronary arteries (see Fig. 12.38D), leading to ischemic injury. Within 5 years of transplantation, 50% of patients develop significant allograft vasculopathy, and virtually all patients have lesions within 10 years. The pathogenesis of allograft vasculopathy involves immunologic responses that induce local production of growth factors which promote intimal smooth muscle cell recruitment and proliferation with ECM synthesis. Allograft vasculopathy is a particularly vexing problem because it can lead to silent MI (transplant patients have denervated hearts and do not typically experience angina), progressive CHF, or sudden cardiac death.

Other postoperative complications include infections and malignancies, particularly Epstein-Barr virus–associated B-cell lymphomas that arise in the setting of chronic T-cell immunosuppression. Despite these problems, the overall outlook is reasonably promising; the 1-year survival is 90%, and 5-year survival is greater than 70%.

CARDIAC DEVICES

Some of the most dramatic recent advances in cardiovascular medicine involve the use of mechanical devices. Thus, stents are now routinely deployed to maintain vascular patency (especially in the coronary arteries; Chapter 11), and endovascular conduit repairs are common approaches for treating abdominal aortic aneurysms. Implantable pacemakers and cardioverter defibrillators are indispensable for patients with cardiac rhythm disorders, and transcatheter aortic valve replacement (discussed earlier) has broadened the population that can benefit from valve replacement. Although impressive, these various devices are not without (somewhat predictable) risk. Mechanical failure can occur with any device, including strut fracture in stents, or lead fracture in pacing devices. Anything inserted into the cardiovascular system also has the potential to develop a thrombus that may become occlusive or embolize, and a foreign body is always a potential nidus for persistent (and difficult-to-treat)

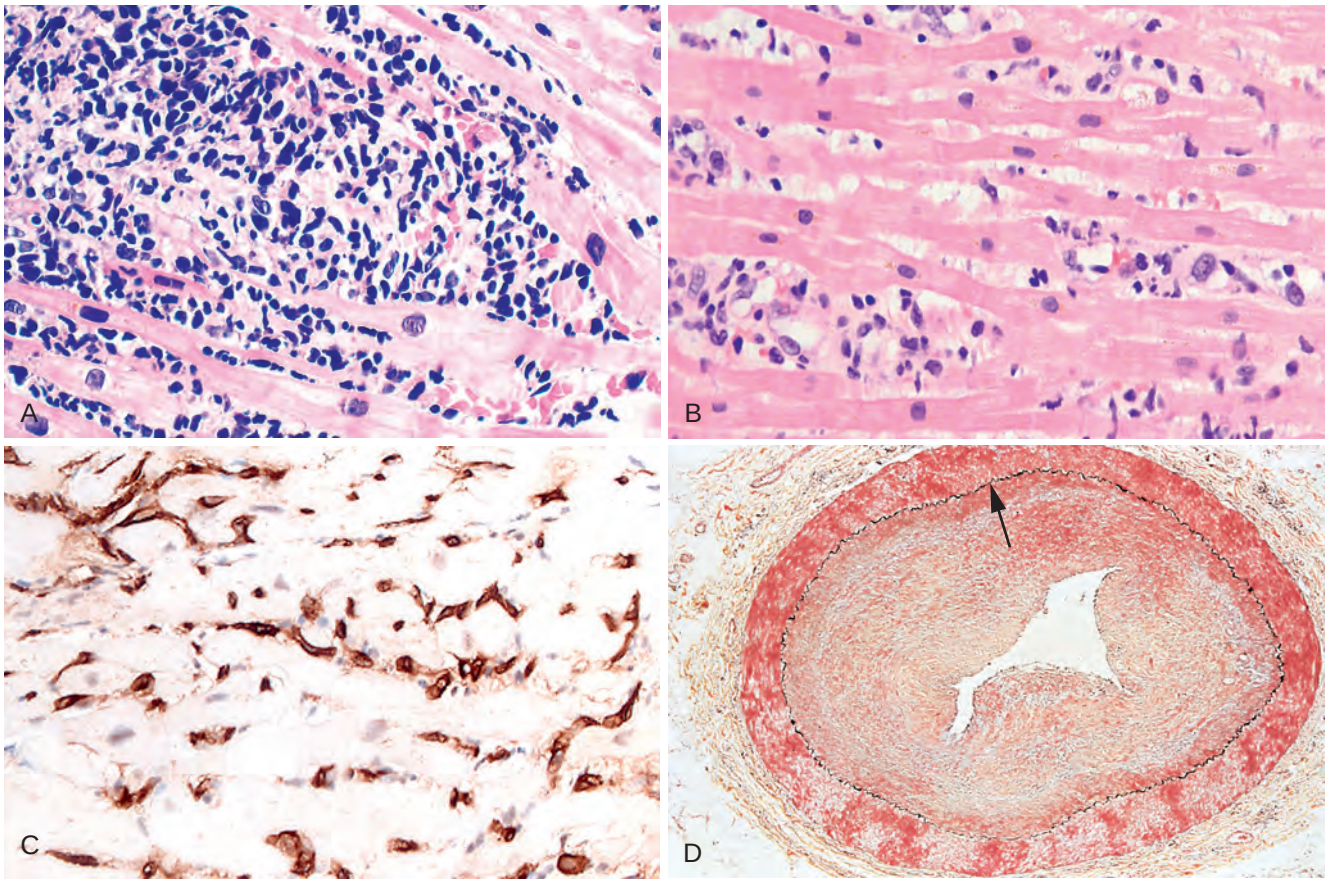

Figure 12.38 Complications of heart transplantation. (A) Cellular allograft rejection, typified by lymphocytic infiltrate associated with cardiac myocyte damage. B and C, Antibody-mediated rejection. (B) Hematoxylin and eosin–stained section shows plump, activated endothelium with adherent neutrophils and monocytes, but a sparse interstitial infiltrate; there is also perivascular edema. (C) immunohistochemistry for the complement C4d component shows sharp outlining of the capillaries *(brown stain)*, reflecting complement activation and deposition. (D) Allograft vasculopathy, with severe diffuse concentric intimal thickening producing critical stenosis. The internal elastic lamina *(arrow)* and media are intact (Movat pentachrome stain, elastin black). infection. Fortunately, the manifest benefits significantly outweigh the potential risks.

Ventricular Assist Devices

Perhaps the most impressive engineering advances have occurred in the development of VADs. These allow the support of patients with cardiac failure caused by conditions ranging from transiently stunned myocardium after surgery, to permanent MI, to progressive cardiomyopathy. Given the limited availability of hearts suitable for transplantation, VADs can provide important life-sustaining support for end-stage failure patients, allowing them to survive (and indeed to improve their overall conditioning status) until a suitable donor can be identified. Increasingly, VADs are also being implanted as "destination therapy" for patients who are not otherwise candidates for transplantation (e.g., a patient with a history of malignancy and heart failure).

CHAPTER 13

Diseases of White Blood Cells, Lymph Nodes, Spleen, and Thymus

CHAPTER CONTENTS

The components of the hematopoietic system have been traditionally divided into the *myeloid tissues,* which include the bone marrow and the cells derived from it (e.g., red cells, platelets, granulocytes, and monocytes), and the *lymphoid tissues,* consisting of the thymus, lymph nodes, and spleen. It is important to recognize, however, that this subdivision is artificial with respect to both the normal physiology of hematopoietic cells and the diseases affecting them. For example, although bone marrow contains relatively few lymphocytes, it is the source of all lymphoid progenitors and the home of long-lived plasma cells and memory lymphocytes. Similarly, neoplastic disorders of myeloid progenitor cells (myeloid leukemias) originate in the bone marrow but secondarily involve the spleen and (to a lesser degree) the lymph nodes. Some red cell disorders (e.g., immunohemolytic anemia, discussed in Chapter 14) result from the formation of autoantibodies, indicating a primary disorder of lymphocytes. Thus it is not possible to draw neat lines between diseases involving the myeloid and lymphoid tissues.

Recognizing this difficulty, we somewhat arbitrarily divide diseases of the hematopoietic tissues into two chapters. In this chapter we discuss white cell diseases and disorders affecting the spleen and thymus. In Chapter 14 we consider diseases of red cells and those affecting hemostasis. Before delving into specific diseases, we will briefly discuss the origins of hematopoietic cells, since many disorders of white cells and red cells involve disturbances of their normal development and maturation.

Normal Hematopoiesis

Blood cell progenitors first appear during the third week of embryonic development in the yolk sac. Cells derived from the yolk sac are the source of long-lived tissue macrophages such as microglial cells in the brain and Kupffer cells in the liver (Chapter 3), but the contribution of the yolk sac to blood formation, mainly in the form of embryonic red cells, is only transient. Definitive *hematopoietic stem cells* (HSCs) arise several weeks later in the mesoderm of the intraembryonic aorta/gonad/mesonephros region. During the third month of embryogenesis, HSCs migrate to the liver, which becomes the chief site of blood cell formation until shortly before birth. HSCs also take up residence in the fetal placenta; this pool of HSCs is of uncertain physiologic relevance but has substantial clinical importance, as HSCs harvested at birth from umbilical cord blood are used in therapeutic HSC transplantation. By the fourth month of development, HSCs shift in location yet again to the bone marrow. By birth, marrow throughout the skeleton is hematopoietically active, and hepatic hematopoiesis dwindles to a trickle, persisting only in scattered foci that become inactive soon after birth. After puberty, hematopoiesis ceases in distal bones and becomes restricted to the axial skeleton. Thus in normal adults, only about half of the marrow space is hematopoietically active.

The formed elements of blood—red cells, granulocytes, monocytes, platelets, and lymphocytes—have a common origin from HSCs, pluripotent cells that sit at the apex of a hierarchy of bone marrow progenitors (Fig. 13.1). Most evidence supporting this scheme comes from studies in mice, but human hematopoiesis is believed to proceed in a similar way. The development of mature blood cells from HSCs involves progressive commitment to increasingly specialized cell populations. HSCs give rise to several kinds of early progenitor cells that have more restricted differentiation potential, such that they ultimately produce mainly myeloid cells or lymphoid cells. The origins of lymphoid cells are revisited when tumors derived from these cells are discussed. These early progenitors in turn give "birth" to progenitors that are further constrained in their differentiation potential. Some of these cells are referred to as *colony-forming units* (see Fig. 13.1) because they produce colonies composed of specific kinds of mature cells when grown in culture. From the various committed progenitors are derived the morphologically recognizable precursors, such as myeloblasts, proerythroblasts, and megakaryoblasts, which are the immediate progenitors of mature granulocytes, red cells, and platelets.

HSCs have two essential properties that are required for the maintenance of hematopoiesis: pluripotency and the capacity for self-renewal. Pluripotency refers to the ability of a single HSC to generate all mature blood cells. When an HSC divides, at least one daughter cell must self-renew to avoid stem cell depletion. Self-renewing divisions occur within a specialized marrow niche, in which stromal cells and secreted factors nurture and protect the HSCs. As one might surmise from their ability to migrate during embryonic development, HSCs are not sessile. Particularly under conditions of stress, such as severe anemia or acute inflammation, HSCs are mobilized from the bone marrow and appear in the peripheral blood. In fact, HSCs used in transplantation are now mainly collected from the peripheral blood of donors treated with granulocyte colony-stimulating factor (G-CSF), one of the factors that can mobilize marrow HSCs from their stem cell niches.

The marrow response to short-term physiologic needs is regulated by hematopoietic growth factors through their effects on the committed progenitors. These growth factors are called *colony-stimulating factors (CSFs)* because they were discovered by their ability to support the growth of colonies of blood cells in vitro. Because mature blood elements are terminally differentiated cells with finite lifespans, their numbers must be constantly replenished. In current models of hematopoiesis, some divisions of HSCs give rise to cells referred to as *multipotent progenitors,* which are more proliferative than HSCs but have a lesser capacity for self-renewal (see Fig. 13.1). Division of multipotent progenitors gives rise to at least one daughter cell that leaves the stem cell pool and begins to differentiate. Once past this threshold, these newly committed cells lose the capacity for self-renewal and commence an inexorable journey down a road that leads to terminal differentiation and death. However, as these progenitors differentiate, they also proliferate rapidly in response to growth factors, expanding their numbers. Some growth factors, such as stem cell factor (also called KIT ligand) and FLT3 ligand, act through receptors that are expressed on very early committed progenitors. Others, such as erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, and thrombopoietin, act through receptors that are expressed only on committed progenitors with more restricted differentiation potentials. Feedback loops involving these lineage-specific growth factors tune the marrow output, allowing the numbers of formed blood elements (red cells, white cells, and platelets) to be maintained within appropriate ranges (Table 13.1).

Many diseases alter the production of blood cells. The marrow is the ultimate source of most cells of the innate and adaptive immune system and responds to infectious or inflammatory challenges by increasing its output of granulocytes under the direction of specific growth factors

Table 13.1 Adult Reference Ranges for Blood Cells[a]

Cell Type	Range
White cells ($\times 10^3/\mu L$)	4.8–10.8
Granulocytes (%)	40–70
Neutrophils ($\times 10^3/\mu L$)	1.4–6.5
Lymphocytes ($\times 10^3/\mu L$)	1.2–3.4
Monocytes ($\times 10^3/\mu L$)	0.1–0.6
Eosinophils ($\times 10^3/\mu L$)	0–0.5
Basophils ($\times 10^3/\mu L$)	0–0.2
Red cells ($\times 10^3/\mu L$)	
Men	4.3–5
Women	3.5–5
Platelets ($\times 10^3/\mu L$)	150–450

[a]Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used.

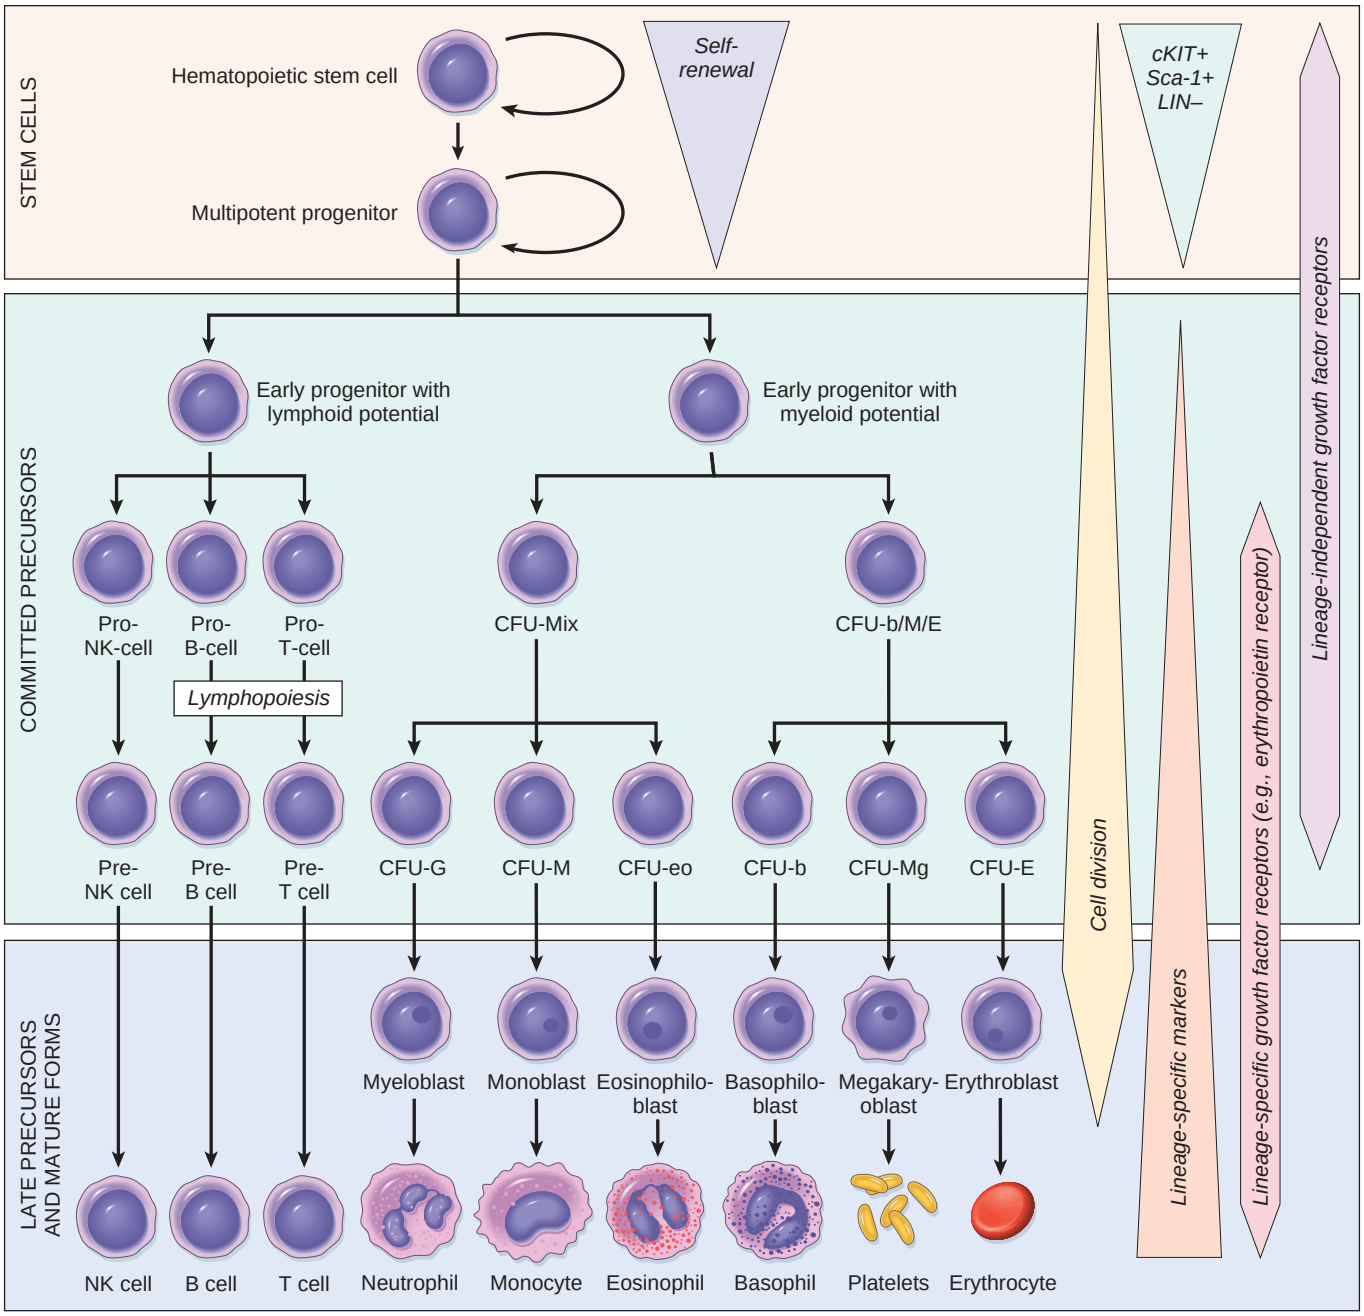

Figure 13.1 Differentiation of blood cells. *CFU*, Colony forming unit; *LIN–*, negative for lineage-specific markers; *NK*, natural killer.

and cytokines. By contrast, many other disorders are associated with defects in hematopoiesis that lead to deficiencies of one or more types of blood cells. Primary tumors of hematopoietic cells are among the most important diseases that interfere with marrow function, but certain genetic diseases, infections, toxins, and nutritional deficiencies, as well as chronic inflammation from any cause, may also decrease the production of blood cells by the marrow.

Tumors of hematopoietic origin are often associated with mutations that block progenitor cell maturation or abrogate their growth factor dependence. The net effect of such derangements is an unregulated clonal expansion of hematopoietic elements, which replace normal marrow progenitors and often spread to other hematopoietic tissues. In some instances these tumors originate from transformed HSCs that retain the ability to differentiate along multiple lineages, whereas in other instances the origin is a more differentiated progenitor that has acquired an abnormal capacity for self-renewal (Chapter 7).

MORPHOLOGY

The bone marrow is a unique microenvironment that supports the orderly proliferation, differentiation, and release of blood cells. It is filled with a network of thin-walled sinusoids lined by a single layer of endothelial cells, which are underlaid by a discontinuous basement membrane and adventitial cells. Within the

interstitium lie clusters of hematopoietic cells and fat cells. Differentiated blood cells enter the circulation by transcellular migration through the endothelial cells.

The normal marrow is organized in subtle, but important, ways. For example, normal megakaryocytes lie next to sinusoids and extend cytoplasmic processes that bud off into the bloodstream to produce platelets, while red cell precursors often surround macrophages that dispose of nuclear remnants produced when red cells disgorge their nucleus prior to release into the bloodstream. Processes that distort the marrow architecture, such as deposits of metastatic cancer or granulomatous disorders, can cause the abnormal release of immature precursors into the peripheral blood, a finding that is referred to as **leukoerythroblastosis.**

Marrow aspirate smears provide the best assessment of the morphology of hematopoietic cells. The most mature marrow precursors can be identified based on their morphology alone. Immature precursors ("blast" forms) of different types are morphologically similar and must be identified definitively using lineage-specific antibodies and histochemical markers (described later under white cell neoplasms). Bone marrow biopsies are a good means for estimating marrow activity. In normal adults the ratio of fat cells to hematopoietic elements is about 1:1. In hypoplastic states (e.g., aplastic anemia) the proportion of fat cells is greatly increased; conversely, fat cells often disappear when the marrow is involved by hematopoietic tumors and in diseases characterized by compensatory hyperplasias (e.g., hemolytic anemias) and neoplastic proliferations such as leukemias. Other disorders (e.g., metastatic cancers and granulomatous diseases) induce local marrow fibrosis. In such cases the marrow usually cannot be aspirated and the lesions are best seen in biopsies.

Disorders of White Cells

Disorders of white blood cells can be classified into two broad categories: proliferative disorders, in which there is an expansion of leukocytes, and leukopenias, which are defined as a deficiency of leukocytes. Proliferations of white cells can be *reactive* or *neoplastic.* Reactive proliferations in the setting of infections or inflammatory processes, when large numbers of leukocytes are needed for an effective host response, are fairly common. Neoplastic disorders, though less frequent, are much more important clinically. In the following discussion we will first describe the leukopenic states and summarize the common reactive disorders and then consider in some detail the malignant proliferations of white cells.

LEUKOPENIA

The number of circulating white cells may be decreased in a variety of disorders. An abnormally low white cell count *(leukopenia)* usually results from reduced numbers of neutrophils *(neutropenia, granulocytopenia)*. *Lymphopenia* is less common; in addition to congenital immunodeficiency diseases (Chapter 6), it is most commonly observed in advanced human immunodeficiency virus (HIV) infection, following therapy with glucocorticoids or cytotoxic drugs, autoimmune disorders, malnutrition, and certain acute viral infections. In the latter setting, lymphopenia actually stems from lymphocyte redistribution rather than a decrease in the number of lymphocytes in the body. Acute viral infections induce production of type I interferons, which activate T lymphocytes and change the expression of surface proteins that regulate T-cell migration. These changes result in the sequestration of activated T cells in lymph nodes and increased adherence to endothelial cells, both of which contribute to lymphopenia. Granulocytopenia is more common and is often associated with diminished granulocyte function and thus merits further discussion.

Neutropenia, Agranulocytosis

Neutropenia, a reduction in the number of neutrophils in the blood, occurs in a wide variety of circumstances. *Agranulocytosis,* a marked reduction in neutrophils, has the serious consequence of making individuals susceptible to bacterial and fungal infections.

Pathogenesis

Neutropenia can be caused by (1) inadequate or ineffective granulopoiesis or (2) increased destruction or sequestration of neutrophils in the periphery. Inadequate or ineffective granulopoiesis is observed in the setting of:

- *Suppression of HSCs,* as occurs in aplastic anemia (Chapter 14) and a variety of infiltrative marrow disorders (e.g., tumors, granulomatous disease); in these conditions, granulocytopenia is accompanied by anemia and thrombocytopenia.
- *Suppression of committed granulocytic precursors* by exposure to certain drugs (discussed later).
- Disease states associated with *ineffective hematopoiesis,* such as megaloblastic anemia (Chapter 14) and myelodysplastic syndrome, in which defective precursors die in the marrow.
- Rare *congenital conditions* (e.g., Kostmann syndrome), in which inherited defects in specific genes impair granulocytic differentiation.

Accelerated destruction or sequestration of neutrophils occurs with:

- *Immunologically mediated injury* to neutrophils, which can be idiopathic, associated with a well-defined immunologic disorder (e.g., systemic lupus erythematosus), or caused by exposure to drugs.
- *Splenomegaly,* in which splenic enlargement leads to sequestration and destruction of neutrophils in the spleen and modest neutropenia, sometimes associated with anemia and often with thrombocytopenia.
- *Increased peripheral utilization,* which can occur in overwhelming bacterial, fungal, or rickettsial infections.

The most common cause of agranulocytosis is drug toxicity. Certain drugs, such as alkylating agents and antimetabolites used in cancer treatment, produce agranulocytosis in a predictable, dose-related fashion. Because such drugs cause a generalized suppression of hematopoiesis,

production of red cells and platelets is also affected. Agranulocytosis may also occur as an idiosyncratic reaction to a large variety of agents including certain antibiotics, anticonvulsants, antiinflammatory drugs, antipsychotic drugs, and diuretics. The neutropenia induced by antipsychotic agents such as chlorpromazine and related phenothiazines results from a toxic effect on granulocytic precursors in the bone marrow. In contrast, agranulocytosis following administration of other drugs, such as sulfonamides, probably stems from antibody-mediated destruction of neutrophils through mechanisms similar to those involved in drug-induced immunohemolytic anemias (Chapter 14).

In some patients with acquired idiopathic neutropenia, autoantibodies directed against neutrophil-specific antigens are detected. Severe neutropenia may also occur in association with monoclonal proliferations of large granular lymphocytes (so-called *LGL leukemia*). The mechanism of this neutropenia is not clear; suppression of granulocytic progenitors by products of the neoplastic cell (usually a CD8+ cytotoxic T cell) is considered most likely.

MORPHOLOGY

The alterations in the **bone marrow** vary with cause. With excessive destruction of neutrophils in the periphery, the marrow is usually hypercellular due to a compensatory increase in granulocytic precursors. Hypercellularity is also the rule with neutropenias caused by ineffective granulopoiesis, as occurs in megaloblastic anemia and myelodysplastic syndrome. Agranulocytosis caused by agents that suppress or destroy granulocyte precursors is understandably associated with marrow hypocellularity.

Infections are a common consequence of agranulocytosis. Ulcerating necrotizing lesions of the gingiva, floor of the mouth, buccal mucosa, pharynx, or elsewhere in the oral cavity (agranulocytic angina) are quite characteristic. These are typically deep, undermined, and covered by gray to green-black necrotic membranes from which numerous bacteria or fungi can be isolated. Less frequently, similar ulcerative lesions occur in the skin, vagina, anus, or gastrointestinal tract. Severe life-threatening invasive bacterial or fungal infections may occur in the lungs, urinary tract, and kidneys. The neutropenic patient is at particularly high risk for deep fungal infections caused by *Candida* and *Aspergillus*. Sites of infection often show a massive growth of organisms with little leukocytic response. In the most dramatic instances, bacteria grow in colonies (botryomycosis) resembling those seen on agar plates.

Clinical Features

The symptoms and signs of neutropenia are related to infection and include malaise, chills, and fever, often followed by marked weakness and fatigability. With agranulocytosis, infections are often overwhelming and may cause death within hours to days.

Serious infections are most likely when the neutrophil count falls below 500/mm^3. Because infections are often fulminant, broad-spectrum antibiotics must be given expeditiously whenever signs or symptoms appear. In some instances, such as following myelosuppressive chemotherapy, neutropenia is treated with G-CSF, a growth factor that stimulates the production of granulocytes from marrow precursors.

REACTIVE PROLIFERATIONS OF WHITE CELLS AND LYMPH NODES

Leukocytosis

Leukocytosis refers to an increase in the number of white cells in the blood. It is a common reaction to a variety of inflammatory states.

Pathogenesis

The peripheral blood leukocyte count is influenced by several factors, including:

- The size of the myeloid and lymphoid precursor and storage cell pools in the bone marrow, thymus, circulation, and peripheral tissues.
- The rate of release of cells from the storage pools into the circulation.
- The proportion of cells that are adherent to blood vessel walls at any time (the marginal pool).
- The rate of extravasation of cells from the blood into tissues.

As discussed in Chapter 3, leukocyte homeostasis is maintained by cytokines, growth factors, and adhesion molecules through their effects on the proliferation, differentiation, and extravasation of leukocytes and their progenitors. Table 13.2 summarizes the major mechanisms of neutrophilic leukocytosis and its causes, the most important of which is infection. In acute infection there is a rapid increase in the egress of mature granulocytes from the bone marrow pool, an alteration that may be mediated through the effects of tumor necrosis factor (TNF) and interleukin-1 (IL-1). If the infection or an inflammatory process is prolonged, IL-1, TNF, and other inflammatory mediators stimulate macrophages, bone marrow stromal cells, and T cells to produce increased amounts of hematopoietic growth factors. These factors enhance the proliferation and differentiation of committed granulocytic progenitors and, over several days, cause a sustained increase in neutrophil production.

Some growth factors preferentially stimulate the production of a single type of leukocyte. For example, IL-5 mainly stimulates eosinophil production, while G-CSF induces

Table 13.2 Mechanisms and Causes of Leukocytosis

Increased Marrow Production
Chronic infection or inflammation (growth factor–dependent)
Paraneoplastic (e.g., Hodgkin lymphoma; growth factor–dependent)
Myeloproliferative neoplasms (e.g., chronic myeloid leukemia; growth factor–independent)
Increased Release From Marrow Stores
Acute inflammation (e.g., with infection)
Chronic inflammation (many causes)
Decreased Margination
Exercise
Catecholamines
Decreased Extravasation Into Tissues
Glucocorticoids

Table 13.3 Causes of Leukocytosis

Type of Leukocytosis	Causes
Neutrophilic leukocytosis	Acute bacterial infections, especially those caused by pyogenic organisms; sterile inflammation caused by, for example, tissue necrosis (myocardial infarction, burns)
Eosinophilic leukocytosis (eosinophilia)	Allergic disorders such as asthma, hay fever, parasitic infestations; drug reactions; certain malignancies (e.g., Hodgkin and some non-Hodgkin lymphomas); autoimmune disorders (e.g., pemphigus, dermatitis herpetiformis) and some vasculitides; atheroembolic disease (transient)
Basophilic leukocytosis (basophilia)	Rare, often indicative of a myeloproliferative neoplasm (e.g., chronic myeloid leukemia)
Monocytosis	Chronic infections (e.g., tuberculosis), bacterial endocarditis, rickettsiosis, and malaria; autoimmune disorders (e.g., systemic lupus erythematosus); inflammatory bowel diseases (e.g., ulcerative colitis)
Lymphocytosis	Accompanies monocytosis in many disorders associated with chronic immunologic stimulation (e.g., tuberculosis, brucellosis); viral infections (e.g., hepatitis A, cytomegalovirus, Epstein-Barr virus); *Bordetella pertussis* infection

neutrophilia. Such factors are differentially produced in response to various pathogenic stimuli, and, as a result, the five principal types of leukocytosis (neutrophilia, eosinophilia, basophilia, monocytosis, and lymphocytosis) tend to be observed in different clinical settings (Table 13.3).

In sepsis or severe inflammatory disorders (e.g., Kawasaki disease), leukocytosis is often accompanied by morphologic changes in neutrophils, such as toxic granulations, Döhle bodies, and cytoplasmic vacuoles (Fig. 13.2). *Toxic granules,* which are coarser and darker than normal neutrophilic granules, represent abnormal azurophilic (primary) granules. *Döhle bodies* are patches of dilated endoplasmic reticulum that appear as sky-blue cytoplasmic "puddles."

In most instances it is not difficult to distinguish reactive and neoplastic leukocytoses, but uncertainties may arise in two settings. Acute viral infections, particularly in children, can cause the appearance of large numbers of activated lymphocytes that resemble neoplastic lymphoid cells. At other times, particularly in severe infections, many immature granulocytes appear in the blood, mimicking a myeloid leukemia *(leukemoid reaction)*. Special laboratory studies (discussed later) are helpful in distinguishing reactive and neoplastic leukocytoses.

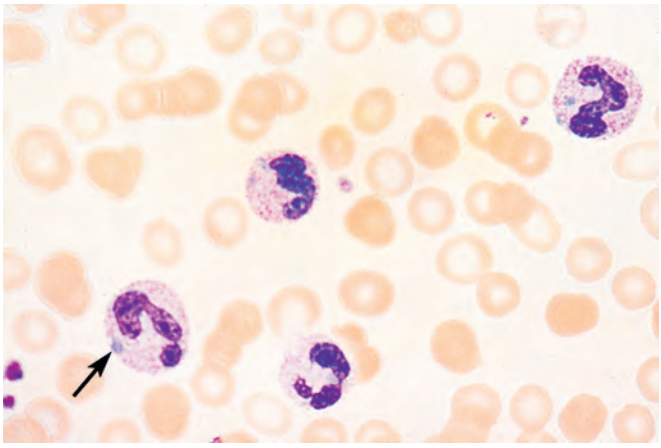

Figure 13.2 Reactive changes in neutrophils. Neutrophils containing coarse purple cytoplasmic granules (toxic granulations) and blue cytoplasmic patches of dilated endoplasmic reticulum (Döhle bodies) *(arrow)* are observed in this peripheral blood smear prepared from a patient with bacterial sepsis.

Lymphadenitis

Following their initial development from precursors in the central (also called primary) lymphoid organs—the bone marrow for B cells and the thymus for T cells—lymphocytes circulate through the blood and, under the influence of specific cytokines and chemokines, home to lymph nodes, spleen, tonsils, adenoids, and Peyer patches, which constitute the peripheral (secondary) lymphoid tissues. Lymph nodes, the most widely distributed and easily accessible lymphoid tissue, are frequently examined for diagnostic purposes. They are discrete encapsulated structures that contain separate B-cell and T-cell zones, each richly invested with phagocytes and antigen-presenting cells (see Fig. 6.8, Chapter 6).

The activation of resident immune cells leads to morphologic changes in lymph nodes. Within several days of antigenic stimulation, the primary follicles enlarge and develop pale-staining *germinal centers,* highly dynamic structures in which B cells acquire the capacity to make high-affinity antibodies against specific antigens. Paracortical T-cell zones may also undergo hyperplasia. The degree and pattern of morphologic change are dependent on the inciting stimulus and the intensity of the response. Trivial injuries and infections induce subtle changes, while more significant infections inevitably produce nodal enlargement and sometimes leave residual scarring. For this reason, lymph nodes in adults are almost never "normal" or "resting," and it is often necessary to distinguish morphologic changes secondary to past experience from those related to present disease. Infections and inflammatory stimuli often elicit regional or systemic immune reactions within lymph nodes. Some that produce distinctive morphologic patterns are described in other chapters. Most, however, cause stereotypical patterns of lymph node reaction designated acute and chronic nonspecific lymphadenitis.

Acute Nonspecific Lymphadenitis

Acute lymphadenitis in the cervical region is most often due to drainage of microbes or microbial products from infections of the teeth or tonsils, while in the axillary or inguinal regions it is most often caused by infections in the extremities. Acute lymphadenitis also occurs in mesenteric lymph nodes in the setting of acute appendicitis and other inflammatory conditions involving the gut (including self-limiting viral infections), a differential diagnosis that plagues the surgeon. Systemic viral infections (particularly in

children) and bacteremia often produce acute generalized lymphadenopathy.

MORPHOLOGY

The nodes are swollen, gray-red, and engorged. Microscopically, there is prominence of large reactive germinal centers containing numerous mitotic figures. Macrophages often contain particulate debris derived from dead bacteria or necrotic cells. When pyogenic organisms are the cause, neutrophils are prominent, and the centers of the follicles may undergo necrosis; sometimes the entire node is converted to pus. With less severe reactions, scattered neutrophils infiltrate about the follicles and accumulate within the lymphoid sinuses. The endothelial cells lining the sinuses become activated and enlarge in size.

Nodes involved by acute lymphadenitis are swollen and painful. When abscess formation is extensive the nodes become fluctuant. The overlying skin is red. Sometimes, suppurative infections penetrate through the capsule of the node and track to the skin to produce draining sinuses. Healing of such lesions is associated with scarring.

Chronic Nonspecific Lymphadenitis

A wide variety of chronic immunologic stimuli may produce nonspecific lymphadenitis. Several different patterns of morphologic change are seen, often within the same lymph node.

MORPHOLOGY

Follicular hyperplasia is caused by stimuli that activate humoral immune responses. It is defined by the presence of large oblong germinal centers (secondary follicles), which are surrounded by a collar of small resting naive B cells (the mantle zone) (Fig. 13.3). Germinal centers are polarized, consisting of two distinct regions: (1) a dark zone with proliferating blast-like B cells (centroblasts) and (2) a light zone composed of B cells with irregular or cleaved nuclear contours (centrocytes). Interspersed among the germinal center B cells is an inconspicuous network of antigen-presenting follicular dendritic cells and macrophages (often referred to as **tingible-body macrophages**) containing the nuclear debris of B cells, which undergo apoptosis if they fail to produce an antibody with a high affinity for antigen.

Causes of follicular hyperplasia include rheumatoid arthritis, toxoplasmosis, and early HIV infection. This form of hyperplasia is morphologically similar to follicular lymphoma (discussed later). Features favoring a reactive (nonneoplastic) hyperplasia include (1) preservation of the lymph node architecture, including the interfollicular T-cell zones and the sinusoids, (2) marked variation in the shape and size of the follicles, and (3) the presence of frequent mitotic figures, phagocytic macrophages, and recognizable light and dark zones, all of which tend to be absent from neoplastic follicles.

Paracortical hyperplasia is caused by stimuli that trigger T-cell–mediated immune responses, such as acute viral infections (e.g., infectious mononucleosis). The T-cell regions typically contain immunoblasts, activated T cells three to four times the size of resting lymphocytes that have round nuclei, open chromatin, several prominent nucleoli, and moderate amounts of pale cytoplasm.

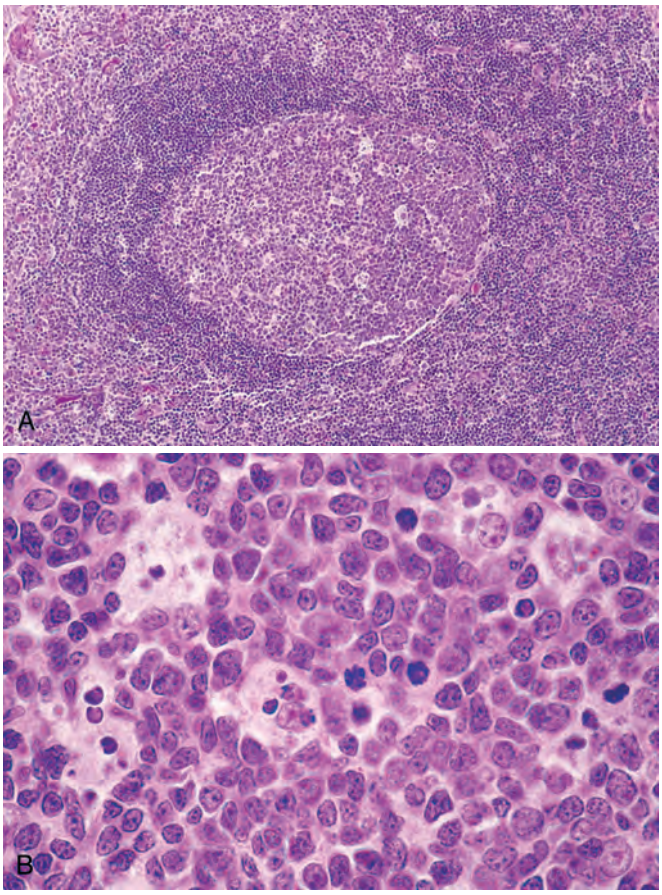

Figure 13.3 Follicular hyperplasia. (A) Low-power view showing a reactive follicle and surrounding mantle zone. The dark-staining mantle zone is more prominent adjacent to the germinal center light zone in the left half of the follicle. The right half of the follicle consists of the dark zone. (B) High-power view of the dark zone shows several mitotic figures and numerous macrophages containing phagocytosed apoptotic cells (tingible bodies).

The expanded T-cell zones encroach on and, in particularly exuberant reactions, may efface the B-cell follicles. In such cases, immunoblasts are so numerous that special studies may be needed to exclude a lymphoid neoplasm. In addition, there is often hypertrophy of sinusoidal and vascular endothelial cells, sometimes accompanied by infiltrating macrophages and eosinophils.

Sinus histiocytosis (also called *reticular hyperplasia*) is marked by an increase in the number and size of the endothelial cells that line lymphatic sinusoids and increased numbers of intrasinusoidal macrophages, which expand and distort the sinusoids. This form of hyperplasia may be particularly prominent in lymph nodes draining cancers such as carcinoma of the breast.

Characteristically, lymph nodes in chronic reactions are nontender, as enlargement occurs slowly over time and acute inflammation with associated tissue damage is absent. Chronic lymphadenitis is particularly common in inguinal and axillary nodes, which drain relatively large areas of the body and are frequently stimulated by immune reactions to trivial injuries and infections of the extremities.

Chronic immune reactions also can promote the appearance of organized collections of immune cells in nonlymphoid

tissues. These collections are sometimes called *tertiary lymphoid organs*. A classic example is that of chronic gastritis caused by *Helicobacter pylori,* in which aggregates of mucosal lymphocytes are seen that simulate the appearance of Peyer patches. A similar phenomenon occurs in rheumatoid arthritis, in which B-cell follicles often appear in the inflamed synovium. Lymphotoxin, a cytokine required for the formation of normal Peyer patches, is probably involved in the establishment of these "extranodal" inflammation-induced collections of lymphoid cells.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a reactive condition marked by cytopenias and signs and symptoms of systemic inflammation related to macrophage activation. For this reason, it is also sometimes referred to as *macrophage activation syndrome*. Some forms are familial and may appear early in life, even in infants, while other forms are sporadic and may affect people of any age.

Pathogenesis

The common feature of all forms of HLH is systemic activation of macrophages and CD8+ cytotoxic T cells. The activated macrophages phagocytose blood cell progenitors in the marrow and formed elements in the peripheral tissues, while the "stew" of mediators released from macrophages and lymphocytes suppress hematopoiesis and produce symptoms of systemic inflammation. These effects lead to cytopenias and a shock-like picture, sometimes referred to as "cytokine storm" or the systemic inflammatory response syndrome (Chapter 4).

Familial forms of HLH are associated with several different mutations, all of which impact the ability of cytotoxic T cells (CTLs) and natural killer (NK) cells to properly form or deploy cytotoxic granules. How these defects lead to HLH is not known. One common trigger for HLH is Epstein-Barr virus infection, suggesting that in some instances HLH stems from a defect in the ability of CD8+ CTLs to kill infected cells. As a result of the persistent infection, the CTLs continue to make cytokines, leading to excessive macrophage activation. HLH is also a common complication of peripheral T-cell lymphoma (discussed later), a tumor of mature T cells that is marked by immune dysregulation. Regardless of the trigger, HLH is uniformly associated with extremely high levels of inflammatory mediators such as interferon-γ, TNF-α, IL-6, and IL-12.

Clinical Features

Most patients present with an acute febrile illness associated with splenomegaly and hepatomegaly. Hemophagocytosis is usually seen on bone marrow examination, but is neither sufficient nor required to make the diagnosis. Laboratory studies typically reveal anemia, thrombocytopenia, and very high levels of plasma ferritin and soluble IL-2 receptor, both indicative of severe inflammation, as well as elevated liver function tests and triglyceride levels, both related to hepatitis. Coagulation studies may show evidence of disseminated intravascular coagulation. If untreated, this picture can progress rapidly to multiorgan failure, shock, and death.

Treatment involves the use of immunosuppressive drugs, "mild" chemotherapy, and administration of an antibody that neutralizes the activity of interferon-γ. Patients with germline mutations that cause HLH or who have persistent/resistant disease are candidates for HSC transplantation. Without treatment, the prognosis is grim, particularly in those with familial forms of the disease, who typically survive for less than 2 months. With prompt treatment, with or without subsequent HSC transplantation, roughly half of patients survive, though many do so with significant sequelae, such as renal damage in adults and growth retardation and intellectual disability in children.

NEOPLASTIC PROLIFERATIONS OF WHITE CELLS: OVERVIEW

Malignancies are clinically the most important disorders of white cells. These diseases fall into three broad categories:

- *Lymphoid neoplasms* include a diverse group of tumors of B-cell, T-cell, and NK-cell origin. In many instances the phenotype of the neoplastic cell closely resembles that of a particular lymphocyte class or stage of maturation, a feature that is used in the diagnosis and classification of these disorders.
- *Myeloid neoplasms* arise from early hematopoietic progenitors. Three categories of myeloid neoplasia are recognized: *acute myeloid leukemias (AMLs),* in which immature progenitor cells accumulate in the bone marrow; *myelodysplastic syndromes (MDSs),* which are associated with ineffective hematopoiesis and resultant peripheral blood cytopenias; and *myeloproliferative neoplasms,* in which increased production of one or more terminally differentiated myeloid elements (e.g., granulocytes) usually leads to elevated peripheral blood counts.
- The *histiocytoses* are uncommon proliferative lesions of macrophages and dendritic cells. Although "histiocyte" (literally, "tissue cell") is an archaic morphologic term, it is still often used. A special type of immature dendritic cell, the Langerhans cell, gives rise to a spectrum of neoplastic disorders referred to as the *Langerhans cell histiocytoses.*

Etiologic and Pathogenetic Factors in White Cell Neoplasia

As in other cancers, the development of white blood cell neoplasms involves genetic alterations, infections, and sometimes a background of chronic inflammation. Different types of tumors show different abnormalities and are, therefore, responsive to different therapies. Before delving into this complexity, we consider themes of general relevance to their etiology and pathogenesis.

Chromosomal Translocations and Other Acquired Mutations. Nonrandom chromosomal abnormalities, most commonly translocations, are present in the majority of white cell neoplasms. Many of these alterations are specifically associated with particular neoplasms and have a critical role in their genesis (Chapter 7).

- *Recurrently affected genes are often those that play crucial roles in the development, growth, or survival of the normal*

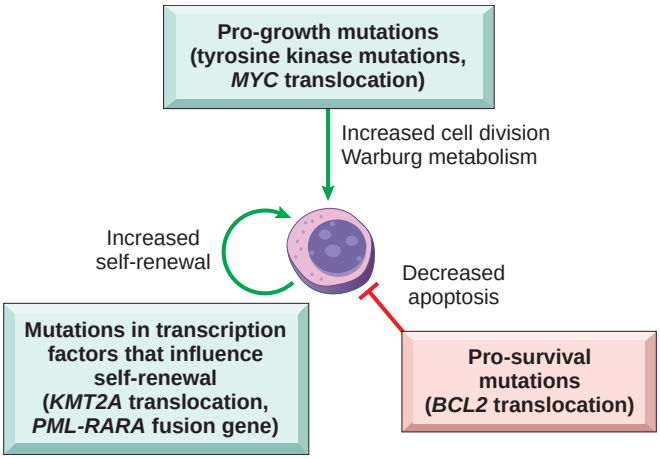

Figure 13.4 Pathogenesis of white cell malignancies. Various tumors harbor mutations that principally effect maturation or enhance self-renewal, drive growth, or prevent apoptosis. Examples of each type of mutation are listed; details are provided later under specific tumor types.

counterpart of the malignant cell. Mutations in certain genes are so strongly associated with specific tumor types that in some instances they are required for particular diagnoses. Some of these mutations produce a "dominant-negative" protein that interferes with a normal function (a loss of function); in others the result is an inappropriate increase in some normal activity (a gain of function).

- *Oncoproteins created by genomic aberrations often block normal maturation, turn on pro-growth signaling pathways, or protect cells from apoptotic cell death.* Fig. 13.4 highlights several well-characterized driver mutations and their pathogenic consequences in particular white cell neoplasms.
  - Many oncoproteins cause an arrest in differentiation, often at a stage when cells are proliferating rapidly. The importance of this mechanism is most evident in the acute leukemias, in which dominant-negative oncogenic mutations involving transcription factors interfere with early stages of lymphoid or myeloid cell differentiation.
  - Other mutations in transcriptional regulators directly enhance the self-renewal of tumors cells, giving them stem cell–like properties. These types of mutations often collaborate with mutations that constitutively activate tyrosine kinases, which in turn activate RAS and its two downstream signaling arms, the PI3K/AKT and MAPK pathways (Chapter 7), thereby driving cell growth.
  - Finally, mutations that inhibit apoptosis are prevalent in certain hematologic malignancies.
- *Proto-oncogenes are often activated in lymphoid cells by errors that occur during attempted antigen receptor gene diversification.* Among lymphoid cells, potentially oncogenic mutations occur most frequently in germinal center B cells. After antigen stimulation, B cells enter germinal centers and upregulate the expression of activation-induced cytosine deaminase (AID), a specialized DNA-modifying enzyme that is essential for two types of immunoglobulin (Ig) gene modifications: *class switching,* an intragenic recombination event in which the IgM heavy-chain constant gene segment is replaced with a different constant segment (e.g., IgG_3), leading to a switch in the class (isotype) of antibody produced, and *somatic hypermutation,* which creates point mutations within Ig genes that may increase antibody affinity for antigen (Chapter 6). Certain proto-oncogenes, such as *MYC,* are activated in germinal center B-cell lymphomas by translocations to the transcriptionally active Ig locus. Remarkably, AID expression induces *MYC/Ig* translocations in a small fraction of normal germinal center B cells, apparently because AID creates lesions in DNA that lead to chromosomal breaks. "Mistargeting" of AID also is implicated in point mutations that upregulate the expression and activity of BCL6, an oncogenic transcription factor with an important role in several B-cell malignancies. Another type of regulated genomic instability that is unique to precursor B and T cells is attributable to V(D)J recombinase, which cuts DNA at specific sites within the Ig and T-cell receptor loci, respectively. This process is essential for generating diversity in assembled antigen receptor genes but sometimes goes awry, leading to the joining of proto-oncogenes to antigen receptor gene regulatory elements. The resulting overexpression of the involved proto-oncogene converts it to an oncogene. This mechanism is particularly prevalent in tumors of precursor T cells but is observed in other types of lymphoid neoplasms as well.

Inherited Genetic Factors. As discussed in Chapter 7, individuals with genetic diseases that promote genomic instability, such as Bloom syndrome, Fanconi anemia, and ataxia telangiectasia, are at increased risk of acute leukemia. In addition, both Down syndrome (trisomy 21) and type I neurofibromatosis are associated with an increased incidence of childhood leukemia.

Viruses. Three lymphotropic viruses—human T-cell leukemia virus-1 (HTLV-1), EBV, and human herpesvirus-8 (HHV-8; also known as Kaposi sarcoma herpesvirus)—have been implicated as causative agents in particular lymphomas. The possible mechanisms of transformation by viruses are discussed in Chapter 7. HTLV-1 is associated with adult T-cell leukemia/lymphoma. EBV is found in a subset of Burkitt lymphoma, 30% to 40% of Hodgkin lymphoma (HL), many B-cell lymphomas arising in the setting of T-cell immunodeficiency, and rare NK-cell lymphomas. In addition to Kaposi sarcoma (Chapter 11), HHV-8 is associated with an unusual B-cell lymphoma that presents as a malignant effusion, often in the pleural cavity.

Chronic Inflammation. Several agents that cause localized chronic inflammation predispose to lymphoid neoplasia, which almost always arises within the inflamed tissue. Examples include the associations between *H. pylori* infection and gastric B-cell lymphomas (Chapter 17); gluten-sensitive enteropathy and intestinal T-cell lymphomas; and even breast implants, which are associated with an unusual subtype of T-cell lymphoma. This can be contrasted with HIV infection, which is associated with an increased risk of B-cell lymphomas that may arise within virtually any organ. Early in the course, T-cell dysregulation by HIV infection causes a systemic hyperplasia of germinal center B cells that is associated with an increased incidence of

germinal center B-cell lymphomas. In advanced infection (acquired immunodeficiency syndrome [AIDS]), severe T-cell immunodeficiency further elevates the risk for B-cell lymphomas, particularly those associated with EBV and KSHV/HHV-8. These relationships are discussed in more detail in Chapter 6.

Iatrogenic Factors. Ironically, radiation therapy and certain forms of chemotherapy used to treat cancer increase the risk of subsequent myeloid and lymphoid neoplasms. This association stems from the mutagenic effects of ionizing radiation and chemotherapeutic drugs on hematolymphoid progenitor cells.

Smoking. The incidence of AML is increased 1.3- to 2-fold in smokers, presumably because of exposure to carcinogens, such as benzene, in tobacco smoke.

LYMPHOID NEOPLASMS

Taken together, the diverse lymphoid neoplasms constitute a complex, clinically important group of cancers, with about 100,000 new cases being diagnosed each year in the United States.

Definitions and Classifications

Neoplasms that present with widespread involvement of the bone marrow and (usually, but not always) the peripheral blood are called *leukemias*. Proliferations of white cells, typically lymphocytes, that usually present as discrete tissue masses are called *lymphomas*. Originally these terms were attached to what were considered distinct entities, but with time and increased understanding these divisions have blurred. Many entities called "lymphoma" occasionally have leukemic presentations, and evolution to "leukemia" is not unusual during the progression of incurable "lymphomas." Conversely, tumors identical to "leukemias" sometimes arise as soft tissue masses without detectable bone marrow disease. Hence the terms leukemia and lymphoma merely reflect the usual tissue distribution of each disease at presentation.

Within the large group of lymphomas, *Hodgkin lymphoma* is segregated from other forms, which constitute the *non-Hodgkin lymphomas (NHLs)*. Hodgkin lymphoma has distinctive pathologic features and is treated in a unique fashion. Another special group of tumors includes *plasma cell neoplasms*. These most often arise in the bone marrow and only infrequently involve lymph nodes or the peripheral blood.

The clinical presentation of lymphoid neoplasms is most often determined by the anatomic distribution of disease. Two-thirds of NHLs and virtually all Hodgkin lymphomas present as enlarged nontender lymph nodes (often >2 cm). The remaining NHLs present with symptoms related to the involvement of extranodal sites (e.g., skin, stomach, or brain). Lymphocytic leukemias most often come to attention because of signs and symptoms related to the suppression of normal hematopoiesis by tumor cells in the bone marrow, whereas the most common plasma cell neoplasm, multiple myeloma, causes bony destruction of the skeleton and often presents with pain due to pathologic fractures. Other symptoms are frequently caused by proteins secreted from tumor cells or from immune cells responding to the tumor. Specific examples include the plasma cell tumors, in which much of the pathophysiology is related to the secretion of whole antibodies or Ig fragments; Hodgkin lymphoma, which is often associated with fever related to the release of cytokines from nonneoplastic inflammatory cells; and peripheral T-cell lymphomas, tumors of functional T cells that often release pro-inflammatory cytokines and chemokines.

Historically, few areas of pathology evoked as much controversy as the classification of lymphoid neoplasms, but consensus has been reached through use of objective molecular diagnostic tools. The current World Health Organization (WHO) classification scheme (Table 13.4) uses morphologic, immunophenotypic, genotypic, and clinical features to sort the lymphoid neoplasms into five broad categories, separated according to the cell of origin:

1. Precursor B-cell neoplasms (neoplasms of immature B cells)
2. Peripheral B-cell neoplasms (neoplasms of mature B cells)
3. Precursor T-cell neoplasms (neoplasms of immature T cells)

Table 13.4 World Health Organization Classification of Lymphoid Neoplasms

I. Precursor B-Cell Neoplasms
B-cell acute lymphoblastic leukemia/lymphoma (B-ALL)
II. Peripheral B-Cell Neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Splenic and nodal marginal zone lymphomas
Extranodal marginal zone lymphoma
Mantle cell lymphoma
Follicular lymphoma
Marginal zone lymphoma
Hairy cell leukemia
Plasmacytoma/plasma cell myeloma
Diffuse large B-cell lymphoma
Burkitt lymphoma
III. Precursor T-Cell Neoplasms
T-cell acute lymphoblastic leukemia/lymphoma (T-ALL)
IV. Peripheral T-Cell and NK-Cell Neoplasms
T-cell prolymphocytic leukemia
Large granular lymphocytic leukemia
Mycosis fungoides/Sézary syndrome
Peripheral T-cell lymphoma, unspecified
Anaplastic large-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Enteropathy-associated T-cell lymphoma
Panniculitis-like T-cell lymphoma
Hepatosplenic γδ T-cell lymphoma
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma
NK-cell leukemia
V. Hodgkin Lymphoma
Classic subtypes
Nodular sclerosis
Mixed cellularity
Lymphocyte-rich
Lymphocyte depletion
Nodular lymphocyte predominant

NK, Natural killer.

4. Peripheral T-cell and NK-cell neoplasms (neoplasms of mature T cells and NK cells)
5. Hodgkin lymphomas (neoplasms of Reed-Sternberg cells and variants)

Before discussing the specific entities, some important principles relevant to lymphoid neoplasms should be emphasized.

- *Lymphoid neoplasia can be suspected based on clinical features, but histologic examination of lymph nodes or other involved tissues is required for diagnosis.* Analysis of lineage-specific protein (marker) expression and genetic alterations is an important complement to the morphologic studies. Markers recognized by antibodies that are helpful in the characterization of lymphomas and leukemias are listed in Table 13.5.
- *Antigen receptor gene rearrangement generally precedes transformation of lymphoid cells; hence all daughter cells derived from the malignant progenitor share the same antigen receptor gene configuration and sequence and synthesize identical antigen receptor proteins (either Igs or T-cell receptors).* In contrast, normal immune responses are comprised of polyclonal populations of lymphocytes that express many different antigen receptors. Thus, analyses of antigen receptor genes and their protein products can be used to distinguish reactive (polyclonal) and malignant (monoclonal) lymphoid proliferations. In addition, each antigen receptor gene rearrangement produces a unique DNA sequence that constitutes a highly specific clonal marker, which can be used to detect small numbers of residual malignant lymphoid cells after therapy.
- *Most lymphoid neoplasms resemble some recognizable stage of B- or T-cell differentiation* (Fig. 13.5), a feature that is used in their classification. The vast majority (85% to 90%) of lymphoid neoplasms are of B-cell origin, with most of the remainder being T-cell tumors; tumors of NK-cell origin are rare.
- *Lymphoid neoplasms are often associated with immune abnormalities.* Both a loss of protective immunity (susceptibility to infection) and a breakdown of tolerance (autoimmunity) may be seen, sometimes in the same patient. In a further ironic twist, individuals with inherited or acquired immunodeficiency are themselves at high risk of developing certain lymphoid neoplasms, particularly those caused by oncogenic viruses (e.g., EBV).
- *Neoplastic B and T cells tend to recapitulate the behavior of their normal counterparts.* Like normal lymphocytes, neoplastic B and T cells express adhesion molecules and chemokine receptors that govern their homing to certain tissue sites, leading to characteristic patterns of involvement. For example, follicular lymphomas home to germinal centers in lymph nodes, whereas cutaneous T-cell lymphomas home to the skin. Variable numbers of neoplastic B and T lymphoid cells also recirculate through the lymphatics and peripheral blood to distant sites; as a result, most lymphoid tumors are widely disseminated at the time of diagnosis. Notable exceptions to this rule include Hodgkin lymphomas, which are sometimes restricted to one group of lymph nodes, and marginal zone B-cell lymphomas, which are often restricted to sites of chronic inflammation.

Table 13.5 Some Immune Cell Antigens Detected by Monoclonal Antibodies

Antigen Designation	Normal Cellular Distribution
Primarily T-Cell Associated	
CD1	Thymocytes and Langerhans cells
CD3	Thymocytes, mature T cells
CD4	Helper T cells, subset of thymocytes
CD5	T cells and small subset of B cells
CD8	Cytotoxic T cells, subset of thymocytes, and some NK cells
Primarily B-Cell Associated	
CD10	Pre-B cells and germinal center B cells
CD19	Pre-B cells and mature B cells but not plasma cells
CD20	Pre-B cells after CD19 and mature B cells but not plasma cells
CD21	EBV receptor; mature B cells and follicular dendritic cells
CD23	Activated mature B cells
CD79a	Marrow pre-B cells and mature B cells
Primarily Monocyte or Macrophage Associated	
CD11c	Granulocytes, monocytes, and macrophages; also expressed by hairy cell leukemias
CD13	Immature and mature monocytes and granulocytes
CD14	Monocytes
CD15	Granulocytes; Reed-Sternberg cells and variants
CD33	Myeloid progenitors and monocytes
CD64	Mature myeloid cells
Primarily NK-Cell Associated	
CD16	NK cells and granulocytes
CD56	NK cells and a subset of T cells
Primarily Stem Cell and Progenitor Cell Associated	
CD34	Pluripotent hematopoietic stem cells and progenitor cells of many lineages
Activation Markers	
CD30	Activated B cells, T cells, and monocytes; Reed-Sternberg cells and variants
Present on All Leukocytes	
CD45	All leukocytes; also known as leukocyte common antigen (LCA)

CD, Cluster designation; *EBV,* Epstein-Barr virus; *NK,* natural killer.

- *Hodgkin lymphoma spreads in an orderly stepwise fashion, whereas most forms of NHL disseminate widely and somewhat unpredictably early in their course.* Hence, while lymphoma staging provides useful prognostic information, it is of most utility in guiding therapy in Hodgkin lymphoma.

We begin our discussion of specific entities with neoplasms of immature lymphoid cells and then move to mature B-cell tumors, plasma cell neoplasms, and tumors of T-cells and NK-cells. Some of the salient molecular and clinical features of these neoplasms are summarized in Table 13.6. We will finish by discussing Hodgkin lymphoma.

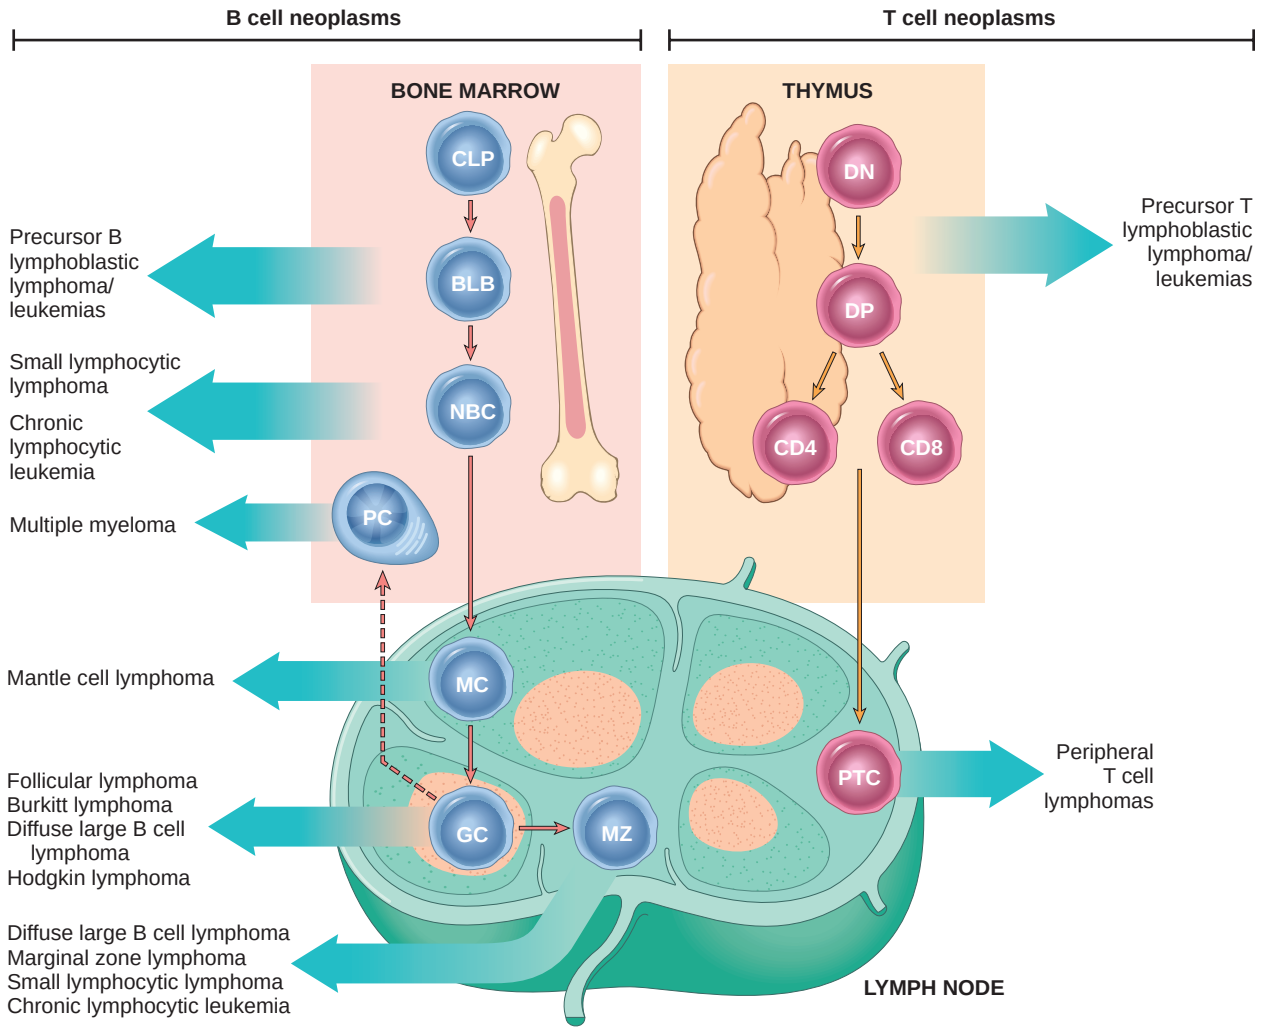

Figure 13.5 Origin of lymphoid neoplasms. Stages of B- and T-cell differentiation from which specific lymphoid tumors emerge are shown. *BLB*, Pre-B lymphoblast; *CLP*, common lymphoid precursor; *DN*, CD4/CD8 double-negative pro-T cell; *DP*, CD4/CD8 double-positive pre-T cell; *GC*, germinal center B cell; *MC*, mantle B cell; *MZ*, marginal zone B cell; *NBC*, naive B cell; *PTC*, peripheral T cell.

Precursor B- and T-Cell Neoplasms

Acute Lymphoblastic Leukemia/Lymphoma

Acute lymphoblastic leukemia/lymphomas (ALLs) are neoplasms composed of immature B (pre-B) or T (pre-T) cells, which are referred to as *lymphoblasts*. About 85% are B-ALLs, which typically manifest as childhood acute leukemias. The less common T-ALLs tend to present in adolescent males as thymic lymphomas. There is, however, considerable overlap in the clinical behavior of B-ALL and T-ALL; for example, B-ALL uncommonly presents as a mass in the skin or a bone, and many T-ALLs present with or evolve to a leukemic picture. Because of their morphologic and clinical similarities, the various forms of ALL are discussed here together.

ALL is the most common cancer of children. Approximately 2500 new cases are diagnosed each year in the United States, most occurring in individuals younger than 15 years of age. ALL is almost three times more common in Caucasians than in African-Americans and is slightly more frequent in boys than in girls. Hispanics have the highest incidence of any ethnic group. B-ALL peaks in incidence at about the age of 3, perhaps because the number of normal bone marrow pre-B cells (the cell of origin) is greatest very early in life. Similarly the peak incidence of T-ALL is in adolescence, the age when the thymus reaches maximum size. B-ALL and T-ALL also occur less frequently in adults of all ages.

Pathogenesis

Many of the chromosomal aberrations seen in ALL dysregulate the expression and function of transcription factors required for normal B- and T-cell development. Most T-ALLs have mutations in *NOTCH1*, a gene that is essential for T-cell development, while a high fraction of B-ALLs have mutations affecting genes such as *PAX5*, *TCF3*, *ETV6*, and *RUNX1*, all of which are required for the proper differentiation of early hematopoietic precursors. By disturbing the expression and function of "master" regulatory factors, these mutations promote maturation arrest and increased self-renewal, a stem cell–like phenotype. Similar themes are relevant in the genesis of AML (discussed later).

In keeping with the multistep origin of cancer (Chapter 7), mutations in transcription factor genes are not sufficient to produce ALL. The identity of other driver mutations is

Table 13.6 Summary of Major Types of Lymphoid Leukemias and Non-Hodgkin Lymphomas

Diagnosis	Cell of Origin	Genotype	Salient Clinical Features
Neoplasms of Immature B and T Cells			
B-cell acute lymphoblastic leukemia/lymphoma[a]	Bone marrow precursor B cell	Diverse chromosomal translocations; t(12;21) involving *RUNX1* and *ETV6* present in 25%	Predominantly children; symptoms relating to marrow replacement and pancytopenia; aggressive
T-cell acute lymphoblastic leukemia/lymphoma	Precursor T cell (often of thymic origin)	Diverse chromosomal translocations; *NOTCH1* mutations (50%–70%)	Predominantly adolescent males; thymic masses and variable bone marrow involvement; aggressive
Neoplasms of Mature B Cells			
Burkitt lymphoma[a]	Germinal center B cell	Translocations involving *MYC* and Ig loci, usually t(8;14); subset EBV-associated	Adolescents or young adults with extranodal masses; uncommonly presents as "leukemia"; aggressive
Diffuse large B-cell lymphoma[b]	Germinal center or post–germinal center B cell	Diverse chromosomal rearrangements, most often of *BCL6* (30%), *BCL2* (10%), or *MYC* (5%)	All ages, but most common in older adults; often appears as a rapidly growing mass; 30% extranodal; aggressive
Extranodal marginal zone lymphoma	Memory B cell	t(11;18), t(1;14), and t(14;18) creating *MALT1-IAP2*, *BCL10-IGH*, and *MALT1-IGH* fusion genes, respectively	Arises at extranodal sites in adults with chronic inflammatory diseases; may remain localized; indolent
Follicular lymphoma[b]	Germinal center B cell	t(14;18) creating *BCL2-IGH* fusion gene	Older adults with generalized lymphadenopathy and marrow involvement; indolent
Hairy cell leukemia	Memory B cell	Activating *BRAF* mutations	Older men with pancytopenia and splenomegaly; indolent
Mantle cell lymphoma	Naive B cell	t(11;14) creating cyclin D1–*IGH* fusion gene	Older men with disseminated disease; moderately aggressive
Multiple myeloma/solitary plasmacytoma[b]	Post–germinal center bone marrow homing plasma cell	Diverse rearrangements involving *IGH*; 13q deletions	Myeloma: older adults with lytic bone lesions, pathologic fractures, hypercalcemia, and renal failure; moderately aggressive Plasmacytoma: isolated plasma cell masses in bone or soft tissue; indolent
Small lymphocytic lymphoma/chronic lymphocytic leukemia	Naive B cell or memory B cell	Trisomy 12, deletions of 11q, 13q, and 17p; *NOTCH1* mutations; splicing factor mutations	Older adults with bone marrow, lymph node, spleen, and liver disease; autoimmune hemolysis and thrombocytopenia in a minority; indolent
Neoplasms of Mature T Cells or NK Cells			
Adult T-cell leukemia/lymphoma	Helper T cell	HTLV-1 provirus present in tumor cells	Adults with cutaneous lesions, marrow involvement, and hypercalcemia; occurs mainly in Japan, West Africa, and the Caribbean; aggressive
Peripheral T-cell lymphoma, unspecified	Helper or cytotoxic T cell	No specific chromosomal abnormality	Mainly older adults; usually presents with lymphadenopathy; aggressive
Anaplastic large-cell lymphoma	Cytotoxic T cell	Rearrangements of *ALK* (anaplastic large cell lymphoma kinase) in a subset	Children and young adults, usually with lymph node and soft tissue disease; aggressive
Extranodal NK/T-cell lymphoma	NK-cell (common) or cytotoxic T cell (rare)	EBV-associated; no specific chromosomal abnormality	Adults with destructive extranodal masses, most commonly sinonasal; aggressive
Mycosis fungoides/Sézary syndrome	Helper T cell	No specific chromosomal abnormality	Adult patients with cutaneous patches, plaques, nodules, or generalized erythema; indolent
Large granular lymphocytic leukemia	Two types: cytotoxic T cell and NK cell	Point mutations in *STAT3*	Adult patients with splenomegaly, neutropenia, and anemia, sometimes accompanied by autoimmune disease

[a]Most common tumors in children.

[b]Most common tumors in adults.

EBV, Epstein-Barr virus; *HTLV-1,* human T-cell leukemia virus-1; *Ig,* immunoglobulin; *NK,* natural killer.

incomplete, but aberrations that promote cell growth, such as mutations that increase tyrosine kinase activity and RAS signaling, are commonly present. Emerging data from deep sequencing of ALL genomes suggest that fewer than 10 mutations are sufficient to produce full-blown ALL; hence compared to solid tumors, ALL is genetically simple.

Approximately 90% of ALLs have numerical or structural chromosomal changes. Most common is hyperploidy (>50 chromosomes), but hypoploidy and a variety of balanced chromosomal translocations also are seen. Changes in chromosome numbers are of uncertain pathogenic significance but are important because they frequently correlate with immunophenotype and sometimes prognosis. For example, hyperdiploidy and hypodiploidy are seen only in B-ALL and are associated with better and worse prognoses, respectively. In addition, B-ALL and T-ALL are associated with completely

different sets of translocations; thus, while morphologically identical, they are genetically quite distinct.

MORPHOLOGY

In leukemic presentations, **the marrow is hypercellular and packed with lymphoblasts,** which replace normal marrow elements. Mediastinal thymic masses occur in 50% to 70% of T-ALLs, which are also more likely than B-ALL to be associated with lymphadenopathy and splenomegaly. In both B-ALL and T-ALL, the tumor cells have scant basophilic cytoplasm and nuclei somewhat larger than those of small lymphocytes (Fig. 13.6A). The nuclear chromatin is delicate and finely stippled, and nucleoli are usually small and often demarcated by a rim of condensed chromatin. The nuclear membrane is often deeply subdivided, imparting a convoluted appearance. In keeping with the aggressive clinical behavior, the mitotic rate is high. As with other rapidly growing lymphoid tumors, interspersed macrophages ingesting apoptotic tumor cells may impart a "starry sky" appearance (shown in Fig. 13.15).

Because of their different responses to chemotherapy, ALL must be distinguished from AML, a neoplasm of immature myeloid cells that can cause identical signs and symptoms. **Compared with myeloblasts, lymphoblasts have more condensed chromatin, less conspicuous nucleoli, and smaller amounts of cytoplasm that usually lacks granules.** However, these morphologic distinctions are not absolute, and definitive diagnosis relies on stains performed with antibodies specific for B- and T-cell antigens (Fig. 13.6B and C). Histochemical stains are also helpful, in that (in contrast to myeloblasts) lymphoblasts are myeloperoxidase-negative and often contain periodic acid–Schiff–positive cytoplasmic material.

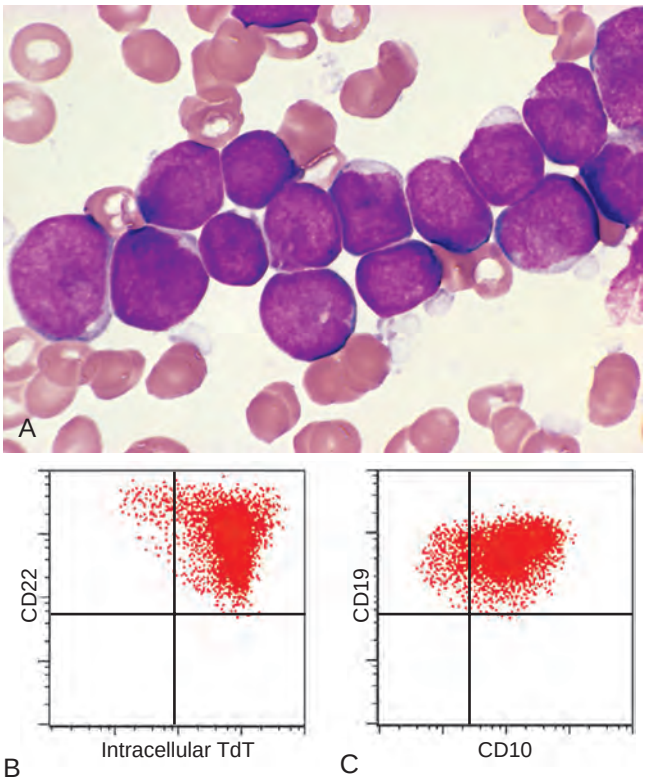

Figure 13.6 (A) Acute lymphoblastic leukemia/lymphoma (ALL). Lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. (B and C) Phenotype of ALL shown in (A) analyzed by flow cytometry. (B) The lymphoblasts represented by the *red dots* express terminal deoxynucleotidyl transferase *(TdT)* and the B-cell marker CD22. (C) The same cells are positive for two other markers, CD10 and CD19, commonly expressed on pre-B lymphoblasts. Thus this is a B-ALL. (A, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.; B and C, courtesy Dr. Louis Picker, Oregon Health Science Center, Portland, Ore.)

Immunophenotype. Immunostaining for terminal deoxynucleotidyl transferase (TdT), a specialized DNA polymerase that is expressed only in pre-B and pre-T lymphoblasts, is positive in more than 95% of cases (Fig. 13.6B). B-ALLs are arrested at various stages of pre–B-cell development, which correlate with the expression of certain proteins. The lymphoblasts usually express the pan B-cell marker CD19 and the transcription factor PAX5 as well as CD10. In very immature B-ALLs, CD10 is negative. Alternatively, more mature "late pre-B" ALLs express CD10, CD19, CD20, and cytoplasmic IgM heavy chain (μ chain). Similarly, T-ALLs are arrested at various stages of pre–T-cell development. In most cases the cells are positive for CD1, CD2, CD5, and CD7. The more immature tumors are usually negative for surface CD3, CD4, and CD8, whereas "late" pre–T-cell tumors are positive for these markers.

Clinical Features

Although ALLs and AMLs are genetically and immunophenotypically distinct, they are clinically very similar. In both, the accumulation of neoplastic "blasts" in the bone marrow suppresses normal hematopoiesis by physical crowding, competition for growth factors, and other poorly understood mechanisms. The common features and those more characteristic of ALL are the following:

- *Abrupt stormy onset* within days to a few weeks of the first symptoms.
- *Symptoms related to depression of marrow function,* including fatigue due to anemia; fever, reflecting infections secondary to neutropenia; and bleeding due to thrombocytopenia.
- *Mass effects caused by neoplastic infiltration* (which are more common in ALL), including bone pain resulting from marrow expansion and infiltration of the subperiosteum; generalized lymphadenopathy, splenomegaly, and hepatomegaly; testicular enlargement; and, in T-ALL, complications related to compression of large vessels and airways in the mediastinum.
- *Central nervous system manifestations* such as headache, vomiting, and nerve palsies resulting from meningeal spread, all of which are also more common in ALL.

Treatment of pediatric ALL is one of the great success stories of oncology. With aggressive chemotherapy about 95% of children with ALL obtain a complete remission, and 75% to 85% are cured. Despite these achievements, however, ALL remains a leading cause of cancer deaths in children, and only 35% to 40% of adults are cured. Several factors are associated with a worse prognosis: (1) age younger than 2 years, largely because of the strong association of infantile ALL with translocations involving the *MLL* gene; (2) presentation in adolescence or adulthood; and (3) peripheral

blood blast counts greater than 100,000, which probably reflects a high tumor burden. Favorable prognostic markers include (1) age between 2 and 10 years; (2) a low white cell count; (3) hyperdiploidy; (4) trisomy of chromosomes 4, 7, and 10; and (5) the presence of a t(12;21). Notably, the molecular detection of residual disease after therapy is predictive of a worse outcome in both B-ALL and T-ALL and is being used to guide clinical trials.

Although most chromosomal aberrations in ALL alter the function of transcription factors, the t(9;22) instead creates a fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase (described in more detail under Chronic Myeloid Leukemia). In B-ALL, the BCR-ABL protein is usually 190 kDa in size and has stronger tyrosine kinase activity than the form of BCR-ABL that is found in chronic myeloid leukemia, in which a BCR-ABL protein of 210 kDa in size is usually seen. Treatment of t(9;22)-positive ALLs with BCR-ABL kinase inhibitors in combination with conventional chemotherapy is highly effective and has greatly improved the outcome for this molecular subtype of B-ALL in children and adults. Of interest, cryptic rearrangements involving genes encoding tyrosine kinases other than ABL also have been described in B-ALL, particularly in adults, and these too may be therapeutic targets. The outlook for adults with ALL lacking "targetable" molecular lesions remains more guarded, in part because of differences in the molecular pathogenesis of adult and childhood ALL, and also because older adults cannot tolerate the intensive chemotherapy regimens that are curative in children. Dramatic responses in B-ALL have been achieved with chimeric antigen receptor T cells directed against the B-cell antigen CD19 (Chapter 7), but at high cost and with associated toxicities that have sometimes proved fatal.

KEY CONCEPTS

ACUTE LYMPHOBLASTIC LEUKEMIA/ LYMPHOBLASTIC LYMPHOMA

- Most common type of cancer in children; may be derived from either precursor B or T cells.
- Highly aggressive tumors manifest with signs and symptoms of bone marrow failure or as rapidly growing masses.
- Tumor cells contain genetic lesions that block differentiation, leading to the accumulation of immature, nonfunctional blasts.
- A subset of tumors contains activating mutations in tyrosine kinases (e.g., BCR-ABL) that are important targets of therapy.

Peripheral B-Cell Neoplasms

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL) differ only in the degree of peripheral blood lymphocytosis. Most affected patients have sufficient lymphocytosis to fulfill the diagnostic requirement for CLL (absolute lymphocyte count >5000/mm^3). **CLL is the most common leukemia of adults in the Western world.** There are about 15,000 new cases of CLL each year in the United States. The median age at diagnosis is 60 years, and there is a 2:1 male predominance. In contrast, SLL constitutes only 4% of NHLs. CLL/SLL is much less common in Japan and other Asian countries than in the West.

Pathogenesis

Unlike most other lymphoid malignancies, chromosomal translocations are rare in CLL/SLL. The most common genetic anomalies are deletions of 13q14.3, 11q, and 17p and trisomy 12q. Molecular characterization of the region deleted on chromosome 13 has implicated two microRNAs, miR-15a and miR-16-1, tumor suppressor genes. Loss of these mIRs is believed to result in overexpression of the anti-apoptotic protein BCL2, which is uniformly observed in CLL/SLL. DNA sequencing has revealed that the Ig genes of some CLL/SLL are somatically hypermutated, whereas others are not, suggesting that the cell of origin may be either a post–germinal center memory B cell or a naive B cell. For unclear reasons, tumors with unmutated Ig segments (those putatively of naive B-cell origin) pursue a more aggressive course. Deep sequencing of CLL genomes has also revealed gain-of-function mutations involving the NOTCH1 receptor in 10% to 18% of tumors, as well as frequent mutations in genes that regulate RNA splicing.

The growth of CLL/SLL cells is largely confined to proliferation centers (described later), where tumor cells receive critical cues from the microenvironment. Stromal cells in proliferation centers express a variety of factors that stimulate the activity of the transcription factors nuclear factor kappa B (NF-κB), which promotes cell survival, and MYC, which promotes cell growth. Other critical signals are generated by the B-cell receptor (membrane bound Ig), which triggers a signaling pathway that includes Bruton tyrosine kinase (BTK). The importance of BTK in B cells is emphasized by congenital X-linked agammaglobulinemia (Chapter 6), a failure of B-cell development that is caused by loss-of-function mutations in the *BTK* gene. Notably, BTK inhibitors produce sustained therapeutic responses in a high fraction of CLL patients, indicating that CLL cells depend on B-cell receptor signaling and BTK activity for their growth and survival.

MORPHOLOGY

Lymph nodes are diffusely effaced by predominantly small lymphocytes 6 to 12 μm in diameter with round to slightly irregular nuclei, condensed chromatin, and scant cytoplasm (Fig. 13.7). Admixed are variable numbers of larger activated lymphocytes that often gather in loose aggregates referred to as **proliferation centers** that contain mitotically active cells. When present, **proliferation centers are pathognomonic for CLL/SLL.** The blood contains variable numbers of small round lymphocytes with scant cytoplasm (Fig. 13.8). Some of these cells are usually disrupted in the process of making smears, producing so-called **smudge cells.** In almost all cases, the bone marrow, spleen, and liver (Fig. 13.9) also are involved, albeit to widely varying degrees.

Immunophenotype. CLL/SLL has a distinctive immunophenotype. The tumor cells express the pan B-cell markers CD19 and CD20, as well as CD23 and CD5, the latter a marker that is found on a small subset of normal B cells. Low-level expression of surface Ig (usually IgM or IgM and IgD) is also typical, as is high-level expression of BCL2.

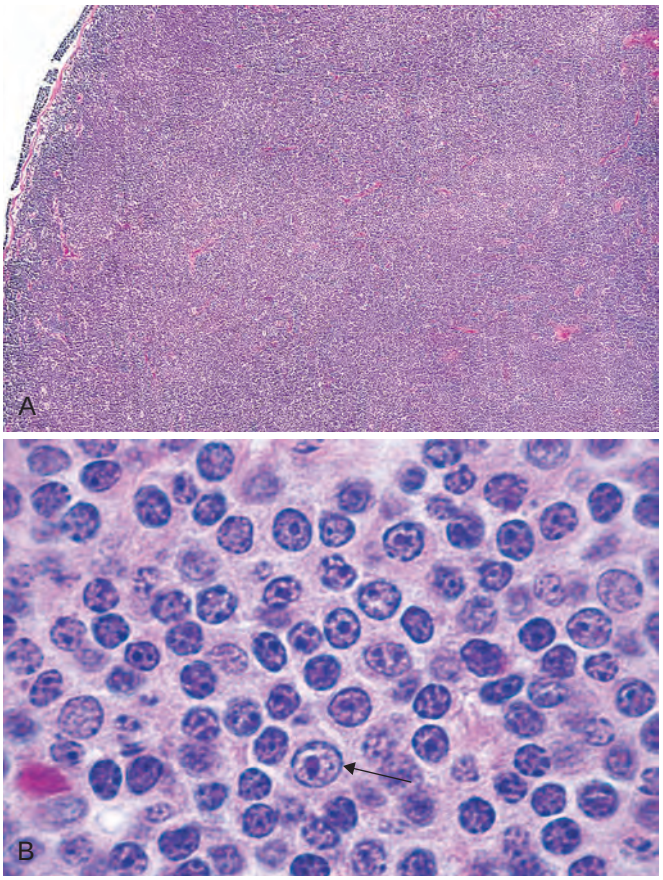

Figure 13.7 Small lymphocytic lymphoma/chronic lymphocytic leukemia (lymph node). (A) Low-power view shows diffuse effacement of nodal architecture. (B) At high power the majority of the tumor cells are small round lymphocytes. A prolymphocyte, a larger cell with a centrally placed nucleolus, is also present in this field *(arrow)*. (A, Courtesy Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

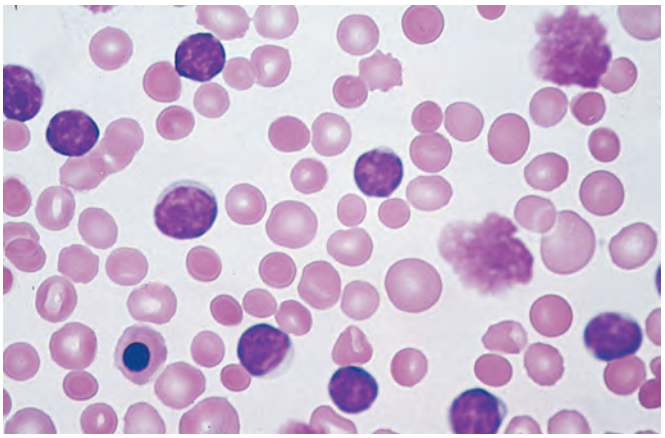

Figure 13.8 Chronic lymphocytic leukemia. This peripheral blood smear is flooded with small lymphocytes with condensed chromatin and scant cytoplasm. A characteristic finding is the presence of disrupted tumor cells (smudge cells), two of which are present in this smear. A coexistent autoimmune hemolytic anemia (Chapter 14) explains the presence of spherocytes (hyperchromatic, round erythrocytes). A nucleated erythroid cell is present in the lower left-hand corner of the field. In this setting, circulating nucleated red cells could stem from premature release of progenitors in the face of severe anemia, marrow infiltration by tumor (leukoerythroblastosis), or both.

Clinical Features

Patients are often asymptomatic at diagnosis. When symptoms appear, they are nonspecific and include easy fatigability, weight loss, and anorexia. Generalized lymphadenopathy and hepatosplenomegaly are present in 50% to 60% of symptomatic patients. The leukocyte count is highly variable; leukopenia can be seen in individuals with SLL and marrow involvement, while counts in excess of 200,000/mm^3 are sometimes seen in CLL patients with heavy tumor burdens. A small monoclonal Ig "spike" is present in the blood of some patients. At the other end of the spectrum are asymptomatic patients with monoclonal B cells in their peripheral blood that number too few to merit the diagnosis of CLL. This condition, referred to a monoclonal lymphocytosis of uncertain significance, is considered to be a precursor lesion and progresses to symptomatic CLL at a rate of 1% per year.

CLL/SLL disrupts normal immune function through uncertain mechanisms. Hypogammaglobulinemia is common and contributes to an increased susceptibility to infection, particularly those caused by bacteria. Conversely, 10% to 15% of patients develop hemolytic anemia or thrombocytopenia due to autoantibodies made by nonneoplastic B cells.

The course and prognosis are extremely variable and depend primarily on the clinical stage. Overall median survival is 4 to 6 years but is more than 10 years in individuals with minimal tumor burden at diagnosis. Other variables that correlate with a worse outcome include (1) the presence of deletions of 11q and 17p (the latter involving *TP53*), (2) a lack of somatic hypermutation, (3) the expression of ZAP-70, a protein that augments signals produced by the Ig receptor, and (4) the presence of *NOTCH1* mutations. Symptomatic patients are generally treated with "gentle" chemotherapy and immunotherapy with antibodies against proteins found on the surface of CLL/SLL cells, particularly CD20. Newly available, highly active targeted therapies include BTK inhibitors and BCL2 inhibitors; their impact on the disease course is still being determined.

Another factor that impacts patient survival is the tendency of CLL/SLL to transform to a more aggressive tumor. Most commonly this takes the form of a transformation to diffuse large B-cell lymphoma (DLBCL), so-called *Richter syndrome* (approximately 5% to 10% of patients). Richter syndrome is often heralded by the development of a rapidly enlarging mass within a lymph node or the spleen. It is often associated with acquisition of new abnormalities involving *TP53* or *MYC* and is an ominous event, with most patients surviving less than 1 year.

Follicular Lymphoma

Follicular lymphoma is the most common form of indolent NHL in the United States, trailing only diffuse large B-cell lymphoma (discussed later) in frequency among lymphomas. It affects 15,000 to 20,000 individuals per year. It usually presents in middle age and afflicts males and females equally. It is less common in Europe and rare in Asian populations.

Pathogenesis

Follicular lymphoma is strongly associated with chromosomal translocations involving *BCL2*. Its hallmark is a (14;18) translocation that juxtaposes the *IGH* locus on chromosome 14 and the *BCL2* locus on chromosome 18. The t(14;18) is seen in up to 90% of follicular lymphomas and leads to overexpression of BCL2 (see Fig. 13.12). BCL2 antagonizes apoptosis (Chapters 2 and 7) and promotes the survival of follicular lymphoma cells. Notably, while normal germinal centers contain numerous B cells undergoing apoptosis, follicular lymphoma is characteristically devoid of apoptotic cells. Deep sequencing of follicular lymphoma genomes have identified mutations in the *KMT2D* gene in about 90% of cases as well. *KMT2D* encodes a histone methyltransferase, suggesting that epigenetic abnormalities such as changes in the patterns of histone marks have an important role in this neoplasm.

Particularly early in the disease, follicular lymphoma cells growing in lymph nodes are found within a network of reactive follicular dendritic cells admixed with macrophages and T cells. Expression profiling studies have shown that differences in the genes expressed by these stromal cells are predictive of outcome, implying that the response of follicular lymphoma cells to therapy is influenced by the surrounding microenvironment.

MORPHOLOGY

In most cases, a nodular or nodular and diffuse growth pattern is observed in involved lymph nodes (Fig. 13.10A). Two principal cell types are present in varying proportions: (1) small cells with irregular or cleaved nuclear contours and scant cytoplasm, referred to as **centrocytes** (small cleaved cells), and (2) larger cells with open nuclear chromatin, several nucleoli, and modest amounts of cytoplasm, referred to as **centroblasts** (Fig. 13.10B). In most follicular lymphomas, centrocytes are in the majority. Peripheral blood involvement sufficient to produce lymphocytosis (usually <20,000 cells/mm^3) is seen in about 10% of cases. Bone marrow involvement occurs in 85% of cases and characteristically takes the form of paratrabecular lymphoid aggregates. The splenic white pulp (Fig. 13.11) and hepatic portal triads are also frequently involved.

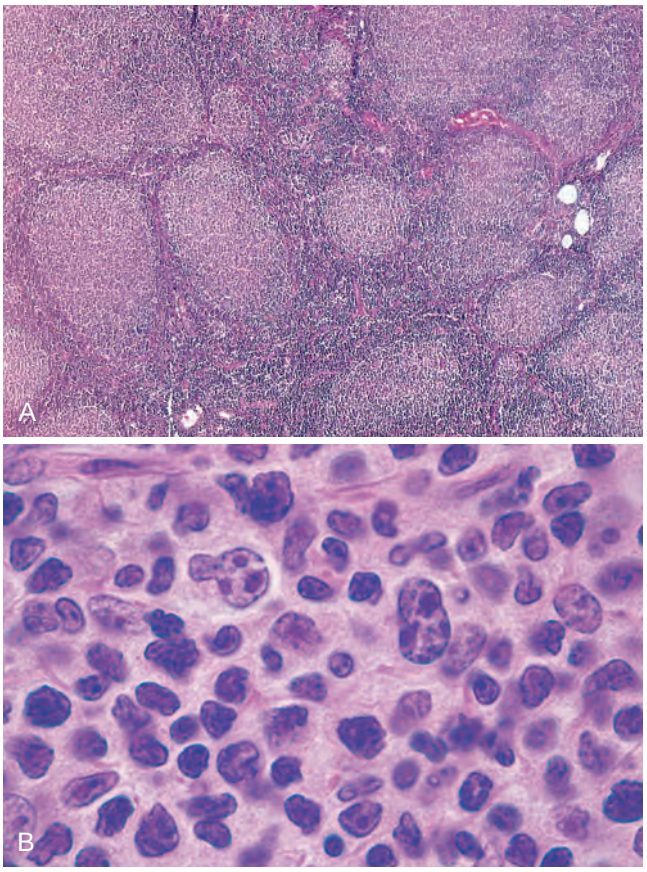

Figure 13.10 Follicular lymphoma (lymph node). (A) Nodular aggregates of lymphoma cells are present throughout lymph node. (B) At high magnification, small lymphoid cells with condensed chromatin and irregular or cleaved nuclear outlines (centrocytes) are mixed with a population of larger cells with nucleoli (centroblasts). (A, Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

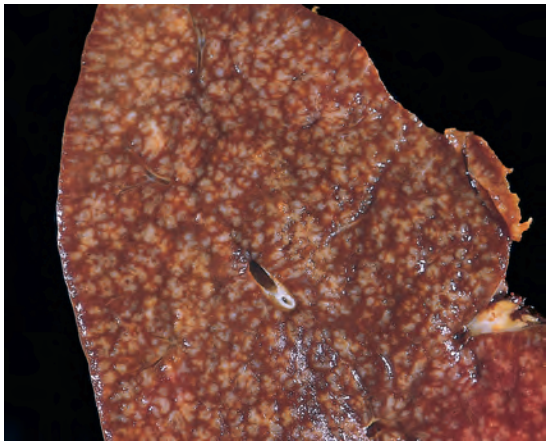

Figure 13.11 Follicular lymphoma (spleen). Prominent nodules represent white pulp follicles expanded by follicular lymphoma cells. Other indolent B-cell lymphomas (small lymphocytic lymphoma, mantle cell lymphoma, marginal zone lymphoma) can produce an identical pattern of involvement. (Courtesy Dr. Jeffrey Jorgenson, Department of Hematopathology, MD Anderson Cancer Center, Houston, Tex.)

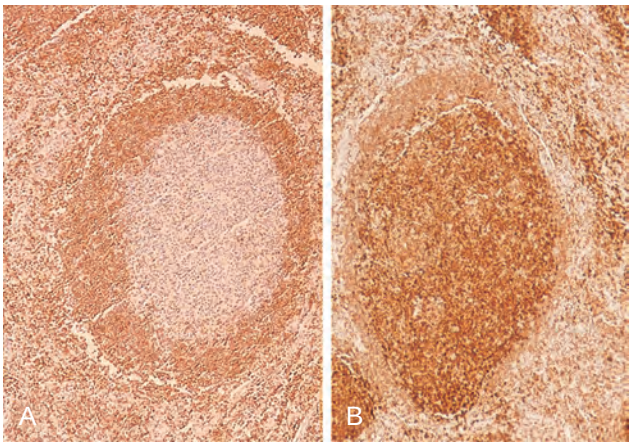

Figure 13.12 BCL2 expression in reactive and neoplastic follicles. BCL2 protein was detected by using an immunohistochemical technique that produces a brown stain. In reactive follicles (A), BCL2 is present in mantle zone cells but not follicular-center B cells, whereas follicular lymphoma cells (B) show strong BCL2 staining. (Courtesy Dr. Jeffrey Jorgenson, Department of Hematopathology, MD Anderson Cancer Center, Houston, Tex.)

Immunophenotype. The neoplastic cells closely resemble normal germinal center B cells, expressing CD19, CD20, CD10, surface Ig, and BCL6. Unlike CLL/SLL and mantle cell lymphoma, CD5 is not expressed. BCL2 is expressed in more than 90% of cases, in distinction to normal follicular center B cells, which are BCL2-negative (Fig. 13.12).

Clinical Features

Follicular lymphoma tends to present with painless, generalized lymphadenopathy. Involvement of extranodal sites, such as the gastrointestinal tract, central nervous system, or testis, is relatively uncommon. Although incurable, it usually follows an indolent waxing and waning course. Survival (median, 7 to 9 years) is not improved by aggressive therapy; hence the usual approach is to palliate patients with low-dose chemotherapy or immunotherapy (e.g., anti-CD20 antibody) when they become symptomatic. Like CLL, it also is responsive to inhibitors of B-cell receptor signaling (e.g., BTK inhibitors) and inhibitors of BCL2.

Histologic transformation occurs in 30% to 50% of follicular lymphomas, most commonly to DLBCL. These transformation events are frequently associated with aberrations that increase the expression of *MYC,* which you will recall drives Warburg metabolism and rapid cell growth. Follicular lymphomas show evidence of ongoing somatic hypermutation, which may promote transformation by causing point mutations or chromosomal aberrations. The median survival is less than 1 year after transformation.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) is the most common form of NHL. Each year in the United States there are about 25,000 new cases. There is a slight male predominance. The median patient age is about 60 years, but DLBCL also occurs in young adults and children.

Pathogenesis

Genetic, gene expression profiling, and immunohistochemical studies indicate that DLBCL is molecularly heterogeneous. One frequent pathogenic event is dysregulation of BCL6, a DNA-binding zinc-finger transcriptional repressor that is required for the formation of normal germinal centers. About 30% of DLBCLs contain various translocations that have in common a breakpoint in *BCL6* at chromosome 3q27. Acquired mutations in *BCL6* promoter sequences that abrogate *BCL6* autoregulation (an important negative-regulatory mechanism) are seen even more frequently. It is hypothesized that both types of lesions are inadvertent by-products of somatic hypermutation that result in overexpression of *BCL6,* which has several important consequences. BCL6 represses the expression of factors that normally serve to promote germinal center B-cell differentiation, growth arrest, and apoptosis, and each of these effects is believed to contribute to the development of DLBCL. Mutations similar to those found in *BCL6* are also seen in multiple other oncogenes, including *MYC,* suggesting that somatic hypermutation in DLBCL cells is "mistargeted" to a wide variety of loci.

Another 10% to 20% of tumors are associated with the t(14;18) (discussed earlier under Follicular Lymphoma), which leads to the overexpression of the antiapoptotic protein BCL2. Tumors with *BCL2* rearrangements usually lack *BCL6* rearrangements, suggesting that these rearrangements define two distinct molecular classes of DLBCL. Some tumors with *BCL2* rearrangements may arise from unrecognized underlying follicular lymphomas, which frequently transform to DLBCL. Roughly 5% of DLBCLs are associated with translocations involving *MYC;* these tumors may have a distinctive biology (discussed later under Burkitt lymphoma). Finally, sequencing of DLBCL genomes has identified frequent mutations in genes encoding histone acetyltransferases such as p300 and CREBP, proteins that regulate gene expression by modifying histones and altering chromatin structure.

MORPHOLOGY

The common features are a relatively **large cell size** (usually four to five times the diameter of a small lymphocyte) and a **diffuse pattern of growth** (Fig. 13.13). Other morphologic features show substantial variation. Most commonly, the tumor

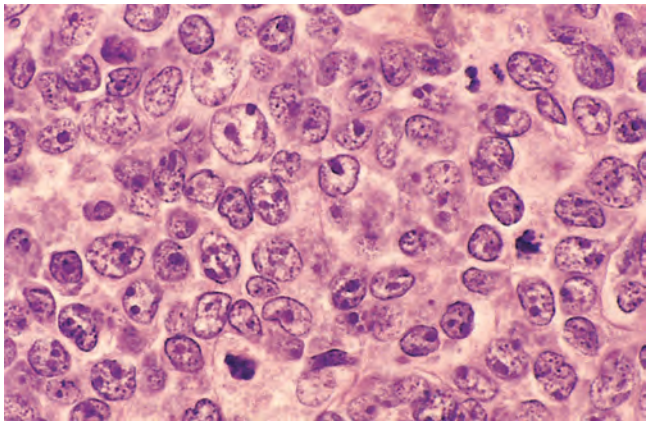

Figure 13.13 Diffuse large B-cell lymphoma. Tumor cells have large nuclei, open chromatin, and prominent nucleoli. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

cells have a round or oval nucleus that appears vesicular due to margination of chromatin to the nuclear membrane, but large multilobated or irregular nuclei are prominent in some cases. Nucleoli may be two to three in number and located adjacent to the nuclear membrane or single and centrally placed. The cytoplasm is usually moderately abundant and may be pale or basophilic. More anaplastic tumors may contain multinucleated cells with large inclusion-like nucleoli that resemble Reed-Sternberg cells (the malignant cell of Hodgkin lymphoma).

Immunophenotype. These mature B-cell tumors express CD19 and CD20 and show variable expression of germinal center B-cell markers such as CD10 and BCL6. Most have surface Ig. High-level expression of both MYC and BCL2 proteins is seen in some cases and may predict more aggressive behavior.

Special Subtypes. Several subtypes of DLBCL are sufficiently distinctive to merit brief discussion.

- *Immunodeficiency-associated large B-cell lymphoma* occurs in the setting of T-cell immunodeficiency (e.g., in advanced HIV infection and in recipients of organ or HSC transplants). The neoplastic B cells are usually infected with EBV, which plays a critical pathogenic role. Restoration of T-cell immunity may lead to regression of these proliferations.
- *Primary effusion lymphoma* presents as a malignant pleural or ascitic effusion, mostly in patients with advanced HIV infection or in older adults. The tumor cells are often anaplastic in appearance and typically fail to express surface B- or T-cell markers, but have clonal *IGH* gene rearrangements. In all cases the tumor cells are infected with HHV-8, which appears to have a causal role.

Clinical Features

DLBCL typically presents as a rapidly enlarging mass at a nodal or extranodal site. It can arise virtually anywhere in the body. Waldeyer ring, the oropharyngeal lymphoid tissue that includes the tonsils and adenoids, is involved commonly. Primary or secondary involvement of the liver and spleen may take the form of large destructive masses (Fig. 13.14).

Figure 13.14 Diffuse large B-cell lymphoma involving the spleen. The isolated large mass is typical. In contrast, indolent B-cell lymphomas usually produce multifocal expansion of white pulp (see Fig. 13.11). (Courtesy Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, Mass.)

Extranodal sites include the gastrointestinal tract, skin, bone, brain, and other tissues. Bone marrow involvement is relatively uncommon and usually occurs late in the course. Rarely, a leukemic picture emerges.

DLBCLs are aggressive tumors that are rapidly fatal without treatment. With intensive combination chemotherapy, 60% to 80% of patients achieve a complete remission, and 40% to 50% are cured. Adjuvant therapy with anti-CD20 antibody improves both the initial response and the overall outcome. Individuals with limited disease fare better than those with widespread disease or bulky tumor masses. Expression profiling has identified several distinct molecular subtypes, including one resembling germinal center B cells and a second resembling activated post–germinal center B cells, each with differing clinical outcomes. DLBCLs with *MYC* translocations have a worse prognosis than those without and may be better treated with chemotherapy regimens that are now standard for Burkitt lymphoma. CAR T cells directed against the B-cell antigen CD19 are now available for the treatment of patients with relapsed refractory DLBCL.

Burkitt Lymphoma

Within the category of Burkitt lymphoma fall (1) African (endemic) Burkitt lymphoma, (2) sporadic (nonendemic) Burkitt lymphoma, and (3) a subset of aggressive lymphomas occurring in individuals infected with HIV. Burkitt lymphomas occurring in these three settings are histologically identical but have distinct clinical, genotypic, and virologic characteristics.

Pathogenesis

All forms of Burkitt lymphoma are associated with translocations of the *MYC* gene on chromosome 8 that lead to increased MYC protein levels. MYC is a master transcriptional regulator that increases the expression of genes that are required for aerobic glycolysis, the so-called Warburg effect (Chapter 7). When nutrients such as glucose and glutamine are available, Warburg metabolism allows cells to biosynthesize all the building blocks—nucleotides, lipids, proteins—that are needed for growth and cell division. In line with the importance of MYC in regulating proliferation, Burkitt lymphoma is among the fastest-growing human tumors. The *MYC* translocation partner is usually the *IGH* locus [t(8;14)], but may also be the Ig κ [t(2;8)] or λ [t(8;22)] light chain loci. The breakpoints in the *IGH* locus in sporadic Burkitt lymphoma are usually found in the class switch regions, whereas the breakpoints in endemic Burkitt lymphoma tend to lie within more 5′ V(D)J sequences. The basis for this subtle molecular distinction is not known, but both types of translocations can be induced in germinal center B cells by AID, a specialized DNA-modifying enzyme required for both Ig class switching and somatic hypermutation (see earlier). The net effect of these translocations is similar; the *MYC* coding sequence is repositioned adjacent to strong Ig enhancer elements, which drive increased *MYC* expression. In addition, the translocated *MYC* allele often harbors point mutations that stabilize MYC protein and further increase its activity.

Sequencing of the genomes of Burkitt lymphoma cells has revealed that most tumors have mutations that increase the activity of the transcription factor TCF3 (also known as

E2A), an important regulator of gene expression in germinal center B cells. It is believed that TCF3 drives the expression of a set of genes, including cyclin D, that collaborate with MYC to enable the very rapid growth that characterizes Burkitt lymphoma.

Essentially all endemic Burkitt lymphomas are latently infected with EBV, which also is present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases. The configuration of the EBV DNA is identical in all tumor cells within individual cases, indicating that infection precedes transformation. Although this places EBV at the "scene of the crime," its precise role in the genesis of Burkitt lymphoma remains speculative (Chapter 7).

MORPHOLOGY

Involved tissues are effaced by a diffuse infiltrate of intermediate-sized lymphoid cells 10 to 25 μm in diameter with round or oval nuclei, coarse chromatin, several nucleoli, and a moderate amount of cytoplasm (Fig. 13.15). **The tumor exhibits a high mitotic index and contains numerous apoptotic cells,** the nuclear remnants of which are phagocytosed by interspersed benign macrophages. These phagocytes have abundant clear cytoplasm, creating a characteristic **"starry sky" pattern.** When the bone marrow is involved, aspirates reveal tumor cells with slightly clumped nuclear chromatin, two to five distinct nucleoli, and **royal blue cytoplasm containing clear cytoplasmic vacuoles.**

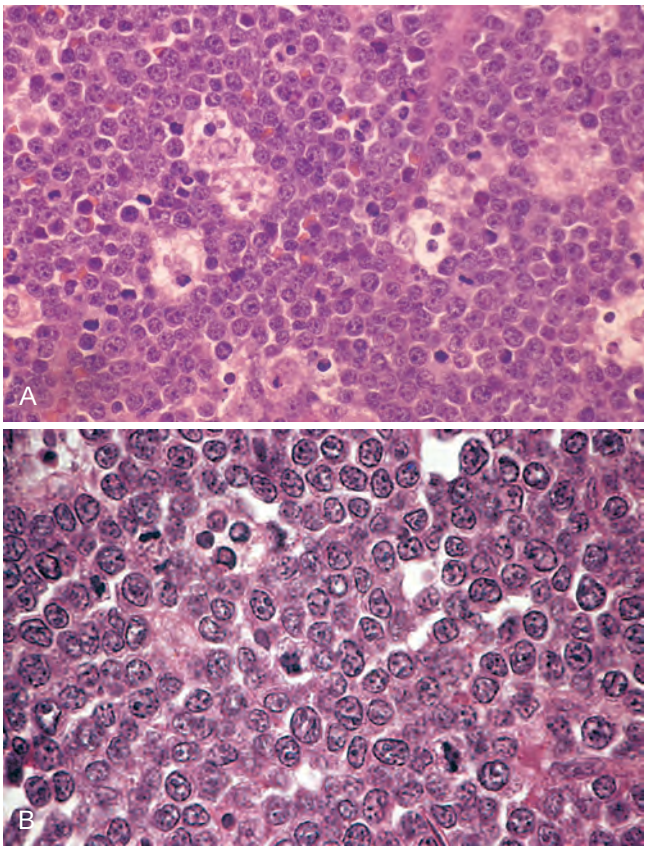

Figure 13.15 Burkitt lymphoma. (A) At low power, numerous pale tingible body macrophages are evident, producing a "starry sky" appearance. (B) At high power, tumor cells have multiple small nucleoli and high mitotic index. The lack of significant variation in nuclear shape and size lends a monotonous appearance. (B, Courtesy Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Immunophenotype. These are tumors of mature B cells that express surface IgM, CD19, CD20, CD10, and BCL6, a phenotype consistent with a germinal center B-cell origin. Unlike most other tumors of germinal center origin, Burkitt lymphoma almost always fails to express the antiapoptotic protein BCL2.

Clinical Features

Both endemic and sporadic Burkitt lymphomas are found mainly in children or young adults; overall, Burkitt lymphoma accounts for about 30% of childhood NHLs in the United States. Most tumors manifest at extranodal sites. Endemic Burkitt lymphoma often presents as a mass involving the mandible and shows an unusual predilection for involvement of abdominal viscera, particularly the kidneys, ovaries, and adrenal glands. In contrast, sporadic Burkitt lymphoma most often appears as a mass involving the ileocecum and peritoneum. Involvement of the bone marrow and peripheral blood is uncommon, especially in endemic cases.

Burkitt lymphoma is very aggressive but responds well to intensive chemotherapy. Most children and young adults can be cured. The outcome is more guarded in older adults.

Mantle Cell Lymphoma

Mantle cell lymphoma is an uncommon lymphoid neoplasm that makes up about 2.5% of NHL in the United States and 7% to 9% of NHL in Europe. It usually presents in the fifth to sixth decades of life and shows a male predominance. As the name implies, the tumor cells closely resemble the normal mantle zone B cells that surround germinal centers.

Pathogenesis

Virtually all mantle cell lymphomas have an (11;14) translocation involving the *IGH* locus on chromosome 14 and the cyclin D1 locus on chromosome 11 that leads to overexpression of cyclin D1. The resulting up-regulation of cyclin D1 promotes G_1- to S-phase progression during the cell cycle, as was described in Chapter 7.

MORPHOLOGY

At diagnosis the majority of patients have generalized lymphadenopathy, and 20% to 40% have peripheral blood involvement. Frequent sites of extranodal involvement include the bone marrow, spleen, liver, and gut. Occasionally, mucosal involvement of the small bowel or colon produces polyp-like lesions (lymphomatoid polyposis); of all forms of NHL, mantle cell lymphoma is most likely to spread in this fashion.

Nodal tumor cells may surround reactive germinal centers to produce a nodular appearance at low power or diffusely efface the node. **Typically, the proliferation consists of a homogeneous population of small lymphocytes with irregular**

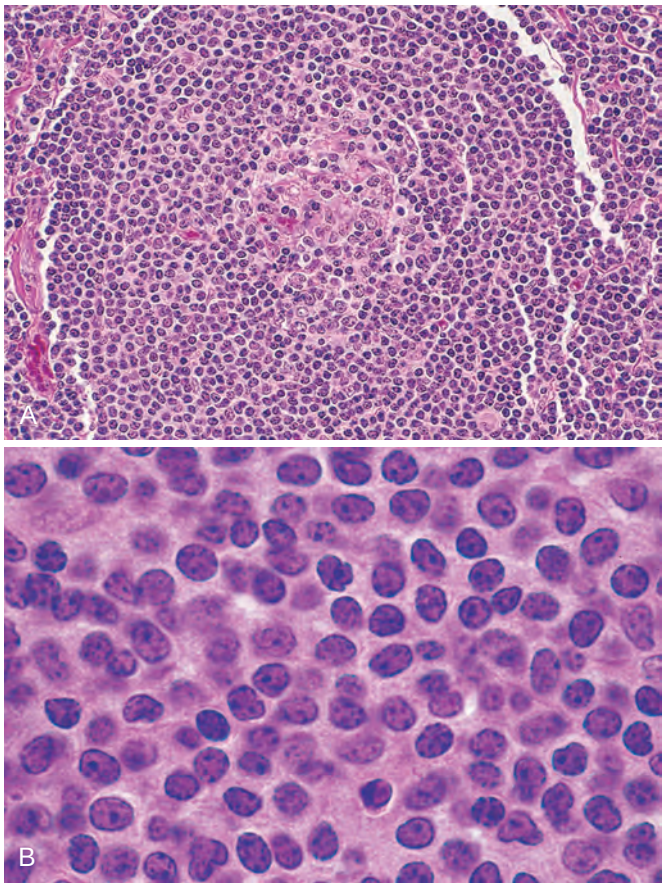

Figure 13.16 Mantle cell lymphoma. (A) At low power, neoplastic lymphoid cells surround a small, atrophic germinal center, producing a mantle zone pattern of growth. (B) High-power view shows a homogeneous population of small lymphoid cells with somewhat irregular nuclear outlines, condensed chromatin, and scant cytoplasm. Large cells resembling prolymphocytes (seen in chronic lymphocytic leukemia) and centroblasts (seen in follicular lymphoma) are absent.

to occasionally deeply clefted (cleaved) nuclear contours (Fig. 13.16). Large cells resembling centroblasts and proliferation centers are absent, distinguishing mantle cell lymphoma from follicular lymphoma and CLL/SLL, respectively. In most cases the nuclear chromatin is condensed, nucleoli are inconspicuous, and the cytoplasm is scant. Occasionally, tumors composed of intermediate-sized cells with more open chromatin and a brisk mitotic rate are observed; immunophenotyping is necessary to distinguish these "blastoid" variants from ALL.

Immunophenotype. Mantle cell lymphomas express high levels of cyclin D1, CD19, and CD20 and moderately high levels of surface Ig (usually IgM and IgD with κ or λ light chain). This tumor is usually CD5+ and CD23–, which help to distinguish it from CLL/SLL. The *IGH* genes lack somatic hypermutation, supporting an origin from a naive B cell.

Clinical Features

The most common presentation is painless lymphadenopathy. Symptoms related to involvement of the spleen (present in approximately 50% of cases) and gut also are common. Mantle cell lymphoma is moderately aggressive and incurable; the median survival is 8 to 10 years. The blastoid variant, a "proliferative" expression profiling signature, and *TP53* mutations are associated with shorter survivals.

Marginal Zone Lymphomas

The category of marginal zone lymphomas encompasses a heterogeneous group of B-cell tumors that arise within lymph nodes, spleen, or extranodal tissues. The extranodal tumors were initially recognized at mucosal sites and are often referred to as mucosa-associated lymphoid tumors (or MALTomas). In most cases, the tumor cells show evidence of somatic hypermutation and are considered to be of memory B-cell origin.

Although all marginal zone lymphomas share certain features, those occurring at extranodal sites deserve special attention because of their unusual pathogenesis and three exceptional characteristics.

- They often arise within tissues involved by chronic inflammatory disorders of autoimmune or infectious etiology; examples include the salivary gland in Sjögren disease, the thyroid gland in Hashimoto thyroiditis, and the stomach in *Helicobacter* gastritis.
- They remain localized for prolonged periods, spreading systemically only late in their course.
- They may regress if the inciting agent (e.g., *H. pylori*) is eradicated.

These characteristics suggest that **extranodal marginal zone lymphomas arising in chronically inflamed tissues lie on a continuum between reactive lymphoid hyperplasia and full-blown lymphoma.** The disease begins as a polyclonal immune reaction. With the acquisition of unknown initiating mutations, a B-cell clone emerges that still depends on antigen-stimulated T-helper cells for signals that drive growth and survival. At this stage, withdrawal of the responsible antigen causes tumor involution. A clinically relevant example is found in gastric MALToma, in which antibiotic therapy directed against *H. pylori* often leads to tumor regression (Chapter 17). With time, however, tumors may acquire additional mutations that render their growth and survival antigen-independent, such as (11;18), (14;18), or (1;14) chromosomal translocations, which are relatively specific for extranodal marginal zone lymphomas. All of these translocations up-regulate the expression and function of BCL10 or MALT1, protein components of a signaling complex that activates NF-κB and promotes the growth and survival of B cells. With further clonal evolution, spread to distant sites and transformation to DLBCL may occur. This theme of polyclonal-to-monoclonal transition during lymphomagenesis is also applicable to the pathogenesis of EBV-induced lymphoma and is discussed more fully in Chapter 7.

Hairy Cell Leukemia

This rare but distinctive B-cell neoplasm constitutes about 2% of all leukemias. It is predominantly a disease of middle-aged white males, with a median age of 55 and a male-to-female ratio of 5:1.

Pathogenesis

Hairy cell leukemia is associated in more than 90% of cases with activating point mutations in the serine/threonine

kinase BRAF, which lies immediately downstream of RAS in the MAPK signaling cascade (Chapter 7). The specific mutation, a valine to glutamate substitution at residue 600, is also found at high frequencies in many other neoplasms, including melanoma and Langerhans cell histiocytosis (discussed later).

MORPHOLOGY

Hairy cell leukemia derives its picturesque name from the appearance of the leukemic cells, which have **fine hair-like projections** that are best recognized under the phase-contrast microscope (Fig. 13.17). On routine peripheral blood smears, hairy cells have round, oblong, or reniform nuclei and moderate amounts of pale blue cytoplasm with thread-like or bleb-like extensions. The number of circulating cells is highly variable. The marrow is involved by a diffuse interstitial infiltrate of cells with oblong or reniform nuclei, condensed chromatin, and pale cytoplasm. Because these cells are enmeshed in an extracellular matrix composed of reticulin fibrils, they usually are inaspirable (a clinical difficulty referred to as a "dry tap") and are seen only in marrow biopsies. The splenic red pulp is usually heavily infiltrated, leading to obliteration of white pulp and a beefy red gross appearance. Hepatic portal triads are also involved frequently.

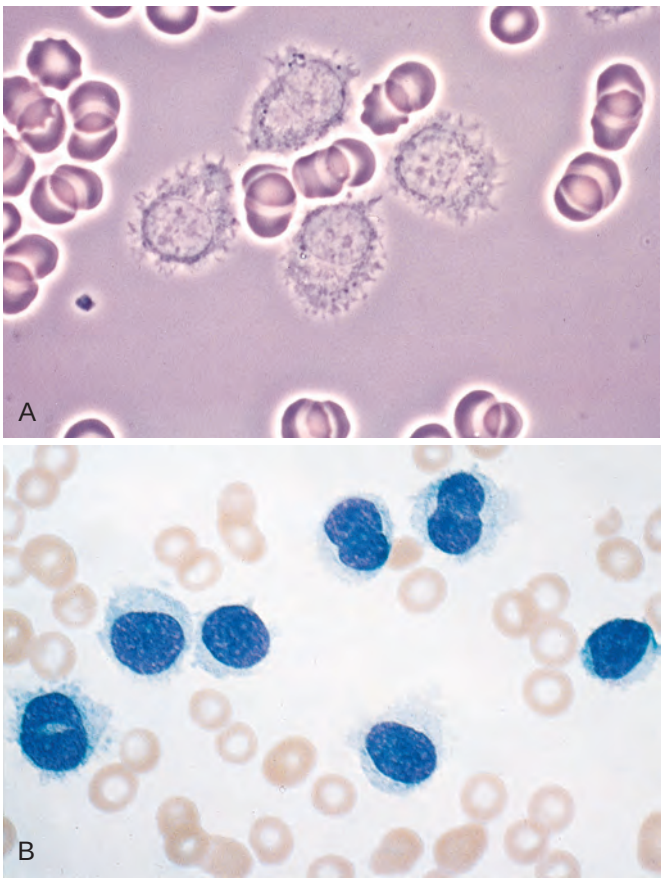

Figure 13.17 Hairy cell leukemia (peripheral blood smear). (A) Phase-contrast microscopy shows tumor cells with fine hairlike cytoplasmic projections. (B) In stained smears, these cells have round or folded nuclei and modest amounts of pale blue, agranular cytoplasm.

Immunophenotype. Hairy cell leukemias typically express the pan-B-cell markers CD19 and CD20; surface Ig (usually IgG); and certain relatively distinctive markers, such as CD11c, CD25, CD103, and annexin A1.

Clinical Features

Clinical manifestations result largely from infiltration of the bone marrow, liver, and spleen. Splenomegaly, often massive, is the most common and sometimes the only abnormal physical finding. Hepatomegaly is less common and not as marked; lymphadenopathy is rare. Pancytopenia resulting from marrow involvement and sequestration of cells in the enlarged spleen is seen in more than half the cases. About one-third of those affected present with infections. There is an increased incidence of atypical mycobacterial infections, possibly related to monocytopenia of uncertain origin, which is commonly seen in this disease.

Hairy cell leukemia follows an indolent course. For unclear reasons, it is exceptionally sensitive to "gentle" chemotherapeutic regimens, which produce long-lasting remissions. Tumors often relapse after 5 or more years, yet generally respond well when retreated with the same agents, a feature that is highly unusual among human cancers. BRAF inhibitors appear to produce excellent responses in tumors that have failed conventional chemotherapy. The overall prognosis is excellent.

KEY CONCEPTS

COMMON FORMS OF LYMPHOID LEUKEMIA AND LYMPHOMA

Small Lymphocytic Lymphoma/Chronic Lymphocytic Leukemia

- Most common leukemia of adults.
- Tumor of mature B cells that usually manifests with bone marrow and lymph node involvement.
- Indolent course, commonly associated with immune abnormalities, including an increased susceptibility to infection and autoimmune disorders.

Follicular Lymphoma

- Most common indolent lymphoma of adults.
- Tumor cells recapitulate the growth pattern of normal germinal center B cells; most cases are associated with a (14;18) translocation that results in overexpression of BCL2.

Diffuse Large B-Cell Lymphoma

- Most common lymphoma of adults.
- Heterogeneous group of mature B-cell tumors that shares a large cell morphology and aggressive clinical behavior.
- Rearrangements or mutations of *BCL6* gene are recognized associations; one-third carry a (14;18) translocation involving *BCL2* and may arise from follicular lymphomas; about 5% have translocations involving *MYC*.

Burkitt Lymphoma

- Very aggressive tumor of mature B cells that usually arises at extranodal sites.

- Strongly associated with translocations involving the *MYC* proto-oncogene.
- Tumor cells often are latently infected by EBV.

Mantle Cell Lymphoma

- Tumor of naive B cells that pursues a moderately aggressive course.
- Highly associated with translocations involving the cyclin D1 gene.

Marginal Zone Lymphoma

- Indolent tumors of antigen-primed B cells that arise at sites of chronic immune stimulation.
- Often remain localized for long periods of time.

Hairy Cell Leukemia

- Morphologically distinct, very indolent tumor of mature B cells that involves spleen and marrow.
- Highly associated with mutations in the BRAF serine/threonine kinase.

Peripheral T- and NK-Cell Neoplasms

These categories include a heterogeneous group of neoplasms having phenotypes resembling mature T cells or NK cells. Peripheral T-cell tumors make up about 5% to 10% of NHLs in the United States and Europe, while NK-cell tumors are rare. By contrast, for unknown reasons both T- and NK-cell tumors occur more frequently in the Far East. Only the most common diagnoses and those of particular pathogenetic interest will be discussed.

Peripheral T-Cell Lymphoma, Unspecified

Although the WHO classification includes a number of distinct peripheral T-cell neoplasms, many of these lymphomas are not easily categorized and are lumped into a "wastebasket" diagnosis, *peripheral T-cell lymphoma, unspecified*. As might be expected, no morphologic feature is pathognomonic, but certain findings are characteristic. These tumors efface lymph nodes diffusely and are typically composed of a pleomorphic mixture of variably sized malignant T cells (Fig. 13.18). There is often a prominent infiltrate of reactive cells, such as eosinophils and macrophages, probably attracted by tumor-derived cytokines. Brisk neoangiogenesis may also be seen.

By definition, all peripheral T-cell lymphomas are derived from mature T cells. They usually express CD2, CD3, CD5, and either αβ or γδ T-cell receptors. Some also express CD4 or CD8; such tumors are taken to be of helper or cytotoxic T-cell origin, respectively. However, many tumors have phenotypes that do not resemble any known normal T cell. In difficult cases where the differential diagnosis lies between lymphoma and a florid reactive process, DNA analysis is used to confirm the presence of clonal T-cell receptor gene rearrangements.

Most patients present with generalized lymphadenopathy, sometimes accompanied by eosinophilia, pruritus, fever, and weight loss. Although cures of peripheral T-cell lymphoma have been reported, these tumors have a significantly worse prognosis than comparably aggressive mature B-cell neoplasms (e.g., DLBCL).

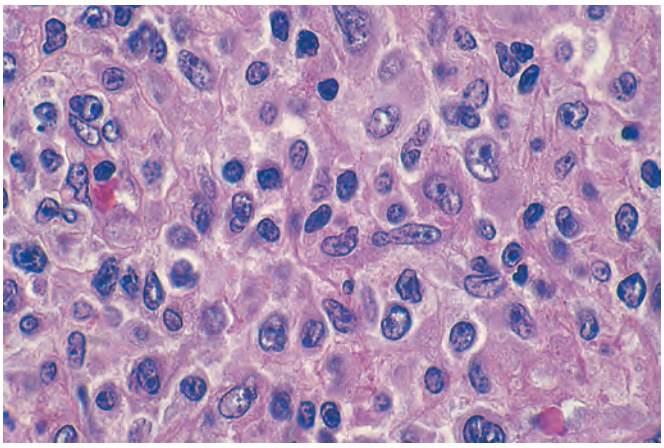

Figure 13.18 Peripheral T-cell lymphoma, unspecified (lymph node). A spectrum of small, intermediate, and large lymphoid cells, many with irregular nuclear contours, is visible.

Anaplastic Large-Cell Lymphoma (ALK Positive)

This uncommon entity is defined by the presence of rearrangements in the *ALK* gene on chromosome 2p23. These rearrangements break the *ALK* locus and lead to the formation of chimeric genes encoding ALK fusion proteins, constitutively active tyrosine kinases that trigger the RAS and JAK/STAT signaling pathways.

As the name implies, this tumor is typically composed of large anaplastic cells, some containing horseshoe-shaped nuclei and voluminous cytoplasm (so-called *hallmark cells*) (Fig. 13.19A). The tumor cells often cluster about venules and infiltrate lymphoid sinuses, mimicking the appearance of metastatic carcinoma. ALK is not expressed in normal lymphocytes; thus the detection of ALK protein in tumor cells (Fig. 13.19B) is a reliable indicator of an *ALK* gene rearrangement.

T-cell lymphomas with *ALK* rearrangements tend to occur in children or young adults, frequently involve soft tissues, and carry a very good prognosis (unlike other aggressive peripheral T-cell neoplasms). The cure rate with chemotherapy is 75% to 80%. Inhibitors of ALK have been developed and have produced excellent responses in some tumors that have failed to respond to conventional chemotherapy.

T-cell lymphomas that are morphologically similar but lack ALK rearrangements (termed ALK– anaplastic large cell lymphoma) tend to occur in older adults and have a substantially worse prognosis. Both ALK+ and ALK– tumors usually express CD30, a member of the TNF receptor family. Notably, recombinant antibodies linked to toxins that recognize CD30 have significant antitumor activity against CD30+ T-cell lymphomas and Hodgkin lymphoma, another CD30+ tumor (described later).

Adult T-Cell Leukemia/Lymphoma

This neoplasm of CD4+ T cells is observed only in adults infected by HTLV-1 (Chapter 7). It occurs mainly in regions where HTLV-1 is endemic, namely southern Japan, West Africa, and the Caribbean basin. Common findings include skin lesions, generalized lymphadenopathy, hepatosplenomegaly, peripheral blood lymphocytosis, and hypercalcemia.

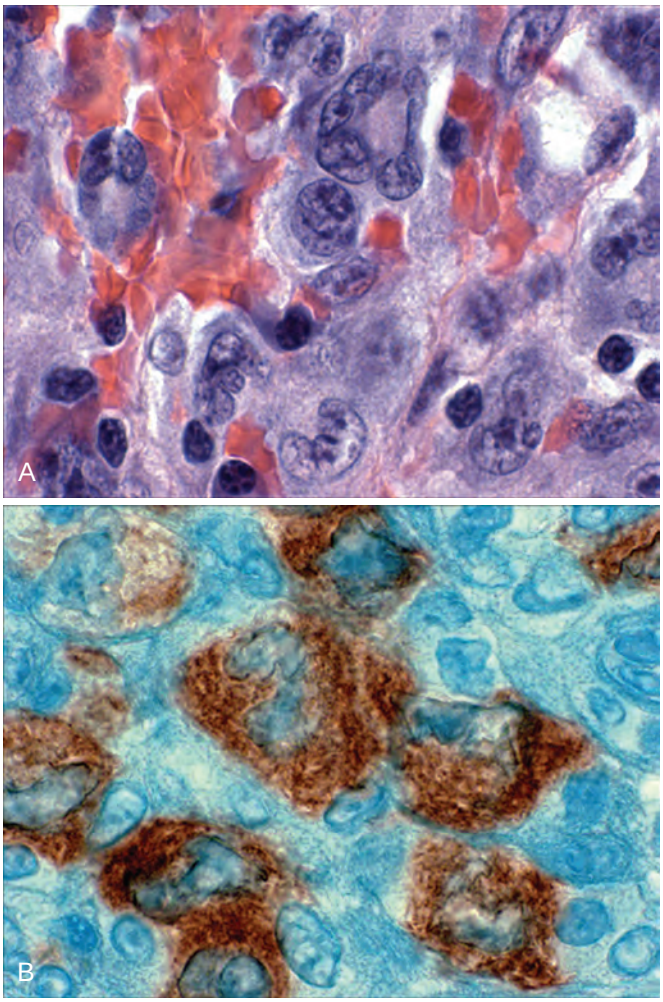

Figure 13.19 Anaplastic large-cell lymphoma. (A) Several hallmark cells with horseshoe-like or embryoid nuclei and abundant cytoplasm lie near the center of the field. (B) Immunohistochemical stain demonstrating the presence of ALK fusion protein. (Courtesy Dr. Jeffery Kutok, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

In addition to adult T-cell leukemia/lymphoma, HTLV-1 infection also may give rise to a progressive demyelinating disease of the central nervous system and spinal cord (Chapter 28).

The appearance of the tumor cells varies, but cells with multilobated nuclei ("cloverleaf" or "flower" cells) are frequently observed. The tumor cells always contain clonal HTLV-1 proviruses, suggesting a direct pathogenic role for the virus. However, while several proviral proteins have been implicated in the development of adult T-cell leukemia/lymphoma (Chapter 7), the tumor develops in only a small fraction of those who are infected, usually after a latent period of decades, and details of the transformation process remain poorly understood.

Most patients present with rapidly progressive disease that is fatal within months to 1 year despite aggressive chemotherapy. Less commonly, the tumor involves only the skin and follows a much more indolent course, like that of mycosis fungoides (described next).

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides and Sézary syndrome are different manifestations of a tumor of CD4+ helper T cells that home to the skin. Clinically, the cutaneous lesions of *mycosis fungoides* typically progress through three somewhat distinct stages, an inflammatory *premycotic phase,* a *plaque phase,* and a *tumor phase* (Chapter 25). Histologically, the epidermis and upper dermis are infiltrated by neoplastic T cells, which often have a cerebriform appearance due to marked infolding of the nuclear membrane. Late disease progression is characterized by extracutaneous spread, most commonly to lymph nodes and bone marrow.

Sézary syndrome is a variant in which skin involvement is manifested as a *generalized exfoliative erythroderma.* In contrast to mycosis fungoides, the skin lesions rarely proceed to tumefaction, and there is an associated leukemia of "Sézary" cells with characteristic cerebriform nuclei.

The tumor cells express the adhesion molecule cutaneous leukocyte antigen and the chemokine receptors CCR4 and CCR10, all of which contribute to the homing of normal CD4+ T cells to the skin. Although cutaneous disease dominates the clinical picture, sensitive molecular analyses have shown that the tumor cells circulate through the blood, marrow, and lymph nodes even early in the course. Nevertheless, these are indolent tumors, with a median survival of roughly 10 years. Transformation to aggressive T-cell lymphoma occurs occasionally as a terminal event.

Large Granular Lymphocytic Leukemia

T- and NK-cell variants of this rare neoplasm are recognized, both of which occur mainly in adults. Individuals with T-cell disease usually present with mild to moderate lymphocytosis and splenomegaly. Lymphadenopathy and hepatomegaly are usually absent. NK-cell disease often presents in an even more subtle fashion, with little or no lymphocytosis or splenomegaly.

Approximately 30% to 40% of large granular lymphocytic leukemias have acquired mutations in the transcription factor STAT3, which functions downstream of cytokine receptors. These mutations occur in both T- and NK-cell forms of the disease and result in cytokine-independent activation of STAT3, which appears to have a major role in the pathogenesis of these proliferations.

The tumor cells are large lymphocytes with abundant blue cytoplasm and a few coarse azurophilic granules, best seen in peripheral blood smears. The marrow usually contains a sparse interstitial lymphocytic infiltrate that is difficult to appreciate without immunohistochemical stains. Infiltrates also are usually present in the spleen and liver. T-cell variants express CD3 on their surfaces, whereas NK-cell variants lack surface CD3 and express NK markers such as CD56.

Despite the relative paucity of marrow infiltration, **neutropenia and anemia dominate the clinical picture.** Neutropenia may be accompanied by a striking decrease in late myeloid forms in the marrow. Rarely, *pure red cell aplasia* is seen. There is also an increased incidence of rheumatologic disorders. Some patients with *Felty syndrome,* a triad of rheumatoid arthritis, splenomegaly, and neutropenia, have this disorder as an underlying cause. The basis for these varied clinical abnormalities is unknown, but autoimmunity, provoked in some way by the tumor, seems likely.

The course is variable, being largely dependent on the severity of the cytopenias and their responsiveness to low-dose chemotherapy or steroids. In general, tumors of T-cell origin pursue an indolent course, whereas NK-cell tumors behave more aggressively.

Extranodal NK/T-Cell Lymphoma

This neoplasm is rare in the United States and Europe, but constitutes as many as 3% of NHLs in Asia. It most frequently presents as a destructive nasopharyngeal mass; less common sites of presentation include the testis and the skin. The tumor cell infiltrate typically surrounds and invades small vessels, leading to extensive *ischemic necrosis.* In touch preparations, *large azurophilic granules* are seen in the cytoplasm of the tumor cells that resemble those found in normal NK cells.

Extranodal NK/T-cell lymphoma is highly associated with Epstein-Barr virus (EBV). Within individual patients, all of the tumor cells contain identical EBV episomes, indicating that the tumor originates from a single EBV-infected cell. How EBV gains entry is uncertain, since the tumor cells do not express CD21, the surface protein that serves as the B-cell EBV receptor. Most tumors are CD3– and lack T-cell receptor rearrangements and express NK-cell markers, supporting an NK-cell origin. No consistent chromosome aberration has been described.

Most extranodal NK/T-cell lymphomas are highly aggressive neoplasms that respond well to radiation therapy but are resistant to chemotherapy. Thus, the prognosis is generally poor in patients with advanced disease. Recent work has shown, however, that like other virus-driven cancers, extranodal NK/T-cell lymphoma responds well to immune checkpoint inhibitors, albeit with all of the attendant risks (e.g., autoimmune disease) that are associated with these agents.

KEY CONCEPTS

PERIPHERAL T- AND NK-CELL NEOPLASMS

Peripheral NK/T-cell Lymphomas and Leukemias

- Anaplastic large cell lymphoma: Aggressive T cell tumor, associated in a subset with translocations that lead to constitutive activation of the ALK tyrosine kinase.
- Adult T cell leukemia/lymphoma: Aggressive tumor of CD4+ T cells that is uniformly associated with HTLV-1 infection.
- Large granular lymphocytic leukemia: Indolent tumor of cytotoxic T cells or NK cells that is associated with mutations in the transcription factor STAT3 and with autoimmune phenomena and cytopenias.
- Extranodal NK/T cell lymphoma: Aggressive tumor, usually derived from NK cells, that is strongly associated with EBV infection.

Plasma Cell Neoplasms and Related Disorders

These B-cell proliferations contain neoplastic plasma cells that virtually always secrete monoclonal Ig or Ig fragments, which serve as tumor markers and often have pathologic consequences. Collectively, the plasma cell neoplasms account for about 15% of deaths caused by lymphoid neoplasms. The most common and deadly of these neoplasms is multiple myeloma, of which there are about 15,000 new cases per year in the United States.

A monoclonal Ig identified in the blood is referred to as an *M component,* in reference to myeloma. Because complete M components have molecular weights of 160,000 or higher, they are restricted to the plasma and extracellular fluid and excluded from the urine in the absence of glomerular damage. However, **neoplastic plasma cells often synthesize excess light chains along with complete Igs.** Occasionally only light chains are produced, and rare tumors secrete only heavy chains. In most patients with plasma cell tumors, the level of free light chains is elevated and markedly skewed toward one light chain (e.g., κ) at the expense of the second (e.g., λ). Because free light chains are small in size, they are also excreted in the urine, where they are referred to as *Bence Jones proteins.*

Terms used to describe the abnormal Igs associated with plasma cell neoplasms include *monoclonal gammopathy* and *paraproteinemia.* These abnormal proteins are associated with the following clinicopathologic entities:

- *Multiple myeloma (plasma cell myeloma),* the most important plasma cell neoplasm, usually presents as tumor masses scattered throughout the skeletal system. *Solitary myeloma (plasmacytoma)* is an infrequent variant that presents as a single mass in bone or soft tissue. *Smoldering myeloma* refers to another uncommon variant defined by a lack of symptoms and a high plasma M component.
- *Waldenström macroglobulinemia* is a syndrome in which high levels of IgM lead to symptoms related to hyperviscosity of the blood. It occurs in older adults, most commonly in association with lymphoplasmacytic lymphoma (described later).
- *Heavy-chain disease* is a rare monoclonal gammopathy seen in association with a diverse group of disorders, including lymphoplasmacytic lymphoma and an unusual small bowel marginal zone lymphoma that occurs in malnourished populations (so-called *Mediterranean lymphoma*). The common feature is the synthesis and secretion of free heavy-chain fragments.
- *Primary or immunocyte-associated amyloidosis* results from a monoclonal proliferation of plasma cells secreting light chains (usually of λ isotype) that are deposited as amyloid. Some patients have overt multiple myeloma, but others have only a minor clonal population of plasma cells in the marrow.
- *Monoclonal gammopathy of undetermined significance (MGUS)* is applied to patients without signs or symptoms who have small to moderately large M components in their blood. MGUS is very common in older adults and may transform to multiple myeloma or other symptomatic plasma cell neoplasms.

With this background, we now turn to some of these specific entities; primary amyloidosis is discussed in Chapter 6.

Multiple Myeloma

Multiple myeloma is a plasma cell neoplasm commonly associated with lytic bone lesions, hypercalcemia, renal failure, and acquired immune abnormalities. Although bony disease dominates, it can spread late in its course to lymph nodes and extranodal sites. Multiple myeloma causes

1% of cancer deaths in Western countries. Its incidence is higher in men and people of African descent. It is chiefly a disease of older adults, with a peak age of incidence of 65 to 70 years.

Pathogenesis

Multiple myeloma is genetically heterogeneous and is associated with frequent rearrangements involving the *IGH* locus on chromosome 14q32 and various proto-oncogenes. Included among the rearranged genes are the cell cycle–regulatory genes cyclin D1 on chromosome 11q13 and cyclin D3 on chromosome 6p21. Deletions of chromosome 17p that involve the *TP53* tumor suppressor locus also occur and are associated with a poor outcome. Late-stage, highly aggressive forms of the disease such as plasma cell leukemia are associated with rearrangements involving *MYC*. Deep sequencing of myeloma genomes has identified frequent mutations involving components of the NF-κB pathway, which supports B-cell survival.

The proliferation and survival of myeloma cells are dependent on several cytokines, most notably IL-6, which is an important growth factor for plasma cells. It is produced by the tumor cells themselves and by resident marrow stromal cells. High serum levels of IL-6 are seen in patients with active disease and are associated with a poor prognosis. Myeloma cell growth and survival are also augmented by direct physical interactions with bone marrow stromal cells, a phenomenon that is an area of intense research interest.

Factors produced by neoplastic plasma cells mediate bone destruction, the major pathologic feature of multiple myeloma. One important factor appears to be myeloma-derived MIP1α (also known as CCL3), a chemokine that augments osteoclast formation through several different mechanisms. Other factors released from tumor cells, such as modulators of the Wnt pathway, are potent inhibitors of osteoblast function. The net effect is a marked increase in bone resorption, which leads to hypercalcemia and pathologic fractures.

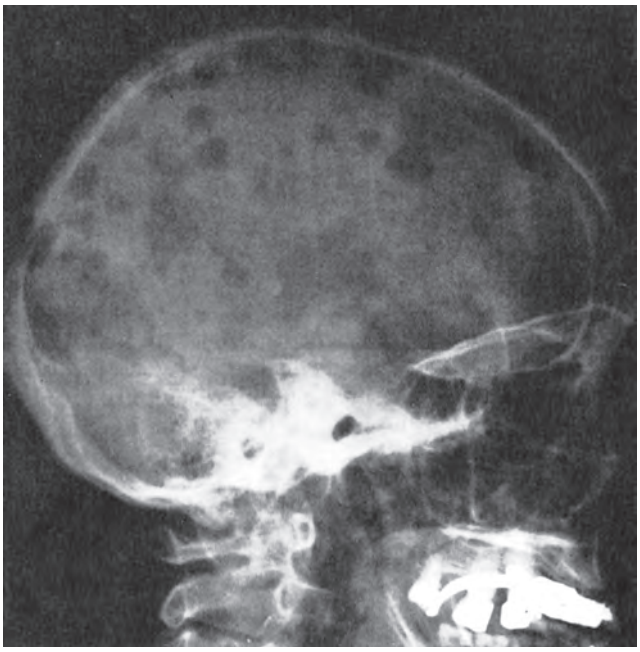

Figure 13.20 Multiple myeloma of the skull (radiograph, lateral view). The sharply punched-out bone lesions are most obvious in the calvaria.

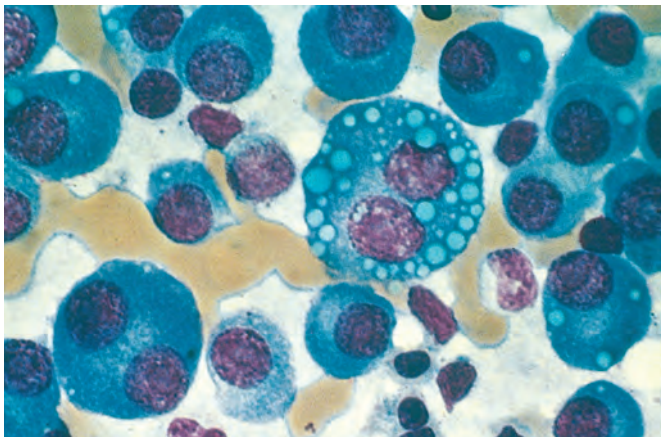

Figure 13.21 Multiple myeloma (bone marrow aspirate). Normal marrow cells are largely replaced by plasma cells including forms with multiple nuclei, prominent nucleoli, and cytoplasmic droplets containing immunoglobulin.

MORPHOLOGY

Multiple myeloma usually presents as destructive plasma cell tumors (plasmacytomas) involving the axial skeleton. The bones most commonly affected (in descending order of frequency) are the vertebral column, ribs, skull, pelvis, femur, clavicle, and scapula. Lesions begin in the medullary cavity, erode cancellous bone, and progressively destroy the bony cortex, often leading to pathologic fractures; these are most common in the vertebral column but may occur in any affected bone. **The bone lesions appear radiographically as punched-out defects, usually 1 to 4 cm in diameter** (Fig. 13.20), and consist of soft, gelatinous, red tumor masses. Less commonly, widespread myelomatous bone disease produces diffuse demineralization (osteopenia) rather than focal defects.

Even away from overt tumor masses, the marrow contains an increased number of plasma cells, which usually constitute more than 30% of the cellularity. The plasma cells may infiltrate the interstitium in a subtle fashion or completely replace normal elements. Like their benign counterparts, malignant plasma cells have a perinuclear clearing due to a prominent Golgi apparatus and an eccentrically placed nucleus (Fig. 13.21). Relatively normal-appearing plasma cells, **plasmablasts** with vesicular nuclear chromatin and a prominent single nucleolus, or **bizarre, multinucleated cells** may predominate. Other cytologic variants stem from the dysregulated synthesis and secretion of Ig, which often leads to intracellular accumulation of intact or partially degraded protein. Such variants include **flame cells** with fiery red cytoplasm, **Mott cells** with multiple grapelike cytoplasmic droplets, and cells containing a variety of other inclusions, including fibrils, crystalline rods, and globules. The globular inclusions are referred to as **Russell bodies** (if cytoplasmic) or **Dutcher bodies** (if nuclear). In advanced disease, plasma cell infiltrates may be present in the spleen, liver, kidneys, lungs, lymph nodes, and other soft tissues.

Commonly, high levels of M protein in the blood cause red cells to stick to one another in linear arrays in smears, a finding referred to as **rouleaux formation.** Rouleaux formation is characteristic but not specific, as it may be seen in other conditions in which Ig levels are elevated, such as lupus erythematosus and early HIV infection. Rarely, tumor cells flood the peripheral blood, giving rise to **plasma cell leukemia.**

Bence Jones proteins are excreted in the kidney and contribute to a form of renal disease called **myeloma kidney.** This important complication is discussed in detail in Chapter 20.

Immunophenotype. Plasma cell tumors are positive for CD138, an adhesion molecule also known as syndecan-1, and often express CD56, a feature that can be helpful in identifying small populations of neoplastic cells.

Clinical Features

The clinical features of multiple myeloma stem from (1) the effects of plasma cell growth in tissues, particularly the bones; (2) the production of excessive Igs, which often have abnormal physicochemical properties; and (3) the suppression of normal humoral immunity.

Bone resorption often leads to pathologic fractures and chronic pain. The attendant hypercalcemia can give rise to neurologic manifestations, such as confusion, weakness, lethargy, constipation, and polyuria, and contributes to renal dysfunction. Decreased production of normal Igs sets the stage for recurrent bacterial infections. Cellular immunity is relatively unaffected. Of great significance is renal insufficiency, which trails only infections as a cause of death. The pathogenesis of renal failure (Chapter 20), which occurs in up to 50% of patients, is multifactorial. However, the single most important factor seems to be Bence Jones proteinuria, as the excreted light chains are toxic to renal tubular epithelial cells. Certain light chains (particularly those of the λ6 and λ3 families) are prone to cause amyloidosis of the AL type (Chapter 6), which can exacerbate renal dysfunction and deposit in other tissues as well.

In 99% of patients, laboratory analyses reveal increased levels of Igs in the blood and/or light chains (Bence Jones proteins) in the urine. The monoclonal Igs are usually first detected as abnormal protein "spikes" in serum or urine electrophoresis and then further characterized by immunofixation (Fig. 13.22). Most myelomas are associated with more than 3 g/dL of serum Ig and/or more than 6 mg/dL of urine Bence Jones protein. The most common monoclonal Ig (M protein) is IgG (approximately 55% of patients), followed by IgA (approximately 25% of cases). Myelomas expressing IgM, IgD, or IgE occur but are rare. Excessive production and aggregation of M proteins, usually of the IgA or IgG_3 subtype, leads to symptoms related to hyperviscosity (described under Lymphoplasmacytic Lymphoma) in about 7% of patients. Both free light chains and a serum M protein are observed together in 60% to 70% of patients. However, in about 20% of patients only free light chains are present, and around 1% of myelomas are nonsecretory; hence the absence of M proteins does not completely exclude the diagnosis.

The clinicopathologic diagnosis of multiple myeloma relies on identification of clonal plasma cells in the marrow and the presence of CRAB criteria (hypercalcemia, renal dysfunction, anemia, and bone lesions). It can be strongly suspected when the distinctive radiographic changes are present, but definitive diagnosis requires a bone marrow examination and tests assessing calcium levels, renal function, blood counts, and serum and urine Igs.

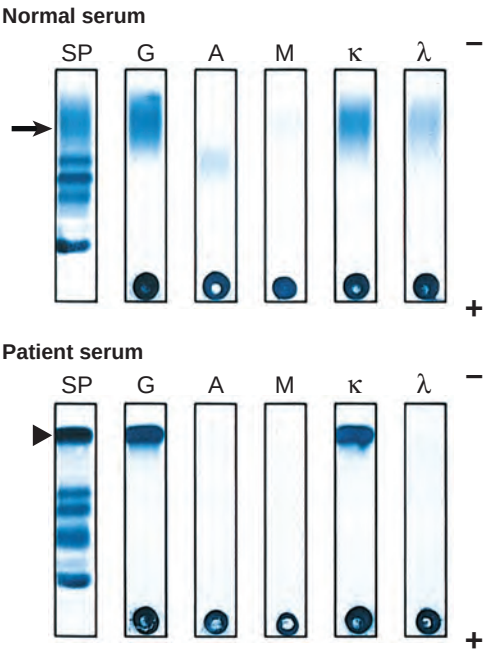

Figure 13.22 M protein detection in multiple myeloma. Serum protein electrophoresis *(SP)* is used to screen for a monoclonal immunoglobulin (Ig) (M protein). Polyclonal IgG in normal serum *(arrow)* appears as a broad band; in contrast, serum from a patient with multiple myeloma contains a single sharp protein band *(arrowhead)* in this region of the electropheretogram. The suspected monoclonal Ig is confirmed and characterized by immunofixation, in which proteins are trapped in the gel with antibodies specific for IgG *(G)*, IgA *(A)*, IgM *(M)*, or kappa *(κ)*, or lambda *(λ)* light chain and then visualized with a protein stain. Note the sharp band in the patient serum is cross-linked by antisera specific for IgG heavy chain and kappa light chain, indicating the presence of an IgGκ M protein. Levels of polyclonal IgG, IgA *(A)*, and lambda light chain *(λ)* are also decreased in the patient serum relative to normal, a finding typical of multiple myeloma. (Courtesy Dr. David Sacks, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

The prognosis is variable. The median survival is 4 to 7 years, and cures have yet to be achieved. Patients with multiple bony lesions, if untreated, rarely survive for more than 6 to 12 months, whereas patients with "smoldering myeloma" may be asymptomatic for many years. Translocations involving cyclin D1 are associated with a good outcome, whereas deletions of 13q, deletions of 17p, and the t(4;14) all portend a more aggressive course.

While still incurable, outcomes have improved over the past decade with advances in therapy. Myeloma cells are sensitive to inhibitors of the proteasome, a cellular organelle that degrades unwanted and misfolded proteins (Chapter 2). Because of the high levels of Ig synthesis, misfolding of Ig heavy and light chains may occur even in normal plasma cells, and this tendency may be exacerbated in myeloma cells in which heavy and light chain synthesis is unbalanced. If these misfolded proteins are not degraded in proteasomes, they trigger apoptosis. Proteasome inhibitors induce cell

death by exploiting this vulnerability and also seem to retard bone resorption through effects on stromal cells. Thalidomide and related compounds such as lenalidomide also have activity against myeloma. Interestingly, this also appears to involve changes in protein degradation, as lenalidomide redirects and activates certain ubiquitin ligases, thereby targeting proteins for proteolysis that are required for myeloma growth. Bisphosphonates, drugs that inhibit bone resorption, reduce pathologic fractures and limit hypercalcemia. HSC transplantation prolongs life but has not been proven to be curative.

Smoldering Myeloma

This entity defines a middle ground between multiple myeloma and MGUS. Plasma cells make up 10% to 30% of the marrow cellularity, and the serum M protein level is greater than 3 g/dL, but patients are asymptomatic. About 75% of patients progress to multiple myeloma over a 15-year period.

Solitary Osseous Plasmacytoma

About 3% to 5% of plasma cell neoplasms present as a solitary lesion of bone or soft tissue. The bone lesions tend to occur in the same locations as in multiple myeloma. Extraosseous lesions are often located in the lungs, oronasopharynx, or nasal sinuses. Modest elevations of M proteins in the blood or urine may be found in some patients. Solitary osseous plasmacytoma almost inevitably progresses to multiple myeloma, but this can take 10 to 20 years or longer. In contrast, extraosseous plasmacytomas, particularly those involving the upper respiratory tract, are frequently cured by local resection.

Monoclonal Gammopathy of Undetermined Significance

MGUS is the most common plasma cell disorder, occurring in about 3% of persons older than 50 years of age and in about 5% of individuals older than 70 years of age. By definition, patients are asymptomatic and the serum M protein level is less than 3 g/dL. **Approximately 1% of patients with MGUS develop a symptomatic plasma cell neoplasm, usually multiple myeloma, per year.** The clonal plasma cells in MGUS contain many of the same chromosomal translocations and deletions that are found in full-blown multiple myeloma, indicating that MGUS is an early stage of myeloma development. As with smoldering myeloma, progression to multiple myeloma is unpredictable; hence, periodic assessment of serum M component levels and Bence Jones proteinuria is warranted.

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma is a B-cell neoplasm of older adults that usually presents in the sixth or seventh decade of life. Although superficially resembling CLL/SLL, it differs in that a substantial fraction of the tumor cells undergo terminal differentiation to plasma cells. Most commonly, the plasma cell component secretes monoclonal IgM, often in amounts sufficient to cause a hyperviscosity syndrome known as *Waldenström macroglobulinemia*. Unlike multiple myeloma, complications stemming from the secretion of free light chains (e.g., renal failure and amyloidosis) are relatively rare, and bone destruction does not occur.

Pathogenesis

Virtually all cases of lymphoplasmacytic lymphoma are associated with acquired mutations in *MYD88*. *MYD88* encodes an adaptor protein that participates in signaling events that activate NF-κB, which may promote the growth and survival of the tumor cells.

MORPHOLOGY

Typically, the marrow contains an infiltrate of lymphocytes, plasma cells, and plasmacytoid lymphocytes in varying proportions, often accompanied by mast cell hyperplasia (Fig. 13.23). Some tumors also contain a population of larger lymphoid cells with more vesicular nuclear chromatin and prominent nucleoli. Periodic acid–Schiff–positive inclusions containing Ig are frequently seen in the cytoplasm **(Russell bodies)** or the nucleus **(Dutcher bodies)** of some of the plasma cells. At diagnosis the tumor has usually disseminated to the lymph nodes, spleen, and liver. Infiltration of the nerve roots, meninges, and more rarely the brain can also occur with disease progression.

Immunophenotype. The lymphoid component expresses B-cell markers such as CD20 and surface Ig, whereas the plasma cell component secretes the same Ig that is expressed on the surface of the lymphoid cells, usually IgM.

Clinical Features

The dominant presenting complaints are nonspecific and include weakness, fatigue, and weight loss. Approximately half the patients have lymphadenopathy, hepatomegaly, and splenomegaly. Anemia caused by marrow infiltration is common. About 10% of patients have autoimmune hemolysis caused by cold agglutinins, IgM antibodies that bind to red cells at temperatures of less than 37°C (Chapter 14).

Patients with IgM-secreting tumors have additional signs and symptoms stemming from the physicochemical

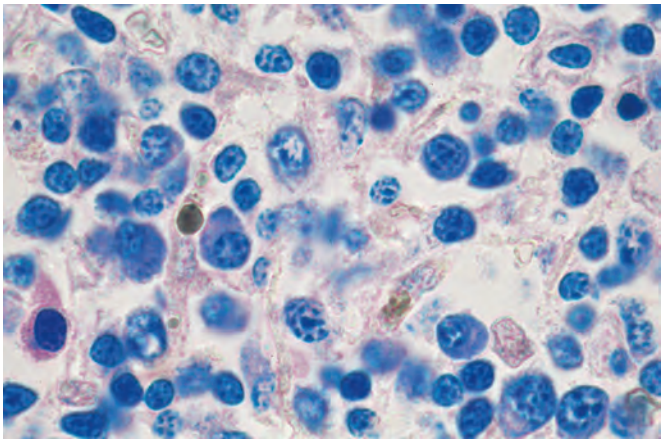

Figure 13.23 Lymphoplasmacytic lymphoma. Bone marrow biopsy shows a characteristic mixture of small lymphoid cells exhibiting various degrees of plasma cell differentiation. In addition, a mast cell with purplish red cytoplasmic granules is present at the left-hand side of the field.

properties of IgM. Because of its large size, at high concentrations IgM greatly increases the viscosity of the blood, giving rise to a *hyperviscosity syndrome* characterized by the following:

- *Visual impairment* associated with venous congestion, reflected by striking tortuosity and distention of retinal veins; retinal hemorrhages and exudates may also contribute to the visual problems.
- *Neurologic problems* such as headaches, dizziness, deafness, and stupor, all stemming from sluggish blood flow.
- *Bleeding* related to the formation of complexes between macroglobulins and clotting factors as well as interference with platelet function.
- *Cryoglobulinemia* resulting from the precipitation of macroglobulins at low temperatures, producing symptoms such as Raynaud phenomenon and cold urticaria.

Lymphoplasmacytic lymphoma is an indolent disorder. Because most IgM is intravascular, symptoms caused by the high IgM levels (e.g., hyperviscosity and hemolysis) can be alleviated by plasmapheresis. Tumor growth can be controlled with low doses of chemotherapeutic drugs and immunotherapy with anti-CD20 antibody. Like other indolent B-cell tumors, lymphoplasmacytic lymphoma is highly responsive to BTK inhibitors, indicating a dependence of the tumor cells on the B-cell receptor signaling pathway. Transformation to large-cell lymphoma occurs but is uncommon. Median survival is about 8 years and may improve further with the recent addition of BTK inhibitors to the therapeutic armamentarium.

KEY CONCEPTS

PLASMA CELL NEOPLASMS

Multiple Myeloma

- Plasma cell tumor that manifests with multiple lytic bone lesions associated with pathologic fractures and hypercalcemia.
- Neoplastic plasma cells suppress normal humoral immunity and secrete partial Igs that are nephrotoxic.
- Associated with diverse translocations involving the *IGH* locus; frequent dysregulation and overexpression of D cyclins.
- May be associated with AL amyloidosis (as may other neoplasms later).

Other Plasma Cell Neoplasms

- MGUS: common in older adults, progresses to myeloma at a rate of 1% per year.
- Smoldering myeloma: disseminated disease that pursues an unusually indolent course.
- Solitary osseous plasmacytoma: solitary bone lesion identical to disseminated myeloma; most progress to myeloma within 7 to 10 years.
- Extramedullary plasmacytoma: solitary mass, usually in the upper aerodigestive tract; rarely progresses to systemic disease.
- Lymphoplasmacytic lymphoma: B-cell lymphoma that exhibits plasmacytic differentiation; clinical symptoms dominated by hyperviscosity related to high levels of tumor-derived IgM; highly associated with mutations in the *MYD88* gene.

Table 13.7 Differences Between Hodgkin and Non-Hodgkin Lymphomas

Hodgkin Lymphoma	Non-Hodgkin Lymphoma
More often localized to a single axial group of nodes (cervical, mediastinal, para-aortic)	More frequent involvement of multiple peripheral nodes
Orderly spread by contiguity	Noncontiguous spread
Mesenteric nodes and Waldeyer ring rarely involved	Waldeyer ring and mesenteric nodes commonly involved
Extranodal presentation rare	Extranodal presentation common

Hodgkin Lymphoma

Hodgkin lymphoma encompasses a group of lymphoid neoplasms that differ from NHL in several respects (Table 13.7). While NHLs frequently occur at extranodal sites and spread in an unpredictable fashion, **Hodgkin lymphoma arises in a single node or chain of nodes and spreads first to anatomically contiguous lymphoid tissues. Morphologically, the distinctive feature of Hodgkin lymphoma is the presence of neoplastic giant cells called Reed-Sternberg cells.** These cells release factors that induce the accumulation of reactive lymphocytes, macrophages, and granulocytes, which typically make up greater than 90% of the tumor cellularity. Molecular studies have shown that the neoplastic Reed-Sternberg cells are derived from germinal center or post–germinal center B cells.

Hodgkin lymphoma accounts for 0.7% of all new cancers in the United States; there are about 8000 cases each year. The average age at diagnosis is 32 years. It is one of the most common cancers of young adults and adolescents, but also occurs in the aged. It was the first human cancer to be successfully treated with radiation therapy and chemotherapy and is curable in most cases.

Classification. The WHO classification recognizes five subtypes of Hodgkin lymphoma:

1. Nodular sclerosis
2. Mixed cellularity
3. Lymphocyte-rich
4. Lymphocyte depletion
5. Nodular lymphocyte predominance

In the first four subtypes—nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte depletion—the Reed-Sternberg cells have a similar distinctive immunophenotype. These subtypes are often lumped together as *classic* forms of Hodgkin lymphoma. In the remaining subtype, lymphocyte predominance, the Reed-Sternberg cells have a B-cell immunophenotype that differs from that of the classic types.

Pathogenesis

The origin of the neoplastic Reed-Sternberg cells of classic Hodgkin lymphoma was solved through elegant molecular studies of single isolated Reed-Sternberg cells. These revealed clonal *IGH* gene rearrangements and the telltale signs of somatic hypermutation, establishing that Reed-Sternberg cells originate from a germinal center or post–germinal center B cell. Despite their B-cell origin, the Reed-Sternberg cells

of classic Hodgkin lymphoma fail to express most B-cell–specific genes, including the Ig genes. The cause of this wholesale reprogramming of gene expression has yet to be explained and presumably results from widespread epigenetic changes of uncertain etiology.

Activation of the transcription factor NF-κB is a common event in classic Hodgkin lymphoma and turns on genes that are believed to promote the growth and survival of Reed-Sternberg cells. This can occur by several mechanisms:

- EBV+ tumor cells express latent membrane protein-1 (LMP-1), a protein encoded by the EBV genome that transmits signals that up-regulate NF-κB.
- Activation of NF-κB may occur in EBV– tumors as a result of acquired loss-of-function mutations in IκB or TNF-α–induced protein 3, both of which are negative regulators of NF-κB.

It is hypothesized that activation of NF-κB rescues "crippled" germinal center B cells that cannot express Ig from apoptosis, setting the stage for the acquisition of other unknown mutations that collaborate to produce Reed-Sternberg cells. Little is known about the basis for the morphology of Reed-Sternberg cells and variants, but it is intriguing that EBV-infected B cells resembling Reed-Sternberg cells may be found in the lymph nodes of individuals with infectious mononucleosis, strongly suggesting that EBV-encoded proteins play a part in the remarkable metamorphosis of B cells into Reed-Sternberg cells.

Reed-Sternberg cells are aneuploid and possess diverse clonal chromosomal aberrations. Copy number gains in the *REL* proto-oncogene on chromosome 2p are particularly common and may also contribute to increases in NF-κB activity. Also frequent are copy number gains in genes encoding PD-L1 and PD-L2, located together on chromosome 9p, which you will recall are immune checkpoint proteins that inhibit antitumor T-cell responses (Chapter 7).

The florid accumulation of reactive cells in tissues involved by classic Hodgkin lymphoma occurs in response to a wide variety of cytokines (e.g., IL-5, IL-10, and M-CSF), chemokines (e.g., eotaxin), and other factors that are secreted by Reed-Sternberg cells. Once attracted, the reactive cells produce factors that support the growth and survival of the tumor cells and further modify the reactive cell response. For example, eosinophils and T cells express ligands that activate the CD30 and CD40 receptors found on Reed-Sternberg cells, producing signals that up-regulate NF-κB. Although Reed-Sternberg cells induce a host response, it is ineffective because of factors produced by the Reed-Sternberg cells. Most notably among these factors are PD-L1 and PD-L2, which antagonize cytotoxic T-cell responses. Other examples of "cross-talk" between Reed-Sternberg cells and surrounding reactive cells are provided in Fig. 13.28.

MORPHOLOGY

Identification of Reed-Sternberg cells and their variants is essential for the diagnosis. **Diagnostic Reed-Sternberg cells are large cells (45 μm in diameter) with multiple nuclei or a single nucleus with multiple nuclear lobes, each with a large inclusion-like nucleolus about the size of a small lymphocyte (5 to 7 μm in diameter)** (Fig. 13.24A). The cytoplasm is abundant. Several Reed-Sternberg cell variants are also recognized. **Mononuclear variants** contain a single nucleus with a large inclusion-like nucleolus (Fig. 13.24B). **Lacunar cells** (seen in the nodular sclerosis subtype) have more delicate, folded, or multilobate nuclei and abundant pale cytoplasm that is often disrupted during the cutting of sections, leaving the nucleus sitting in an empty space (a lacuna) (Fig. 13.24C). In classic forms of Hodgkin lymphoma, Reed-Sternberg cells undergo a peculiar form of cell death in which the cells shrink and become pyknotic, a process described as "mummification." **Lymphohistiocytic variants** (L&H cells) with polypoid nuclei, inconspicuous nucleoli, and moderately abundant cytoplasm are characteristic of the lymphocyte predominance subtype (Fig. 13.24D).

Hodgkin lymphoma must be distinguished from other conditions in which cells resembling Reed-Sternberg cells may be seen, such as infectious mononucleosis, solid tissue cancers, and large-cell NHLs. The diagnosis of Hodgkin lymphoma depends on the identification of Reed-Sternberg cells in a background of non-neoplastic inflammatory cells. Reed-Sternberg cells also have a characteristic immunohistochemical profile, a feature that is used to confirm the morphologic impression.

With this as background, we turn to the subclasses of Hodgkin lymphoma, pointing out some of the salient morphologic and immunophenotypic features of each (Table 13.8). The clinical manifestations common to all are presented later.

Nodular Sclerosis Type. This is the most common form of Hodgkin lymphoma, constituting 65% to 70% of cases. It is characterized by the presence of lacunar variant Reed-Sternberg cells and the **deposition of collagen in bands that divide involved lymph nodes into circumscribed nodules** (Fig. 13.25). The fibrosis may be scant or abundant. The Reed-Sternberg cells are found in a polymorphous background of T cells, eosinophils, plasma cells, and macrophages. Diagnostic Reed-Sternberg cells are often uncommon. The Reed-Sternberg cells in this and other classic Hodgkin lymphoma subtypes have a characteristic immunophenotype; they are positive for PAX5 (a B-cell transcription factor), CD15, and CD30 and negative for other B-cell markers, T-cell markers, and CD45 (leukocyte common antigen). As in other forms of Hodgkin lymphoma, involvement of the spleen, liver, bone marrow, and other organs and tissues may appear in due course in the form of irregular tumor nodules resembling those seen in lymph nodes. This subtype is uncommonly associated with EBV.

The nodular sclerosis type occurs with equal frequency in males and females. It has a propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes of adolescents or young adults. The prognosis is excellent.

Mixed-Cellularity Type. This form of Hodgkin lymphoma constitutes about 20% to 25% of cases. Involved lymph nodes are diffusely effaced by a heterogeneous cellular infiltrate, which includes T cells, eosinophils, plasma cells, and benign macrophages admixed with Reed-Sternberg cells (Fig. 13.26). **Diagnostic Reed-Sternberg cells and mononuclear variants are usually plentiful. The Reed-Sternberg cells are infected with EBV in about 70% of cases.** The immunophenotype is identical to that observed in the nodular sclerosis type.

Mixed-cellularity Hodgkin lymphoma is more common in males. Compared with the lymphocyte predominance and nodular sclerosis subtypes, it is more likely to be associated with older age, systemic symptoms such as night sweats and weight loss, and advanced tumor stage. Nonetheless, the overall prognosis is very good.

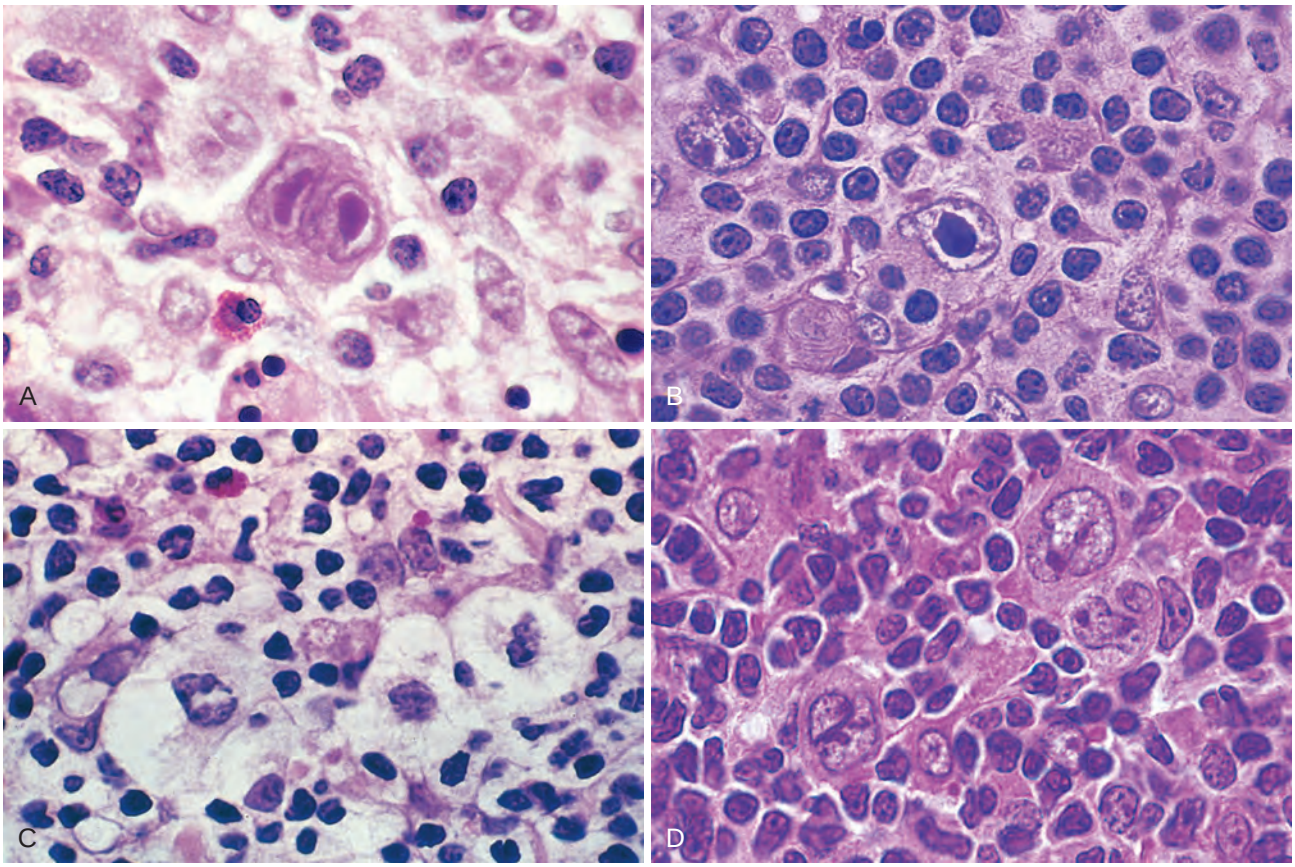

Figure 13.24 Reed-Sternberg cells and variants. (A) Diagnostic Reed-Sternberg cell, with two nuclear lobes, large inclusion-like nucleoli, and abundant cytoplasm, surrounded by lymphocytes, macrophages, and an eosinophil. (B) Reed-Sternberg cell, mononuclear variant. (C) Reed-Sternberg cell, lacunar variant. This variant has a folded or multilobated nucleus and lies within a open space, which is an artifact created by disruption of the cytoplasm during tissue sectioning. (D) Reed-Sternberg cell, lymphohistiocytic variant. Several such variants with multiply infolded nuclear membranes, small nucleoli, fine chromatin, and abundant pale cytoplasm are present. Table 13.8 Subtypes of Hodgkin Lymphoma

Subtype	Morphology and Immunophenotype	Typical Clinical Features
Nodular sclerosis	Frequent lacunar cells and occasional diagnostic RS cells; background infiltrate composed of T lymphocytes, eosinophils, macrophages, and plasma cells; fibrous bands dividing cellular areas into nodules. RS cells CD15+, CD30+; usually EBV–	Most common subtype; usually stage I or II disease; frequent mediastinal involvement; equal occurrence in males and females, most patients young adults
Mixed cellularity	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes, eosinophils, macrophages, plasma cells; RS cells CD15+, CD30+; 70% EBV+	More than 50% present as stage III or IV disease; occurrence greater in males than females; biphasic incidence, peaking in young adults and again in adults older than 55
Lymphocyte-rich	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes; RS cells CD15+, CD30+; 40% EBV+	Uncommon; occurrence greater in males than females; tends to be seen in older adults
Lymphocyte depletion	Reticular variant: Frequent diagnostic RS cells and variants and a paucity of background reactive cells; RS cells CD15+, CD30+; most EBV+	Uncommon; more common in older men, HIV-infected individuals, and people in low income countries; often presents with advanced disease
Nodular lymphocyte predominant	Frequent L&H (popcorn cell) variants in a background of follicular dendritic cells and reactive B cells; RS cells CD20+, CD15–, CD30–; EB–	Uncommon; young males with cervical or axillary lymphadenopathy; mediastinal

HIV, human immunodeficiency virus; *L&H,* lymphohistiocytic; *RS,* Reed-Sternberg.

A diagnostic, binucleate Reed-Sternberg cell is surrounded by reactive cells including eosinophils (bright red cytoplasm), lymphocytes, and macrophages. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Lymphocyte-Rich Type. This is an uncommon form of classic Hodgkin lymphoma in which **reactive lymphocytes make up the vast majority of the cellular infiltrate.** In most cases, involved lymph nodes are diffusely effaced, but vague nodularity due to the presence of residual B-cell follicles is sometimes seen. This entity is distinguished from the lymphocyte predominance type by the presence of frequent mononuclear variants and diagnostic Reed-Sternberg cells with a "classic" immunophenotypic profile. It is associated with EBV in about 40% of cases and has a very good to excellent prognosis.

Lymphocyte Depletion Type. This is the least common form of Hodgkin lymphoma, amounting to less than 5% of cases. It is characterized by a paucity of lymphocytes and a relative abundance of Reed-Sternberg cells or their pleomorphic variants. The immunophenotype of the Reed-Sternberg cells is identical to that seen in other classic types of Hodgkin lymphoma. Immunophenotyping is essential, since most tumors suspected of being lymphocyte depletion Hodgkin lymphomas actually prove to be large-cell NHLs. **The Reed-Sternberg cells are infected with EBV in over 90% of cases.**

Lymphocyte depletion Hodgkin lymphoma occurs predominantly in older adults, in HIV-positive individuals of any age, and in individuals living in lower-income countries. Advanced stage and systemic symptoms are frequent, and the overall outcome is less favorable than in the other subtypes.

Nodular Lymphocyte Predominance Type. This uncommon "nonclassic" variant of Hodgkin lymphoma accounts for about 5% of cases. Involved nodes are effaced by nodules of small lymphocytes admixed with variable numbers of macrophages (Fig. 13.27). "Classic" Reed-Sternberg cells are usually difficult to find. Instead, this tumor contains so-called L&H variants with multilobed nuclei resembling popcorn kernels (popcorn cell). Eosinophils and plasma cells are usually scant or absent.

In contrast to the Reed-Sternberg cells found in classic forms of Hodgkin lymphoma, **L&H variants express B-cell markers typical of germinal center B cells,** such as CD20 and BCL6, and are usually negative for CD15 and CD30. The nodular pattern of growth is due to the presence of expanded B-cell follicles populated by L&H variants, numerous reactive B cells, and follicular dendritic cells. The *IGH* genes of the L&H variants show evidence of ongoing somatic hypermutation, further marking these cells as transformed germinal center B cells. In 3% to 5% of cases, this type transforms into a tumor resembling diffuse large B-cell lymphoma. EBV is rarely associated with this subtype.

A majority of patients are males, usually younger than 35 years of age, presenting with cervical or axillary lymphadenopathy. Mediastinal and bone marrow involvement is rare. In some series, this form of Hodgkin lymphoma is more likely to recur than the classic subtypes, but the prognosis is excellent.

Clinical Features

Hodgkin lymphoma most commonly presents as painless lymphadenopathy. Patients with the nodular sclerosis or lymphocyte predominance types tend to have stage I or II disease and are usually free of systemic manifestations. Patients with disseminated disease (stages III and IV) or the mixed-cellularity or lymphocyte depletion subtypes are

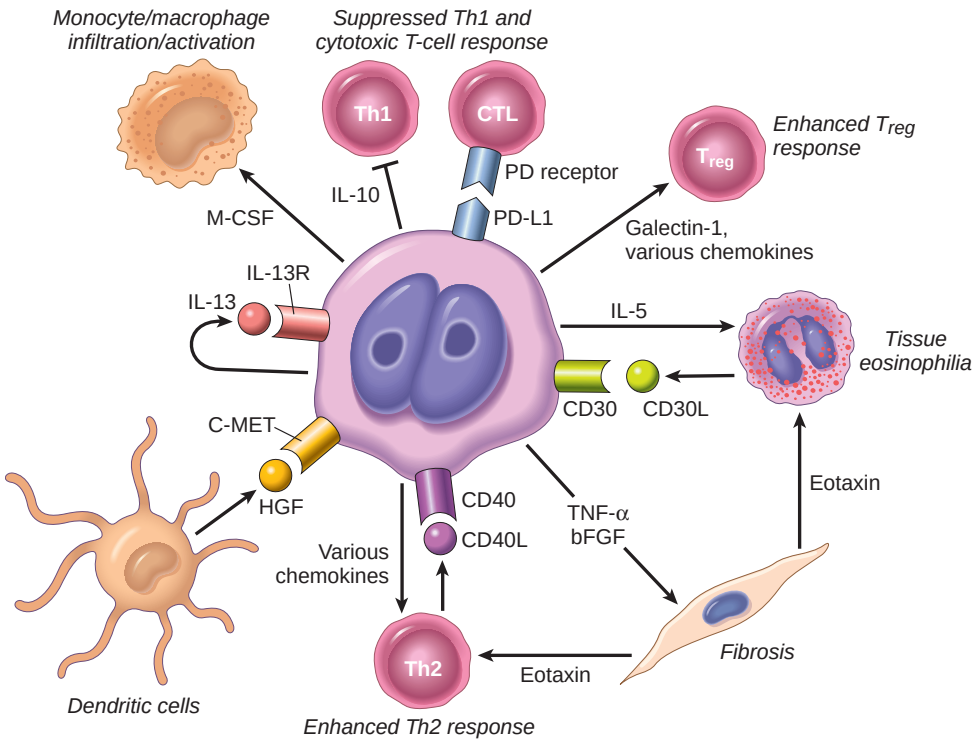

Figure 13.28 Proposed signals mediating crosstalk between Reed-Sternberg cells and surrounding normal cells in classic forms of Hodgkin lymphoma. *bFGF*, basic fibroblast growth factor; *CD30L*, CD30 ligand; *CTL*, CD8+ cytotoxic T cell; *HGF*, hepatocyte growth factor (binds to the c-MET receptor); *IL*, interleukin; *M-CSF*, monocyte colony-stimulating factor; *Th1*, *Th2*, CD4+ T helper cell subsets; *TNF-α*, tumor necrosis factor-α; T_{reg}, regulatory T cell.

more likely to have constitutional symptoms such as fever, night sweats, and weight loss. Cutaneous immune unresponsiveness (also called anergy) resulting from depressed cell-mediated immunity is seen in most cases of classic Hodgkin lymphoma and is attributable to the expression of factors such as IL-10 by Reed-Sternberg cells that suppress Th1 immune responses. This is but one of many examples of cross-talk between Reed-Sternberg cells, various stromal cells, and immune cells (Fig. 13.28).

The spread of Hodgkin lymphoma is remarkably stereotypic: nodal disease first, then splenic disease, hepatic disease, and finally involvement of the marrow and other tissues. Staging involves physical examination; radiologic imaging of the abdomen, pelvis, and chest; and biopsy of the bone marrow (Table 13.9). With current treatment protocols, tumor stage rather than histologic type is the most important prognostic variable. The cure rate of patients with stages I and IIA is close to 90%. Even with advanced disease (stages IVA and IVB), disease-free survival at 5 years is 60% to 70%.

Low-stage localized Hodgkin lymphoma can be cured with involved field radiotherapy, and indeed cure of such patients was one of the early success stories in oncology. However, it was subsequently recognized that long-term survivors treated with radiotherapy had a much higher incidence of certain other malignancies, including lung cancer, melanoma, and breast cancer. Patients treated with early chemotherapy regimens containing alkylating agents also had a high incidence of secondary tumors, particularly AML. These sobering results spurred the development of current treatment regimens, which minimize the use of radiotherapy and employ less genotoxic chemotherapeutic agents; as a result, the incidence of secondary tumors appears to have been reduced markedly, without any loss of therapeutic efficacy.

Table 13.9 Clinical Staging of Hodgkin and Non-Hodgkin Lymphomas (Ann Arbor Classification)

Stage	Distribution of Disease
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or localized involvement of an extralymphatic organ or site (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm without (III) or with (IIIE) localized involvement of an extralymphatic organ or site
IV	Diffuse involvement of one or more extralymphatic organs or sites with or without lymphatic involvement
All stages are further divided on the basis of the absence (A) or presence (B) of the following symptoms: unexplained fever, drenching night sweats, and/or unexplained weight loss of greater than 10% of normal body weight.	

Data from Carbone PT, et al: Symposium (Ann Arbor): Staging in Hodgkin's disease, *Cancer Res* 31:1707, 1971.

For patients with classic Hodgkin lymphoma who fail conventional therapy, immune checkpoint inhibitors that block PD-1, the receptor for PD-L1 and PD-L2, have proven to be highly effective. These agents prevent the CD8+ cytotoxic T-cell "exhaustion" that is caused by PD-L1 and PD-L2 expressed on Reed-Sternberg cells (see Fig. 13.28) and lead to sustained responses in almost 90% of cases;

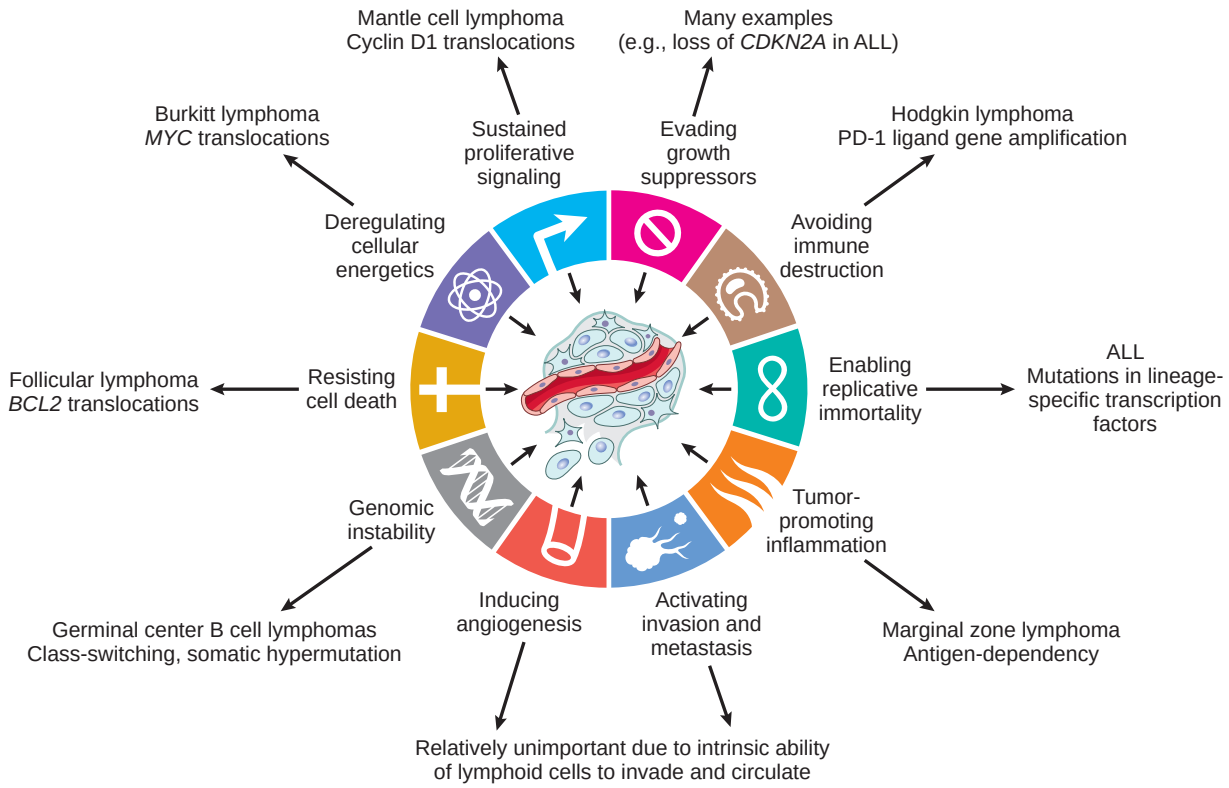

Figure 13.29 Cancer hallmarks exemplified by particular lymphoid neoplasms. See text for details.

indeed, classic Hodgkin lymphoma appears to be the human cancer that is most responsive to immune checkpoint inhibitor therapy.

KEY CONCEPTS

HODGKIN LYMPHOMA

- Unusual tumor consisting mostly of reactive lymphocytes, macrophages, eosinophils, plasma cells and stromal cells mixed with rare tumor giant cells called Reed-Sternberg cells and variants.
- Two broad types, classic (which has several subtypes) and nodular lymphocyte predominant, which are distinguished based on morphologic and immunophenotypic grounds.
- Reed-Sternberg cells of classic types express multiple cytokines, chemokines, and ligands that influence the host response, and the responding host cells in turn make factors that support the growth of the tumor cells.
- Classic forms are frequently associated with acquired mutations that activate the transcription factor NF-κB and with EBV infection.
- Lymphocyte predominance type expresses B-cell markers and is not associated with EBV.
- Classic Hodgkin lymphoma is highly responsive to immune checkpoint inhibitors, which antagonize the activity of PD-L1 and PD-L2 expressed on the surface of Reed-Sternberg cells.

Pathogenic Lessons From Lymphoid Neoplasms

Before ending our review of lymphoid neoplasms, it is worthwhile pausing to summarize the manner in which common driver mutations in specific entities produce changes in cellular behavior that exemplify particular hallmarks of cancer. Some of the best characterized pathogenic mechanisms are summarized in Fig. 13.29, including dysregulation of MYC in Burkitt lymphoma (leading to Warburg metabolisms and rapid cell growth); dysregulation of BCL2 in follicular lymphoma (leading to resistance to apoptosis); PD-1 ligand gene amplification in Hodgkin lymphoma (leading to evasion of host immunity); events leading to loss of cell cycle control (cyclin D1 rearrangements in mantle cell lymphoma and loss of the *CDKN2A* gene in acute lymphoblastic leukemia [ALL]); mutations in various transcription factors, particularly in ALL, that block differentiation and enhance "leukemia stem cell" self-renewal; and chronic immune stimulation, in marginal zone lymphoma. Such alterations not only highlight important pathogenic principles, but are increasingly the targets of effective therapies, such as antibodies that block PD-1 (Hodgkin lymphoma) and drugs that antagonize BCL2 (follicular lymphoma and other B-cell tumors). By contrast, because lymphoid cells normally circulate throughout the body, there is relatively little selective pressure in lymphoid malignancies for aberrations that increase angiogenesis or activate invasion and metastasis, points of distinction from other forms of cancer.

MYELOID NEOPLASMS

The common feature of this heterogeneous group of neoplasms is their origin from hematopoietic progenitor cells. These diseases primarily involve the marrow and to

a lesser degree the secondary hematopoietic organs (spleen, liver, and lymph nodes) and usually present with symptoms related to altered hematopoiesis. Three broad, major categories of myeloid neoplasms exist:

- *Acute myeloid leukemias,* in which an accumulation of immature myeloid forms (blasts) in the bone marrow suppresses normal hematopoiesis
- *Myelodysplastic syndromes,* in which defective maturation of myeloid progenitors gives rise to ineffective hematopoiesis, leading to cytopenias
- *Myeloproliferative neoplasms,* in which there is usually increased production of one or more types of blood cells

The pathogenesis of myeloid neoplasms is best understood in the context of normal hematopoiesis, which involves a hierarchy of HSCs, committed progenitors, and more differentiated elements (see Fig. 13.1). Normal hematopoiesis is finely tuned by homeostatic feedback mechanisms involving cytokines and growth factors that modulate the production of red cells, white cells, and platelets by the marrow. These mechanisms are deranged by myeloid neoplasms, which "escape" from normal homeostatic controls and suppress the function of residual normal HSCs and progenitors. The specific manifestations of the different myeloid neoplasms are influenced by

- *The position of the transformed cell within the hierarchy of progenitors* (i.e., a pluripotent HSC versus a more committed progenitor).
- *The effect of the transforming events on differentiation*, which may be inhibited, skewed, or deranged by particular oncogenic mutations.

Given that all myeloid neoplasms originate from transformed hematopoietic progenitors, it is not surprising that divisions between these neoplasms are sometimes blurred. Myeloid neoplasms, like other malignancies, tend to evolve over time to more aggressive forms of disease. In particular, both myelodysplastic syndromes and myeloproliferative neoplasms often "transform" to acute myeloid leukemia. In one of the most important myeloproliferative neoplasms, chronic myeloid leukemia, transformation to acute lymphoblastic leukemia is also seen, indicating that it originates from a transformed pluripotent HSC. As a final twist, it is now evident that many older adults with normal blood counts have clonal hematopoiesis, a state in which a substantial portion of the marrow output is the product of an expanded hematopoietic clone that bears one or more driver mutations associated with hematopoietic neoplasia, most commonly myeloid disease. These patients are not only at risk for hematopoietic neoplasms such as myelodysplastic syndromes, but also are at increased risk for cardiovascular disease (discussed in Chapter 12).

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is a tumor of hematopoietic progenitors caused by acquired oncogenic mutations that impede differentiation, leading to the accumulation of immature myeloid blasts in the marrow. The replacement of the marrow with blasts produces marrow failure and complications related to anemia, thrombocytopenia, and neutropenia. AML occurs at all ages, but the incidence rises throughout life, peaking after 60 years of age. There are about 13,000 new cases each year in the United States.

Classification. AML is quite heterogeneous, reflecting the complexities of myeloid cell differentiation. The current WHO classification subdivides AML into four categories (Table 13.10). The first includes forms of AML that are associated with particular genetic aberrations, which are important because they correlate with prognosis and guide therapy. Also included are categories of AML arising from myelodysplastic syndrome (MDS) or with MDS-like features and therapy-related AML. AMLs in these categories have distinct genetic features and respond poorly to therapy. A fourth "wastebasket" category includes AMLs lacking any of these features. These are classified based on the degree of differentiation and the lineage of the leukemic blasts. Given the increasing role of cytogenetic and molecular features in directing therapy, a further shift toward genetic classification of AML is both inevitable and desirable.

Pathogenesis

Driver mutations in AML tend to fall into four functional categories:

- *Transcription factor mutations that interfere with normal myeloid differentiation.* For example, the two most common chromosomal rearrangements, t(8;21) and inv(16), disrupt the *RUNX1* and *CBFB* genes, respectively. These two genes encode polypeptides that bind one another to form a RUNX1/CBFB transcription factor that is required for normal hematopoiesis. The t(8;21) and the inv(16) create chimeric genes encoding fusion proteins that interfere with the function of RUNX1/CBFB and block the maturation of myeloid cells. Another important example is found in acute promyelocytic leukemia, a distinctive subtype of AML associated with the t(15;17). The t(15;17) creates a fusion gene encoding a chimeric protein consisting of the retinoic acid receptor-α (RARα) and a portion of a protein called PML. As discussed in Chapter 7, this fusion protein interferes with the terminal differentiation of granulocytes, an effect that can be overcome by treatment with all-*trans*-retinoic acid and arsenic trioxide.
- *Mutation of signaling proteins that result in constitutive activation of pro-growth/survival pathways.* For example, AMLs with the t(15;17) also frequently have activating mutations in FLT3, a receptor tyrosine kinase that transmits signals that mimic normal growth factor signaling, thereby increasing cellular proliferation and survival. The combination of PML-RARα and activated FLT3 is a potent inducer of AML in mice, whereas expression of PML-RARα alone is only weakly leukemogenic. Mutations in a large number of other genes involved in pro-growth signaling, such as RAS, also occur in subsets of AML.
- *Mutation of genes that regulate or maintain the "epigenome."* Some of these mutations lead to abnormal DNA methylation patterns or involve members of the cohesin family, proteins that regulate the three-dimensional organization of chromatin in the nucleus. Another group of mutations involving the enzymes IDH1 or IDH2 result in the acquisition of a new enzymatic activity that produces the oncometabolite 2-hydroxyglutarate (described in Chapter 7). IDH inhibitors are effective in treating IDH-mutated forms of AML. The precise mechanism by which

Table 13.10 Major Subtypes of AML in the World Health Organization Classification

Class	Prognosis	Morphology/Comments
I. AML With Genetic Aberrations		
AML with t(8;21)(q22;q22); *RUNX1/RUNXT1* fusion gene	Favorable	Full range of myelocytic maturation; Auer rods easily found; abnormal cytoplasmic granules
AML with inv(16)(p13;q22); *CBFB/MYH11* fusion gene	Favorable	Myelocytic and monocytic differentiation; abnormal eosinophilic precursors with abnormal basophilic granules
AML with t(15;17)(q22;11-12); *RARA/PML* fusion gene	Very favorable	Numerous Auer rods, often in bundles within individual progranulocytes; primary granules usually very prominent, but inconspicuous in microgranular variant; high incidence of DIC
AML with t(11q23;v); diverse *KMT2A* fusion genes	Poor	Usually some degree of monocytic differentiation
AML with normal cytogenetics and mutated *NPM1*	Favorable	Detected by DNA sequencing
II. AML With MDS-Like Features		
With prior MDS	Poor	Diagnosis based on clinical history
AML with multilineage dysplasia	Poor	Maturing cells with dysplastic features typical of MDS
AML with MDS-like cytogenetic aberrations	Poor	Associated with 5q-, 7q-, 20q- aberrations
III. AML, Therapy-Related		
	Very poor	If following alkylator therapy or radiation therapy, 2- to 8-year latency period, MDS-like cytogenetic aberrations (e.g., 5q-, 7q-); if following topoisomerase II inhibitor (e.g., etoposide) therapy, 1- to 3-year latency, translocations involving *KMT2A* (11q23)
IV. AML, Not Otherwise Specified		
AML, minimally differentiated	Intermediate	Negative for myeloperoxidase; myeloid antigens detected on blasts by flow cytometry
AML without maturation	Intermediate	>3% of blasts positive for myeloperoxidase
AML with myelocytic maturation	Intermediate	Full range of myelocytic maturation
AML with myelomonocytic maturation	Intermediate	Myelocytic and monocytic differentiation
AML with monocytic maturation	Intermediate	Nonspecific esterase-positive monoblasts and promonocytes predominate in marrow; may see monoblasts or mature monocytes in the blood
AML with erythroid maturation	Intermediate	Erythroid/myeloid subtype defined by >50% dysplastic maturing erythroid precursors and >20% myeloblasts; pure erythroid subtype defined by >80% erythroid precursors without myeloblasts
AML with megakaryocytic maturation	Intermediate	Blasts of megakaryocytic lineage predominate; detected with antibodies against megakaryocyte-specific markers (GPIIb/IIIa or vWF); often associated with marrow fibrosis; most common AML in Down syndrome

AML, Acute myeloid leukemia; *DIC,* disseminated intravascular coagulation; *GPIIb/IIIa,* glycoprotein IIb-IIIa; *MDS,* myelodysplastic syndrome; *vWF,* von Willebrand factor.

disturbances of the epigenome contribute to the development of AML remains to be determined, but presumably they lead to alterations in gene expression that contribute to the acquisition of one or more cancer hallmarks.

- *Mutation of TP53 or genes that regulate p53.* With increasingly routine sequencing of AML genomes, it has become apparent that AMLs with mutations that impair p53 function have distinctive clinicopathologic features, including associations with complex karyotype, marked dysplasia, and particularly poor prognosis due to resistance to standard therapies.

MORPHOLOGY

The diagnosis of AML is based on the presence of at least 20% myeloid blasts in the bone marrow. Several types of myeloid blasts are recognized, and individual tumors may have more than one type of blast or blasts with hybrid features. **Myeloblasts** have delicate nuclear chromatin, two to four nucleoli, and more voluminous cytoplasm than lymphoblasts (Fig. 13.30A). The cytoplasm often contains fine, peroxidase-positive azurophilic granules. **Auer rods,** distinctive needle-like azurophilic granules, are present in many cases; they are particularly numerous in AML with the t(15;17) (acute promyelocytic leukemia) (Fig. 13.31A). **Monoblasts** (Fig. 13.31B) have folded or lobulated nuclei, lack Auer rods, and are nonspecific esterase-positive. In some AMLs, blasts show megakaryocytic differentiation, which is often accompanied by marrow fibrosis caused by the release of fibrogenic cytokines. Rarely, the blasts of AML show erythroid differentiation.

The number of leukemic cells in the blood is highly variable. Blasts may be more than 100,000/mm^3, but are under 10,000/mm^3 in about 50% of patients. **Occasionally, blasts are entirely absent from the blood (aleukemic leukemia).** For this reason, a bone marrow examination is essential to exclude acute leukemia in pancytopenic patients.

Immunophenotype. Because it can be difficult to distinguish myeloblasts and lymphoblasts morphologically, the diagnosis of AML is confirmed by performing stains for myeloid-specific antigens (Fig. 13.30B and C).

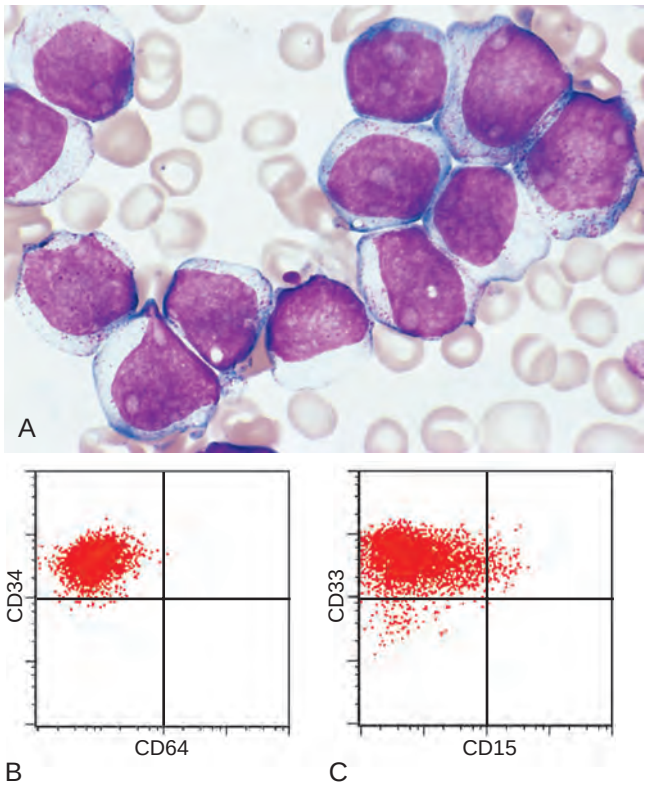

Figure 13.30 (A) Acute myeloid leukemia without maturation (FAB M1 subtype). Myeloblasts have delicate nuclear chromatin, prominent nucleoli, and fine azurophilic granules in the cytoplasm. (B) In the flow cytometric analysis shown, myeloid blasts, represented by the *red dots*, express CD34, a marker of multipotent stem cells, but do not express CD64, a marker of mature myeloid cells. (C) The same myeloid blasts express CD33, a marker of immature myeloid cells, and a subset express CD15, a marker of more mature myeloid cells. Thus these blasts are myeloid cells showing limited maturation. (A, Courtesy Dr. Robert W. McKenna Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.; B and C, courtesy Dr. Louis Picker, Oregon Health Science Center, Portland, Ore.)

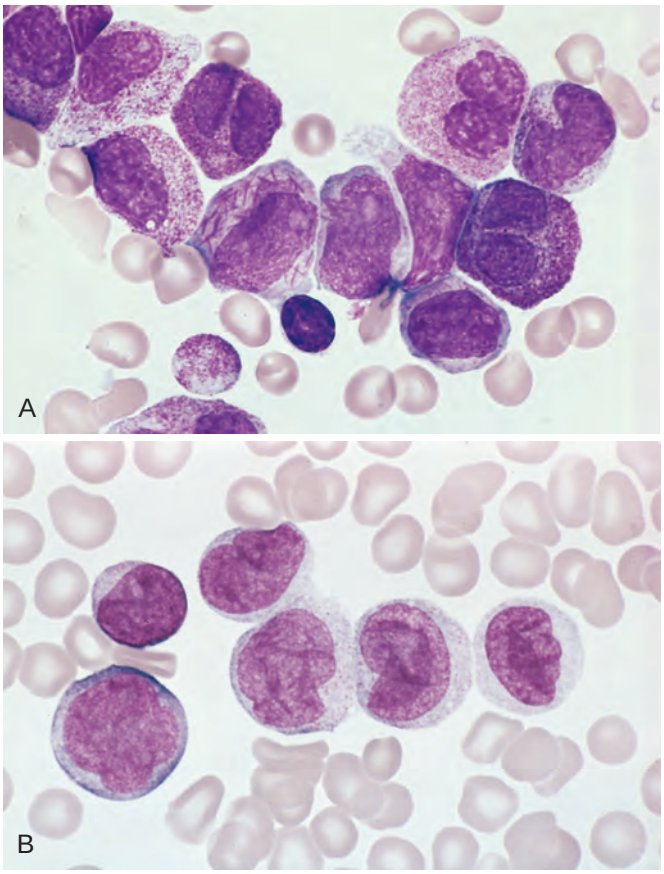

Figure 13.31 Acute myeloid leukemia subtypes. (A) Acute promyelocytic leukemia with the t(15;17) (FAB M3 subtype). Bone marrow aspirate shows neoplastic promyelocytes with abnormally coarse and numerous azurophilic granules. Other characteristic findings include the presence of several cells with bilobed nuclei and a cell in the center of the field that contains multiple needle-like Auer rods. (B) Acute myeloid leukemia with monocytic differentiation (FAB M5b subtype). Peripheral smear shows one monoblast and five promonocytes with folded nuclear membranes. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Cytogenetics. Cytogenetic analysis has a central role in the classification of AML. Karyotypic aberrations are detected in 50% to 70% of cases with standard techniques and in approximately 90% of cases using special high-resolution banding. Particular chromosomal abnormalities correlate with certain clinical features. AML arising de novo in younger adults is commonly associated with balanced chromosomal translocations, particularly t(8;21), inv(16), and t(15;17). In contrast, AML following MDS or exposure to DNA-damaging agents (such as chemotherapy or radiation therapy) often has deletions or monosomies involving chromosomes 5 and 7 and usually lack chromosomal translocations. The exception to this rule is AML occurring after treatment with topoisomerase II inhibitors, which is strongly associated with translocations involving the *KTM2A* gene on chromosome 11q23. AML in older adults also is more likely to be associated with "bad" aberrations, such as deletions of chromosomes 5q and 7q and complex karyotypic abnormalities, features that are associated with mutations that impair p53 function.

Clinical Features

Most patients present within weeks or a few months of the onset of symptoms with complaints related to anemia, neutropenia, and thrombocytopenia, most notably fatigue, fever, and spontaneous mucosal and cutaneous bleeding. You will remember that these findings are very similar to those produced by ALL. Thrombocytopenia results in abnormal bleeding, which often is prominent. Cutaneous petechiae and ecchymoses, serosal hemorrhages into the linings of the body cavities and viscera, and mucosal hemorrhages into the gingivae and urinary tract are common. Procoagulants and fibrinolytic factors released by leukemic cells, especially in AML with the t(15;17), exacerbate the bleeding tendency. Infections are frequent, particularly in the oral cavity, skin, lungs, kidneys, urinary bladder, and colon, and are often caused by opportunists such as fungi, *Pseudomonas,* and commensals.

Signs and symptoms related to involvement of tissues other than the marrow are usually less striking in AML than in ALL, but tumors with monocytic differentiation often infiltrate the skin (leukemia cutis) and the gingiva; this probably reflects the normal tendency of monocytes to extravasate into tissues. Central nervous system spread is less common than in ALL. AML occasionally presents as

a localized soft tissue mass known variously as a myeloblastoma, myeloid sarcoma, or chloroma. Without systemic treatment, such tumors inevitably progress to full-blown AML over time.

The overall prognosis is guarded, as AML is a difficult disease to treat; about 60% of patients achieve complete remission with chemotherapy, but only 15% to 30% remain free of disease for 5 years. However, the outcome varies markedly among different molecular subtypes. With targeted therapy using all-*trans*-retinoic acid and arsenic salts (described in Chapter 7), AMLs with the t(15;17) have the best prognosis of any type, being curable in more than 90% of patients. AMLs with t(8;21) or inv(16) also have a relatively good prognosis with conventional chemotherapy. By contrast, the prognosis is much worse for patients with AML who are over age 60 years, or who develop disease following MDS or genotoxic therapy, in large part because "good" genetic subtypes are rare in these settings and also because those that follow genotoxic therapy are often associated with *TP53* mutations. These "high-risk" forms of AML (as well as relapsed AML of all types) are treated with HSC transplantation when possible. Encourgingly, new therapies have emerged from insights gained from DNA sequencing; one success story is the deployment of inhibitors of mutated forms of IDH, which often produce excellent responses in patients with *IDH*-mutated AML.

Myelodysplastic Syndrome

The term "*myelodysplastic syndrome*" refers to a group of clonal stem cell disorders characterized by maturation defects that are associated with ineffective hematopoiesis and a high risk of transformation to AML. In MDS, the bone marrow is partly or wholly replaced by the clonal progeny of a neoplastic multipotent stem cell that retains the capacity to differentiate but does so in an ineffective and disordered fashion. Because the "birthing process" of blood cells is defective in MDS, patients have peripheral blood cytopenias of varying severity.

MDS may be either primary (idiopathic) or secondary to previous genotoxic drug or radiation therapy (t-MDS). t-MDS usually appears from 2 to 8 years after the genotoxic exposure. All forms of MDS can transform to AML, but transformation occurs with highest frequency and most rapidly in t-MDS. Although characteristic morphologic changes are typically seen in the marrow and the peripheral blood, the diagnosis frequently requires correlation with other laboratory tests. Cytogenetic analysis is often helpful, since certain chromosomal aberrations (discussed later) are often observed, and DNA sequencing also is now routinely used to help establish the diagnosis.

Pathogenesis

MDS is associated with driver mutations that partially overlap with those seen in AML, which is unsurprising given that MDS often evolves to AML. The affected proteins can be lumped into three major functional categories, as follows:

- *Epigenetic factors.* Frequent mutations are seen involving many of the same epigenetic factors that are mutated in AML, including factors that regulate DNA methylation, histone modifications, and chromatin looping; thus like AML, dysregulation of the epigenome appears to be important in the genesis of MDS.
- *RNA splicing factors.* A subset of tumors has mutations involving components of the 3′ end of the RNA splicing machinery. Precisely how these mutations contribute to the development of MDS has yet to be determined.
- *Transcription factors.* These mutations affect transcription factors that are required for normal myelopoiesis and may contribute to the deranged differentiation that characterizes MDS. Notably, classic chromosomal rearrangements that are seen in de novo AML, such as the t(8;21), inv(16), and t(15;17), are not seen in MDS; instead, most of the mutations are loss-of-function mutations in genes such as *RUNX1*.

In addition, roughly 10% of MDS cases have loss-of-function mutations in *TP53,* which as in AML correlate with the presence of a complex karyotype and particularly poor clinical outcomes. Both primary MDS and t-MDS are associated with similar recurrent chromosomal abnormalities, including monosomies 5 and 7; deletions of 5q, 7q, and 20q; and trisomy 8. As with aneuploidy in other cancers, how these aberrations contribute to MDS is incompletely understood. One idea is that the gain or loss of single copies of key genes is sufficient to give cells a growth advantage and that aneuploidy is one way to achieve this result. For example, subtle increases in the notorious oncoprotein MYC is sufficient to stimulate cell growth. Notably, the *MYC* gene is located on chromosome 8, and trisomy 8 is one of the most common forms of aneuploidy in a wide range of myeloid tumors. Similarly, the region that is commonly lost on chromosome 5q contains a gene encoding the ribosomal protein RPS14. In experimental systems, loss of one copy of RPS14 produces ineffective erythropoiesis, one of the hallmarks of MDS.

MDS appears to frequently arise from an asymptomatic state called clonal hematopoiesis of indeterminate potential (CHIP), defined by the presence of one or more pathogenic mutations associated with MDS in an individual with normal blood counts. Like CHIP (as discussed in Chapter 11), MDS patients show evidence of pro-inflammatory state and are at increased risk of dying from cardiovascular disease. Recent work suggests that MDS-associated inflammation may stem from activation of the inflammasome in neoplastic myeloid cells; precisely how this occurs remains to be determined.

MORPHOLOGY

Although the marrow is usually hypercellular at diagnosis, it is sometimes normocellular or, less commonly, hypocellular. The most characteristic finding is disordered (dysplastic) differentiation affecting the erythroid, granulocytic, monocytic, and megakaryocytic lineages to varying degrees (Fig. 13.32). Within the erythroid series, common abnormalities include **ring sideroblasts,** erythroblasts with iron-laden mitochondria visible as perinuclear granules in Prussian blue–stained aspirates or biopsies; **megaloblastoid maturation,** resembling that seen in vitamin B_{12} and folate deficiency (Chapter 14); and **nuclear budding abnormalities,** recognized as nuclei with misshapen, often polyploid, outlines. Neutrophils frequently contain decreased numbers of secondary granules, toxic granulations, and/or Döhle bodies. **Pseudo–Pelger-Hüet**

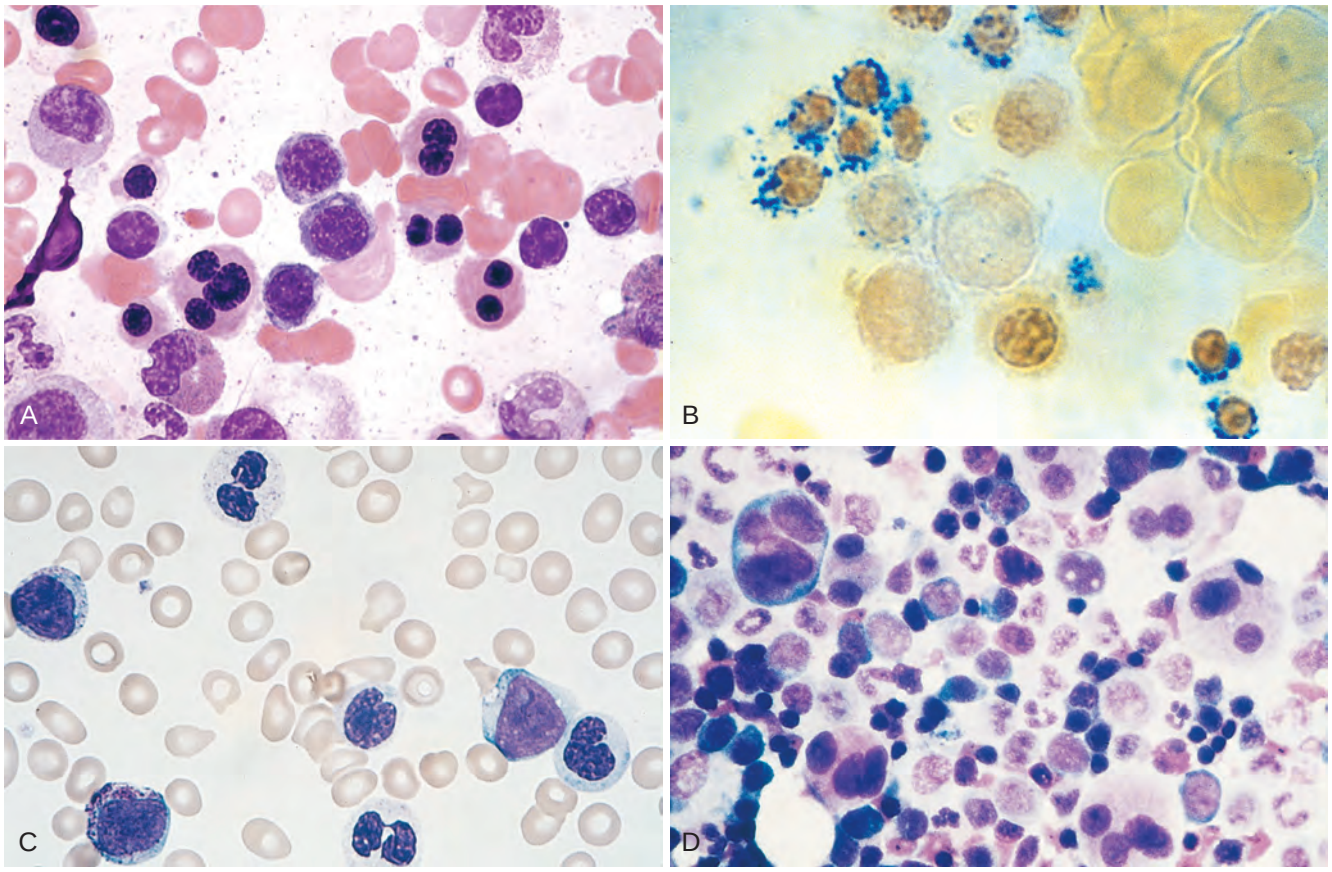

Figure 13.32 Myelodysplasia. Characteristic forms of dysplasia are shown. (A) Nucleated red cell progenitors with multilobated or multiple nuclei. (B) Ringed sideroblasts, erythroid progenitors with iron-laden mitochondria seen as blue perinuclear granules (Prussian blue stain). (C) Pseudo-Pelger-Hüet cells, neutrophils with only two nuclear lobes instead of the normal three to four, are observed at the top and bottom of this field. (D) Megakaryocytes with multiple nuclei instead of the normal single multilobated nucleus. (A, B, and D, Marrow aspirates; C, peripheral blood smear.)

cells, neutrophils with only two nuclear lobes, are commonly observed, and neutrophils are seen occasionally that completely lack nuclear segmentation. Megakaryocytes with single nuclear lobes or multiple separate nuclei **(pawn ball megakaryocytes)** are also characteristic. **Myeloid blasts** may be increased but make up less than 20% of the overall marrow cellularity. The blood often contains pseudo–Pelger-Hüet cells, giant platelets, macrocytes, and poikilocytes, accompanied by a relative or absolute monocytosis. Myeloid blasts usually make up less than 10% of the leukocytes in the blood.

Clinical Features

Primary MDS is predominantly a disease of older adults; the mean age of onset is 70 years. In up to half of the cases, it is discovered incidentally on routine blood testing. When symptomatic, it presents with weakness, infections, and hemorrhages, all due to pancytopenia.

Primary MDS is divided into six categories based on morphologic and cytogenetic features in the WHO classification, details of which are beyond our scope. Several prognostic scoring systems have been developed. In each, worse outcomes are (understandably) predicted by higher blast counts and more severe cytopenias, as well as the presence of multiple clonal chromosomal abnormalities.

Depending on the prognostic group, the median survival in primary MDS varies from less than 6 months to greater than 5 years. Progression to AML is more likely and occurs more rapidly in poor prognosis groups and is often accompanied by the appearance of additional cytogenetic abnormalities. Patients frequently succumb to the complications of thrombocytopenia (bleeding) and neutropenia (infection). The outlook is even grimmer in t-MDS, which has a median survival of only 4 to 8 months and often progresses to AML within 2 to 3 months of diagnosis.

Treatment options are fairly limited. In younger patients, allogeneic HSC transplantation offers hope for reconstitution of normal hematopoiesis and possible cure. Older patients with MDS are treated supportively with antibiotics and blood product transfusions. Thalidomide-like drugs and DNA methylation inhibitors improve the effectiveness of hematopoiesis and the peripheral blood counts in a subset of patients. The presence of isolated 5q deletion is correlated with a hematologic response to thalidomide-like drugs, but response to DNA methylation inhibitors remains unpredictable.

Myeloproliferative Neoplasms

The common pathogenic feature of myeloproliferative neoplasms is the presence of mutated, constitutively

activated tyrosine kinases or other acquired aberrations in signaling pathways that lead to growth factor independence. Hematopoietic growth factors act on normal progenitors by binding to surface receptors and activating tyrosine kinases, which turn on pathways that promote growth and survival (Chapter 7). The mutated tyrosine kinases found in myeloproliferative neoplasms circumvent normal controls and lead to growth factor–independent proliferation and survival of marrow progenitors. Because the tyrosine kinase mutations underlying the various myeloproliferative neoplasms do not impair differentiation, the most common consequence is an increase in the production of one or more mature blood elements. Most myeloproliferative neoplasms originate in multipotent myeloid progenitors, whereas others arise in pluripotent stem cells that give rise to both lymphoid and myeloid cells.

There is a considerable degree of clinical and morphologic overlap among myeloproliferative neoplasms. The common features include:

- *Increased proliferative drive* in the bone marrow
- Homing of the neoplastic stem cells to secondary hematopoietic organs, producing *extramedullary hematopoiesis*
- Variable transformation to a spent phase characterized by *marrow fibrosis* and peripheral blood *cytopenias*
- Variable transformation to *acute leukemia*

Certain myeloproliferative neoplasms are strongly associated with activating mutations in specific tyrosine kinases. This insight and the availability of kinase inhibitors have increased the importance of molecular tests for tyrosine kinase mutations, both for purposes of diagnosis and the selection of therapy. This discussion is confined to the more common myeloproliferative neoplasms, which are classified based on clinical, laboratory, and molecular criteria. Systemic mastocytosis, a distinctive neoplasm that is associated with mutations in the KIT tyrosine kinase, is discussed under disorders of the skin (Chapter 25). The association of various myeloproliferative neoplasms with specific tyrosine kinase mutations (including rare disorders not discussed here) is summarized in Table 13.11.

Chronic Myeloid Leukemia

CML is distinguished from other myeloproliferative neoplasms by the presence of a chimeric *BCR-ABL* gene derived from portions of the *BCR* gene on chromosome 22 and the *ABL* gene on chromosome 9. *BCR-ABL* directs the synthesis of a constitutively active BCR-ABL tyrosine kinase, which in CML is usually 210 kDa in size. In more than 90% of cases, *BCR-ABL* is created by a reciprocal (9;22)(q34;q11) translocation (the so-called *Philadelphia chromosome* [Ph]). In the remaining cases the *BCR-ABL* fusion gene is formed by cytogenetically complex or cryptic rearrangements and must be detected by other methods, such as fluorescence in situ hybridization or polymerase chain reaction (PCR)–based tests. The cell of origin is a pluripotent HSC.

Pathogenesis

Tyrosine kinases are normally regulated by ligand-mediated dimerization and autophosphorylation, which creates an activated kinase capable of phosphorylating other protein substrates (Chapters 3 and 7). The BCR moiety of BCR-ABL contains a dimerization domain that self-associates, leading to the activation of the ABL tyrosine kinase moiety (Fig. 13.33). The ABL kinase in turn phosphorylates proteins that induce signaling through the same pro-growth and pro-survival pathways that are turned on by hematopoietic growth factors, including the RAS and JAK/STAT pathways. For unknown reasons, BCR-ABL preferentially drives the proliferation of granulocytic and megakaryocytic progenitors and also causes the abnormal release of immature granulocytic forms from the marrow into the blood.

MORPHOLOGY

The marrow is markedly **hypercellular** because of massively increased numbers of maturing granulocytic precursors, which usually include an elevated proportion of eosinophils and basophils. Megakaryocytes are also increased and usually include small, dysplastic forms. Erythroid progenitors are present in normal or

Table 13.11 Mutations That Activate Tyrosine Kinase Signaling in Myeloproliferative Neoplasms

Disorder	Mutation	Frequency[a]	Consequences
Chronic myeloid leukemia	*BCR-ABL* fusion gene	100%	Constitutive ABL kinase activation
Polycythemia vera	*JAK2* mutations	>95%	Constitutive JAK2 kinase activation
Essential thrombocythemia	*JAK2* mutations *CALR* mutations *MPL* mutations	50%–60% 25%–35% 5%–10%	Constitutive JAK2 kinase activation Alternative MPL ligand Constitutive MPL kinase activation
Primary myelofibrosis	*JAK2* mutations *CALR* mutations *MPL* mutations	50%–60% 25%–35% 5%–10%	Constitutive JAK2 kinase activation Alternative MPL ligand Constitutive MPL kinase activation
Systemic mastocytosis	*KIT* mutations	>90%	Constitutive KIT kinase activation
Chronic eosinophilic leukemia	*FIP1L1-PDGFRA* fusion gene *PDE4DIP-PDGFRB* fusion gene	Common Rare	Constitutive PDGFRα kinase activation Constitutive PDGFRβ kinase activation
Myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene mutations[b]	Various fusion genes involving *FGFR1*, *PDGFRA*, *PDGFRB*, or *JAK2*	100%	Constitutive tyrosine kinase activation

[a]Refers to frequency within a diagnostic category.

[b]Rare disorder originating in pluripotent hematopoietic stem cells that presents with concomitant myeloproliferative neoplasm and lymphoblastic leukemia/lymphoma.

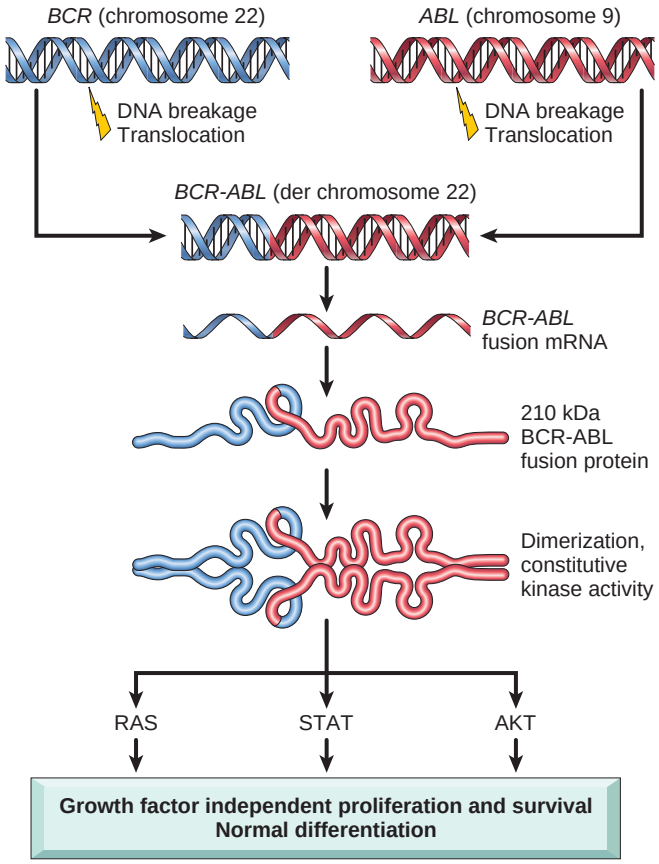

Figure 13.33 Pathogenesis of chronic myeloid leukemia. Breakage and joining of *BCR* and *ABL* creates a chimeric *BCR-ABL* fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase. BCR-ABL activates multiple downstream pathways, which drive growth factor–independent proliferation and survival of bone marrow progenitors. Because BCR-ABL does not interfere with differentiation, the net result is an increase in mature elements in the peripheral blood, particularly granulocytes and platelets. *der,* Derivative chromosome.

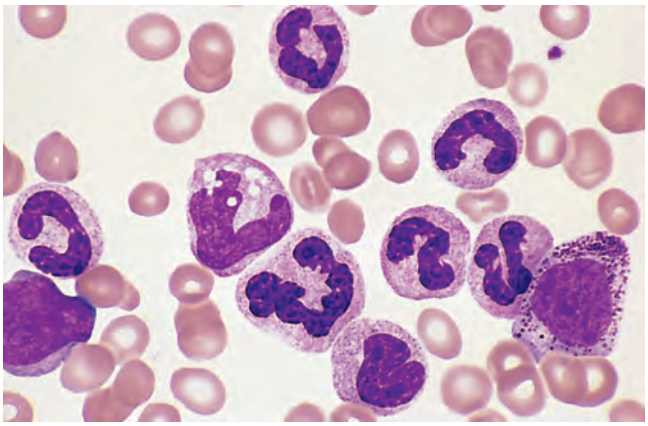

Figure 13.34 Chronic myeloid leukemia. Peripheral blood smear shows many mature neutrophils, some metamyelocytes, and a myelocyte. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Figure 13.35 Chronic myeloid leukemia (spleen). Enlarged spleen (2630 g; normal: 150 to 200 g) with greatly expanded red pulp stemming from neoplastic hematopoiesis. (Courtesy Dr. Daniel Jones, Department of Pathology, Ohio State University, Columbus, OH.)

mildly decreased numbers. A characteristic finding is the presence of scattered macrophages with abundant wrinkled, green-blue cytoplasm—so-called sea-blue histiocytes. Increased deposition of reticulin is typical, but overt marrow fibrosis is rare early in the course. The blood reveals a **leukocytosis, often exceeding 100,000 cells/mm^3** (Fig. 13.34), which consists predominantly of neutrophils, band forms, metamyelocytes, myelocytes, eosinophils, and basophils. Blasts usually make up less than 10% of the circulating cells. Platelets are also usually increased, sometimes markedly. The spleen is often greatly enlarged as a result of extensive extramedullary hematopoiesis (Fig. 13.35), and often contains infarcts of varying age. Extramedullary hematopoiesis can also produce mild hepatomegaly and lymphadenopathy.

Clinical Features

CML is primarily a disease of adults but also occurs in children and adolescents. The peak incidence is in the fifth to sixth decades of life. There are about 4500 new cases per year in the United States.

The onset is insidious. Mild-to-moderate anemia and hypermetabolism due to increased cell turnover lead to fatigability, weakness, weight loss, and anorexia. Sometimes the first symptom is a dragging sensation in the abdomen caused by splenomegaly or the acute onset of left upper quadrant pain due to splenic infarction. CML is best differentiated from other myeloproliferative neoplasms by detection of the *BCR-ABL* fusion gene through either chromosomal analysis or PCR-based tests.

The natural history of untreated disease is one of slow progression; without any treatment, the median survival is about 3 years. After a variable period averaging 3 years, about 50% of patients enter an "accelerated phase" marked by increasing anemia and thrombocytopenia, sometimes accompanied by a rise in the number of basophils in the blood. Additional clonal cytogenetic abnormalities, such as trisomy 8, isochromosome 17q, or duplication of the Ph chromosome, often appear. Within 6 to 12 months, the accelerated phase terminates in a picture resembling acute leukemia *(blast crisis)*. In the other 50% of patients, blast crises occur abruptly without an accelerated phase. In 70% of crises, the blasts are of myeloid origin (myeloid blast crisis), whereas in most of the remainder the blasts are of pre–B cell origin (lymphoid blast crisis). This is taken as evidence that CML originates from a pluripotent stem cell with both myeloid and lymphoid potential.

Given that acute leukemias often stem from complementary mutations involving a transcription factor and a tyrosine kinase, it might be predicted that blast crisis would be caused by an acquired mutation in a key transcriptional regulator. This prediction has been realized in lymphoid blast crisis, in which 85% of cases are associated with mutations that interfere with the activity of Ikaros, a transcription factor encoded by the gene *IKZF1* that regulates the differentiation of hematopoietic progenitors. The same types of Ikaros mutations are also seen in BCR-ABL–positive B-ALL, suggesting that these two varieties of aggressive leukemia have a similar molecular origin.

Understanding of the pathogenesis of CML has led to the use of drugs that target BCR-ABL. Treatment with BCR-ABL inhibitors results in sustained hematologic remissions in greater than 90% of patients, with generally tolerable side effects. These inhibitors markedly decrease the number of BCR-ABL–positive cells in the marrow and elsewhere, but do not extinguish the CML "stem cell," which persists at low levels. As a result, it is not clear if BCR-ABL inhibitors are ever truly curative. However, this form of targeted therapy controls blood counts and substantially decreases the risk of transformation to the accelerated phase and blast crisis, which is the greatest threat to the patient. It may be that by lowering the proliferative drive of the BCR-ABL–positive progenitors, BCR-ABL inhibitors decrease the rate at which these cells acquire mutations that lead to disease progression.

The other major threat to the patient is the emergence of resistance to first-generation BCR-ABL inhibitors, which in about 50% of cases stems from mutations in BCR-ABL and in the remaining cases mutations in other kinases. This problem has been overcome in part by development of second- and third-generation kinase inhibitors that are active against mutated forms of BCR-ABL. For relatively young patients, HSC transplantation performed in the stable phase is curative in about 75% of cases. The outlook is less favorable once the accelerated phase or blast crisis supervenes, as transplantation and treatment with BCR-ABL inhibitors are both less effective in these settings.

Polycythemia Vera

Polycythemia vera (PCV) is characterized by increased marrow production of red cells, granulocytes, and platelets (panmyelosis), but it is the increase in red cells (polycythemia) that is responsible for most of the clinical symptoms. PCV must be differentiated from relative polycythemia resulting from hemoconcentration and other causes of absolute polycythemia (Chapter 14).

Pathogenesis

In PCV, the transformed progenitor cells have markedly decreased requirements for erythropoietin and other hematopoietic growth factors due to activating mutations in the tyrosine kinase JAK2. JAK2 participates in the JAK/STAT pathway, which lies downstream of multiple hematopoietic growth factor receptors, including the erythropoietin receptor. Because the pathway is constitutively active and red cell numbers are abnormally high, serum erythropoietin levels in PCV are low. This is in contradistinction to secondary forms of polycythemia, in which erythropoietin levels are high. The elevated hematocrit leads to increased blood viscosity and sludging. These hemodynamic factors, together with thrombocytosis and abnormal platelet function, make patients with PCV prone to both thrombosis and bleeding.

More than 97% of cases are associated with a mutation in *JAK2* that results in a valine-to-phenylalanine substitution at residue 617; other *JAK2* mutations are found in most (and perhaps all) of the remaining cases. The mutated forms of *JAK2* found in PCV render hematopoietic cell lines growth factor–independent and when expressed in murine bone marrow progenitors cause a PCV-like disease that is associated with marrow fibrosis. In 25% to 30% of cases the tumor cells contain two mutated copies of *JAK2,* a genotype that is associated with higher white cell counts, more significant splenomegaly, symptomatic pruritus, and a greater rate of progression to the spent phase.

The proliferative drive in PCV (and other myeloproliferative neoplasms associated with *JAK2* mutations) is less than in CML, which is associated with more pronounced marrow hypercellularity, leukocytosis, and splenomegaly. Presumably, JAK2 signals are quantitatively weaker or qualitatively different from those produced by BCR-ABL (see Fig. 13.33).

MORPHOLOGY

The marrow is hypercellular, but some residual fat is usually present. **The increase in red cell progenitors is subtle and usually accompanied by an increase in granulocytic precursors and megakaryocytes as well.** At diagnosis, a moderate to marked increase in reticulin fibers is seen in about 10% of marrows. Mild organomegaly is common, being caused early in the course largely by congestion; at this stage extramedullary hematopoiesis is minimal. The peripheral blood often contains increased numbers of basophils and abnormally large platelets.

Late in the course, PCV often progresses to a **spent phase** characterized by extensive marrow fibrosis that displaces hematopoietic cells. This is accompanied by increased extramedullary hematopoiesis in the spleen and liver, often leading to prominent organomegaly (Fig. 13.36). Transformation to AML, with its typical features, occurs in about 1% of patients.

Figure 13.36 Polycythemia vera, spent phase. Massive splenomegaly (3020 g; normal: 150 to 200 g) largely due to extramedullary hematopoiesis occurring in the setting of advanced marrow myelofibrosis. (Courtesy Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, Mass.)

Clinical Features

PCV is uncommon, having an incidence of 1 to 3 per 100,000 per year. It appears insidiously, usually in adults of late middle age. Most symptoms are related to the increased red cell mass and hematocrit. Usually, there is also an increased total blood volume. Together, these factors cause abnormal blood flow, particularly on the low-pressure venous side of the circulation, which becomes greatly distended. Patients are plethoric and cyanotic due to stagnation and deoxygenation of blood in peripheral vessels. Headache, dizziness, hypertension, and gastrointestinal symptoms are common. Intense pruritus and peptic ulceration may occur, both possibly resulting from the release of histamine from basophils. High cell turnover gives rise to hyperuricemia; symptomatic gout is seen in 5% to 10% of cases.

More ominously, the abnormal blood flow and platelet function that accompany PCV lead to an increased risk of both major bleeding and thrombotic episodes. About 25% of patients first come to attention due to deep venous thrombosis, myocardial infarction, or stroke. Thromboses sometimes also occur in the hepatic veins (producing Budd-Chiari syndrome) and the portal and mesenteric veins (leading to bowel infarction). It must be remembered that thrombotic complications may precede the appearance of the typical hematologic findings. Minor hemorrhages (epistaxis, bleeding gums) are common, and life-threatening hemorrhages occur in 5% to 10% of cases.

The hemoglobin concentration is typically greater than 16 g/dL, and the hematocrit is often 55% or more. Sometimes chronic bleeding leads to iron deficiency, which can suppress erythropoiesis sufficiently to lower the hematocrit into the normal range, an example of two defects counteracting one another to "correct" a laboratory abnormality. The white cell count ranges from 12,000 to 50,000 cells/mm^3, and the platelet count is often greater than 500,000 platelets/mm^3. The platelets usually exhibit morphologic abnormalities such as giant forms and are often defective in functional aggregation studies.

Without treatment, death from bleeding or thrombosis occurs within months of diagnosis. However, simply maintaining the red cell mass at nearly normal levels by phlebotomy extends the median survival to about 10 years. Although JAK2 inhibitors are an obvious targeted therapy for PCV, current JAK2 inhibitors are not as effective as was hoped (possibly because of the quality of the available drugs) and are used mainly in patients with significant splenomegaly. Extended survival with treatment has revealed that PCV tends to evolve to a "spent phase," during which clinical and anatomic features of primary myelofibrosis develop. The disease undergoes this transition in about 15% to 20% of patients after an average period of 10 years. It is marked by the appearance of obliterative fibrosis in the bone marrow (myelofibrosis) and extensive extramedullary hematopoiesis, principally in the spleen, which enlarges greatly. The mechanisms underlying the progression to the spent phase are not known.

In about 2% of patients, PCV transforms to AML. Surprisingly, the AML clone often lacks *JAK2* mutations, suggesting that the causative *JAK2* mutations occur in an abnormal stem cell that already harbors other oncogenic mutations and therefore is "at risk" for giving rise to several different myeloid tumors. Unlike CML, transformation to ALL is rarely observed, consistent with the cell of origin being a progenitor committed to myeloid differentiation.

Essential Thrombocytosis

Essential thrombocytosis (ET) is associated with diverse mutations that increase JAK-STAT signaling and mimic constitutive growth factor receptor signaling. Over 90% of cases have either activating mutations in JAK2 (approximately 50% to 60% of cases); MPL (5% to 10% of cases), a receptor tyrosine kinase that is normally activated by thrombopoietin and that signals through JAK2; or calreticulin (approximately 30% of cases). Remarkably, the mutated forms of CALR seen in ET are secreted and bind and activate the thrombopoietin receptor, an example of an oncogenic autocrine feedback loop.

ET manifests clinically with elevated platelet counts and is separated from PCV and primary myelofibrosis based on the absence of polycythemia and marrow fibrosis, respectively. In cases without tyrosine kinase mutations, causes of reactive thrombocytosis, such as inflammatory disorders and iron deficiency, must be excluded before the diagnosis can be established.

Pathogenesis

Constitutive JAK2 or MPL signaling renders the progenitors thrombopoietin-independent and leads to hyperproliferation. The *JAK2* mutation is the same as that found in almost all cases of PCV. Why some patients with *JAK2* mutations present with PCV and others with ET is not understood. Some cases thought to be ET may in fact be PCV disguised by iron deficiency (which is more common in individuals diagnosed with ET), but this is probably true of only a small fraction of patients. As mentioned, most cases without JAK2 or MPL mutations have calreticulin mutations instead.

MORPHOLOGY

Bone marrow cellularity is usually only mildly increased, but megakaryocytes are often markedly increased in number and include abnormally large forms. Delicate reticulin fibrils are often seen, but the overt fibrosis of primary myelofibrosis (see later) is absent. Peripheral smears usually reveal abnormally large platelets (Fig. 13.37), often accompanied by mild leukocytosis. Modest degrees of extramedullary hematopoiesis may occur, producing mild organomegaly in about 50% of patients. Uncommonly, a spent phase of marrow fibrosis or transformation to AML supervenes.

Clinical Features

The incidence of ET is 1 to 3 per 100,000 per year. It usually occurs past the age of 60 but may also be seen in young adults. Dysfunctions of platelets derived from the neoplastic clone can lead to thrombosis and hemorrhage, the major clinical manifestations. Platelets are not only increased in number but also frequently demonstrate qualitative abnormalities in functional tests. The types of thrombotic events resemble those observed in PCV; they include deep venous thrombosis, portal and hepatic vein thrombosis, and myocardial infarction. One characteristic symptom is *erythromelalgia,* a throbbing and burning of hands and feet caused by occlusion of small arterioles by platelet aggregates, which also may be seen in PCV.

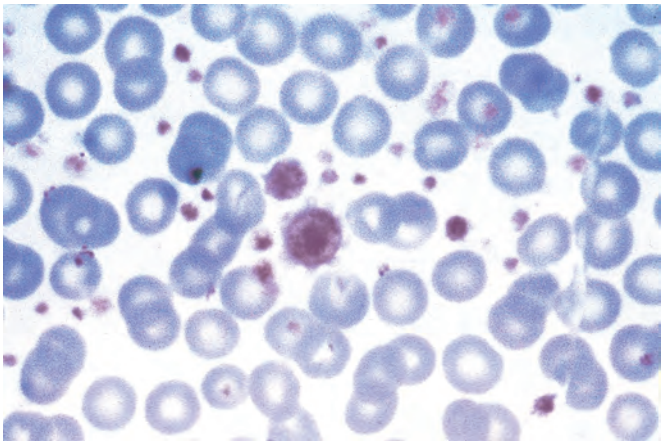

Figure 13.37 Essential thrombocytosis. Peripheral blood smear shows marked thrombocytosis including giant platelets approximating the size of surrounding red cells.

ET is an indolent disorder with long asymptomatic periods punctuated by occasional thrombotic or hemorrhagic crises. Median survival times are 12 to 15 years. Thrombotic complications are most likely in patients with very high platelet counts and homozygous *JAK2* mutations. Therapy consists of "gentle" chemotherapeutic agents that suppress thrombopoiesis.

Primary Myelofibrosis

The hallmark of primary myelofibrosis is the development of obliterative marrow fibrosis. The replacement of the marrow by fibrous tissue reduces bone marrow hematopoiesis, leading to cytopenias and extensive extramedullary hematopoiesis. Histologically, the appearance is identical to the spent phase that occurs occasionally late in the course of other myeloproliferative neoplasms. The genetics of primary myelofibrosis is very similar to ET; approximately 90% cases have activating mutations of *JAK2, CALR,* or *MPL.*

Pathogenesis

The chief pathologic feature is the extensive deposition of collagen in the marrow by nonneoplastic fibroblasts. The fibrosis inexorably displaces hematopoietic elements, including stem cells, from the marrow and eventually leads to marrow failure. It is probably caused by the inappropriate release of fibrogenic factors from neoplastic megakaryocytes. Two factors synthesized by megakaryocytes have been implicated: *platelet-derived growth factor* and *TGF-β.* As you recall, platelet-derived growth factor and TGF-β are fibroblast mitogens. In addition, TGF-β promotes collagen deposition and causes angiogenesis, both of which are observed in myelofibrosis (Chapter 3).

As marrow fibrosis progresses, circulating HSCs take up residence in niches in secondary hematopoietic organs, such as the spleen, the liver, and the lymph nodes, leading to the appearance of extramedullary hematopoiesis. For incompletely understood reasons, red cell production at extramedullary sites is disordered. This factor and the concomitant suppression of marrow function result in moderate to severe anemia. It is not clear whether primary myelofibrosis is truly distinct from PCV and ET or merely reflects unusually rapid progression to the spent phase.

MORPHOLOGY

Early in the course, the marrow is often hypercellular due to increases in maturing cells of all lineages, a feature reminiscent of PCV. Morphologically, the erythroid and granulocytic precursors appear normal, but megakaryocytes are large, dysplastic, and abnormally clustered. At this stage fibrosis is minimal, and the blood may show leukocytosis and thrombocytosis. **With progression, the marrow becomes more hypocellular and diffusely fibrotic.** Clusters of atypical megakaryocytes with unusual nuclear shapes (described as "cloud-like") are seen, and hematopoietic elements are often found within dilated sinusoids, which is a manifestation of severe architectural distortion caused by the fibrosis. Very late in the course, the fibrotic marrow space may be converted into bone, a change called "osteosclerosis." These features are identical to those seen in the spent phase of other myeloproliferative neoplasms.

Fibrotic obliteration of the marrow space leads to extensive extramedullary hematopoiesis, principally in the spleen, which is usually markedly enlarged, sometimes up to 4000 g. Grossly, such spleens are firm and diffusely red to gray. As in CML, subcapsular infarcts are common (see Fig. 13.41). Initially, extramedullary hematopoiesis is confined to the sinusoids, but later it expands into the cords. The liver may be enlarged moderately by sinusoidal foci of extramedullary hematopoiesis. Hematopoiesis may also appear within lymph nodes, but significant lymphadenopathy is uncommon.

The marrow fibrosis is reflected in several characteristic blood findings (Fig. 13.38). Marrow distortion leads to the premature release of nucleated erythroid and early granulocyte progenitors **(leukoerythroblastosis)**, and immature cells also enter the circulation from sites of extramedullary hematopoiesis. **Teardrop-shaped red cells** (dacryocytes), cells that were probably damaged during the birthing process in the fibrotic marrow, are also often seen. Although characteristic of primary myelofibrosis, leukoerythroblastosis and teardrop red cells are seen in many infiltrative disorders of the marrow, including granulomatous diseases and metastatic tumors. Other common, albeit nonspecific, blood findings include abnormally large platelets and basophilia.

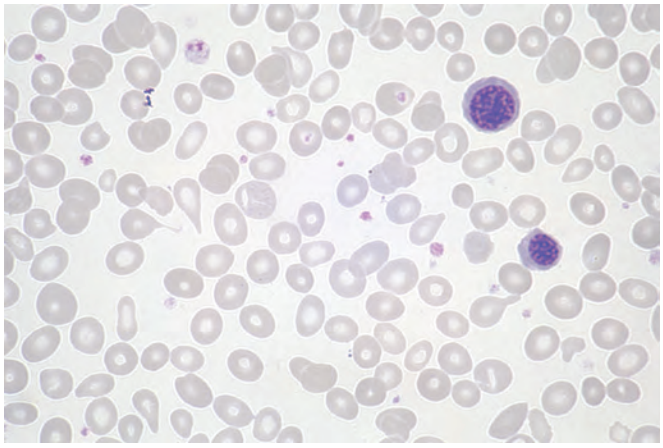

Figure 13.38 Primary myelofibrosis (peripheral blood smear). Two nucleated erythroid precursors and several teardrop-shaped red cells (dacryocytes) are evident. Immature myeloid cells were present in other fields. An identical picture can be seen in other diseases producing marrow distortion and fibrosis.

Clinical Features

Primary myelofibrosis is less common than PCV and ET and usually occurs in individuals older than 60 years of age. Except when preceded by another myeloproliferative neoplasm, it comes to attention because of progressive anemia and splenomegaly, which produces a sensation of fullness in the left upper quadrant. Nonspecific symptoms such as fatigue, weight loss, and night sweats result from an increase in metabolism associated with the expanding mass of hematopoietic cells. Hyperuricemia and secondary gout due to a high rate of cell turnover can complicate the picture.

Laboratory studies typically show a moderate to severe normochromic normocytic anemia accompanied by leukoerythroblastosis. The white cell count is usually normal or mildly reduced, but can be markedly elevated (80,000 to 100,000 cells/mm^3) early in the course. The platelet count is usually normal or elevated at the time of diagnosis, but thrombocytopenia may supervene as the disease progresses. These blood findings are not specific; bone marrow biopsy is essential for diagnosis.

Primary myelofibrosis is a much more difficult disease to treat than PCV or ET. The course is variable, but the median survival is in the range of 3 to 5 years. Threats to life include intercurrent infections, thrombotic episodes, bleeding related to platelet abnormalities, and transformation to AML, which occurs in 5% to 20% of cases. When myelofibrosis is extensive, AML sometimes arises at extramedullary sites, including lymph nodes and soft tissues. JAK2 inhibitors are approved to treat this disease and are effective at decreasing the splenomegaly and constitutional symptoms. HSC transplantation offers some hope for cure in patients young and fit enough to withstand the procedure.

KEY CONCEPTS

MYELOID NEOPLASMS

Myeloid tumors occur mainly in adults and fall into three major groups.

AML

- Aggressive tumor comprised of immature myeloid lineage blasts, which replace the marrow and suppress normal hematopoiesis.
- Associated with diverse acquired mutations that lead to expression of abnormal transcription factors, which interfere with myeloid differentiation.
- Often also associated with mutations in genes encoding growth factor receptor signaling pathway components or regulators of the epigenome.

Myeloproliferative Neoplasms

- Myeloid tumors in which production of formed myeloid elements is initially increased, leading to high blood counts and extramedullary hematopoiesis.
- Commonly associated with acquired mutations that lead to constitutive activation of tyrosine kinases, which mimic signals from normal growth factors. The most common pathogenic kinases are BCR-ABL (associated with CML) and mutated *JAK2* (associated with PCV and primary myelofibrosis).
- All can transform to acute leukemia and to a spent phase of marrow fibrosis associated with anemia, thrombocytopenia, and splenomegaly.

MDS

- Myeloid tumors characterized by disordered and ineffective hematopoiesis and dysmaturation.
- May occur de novo or following genotoxic exposures.
- Frequently harbor mutations in splicing factors, epigenetic regulators, and transcription factors.
- Manifest with one or more cytopenias and often progress to AML.

Langerhans Cell Histiocytosis

The term *histiocytosis* is an "umbrella" designation for a variety of proliferative disorders of dendritic cells or macrophages. Some, such as rare "histiocytic" sarcomas, are clearly malignant, whereas others, such as reactive proliferations of macrophages in lymph nodes, are clearly benign. Lying between these two extremes are the Langerhans cell histiocytoses, a spectrum of clonal proliferations of a special type of immature dendritic cell called the Langerhans cell. Because Langerhans cells are part of the innate immune system, these tumors (as well as other clonal histiocytoses) can be considered unusual myeloid neoplasms.

Pathogenesis

The origin and nature of the proliferating cells in Langerhans cell histiocytosis has been controversial, but it is now recognized that the majority of cases have driver mutations in cancer-associated genes and are probably best considered neoplasms, albeit with an unusual proclivity for spontaneous remission. The most common mutation is an activating valine-to-glutamate substitution at residue 600 in BRAF, already discussed for its role in hairy cell leukemia, which is present in 55% to 60% of cases. Less common mutations have also been detected in TP53, RAS, and the receptor tyrosine kinase MET.

One factor that contributes to the homing of neoplastic Langerhans cells is the aberrant expression of chemokine receptors. For example, while normal epidermal Langerhans cells express CCR6, their neoplastic counterparts express both CCR6 and CCR7. This allows the neoplastic cells to migrate into tissues that express the relevant chemokines—CCL20 (a ligand for CCR6) in skin and bone and CCL19 and CCL21 (ligands for CCR7) in lymphoid organs.

MORPHOLOGY

Regardless of the clinical picture, the proliferating Langerhans cells have abundant, often vacuolated cytoplasm and vesicular nuclei containing linear grooves or folds (Fig. 13.39A). The presence of *Birbeck granules* in the cytoplasm is characteristic. Birbeck granules are pentalaminar tubules, often with a dilated terminal end producing a tennis racket–like appearance (Fig. 13.39B), which contain the protein langerin. In addition, the tumor cells also typically express HLA-DR, S-100, and CD1a.

Clinical Features

Langerhans cell histiocytosis presents as several clinicopathologic entities:

- *Multifocal multisystem Langerhans cell histiocytosis (Letterer-Siwe disease)* occurs most frequently before 2 years of age

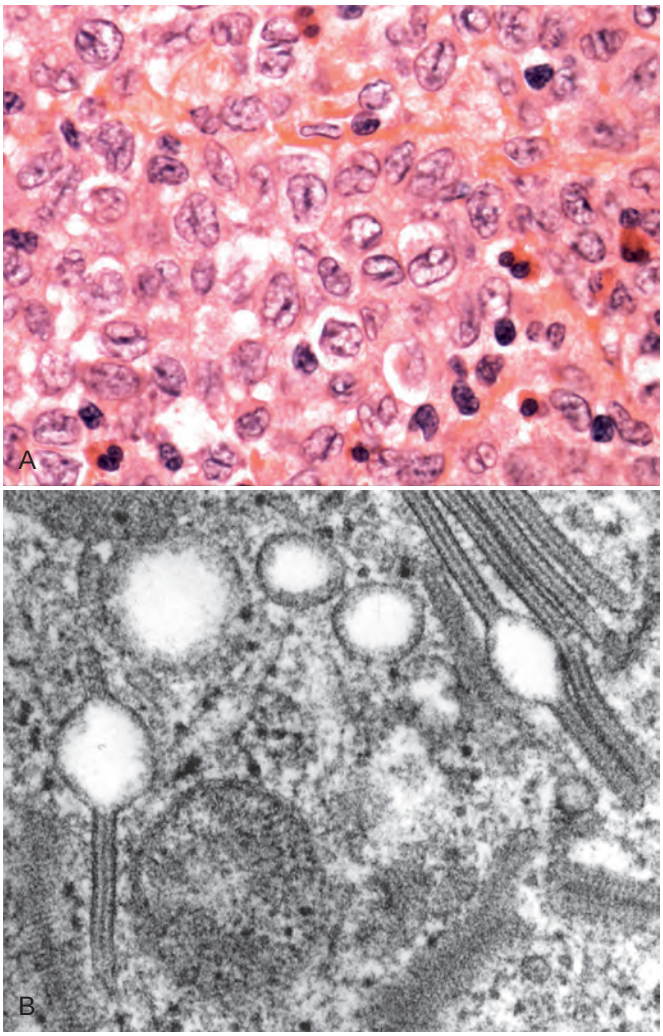

Figure 13.39 Langerhans cell histiocytosis. (A) Langerhans cells with folded or grooved nuclei and moderately abundant pale cytoplasm are mixed with a few eosinophils. (B) An electron micrograph shows rodlike Birbeck granules with characteristic periodicity and dilated terminal end. (B, Courtesy Dr. George Murphy, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

but occasionally affects adults. A dominant clinical feature is the development of cutaneous lesions resembling a seborrheic eruption, which is caused by infiltrates of Langerhans cells over the front and back of the trunk and on the scalp. Most of those affected have concurrent hepatosplenomegaly, lymphadenopathy, pulmonary lesions, and (eventually) destructive osteolytic bone lesions. Extensive infiltration of the marrow often leads to anemia, thrombocytopenia, and a predisposition to recurrent infections, such as otitis media and mastoiditis. In some instances the proliferating cells are quite anaplastic; such tumors are sometimes referred to as Langerhans cell sarcoma. The course of untreated disease is rapidly fatal. With intensive chemotherapy, 50% of patients survive 5 years.

- *Unifocal and multifocal unisystem Langerhans cell histiocytosis (eosinophilic granuloma)* is characterized by proliferations of Langerhans cells admixed with variable numbers of eosinophils, lymphocytes, plasma cells, and neutrophils. Eosinophils are usually, but not always, a prominent component of the infiltrate. It typically arises within the medullary cavities of bones, most commonly the calvaria, ribs, and femur. Less commonly, unisystem lesions of identical histology arise in the skin, lungs, or stomach. *Unifocal lesions* most commonly affect the skeletal system in older children or adults. Bone lesions can be asymptomatic or cause pain, tenderness, and, in some instances, pathologic fractures. Unifocal disease is indolent and may heal spontaneously or may be cured by local excision or irradiation. *Multifocal unisystem disease* usually affects young children, who present with multiple erosive bony masses that sometimes expand into adjacent soft tissue. Involvement of the posterior pituitary stalk of the hypothalamus leads to diabetes insipidus in about 50% of patients. The combination of calvarial bone defects, diabetes insipidus, and exophthalmos is referred to as the *Hand-Schüller-Christian* triad. Many patients experience spontaneous regression; others can be treated successfully with chemotherapy. BRAF inhibitors are active against *BRAF*-mutated disease but are not curative; combinations of BRAF inhibitors and chemotherapy are being tested in clinical trials.
- *Pulmonary Langerhans cell histiocytosis* represents a special category of disease, most often seen in adult smokers, which may regress spontaneously upon cessation of smoking. These lesions have been described as reactive proliferations of Langerhans cells, but fully 40% are associated with BRAF mutations, suggesting that in many instances they too are neoplastic in origin.

Spleen

The spleen is an ingeniously designed filter for the blood and a site of immune responses to blood-borne antigens. Normally in the adult it weighs about 150 g and is enclosed within a thin, glistening, slate-gray connective tissue capsule. Its cut surface reveals extensive red pulp dotted with gray specks, which are the white pulp follicles. These consist of an artery with an eccentric collar of T lymphocytes, the so-called periarteriolar lymphatic sheath. At intervals this sheath expands to form lymphoid follicles containing mainly B lymphocytes, which are capable of developing into germinal centers identical to those seen in lymph nodes in response to antigenic stimulation (Fig. 13.40).

The red pulp of the spleen is traversed by numerous thin-walled vascular sinusoids, separated by the splenic cords or "cords of Billroth." The endothelial lining of the sinusoid is discontinuous, providing a passage for blood cells between the sinusoids and cords. The cords contain a labyrinth of macrophages loosely connected through long dendritic processes to create both a physical and a functional filter. As it traverses the red pulp, the blood takes two routes

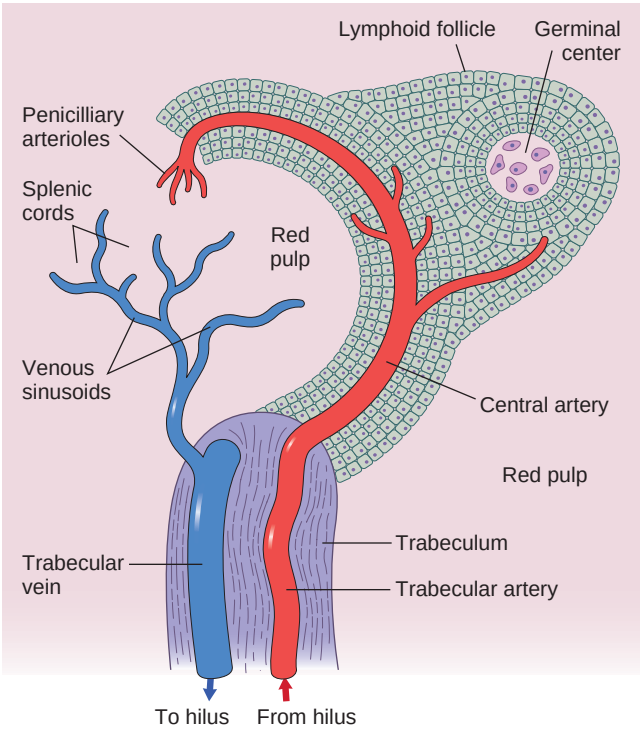

Figure 13.40 Normal splenic architecture. (Modified from Faller DV: Diseases of the spleen. In Wyngaarden JB, Smith LH, editors: *Cecil Textbook of Medicine*, ed 18, Philadelphia, 1988, WB Saunders, p 1036.)

to reach the splenic veins. Some flows through capillaries into the cords, from which blood cells squeeze through gaps in the discontinuous basement of the endothelial lining to reach the sinusoids; this is the so-called open circulation or slow compartment. In the other "closed circuit," blood passes rapidly and directly from the capillaries to the splenic veins. Although only a small fraction of the blood pursues the "open" route, during the course of a day the entire blood volume passes through the cords, where it is closely examined by macrophages.

The spleen has four functions that impact disease states:

- *Phagocytosis of blood cells and particulate matter.* As is discussed under the hemolytic anemias (Chapter 14), red cells undergo extreme deformation during passage from the cords into the sinusoids. In conditions in which red cell deformability is decreased, red cells become trapped in the cords and are more readily phagocytosed by macrophages. Splenic macrophages also are responsible for "pitting" of red cells, the process by which inclusions such as *Heinz bodies* and *Howell-Jolly bodies* are excised, and for the removal of particles, such as bacteria, from the blood.
- *Antibody production.* Dendritic cells in the periarterial lymphatic sheath trap antigens and present them to T lymphocytes. T- and B-cell interaction at the edges of white pulp follicles leads to the generation of antibody-secreting plasma cells, which are found mainly within the sinuses of the red pulp. The spleen seems to be an important site of production of antibodies against microbial polysaccharides as well as autoantibodies against a variety of self antigens.
- *Hematopoiesis.* During fetal development, the spleen may be a minor site of hematopoiesis, but this normally disappears by birth. However, the spleen can become a major site of compensatory extramedullary hematopoiesis in the setting of severe chronic anemia (e.g., in patients with thalassemia, described in Chapter 14) and in patients with myeloproliferative neoplasms, such as CML and primary myelofibrosis.
- *Sequestration of formed blood elements.* The normal spleen contains only about 30 to 40 mL of red cells, but this volume increases greatly with splenomegaly. The spleen also normally harbors approximately 30% to 40% of the total platelet mass in the body. With splenomegaly, up to 80% to 90% of the total platelet mass may be sequestered in the interstices of the red pulp, producing thrombocytopenia. Similarly, the enlarged spleen may trap white cells and thereby induce leukopenia.

As the largest unit of the mononuclear phagocyte system, the spleen is involved in all systemic inflammations, generalized hematopoietic disorders, and many metabolic disturbances. In each, the spleen undergoes enlargement *(splenomegaly)*, which is the major manifestation of disorders of this organ. It is rarely the primary site of disease. Splenic insufficiency due to splenectomy or autoinfarction (as in sickle-cell disease) has one major clinical manifestation, an increased susceptibility to sepsis caused by encapsulated bacteria such as pneumococci, meningococci, and *Haemophilus influenzae.* The decreases in phagocytic capacity and antibody production that result from asplenia both contribute to the increased risk of sepsis, which may be fatal. All asplenic individuals should be vaccinated against these agents to reduce the risk of this tragic complication.

SPLENOMEGALY

When sufficiently enlarged, the spleen causes a dragging sensation in the left upper quadrant and, through pressure on the stomach, discomfort after eating. In addition, enlargement can cause a syndrome known as *hypersplenism,* which is characterized by anemia, leukopenia, and/or thrombocytopenia. The probable cause of the cytopenias is increased sequestration of formed elements and the consequent enhanced phagocytosis by the splenic macrophages.

Table 13.12 lists major disorders associated with splenomegaly. Splenomegaly in virtually all the conditions mentioned has been discussed elsewhere. A few disorders are left to consider.

Nonspecific Acute Splenitis

Enlargement of the spleen occurs in any blood-borne infection. The nonspecific splenic reaction in these infections is caused both by the microbiologic agents themselves and by cytokines that are released as part of the immune response.

MORPHOLOGY

The spleen is enlarged (200 to 400 g) and soft. Microscopically, the major feature is acute congestion of the red pulp, which may

Table 13.12 Disorders Associated With Splenomegaly

I. Infections
Nonspecific splenitis of various blood-borne infections (particularly infectious endocarditis)
Infectious mononucleosis
Tuberculosis
Typhoid fever
Brucellosis
Cytomegalovirus
Syphilis
Malaria
Histoplasmosis
Toxoplasmosis
Kala-azar
Trypanosomiasis
Schistosomiasis
Leishmaniasis
Echinococcosis
II. Congestive States Related to Portal Hypertension
Cirrhosis of the liver
Portal or splenic vein thrombosis
Cardiac failure
III. Lymphohematogenous Disorders
Hodgkin lymphoma
Non-Hodgkin lymphomas and lymphocytic leukemias
Multiple myeloma
Myeloproliferative neoplasms
Hemolytic anemias
IV. Immunologic-Inflammatory Conditions
Rheumatoid arthritis
Systemic lupus erythematosus
V. Storage Diseases
Gaucher disease
Niemann-Pick disease
Mucopolysaccharidoses
VI. Miscellaneous Disorders
Amyloidosis
Primary neoplasms and cysts
Secondary neoplasms

encroach on and virtually efface the lymphoid follicles. Neutrophils, plasma cells, and occasionally eosinophils are usually present throughout the white and red pulp. At times the white pulp follicles may undergo necrosis, particularly when the causative agent is a hemolytic streptococcus. Rarely, abscess formation occurs.

Congestive Splenomegaly

Chronic venous outflow obstruction causes a form of splenic enlargement referred to as *congestive splenomegaly*. Venous obstruction may be caused by intrahepatic disorders that retard portal venous drainage or extrahepatic disorders that directly impinge upon the portal or splenic veins. All of these disorders ultimately lead to portal or splenic vein hypertension. Systemic, or central, venous congestion is encountered in cardiac decompensation involving the right side of the heart, as can occur in tricuspid or pulmonic valvular disease, chronic cor pulmonale, or following left-sided heart failure. Systemic congestion is associated with only moderately enlarged spleens that rarely exceed 500 g in weight.

Cirrhosis of the liver is the main cause of massive congestive splenomegaly. The "pipe-stem" hepatic fibrosis of schistosomiasis causes particularly severe congestive splenomegaly, while the diffuse fibrous scarring of alcoholic cirrhosis and pigment cirrhosis also evokes profound enlargements. Other forms of cirrhosis are less commonly implicated.

Congestive splenomegaly also may be caused by obstruction of the extrahepatic portal vein or splenic vein. This can stem from *portal vein thrombosis,* which is usually associated with some intrahepatic obstructive disease or inflammation of the portal vein *(pyelophlebitis)*, such as follows intraperitoneal infections. Thrombosis of the splenic vein can be caused by infiltrating tumors arising in neighboring organs, such as carcinomas of the stomach or pancreas.

MORPHOLOGY

Long-standing splenic congestion produces marked enlargement (1000 to 5000 g). The organ is firm, and the capsule is usually thickened and fibrous. Microscopically, the red pulp is congested early in the course but becomes increasingly fibrotic and cellular with time. The elevated portal venous pressure stimulates the deposition of collagen in the basement membrane of the sinusoids, which appear dilated because of the rigidity of their walls. The resultant slowing of blood flow from the cords to the sinusoids prolongs the exposure of the blood cells to macrophages, resulting in excessive destruction (hypersplenism).

Splenic Infarcts

Splenic infarcts are common lesions caused by the occlusion of the major splenic artery or any of its branches. The lack of extensive collateral blood supply predisposes to infarction following vascular occlusion. The spleen, along with kidneys and brain, ranks as one of the most frequent sites where emboli lodge. In normal-sized spleens, infarcts are most often caused by emboli that arise from the heart. The infarcts can be small or large, be single or multiple, or even involve the entire organ. They are usually bland except in individuals with infectious endocarditis of the mitral or aortic valves, in whom septic infarcts are common. Infarcts also are common in markedly enlarged spleens, regardless of cause, presumably because the blood supply is tenuous and easily compromised.

MORPHOLOGY

Bland infarcts are characteristically pale, wedge-shaped, and subcapsular in location. The overlying capsule is often covered with fibrin (Fig. 13.41). In septic infarcts this appearance is modified by the development of suppurative necrosis. In the course of healing, large depressed scars often develop.

NEOPLASMS

Neoplastic involvement of the spleen is rare except in myeloid and lymphoid tumors, which often cause splenomegaly

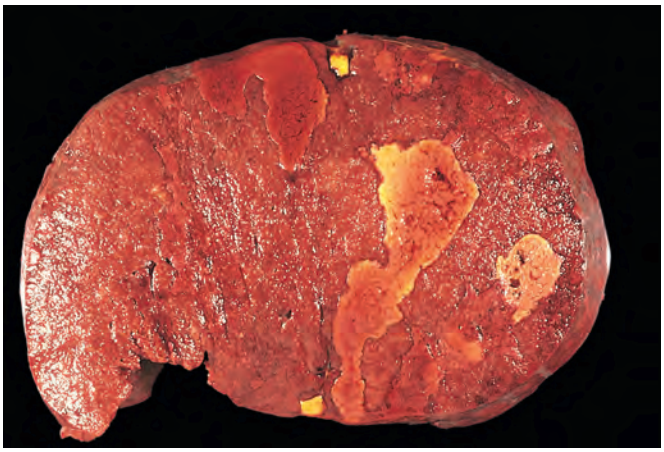

Figure 13.41 Splenic infarcts. Multiple well-circumscribed infarcts are present in this spleen, which is massively enlarged (2820 g; normal: 150 to 200 g) by extramedullary hematopoiesis secondary to a myeloproliferative neoplasm (myelofibrosis). Recent infarcts are hemorrhagic, whereas older, more fibrotic infarcts are a pale yellow-gray color.

(discussed earlier). Benign fibromas, osteomas, chondromas, lymphangiomas, and hemangiomas may arise in the spleen. Of these, lymphangiomas and hemangiomas are most common and often cavernous in type.

CONGENITAL ANOMALIES

Complete absence of the spleen is rare and is usually associated with other congenital abnormalities, such as situs inversus and cardiac malformations. Hypoplasia is a more common finding.

Accessory spleens (spleniculi) are common, being present singly or multiply in 20% to 35% of postmortem examinations. They are small, spherical structures that are histologically and functionally identical to the normal spleen. They can be found at any place within the abdominal cavity. Accessory spleens are of clinical importance in some hematologic disorders, such as hereditary spherocytosis (Chapter 14), where splenectomy may be used as a treatment. If an accessory spleen is overlooked, the therapeutic benefit of removal of the definitive spleen may be reduced or lost entirely.

RUPTURE

Splenic rupture is usually precipitated by blunt trauma. Much less often, it occurs in the apparent absence of a physical blow. Such "spontaneous ruptures" never involve truly normal spleens but rather stem from some minor physical insult to a spleen made fragile by an underlying condition. The most common predisposing conditions are infectious mononucleosis, malaria, typhoid fever, and lymphoid neoplasms, which may cause the spleen to enlarge rapidly, producing a thin, tense capsule that is susceptible to rupture. This dramatic event often precipitates intraperitoneal hemorrhage, which must be treated by prompt splenectomy to prevent death from blood loss. Chronically enlarged spleens are unlikely to rupture because of the toughening effect of extensive reactive fibrosis.

Thymus

Once an organ buried in obscurity, the thymus has a starring role in cell-mediated immunity (Chapter 6). Here, our interest centers on the disorders of the gland itself.

The thymus is embryologically derived from the third and, inconstantly, the fourth pair of pharyngeal pouches. At birth it weighs 10 to 35 g. It grows until puberty, achieving a maximum weight of 20 to 50 g, and thereafter undergoes progressive involution to little more than 5 to 15 g in older adults. The thymus also may involute in children and young adults in response to severe illness and HIV infection.

The fully developed thymus is composed of two fused, well-encapsulated lobes. Fibrous extensions of the capsule divide each lobe into numerous lobules, each with an outer cortical layer enclosing the central medulla. Diverse types of cells populate the thymus, but thymic epithelial cells and immature T lymphocytes, also called thymocytes, predominate. Epithelial cells in the cortex are polygonal in shape and have an abundant cytoplasm with dendritic extensions that contact adjacent cells. In contrast, the epithelial cells in the medulla are densely packed, often spindle-shaped, and have scant cytoplasm devoid of interconnecting processes. Whorls of medullary epithelial cells create *Hassall corpuscles,* with their characteristic keratinized cores.

As you know from consideration of the thymus in relation to immunity (Chapter 6), progenitor cells migrate from the marrow to the thymus and mature into T cells, which are exported to the periphery, but only after they have been educated in the "thymic university" to distinguish between self antigens and non–self antigens. During adulthood the thymic production of T cells slowly declines as the organ atrophies.

Macrophages, dendritic cells, a minor population of B lymphocytes, rare neutrophils and eosinophils, and scattered myoid (muscle-like) cells are also found within the thymus. The myoid cells are of particular interest because they likely play some role in the development of myasthenia gravis, a musculoskeletal disorder of immune origin.

Pathologic changes within the thymus are limited and will be described here. The changes associated with myasthenia gravis are considered in Chapter 27.

DEVELOPMENTAL DISORDERS

Thymic hypoplasia or *aplasia* is seen in DiGeorge syndrome, which is marked by severe defects in cell-mediated immunity and variable abnormalities of parathyroid development and function. As discussed in Chapter 5, DiGeorge syndrome is often associated with other developmental defects as part of the 22q11 deletion syndrome.

Isolated *thymic cysts* are uncommon lesions that are usually discovered incidentally postmortem or during surgery. They rarely exceed 4 cm in diameter, can be spherical or arborizing, and are lined by stratified to columnar epithelium. The fluid contents can be serous or mucinous and are often modified by hemorrhage.

While isolated cysts are not clinically significant, neoplastic thymic masses (whatever their origin) compress and distort adjacent normal thymus and sometimes cause cysts to form. Therefore the presence of a cystic thymic lesion in a symptomatic patient should provoke a thorough search for a neoplasm, particularly a lymphoma or a thymoma.

THYMIC HYPERPLASIA

The term thymic hyperplasia is misleading, since it usually applies to the appearance of B-cell germinal centers within the thymus, a finding that is referred to as *thymic follicular hyperplasia*. Such B-cell follicles are present in only small numbers in the normal thymus. Although follicular hyperplasia can occur in a number of chronic inflammatory and immunologic states, it is most frequently encountered in myasthenia gravis, in which it is found in 65% to 75% of cases (Chapter 27). Similar thymic changes are sometimes encountered in Graves disease, systemic lupus erythematosus, scleroderma, rheumatoid arthritis, and other autoimmune disorders.

In other instances, a morphologically normal thymus is simply large for the age of the patient. As mentioned, the size of the thymus varies widely, and whether this constitutes a true hyperplasia or is merely a variant of normal is unclear. The main significance of this form of thymic "hyperplasia" is that it may be mistaken radiologically for a thymoma, leading to unnecessary surgical procedures.

THYMOMA

A diversity of neoplasms may arise in the thymus—germ cell tumors, lymphomas, carcinoids, and others—but **the designation "thymoma" is restricted to tumors of thymic epithelial cells.** Such tumors typically also contain benign immature T cells (thymocytes).

The WHO has created a classification system based on histology for thymomas, but its clinical utility remains uncertain. We instead use a classification that relies on the most important prognostic features, the surgical stage and the presence or absence of overt cytologic features of malignancy. In this simple system there are only three histologic subtypes:

- Tumors that are cytologically benign and noninvasive
- Tumors that are cytologically benign but invasive or metastatic
- Tumors that are cytologically malignant (thymic carcinoma)

In all categories the tumors usually occur in adults older than 40 years of age; thymomas are rare in children. Males and females are affected equally. Most tumors arise in the anterior superior mediastinum, but sometimes they occur in the neck, thyroid, pulmonary hilus, or elsewhere. They are uncommon in the posterior mediastinum. Thymomas account for 20% to 30% of tumors in the anterosuperior mediastinum, which is also a common location for certain lymphomas.

MORPHOLOGY

Macroscopically, thymomas are lobulated, firm, gray-white masses of up to 15 to 20 cm in size. They sometimes have areas of cystic necrosis and calcification. Most are encapsulated, but 20% to 25% of tumors penetrate the capsule and infiltrate perithymic tissues and structures.

Noninvasive thymomas are most often composed of medullary-type epithelial cells or a mixture of medullary- and cortical-type epithelial cells. The medullary-type epithelial cells are elongated or spindle-shaped (Fig. 13.42A). There is usually a sparse infiltrate of thymocytes, which often recapitulate the phenotype of medullary thymocytes. In mixed thymomas there is an admixture of polygonal cortical-type epithelial cells and a denser infiltrate of thymocytes. The medullary and mixed patterns

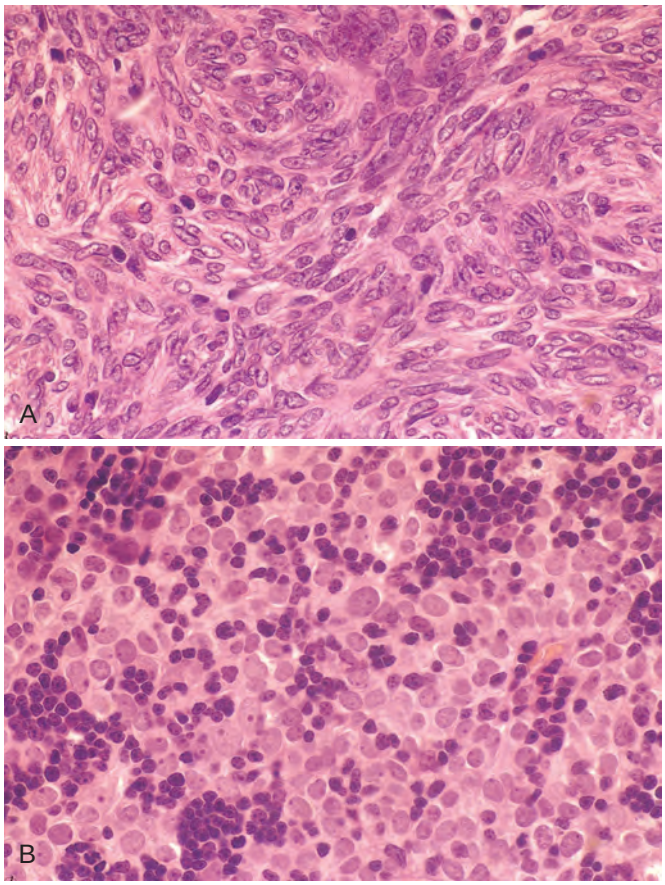

Figure 13.42 Thymoma. (A) Benign thymoma (medullary type). The neoplastic epithelial cells are arranged in a swirling pattern and have bland, oval to elongated nuclei with inconspicuous nucleoli. Only a few small, reactive lymphoid cells are interspersed. (B) Malignant thymoma, type I. The neoplastic epithelial cells are polygonal and have round to oval, bland nuclei with inconspicuous nucleoli. Numerous small, reactive lymphoid cells are interspersed. The morphologic appearance of this tumor is identical to that of benign thymomas of the cortical type. In this case, however, the tumor was locally aggressive, invading adjacent lung and pericardium.

together account for about 50% of all thymomas. Tumors that have a substantial proportion of medullary-type epithelial cells are usually noninvasive.

Invasive thymoma refers to a tumor that is cytologically benign but locally invasive. These tumors are much more likely to metastasize. The epithelial cells are most commonly of the cortical variety, with abundant cytoplasm and rounded vesicular nuclei (Fig. 13.42B), and are usually mixed with numerous thymocytes. In some cases the neoplastic cells show cytologic atypia, a feature that correlates with a propensity for more aggressive behavior. These tumors account for about 20% to 25% of all thymomas. **By definition, invasive thymomas penetrate through the capsule into surrounding structures.** The extent of invasion has been subdivided into various stages, which are beyond our scope. With minimal invasion, complete excision yields a 5-year survival rate of greater than 90%, whereas extensive invasion is associated with a 5-year survival rate of less than 50%.

Thymic carcinoma represents about 5% of thymomas. Macroscopically, they are usually fleshy, obviously invasive masses, sometimes accompanied by metastases to sites such as the lungs. Microscopically, most are **squamous cell carcinomas.** Another distinctive variant is **lymphoepithelioma-like carcinoma,** a tumor composed of sheets of cells that bears a close histologic resemblance to nasopharyngeal carcinoma. About 50% of lymphoepithelioma-like carcinomas contain monoclonal EBV genomes, consistent with a role for EBV in their pathogenesis. A variety of other, less common histologic patterns of thymic carcinoma have been described; all exhibit cytologic atypia seen in other carcinomas.

Clinical Features

About 40% of thymomas present with symptoms stemming from impingement on mediastinal structures. Another 30% to 45% are detected in the course of evaluating patients with myasthenia gravis. The rest are discovered incidentally during imaging studies or cardiothoracic surgery. In addition to myasthenia gravis, other associated autoimmune disorders include hypogammaglobulinemia, pure red cell aplasia, Graves disease, pernicious anemia, dermatomyositis-polymyositis, and Cushing syndrome. The basis for these associations is uncertain, but the thymocytes that arise within thymomas give rise to long-lived CD4+ and CD8+ T cells, and cortical thymomas rich in thymocytes are more likely to be associated with autoimmune disease. Hence it seems likely that abnormalities in the selection or "education" of T cells maturing within the environment of the neoplasm contribute to the development of diverse autoimmune disorders.

CHAPTER 14

Red Blood Cell and Bleeding Disorders

CHAPTER CONTENTS

In this chapter, we will first consider diseases of red cells. By far, the most common and important are the anemias, red cell deficiency states that usually have a nonneoplastic basis. We will then complete our review of blood diseases by discussing the major bleeding disorders and complications of blood transfusion.

ANEMIAS

Anemia is defined as a reduction of the total circulating red cell mass below normal limits. Anemia reduces the oxygen-carrying capacity of the blood, leading to tissue hypoxia. In practice, the measurement of red cell mass is not easy, and anemia is usually diagnosed based on a reduction in the *hematocrit* (the ratio of packed red cells to total blood volume) and the *hemoglobin concentration* of the blood to levels that are below the normal range. These values correlate with the red cell mass except when there are changes in plasma volume caused by fluid retention or dehydration.

There are many classifications of anemia. We will follow one based on underlying mechanisms that is presented in Table 14.1. A second clinically useful approach classifies anemia according to alterations in red cell morphology, which often point to particular causes. Morphologic characteristics that provide etiologic clues include red cell size (normocytic, microcytic, or macrocytic); degree of hemoglobinization, reflected in the color of red cells (normochromic or hypochromic); and shape. Microcytic hypochromic anemias are caused by disorders of hemoglobin synthesis, and macrocytic anemias often stem from abnormalities that impair the maturation of erythroid precursors in the bone marrow. Normochromic, normocytic anemias have diverse etiologies; in some of these anemias, characteristic abnormalities of red cell shape provide an important clue as to the cause. Red cell shape is assessed through visual inspection of peripheral smears, whereas as other red cell indices are determined in clinical laboratories with special instrumentation. The most useful of these indices are as follows:

- *Mean cell volume:* the average volume of a red cell expressed in femtoliters (fL)
- *Mean cell hemoglobin:* the average content (mass) of hemoglobin per red cell, expressed in picograms (pg)
- *Mean cell hemoglobin concentration:* the average concentration of hemoglobin in a given volume of packed red cells, expressed in grams per deciliter (g/dL)
- *Red cell distribution width:* the coefficient of variation of red cell volume

Table 14.1 Classification of Anemia According to Underlying Mechanism

Mechanism	Specific Examples
Blood Loss	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances[a]
Increased Red Cell Destruction (Hemolysis)	
Inherited genetic defects	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
Deficient globin synthesis	Thalassemia syndromes
Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
Acquired genetic defects	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-induced, autoimmune disorders
Mechanical trauma	
Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura
Cardiac traumatic hemolysis	Defective cardiac valves
Repetitive physical trauma	Bongo drumming, marathon running, karate chopping
Infections of red cells	Malaria, babesiosis
Toxic or chemical injury	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	Hypersplenism
Decreased Red Cell Production	
Inherited genetic defects	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
Nutritional deficiencies	
Deficiencies affecting DNA synthesis	B_{12} and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency
Erythropoietin deficiency	Renal failure, anemia of chronic inflammation
Immune-mediated injury of progenitors	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	Anemia of chronic inflammation
Primary hematopoietic neoplasms	Acute leukemia, myelodysplastic syndrome, myeloproliferative neoplasms (Chapter 13)
Space-occupying marrow lesions	Metastatic neoplasms, granulomatous disease
Infections of red cell progenitors	Parvovirus B19 infection
Unknown mechanisms	Endocrine disorders, hepatocellular liver disease

G6PD, Glucose-6-phosphate dehydrogenase.

[a]Most often anemia stems from iron deficiency, not bleeding per se.

Adult reference ranges for red cell indices are shown in Table 14.2.

Whatever its cause, when sufficiently severe anemia leads to manifestations related to the diminished hemoglobin and oxygen content of the blood. Patients appear pale and often report weakness, malaise, easy fatigability, and dyspnea on mild exertion. Hypoxia can cause fatty change in the liver, myocardium, and kidney. On occasion, myocardial hypoxia manifests as angina pectoris, particularly when complicated by pre-existing coronary artery disease. With acute blood loss and shock, oliguria and anuria can develop as a result of renal hypoperfusion. Central nervous system hypoxia can cause headache, dimness of vision, and faintness.

Anemias of Blood Loss

Acute Blood Loss

The effects of acute blood loss are mainly due to the loss of intravascular volume, which if massive can lead to cardiovascular collapse, shock, and death. The clinical features depend on the rate of hemorrhage and whether

Table 14.2 Adult Reference Ranges for Red Cells[a]

Measurement (Units)	Men	Women
Hemoglobin (g/dL)	13.6–17.2	12.0–15.0
Hematocrit (%)	39–49	33–43
Red cell count ($\times 10^6/\mu L$)	4.3–5.9	3.5–5.0
Reticulocyte count (%)	0.5–1.5	
Mean cell volume (fL)	82–96	
Mean cell hemoglobin (pg)	27–33	
Mean cell hemoglobin concentration (g/dL)	33–37	
Red cell distribution width	11.5–14.5	

[a]Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used in interpreting test results.

the bleeding is external or internal. If the patient survives, the blood volume is rapidly restored by movement of water from the interstitial fluid compartment to the intravascular compartment. This fluid shift produces hemodilution and lowers the hematocrit. The resulting reduction in tissue oxygenation triggers increased secretion of erythropoietin from the kidney, which stimulates the proliferation of committed erythroid progenitors (colony-forming unit–erythroid [CFU–E]) in the marrow (see Fig. 13.1). It takes about 5 days for the progeny of these CFU–Es to mature and appear as newly released red cells (reticulocytes) in the peripheral blood. The iron in hemoglobin is recaptured if red cells extravasate into tissues, whereas bleeding into the gut or out of the body leads to iron loss and possible iron deficiency, which can hamper the restoration of normal red cell counts.

Significant bleeding results in predictable changes in the blood involving not only red cells, but also white cells and platelets. If the bleeding is sufficiently massive to cause a decrease in blood pressure, the compensatory release of adrenergic hormones mobilizes granulocytes from the intravascular marginal pool and results in leukocytosis. Initially, red cells appear normal in size and color (normocytic, normochromic). However, as marrow production increases, there is a striking increase in the reticulocyte count (reticulocytosis), which reaches 10% to 15% after 7 days. Reticulocytes are larger than normal red cells and have blue-red polychromatophilic cytoplasm due to the presence of RNA, a feature that allows them to be identified in the clinical laboratory. Early recovery from blood loss also is often accompanied by thrombocytosis, which results from an increase in platelet production.

Chronic Blood Loss

Chronic blood loss induces anemia only when the rate of loss exceeds the regenerative capacity of the marrow or when iron reserves are depleted and iron deficiency anemia appears (see later).

Hemolytic Anemias

Hemolytic anemias share the following features:

- *A shortened red cell life span* below the normal 120 days
- *Elevated erythropoietin levels and a compensatory increase in erythropoiesis*
- *Accumulation of hemoglobin degradation products* that are created as part of the process of red cell hemolysis

The physiologic destruction of senescent red cells takes place within macrophages, which are abundant in the spleen, liver, and bone marrow. This process appears to be triggered by **age-dependent changes** in red cell surface proteins, which lead to their recognition and removal by phagocytes. In the great majority of hemolytic anemias, the premature destruction of red cells also occurs within phagocytes, an event that is referred to as extravascular hemolysis. If persistent, extravascular hemolysis leads to a hyperplasia of phagocytes manifested by varying degrees of *splenomegaly*.

Extravascular hemolysis is most commonly caused by alterations that make red cells less deformable. Extreme changes in shape are required for red cells to navigate the splenic sinusoids successfully. Reduced deformability makes this passage difficult, leading to red cell sequestration and phagocytosis by macrophages located within the splenic cords. Regardless of the cause, the principal clinical features of extravascular hemolysis are anemia, splenomegaly, and jaundice. Some hemoglobin inevitably escapes from phagocytes, which leads to variable decreases in plasma haptoglobin, an α_2-globulin that binds free hemoglobin and prevents its excretion in the urine. Because much of the premature destruction of red cells occurs in the spleen, individuals with extravascular hemolysis often benefit from splenectomy.

Intravascular hemolysis of red cells may be caused by mechanical injury, complement fixation, intracellular parasites (e.g., falciparum malaria, Chapter 8), **or exogenous toxic factors.** Compared to extravascular hemolysis, it occurs less commonly; sources of mechanical injury include trauma caused by cardiac valves, narrowing of the microcirculation by thrombi, or repetitive physical trauma (e.g., marathon running and bongo drum beating). Complement fixation occurs in a variety of situations in which antibodies recognize and bind red cell antigens. Toxic injury is exemplified by clostridial sepsis, which results in the release of enzymes that digest the red cell membrane.

Whatever the mechanism, intravascular hemolysis is manifested by anemia, hemoglobinemia, hemoglobinuria, hemosiderinuria, and jaundice. Free hemoglobin released from lysed red cells is promptly bound by haptoglobin, producing a complex that is rapidly cleared by mononuclear phagocytes. As serum haptoglobin is depleted, free hemoglobin oxidizes to methemoglobin, which is brown in color. The renal proximal tubular cells reabsorb and break down much of the filtered hemoglobin and methemoglobin, but some passes out in the urine, imparting a red-brown color. Iron released from hemoglobin can accumulate within tubular cells, giving rise to *renal hemosiderosis*. Concomitantly, heme groups derived from hemoglobin-haptoglobin complexes are metabolized to bilirubin within mononuclear phagocytes, leading to jaundice. Unlike in extravascular hemolysis, splenomegaly is not seen.

In all types of uncomplicated hemolytic anemia, the excess serum bilirubin is unconjugated. The level of hyperbilirubinemia depends on the functional capacity of the liver and the rate of hemolysis. When the liver is normal, jaundice is rarely severe, but excessive bilirubin excreted by the liver into the biliary tract often leads to the formation of gallstones derived from heme pigments.

MORPHOLOGY

Certain changes are seen in hemolytic anemia regardless of cause or type. Anemia and lowered tissue oxygen tension trigger the production of erythropoietin, which stimulates erythroid differentiation and leads to the appearance of **increased numbers of erythroid precursors (normoblasts)** in the marrow (Fig. 14.1). Compensatory increases in erythropoiesis result in a **prominent reticulocytosis** in the peripheral blood. The phagocytosis of red cells leads to the accumulation of the iron-containing pigment **hemosiderin,** particularly in the spleen, liver, and bone marrow. Such iron accumulation is referred to as **hemosiderosis**. If the anemia is severe, **extramedullary hematopoiesis** can appear in the liver, spleen, and lymph nodes. With chronic hemolysis, elevated biliary excretion of bilirubin promotes the formation of **pigment gallstones** (cholelithiasis).

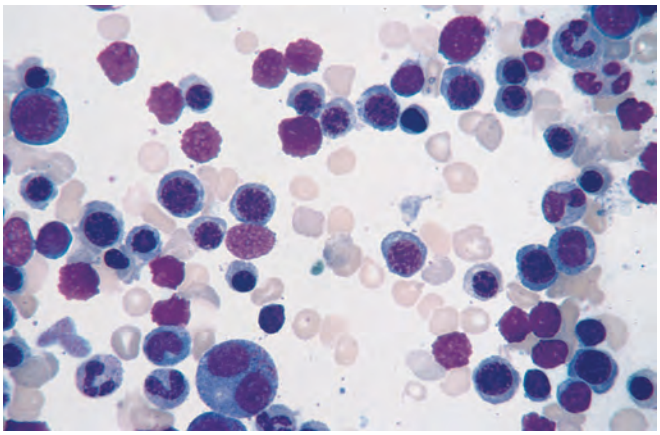

Figure 14.1 Marrow aspirate smear from a patient with hemolytic anemia. There is an increased number of maturing erythroid progenitors (normoblasts). (Courtesy Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

The hemolytic anemias can be classified in a variety of ways; here, we rely on the underlying mechanisms (see Table 14.1). We begin by discussing the major inherited forms of hemolytic anemia, and then move on to the acquired forms that are most common or of particular pathophysiologic interest.

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is an inherited disorder caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction. The prevalence of HS is highest in northern Europe, where rates of 1 in 5000 are reported. An autosomal dominant inheritance pattern is seen in about 75% of cases. The remaining patients have a more severe form of the disease that is usually caused by the inheritance of two different defects (a state known as compound heterozygosity).

Pathogenesis

The remarkable deformability and durability of the normal red cell are attributable to the physicochemical properties of its specialized membrane skeleton (Fig. 14.2), which lies closely apposed to the internal surface of the plasma membrane. Its chief protein component, spectrin, consists of two polypeptide chains, α and β, which form intertwined (helical) flexible heterodimers. The "head" regions of spectrin dimers self-associate to form tetramers, and the "tails" associate with actin oligomers. Each actin oligomer can bind multiple spectrin tetramers, thus creating a two-dimensional spectrin-actin skeleton that is connected to the cell membrane by two distinct interactions. The first, involving the proteins ankyrin and band 4.2, binds spectrin to the transmembrane ion transporter, band 3. The second, involving protein 4.1, binds the "tail" of spectrin to another transmembrane protein, glycophorin A.

HS is caused by diverse mutations that lead to an insufficiency of membrane skeletal components. As a result of these alterations, the life span of affected red cells is decreased on average to 10 to 20 days from the normal 120 days. The pathogenic mutations most commonly affect ankyrin, band 3, spectrin, or band 4.2, the proteins involved in one of the two tethering interactions. Most mutations cause frameshifts or introduce premature stop codons, such

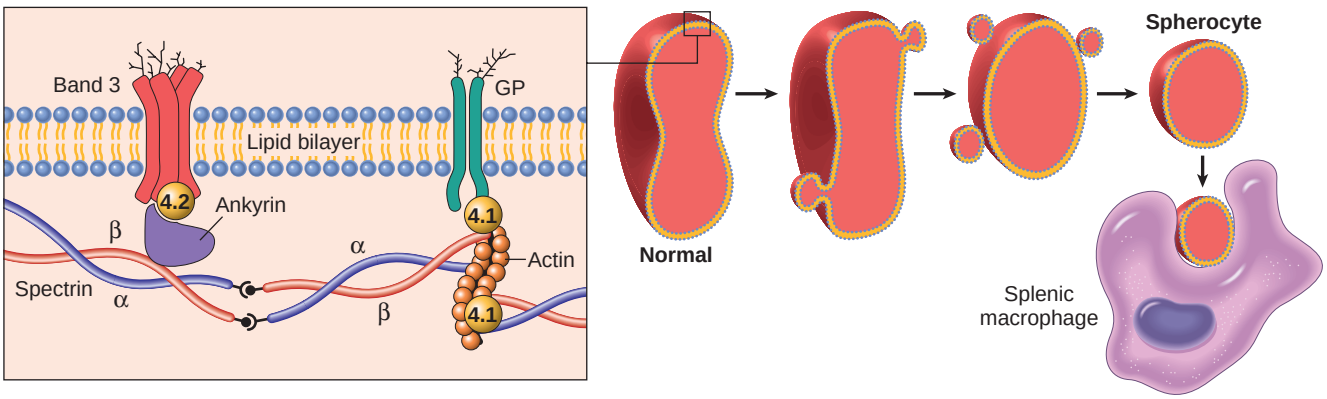

Figure 14.2 Role of the red cell membrane skeleton in hereditary spherocytosis. The *left panel* shows the normal organization of the major red cell membrane skeletal proteins. Various mutations involving α-spectrin, β-spectrin, ankyrin, band 4.2, or band 3 that weaken the interactions between these proteins cause red cells to lose membrane fragments as they age. To accommodate the resultant change in the ratio of surface area to volume, these cells adopt a spherical shape. Spherocytic cells are less deformable than normal ones and therefore become trapped in the splenic cords, where they are phagocytosed by macrophages. *GP,* Glycophorin.

that the mutated allele fails to produce any protein. The resulting deficiency of the affected protein reduces the assembly of the skeleton as a whole, destabilizing the overlying plasma membrane. Young HS red cells are normal in shape, but the destabilized lipid bilayer sheds membrane fragments as red cells age in the circulation. The loss of membrane relative to cytoplasm "forces" the cells to assume the smallest possible diameter for a given volume, namely, a sphere. Compound heterozygosity for two defective alleles understandably results in more profound membrane skeleton deficiency and more severe disease.

The invariably beneficial effects of splenectomy prove that the spleen has a cardinal role in the premature demise of spherocytes. The travails of spherocytic red cells are fairly well defined. In the life of the portly, inflexible spherocyte, the spleen is the villain. Normal red cells must undergo extreme deformation to leave the cords of Billroth and enter the sinusoids. Because of their spheroidal shape and reduced deformability, the hapless spherocytes are trapped in the splenic cords, where they are easy prey for macrophages. The splenic environment also exacerbates the tendency of HS red cells to lose membrane along with K^+ ions and H_2O; prolonged splenic exposure (erythrostasis), depletion of red cell glucose, and diminished red cell pH have all been suggested to contribute to these abnormalities (Fig. 14.3). After splenectomy the spherocytes persist, but the anemia is corrected.

MORPHOLOGY

The most specific morphologic finding is **spherocytosis,** apparent on smears as small, dark-staining (hyperchromic) red cells lacking the central zone of pallor (Fig. 14.4). Spherocytosis is distinctive but not pathognomonic, as spherocytes are also seen in other disorders associated with red cell membrane loss, such as in autoimmune hemolytic anemia. Other features are common to all hemolytic anemias. These include reticulocytosis, marrow erythroid hyperplasia, hemosiderosis, and mild jaundice. **Cholelithiasis** (pigment stones) occurs in 40% to 50% of affected adults. Moderate **splenomegaly** is characteristic (500 to 1000 g); in few other hemolytic anemias is the spleen enlarged as much or as consistently. Splenomegaly results from congestion of the cords of Billroth and increased numbers of phagocytes.

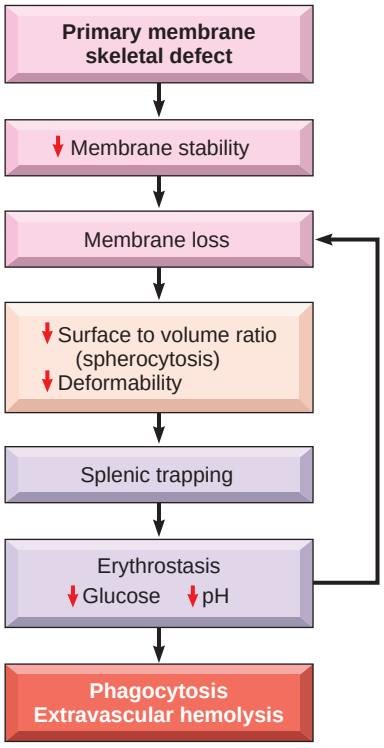

Figure 14.3 Pathophysiology of hereditary spherocytosis.

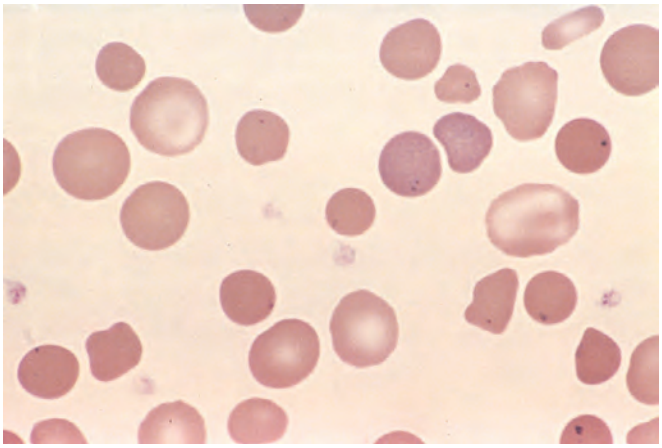

Figure 14.4 Hereditary spherocytosis (peripheral smear). Note the anisocytosis and several dark-appearing spherocytes with no central pallor. Howell-Jolly bodies (small, dark nuclear remnants) also are seen in some of the red cells of this asplenic patient. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Clinical Features

The diagnosis is based on family history, hematologic findings, and laboratory evidence. In two-thirds of cases, the red cells are abnormally sensitive to osmotic lysis when incubated in hypotonic salt solutions, which causes the influx of water into spherocytes with little margin for expansion. HS red cells also have an increased mean cell hemoglobin concentration, due to dehydration caused by the loss of K^+ and H_2O.

The characteristic clinical features are anemia, splenomegaly, and jaundice. The severity varies greatly. In a small minority (mainly compound heterozygotes), HS presents at birth with marked jaundice and requires exchange transfusions. In 20% to 30% of patients, the disease is so mild as to be virtually asymptomatic; here the decreased red cell survival is readily compensated for by increased erythropoiesis. In most, however, the compensatory changes are outpaced, producing a chronic hemolytic anemia of mild to moderate severity.

The generally stable clinical course is sometimes punctuated by *aplastic crises,* usually triggered by an acute parvovirus infection. Parvovirus infects and kills red cell progenitors, causing all red cell production to cease until an immune response clears the virus, generally in 1 to 2 weeks. Because of the reduced life span of HS red cells, cessation of erythropoiesis

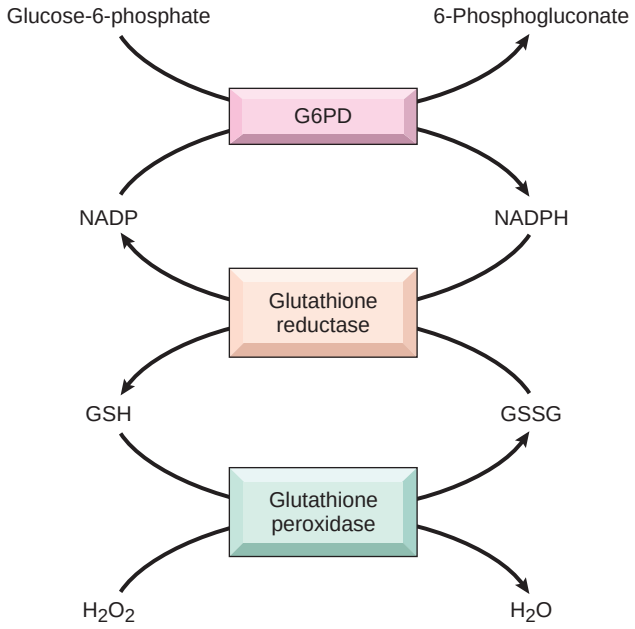

Figure 14.5 Role of glucose-6-phosphate dehydrogenase (G6PD) in defense against oxidant injury. Detoxification of H_2O_2, a potential oxidant, requires reduced glutathione (GSH), which is generated in a reaction that requires reduced nicotinamide adenine dinucleotide (NADPH). The synthesis of NADPH depends on the activity of G6PD. *GSSG*, Oxidized glutathione; *NADP*, nicotinamide adenine dinucleotide phosphate.

for even short periods leads to sudden worsening of the anemia. Transfusions may be necessary to support the patient during the acute phase of the infection. *Hemolytic crises* are produced by intercurrent events leading to increased splenic destruction of red cells (e.g., infectious mononucleosis and its attendant increase in spleen size); these are clinically less significant than aplastic crises. Gallstones, found in many patients, may also produce symptoms. Splenectomy treats the anemia and its complications, but brings with it an increased risk of sepsis because the spleen acts as an important filter for blood-borne bacteria.

Hemolytic Disease Due to Red Cell Enzyme Defects: Glucose-6-Phosphate Dehydrogenase Deficiency

Abnormalities in the hexose monophosphate shunt or glutathione metabolism resulting from deficient or impaired enzyme function reduce the ability of red cells to protect themselves against oxidative injuries and lead to hemolysis. The most important of these enzyme derangements is hereditary deficiency of glucose-6-phosphate dehydrogenase (G6PD) activity. G6PD reduces nicotinamide adenine dinucleotide phosphate (NADP) to NADPH while oxidizing glucose-6-phosphate (Fig. 14.5). NADPH then provides reducing equivalents needed for conversion of oxidized glutathione to reduced glutathione, which protects against oxidant injury by participating as a cofactor in reactions that neutralize compounds such as H_2O_2 (see Fig. 14.5).

G6PD deficiency is a recessive X-linked trait, placing males at much higher risk for symptomatic disease. Several hundred G6PD genetic variants exist, but most clinically significant hemolytic anemia is associated with only two variants, designated $G6PD^-$ and G6PD Mediterranean. $G6PD^-$ is present in about 10% of American blacks; G6PD Mediterranean, as the name implies, is prevalent in the Middle East. The high frequency of these variants in each population is believed to stem from a protective effect against *Plasmodium falciparum* malaria (discussed later). G6PD variants associated with hemolysis result in misfolding of the protein, making it more susceptible to proteolytic degradation. Compared with the most common normal variant, G6PD B, the half-life of $G6PD^-$ is moderately reduced, whereas that of G6PD Mediterranean is more markedly abnormal. Because mature red cells do not synthesize new proteins, as red cells age $G6PD^-$ and G6PD Mediterranean enzyme activities quickly fall to levels that are inadequate to protect against oxidant stress. Thus, older red cells are much more prone to hemolysis than younger ones.

The episodic hemolysis that is characteristic of G6PD deficiency is caused by exposures that generate oxidant stress. The most common triggers are infections, in which oxygen-derived free radicals are produced by activated leukocytes. Many infections can trigger hemolysis; viral hepatitis, pneumonia, and typhoid fever are among those most likely to do so. The other important initiators are drugs and certain foods. The drugs implicated are numerous, including antimalarials (e.g., primaquine and chloroquine), sulfonamides, nitrofurantoins, and others. Some drugs cause hemolysis only in individuals with the more severe Mediterranean variant. The most frequently cited food is the *fava bean,* which generates oxidants when metabolized. "Favism" is endemic in the Mediterranean, Middle East, and parts of Africa where consumption is prevalent. Uncommonly, G6PD deficiency presents as neonatal jaundice or a chronic low-grade hemolytic anemia in the absence of infection or known environmental triggers.

Oxidants cause both intravascular and extravascular hemolysis in G6PD-deficient individuals. Exposure of G6PD-deficient red cells to high levels of oxidants causes the cross-linking of reactive sulfhydryl groups on globin chains, which become denatured and form membrane-bound precipitates known as *Heinz bodies.* These are seen as dark inclusions within red cells stained with crystal violet (Fig. 14.6). Heinz bodies can damage the membrane sufficiently to cause intravascular hemolysis. Less severe membrane damage results in decreased red cell deformability. As inclusion-bearing red cells pass through the splenic cords, macrophages pluck out the Heinz bodies. As a result of membrane damage, some of these partially devoured cells retain an abnormal shape, appearing to have a bite taken out of them (see Fig. 14.6). Other less severely damaged cells become spherocytes due to loss of membrane surface area. Both bite cells and spherocytes are trapped in splenic cords and removed by phagocytes.

Acute intravascular hemolysis, marked by anemia, hemoglobinemia, and hemoglobinuria, usually begins 2 to 3 days following exposure of G6PD-deficient individuals to environmental triggers. Because only older red cells are at risk for lysis, the episode is self-limited, as hemolysis ceases when only younger G6PD-replete red cells remain (even if exposure to the trigger, e.g., an offending drug, continues). The recovery phase is heralded by reticulocytosis. Because hemolytic episodes related to G6PD deficiency occur intermittently, features related to chronic hemolysis (e.g., splenomegaly, cholelithiasis) are absent.

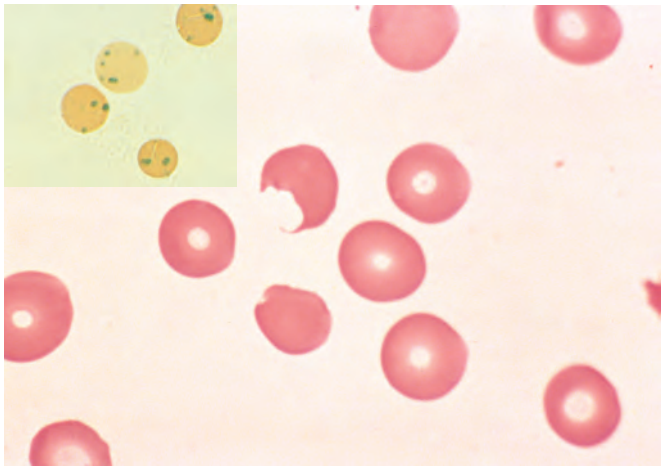

Figure 14.6 Glucose-6-phosphate dehydrogenase deficiency: effects of oxidant drug exposure (peripheral blood smear). *Inset,* Red cells with precipitates of denatured globin (Heinz bodies) revealed by supravital staining. As the splenic macrophages pluck out these inclusions, "bite cells" like the one in this smear are produced. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Sickle Cell Disease

Sickle cell disease is a common hereditary hemoglobinopathy caused by a point mutation in β-globin that promotes the polymerization of deoxygenated hemoglobin, leading to red cell distortion, hemolytic anemia, microvascular obstruction, and ischemic tissue damage. Several hundred hemoglobinopathies caused by various mutations in globin genes are known, but only those associated with sickle cell disease are prevalent enough in the United States to merit discussion. Hemoglobin (Hb) is a tetrameric protein composed of two pairs of globin chains, each with its own heme group. Normal adult red cells contain mainly HbA ($\alpha_2\beta_2$), along with small amounts of HbA_2 ($\alpha_2\delta_2$) and fetal hemoglobin (HbF; $\alpha_2\gamma_2$). Sickle cell disease is caused by a missense mutation in the β-globin gene that leads to the replacement of a charged glutamate residue with a hydrophobic valine residue. The abnormal physiochemical properties of the resulting sickle hemoglobin (HbS) are responsible for the disease.

About 8% to 10% of African Americans in the United States are heterozygous for HbS, a largely asymptomatic condition known as *sickle cell trait.* The offspring of two heterozygotes has a 1 in 4 chance of being homozygous for the sickle mutation, a state that produces symptomatic sickle cell disease, which afflicts 70,000 to 100,000 individuals in the United States. In affected individuals, almost all the hemoglobin in the red cell is HbS ($\alpha_2\beta^s_2$).

The high prevalence of sickle cell trait in certain African populations stems from its protective effects against falciparum malaria. Genetic studies have shown that the sickle hemoglobin mutation has arisen independently at least six times in areas of Africa in which falciparum malaria is endemic, providing clear evidence of strong Darwinian selection. Parasite densities are lower in infected, heterozygous HbAS children than in infected, normal HbAA children, and AS children are significantly less likely to have severe disease or to die from malaria. Although mechanistic details are lacking, two scenarios to explain these observations are favored:

- Metabolically active intracellular parasites consume oxygen and decrease intracellular pH, both of which promote sickling of AS red cells. These distorted, stiff cells may be cleared more rapidly by splenic and hepatic phagocytes, keeping parasite loads low.
- Sickling also impairs the formation of membrane knobs containing a protein made by the parasite called *PfEMP-1.* These membrane knobs are implicated in adhesion of infected red cells to endothelium, which is believed to have an important pathogenic role in the most severe form of the disease, cerebral malaria.

It has been suggested that G6PD deficiency and thalassemia also protect against malaria by increasing the clearance and decreasing the adherence of infected red cells, possibly by raising levels of oxidant stress and causing membrane damage in the parasite-bearing cells that leads to their rapid removal from the bloodstream.

Pathogenesis

The major pathologic manifestations—chronic hemolysis, microvascular occlusions, and tissue damage—all stem from the tendency of HbS molecules to stack into polymers when deoxygenated. Initially, this process converts the red cell cytosol from a freely flowing liquid into a viscous gel. With continued deoxygenation, HbS molecules assemble into long needlelike fibers within red cells, producing a distorted sickle or holly-leaf shape.

Several variables affect the rate and degree of sickling:

- *Interaction of HbS with the other types of hemoglobin.* In heterozygotes with sickle cell trait, about 40% of the hemoglobin is HbS and the rest is HbA, which interferes with HbS polymerization. As a result, red cells in heterozygous individuals only sickle if exposed to prolonged, relatively severe hypoxia. HbF inhibits the polymerization of HbS even more than HbA; hence, infants with sickle cell disease do not become symptomatic until they reach 5 or 6 months of age, when the level of HbF normally falls. However, in some individuals HbF expression remains relatively high, a condition known as *hereditary persistence of fetal hemoglobin;* in these individuals, sickle cell disease is much less severe. Another variant hemoglobin, HbC, also is common in regions where HbS is found; overall, about 2% to 3% of American blacks are HbC heterozygotes, and about 1 in 1250 are compound HbS/HbC heterozygotes. In HbSC red cells, the percentage of HbS is 50%, as compared with only 40% in HbAS cells. Moreover, with aging HbSC cells tend to lose salt and water and become dehydrated, an effect that increases the intracellular concentration of HbS. These factors increase the tendency for HbS to polymerize, and as a result compound HbSC heterozygotes have a symptomatic sickling disorder termed *HbSC disease* that is somewhat milder than sickle cell disease.
- *Mean cell hemoglobin concentration* (MCHC). Higher HbS concentrations increase the probability that aggregation and polymerization will occur during any given period of deoxygenation. Thus, intracellular dehydration, which increases the MCHC, facilitates sickling. Conversely, conditions that decrease the MCHC reduce disease

severity. This occurs when an individual who is homozygous for HbS also has coexistent α-thalassemia, which reduces Hb synthesis and leads to milder disease.

- *Intracellular pH.* A decrease in pH reduces the oxygen affinity of hemoglobin, thereby increasing the fraction of deoxygenated HbS at any given oxygen tension and augmenting the tendency for sickling.
- *Transit time of red cells through microvascular beds.* As will be discussed, much of the pathology of sickle cell disease is related to vascular occlusion caused by sickling within microvascular beds. Transit times in most normal microvascular beds are too short for significant aggregation of deoxygenated HbS to occur, and as a result sickling is confined to microvascular beds with slow transit times. Blood flow is sluggish in the normal spleen and bone marrow, which are prominently affected in sickle cell disease, and also in vascular beds that are inflamed. The movement of blood through inflamed tissues is slowed because of the adhesion of leukocytes to activated endothelial cells and the transudation of fluid through leaky vessels. As a result, inflamed vascular beds are prone to sickling and occlusion.

Sickling causes cumulative damage to red cells through several mechanisms. As HbS polymers grow, they herniate through the membrane skeleton and project from the cell ensheathed only by the lipid bilayer. This severe derangement in membrane structure causes an influx of Ca^{2+} ions, which induce the cross-linking of membrane proteins and activate an ion channel that leads to the efflux of K^+ and H_2O. As a result, with repeated sickling episodes, red cells become dehydrated, dense, and rigid (Fig. 14.7). Eventually, the most severely damaged cells are converted to nondeformable irreversibly sickled cells that retain a sickle shape, even when fully oxygenated. The severity of the hemolysis correlates with the percentage of irreversibly sickled cells, which are rapidly sequestered and removed by mononuclear phagocytes (extravascular hemolysis). Sickled red cells are also mechanically fragile, leading to some intravascular hemolysis as well.

The pathogenesis of the microvascular occlusions, which are responsible for the most serious clinical features, is far less certain. Microvascular occlusions are not related to the number of irreversibly sickled cells, but instead may be dependent on more subtle red cell membrane damage and local factors, such as inflammation or vasoconstriction, that tend to slow or arrest the movement of red cells through microvascular beds (see Fig. 14.7). As mentioned earlier, sickle red cells express higher than normal levels of adhesion molecules and are sticky. Mediators released from granulocytes during inflammatory reactions up-regulate the expression of adhesion molecules on endothelial cells (Chapter 3) and further enhance the tendency for sickle red cells to arrest during transit through the microvasculature. The stagnation of red cells within inflamed vascular beds results in extended exposure to low oxygen tension, sickling, and vascular obstruction. Once started, it is easy to envision how a vicious cycle of sickling, obstruction, hypoxia, and more sickling ensues. Depletion of nitric oxide (NO) also may play a part in the vascular occlusions. Free hemoglobin released from lysed sickle red cells can bind and inactivate NO, a potent vasodilator and inhibitor of platelet aggregation. This in turn may lead to increased vascular tone (narrowing of vessels) and enhanced platelet aggregation, both of which may contribute to red cell stasis, sickling, and (in some instances) thrombosis.

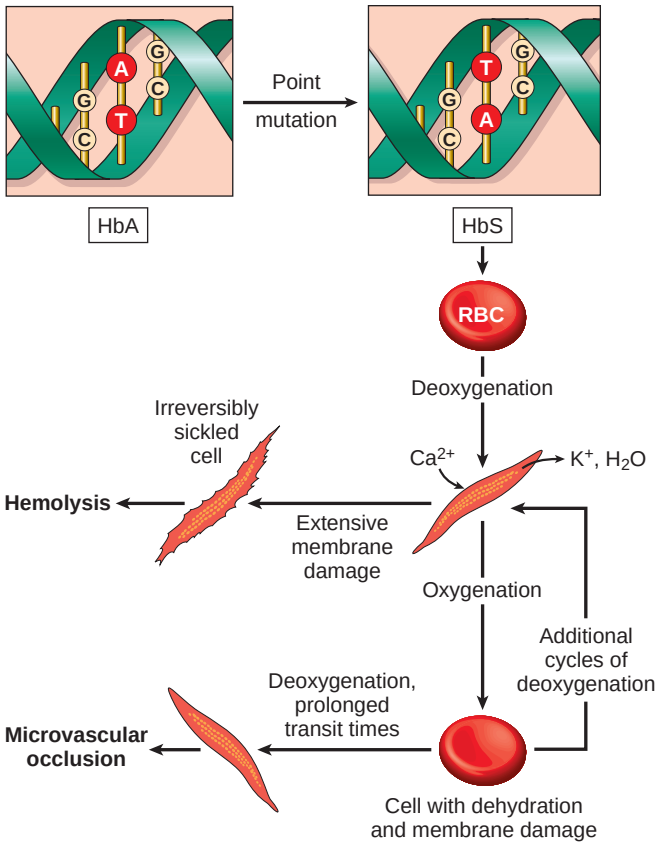

Figure 14.7 Pathophysiology of sickle cell disease. *HbA*, Hemoglobin A; *HbS*, hemoglobin S; *RBC*, red blood cell.

MORPHOLOGY

In sickle cell anemia, the peripheral blood demonstrates variable numbers of **irreversibly sickled cells,** reticulocytosis, and target cells, which result from red cell dehydration (Fig. 14.8). **Howell-Jolly bodies** (small nuclear remnants) also are present in red cells due to asplenia (see later). The bone marrow is hyperplastic as a result of a compensatory erythroid hyperplasia. Marked expansion of the marrow leads to bone resorption and secondary new bone formation, producing prominent cheekbones and changes in the skull that resemble a "crewcut" on radiographic studies. Extramedullary hematopoiesis may also appear. The increased breakdown of hemoglobin may cause hyperbilirubinemia and formation of pigment gallstones.

In early childhood, the spleen is enlarged (up to 500 g) by red pulp congestion caused by the trapping of sickled red cells in the cords and sinuses (Fig. 14.9). With time, however, chronic erythrostasis leads to splenic infarction, fibrosis, and progressive shrinkage, so that by adolescence or early adulthood only a small nubbin of fibrous splenic tissue is left, a process called **autosplenectomy** (Fig. 14.10). Infarctions caused by vascular occlusions may occur in many other tissues as well, including the bones, brain, kidney, liver, retina, and pulmonary vessels, the latter sometimes producing cor pulmonale. In adult patients, vascular stagnation in subcutaneous tissues often leads to leg ulcers; this complication is rare in children.

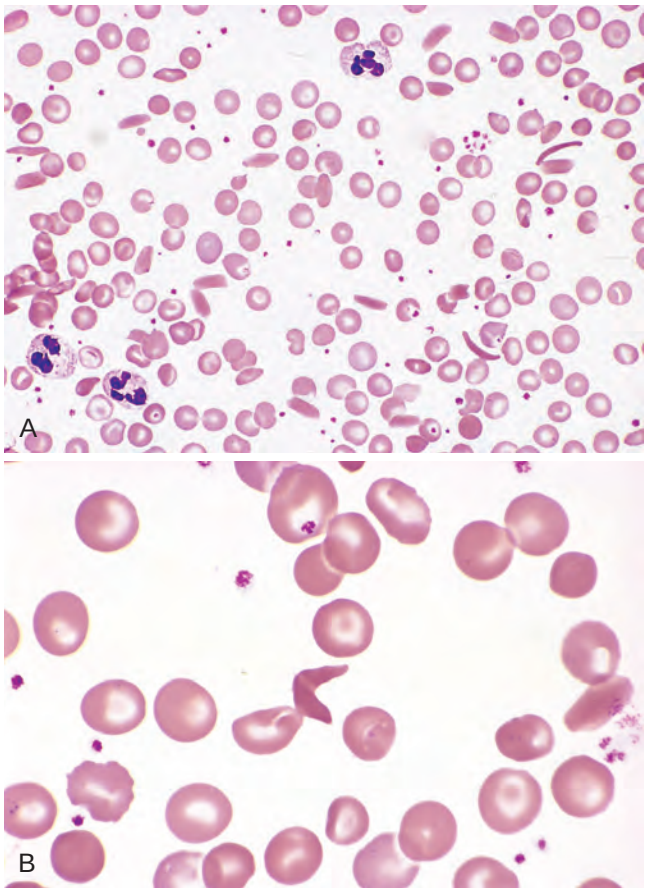

Figure 14.8 Sickle cell disease (peripheral blood smear). (A) Low magnification shows irreversibly sickled cells as well as target cells and red cell anisocytosis and poikilocytosis. (B) Higher magnification shows an irreversibly sickled cell in the center. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

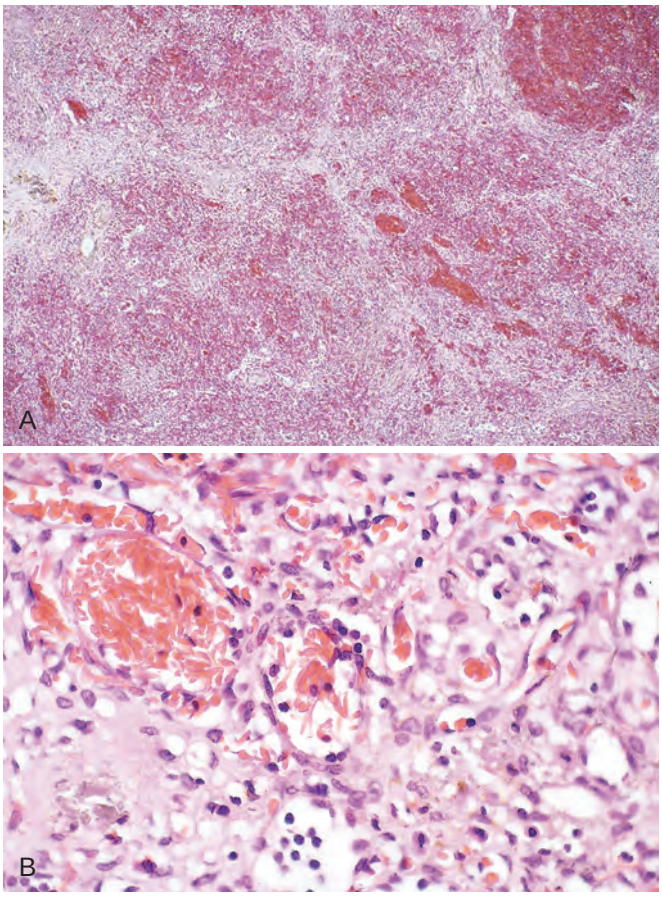

Figure 14.9 (A) Spleen in sickle cell disease (low power). Red pulp cords and sinusoids are markedly congested; between the congested areas, pale areas of fibrosis resulting from ischemic damage are evident. (B) Under high power, splenic sinusoids are dilated and filled with sickled red cells. (Courtesy Dr. Darren Wirthwein, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Clinical Features

Sickle cell disease causes a moderately severe hemolytic anemia (hematocrit 18% to 30%) associated with reticulocytosis, hyperbilirubinemia, and the presence of irreversibly sickled cells. Its course is punctuated by a variety of "crises." *Vaso-occlusive crises,* also called *pain crises,* are episodes of hypoxic injury and infarction that cause severe pain in the affected region. Although infection, dehydration, and acidosis (all of which favor sickling) may act as triggers, in most instances no predisposing cause is identified. The most commonly involved sites are the bones, lungs, liver, brain, spleen, and penis. In children, painful bone crises are extremely common and often difficult to distinguish from acute osteomyelitis. These frequently manifest as the *hand-foot syndrome* or dactylitis of the bones of the hands and feet. *Acute chest syndrome* is a particularly dangerous type of vaso-occlusive crisis involving the lungs that typically presents with fever, cough, chest pain, and pulmonary infiltrates. Pulmonary inflammation (such as may be induced by an infection) may cause blood flow to become sluggish and "spleenlike," leading to sickling and vaso-occlusion. This compromises pulmonary function, creating a potentially fatal cycle of worsening pulmonary and systemic hypoxemia, sickling, and vaso-occlusion. *Priapism* affects up to 45% of males after puberty and may lead to hypoxic damage and erectile dysfunction. Other disorders related to vascular obstruction, particularly stroke and retinopathy leading to loss of visual acuity and even blindness, can take a devastating toll. Factors proposed to contribute to stroke include the adhesion of sickle red cells

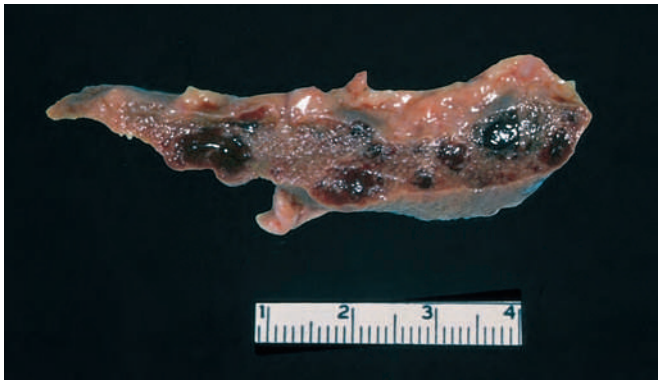

Figure 14.10 "Autoinfarcted" splenic remnant in sickle cell disease. (Courtesy Drs. Dennis Burns and Darren Wirthwein, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

to arterial vascular endothelium and vasoconstriction caused by the depletion of NO by free hemoglobin.

Although occlusive crises are the most common cause of patient morbidity and mortality, several other acute events complicate the course. *Sequestration crises* occur in children with intact spleens. Massive entrapment of sickled red cells leads to rapid splenic enlargement, hypovolemia, and sometimes shock. Both sequestration crises and the acute chest syndrome may be fatal and sometimes require prompt treatment with exchange transfusions. *Aplastic crises* stem from the infection of red cell progenitors by parvovirus B19, which causes a transient cessation of erythropoiesis and a sudden worsening of the anemia.

In addition to these dramatic crises, chronic tissue hypoxia takes a subtle but important toll. Chronic hypoxia is responsible for a generalized impairment of growth and development, as well as organ damage affecting the spleen, heart, kidneys, and lungs. Sickling provoked by hypertonicity in the renal medulla causes damage that eventually leads to *hyposthenuria* (the inability to concentrate urine), which increases the propensity for dehydration and its attendant risks.

Increased susceptibility to infection with encapsulated organisms is another threat. This is due in large part to altered splenic function, which is severely impaired in children by congestion and poor blood flow, and completely absent in adults because of splenic infarction. Defects of uncertain etiology in the alternative complement pathway also impair the opsonization of bacteria. *Pneumococcus pneumoniae* and *Haemophilus influenzae* septicemia and meningitis are common, particularly in children, but can be reduced by vaccination and prophylactic antibiotics.

It must be emphasized that there is great variation in the clinical manifestations of sickle cell disease. Some individuals suffer repeated vaso-occlusive crises, whereas others have only mild symptoms. The basis for this wide range in disease expression is not understood; both modifying genes and environmental factors are suspected.

The diagnosis is suggested by the clinical findings and the presence of irreversibly sickled red cells and is confirmed by various tests for sickle hemoglobin. Prenatal diagnosis is possible by analysis of fetal DNA obtained by amniocentesis or chorionic biopsy. Newborn screening for sickle hemoglobin is now routinely performed in all 50 states, typically using samples obtained by heel stick at birth.

The outlook for patients with sickle cell disease has improved considerably over the past 10 to 20 years. About 90% of patients survive to 20 years of age, and close to 50% survive beyond the fifth decade. The mainstay of treatment is an inhibitor of DNA synthesis, hydroxyurea, which has several beneficial effects. These include (1) an increase in red cell HbF levels, which occurs by unknown mechanisms; and (2) an anti-inflammatory effect, which stems from an inhibition of leukocyte production. These activities (and possibly others) are believed to act in concert to decrease crises related to vascular occlusions in both children and adults. When added to hydroxyurea, L-glutamine has been shown to decrease pain crises; the mechanism is uncertain, but it may involve changes in metabolism that decrease oxidant stress in red cells. Hematopoietic stem cell transplantation offers a chance at cure and is increasingly being explored as a therapeutic option. Another exciting new approach involves using gene editing (CRISPR technology) to reverse hemoglobin switching, so that hematopoietic stem cells produce red cells that express fetal hemoglobin instead of sickle hemoglobin. A clinical trial testing this approach is ongoing and has produced excellent responses.

Thalassemia

Thalassemia is a genetically heterogeneous disorder caused by germline mutations that decrease the synthesis of either α-globin or β-globin, leading to anemia, tissue hypoxia, and red cell hemolysis related to the imbalance in globin chain synthesis. The two α chains in HbA are encoded by an identical pair of α-globin genes on chromosome 16, and the two β chains are encoded by a single β-globin gene on chromosome 11. β-thalassemia is caused by deficient synthesis of β chains, whereas α-thalassemia is caused by deficient synthesis of α chains. The hematologic consequences of diminished synthesis of one globin chain stem not only from hemoglobin deficiency but also from a relative excess of the other globin chain, particularly in β-thalassemia (described later).

Thalassemia is endemic in the Mediterranean basin (indeed, *thalassa* means "sea" in Greek) as well as the Middle East, tropical Africa, the Indian subcontinent, and Asia, and in aggregate is among the most common inherited disorders of humans. As with sickle cell disease and other common inherited red cell disorders, its prevalence seems to be explained by the protection it affords heterozygous carriers against malaria. Although we discuss thalassemia with other inherited forms of anemia associated with hemolysis, it is important to recognize that the defects in globin synthesis that underlie these disorders cause anemia through two mechanisms: decreased red cell production, and decreased red cell lifespan.

β-Thalassemia

β-thalassemia is caused by mutations that diminish the synthesis of β-globin chains. Its clinical severity varies widely due to heterogeneity in the causative mutations. We will begin our discussion with the molecular lesions in β-thalassemia and then relate the clinical variants to specific underlying molecular defects.

Molecular Pathogenesis

The causative mutations fall into two categories: (1) β^0 mutations, associated with absent β-globin synthesis, and (2) β^+ mutations, characterized by reduced (but detectable) β-globin synthesis. Sequencing of β-thalassemia genes has revealed more than 100 different causative mutations, mostly consisting of point mutations, which fall into three major classes:

- *Splicing mutations.* These are the most common cause of β^+-thalassemia. Some of these mutations destroy normal RNA splice junctions and completely prevent the production of normal β-globin mRNA, resulting in β^0-thalassemia. Others create an "ectopic" splice site within an intron. Because the flanking normal splice site remains, both normal and abnormal splicing occurs and some normal β-globin mRNA is made, resulting in β^+-thalassemia.
- *Promoter region mutations.* These mutations reduce transcription by 75% to 80%. Some normal β-globin is synthesized; thus, these mutations are associated with β^+-thalassemia.

- *Chain terminator mutations.* These are the most common cause of β^0-thalassemia. They consist of either nonsense mutations that introduce a premature stop codon or small insertions or deletions that shift the mRNA reading frames (frameshift mutations; Chapter 5). Both block translation and prevent the synthesis of any functional β-globin.

Impaired β-globin synthesis results in anemia by two mechanisms (Fig. 14.11). The deficit in HbA synthesis produces "underhemoglobinized" hypochromic, microcytic red cells with subnormal oxygen transport capacity. Even more important is the diminished survival of red cells and their precursors, which results from the imbalance in α- and β-globin synthesis. Unpaired α chains precipitate within red cell precursors, forming insoluble inclusions. These inclusions cause a variety of untoward effects, but membrane damage is the proximal cause of most red cell pathology. Many red cell precursors succumb to membrane damage and undergo apoptosis. In severe β-thalassemia, it is estimated that 70% to 85% of red cell precursors suffer this fate, which leads to *ineffective erythropoiesis*. Those red cells that are released from the marrow also contain inclusions and have membrane damage, leaving theme prone to splenic sequestration and extravascular hemolysis.

In severe β-thalassemia, ineffective erythropoiesis creates several additional problems. Erythropoietic drive in the setting of severe uncompensated anemia leads to massive erythroid hyperplasia in the marrow and extensive extramedullary hematopoiesis. The expanding mass of red cell precursors erodes the bony cortex, impairs bone growth, and produces skeletal abnormalities (described later). Extramedullary hematopoiesis involves the liver, spleen, and lymph nodes, and in extreme cases produces extraosseous masses in the thorax, abdomen, and pelvis. The metabolically active erythroid progenitors steal nutrients from other tissues that are already oxygen-starved, causing severe cachexia in untreated patients.

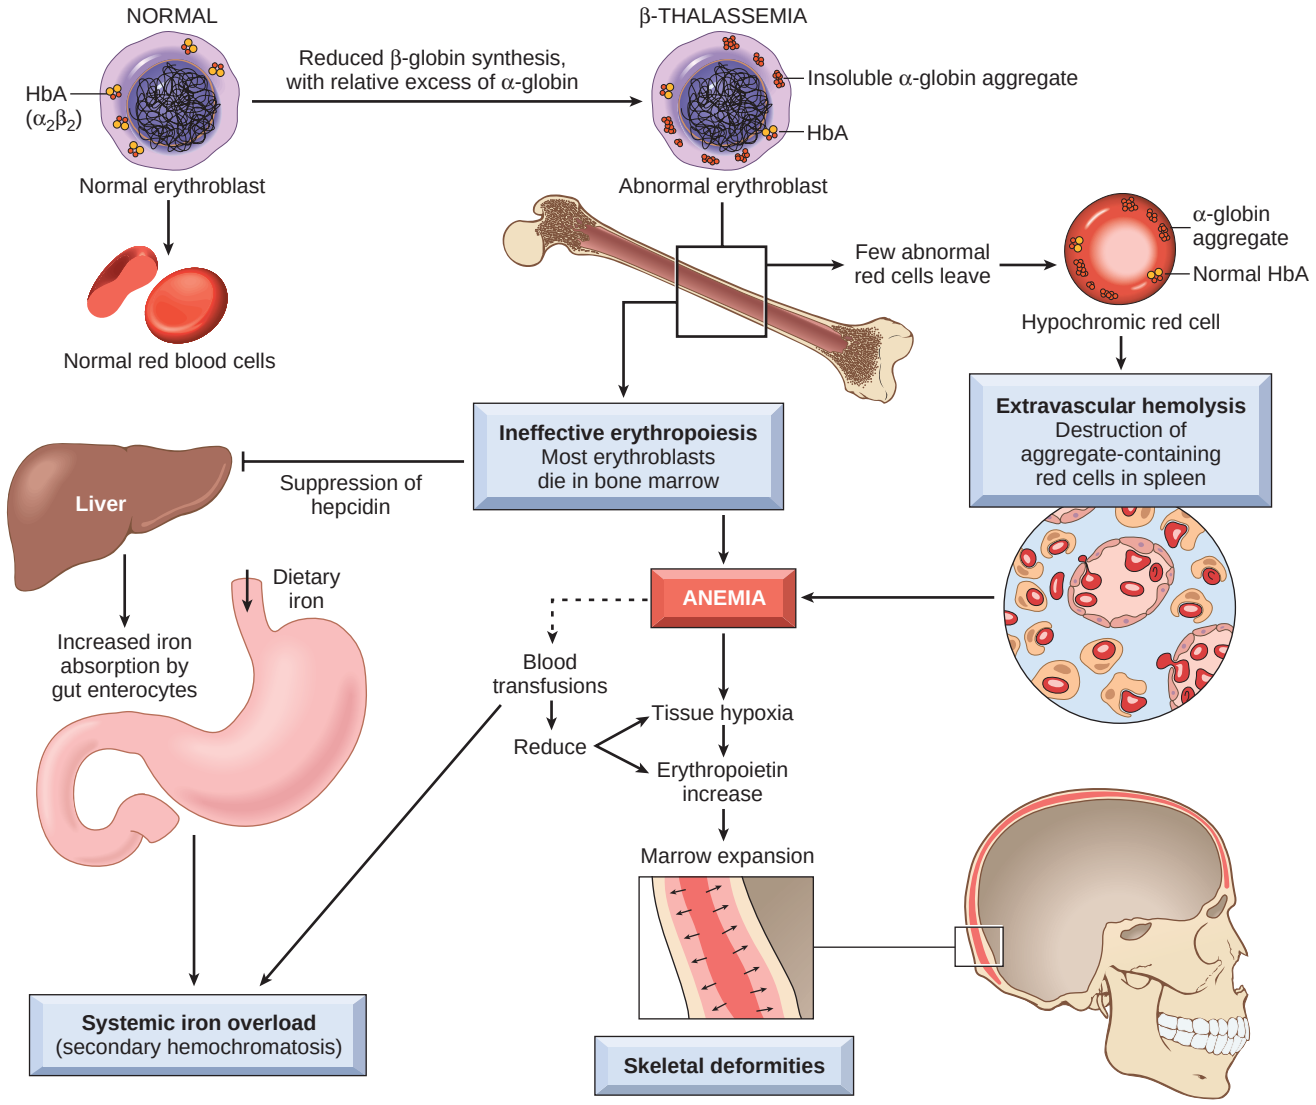

Figure 14.11 Pathogenesis of β-thalassemia major. Note that the aggregates of unpaired α-globin chains, a hallmark of the disease, are not visible in routinely stained blood smears. Blood transfusions are a double-edged sword, diminishing the anemia and its attendant complications, but also adding to the systemic iron overload. *HbA*, Hemoglobin A.

Another serious complication of ineffective erythropoiesis is excessive absorption of dietary iron. Erythroid precursors secrete a hormone called erythroferrone that inhibits production of hepcidin, a key negative regulator of iron uptake in the gut (described later in this chapter). In thalessemia, the marked expansion of erythroid precursors leads to increased absorption of iron from the gut (Fig. 14.12), and this together with repeated blood transfusions inevitably lead to severe iron accumulation *(secondary hemochromatosis)* unless preventive steps are taken. Injury to parenchymal organs, particularly the heart and liver, often follows (Chapter 18).

Clinical Syndromes

The relationships of clinical phenotypes to underlying genotypes are summarized in Table 14.3. Clinical classification of β-thalassemia is based on the severity of the anemia, which in turn depends on the genetic defect (β^+ or β^0) and the gene dosage (homozygous or heterozygous). In general, individuals with two β-thalassemia alleles (β^+/β^+, β^+/β^0, or β^0/β^0) have a severe, transfusion-dependent anemia called β-thalassemia major. Heterozygotes with one β-thalassemia gene and one normal gene (β^+/β or β^0/β) usually have a mild asymptomatic microcytic anemia. This condition is referred to as β-thalassemia minor or β-thalassemia trait. A third genetically heterogeneous variant of moderate severity is called β-thalassemia intermedia. This category includes milder variants of β^+/β^+ or β^+/β^0-thalassemia and unusual forms of heterozygous β-thalassemia. Some patients with β-thalassemia intermedia have two defective β-globin genes and an α-thalassemia gene defect, which improves the effectiveness of erythropoiesis and red cell survival by lessening the imbalance in α- and β-chain synthesis. In other rare but informative cases, affected individuals have a single β-globin defect and one or two extra copies of normal α-globin genes (stemming from a gene duplication event), which worsens the chain imbalance. These unusual forms of the disease emphasize the cardinal role of unpaired α-globin chains in the pathology. The clinical and morphologic features of β-thalassemia intermedia are not described separately but can be surmised from the following discussions of β-thalassemia major and β-thalassemia minor.

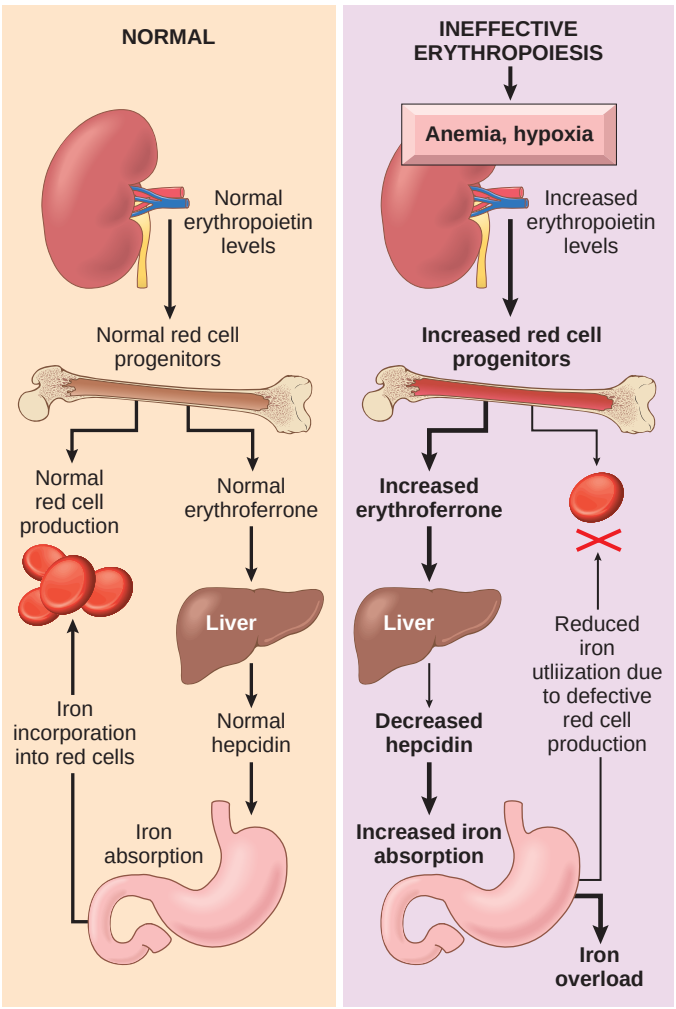

Figure 14.12 Mechanism of iron overload due to ineffective hematopoiesis. In the setting of ineffective erythropoiesis, such as in those with severed thalassemia, increased release of erythroferrone from the expanded mass of erythroid progenitors suppresses hepcidin production, leading to increased iron uptake from the gut.

Table 14.3 Clinical and Genetic Classification of Thalassemia

Clinical Syndrome	Genotype	Clinical Features	Molecular Genetics
β-Thalassemia			
β-Thalassemia major	Homozygous β-thalassemia (β^0/β^0, β^+/β^+, β^0/β^+)	Severe; requires blood transfusions	Mainly point mutations that lead to defects in the transcription, splicing, or translation of β-globin mRNA
β-Thalassemia intermedia	Variable (β^0/β^+, β^+/β^+, β^0/β, β^+/β)	Severe but does not require regular blood transfusions	
β-Thalassemia minor	Heterozygous β-thalassemia (β^0/β, β^+/β)	Asymptomatic with mild or absent anemia; red cell abnormalities seen	
α-Thalassemia			
Silent carrier	$-/\alpha\ \alpha/\alpha$	Asymptomatic; no red cell abnormality	Mainly gene deletions
α-Thalassemia trait	$-/-\ \alpha/\alpha$ (Asian) $-/\alpha\ -/\alpha$ (black African, Asian)	Asymptomatic, like β-thalassemia minor	
HbH disease	$-/-\ -/\alpha$	Severe; resembles β-thalassemia intermedia	
Hydrops fetalis	$-/-\ -/-$	Lethal in utero without transfusions	

β-Thalassemia Major. β-Thalassemia major is most common in Mediterranean countries, parts of Africa, and Southeast Asia. In the United States, the incidence is highest in immigrants from these areas. The anemia manifests 6 to 9 months after birth as hemoglobin synthesis switches from HbF to HbA. In untransfused patients, hemoglobin levels are 3 to 6 g/dL. The red cells may completely lack HbA (β^0/β^0 genotype) or contain small amounts (β^+/β^+ or β^0/β^+ genotypes). The major red cell hemoglobin is HbF, which is markedly elevated. HbA_2 levels are sometimes high but more often are normal or low.

MORPHOLOGY

Blood smears show severe red cell abnormalities, including marked variation in size **(anisocytosis)** and shape **(poikilocytosis), microcytosis,** and **hypochromia.** Target cells (so called because hemoglobin collects in the center of the cell), basophilic stippling, and fragmented red cells also are common. Inclusions of aggregated α chains are efficiently removed by the spleen and not easily seen. The reticulocyte count is elevated, but is lower than expected for the severity of anemia because of ineffective erythropoiesis. Variable numbers of poorly hemoglobinized nucleated red cell precursors (normoblasts) are seen in the peripheral blood as a result of "stress" erythropoiesis and abnormal release of red cell precursors from sites of extramedullary hematopoiesis.

Other major alterations involve the bone marrow and spleen. In untransfused patients, there is a striking expansion of hematopoietically active marrow. In the bones of the face and skull, the burgeoning marrow erodes existing cortical bone and induces new bone formation, giving rise to a "crewcut" appearance on radiographic studies (Fig. 14.13). Both phagocyte hyperplasia and extramedullary hematopoiesis contribute to enlargement of the spleen, which can weigh as much as 1500 g. The liver and the lymph nodes also may be enlarged by extramedullary hematopoiesis.

Hemosiderosis and secondary hemochromatosis, the two manifestations of iron overload (Chapter 18), inevitably occur unless chelation therapy is given. The deposited iron often damages organs, most notably the heart, liver, and pancreas.

The clinical course of β-thalassemia major is brief unless blood transfusions are given. Untreated children suffer from growth retardation and die at an early age from the effects of anemia. In those who survive long enough, the cheekbones and other bony prominences are enlarged and distorted. Hepatosplenomegaly due to extramedullary hematopoiesis is usually present. Although blood transfusions improve the anemia and suppress complications related to excessive erythropoiesis, they lead to complications of their own. Cardiac disease resulting from progressive iron overload and secondary hemochromatosis (Chapter 18) is an important cause of death, particularly in heavily transfused patients, who must be treated with iron chelators to prevent this complication. With transfusions and iron chelation, survival into the third decade is possible, but the overall outlook remains guarded. Hematopoietic stem cell transplantation is the only therapy offering a cure and is being used increasingly. Prenatal diagnosis is possible by molecular analysis of DNA.

β-Thalassemia Minor. β-Thalassemia minor is much more common than β-thalassemia major and understandably affects the same ethnic groups. Most patients are heterozygous carriers of a β^+ or β^0 allele. These patients are usually asymptomatic. Anemia, if present, is mild. The peripheral blood smear typically shows hypochromia, microcytosis, basophilic stippling, and target cells. Mild erythroid hyperplasia is seen in the bone marrow. Hemoglobin electrophoresis usually reveals an increase in HbA_2 ($\alpha_2\delta_2$) to 4% to 8% of the total hemoglobin (normal, 2.5% ± 0.3%), reflecting an elevated ratio of δ-chain to β-chain synthesis. HbF levels are generally normal or occasionally slightly increased.

Recognition of β-thalassemia trait is important for two reasons: (1) it may be mistaken for iron deficiency, and (2) it has implications for genetic counseling. Iron deficiency (the most common cause of microcytic anemia) can usually be excluded by measurement of serum iron, total iron-binding capacity, and serum ferritin (see the Iron Deficiency Anemia section later in this chapter). The increase in HbA_2 is diagnostically useful, particularly in individuals (such as women of childbearing age) who are at high risk of iron deficiency.

α-Thalassemia

α-Thalassemia is caused by inherited deletions that result in reduced or absent synthesis of α-globin chains. Normal individuals have four α-globin genes, and the severity of α-thalassemia depends on how many α-globin genes are affected. As in β-thalassemias, the anemia stems both from inadequate hemoglobin synthesis and the presence of excess, unpaired β, γ, and δ globin chains, which vary in type at different ages. In newborns with α-thalassemia, excess unpaired γ-globin chains form γ_4 tetramers known as *hemoglobin Barts,* whereas in older children and adults excess β-globin chains form β_4 tetramers known as *HbH.* Because free β and γ chains are more soluble than free α chains and form fairly stable homotetramers, hemolysis and ineffective erythropoiesis are less severe than in β-thalassemia. A variety of molecular lesions give rise to α-thalassemia, but gene deletion is the most common cause of reduced α-chain synthesis.

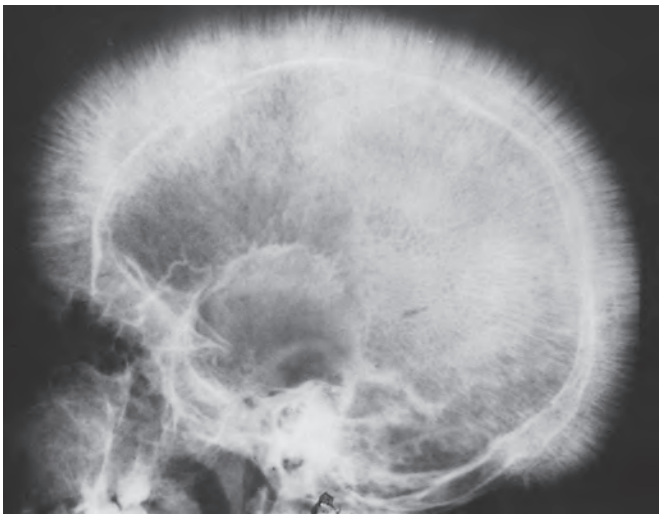

Figure 14.13 β-Thalassemia major. X-ray film of the skull showing new bone formation on the outer table, producing perpendicular radiations resembling a crewcut. (Courtesy Dr. Jack Reynolds, Department of Radiology, University of Texas Southwestern Medical School, Dallas, Tex.)

Clinical Syndromes

The clinical syndromes are determined and classified by the number of α-globin genes that are deleted. Each of the four α-globin genes normally contributes 25% of the total α-globin chains. α-Thalassemia syndromes stem from combinations of deletions that remove one to four α-globin genes. Not surprisingly, the severity of the clinical syndrome is proportional to the number of α-globin genes that are deleted. The different types of α-thalassemia and their salient clinical features are listed in Table 14.3.

Silent Carrier State. Silent carrier state is associated with the deletion of a single α-globin gene, which causes a barely detectable reduction in α-globin chain synthesis. These individuals are completely asymptomatic but have slight microcytosis.

α-Thalassemia Trait. α-Thalassemia trait is caused by the deletion of two α-globin genes from a single chromosome (α/α −/−) or the deletion of one α-globin gene from each of the two chromosomes (α/− α/−) (see Table 14.3). The former genotype is more common in Asian populations, the latter in regions of Africa. Both genotypes produce similar deficiencies of α-globin, but they have different implications for the children of affected individuals, who are at risk of clinically significant α-thalassemia (HbH disease or hydrops fetalis) only when at least one parent has the −/− haplotype. As a result, symptomatic α-thalassemia is relatively common in Asian populations and rare in African populations. The clinical picture in α-thalassemia trait is identical to that described for β-thalassemia minor, that is, small red cells (microcytosis), minimal or no anemia, and no abnormal physical signs. HbA_2 levels are normal or low.

Hemoglobin H (HbH) Disease. HbH disease is caused by deletion of three α-globin genes. It is most common in Asian populations. With only one normal α-globin gene, the synthesis of α chains is markedly reduced, and tetramers of β-globin, called HbH, form. HbH has an extremely high affinity for oxygen and therefore is not useful for oxygen delivery, leading to tissue hypoxia disproportionate to the level of hemoglobin. Additionally, HbH is prone to oxidation, which causes it to precipitate and form intracellular inclusions that promote red cell sequestration and phagocytosis in the spleen. The result is a moderately severe anemia resembling β-thalassemia intermedia.

Hydrops Fetalis. Hydrops fetalis, the most severe form of α-thalassemia, is caused by deletion of all four α-globin genes. In the fetus, excess γ-globin chains form tetramers (hemoglobin Barts) that have such a high affinity for oxygen that they deliver little to tissues. Survival in early development is due to the expression of ζ chains, an embryonic globin that pairs with γ chains to form a functional $\zeta_2\gamma_2$ Hb tetramer. Signs of fetal distress usually become evident by the third trimester of pregnancy. In the past, severe tissue anoxia led to death in utero or shortly after birth; with intrauterine transfusion many affected infants are now saved. The fetus shows severe pallor, generalized edema, and massive hepatosplenomegaly similar to that seen in hemolytic disease of the newborn (Chapter 10). There is a lifelong dependence on blood transfusions for survival, with the associated risk of iron overload. Hematopoietic stem cell transplantation can be curative.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a disease that results from acquired mutations in the phosphatidylinositol glycan complementation group A gene *(PIGA)*, an enzyme that is essential for the synthesis of certain membrane-associated complement regulatory proteins. PNH has an incidence of 2 to 5 per million in the United States. Despite its rarity, it has fascinated hematologists because it is the only hemolytic anemia caused by an acquired genetic defect. Recall that proteins are anchored into the lipid bilayer in two ways. Most have a hydrophobic region that spans the cell membrane; these are called transmembrane proteins. The others are attached to the cell membrane through a covalent linkage to a specialized phospholipid called glycosylphosphatidylinositol (GPI). In PNH, these GPI-linked proteins are deficient because of somatic mutations that inactivate PIGA. *PIGA* is X-linked and subject to lyonization (random inactivation of one X chromosome in cells of females; Chapter 5). As a result, a single acquired mutation in the active *PIGA* gene of any given cell is sufficient to produce a deficiency state. Because the causative mutations occur in a hematopoietic stem cell, all of its clonal progeny (red cells, white cells, and platelets) are deficient in GPI-linked proteins. Typically, only a subset of stem cells acquires the mutation, and the mutant clone coexists with the progeny of normal stem cells that are not PIGA deficient.

Remarkably, most normal individuals harbor small numbers of bone marrow cells with *PIGA* mutations identical to those that cause PNH. It is hypothesized that these cells increase in numbers (thus producing clinically evident PNH) only in rare instances where they have a selective advantage, such as in the setting of autoimmune reactions against GPI-linked antigens. Such a scenario might explain the frequent association of PNH and aplastic anemia, a marrow failure syndrome (discussed later) that has an autoimmune basis in many individuals.

PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: (1) decay-accelerating factor, or CD55; (2) membrane inhibitor of reactive lysis, or CD59; and (3) C8-binding protein. Of these factors, the most important is CD59, a potent inhibitor of C3 convertase that prevents the spontaneous activation of the alternative complement pathway.

Red cells deficient in GPI-linked factors are abnormally susceptible to lysis or injury by complement. This manifests as intravascular hemolysis, which is caused by the C5b-C9 membrane attack complex. The hemolysis is paroxysmal and nocturnal in only 25% of cases; chronic hemolysis without dramatic hemoglobinuria is more typical. The tendency for red cells to lyse at night is explained by a slight decrease in blood pH during sleep, which increases the activity of complement. The anemia is variable but usually mild to moderate in severity. The loss of heme iron in the urine (hemosiderinuria) eventually leads to iron deficiency, which can exacerbate the anemia if untreated.

Thrombosis is the leading cause of disease-related death in individuals with PNH. About 40% of patients suffer from venous thrombosis, often involving the hepatic, portal, or

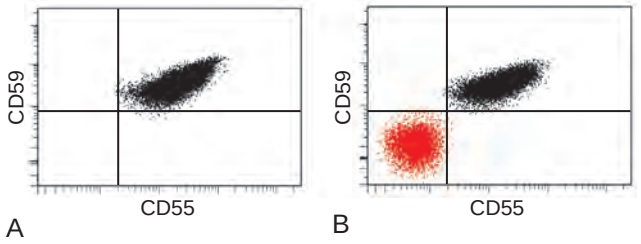

Figure 14.14 Paroxysmal nocturnal hemoglobinuria (PNH). (A) Flow cytogram of blood from a normal individual shows that the red cells express two phosphatidylinositol glycan (PIG)-linked membrane proteins, CD55 and CD59, on their surfaces. (B) Flow cytogram of blood from a patient with PNH shows a population of red cells that is deficient in both CD55 and CD59. As is typical of PNH, a second population of CD55+/CD59+ red cells that is derived from residual normal hematopoietic stem cells also is present. (Courtesy Dr. Scott Rodig, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

cerebral veins. How complement activation leads to thrombosis in patients with PNH is not clear; the absorption of NO by free hemoglobin (discussed in the Sickle Cell Disease section earlier in this chapter) may be one contributing factor, and a role for endothelial damage caused by the C5-9 membrane attack complex is also suspected.

About 5% to 10% of patients eventually develop acute myeloid leukemia or a myelodysplastic syndrome, indicating that PNH may arise in the context of genetic damage to hematopoietic stem cells.

PNH is diagnosed by flow cytometry, which provides a sensitive means for detecting red cells that are deficient in GPI-linked proteins such as CD59 (Fig. 14.14). The cardinal role of complement activation in PNH pathogenesis has been proven by therapeutic use of a monoclonal antibody called Eculizumab that prevents the conversion of C5 to C5a. This inhibitor not only reduces the hemolysis and attendant transfusion requirements, but also lowers the risk of thrombosis by up to 90%. The drawbacks to C5 inhibitor therapy are its high cost and an increased risk of serious or fatal meningococcal infection (as is true in individuals with inherited complement defects). Immunosuppressive drugs are sometimes beneficial for those with evidence of marrow aplasia. The only cure is hematopoietic stem cell transplantation.

Immunohemolytic Anemia

Immunohemolytic anemia is caused by antibodies that recognize red cells and lead to their premature destruction. Although these disorders are commonly referred to as autoimmune hemolytic anemias, the designation immunohemolytic anemia is preferred because the immune reaction is initiated in some instances by an ingested drug. Immunohemolytic anemia can be classified based on the characteristics of the responsible antibody (Table 14.4).

The diagnosis of immunohemolytic anemia requires the detection of antibodies and/or complement on red cells from the patient. This is done using the *direct Coombs antiglobulin test,* in which the patient's red cells are mixed with sera containing antibodies that are specific for human immunoglobulin or complement. If either immunoglobulin or complement is present on the surface of the red cells, the antibodies cause agglutination, which is appreciated visually as clumping. In the *indirect Coombs antiglobulin test,* the patient's serum is tested for its ability to agglutinate commercially available red cells bearing particular defined antigens. This test is used to characterize the antigen target and temperature dependence of the responsible antibody. Quantitative immunologic tests to measure such antibodies directly also are available.

Warm Antibody Type. This form constitutes approximately 80% of cases of immunohemolytic anemia. It is caused by antibodies that bind stably to red cells at 37°C. About 50% of cases are idiopathic (primary); others are related to a predisposing condition (see Table 14.4) or exposure to a drug. Most causative antibodies are of the IgG class; less commonly, IgA antibodies are the culprits. The red cell hemolysis is mostly extravascular. IgG-coated red cells bind to Fc receptors on phagocytes, which remove red cell membrane during "partial" phagocytosis. As in hereditary spherocytosis, the loss of membrane converts the red cells to spherocytes, which are sequestered and destroyed in the spleen. Moderate splenomegaly due to hyperplasia of splenic phagocytes is usually seen.

As with other autoimmune disorders, the cause of primary immunohemolytic anemia is unknown. In cases that are idiopathic, the antibodies are directed against red cell surface proteins, often components of the Rh blood group complex. In drug-induced cases, two mechanisms have been described.

- *Antigenic drugs.* In this setting hemolysis usually follows large, intravenous doses of the offending drug and occurs 1 to 2 weeks after therapy is initiated. These drugs, exemplified by penicillin and cephalosporins, bind to the red cell membrane and create a new antigenic determinant that is recognized by antibodies. The responsible antibodies sometimes fix complement and cause intravascular hemolysis, but more often they act as opsonins that promote extravascular hemolysis within phagocytes.
- *Tolerance-breaking drugs.* These drugs, of which the antihypertensive agent α-methyldopa is the prototype, break tolerance in some unknown manner that leads to the production of antibodies against red cell antigens, particularly the Rh blood group antigens. About 10% of patients taking α-methyldopa develop autoantibodies, as assessed by the direct Coombs test, and roughly 1% develop clinically significant hemolysis.

Table 14.4 Classification of Immunohemolytic Anemia

Warm Antibody Type (IgG Antibodies Active at 37°C)
Primary (idiopathic)
Secondary
Autoimmune disorders (particularly systemic lupus erythematosus)
Drugs
Lymphoid neoplasms
Cold Agglutinin Type (IgM Antibodies Active Below 37°C)
Acute (mycoplasmal infection, infectious mononucleosis)
Chronic
Idiopathic
Lymphoid neoplasms
Cold Hemolysin Type (IgG Antibodies Active Below 37°C)
Rare; occurs mainly in children following viral infections

Treatment of warm antibody immunohemolytic anemia centers on the removal of initiating factors (i.e., drugs); when this is not feasible, immunosuppressive drugs and splenectomy are the mainstays.

Cold Agglutinin Type. This type of immunohemolytic anemia is caused by IgM antibodies that bind to red cells avidly at low temperatures (0°C to 4°C) but not at 37°C. It accounts for 15% to 20% of cases. Cold agglutinin antibodies sometimes appear transiently following certain infections, such as with *Mycoplasma pneumoniae,* Epstein-Barr virus, cytomegalovirus, influenza virus, and human immunodeficiency virus (HIV). In these settings, the disorder is self-limited and the antibodies rarely induce clinically important hemolysis. Chronic cold agglutinin immunohemolytic anemia occurs in association with certain B-cell neoplasms or as an idiopathic condition.

Clinical symptoms result from binding of IgM to red cells in vascular beds where the temperature may fall below 30°C, such as in exposed fingers, toes, and ears. IgM binding agglutinates red cells and fixes complement rapidly. As the blood recirculates and warms, IgM is released, usually before complement-mediated hemolysis can occur; therefore, intravascular hemolysis is usually not seen. However, the transient interaction with IgM is sufficient to deposit sublytic quantities of C3b, an excellent opsonin, which leads to the removal of red cells by phagocytes in the spleen, liver, and bone marrow (extravascular hemolysis). The hemolysis is of variable severity. Vascular obstruction caused by agglutinated red cells may produce pallor, cyanosis, and Raynaud phenomenon (Chapter 11) in parts of the body that are exposed to cold temperatures. Chronic cold agglutinin immunohemolytic anemia caused by IgM antibodies may be difficult to treat. The best approach, when possible, is avoidance of cold temperatures.

Cold Hemolysin Type. Cold hemolysins are autoantibodies responsible for an unusual entity known as *paroxysmal cold hemoglobinuria.* This rare disorder may cause substantial, sometimes fatal, intravascular hemolysis and hemoglobinuria. The autoantibodies are IgGs that bind to the P blood group antigen on the red cell surface in cool, peripheral regions of the body. Complement-mediated lysis occurs when the cells recirculate to the body's warm core, where the complement cascade functions more efficiently. Most cases are seen in children following viral infections; in this setting the disorder is transient, and most of those affected recover within 1 month.

Hemolytic Anemia Resulting From Trauma to Red Cells

The most significant hemolysis caused by trauma to red cells is seen in individuals with cardiac valve prostheses and microangiopathic disorders. Artificial mechanical cardiac valves are more frequently implicated than are bioprosthetic porcine or bovine valves. The hemolysis stems from shear forces produced by turbulent blood flow and pressure gradients across damaged valves. *Microangiopathic hemolytic anemia* is most commonly seen with disseminated intravascular coagulation (DIC), but it also occurs in thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), malignant hypertension, systemic lupus erythematosus, and disseminated cancer. The common pathogenic feature in these disorders is microvascular lesions that result in luminal narrowing, often due to the deposition of thrombi, producing shear stresses that mechanically injure passing red cells. Regardless of the cause, traumatic damage leads to intravascular hemolysis and the appearance of red cell fragments *(schistocytes),* "burr cells," "helmet cells," and "triangle cells" in blood smears (Fig. 14.15).

KEY CONCEPTS

Hereditary Spherocytosis

- Autosomal dominant disorder caused by mutations that affect the red cell membrane skeleton, leading to loss of membrane and eventual conversion of red cells to spherocytes, which are phagocytosed and removed in the spleen
- Manifested by anemia and splenomegaly

Thalassemias

- Autosomal codominant disorders caused by mutations in α- or β-globin that reduce hemoglobin synthesis, resulting in a microcytic, hypochromic anemia.
- In β-thalassemia, unpaired α-globin chains form aggregates that damage red cell precursors and further impair erythropoiesis.
- Ineffective erythropoesis increases iron absorption and can lead to systemic iron overload.

Sickle Cell Anemia

- Autosomal recessive disorder resulting from a mutation in β-globin that causes deoxygenated hemoglobin to self-associate into long polymers that distort (sickle) the red cell
- Episodic lockage of vessels by sickle red cells causes pain crises and tissue infarction, particularly of the marrow and spleen
- Red cell membrane damage caused by repeated bouts of sickling results in a moderate to severe hemolytic anemia

Glucose-6-Phosphate Dehydrogenase Deficiency

- X-linked disorder caused by mutations that destabilize G6PD, making red cells susceptible to oxidant damage

Immunohemolytic Anemias

- Caused by antibodies against either normal red cell constituents or antigens modified by haptens (e.g., drugs)
- Antibody binding results in either red cell opsonization and extravascular hemolysis or (uncommonly) complement fixation and intravascular hemolysis

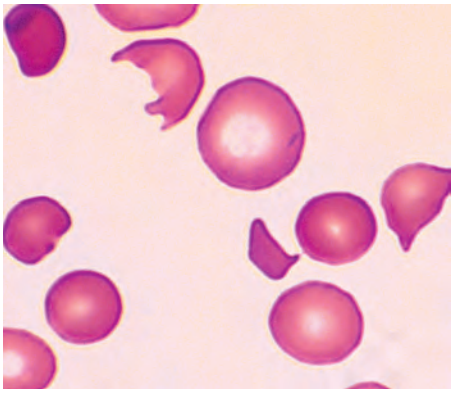

Figure 14.15 Microangiopathic hemolytic anemia. A peripheral blood smear from a patient with hemolytic uremic syndrome shows several fragmented red cells. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Anemias of Diminished Erythropoiesis

Although anemias caused by inadequate red cell production are heterogeneous, they can be classified into several major categories based on pathophysiology (see Table 14.1). The most common and important anemias associated with red cell underproduction are those caused by nutritional deficiencies, followed by those that arise secondary to chronic inflammation or renal failure. Also included are less common disorders that lead to generalized bone marrow failure, such as aplastic anemia, primary hematopoietic neoplasms (Chapter 13), and infiltrative disorders that replace the marrow (e.g., metastatic cancer and disseminated granulomatous disease). We first discuss the extrinsic causes of diminished erythropoiesis, which are more common and clinically important, and then non-neoplastic intrinsic causes.

Megaloblastic Anemia

The common theme among the various causes of megaloblastic anemia is an impairment of DNA synthesis that leads to ineffective hematopoiesis and distinctive morphologic changes, including abnormally large erythroid precursors and red cells. The causes of megaloblastic anemia are given in Table 14.5. The following discussion first describes the common features and then turns to the two principal subtypes: pernicious anemia (the major form of vitamin B_{12} deficiency anemia) and folate deficiency anemia.

Some of the metabolic roles of vitamin B_{12} and folate are considered later. For now it suffices that vitamin B_{12} and folic acid are coenzymes required for the synthesis of thymidine, one of the four bases found in DNA. A deficiency of these vitamins or impairment of their metabolism results in defective nuclear maturation due to deranged or inadequate DNA synthesis, with an attendant delay or block in cell division.

Table 14.5 Causes of Megaloblastic Anemia

Vitamin B_{12} Deficiency
Decreased Intake
Inadequate diet, vegetarianism
Impaired Absorption
Intrinsic factor deficiency Pernicious anemia Gastrectomy Malabsorption states Diffuse intestinal disease (e.g., lymphoma, systemic sclerosis) Ileal resection, ileitis Competitive parasitic uptake Fish tapeworm infestation Bacterial overgrowth in blind loops and diverticula of bowel
Folic Acid Deficiency
Decreased Intake
Inadequate diet, alcoholism, infancy
Impaired Absorption
Malabsorption states Intrinsic intestinal disease Anticonvulsants, oral contraceptives
Increased Loss
Hemodialysis
Increased Requirement
Pregnancy, infancy, disseminated cancer, markedly increased hematopoiesis
Impaired Utilization
Folic acid antagonists
Unresponsive to Vitamin B_{12} or Folic Acid Therapy
Metabolic inhibitors of DNA synthesis and/or folate metabolism (e.g., methotrexate)

Modified from Beck WS: Megaloblastic anemias. In Wyngaarden JB, Smith LH, editors: *Cecil Textbook of Medicine*, ed 18, Philadelphia, 1988, WB Saunders, p 900.

MORPHOLOGY

Certain peripheral blood findings are common to all forms of megaloblastic anemia. The presence of red cells that are macrocytic and oval **(macro-ovalocytes)** is highly characteristic. Because they are larger than normal and contain ample hemoglobin, most macrocytes lack the central pallor of normal red cells and even appear "hyperchromic," but the mean cell hemoglobin content is not elevated. There is marked variation in red cell size (anisocytosis) and shape (poikilocytosis). The reticulocyte count is low. Nucleated red cell progenitors occasionally appear in the circulating blood when anemia is severe. Neutrophils are also larger than normal and show **nuclear hypersegmentation,** having five or more nuclear lobules instead of the normal three to four (Fig. 14.16).

The marrow is usually markedly hypercellular as a result of increased numbers of hematopoietic precursors. **Megaloblastic changes** are detected at all stages of erythroid development**.** The most primitive cells (promegaloblasts) are large, with a deeply basophilic cytoplasm, prominent nucleoli, and a distinctive, fine nuclear chromatin pattern (Fig. 14.17). As these cells differentiate and begin to accumulate hemoglobin, the nucleus retains its finely distributed chromatin instead of developing the clumped pyknotic chromatin typical of normoblasts. Although nuclear maturation is delayed, cytoplasmic maturation and hemoglobin accumulation proceed at a normal pace, leading to nuclear-to-cytoplasmic asynchrony. Because DNA synthesis is impaired in all proliferating cells, granulocytic precursors also display dysmaturation in the form of **giant metamyelocytes** and **band forms.** Megakaryocytes also may be abnormally large and have bizarre, multilobate nuclei.

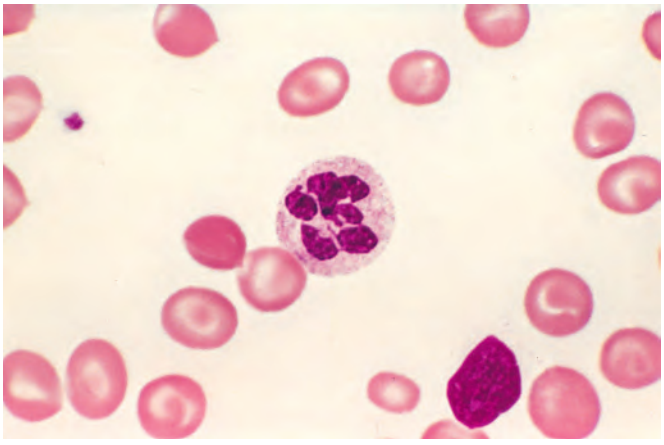

Figure 14.16 Megaloblastic anemia. A peripheral blood smear shows a hypersegmented neutrophil with a six-lobed nucleus. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

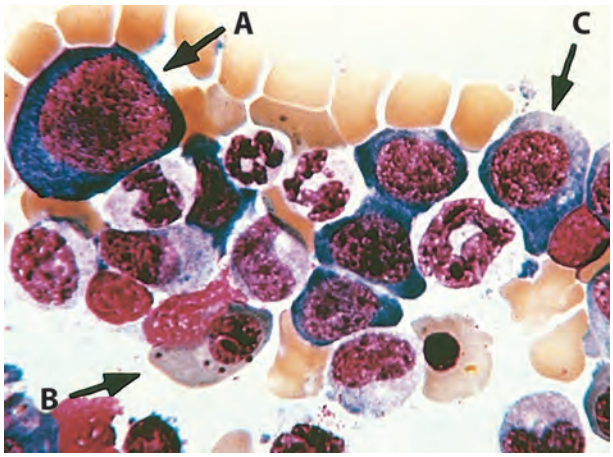

Figure 14.17 Megaloblastic anemia (bone marrow aspirate). *A to C,* Megaloblasts in various stages of differentiation. Note that the orthochromatic megaloblast *(B)* is hemoglobinized (as revealed by cytoplasmic color), but in contrast to normal orthochromatic normoblasts, the nucleus is not pyknotic. The early erythroid precursors *(A and C)* and the granulocytic precursors also are enlarged and have abnormally immature chromatin. (Courtesy Dr. Jose Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

The marrow hyperplasia is a response to increased levels of growth factors, such as erythropoietin. However, the derangement in DNA synthesis causes most precursors to undergo apoptosis in the marrow (an example of ineffective hematopoiesis) and leads to pancytopenia. The anemia is further exacerbated by a mild degree of red cell hemolysis of uncertain etiology.

Vitamin B_{12} Deficiency Anemia: Pernicious Anemia

Pernicious anemia is a specific form of megaloblastic anemia caused by an autoimmune gastritis that impairs the production of intrinsic factor, which is required for vitamin B_{12} uptake from the gut.

Normal Vitamin B_{12} Metabolism. Vitamin B_{12} is a complex organometallic compound also known as cobalamin that is present in animal products such as meat, fish, milk, and eggs. The daily requirement is 2 to 3 μg. A diet that includes animal products contains significantly more than the minimal daily requirement and normally results in the accumulation of intrahepatic stores of vitamin B_{12} that are sufficient to last for several years. By contrast, plants and vegetables contain little cobalamin, and strictly vegetarian or macrobiotic diets do not provide adequate amounts of this essential nutrient.

Absorption of vitamin B_{12} requires intrinsic factor, which is secreted by the parietal cells of the fundic mucosa (Fig. 14.18). Vitamin B_{12} is freed from binding proteins in food through the action of pepsin in the stomach and binds to a salivary protein called *haptocorrin*. In the duodenum, bound vitamin B_{12} is released from haptocorrin by the action of pancreatic proteases and associates with intrinsic factor. This complex is transported to the ileum, where it is endocytosed by ileal enterocytes that express a receptor for intrinsic factor called *cubilin* on their surfaces. Within ileal cells, vitamin B_{12} associates with a major carrier protein, transcobalamin II, and is secreted into the plasma. Transcobalamin II delivers

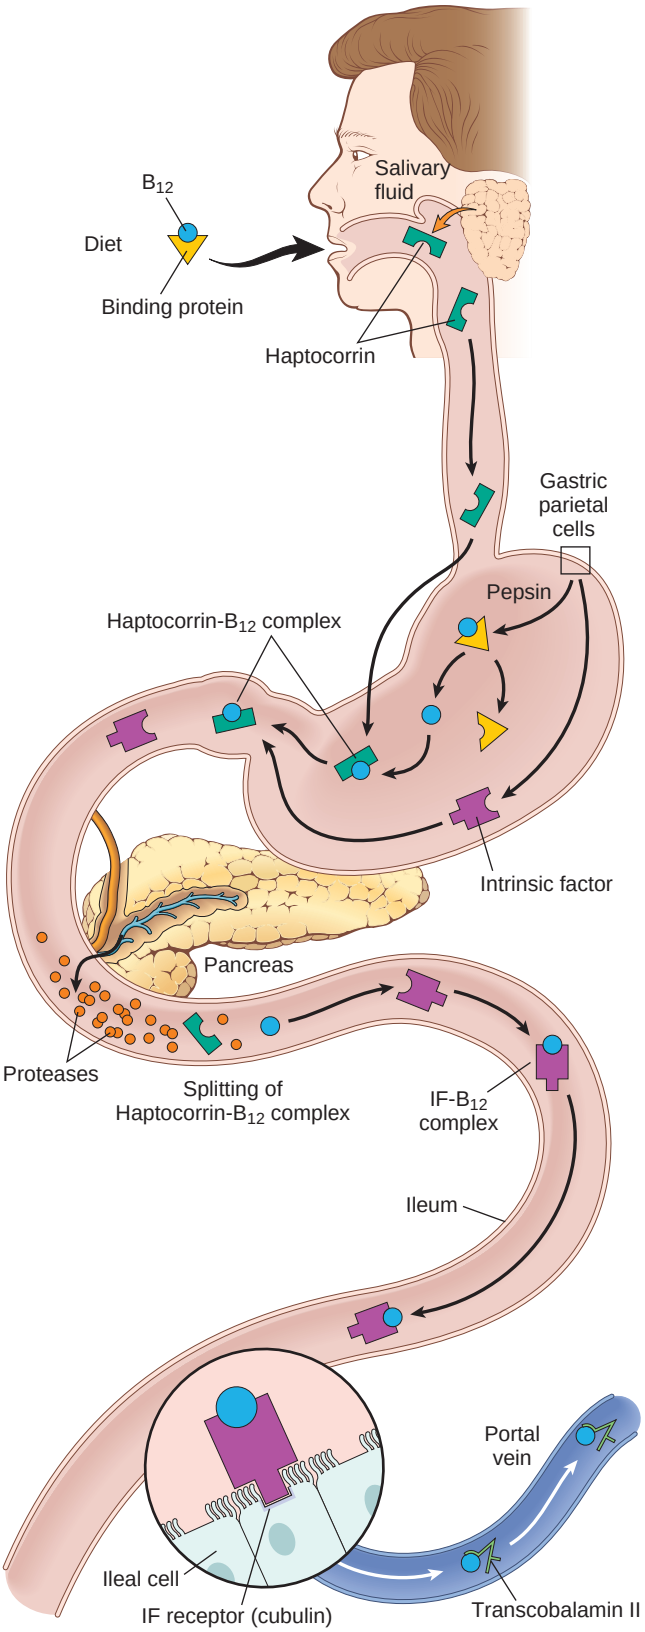

Figure 14.18 Schematic illustration of vitamin B_{12} absorption. *IF,* Intrinsic factor; *haptocorrin, cubilin,* see text.

vitamin B_{12} to the liver and other cells of the body, including rapidly proliferating cells in the bone marrow and the gastrointestinal tract. In addition to this major pathway, oral B_{12} can also be absorbed (albeit inefficiently) by passive diffusion, making it feasible to treat pernicious anemia with high doses of oral vitamin B_{12}.

Biochemical Functions of Vitamin B_{12}. Only two reactions in humans are known to require vitamin B_{12}. In one, methylcobalamin serves as an essential cofactor in the conversion of homocysteine to methionine by methionine synthase (Fig. 14.19). In the process, methylcobalamin yields a methyl group that is recovered from N^5-methyltetrahydrofolic acid (N^5-methyl FH_4), the principal form of folic acid in plasma. In the same reaction, N^5-methyl FH_4 is converted to tetrahydrofolic acid (FH_4). FH_4 is crucial because it is required (through its derivative $N^{5,10}$-methylene FH_4) for the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), a building block for DNA. It is postulated that impaired DNA synthesis in vitamin B_{12} deficiency stems from the reduced availability of FH_4, most of which is "trapped" as N^5-methyl FH_4. The FH_4 deficit may be exacerbated by an "internal" deficiency of metabolically active polyglutamylated forms of FH_4. This stems from a requirement for vitamin B_{12} in the synthesis of methionine, which contributes a carbon group that is needed in the metabolic reactions that create folate polyglutamates (Fig. 14.20). Whatever the mechanism, lack of folate is the proximate cause of anemia in vitamin B_{12} deficiency, as the anemia improves following the administration of folic acid.

The neurologic complications associated with vitamin B_{12} deficiency are more enigmatic, because they are not improved (and may actually be worsened) by folate administration. The other known reaction that depends on vitamin B_{12} is the isomerization of methylmalonyl coenzyme A to succinyl coenzyme A by the enzyme methylmalonyl-coenzyme A mutase, which requires adenosylcobalamin. A deficiency of vitamin B_{12} thus leads to increased plasma and urine levels of methylmalonic acid. Interruption of this reaction and the consequent buildup of methylmalonate and propionate (a precursor) could lead to the formation and incorporation of abnormal fatty acids into neuronal lipids. It has been suggested that this biochemical abnormality predisposes to myelin breakdown, producing subacute combined degeneration of the spinal cord (Chapter 28). However, rare individuals with hereditary deficiencies of methylmalonyl-coenzyme A mutase do not suffer from these abnormalities, casting doubt on this explanation.

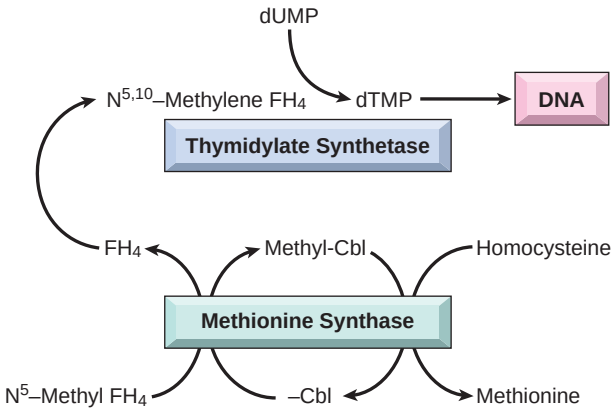

Figure 14.19 Relationship of N^5-methyl FH_4, methionine synthase, and thymidylate synthetase. In cobalamin (Cbl) deficiency, folate is sequestered as N^5-methyl FH_4. This ultimately deprives thymidylate synthetase of its folate coenzyme ($N^{5,10}$-methylene FH_4), thereby impairing DNA synthesis. *dTMP,* Deoxythymidine monophosphate; *dUMP,* deoxyuridine monophosphate; *FH_4,* tetrahydrofolic acid.

Pernicious Anemia

Incidence. Although somewhat more prevalent in Scandinavian and other Caucasian populations, pernicious anemia occurs in all racial groups, including people of African descent and Hispanics. It is a disease of older adults; the median age at diagnosis is 60 years, and it is rare in people younger than 30 years of age. A genetic predisposition is strongly suspected, but no definable genetic pattern of transmission has been discerned. As described later, many affected individuals have a tendency to form antibodies against multiple self antigens.

Pathogenesis

Pernicious anemia is believed to result from an autoimmune attack on the gastric mucosa. Histologically, there is a chronic atrophic gastritis marked by a loss of parietal cells, a prominent infiltrate of lymphocytes and plasma cells, and megaloblastic changes in mucosal cells similar to those found in erythroid precursors. Three types of autoantibodies are present in many, but not all, patients. About 75% of patients have a type I antibody that blocks the binding of vitamin B_{12} to intrinsic factor. Type I antibodies are found in both plasma and gastric juice. Type II antibodies prevent binding of the intrinsic factor–vitamin B_{12} complex and also are present in a large proportion of patients with pernicious anemia. Both type I and type II antibodies are found in plasma and gastric juice. Type III antibodies are present in 85% to 90% of patients and recognize the α and β subunits of the gastric proton pump, a component of the microvilli of the canalicular system of the gastric parietal cell. Type III antibodies are not specific, as they are found in as many as 50% of older adults with idiopathic chronic gastritis.

Autoantibodies are of diagnostic utility, but are not thought to be the primary cause of the gastric pathology; rather, it seems that an autoreactive T-cell response initiates gastric mucosal injury and triggers the formation of autoantibodies. When the mass of intrinsic factor–secreting cells falls below a threshold (and reserves of stored vitamin B_{12} are depleted), anemia develops. Notably, pernicious anemia also is associated with other autoimmune disorders, particularly autoimmune thyroiditis and adrenalitis, suggesting that it arises in individuals with a predisposition to develop autoimmunity.

Vitamin B_{12} deficiency also may arise from causes other than pernicious anemia. Most of these impair absorption of the vitamin at one of the steps outlined earlier (see Table 14.5). With achlorhydria and loss of pepsin secretion (which occurs in some older adults), vitamin B_{12} is not readily released from proteins in food. With gastrectomy, intrinsic factor is lost. With insufficiency of the exocrine pancreas, vitamin B_{12} cannot be released from haptocorrin-vitamin B_{12} complexes. Ileal resection or diffuse ileal disease may prevent adequate absorption of intrinsic factor–vitamin B_{12} complex. Certain tapeworms (particularly those acquired by eating raw fish) compete with the host for B_{12} and can induce a deficiency state. In some settings, such as pregnancy, hyperthyroidism, disseminated cancer, and chronic infection, an increased demand for vitamin B_{12} may produce a relative deficiency, even with normal absorption.

MORPHOLOGY

The findings in the bone marrow and blood in pernicious anemia are similar to those described earlier for other forms of megaloblastic anemia. The stomach typically shows diffuse chronic gastritis (Chapter 17). The most characteristic alteration is **fundic gland atrophy,** affecting both chief cells and parietal cells, the latter being virtually absent. The glandular epithelium is replaced by mucus-secreting goblet cells that resemble those lining the large intestine, a form of metaplasia referred to as **intestinalization.** Some of the affected cells and their nuclei may be twice normal in size, a "megaloblastic" change analogous to that seen in the marrow. With time, the tongue may take on a shiny, glazed, "beefy" appearance **(atrophic glossitis).** Because the gastric atrophy and metaplastic changes are due to autoimmunity, they persist following parenteral administration of vitamin B_{12}, whereas the "megaloblastic" changes in the marrow and gut are readily reversible.

Central nervous system lesions are found in about three-fourths of all cases of florid pernicious anemia but can also be seen in the absence of overt hematologic findings. The principal alterations involve the cord, where there is **demyelination of the dorsal and lateral spinal tracts,** sometimes followed by loss of axons. These changes may give rise to spastic paraparesis, sensory ataxia, and severe paresthesias in the lower limbs. Less frequently, degenerative changes occur in the ganglia of the posterior roots and in peripheral nerves (Chapter 28).

Clinical Features

Pernicious anemia is insidious in onset, and the anemia is often quite severe by the time it comes to medical attention. The course is progressive unless halted by therapy.

The diagnosis is based on (1) a moderate to severe megaloblastic anemia, (2) leukopenia with hypersegmented granulocytes, (3) low serum vitamin B_{12}, and (4) elevated serum levels of homocysteine and methylmalonic acid. Serum antibodies to intrinsic factor are highly specific for pernicious anemia. The diagnosis is confirmed by an outpouring of reticulocytes and a rise in hematocrit levels beginning about 5 days after parenteral administration of vitamin B_{12}.

Persons with atrophy and metaplasia of the gastric mucosa due to pernicious anemia are at increased risk for gastric carcinoma (Chapter 17). With parenteral or high-dose oral vitamin B_{12}, the anemia is cured and the progression of the peripheral neurologic disease can be reversed or at least halted, but the changes in the gastric mucosa and the risk of carcinoma are unaffected.

Anemia of Folate Deficiency

A deficiency of folic acid (more properly, pteroylmonoglutamic acid) results in a megaloblastic anemia having the same pathologic features as that caused by vitamin B_{12} deficiency. FH_4 derivatives act as intermediates in the transfer of one-carbon units such as formyl and methyl groups to various compounds (see Fig. 14.20). FH_4 serves as an acceptor of one-carbon fragments from compounds such as serine and formiminoglutamic acid. The FH_4 derivatives so generated in turn donate the acquired one-carbon fragments in reactions synthesizing various metabolites. FH_4, then, can be viewed as the biologic "middleman" in a series of swaps involving one-carbon moieties. The most important metabolic processes depending on such transfers are (1) purine synthesis; (2) the conversion of homocysteine to methionine, a reaction also requiring vitamin B_{12}; and (3) dTMP synthesis. In the first two reactions, FH_4 is regenerated from its one-carbon carrier derivatives and is available to accept another one-carbon moiety and reenter the donor pool. In the synthesis of dTMP, dihydrofolic acid (FH_2) is produced that must be reduced by dihydrofolate reductase for reentry into the FH_4 pool. The reductase step is significant, because this enzyme is susceptible to inhibition by various drugs. Among the molecules whose synthesis is dependent on folates, dTMP is perhaps the most important biologically, because it is required for DNA synthesis. It should be apparent from this discussion that **suppressed synthesis of DNA, the common denominator of folic acid and vitamin B_{12} deficiency, is the immediate cause of megaloblastosis.**

Etiology

The three major causes of folic acid deficiency are (1) decreased intake, (2) increased requirements, and (3) impaired utilization (see Table 14.5). Humans depend on dietary sources for folic acid. Most normal diets contain ample amounts. The richest sources are green vegetables such as lettuce, spinach, asparagus, and broccoli. Certain fruits (e.g., lemons, bananas, melons) and animal sources (e.g., liver) contain lesser amounts. The folic acid in these foods is largely in the form of folylpolyglutamates. Although abundant in raw foods, polyglutamates are sensitive to heat; boiling, steaming, or frying food for 5 to 10 minutes destroys up to 95% of the folate content. Intestinal conjugases split the polyglutamates into monoglutamates that are absorbed in the proximal jejunum. During intestinal absorption they are modified to 5-methyltetrahydrofolate,

the transport form of folate. The body's reserves of folate are relatively modest, and a deficiency can arise within weeks to months if intake is inadequate.

Decreased intake can result from either a nutritionally inadequate diet or impairment of intestinal absorption. A normal diet contains folate in excess of the minimal daily adult requirement. Inadequate dietary intakes are almost invariably associated with grossly deficient diets, which are most frequently encountered in chronic alcoholics, the indigent, and the very old. In alcoholics with cirrhosis, other mechanisms of folate deficiency such as trapping of folate within the liver, excessive urinary loss, and disordered folate metabolism also have been implicated. Under these circumstances, the megaloblastic anemia is often accompanied by general malnutrition and manifestations of other avitaminoses, including cheilosis, glossitis, and dermatitis. Malabsorption syndromes, such as sprue, may lead to inadequate folate absorption, as may infiltrative diseases of the small intestine (e.g., lymphoma). In addition, certain drugs, particularly the anticonvulsant phenytoin and oral contraceptives, interfere with absorption.

Despite normal intake of folic acid, a relative deficiency can be encountered when requirements are increased. Conditions in which this is seen include pregnancy, infancy, derangements associated with hyperactive hematopoiesis (e.g., chronic hemolytic anemia), and disseminated cancer. In all of these circumstances, the demands of increased DNA synthesis render normal intake inadequate.

Folic acid antagonists, such as methotrexate, inhibit dihydrofolate reductase and lead to a deficiency of FH_4. Inhibition of folate metabolism affects all rapidly proliferating tissues, particularly the bone marrow and the gastrointestinal tract. Many chemotherapeutic drugs used in the treatment of cancer damage DNA or inhibit DNA synthesis through other mechanisms, and these also cause megaloblastic changes in rapidly dividing cells.

As mentioned earlier, the megaloblastic anemia that results from folic acid deficiency is identical to that encountered in vitamin B_{12} deficiency. Thus, the diagnosis of folate deficiency can be made only by demonstration of decreased serum or red cell folate levels. As in vitamin B_{12} deficiency, serum homocysteine levels are increased, but methylmalonate concentrations are normal. Importantly, neurologic changes do not occur.

Although prompt hematologic response heralded by reticulocytosis follows the administration of folic acid, it should be remembered that the hematologic symptoms of vitamin B_{12} deficiency anemia also respond to folate therapy. As mentioned earlier, folate does not prevent (and may even exacerbate) the neurologic deficits seen in vitamin B_{12} deficiency states. It is thus essential to exclude vitamin B_{12} deficiency as the cause of megaloblastic anemia before initiating therapy with folate.

Iron Deficiency Anemia

Deficiency of iron is the most common nutritional disorder in the world and results in clinical signs and symptoms that are mostly related to inadequate hemoglobin synthesis. Although the prevalence of iron deficiency anemia is higher in low income countries, this form of anemia is common in the United States, particularly in toddlers, adolescent girls, and women of childbearing age. The factors underlying iron deficiency differ somewhat in various population groups and can be best considered in the context of normal iron metabolism.

Table 14.6 Iron Distribution in Healthy Young Adults (mg)

Pool	Men	Women
Total	3450	2450
Functional		
Hemoglobin	2100	1750
Myoglobin	300	250
Enzymes	50	50
Storage		
Ferritin, hemosiderin	1000	400

Iron Metabolism. The normal daily Western diet contains about 10 to 20 mg of iron, mostly in the form of heme in animal products, with the remainder being inorganic iron in vegetables. About 20% of heme iron (in contrast with 1% to 2% of nonheme iron) is absorbable, so the average Western diet contains sufficient iron to balance fixed daily losses. The total body iron content is normally about 2.5 g in women and as high as 6 g in men, and it can be divided into functional and storage compartments (Table 14.6). About 80% of the functional iron is found in hemoglobin; the rest is in myoglobin and iron-containing enzymes such as catalase and cytochromes. The storage pool represented by hemosiderin and ferritin contains about 15% to 20% of total body iron. The major sites of storage iron are the liver and mononuclear phagocytes. Healthy young females have smaller iron stores than do males, primarily because of blood loss during menstruation, and often develop iron deficiency due to excessive loss or increased demand associated with menstruation and pregnancy, respectively.

Iron in the body is recycled between the functional and storage pools (Fig. 14.21). It is transported in plasma by an iron-binding protein called *transferrin,* which is synthesized in the liver. In normal individuals, transferrin is about one-third saturated with iron, yielding serum iron levels that average 120 μg/dL in men and 100 μg/dL in women. The major function of plasma transferrin is to deliver iron to cells, including erythroid precursors, which require iron to synthesize hemoglobin. Erythroid precursors possess high-affinity receptors for transferrin that mediate iron import through receptor-mediated endocytosis.

Free iron is highly toxic (Chapter 18), and storage iron must therefore be sequestered. This is achieved by the binding of storage iron to either ferritin or hemosiderin. Ferritin is a ubiquitous protein-iron complex that is found at highest levels in the liver, spleen, bone marrow, and skeletal muscles. In the liver, most ferritin is stored within the parenchymal cells; in other tissues, such as the spleen and the bone marrow, it is found mainly in macrophages. Hepatocyte iron is derived from plasma transferrin, whereas storage iron in macrophages is derived from the breakdown of red cells. Intracellular ferritin is located in the cytosol and in lysosomes, in which partially degraded protein shells of ferritin aggregate into hemosiderin granules. Iron in hemosiderin is chemically reactive and turns blue-black when exposed to potassium ferrocyanide, which is the basis for the *Prussian blue stain*. With normal iron stores, only

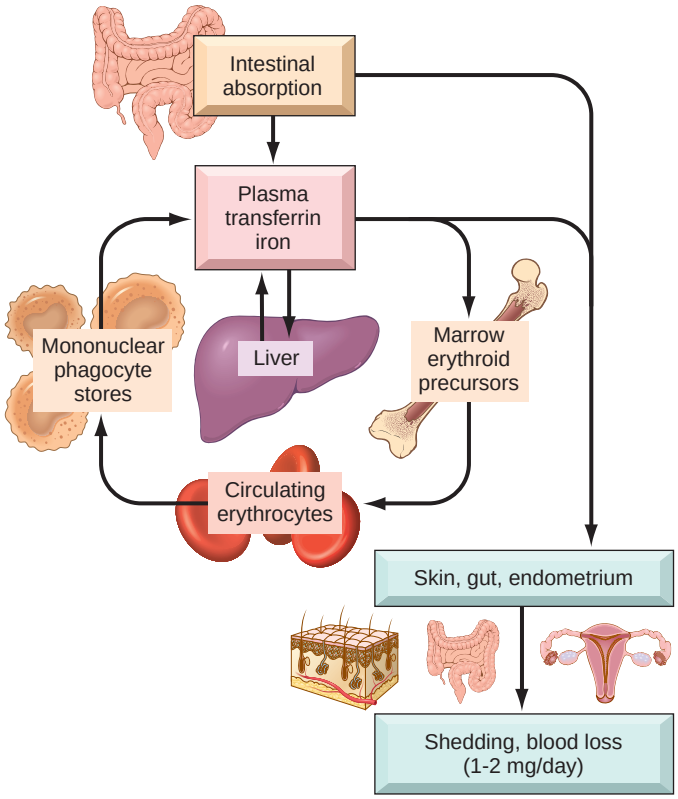

Figure 14.21 Iron metabolism. Iron absorbed from the gut is bound to plasma transferrin and transported to the bone marrow, where it is delivered to developing red cells and incorporated into hemoglobin. Mature red cells are released into the circulation and, after 120 days, are ingested by macrophages, primarily in the spleen, liver, and bone marrow. Here iron is extracted from hemoglobin and recycled to plasma transferrin. At equilibrium, iron absorbed from the gut is balanced by losses in shed keratinocytes, enterocytes, and (in women) endometrium.

trace amounts of hemosiderin are found in the body, principally in macrophages in the bone marrow, spleen, and liver, most being stored as ferritin. In iron-overloaded cells, most iron is stored in hemosiderin.

Because plasma ferritin is derived largely from the storage pool of body iron, its levels correlate with body iron stores. In iron deficiency, serum ferritin is below 12 µg/L, whereas in iron overload values approaching 5000 µg/L may be seen. Of physiologic importance, the storage iron pool can be readily mobilized if iron requirements increase, as may occur after loss of blood.

Because iron is essential for cellular metabolism and highly toxic in excess, total body iron stores must be regulated meticulously. Iron balance is maintained by regulating the absorption of dietary iron in the proximal duodenum. There is no regulated pathway for iron excretion, which is limited to the 1 to 2 mg lost each day through the shedding of mucosal and skin epithelial cells. By contrast, as body iron stores increase, absorption decreases, and vice versa.

The pathways responsible for the absorption of iron from the gut are now understood in reasonable detail (Fig. 14.22) and differ for nonheme and heme iron. Luminal nonheme iron is mostly in the Fe^{3+} (ferric) state and must first be reduced to Fe^{2+} (ferrous) iron by ferrireductases, such as b cytochromes and STEAP3. Fe^{2+} iron is then transported across the apical membrane by divalent metal transporter 1 (DMT1). Heme iron is moved across the apical membrane into the cytoplasm through transporters that are incompletely characterized. Here, it is metabolized to release Fe^{2+} iron, which enters a common pool with nonheme Fe^{2+} iron. The absorption of nonheme iron is variable and often inefficient, being inhibited by substances in the diet that bind and stabilize Fe^{3+} iron and enhanced by substances that stabilize Fe^{2+} iron (described later). Frequently, less than 5% of dietary nonheme iron is absorbed. In contrast, about 20% of the heme iron derived from hemoglobin, myoglobin, and other animal proteins is absorbed.

Once in duodenal cells, Fe^{2+} iron can follow one of two pathways: transport to the blood or storage as mucosal iron. Fe^{2+} iron destined for the circulation is transported from the cytoplasm across the basolateral enterocyte membrane by ferroportin. This process is coupled to the oxidation of Fe^{2+} iron to Fe^{3+} iron, which is carried out by the iron oxidases hephaestin and ceruloplasmin. Newly absorbed Fe^{3+} iron binds rapidly to transferrin, which delivers iron to red cell progenitors in the marrow (see Fig. 14.21). Both DMT1 and ferroportin are widely distributed in the body and are involved in iron transport in other tissues as well. For example, DMT1 mediates the uptake of "functional" iron (derived from endocytosed transferrin) across lysosomal membranes into the cytosol of red cell precursors in the bone marrow, and ferroportin plays an important role in the release of storage iron from macrophages.

Iron absorption in the duodenum is regulated by *hepcidin*, a small circulating peptide that is synthesized and released from the liver in response to increases in intrahepatic iron levels. Hepcidin inhibits iron transfer from the enterocyte to plasma by binding to ferroportin, causing it to be endocytosed and degraded. As a result, as hepcidin levels rise, iron becomes trapped within duodenal cells in the form of mucosal ferritin and is lost as these cells slough. Thus, when the body is replete with iron, high hepcidin levels inhibit its absorption into the blood. Conversely, with low body stores of iron, hepcidin levels fall, facilitating iron absorption. By inhibiting ferroportin, hepcidin not only reduces iron uptake from enterocytes but also suppresses iron release from macrophages, an important source of the iron that is used by erythroid precursors to make hemoglobin.

Alterations in hepcidin have a central role in diseases involving disturbances of iron metabolism. This is illustrated by the following examples.

- As described later in this chapter, the *anemia of chronic inflammation* is caused in part by inflammatory mediators that increase hepatic hepcidin production.
- A rare form of microcytic anemia is caused by mutations that disable TMPRSS6, a hepatic transmembrane serine protease that normally suppresses hepcidin production when iron stores are low. Affected patients have high hepcidin levels, resulting in reduced iron absorption and failure to respond to iron therapy.
- Conversely, hepcidin activity is inappropriately low in both primary and secondary *hemochromatosis*, a syndrome caused by systemic iron overload. As discussed in Chapter 18, the various inherited forms of primary hemochromatosis are associated with mutations in hepcidin or the genes that regulate hepcidin expression. Secondary hemochromatosis can occur in diseases associated

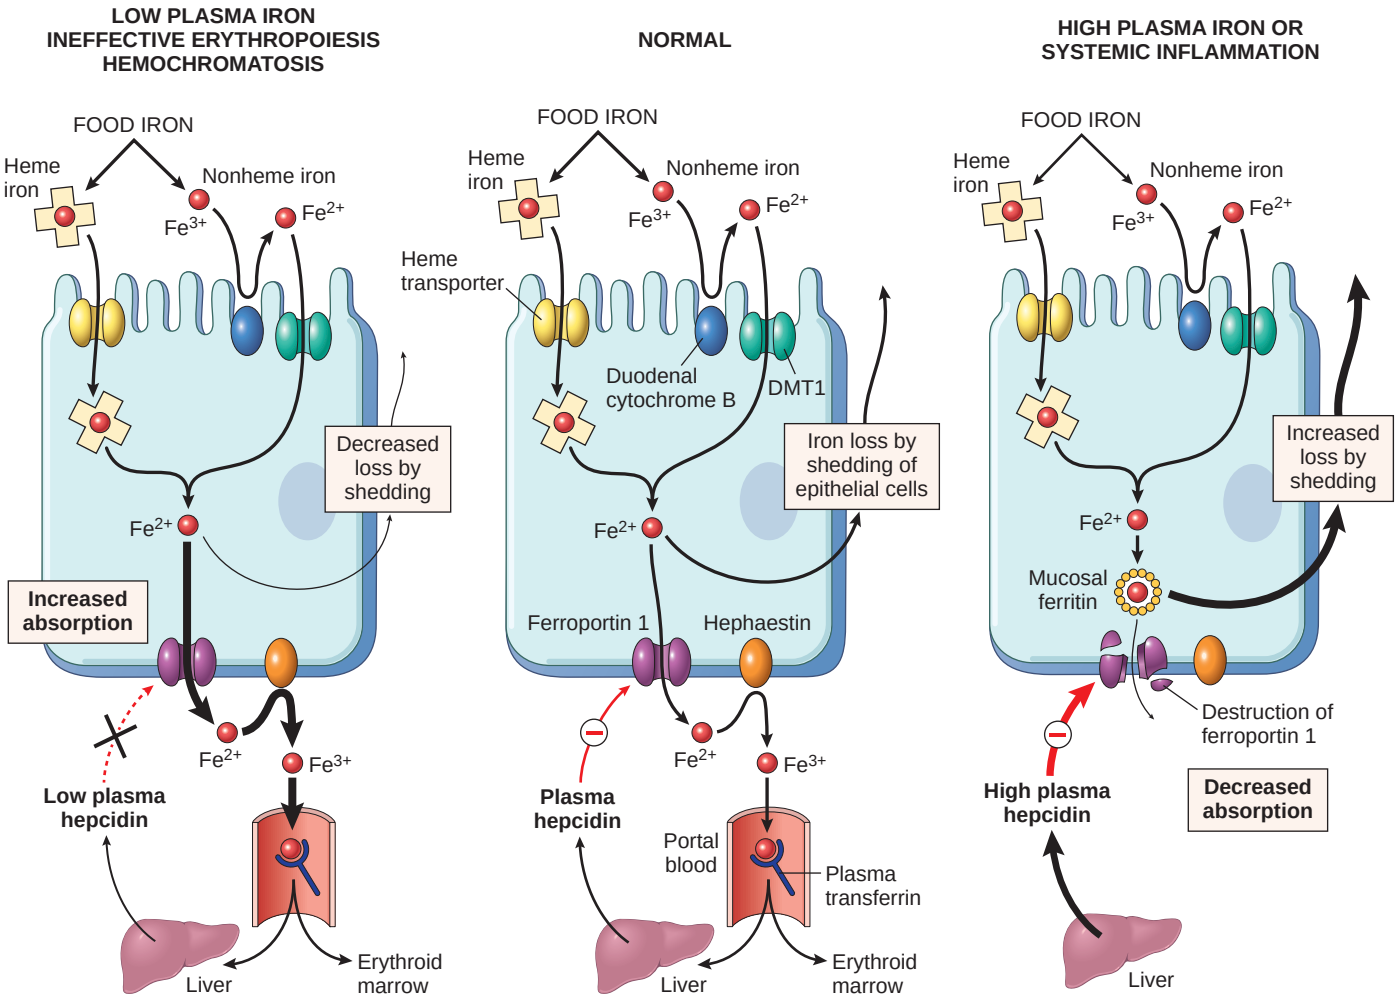

Figure 14.22 Regulation of iron absorption. Duodenal epithelial cell uptake of heme and nonheme iron is described in the text. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin balances iron uptake and loss to and maintains iron homeostasis by downregulating ferroportin and limiting iron uptake *(middle panel)*. Hepcidin rises in the setting of systemic inflammation or when liver iron levels are high, decreasing iron uptake and increasing iron loss during the shedding of duodenocytes *(right panel)*. Conversely, hepcidin levels fall in the setting of low plasma iron, primary hemochromatosis, or ineffective hematopoiesis *(left panel)*, leading to a rise in iron absorption. *DMT1*, Divalent metal transporter 1.

with ineffective erythropoiesis, such as β-thalassemia major (discussed earlier) and myelodysplastic syndrome (Chapter 13), due to expansion of erythroid progenitors and release of increased amounts of erythroferrone, which inhibits hepatic hepcidin production.

Etiology. Iron deficiency can result from (1) dietary lack, (2) impaired absorption, (3) increased requirement, or (4) chronic blood loss. To maintain a normal iron balance, about 1 mg of iron must be absorbed from the diet every day. Because only 10% to 15% of ingested iron is absorbed, the daily iron requirement is 7 to 10 mg for adult men and 7 to 20 mg for adult women. Because the average daily dietary intake of iron in the Western world is about 15 to 20 mg, most men ingest more than adequate iron, whereas many women consume marginal amounts of iron. The bioavailability of dietary iron is as important as the overall content. The absorption of inorganic iron is influenced by other dietary contents. It is enhanced by ascorbic acid, citric acid, amino acids, and sugars in the diet, and it is inhibited by tannates (found in tea), carbonates, oxalates, and phosphates.

Dietary lack is rare in high income countries, where on average about two-thirds of the dietary iron is in the form of heme, mainly in meat. The situation is different in low income countries, where food is less abundant and most dietary iron is found in plants in the poorly absorbable inorganic form. Dietary iron inadequacy occurs in even high income societies in the following groups:

- *Infants,* who are at high risk due to the very small amounts of iron in milk. Human breast milk provides only about 0.3 mg/L of iron. Cow's milk contains about twice as much iron, but its bioavailability is poor.
- *The impoverished*, who can have suboptimal diets for socioeconomic reasons at any age
- *Older adults*, who often have restricted diets with little meat because of limited income or poor dentition
- *Teenagers* who subsist on "junk" food

Impaired absorption is found in sprue, other causes of fat malabsorption (steatorrhea), and chronic diarrhea. Gastrectomy diminishes iron absorption by decreasing the acidity of the proximal duodenum (acidity enhances

uptake) and by increasing the speed with which gut contents pass through the duodenum. Specific items in the diet, as is evident from the preceding discussion, can also affect absorption.

Increased requirement is an important cause of iron deficiency in growing infants, children, and adolescents, as well as premenopausal women, particularly during pregnancy. Economically deprived women having multiple, closely spaced pregnancies are at exceptionally high risk.

Chronic blood loss is the most common cause of iron deficiency in high income societies. External hemorrhage or bleeding into the gastrointestinal, urinary, or genital tracts depletes iron reserves. Iron deficiency in adult men and postmenopausal women in high income countries must be attributed to gastrointestinal blood loss until proven otherwise. To prematurely ascribe iron deficiency in such individuals to any other cause is to run the risk of missing a gastrointestinal cancer or other bleeding lesion. An alert clinician investigating unexplained iron deficiency anemia occasionally discovers an occult bleeding source such as a cancer and thereby saves a life.

Pathogenesis

Whatever its basis, iron deficiency leads to inadequate hemoglobin production and hypochromic microcytic anemia. At the outset of chronic blood loss or other states of negative iron balance, reserves in the form of ferritin and hemosiderin may be adequate to maintain normal hemoglobin and hematocrit levels as well as normal serum iron and transferrin saturation. Progressive depletion of these reserves first lowers serum iron and transferrin saturation levels without producing anemia. In this early stage, there is increased erythroid activity in the bone marrow. Anemia appears only when iron stores are completely depleted and is accompanied by lower than normal serum iron, ferritin, and transferrin saturation levels.

MORPHOLOGY

The bone marrow reveals a mild to moderate increase in erythroid progenitors. A diagnostically significant finding is the **absence of stainable iron in macrophages,** which is best assessed by performing Prussian blue stains on smears of aspirated marrow. In peripheral blood smears, the red cells are small **(microcytic)** and pale **(hypochromic).** Normal red cells with sufficient hemoglobin have a zone of central pallor measuring about one third of the cell diameter. In established iron deficiency, the zone of pallor is enlarged; hemoglobin may be seen only in a narrow peripheral rim (Fig. 14.23). Poikilocytosis in the form of small, elongated red cells (pencil cells) also is characteristically seen.

Clinical Features

The clinical manifestations of the anemia are nonspecific and were detailed earlier. The dominating signs and symptoms frequently relate to the underlying cause, for example, gastrointestinal or gynecologic disease, malnutrition, pregnancy, or malabsorption. In severe long-standing iron deficiency, depletion of iron-containing enzymes in cells throughout the body also causes other changes, including koilonychia, alopecia, atrophic changes in the tongue and gastric mucosa, and intestinal malabsorption. Depletion of iron from the central nervous system may lead to the appearance of pica, in which affected individuals have a craving for non-foodstuffs such as clay or food ingredients such as flour, and periodically move their limbs during sleep. Pica is also seen in association with developmental disorders such as autism (in the absence of iron deficiency). Esophageal webs may appear together with microcytic hypochromic anemia and atrophic glossitis to complete the triad of findings in the rare *Plummer-Vinson syndrome* (Chapter 17).

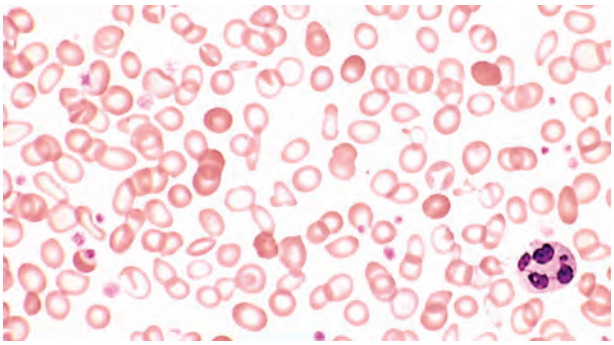

Figure 14.23 Iron deficiency (peripheral blood smear). Note the hypochromic microcytic red cells containing a narrow rim of peripheral hemoglobin. Scattered fully hemoglobinized cells, present due to recent blood transfusion, stand in contrast. (Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

The diagnosis of iron deficiency anemia ultimately rests on laboratory studies. Both the hemoglobin and hematocrit are depressed, usually to a moderate degree, in association with hypochromia, microcytosis, and modest poikilocytosis. The serum iron and ferritin are low, and the total plasma iron-binding capacity (reflecting elevated transferrin levels) is high. Low serum iron with increased iron-binding capacity results in a reduction of transferrin saturation to below 15%. Reduced iron stores inhibit hepcidin synthesis, and its serum levels fall. In uncomplicated cases, oral iron supplementation produces an increase in reticulocytes in about 5 to 7 days that is followed by a steady increase in blood counts and the normalization of red cell indices.

Anemia of Chronic Inflammation

Impaired red cell production associated with chronic diseases that produce systemic inflammation is a common cause of anemia in hospitalized patients. This form of anemia stems from a reduction in the proliferation of erythroid progenitors and impaired iron utilization. The chronic illnesses associated with this form of anemia can be grouped into three categories:

- *Chronic microbial infections,* such as osteomyelitis, bacterial endocarditis, and lung abscess
- *Chronic immune disorders,* such as rheumatoid arthritis and inflammatory bowel disease
- *Neoplasms,* such as carcinomas of the lung and breast, and Hodgkin lymphoma

The anemia of chronic inflammation is associated with low serum iron, reduced total iron-binding capacity, and abundant stored iron in tissue macrophages. Several effects

of inflammation contribute to the observed abnormalities. Most notably, certain inflammatory mediators, particularly interleukin-6 (IL-6), stimulate an increase in the hepatic production of hepcidin. As discussed earlier, hepcidin inhibits ferroportin function in macrophages and reduces the transfer of iron from the storage pool to developing erythroid precursors in the bone marrow. As a result, the erythroid precursors are starved for iron in the midst of plenty. In addition, these progenitors do not proliferate adequately because erythropoietin levels are inappropriately low for the degree of anemia. The precise mechanism underlying the reduction in erythropoietin is uncertain; direct suppression of renal erthropoietin production by inflammatory cytokines is suspected.

What might be the reason for iron sequestration in the setting of inflammation? The best guess is that it enhances the body's ability to fend off certain infections, particularly those caused by bacteria (e.g., *H. influenzae*) that require iron for pathogenicity. In this regard it is interesting to consider that hepcidin is structurally related to defensins, a family of peptides that have intrinsic antibacterial activity. This connection highlights the poorly understood but intriguing relationship between inflammation, innate immunity, and iron metabolism.

The anemia is usually mild, and the dominant symptoms are those of the underlying disease. The red cells can be normocytic and normochromic, or hypochromic and microcytic, as in anemia of iron deficiency. The presence of increased storage iron in marrow macrophages, a high serum ferritin level, and a reduced total iron-binding capacity readily rule out iron deficiency as the cause of anemia. Only successful treatment of the underlying condition reliably corrects the anemia, but some patients, particularly those with cancer, benefit from administration of erythropoietin.

Aplastic Anemia

Aplastic anemia refers to a syndrome of chronic primary hematopoietic failure and attendant pancytopenia (anemia, neutropenia, and thrombocytopenia). In the majority of patients, autoimmune mechanisms are suspected, but inherited or acquired abnormalities of hematopoietic stem cells also contribute in a subset of patients.

Etiology. The most common circumstances associated with aplastic anemia are listed in Table 14.7. Most cases of "known" etiology follow exposure to chemicals and drugs. Some of the associated agents (including many cancer chemotherapy drugs and the organic solvent benzene) cause marrow suppression that is dose related and reversible. In other instances, aplastic anemia arises in an unpredictable, idiosyncratic fashion following exposure to drugs that normally cause little or no marrow suppression. The implicated drugs in these idiosyncratic reactions include chloramphenicol and gold salts.

Persistent marrow aplasia can also appear after a variety of viral infections, most commonly viral hepatitis, which is associated with approximately 5% of cases. Why aplastic anemia develops in certain individuals is not understood.

Whole-body irradiation can destroy hematopoietic stem cells in a dose-dependent fashion. Persons who receive therapeutic irradiation or are exposed to radiation in nuclear accidents (e.g., Chernobyl) are at risk for marrow aplasia.

Table 14.7 Major Causes of Aplastic Anemia

Physical Agents
Whole-body irradiation
Viral infections
Hepatitis (unknown virus)
Cytomegalovirus infections
Epstein-Barr virus infections
Herpes zoster (varicella zoster)
Inherited
Fanconi anemia
Telomerase defects

Specific abnormalities underlying some cases of aplastic aplasia are as follows.

- *Fanconi anemia* is a rare autosomal recessive disorder caused by defects in a multiprotein complex that is required for DNA repair (Chapter 7). Marrow hypofunction becomes evident early in life and is often accompanied by multiple congenital anomalies, such as hypoplasia of the kidney and spleen, and bone anomalies, commonly involving the thumbs or radii.
- Inherited defects in *telomerase* are found in 5% to 10% of adult-onset aplastic anemia. Telomerase is required for cellular immortality and limitless replication (Chapters 1 and 7). It might be anticipated, therefore, that deficits in telomerase activity could result in premature hematopoietic stem cell exhaustion and marrow aplasia.
- Even more common than telomerase mutations are abnormally short telomeres, which are found in the marrow cells of as many as one-half of those affected with aplastic anemia. It is unknown whether this shortening is due to other unappreciated telomerase defects or is a consequence of excessive stem cell replication.

In most instances, however, no initiating factor can be identified; about 65% of cases fall into this idiopathic category.

Pathogenesis

The pathogenesis of aplastic anemia is not fully understood. Indeed, it is unlikely that a single mechanism underlies all cases. However, two major etiologies have been invoked:

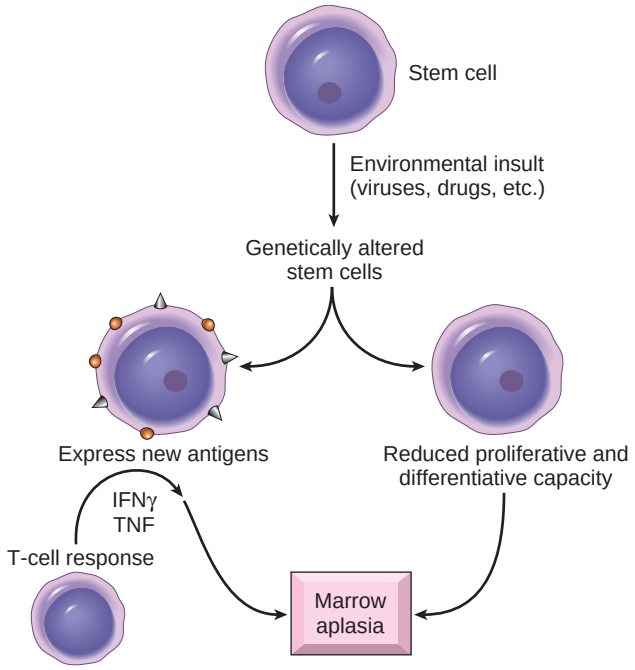

Figure 14.24 Pathophysiology of aplastic anemia. Damaged stem cells can produce progeny expressing neoantigens that evoke an autoimmune reaction, or give rise to a clonal population with reduced proliferative capacity. Either pathway could lead to marrow aplasia. See text for abbreviations.

an extrinsic, immune-mediated suppression of marrow progenitors, and an intrinsic abnormality of stem cells (Fig. 14.24).

Experimental studies have focused on a model in which activated T cells suppress hematopoietic stem cells. Stem cells may first be antigenically altered by exposure to drugs, infectious agents, or other unidentified environmental insults. This provokes a cellular immune response, during which activated Th1 cells produce cytokines such as interferon-γ (IFN-γ) and TNF that suppress and kill hematopoietic progenitors. This scenario is supported by several observations.

- Analysis of the few remaining marrow stem cells from aplastic anemia marrows has revealed that genes involved in apoptosis and death pathways are up-regulated; of note, the same genes are up-regulated in normal stem cells exposed to interferon-γ.
- Even more compelling (and clinically relevant) evidence comes from experience with immunosuppressive therapy. Antithymocyte globulin and other immunosuppressive drugs such as cyclosporine produce responses in 60% to 70% of patients. It is proposed that these therapies work by suppressing or killing autoreactive T-cell clones. The antigens recognized by the autoreactive T cells are not well defined. In some instances GPI-linked proteins may be the targets, possibly explaining the previously noted association of aplastic anemia and PNH.

Alternatively, the notion that aplastic anemia results from a fundamental stem cell abnormality is supported by the presence of karyotypic aberrations and acquired mutations involving cancer genes in many cases; the occasional transformation of aplasias into myeloid neoplasms, typically myelodysplastic syndrome or acute myeloid leukemia; and the association with abnormally short telomeres. Some marrow insult (or a predisposition to DNA damage) presumably results in sufficient injury to limit the proliferative and differentiation capacity of stem cells. If the damage is extensive enough, aplastic anemia results. These two mechanisms are not mutually exclusive, because genetically altered stem cells might also express "neoantigens" that could serve as targets for a T-cell attack.

MORPHOLOGY

The markedly hypocellular bone marrow is largely devoid of hematopoietic cells; often only fat cells, fibrous stroma, and scattered lymphocytes and plasma cells remain. Marrow aspirates often yield little material (a "dry tap"); hence, aplasia is best appreciated in marrow biopsies (Fig. 14.25). Other nonspecific pathologic changes are related to granulocytopenia and thrombocytopenia, such as mucocutaneous bacterial infections and abnormal bleeding, respectively. If the anemia necessitates multiple transfusions, systemic hemosiderosis can appear.

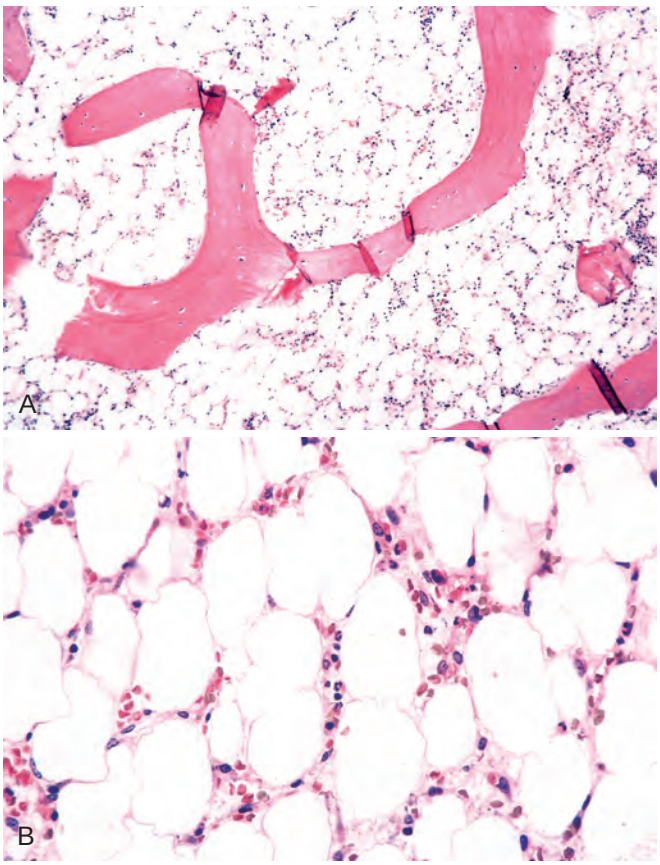

Figure 14.25 Aplastic anemia (bone marrow biopsy). Markedly hypocellular marrow contains mainly fat cells. (A) Low power. (B) High power. (Courtesy Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

Clinical Features

Aplastic anemia can occur at any age and in either sex. The onset is usually insidious. Initial manifestations vary depending on which cell line is predominantly affected, but pancytopenia ultimately appears, with the expected consequences. Anemia leads to progressive weakness, pallor, and dyspnea; thrombocytopenia is heralded by petechiae and ecchymoses; and neutropenia manifests as frequent and persistent infections or the sudden onset of chills, fever, and prostration. Splenomegaly is characteristically absent; if present, the diagnosis of aplastic anemia should be seriously questioned. The red cells are usually slightly macrocytic and normochromic. Reticulocytopenia is the rule.

The diagnosis rests on examination of a bone marrow biopsy. It is important to distinguish aplastic anemia from other causes of pancytopenia, such as "aleukemic" leukemia and myelodysplastic syndrome (Chapter 13), which can have identical clinical manifestations. In aplastic anemia, the marrow is hypocellular (usually markedly so), whereas myeloid neoplasms are usually associated with hypercellular marrows filled with neoplastic progenitors.

The prognosis is variable. Stem cell transplantation is the treatment of choice in those with a suitable donor and provides a 5-year survival of more than 75%. Older patients or those without suitable donors often respond well to immunosuppressive therapy.

Pure Red Cell Aplasia

Pure red cell aplasia is a primary marrow disorder in which only erythroid progenitors are suppressed. In severe cases, red cell progenitors are completely absent from the marrow. It may occur in association with neoplasms, particularly thymoma and large granular lymphocytic leukemia (Chapter 13), drug exposures, autoimmune disorders, and parvovirus infection (see later). With the exception of those with parvovirus infection, it is likely that most cases have an autoimmune basis. When a thymoma is present, resection leads to hematologic improvement in about one-half of the patients. In patients without thymoma, immunosuppressive therapy is often beneficial. Plasmapheresis also may be helpful in unusual patients with neutralizing antibodies to erythropoietin, which may appear de novo or following the administration of recombinant erythropoietin.

A special form of red cell aplasia occurs in individuals infected with parvovirus B19, which preferentially infects and destroys red cell progenitors. Normal individuals clear parvovirus infections within 1 to 2 weeks; as a result, the aplasia is transient and clinically unimportant. However, as mentioned earlier, in persons with moderate to severe hemolytic anemias, even a brief cessation of erythropoiesis results in rapid worsening of the anemia, producing an aplastic crisis. In those who are severely immunosuppressed (e.g., persons with advanced HIV infection), an ineffective immune response sometimes permits the infection to persist, leading to chronic red cell aplasia and a moderate to severe anemia.

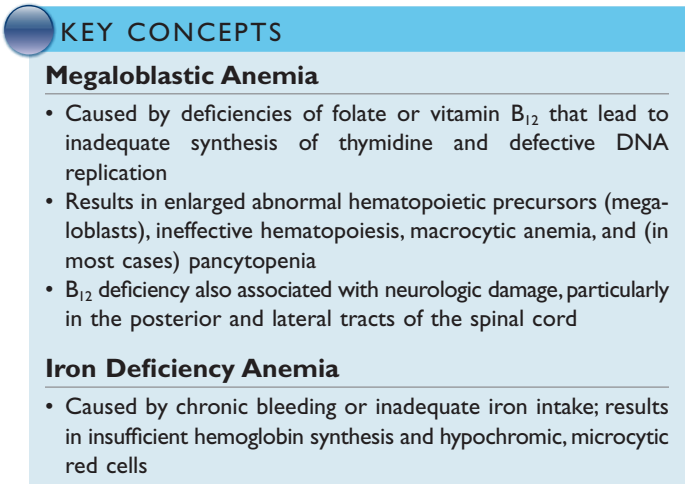
Other Forms of Marrow Failure

Myelophthisic anemia **describes a form of marrow failure in which space-occupying lesions replace normal marrow elements.** The most common cause is metastatic cancer, most often carcinoma arising in the breast, lung, and prostate. However, any infiltrative process (e.g., granulomatous disease) involving the marrow can produce identical findings. Myelophthisic anemia also is a feature of the spent phase of myeloproliferative neoplasms (Chapter 13). All of the responsible diseases cause marrow distortion and fibrosis, which displace normal marrow elements and disturb mechanisms that regulate the egress of red cells and granulocytes from the marrow. The latter effect causes the premature release of nucleated erythroid precursors and immature granulocytic forms *(leukoerythroblastosis)* into the circulation and the appearance of *teardrop-shaped red cells,* which are believed to be deformed during their tortuous escape from the fibrotic marrow.

Chronic renal failure, whatever its cause, is almost invariably associated with an anemia that tends to be roughly proportional to the severity of the uremia. The basis of anemia in renal failure is multifactorial, but the dominant cause is the diminished synthesis of erythropoietin by the damaged kidneys, leading to inadequate red cell production. Uremia also reduces red cell lifespan and impairs platelet function (both through uncertain mechanisms), and these effects may also contribute to anemia through extravascular hemolysis, abnormal bleeding, and eventually iron deficiency. Administration of recombinant erythropoietin and iron replacement therapy significantly improves the anemia.

Hepatocellular disease, whether toxic, infectious, or cirrhotic, is associated with anemia attributed to decreased marrow function. Folate and iron deficiencies caused by poor nutrition and excessive bleeding often exacerbate anemia in this setting. Erythroid progenitors are preferentially affected; depression of the white cell and platelet counts also occurs, but less frequently. The anemia is often slightly macrocytic due to lipid abnormalities associated with liver failure, which cause red cell membranes to acquire phospholipid and cholesterol as they circulate in the peripheral blood, thereby increasing cell size.

Endocrine disorders, particularly hypothyroidism, also may be associated with a mild normochromic, normocytic anemia.



Anemia of Chronic Inflammation

- Caused by inflammatory cytokines, which increase hepcidin levels, thereby reducing iron absorption and sequestering iron in macrophages, and also suppress erythropoietin production

Aplastic Anemia

- Caused by bone marrow failure (hypocellularity) due to diverse causes, including exposures to toxins and radiation, idiosyncratic reactions to drugs and viruses, and inherited defects in telomerase and DNA repair

Pure Red Cell Aplasia

- Acute: Parvovirus B19 infection
- Chronic: Associated with thymoma, large granular lymphocytic leukemia, presence of neutralizing antibodies against erythropoietin, and other autoimmune phenomenon

Other Causes of Underproduction Anemias

- Marrow replacement (tumors, granulomatous disease; so-called myelophthisic anemias), renal failure, endocrine disorders, liver failure

POLYCYTHEMIA

Polycythemia denotes an abnormally high number of circulating red cells, usually with a corresponding increase in the hemoglobin level. It may be relative (when there is hemoconcentration due to decreased plasma volume) or absolute (when there is an increase in the total red cell mass). Relative polycythemia results from dehydration, such as occurs with deprivation of water, prolonged vomiting or diarrhea, or excessive use of diuretics. It also is associated with a condition of unknown etiology called stress polycythemia, or *Gaisböck syndrome*. Affected individuals are usually males who are hypertensive, obese, and anxious ("stressed"). Absolute polycythemia is *primary* when it results from an intrinsic abnormality of hematopoietic precursors and *secondary* when it stems from the response of red cell progenitors to elevated levels of erythropoietin. A pathophysiologic classification of polycythemia divided along these lines is given in Table 14.8.

The most common cause of primary polycythemia is *polycythemia vera,* a myeloproliferative neoplasm associated with mutations that lead to erythropoietin-independent growth of red cell progenitors (Chapter 13). Much less commonly, primary polycythemia results from familial erythropoietin receptor mutations that induce erythropoietin-independent receptor activation. One such individual won Olympic gold medals in cross-country skiing, having benefited from this natural form of blood doping! Secondary polycythemia stems from compensatory or pathologic increases in erythropoietin secretion. Causes of the latter include erythropoietin-secreting tumors and rare (but illustrative) inherited defects in various components of the renal oxygen-sensing pathway. These defects stabilize HIF-1α, a transcription factor that stimulates the transcription of the erythropoietin gene.

Table 14.8 Pathophysiologic Classification of Polycythemia

BLEEDING DISORDERS: HEMORRHAGIC DIATHESES

Excessive bleeding can result from (1) increased fragility of vessels, (2) platelet deficiency or dysfunction, and (3) derangement of coagulation, alone or in combination. Before discussing specific bleeding disorders, it is helpful to review the common laboratory tests used in the evaluation of a bleeding diathesis. The normal hemostatic response involves the blood vessel wall, the platelets, and the clotting cascade (Chapter 4). The following tests are used to evaluate different aspects of hemostasis:

- *Prothrombin time (PT).* This test assesses the extrinsic and common coagulation pathways. The clotting of plasma after addition of an exogenous source of tissue thromboplastin (e.g., brain extract) and Ca^{2+} ions is measured in seconds. A prolonged PT can result from deficiency or dysfunction of factor V, factor VII, factor X, prothrombin, or fibrinogen.
- *Partial thromboplastin time (PTT).* This test assesses the intrinsic and common clotting pathways. The clotting of plasma after addition of kaolin, cephalin, and Ca^{2+} ions is measured in seconds. Kaolin activates the contact-dependent factor XII and cephalin substitutes for platelet phospholipids. Prolongation of the PTT can be due to deficiency or dysfunction of factors V, VIII, IX, X, XI, or XII, prothrombin, or fibrinogen, or to interfering antiphospholipid antibodies (Chapter 4).
- *Platelet counts.* These are obtained on anticoagulated blood using an electronic particle counter. The reference range is 150×10^3 to 350×10^3 platelets/μL. Abnormal platelet counts should be confirmed by inspection of a peripheral blood smear, as clumping of platelets during automated counting can cause spurious "thrombocytopenia." High counts may be indicative of a myeloproliferative neoplasm, such as essential thrombocythemia (Chapter 13), but are more likely to reflect reactive processes that increase platelet production (e.g., systemic inflammation).

- *Tests of platelet function.* At present, no single test provides an adequate assessment of the complex functions of platelets. Specialized tests that can be useful in particular clinical settings include tests of platelet aggregation, which measure the ability of platelets to adhere to one another in response to agonists like thrombin; and quantitative and qualitative tests of von Willebrand factor, which plays an important role in platelet adhesion to the extracellular matrix (Chapter 4). An older test, the bleeding time, is time-consuming and difficult to standardize and has been largely discarded. Instrument-based assays that provide quantitative measures of platelet function are used in some centers but remain imperfect at predicting bleeding risk, presumably because of difficulties in simulating in vivo clotting in the laboratory.

More specialized tests are available to measure the levels of specific clotting factors, fibrinogen, fibrin split products, and the presence of circulating anticoagulants.

Bleeding Disorders Caused by Vessel Wall Abnormalities

Disorders in this category are relatively common but do not usually cause serious bleeding problems. Most often, they present with small hemorrhages (petechiae and purpura) in the skin or mucous membranes, particularly the gingivae. On occasion, more significant hemorrhages occur into joints, muscles, and subperiosteal locations, or take the form of menorrhagia, nosebleeds, gastrointestinal bleeding, or hematuria. The platelet count and tests of coagulation (PT, PTT) are usually normal, pointing by exclusion to the underlying problem.

The clinical conditions in which vessel wall abnormalities cause bleeding include the following:

- *Infections* often induce petechial and purpuric hemorrhages, particularly meningococcemia, other forms of septicemia, infective endocarditis, and several of the rickettsioses. The involved mechanisms include microbial damage to the microvasculature (vasculitis) and disseminated intravscular coagulation.
- *Drug reactions* sometimes take the form of cutaneous petechiae and purpura without causing thrombocytopenia. In many instances the vascular injury is mediated by the deposition of drug-induced immune complexes in vessel walls, leading to hypersensitivity *(leukocytoclastic)* vasculitis (Chapter 11).
- *Scurvy* and the *Ehlers-Danlos syndrome* are associated with microvascular bleeding due to collagen defects that weaken vessel walls. Acquired vascular fragility accounts for the spontaneous purpura that are commonly seen in older adults and the skin hemorrhages that are seen with *Cushing syndrome,* in which the protein-wasting effects of excessive corticosteroid production cause loss of perivascular extracellular matrix.
- *Henoch-Schönlein purpura* is a systemic immune disorder characterized by purpura, colicky abdominal pain, polyarthralgia, and acute glomerulonephritis (Chapter 20). These changes result from the deposition of circulating immune complexes within vessels throughout the body and within the glomerular mesangial regions.
- *Hereditary hemorrhagic telangiectasia* (also known as *Weber-Osler-Rendu syndrome*) is an autosomal dominant disorder that can be caused by mutations in at least five different genes, most of which modulate TGF-β signaling. It is characterized by dilated, tortuous blood vessels with thin walls that bleed readily. Bleeding can occur anywhere, but it is most common under the mucous membranes of the nose (epistaxis), tongue, mouth, and eyes, and throughout the gastrointestinal tract.
- *Perivascular amyloidosis* can weaken blood vessel walls and cause bleeding. This complication is most common with amyloid light-chain (AL) amyloidosis (Chapter 6) and often manifests as mucocutaneous petechiae.

Among these conditions, serious bleeding is most often associated with hereditary hemorrhagic telangiectasia. The bleeding in each is nonspecific, and the diagnosis is based on the recognition of other more specific associated findings.

Bleeding Related to Reduced Platelet Number: Thrombocytopenia

Reduction in platelet number (thrombocytopenia) constitutes an important cause of generalized bleeding. A count less than 150,000 platelets/μL is generally considered to constitute thrombocytopenia. Platelet counts in the range of 20,000 to 50,000 platelets/μL can aggravate posttraumatic bleeding, and platelet counts less than 20,000 platelets/μL may be associated with spontaneous (nontraumatic) bleeding. When thrombocytopenia is isolated, the PT and PTT are normal.

You will recall that following a vascular injury, platelets adhere and aggregate to form the primary hemostatic plug and also promote key reactions in the coagulation cascade that lead to secondary hemostasis and formation of a fibrin clot (Chapter 4). Spontaneous bleeding associated with thrombocytopenia most often involves small vessels. Common sites for such hemorrhages are the skin and the mucous membranes of the gastrointestinal and genitourinary tracts. Most feared, however, is intracranial bleeding, which is a threat to any patient with a markedly depressed platelet count.

The causes of thrombocytopenia fall into four major categories (Table 14.9).

- *Decreased platelet production.* This can result from conditions that depress marrow output generally (such as aplastic anemia and leukemia) or affect megakaryocytes selectively. Examples of the latter include certain drugs and alcohol, which may suppress platelet production through uncertain mechanisms when taken in large amounts; HIV, which may infect megakaryocytes and inhibit platelet production; and myelodysplastic syndrome (Chapter 13), which occasionally presents with isolated thrombocytopenia.
- *Decreased platelet survival.* This important mechanism of thrombocytopenia may have an immunologic or nonimmunologic basis. In immune thrombocytopenia, destruction is caused by the deposition of antibodies or immune complexes on platelets. Autoimmune thrombocytopenia is discussed in the following section. Alloimmune thrombocytopenia can arise when platelets are transfused or when platelets cross the placenta from the fetus into the pregnant mother. In the latter case, IgG antibodies

Table 14.9 Causes of Thrombocytopenia

Decreased Production of Platelets
Selective impairment of platelet production
Drug-induced: alcohol, thiazides, cytotoxic drugs
Infections: measles, human immunodeficiency virus (HIV)
Nutritional deficiencies
B_{12}, folate deficiency (megaloblastic leukemia)
Aplastic anemia (see Table 14.7)
Bone marrow replacement
Leukemia, disseminated cancer, granulomatous disease
Ineffective hematopoiesis
Myelodysplastic syndromes (Chapter 13)
Decreased Platelet Survival
Immunologic destruction
Chromic immune thrombocytopenic purpura
Acute immune thrombocytopenic purpura
Systemic lupus erythematosus, B-cell lymphoid neoplasms
Alloimmune: posttransfusion and neonatal
Drug-associated: quinidine, heparin, sulfa compounds
Infections: HIV, infectious mononucleosis (transient, mild), dengue fever
Nonimmunologic destruction
Disseminated intravascular coagulation
Thrombotic microangiopathies
Giant hemangiomas
Sequestration
Hypersplenism
Dilution
Transfusions

made in the mother may cause clinically significant thrombocytopenia in the fetus. This is reminiscent of hemolytic disease of the newborn, in which red cells are the target (Chapter 10). The most important nonimmunologic causes are *disseminated intravascular coagulation (DIC)* and the *thrombotic microangiopathies,* in which unbridled, often systemic, platelet activation reduces platelet life span. Nonimmunologic destruction of platelets may also be caused by mechanical injury, such as in individuals with prosthetic heart valves.

- *Sequestration.* The spleen normally sequesters 30% to 35% of the body's platelets, but this can rise to 80% to 90% when the spleen is enlarged, producing moderate degrees of thrombocytopenia.
- *Dilution.* Massive transfusions can produce dilutional thrombocytopenia.

Chronic Immune Thrombocytopenic Purpura

Chronic immune thrombocytopenic purpura (ITP) is caused by autoantibody-mediated destruction of platelets. It can occur in the setting of a variety of predisposing conditions and exposures (secondary) or in the absence of any known risk factors (primary or idiopathic). The contexts in which chronic ITP occurs secondarily are numerous and include individuals with systemic lupus erythematosus (Chapter 6), HIV infection, and B-cell neoplasms such as chronic lymphocytic leukemia (Chapter 13). The diagnosis of primary chronic ITP is made only after secondary causes are excluded.

Pathogenesis

Autoantibodies, most often directed against platelet membrane glycoproteins IIb–IIIa or Ib–IX, can be demonstrated in the plasma and bound to the platelet surface in about 80% of patients. In the overwhelming majority of cases, the antiplatelet antibodies are of the IgG class. As in autoimmune hemolytic anemias, antiplatelet antibodies act as opsonins that are recognized by IgG Fc receptors expressed on phagocytes (Chapter 6), leading to increased platelet destruction. The thrombocytopenia is usually markedly improved by splenectomy, indicating that the spleen is the major site of removal of opsonized platelets. The splenic red pulp also is rich in plasma cells, and part of the benefit of splenectomy may stem from the removal of a source of autoantibodies. In some instances the autoantibodies may also bind to and damage megakaryocytes, leading to decreases in platelet production that further exacerbate the thrombocytopenia.

MORPHOLOGY

The principal changes of thrombocytopenic purpura are found in the spleen, bone marrow, and blood, but they are not specific. Secondary changes related to the bleeding diathesis may be found anywhere in the body. The spleen is of normal size. Typically, there is congestion of the sinusoids and enlargement of the splenic follicles, often associated with prominent reactive germinal centers. In many instances scattered megakaryocytes are found within the sinuses, possibly representing a mild form of extramedullary hematopoiesis driven by elevated levels of thrombopoietin. **The marrow reveals a modestly increased number of megakaryocytes.** Some are apparently immature, with large, nonlobulated, single nuclei. These findings are not specific but merely reflect accelerated thrombopoiesis, being found in most forms of thrombocytopenia resulting from increased platelet destruction. The importance of bone marrow examination is to rule out thrombocytopenias resulting from marrow failure or other primary marrow disorders. The secondary changes relate to hemorrhage, often in the form of **petechial bleeds into the skin and mucous membranes.** The **peripheral blood often reveals abnormally large platelets** (megathrombocytes), which are a sign of accelerated thrombopoiesis.

Clinical Features

Chronic ITP occurs most commonly in adult women younger than 40 years of age. The female-to-male ratio is 3:1. It is often insidious in onset and is characterized by bleeding into the skin and mucosal surfaces. Pinpoint hemorrhages *(petechiae)* are especially prominent in the dependent areas where the capillary pressure is higher. Petechiae can become confluent, giving rise to *ecchymoses.* Often there is a history of easy bruising, nosebleeds, gingival bleeding, and hemorrhages into soft tissues from relatively minor trauma. The disease may manifest first with melena, hematuria, or excessive menstrual flow. Subarachnoid hemorrhage and intracerebral hemorrhage are serious and sometimes fatal complications, but fortunately are rare in treated patients. Splenomegaly and lymphadenopathy are not seen in primary disease, and their presence should lead one to consider other diagnoses, such as ITP secondary to a B-cell neoplasm.

Typical laboratory findings are reflective of isolated thrombocytopenia. A low platelet count, normal or increased megakaryocytes in the bone marrow, and large platelets in the peripheral blood are taken as presumptive evidence of

accelerated platelet destruction. The PT and PTT are normal. Tests for platelet autoantibodies suffer from low sensitivity and specificity and are not clinically useful. Therefore, the diagnosis is one of exclusion and can be made only after other causes of thrombocytopenia (such as those listed in Table 14.9) have been ruled out.

Almost all patients respond to glucocorticoids (which inhibit phagocyte function), but many relapse following withdrawal of steroids. Those with moderately severe thrombocytopenia (platelet counts >30,000/mL) can be followed carefully, and in some of these individuals ITP may spontaneously remit. In individuals with severe thrombocytopenia, splenectomy normalizes the platelet count in about two-thirds of patients, but with the attendant increased risk of bacterial sepsis. Immunomodulatory agents such as intravenous immunoglobulin or anti-CD20 antibody (rituximab) are often effective in patients who relapse after splenectomy or for whom splenectomy is contraindicated. Peptides that mimic the effects of thrombopoietin (so-called *TPO-mimetics*) also may be effective in improving platelet counts in individuals with disease that is refractory to other treatments.

Acute Immune Thrombocytopenic Purpura

Like chronic ITP, this condition is caused by autoantibodies to platelets, but its clinical features and course are distinct. Acute ITP is mainly a disease of childhood occurring with equal frequency in both sexes. Symptoms appear abruptly, often 1 to 2 weeks after a self-limited viral illness, which appears to trigger the development of autoantibodies through uncertain mechanisms. Unlike chronic ITP, acute ITP is self-limited, usually resolving spontaneously within 6 months. Glucocorticoids are given only if the thrombocytopenia is severe. In about 20% of children, usually those without a viral prodrome, thrombocytopenia persists; these children have a childhood form of chronic ITP that follows a course similar to the adult disease.

Drug-Induced Thrombocytopenia

Drugs can induce thrombocytopenia through direct effects on platelets and secondary to immunologically mediated platelet destruction. The drugs most commonly implicated are quinine, quinidine, and vancomycin, all of which induce drug-dependent antibody binding to platelet glycoproteins. Much more rarely, drugs induce true autoantibodies through unknown mechanisms. Thrombocytopenia, which may be severe, can occur in those who are taking platelet inhibitory drugs that bind glycoprotein IIb/IIIa; it is hypothesized that these drugs induce conformational changes in glycoprotein IIb/IIIa and create an immunogenic epitope.

Heparin-induced thrombocytopenia (HIT) has a distinctive pathogenesis and is of particular importance because of its potential for severe clinical consequences (Chapter 4). Thrombocytopenia occurs in about 5% of persons receiving heparin and is of two types:

- *Type I HIT occurs rapidly after the onset of therapy and is of little clinical importance,* sometimes resolving despite the continuation of therapy. It most likely results from a direct platelet-aggregating effect of heparin.
- *Type II HIT is less common but is often life threatening.* It occurs 5 to 14 days after therapy begins (or sooner if the person has been sensitized to heparin) and, paradoxically, often leads to venous and arterial thrombosis. It is caused by antibodies that recognize complexes of heparin and platelet factor 4, a normal component of platelet granules. Binding of antibody to these complexes activates platelets and promotes thrombosis, even in the setting of thrombocytopenia. Failure to immediately stop heparin and institute an alternative nonheparin anticoagulant may lead to clot formation within large arteries, vascular insufficiency, and limb loss, as well as deep venous thrombosis with the attendant risk of pulmonary thromboembolism. The risk of type II HIT is lowered, but not completely eliminated, by the use of low-molecular-weight heparin preparations. Once type II HIT develops, even low-molecular-weight heparins exacerbate the thrombotic tendency and must be avoided.

HIV-Associated Thrombocytopenia

Thrombocytopenia is one of the most common hematologic manifestations of HIV infection. Both decreased platelet production and increased platelet destruction contribute. CD4 and CXCR4, the receptor and co-receptor, respectively, for HIV, are found on megakaryocytes, allowing these cells to be infected. HIV-infected megakaryocytes are prone to apoptosis, and their ability to produce platelets is impaired. HIV infection also causes B-cell hyperplasia and dysregulation (possibly due to its direct effects on CD4+ T cells), which predisposes to the development of autoantibodies. In some instances, the antibodies are directed against platelet membrane glycoprotein IIb–III complexes. As in other immune cytopenias, the autoantibodies opsonize platelets, promoting their destruction by mononuclear phagocytes in the spleen and elsewhere. The deposition of immune complexes on platelets also may contribute thrombocytopenia in some HIV-infected patients.

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura (TTP) and Hemolytic Uremic Syndrome (HUS)

Thrombotic microangiopathies encompasses a spectrum of clinical syndromes that are caused by insults that lead to excessive activation of platelets, which deposit as thrombi in small blood vessels. This group of disorders includes TTP and HUS.

According to its original description, TTP was defined as the pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, transient neurologic deficits, and renal failure. HUS also is associated with microangiopathic hemolytic anemia and thrombocytopenia but is distinguished by the absence of neurologic symptoms, the prominence of acute renal failure, and its frequent occurrence in children. With time, experience, and increased mechanistic insight, however, these distinctions have blurred. Many adult patients with "TTP" lack one or more of the five criteria, and some patients with "HUS" have fever and neurologic dysfunction.

In both conditions, intravascular thrombi cause a microangiopathic hemolytic anemia and widespread organ dysfunction, and the attendant consumption of platelets leads to thrombocytopenia. It is believed that the varied clinical manifestations of TTP and HUS are related to differing proclivities for thrombus formation in tissues. Although DIC (discussed later) and thrombotic microangiopathies share features such as microvascular occlusion and

microangiopathic hemolytic anemia, they are pathogenically distinct. In TTP and HUS (unlike in DIC), activation of the coagulation cascade is not of primary importance, and hence laboratory tests of coagulation, such as the PT and PTT, are usually normal.

Although certain features of the various thrombotic microangiopathies overlap, the triggers for the pathogenic platelet activation are distinctive and provide a more satisfying and clinically relevant way of thinking about these disorders (summarized in Table 14.10). **TTP is caused by a deficiency in a plasma enzyme called ADAMTS13, also designated "vWF metalloprotease."** ADAMTS13 degrades very high-molecular-weight multimers of vWF. In its absence, large multimers accumulate in plasma and tend to promote spontaneous platelet activation and aggregation. Superimposition of endothelial cell injury (caused by some other condition) may further promote the formation of platelet aggregates, thus initiating or exacerbating clinically evident TTP.

ADAMTS13 deficiency may be inherited or acquired. In the acquired form, an autoantibody that inhibits the metalloprotease activity of ADAMTS13 is present. Less commonly, patients inherit an inactivating mutation in *ADAMTS13*. In those with hereditary ADAMTS13 deficiency, the onset is often delayed until adolescence, and the symptoms are episodic. Thus, factors other than ADAMTS13 deficiency (e.g., a superimposed vascular injury or prothrombotic state) must be involved in triggering full-blown TTP.

TTP is an important diagnosis to consider in any patient presenting with thrombocytopenia and microangiopathic hemolytic anemia, because delays in diagnosis can be fatal. With plasma exchange, which removes autoantibodies and provides functional ADAMTS13, TTP (which once was uniformly fatal) can be treated successfully in more than 80% of patients.

In contrast, HUS is associated with normal levels of ADAMTS13 and is initiated by several other distinct defects. **"Typical" HUS is strongly associated with infectious gastroenteritis caused by *Escherichia coli* strain O157:H7, which elaborates a Shiga-like toxin.** This toxin is absorbed from the inflamed gastrointestinal mucosa into the circulation, where it is believed to directly or indirectly alter endothelial cell function in some manner that provokes platelet activation and aggregation. Children and older adults are at highest risk. Those affected present with bloody diarrhea, and a few days later HUS makes its appearance.

"Atypical" HUS is often associated with defects in complement factor H, membrane cofactor protein (CD46), or factor I, proteins that act to prevent excessive activation of the alternative complement pathway. Deficiencies of these proteins may be caused by inherited defects or acquired inhibitory autoantibodies and are associated with a remitting, relapsing clinical course.

Unlike TTP, the basis for the platelet activation in typical and atypical HUS is unclear. As in paroxysmal nocturnal hemoglobinuria (discussed earlier), therapeutic antibodies that inhibit the activation of the complement factor C5 are effective in preventing thrombosis in patients with atypical HUS, proving that excessive complement activation has a central role in this form of the disease. Immunosuppression also may be beneficial to patients with inhibitory autoantibodies. Typical HUS is treated supportively. Patients who survive the acute insult usually recover, but some have permanent renal damage and require dialysis or renal transplantation. The impact of HUS and TTP on the kidneys is discussed further in Chapter 20.

Thrombotic microangiopathies resembling HUS also may be seen following exposures to other agents that damage endothelial cells (e.g., certain drugs and radiation therapy). The prognosis in these settings is guarded, because the HUS is often complicated by chronic, life-threatening conditions.

Table 14.10 Thrombotic Microangiopathies: Causes and Associations

Thrombotic Thrombocytopenic Purpura
Deficiency of ADAMTS13 Inherited Acquired (autoantibodies)
Hemolytic Uremic Syndrome
Typical: Escherichia coli *strain O157:H7 infection* Endothelial damage by Shiga-like toxin
Atypical: alternative complement pathway inhibitor deficiencies (complement factor H, membrane cofactor protein [CD46], or factor I) Inherited Acquired (autoantibodies)
Miscellaneous associations Drugs (cyclosporine, chemotherapeutic agents) Radiation, bone marrow transplantation Other infections (HIV, pneumococcal sepsis) Conditions associated with autoimmunity (systemic lupus erythematosus, HIV infection, lymphoid neoplasms)

HIV, Human immunodeficiency virus.

Bleeding Disorders Related to Defective Platelet Function

Qualitative defects of platelet function can be inherited or acquired. Several inherited disorders characterized by abnormal platelet function and normal platelet counts have been described. A brief discussion of these rare diseases is warranted because they provide insight into the molecular mechanisms of platelet function.

Inherited disorders of platelet function can be classified into three pathogenically distinct groups: (1) defects of adhesion, (2) defects of aggregation, and (3) disorders of platelet secretion (release reaction).

- *Bernard-Soulier syndrome* illustrates the consequences of defective adhesion of platelets to subendothelial matrix. It is an autosomal recessive disorder caused by an inherited deficiency of the platelet membrane glycoprotein complex Ib–IX. This glycoprotein is a receptor for vWF and is essential for normal platelet adhesion to the subendothelial extracellular matrix (Chapter 4). Affected patients have a variable, often severe, bleeding tendency.
- *Glanzmann thrombasthenia* exemplifies bleeding due to defective platelet aggregation. It is transmitted as an autosomal recessive trait. Thrombasthenic platelets fail to aggregate in response to adenosine diphosphate (ADP), collagen, epinephrine, or thrombin because of deficiency or dysfunction of glycoprotein IIb–IIIa, an integrin that participates in "bridge formation" between platelets by binding fibrinogen. The associated bleeding tendency is often severe.

- *Storage pool disorders* are characterized by the defective release of certain mediators of platelet activation, such as thromboxanes and granule-bound ADP. The biochemical defects underlying these disorders are varied, complex, and beyond the scope of our discussion.

Among the acquired defects of platelet function, two are clinically significant. The first is caused by ingestion of aspirin and other nonsteroidal anti-inflammatory drugs. Aspirin is a potent, irreversible inhibitor of cyclooxygenase, an enzyme that is required for the synthesis of thromboxane A_2 and prostaglandins (Chapter 3). These mediators play important roles in platelet aggregation and subsequent release reactions (Chapter 4). The antiplatelet effects of aspirin form the basis for its use in preventing coronary thrombosis (Chapter 12). Uremia (Chapter 20) is the second common condition associated with acquired defects in platelet function. The pathogenesis of platelet dysfunction in uremia is complex and involves defects in adhesion, granule secretion, and aggregation.

Hemorrhagic Diatheses Related to Abnormalities in Clotting Factors

Inherited or acquired deficiencies of virtually every coagulation factor have been reported as causes of bleeding diatheses. Bleeding due to coagulation factor deficiencies commonly manifest as large posttraumatic ecchymoses or hematomas, or prolonged bleeding from a laceration or after a surgical procedure. Unlike bleeding seen with thrombocytopenia, bleeding due to coagulation factor deficiencies often occurs into the gastrointestinal and urinary tracts and into weight-bearing joints (hemarthrosis). Typical stories include the patient who oozes blood for days after a tooth extraction or who develops a hemarthrosis after minor stress on a knee joint.

Hereditary deficiencies typically affect a single clotting factor. The most common and important inherited deficiencies of coagulation factors affect factor VIII (hemophilia A) and factor IX (hemophilia B). Deficiencies of vWF (von Willebrand disease) also are discussed here, as this factor influences both coagulation and platelet function.

Acquired deficiencies usually involve multiple coagulation factors and can be caused by decreased protein synthesis or a shortened protein half-life. Vitamin K deficiency (Chapter 9) impairs the synthesis of factors II, VII, IX, X and protein C. Many coagulatiion factors are made in the liver, and inadequate synthesis is often observed in severe parenchymal liver disease. By contrast, in DIC, multiple coagulation factors are consumed, leading to their deficiency. Acquired deficiencies of single factors occur, but are rare. These are usually caused by inhibitory autoantibodies.

Factor VIII–vWF Complex

The two most common inherited disorders of bleeding, hemophilia A and von Willebrand disease, are caused by qualitative or quantitative defects involving factor VIII and vWF, respectively. Before we discuss these disorders, it will be helpful to review the structure and function of these two proteins, which exist together in the plasma as part of a single large complex.

Factor VIII is an essential cofactor of factor IX, which converts factor X to factor Xa (Fig. 14.26; Chapter 4). It is made by endothelial cells, whereas vWF is made by both endothelial cells and megakaryocytes, which are the source of the vWF that is present in platelet α-granules. Once secreted into the blood, factor VIII binds to and is stabilized by vWF, an interaction that increases the half-life of factor VIII from about 2.4 hours to about 12 hours.

vWF secreted into the circulation by endothelial cells exists as multimers containing as many as 100 subunits that can exceed 20×10^6 daltons in molecular mass. Some of the

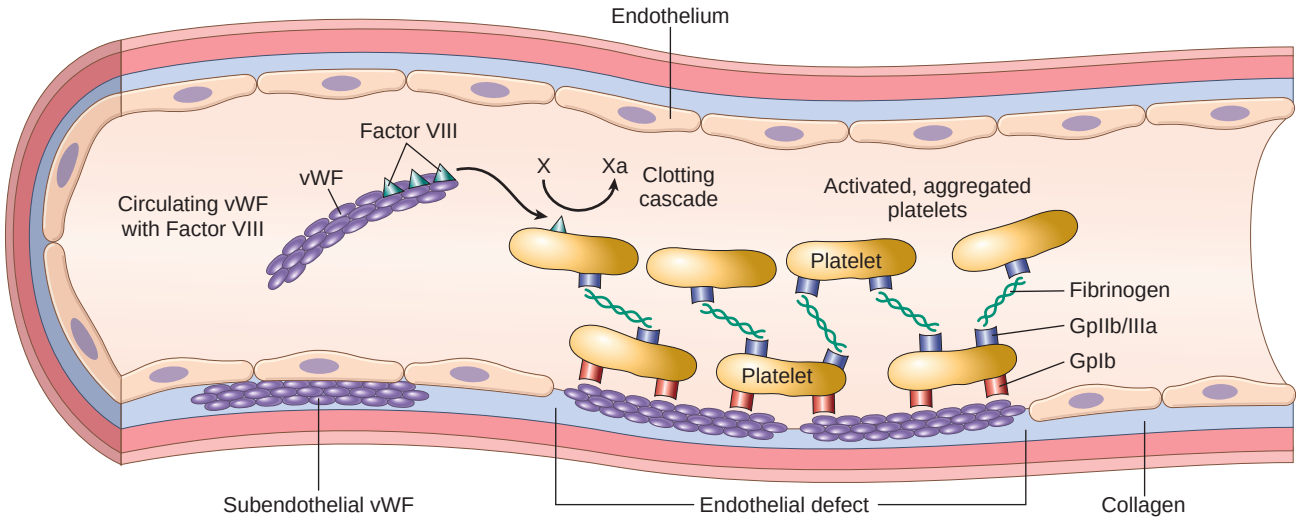

Figure 14.26 Structure and function of factor VIII–von Willebrand factor (vWF) complex. Factor VIII is synthesized in the liver and kidney, and vWF is made in endothelial cells and megakaryocytes. The two associate to form a complex in the circulation. vWF is also present in the subendothelial matrix of normal blood vessels and the α-granules of platelets. Following endothelial injury, exposure of subendothelial vWF causes adhesion of platelets, primarily via the glycoprotein Ib (GpIb) platelet receptor. Circulating vWF and vWF released from the α-granules of activated platelets can bind exposed subendothelial matrix, further contributing to platelet adhesion and activation. Activated platelets form hemostatic aggregates; fibrinogen participates in aggregation through bridging interactions with the glycoprotein IIb/IIIa (GpIIb/IIIa) platelet receptor. Factor VIII takes part in the coagulation cascade as a cofactor in the activation of factor X on the surface of activated platelets.

secreted vWF also is deposited in the subendothelial matrix, where it lies ready to promote platelet adhesion if the endothelial lining is disrupted (see Fig. 14.26). In addition to factor VIII, vWF interacts with several other proteins involved in hemostasis, including collagen, heparin, and platelet membrane glycoproteins. The most important hemostatic function of vWF is to promote the adhesion of platelets to the subendothelial matrix. This occurs through bridging interactions between platelet glycoprotein Ib–IX, vWF, and matrix components such as collagen. vWF also may promote platelet aggregation by binding to activated GpIIb/IIIa integrins; this activity may be of particular importance under conditions of high shear stress (such as occurs in small vessels).

Factor VIII and vWF protein levels are measured by immunologic techniques. Factor VIII function is measured by performing coagulation assays with mixtures of patient plasma and factor VIII–deficient plasma, and vWF function is assessed using the ristocetin agglutination test. The latter is performed by adding patient plasma to normal formalin-fixed platelets in the presence of ristocetin, a small molecule that binds and "activates" vWF. Ristocetin induces multivalent vWF multimers to bind platelet glycoprotein Ib–IX and form interplatelet "bridges." The resultant clumping (agglutination) of platelets reflects the vWF activity of the sample.

Von Willebrand Disease

Von Willebrand disease is the most common inherited bleeding disorder of humans, affecting about 1% of adults in the United States. The bleeding tendency is usually mild and often goes unnoticed until some hemostatic stress, such as surgery or a dental procedure, reveals its presence. The most common presenting symptoms are spontaneous bleeding from mucous membranes (e.g., epistaxis), excessive bleeding from wounds, or menorrhagia. It is usually transmitted as an autosomal dominant disorder, but rare autosomal recessive variants also exist.

Von Willebrand disease is clinically and molecularly heterogeneous; hundreds of vWF variants have been described, only a few of which have been formally proven to cause disease. Three types are recognized, each with a range of phenotypes:

- *Type 1 and type 3 von Willebrand disease are associated with quantitative defects in vWF.* Type 1, an autosomal dominant disorder characterized by a mild to moderate vWF deficiency, accounts for about 70% of all cases. Incomplete penetrance and variable expressivity are commonly observed, but it generally is associated with mild disease. Type 1 disease is associated with a spectrum of mutations, including point substitutions that interfere with maturation of the vWF protein or that result in rapid clearance from the plasma. Type 3 disease is an autosomal disorder usually caused by deletions or frameshift mutations involving both alleles, resulting in little to no vWF synthesis. Because vWF stabilizes factor VIII in the circulation, factor VIII levels are also reduced in type 3 disease and the associated bleeding disorder is often severe.
- *Type 2 von Willebrand disease is characterized by qualitative defects in vWF;* there are several subtypes, of which type 2A is the most common. It is inherited as an autosomal dominant disorder. vWF is expressed in normal amounts, but missense mutations are present that lead to defective multimer assembly. As a result, large- and intermediate-sized multimers, the most active forms of vWF, are missing from plasma. Type 2 von Willebrand disease accounts for 25% of all cases and is associated with mild to moderate bleeding.

Patients with von Willebrand disease have defects in platelet function despite having normal platelet counts. The plasma level of active vWF, measured as the ristocetin cofactor activity, is reduced. Because a deficiency of vWF decreases the stability of factor VIII, type 1 and type 3 von Willebrand disease are associated with a prolonged PTT.

Even within families in which a single defective vWF allele is segregating, wide variability in clinical expression is common. This is due in part to modifying genes that influence circulating levels of vWF, which have a broad range in normal populations. Persons with types 1 or 2 von Willebrand disease facing hemostatic challenges (dental work, surgery) can be treated with desmopressin (which stimulates vWF release), infusions of plasma concentrates containing factor VIII and vWF, or with recombinant vWF. By contrast, rare patients with type 3 disease must be treated prophylactically with plasma concentrates and factor VIII infusions to prevent severe "hemophilia-like" bleeding.

Hemophilia A (Factor VIII Deficiency)

Hemophilia A, the most common hereditary disease associated with life-threatening bleeding, is caused by mutations in factor VIII, an essential cofactor for factor IX in the coagulation cascade. Hemophilia A is inherited as an X-linked recessive trait and thus affects mainly males and homozygous females. Rarely, excessive bleeding occurs in heterozygous females, presumably as a result of inactivation of the X chromosome bearing the normal factor VIII allele by chance in most cells (unfavorable lyonization). About 30% of patients have no family history; their disease is caused by new mutations.

Hemophilia A exhibits a wide range of clinical severity that correlates well with the level of factor VIII activity. Those with less than 1% of normal levels have severe disease; those with 2% to 5% of normal levels have moderately severe disease; and those with 6% to 50% of normal levels have mild disease. The varying degrees of factor VIII deficiency are largely explained by heterogeneity in the causative mutations. The most severe deficiencies result from an inversion involving the X chromosome that completely abolishes the synthesis of factor VIII. Less commonly, severe hemophilia A is associated with point mutations in factor VIII that impair the function of the protein. In such cases, factor VIII protein levels may be normal by immunoassay. Mutations permitting some active factor VIII to be synthesized are associated with mild to moderate disease.

In all symptomatic cases, there is a tendency toward easy bruising and massive hemorrhage after trauma or operative procedures. In addition, "spontaneous" hemorrhages frequently occur in regions of the body that are susceptible to trauma, particularly the joints, where they are known as *hemarthroses.* Recurrent bleeding into the joints leads to progressive deformities that can be crippling. Petechiae are characteristically absent.

Patients with hemophilia A have a prolonged PTT and a normal PT, results that point to an abnormality of the

intrinsic coagulation pathway. Factor VIII–specific assays are required for diagnosis. As explained in Chapter 4, the bleeding diathesis reflects the pre-eminent role of the factor VIIIa/factor IXa complex in activation of factor X in vivo. The precise explanation for the tendency of hemophiliacs to bleed at particular sites (joints, muscles, and the central nervous system) remains uncertain.

Hemophilia A is treated with infusions of recombinant factor VIII. About 15% of patients with severe hemophilia A develop antibodies that bind and inhibit factor VIII, probably because the protein is perceived as foreign, having never been "seen" by the immune system. Recently, bispecific antibodies have been developed that bind factor IXa to factor X; these antibodies bypass the need for factor VIII and are particularly effective in patients with factor VIII antibody inhibitors. Before the development of recombinant factor VIII therapy, thousands of hemophiliacs received plasma-derived factor VIII concentrates containing HIV, and many developed AIDS (Chapter 6). The risk of HIV transmission has been eliminated, but tragically too late for an entire generation of hemophiliacs. Efforts to develop somatic gene therapy for hemophilia are ongoing.

Hemophilia B (Christmas Disease, Factor IX Deficiency)

Severe factor IX deficiency produces a disorder clinically indistinguishable from factor VIII deficiency (hemophilia A). This should not be surprising, given that factors VIII and IX function together to activate factor X. A wide spectrum of mutations involving the gene that encodes factor IX is found in hemophilia B. Like hemophilia A, it is inherited as an X-linked recessive trait and shows variable clinical severity. In about 15% of these patients, factor IX protein is present but is nonfunctional. As with hemophilia A, the PTT is prolonged and the PT is normal. Diagnosis of Christmas disease (named after the first patient identified with this condition, and not the holiday) is possible only by assay of the factor levels. The disease is treated with infusions of recombinant factor IX.

Disseminated Intravascular Coagulation (DIC)

DIC is an acute, subacute, or chronic thrombohemorrhagic disorder characterized by the excessive activation of coagulation and the formation of thrombi in the microvasculature. It occurs as a secondary complication of many disorders. Sometimes the coagulopathy is localized to a specific organ or tissue. As a consequence of the thrombotic diathesis, there is consumption of platelets, fibrin, and coagulation factors and, secondarily, activation of fibrinolysis. DIC can present with signs and symptoms relating to tissue hypoxia and infarction caused by microthrombi; hemorrhage, due to depletion of factors required for hemostasis and activation of fibrinolytic mechanisms; or both.

Etiology and Pathogenesis

At the outset, it must be emphasized that DIC is not a primary disease, but rather is an acquired coagulopathy that may occur in the course of a variety of clinical conditions. In discussing the general mechanisms underlying DIC, it is useful to briefly review the normal process of blood coagulation and clot removal (Chapter 4).

Clotting in vivo is initiated by exposure of tissue factor, which activates factor VII. The most important effect of tissue factor/factor VII complexes is activation of factor IX, which in turn activates factor X. Activation of factor X leads to the generation of thrombin, the central player in clotting. At sites where the endothelium is disrupted, thrombin converts fibrinogen to fibrin; feeds back to activate factors IX, VIII, and V; stimulates fibrin crosslinking; inhibits fibrinolysis; and activates platelets, all of which augment the formation of a stable clot. To prevent runaway clotting, this process must be sharply limited to the site of tissue injury. Remarkably, as thrombin is swept away in the bloodstream and encounters uninjured vessels, it is converted to an anticoagulant through binding to thrombomodulin, a protein found on the surface of endothelial cells. The thrombin-thrombomodulin complex activates protein C, an important inhibitor of factor V and factor VIII. Other activated coagulation factors are removed from the circulation by the liver, and, as you will recall, the blood also contains several potent fibrinolytic factors, such as plasmin. These and additional checks and balances normally ensure that just enough clotting occurs at the right place and time.

From this brief review, it should be clear that DIC could result from pathologic activation of coagulation or impairment of clot-inhibiting mechanisms. Because the latter rarely constitute primary mechanisms of DIC, we will focus on the abnormal initiation of clotting.

Two major mechanisms trigger DIC: (1) release of tissue factor or other procoagulants into the circulation, and (2) widespread injury of endothelial cells. Procoagulants such as tissue factor can be derived from a variety of sources, such as the placenta in obstetric complications or tissues injured by trauma or burns. Mucus released from certain adenocarcinomas may also act as a procoagulant by directly activating factor X.

Endothelial injury can initiate DIC in several ways. Injuries that cause endothelial cell necrosis expose the subendothelial matrix, leading to the activation of platelets and the coagulation pathway. However, even subtle endothelial injuries can unleash procoagulant activity. One mediator of endothelial injury is TNF, which is implicated in DIC occurring with sepsis. TNF induces endothelial cells to express tissue factor on their cell surfaces and to decrease the expression of thrombomodulin, tilting the checks and balances that govern hemostasis towards coagulation. In addition, TNF up-regulates the expression of adhesion molecules on endothelial cells, thereby promoting the adhesion of leukocytes, which can damage endothelial cells by releasing reactive oxygen species and preformed proteases. Widespread endothelial injury may also be produced by deposition of antigen-antibody complexes (e.g., systemic lupus erythematosus), temperature extremes (e.g., heat stroke, burns), or microorganisms (e.g., meningococci, rickettsiae).

DIC is most commonly associated with obstetric complications, malignant neoplasms, sepsis, and major trauma. The triggers in these conditions are often multiple and interrelated. For example, in bacterial infections, endotoxins can inhibit the endothelial expression of thrombomodulin directly or indirectly by stimulating immune cells to make TNF, and also can activate factor XII. Antigen-antibody complexes formed in response to infection can activate the classical complement pathway, giving rise to complement fragments

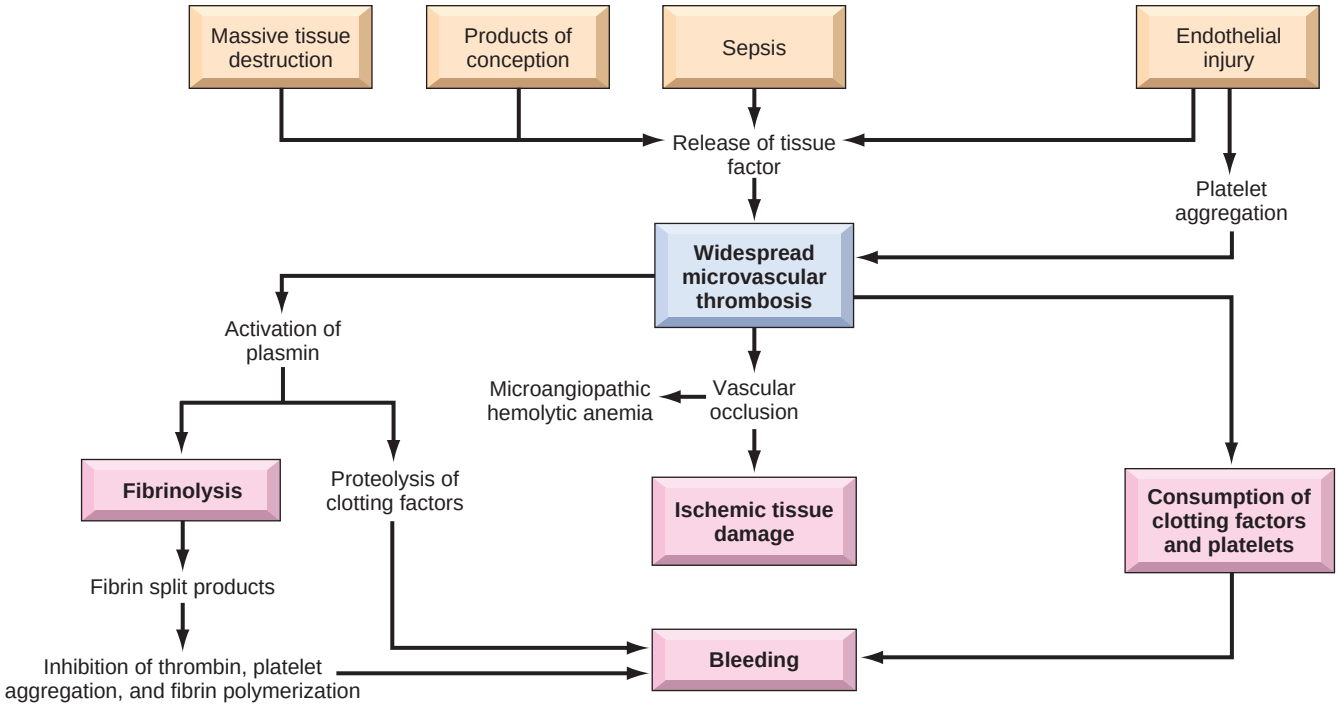

Figure 14.27 Pathophysiology of disseminated intravascular coagulation.

that secondarily activate platelets and granulocytes. In massive trauma, extensive surgery, and severe burns, the major trigger is the release of procoagulants such as tissue factor. In obstetric conditions, procoagulants derived from the placenta, dead retained fetus, or amniotic fluid may enter the circulation. Hypoxia, acidosis, and shock, which often coexist in very ill patients, also can cause widespread endothelial injury, and supervening infections can complicate problems further. Among cancers, acute promyelocytic leukemia and adenocarcinomas of the lung, pancreas, colon, and stomach are most frequently associated with DIC.

The possible consequences of DIC are twofold (Fig. 14.27).

- *Widespread deposition of fibrin* within the microcirculation. This leads to ischemia of the more severely affected or more vulnerable organs and a microangiopathic hemolytic anemia, which results from the fragmentation of red cells as they squeeze through the narrowed microvasculature.
- *Consumption of platelets and clotting factors* and the activation of plasminogen, leading to a hemorrhagic diathesis. Plasmin not only cleaves fibrin, but it also digests factors V and VIII, reducing their concentration further. In addition, fibrin degradation products resulting from fibrinolysis inhibit platelet aggregation, fibrin polymerization, and thrombin.

MORPHOLOGY

Thrombi are most often found in the brain, heart, lungs, kidneys, adrenals, spleen, and liver, in decreasing order of frequency, but any tissue can be affected. Affected kidneys may have small thrombi in the glomeruli that evoke only reactive swelling of endothelial cells or, in severe cases, microinfarcts or even **bilateral renal cortical necrosis.** Numerous fibrin thrombi may be found in alveolar capillaries, sometimes associated with pulmonary edema and fibrin exudation, creating "hyaline membranes" reminiscent of acute respiratory distress syndrome (Chapter 15). In the central nervous system, fibrin thrombi may cause microinfarcts, occasionally complicated by simultaneous hemorrhage, which can sometimes lead to variable neurologic signs and symptoms. In meningococcemia, fibrin thrombi within the microcirculation of the adrenal cortex are the probable basis for the massive adrenal hemorrhages seen in **Waterhouse-Friderichsen syndrome** (Chapter 24). An unusual form of DIC occurs in association with giant hemangiomas **(Kasabach-Merritt syndrome)** in which thrombi form within the neoplasm because of stasis and recurrent trauma to fragile blood vessels.

Clinical Features

The onset of DIC may be fulminant, as in sepsis or amniotic fluid embolism, or insidious and chronic, as in cases of carcinomatosis or retention of a dead fetus. It is almost impossible to detail all of the potential clinical presentations, but a few common patterns are worthy of description. These include microangiopathic hemolytic anemia; dyspnea, cyanosis, and respiratory failure; convulsions and coma; oliguria and acute renal failure; and sudden or progressive circulatory failure and shock. In general, acute DIC, associated (for example) with obstetric complications or major trauma, is dominated by a bleeding diathesis, whereas chronic DIC, such as occurs in cancer patients, tends to present with thrombotic complications. Diagnosis is based on clinical observation and laboratory studies, including measurement of fibrinogen levels, platelets, PT and PTT, and fibrin degradation products, particularly D-dimers.

The prognosis is highly variable and largely depends on the underlying disorder. The only definitive treatment is to remove or treat the inciting cause. Management requires meticulous maneuvering between the Scylla of thrombosis and the Charybdis of bleeding diathesis. Administration of anticoagulants or procoagulants has been advocated in specific settings, but not without controversy.

KEY CONCEPTS

Immune Thrombocytopenic Purpura

- Caused by autoantibodies against platelet antigens
- May be triggered by drugs, infections, or lymphomas, or may be idiopathic

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

- Both manifest with thrombocytopenia, microangiopathic hemolytic anemia, and renal failure; fever and CNS involvement are more typical of TTP.
- TTP: Caused by acquired or inherited deficiencies of ADAMTS 13, a plasma metalloprotease that cleaves very-high-molecular-weight multimers of vWF. Deficiency of ADAMTS 13 results in abnormally large vWF multimers that activate platelets.
- HUS: caused by deficiencies of complement regulatory proteins or agents that damage endothelial cells, such as a Shiga-like toxin elaborated by *E. coli* strain O157:H7. These abnormalities initiate platelet activation, platelet aggregation, and microvascular thrombosis.

Von Willebrand Disease

- Autosomal dominant disorder caused by mutations in vWF, a large protein that promotes the adhesion of platelets to subendothelial collagen and stabilizes factor VIII
- Typically causes a mild to moderate bleeding disorder resembling that associated with thrombocytopenia

Hemophilia

- Hemophilia A: X-linked disorder caused by mutations in factor VIII. Affected males typically present with severe bleeding into soft tissues and joints and have a prolonged PTT.
- Hemophilia B: X-linked disorder caused by mutations in coagulation factor IX. It is clinically identical to hemophilia A.

Disseminated Intravascular Coagulation

- Syndrome in which systemic activation of the coagulation leads to consumption of coagulation factors and platelets
- Can produce bleeding, vascular occlusion, and tissue hypoxemia in various combinations
- Common triggers: sepsis, major trauma, certain cancers, obstetric complications

Complications of Transfusion

Blood products are often rightly called the gift of life, permitting people to survive traumatic injuries and procedures such as hematopoietic stem cell transplantation and complex surgical procedures that would otherwise prove fatal. Over 5 million red cell transfusions are given in US hospitals each year. Thanks to improved screening of donors, blood products (packed red blood cells, platelets, and fresh-frozen plasma) are safer than ever before.

Nevertheless, complications still occur. Most are minor and transient. The most common is referred to as a *febrile nonhemolytic reaction,* which takes the form of fever and chills, sometimes with mild dyspnea, within 6 hours of a transfusion of red cells or platelets. These reactions are thought to be caused by inflammatory mediators derived from donor leukocytes. The frequency of these reactions increases with the storage age of the product and is decreased by measures that limit donor leukocyte contamination. Symptoms respond to antipyretics and are short-lived.

Other transfusion reactions are uncommon or rare, but can have severe and sometimes fatal consequences, and therefore merit discussion.

Allergic Reactions

Severe, potentially fatal allergic reactions may occur when blood products containing certain antigens are given to previously sensitized recipients. These are most likely to occur in patients with IgA deficiency, which has a frequency of 1:300 to 1:500 people. In this instance, the reaction is triggered by IgG antibodies that recognize IgA in the infused blood product. Fortunately, most patients with IgA deficiency do not develop such antibodies and these severe reactions are rare, occurring in 1 in 20,000 to 1 in 50,000 transfusions. Urticarial allergic reactions may be triggered by the presence an allergen in the donated blood product that is recognized by IgE antibodies in the recipient. These are considerably more common, occurring in 1% to 3% of transfusions, but are generally mild. In most instances, symptoms respond to antihistamines and do not require discontinuation of the transfusion.

Hemolytic Reactions

Acute hemolytic reactions are usually caused by preformed IgM antibodies against donor red cells that fix complement. They most commonly stem from an error in patient identification or tube labeling that allows a patient to receive an ABO-incompatible unit of blood. Preexisting high-affinity "natural" IgM antibodies, usually against polysaccharide blood group antigens A or B, bind to red cells and rapidly induce complement-mediated lysis, intravascular hemolysis, and hemoglobinuria. Fever, shaking chills, and flank pain appear rapidly. The direct Coombs test is typically positive, unless all of the donor red cells have lysed. The signs and symptoms are due to complement activation rather than intravascular hemolysis per se, as osmotic lysis of red cells (e.g., by mistakenly infusing red cells and 5% dextrose in water simultaneously) produces hemoglobinuria without any of the other symptoms of a hemolytic reaction. In severe cases, the process may rapidly progress to DIC, shock, acute renal failure, and occasionally death.

Delayed hemolytic reactions are caused by antibodies that recognize red cell antigens that the recipient was sensitized to previously, for example, through a prior blood transfusion. These are typically caused by IgG antibodies to foreign protein antigens and are associated with a positive direct Coombs test and laboratory features of hemolysis (e.g., low haptoglobin and elevated lactate dehydrogenase). Antibodies to antigens such as Rh, Kell, and Kidd often induce sufficient complement activation to cause severe and

potentially fatal reactions identical to those resulting from ABO mismatches. Other antibodies that do not fix complement typically result in red cell opsonization, extravascular hemolysis, and spherocytosis, and are associated with relatively minor signs and symptoms.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a severe, frequently fatal complication in which factors in a transfused blood product trigger the activation of neutrophils in the lung microvasculature. The incidence of TRALI is low, probably less than 1 in 10,000 transfusions, but it may occur more frequently in patients with preexisting lung disease. Though its pathogenesis is incompletely understood, current models favor a "two-hit" hypothesis. The first is neutrophil sequestration and priming in the microvasculature of the lung. It is postulated that endothelial cells are involved both in sequestration and priming; the former by up-regulation of adhesion molecules and the latter by release of cytokines. The second hit involves activation of primed neutrophils by a factor present in the transfused blood product.

A variety of factors have been implicated as "second hits," but the leading candidates are antibodies in the transfused blood product that recognize antigens expressed on neutrophils. By far the most common antibodies associated with TRALI are those that bind major histocompatibility complex (MHC) antigens. These antibodies are often found in multiparous women, who generate such antibodies in response to foreign MHC antigens expressed by the fetus. In other cases, donor antibodies to neutrophil-specific antigens have been implicated as triggers.

Although TRALI has been associated with virtually all plasma-containing blood products, it is more likely to occur following transfusion of products containing high levels of donor antibody, such as fresh-frozen plasma and platelets. The presentation is dramatic, consisting of sudden-onset respiratory failure, during or soon after a transfusion. Diffuse bilateral pulmonary infiltrates that do not respond to diuretics are seen on chest imaging. Other associated findings include fever, hypotension, and hypoxemia. The treatment is largely supportive, and the outcome is guarded; mortality is 5% in uncomplicated cases and up to 67% in the severely ill. TRALI is important to recognize, because donor products that induce the complication in one patient are much more likely to do so in a second. Indeed, measures taken to exclude multiparous women from plasma donation have sharply reduced the incidence of TRALI.

Infectious Complications

Virtually any infectious agent can be transmitted through blood products, but bacterial and viral infections are the dominant culprits. Most bacterial infections are caused by skin flora, indicating that the contamination occurred at the time that the product was taken from the donor. Significant bacterial contamination (sufficient to produce symptoms) is much more common in platelet preparations than in red cell preparations, due in large part to the fact that platelets (unlike red cells) must be stored at room temperature, a condition favorable for bacterial growth. Rates of bacterial infection following platelet transfusion are as high as 1 in 5000, with infections secondary to red cell transfusions being several orders of magnitude less frequent. Many of the symptoms (fever, chills, hypotension) resemble those of hemolytic and nonhemolytic transfusion reactions, and it may be necessary to start broad-spectrum antibiotics prospectively in symptomatic patients while awaiting laboratory results.

Advances in donor selection, donor screening, and infectious disease testing have dramatically decreased the incidence of viral transmission by blood products. However, on rare occasions when the donor is acutely infected but the virus is not yet detectable with current nucleic acid testing technology, there can be transfusion-related transmission of viruses such as HIV, hepatitis C, and hepatitis B. Rates of transmission of HIV, hepatitis C, and hepatitis B are estimated to be 1 in 1.5 million, 1 in 1.2 million, and 1 in 1 million, respectively. There also remains a low risk of "exotic" infectious agents such as West Nile virus, trypanosomiasis, and babesiosis.

CHAPTER 15

The Lung

Aliya N. Husain

CHAPTER CONTENTS

The lungs are ingeniously constructed to carry out their cardinal function, the exchange of gases between inspired air and blood. Developmentally, the respiratory system is an outgrowth from the ventral wall of the foregut. The midline trachea develops two lateral outpocketings, the lung buds, which eventually divide into branches called lobar bronchi, three on the right and two on the left, thus giving rise to three lobes on the right and two on the left. The lobar bronchi allow air to pass in and out of the lung. They have firm cartilaginous walls that provide mechanical support and are lined by columnar ciliated epithelium with abundant subepithelial glands that produce mucus, which impedes the entry of microbes. The right mainstem bronchus is more vertical and directly in line with the trachea. Consequently, aspirated foreign materials such as vomitus, blood, and foreign bodies tend to enter the right lung more often than the left.

The right and left lobar bronchi branch to give rise to progressively smaller airways that are accompanied by a dual arterial supply from the pulmonary and bronchial arteries. Distally, the bronchi give way to *bronchioles*, which are distinguished by the lack of cartilage and the presence of submucosal glands within their walls. Further branching

of bronchioles leads to the *terminal bronchioles,* which are less than 2 mm in diameter. Beyond the terminal bronchiole is the *acinus,* a roughly spherical structure with a diameter of about 7 mm. An acinus is composed of a *respiratory bronchiole* (which gives off several alveoli from its sides), *alveolar ducts,* and *alveolar sacs,* the blind ends of the respiratory passages, whose walls are formed entirely of alveoli, the site of gas exchange. A cluster of three to five terminal bronchioles, each with its appended acinus, is referred to as the pulmonary *lobule*.

Except for the true vocal cords, which are covered by stratified squamous epithelium, the entire respiratory tree, including the larynx, trachea, and bronchioles, is normally lined mainly by tall, columnar, pseudostratified, ciliated epithelial cells and a smaller population of non-ciliated cells called club cells that secrete a number of protective substances into the airway. There also are scattered cells called ionocytes that express high levels of the cystic fibrosis transmembrane conductance regulator (CFTR) and appear to modulate the ion content and viscosity of bronchial secretions. In addition, the bronchial mucosa contains neuroendocrine cells with neurosecretory-type granules that can release a variety of factors including serotonin, calcitonin, and gastrin-releasing peptide (bombesin). Numerous mucus-secreting goblet cells and submucosal glands also are dispersed throughout the walls of the trachea and bronchi (but not the bronchioles).

The microscopic structure of the alveolar walls (or alveolar septa) consists of the following (Fig. 15.1):

- An intertwining network of *anastomosing capillaries* lined with endothelial cells.
- *Basement membrane and surrounding interstitium,* which separates the endothelial cells from the alveolar lining epithelial cells. In thin portions of the alveolar septum the basement membranes of epithelium and endothelium are fused, whereas in thicker portions they are separated by an interstitial space *(pulmonary interstitium)* containing fine elastic fibers, small bundles of collagen, a few fibroblast-like interstitial cells, smooth muscle cells, mast cells, and rare lymphocytes and monocytes.

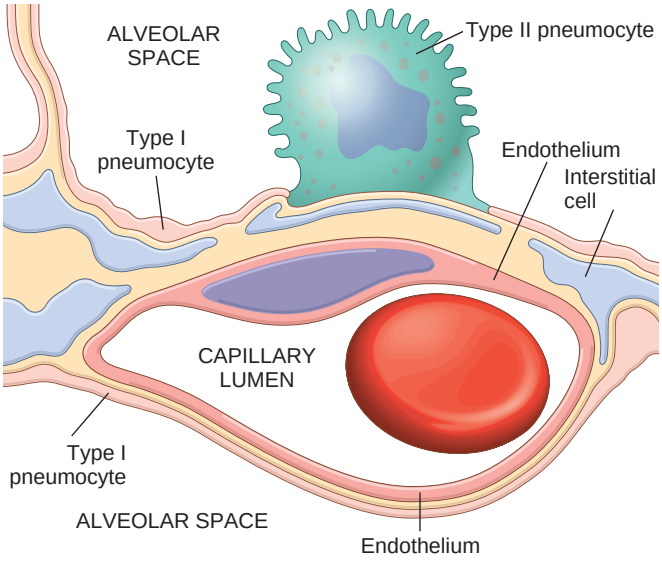

Figure 15.1 Microscopic structure of the alveolar wall. Note that the basement membrane *(yellow)* is thin on one side and widened where it is continuous with the interstitial space. Portions of interstitial cells are shown.

- *Alveolar epithelium,* a continuous layer of two cell types: flat, plate-like *type I pneumocytes,* covering 95% of the alveolar surface, and rounded *type II pneumocytes*. Type II cells synthesize *surfactant* (which forms a very thin layer over the alveolar cell membranes) and are involved in the repair of alveolar damage through their ability to proliferate and give rise to type I cells.

The alveolar walls are perforated by numerous *pores of Kohn,* which permit the passage of bacteria and exudate between adjacent alveoli (see Fig. 15.35B). Scattered resident *alveolar macrophages* also are present, either loosely attached to epithelial cells or lying free within the alveolar spaces.

CONGENITAL ANOMALIES

Developmental anomalies of the lung are rare. The most common of these include the following:

- *Pulmonary hypoplasia* is a defect in the development of both lungs (one may be more affected than the other) that results in decreased lung size. It is caused by abnormalities that compress the lung or impede lung expansion in utero, such as congenital diaphragmatic hernia and oligohydramnios. Severe hypoplasia is fatal in the early neonatal period.
- *Foregut cysts* arise from abnormal detachments of primitive foregut and are most often located in the hilum or middle mediastinum. Depending on the wall structure, these cysts are classified as bronchogenic (most common), esophageal, or enteric. A bronchogenic cyst is rarely connected to the tracheobronchial tree. It is lined by ciliated pseudostratified columnar epithelium and has a wall containing bronchial glands, cartilage, and smooth muscle. They may come to attention due to symptoms resulting from compression of nearby structures or superimposed infection or may be incidental findings.
- *Pulmonary sequestration* is a discrete area of lung tissue that (1) is not connected to the airways and (2) has an abnormal blood supply arising from the aorta or its branches. *Extralobar sequestration* is external to the lung and most commonly presents in infants as a mass lesion. It may be associated with other congenital anomalies. *Intralobar sequestration* occurs within the lung. It usually presents in older children, often due to recurrent localized infections or bronchiectasis.

Other, less common congenital abnormalities include tracheal and bronchial anomalies (atresia, stenosis, tracheoesophageal fistula), vascular anomalies, congenital pulmonary airway malformation, and congenital lobar overinflation (emphysema).

ATELECTASIS (COLLAPSE)

Atelectasis refers either to incomplete expansion of the lungs (neonatal atelectasis) or to the collapse of previously inflated lung, and results in areas of poorly aerated pulmonary parenchyma. The main types of acquired atelectasis, which is encountered principally in adults, are the following (Fig. 15.2).

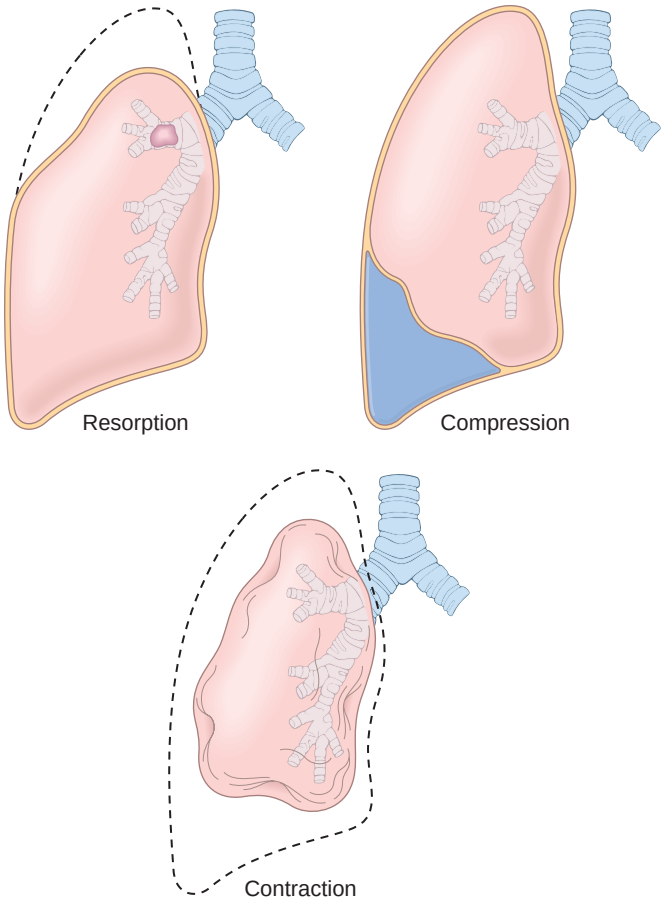

Figure 15.2 Various forms of acquired atelectasis. *Dashed lines* indicate normal lung volume.

- *Resorption atelectasis* stems from obstruction of an airway. Over time, air is resorbed from distal alveoli, which collapse. Since lung volume is diminished, the mediastinum shifts *toward* the atelectatic lung. Airway obstruction is most often caused by excessive secretions (e.g., mucus plugs) or exudates within smaller bronchi, as may occur in bronchial asthma, chronic bronchitis, bronchiectasis, and postoperative states. Aspiration of foreign bodies and intrabronchial tumors may also lead to airway obstruction and atelectasis.
- *Compression atelectasis* results whenever significant volumes of fluid (transudate, exudate, or blood), tumor, or air *(pneumothorax)* accumulate within the pleural cavity. With compression atelectasis, the mediastinum shifts *away* from the affected lung.
- *Contraction atelectasis* occurs when focal or generalized pulmonary or pleural fibrosis prevents full lung expansion.

Significant atelectasis reduces oxygenation and predisposes to infection. Except in cases caused by fibrosis, atelectasis is a reversible disorder.

PULMONARY EDEMA

Pulmonary edema (excessive interstitial fluid in the alveoli) can result from hemodynamic disturbances (cardiogenic pulmonary edema) or increased capillary permeability due to microvascular injury (non-cardiogenic pulmonary edema) (Table 15.1). A general consideration of edema is given in Chapter 4, and pulmonary congestion and edema are described briefly in the context of congestive heart failure (Chapter 12). Whatever the clinical setting, pulmonary congestion and edema produce heavy, wet lungs. Therapy and outcome depend on the underlying etiology.

Hemodynamic Pulmonary Edema

Hemodynamic pulmonary edema is caused by *increased hydrostatic pressure* and occurs most commonly in left-sided congestive heart failure. Edema accumulates initially in the basal regions of the lower lobes because hydrostatic pressure is greatest in these sites (dependent edema). Histologically, the alveolar capillaries are engorged, and there is an intra-alveolar transudate that appears as finely granular pale pink material. Alveolar microhemorrhages and *hemosiderin-laden macrophages ("heart failure" cells)* may be present. In long-standing pulmonary congestion (e.g., as seen in mitral stenosis), hemosiderin-laden macrophages are abundant, and fibrosis and thickening of the alveolar walls cause the soggy lungs to become firm and brown *(brown induration)*. These changes not only impair respiratory function but also predispose to infection.

Table 15.1 Classification and Causes of Pulmonary Edema

Hemodynamic Edema
Increased hydrostatic pressure (increased pulmonary venous pressure)
Left-sided heart failure (common)
Volume overload
Pulmonary vein obstruction
Decreased oncotic pressure (less common)
Hypoalbuminemia
Nephrotic syndrome
Liver disease
Protein-losing enteropathies
Lymphatic obstruction (rare)
Edema Due to Alveolar Wall Injury (Microvascular or Epithelial Injury)
Direct injury
Infections: bacterial pneumonia
Inhaled gases: high concentrations of oxygen, smoke
Liquid aspiration: gastric contents, near-drowning
Radiation
Lung trauma
Indirect injury
Systemic inflammatory response syndrome (e.g., associated with sepsis, burns, pancreatitis, extensive trauma)
Blood transfusion–related
Drugs and chemicals: chemotherapeutic agents (bleomycin), other medications (methadone, amphotericin B), heroin, cocaine, kerosene, paraquat
Edema of Undetermined Origin
High altitude
Neurogenic (central nervous system trauma)

Edema Caused by Microvascular (Alveolar) Injury

Non-cardiogenic pulmonary edema is caused by injury of the alveolar septa. Primary injury to the vascular endothelium or damage to alveolar epithelial cells (with secondary microvascular injury) produces an inflammatory exudate that leaks into the interstitial space and, in more severe cases, into the alveoli. Injury-related alveolar edema is an important feature of a serious and often fatal condition, *acute respiratory distress syndrome* (discussed below).

ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME (DIFFUSE ALVEOLAR DAMAGE)

Acute lung injury (ALI) is characterized by the abrupt onset of hypoxemia and bilateral pulmonary edema in the absence of cardiac failure (non-cardiogenic pulmonary edema). Acute respiratory distress syndrome (ARDS) is a manifestation of severe ALI. Both ARDS and ALI are associated with inflammation-associated increases in pulmonary vascular permeability, edema, and epithelial cell death. The histologic manifestation of these diseases is *diffuse alveolar damage*.

ALI is a well-recognized complication of diverse conditions including both pulmonary and systemic disorders (Table 15.2). In many cases, several predisposing conditions are present (e.g., shock, oxygen therapy, and sepsis). In other uncommon instances, ALI appears acutely in the absence of known triggers and follows a rapidly progressive clinical course, a condition known as *acute interstitial pneumonia*.

Table 15.2 Conditions Associated With Development of Acute Respiratory Distress Syndrome

Infection
Sepsis[a]
Diffuse pulmonary infections[a]
Viral, *Mycoplasma*, and *Pneumocystis* pneumonia; miliary tuberculosis
Gastric aspiration[a]
Physical/Injury
Mechanical trauma including head injuries[a]
Pulmonary contusions
Near-drowning
Fractures with fat embolism
Burns
Ionizing radiation
Inhaled Irritants
Oxygen toxicity
Smoke
Irritant gases and chemicals
Chemical Injury
Heroin or methadone overdose
Acetylsalicylic acid
Barbiturate overdose
Paraquat
Hematologic Conditions
Transfusion-associated lung injury (TRALI)
Disseminated intravascular coagulation
Pancreatitis
Uremia
Cardiopulmonary Bypass
Hypersensitivity Reactions
Organic solvents
Drugs

[a]More than 50% of cases of acute respiratory distress syndrome are associated with these four conditions.

Pathogenesis

ALI/ARDS is initiated by injury of pneumocytes and pulmonary endothelium, setting in motion a vicious cycle of increasing inflammation and pulmonary damage (Fig. 15.3).

- *Endothelial activation* is an important early event. In some instances, endothelial activation is secondary to pneumocyte injury, which is sensed by resident alveolar macrophages. In response, these immune sentinels secrete mediators such as tumor necrosis factor (TNF) that act on the neighboring endothelium. Alternatively, circulating inflammatory mediators may activate pulmonary endothelium directly in the setting of severe tissue injury or sepsis. Some of these mediators injure endothelial cells, while others (notably cytokines) induce endothelial cells to express increased levels of adhesion molecules, procoagulant proteins, and chemokines.
- *Adhesion and extravasation of neutrophils.* Neutrophils adhere to the activated endothelium and migrate into the interstitium and the alveoli, where they degranulate and release inflammatory mediators including proteases, reactive oxygen species, and cytokines. Experimental evidence suggest that neutrophil extracellular traps (NETs) are released and also contribute directly to lung damage. These injuries and associated proinflammatory factors set in motion a vicious cycle of inflammation and endothelial damage that lies at the heart of ALI/ARDS.
- *Accumulation of intra-alveolar fluid and formation of hyaline membranes.* Endothelial activation and injury make pulmonary capillaries leaky, allowing interstitial and intra-alveolar edema fluid to form. Damage and necrosis of type II alveolar pneumocytes lead to surfactant abnormalities, further compromising alveolar gas exchange. Ultimately the inspissated protein-rich edema fluid and debris from dead alveolar epithelial cells organize into hyaline membranes, a characteristic feature of ALI/ARDS.
- *Resolution of injury* is impeded in ALI/ARDS due to epithelial necrosis and inflammatory damage that impairs the ability of remaining cells to assist with edema resorption. Eventually, however, if the inflammatory stimulus lessens, macrophages remove intra-alveolar debris and release fibrogenic cytokines such as transforming growth factor β (TGF-β) and platelet-derived growth factor. These factors stimulate fibroblast growth and collagen deposition, leading to fibrosis of alveolar walls. Residual type II pneumocytes proliferate to replace type I pneumocytes, reconstituting the alveolar lining. Endothelial restoration occurs through proliferation of uninjured capillary endothelium.

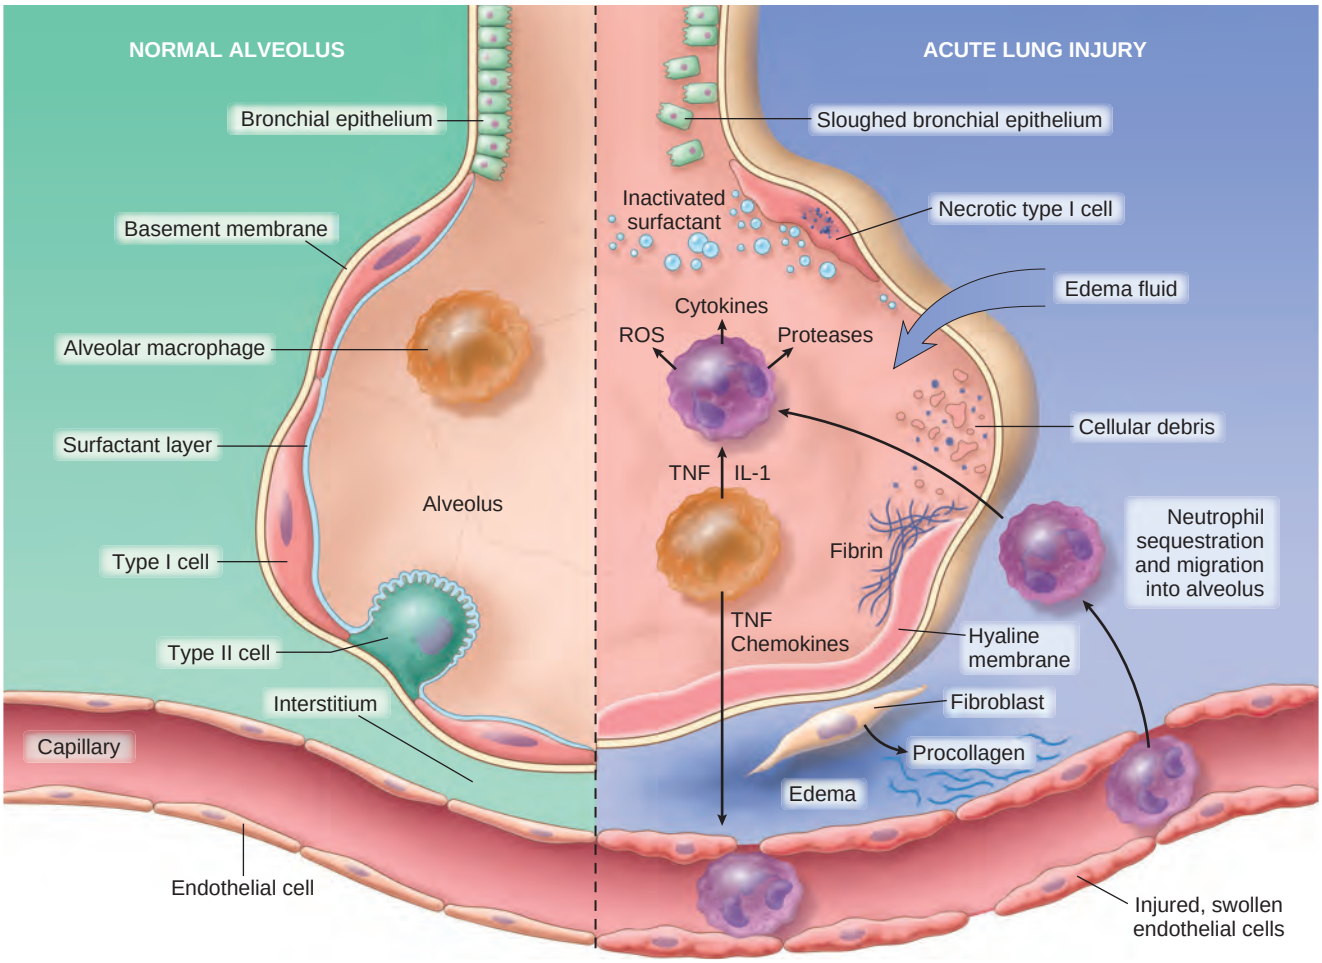

Figure 15.3 The normal alveolus *(left side)* compared with the injured alveolus in the early phase of acute lung injury and acute respiratory distress syndrome. *IL-1*, Interleukin-1; *ROS*, reactive oxygen species; *TNF*, tumor necrosis factor. (Modified with permission from Matthay MA, Ware LB, Zimmerman GA: The acute respiratory distress syndrome, *J Clin Invest* 122:2731, 2012.)

The lesions in ARDS are not evenly distributed, and as a result there are typically areas that are stiff and poorly aerated and regions that have nearly normal levels of compliance and ventilation. Because poorly aerated regions continue to be perfused, there is a mismatch of ventilation and perfusion, a phenomenon that exacerbates the hypoxemia and cyanosis.

Epidemiologic studies have shown that ALI/ARDS is more common and has a worse prognosis in chronic alcoholics and in smokers. Genome-wide association studies have identified a number of genetic variants that increase the risk of ARDS, some of which map to genes linked to inflammation and coagulation.

MORPHOLOGY

In the acute exudative stage, the lungs are heavy, firm, red, and boggy. They exhibit congestion, interstitial and intra-alveolar edema, inflammation, fibrin deposition, and **diffuse alveolar damage.** The alveolar walls become lined with waxy **hyaline membranes** (Fig. 15.4) that are morphologically similar to those seen in hyaline membrane disease of neonates (Chapter 10). Alveolar hyaline membranes consist of fibrin-rich edema fluid mixed with the remnants of necrotic epithelial cells. In the proliferative or organizing stage, type II pneumocytes proliferate, and granulation tissue forms in the alveolar walls and spaces. In most cases the granulation tissue resolves, leaving minimal functional impairment. Sometimes, however, fibrotic thickening (scarring) of the alveolar septa ensues (late fibrotic stage).

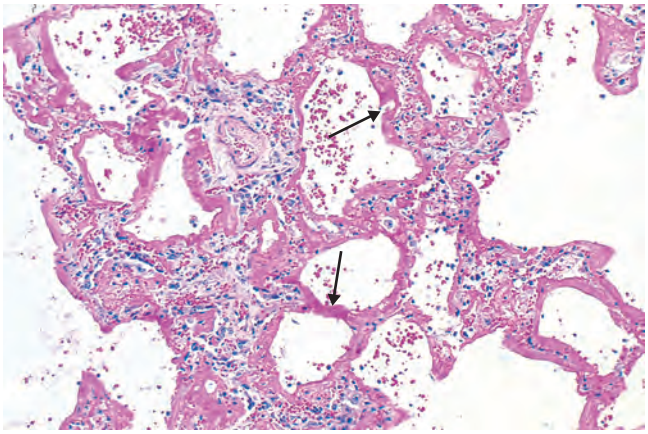

Figure 15.4 Diffuse alveolar damage (acute respiratory distress syndrome). Some of the alveoli are collapsed, while others are distended. Many are lined by hyaline membranes *(arrows)*.

Clinical Features

Profound dyspnea and tachypnea herald ALI/ARDS, followed by increasing respiratory failure, hypoxemia, cyanosis, and the appearance of diffuse bilateral infiltrates on radiographic examination. Hypoxemia may be refractory to oxygen therapy due to ventilation-perfusion mismatch, and respiratory acidosis can develop. Early in the course, the lungs become stiff due to loss of functional surfactant, leading to the need for intubation and high ventilatory pressures to maintain adequate gas exchange.

There are no proven specific treatments for ARDS, which is common in acutely ill patients and continues to take a high toll, even in patients receiving state-of-the-art supportive care. In a 2016 study of intensive care units in 50 countries, the incidence of ARDS was 10.4%, and mortality rates were 35% for mild, 40% for moderate, and 46% for severe ARDS. The majority of deaths are attributable to sepsis, multiorgan failure, or severe lung injury. Most survivors recover pulmonary function, but in a minority of patients, the lung damage results in interstitial fibrosis and chronic pulmonary disease.

KEY CONCEPTS

ACUTE RESPIRATORY DISTRESS SYNDROME

- ARDS is a clinical syndrome of progressive respiratory insufficiency caused by diffuse alveolar damage in the setting of sepsis, severe trauma, or diffuse pulmonary infection.
- Damage to endothelial and alveolar epithelial cells and secondary inflammation are the key initiating events and the basis of lung damage.
- The characteristic histologic finding is hyaline membranes lining alveolar walls, accompanied by edema, scattered neutrophils and macrophages, and epithelial necrosis.

OBSTRUCTIVE AND RESTRICTIVE LUNG DISEASES

Obstructive lung diseases are characterized by an increase in resistance to airflow due to diffuse airway disease, which may affect any level of the respiratory tract. These are contrasted with restrictive diseases, which are characterized by reduced expansion of lung parenchyma and decreased total lung capacity. The clinical distinction between these diseases is based primarily on pulmonary function tests. In individuals with diffuse obstructive disorders, pulmonary function tests show decreased maximal airflow rates during forced expiration, usually expressed as forced expiratory volume at 1 second (FEV_1) over forced ventilatory capacity (FVC). An FEV_1/FVC ratio of less than 0.7 generally indicates obstructive disease. Expiratory airflow obstruction may be caused by a variety of conditions (Table 15.3), each with characteristic pathologic changes and different mechanisms of airflow obstruction. As discussed later, however, the divisions between these entities are not "clean," and many patients have diseases with overlapping features. By contrast, restrictive diseases are associated with proportionate decreases in both total lung capacity and FEV_1, such that the FEV_1/FVC ratio remains normal. Restrictive defects occur in two broad kinds of conditions: (1) *chest wall disorders* (e.g., severe obesity, pleural diseases, kyphoscoliosis, and neuromuscular diseases such as poliomyelitis) and (2) *chronic interstitial and infiltrative diseases,* such as pneumoconioses and interstitial fibrosis.

OBSTRUCTIVE LUNG DISEASES

Common obstructive lung diseases include chronic obstructive pulmonary disease (COPD), asthma, and bronchiectasis (Table 15.3). COPD has two major clinicopathologic manifestations, emphysema and chronic bronchitis, which are often found together in the same patient, almost certainly because they share the same major etiologic factor—cigarette smoking. While asthma is distinguished from chronic bronchitis and emphysema by the presence of reversible bronchospasm, some patients with otherwise typical asthma also develop an irreversible component (Fig. 15.5). Conversely, some patients with otherwise typical COPD have a reversible component. Clinicians commonly label such patients as having COPD/asthma.

Chronic Obstructive Pulmonary Disease

COPD, a major public health problem, is defined by the World Health Organization (WHO) as "a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities caused by exposure to noxious particles or gases." It is currently the fourth

Table 15.3 Disorders Associated With Airflow Obstruction: The Spectrum of Chronic Obstructive Pulmonary Disease

Clinical Term	Anatomic Site	Major Pathologic Changes	Etiology	Signs/Symptoms
Chronic bronchitis	Bronchus	Mucous gland hyperplasia, hypersecretion	Tobacco smoke, air pollutants	Cough, sputum production
Bronchiectasis	Bronchus	Airway dilation and scarring	Persistent or severe infections	Cough, purulent sputum, fever
Asthma	Bronchus	Smooth muscle hyperplasia, excess mucus, inflammation	Immunologic or undefined causes	Episodic wheezing, cough, dyspnea
Emphysema	Acinus	Airspace enlargement; wall destruction	Tobacco smoke	Dyspnea
Small airways disease, bronchiolitis[a]	Bronchiole	Inflammatory scarring/obliteration	Tobacco smoke, air pollutants, miscellaneous	Cough, dyspnea

[a]Can be seen with any form of obstructive lung disease or as an isolated finding.

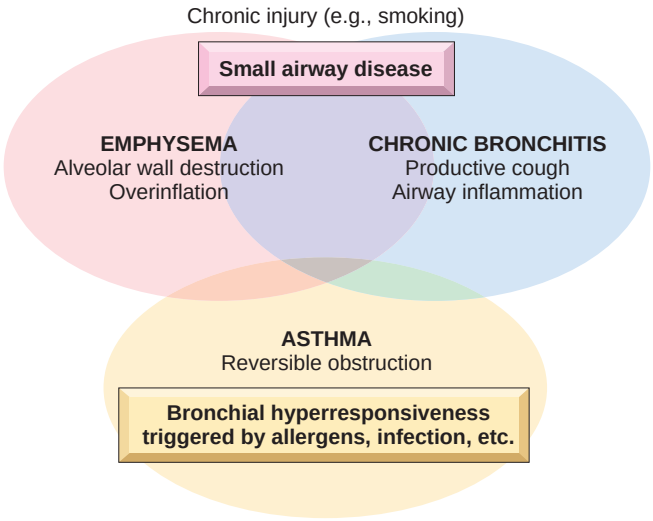

Figure 15.5 Schematic representation of overlap between chronic obstructive lung diseases.

leading cause of death in the world and is projected to rank third by 2020 due to increases in cigarette smoking in countries such as China. There is a strong association between heavy cigarette smoking and COPD. Overall, 35% to 50% of heavy smokers develop COPD; conversely about 80% of COPD is attributable to smoking. Women and African Americans who smoke heavily are more susceptible than other groups. Additional risk factors include poor lung development early in life, exposure to environmental and occupational pollutants, airway hyperresponsiveness, and certain genetic polymorphisms.

Recognizing that emphysema and chronic bronchitis often occur together in patients with COPD, it is still useful to discuss these patterns of lung injury and associated functional abnormalities individually to highlight the pathophysiologic basis of different causes of airflow obstruction. We will finish our discussion by returning to the clinical features of COPD.

Emphysema

Emphysema is defined by irreversible enlargement of the airspaces distal to the terminal bronchiole, accompanied by destruction of their walls. Subtle but functionally important small airway fibrosis (distinct from chronic bronchitis) is also present and is a significant contributor to airflow obstruction. Emphysema is classified according to its anatomic distribution within the lobule. Recall that the lobule is a cluster of acini, the terminal respiratory units. Based on the segments of the respiratory units that are involved, emphysema is subdivided into four major types: (1) *centriacinar,* (2) *panacinar,* (3) *paraseptal,* and (4) *irregular.* Of these, only the first two cause clinically significant airflow obstruction (Fig. 15.6).

- *Centriacinar (centrilobular) emphysema.* Centriacinar emphysema is the most common form, constituting more than 95% of clinically significant cases. It occurs predominantly in heavy smokers with COPD. In this type of emphysema the central or proximal parts of the acini, formed by respiratory bronchioles, are affected, whereas distal alveoli are spared (Figs. 15.6B and 15.7A). Thus, both emphysematous and normal airspaces exist within the same acinus and lobule. The lesions are more common and usually more pronounced in the upper lobes, particularly in the apical segments. In severe centriacinar emphysema, the distal acinus may also be involved, making differentiation from panacinar emphysema difficult.
- *Panacinar (panlobular) emphysema.* Panacinar emphysema is associated with *α1-antitrypsin deficiency* (Chapter 18) and is exacerbated by smoking. In this type the acini are uniformly enlarged from the level of the respiratory bronchiole to the terminal blind alveoli (Figs. 15.6C and 15.7B). In contrast to centriacinar emphysema, panacinar emphysema tends to occur more commonly in the lower zones and in the anterior margins of the lung, and it is usually most severe at the bases.
- *Distal acinar (paraseptal) emphysema.* Distal acinar emphysema probably underlies many cases of spontaneous pneumothorax in young adults. In this type the proximal portion of the acinus is normal, and the distal part is predominantly involved. The emphysema is more striking adjacent to the pleura, along the lobular connective tissue septa, and at the margins of the lobules. It occurs adjacent to areas of fibrosis, scarring, or atelectasis and is usually more severe in the upper half of the lungs. The characteristic finding is multiple enlarged airspaces, ranging from less than 0.5 cm to more than 2.0 cm in diameter, which sometimes form cyst-like structures.

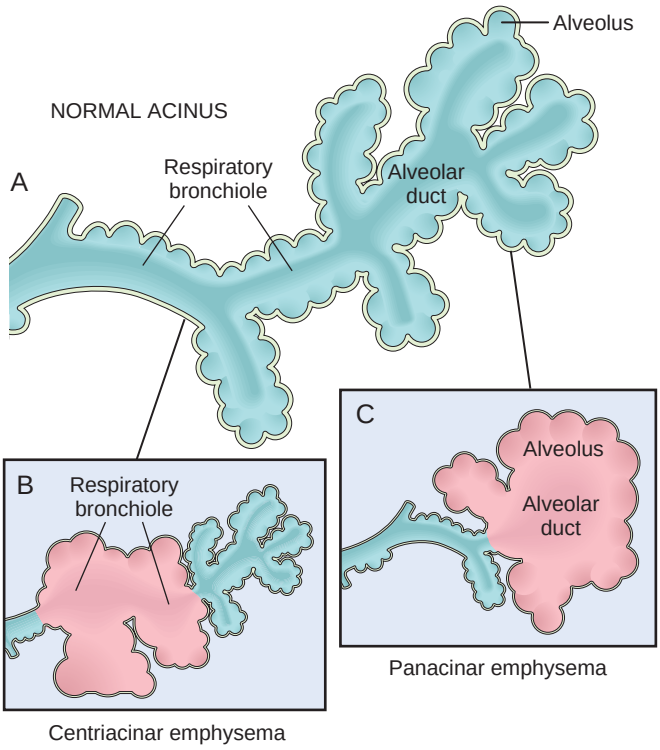

Figure 15.6 Clinically significant patterns of emphysema. (A) Structure of the normal acinus. (B) Centriacinar emphysema with dilation that initially affects the respiratory bronchioles. (C) Panacinar emphysema with initial distention of the alveolus and alveolar duct.

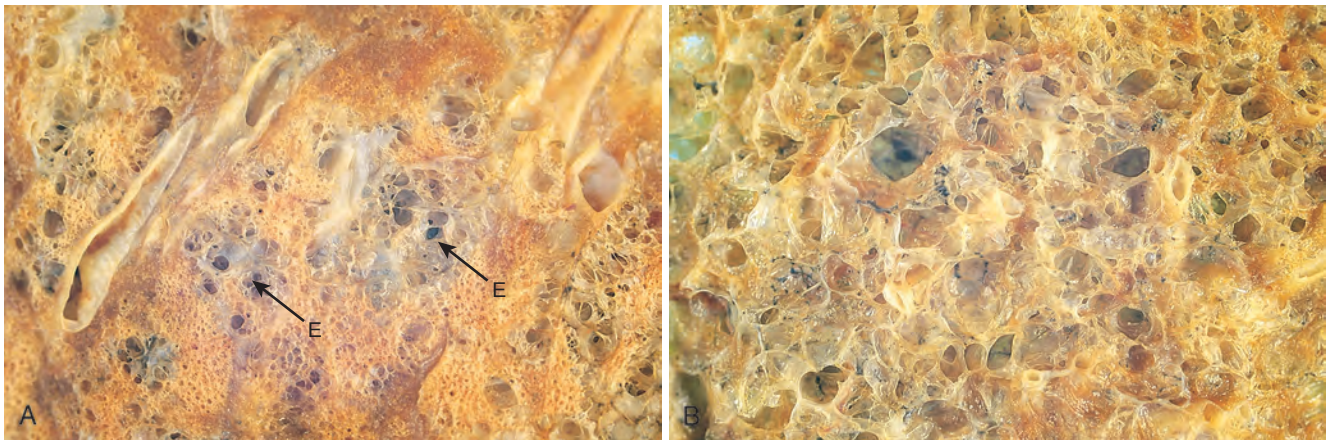

Figure 15.7 (A) Centriacinar emphysema. Central areas show marked emphysematous damage *(E)* surrounded by relatively spared alveolar spaces. (B) Panacinar emphysema involving the entire pulmonary lobule.

- *Airspace enlargement with fibrosis (irregular emphysema).* Irregular emphysema, so named because the acinus is irregularly involved, is almost invariably associated with scarring. In most instances it occurs in small foci and is clinically insignificant.

Pathogenesis

Clinically significant emphysema is largely confined to smokers and to patients with α_1-antitrypsin deficiency, highlighting the importance of these two etiologic factors. Mechanisms relating to these factors that contribute to the development of emphysema include the following (Fig. 15.8):

- *Toxic injury and inflammation.* Inhaled cigarette smoke and other noxious particles damage respiratory epithelium and cause inflammation, which results in variable degrees of parenchymal destruction. A wide variety of inflammatory mediators (including leukotriene B_4, interleukin [IL]-8, TNF, and others) are increased in the affected parts of the lung. These mediators are released by resident epithelial cells and macrophages and variously attract inflammatory cells from the circulation (chemotactic factors), amplify the inflammatory process (proinflammatory cytokines), and induce structural changes (growth factors). Chronic inflammation also leads to the accumulation of T and B cells in affected parts of the lung, but the role of adaptive immunity in emphysema is currently uncertain.
- *Protease-antiprotease imbalance.* Several proteases are released from the inflammatory cells and epithelial cells that break down connective tissue components. In patients who develop emphysema, there is a relative deficiency of protective antiproteases, which in some instances has a genetic basis (discussed later).
- *Oxidative stress.* Substances in tobacco smoke, alveolar damage, and inflammatory cells all produce oxidants, which may beget tissue damage, endothelial dysfunction, and inflammation. The role of oxidants is supported by studies of mice in which the *NRF2* gene is inactivated. NRF2 is a transcription factor that serves as a sensor for oxidants in many cell types including alveolar epithelial cells. Intracellular oxidants activate *NRF2,* which upregulates the expression of genes that protect cells from oxidant damage. Mice without *NRF2* are significantly more sensitive to tobacco smoke than normal mice, and genetic variants in *NRF2, NRF2* regulators, and *NRF2* target genes are all associated with smoking-related lung disease in humans.
- *Infection.* Although infection is not thought to play an initiating role in the tissue destruction, bacterial and/or viral infections may acutely exacerbate existing disease.

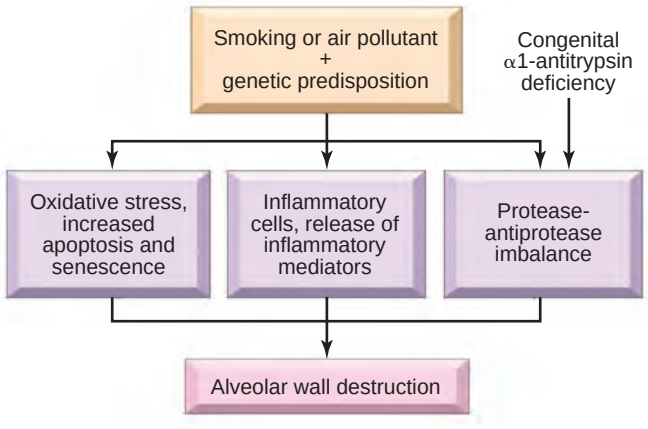

Figure 15.8 Pathogenesis of emphysema. See text for details.

The idea that proteases are important is based in part on the observation that patients with a genetic deficiency of the antiprotease α_1-antitrypsin have a markedly enhanced tendency to develop emphysema that is compounded by smoking. About 1% of all patients with emphysema have this defect. α_1-Antitrypsin, normally present in serum, tissue fluids, and macrophages, is a major inhibitor of proteases (particularly elastase) secreted by neutrophils during inflammation. It is encoded by the proteinase inhibitor *(Pi)* locus on chromosome 14. The *Pi* locus is polymorphic, and approximately 0.012% of the U.S. population is homozygous for the *Z* allele, a genotype associated with very low serum levels of α_1-antitrypsin. More than 80% of *ZZ* individuals develop symptomatic panacinar emphysema, which occurs at an earlier age and is of greater severity if the individual smokes. It is postulated that any injury (e.g., that induced by smoking) that increases the activation and influx of

neutrophils into the lung leads to local release of proteases, which in the absence of α_1-antitrypsin activity result in excessive digestion of elastic tissue and, with time, emphysema.

Several other genetic variants have also been linked to risk of emphysema. Among these are variants of the nicotinic acetylcholine receptor that are hypothesized to influence the addictiveness of tobacco smoke and thus the behavior of smokers. Not surprisingly, the same variants are also linked to lung cancer risk, emphasizing the importance of smoking in both of these diseases.

A number of factors contribute to airway obstruction in emphysema. Small airways are normally held open by the elastic recoil of the lung parenchyma. The loss of elastic tissue in the walls of alveoli that surround respiratory bronchioles reduces radial traction, leading to collapse of respiratory bronchioles during expiration and functional airflow obstruction in the absence of mechanical obstruction. In addition, even young smokers often have changes related to small airway inflammation that also contribute to airway narrowing and obstruction (described later).

MORPHOLOGY

Advanced emphysema produces voluminous lungs, often overlapping the heart anteriorly. Generally, in patients with smoking-related disease, the upper two-thirds of the lungs are more severely affected. Large alveoli can easily be seen on the cut surface of fixed lungs (see Fig. 15.7). Apical blebs or bullae characteristic of irregular emphysema may appear in patients with advanced disease.

Microscopically, abnormally large alveoli are separated by thin septa with focal centriacinar fibrosis. There is loss of attachments between alveoli and the outer wall of small airways. The pores of Kohn are so large that septa appear to be floating or protrude blindly into alveolar spaces with a club-shaped end. As alveolar walls are destroyed, there is a decrease in the capillary bed area. With advanced disease, there are even larger abnormal airspaces and possibly blebs or bullae, which often deform and compress the respiratory bronchioles and vasculature of the lung. Inflammatory changes in small airways are often superimposed (described next under chronic bronchitis), as are vascular changes related to pulmonary hypertension stemming from local hypoxemia and loss of capillary beds.

Chronic Bronchitis

Chronic bronchitis is defined clinically as persistent cough with sputum production for at least 3 months in at least 2 consecutive years in the absence of any other identifiable cause. Longstanding chronic bronchitis is associated with progressive lung dysfunction, which may be so severe as to lead to hypoxemia, pulmonary hypertension, and cor pulmonale.

Pathogenesis

The primary or initiating factor in the genesis of chronic bronchitis is exposure to noxious or irritating inhaled substances such as tobacco smoke (90% of those affected are smokers) and dust from grain, cotton, and silica. Several factors contribute to its pathogenesis.

- *Mucus hypersecretion.* The earliest feature of chronic bronchitis is hypersecretion of mucus in the large airways, associated with enlargement of the submucosal glands in the trachea and bronchi. The basis for mucus hypersecretion is incompletely understood, but it appears to involve inflammatory mediators such as histamine and IL-13. With time, there is also a marked increase in goblet cells in small airways—small bronchi and bronchioles—leading to excessive mucus production that contributes to airway obstruction. It is thought that both the enlargement of submucosal glands and the increase in numbers of goblet cells are protective reactions against tobacco smoke or other pollutants (e.g., sulfur dioxide and nitrogen dioxide).
- *Acquired cystic fibrosis transmembrane conductance regulator (CFTR) dysfunction.* There is substantial evidence that smoking leads to acquired CFTR dysfunction, which in turn causes the secretion of abnormal, dehydrated mucus that exacerbates the severity of chronic bronchitis.
- *Inflammation.* Inhalants that induce chronic bronchitis cause cellular damage, eliciting both acute and chronic inflammatory responses involving neutrophils, lymphocytes, and macrophages. Long-standing inflammation and accompanying fibrosis involving small airways (small bronchi and bronchioles, less than 2 to 3 mm in diameter) can also lead to chronic airway obstruction.
- *Infection.* Infection does not initiate chronic bronchitis, but is probably significant in maintaining it and may be critical in producing acute exacerbations.

Cigarette smoke predisposes to chronic bronchitis in several ways. Not only does it damage airway-lining cells, leading to chronic inflammation, but it also interferes with the ciliary action of the respiratory epithelium, preventing the clearance of mucus and increasing the risk of infection.

MORPHOLOGY

Grossly, there is hyperemia, swelling, and edema of the mucous membranes, frequently accompanied by excessive mucinous or mucopurulent secretions. Sometimes, heavy casts of secretions and pus fill the bronchi and bronchioles. The characteristic microscopic features are chronic inflammation of the airways (predominantly lymphocytes and macrophages); thickening of the bronchiolar wall due to smooth muscle hypertrophy, deposition of extracellular matrix in the muscle layer, and peribronchial fibrosis; goblet cell hyperplasia; and enlargement of the mucus-secreting glands of the trachea and bronchi. Of these, the most striking change is an increase in the size of the mucous glands. This increase can be assessed by the ratio of the thickness of the mucous gland layer to the thickness of the wall between the epithelium and the cartilage **(Reid index)**. The Reid index (normally 0.4) is increased in chronic bronchitis, usually in proportion to the severity and duration of the disease. The mucus plugging, inflammation, and fibrosis may lead to marked narrowing of bronchioles, and in the most severe cases, there may be obliteration of lumen due to fibrosis **(bronchiolitis obliterans)**. The bronchial epithelium may also exhibit squamous metaplasia and dysplasia due to the irritating and mutagenic effects of substances in tobacco smoke.

Clinical Features of COPD

Most affected patients have a smoking history of 40 pack-years or greater. COPD often presents insidiously with slowly

Table 15.4 Predominant Features of Emphysema and Chronic Bronchitis

	Bronchitis	Emphysema
Age, years	40–45	50–75
Dyspnea	Mild; late	Severe; early
Cough	Early; copious sputum	Late; scanty sputum
Infections	Common	Occasional
Respiratory insufficiency	Early, periodic	End-stage
Cor pulmonale	Common	Uncommon, end-stage
Airway resistance	Increased	Normal or slightly increased
Elastic recoil	Normal	Low
Chest radiograph	Prominent vessels; large heart size	Hyperinflation; normal heart size
Appearance	Blue bloater	Pink puffer

increasing dyspnea on exertion and chronic cough with sputum production, slight at first but increasing over time. Other patients present with exacerbations caused by superimposed infection that can lead to confusion with other disorders, such as asthma (due to wheezing). The most important diagnostic test is spirometry, which typically shows an FEV_1/FVC ratio of less than 0.7.

Once COPD appears, symptoms often wax and wane over time and are generally worse in the morning. The clinical picture varies according to the severity of the disease and the relative contributions of emphysematous and bronchitic changes (Table 15.4). At one extreme end of the spectrum lie "*pink puffers,*" patients in whom emphysema dominates. Classically, the patient is barrel-chested and dyspneic, with obviously prolonged expiration, sits forward in a hunched-over position, and breathes through pursed lips. Cough is often slight, overdistention of the lungs is severe, diffusion capacity is low, and blood gas values are relatively normal at rest. Weight loss is common and can be so severe as to suggest an occult cancer. At the other end lie patients with pure chronic bronchitis, ingloriously referred to as "*blue bloaters.*" Their cardinal symptom is a persistent cough productive of sputum, coupled with hypercapnia, hypoxemia, and mild cyanosis. Most patients are somewhere in the middle, with signs and symptoms stemming from both bronchitic and emphysematous changes.

Treatment options include smoking cessation, oxygen therapy, long-acting bronchodilators with inhaled corticosteroids, antibiotics, physical therapy, bullectomy, and, in selected patients, lung volume reduction surgery and lung transplantation. Even with intervention, however, COPD often progresses and frequently proves fatal. Long-standing COPD, particularly in patients with a bronchitic component, commonly leads to pulmonary hypertension, cor pulmonale, and death due to heart failure. Death may also result from acute respiratory failure due to acute infections superimposed on COPD. In patients with emphysematous changes, subpleural blebs may rupture, leading to fatal pneumothorax. The best hope for a major change in this dire picture is more effective programs aimed at prevention of smoking and other environmental exposures.

KEY CONCEPTS

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

- Most common in long-standing tobacco smokers (typically >40 pack-years); air pollutants also contribute.
- Underlying pulmonary pathology usually includes both chronic bronchitis and emphysema.
- Often fatal due to development of heart failure or of respiratory failure due to superimposed infection.

Emphysema

- In COPD, usually follows a centroacinar distribution characterized by permanent enlargement of airspaces distal to terminal bronchioles.
- Particularly severe in patients with α_1-antitrypsin deficiency, in which a panacinar pattern of emphysematous change may be seen.
- Tissue destruction is caused by elastases and oxidants released from inflammatory cells, particularly neutrophils, which are responding to cellular injury caused by tobacco smoke and pollutants.

Chronic Bronchitis

- Defined as persistent productive cough for at least 3 consecutive months in at least 2 consecutive years.
- Dominant pathologic features are mucus hypersecretion due to enlargement of mucus-secreting glands and chronic inflammation associated with bronchiolar wall fibrosis.

Other Forms of Emphysema

In addition to emphysema occurring in the setting of COPD, several other conditions may be associated with lung overinflation or focal emphysematous change and are mentioned here in brief.

- *Compensatory hyperinflation.* This term is used to designate dilation of alveoli in response to loss of lung substance elsewhere, for example, following surgical removal of a lung or lobe with cancer.
- *Obstructive overinflation.* In this condition the lung expands because air is trapped within it. A common cause is subtotal obstruction of an airway by a tumor or foreign object. In infants, it may be caused by *congenital lobar overinflation*, which most often results from hypoplasia of bronchial cartilage. Overinflation occurs either (1) because of an obstruction that acts as ball valve, allowing air to enter on inspiration while preventing its exodus on expiration, or (2) because collaterals bring in air behind the obstruction. These collaterals consist of the *pores of Kohn* and other direct accessory bronchioloalveolar connections (the *canals of Lambert*). Obstructive overinflation can be life-threatening if the affected portion distends sufficiently to compress the adjacent uninvolved lung.
- *Bullous emphysema.* This is a descriptive term for large subpleural blebs or bullae (spaces greater than 1 cm in diameter in the distended state) that can occur in any form of emphysema (Fig. 15.9), often near the apex. Rupture of the bullae may give rise to pneumothorax.
- *Interstitial emphysema.* Entrance of air into the connective tissue stroma of the lung, mediastinum, or subcutaneous

Figure 15.9 Bullous emphysema. Note the large subpleural bullae *(upper left)*.

tissue produces *interstitial emphysema.* In most instances, it is caused by alveolar tears that occur in patients with pulmonary emphysema due to transient increases in intra-alveolar pressure, for example, during coughing. Less commonly, chest wounds or fractured ribs that puncture the lung provide the portal for entrance of air into surrounding soft tissues.

Asthma

Asthma is a heterogeneous disease, usually characterized by chronic airway inflammation and variable expiratory airflow obstruction that produces symptoms such as wheezing, shortness of breath, chest tightness, and cough, which vary over time and in intensity. Symptomatic episodes are most likely to occur at night or in the early morning and are produced by bronchoconstriction that is at least partly reversible, either spontaneously or with treatment. Rarely, an unremitting attack called *acute severe asthma* (formerly known as *status asthmaticus*) may prove fatal; usually, such patients have a long history of asthma. Between the attacks, patients may be virtually asymptomatic. Of note, there has been a significant increase in the incidence of asthma in the Western world over the past 40 to 50 years, a trend that has now started to abate. However, the prevalence of asthma continues to increase in lower income countries and in some ethnic groups in which its prevalence was previously low.

Asthma has several distinct clinical phenotypes, each with different underlying pathogenic mechanisms. It may be categorized as *atopic* (evidence of allergen sensitization and immune activation, often in a patient with allergic rhinitis or eczema) or *nonatopic* (no evidence of allergen sensitization), of which several subtypes exist. In all types, episodes of bronchospasm may have diverse triggers, such as respiratory infections (especially viral infections), irritants (e.g., smoke, fumes), cold air, stress, and exercise. One biologically meaningful and clinically useful way to classify asthma is based on its triggers. We will first briefly describe the various major subtypes of asthma, and then will delve more deeply into its pathogenesis.

Atopic Asthma. This type of asthma is a classic example of an IgE-mediated (type I) hypersensitivity reaction (discussed in Chapter 6). The disease usually begins in childhood and is triggered by environmental allergens, such as dusts, pollens, cockroach or animal dander, and foods, which most frequently act in synergy with other proinflammatory environmental cofactors, most notably respiratory viral infections. A positive family history of asthma is common, and a skin test with the offending antigen in these patients results in an immediate wheal-and-flare reaction. Atopic asthma may also be diagnosed based on high total serum IgE levels or evidence of allergen sensitization by serum radioallergosorbent tests (RASTs), which can detect the presence of IgE antibodies that are specific for individual allergens.

Non-Atopic Asthma. Individuals with non-atopic asthma do not have evidence of allergen sensitization, and skin test results are usually negative. A positive family history of asthma is less common in these patients. Respiratory infections due to viruses (e.g., rhinovirus, parainfluenza virus, and respiratory syncytial virus) are common triggers in non-atopic asthma. Inhaled air pollutants such as tobacco smoke, sulfur dioxide, ozone, and nitrogen dioxide may also contribute to the chronic airway inflammation and hyperreactivity in some cases. As already mentioned, in some instances attacks may be triggered by seemingly innocuous events, such as exposure to cold and even exercise.

Drug-Induced Asthma. Several pharmacologic agents provoke asthma. Aspirin-sensitive asthma is an uncommon type, occurring in individuals with recurrent rhinitis and nasal polyps. These individuals are exquisitely sensitive to small doses of aspirin as well as other non-steroidal anti-inflammatory medications, and they experience not only asthmatic attacks but also urticaria. Aspirin and related drugs trigger asthma in these patients by inhibiting the cyclooxygenase pathway of arachidonic acid metabolism, leading to a rapid decrease in prostaglandin E_2. Normally prostaglandin E_2 inhibits enzymes that generate proinflammatory mediators such as leukotrienes B_4, C_4, D_4, and E_4, which are believed to have central roles in aspirin-induced asthma.

Occupational Asthma. This form of asthma may be triggered by fumes (epoxy resins, plastics), organic and chemical dusts (wood, cotton, platinum), gases (toluene), or other chemicals (formaldehyde, penicillin products). Only minute quantities of chemicals are required to induce the attack, which usually occurs after repeated exposure. The

underlying mechanisms vary according to stimulus and include type I reactions, direct liberation of bronchoconstrictor substances, and hypersensitivity responses of unknown origin.

Pathogenesis

Atopic asthma, the most common form of the disease, is caused by a Th2-mediated IgE response to environmental allergens in genetically predisposed individuals. Airway inflammation is central to the disease pathophysiology and causes airway dysfunction partly through the release of potent inflammatory mediators and partly through remodeling of the airway wall. As the disease becomes more severe, there is increased local secretion of growth factors, which induce mucous gland enlargement, smooth muscle proliferation, angiogenesis, and fibrosis. Varying combinations of these processes help explain the different asthma subtypes, their response to treatment, and their natural history over a person's lifetime.

The contributions of the immune response, genetics, and environment are discussed separately below, although they are closely intertwined.

Th2 Responses, IgE, and Inflammation. **A fundamental abnormality in asthma is an exaggerated Th2 response to normally harmless environmental antigens** (Fig. 15.10). Th2 cells secrete cytokines that promote inflammation and stimulate B cells to produce IgE and other antibodies. These cytokines include IL-4, which stimulates the production of IgE; IL-5, which activates locally recruited eosinophils; and IL-13, which stimulates mucus secretion from bronchial submucosal glands and also promotes IgE production by B cells. The T cells and epithelial cells secrete chemokines that recruit more T cells and eosinophils, thus exacerbating the reaction. As in other allergic reactions (Chapter 6), IgE binds to the Fc receptors on submucosal mast cells, and repeat exposure to the allergen triggers the mast cells to release granule contents and produce cytokines and other mediators, which collectively induce the early-phase (immediate hypersensitivity) reaction and the late-phase reaction.

The early-phase reaction is dominated by bronchoconstriction, increased mucus production, variable degrees of vasodilation, and increased vascular permeability. Bronchoconstriction is triggered by direct stimulation of subepithelial vagal (parasympathetic) receptors through both central and local reflexes triggered by mediators produced by mast cells and other cells in the reaction. The late-phase reaction is dominated by recruitment of leukocytes, notably eosinophils, neutrophils, and more T cells. Although Th2 cells are the dominant T-cell type involved in the disease, other T cells that contribute to the inflammation include Th17 (IL-17 producing) cells, which recruit neutrophils.

Many mediators produced by leukocytes and epithelial cells have been implicated in the asthmatic response. The long list of "suspects" in acute asthma can be ranked based on the clinical efficacy of pharmacologic intervention with antagonists of specific mediators.

- Mediators whose role in bronchospasm is clearly supported by efficacy of pharmacologic intervention are (1) *leukotrienes* C_4, D_4, and E_4, which cause prolonged bronchoconstriction as well as increased vascular permeability and increased mucus secretion; (2) *acetylcholine,* released from intrapulmonary parasympathetic nerves, which can cause airway smooth muscle constriction by directly stimulating muscarinic receptors; (3) *IL-5,* antagonists of which are effective in treating severe forms of asthma that are associated with peripheral blood eosinophilia; and (4) *galectin-10* (GAL10), which is released from eosinophils and forms crystals known as *Charcot-Leyden crystals*. Long recognized as a feature of asthma, recent studies have shown that these crystals are strong inducers of inflammation and mucus production.
- A second group of agents are present at the "scene of the crime" but seem to have relatively minor contributions on the basis of lack of efficacy of potent antagonists or synthesis inhibitors. These include (1) *histamine,* a potent bronchoconstrictor; (2) *prostaglandin* D_2, which elicits bronchoconstriction and vasodilation; and (3) *platelet-activating factor,* which causes aggregation of platelets and release of serotonin from their granules. These mediators might yet prove important in certain types of chronic or non-allergic asthma.
- Finally, a large third group comprises "suspects" for whom specific antagonists or inhibitors are not available or have been insufficiently studied as yet. These include IL-4, IL-13, TNF, chemokines (e.g., eotaxin, also known as CCL11), neuropeptides, nitric oxide, bradykinin, and endothelins.

It is thus clear that multiple mediators contribute to the acute asthmatic response. Moreover, the composition of this "mediator soup" likely varies among individuals or different types of asthma. The appreciation of the importance of inflammatory cells and mediators in asthma has led to greater emphasis on anti-inflammatory drugs, such as corticosteroids, in its treatment.

Genetic Susceptibility. Susceptibility to atopic asthma is multigenic and often associated with increased incidence of other allergic disorders, such as allergic rhinitis (hay fever) and eczema. Genetic polymorphisms linked to asthma and other allergic disorders were described in Chapter 6. Suffice it to say here that many of these are likely to influence immune responses and the subsequent inflammatory reaction. Some of the stronger or more interesting genetic variants associated with asthma include the following:

- A susceptibility locus for asthma located on chromosome 5q, near the gene cluster encoding the cytokines IL-3, IL-4, IL-5, IL-9, and IL-13 and the IL-4 receptor. Among the genes in this cluster, polymorphisms in the *IL13* gene have the strongest and most consistent associations with asthma or allergic disease, while IL-4 receptor gene variants are associated with atopy, elevated total serum IgE, and asthma.
- Particular class II HLA alleles linked to production of IgE antibodies against some antigens, such as ragweed pollen.
- Variants associated with the genes encoding IL-33, a member of the IL-1 family of cytokines, and its receptor, ST2, which induce the production of Th2 cytokines.
- Variants associated with the gene encoding thymic stromal lymphopoietin (TSLP), a cytokine produced by epithelium that may have a role in initiating allergic reactions.

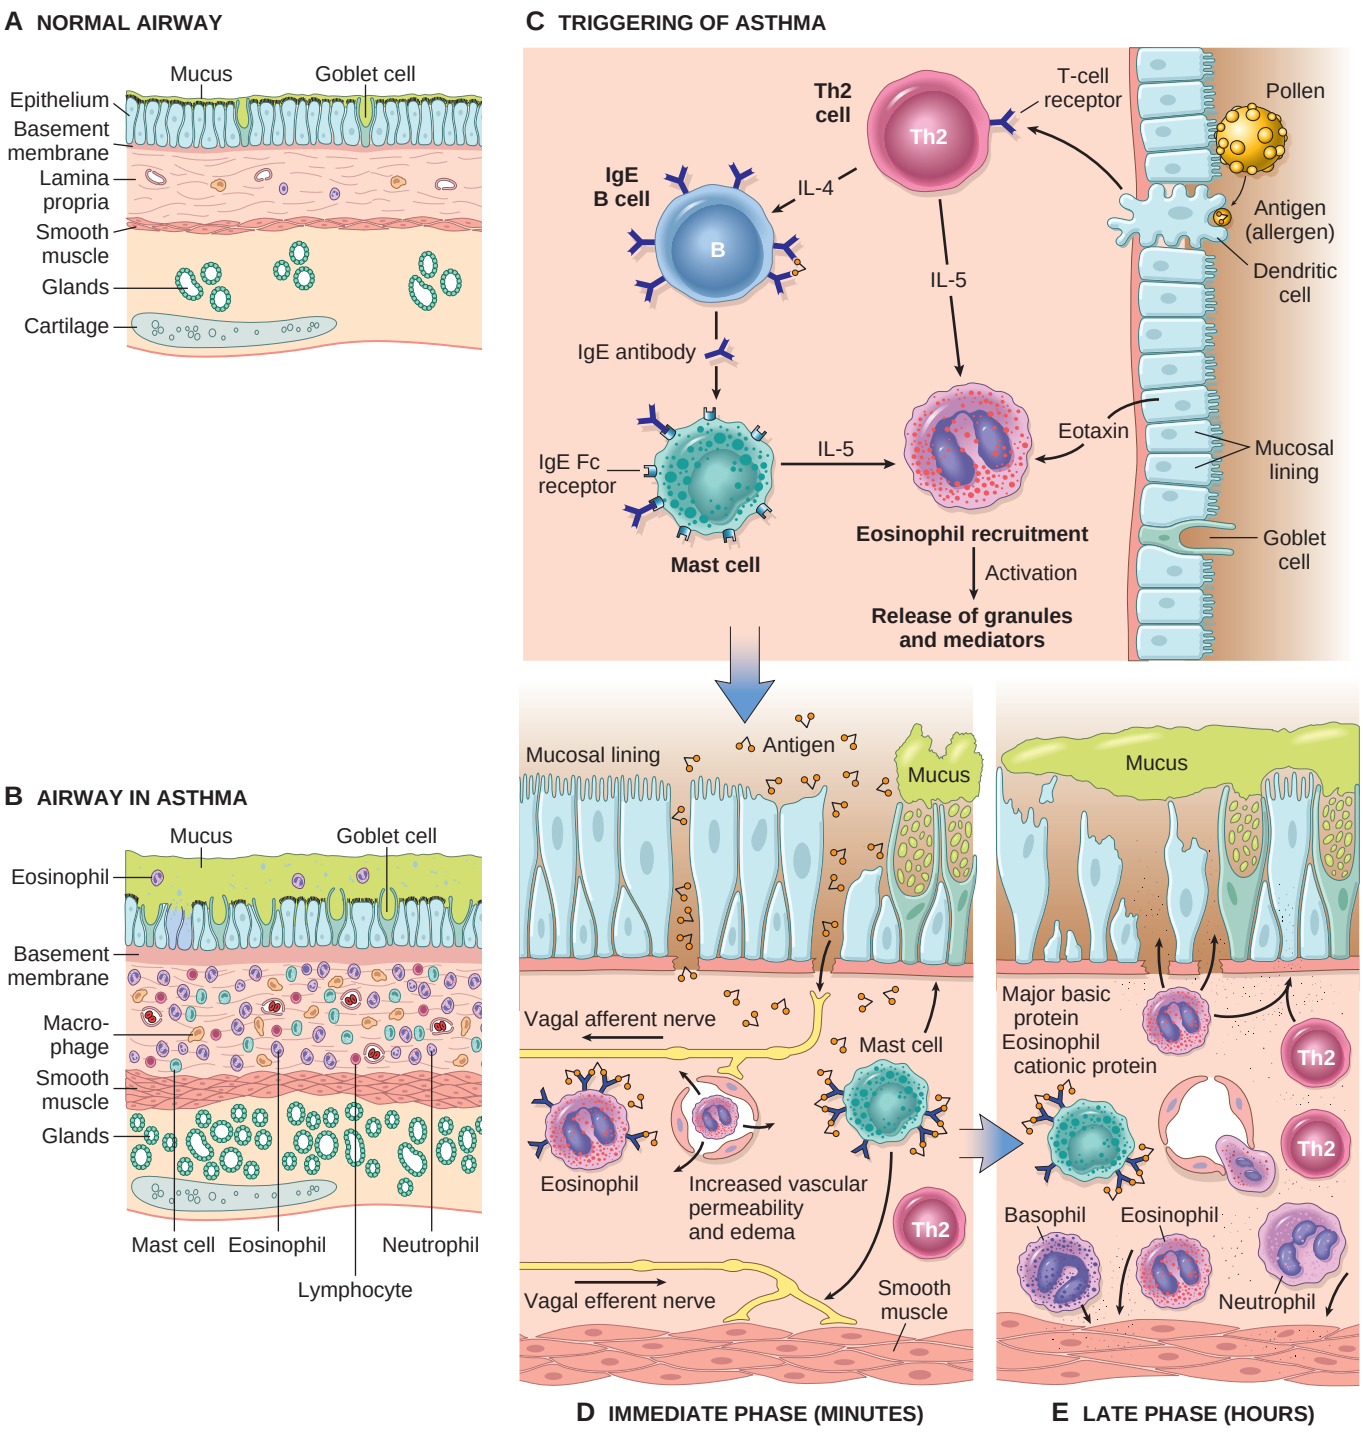

Figure 15.10 (A and B) Comparison of a normal airway and an airway involved by asthma. The asthmatic airway is marked by accumulation of mucus in the bronchial lumen secondary to an increase in the number of mucus-secreting goblet cells in the mucosa and hypertrophy of submucosal glands; intense chronic inflammation due to recruitment of eosinophils, macrophages, and other inflammatory cells; thickened basement membrane; and hypertrophy and hyperplasia of smooth muscle cells. (C) Inhaled allergens (antigen) elicit a Th2-dominated response favoring IgE production and eosinophil recruitment. (D) On re-exposure to antigen, the immediate reaction is triggered by antigen-induced cross-linking of IgE bound to Fc receptors on mast cells. These cells release preformed mediators that directly and via neuronal reflexes induce bronchospasm, increased vascular permeability, mucus production, and recruitment of leukocytes. (E) Leukocytes recruited to the site of reaction (neutrophils, eosinophils, and basophils; lymphocytes and monocytes) release additional mediators that initiate the late phase reaction. Several factors released from eosinophils (e.g., major basic protein, eosinophil cationic protein) also cause damage to the epithelium. *IL-5,* Interleukin-5.

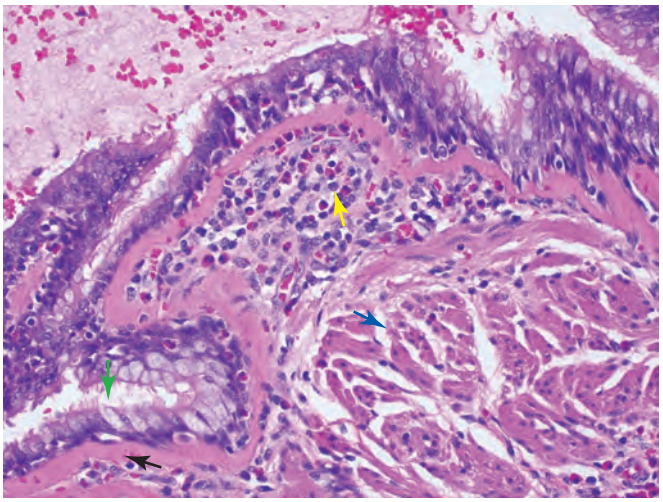

Figure 15.11 Bronchus from an asthmatic patient showing goblet cell hyperplasia *(green arrow)*, sub–basement membrane fibrosis *(black arrow)*, eosinophilic inflammation *(yellow arrow)*, and muscle hypertrophy *(blue arrow)*.

Environmental Factors. Asthma is a disease of industrialized societies where the majority of people live in cities. Two ideas, neither wholly satisfying, have been proposed to explain this association. First, industrialized environments contain many airborne pollutants that can serve as allergens to initiate the Th2 response. Second, city life tends to limit the exposure of very young children to certain antigens, particularly microbial antigens, and exposure to such antigens may protect children from asthma and atopy. The idea that microbial exposure during early life reduces the later incidence of allergic (and some autoimmune) diseases has been popularized as the hygiene hypothesis. Although the underlying mechanisms of this protective effect are unclear, it has spurred trials of probiotics and intentional early exposure of children to putative allergens to decrease their risk of later developing allergies.

Infections do not cause asthma by themselves, but may be important co-factors. Young children with aeroallergen sensitization who develop lower respiratory tract viral infections (rhinovirus type C, respiratory syncytial virus) have a 10- to 30-fold increased risk of developing persistent and/or severe asthma. Both viral and bacterial infections (identified by cultures and non-culture tools) are associated with acute exacerbations of the disease.

Over time, repeated bouts of allergen exposure and immune reactions result in structural changes in the bronchial wall, referred to as *airway remodeling*. These changes, described later in greater detail, include hypertrophy and hyperplasia of bronchial smooth muscle, epithelial injury, increased airway vascularity, subepithelial mucous gland enlargement, and subepithelial fibrosis.

A small subset of patients with asthma, many of whom have severe disease that is refractory to glucocorticoids, has inflammatory infiltrates that are enriched for neutrophils rather than eosinophils. This form of the disease may be driven by a Th17 T-cell response to chronic bacterial colonization of the lung.

MORPHOLOGY

In patients dying of acute severe asthma (status asthmaticus), the lungs are overinflated and contain small areas of atelectasis. The most striking gross finding is occlusion of bronchi and bronchioles by thick, tenacious mucus plugs, which often contain shed epithelium. A characteristic finding in sputum or bronchoalveolar lavage specimens of patients with atopic asthma is **Curschmann spirals,** which may result from extrusion of mucus plugs from subepithelial mucous gland ducts or bronchioles. Also present are numerous eosinophils and **Charcot-Leyden crystals** composed of the eosinophil-derived protein galectin-10. The other characteristic histologic findings of asthma, collectively called **airway remodeling** (Figs. 15.10B and 15.11), include:

- Thickening of airway wall
- Sub–basement membrane fibrosis (due to deposition of type I and III collagens)
- Increased vascularity
- Increase in the size of the submucosal glands and number of airway goblet cells
- Hypertrophy and/or hyperplasia of the bronchial wall muscle with increased extracellular matrix

While acute airflow obstruction is primarily attributed to muscular bronchoconstriction, acute edema, and mucus plugging, airway remodeling may contribute to chronic irreversible airway obstruction.

Clinical Features

A classic acute asthmatic attack lasts up to several hours. In some patients, however, the cardinal symptoms of chest tightness, dyspnea, wheezing, and coughing (with or without sputum production) are present at a low level constantly. In its most severe form, acute severe asthma, the paroxysm persists for days or even weeks, sometimes causing airflow obstruction that is so extreme that marked cyanosis or even death ensues.

The diagnosis is based on demonstration of an increase in airflow obstruction (from baseline levels); difficulty with exhalation (prolonged expiration, wheeze); and (in those with atopic asthma) identification of eosinophilia in the peripheral blood and eosinophils, Curschmann spirals, and Charcot-Leyden crystals in the sputum. In the usual case with intervals of freedom from respiratory difficulty, the disease is more discouraging and disabling than lethal, and most individuals are able to maintain a productive life.

Therapy is based on the severity of the disease. The centerpieces of standard therapy are bronchodilators, glucocorticoids, and leukotriene antagonists. For severe and difficult-to-treat asthma in adolescents and adults, novel biologic therapies targeting inflammatory mediators such as IL-5 blocking antibodies, which is effective in severe asthma associated with Th2 immune responses and peripheral blood eosinophilia, are now available. Up to 50% of childhood asthma remits in adolescence only to return in adulthood in a significant number of patients. In other cases there is a variable decline in baseline lung function over time.

KEY CONCEPTS

ASTHMA

- Asthma is characterized by reversible bronchoconstriction caused by airway hyperresponsiveness to a variety of stimuli.
- Atopic asthma is caused by a Th2 and IgE-mediated immunologic reaction to environmental allergens and is characterized by acute-phase (immediate) and late-phase reactions. The Th2 cytokines IL-4, IL-5, and IL-13 are important mediators.
- Triggers for non-atopic asthma are less clear but include viral infections and inhaled air pollutants, which can also trigger atopic asthma.
- Eosinophils are key inflammatory cells in atopic asthma; other inflammatory cells implicated in its pathogenesis include mast cells, neutrophils, and T lymphocytes.
- Airway remodeling (sub–basement membrane fibrosis, hypertrophy of bronchial glands, and smooth muscle hyperplasia) adds an irreversible component to the obstructive disease.

Bronchiectasis

Bronchiectasis is a disorder in which destruction of smooth muscle and elastic tissue by inflammation stemming from persistent or severe infections leads to permanent dilation of bronchi and bronchioles. Because of better control of lung infections, bronchiectasis is now uncommon, but may still develop in association with the following:

- *Congenital or hereditary conditions that predispose to chronic infections,* including cystic fibrosis, intralobar sequestration of the lung, immunodeficiency states, primary ciliary dyskinesia, and Kartagener syndrome.
- *Severe necrotizing pneumonia* caused by bacteria, viruses, or fungi; this may be a single severe episode or recurrent infections.
- *Bronchial obstruction,* due to tumor, foreign body, or mucus impaction; in each instance the bronchiectasis is localized to the obstructed lung segment.
- *Immune disorders,* including rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, and the posttransplant setting (chronic rejection after lung transplant and chronic graft-versus-host disease after hematopoietic stem cell transplantation).
- Up to 50% of cases are *idiopathic,* lacking the aforementioned associations, in which there appears to be dysfunctional host immunity to infectious agents leading to chronic inflammation.

Pathogenesis

Obstruction and infection are the major conditions associated with bronchiectasis. **The infections that lead to bronchiectasis are usually the result of a defect in airway clearance.** Sometimes this defect stems from airway obstruction, leading to distal pooling of secretions.

Both mechanisms are readily apparent in a severe form of bronchiectasis that is associated with cystic fibrosis (Chapter 10). In cystic fibrosis the primary defect in ion transport results in thick viscous secretions that perturb mucociliary clearance and lead to airway obstruction. This sets the stage for chronic bacterial infections, which cause widespread damage to airway walls. With destruction of supporting smooth muscle and elastic tissue, the bronchi become markedly dilated, while smaller bronchioles are progressively obliterated as a result of fibrosis (bronchiolitis obliterans).

Primary ciliary dyskinesia is an autosomal recessive disease with a frequency of 1 in 10,000 to 20,000 births. The disease-causing mutations result in ciliary dysfunction due to defects in ciliary motor proteins (e.g., mutations involving dynein), again preventing mucociliary clearance, setting the stage for recurrent infections that lead to bronchiectasis. Ciliary function also is necessary during embryogenesis to ensure proper rotation of the developing organs in the chest and abdomen; in its absence, their location becomes a matter of chance. As a result, approximately half of patients with primary ciliary dyskinesia have *Kartagener syndrome,* marked by situs inversus or a partial lateralizing abnormality associated with bronchiectasis and sinusitis. Males with this condition also tend to be infertile as a result of sperm dysmotility.

Allergic bronchopulmonary aspergillosis occurs in patients with asthma or cystic fibrosis and frequently leads to the development of bronchiectasis. It is a hyperimmune response to the fungus *Aspergillus fumigatus.* Sensitization to *Aspergillus* leads to activation of Th2 helper T cells, which release cytokines that recruit eosinophils and other leukocytes. Characteristically, there are high serum IgE levels, serum antibodies to *Aspergillus,* intense airway inflammation with eosinophils, and formation of mucus plugs, which play a primary role in the development of bronchiectasis.

MORPHOLOGY

Bronchiectasis usually affects the lower lobes bilaterally, particularly air passages that are vertical, and is most severe in the more distal bronchi and bronchioles. When tumor or aspiration of foreign bodies leads to bronchiectasis, the involvement is localized. **The airways are dilated, sometimes up to four times normal size.** Characteristically, the bronchi and bronchioles are so dilated that they can be followed almost to the pleural surfaces. By contrast, in the normal lung, the bronchioles cannot be followed by eye beyond a point 2 to 3 cm from the pleural surfaces. On the cut surface of the lung, the dilated bronchi appear cystic and are filled with mucopurulent secretions (Fig. 15.12).

The histologic findings vary with the activity and chronicity of the disease. In the full-blown, active case there is an intense acute and chronic inflammatory exudation within the walls of the bronchi and bronchioles, associated with desquamation of the lining epithelium and extensive ulceration. There also may be squamous metaplasia of the remaining epithelium in response to chronic inflammation, further diminishing mucociliary clearance. In some instances, necrosis destroys the bronchial or bronchiolar walls and forms a lung abscess. Fibrosis of the bronchial and bronchiolar walls and peribronchiolar fibrosis develop in more chronic cases, leading to varying degrees of subtotal or total obliteration of bronchiolar lumens.

Haemophilus influenzae is found in approximately half and *Pseudomonas aeruginosa* in 12% to 30% of sputum cultures from patients with bronchiectasis, with four other types of bacteria

Figure 15.12 Bronchiectasis in a patient with cystic fibrosis, who underwent lung transplantation. Cut surface of lung shows markedly distended peripheral bronchi filled with mucopurulent secretions.

(including non-tuberculous mycobacteria) making up most of the remaining cases in patients from different geographic locations. This observation suggests that the inflamed, mucoid, sometimes anaerobic, bronchiectatic microenvironment favors colonization by a relatively few microbial species. In allergic bronchopulmonary aspergillosis, fungal hyphae can be seen on special stains within the mucoinflammatory contents of the dilated segmental bronchi. In late stages the fungus may infiltrate the bronchial wall.

Clinical Features

Bronchiectasis causes severe, persistent cough; expectoration of foul smelling, sometimes bloody sputum; dyspnea and orthopnea in severe cases; and, on occasion, hemoptysis, which may be massive. Symptoms are often episodic and are precipitated by upper respiratory tract infections or the introduction of new pathogenic agents. Paroxysms of cough are particularly frequent when the patient rises in the morning, as the change in position causes collections of pus and secretions to drain into the bronchi. Obstructive respiratory insufficiency can lead to marked dyspnea and cyanosis. However, current treatments with better antibiotics and physical therapy have improved outcomes considerably, and life expectancy has almost doubled. Hence, cor pulmonale, brain abscesses, and amyloidosis are less frequent complications of bronchiectasis currently than in the past.

CHRONIC DIFFUSE INTERSTITIAL (RESTRICTIVE) DISEASES

Restrictive lung disorders fall into two general categories: (1) *chronic interstitial and infiltrative diseases,* such as pneumoconioses and interstitial fibrosis of unknown etiology, and (2) *chest wall disorders* (e.g., neuromuscular diseases such as poliomyelitis, severe obesity, pleural diseases, and kyphoscoliosis), which are not discussed here.

Chronic interstitial pulmonary diseases are a heterogeneous group of disorders characterized predominantly by inflammation and fibrosis of the lung interstitium associated with pulmonary function studies indicative of restrictive lung disease. Diffuse restrictive diseases are categorized based on histology and clinical features (Table 15.5). Many of the entities are of unknown cause and pathogenesis, and some have an intra-alveolar as well as an interstitial component. Patients have dyspnea, tachypnea, end-inspiratory crackles, and eventual cyanosis, without wheezing or other evidence of airway obstruction. The classic functional abnormalities are reductions in diffusion capacity, lung volume, and lung compliance. Chest radiographs show bilateral lesions that take the form of small nodules, irregular lines, or *ground-glass shadows,* all corresponding to areas of interstitial fibrosis. Although the entities can often be distinguished in their early stages, advanced forms are hard to differentiate because all result in diffuse scarring of the lung, often referred to as *end-stage lung* or *honeycomb lung*. Eventually, secondary pulmonary hypertension and right-sided heart failure (cor pulmonale) may result.

Fibrosing Diseases

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (IPF) refers to a clinicopathologic syndrome marked by progressive interstitial pulmonary fibrosis and respiratory failure. In Europe the

term *cryptogenic fibrosing alveolitis* is more popular. IPF has characteristic radiologic, pathologic, and clinical features. The histologic pattern of fibrosis is referred to as usual interstitial pneumonia (UIP), which can often be diagnosed based on its characteristic appearance on computed tomography scans. The UIP pattern can also be seen in other diseases, notably connective tissue diseases, chronic hypersensitivity pneumonia, and asbestosis; these must be distinguished from IPF based on other clinical, laboratory, and histologic features.

Pathogenesis

While the cause of IPF remains unknown, it appears that it arises in genetically predisposed individuals who are prone to aberrant repair of recurrent alveolar epithelial cell injuries caused by environmental exposures (Fig. 15.13). The implicated factors are as follows:

- *Environmental factors.* Most important among these is cigarette smoking, which increases the risk of IPF several-fold. IPF incidence is also increased in individuals who are exposed to air pollution, microaspiration, metal fumes, and wood dust, or who work in certain occupations, including farming, hairdressing, and stone polishing. It is hypothesized that exposure to environmental irritants or toxins in each of these contexts causes recurrent alveolar epithelial cell damage.
- *Genetic factors.* The vast majority of individuals who smoke or who have other environmental exposures linked to IPF do not develop the disorder, indicating that additional factors are required for its development. Mutations in the *TERT, TERC, PARN,* and *RTEL1* genes, all of which are involved with the maintenance of telomeres, are associated with increased risk of IPF. You will recall that maintenance of telomeres (the ends of chromosomes) is necessary to prevent cellular senescence. Up to 15% of familial IPF is associated with inherited defects in genes that maintain telomeres, while up to 25% of sporadic IPF cases are associated with abnormal telomere shortening in peripheral blood lymphocytes, a finding that also points to a problem with telomere maintenance. Other, rare familial forms of IPF are associated with mutations in genes encoding components of surfactant; these mutations create folding defects in the affected proteins, leading to activation of the unfolded protein response in type II pneumocytes. This in turn appears to make pneumocytes more sensitive to environmental insults, leading to cellular dysfunction and injury. Finally, roughly one-third of IPF cases are associated with a single-nucleotide polymorphism in the promoter of the *MUC5B* gene that greatly increases the secretion of MUC5B, a member of the mucin family. This may in turn alter mucociliary clearance, but precisely how this alteration relates to IPF risk is uncertain.
- *Age.* IPF is a disease of older individuals, rarely appearing before the age of 50 years. Whether this association stems from aging-related telomere shortening or from other acquired changes associated with aging is unknown.

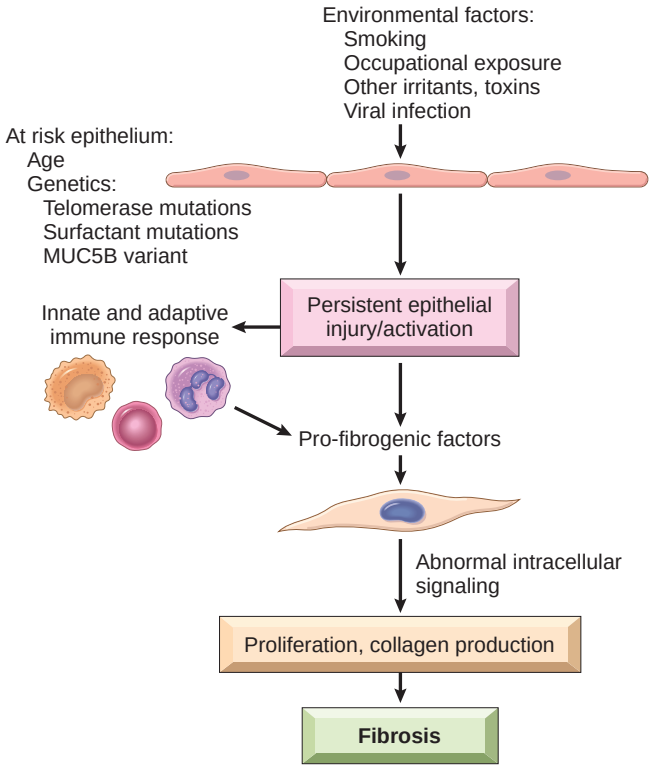

Figure 15.13 Proposed pathogenic mechanisms in idiopathic pulmonary fibrosis. Environmental factors that are potentially injurious to alveolar epithelium interact with genetic or aging-related factors that place epithelium at risk, creating a persistent epithelial injury. Factors secreted from injured/activated epithelium, possibly augmented by factors released from innate and adaptive immune cells responding to "danger" signals produced by damaged epithelium, activate interstitial fibroblasts. There is some evidence that these activated fibroblasts exhibit signaling abnormalities that lead to increased signaling through the PI3K/AKT pathway. The activated fibroblasts synthesize and deposit collagen, leading to interstitial fibrosis and eventual respiratory failure.

It is easy to imagine how some of the factors cited herein might combine to exacerbate alveolar epithelial cell damage and senescence, which seems to be the initiating event in IPF, but it must be admitted that the pathogenesis of IPF is complex and poorly understood. For example, it is unknown precisely how alveolar epithelial cell damage translates into interstitial fibrosis. One model holds that the injured epithelial cells are the source of profibrogenic factors such as TGF-β, whereas a second, non–mutually exclusive model proposes that innate and adaptive immune cells produce such factors as part of the host response to epithelial cell damage. Other work has described abnormalities in the fibroblasts themselves that involve changes in intracellular signaling and features reminiscent of epithelial mesenchymal transition (Chapter 7), but a causal link between these alterations and fibrosis has not been established.

MORPHOLOGY

Grossly, the pleural surfaces of the lung are cobblestoned as a result of the retraction of scars along the interlobular septa. The cut surface shows firm, rubbery white areas of fibrosis, which occurs preferentially in the lower lobes, the **subpleural regions,** and along the **interlobular septa.** Microscopically, the hallmark is **patchy interstitial fibrosis,** which varies in intensity (Fig. 15.14) and age. The earliest lesions contain an exuberant proliferation of fibroblasts **(fibroblastic foci).** With time these areas become more fibrotic and less cellular. Quite typical is the

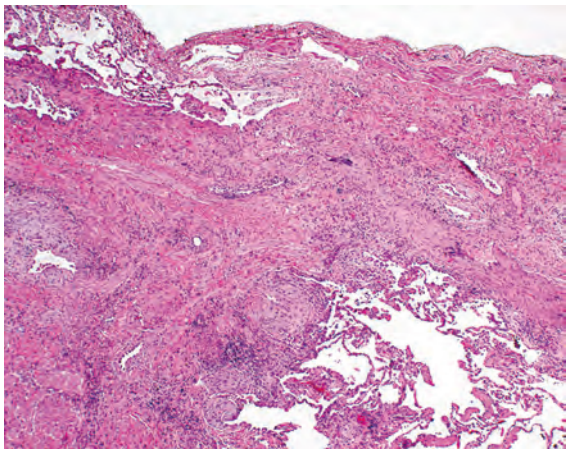

Figure 15.14 Usual interstitial pneumonia. The fibrosis is more pronounced in the subpleural region. (Courtesy Dr. Nicole Cipriani, Department of Pathology, University of Chicago, Chicago, Ill.)

coexistence of both early and late lesions (Fig. 15.15). The dense fibrosis causes the destruction of alveolar architecture and the formation of cystic spaces lined by hyperplastic type II pneumocytes or bronchiolar epithelium **(honeycomb fibrosis)**. With adequate sampling, these diagnostic histologic changes (i.e., areas of dense fibrosis and fibroblastic foci) can be identified even in advanced IPF. There is mild to moderate inflammation within the fibrotic areas, consisting of mostly lymphocytes admixed with a few plasma cells, neutrophils, eosinophils, and mast cells. Foci of squamous metaplasia and smooth muscle hyperplasia may be present, along with pulmonary arterial hypertensive changes (intimal fibrosis and medial thickening). In acute exacerbations, DAD may be superimposed on these chronic changes.

Clinical Features

IPF begins insidiously with gradually increasing dyspnea on exertion and dry cough. Most patients are 55 to 75 years old at presentation. Hypoxemia, cyanosis, and clubbing occur late in the course. The course in individual patients is unpredictable. Usually there is slowly progressive respiratory failure, but some patients have acute exacerbations and follow a rapid downhill clinical course. The median survival is about 3.8 years after diagnosis. Lung transplantation is the only definitive therapy; however, two drugs, a tyrosine kinase inhibitor and a TGF-β antagonist, have both been shown to slow disease progression and represent the first effective (albeit modestly so) targeted therapies for IPF.

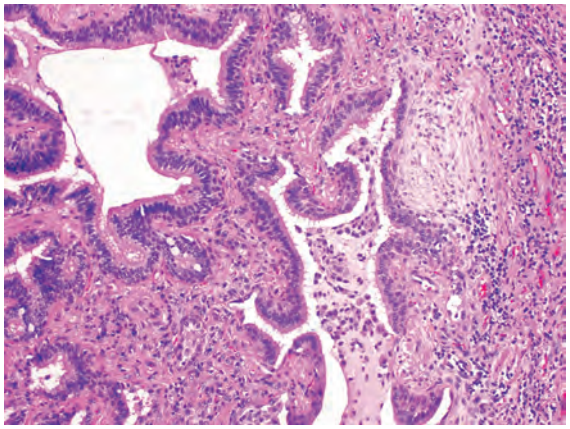

Figure 15.15 Usual interstitial pneumonia. Fibroblastic focus with fibers running parallel to surface and bluish myxoid extracellular matrix. Honeycombing is present on the left.

Nonspecific Interstitial Pneumonia

Despite its "nonspecific" name, this entity is important to recognize, since these patients have a much better prognosis than patients with UIP. Nonspecific interstitial pneumonia is most often associated with connective tissue disease but may also be idiopathic.

MORPHOLOGY

On the basis of its histology, nonspecific interstitial pneumonia is divided into cellular and fibrosing patterns. The cellular pattern consists primarily of mild to moderate chronic interstitial inflammation, containing lymphocytes and a few plasma cells, in a uniform or patchy distribution. The fibrosing pattern consists of diffuse or patchy interstitial fibrotic lesions of roughly the same stage of development, an important distinction from UIP. Fibroblastic foci, honeycombing, hyaline membranes, and granulomas are absent.

Clinical Features

Patients present with dyspnea and cough of several months' duration. They are more likely to be female nonsmokers in their sixth decade of life. On imaging, the lesions have the appearance of bilateral, symmetric, predominantly lower lobe reticular opacities. Patients having the cellular pattern are somewhat younger than those with the fibrosing pattern and have a better prognosis.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia is most often seen as a response to infection or inflammatory injury of the lungs. It has been associated with viral and bacterial pneumonias, inhaled toxins, drugs, connective tissue disease, and graft-versus-host disease in hematopoietic stem cell transplant recipients. Patients present with cough and dyspnea and have patchy subpleural or peribronchial areas of airspace consolidation radiographically. Histologically, it is characterized by the presence of polypoid plugs of loose organizing connective tissue (Masson bodies) within alveolar ducts, alveoli, and often bronchioles (Fig. 15.16). The connective tissue is all of the same age, and the underlying lung architecture is normal. There is no interstitial fibrosis or honeycomb lung. Some patients recover spontaneously, but most need treatment with oral steroids for 6 months or longer for complete recovery. The long-term prognosis is dependent on the underlying disorder.

Pulmonary Involvement in Autoimmune Diseases

Many autoimmune diseases (also referred to as connective tissue diseases because of their frequent association with arthritis) can involve the lung at some point in their course. Those that are well recognized for producing pulmonary disease include systemic lupus erythematosus, rheumatoid arthritis, progressive systemic sclerosis (scleroderma), and dermatomyositis-polymyositis. Pulmonary involvement can take different histologic patterns; nonspecific interstitial

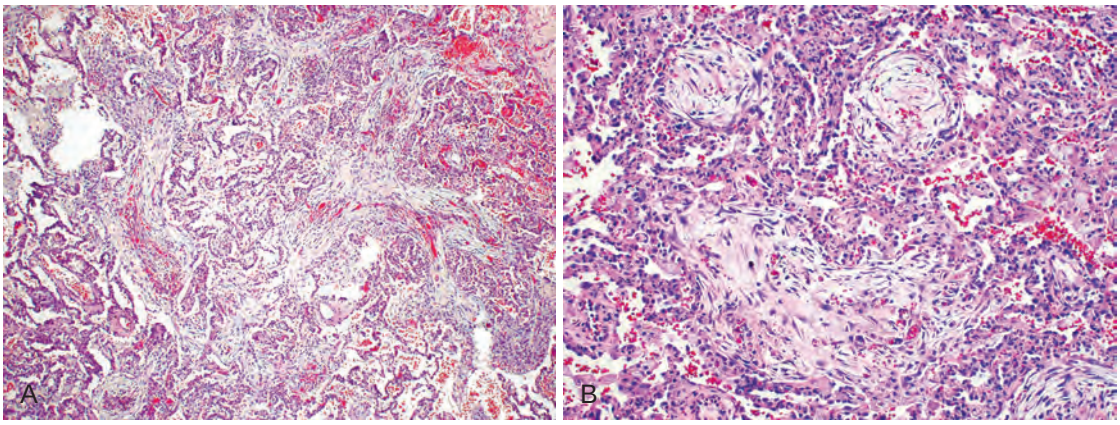

Figure 15.16 Cryptogenic organizing pneumonia. Some alveolar spaces are filled with balls of fibroblasts (Masson bodies), while the alveolar walls are relatively normal. (A) Low power. (B) High power.

pneumonia, usual interstitial pneumonia, organizing pneumonia, and bronchiolitis are the most common.

- *Rheumatoid arthritis* is associated with pulmonary involvement in 30% to 40% of patients as (1) chronic pleuritis, with or without effusion; (2) diffuse interstitial pneumonitis and fibrosis; (3) intrapulmonary rheumatoid nodules; (4) follicular bronchiolitis; or (5) pulmonary hypertension. When lung disease occurs in the setting of rheumatoid arthritis and a pneumoconiosis (described next), it is referred to as *Caplan syndrome*.
- *Systemic sclerosis* (scleroderma) is associated with diffuse interstitial fibrosis (nonspecific interstitial pattern more common than usual interstitial pattern) and pleural involvement.
- *Lupus erythematosus* may cause patchy, transient parenchymal infiltrates or occasionally severe lupus pneumonitis, as well as pleuritis and pleural effusions.

Pulmonary involvement in these diseases has a variable prognosis that is determined by the extent and histologic pattern of involvement.

KEY CONCEPTS

CHRONIC INTERSTITIAL LUNG DISEASES

- Diffuse interstitial fibrosis of the lung gives rise to restrictive lung diseases characterized by reduced lung compliance and reduced FVC. The ratio of FEV_1 to FVC is normal.
- Ididopathic pulmonary fibrosis is prototypic of restrictive lung diseases. It is characterized by patchy interstitial fibrosis, fibroblastic foci, and formation of cystic spaces (honeycomb lung). This histologic pattern is known as usual interstitial fibrosis.
- The cause of idiopathic pulmonary fibrosis is unknown, but genetic analyses point to roles for senescence of alveolar epithelium (due to telomere shortening), altered mucin production, and abnormal signaling in alveolar fibroblasts. Injury to alveolar epithelial cells sets in motion events that lead to increased local production of fibrogenic cytokines, such as TGF-β.

Pneumoconioses

The term *pneumoconiosis,* originally coined to describe the non-neoplastic lung reaction to inhalation of mineral dusts encountered in the workplace, now also includes disease induced by chemical fumes and vapors. A simplified classification is presented in Table 15.6. Where implemented, regulations limiting worker exposure have resulted in a marked decrease in dust-associated diseases.

Pathogenesis

Specific factors that influence the development of dust-borne pneumoconiosis include the following:

- *Dust retention,* which is determined by the dust concentration in ambient air, the duration of exposure, and the effectiveness of clearance mechanisms. Any influence, such as cigarette smoking, that impairs mucociliary clearance significantly increases the accumulation of dust in the lungs.
- *Particle size.* The most dangerous particles are from 1 to 5 μm in diameter because particles of this size can reach the terminal small airways and air sacs and deposit in their linings.
- *Particle solubility and cytotoxicity,* which are influenced by particle size. In general, small particles composed of injurious substances of high solubility are more likely to produce rapid-onset acute lung injury. By contrast, larger particles are more likely to resist dissolution and may persist within the lung parenchyma for years. These tend to evoke fibrosing collagenous pneumoconioses, such as is characteristic of *silicosis.*
- *Particle uptake by epithelial cells or egress across epithelial linings,* which allows direct interactions with fibroblasts and interstitial macrophages to occur. Some particles may reach the lymph nodes through lymphatic drainage directly or within migrating macrophages and thereby initiate an adaptive immune response to components of the particulates or to self-proteins modified by the particles or both.
- *Activation of the inflammasome* (Chapter 3), which occurs following the phagocytosis of certain particles by macrophages. This innate immune response amplifies the intensity and the duration of the local reaction.
- *Tobacco smoking,* which worsens the effects of all inhaled mineral dusts, but particularly those caused by asbestos.

Table 15.6 Lung Diseases Caused by Air Pollutants

Agent	Disease	Exposure
Mineral Dusts		
Coal dust	Anthracosis Macules Progressive massive fibrosis Caplan syndrome	Coal mining (particularly hard coal)
Silica	Silicosis Caplan syndrome	Metal casting work, sandblasting, hard rock mining, stone cutting, others
Asbestos	Asbestosis Pleural plaques Caplan syndrome Mesothelioma Carcinoma of the lung, larynx, stomach, colon	Mining, milling, manufacturing, and installation and removal of insulation
Beryllium	Acute berylliosis Beryllium granulomatosis Lung carcinoma (?)	Mining, manufacturing
Iron oxide	Siderosis	Welding
Barium sulfate	Baritosis	Mining
Tin oxide	Stannosis	Mining
Organic Dusts That Induce Hypersensitivity Pneumonitis		
Moldy hay	Farmer's lung	Farming
Bagasse	Bagassosis	Manufacturing wallboard, paper
Bird droppings	Bird breeder's lung	Bird handling
Organic Dusts That Induce Asthma		
Cotton, flax, hemp	Byssinosis	Textile manufacturing
Red cedar dust	Asthma	Lumbering, carpentry
Chemical Fumes and Vapors		
Nitrous oxide, sulfur dioxide, ammonia, benzene, insecticides	Bronchitis, asthma Pulmonary edema ARDS Mucosal injury Fulminant poisoning	Occupational and accidental exposure

ARDS, Acute respiratory distress syndrome.

In general, only a small percentage of exposed people develop occupational respiratory diseases, implying a genetic predisposition to their development. Many of the diseases listed in Table 15.6 are quite uncommon; hence only a select few that cause pulmonary fibrosis are presented next.

Coal Workers' Pneumoconiosis

Coal workers' pneumoconiosis is lung disease caused by inhalation of coal particles and other admixed forms of dust. Dust reduction measures in coal mines around the globe have drastically reduced its incidence. The spectrum of lung findings in coal workers is wide, varying from asymptomatic anthracosis, to simple coal workers' pneumoconiosis with little to no pulmonary dysfunction, to complicated coal workers' pneumoconiosis, or *progressive massive fibrosis,* in which lung function is compromised. Contaminating silica in the coal dust favors the development of progressive disease. In most cases, carbon dust itself is the major culprit, and studies have shown that complicated lesions contain much more dust than simple lesions. Coal workers may also develop emphysema and chronic bronchitis independent of smoking.

MORPHOLOGY

Carbon deposits are dark black in color and are readily visible grossly and microscopically. **Anthracosis** is the most innocuous coal-induced pulmonary lesion in coal miners and is also seen to some degree in urban dwellers and tobacco smokers. Inhaled carbon pigment is engulfed by alveolar or interstitial macrophages, which accumulate in the connective tissue adjacent to the lymphatics and in organized lymphoid tissue adjacent to the bronchi or in the lung hilus.

Simple coal workers' pneumoconiosis is characterized by **coal macules** (1 to 2 mm in diameter) and somewhat larger **coal nodules.** Coal macules consist of carbon-laden macrophages; nodules also contain a delicate network of collagen fibers. Although these lesions are scattered throughout the lung, the upper lobes and upper zones of the lower lobes are more heavily involved. They are located primarily adjacent to respiratory bronchioles, the site of initial dust accumulation. In due course dilation of adjacent alveoli occurs, sometimes giving rise to **centrilobular emphysema.**

Complicated coal workers' pneumoconiosis (progressive massive fibrosis) occurs on a background of simple disease and generally requires many years to develop. It is characterized by

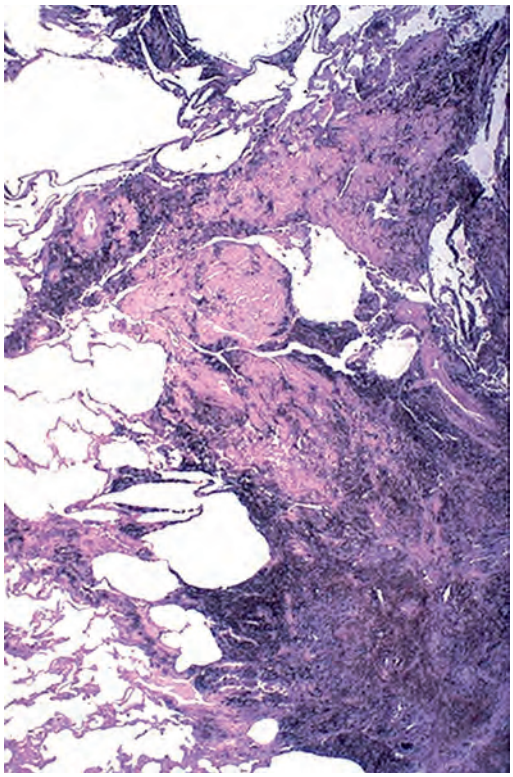

Figure 15.17 Progressive massive fibrosis in a coal worker. A large amount of black pigment is associated with dense interstitial fibrosis. (From Klatt EC: *Robbins and Cotran Atlas of Pathology*, ed 2, Philadelphia, 2010, Saunders, p 121.)

intensely blackened scars 1 cm or larger, sometimes up to 10 cm in greatest diameter. They are usually multiple. Microscopically, the lesions consist of dense collagen and pigment (Fig. 15.17). The center of the lesion is often necrotic, most likely due to local ischemia.

Clinical Features

Coal workers' pneumoconiosis is usually benign, causing little decrement in lung function. Even mild forms of complicated coal workers' pneumoconiosis do not affect lung function significantly. In a minority of cases (fewer than 10%), progressive massive fibrosis develops, leading to increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale. Once progressive massive fibrosis develops, it may continue to worsen even if further exposure to dust is prevented. Unlike silicosis (discussed next), there is no convincing evidence that coal workers' pneumoconiosis increases susceptibility to tuberculosis, nor does it predispose to cancer in the absence of smoking. However, domestic indoor use of "smoky coal" (bituminous) for cooking and heating, a common practice in lower income parts of the world, is associated with an increased risk of lung cancer death, even in those who do not smoke.

Silicosis

Silicosis is a common lung disease caused by inhalation of proinflammatory crystalline silicon dioxide (silica). It usually presents after decades of exposure as slowly progressing, nodular, fibrosing pneumoconiosis. Currently, silicosis is the most prevalent chronic occupational disease in the world. Both dose and race are important in developing silicosis (African Americans are at higher risk than Caucasians). As shown in Table 15.6, workers in a large number of occupations are at risk, including individuals involved with the repair, rehabilitation, or demolition of concrete structures such as buildings and roads. The disease also occurs in workers producing stressed denim by sandblasting, stone carvers, and jewelers using chalk molds. Occasionally, heavy exposure over months to a few years can result in acute silicosis, a disorder characterized by the accumulation of abundant lipoproteinaceous material within alveoli (identical morphologically to alveolar proteinosis, discussed later).

Pathogenesis

Phagocytosis of inhaled silica crystals by macrophages activates the inflammasome and stimulates the release of inflammatory mediators, particularly IL-1 and IL-18. This in turn leads to the recruitment of additional inflammatory cells and activates interstitial fibroblasts, leading to collagen deposition. Silica occurs in both crystalline and amorphous forms, but crystalline forms (including quartz, cristobalite, and tridymite) are much more fibrogenic. Of these, quartz is most commonly implicated. The lack of severe responses to silica in coal and hematite miners is thought to be due to coating of silica with other minerals, especially clay components, which render the silica less toxic. Although amorphous silicates are biologically less active than crystalline silica, heavy lung burdens of these minerals may also produce lesions.

MORPHOLOGY

Silicosis is characterized grossly in its early stages by tiny, barely palpable, discrete pale to blackened (if coal dust is also present) nodules in the hilar lymph nodes and upper zones of the lungs. As the disease progresses, these nodules coalesce into **hard, collagenous scars** (Fig. 15.18). Some nodules may undergo central

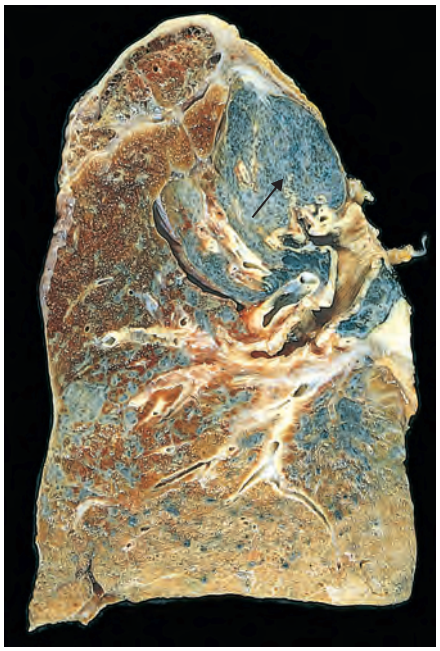

Figure 15.18 Advanced silicosis. Scarring has contracted the upper lobe into a small dark mass *(arrow)*. Note the dense pleural thickening. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

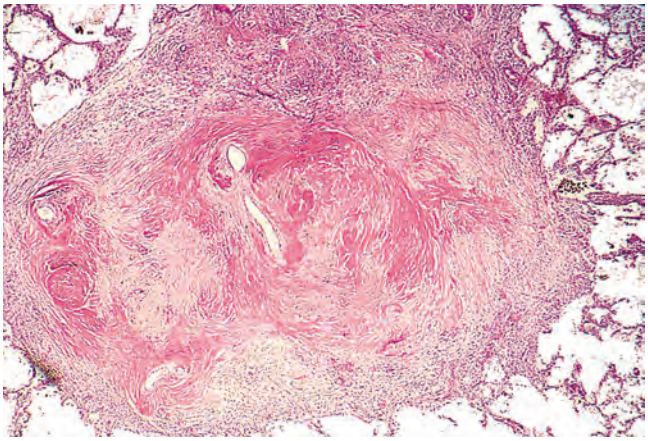

Figure 15.19 Several coalescent collagenous silicotic nodules. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

softening and cavitation due to superimposed tuberculosis or to ischemia. Fibrotic lesions may also occur in the hilar lymph nodes and pleura. Sometimes, thin sheets of calcification occur in the lymph nodes and are seen radiographically as **eggshell calcification** (i.e., calcium surrounding a zone lacking calcification). If the disease continues to progress, expansion and coalescence of lesions may produce progressive massive fibrosis. Histologic examination reveals the hallmark lesion characterized by a central area of whorled collagen fibers with a more peripheral zone of dust-laden macrophages (Fig. 15.19). Examination of the nodules by polarized microscopy reveals weakly birefringent silicate particles.

Clinical Features

The onset of silicosis may be slow and insidious (10 to 30 years after exposure; this is most common), accelerated (within 10 years of exposure), or rapid (weeks or months after intense exposure to fine dust high in silica; this is rare). Chest radiographs typically show a fine nodularity in the upper zones of the lung. Pulmonary function is either normal or only moderately affected early in the course, and most patients do not develop shortness of breath until progressive massive fibrosis supervenes. The disease may continue to worsen even if the patient is no longer exposed. It is slow to kill, but impaired pulmonary function may severely limit activity.

Silicosis also is associated with an increased susceptibility to *tuberculosis* and a twofold increased risk of lung cancer. The former may be because crystalline silica inhibits the ability of pulmonary macrophages to kill phagocytosed mycobacteria. The link to cancer is not fully understood, but it is but one of many chronic inflammatory conditions that increase the risk of carcinoma in involved tissues (Chapter 7).

Asbestos-Related Diseases

Asbestos is a family of proinflammatory crystalline hydrated silicates that are associated with pulmonary fibrosis and various forms of cancer. Use of asbestos is tightly restricted in many higher income countries; however, there is little, if any, control in lower income parts of the world. Asbestos-related diseases include:

- Localized fibrous plaques or, rarely, diffuse pleural fibrosis
- Pleural effusions, recurrent
- Parenchymal interstitial fibrosis *(asbestosis)*
- Lung carcinoma
- Mesothelioma
- Laryngeal, ovarian, and perhaps other extrapulmonary neoplasms, including colon carcinoma
- Increased risks for systemic autoimmune diseases and cardiovascular disease also have been proposed

The increased incidence of asbestos-related cancers in family members of asbestos workers has alerted the general public to the potential hazards of even low-level exposure to asbestos. However, the necessity of expensive asbestos abatement programs for environments such as schools with low, but measurable, airborne asbestos fiber counts remains a matter of contention.

Pathogenesis

The disease-causing capabilities of the different forms of asbestos depend on concentration, size, shape, and solubility. Asbestos occurs in two distinct geometric forms, serpentine and amphibole. The serpentine chrysotile form accounts for 90% of the asbestos used in industry. Amphiboles, even though less prevalent, are more pathogenic than chrysotiles, particularly with respect to induction of mesothelioma, a malignant tumor derived from the lining cells of pleural surfaces (described later).

The greater pathogenicity of amphiboles is apparently related to their aerodynamic properties and solubility. Chrysotiles, with their more flexible, curled structure, are likely to become impacted in the upper respiratory passages and removed by the mucociliary elevator. Furthermore, once trapped in the lungs, chrysotiles are gradually leached from the tissues because they are more soluble than amphiboles. In contrast, the straight, stiff amphiboles may align themselves with the airstream and thus be delivered deeper into the lungs, where they can penetrate epithelial cells and reach the interstitium. Both amphiboles and serpentines are fibrogenic, and increasing doses are associated with a higher incidence of asbestos-related diseases.

In contrast to other inorganic dusts, asbestos acts as a tumor initiator and a tumor promoter (Chapter 7). Some of its oncogenic effects are mediated by reactive free radicals generated by asbestos fibers, which preferentially localize in the distal lung, close to the mesothelial cells of the pleura. Toxic chemicals adsorbed onto the asbestos fibers also likely contribute to the oncogenicity of the fibers. For example, the adsorption of carcinogens in tobacco smoke onto asbestos fibers may be the basis for the remarkable synergy between tobacco smoking and the development of lung carcinoma in asbestos workers. Smoking also enhances the effect of asbestos by interfering with the mucociliary clearance of fibers. One study of asbestos workers found a fivefold increase of lung carcinoma with asbestos exposure alone, while asbestos exposure and smoking together led to a 55-fold increase in the risk.

Once phagocytosed by macrophages, asbestos fibers activate the inflammasome and stimulate the release of proinflammatory factors and fibrogenic mediators. The initial injury occurs at bifurcations of small airways and ducts, where asbestos fibers land, penetrate, and are directly toxic to pulmonary parenchymal cells. Macrophages, both

alveolar and interstitial, attempt to ingest and clear the fibers. Long-term deposition of fibers and persistent release of mediators (e.g., reactive oxygen species, proteases, cytokines, and growth factors) eventually lead to generalized interstitial pulmonary inflammation and fibrosis.

MORPHOLOGY

Asbestosis is marked by **diffuse pulmonary interstitial fibrosis,** which is distinguished from diffuse interstitial fibrosis resulting from other causes only by the presence of **asbestos bodies.** Asbestos bodies are golden brown, fusiform or beaded rods with a translucent center that consist of asbestos fibers coated with an iron-containing proteinaceous material (Fig. 15.20). They arise when macrophages phagocytose asbestos fibers; the iron is presumably derived from phagocyte ferritin. Other inorganic particulates may become coated with similar iron-protein complexes and are called **ferruginous bodies.**

Asbestosis begins as fibrosis around respiratory bronchioles and alveolar ducts and extends to involve adjacent alveolar sacs and alveoli. The fibrosis distorts the architecture, creating enlarged airspaces enclosed by thick fibrous walls; eventually the affected regions become honeycombed. The pattern of fibrosis is histologically similar to that seen in usual interstitial fibrosis, with fibroblastic foci and varying degrees of fibrosis. In contrast to coal workers' pneumoconiosis and silicosis, asbestosis begins in the lower lobes and subpleurally, with the middle and upper lobes becoming affected as fibrosis progresses. The scarring may trap and narrow pulmonary arteries and arterioles, causing pulmonary hypertension and cor pulmonale.

Pleural plaques, the most common manifestation of asbestos exposure, are well-circumscribed plaques of dense collagen that are often calcified (Fig. 15.21). They develop most frequently on the anterior and posterolateral aspects of the parietal pleura and over the domes of the diaphragm. The size and number of pleural plaques do not correlate with the level of exposure to asbestos or the time since exposure. They also do not contain identifiable asbestos bodies; however, only rarely do they occur in individuals without a history or evidence of asbestos exposure. Uncommonly, asbestos exposure induces pleural effusions, which are usually serous but may be bloody. Rarely, diffuse visceral pleural fibrosis may occur and, in advanced cases, bind the lung to the thoracic wall.

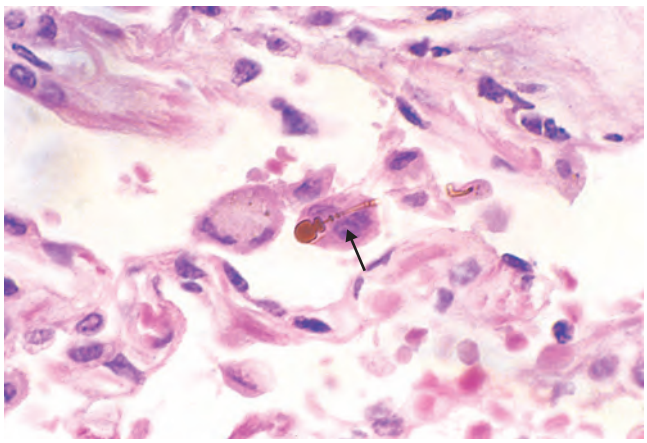

Figure 15.20 High-power detail of an asbestos body, revealing the typical beading and knobbed ends *(arrow)*.

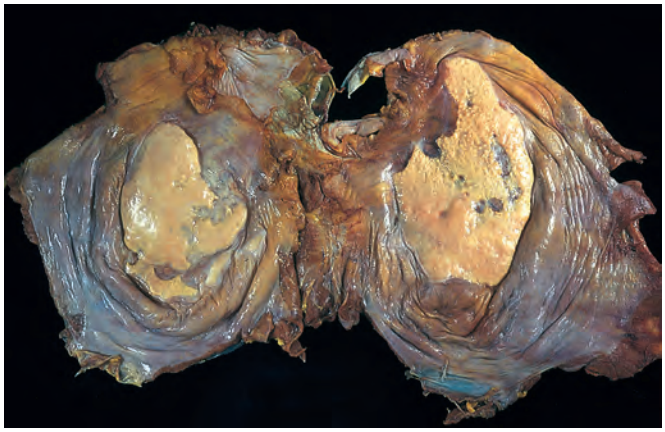

Figure 15.21 Asbestos-related pleural plaques. Large, discrete fibrocalcific plaques are seen on the pleural surface of the diaphragm. (Courtesy Dr. John Godleski, Brigham and Women's Hospital, Boston, Mass.)

Both lung carcinomas and mesotheliomas (pleural and peritoneal) develop in workers exposed to asbestos (see sections on Carcinomas and Pleural Tumors).

Clinical Features

The clinical findings in asbestosis are very similar to those caused by other diffuse interstitial lung diseases (discussed earlier). They rarely appear fewer than 10 years after first exposure and are more common after 20 to 30 years. Dyspnea is usually the first manifestation; at first, it is provoked by exertion, but later is present even at rest. Cough associated with production of sputum, when present, is likely to be due to smoking rather than asbestosis. Chest x-ray studies reveal irregular linear densities, particularly in both lower lobes. With advancement of the pneumoconiosis, a honeycomb pattern develops. The disease may remain static or progress to respiratory failure, cor pulmonale, and death. Pleural plaques are usually asymptomatic and are detected on radiographs as circumscribed densities. Asbestosis complicated by lung or pleural cancer is associated with a particularly grim prognosis.

KEY CONCEPTS

PNEUMOCONIOSES

- Pneumoconioses encompass a group of chronic fibrosing diseases of the lung resulting from exposure to organic and inorganic particulates, most commonly mineral dust.
- Pulmonary alveolar macrophages play a central role in the pathogenesis of lung injury by promoting inflammation and producing fibrogenic cytokines.
- Coal dust–induced disease varies from asymptomatic anthracosis to simple coal workers' pneumoconiosis (coal macules or nodules, and centrilobular emphysema), to progressive massive fibrosis, manifested by increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale.
- Silicosis is the most common pneumoconiosis in the world, and crystalline silica (e.g., quartz) is the usual culprit. The lung disease is progressive even after exposure stops.

- The manifestations of silicosis range from asymptomatic silicotic nodules to large areas of dense fibrosis; persons with silicosis also have an increased susceptibility to tuberculosis. There is twofold increased risk of lung cancer.
- Asbestos fibers come in two forms; the stiff amphiboles have a greater fibrogenic and carcinogenic potential than the serpentine chrysotiles.
- Asbestos exposure is linked with six disease processes: (1) parenchymal interstitial fibrosis (asbestosis); (2) localized pleural plaques (asymptomatic) or rarely diffuse pleural fibrosis; (3) recurrent pleural effusions; (4) lung carcinoma; (5) malignant pleural and peritoneal mesotheliomas; and (6) laryngeal cancer.
- Cigarette smoking increases the risk of lung cancer in the setting of asbestos exposure; even family members of workers exposed to asbestos are at increased risk for lung carcinoma and mesothelioma.

Complications of Therapies

Drug-Induced Lung Diseases. An increasing number of prescription drugs have been found to cause a variety of acute and chronic alterations in lung structure and function, interstitial fibrosis, bronchiolitis obliterans, and eosinophilic pneumonia. For example, cytotoxic drugs used in cancer therapy (e.g., bleomycin) cause pulmonary damage and fibrosis as a result of direct toxicity and by stimulating the influx of inflammatory cells into the alveoli. Amiodarone, a drug used to treat cardiac arrhythmias, is preferentially concentrated in the lung and causes significant pneumonitis in 5% to 15% of patients receiving it. Cough induced by angiotensin-converting enzyme inhibitors is very common.

Illicit intravenous drug abuse most often causes lung infections. In addition, particulate matter used to cut drugs may lodge in the lung microvasculature, producing granulomatous inflammation and fibrosis.

Radiation-Induced Lung Diseases. Radiation pneumonitis is a well-known complication of radiotherapy for thoracic tumors (lung, esophageal, breast, mediastinal). It most often involves the lung within the radiation field and occurs in acute and chronic forms. Acute radiation pneumonitis (lymphocytic alveolitis or hypersensitivity pneumonitis) occurs 1 to 6 months after irradiation in 3% to 44% of patients, depending on dose and age. It manifests with fever, dyspnea out of proportion to the volume of lung irradiated, pleural effusion, and pulmonary infiltrates. Morphologic changes are those of diffuse alveolar damage associated with atypia of hyperplastic type II pneumocytes and fibroblasts. Epithelial cell atypia and foam cells within vessel walls are also characteristic of radiation damage. With steroid therapy, these symptoms may resolve completely, but other cases progress to chronic radiation pneumonitis (pulmonary fibrosis), which also may occur without antecedent, clinically apparent, acute radiation pneumonitis. In its most severe form, chronic radiation pneumonitis and associated progressive fibrosis can lead to cyanosis, pulmonary hypertension, and cor pulmonale.

Granulomatous Diseases

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown cause that may involve many tissues and organs. Its various clinical presentations are protean, but the most common are bilateral hilar lymphadenopathy or parenchymal lung involvement, occurring in 90% of cases. Eye and skin lesions are next in frequency. Since other diseases, including mycobacterial and fungal infections and berylliosis, can also produce noncaseating granulomas, the diagnosis is one of exclusion.

Sarcoidosis usually occurs in adults younger than 40 years of age but can affect any age group. The prevalence is higher in women but varies widely in different countries and populations. In the United States the rates are highest in the Southeast and are 10 times higher in African-Americans than in Caucasians. In contrast, the disease is rare among the Chinese and Southeast Asians. Patterns of organ involvement also vary with race.

Pathogenesis

Although several lines of evidence suggest that sarcoidosis is a disease of disordered immune regulation in genetically predisposed individuals, its etiology is unknown. There are several immunologic abnormalities in the local milieu of sarcoid granulomas that suggest a cell-mediated immune response to an unidentified antigen. These abnormalities include:

- Intra-alveolar and interstitial accumulation of CD4+ T cells, resulting in CD4/CD8 T-cell ratios ranging from 5:1 to 15:1, suggesting pathogenic involvement of CD4+ helper T cells. There is oligoclonal expansion of T-cell subsets as determined by analysis of T-cell receptor rearrangement, consistent with an antigen-driven proliferation.
- Increased levels of T cell–derived Th1 cytokines such as IL-2 and interferon (IFN)-γ, which may be responsible for T-cell expansion and macrophage activation, respectively.
- Increased levels of several cytokines in the local environment (IL-8, TNF, macrophage inflammatory protein 1α) that favor recruitment of additional T cells and monocytes and contribute to the formation of granulomas. TNF in particular is released at high levels by activated alveolar macrophages, and the TNF concentration in the bronchoalveolar fluid is a marker of disease activity.
- Impaired dendritic cell function.

Additionally, there are systemic immunologic abnormalities in individuals with sarcoidosis. Both anergy to common skin test antigens, such as *Candida* or tuberculosis purified protein derivative (PPD), and polyclonal hypergammaglobulinemia, another manifestation of helper T-cell dysregulation, are frequently observed. Evidence of genetic influences includes familial and racial clustering of cases and the association with certain human leukocyte antigen (HLA) genotypes (e.g., HLA-A1 and HLA-B8).

MORPHOLOGY

Virtually every organ in the body has been described as being affected by sarcoidosis, at least on rare occasions. Involved tissues contain well-formed **non-necrotizing granulomas** (Fig. 15.22) composed of aggregates of tightly clustered epithelioid macrophages, often with giant cells. Central necrosis is unusual. With chronicity the granulomas may become enclosed within fibrous rims or may eventually be replaced by hyaline fibrous scars.

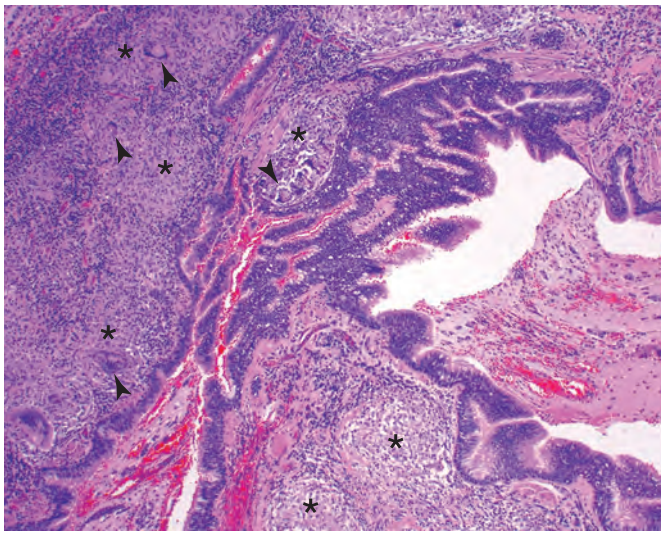

Figure 15.22 Bronchus with characteristic noncaseating sarcoidal granulomas *(asterisks)*, with many multinucleated giant cells *(arrowheads)*. Note subepithelial location of granulomas.

Laminated concretions composed of calcium and proteins known as **Schaumann bodies** and stellate inclusions known as **asteroid bodies** are found within giant cells in approximately 60% of the granulomas. Though characteristic, these microscopic features are not pathognomonic of sarcoidosis because asteroid and Schaumann bodies may be encountered in other granulomatous diseases (e.g., tuberculosis).

The **lung** is a common site of involvement. Macroscopically, there is usually no demonstrable alteration, although in advanced cases coalescence of granulomas produces small nodules that are palpable or visible as 1 to 2 cm, noncaseating, noncavitated consolidations. The lesions are distributed primarily along the lymphatics around bronchi and blood vessels, although alveolar lesions and pleural involvement are also seen. The relatively high frequency of granulomas in the bronchial submucosa accounts for the high diagnostic yield of bronchoscopic biopsies. There seems to be a strong tendency for lesions to heal in the lungs, so varying stages of fibrosis and hyalinization are often found.

Lymph nodes are involved in almost all cases, particularly the hilar and mediastinal nodes, but any node in the body may be affected. Nodes are characteristically enlarged, discrete, and sometimes calcified. Tonsillar granulomas are seen in about one-fourth to one-third of cases. The **spleen** is involved in about 75% of cases, but overt splenomegaly is seen in only 20% of cases. On occasion, granulomas may coalesce to form small nodules that are visible macroscopically. The **liver** is affected slightly less often than the spleen. It may be moderately enlarged and typically contains scattered granulomas, more in portal triads than in the lobular parenchyma.

The **bone marrow** is involved in about 20% of cases. Radiologically, visible bone lesions have a particular tendency to involve phalangeal bones of the hands and feet, creating small circumscribed areas of bone resorption within the marrow cavity and a diffuse reticulated pattern throughout the cavity, with widening of the bony shafts or new bone formation on the outer surfaces.

Skin lesions, encountered in 25% of cases, assume a variety of appearances, including discrete subcutaneous nodules; focal, slightly elevated, erythematous plaques; or flat lesions that are slightly reddened and scaling, resembling those of systemic lupus erythematosus. Lesions may also appear on the mucous membranes of the oral cavity, larynx, and upper respiratory tract. Other patients present with **erythema nodosum**, painful erythematous nodules on the shins that stem from septal panniculitis.

Ocular involvement, seen in 25% of cases, takes the form of iritis or iridocyclitis and may be bilateral or unilateral. Consequently, corneal opacities, glaucoma, and total loss of vision may occur. These ocular lesions are frequently accompanied by inflammation of the lacrimal glands and suppression of lacrimation (**sicca syndrome**). Bilateral sarcoidosis of the parotid, submaxillary, and sublingual glands constitutes the combined uveoparotid involvement designated as Mikulicz syndrome (Chapter 16).

Muscle involvement is underdiagnosed, since it may be asymptomatic. Muscle weakness, aches, tenderness, and fatigue should prompt consideration of occult sarcoid myositis, which can be diagnosed by muscle biopsy. Sarcoid granulomas occasionally occur in the heart, kidneys, central nervous system (neurosarcoidosis, seen in 5% to 15% of cases), and endocrine glands, particularly in the pituitary, as well as in other body tissues.

Clinical Features

Because of its varying severity and inconstant tissue distribution, sarcoidosis may present with diverse features. It may be discovered unexpectedly on routine chest films as bilateral hilar adenopathy or may present with peripheral lymphadenopathy, cutaneous lesions, eye involvement, splenomegaly, or hepatomegaly. In the great majority of cases, however, individuals seek medical attention because of the insidious onset of respiratory abnormalities (shortness of breath, cough, chest pain, hemoptysis) or of constitutional signs and symptoms (fever, fatigue, weight loss, anorexia, night sweats).

Sarcoidosis follows an unpredictable course. It may be inexorably progressive or marked by periods of activity interspersed with remissions, sometimes permanent, that may be spontaneous or induced by steroid therapy. Overall, 65% to 70% of affected patients recover with minimal or no residual manifestations. Twenty percent have permanent loss of some lung function or some permanent visual impairment. Of the remaining 10% to 15%, some die of cardiac or central nervous system damage, but most succumb to progressive pulmonary fibrosis and cor pulmonale.

KEY CONCEPTS

SARCOIDOSIS

- Sarcoidosis is a multisystem disease of unknown etiology; the diagnostic histopathologic feature is the presence of noncaseating granulomas in various tissues.
- Immunologic abnormalities include high levels of CD4+ T cells in the lung that secrete Th1-dependent cytokines such as IFN-γ and IL-2 locally.
- Clinical manifestations include lymph node enlargement, eye involvement (sicca syndrome [dry eyes], iritis, or iridocyclitis), skin lesions (e.g., erythema nodosum), and visceral (liver, skin, marrow) involvement. Lung involvement occurs in 90% of cases, with formation of granulomas and interstitial fibrosis.

Hypersensitivity Pneumonitis

The term *hypersensitivity pneumonitis* describes a spectrum of immunologically mediated, predominantly interstitial lung disorders caused by intense, often prolonged exposure to inhaled organic antigens. Affected individuals have an abnormal sensitivity or heightened reactivity to the causative antigen, which, in contrast to asthma, leads to pathologic changes that primarily involve the alveolar walls (thus the synonym *extrinsic allergic alveolitis*). It is important to recognize these diseases early in their course because progression to serious chronic fibrotic lung disease can be prevented by removal of the environmental agent.

Most commonly, hypersensitivity results from the inhalation of organic dust containing antigens made up of the spores of thermophilic bacteria, fungi, animal proteins, or bacterial products. Numerous syndromes are described, depending on the occupation or exposure of the individual. *Farmer's lung* results from exposure to dusts generated from humid, warm, newly harvested hay that permits the rapid proliferation of the spores of thermophilic actinomycetes. *Pigeon breeder's lung* (bird fancier's disease) is provoked by proteins from serum, excreta, or feathers of birds. *Humidifier* or *air-conditioner lung* is caused by thermophilic bacteria in heated water reservoirs. Pet birds and moldy basements are easily missed unless asked about specifically.

Several lines of evidence suggest that hypersensitivity pneumonitis is an immunologically mediated disease:

- Bronchoalveolar lavage specimens from the acute phase show increased levels of proinflammatory chemokines such as macrophage inflammatory protein 1α and IL-8.
- Bronchoalveolar lavage specimens also consistently demonstrate increased numbers of both CD4+ and CD8+ T lymphocytes.
- Most patients have specific antibodies against the causative antigen in their serum.
- Complement and immunoglobulins have been demonstrated within vessel walls by immunofluorescence.
- The presence of non-necrotizing granulomas in two-thirds of the patients suggests that T cell–mediated (type IV) hypersensitivity reactions against the implicated antigens have a pathogenic role.

MORPHOLOGY

Histologic changes depend on the phase of the disease; acute alveolar damage is seen in the first hours and few days after antigen exposure, while subacute changes are characteristically centered on bronchioles. They include interstitial pneumonitis, consisting primarily of lymphocytes, plasma cells, and macrophages (eosinophils are rare), as well as non-necrotizing granulomas (Fig. 15.23). Interstitial fibrosis with fibroblastic foci, honeycombing, and obliterative bronchiolitis together with granulomas is seen in the chronic phase.

Clinical Features

The clinical manifestations are varied. Acute attacks, which follow inhalation of antigenic dust in sensitized patients, consist of episodes of fever, dyspnea, cough, and leukocytosis. Micronodular interstitial infiltrates may appear in the chest radiograph, and pulmonary function tests show an acute restrictive disorder. Symptoms usually appear 4 to 6 hours after exposure and may last for 12 hours to several days. They recur with re-exposure. If exposure is continuous and protracted, a chronic form of the disease supervenes, leading to progressive fibrosis, dyspnea, and cyanosis—a picture similar to that seen in other forms of chronic interstitial disease.

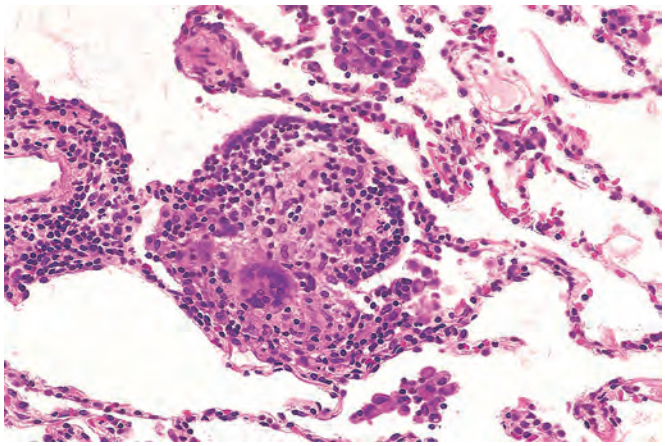

Figure 15.23 Hypersensitivity pneumonitis. Loosely formed interstitial granulomas and chronic inflammation are characteristic.

Pulmonary Eosinophilia

Although relatively rare, there are several clinical and pathologic pulmonary entities that are characterized by an infiltration of eosinophils, recruited in part by elevated alveolar levels of eosinophil attractants such as IL-5. Pulmonary eosinophilia is divided into the following categories:

- *Acute eosinophilic pneumonia with respiratory failure.* This is an acute illness of unknown cause. It has a rapid onset with fever, dyspnea, and hypoxemic respiratory failure. The chest radiograph shows diffuse infiltrates, and bronchoalveolar lavage fluid contains more than 25% eosinophils. Histology shows diffuse alveolar damage and many eosinophils. There is a prompt response to corticosteroids.
- *Secondary eosinophilia,* which occurs in a number of parasitic, fungal, and bacterial infections; in hypersensitivity pneumonitis; in drug allergies; and in association with asthma, allergic bronchopulmonary aspergillosis, or *Churg-Strauss syndrome,* a form of vasculitis.
- *Idiopathic chronic eosinophilic pneumonia,* characterized by focal areas of cellular consolidation of the lung substance distributed chiefly in the periphery of the lung fields. Prominent in these lesions are aggregates of lymphocytes and eosinophils within the septal walls and the alveolar spaces. Interstitial fibrosis and organizing pneumonia are often present. These patients have cough, fever, night sweats, dyspnea, and weight loss, all of which respond to corticosteroid therapy. Chronic eosinophilic pneumonia is diagnosed when other causes of pulmonary eosinophilia are excluded.

Smoking-Related Interstitial Diseases

Smoking-related diseases can be grouped into obstructive diseases (emphysema and chronic bronchitis, already

discussed) and restrictive or interstitial diseases. A majority of individuals with idiopathic pulmonary fibrosis are smokers; however, the role of cigarette smoking in its pathogenesis has not been clarified yet. Desquamative interstitial pneumonia and respiratory bronchiolitis–associated interstitial lung disease are two other smoking-associated interstitial lung diseases worthy of brief mention.

Desquamative Interstitial Pneumonia

Desquamative interstitial pneumonia is characterized by large collections of macrophages in the airspaces of a current or former smoker. The macrophages were originally thought to be desquamated pneumocytes—thus the misnomer "desquamative interstitial pneumonia."

MORPHOLOGY

The most striking finding is the accumulation of a large number of macrophages with abundant cytoplasm containing dusty brown pigment **(smokers' macrophages)** in the airspaces (Fig. 15.24). Some of the macrophages contain lamellar bodies (composed of surfactant) within phagocytic vacuoles, presumably derived from necrotic type II pneumocytes. The alveolar septa are thickened by a sparse inflammatory infiltrate of lymphocytes, plasma cells, and occasional eosinophils. The septa are lined by plump, cuboidal pneumocytes. Interstitial fibrosis, when present, is mild. Emphysema is often present.

Desquamative interstitial pneumonia usually presents in the fourth or fifth decade of life and is now equally common in men and women. Virtually all patients are cigarette smokers. Presenting symptoms include an insidious onset of dyspnea and dry cough over weeks or months, often associated with clubbing of digits. Pulmonary function tests usually show a mild restrictive abnormality and moderately decreased diffusing capacity. Patients with desquamative interstitial pneumonia typically have an excellent response to steroid therapy and cessation of smoking, but occasionally patients progress to interstitial fibrosis.

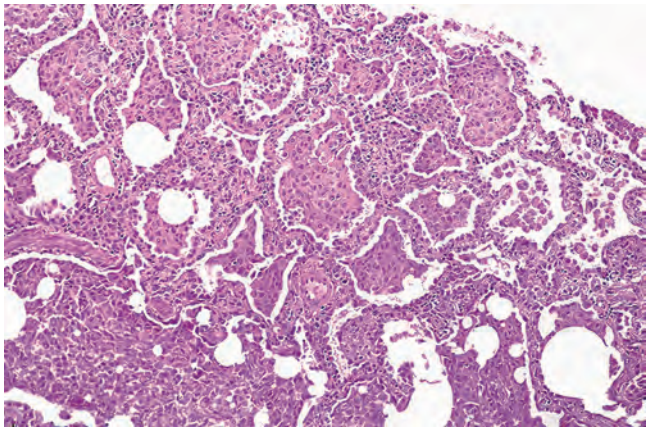

Figure 15.24 Desquamative interstitial pneumonia. Medium-power detail of lung demonstrates the accumulation of large numbers of macrophages within the alveolar spaces and only mild fibrous thickening of the alveolar walls.

Respiratory Bronchiolitis–Associated Interstitial Lung Disease

Respiratory bronchiolitis–associated interstitial lung disease is marked by chronic inflammation and peribronchiolar fibrosis. It is a common histologic lesion in cigarette smokers. It is characterized by the presence of pigmented intraluminal macrophages within first- and second-order respiratory bronchioles. In its mildest form, it is most often an incidental finding in the lungs of smokers or ex-smokers. The term *respiratory bronchiolitis–associated interstitial lung disease* is used for patients who develop significant pulmonary symptoms, abnormal pulmonary function, and imaging abnormalities.

MORPHOLOGY

The changes are patchy at low magnification and have a bronchiolocentric distribution. Respiratory bronchioles, alveolar ducts, and peribronchiolar spaces contain aggregates of dusty brown macrophages **(smokers' macrophages)** similar to those seen in desquamative interstitial pneumonia. There is a patchy submucosal and peribronchiolar infiltrate of lymphocytes and histiocytes. Mild peribronchiolar fibrosis is also seen, which expands contiguous alveolar septa. Centrilobular emphysema is common but not severe. Desquamative interstitial pneumonia is often found in different parts of the same lung.

Symptoms are usually mild, consisting of gradual onset of dyspnea and cough in patients who are typically current cigarette smokers with exposures of over 30 pack-years in the fourth or fifth decade of life. Cessation of smoking usually results in improvement.

Pulmonary Langerhans Cell Histiocytosis

Pulmonary Langerhans cell histiocytosis is a rare disease characterized by focal collections of Langerhans cells (often accompanied by eosinophils). As these lesions progress, scarring occurs, leading to airway destruction and alveolar damage that result in the appearance of irregular cystic spaces. Imaging of the chest shows characteristic cystic and nodular abnormalities. Langerhans cells are immature dendritic cells with grooved, indented nuclei and abundant cytoplasm. They are positive for S100, CD1a, and CD207 (langerin) and are negative for CD68.

More than 90% of affected patients are relatively young adult smokers or ex-smokers; among smokers, about half improve after smoking cessation, suggesting that in some cases the lesions are a reactive inflammatory process. However, in other cases the Langerhans cells have activating mutations in the serine/threonine kinase BRAF, a feature consistent with a neoplastic process that is also commonly seen in Langerhans cell histiocytosis involving other tissues (Chapter 13). A neoplastic basis may explain why the disease progresses in some patients, sometimes even necessitating lung transplantation.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis (PAP) is a rare disease caused by defects in pulmonary macrophage function due

to deficient granulocyte-macrophage colony-stimulating factor (GM-CSF) signaling, which results in the accumulation of surfactant in the intra-alveolar and bronchiolar spaces. PAP is characterized radiologically by bilateral patchy asymmetric pulmonary opacifications. There are three distinct classes of disease—autoimmune (formerly called acquired), secondary, and congenital—each with a similar spectrum of histologic changes.

- *Autoimmune PAP* is caused by autoantibodies that bind and neutralize the function of GM-CSF. It occurs primarily in adults, represents 90% of all cases of PAP, and lacks any familial predisposition. Knockout of the GM-CSF gene in mice induces PAP, and these mice are "cured" by treatment with GM-CSF. Loss of GM-CSF signaling blocks the terminal differentiation of alveolar macrophages, impairing their ability to catabolize surfactant.
- *Secondary PAP* is uncommon and is associated with diverse diseases, including hematopoietic disorders, malignancies, immunodeficiency disorders, lysinuric protein intolerance (an inborn error of amino acid metabolism), and acute silicosis and other inhalational syndromes. It is speculated that these diseases somehow impair GM-CSF–dependent signaling or downstream events involved in macrophage maturation or function, again leading to inadequate clearance of surfactant from alveolar spaces.
- *Hereditary PAP* is extremely rare, occurs in neonates, and is caused by loss-of-function mutations in the genes that encode GM-CSF or the GM-CSF receptor.

MORPHOLOGY

The disease is characterized by the accumulation of intra-alveolar precipitates containing surfactant proteins, causing focal-to-confluent consolidation of large areas of the lungs with minimal inflammatory reaction (Fig. 15.25). As a consequence there is a marked increase in the size and weight of the lung. The alveolar precipitate is pink, homogeneous, and periodic acid–Schiff–positive and contains cholesterol clefts and surfactant proteins (which can be demonstrated by immunohistochemical stains). Ultrastructurally, the surfactant lamellae in type II pneumocytes are normal, in contrast to surfactant dysfunction disorders (described next).

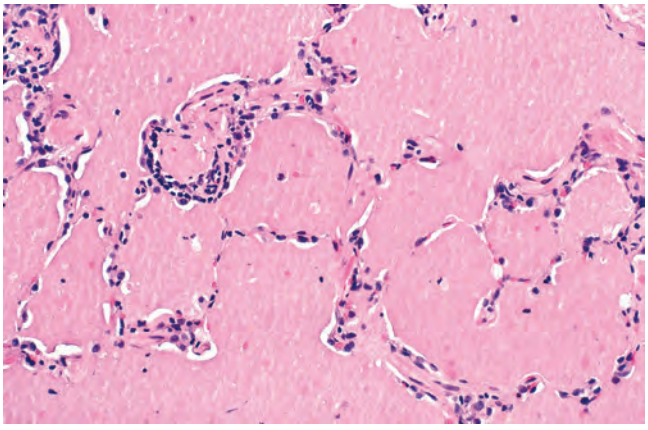

Figure 15.25 Pulmonary alveolar proteinosis. The alveoli are filled with a dense, amorphous, protein-lipid granular precipitate, while the alveolar walls are normal.

Clinical Features

Adult patients, for the most part, present with cough and abundant sputum that often contains chunks of gelatinous material. Some have symptoms lasting for years, often with intermittent febrile illnesses caused by secondary pulmonary infections with a variety of organisms. Progressive dyspnea, cyanosis, and respiratory insufficiency may occur, but other patients follow a benign course, with eventual resolution of the lesions. Whole-lung lavage is the standard of care and provides benefit regardless of the underlying defect. GM-CSF therapy is safe and effective in more than half of patients with autoimmune PAP, and therapy directed at the underlying disorder may also be helpful. Primary disease is treated with GM-CSF replacement therapy, sometimes followed by allogeneic hematopoietic stem cell transplantation, which can be curative.

Surfactant Dysfunction Disorders

Surfactant dysfunction disorders are diseases caused by diverse mutations in genes encoding proteins involved in surfactant trafficking or secretion. Clinical manifestations range from neonatal respiratory failure to adult-onset interstitial lung disease. The most commonly mutated genes are the following:

- *ATP-binding cassette protein member 3 (ABCA3)* is the most frequently mutated gene in surfactant dysfunction disorders. Mutations in *ABCA3* are associated with an autosomal recessive disorder that usually presents in the first few months of life with rapidly progressive respiratory failure followed by death. Less commonly, it comes to attention in older children and in adults with chronic interstitial lung disease.
- The second most commonly mutated gene in surfactant dysfunction disorders encodes *surfactant protein C*. This form has an autosomal dominant mode of inheritance and has a highly variable course.
- The third most commonly mutated gene in surfactant dysfunction disorders encodes *surfactant protein B*. This form has an autosomal recessive mode of inheritance. Typically, the infant is full term and develops progressive respiratory distress shortly after birth. Death ensues between 3 and 6 months of age unless lung transplantation is performed.

MORPHOLOGY

There is a variable amount of intra-alveolar pink granular material, type II pneumocyte hyperplasia, interstitial fibrosis, and alveolar simplification. Immunohistochemical stains show the lack of surfactant proteins C and B in their respective deficiencies. Ultrastructurally, abnormalities in lamellar bodies in type II pneumocytes can be seen in all three; small lamellar bodies with electron dense cores are diagnostic for *ABCA3* mutation (Fig. 15.26).

DISEASES OF VASCULAR ORIGIN

Pulmonary Embolism and Infarction

Pulmonary embolism is an important cause of morbidity and mortality, particularly in patients who are bedridden,

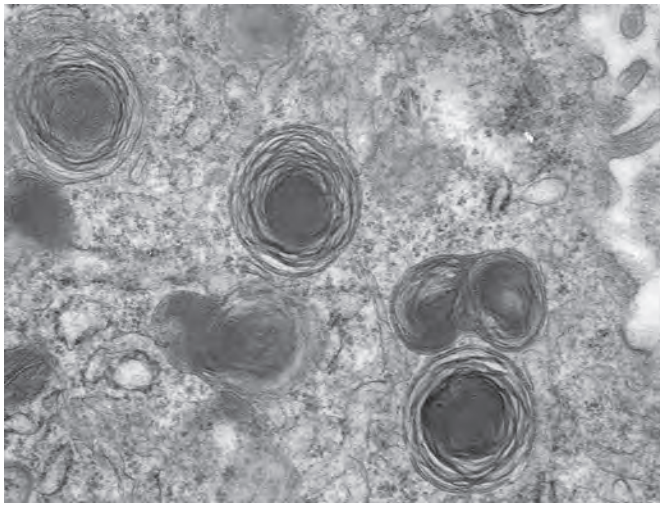

Figure 15.26 Pulmonary alveolar proteinosis associated with mutation of the *ABCA3* gene. An electron micrograph shows type 2 pneumocytes containing small surfactant lamellae with electron dense cores, an appearance that is characteristic of cases associated with *ABCA3* mutations.

but also in a wide range of conditions that are associated with hypercoagulability. Blood clots that occlude the large pulmonary arteries are almost always embolic in origin. The usual source—thrombi in the deep veins of the leg (>95% of cases)—and the magnitude of the clinical problem were discussed in Chapter 4. Pulmonary embolism causes more than 50,000 deaths in the United States each year. Its incidence at autopsy has varied from 1% in the general population of hospital patients to 30% in patients dying after severe burns, trauma, or fractures. It is the sole or major contributing cause of death in about 10% of adults who die acutely in hospitals. By contrast, large-vessel pulmonary thromboses are rare and develop only in the presence of pulmonary hypertension and heart failure.

Pathogenesis

Pulmonary embolism usually occurs in patients with a predisposing condition that produces an increased tendency to clot (thrombophilia). Patients often have cardiac disease or cancer or have been immobilized for several days or weeks prior to the appearance of a symptomatic embolism. Patients with hip fractures are at particularly high risk. Hypercoagulable states, either primary (e.g., factor V Leiden, prothrombin mutations, and antiphospholipid syndrome) or secondary (e.g., obesity, recent surgery, cancer, oral contraceptive use, pregnancy), are important risk factors. Indwelling central venous lines can be a nidus for formation of right atrial thrombi, which can embolize to the lungs. Rarely, pulmonary embolism may consist of fat, air, or tumor. Small bone marrow emboli are often seen in patients who die after chest compressions performed during resuscitative efforts.

The pathophysiologic response and clinical significance of pulmonary embolism depend on the extent to which pulmonary artery blood flow is obstructed, the size of the occluded vessels, the number of emboli, and the cardiovascular health of the patient. Emboli have two deleterious pathophysiologic consequences: *respiratory compromise* due to the nonperfused, although ventilated, segment; and *hemodynamic compromise* due to increased resistance to pulmonary blood flow caused by the embolic obstruction. Sudden death often ensues, largely as a result of the blockage of blood flow through the lungs. Death may also be caused by acute right-sided heart failure *(acute cor pulmonale)*.

MORPHOLOGY

Large emboli lodge in the main pulmonary artery or its major branches or at the bifurcation as a saddle embolus (Fig. 15.27). Smaller emboli travel out into the more peripheral vessels, where they may cause hemorrhage or infarction. In patients with adequate cardiovascular function, the bronchial arterial supply sustains the lung parenchyma; in this instance, hemorrhage may occur, but there is no infarction. In those in whom cardiovascular function is already compromised, such as patients with heart or lung disease, infarction is more likely. Overall, about 10% of emboli cause infarction. About 75% of infarcts affect the lower lobes, and in more than half, multiple lesions occur. They vary in size from barely visible to massive lesions involving large parts of a lobe. Typically, they extend to the periphery of the lung as a wedge with the apex pointing toward the hilus of the lung. In many cases, an occluded vessel is identified near the apex of the infarct. Pulmonary embolus can be distinguished from a postmortem clot by the presence of the lines of Zahn in the thrombus (Chapter 4).

The pulmonary infarct is classically hemorrhagic and appears as a raised, red-blue area in the early stages (Fig. 15.28). Often, the apposed pleural surface is covered by a fibrinous exudate. The red cells begin to lyse within 48 hours, and the infarct becomes paler and eventually red-brown as hemosiderin is produced. With the passage of time, fibrous replacement begins at the margins as a gray-white peripheral zone and eventually converts the infarct into a contracted scar. Histologically, the hemorrhagic area shows ischemic necrosis of the alveolar walls, bronchioles, and vessels. If the infarct is caused by an infected embolus, the neutrophilic inflammatory reaction can be intense. Such lesions are referred to as **septic infarcts,** some of which turn into abscesses.

Clinical Features

A large pulmonary embolus is one of the few causes of virtually instantaneous death. During cardiopulmonary resuscitation in such instances, the patient frequently is said

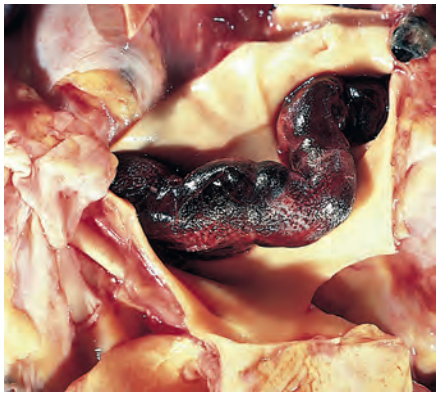

Figure 15.27 Large saddle embolus from the femoral vein lying astride the main left and right pulmonary arteries. (From the teaching collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, Tex.)

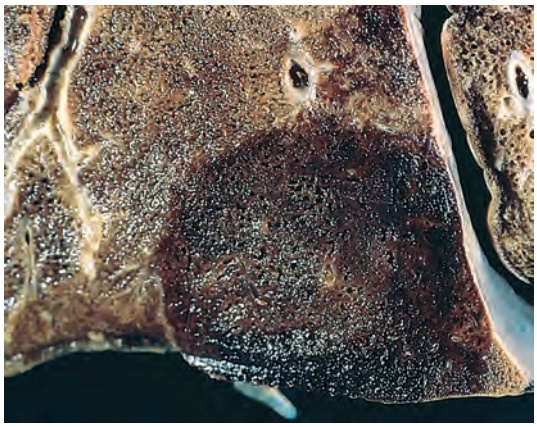

Figure 15.28 Acute hemorrhagic pulmonary infarct.

to have electromechanical dissociation, in which the electrocardiogram has a rhythm, but no pulses are palpated because no blood is entering the pulmonary arterial circulation. If the patient survives after a sizable pulmonary embolus, however, the clinical syndrome may mimic myocardial infarction, with severe chest pain, dyspnea, and shock. Small emboli are silent or induce only transient chest pain and cough. In the remaining group of patients with symptomatic pulmonary embolism, the most common presenting symptoms (in descending order) are dyspnea, pleuritic pain, and cough, accompanied in about half of cases by calf or thigh swelling or pain. Emboli that lead to pulmonary infarction may additionally produce fever and hemoptysis. An overlying fibrinous pleuritis may produce a pleural friction rub.

In hemodynamically stable patients with a low to moderate risk of pulmonary embolism, D-dimer measurement is a useful screening test, as a normal D-dimer level excludes pulmonary embolism. Definitive diagnosis is usually made by computed tomographic pulmonary angiogram, which identifies obstructed pulmonary arteries. Rarely, other diagnostic methods, such as ventilation-perfusion scanning, are required. Deep vein thrombosis can be diagnosed with duplex ultrasonography. Chest radiography may be normal or disclose a pulmonary infarct, usually 12 to 36 hours after it has occurred, as a wedge-shaped infiltrate.

After the initial acute insult, emboli often resolve via contraction and fibrinolysis, particularly in relatively young patients. If unresolved, with time multiple small emboli may lead to pulmonary hypertension and chronic cor pulmonale. Perhaps most important is that a small embolus may presage a larger one. In the presence of an underlying predisposing condition, patients with a pulmonary embolus have a 30% chance of suffering a second embolus.

Prevention of pulmonary embolism is a major clinical challenge for which there is no easy solution. Prophylactic therapy includes early ambulation in postoperative and postpartum patients, elastic stockings and graduated compression stockings for bedridden patients, and anticoagulation in high-risk individuals. Treatment of pulmonary embolism includes anticoagulation and supportive measures; thrombolysis may have some benefit in patients with severe complications (e.g., shock), but carries a high risk of bleeding. Those at risk of recurrent pulmonary embolism in whom anticoagulation is contraindicated may be fitted with an inferior vena cava filter (an "umbrella") that catches clots before they reach the lungs.

KEY CONCEPTS

PULMONARY EMBOLISM

- Almost all large pulmonary artery thrombi are embolic in origin, usually arising from the deep veins of the lower leg.
- Risk factors include prolonged bed rest, leg surgery, severe trauma, congestive heart failure, use of oral contraceptives (especially those with high estrogen content), disseminated cancer, and inherited forms of hypercoagulability.
- The vast majority (60% to 80%) of emboli are clinically silent, a minority (5%) cause acute cor pulmonale, shock, or death (typically from large "saddle emboli"), and the remainder cause symptoms related to ventilation-perfusion mismatch and/or pulmonary infarction, particularly dyspnea and pleuritic chest pain.
- Risk of recurrence is high, and recurrent embolism may eventually lead to pulmonary hypertension and cor pulmonale.

Pulmonary Hypertension

Pulmonary hypertension is defined as a mean pulmonary artery pressure greater than or equal to 25 mm Hg at rest. Based on underlying mechanisms, the WHO has classified pulmonary hypertension into five groups: (1) pulmonary arterial hypertension, a diverse collection of disorders that all primarily impact small pulmonary muscular arteries; (2) pulmonary hypertension due to left heart failure; (3) pulmonary hypertension due to lung diseases and/or hypoxia; (4) chronic thromboembolic pulmonary hypertension and other obstructions; and (5) pulmonary hypertension with unclear and/or multifactorial mechanisms.

Pathogenesis

As can be gathered from the above classification, pulmonary hypertension has diverse causes even within each group. It is most frequently associated with structural cardiopulmonary conditions that increase either pulmonary blood flow, pulmonary vascular resistance, or left heart resistance to blood flow. Some of the more common causes are the following:

- *Chronic obstructive or interstitial lung diseases* (group 3). These diseases obliterate alveolar capillaries, increasing pulmonary resistance to blood flow and, secondarily, pulmonary blood pressure.
- *Antecedent congenital or acquired heart disease* (group 2). Mitral stenosis, for example, causes an increase in left atrial pressure and pulmonary venous pressure that is eventually transmitted to the arterial side of the pulmonary vasculature, leading to hypertension.
- *Recurrent thromboemboli* (group 4). Recurrent pulmonary emboli may cause pulmonary hypertension by reducing the functional cross-sectional area of the pulmonary vascular bed, which in turn leads to an increase in pulmonary vascular resistance.
- *Autoimmune diseases* (group 1). Several of these diseases (most notably systemic sclerosis) involve the pulmonary vasculature and/or the interstitium, leading to increased vascular resistance and pulmonary hypertension.

- *Obstructive sleep apnea* (group 3) is a common disorder that is associated with obesity and hypoxemia. It is now recognized to be a significant contributor to the development of pulmonary hypertension and cor pulmonale.

Uncommonly, pulmonary hypertension is encountered in patients in whom all known causes are excluded; this is referred to as *idiopathic pulmonary arterial hypertension* and also falls into group 1 disease. However, "idiopathic" is a bit of a misnomer, as up to 80% of "idiopathic" cases (sometimes referred to as primary pulmonary hypertension) have a genetic basis, sometimes being inherited in families as an autosomal dominant trait. Within these families, there is incomplete penetrance, and only 10% to 20% of the family members actually develop overt disease.

As is often the case, much has been learned about the pathogenesis of pulmonary hypertension by investigating the molecular basis of the uncommon familial form of the disease. The first mutation to be discovered in familial pulmonary arterial hypertension was in the gene encoding bone morphogenetic protein receptor type 2 *(BMPR2)*. Inactivating germline mutations in the *BMPR2* gene are found in 75% of the familial cases of pulmonary hypertension and 25% of sporadic cases. Subsequently other mutations have been discovered that also converge on the BMPR2 pathway and affect intracellular signaling. It has also been demonstrated that *BMPR2* is downregulated in lungs from some patients with idiopathic pulmonary arterial hypertension without *BMPR2* mutations.

BMPR2 is a cell surface protein belonging to the TGF-β receptor superfamily, which binds a variety of cytokines, including TGF-β, bone morphogenetic protein (BMP), activin, and inhibin. Originally described as a pathway that regulates bone growth, BMP-BMPR2 signaling is now known to be important for embryogenesis, apoptosis, and cell proliferation and differentiation. Details remain to be worked out, but it appears that haploinsufficiency for BMPR2 leads to dysfunction and proliferation of endothelial cells and vascular smooth muscle cells. Because only 10% to 20% of individuals with *BMPR2* mutations develop disease, it is likely that modifier genes and/or environmental triggers also contribute to the pathogenesis of the disorder. A two-hit model has been proposed whereby a genetically susceptible individual with a *BMPR2* mutation requires additional genetic or environmental insults to develop the disease (Fig. 15.29).

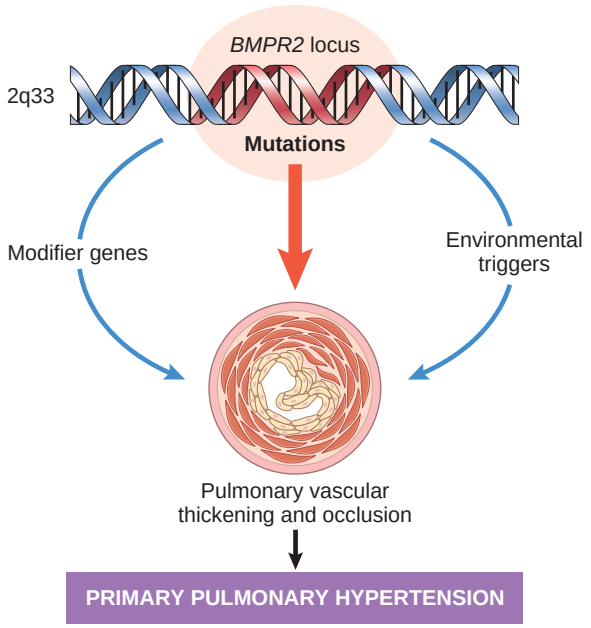

Figure 15.29 Pathogenesis of primary (idiopathic) pulmonary hypertension. See text for details.

MORPHOLOGY

All forms of pulmonary hypertension are associated with **medial hypertrophy of the pulmonary muscular and elastic arteries** and **right ventricular hypertrophy.** The presence of many organizing or recanalized thrombi favors recurrent pulmonary emboli as the cause, and the coexistence of diffuse pulmonary fibrosis, or severe emphysema and chronic bronchitis, points to chronic hypoxia and loss of capillary beds as initiating events. The vessel changes can involve the entire arterial tree, from the main pulmonary arteries down to the arterioles (Fig. 15.30). In the most severe cases, the thickening of the walls of the pulmonary artery and its major branches take on some features of systemic atherosclerosis, but classic atherosclerotic changes are not seen. Instead, the arterioles and small arteries (40 to 300 μm in diameter) are prominently affected by striking medial hypertrophy and intimal fibrosis, sometimes narrowing the lumens to pinpoint channels. One extreme in the spectrum of pathologic changes is the plexiform lesion, so called because a tuft of capillary formations is present, producing a network, or web, that spans the lumens of dilated thin-walled, small arteries and may extend outside the vessel. Plexiform lesions are most prominent in idiopathic and familial pulmonary hypertension (group 1), unrepaired congenital heart disease with left-to-right shunts (group 2), and pulmonary hypertension associated with human immunodeficiency virus (HIV) infection and drugs (also group 1).

Clinical Features

Idiopathic (often inherited) forms of pulmonary hypertension are most common in women who are 20 to 40 years of age, but may occasionally present in childhood. Clinical signs and symptoms in all types become evident only in advanced disease. In cases of idiopathic disease, the presenting features are usually dyspnea and fatigue, but some patients have chest pain of the anginal type. Over time, severe respiratory distress, cyanosis, and right ventricular hypertrophy occur, and death from decompensated cor pulmonale, often with superimposed thromboembolism and pneumonia, ensues within 2 to 5 years in 80% of patients.

Treatment choices depend on the underlying cause. For patients with secondary disease, therapy is directed at the trigger (e.g., thromboembolic disease or hypoxemia). A variety of vasodilators have been used with varying success in those with group 1 or refractory disease belonging to other groups. Lung transplantation provides definitive treatment for selected patients.

Diffuse Pulmonary Hemorrhage Syndromes

Pulmonary hemorrhage is a dramatic complication of some interstitial lung disorders. *Pulmonary hemorrhage syndromes*

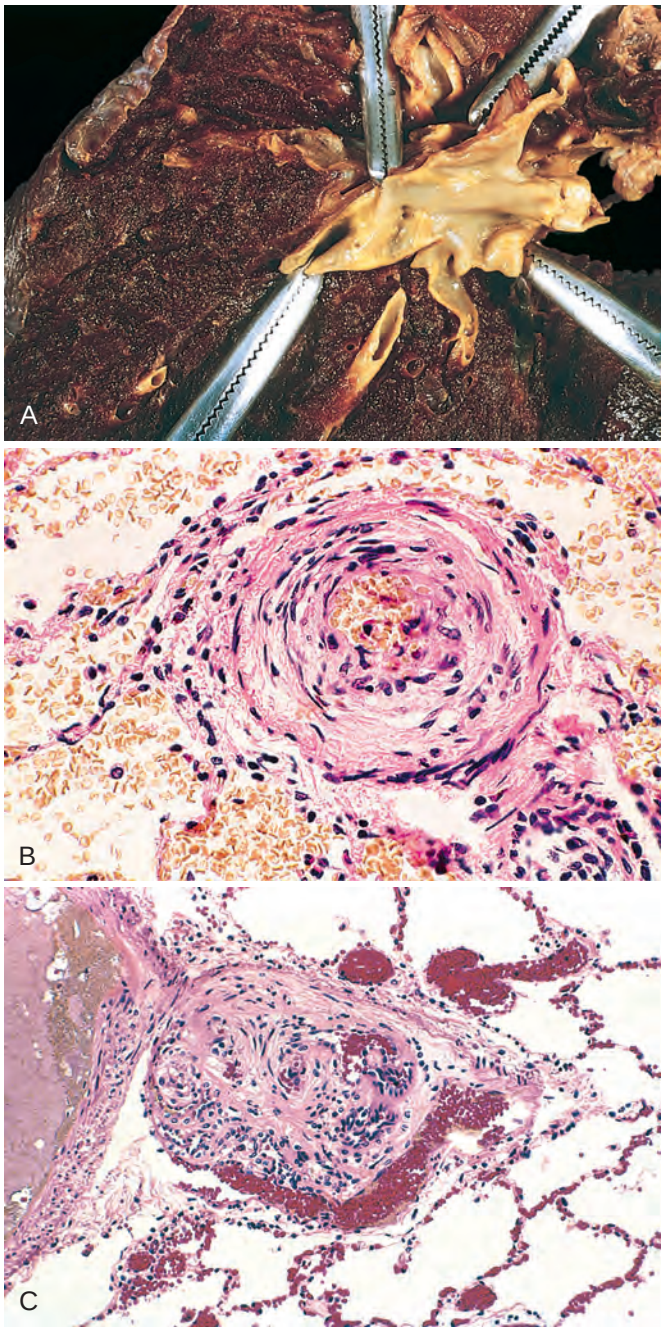

Figure 15.30 Vascular changes in pulmonary arterial hypertension. (A) Atheroma-like changes, a finding usually limited to large vessels. (B) Marked medial hypertrophy. (C) Plexiform lesion of small arteries that is characteristic of advanced pulmonary hypertension.

(Fig. 15.31) include (1) Goodpasture syndrome, (2) idiopathic pulmonary hemosiderosis, and (3) vasculitis-associated hemorrhage. The latter encompasses conditions such as hypersensitivity angiitis, polyangiitis with granulomatosis, and systemic lupus erythematosus (Chapter 11).

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis is a rare disorder characterized by intermittent, diffuse alveolar hemorrhage. Most cases occur in young children, although the disease has been reported in adults as well. It usually presents with an insidious onset of productive cough, hemoptysis, and anemia associated with diffuse pulmonary infiltrates.

The cause and pathogenesis are unknown, and anti–basement membrane antibodies (the cause of Goodpasture syndrome) are undetectable. However, favorable response to long-term immunosuppression with prednisone and/or azathioprine indicates that an immunologic mechanism may be involved in the pulmonary capillary damage underlying alveolar bleeding. In addition, long-term follow-up shows that some affected patients develop other immune disorders.

Goodpasture Syndrome (Anti–Glomerular Basement Membrane Antibody Disease With Pulmonary Involvement)

Goodpasture syndrome is an uncommon autoimmune disease in which kidney and lung injury are caused by circulating autoantibodies against the noncollagenous domain of the α3 chain of collagen IV. When only renal disease is caused by this antibody, it is called anti–glomerular basement membrane disease. The term *Goodpasture syndrome* applies to the 40% to 60% of patients who develop pulmonary hemorrhage in addition to renal disease. Although any age can be affected, most cases occur in the teens or 20s, and in contrast to many other autoimmune diseases, there is a male preponderance. The majority of patients are active smokers.

Pathogenesis

The immunopathogenesis of the syndrome and the nature of the Goodpasture antigens are described in Chapter 20. The pathogenic antibodies initiate inflammatory destruction of the basement membrane in renal glomeruli and pulmonary alveoli, giving rise to rapidly progressive glomerulonephritis and a necrotizing hemorrhagic interstitial pneumonitis. The trigger that initiates the production of anti–basement

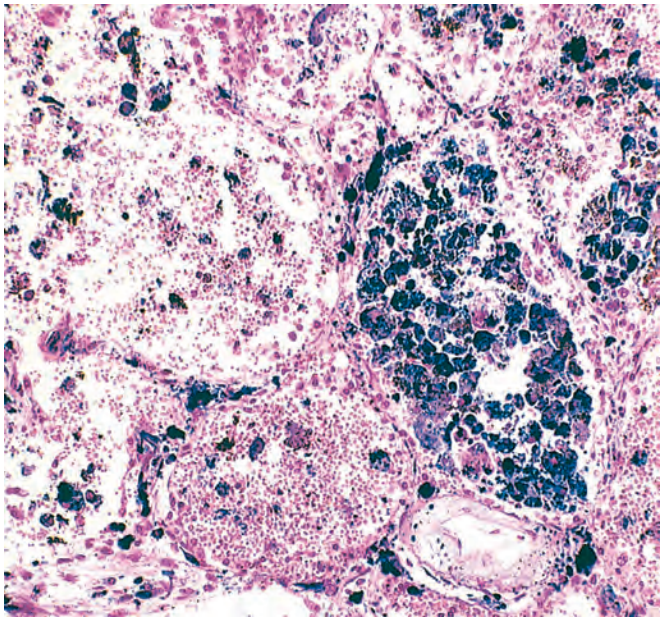

Figure 15.31 Diffuse pulmonary hemorrhage syndrome. There is acute intra-alveolar hemorrhage and hemosiderin-laden macrophages, reflecting previous hemorrhage (Prussian blue iron stain).

membrane antibodies is unknown. In addition to autoreactive B cells, some experimental evidence suggests that T cells also contribute, both by enhancing B-cell function and by participating directly in glomerular damage and crescent formation. As with other autoimmune disorders, there is an association with certain HLA subtypes (e.g., HLA-DRB1*1501 and HLA-DRB1*1502).

MORPHOLOGY

In the classic case, the lungs are heavy, with areas of red-brown consolidation. Histologically, there is focal necrosis of alveolar walls associated with intra-alveolar hemorrhages. Often the alveoli contain hemosiderin-laden macrophages (see Fig. 15.31). In later stages there may be fibrous thickening of the septa, hyperplasia of type II pneumocytes, and organization of blood in alveolar spaces. In many cases, immunofluorescence studies reveal linear deposits of immunoglobulins along the basement membranes of the septal walls. The kidneys have the characteristic findings of focal proliferative glomerulonephritis in early cases or crescentic glomerulonephritis in patients with rapidly progressive glomerulonephritis. Diagnostic linear deposits of immunoglobulins and complement are seen by immunofluorescence studies along the glomerular basement membranes even in the few patients without renal disease.

Clinical Features

Most cases begin with respiratory symptoms, principally hemoptysis, and radiographic evidence of focal pulmonary consolidations. Soon, manifestations of glomerulonephritis appear, leading to rapidly progressive renal failure. The most common cause of death is uremia. The once dismal prognosis for this disease has been markedly improved by intensive plasmapheresis. This procedure is thought to be beneficial by removing anti–basement membrane antibodies and possibly other mediators of immunologic injury. Simultaneous immunosuppressive therapy inhibits further antibody production, ameliorating both lung hemorrhage and glomerulonephritis.

Polyangiitis With Granulomatosis

Previously called Wegener granulomatosis, this autoimmune disease most often involves the upper respiratory tract and/or the lungs, with hemoptysis being the common presenting symptom. Its features are discussed in Chapter 11. Here, it suffices to emphasize that a transbronchial lung biopsy might provide the only tissue available for diagnosis. Since the amount of tissue is small, necrosis and granulomatous vasculitis might not be present. Rather, the diagnostically important histologic features are capillaritis and scattered, poorly formed granulomas (unlike those of sarcoidosis, which are rounded and well-defined).

PULMONARY INFECTIONS

Respiratory tract infections are more frequent than infections of any other organ and account for the largest number of workdays lost in the general population. The vast majority consist of upper respiratory tract infections caused by viruses (common cold, pharyngitis), but bacterial, viral, mycoplasmal, and fungal infections of the lung (pneumonia) account for an enormous amount of morbidity and are responsible for 2.3% of all deaths in the United States. Pneumonia can be very broadly defined as any infection of the lung parenchyma.

Pulmonary antimicrobial defense mechanisms are described in Chapter 8. Pneumonia can result whenever these local defense mechanisms are impaired or the systemic resistance of the host is lowered. Factors that impair resistance include chronic diseases, immunologic deficiencies, treatment with immunosuppressive agents, and leukopenia. Local pulmonary defense mechanisms may also be compromised by many factors, including:

- *Loss or suppression of the cough reflex,* as a result of altered sensorium (e.g., coma), anesthesia, neuromuscular disorders, drugs, or chest pain, any of which may lead to *aspiration* of gastric contents.
- *Dysfunction of the mucociliary apparatus,* which can be caused by cigarette smoke, inhalation of hot or corrosive gases, viral diseases, or genetic defects of ciliary function (e.g., immotile cilia syndrome).
- *Accumulation of secretions* in conditions such as cystic fibrosis and bronchial obstruction.
- *Interference with the phagocytic and bactericidal activities of alveolar macrophages* by alcohol, tobacco smoke, anoxia, or oxygen intoxication.
- *Pulmonary congestion and edema.*

Defects in innate immunity (including neutrophil and complement defects) and humoral immunodeficiency typically lead to an increased incidence of infections with pyogenic bacteria. Germline mutations in MyD88 (an adaptor for several Toll-like receptors [TLRs] that is important for activation of the transcription factor nuclear factor kappa B [NF-κB]) are also associated with destructive bacterial (pneumococcal) pneumonias. On the other hand, cell-mediated immune defects (congenital and acquired) lead to increased infections with intracellular microbes such as mycobacteria and herpesviruses as well as with microorganisms of very low virulence, such as the fungus *Pneumocystis jiroveci*.

Several other points should be emphasized. First, to paraphrase the French physician Louis Cruveilhier in 1919 (during the Spanish flu epidemic), "flu condemns, and additional infection executes." The most common cause of death in viral influenza epidemics is superimposed bacterial pneumonia. Second, although the portal of entry for most bacterial pneumonias is the respiratory tract, hematogenous seeding of the lungs from another organ may occur and may be difficult to distinguish from primary pneumonia. Finally, many patients with chronic diseases acquire terminal pneumonia while hospitalized *(nosocomial infection)* because of several factors: bacteria common to the hospital environment may have acquired resistance to antibiotics; opportunities for spread are increased; invasive procedures, such as intubations and injections, are common; and bacteria may contaminate equipment used in respiratory care units.

Pneumonia is classified based on the etiologic agent or, if no pathogen can be isolated (which occurs in about 50% of cases), by the clinical setting in which the infection occurs.

Table 15.7 Pneumonia Syndromes

Community-Acquired Acute Pneumonia
Streptococcus pneumoniae
Haemophilus influenzae
Moraxella catarrhalis
Staphylococcus aureus
Legionella pneumophila
Enterobacteriaceae *(Klebsiella pneumoniae)* and *Pseudomonas* spp.
Mycoplasma pneumoniae
Chlamydia spp. *(C. pneumoniae, C. psittaci, C. trachomatis)*
Coxiella burnetii (Q fever)
Viruses: respiratory syncytial virus, parainfluenza virus, and human metapneumovirus (children); influenza A and B (adults); adenovirus (military recruits)
Health Care–Associated Pneumonia
Staphylococcus aureus, methicillin-sensitive
Staphylococcus aureus, methicillin-resistant
Pseudomonas aeruginosa
Streptococcus pneumoniae
Hospital-Acquired Pneumonia
Gram-negative rods, Enterobacteriaceae (*Klebsiella* spp., *Serratia marcescens*, *Escherichia coli*) and *Pseudomonas* spp.
Staphylococcus aureus (usually methicillin-resistant)
Aspiration Pneumonia
Anaerobic oral flora *(Bacteroides, Prevotella, Fusobacterium, Peptostreptococcus)*, admixed with aerobic bacteria *(Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae, Pseudomonas aeruginosa)*
Chronic Pneumonia
Nocardia
Actinomyces
Granulomatous: *Mycobacterium tuberculosis* and atypical mycobacteria, *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis*
Necrotizing Pneumonia and Lung Abscess
Anaerobic bacteria (extremely common), with or without mixed aerobic infection
Staphylococcus aureus, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, and type 3 pneumococcus (uncommon)
Pneumonia in the Immunocompromised Host
Cytomegalovirus
Pneumocystis jiroveci
Mycobacterium avium-intracellulare complex
Invasive aspergillosis
Invasive candidiasis
"Usual" bacterial, viral, and fungal organisms (listed herein)

The latter considerably narrows the list of suspected pathogens, providing a guide for empirical antimicrobial therapy. As Table 15.7 indicates, pneumonia can arise in seven distinct clinical settings ("pneumonia syndromes"), and the implicated pathogens are fairly specific to each category.

Community-Acquired Bacterial Pneumonias

Community-acquired acute pneumonia refers to lung infection in otherwise healthy individuals that is acquired from the normal environment (in contrast to hospital-acquired pneumonia). It may be bacterial or viral. Clinical and radiologic features are usually insensitive in differentiating between viral and bacterial infections. One marker of inflammation, procalcitonin, an acute-phase reactant produced primarily in the liver, is more significantly elevated in bacterial than viral infections and has some predictive value, but is not specific, as it is also markedly elevated in other severe inflammatory disorders, such as systemic inflammatory response syndrome (SIRS) (Chapter 4).

Often, a bacterial infection follows an upper respiratory tract viral infection. Bacterial invasion of the lung parenchyma causes the alveoli to be filled with an inflammatory exudate, thus causing consolidation ("solidification") of the pulmonary tissue. Many variables, such as the specific etiologic agent, the host reaction, and the extent of involvement, determine the precise form of pneumonia. Predisposing conditions include extremes of age, chronic diseases (congestive heart failure, COPD, and diabetes), congenital or acquired immune deficiencies, and decreased or absent splenic function. The latter puts the patient at risk for infection with encapsulated bacteria such as pneumococcus.

Streptococcus pneumoniae

***Streptococcus pneumoniae*, or *pneumococcus*, is the most common cause of community-acquired acute pneumonia.** Examination of Gram-stained sputum is an important step in the diagnosis of acute pneumonia. The presence of numerous neutrophils containing the typical gram-positive, lancet-shaped diplococci supports the diagnosis of pneumococcal pneumonia, but it must be remembered that *S. pneumoniae* is a part of the endogenous flora in 20% of adults, and therefore false-positive results may be obtained. Isolation of pneumococci from blood cultures is more specific but less sensitive (in the early phase of illness, only 20% to 30% of patients have positive blood cultures). Pneumococcal vaccines containing capsular polysaccharides from the common serotypes are used in individuals at high risk for pneumococcal sepsis.

Haemophilus influenzae

Haemophilus influenzae is a pleomorphic, gram-negative organism that occurs in encapsulated and nonencapsulated forms. There are six serotypes of the encapsulated form (types a to f), of which type b is the most virulent. Antibodies against the capsule protect the host from *H. influenzae* infection; hence the capsular polysaccharide b is incorporated in the widely used vaccine against *H. influenzae*. With routine use of *H. influenzae* vaccines, the incidence of disease caused by the b serotype has declined significantly. By contrast, infections with nonencapsulated forms, also called *nontypeable forms*, are increasing. These are less virulent and tend to spread along the surface of the upper respiratory tract, producing otitis media (infection of the middle ear), sinusitis, and bronchopneumonia. Neonates and children with comorbidities such as prematurity, malignancy, and immunodeficiency are at high risk for development of invasive infection.

H. influenzae pneumonia, which may follow a viral respiratory infection, is a pediatric emergency and has a high mortality rate. Descending laryngotracheobronchitis results in airway obstruction as the smaller bronchi are plugged by dense, fibrin-rich exudates containing neutrophils, similar to that seen in pneumococcal pneumonias. Pulmonary consolidation is usually lobular and patchy but may be confluent and involve the entire lung lobe. Before a vaccine became widely available, *H. influenzae* was a common cause of suppurative meningitis in children up to

5 years of age. *H. influenzae* also causes an acute, purulent conjunctivitis (pink eye) in children and, in predisposed older patients, may cause septicemia, endocarditis, pyelonephritis, cholecystitis, and suppurative arthritis. Finally, *H. influenzae* is the most common bacterial cause of acute exacerbations of COPD.

Moraxella catarrhalis

Moraxella catarrhalis is recognized as a cause of bacterial pneumonia, especially in the elderly. It is the second most common bacterial cause of acute exacerbation of COPD. Along with *S. pneumoniae* and *H. influenzae, M. catarrhalis* is one of the three most common causes of otitis media in children.

Staphylococcus aureus

Staphylococcus aureus is an important cause of secondary bacterial pneumonia in children and healthy adults following viral respiratory illnesses (e.g., measles in children and influenza in both children and adults). Staphylococcal pneumonia is associated with a high incidence of complications, such as lung abscess and empyema. *Intravenous drug users* are at high risk for development of staphylococcal pneumonia in association with endocarditis. It is also an important cause of hospital-acquired pneumonia.

Klebsiella pneumoniae

Klebsiella pneumoniae is the most frequent cause of gram-negative bacterial pneumonia. It commonly afflicts debilitated and malnourished people, particularly *chronic alcoholics*. Thick, mucoid (often blood-tinged) sputum is characteristic because the organism produces an abundant viscid capsular polysaccharide, which the patient may have difficulty expectorating.

Pseudomonas aeruginosa

Although *Pseudomonas aeruginosa* most commonly causes hospital-acquired infections, it is mentioned here because of its occurrence in cystic fibrosis and immunocompromised patients. It is common in patients who are neutropenic, and it has a propensity to invade blood vessels with consequent extrapulmonary spread. *Pseudomonas* septicemia is a very fulminant disease.

Legionella pneumophila

Legionella pneumophila is the agent of legionnaires' disease, the form of pneumonia caused by this organism. It also causes Pontiac fever, a related self-limited upper respiratory tract infection. This organism flourishes in artificial aquatic environments, such as water-cooling towers and the tubing systems of domestic (potable) water supplies. It is transmitted by either inhalation of aerosolized organisms or aspiration of contaminated drinking water. *Legionella* pneumonia is common in individuals with predisposing conditions such as cardiac, renal, immunologic, or hematologic disease. Organ transplant recipients are particularly susceptible. It can be quite severe, frequently requiring hospitalization, and immunosuppressed patients have fatality rates of up to 50%. The diagnosis can be made rapidly by detecting *Legionella* DNA in sputum using a polymerase chain reaction (PCR)–based test or by identification of *Legionella* antigens in the urine; culture remains the diagnostic gold standard, but takes 3 to 5 days.

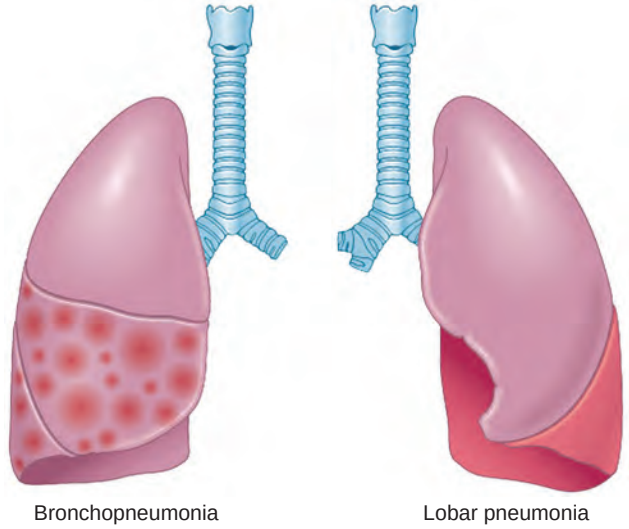

Figure 15.32 Comparison of bronchopneumonia and lobar pneumonia.

Mycoplasma pneumoniae

Mycoplasma infections are particularly common among children and young adults. They occur sporadically or as local epidemics in closed communities (schools, military camps, and prisons).

MORPHOLOGY

Bacterial pneumonia has two patterns of anatomic distribution: lobular bronchopneumonia and lobar pneumonia (Fig. 15.32). Patchy consolidation of the lung is the dominant characteristic of **bronchopneumonia** (Fig. 15.33), while consolidation of a large portion of a lobe or of an entire lobe defines **lobar**

Figure 15.33 Bronchopneumonia. Section of lung showing patches of consolidation *(arrows)*.

Figure 15.34 Lobar pneumonia—gray hepatization. The lower lobe is uniformly consolidated.

pneumonia (Fig. 15.34). These anatomic categorizations may be difficult to apply in individual cases because patterns overlap. The patchy involvement may become confluent, producing lobar consolidation. Moreover, the same organisms may produce either pattern depending on patient susceptibility. **Most important from the clinical standpoint are identification of the causative agent and determination of the extent of disease.**

In lobar pneumonia, four stages of the inflammatory response have classically been described: congestion, red hepatization, gray hepatization, and resolution. In the first stage of **congestion,** the lung is heavy, boggy, and red. It is characterized by vascular engorgement, intra-alveolar edema fluid containing a few neutrophils, and the presence of bacteria, which may be numerous. In the next stage of **red hepatization**, there is massive confluent exudation, as neutrophils, red cells, and fibrin fill the alveolar spaces (Fig. 15.35A). On gross examination, the lobe is red, firm, and airless, with a liver-like consistency, hence the name hepatization. The third stage of **gray hepatization** is marked by progressive disintegration of red cells and the persistence of a fibrinosuppurative exudate (Fig. 15.35B), resulting in a color change to grayish-brown. In the final stage of **resolution,** the exudate within the alveolar spaces is broken down by enzymatic digestion to produce granular, semifluid debris that is resorbed, ingested by macrophages, expectorated, or organized by fibroblasts growing into it (Fig. 15.35C). Pleural fibrinous reaction to the underlying inflammation, often present in the early stages if the consolidation extends to the lung surface **(pleuritis)**, may similarly resolve. More often it undergoes organization, leaving fibrous thickening or permanent adhesions.

Foci of **bronchopneumonia** are consolidated areas of acute suppurative inflammation. The consolidation may be confined to one lobe but is more often multilobar and frequently bilateral and basal because of the tendency of secretions to gravitate to the lower lobes. Well-developed lesions are slightly elevated, dry, granular, gray-red to yellow, and poorly delimited at their margins (see Fig. 15.33). Histologically, the reaction usually elicits a neutrophil-rich exudate that fills the bronchi, bronchioles, and adjacent alveolar spaces (see Fig. 15.35A).

Complications of pneumonia include (1) tissue destruction and necrosis, causing **abscess formation** (particularly common with pneumococcal or *Klebsiella* infections); (2) spread of infection

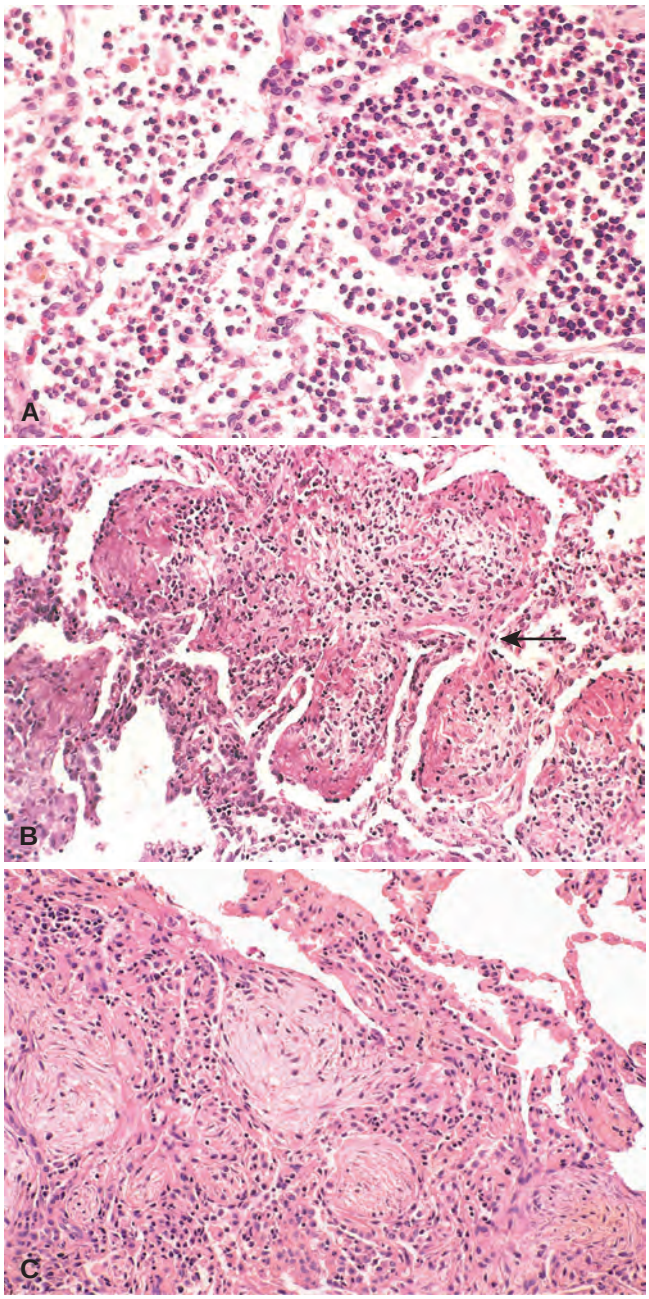

Figure 15.35 Stages of bacterial pneumonia. (A) Acute pneumonia. The congested septal capillaries and numerous intra-alveolar neutrophils are characteristic of early red hepatization. Fibrin nets have not yet formed. (B) Early organization of intra-alveolar exudate, seen focally to be streaming through the pores of Kohn *(arrow)*. (C) Advanced organizing pneumonia. The exudates have been converted to fibromyxoid masses rich in macrophages and fibroblasts.

to the pleural cavity, causing an intrapleural fibrinosuppurative reaction known as **empyema;** and (3) **bacteremic dissemination** to the heart valves, pericardium, brain, kidneys, spleen, or joints, causing abscesses, endocarditis, meningitis, or suppurative arthritis.

Clinical Features

The major symptoms of community-acquired acute bacterial pneumonia are abrupt onset of high fever, shaking chills, and cough producing mucopurulent sputum and occasionally hemoptysis. When pleuritis is present it is accompanied by pleuritic pain and pleural friction rub. The whole lobe is radiopaque in lobar pneumonia, whereas there are focal opacities in bronchopneumonia.

The clinical picture is markedly modified by the administration of effective antibiotics. Appropriately treated patients may become afebrile with few clinical signs 48 to 72 hours after the initiation of antibiotics. The identification of the organism and the determination of its antibiotic sensitivity are the keystones of therapy. Fewer than 10% of patients with pneumonia severe enough to merit hospitalization now succumb, and in most instances death results from a complication, such as empyema, meningitis, endocarditis, or pericarditis, or is attributable to some predisposing influence, such as debility or chronic alcoholism.

Community-Acquired Viral Pneumonia

Common viral infections include influenza virus types A and B, respiratory syncytial viruses, human metapneumovirus, adenovirus, rhinoviruses, rubeola, and varicella viruses. Any of these agents can cause a relatively mild upper respiratory tract infection, recognized as the common cold, or a more severe lower respiratory tract infection. Factors that favor extension of the infection to the lung include extremes of age, malnutrition, alcoholism, and underlying debilitating illnesses.

Although the molecular details vary, all of the viruses that cause pneumonia produce disease through similar general mechanisms. These viruses have tropisms that allow them to attach to and enter respiratory lining cells. Viral replication and gene expression leads to cytopathic changes, inducing cell death and secondary inflammation. The resulting damage and impairment of local pulmonary defenses, such as mucociliary clearance, may predispose to bacterial superinfections, which are often more serious than the viral infection itself.

Influenza

Influenza viruses of type A infect humans, pigs, horses, and birds and are the major cause of pandemic and epidemic influenza infections. The influenza genome encodes several proteins, but the most important from the vantage point of viral virulence are the hemagglutinin and neuraminidase proteins. Hemagglutinin has three major subtypes (H1, H2, H3), while neuraminidase has two (N1, N2). Both proteins are embedded in a lipid bilayer, which constitutes the influenza virus envelope. Hemagglutinin is particularly important, as it serves to attach the virus to its cellular target via sialic acid residues on surface polysaccharides. Following uptake of the virus into endosomal vesicles, acidification of the endosome triggers a conformation change in hemagglutinin that allows the viral envelope to fuse with the host cell membrane, releasing the viral genomic RNAs into the cytoplasm of the cell. Neuraminidase in turn facilitates the release of newly formed virions that are budding from infected cells by cleaving sialic acid residues. Neutralizing host antibodies against viral hemagglutinin and neuraminidase prevent and ameliorate, respectively, infection with influenza virus.

The viral genome is composed of eight single-stranded RNAs, each encoding one or more proteins. The RNAs are packaged into helices by nucleoproteins that determine the influenza virus type (A, B, or C). A single subtype of influenza virus A predominates throughout the world at a given time. Epidemics of influenza are caused by spontaneous mutations that alter antigenic epitopes on the viral hemagglutinin and neuraminidase proteins. These antigenic changes *(antigenic drift)* result in new viral strains that are sufficiently different to elude, at least in part, anti-influenza antibodies produced in members of the population in response to prior exposures to other flu strains. Usually, however, these new strains bear sufficient resemblance to prior strains that some members of the population are at least partially resistant to infection. By contrast, pandemics, which are longer and more widespread than epidemics, occur when both the hemagglutinin and the neuraminidase genes are replaced through recombination with animal influenza viruses *(antigenic shift)*. In this instance, essentially all individuals are susceptible to the new influenza virus.

If the host lacks protective antibodies, the virus infects pneumocytes and elicits several cytopathic changes. Shortly after entry into pneumocytes, the viral infection inhibits sodium channels, producing electrolyte and water shifts that lead to fluid accumulation in the alveolar lumen. This is followed by the death of the infected cells through several mechanisms, including inhibition of host cell messenger RNA translation and activation of caspases leading to apoptosis. The death of epithelial cells exacerbates the fluid accumulation and releases "danger signals" that activate resident macrophages. In addition, prior to their death, infected epithelial cells release a variety of inflammatory mediators, including several chemokines and cytokines, adding fuel to the inflammatory fire. In addition, mediators released from epithelial cells and macrophages activate the nearby pulmonary endothelium and serve as chemoattractants for neutrophils, which migrate into the interstitium within the first day or two of infection. In some cases viral infection may cause sufficient lung injury to produce ARDS, but more often severe pulmonary disease stems from a superimposed bacterial pneumonia. Of these, secondary pneumonias caused by *S. aureus* are particularly common and often life-threatening.

Control of the infection relies on several host mechanisms. The presence of viral products induces innate immune responses in infected cells, such as the production of α- and β-interferon. These mediators upregulate the expression of the *MX1* gene, which encodes a guanosine triphosphatase that interferes with viral gene transcription and viral replication. As with other viral infections, natural killer cells and cytotoxic T cells can recognize and kill infected host cells, limiting viral replication and viral spread to adjacent pneumocytes. The cellular immune response is eventually

augmented by development of antibody responses to the viral hemagglutinin and neuraminidase proteins.

Insight into future pandemics has come from studying past pandemics. DNA analysis of viral genomes retrieved from the lungs of a soldier who died in the great 1918 influenza pandemic that killed between 20 million and 40 million people worldwide identified swine influenza sequences, consistent with this virus having its origin in a "antigenic shift." The first flu pandemic of this century, in 2009, was also caused by an antigenic shift involving a virus of swine origin. It caused particularly severe infections in young adults, apparently because older adults had antibodies against past influenza strains that conveyed at least partial protection. Comorbidities such as diabetes, heart disease, lung disease, and immunosuppression were also associated with a higher risk of severe infection.

What then might be the source of the next great pandemic? There is no certainty, but one concern is centered on avian influenza, which normally infects birds. One such strain, type H5N1, has spread throughout the world in wild and domestic birds. Fortunately, the transmission of the current H5N1 avian virus is inefficient. However, if H5N1 influenza recombines with an influenza that is highly infectious for humans, a strain might result that is capable of sustained human-to-human transmission (and thus of causing the next great pandemic).

Human Metapneumovirus

Human metapneumovirus, a paramyxovirus discovered in 2001, is found worldwide and is associated with upper and lower respiratory tract infections. Infections can occur in any age group but are most common in young children, elderly adults, and immunocompromised patients. Some infections, such as bronchiolitis and pneumonia, are severe; overall, metapneumovirus is responsible for 5% to 10% of hospitalizations and 12% to 20% of outpatient visits of children suffering from acute respiratory tract infections. Such infections are clinically indistinguishable from those caused by human respiratory syncytial virus and are often mistaken for influenza. The first human metapneumovirus infection occurs during early childhood, but reinfections are common throughout life, especially in older subjects. Diagnostic methods include PCR tests for viral RNA. Treatment generally focuses on supportive measures. Although work is ongoing, a clinically effective and safe vaccine has yet to be developed.

Human Coronaviruses

Coronaviruses are enveloped, positive-sense RNA viruses that infect humans and several other vertebrate species. Weakly pathogenic coronaviruses cause mild cold-like upper respiratory tract infections, while highly pathogenic ones may cause severe, often fatal pneumonia. An example of a highly pathogenic type is SARS-CoV-2, a strain that emerged in late 2019 in China that is producing a still evolving pandemic as of early 2020 (discussed in Chapter 8). Highly pathogenic coronaviruses like SARS-CoV-2 bind the ACE2 protein on the surface of pulmonary alveolar epithelial cells, explaining the tropism of these viruses for the lung. With highly pathogenic forms in susceptible hosts, typically older individuals with comorbid conditions, the host immune response and locally released cytokines often produce acute lung injury and ARDS.

MORPHOLOGY

All viral infections produce similar morphologic changes. Upper respiratory infections are marked by mucosal hyperemia and swelling, infiltration of the submucosa by mononuclear cells (mainly lymphocytes and monocytes), and overproduction of mucus secretions. The swollen mucosa and viscous exudate may plug the nasal channels, sinuses, or the Eustachian tubes, leading to suppurative secondary bacterial infection. Virus-induced tonsillitis causing hyperplasia of the lymphoid tissue within the Waldeyer ring is frequent in children.

In viral **laryngotracheobronchitis** and **bronchiolitis** there is vocal cord swelling and abundant mucus production. Impairment of bronchociliary function invites bacterial superinfection with more marked suppuration. Plugging of small airways may give rise to focal lung atelectasis. With more severe bronchiolar involvement, widespread plugging of secondary and terminal airways by cell debris, fibrin, and inflammatory exudate may, if prolonged, lead to organization and fibrosis, resulting in obliterative bronchiolitis and permanent lung damage.

Lung involvement may be quite patchy or may involve whole lobes bilaterally or unilaterally. The affected areas are red-blue and congested. Pleuritis or pleural effusions are infrequent. The histologic pattern depends on the severity of the disease. **Predominant is an interstitial inflammatory reaction involving the walls of the alveoli.** The alveolar septa are widened and edematous and usually contain a mononuclear inflammatory infiltrate of lymphocytes, macrophages, and occasionally plasma cells. In severe cases, neutrophils may also be present. The alveoli may be free of exudate, but in many patients there is intra-alveolar proteinaceous material and a cellular exudate. When complicated by ARDS, pink hyaline membranes line the alveolar walls (see Fig. 15.4). Eradication of the infection is followed by reconstitution of the normal lung architecture.

Superimposed bacterial infection modifies this picture by causing ulcerative bronchitis, bronchiolitis, and bacterial pneumonia. Some viruses, such as herpes simplex, varicella, and adenovirus, may be associated with necrosis of bronchial and alveolar epithelium and acute inflammation. Characteristic viral cytopathic changes are described in Chapter 8.

Clinical Features

The clinical course of viral pneumonia is extremely varied. Many cases masquerade as severe upper respiratory tract infections or as chest colds. Even individuals with well-developed atypical pneumonia have few localizing symptoms. Cough may be absent, and the major manifestations may consist only of fever, headache, and myalgia. The edema and exudation often cause ventilation-perfusion mismatch leading to hypoxemia and thus evoke symptoms out of proportion to the scant physical findings.

Viral pneumonias are usually mild and resolve spontaneously without any lasting sequelae. However, interstitial viral pneumonias may assume epidemic proportions, and in such instances even a low rate of complications can lead to significant morbidity and mortality, as is typically true of influenza epidemics.

Health Care–Associated Pneumonia

Health care–associated pneumonia was recently described as a distinct clinical entity associated with several risk factors. These are hospitalization of at least 2 days within the recent

past; presentation from a nursing home or long-term care facility; attending a hospital or hemodialysis clinic; and recent intravenous antibiotic therapy, chemotherapy, or wound care. The most common organisms isolated are methicillin-resistant *S. aureus* and *P. aeruginosa.* These patients have a higher mortality than those with community-acquired pneumonia.

Hospital-Acquired Pneumonia

Hospital-acquired pneumonias are defined as pulmonary infections acquired in the course of a hospital stay. They are common in patients with severe underlying disease, immunosuppression, prolonged antibiotic therapy, or invasive access devices such as intravascular catheters. Patients on mechanical ventilation are at particularly high risk. Superimposed on an underlying disease (that caused hospitalization), hospital-acquired infections are serious and often life-threatening. Gram-positive cocci (mainly *S. aureus*) and gram-negative rods (Enterobacteriaceae and *Pseudomonas* species) are the most common isolates. The same organisms predominate in ventilator-associated pneumonia, with gram-negative bacilli being somewhat more common in this setting.

KEY CONCEPTS

ACUTE PNEUMONIA

- *S. pneumoniae* (the pneumococcus) is the most common cause of community-acquired acute pneumonia; the distribution of inflammation is usually lobar.
- Lobar pneumonias evolve through four stages: congestion, red hepatization, gray hepatization, and resolution.
- Other common causes of acute bacterial pneumonias in the community include *H. influenzae* and *M. catarrhalis* (both associated with acute exacerbations of COPD), *S. aureus* (usually secondary to viral respiratory infections), *K. pneumoniae* (observed in patients who are chronic alcoholics), *P. aeruginosa* (seen in persons with cystic fibrosis and in those with neutropenia), and *L. pneumophila,* seen particularly in individuals with co-morbid conditions (e.g., heart or lung disease) and in organ transplant recipients.
- Important causes of community-acquired viral pneumonia include influenza virus, metapneumonia virus, and coronavirus COVID-19, the latter a newly emergent pathogen.
- Bacterial pneumonias are characterized by predominantly intra-alveolar neutrophilic inflammation, while viral pneumonia shows interstitial lymphocytic inflammation.

Aspiration Pneumonia

Aspiration pneumonia occurs in markedly debilitated patients or those who aspirate gastric contents either while unconscious (e.g., after a stroke) or during repeated vomiting. These patients have abnormal gag and swallowing reflexes that predispose to aspiration. The resultant pneumonia is partly chemical due to the irritating effects of gastric acid and partly bacterial (from the oral flora). Typically, more than one organism is recovered on culture, aerobes being more common than anaerobes. This type of pneumonia is often necrotizing, pursues a fulminant clinical course, and is a frequent cause of death. In patients who survive, lung abscess is a common complication.

Microaspiration, in contrast, occurs frequently in almost all people, especially those with gastroesophageal reflux disease. It usually results in small, poorly formed non-necrotizing granulomas with multinucleated foreign body giant cell reaction. It is usually inconsequential, but may exacerbate other pre-existing lung diseases such as asthma, interstitial fibrosis, and lung rejection.

Lung Abscess

The term *pulmonary abscess* describes a local suppurative process that produces necrosis of lung tissue. Oropharyngeal surgical or dental procedures, sinobronchial infections, and bronchiectasis play important roles in their development.

Etiology and Pathogenesis

Under appropriate circumstances any bacterial pathogen can produce an abscess; those that do so most commonly include aerobic and anaerobic streptococci, *S. aureus,* and a host of gram-negative organisms. Mixed infections often occur because of the important causal role played by inhalation of foreign material. Anaerobic organisms normally found in the oral cavity, including members of the *Bacteroides, Fusobacterium,* and *Peptococcus* genera, are the exclusive isolates in about 60% of cases. The causative organisms are introduced by the following mechanisms:

- *Aspiration of infective material* (the most frequent cause). Risk factors include suppressed cough reflexes (e.g., acute alcohol intoxication, opioid abuse, coma, anesthesia, seizure disorders), severe dysphagia (e.g., neurologic deficits, esophageal disease), protracted vomiting, and poor dental hygiene. Aspiration first causes pneumonia, which progresses to tissue necrosis and formation of lung abscess.
- *Antecedent primary lung infection.* Postpneumonic abscess formations are usually associated with *S. aureus, K. pneumoniae,* and pneumococcus. Posttransplant or otherwise immunosuppressed individuals are at special risk.
- *Septic embolism.* Infected emboli may arise from thrombophlebitis in any portion of the systemic venous circulation or from the vegetations of infective bacterial endocarditis on the right side of the heart and lodge in the lung.
- *Neoplasia.* Secondary infection is particularly common in bronchopulmonary segments obstructed by a primary or secondary malignancy *(postobstructive pneumonia).*
- *Miscellaneous.* Traumatic penetrations of the lungs; direct extension of suppurative infections from the esophagus, spine, subphrenic space, or pleural cavity; and hematogenous seeding of the lung by pyogenic organisms all may lead to lung abscess formation.

When all these causes are excluded, there are still cases in which no discernible basis for the abscess formation can be identified. These are referred to as *primary cryptogenic lung abscesses.*

MORPHOLOGY

Abscesses vary in diameter from a few millimeters to large cavities of 5 to 6 cm (Fig. 15.36). They may affect any part of the lung and may be single or multiple. Pulmonary abscesses due to aspiration are more common on the right (because of the more vertical right main bronchus) and are most often single. Abscesses that

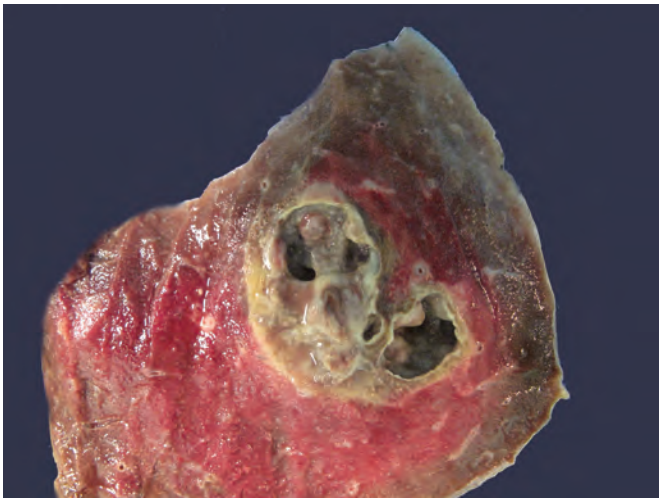

Figure 15.36 Cut surface of lung showing two abscesses. (Courtesy Dr. M. Kamran Mirza, University of Chicago, Chicago, Ill.)

develop in the course of pneumonia or bronchiectasis are usually multiple, basal, and diffusely scattered. Septic emboli and pyemic abscesses are multiple and may affect any region of the lungs.

The **cardinal histologic change in all abscesses is suppurative destruction of the lung parenchyma within the central area of cavitation.** The abscess cavity may be filled with suppurative debris or, if there is communication with an air passage, may be partially drained to create an air-containing cavity. Superimposed saprophytic infections are prone to develop within the necrotic debris. Continued infection leads to large, poorly demarcated, fetid, green-black, multilocular cavities designated gangrene of the lung. In chronic cases considerable fibroblastic proliferation produces a fibrous wall.

Clinical Features

The manifestations of pulmonary abscesses are much like those of bronchiectasis and characteristically include cough, fever, and copious amounts of foul-smelling purulent or sanguineous sputum. Fever, chest pain, and weight loss are common. Clubbing of the fingers and toes may appear. The diagnosis can be only suspected from the clinical findings and must be confirmed radiologically. Whenever an abscess is discovered in older individuals, it is important to rule out an underlying carcinoma, which is present in 10% to 15% of cases.

The course of abscesses is variable. With antimicrobial therapy, most resolve, leaving behind a scar. Complications include extension of the infection into the pleural cavity, hemorrhage, the development of *brain abscesses* or *meningitis* from septic emboli, and (rarely) secondary amyloidosis (type AA).

Chronic Pneumonia

Chronic pneumonia is most often a localized lesion in the immunocompetent patient, with or without regional lymph node involvement. Typically the inflammatory reaction is granulomatous and is caused by bacteria (e.g., *Mycobacterium tuberculosis*) or fungi (e.g., *Histoplasma capsulatum*). Tuberculosis of the lung and other organs is described in Chapter 8. Chronic pneumonias caused by fungi are discussed here.

Histoplasmosis

H. capsulatum infection is acquired by inhalation of dust particles from soil contaminated with bird or bat droppings that contain small spores (microconidia), the infectious form of the fungus. It is endemic along the Ohio and Mississippi rivers and in the Caribbean. It is also found in Mexico, Central and South America, parts of eastern and southern Europe, Africa, eastern Asia, and Australia. Like *M. tuberculosis, H. capsulatum* is an intracellular pathogen that is found mainly in phagocytes. The clinical presentations and morphologic lesions of histoplasmosis bear a striking resemblance to those of tuberculosis, including (1) a self-limited and often latent primary pulmonary involvement, which may result in coin lesions on chest radiography; (2) chronic, progressive, secondary lung disease, which is localized to the lung apices and causes cough, fever, and night sweats; (3) spread to extrapulmonary sites, including mediastinum, adrenal glands, liver, or meninges; and (4) widely disseminated disease in immunocompromised patients. Histoplasmosis can occur in immunocompetent individuals but as per usual is more severe in those with depressed cell mediated immunity.

The pathogenesis of histoplasmosis is incompletely understood. The portal of entry is virtually always the lung. Macrophages ingest but cannot kill the organism without T-cell help, and this allows the organism to multiply within phagolysosomes and disseminate prior to the development of T-cell immunity, which takes 1 to 2 weeks. In individuals with adequate cell-mediated immunity, the infection is controlled by Th1 helper T cells that recognize fungal antigens and subsequently secrete IFN-γ, which activates macrophages and enables them to kill intracellular yeasts. In addition, *Histoplasma* induces macrophages to secrete TNF, which recruits and stimulates other macrophages to kill *Histoplasma.*

MORPHOLOGY

In the lungs of otherwise healthy adults, *Histoplasma* infections produce **granulomas,** which usually become necrotic and may coalesce to produce areas of consolidation. With spontaneous resolution or effective treatment, these lesions undergo fibrosis and concentric calcification (tree-bark appearance) (Fig. 15.37A). Histologic differentiation from tuberculosis, sarcoidosis, and coccidioidomycosis requires identification of the 3- to 5-μm thin-walled yeast forms, which may persist in tissues for years. In **fulminant disseminated histoplasmosis,** which occurs in immunosuppressed individuals, granulomas do not form; instead, there are focal accumulations of mononuclear phagocytes filled with fungal yeasts throughout the body (Fig. 15.37B).

The diagnosis of histoplasmosis may be established by serologic tests for antibodies and fungal antigens, culture, or identification of the fungus in tissue biopsies. The majority of cases resolve spontaneously. Progressive disease or disease in immunocompromised patients is treated with antifungal agents.

Blastomycosis

Blastomyces dermatitidis is a soil-inhabiting dimorphic fungus. It causes disease in the central and southeastern United States; infection also occurs in Canada, Mexico, the Middle East, Africa, and India. There are three clinical forms: *pulmonary*

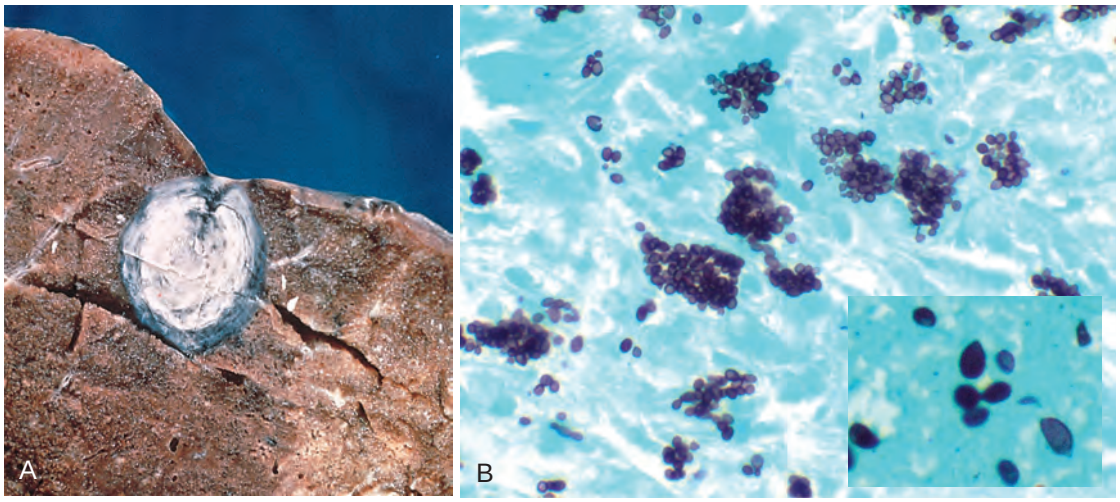

Figure 15.37 Histoplasmosis. (A) Laminated *Histoplasma* granuloma of the lung. (B) *Histoplasma capsulatum* yeast forms fill phagocytes in the lung of a patient with disseminated histoplasmosis; *inset* shows high-power detail of pear-shaped, thin-based budding yeasts (silver stain).

blastomycosis, disseminated blastomycosis, and a rare *primary cutaneous form* that results from direct inoculation of organisms into the skin. The pneumonia most often resolves spontaneously, but it may persist or progress to a chronic lesion.

MORPHOLOGY

In the normal host, the lung lesions of blastomycosis are suppurative granulomas. Macrophages have a limited ability to ingest and kill *B. dermatitidis*, and the persistence of the yeast cells leads to the recruitment of neutrophils. In tissue, *B. dermatitidis* is a round, 5- to 15-μm yeast cell that divides by broad-based budding. It has a thick, double-contoured cell wall, and visible nuclei (Fig. 15.38). Involvement of the skin and larynx is associated with marked epithelial hyperplasia, which may be mistaken for squamous cell carcinoma.

Coccidioidomycosis

Almost everyone who inhales the spores of *Coccidioides immitis* becomes infected and develops a delayed-type hypersensitivity reaction to the fungus, but most remain asymptomatic. Indeed, more than 80% of people in endemic areas of the southwestern and western United States and in Mexico have a positive skin test reaction. One reason for the infectivity of *C. immitis* is that infective arthroconidia, when ingested by alveolar macrophages, block fusion of the phagosome and lysosome and so resist intracellular killing. Approximately 10% of infected people develop lung lesions, and less than 1% of people develop disseminated *C. immitis* infection, which frequently involves the skin and meninges. Certain ethnic groups (e.g., Filipinos and African Americans) and the immunosuppressed are at high risk for disseminated disease.

MORPHOLOGY

Within macrophages or giant cells, *C. immitis* is present as thick-walled, nonbudding spherules 20 to 60 μm in diameter, often filled with small endospores. A pyogenic reaction is superimposed when the spherules rupture to release the endospores (Fig. 15.39). Rare progressive *C. immitis* disease involves the lungs, meninges, skin, bones, adrenals, lymph nodes, spleen, or liver. At all these sites, the inflammatory response may be purely granulomatous, pyogenic, or mixed.

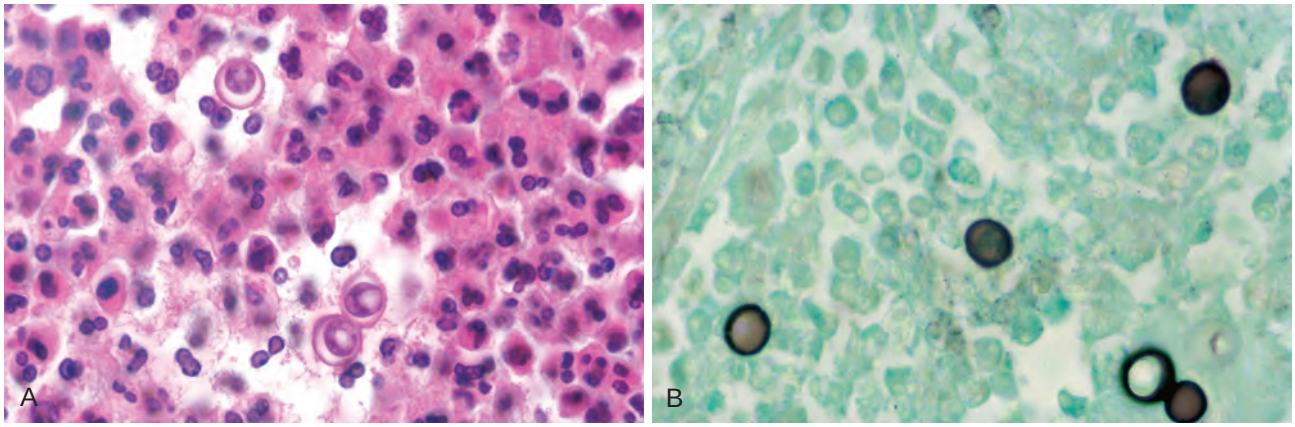

Figure 15.38 Blastomycosis. (A) Rounded budding yeasts, larger than neutrophils, are present. Note the characteristic thick wall and nuclei (not seen in other fungi). (B) Silver stain.

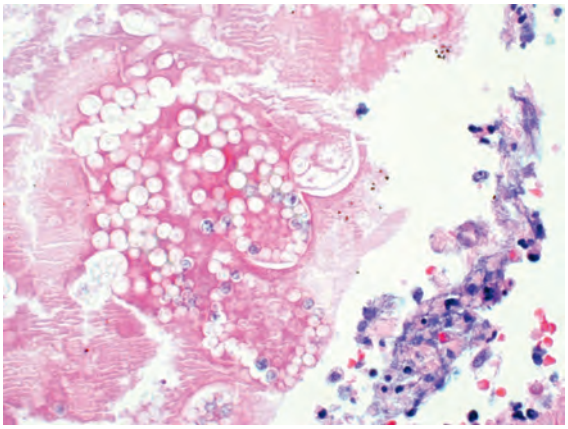

Figure 15.39 Coccidioidomycosis. Intact and ruptured spherules are seen.

Pneumonia in the Immunocompromised Host

The appearance of a pulmonary infiltrate, with or without signs of infection (e.g., fever), is one of the most common and serious complications in patients whose immune defenses are suppressed by disease, immunosuppressive therapy for organ or hematopoietic stem cell transplants, chemotherapy for tumors, or irradiation. In addition to the usual pathogens, a wide variety of so-called opportunistic infectious agents, many of which rarely cause infection in normal hosts, can cause pneumonia, and often more than one agent is involved. Mortality from these opportunistic infections is high. Table 15.8 lists some of the opportunistic agents according to their prevalence and whether they cause local or diffuse pulmonary infiltrates. The differential diagnosis of such infiltrates includes drug reactions and involvement of the lung by tumor. The specific infections are discussed in Chapter 8. Of these, the ones that commonly involve the lung can be classified according to the etiologic agent: (1) bacteria (*P. aeruginosa*, *Mycobacterium* species, *L. pneumophila*, and *Listeria monocytogenes*), (2) viruses (cytomegalovirus [CMV] and herpesvirus), and (3) fungi (*P. jiroveci*, *Candida* species, *Aspergillus* species, the Phycomycetes, and *Cryptococcus neoformans*).

Table 15.8 Causes of Pulmonary Infiltrates in Immunocompromised Hosts

Diffuse Infiltrates	Focal Infiltrates
Common	
Cytomegalovirus	Gram-negative bacterial infections
Pneumocystis jiroveci	*Staphylococcus aureus*
Drug reaction	*Aspergillus*
	Candida
	Malignancy
Uncommon	
Bacterial pneumonia	*Cryptococcus*
Aspergillus	*Mucor*
Cryptococcus	*Pneumocystis jiroveci*
Malignancy	*Legionella pneumophila*

Pulmonary Disease in Human Immunodeficiency Virus Infection

Pulmonary disease accounts for 30% to 40% of hospitalizations in HIV-infected individuals. Although the use of potent antiretroviral agents and effective chemoprophylaxis has markedly altered the incidence and outcome of pulmonary disease in HIV-infected persons, the plethora of infectious agents and other pulmonary lesions make diagnosis and treatment a distinct challenge. Some of the individual microbial agents afflicting HIV-infected individuals have already been discussed; this section focuses only on the general principles of HIV-associated pulmonary disease.

- *Despite the emphasis on opportunistic infections, it must be remembered that bacterial lower respiratory tract infections caused by the "usual" pathogens are among the most serious pulmonary disorders in HIV infection.* The implicated organisms include *S. pneumoniae, S. aureus, H. influenzae,* and gram-negative rods. Bacterial pneumonias in HIV-infected persons are more common, more severe, and more often associated with bacteremia than in those without HIV infection.
- *Not all pulmonary infiltrates in HIV-infected individuals are infectious in etiology.* A host of noninfectious diseases, including Kaposi sarcoma (Chapters 6 and 11), non-Hodgkin lymphoma (Chapter 13), and lung cancer, occur with increased frequency and must be excluded.
- *The CD4+ T-cell count determines the risk of infection with specific organisms.* As a rule of thumb, bacterial and tubercular infections are more likely at higher CD4+ counts (>200 cells/mm^3). *Pneumocystis* pneumonia usually strikes at CD4+ counts less than 200 cells/mm^3, while CMV, fungal, and *Mycobacterium avium-intracellulare* complex infections are uncommon until the disease is very advanced (CD4+ counts less than 50 cells/mm^3).

Finally, pulmonary disease in HIV-infected persons may result from more than one cause, and even common pathogens may present with atypical manifestations. Therefore the diagnostic work-up of these patients may be more extensive (and expensive) than would be necessary in an immunocompetent individual.

LUNG TRANSPLANTATION

Indications for transplantation may include almost all non-neoplastic terminal lung diseases, provided that the patient does not have any other serious disease that would preclude lifelong immunosuppressive therapy. The most common indications are end-stage COPD, idiopathic pulmonary fibrosis, cystic fibrosis, and idiopathic/familial pulmonary arterial hypertension. Although bilateral lung transplantation offers better survival as compared to single lung, the latter may be performed to benefit two recipients from a single (and all too scarce) donor. When bilateral chronic infection is present (e.g., cystic fibrosis, bronchiectasis), both lungs of the recipient must be replaced to remove the reservoir of infection.

With improving surgical and organ preservation techniques, postoperative complications (e.g., anastomotic

dehiscence, vascular thrombosis, primary graft dysfunction) are becoming rare. The transplanted lung is subject to two major complications: infection and rejection.

- *Pulmonary infections* in lung transplant patients are essentially those of any immunocompromised host, discussed earlier. In the early posttransplant period (the first few weeks), bacterial infections are most common. With ganciclovir prophylaxis and matching of donor-recipient CMV status, CMV pneumonia occurs less frequently and is less severe, although some resistant strains are emerging. Most infections occur in the third to twelfth month after transplantation. *P. jiroveci* pneumonia is rare, since almost all patients receive adequate prophylaxis, usually with trimethoprim-sulfamethoxazole (Bactrim). Fungal infections are mostly due to *Aspergillus* and *Candida* species, and they may involve the bronchial anastomotic site and/or the lung.
- *Acute lung allograft rejection* occurs to some degree in all patients despite routine immunosuppression. It most often appears several weeks to months after surgery but also may present years later or whenever immunosuppression is decreased. Patients present with fever, dyspnea, cough, and radiologic infiltrates. Since these are similar to the picture of infections, diagnosis often relies on transbronchial biopsy.
- *Chronic lung allograft rejection* is a significant problem in at least half of all patients by 3 to 5 years posttransplant. It is manifested by cough, dyspnea, and an irreversible decrease in lung function due to pulmonary fibrosis.

MORPHOLOGY

The morphologic features of acute rejection are primarily those of inflammatory infiltrates (lymphocytes, plasma cells, and few neutrophils and eosinophils) around small vessels, in the submucosa of airways, or both. The major morphologic correlate of chronic rejection is **bronchiolitis obliterans,** the partial or complete occlusion of small airways by fibrosis, with or without active inflammation (Fig. 15.40). Bronchiolitis obliterans is patchy and therefore difficult to diagnose via transbronchial biopsy. Bronchiectasis and pulmonary fibrosis may also develop with long-standing chronic rejection.

Acute cellular airway rejection (the presumed forerunner of later, fibrous obliteration of these airways) is generally responsive to therapy, but the treatment of established bronchiolitis obliterans has been disappointing. Its progress may be slowed or even halted for some time, but it cannot be reversed. Infrequent complications of lung transplantation include Epstein-Barr virus (EBV)–associated B-cell lymphoma, which most often arises within the lung allograft. With continuing improvement in surgical, immunosuppressive, and antimicrobial therapies, the outcome of lung transplantation has improved considerably. The overall median survival is 6 years, with younger patients and those undergoing bilateral lung transplantation having better outcomes.

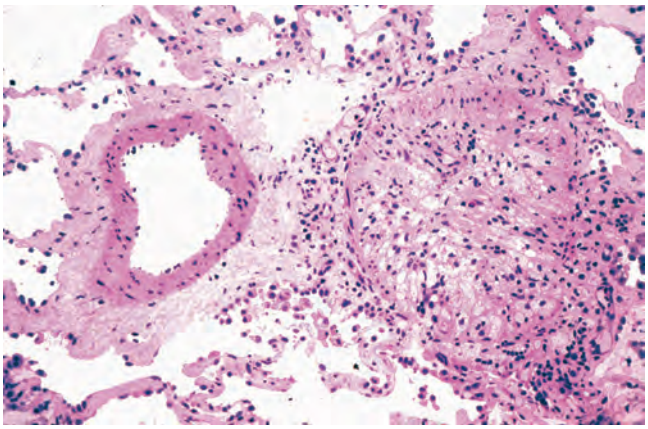

Figure 15.40 Chronic rejection of lung allograft associated with bronchiole (bronchiolitis obliterans). An adjacent pulmonary artery is normal. (Courtesy Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, Ill.)

TUMORS

Of the wide variety of benign and malignant tumors that may arise in the lung, 90% to 95% are carcinomas, about 5% are carcinoid tumors, and 2% to 5% are mesenchymal and other miscellaneous neoplasms.

Carcinomas

Lung cancer is currently the most frequently diagnosed major cancer and the most common cause of cancer mortality worldwide. Globally, in 2018 there were an estimated 2.1 million new cases and 1.8 million lung cancer deaths. The number of new cases of lung cancer in 2018 in the United States is expected to number approximately 230,000 (note that in 1950 it was 18,000), accounting for about 14% of cancer diagnoses and taking more than 150,000 lives, which amounts to roughly 28% of all cancer-related deaths. Each year, lung cancer kills more people than colon, breast, and prostate cancer combined. It is generally a disease of older adults, occurring most often between ages 55 and 84 years, with a peak incidence between 65 and 74 years. Only 2% of all cases occur before the age of 40.

Because lung cancer is strongly linked to cigarette smoking, changes in smoking habits greatly influence lung cancer incidence and mortality as well as the prevalence of the various histologic types of lung cancer. Since the early 1990s, lung cancer incidence and mortality rates have been decreasing in men due to a decrease in male smoking over the past 35 years. However, the decrease in smoking among women has lagged behind that of men. Since 1987 more women have died each year of lung cancer than of breast cancer, which for more than 40 years had been the leading cause of cancer death in women.

Etiology and Pathogenesis

Most (but not all) lung cancers are associated with a well-known carcinogen—cigarette smoke. In addition, there are other genetic and environmental factors. Lung cancers are

broadly classified into small cell and non–small cell types, with the latter group including adenocarcinoma and squamous cell carcinoma. The driver mutations that cause lung cancer vary among these histologic subtypes, as will be described later.

Tobacco Smoking. **About 80% of lung cancers occur in active smokers or those who stopped recently, and there is a nearly linear correlation between the frequency of lung cancer and pack-years of cigarette smoking.** The increased risk is 60 times greater in habitual heavy smokers (two packs a day for 20 years) than in nonsmokers. However, since lung cancer develops in only 10% to 15% of smokers, there are likely to be other factors that interact with smoking to predispose individuals to this deadly disease. For unclear reasons, it appears that women are more susceptible to carcinogens in tobacco than men. Although cessation of smoking decreases the risk for lung cancer over time, it may never return to baseline levels. In fact, genetic changes that predate lung cancer can persist for many years in the bronchial epithelium of former smokers. Pipe and cigar smokers also incur an elevated risk, albeit only modestly. Chewing tobacco is not a safe substitute for smoking cigarettes or cigars, as these products spare the lung but cause oral cancers and can lead to nicotine addiction. The long-term effects of electronic cigarette aerosols are not known, as "vaping" is a relatively recent phenomenon (Chapter 9).

Unfortunately, the carcinogenic effects of tobacco smoke extend to those who live and work with smokers. *Secondhand smoke,* or environmental tobacco smoke, contains numerous human carcinogens for which there is no safe level of exposure. It is estimated that each year about 3000 nonsmoking adults die of lung cancer as a result of breathing secondhand smoke.

What of heavy smokers who never develop cancer? While some of this may be a matter of chance, the mutagenic effect of carcinogens in smoke is modified by genetic variants. Recall that many chemicals (procarcinogens) are converted into carcinogens via activation by the highly polymorphic P-450 monooxygenase enzyme system (Chapter 9). Specific P-450 variants have an increased capacity to activate procarcinogens in cigarette smoke, and smokers with these variants incur a greater risk of lung cancer. Similarly, individuals whose peripheral blood lymphocytes show more numerous chromosomal breakages after exposure to tobacco-related carcinogens (mutagen sensitivity genotype) have a greater than 10-fold higher risk of developing lung cancer as compared with controls, presumably because of genetic variation in genes involved in DNA repair.

The histologic changes that correlate with steps along the path to neoplastic transformation are best documented for squamous cell carcinoma and are described in more detail later. There is a linear correlation between the intensity of exposure to cigarette smoke and the appearance of ever more worrisome epithelial changes. These begin with rather innocuous-appearing basal cell hyperplasia and squamous metaplasia and progress to squamous dysplasia and carcinoma in situ, the last stage before progression to invasive cancer.

Industrial Hazards. Certain industrial exposures, such as asbestos, arsenic, chromium, uranium, nickel, vinyl chloride, and mustard gas, increase the risk of developing lung cancer. High-dose ionizing radiation is carcinogenic. There was an increased incidence of lung cancer among survivors of the Hiroshima and Nagasaki atomic bomb blasts, as well as in workers heavily involved in clean-up after the Chernobyl disaster. Uranium is weakly radioactive, but lung cancer rates among nonsmoking uranium miners are four times higher than those in the general population, and among smoking miners they are about 10 times higher. Asbestos exposure also increases the risk for lung cancer development. The latent period before the development of lung cancer is 10 to 30 years. Lung cancer is the most frequent malignancy in individuals exposed to asbestos, particularly when coupled with smoking. Asbestos workers who do not smoke have a five-fold greater risk of developing lung cancer than do nonsmoking control subjects, whereas those who smoke have a 55-fold greater risk.

Air Pollution. It is uncertain whether air pollution, by itself, increases the risk of lung cancer, but it likely adds to the risk in those who smoke or are exposed to secondhand smoke. It may do so through several different mechanisms. Chronic exposure to air particulates in smog may cause lung irritation, inflammation, and repair, and you will recall that chronic inflammation and repair increases the risk of a variety of cancers (Chapter 7). A specific form of air pollution that may contribute to an increased risk of lung cancer is radon gas. Radon is a ubiquitous radioactive gas that has been linked epidemiologically to increased lung cancer in uranium miners. Other underground miners and workers in locations below ground, such as subways, tunnels, and basements, are at increased risk for radon exposure. This has generated concern that low-level exposure (e.g., in well-insulated homes in areas with naturally high levels of radon in soil) may also increase the incidence of lung cancer.

Acquired Mutations. As with other cancers (Chapter 7), smoking-related carcinomas of the lung arise by a stepwise accumulation of oncogenic "driver" mutations that result in the neoplastic transformation of pulmonary epithelial cells. Some of the genetic changes associated with cancers can be found in the "benign" bronchial epithelium of smokers without lung cancers, suggesting that large areas of the respiratory mucosa are mutagenized by exposure to carcinogens in tobacco smoke ("field effect"). On this fertile soil, cells that accumulate just the "wrong" panoply of complementary driver mutations to acquire all of the hallmarks of cancer develop into carcinomas.

The major histologic subtypes of lung cancer each have distinctive molecular features, as follows:

- *Adenocarcinoma* is associated with tobacco smoking, but less so than other histologic subtypes; as a result, it is the most common subtype in never-smokers (described below). About one-third of adenocarcinomas have oncogenic gain-of-function mutations involving components of growth factor receptor signaling pathways; these are important to recognize because they often can be targeted with specific inhibitors (discussed later). These include gain-of-function mutations in genes encoding several different receptor tyrosine kinases, such as: *EGFR,* in 10% to 15% of tumors in Caucasians and a higher percentage of nonsmoking Asian women; *ALK,* in 3% to 5% of tumors;

ROS1, in 1% of tumors; *MET,* in 2% to 5% of tumors; and *RET,* in 1% to 2% of tumors. Other tumors have gain-of-function mutations in serine/threonine kinases (*BRAF,* 2% of tumors, and *PI3K,* 2% of tumors) or in the *KRAS* gene (roughly 30% of tumors), all of which encode signaling molecules that lie downstream of receptor tyrosine kinases in growth factor signaling pathways.

- *Squamous cell carcinoma* is highly associated with exposure to tobacco smoke and harbors diverse genetic aberrations, many of which are chromosome deletions involving tumor suppressor loci. These losses, especially those involving 3p, 9p (site of the *CDKN2A* gene), and 17p (site of the *TP53* gene), are early events in tumor evolution, being detected at an appreciable frequency in the histologically normal respiratory mucosal cells of smokers. Most tumors have mutations in *TP53*, and p53 protein overexpression (as seen by immunohistochemical staining), a marker of *TP53* mutations, is an early event, being reported in 10% to 50% of squamous dysplasias and 60% to 90% of squamous cell carcinoma in situ. The *CDKN2A* tumor suppressor gene, which encodes the cyclin-dependent kinase inhibitor p16, is mutated in 65% of tumors. Many squamous cell carcinomas also have amplification of *FGFR1,* a gene encoding the fibroblast growth factor receptor tyrosine kinase.
- *Small cell carcinoma* is virtually always smoking related and has the highest mutational burden among lung cancers. There is almost universal inactivation of both *TP53* and *RB,* and unusual transformations of non–small cell carcinoma to small cell carcinoma are often associated with acquisition of *RB* loss-of-function mutations, emphasizing the importance of *RB* inactivation in this lung cancer subtype. Loss of chromosome 3p also occurs in nearly all of these tumors and is seen even in histologically normal lung epithelium, suggesting that this also is a critical early event. This subtype is also commonly associated with amplification of genes of the *MYC* family.

Lung Cancer in Never-Smokers. The WHO estimates that 25% of lung cancer worldwide occurs in never-smokers. This percentage is probably closer to 10% to 15% in Western countries. These cancers occur more commonly in women, and most are adenocarcinomas, often with targetable mutations/co-mutations. Cancers in nonsmokers are more likely to have *EGFR* mutations and almost never have *KRAS* mutations; *TP53* mutations are not uncommon, but occur less frequently than in smoking-related cancers.

Precursor (Preinvasive) Lesions. Four types of morphologic precursor epithelial lesions are recognized: (1) atypical adenomatous hyperplasia, (2) adenocarcinoma in situ, (3) squamous dysplasia and carcinoma in situ, and (4) diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. It should be remembered that the term *precursor* does not imply that progression to cancer is inevitable. Currently it is not possible to distinguish between precursor lesions that progress and those that remain localized or regress.

Classification

Tumor classification is important for consistency in patient treatment and provides a uniform basis for epidemiologic and biologic studies. The most recent classification of lung cancer is given in Table 15.9. Several histologic variants of each type of lung cancer are described; however, their clinical significance is still undetermined except as mentioned herein. The relative proportions of the major categories are:

- Adenocarcinoma (50%)
- Squamous cell carcinoma (20%)
- Small cell carcinoma (15%)
- Large cell carcinoma (2%)
- Other (13%)

There may be mixtures of histologic patterns, even in the same cancer. Thus combinations of squamous cell carcinoma and adenocarcinoma or small cell and squamous cell carcinoma occur in about 14% and 5% of patients, respectively.

The incidence of adenocarcinoma has increased significantly in the last 2 decades, and it is now the most common form of lung cancer in women and men. The basis for this change is unclear. One possible factor is the increase in women smokers, but this only highlights our ignorance about why women develop adenocarcinoma more frequently. Another possibility is that changes in cigarettes (altered filter tips and decreased tar and nicotine) may have caused smokers to inhale more deeply, increasing the exposure of peripheral airways and cells with a predilection to give rise to adenocarcinoma to carcinogens.

Table 15.9 Histologic Classification of Malignant Epithelial Lung Tumors

Tumor Classification
Adenocarcinoma
Lepidic, acinar, micropapillary, papillary, solid (according to predominant pattern)
Invasive mucinous adenocarcinoma
Minimally invasive adenocarcinoma (nonmucinous, mucinous)
Squamous cell carcinoma
Keratinizing, nonkeratinizing, basaloid
Neuroendocrine tumors
Small cell carcinoma
Combined small cell carcinoma
Large cell neuroendocrine carcinoma
Combined large-cell neuroendocrine carcinoma
Carcinoid tumor
Typical, atypical
Other uncommon types
Large cell carcinoma
Adenosquamous carcinoma
Sarcomatoid carcinoma
Pleomorphic, spindle cell, giant cell carcinoma, carcinosarcoma, pulmonary blastoma
Others such as lymphoepithelioma-like carcinoma and NUT carcinoma
Salivary gland–type tumors

MORPHOLOGY

Lung carcinomas may arise in the peripheral lung (more often adenocarcinomas) or in the central/hilar region (more often squamous cell carcinomas), sometimes in association with recognizable precursor lesions.

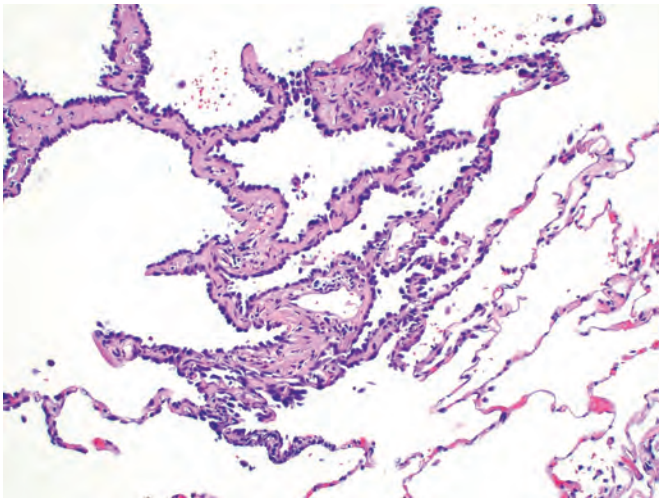

Figure 15.41 Atypical adenomatous hyperplasia. The epithelium is cuboidal, and there is mild interstitial fibrosis.

Atypical adenomatous hyperplasia is a small precursor lesion (≤5 mm) characterized by dysplastic pneumocytes lining alveolar walls that are mildly fibrotic (Fig. 15.41). It can be single or multiple and can be in the lung adjacent to invasive tumor or away from it.

Adenocarcinoma in situ (formerly called bronchioloalveolar carcinoma) is a lesion that is less than 3 cm in size and is composed entirely of dysplastic cells growing along pre-existing alveolar septa. The cells have more dysplasia than atypical adenomatous hyperplasia and may or may not have intracellular mucin (Fig. 15.42).

Adenocarcinoma is an invasive malignant epithelial tumor with glandular differentiation or mucin production by the tumor cells. Adenocarcinomas grow in various patterns, including acinar, lepidic, papillary, micropapillary, and solid. Compared with squamous cell cancers, these lesions are usually more peripherally located and tend to be smaller. They vary histologically from well-differentiated tumors with obvious glandular elements (Fig. 15.43A), to papillary lesions resembling other papillary carcinomas, to solid masses with only occasional mucin-producing glands and cells. The majority express thyroid transcription factor-1 (TTF-1) (Fig. 15.43A inset), a protein first identified in the thyroid that is required for normal lung development. At the periphery of the tumor there is often a lepidic pattern of spread, in which the tumor cells "crawl" along normal-appearing alveolar septa. Tumors (≤3 cm) with a small invasive component (≤5 mm) associated with scarring and a peripheral lepidic growth pattern are called **microinvasive adenocarcinoma.** These have a far better prognosis than invasive carcinomas of the same size. **Mucinous adenocarcinomas** tend to spread aerogenously, forming satellite tumors; thus, these are less likely to be cured by surgery. They may present as a solitary nodule or as multiple nodules, or an entire lobe may be consolidated by tumor, mimicking lobar pneumonia.

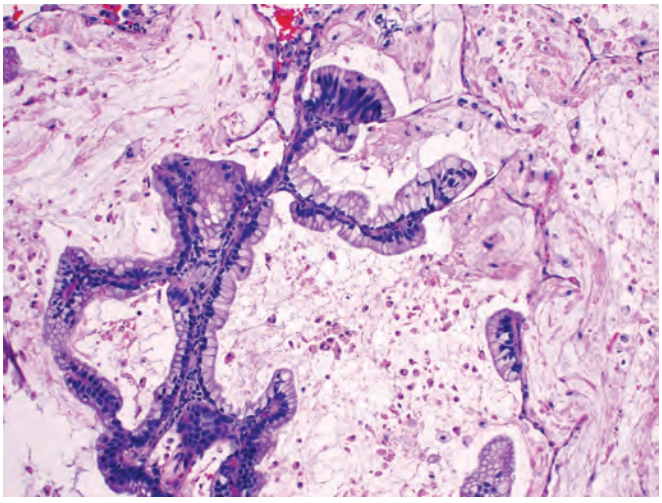

Figure 15.42 Adenocarcinoma in situ, mucinous subtype. Characteristic growth along pre-existing alveolar septa is evident, without invasion.

Squamous cell carcinoma is more common in men and is strongly associated with smoking. Precursor lesions that give rise to invasive squamous cell carcinoma are well characterized. Squamous cell carcinomas are often antedated by **squamous metaplasia** or **dysplasia** in the bronchial epithelium, which then transforms to **carcinoma in situ,** a phase that may last for years (Fig. 15.44). By this time, atypical cells may be identified in cytologic smears of sputum or in bronchial lavage fluids or brushings (Fig. 15.45), but the lesion is asymptomatic and undetectable on radiographs. Eventually, an invasive squamous cell carcinoma appears. The tumor may then follow a variety of paths. It may grow exophytically into the bronchial lumen, producing an intraluminal mass. With further enlargement the bronchus becomes obstructed, leading to distal atelectasis and infection. The tumor may also penetrate the wall of the bronchus and infiltrate along the peribronchial tissue (Fig. 15.46) into the adjacent carina or mediastinum. In other instances, the tumor grows along a broad front to produce a cauliflower-like intraparenchymal mass that compresses the surrounding lung. As in almost all types of lung cancer, the neoplastic tissue is gray-white and firm to hard. Especially when the tumors are bulky, focal areas of hemorrhage or necrosis may appear to produce red or yellow-white mottling and softening. Sometimes these necrotic foci cavitate.

Histologically, squamous cell carcinoma is characterized by the presence of keratinization and/or intercellular bridges. Keratinization may take the form of squamous pearls or individual cells with markedly eosinophilic cytoplasm (see Fig. 15.43B). These features are prominent in well-differentiated tumors, are easily seen but not extensive in moderately differentiated tumors, and are focally seen in poorly differentiated tumors. Mitotic activity is higher in poorly differentiated tumors. In the past, most squamous cell carcinomas arose centrally from the segmental or subsegmental bronchi, but the incidence of squamous cell carcinoma of the peripheral lung is increasing. Squamous metaplasia, epithelial dysplasia, and foci of frank carcinoma in situ may be seen in bronchial epithelium adjacent to the tumor mass (see Fig. 15.44).

Small cell carcinoma is a highly malignant tumor with a strong relationship to cigarette smoking; only about 1% occurs in nonsmokers. Tumors may arise in major bronchi or in the periphery of the lung. There is no known pre-invasive phase. They are the most aggressive of lung tumors, metastasizing widely and virtually always proving to be fatal.

Small cell carcinoma is comprised of relatively small cells with scant cytoplasm, ill-defined cell borders, finely granular nuclear

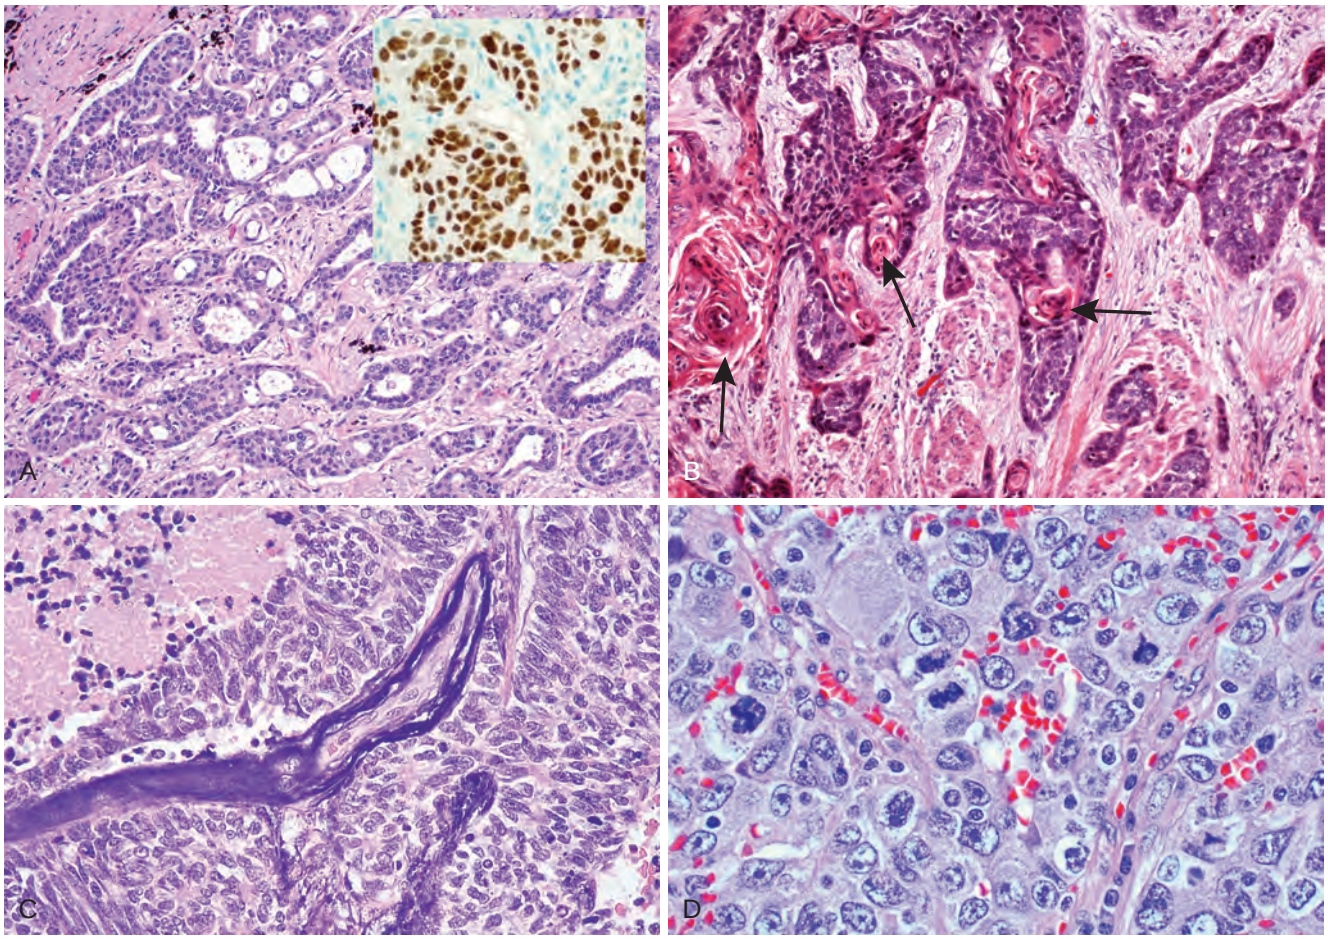

Figure 15.43 Histologic variants of lung carcinoma. (A) Gland-forming adenocarcinoma; *inset* shows thyroid transcription factor 1 (TTF-1) expression, as detected by immunohistochemistry. (B) Well-differentiated squamous cell carcinoma showing keratinization *(arrow)*. (C) Small cell carcinoma. There are islands of small, deeply basophilic cells and areas of necrosis. (D) Large cell carcinoma. The tumor cells are pleomorphic and show no evidence of squamous or glandular differentiation.

chromatin (salt and pepper pattern), and absent or inconspicuous nucleoli (see Fig. 15.43C). The cells are round, oval, or spindle-shaped, and nuclear molding is prominent. There is no absolute size for the tumor cells, but in general they are smaller than three times the diameter of a small resting lymphocyte (a size of about 25 μm). The mitotic count is high. The cells grow in clusters that exhibit neither glandular nor squamous organization. Necrosis is common and often extensive. Basophilic staining of vascular walls due to encrustation by DNA from necrotic tumor cells (Azzopardi effect) is frequently present. Combined small cell carcinoma is a variant in which typical small cell carcinoma is mixed with non–small cell histologies, such as large cell neuroendocrine carcinoma or even spindled cell morphologies resembling sarcoma.

Electron microscopy shows dense-core neurosecretory granules, about 100 nm in diameter, in two-thirds of cases of small cell carcinoma. The occurrence of neurosecretory granules; the expression of neuroendocrine markers such as chromogranin, synaptophysin, and CD56; and the ability of some of these tumors to secrete hormones (e.g., parathormone-related protein, a cause of paraneoplastic hypercalcemia) suggest that this tumor originates from neuroendocrine progenitor cells, which are present in the lining bronchial epithelium. This simplistic idea is challenged, however, by the existence of tumors comprised of a mixture of small cell carcinoma and other histologies and well-documented "transformations" of non–small cell carcinoma to small cell carcinoma. Among the various types of lung cancer, small cell carcinoma is the one that is most commonly associated with ectopic hormone production (discussed later).

Large cell carcinoma is an undifferentiated malignant epithelial tumor that lacks the cytologic features of other forms of lung cancer. The cells typically have large nuclei, prominent nucleoli, and a moderate amount of cytoplasm (see Fig. 15.43D). Large cell carcinoma is a diagnosis of exclusion since it expresses none of the markers associated with adenocarcinoma (TTF-1, napsin A) or squamous cell carcinoma (p40, p63). One histologic variant is large cell neuroendocrine carcinoma, which has molecular features similar to those of small cell carcinoma, but is comprised of tumor cells of larger size.

Combined Carcinoma. Approximately 4% to 5% of all lung carcinomas have a combined histology, including two or more of the aforementioned types.

Any type of lung carcinoma may extend to the pleural surface and then spread within the pleural cavity or into the pericardium. Metastases to the bronchial, tracheal, and mediastinal nodes can

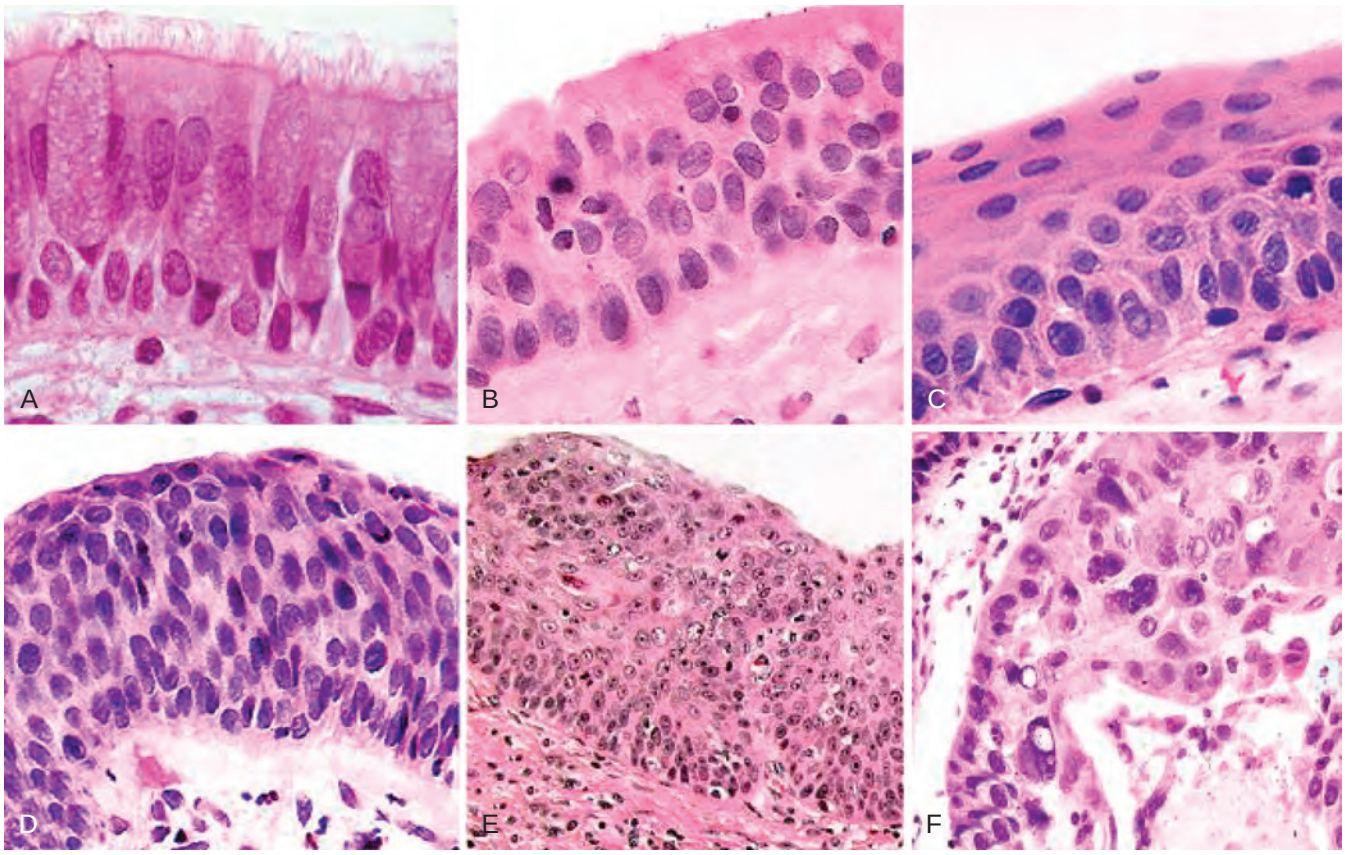

Figure 15.44 Precursor lesions of squamous cell carcinomas. Some of the earliest ("mild") changes in smoking-damaged respiratory epithelium include goblet cell hyperplasia (A), basal cell (or reserve cell) hyperplasia (B), and squamous metaplasia (C). More ominous changes include the appearance of squamous dysplasia (D), characterized by the presence of disordered squamous epithelium, with loss of nuclear polarity, nuclear hyperchromasia, pleomorphism, and mitotic figures. Squamous dysplasia may progress through the stages of mild, moderate, and severe dysplasia. Carcinoma in situ (E), the stage immediately preceding invasive squamous carcinoma (F), by definition has not penetrated the basement membrane and has cytologic features similar to those in frank carcinoma. (A–E, Courtesy Dr. Adi Gazdar, Department of Pathology, University of Texas, Southwestern Medical School, Dallas, Tex. F, Reproduced with permission from Travis WD, et al, editors: *World Health Organization Histological Typing of Lung and Pleural Tumors*, Heidelberg, 1999, Springer.)

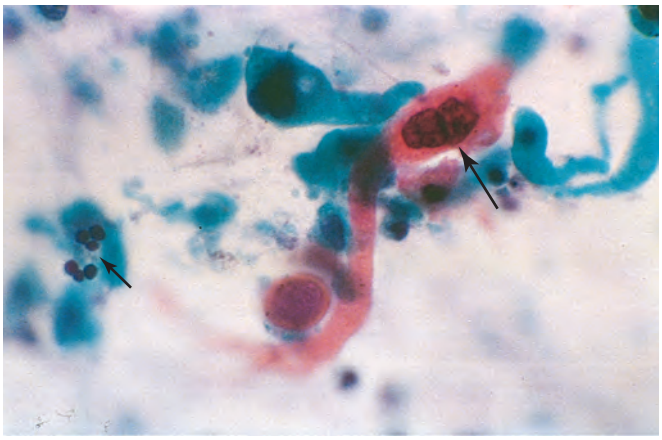

Figure 15.45 Cytologic diagnosis of lung cancer. A sputum specimen shows an orange-staining, keratinized squamous carcinoma cell with a prominent hyperchromatic nucleus *(large arrow)*. Note the size of the tumor cells compared with normal neutrophils *(small arrow)*.

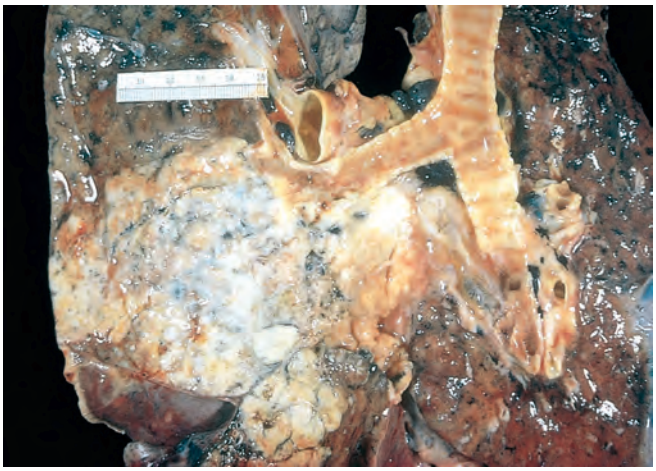

Figure 15.46 Lung carcinoma. The gray-white tumor infiltrates the lung parenchyma. Histologic sections identified this tumor as a squamous cell carcinoma.

be found in most cases. The frequency of nodal involvement varies slightly with the histologic pattern but averages greater than 50%.

Distant spread of lung carcinoma occurs through both lymphatic and hematogenous pathways. These tumors often spread early throughout the body except for squamous cell carcinoma, which metastasizes late outside the thorax. Metastasis may be the first manifestation of an underlying occult pulmonary lesion. No organ or tissue is spared, but the adrenal glands, for obscure reasons, are involved in more than half of the cases. The liver (30% to 50%), brain (20%), and bone (20%) are other favored sites of metastases.

Secondary Pathology. Lung carcinomas have local effects that may cause several pathologic changes in the lung distal to the point of bronchial involvement. Partial obstruction may cause marked **focal emphysema;** total obstruction may lead to **atelectasis.** The impaired drainage of the airways is a common cause for **severe suppurative or ulcerative bronchitis** or **bronchiectasis. Pulmonary abscesses** sometimes call attention to an otherwise silent carcinoma. Compression or invasion of the superior vena cava can cause venous congestion and edema of the head and arm and, ultimately, circulatory compromise—the **superior vena cava syndrome.** Extension to the pericardial or pleural sacs may cause **pericarditis** (Chapter 12) or **pleuritis** with significant effusions. Apical lung cancers in the superior pulmonary sulcus tend to invade the neural structures around the trachea, including the cervical sympathetic plexus, and produce a group of clinical findings that includes severe pain in the distribution of the ulnar nerve and *Horner syndrome* (enophthalmos, ptosis, miosis, and anhidrosis) on the same side as the lesion. Such tumors are also referred to as *Pancoast tumors*.

Staging. A uniform TNM system for staging cancer according to its anatomic extent at the time of diagnosis is useful, particularly for comparing treatment results from different centers (Table 15.10).

Table 15.10 International Staging System for Lung Cancer

TNM Staging	
Tis	Carcinoma in situ Adenocarcinoma in situ: adenocarcinoma with pure lepidic pattern, ≤3 cm Squamous cell carcinoma in situ
T1	Tumor ≤3 cm without pleural or mainstem bronchus involvement (T1mi, minimally invasive adenocarcinoma; T1a, <1 cm; T1b, 1–2 cm; T1c, 2–3 cm)
T2	Tumor 3–5 cm or involvement of mainstem bronchus but not of carina, visceral pleural involvement, or lobar atelectasis (T2a, 3–4 cm; T2b, 4–5 cm)
T3	Tumor >5–7 cm or one with involvement of parietal pleura, chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium, or separate tumor nodules in the same lobe
T4	Tumor >7 cm or any tumor with invasion of mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina, or separate tumor nodules in a different ipsilateral lobe
N0	No metastasis to regional lymph nodes
N1	Ipsilateral intraparenchymal or peribronchial or hilar nodal involvement
N2	Metastasis to ipsilateral mediastinal or subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal or hilar lymph nodes, ipsilateral or contralateral scalene, or supraclavicular lymph nodes
M0	No distant metastasis
M1	Distant metastasis (M1a, separate tumor nodule in contralateral lobe or pleural nodules or malignant pleural or pericardial effusion; M1b, single extrathoracic metastasis in a single organ; M1c, multiple extrathoracic metastases)

Stage Grouping			
Stage 0	Tis	N0	M0
Stage IA	IA1, T1mi or T1a; IA2, T1b; IA3, T1c	N0	M0
Stage IB	T2a	N0	M0
Stage IIA	T2b	N0 N1	M0 M0
Stage IIB	T2b T1a, T1b, T1c, T2a, T2b T3	N0 N1 N0	M0 M0 M0
Stage IIIA	T1a, T1b, T1c, T2a, T2b T3 T4	N2 N1 N0, N1	M0 M0 M0
Stage IIIB	T1a, T1b, T1c, T2a, T2b T3, T4	N3 N2	M0 M0
Stage IIIC	T3, T4	N3	M0
Stage IVA	T any	N any	M1a, M1b
Stage IVB	T any	N any	M1c

Clinical Features

Lung cancer is one of the most insidious and aggressive neoplasms in the realm of oncology. In the usual case it is discovered in patients in their 50s or older whose symptoms are of several months' duration. The major presenting complaints are cough (75%), weight loss (40%), chest pain (40%), and dyspnea (20%). Some of the more common local manifestations of lung cancer and their pathologic bases are listed in Table 15.11.

Not infrequently, lung cancer is recognized though biopsy of tissues involved by metastatic disease. Symptoms of metastases depend on the site, for example, back pain in bone metastases and headache, hemiparesis, cranial nerve damage, and seizures in brain metastases.

The best "treatment" for lung cancer is smoking prevention, which has lowered lung cancer incidence in the United States among men; however, 15% of adults still smoke, and even those who quit remain at elevated risk for an extended period of time. This reality has led to early detection trials in high-risk individuals using low-dose computed tomography, which is capable of detecting some early (resectable) non–small cell lung cancers, but at a cost of a high incidence of false-positive (noncancer) findings. Overall, the outlook is poor for most patients. Even with incremental improvements in thoracic surgery, radiation therapy, and chemotherapy, the overall 5-year survival rate is only 18.7%. The 5-year survival rate is 52% for cases detected when the disease is still localized, 22% when there is regional metastasis, and only 4% with distant metastases. In general, adenocarcinoma and squamous cell carcinoma tend to remain localized longer and have a slightly better prognosis than small cell carcinoma, which is usually advanced by the time it is discovered.

Table 15.11 Local Effects of Lung Tumor Spread

Clinical Feature	Pathologic Basis
Cough (50%–75%)	Involvement of central airways
Hemoptysis (25%–50%)	Hemorrhage from tumor in airway
Chest pain (20%)	Extension of tumor into mediastinum, pleura, or chest wall
Pneumonia, abscess, lobar collapse	Airway obstruction by tumor
Lipoid pneumonia	Tumor obstruction; accumulation of cellular lipid in foamy macrophages
Pleural effusion	Tumor spread into pleura
Hoarseness	Recurrent laryngeal nerve invasion
Dysphagia	Esophageal invasion
Diaphragm paralysis	Phrenic nerve invasion
Rib destruction	Chest wall invasion
SVC syndrome	SVC compression by tumor
Horner syndrome	Sympathetic ganglia invasion
Pericarditis, tamponade	Pericardial involvement

SVC, Superior vena cava.

Treatment of patients with adenocarcinoma and activating mutations in *EGFR* (present in about 15% of all cases) or in other tyrosine kinases with specific kinase inhibitors prolongs survival. Many tumors that recur carry new mutations that generate resistance to these inhibitors, proving that these drugs are "hitting" their target. In contrast, activating *KRAS* mutations (present in approximately 30% of cases of adenocarcinoma) appear to be associated with a worse prognosis, regardless of treatment, in an already grim disease. Because of the mutagenic effects of carcinogens in tobacco smoke, lung cancers have a high burden of potentially antigenic neoantigens. Accordingly, both adenocarcinoma and squamous cell carcinoma respond in subsets of cases to checkpoint inhibitor therapy, which has produced improvements in survival and is now approved for use.

Small cell carcinoma is quite sensitive to radiation therapy and chemotherapy, and approximately 10% of patients with limited disease survive for 5 years and may be cured. Unfortunately, however, most patients present with advanced stage disease; for these patients, despite excellent initial responses to chemotherapy, the median survival is approximately 10 months and the cure rate is close to zero. New approaches involving use of antibody-drug conjugates that deliver chemotherapy selectively to tumor cells and immune checkpoint inhibitors are being tested.

Paraneoplastic Syndromes. Lung carcinoma can be associated with several paraneoplastic syndromes (Chapter 7), some of which may antedate the development of a detectable pulmonary lesion. The hormones or hormone-like factors elaborated by lung cancer cells and associated syndromes include:

- *Antidiuretic hormone* (ADH), inducing hyponatremia due to inappropriate ADH secretion
- *Adrenocorticotropic hormone* (ACTH), producing Cushing syndrome
- *Parathormone, parathyroid hormone-related peptide, prostaglandin E, and some cytokines,* all implicated in the hypercalcemia often seen with lung cancer
- *Calcitonin,* causing hypocalcemia
- *Gonadotropins,* causing gynecomastia
- *Serotonin and bradykinin,* associated with the carcinoid syndrome

The incidence of clinically significant paraneoplastic syndromes related to these factors in lung cancer patients ranges from 1% to 10%, although a much higher proportion of patients show elevated serum levels of these (and other) peptide hormones. Any histologic type of tumor may occasionally produce any one of the hormones, but tumors that produce ACTH and ADH are predominantly small cell carcinomas, whereas those that produce hypercalcemia are mostly squamous cell carcinomas.

Other systemic manifestations of lung carcinoma include the *Lambert-Eaton myasthenic syndrome* (Chapter 27), in which muscle weakness is caused by autoantibodies (possibly elicited by tumor ionic channels) directed to the neuronal calcium channel; *peripheral neuropathy,* usually purely sensory; dermatologic abnormalities, including *acanthosis nigricans* (Chapter 25); hematologic abnormalities, such as *leukemoid reactions;* hypercoagulable states, such as *Trousseau syndrome* (deep vein thrombosis and thromboembolism); and finally, a peculiar abnormality of connective tissue called *hypertrophic pulmonary osteoarthropathy,* associated with clubbing of the fingers.

KEY CONCEPTS

CARCINOMAS OF THE LUNG

- The three major histologic subtypes are adenocarcinoma (most common), squamous cell carcinoma, and small cell carcinoma.
- Each of these is clinically and genetically distinct. Small cell lung carcinomas are best treated by chemotherapy because almost all are metastatic at presentation. The other carcinomas may be curable by surgery if limited to the lung. Combination chemotherapy also is available along with tyrosine kinase inhibitors for those with *EGFR*, *ALK*, *ROS*, and *MET* mutations.
- Smoking is the most important risk factor for lung cancer; the most common subtype related to smoking in men and women is adenocarcinoma. Adenocarcinoma also is the most common subtype in non-smokers.
- Precursor lesions include atypical adenomatous hyperplasia and adenocarinoma in situ (formerly bronchioloalveolar carcinoma) for adenocarcinomas and squamous dysplasia for squamous cell carcinoma.
- Tumors 3 cm or less in diameter characterized by pure growth along pre-existing structures (lepidic pattern) without stromal invasion are now called adenocarcinoma in situ.
- Lung cancers, particularly small cell lung carcinomas, often cause paraneoplastic syndromes.

Neuroendocrine Proliferations and Tumors

The normal lung contains neuroendocrine cells within the epithelium as single cells or as clusters, the neuroepithelial bodies. Virtually all pulmonary neuroendocrine cell hyperplasias are secondary to airway fibrosis and/or inflammation. The exception is a rare disorder called *diffuse idiopathic*

pulmonary neuroendocrine cell hyperplasia, in which hyperplasia occurs in the absence of an inflammatory stimulus.

Neoplasms of neuroendocrine cells in the lung include benign *tumorlets,* small, inconsequential, hyperplastic nests of neuroendocrine cells seen in areas of scarring or chronic inflammation; *carcinoids;* and the (already discussed) highly aggressive small cell carcinoma and large cell neuroendocrine carcinoma of the lung. Carcinoid tumors are classified separately, since they differ significantly from carcinomas with evidence of neuroendocrine differentiation in terms of incidence and clinical, epidemiologic, histologic, and molecular characteristics. For example, in contrast to small cell and large cell neuroendocrine carcinomas, carcinoids may occur in patients with multiple endocrine neoplasia type 1.

Carcinoid Tumors

Carcinoid tumors represent 1% to 5% of all lung tumors. Most patients with these tumors are younger than 60 years of age, and the incidence is equal for both sexes. Approximately 20% to 40% of patients are nonsmokers. Carcinoid tumors are low-grade malignant epithelial neoplasms that are subclassified into *typical* and *atypical carcinoids*.

MORPHOLOGY

Carcinoids may arise centrally or may be peripheral. On gross examination, the central tumors grow as finger-like or spherical polypoid masses that commonly project into the lumen of the bronchus and are usually covered by an intact mucosa (Fig. 15.47A). They rarely exceed 3 to 4 cm in diameter. Most are confined to the mainstem bronchi. Others, however, penetrate the bronchial wall to fan out in the peribronchial tissue, producing the so-called **collar-button lesion.** Peripheral tumors are solid and nodular.

Histologically, the tumor is composed of organoid, trabecular, palisading, ribbon, or rosette-like arrangements of cells separated by a delicate fibrovascular stroma. In common with the lesions of the gastrointestinal tract, the individual cells are quite regular and have uniform round nuclei and a moderate amount of eosinophilic cytoplasm (Fig. 15.47B). Typical carcinoids have fewer than two mitoses per 10 high-power fields and lack necrosis, while atypical carcinoids have between two and 10 mitoses per 10 high-power fields and/or foci of necrosis. Atypical carcinoids also show increased pleomorphism, have more prominent nucleoli, and are more likely to grow in a disorganized fashion and invade lymphatics. On electron microscopy the cells exhibit the dense-core granules characteristic of other neuroendocrine tumors and, by immunohistochemistry, are found to contain serotonin, neuron-specific enolase, bombesin, calcitonin, or other peptides.

Clinical Features

The clinical manifestations of bronchial carcinoids emanate from their intraluminal growth, their capacity to metastasize, and the ability of some of the lesions to elaborate vasoactive amines. Persistent cough, hemoptysis, impairment of drainage of respiratory passages with secondary infections, bronchiectasis, emphysema, and atelectasis are all by-products of the intraluminal growth of these lesions.

Most interesting are functioning lesions capable of producing the classic *carcinoid syndrome,* characterized by intermittent attacks of diarrhea, flushing, and cyanosis. Approximately, 10% of bronchial carcinoids give rise to this syndrome. Overall, most bronchial carcinoids do not have secretory activity and do not metastasize to distant sites but follow a relatively benign course for long periods and are therefore amenable to resection. The reported 5-year survival rates are 95% for typical carcinoids, 70% for atypical carcinoids, 30% for large cell neuroendocrine carcinoma, and 5% for small cell carcinoma, respectively.

Miscellaneous Tumors

Benign and malignant mesenchymal tumors, such as inflammatory myofibroblastic tumor, fibroma, fibrosarcoma, lymphangioleiomyomatosis, leiomyoma, leiomyosarcoma, lipoma, hemangioma, and chondroma, may occur in the lung but are rare. Hematolymphoid tumors similar to those described in other organs, may also affect the lung, either as isolated lesions or, more commonly, as part of a generalized disorder. These include Langerhans cell histiocytosis,

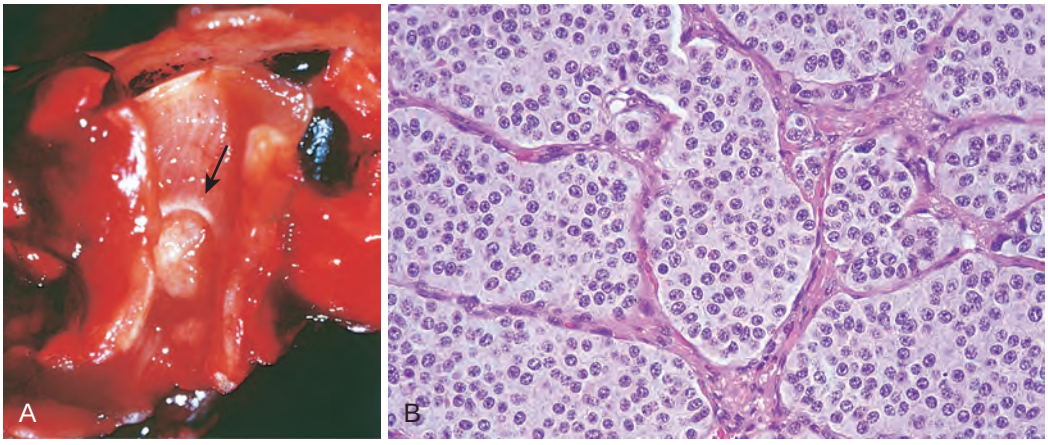

Figure 15.47 Bronchial carcinoid. (A) Carcinoid growing as a spherical mass *(arrow)* protruding into the lumen of the bronchus. (B) The tumor cells have small, rounded, uniform nuclei and moderate amounts of cytoplasm. (Courtesy Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, Ill.)

Hodgkin lymphomas, lymphomatoid granulomatosis, an unusual EBV-positive B-cell lymphoma, and low-grade extranodal marginal zone B-cell lymphoma (Chapter 13).

Pulmonary *hamartoma* is a relatively common lesion that is usually discovered as an incidental, rounded radio-opacity *(coin lesion)* on a routine chest film. Most are solitary, less than 3 to 4 cm in diameter, and well circumscribed. Pulmonary hamartoma consists of nodules of connective tissue intersected by epithelial clefts. Cartilage is the most common connective tissue, but there may also be fibrous tissue and fat. The clefts are lined by ciliated or nonciliated epithelium (Fig. 15.48). The traditional term hamartoma is retained for this lesion, but it is in fact a clonal neoplasm associated with chromosomal aberrations involving either 6p21 or 12q14-q15. These aberrations are found in the mesenchymal component, while the epithelial component appears to represent entrapped respiratory epithelium.

Lymphangioleiomyomatosis is a pulmonary disorder that primarily affects young women of childbearing age. It is characterized by a proliferation of perivascular epithelioid cells that express markers of both melanocytes and smooth muscle cells. The proliferation distorts the involved lung, leading to cystic, emphysema-like dilation of terminal airspaces, thickening of the interstitium, and obstruction of lymphatic vessels. The lesional epithelioid cells frequently harbor loss-of-function mutations in the tumor suppressor *TSC2*, one of the loci linked to tuberous sclerosis (Chapter 28). The protein encoded by *TSC2,* tuberin, is a negative regulator of mammalian target of rapamycin (mTOR), a key regulator of cellular metabolism. While *TSC2* mutations point to increased mTOR activity as a pathogenic factor, the disorder remains poorly understood. The strong tendency to affect young women suggests that estrogen contributes to the proliferation of perivascular epithelioid cells, which often express estrogen receptors. Patients most commonly present with dyspnea or spontaneous pneumothorax, the latter related to emphysematous changes. The disease tends to be slowly progressive over a period of several decades. mTOR inhibitors slow or prevent the deterioration of lung function, but must be continued indefinitely. Only lung transplantation is curative.

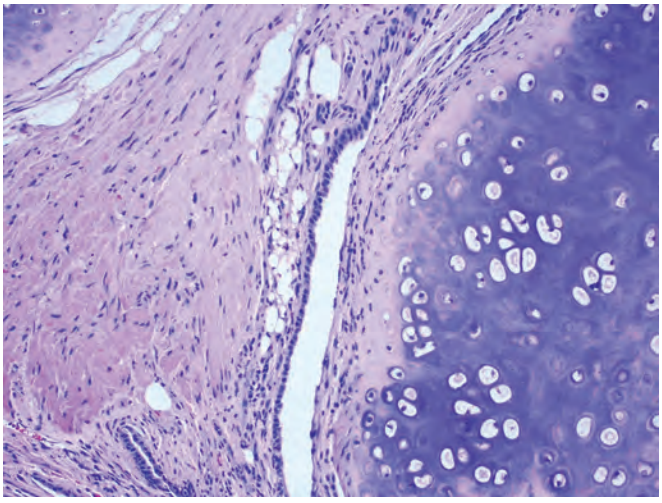

Figure 15.48 Pulmonary hamartoma. There are islands of cartilage, fat, smooth muscle, and entrapped respiratory epithelium.

Bronchogenic cyst
Pericardial cyst
Lymphoma

Inflammatory myofibroblastic tumor is a rare tumor that is more common in children, with an equal male-to-female ratio. Presenting symptoms include fever, cough, chest pain, and hemoptysis. It may also be asymptomatic. Imaging studies usually show a round, well-defined, peripheral mass. Calcification is present in about a quarter of cases. Grossly, the lesion is firm, 3 to 10 cm in diameter, and grayish white. Microscopically, there is proliferation of spindle-shaped fibroblasts and myofibroblasts, lymphocytes, plasma cells, and peripheral fibrosis. Some of these tumors have activating rearrangements of the *ALK* receptor tyrosine kinase gene, located on 2p23, and treatment with ALK inhibitors have produced sustained responses in such cases.

Tumors in the mediastinum may arise in mediastinal structures or may be metastatic from the lung or other organs. They often invade or compress the lungs. Table 15.12 lists the most common tumors in the various compartments of the mediastinum. Specific tumor types are discussed in appropriate sections of this book.

Metastatic Tumors

The lung is the most common site of metastatic neoplasms. Both carcinomas and sarcomas arising anywhere in the body may spread to the lungs via the blood or lymphatics or by direct continuity. Esophageal carcinoma and mediastinal lymphoma may also invade the lung by direct extension.

MORPHOLOGY

The pattern of metastatic spread to the lungs is quite variable. In the usual case, multiple discrete nodules (cannonball lesions) are scattered throughout all lobes, particularly in the lung periphery (Fig. 15.49). Other times spread takes the form of a solitary nodule, endobronchial or pleural involvement, pneumonic consolidation, and/or some combination thereof. Foci of lepidic growth similar to adenocarcinoma in situ are seen occasionally with metastatic carcinomas and may be associated with any of the listed patterns.

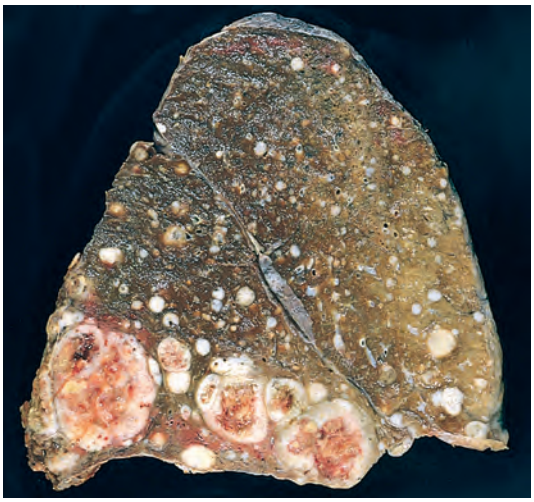

Figure 15.49 Numerous metastases to lung from a renal cell carcinoma. (Courtesy Dr. Michelle Mantel, Brigham and Women's Hospital, Boston, Mass.)

PLEURA

Most pleural disorders stem from complications of disease arising elsewhere in the body. Secondary infections and inflammations are particularly common findings at autopsy. Important primary disorders include (1) intrapleural bacterial infections, presumably the product of seeding from transient bacteremia; and (2) mesothelioma, a primary pleural neoplasm (discussed later).

Pleural Effusion

Pleural effusion is a common manifestation of both primary and secondary pleural diseases, which may be inflammatory or noninflammatory. Normally, no more than 15 mL of serous, relatively acellular, clear fluid lubricates the pleural surface. Accumulation of pleural fluid occurs in the following settings:

- Increased hydrostatic pressure, as in congestive heart failure
- Increased vascular permeability, as in pneumonia
- Decreased osmotic pressure, as in nephrotic syndrome
- Increased intrapleural negative pressure, as in atelectasis
- Decreased lymphatic drainage, as in mediastinal carcinomatosis

Inflammatory Pleural Effusions

Serous, serofibrinous, and fibrinous pleuritis all have an inflammatory basis, differing only in the intensity and duration of the process. The most common causes of pleuritis are disorders associated with inflammation of the underlying lung, such as tuberculosis, pneumonia, lung infarction, lung abscess, and bronchiectasis. Rheumatoid arthritis, systemic lupus erythematosus, uremia, diffuse systemic infections, and metastatic involvement of the pleura can also cause serous or serofibrinous pleuritis. Radiotherapy for tumors in the lung or mediastinum often causes a serofibrinous pleuritis. In most of these disorders, the pleural reaction is minimal, and the fluid exudate is resorbed with either resolution or organization of the fibrinous component. However, large amounts of fluid sometimes accumulate and compress the lung, causing respiratory distress.

A purulent pleural exudate *(empyema)* usually results from bacterial or mycotic seeding of the pleural space. Most commonly, this seeding occurs by contiguous spread of organisms from intrapulmonary infection, but occasionally it occurs through lymphatic or hematogenous dissemination from a more distant source. Rarely, infections below the diaphragm, such as the subdiaphragmatic or liver abscess, may extend by continuity through the diaphragm into the pleural spaces, more often on the right side.

Empyema is characterized by loculated, yellow-green, creamy pus composed of masses of neutrophils admixed with other leukocytes. Although empyema may accumulate in large volumes (up to 500 to 1000 mL), usually the volume is small, and the pus becomes walled off by fibrosis. Empyema may resolve, but more often the exudate organizes into dense, tough fibrous adhesions that frequently obliterate the pleural space or envelop the lungs; either can seriously restrict pulmonary expansion.

Hemorrhagic pleuritis manifested by sanguineous inflammatory exudates is infrequent and is most often associated with hemorrhagic diatheses, rickettsial infections, and neoplastic involvement of the pleural cavity. The sanguineous exudate must be differentiated from hemothorax (discussed later). When hemorrhagic pleuritis is encountered, a careful search should be made for the presence of tumor cells.

Noninflammatory Pleural Effusions

Noninflammatory collections of serous fluid within the pleural cavities are called *hydrothorax*. The fluid is clear and straw colored. Hydrothorax may be unilateral or bilateral, depending on the underlying cause. The most common cause of hydrothorax is heart failure, and for this reason it is usually accompanied by pulmonary congestion and edema. Hydrothorax may also be seen in any other systemic disease associated with generalized edema, such as patients with renal failure or cirrhosis of the liver.

The escape of blood into the pleural cavity is known as *hemothorax*. It is most commonly a complication of trauma or less commonly surgery, but can also accompany rupture of an aortic aneurysm, a setting in which it is almost invariably fatal.

Chylothorax is an accumulation of milky fluid, usually of lymphatic origin, in the pleural cavity. Chyle is milky white because it contains finely emulsified fats. Chylothorax is most often caused by thoracic duct trauma or by obstruction of a major lymphatic duct, usually by a malignancy. Such cancers most commonly arise within the thoracic cavity and invade the lymphatics locally, but occasionally more distant cancers metastasize via the lymphatics and grow within the right lymphatic or thoracic duct, producing obstruction.

Pneumothorax

Pneumothorax refers to air or gas in the pleural cavities and is most commonly associated with emphysema, asthma,

and tuberculosis. It may be spontaneous, traumatic, or therapeutic. Spontaneous pneumothorax may complicate any form of pulmonary disease that causes emphysematous changes. An abscess cavity that communicates either directly with the pleural space or with the lung interstitial tissue may also lead to the escape of air. In the latter circumstance the air may dissect through the lung substance or back through the mediastinum (interstitial emphysema), eventually entering the pleural cavity. Traumatic pneumothorax is usually caused by some perforating injury to the chest wall, but sometimes the trauma pierces the lung and thus provides two avenues for the accumulation of air within the pleural spaces. Resorption of the air in the pleural space occurs in spontaneous and traumatic pneumothorax, provided that the original communication seals itself.

Of the various forms of pneumothorax, the one that attracts the most clinical attention is *spontaneous idiopathic pneumothorax*. This entity is encountered in relatively young people; seems to be due to rupture of small, peripheral, usually apical subpleural blebs; and usually subsides spontaneously as the air is resorbed. Recurrent attacks are common and can be quite disabling.

Pneumothorax may cause marked respiratory distress due to collapse and atelectasis of the lung. In some instances the pleural defect acts as a flap valve and permits the entrance of air during inspiration but fails to permit its escape during expiration. The result is called a *tension pneumothorax,* in which progressively increasing intrapleural pressure may compress vital mediastinal structures and the contralateral lung.

Pleural Tumors

The pleura may be involved by primary or secondary tumors. Secondary metastatic involvement is far more common than are primary tumors. The most frequent metastatic malignancies arise from primary neoplasms of the lung and breast. In addition to these cancers, malignancy from any organ of the body may spread to the pleural spaces. Ovarian carcinomas, for example, tend to cause widespread implants in both the abdominal and thoracic cavities. Most metastatic implants produce a serous or serosanguineous effusion that often contains neoplastic cells. For this reason, careful cytologic examination of the sediment is of considerable diagnostic value.

Solitary Fibrous Tumor

Solitary fibrous tumor is a soft tissue tumor with a propensity to occur in the pleura and, less commonly, in the lung, as well as other sites. The tumor is often attached to the pleural surface by a pedicle. It may be small (1 to 2 cm in diameter) or may reach an enormous size, but it tends to remain confined to the surface of the lung (Fig. 15.50).

Figure 15.50 Solitary fibrous tumor. Cut surface is solid with a whorled appearance. (Courtesy Dr. Justine A. Barletta, Department of Pathology, Brigham and Women's Hospital, Boston, Mass.)

MORPHOLOGY

Grossly, solitary fibrous tumor consists of dense fibrous tissue with occasional cysts filled with viscid fluid. Microscopically, the tumor shows whorls of reticulin and collagen fibers among which are interspersed spindle cells resembling fibroblasts. Rarely, this tumor may be malignant, marked by pleomorphism, mitotic activity, necrosis, and large size (>10 cm). The tumor cells are positive for CD34 and STAT6 and negative for keratin by immunostaining, features that help to distinguish this lesion from malignant mesothelioma (which has the opposite phenotype). The solitary fibrous tumor has no relationship to asbestos exposure.

Solitary fibrous tumor is highly associated with a cryptic inversion of chromosome 12 involving the genes *NAB2* and *STAT6*. This rearrangement creates a *NAB2-STAT6* fusion gene that appears to be virtually unique to solitary fibrous tumor. It encodes a chimeric transcription factor that is hypothesized to be a key driver of tumor development.

Malignant Mesothelioma

Malignant mesothelioma, although rare, has assumed great importance in the past few decades because of its increased incidence among people with heavy exposure to asbestos (see Pneumoconioses). Thoracic mesothelioma arises from either the visceral or the parietal pleura. In coastal areas with shipping industries in the United States and Great Britain, as well as in Canadian, Australian, and South African mining areas, as many as 90% of mesotheliomas are asbestos-related. The lifetime risk of developing mesothelioma in heavily exposed individuals is as high as 7% to 10%. There is a long latent period of 25 to 45 years for the development of asbestos-related mesothelioma, and there seems to be no increased risk of mesothelioma in asbestos workers who smoke. This is in contrast to the risk of asbestos-related lung carcinoma, which is markedly magnified by smoking. Thus, asbestos workers (particularly those who smoke) are at much higher risk of dying of lung carcinoma than mesothelioma.

Asbestos bodies (see Fig. 15.20) are found in increased numbers in the lungs of patients with mesothelioma. Another marker of asbestos exposure, the *asbestos plaque,* has been previously discussed (see Fig. 15.21).

Although several cytogenetic abnormalities have been detected, the most common is homozygous deletion of chromosome 9p leading to loss of the tumor suppressor gene *CDKN2A*, which occurs in about 80% of mesotheliomas. Sequencing of mesothelioma genomes has shown that driver mutations are also common in the *NF2* (neurofibromatosis-2) gene, which encodes a cell signaling regulator; and *BAP1*, which encodes a protein that interacts with the BRCA1 tumor suppressor and appears to function as a chromatin regulator. Of note, individuals with germline mutations in *BAP1* have a markedly elevated risk of mesothelioma, further implicating this tumor suppressor gene in the pathogenesis of the disease.

MORPHOLOGY

Malignant mesothelioma is a diffuse lesion arising from either the visceral or the parietal pleura that spreads widely in the pleural space and is usually associated with extensive pleural effusion and direct invasion of thoracic structures. The affected lung becomes ensheathed by a thick layer of soft, gelatinous, grayish pink tumor tissue (Fig. 15.51).

Microscopically, malignant mesothelioma may be epithelioid (60% to 80%), sarcomatoid (10% to 12%), or biphasic (10% to 15%). This is in keeping with the fact that mesothelial cells have the potential to develop as epithelium-like cells or mesenchymal stromal cells.

The **epithelioid type** of mesothelioma consists of cuboidal, columnar, or flattened cells forming tubular or papillary structures resembling adenocarcinoma (Fig. 15.52A). Immunohistochemical stains are very helpful in differentiating it from pulmonary adenocarcinoma. Most mesotheliomas show strong positivity for keratin proteins, calretinin (Fig. 15.52B), Wilms tumor 1 (WT-1), cytokeratin 5/6, and podoplanin, and unlike adenocarcinomas are negative for Claudin4. This panel of antibodies is diagnostic in a majority of cases when interpreted in the context of morphology and clinical presentation. The mesenchymal type of mesothelioma **(sarcomatoid type)** has an appearance resembling fibrosarcoma.

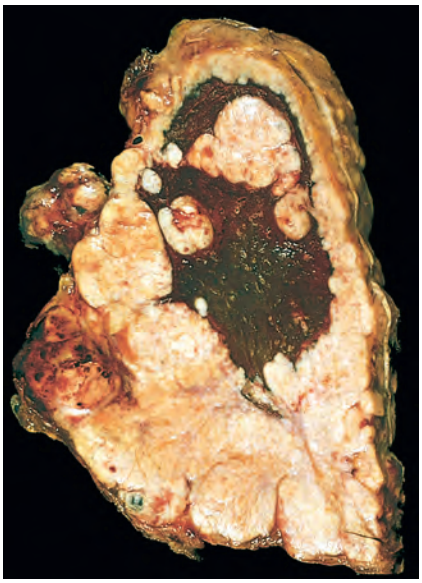

Figure 15.51 Malignant mesothelioma. Note the thick, firm, white pleural tumor tissue that ensheathes the lung.

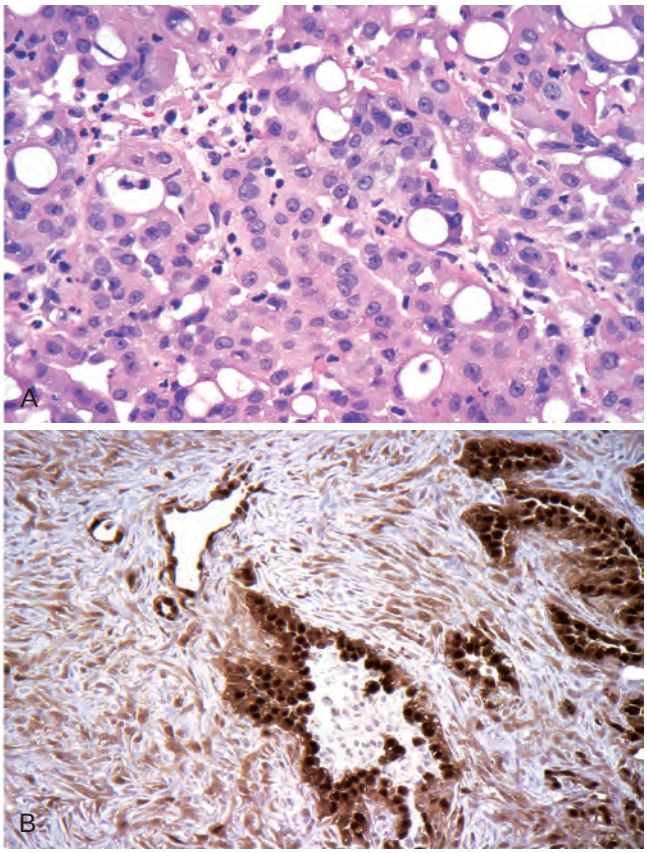

Figure 15.52 Histologic variants of malignant mesothelioma. (A) Epithelioid type. (B) Mixed type, stained for calretinin (immunoperoxidase method). The epithelial component is strongly positive (dark brown), while the sarcomatoid component is less so. (Courtesy Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, Ill.)

Sarcomatoid mesotheliomas tend to have lower expression of many of the markers described previously, and some may be positive only for keratin. The **biphasic type** of mesothelioma contains both epithelioid and sarcomatoid patterns (see Fig. 15.52B).

Clinical Features

The presenting symptoms are chest pain, dyspnea, and, as noted, recurrent pleural effusions. Concurrent pulmonary asbestosis (fibrosis) is present in only 20% of individuals with pleural mesothelioma. The lung is invaded directly, and there is often metastatic spread to the hilar lymph nodes and, eventually, to the liver and other distant organs. Fifty percent of patients die within 12 months of diagnosis, and few survive longer than 2 years. Aggressive therapy (extrapleural pneumonectomy, chemotherapy, radiation therapy) seems to improve this poor prognosis in some patients.

Mesotheliomas also arise in the peritoneum, pericardium, tunica vaginalis, and genital tract (benign adenomatoid tumor) (see Chapter 21). *Peritoneal mesotheliomas* are related to heavy asbestos exposure in 60% of male patients (the number is much lower in females). Although in about half of cases the disease remains confined to the abdominal cavity, intestinal involvement frequently leads to death from intestinal obstruction or inanition.

CHAPTER 16

Head and Neck

Mark W. Lingen • Nicole A. Cipriani

CHAPTER CONTENTS

Diseases of the head and neck range from the common cold to uncommon neoplasms of the ear and nose. The examples discussed in the following sections are organized based on the primary anatomic site at which they occur, that is, oral cavity, upper airways (including the nose, pharynx, larynx, and nasal sinuses), ears, neck, and salivary glands.

Oral Cavity

Diseases of Teeth and Supporting Structures

Caries (Tooth Decay)

Dental caries is caused by focal demineralization of tooth structure (enamel and dentin) by acidic products of bacterial sugar fermentation. Caries is the principal cause of tooth loss before age 35. Caries was previously most common in industrialized countries with abundant, carbohydrate-rich processed and refined foods. Demographics have, however, shifted due to both reduced incidence in industrialized countries and increased incidence in developing nations. The former reflects improved oral hygiene and, in the United States, drinking water fluoridation. Within the crystalline tooth enamel, fluoroapatite (calcium fluorophosphate) is more resistant to acid degradation than hydroxylapatite (calcium apatite). Increasing processed food consumption is associated with greater caries rates in low income countries, where incidence is expected to continue to grow.

Gingivitis

Gingivitis is inflammation of the oral mucosa surrounding the teeth, caused by accumulation of dental plaque and calculus. It may occur at any age but is most prevalent and severe in adolescence. Dental plaque is a sticky, colorless biofilm that collects between and on the surface of the teeth because of poor oral hygiene. It contains a mixture of bacteria (which produce the acid that contributes to caries development), salivary proteins, and desquamated epithelial cells. If not removed, plaque can become mineralized to form calculus (tartar). Gingivitis is characterized by erythema, edema, bleeding, changes in contour, and loss of soft tissue

adaptation to the teeth. Fortunately, it is reversible; therapy is primarily aimed at reducing the accumulation of plaque and calculus via regular oral hygiene.

Periodontitis

Periodontitis is an inflammatory process that affects the supporting structures of the teeth (periodontal ligaments), alveolar bone, and cementum. Sequelae of periodontitis include destruction of the periodontal ligament, which attaches teeth to the alveolar bone. This leads to loosening and eventual tooth loss. Like caries, periodontitis is associated with poor oral hygiene but is also characterized by altered composition of the oral microbiome, which is believed to be important in pathogenesis. For the most part, facultative gram-positive organisms colonize healthy gingival sites; plaque within areas of active periodontitis contains anaerobic and microaerophilic gram-negative flora. Of the 300 bacterial species within the oral cavity, adult periodontitis is associated primarily with *Aggregatibacter (Actinobacillus) actinomycetemcomitans, Porphyromonas gingivalis,* and *Prevotella intermedia*.

Periodontal disease is most frequently localized, but can also be a component of systemic diseases, including acquired immunodeficiency syndrome (AIDS), leukemia, Crohn disease, diabetes, Down syndrome, sarcoidosis, and syndromes associated with neutrophil defects (Chédiak-Higashi syndrome, agranulocytosis, and cyclic neutropenia). Periodontal infections can serve as a site of origin for infective endocarditis and abscesses within the lungs and brain.

INFLAMMATORY/REACTIVE LESIONS

Aphthous Ulcers (Canker Sores)

Aphthous ulcers are common, often recurrent, and painful. The causes are not known, but oral aphthous ulcers affect up to 40% of the population, and are most frequent in the first two decades of life. Aphthous ulcers tend to be clustered within some families and may be associated with immunologic disorders including celiac disease, inflammatory bowel disease, and Behçet disease. The lesions appear as single or multiple, shallow, hyperemic, mucosal ulcerations covered by a thin exudate and rimmed by a narrow zone of erythema (Fig. 16.1). The underlying inflammatory infiltrate is initially mononuclear but becomes neutrophil-rich upon secondary bacterial infection. Lesions typically resolve spontaneously in 7 to 10 days but sometimes persist for weeks, particularly in immunocompromised patients.

Fibrous Proliferative Lesions

The ***irritation fibroma,*** also called *traumatic fibroma* or *focal fibrous hyperplasia,* is a submucosal nodular mass of fibrous connective tissue stroma that occurs primarily on the buccal mucosa along the bite line or the gingiva (Fig. 16.2). It is thought to be a reactive process induced by repetitive trauma. Treatment is complete surgical excision.

Pyogenic granuloma **is typically found on the gingiva of children, young adults, and pregnant women** *(pregnancy tumor).* This exophytic inflammatory lesion is red to purple in color and frequently ulcerated (Fig. 16.3). In some cases, rapid growth can be alarming and elicit concerns of malignancy. Histologically, pyogenic granulomas are a highly vascularized proliferation of organizing granulation tissue. Pyogenic granulomas can regress, mature into dense fibrous masses, or develop into a peripheral ossifying fibroma. Complete surgical excision is the definitive treatment for these lesions.

Figure 16.1 Aphthous ulcer. Single ulceration with an erythematous halo surrounding a yellowish fibrinopurulent membrane.

Peripheral ossifying fibroma is a common gingival growth that is most likely reactive in nature rather than neoplastic. As mentioned earlier, some arise from a long-standing pyogenic granuloma, and others develop *de novo* from cells of the periodontal ligament. Peripheral ossifying fibromas appear as red, ulcerated, nodular lesions of the gingiva. The peak incidence is in young females. Since the lesions have a recurrence rate of 15% to 20%, complete surgical excision down to the periosteum is required.

Peripheral giant cell granuloma is an uncommon oral cavity lesion that likely represents a reactive inflammatory process. It is generally covered by intact gingival mucosa, but may be ulcerated. Histologically, peripheral giant cell granulomas contain aggregates of multinucleate, foreign body–like giant cells separated by a fibroangiomatous stroma. Although not encapsulated, the lesions are usually well delimited and easily excised. They should be differentiated from central giant-cell tumors found within the jaws and from

Figure 16.2 Irritation fibroma. Smooth pink exophytic nodule on the buccal mucosa.

Figure 16.3 Pyogenic granuloma. Erythematous and hemorrhagic exophytic mass arising from the gingival mucosa.

the histologically similar but frequently multiple "brown tumors" seen in hyperparathyroidism (Chapter 24).

INFECTIONS

Herpes Simplex Virus Infections

Oral herpes usually presents as gingivostomatitis in children, pharyngitis in adults, and chronic mucocutaneous infection in immunocompromised individuals. Most orofacial herpetic infections are caused by herpes simplex virus type 1 (HSV-1), but oral HSV-2 (genital herpes) infections do occur. In children, primary infections are most common between 2 and 4 years of age. These are often asymptomatic but may present as acute herpetic gingivostomatitis, with abrupt onset of vesicles and ulcerations of the oral mucosa, in up to 20% of cases. These lesions can be accompanied by lymphadenopathy, fever, and anorexia. In adults, acute herpes pharyngitis is common and may recur.

MORPHOLOGY

Herpes vesicles range in size from a few millimeters to large bullae filled with clear, serous fluid. They rapidly rupture to become painful, red-rimmed, shallow ulcerations. Intracellular and intercellular edema and acantholysis create clefts that may become macroscopic vesicles. Individual epidermal cells at vesicle margins or free within the fluid may contain eosinophilic **intranuclear viral inclusions,** or several cells may fuse to produce giant cells **(multinucleate polykaryons).** These can be demonstrated by the diagnostic **Tzanck test** based on microscopic examination of the vesicle fluid. Vesicles and shallow ulcers usually clear spontaneously within 3 to 4 weeks, but the virus treks along regional nerves and eventually becomes dormant (i.e., latent) within local ganglia (e.g., the trigeminal ganglion).

Most individuals who have been infected harbor latent virus in epithelial cells or ganglia. Reactivation of latent HSV causes *recurrent herpetic stomatitis* and is associated with trauma, allergies, exposure to ultraviolet light, upper respiratory tract infection, pregnancy, menstruation, immunosuppression, and exposure to temperature extremes. In contrast to acute herpetic gingivostomatitis, recurrent herpetic stomatitis occurs at the site of primary inoculation or in mucosa associated with the same ganglion. The lesions appear as groups of small (1 to 3 mm) vesicles on the lips *(herpes labialis),* nasal orifices, buccal mucosa, gingiva, and hard palate. Although they typically resolve in 7 to 10 days, lesions can persist in immunocompromised patients and may require systemic antiviral therapy.

Other viral infections that can involve the oral cavity as well as the head and neck region include herpes zoster, Epstein-Barr virus (EBV; mononucleosis, nasopharyngeal carcinoma, lymphoma), cytomegalovirus, enterovirus (herpangina, hand-foot-and-mouth disease, acute lymphonodular pharyngitis), and rubeola (measles).

Oral Candidiasis (Thrush)

***Candida albicans* is a normal component of the oral flora in approximately 50% of the population and is the most common fungal infection of the oral cavity.** Factors that influence the likelihood of infection include the strain of *C. albicans*, oral microbiome composition, and the individual's immune status. Oral candidiasis can be *pseudomembranous, erythematous,* or *hyperplastic.* The pseudomembranous form, *thrush,* is characterized by a superficial, gray to white inflammatory membrane composed of matted organisms enmeshed in a fibrinosuppurative exudate that can be readily scraped off to reveal an underlying erythematous inflammatory base. The infection typically remains superficial except in the setting of immunosuppression, such as in individuals with organ or bone marrow transplants, neutropenia, chemotherapy-induced immunosuppression, AIDS, or diabetes. Broad-spectrum antibiotics that eliminate or alter the normal bacterial flora of the mouth can also promote thrush.

Deep Fungal Infections

In addition to their usual sites of infection, some deep fungal infections, including histoplasmosis, blastomycosis, coccidioidomycosis, cryptococcosis, zygomycosis, and aspergillosis, have a predilection for the oral cavity, head, and neck. The incidence of oral fungal infections has grown along with increasing numbers immunocompromised patients as a result of diseases such as AIDS, therapies for cancer, and organ transplantation.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASE

Oral lesions are often the first sign of underlying systemic conditions. Some of the more common disease associations and their oral manifestations are cited in Table 16.1. Only hairy leukoplakia is considered in more detail here.

Hairy Leukoplakia

Hairy leukoplakia is a distinctive oral lesion on the lateral border of the tongue caused by EBV that usually occurs

Table 16.1 Oral Manifestations of Some Systemic Diseases

Systemic Disease	Associated Oral Changes
Infectious Diseases	
Scarlet fever	Fiery red tongue with prominent papillae (raspberry tongue); white-coated tongue through which hyperemic papillae project (strawberry tongue)
Measles	Spotty enanthema in the oral cavity often precedes the skin rash; ulcerations on the buccal mucosa about Stensen duct produce Koplik spots
Infectious mononucleosis	Acute pharyngitis and tonsillitis that may cause coating with a gray-white exudative membrane; enlargement of lymph nodes in the neck, palatal petechiae
Diphtheria	Characteristic dirty white, fibrinosuppurative, tough, inflammatory membrane over the tonsils and retropharynx
Human immunodeficiency virus	Predisposition to opportunistic oral infections, particularly herpes virus, Candida, and other fungi; oral lesions of Kaposi sarcoma and hairy leukoplakia (see text)
Dermatologic Conditions[a]	
Lichen planus	Reticulate, lacelike, white keratotic lesions that sometimes ulcerate and rarely form bullae; seen in more than 50% of patients with cutaneous lichen planus; rarely is the sole manifestation
Pemphigus	Vesicles and bullae prone to rupture, leaving hyperemic erosions covered with exudates
Bullous pemphigoid	Oral lesions (mucus membrane pemphigoid) resemble those of pemphigus but can be differentiated histologically
Erythema multiforme	Maculopapular, vesiculobullous eruption that sometimes follows an infection elsewhere, ingestion of drugs, development of cancer, or a collagen vascular disease; when there is widespread mucosal and skin involvement it is referred to as Stevens-Johnson syndrome
Hematologic Disorders	
Pancytopenia (agranulocytosis, aplastic anemia)	Severe oral infections in the form of gingivitis, pharyngitis, tonsillitis; may extend to produce cellulitis of the neck (Ludwig angina)
Leukemia	With depletion of functioning neutrophils, oral lesions similar to those in pancytopenia may develop
Monocytic leukemia	Leukemic infiltration and enlargement of the gingivae, often with accompanying periodontitis
Miscellaneous	
Melanotic pigmentation	May appear in Addison disease, hemochromatosis, fibrous dysplasia of bone (Albright syndrome), and Peutz-Jeghers syndrome (gastrointestinal polyposis)
Phenytoin (Dilantin) ingestion	Striking fibrous enlargement of the gingivae
Pregnancy	A friable, red, pyogenic granuloma protruding from the gingiva (pregnancy tumor)
Rendu-Osler-Weber syndrome	Autosomal dominant disorder with multiple congenital aneurysmal telangiectasias beneath mucosal surfaces of the oral cavity and lips

[a]See Chapter 25.

in immunocompromised patients. In patients infected with the human immunodeficiency virus (HIV), hairy leukoplakia may portend development of AIDS. However, the lesions are increasingly observed in patients who are immunocompromised for other reasons including cancer therapy, transplant-associated immunosuppression, and advanced age. Hairy leukoplakia takes the form of white, confluent patches of fluffy ("hairy"), hyperkeratotic thickenings, almost always situated on the lateral border of the tongue. Unlike thrush, the lesion cannot be scraped off. The distinctive microscopic appearance consists of hyperparakeratosis and acanthosis with "balloon cells" in the upper spinous layer. EBV RNA transcripts and proteins can be detected within the lesional cells. Superimposed candidal infection can add to the "hairiness."

PRECANCEROUS AND CANCEROUS LESIONS

Many epithelial and connective tissue tumors of the head and neck region (e.g., papillomas, hemangiomas, lymphomas) occur elsewhere in the body and are described in other chapters. This discussion considers only the most common oral cancer, squamous cell carcinoma (SCC), and its associated precancerous lesions.

Leukoplakia and Erythroplakia

Leukoplakia is defined by the World Health Organization as "a white patch or plaque that cannot be scraped off and cannot be characterized clinically or pathologically as any other disease." This clinical term is reserved for lesions that are present in the oral cavity for no apparent reason. As such, white patches caused by obvious irritation or entities such as lichen planus and candidiasis are not considered to be leukoplakia. Approximately 3% of the world's population have leukoplakia; 5% to 25% of these lesions are premalignant. Thus, until proven otherwise by histologic evaluation, all leukoplakias must be considered precancerous.

Related to leukoplakia, but much less common and much more ominous, is *erythroplakia,* which is a red, velvety, possibly eroded area within the oral cavity that usually remains level with or may be slightly depressed relative to the surrounding mucosa (Fig. 16.4). The epithelium in

Figure 16.4 Erythroplakia. (A) Red discoloration of the maxillary gingiva. (B) Red lesion of the mandibular alveolar ridge. Biopsy of both lesions revealed carcinoma in situ.

such lesions tends to be markedly atypical, and the risk of malignant transformation is much higher than is leukoplakia. Intermediate forms that have the characteristics of both leukoplakia and erythroplakia are termed *speckled leukoerythroplakia.*

Both leukoplakia and erythroplakia may be seen in adults at any age, but they are usually found in persons 40 to 70 years of age, with a 2:1 male preponderance. Although these lesions have multifactorial origins, the use of tobacco (cigarettes, pipes, cigars, and certain forms of smokeless tobacco) is a common antecedent.

MORPHOLOGY

Leukoplakia may occur anywhere in the oral cavity (favored locations are buccal mucosa, floor of the mouth, ventral surface of the tongue, palate, and gingiva). They appear as solitary or multiple white patches or plaques, often with sharply demarcated borders. They may be slightly thickened and smooth, wrinkled and fissured, or may appear as raised, sometimes corrugated, verrucous plaques (Fig. 16.5A). On histologic examination, they present a spectrum of epithelial changes ranging from hyperkeratosis overlying a thickened, acanthotic but orderly mucosal epithelium to lesions with markedly dysplastic changes, sometimes merging into carcinoma in situ (Fig. 16.5B).

The histologic changes in **erythroplakia** only rarely demonstrate orderly epidermal maturation; virtually all (approximately 90%) display severe dysplasia, carcinoma in situ, or minimally invasive carcinoma. An intense subepithelial inflammatory reaction with vascular dilation that contributes to the reddish appearance of these lesions is often present.

Squamous Cell Carcinoma

Approximately 95% of cancers of the head and neck are SCCs, with the remainder largely consisting of adenocarcinomas of salivary gland origin. Head and neck squamous cell carcinoma (HNSCC) is the sixth most common neoplasm in the world. At current rates, approximately 50,000 cases in the United States and more than 650,000 cases worldwide will be diagnosed each year. The term *head and neck cancer* includes tumors of the oral cavity, pharynx, larynx, and nasal cavities, which are discussed here, and also tumors of the thyroid (Chapter 24) and salivary glands (discussed later in this chapter).

The pathogenesis of SCC is multifactorial.

- *Infection with high-risk human papillomavirus (HPV)* is now the primary cause of SCC of the oropharynx.
- Within North America and Europe, oral cavity SCC has classically been a disease of middle-aged individuals who have been chronic users of *smoked tobacco* and *alcohol*.
- In India and Asia, the chewing of betel quid and paan is a major regional predisposing influence. This concoction, considered a delicacy by some, contains ingredients such as areca nut, slaked lime, and tobacco, wrapped in a betel leaf; many of the ingredients of paan can give rise to carcinogens.
- *Actinic radiation* (sunlight) and pipe smoking are known predisposing influences for cancer of the lower lip.
- The incidence of oral cavity SCC (particularly involving the tongue) in individuals younger than 40 years of age, who have no known risk factors, has been on the rise. The pathogenesis in this group of patients, who are nonsmokers and are not infected with HPV, is unknown.

In the oropharynx, as many as 80% of SCCs, particularly those involving the tonsils, the base of the tongue, and the pharynx, harbor oncogenic variants of HPV, particularly HPV-16. HPV-associated SCC of the oropharynx has increased more than twofold over the past two decades. It is hoped that this trend will be reversed by the HPV vaccine, which is protective against cervical cancer. Early detection of HPV-associated head and neck SCC can be particularly challenging because the anatomic sites of origin (tonsillar crypts, base of tongue, and oropharynx) are not readily accessible or amenable to cytologic screening (unlike the cervix) for premalignant lesions. Unlike the oropharynx, HPV-associated SCC of the oral cavity is relatively uncommon.

Prognosis is dependent on a number of factors including the specific etiology of SCC. The 5-year survival rate of "classic" smoking and alcohol related early-stage SCC is approximately 80%, but survival drops to 20% for late-stage disease. Long-term survival is better in patients with HPV-positive SCC. The dismal outlook in classic SCC reflects diagnosis at advanced stage as well as the frequent presence of multiple primary tumors. Notably, second primary

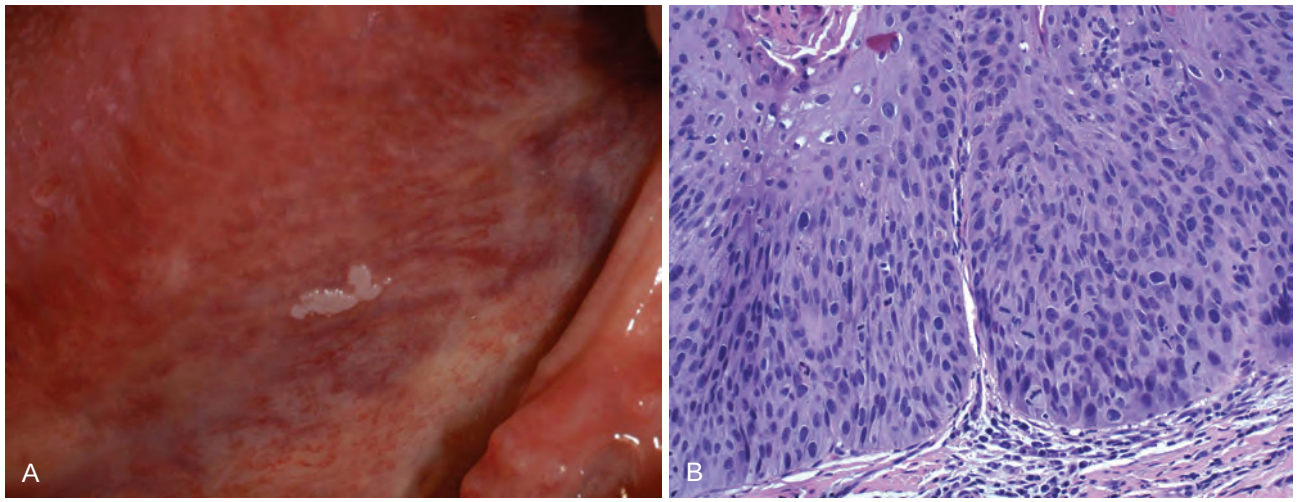

Figure 16.5 Leukoplakia. (A) Clinical appearance of leukoplakia is highly variable. In this example, the lesion is relatively smooth and thin with well-demarcated borders. (B) Histologic appearance of leukoplakia showing severe dysplasia that is characterized by nuclear and cellular pleomorphism, numerous mitotic figures, and a loss of normal maturation.

tumors occur at 3% to 7% per year, the highest rate of among all malignancies. This observation has led to the concept of *field cancerization*, which postulates that multiple individual primary tumors develop independently in the upper aerodigestive tract as a result of years of mucosal exposure to carcinogens. This may explain why there is an almost 35% chance of developing at least one new primary tumor in individuals who survive 5 years after detection of the initial primary tumor. Development of these tumors can be particularly devastating for individuals whose initial lesions were small. The second primary tumors are commonly fatal. Early detection of premalignant lesions is therefore critical for long-term survival of these patients.

Molecular Biology of Squamous Cell Carcinoma. As with other cancers, SCC development is driven by the accumulation of mutations and epigenetic changes that alter the expression and function of oncogenes and tumor suppressor genes. A number of reproducible molecular alterations, some definitively characterized and some inferred, have been identified. In general, these can be categorized as loss of heterozygosity (LOH), copy number alterations, hypermethylation, changes in RNA expression, and somatic DNA mutations.

Several large-scale exome-sequencing studies, including those performed as part of the Cancer Genome Atlas (TCGA), have defined the mutational landscape of SCC. A number of important findings have come from these studies. First, several genes previously proposed as playing critical roles in SCC *(TP53, CDKN2A, PIK3CA)* were shown to be mutated with frequencies sufficient to suggest that they are drivers of cancer development. Second, a number of novel and potentially targetable genetic alterations were identified, particularly *NOTCH1* and its associated pathways and the tumor suppressor *FAT1*, a member of the cadherin family. Third, although *TP53* was the most frequently mutated gene, the mutational frequency for the next most common genes ranged from 1% to 23%, suggesting that there is considerable intertumor variability with respect to the specific mutations harbored in a given tumor. Finally, the mutations identified in HPV-positive and HPV-negative tumors were different. For example, HPV-negative tumors harbored more somatic mutations than HPV-positive tumors. In addition, owing to the expression of the HPV oncoproteins E6 and E7, p53 and RB pathways are typically inactivated in HPV-positive tumors, similar to what has been observed in cervical cancer (Chapter 22). Despite this advanced understanding, targeted therapies for reducing SCC morbidity and mortality remain limited.

Lesions are considered premalignant and at risk for progressing to HNSCC when histologic dysplasia is present. However, the criteria for diagnosing dysplasia are subjective and open to a wide range of interpretation, even among highly qualified pathologists. This, in part, reflects the absence of validated histologic findings that predict malignant transformation of dysplastic lesions. In general, ~15% of premalignant lesions will progress to HNSCC with a mean time interval of 5 years. Our inability to accurately prognosticate on the basis of histologic alterations emphasizes the need to develop molecular criteria for predicting outcomes.

MORPHOLOGY

SCC may arise anywhere in the head and neck region that is lined by stratified squamous epithelium. For the "classic" HPV-negative keratinizing SCC, the favored locations are the ventral surface of the tongue, floor of the mouth, lower lip, soft palate, and gingiva (Table 16.2). Conversely, HPV-associated SCCs are most often nonkeratinizing neoplasms arising in the reticulated epithelium of the tonsillar crypts within the lingual tonsils, base of tongue, soft palate, and pharynx. Although keratinizing SCCs are typically preceded by premalignant lesions, such as leukoplakia and erythroplakia, HPV-associated SCCs tend to develop without a readily identified premalignant (i.e., dysplastic) component.

Early-stage keratinizing SCCs appear as raised, firm, pearly plaques or irregular, roughened, or verrucous areas of mucosal thickening. Either pattern may be superimposed on a background of apparent leukoplakia or erythroplakia. As these lesions enlarge, they typically create ulcerated and protruding masses with irregular and indurated, or rolled, borders (Fig. 16.6A). Conversely, HPV-associated SCCs typically present as small primary tumors that

Table 16.2 Differences Between HPV-Associated and Non-Associated SCC

	Associated With HPV	Not Associated With HPV
Patient Age	Younger	Older
Risk Factors	Number of oral sex partners	Tobacco, alcohol
Location	Oropharynx	Oral cavity
Clinical Presentation	Small primary lesion with bulky nodal disease	Large primary lesion with variable nodal disease
Histology	Nonkeratinizing SCC	Keratinizing SCC
Distant Metastasis	Rare	Common
Clinical Outcomes	Good	Poor
Risk of Second Primary	Low	High

HPV, Human papillomavirus; *SCC,* squamous cell carcinoma.

lack obvious surface mucosal lesions but are accompanied by significant cervical lymphadenopathy.

Keratinizing SCCs begin as dysplastic lesions, which may or may not progress to full-thickness dysplasia (carcinoma in situ) before invading the underlying connective tissue stroma (Fig. 16.6B). This difference in progression should be contrasted with cervical cancer (Chapter 22), in which full-thickness dysplasia, representing carcinoma in situ, typically develops before invasion. Keratinizing SCCs range from well-differentiated to anaplastic, and sometimes sarcomatoid, tumors. However, the degree of histologic differentiation, as determined by the relative degree of keratinization, is not correlated with behavior, including growth rate. SCC tends to infiltrate locally before metastasizing. The routes of extension depend on the primary site. The cervical lymph nodes are favored sites of local metastasis, and the most common sites of distant metastasis are mediastinal lymph nodes, lungs, liver, and bones. Unfortunately, distant metastases are often already present at the time of discovery of the primary lesion.

The histology of **HPV-associated SCC is characterized by the proliferation of nests and lobules of nonkeratinizing and basaloid cells** growing within sheets of lymphocytes (Fig. 16.7A). Immunohistochemical detection of strong p16 protein expression can serve as a marker for HPV-associated SCC (Fig. 16.7B). However, further testing, using PCR or in situ hybridization (ISH) (Fig. 16.7C), may be required in certain cases.

ODONTOGENIC CYSTS AND TUMORS

The overwhelming majority of odontogenic cysts are derived from remnants of odontogenic epithelium present within the jaws. In contrast to the rest of the skeleton, epithelial-lined cysts are common in the jaws. These cysts are subclassified as either inflammatory or developmental (Table 16.3), with only the most common described here.

The *dentigerous cyst* originates around the crown of an unerupted tooth as a result of fluid accumulation between the developing tooth and the dental follicle. Radiographically, these are unilocular lesions most often associated with impacted third molar (wisdom) teeth. Histologically, they are lined by a thin layer of stratified squamous epithelium, and there is frequently a dense chronic inflammatory cell infiltrate in surrounding connective tissue. Complete surgical excision is curative.

The *keratocystic odontogenic tumor,* which was previously referred to as *odontogenic keratocyst*, must be differentiated from other odontogenic cysts because of its aggressive behavior. Keratocystic odontogenic tumors can be seen at any age but are most common between 10 and 40 years of age, in males, and within the posterior mandible. The lesions are well-defined unilocular or multilocular radiolucencies with a lining consisting of a thin layer of keratinized stratified squamous epithelium with a prominent basal cell layer and a corrugated epithelial surface. Treatment requires complete excision because of locally aggressive behavior. Recurrence rates for inadequately removed lesions can be as high as 60%. About 80% of the lesions are solitary, but patients with multiple cysts should be evaluated for nevoid basal cell carcinoma syndrome (Gorlin syndrome), which is associated with mutations in the tumor suppressor gene *PTCH* (Patched) on chromosome 9q22 (Chapter 25).

(B) Immunohistochemistry demonstrating strong nuclear and cytoplasmic tumor cell staining p16. (C) In situ hybridization for high-risk human papillomavirus E6 and E7 mRNA expression.

The *radicular cyst* is a common inflammatory lesion found at the tooth apex. The cysts develop as a result of long-standing inflammation of the tooth *(pulpitis)*, often secondary to advanced carious lesions or local trauma. Necrosis of the pulp tissue may occur and can traverse the length of the root to exit at the apex into the surrounding alveolar bone. Over time, granulation tissue may develop, with subsequent epithelialization that results in a radicular cyst. The older term *periapical granuloma* is still used, even though the lesion does not show true granulomatous inflammation. Periapical inflammatory lesions persist due to continued presence of bacteria or other irritating agents. Successful treatment, therefore, necessitates the complete removal of offending material and restoration or extraction of the tooth.

Odontogenic tumors are a group of lesions with diverse histologic appearances and clinical behavior. Some are true neoplasms (both benign and malignant), and others are more likely hamartomas. Odontogenic tumors are derived from odontogenic epithelium, odontogenic mesenchyme, or both (Table 16.4). The two most common and clinically significant tumors are odontoma and ameloblastoma.

Malignant
Ameloblastic fibrosarcoma

- *Odontoma,* the most common odontogenic tumor, arises from epithelium and is associated with extensive enamel and dentin deposition. These lesions probably represent hamartomas rather than true neoplasms and are cured by local excision.
- *Ameloblastoma* arises from odontogenic epithelium and does not display ectomesenchymal differentiation. It is cystic, slow growing, and locally invasive with a typically indolent course. Treatment requires wide surgical resection to prevent recurrence.

KEY CONCEPTS

ORAL CAVITY

- Caries is the most common cause of tooth loss in persons younger than 35 years of age. The primary cause is tooth destruction by acid end-products of bacterial sugar fermentation.
- Gingivitis is a common, reversible inflammation of the mucosa surrounding the teeth.
- Periodontitis is a chronic inflammatory condition that results in destruction of the supporting structures and eventual tooth loss. It is associated with poor oral hygiene and altered oral microbiota.
- Aphthous ulcers are painful superficial ulcers of unknown etiology.
- Fibromas and pyogenic granulomas are common reactive lesions of the oral mucosa.
- Leukoplakias and erythroplakias are oral mucosal lesions that may undergo malignant transformation.
- The majority of oral cavity and oropharyngeal cancers are SCCs. Oral cavity SCCs are linked to tobacco and alcohol use, but the incidence of HPV-associated lesions has risen dramatically in oropharyngeal SCCs.

Upper Airways

The term *upper airway* is used here to include the nose, pharynx, and larynx. Disorders of these structures are among the most common afflictions of humans, but fortunately the overwhelming majority are more nuisance than threat.

NOSE

Inflammatory diseases, such as the common cold, are the most frequent disorders of the nose and accessory air sinuses. These are most often viral in origin, but can be complicated by superimposed bacterial infections. Destructive inflammatory nasal diseases and primary tumors of the nasal cavity or maxillary sinus occur less frequently.

Inflammatory Lesions

Infectious Rhinitis. Infectious rhinitis, also known as the *common cold,* is caused by one or more viruses. Major offenders are adenoviruses, echoviruses, and rhinoviruses, all of which evoke a profuse catarrhal discharge. During the initial acute stages, the nasal mucosa is thickened, edematous, and red; the nasal cavities are narrowed; and the turbinates are enlarged. These changes may extend, to produce pharyngotonsillitis. Secondary bacterial infection enhances the inflammatory reaction and produces a mucopurulent or sometimes frankly suppurative exudate. Fortunately, these infections clear rapidly. As the saying goes, "in a week if treated, but in 7 days if ignored."

Allergic Rhinitis. Allergic rhinitis (hay fever) is initiated by hypersensitivity to one of a large group of allergens, most commonly plant pollens, fungi, animal allergens, and dust mites. It affects 20% of the US population. As with asthma, allergic rhinitis is an IgE-mediated immune reaction with an early- and late-phase response (see "Immediate [Type I] Hypersensitivity" in Chapter 6). The allergic reaction is characterized by mucosal edema, erythema, and mucus secretion accompanied by eosinophil-rich leukocytic infiltrates.

Nasal Polyps. Recurrent attacks of rhinitis may eventually lead to focal protrusions of the mucosa, producing *nasal polyps,* which may reach 3 to 4 cm in length. Histologically, these polyps consist of edematous mucosa with loose stroma, hyperplastic or cystic mucus glands, and infiltrates of neutrophils, eosinophils, and plasma cells (Fig. 16.8). In the absence of bacterial infection, the mucosal surface is intact, but it may become ulcerated. When multiple or large, nasal polyps may encroach on the airway and impair sinus drainage. Despite features indicating an allergic etiology, most people with nasal polyps are not atopic, and only 0.5% of atopic patients develop nasal polyps.

Chronic Rhinitis. Chronic rhinitis follows repeated episodes of microbial or allergic rhinitis with the eventual development of superimposed bacterial infection. A deviated nasal septum or nasal polyps that impair drainage of secretions contribute to the likelihood of microbial invasion. Superficial desquamation or ulceration of the mucosal epithelium is common. Inflammatory infiltrates include variable numbers of neutrophils, lymphocytes, and plasma cells. Infections may extend into the sinuses.

Sinusitis. Most cases of acute sinusitis are preceded by rhinitis, but maxillary sinusitis occasionally arises by extension of a periapical infection through the bony sinus floor. Responsible microorganisms are usually components of the oral microbiome that elicit an inflammatory reaction. The resulting mucosal edema impairs sinus drainage and may result in *empyema* of the sinus. Outflow obstruction occurs most often in the frontal and, less commonly, anterior ethmoid sinuses. This may occasionally lead to mucus accumulation, producing a so-called *mucocele.*

Acute sinusitis may progress to *chronic sinusitis,* particularly when drainage is disrupted. A polymicrobial infection,

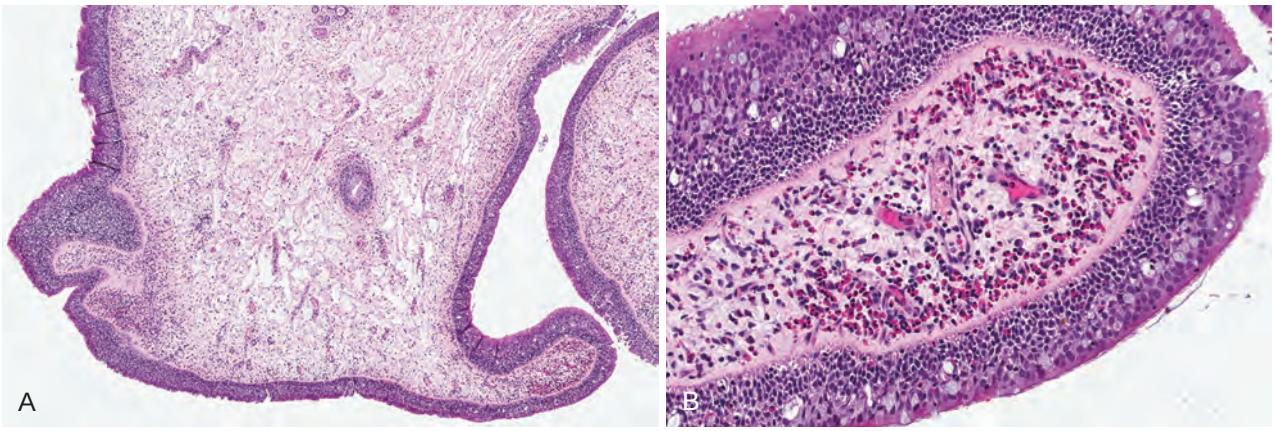

Figure 16.8 (A) Nasal polyps. Low-power magnification showing edematous stroma lined by epithelium. (B) High-power view showing stromal edema, eosinophil-rich inflammatory infiltrate, and respiratory epithelial lining.

largely composed of normal oral microbiome components, is present in most cases. Fungi may cause severe chronic sinusitis (e.g., in mucormycosis), especially in diabetic patients. Sinusitis can, uncommonly, present as a component of *Kartagener syndrome,* which also includes bronchiectasis and situs inversus (Chapter 15), as a result of defective ciliary action. Although most cases of chronic sinusitis are more uncomfortable than disabling or serious, the infections can occasionally spread into the orbit or penetrate into surrounding bone leading to osteomyelitis. Spread into the cranial vault can cause septic thrombophlebitis within a dural venous sinus.

Necrotizing Lesions of the Nose and Upper Airways

Necrotizing ulcerating lesions of the nose and upper respiratory tract may be produced by the following:

- *Acute fungal infections* (including mucormycosis; Chapter 8), particularly in diabetic and immunosuppressed patients
- *Granulomatosis with polyangiitis,* previously called Wegener granulomatosis (Chapter 11)
- *Extranodal NK/T-cell lymphoma, nasal type,* in which the tumor cells harbor EBV (Chapter 13) typically occurs in males of Asian or Latin American descent in the fifth or sixth decade of life; ulceration and bacterial infection frequently complicate the process. Untreated, these neoplasms are almost always rapidly fatal as a result of uncontrolled lymphoma spread and cranial vault penetration or secondary bacterial infection with septic dissemination. Localized cases can often be controlled with radiotherapy, but relapse and recurrence are common and associated with poor outcomes.

NASOPHARYNX

The nasopharyngeal mucosa, related lymphoid structures, and glands may be involved in a wide variety of infections (e.g., diphtheria, infectious mononucleosis) as well as neoplasms.

Inflammatory Lesions

Pharyngitis and tonsillitis frequently accompany viral upper respiratory infections. Rhinoviruses, echoviruses, and adenoviruses are the most common causes; remaining cases are primarily due to various strains of influenza or respiratory syncytial virus. Erythema and edema of the nasopharyngeal mucosa with reactive enlargement of nearby tonsils and lymph nodes are characteristic. Bacterial infection may cause pharyngitis and tonsillitis or, alternatively, occur as a secondary process superimposed on viral infection. β-hemolytic streptococci are the most frequent pathogens, but *Staphylococcus aureus* or other bacteria may also be present. When bacteria are present, exudate and exudative membranes (pseudomembranes) may cover the nasopharyngeal mucosa as well as enlarged nasopalatine and palatine tonsils. *Follicular tonsillitis,* in which enlarged tonsils (due to reactive lymphoid hyperplasia) are dotted by exudate emanating from the tonsillar crypts, is common.

The major importance of streptococcal "sore throat" lies in the possible development of late sequelae, such as rheumatic fever (Chapter 12) and glomerulonephritis (Chapter 20). Whether recurrent episodes of acute tonsillitis favor the development of chronic tonsillar enlargement is open to debate, but regardless of the cause of the enlargement, patients may benefit from surgical excision.

TUMORS OF THE NOSE, SINUSES, AND NASOPHARYNX

Tumors in the nose, sinuses, and nasopharynx are infrequent but include the wide spectrum of mesenchymal and epithelial neoplasms.

Nasopharyngeal Angiofibroma. **Nasopharyngeal angiofibroma is a benign, highly vascular tumor that occurs almost exclusively in adolescent males who are often fair-skinned and red headed.** It is believed to arise within the fibrovascular stroma of the posterolateral wall of the roof of the nasal cavity. Surgical removal, often with preoperative embolization to decrease bleeding, is the treatment

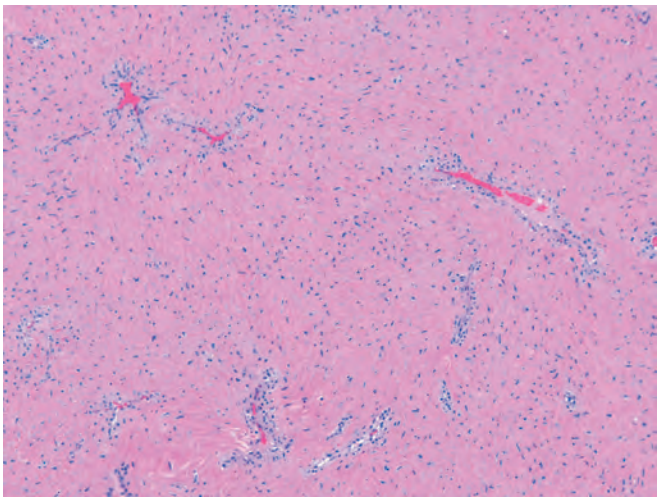

Figure 16.9 Nasopharyngeal angiofibroma showing thin-walled muscular vessels separated by dense collagenous stroma containing small, bland fibroblasts.

of choice. Because nasopharyngeal angiofibroma is often locally aggressive, with intracranial extension, recurrence rates can approach 20%, and 9% of cases can be fatal (Fig. 16.9). Mutations in *CTNNB1*, which encodes *beta-catenin*, are present in the majority of nasopharyngeal angiofibromas. This tumor can also develop sporadically or syndromically in association with familial adenomatous polyposis.

Sinonasal (Schneiderian) Papilloma. **Sinonasal papilloma is a benign neoplasm arising from the respiratory or Schneiderian mucosa lining the nasal cavity and paranasal sinuses.** These lesions occur in three forms: *exophytic* (most common), *endophytic* (or *inverted*), and *oncocytic* (formerly known as *cylindrical cell)*. Sinonasal papillomas are most common in males between 30 and 60 years of age. The endophytic form may invaginate into the underlying stroma (Fig. 16.10). Although this is a benign neoplasm, it can display locally aggressive behavior within both the nose and the paranasal sinuses, including invasion into the orbit or cranial vault, and has a high rate of recurrence if not adequately excised. Malignant transformation occurs in approximately 10% of cases. Most endophytic sinonasal papillomas have *EGFR* gene mutations. The remaining cases generally harbor HPV DNA, often low-risk types 6 and 11.

Olfactory Neuroblastoma (Esthesioneuroblastoma). **Olfactory neuroblastomas arise from neuroectodermal olfactory cells within the mucosa, particularly in the superior aspect of the nasal cavity.** The age distribution is bimodal, with peaks at 15 and 50 years. Patients typically present with nasal obstruction and/or epistaxis. Histologically, olfactory neuroblastomas are *small, blue, round cell neoplasms*, a category that includes lymphoma, small cell carcinoma, Ewing sarcoma/peripheral neuroectodermal tumor, rhabdomyosarcoma, melanoma, and sinonasal undifferentiated carcinoma. Olfactory neuroblastomas are typically composed of well-circumscribed nests and lobules of cells separated by fibrovascular stroma (Fig. 16.11). A fibrillary matrix, representing tangled neuronal cell processes, is often present. Consistent with their neuroendocrine origin, electron microscopy demonstrates membrane-bound secretory granules, and immunohistochemistry is positive for neuron-specific enolase, synaptophysin, CD56, and chromogranin. Depending on tumor stage and grade, combinations of surgery, radiation therapy, and chemotherapy yield 5-year survival rates of 40% to 90%. Genetic aberrations in olfactory neuroblastoma are heterogenous, with cases demonstrating varying chromosomal gains and/or losses.

NUT Midline Carcinoma. **This uncommon tumor occurs in the nasopharynx, salivary gland, or other midline structures of the thorax or abdomen.** It can occur at any age, from infancy to late adulthood, but the true incidence of NUT midline carcinoma is not known, as it is easily mistaken for SCC. Despite this, NUT midline carcinoma is clinically distinctive due to its extremely aggressive behavior and resistance to conventional therapy; most patients survive for less than 1 year following diagnosis. NUT midline carcinomas are uniformly associated with translocations that fuse genes encoding chimeric proteins composed of most of NUT, a chromatin regulator, and a portion of a "chromatin reader" protein, usually BRD4. Drugs that displace BRD4-NUT from chromatin induce NUT midline carcinoma cells to terminally differentiate, and targeted therapy with BRD4-NUT inhibitors is now being tested clinically.

Nasopharyngeal Carcinoma. **Nasopharyngeal carcinoma is characterized by a distinctive geographic distribution, a close anatomic relationship to lymphoid tissue, and an association with EBV infection.** The nomenclature for nasopharyngeal carcinomas continues to evolve, but, at

Figure 16.10 Inverted papilloma. The overlying surface is lined by thin respiratory epithelium; however, the underlying stroma contains multiple nodules of thick neoplastic epithelium growing inward; hence, the term *inverted*.

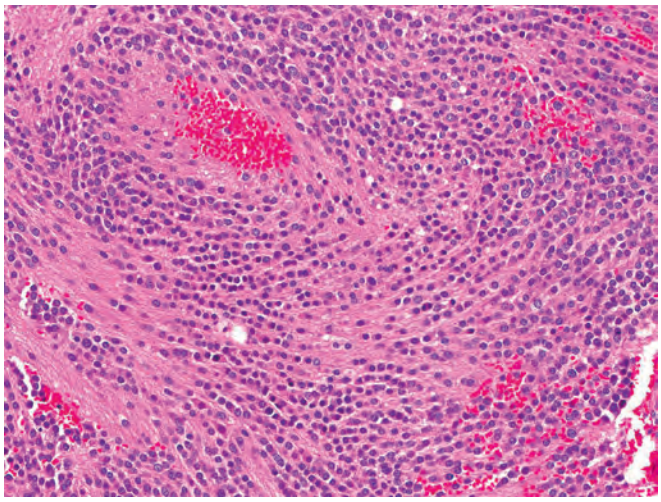

Figure 16.11 Olfactory neuroblastoma is composed of small monotonous cells with round nuclei in an eosinophilic fibrillary stroma. The cells appear to swirl around a blood-filled vascular channel.

present, is described as one of three patterns: (1) keratinizing SCCs, (2) nonkeratinizing SCCs, and (3) basaloid SCCs. *Lymphoepithelioma* or *lymphoepithelial carcinoma* are historic names for this tumor that are no longer used.

The three principal factors that influence development of nasopharyngeal carcinomas are heredity, age, and EBV infection. For example, these neoplasms are particularly common in some parts of Africa, where they are the most frequent childhood cancer. In contrast, nasopharyngeal carcinomas are common in adults in southern China but rarely occur in children. In the United States, nasopharyngeal carcinomas are rare in all age groups. Beyond EBV infection, diets high in nitrosamines, which are found in fermented foods and salted fish, and environmental insults, including smoking and chemical fumes, have been linked to these tumors. In the nonkeratinizing form, most patients have antibodies against EBV early antigens or viral capsid antigens, and PCR can be used to detect EBV DNA in the serum.

MORPHOLOGY

Histologically, keratinizing and nonkeratinizing nasopharyngeal carcinomas resemble well-differentiated and poorly differentiated SCCs arising in other locations. The undifferentiated variant is composed of large epithelial cells with oval or round vesicular nuclei, prominent nucleoli, and indistinct cell borders; the latter impart the appearance of a syncytium (Fig. 16.12B). Abundant, normal-appearing lymphocytes, predominantly T cells, infiltrate the tumors. EBV-encoded RNAs such as EBER-1 or proteins such as LMP-1 can be identified in the malignant epithelial cells by in situ hybridization (Fig. 16.12C) or immunohistochemistry, respectively.

Primary nasopharyngeal carcinomas are often clinically occult until they present at advanced stages with nasal obstruction, epistaxis, and metastases to the cervical lymph nodes in up to 70% of patients. Radiotherapy is the

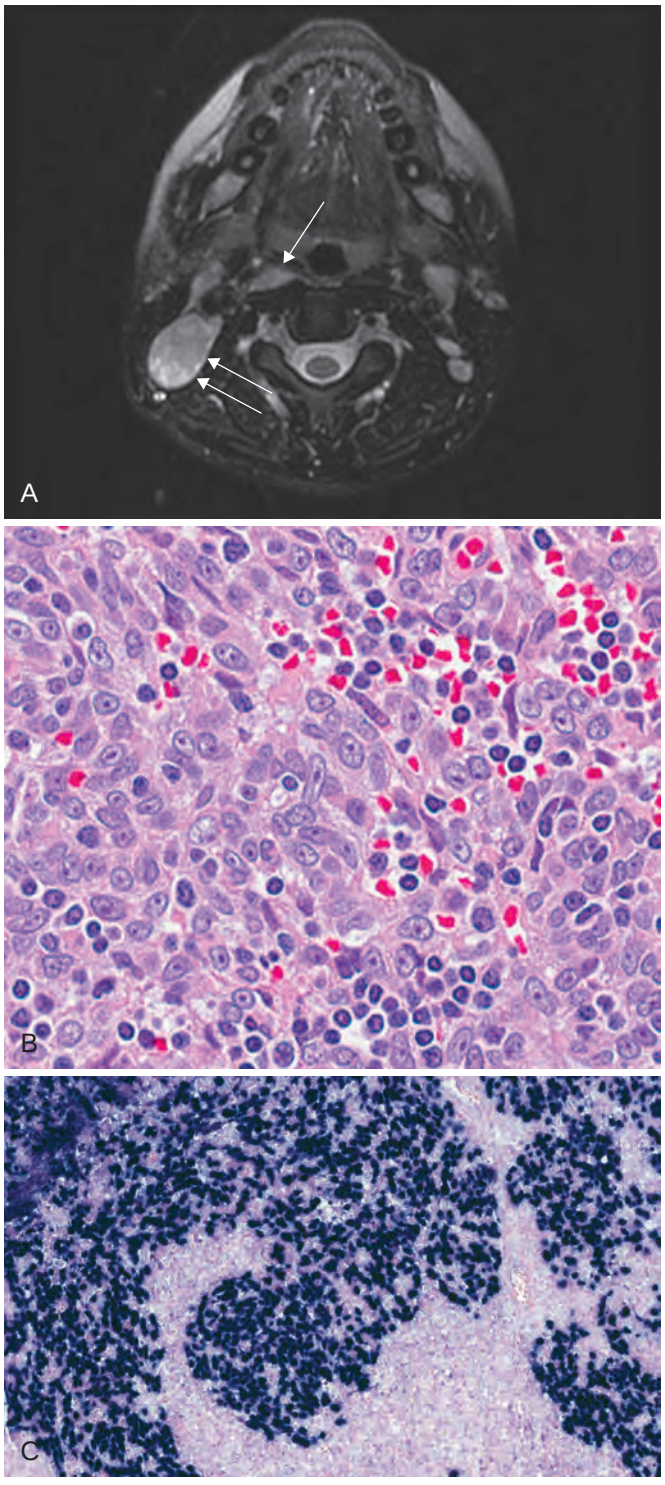

Figure 16.12 Nasopharyngeal carcinoma, nonkeratinizing undifferentiated type. (A) Computed tomography study demonstrating thickening of the nasopharyngeal region *(arrow)* and an enlarged cervical lymph node *(double arrow)*. (B) The syncytial clusters of malignant epithelium are infiltrated by benign lymphocytes. (C) In situ hybridization for EBER-1, a small nuclear RNA encoded by Epstein-Barr virus.

standard treatment and results in an overall 5-year survival of approximately 60%. This, however, varies with histology; the stage-dependent 5-year survival for nonkeratinizing nasopharyngeal carcinoma ranges from 70% to 98%, but that for the keratinizing form is only 20%. These stark differences

have been attributed to divergent therapeutic responses, as undifferentiated carcinomas are the most radiosensitive, and the keratinizing carcinomas are least radiosensitive.

LARYNX

The most common disorders of the larynx are inflammatory. Tumors are uncommon but are amenable to resection, though often at the price of loss of natural voice.

Inflammatory Lesions

Laryngitis may occur as the sole manifestation of allergic, viral, bacterial, or chemical insult, but it is more commonly associated with generalized upper respiratory tract infection, heavy environmental toxin exposure (e.g., tobacco smoke), or gastroesophageal reflux due to irritating effects of gastric contents. The larynx may also be affected in systemic infections, such as tuberculosis and diphtheria. Although most infections are self-limited, the sequelae can be serious, especially in infancy or childhood, when mucosal congestion, exudation, or edema may cause laryngeal obstruction. In particular, laryngoepiglottitis caused by respiratory syncytial virus, *Haemophilus influenzae,* or β-hemolytic streptococci may induce such sudden swelling of the epiglottis and vocal cords in the small airways of infants and young children as to constitute a medical emergency. This is uncommon in adults because of the larger size of the larynx as well as stronger accessory respiratory muscles. *Croup* refers to laryngotracheobronchitis in children that produces a characteristic inspiratory stridor due to airway narrowing. The laryngitis that is common in heavy smokers predisposes to squamous epithelial metaplasia and sometimes overt carcinoma.

Reactive Nodules (Vocal Cord Nodules and Polyps)

Reactive nodules, also called polyps, develop on the vocal cords, most often in heavy smokers or those who impose great strain on their vocal cords (so-called *singer's nodules*) (Fig. 16.13). Because of their strategic location and accompanying inflammation, they characteristically change the character of the voice and often cause progressive hoarseness. Despite this, the risk of developing cancer in these lesions is almost nonexistent. By convention, vocal cord nodules are bilateral and polyps are unilateral. Adults are most often affected. Both nodules and polyps are smooth, rounded, sessile or pedunculated excrescences, generally only a few millimeters in greatest dimension, located usually on the true vocal cords. The histologic features of nodules and polyps are similar; they are covered by squamous epithelium that may become keratotic, hyperplastic, or even slightly dysplastic overlying a loose myxoid connective tissue core. The latter may be variably fibrotic, fibrinous, or highly vascularized. Nodules on opposing vocal cords may impinge on each other and cause ulceration.

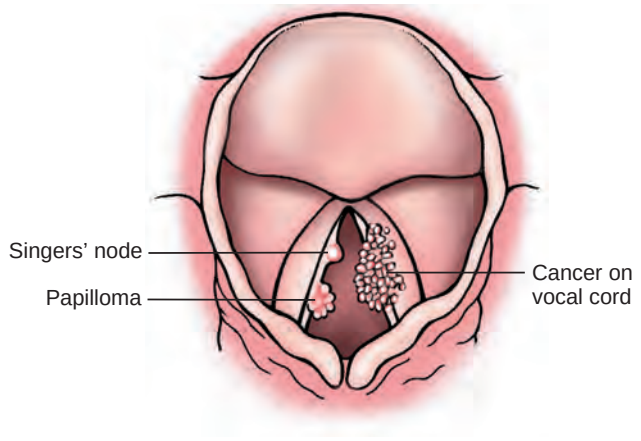

Figure 16.13 Diagrammatic comparison of a singer's nodule, a benign papilloma, and an exophytic carcinoma of the larynx to highlight differences in their clinical appearance.

Squamous Papilloma and Papillomatosis

Laryngeal squamous papillomas are benign neoplasms, usually located on the true vocal cords, that form soft, exophytic proliferations that rarely exceed 1 cm in diameter (see Fig. 16.13). The growths are composed of multiple slender, fingerlike projections supported by central fibrovascular cores and covered by an orderly stratified squamous epithelium. When papillomas develop on the free edge of a vocal cord, trauma may lead to ulceration that can be accompanied by hemoptysis.

Papillomas are usually solitary in adults but are often multiple in children, a condition referred to as *juvenile laryngeal papillomatosis*. The lesions are caused by HPV types 6 and 11 acquired via the maternal birth canal. They frequently recur but only rarely transform to SCC. Although the polyps often regress spontaneously at puberty, the regularity of recurrence requires some children to undergo numerous surgeries.

Carcinoma of the Larynx

Carcinoma of the larynx is typically a squamous cell carcinoma seen in male chronic smokers.

Hyperplasia-Dysplasia-Carcinoma Sequence. **Epithelial alterations in the larynx range from hyperplasia to dysplasia, carcinoma in situ, and invasive carcinoma.** Grossly, epithelial surfaces may be smooth, white or reddened with focal thickenings, roughened by keratosis, or punctuated by irregular verrucous or ulcerated white-pink lesions (see Figs. 16.13 and 16.14).

Nondysplastic hyperplasias have almost no potential for malignant transformation. For lesions with dysplasia, the risk of malignant transformation is directly proportional to the initial grade of dysplasia. For example, the risk of transformation is only 1% to 2% over 5 to 10 years for lesions with mild dysplasia, but increases to 5% to 10% for those with severe dysplasia. Histologic evaluation is the only way to grade dysplasia.

Laryngeal carcinoma is most often related to tobacco smoke; risk is proportional to exposure. Prior to malignant transformation, epithelial changes frequently regress after smoking cessation. Alcohol synergizes with tobacco to increase risk substantially. Nutritional factors, asbestos

exposure, irradiation, and HPV infection can also increase cancer risk.

MORPHOLOGY

About 95% of laryngeal carcinomas are typical SCCs. Most arise on the vocal cords, but they may develop above or below the cords and involve the epiglottis, aryepiglottic folds, or pyriform sinuses. SCCs of the larynx develop similarly to those at other sites, beginning as in situ lesions that become pearly gray, wrinkled mucosal plaques and, ultimately, ulcerated fungating masses (Fig. 16.14). Histologically, the degree of anaplasia is highly variable and can include tumor giant cells and bizarre mitotic figures. As expected of sites in which neoplasia arises following recurrent exposure to environmental carcinogens, squamous hyperplasia with foci of dysplasia or carcinoma in situ may be present within adjacent mucosae.

Laryngeal carcinoma presents most commonly in men within the sixth decade of life. The initial manifestation is often persistent hoarseness, dysphagia, and dysphonia. Prognosis is directly related to clinical stage. In early disease, organ-preserving techniques (e.g., laser surgery, microsurgery, and radiation therapy) are being used with greater frequency. Combined chemotherapy and radiation therapy, with or without laryngectomy, is typically required for more advanced or recurrent disease.

Figure 16.14 Laryngeal carcinoma. Note the large, ulcerated, fungating lesion involving the right vocal cord and pyriform sinus.

KEY CONCEPTS

UPPER AIRWAYS

- Rhinitis can be infectious or allergic in nature and, over time, can lead to chronic rhinitis, sinusitis, and development of nasal polyps.
- Pharyngitis and tonsillitis are typically caused by common upper respiratory tract infection by rhinoviruses, echoviruses, and adenoviruses.
- Nasopharyngeal carcinoma is most often caused by EBV; tumors are most common among African children and Asian adults.
- Laryngitis can be caused by a host of etiologies, including allergic, viral, bacterial, and chemical insults.
- Vocal cord nodules and polyps are reactive lesions seen in smokers or individuals who strain their vocal cords.
- Laryngeal SCC is linked to smoking and alcohol use and is most prevalent in older males.

Ears

Although they rarely shorten life, disorders of the ear often impact its quality. The most common aural disorders, in descending order of frequency, are (1) acute and chronic otitis (most often involving the middle ear and mastoid), sometimes leading to a cholesteatoma; (2) symptomatic otosclerosis; (3) aural polyps; (4) labyrinthitis; (5) carcinomas, largely of the external ear; and (6) paragangliomas, mostly in the middle ear. Only those conditions that have distinctive morphologic features (save for labyrinthitis) are described. Paragangliomas are discussed later.

INFLAMMATORY LESIONS

Acute and chronic otitis media occur most often in infants and children. The origin is typically viral infection that induces a serous exudate. Superimposed bacterial infection, most frequently by *Streptococcus pneumoniae,* nontypeable *H. influenzae,* or *Moraxella catarrhalis,* can lead to suppurative inflammation.

Repeated bouts of acute otitis media with failure of resolution lead to chronic disease. The causative agents are usually *Pseudomonas aeruginosa, S. aureus,* fungus, or, in some cases, a polymicrobial infection. Chronic infection has the potential to perforate the eardrum, encroach on the ossicles or labyrinth, spread into the mastoid spaces, and even penetrate the cranial vault to produce temporal cerebritis or abscess. In individuals with diabetes, otitis media caused by *P. aeruginosa* is especially aggressive and can spread widely, resulting in destructive necrotizing otitis media.

Cholesteatomas are non-neoplastic, cystic lesions associated with chronic otitis media. The cysts are typically 1 to 4 cm in diameter, lined by keratinizing squamous or metaplastic mucus-secreting epithelium, and filled with

amorphous, keratinous debris. Cholesterol spicules may be present. Although the pathogenesis is not clear, it is thought that chronic inflammation and perforation of the eardrum, with ingrowth of the squamous epithelium or metaplasia of the secretory epithelial lining of the middle ear, promote formation of a squamous cell nest that becomes cystic. Cyst rupture induces a brisk inflammatory reaction that includes giant cells engulfing partially necrotic squamous cells and other particulate debris. These lesions, by progressive enlargement, can erode into the ossicles, labyrinth, adjacent bone, or surrounding soft tissue and sometimes produce visible neck masses.

OTOSCLEROSIS

Otosclerosis refers to abnormal bone deposition in the middle ear about the rim of the oval window into which the footplate of the stapes fits. Both ears are usually affected. At first, there is fibrous ankylosis of the footplate. This often occurs in the early decades of life. Over time, bony overgrowth anchors the footplate into the oval window. The severity of the hearing loss reflects the degree of immobilization. Minimal degrees of otosclerosis are common in young to middle-aged adults, but fortunately more severe symptomatic disease is relatively rare. Otosclerosis is familial in most instances, with an autosomal dominant transmission and variable penetrance. The basis for the osseous overgrowth is obscure, but it appears to represent uncoupling of normal bone resorption and bone formation. Thus, it begins with bone resorption, followed by fibrosis and vascularization of the temporal bone in the immediate vicinity of the oval window. Over time the fibrosis is replaced by dense new bone anchoring the footplate of the stapes. In most instances, the process is slowly progressive over the span of decades and can eventually lead to marked hearing loss.

TUMORS

Epithelial and mesenchymal tumors of the external, middle, or internal ear are rare, with the exception of basal cell carcinomas or SCCs arising on the pinna (external ear). These tend to occur in elderly men and are associated with sun exposure. In contrast, SCCs of the ear canal occur most often in middle-aged to elderly women and are not associated with sun exposure. SCCs involving the ear resemble their counterparts at other skin locations, beginning as papules that extend and eventually erode and invade. Despite local invasion, basal cell carcinomas and SCCs involving the pinna rarely spread. The outlook is more bleak when SCCs arise in the external ear canal, as these may invade the cranial cavity or metastasize to regional lymph nodes, accounting for a 5-year survival of only about 50%.

KEY CONCEPTS

EARS

- Infections of the ear are common in children and typically viral in etiology. Chronic infections can be complicated by bacterial infections, which, in turn, can lead to secondary complications including perforated eardrum as well as spreading to the ossicles or mastoid spaces.
- Otosclerosis, with its associated hearing loss, is caused by the abnormal deposition of bone in the middle ear.

Neck

Most of the conditions that involve the neck are described elsewhere (e.g., primary squamous cell and basal cell carcinomas of the skin, melanomas, lymphomas) or are components of systemic disorders (e.g., generalized rashes, lymphadenopathy of infectious mononucleosis, tonsillitis). What remains to be considered here are a few uncommon lesions unique to the neck.

BRANCHIAL CYST (CERVICAL LYMPHOEPITHELIAL CYST)

The vast majority of branchial cysts are thought to arise from remnants of the second branchial arch and are most commonly observed in young adults between 20 and 40 years of age. These benign lesions usually appear on the upper lateral aspect of the neck along the sternocleidomastoid muscle. The slowly-enlarging cysts are well circumscribed, 2 to 5 cm in diameter, and usually lined by stratified squamous or pseudostratified columnar epithelium. The fibrous cyst walls typically contain lymphoid tissue with prominent germinal centers. Cyst contents may be clear and watery or mucinous and may also contain desquamated cells and granular cellular debris. The cysts are readily excised. Similar lesions may appear in the parotid gland or oral cavity beneath the tongue. Branchial cysts do not undergo malignant transformation. Most cystic SCCs in the neck are metastases from cancers of the upper airways or digestive tract.

THYROGLOSSAL DUCT CYST

The thyroid anlage begins in the region of the foramen cecum at the base of the tongue; as the gland develops, it descends to its definitive midline location in the anterior neck. Remnants of this developmental process may persist, resulting in 1- to 4-cm cysts that are lined by stratified squamous epithelium when located near the base of the tongue or by pseudostratified columnar epithelium in lower locations. Transitional epithelial differentiation patterns also occur. The fibrous cyst wall often includes lymphoid aggregates or thyroid remnants. Malignant transformation of the lining epithelium is exceedingly rare. The definitive treatment is surgical excision.

PARAGANGLIOMA (CAROTID BODY TUMOR)

Paragangliomas arise from neuroendocrine cells associated with the sympathetic and parasympathetic nervous systems and occur at many sites. Adrenal medullary pheochromocytomas are the most common paraganglioma (Chapter 24). Approximately 70% of extra-adrenal paragangliomas occur in the head and neck. Although the pathogenesis is not fully understood, loss-of-function mutations in genes encoding succinate dehydrogenase subunits (which are also common in gastrointestinal stromal tumors) or cofactors in mitochondrial oxidative phosphorylation occur frequently in both hereditary and spontaneous paragangliomas. How these mutations contribute to tumor development is not yet clear, but it is suspected that they do so by altering cellular metabolism, which you will recall is one of the hallmarks of neoplasia (Chapter 7). Interestingly, the incidence of these tumors is greater in people living at high altitudes.

Paragangliomas typically develop in two locations:

- *Paravertebral paraganglia* (e.g., organ of Zuckerkandl and, rarely, bladder). Such tumors have sympathetic connections and stain positively for chromaffin, which detects cells producing catecholamines.
- Paraganglia related to the great vessels of the head and neck, the so-called *aorticopulmonary chain,* including the *carotid bodies* (i.e., carotid body tumor); aortic bodies; jugulotympanic ganglia (sometimes referred to as *glomus tympanicum* or *jugulare*); ganglion nodosum of the vagus nerve; and clusters located about the oral cavity, nose, nasopharynx, larynx, and orbit. These are innervated by the parasympathetic nervous system and only rarely produce catecholamines.

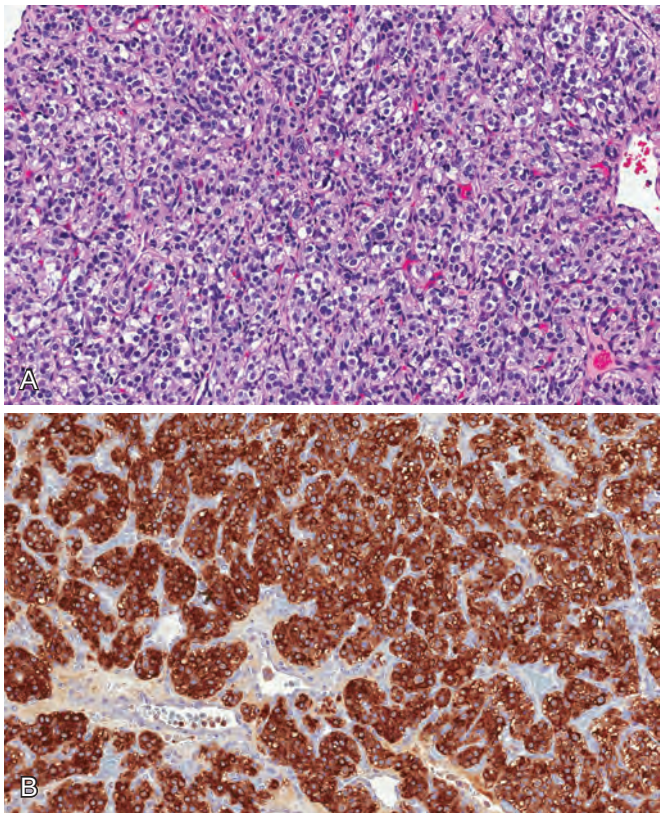

Figure 16.15 Carotid body tumor. (A) Low-power view showing tumor clusters separated by septa (zellballen). The septae are marked by capillaries containing bright red blood cells. (B) Immunohistochemistry demonstrating positivity for chromogranin in the tumor cells.

MORPHOLOGY

The **carotid body tumor** is a typical parasympathetic paraganglioma. It rarely exceeds 6 cm in diameter and arises close to or envelops the bifurcation of the common carotid artery. The tumor tissue is red-pink to brown, and the microscopic features are characteristic of paragangliomas at all sites. Nests (zellballen) of round to oval **chief cells** with abundant, clear or granular, eosinophilic cytoplasm and uniform, round to ovoid, sometimes vesicular, nuclei are surrounded by delicate vascular septae (Fig. 16.15). There is little cellular pleomorphism, and mitoses are scant. The chief cells, which are neuroectodermal in origin, stain strongly for neuroendocrine markers including chromogranin, synaptophysin, neuron-specific enolase, CD56, and CD57. The supporting network of spindle-shaped stromal cells, collectively called *sustentacular cells,* are positive for S-100 protein. Electron microscopy often detects well-demarcated neuroendocrine granules in paravertebral tumors, but the number of these granules is variable, and they tend to be scant in nonfunctioning tumors.

Carotid body tumors, and paragangliomas in general, are rare, slow-growing, painless masses that usually arise in the fifth and sixth decades of life. They commonly occur singly and sporadically but also may be familial. Tumors associated with multiple endocrine neoplasia type 2 most often occur within the adrenal (pheochromocytomas) (Chapter 24), whereas tumors associated with hereditary paraganglioma syndromes (PGL types 1 to 4, involving the succinate dehydrogenase genes) typically involve the head and neck. Approximately one-third of head and neck paragangliomas are thought to be associated with germline mutations. Carotid body tumors frequently recur after incomplete resection and, despite their benign appearance, may metastasize to regional lymph nodes and distant sites. About 50% ultimately prove fatal, largely because of infiltrative growth. Unfortunately, histologic features do not predict the clinical course of a carotid body tumor—mitoses, pleomorphism, and even vascular invasion are not reliable indicators. However, succinate dehydrogenase B *(SDHB)* mutations are associated with the highest rates of metastasis (30% to 50%).

KEY CONCEPTS

NECK

- Branchial cysts arise from the region of the second branchial pouch and typically present in young adults.
- Thyroglossal duct cysts arise due to incomplete descent of the thyroid analog from the foramen cecum in the base of the tongue.
- Seventy percent of extra-adrenal paragangliomas occur in the head and neck. These tumors are most common in the fifth and sixth decades of life and can be hereditary or sporadic. Hereditary head and neck paragangliomas are associated with succinate dehydrogenase gene mutations, occur at younger ages, are often multiple, and can be malignant.

Salivary Glands

There are three major salivary glands, parotid, submandibular, and sublingual, as well as innumerable minor salivary glands distributed throughout the mucosa of the oral cavity; all may be involved by inflammatory or neoplastic disease.

XEROSTOMIA

Xerostomia is defined as a dry mouth resulting from a decrease in the production of saliva. Its incidence has been reported to be as high as 20% in individuals older than 70 years of age in some populations. Xerostomia is characteristic of the autoimmune disorder *Sjögren syndrome* (Chapter 6), in which it is usually accompanied by dry eyes (keratoconjunctivitis sicca). Lack of salivary secretions is also a major complication of radiation therapy for head and neck cancers. Xerostomia is, however, most often a side-effect of commonly-prescribed medications, including anticholinergic, antidepressant/antipsychotic, diuretic, antihypertensive, sedative, muscle relaxant, analgesic, and antihistamine drugs. Xerostomia may present as dry mucosa and/or atrophy of the papillae of the tongue, with fissuring and ulcerations. In Sjögren syndrome, inflammatory enlargement of the salivary glands may also occur. Complications of xerostomia include increased rates of dental caries, candidiasis, and difficulty in swallowing and speaking.

INFLAMMATION (SIALADENITIS)

Sialadenitis may be induced by trauma, viral or bacterial infection, or autoimmune disease. The most prevalent form of sialadenitis is the **mucocele.** The most common viral cause of sialadenitis is **mumps,** which affects the major salivary glands, particularly the parotids, and frequently involves other glandular organs such as the pancreas and testes (Chapter 8).

Mucocele. **Mucoceles are most often found on the lower lip as the result of trauma** (Fig. 16.16A), **occur at all ages, and present as fluctuant lower lip swellings with a blue translucent hue.** This common salivary gland lesion results from either blockage or rupture of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma. Patients may report a history of changes in the size of the lesion, particularly in association with meals. Histologically, mucoceles are pseudocysts lined by inflammatory granulation tissue or fibrous connective tissue and filled with mucin and inflammatory cells, particularly macrophages (Fig. 16.16B). Complete excision of the cyst and accompanying minor salivary gland lobule is required, as incomplete excision may lead to recurrence.

Ranula is a term reserved for epithelial-lined cysts that arise when the duct of the sublingual gland has been damaged. A ranula may become so large that it develops into a *plunging ranula*, a colorful description of a cyst that has dissected through the connective tissue stroma connecting the two bellies of the mylohyoid muscle.

Sialolithiasis and Nonspecific Sialadenitis. **Nonspecific bacterial sialadenitis, involving the submandibular and other major salivary glands, is common and most often caused by infection with *S. aureus* and *Streptococcus viridans* following ductal obstruction by stones *(sialolithiasis).*** Stone formation is sometimes related to obstruction of salivary gland orifices by impacted food debris or local edema after injury, but no underlying cause is detected in many cases. Reduced secretion of saliva, as sometimes occurs in patients receiving long-term phenothiazines, may predispose to secondary bacterial invasion. Similarly, decreased salivary secretions due to dehydration may facilitate bacterial

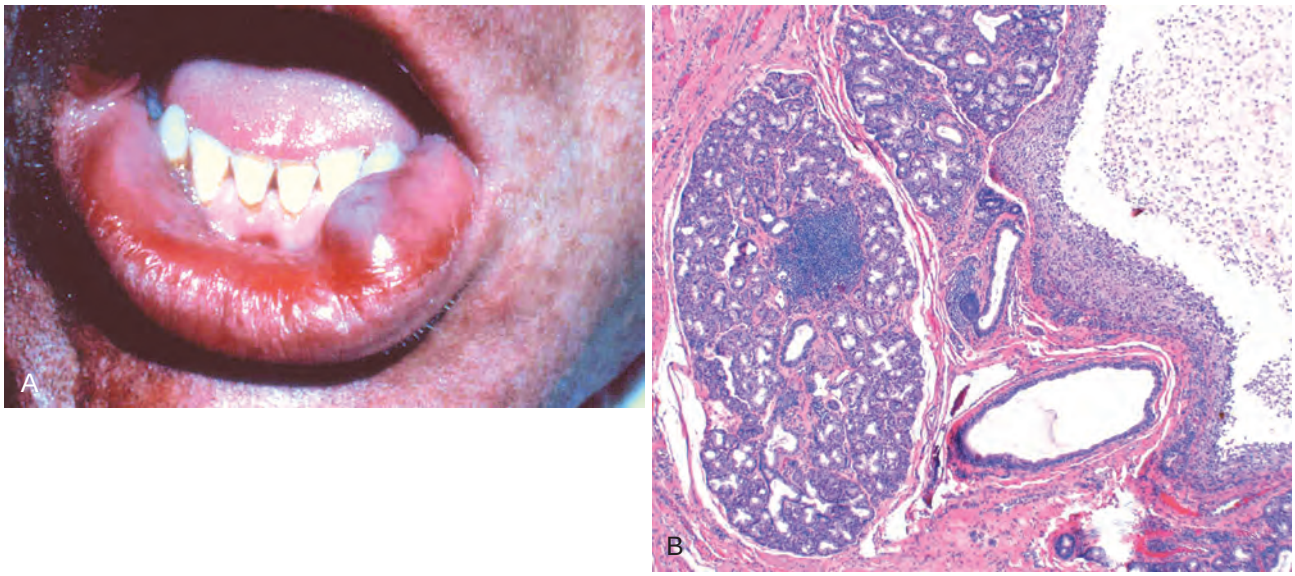

Figure 16.16 Mucocele. (A) Fluctuant fluid-filled lesion on the lower lip subsequent to trauma. (B) Cystlike cavity filled with mucinous material and lined by organizing granulation tissue.

suppurative parotitis, particularly in elderly patients with a recent history of major thoracic or abdominal surgery.

Obstructive processes and bacterial invasion lead to inflammation of the affected glands that is often interstitial or, when induced by staphylococcal or other pyogens, associated with overt suppurative necrosis and abscess formation. Inflammation causes painful enlargement and, sometimes, a purulent ductal discharge. Disease is almost always unilateral and involves a single gland.

NEOPLASMS

Despite their relatively simple morphology, the salivary glands give rise to more than 30 histologically distinct tumors. A classification and the relative incidence of benign and malignant tumors is listed in Table 16.5; not included are the rare benign and malignant mesenchymal neoplasms. Despite this diversity, a small number of neoplasms makes up more than 90% of salivary gland tumors. These will be the focus of the discussion that follows.

Salivary gland neoplasms represent less than 2% of all tumors in humans. About 65% to 80% arise within the parotid, 10% in the submandibular gland, and the remainder in the minor salivary glands, including the sublingual glands. The majority of parotid tumors are benign, but 40% of submandibular, 50% of minor salivary gland, and 70% to 90% of sublingual tumors are malignant. Thus, in general terms, the malignant potential of salivary gland tumors is inversely proportional to gland size, with smaller glands harboring greater numbers of cancers.

Salivary gland tumors occur in adults, with only approximately 5% occurring before 16 years of age. There is a slight female predominance overall, but this can vary with histology. For example, Warthin tumors are much more common in males, perhaps reflecting the historically higher prevalence of smoking, a predisposing factor, among men. Whatever the histologic pattern, parotid gland neoplasms produce distinctive swellings in front of and below the ear. When first diagnosed, both benign and malignant lesions range from 4 to 6 cm in diameter and, except in the case of highly invasive malignant tumors, are mobile on palpation. Benign tumors are often present for many months to several years before coming to clinical attention, but cancers are detected more quickly due to their rapid growth. Despite these generalities, there are no reliable clinical criteria to differentiate benign from malignant lesions.

Table 16.5 Histologic Classification and Incidence of the Most Common Benign and Malignant Tumors of the Salivary Glands

Benign	Malignant
Pleomorphic adenoma (mixed tumor)	Mucoepidermoid carcinoma
Warthin tumor	Acinic cell carcinoma
Oncocytoma	Adenoid cystic carcinoma
Canalicular adenoma	Adenocarcinoma, not otherwise specified
Basal cell adenoma	Carcinoma ex pleomorphic adenoma
Other adenomas	Squamous cell carcinoma
Ductal papillomas	Other carcinomas

Pleomorphic Adenoma

Pleomorphic adenomas are the most common salivary gland neoplasms. They represent about 60% of tumors in the parotid, are less common in the submandibular glands, and are relatively rare in the minor salivary glands. Pleomorphic adenomas are benign tumors that consist of a mixture of ductal (epithelial), myoepithelial, and mesenchymal cells, which explains why they are also termed *mixed tumors.*

Little is known about the origin of pleomorphic adenomas, but radiation exposure increases risk. Equally uncertain is the histogenesis of the various components. One view is that all tumor elements, including those that appear mesenchymal, are of myoepithelial or ductal reserve cell (stem cell) origin. Many cases are associated with chromosomal rearrangements that induce overexpression of PLAG1, a transcription factor that promotes expression of genes that increase cell growth, including components of growth factor receptor signaling pathways. Mutations of the *HMGA2* gene, which encodes a DNA-binding protein, are associated with many of the cases that lack PLAG overexpression.

MORPHOLOGY

Most pleomorphic adenomas present as rounded, well-demarcated masses that rarely exceed 6 cm in greatest dimension (Fig. 16.17). Although encapsulated, in some locations (particularly the palate) the capsule of pleomorphic adenomas is not fully developed, and expansile growth produces protrusions into the surrounding gland. These may lead to recurrences if the tumor is merely enucleated. The cut surface is gray-white with myxoid and blue translucent areas of chondroid (cartilage-like) stroma.

The dominant histologic feature is morphologic heterogeneity. The epithelial elements resembling ductal cells or myoepithelial cells are arranged as ducts, acini, irregular tubules, strands, or sheets of cells. These elements are typically dispersed within a background of loose myxoid and hyaline tissue containing islands of cartilage and, rarely, foci of bone (Fig. 16.18). Sometimes the epithelial cells form well-developed ducts lined by cuboidal to columnar cells with an underlying layer of deeply chromatic, small myoepithelial cells. In other instances, there may be strands or sheets of myoepithelial cells. Islands of well-differentiated squamous epithelium may also be present. In most cases, there is no epithelial dysplasia or mitotic activity. Tumors behave similarly whether they are primarily composed of epithelial or mesenchymal elements.

Pleomorphic adenomas present as painless, slow-growing, mobile, discrete masses within the parotid or submandibular areas or in the buccal cavity. The rate of recurrence following parotidectomy is about 4%. Recurrences occur months to years after surgery. In contrast, recurrence after simple enucleation approaches 25%, likely due to tumor extension beyond the capsule.

Rates of malignant transformation in pleomorphic adenoma correlate with age of the lesion; 2% of tumors that have been present for less than 5 years harbor cancers, but this increases to 10% for those present for more than 15 years. Cancers are usually adenocarcinomas or undifferentiated carcinomas. They are highly infiltrative and may completely

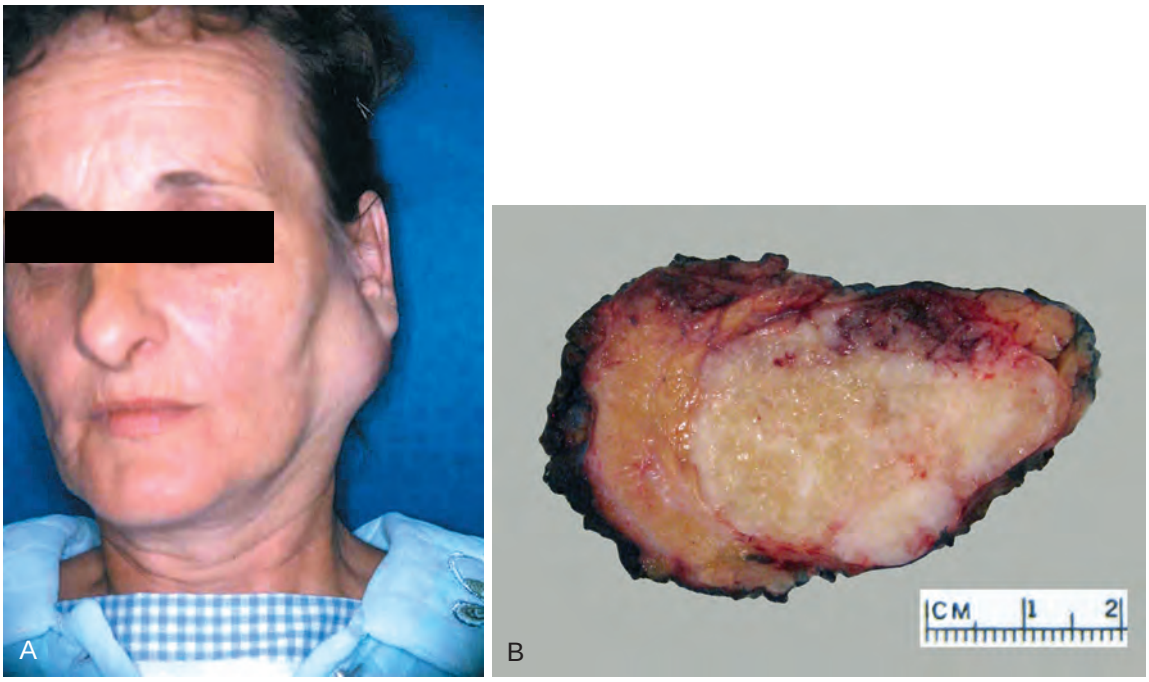

Figure 16.17 Pleomorphic adenoma. (A) Slowly enlarging neoplasm in the parotid gland of many years' duration. (B) Grossly, this representative cross-section of a parotidectomy specimen shows a circumscribed, yellow-white tumor and adjacent normal salivary gland tissue on the left.

replace the precursor lesion, making it difficult to substantiate the diagnosis of carcinoma arising in pleomorphic adenoma, which requires the presence of residual benign pleomorphic adenoma. Regrettably, when they appear, these cancers are among the most aggressive of all salivary gland neoplasms, with mortality rates of 30% to 50% at 5 years.

Warthin Tumor (Papillary Cystadenoma Lymphomatosum)

The *Warthin tumor* is the second most common salivary gland neoplasm. It is unique in that it arises almost exclusively in the parotid gland. Warthin tumors are benign and occur more commonly in males than in females, usually in the fifth to seventh decades of life. The risk is increased eightfold in smokers. Most Warthin tumors are unifocal, but about 10% are multifocal and 10% bilateral.

MORPHOLOGY

Warthin tumors are round to oval encapsulated masses, 2 to 5 cm in diameter, and readily palpable within the superficial parotid gland. Transection reveals a pale gray surface punctuated by narrow cystic or cleftlike spaces filled with mucinous or serous secretions and frequently narrowed by polypoid projections of lymphoepithelial elements. The lining is composed of a double layer of oncocytic cells; the innermost layer is columnar, while cuboidal cells occupy

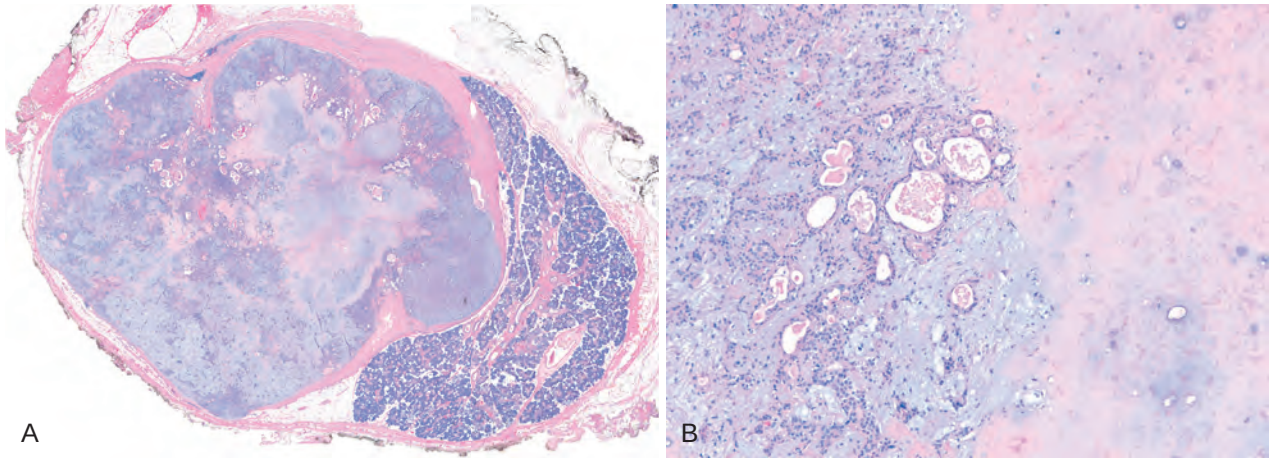

Figure 16.18 Pleomorphic adenoma. (A) Low-power histologic view showing a well-demarcated tumor with adjacent normal salivary gland parenchyma on the right. (B) High-power view showing epithelial and myoepithelial cells forming ducts *(left)* and a chondromyxoid matrix *(right)*.

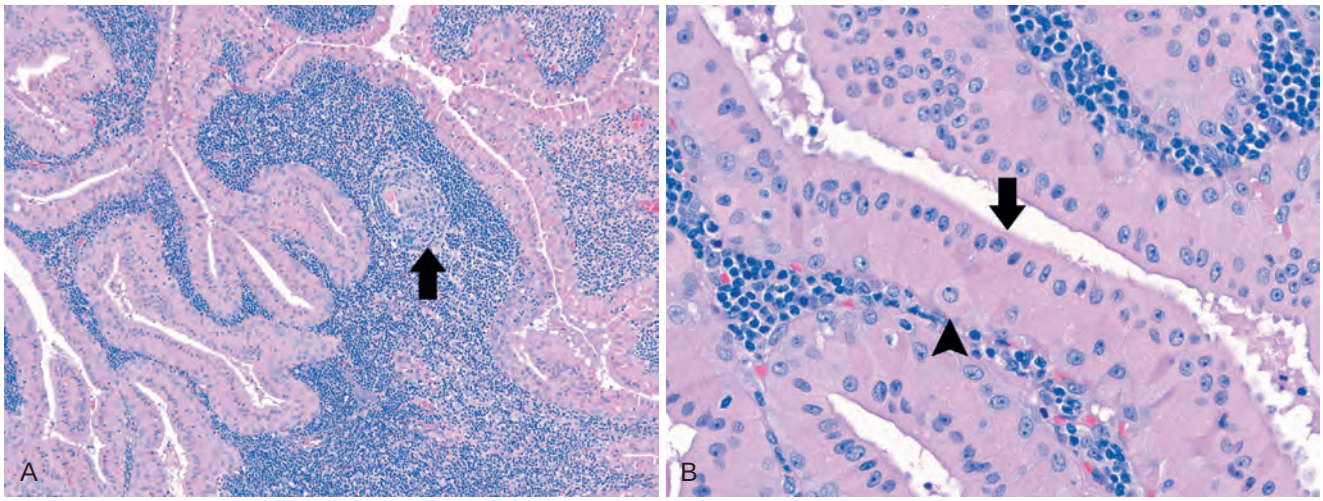

Figure 16.19 Warthin tumor. (A) Low-power view showing epithelial and lymphoid elements. Note the lymphoid follicular germinal center beneath the epithelium *(arrow)*. (B) The epithelium consists of a double layer of oncocytic epithelial cells on a lymphoid stroma, with a columnar luminal layer *(arrow)* associated with a cuboidal layer *(arrowhead)*.

the outer layer (Fig. 16.19). The term **oncocyte** (or swollen cell in Greek) refers to large cells containing numerous mitochondria that impart a granular, eosinophilic appearance to the cytoplasm and have large nuclei with prominent nucleoli. Secretory cells dispersed in the inner layer account for secretions within the dilated lumen. Foci of squamous metaplasia may be present.

The histogenesis of Warthin tumors is debated; it is not clear whether the epithelium is truly neoplastic (monoclonal) or is a reactive proliferation (polyclonal). Regardless, the epithelial cells are thought to secrete chemoattractants for the lymphoid cells, which are reactive. Although Warthin tumors have occasionally arisen within cervical lymph nodes, these neoplasms are benign and have low recurrence rates of only 2% after resection.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common primary malignant tumor of salivary glands, representing about 15% of all salivary gland tumors. Most (60% to 70%) occur in the parotids, but mucoepidermoid carcinomas account for a large fraction of salivary gland neoplasms in the other glands, particularly the minor salivary glands. More than one-half of cases are associated with a balanced (11;19)(q21;p13) chromosomal translocation that creates a fusion gene composed of portions of the *CRTC1* (also known as *MECT1*) and *MAML2* genes. The CRTC1-MAML2 fusion protein is believed to play a key role in the genesis of this tumor, possibly by perturbing Notch and cAMP-dependent signaling pathways.

MORPHOLOGY

Mucoepidermoid carcinomas can grow as large as 8 cm in diameter. Although they appear circumscribed, well-defined capsules are not present, and the tumors are often infiltrative at the margins. On transection, mucoepidermoid carcinomas are pale, gray-white and frequently contain small, mucin-containing cysts. Histology demonstrates cords, sheets, or cystic configurations of squamous, mucous, or intermediate cells that have squamous features and small to large mucus-filled vacuoles (Fig. 16.20A–B). The cytology may be monotonous and bland or, alternatively, highly anaplastic and unmistakably malignant. Accordingly, mucoepidermoid carcinomas are subclassified as low, intermediate, or high grade.

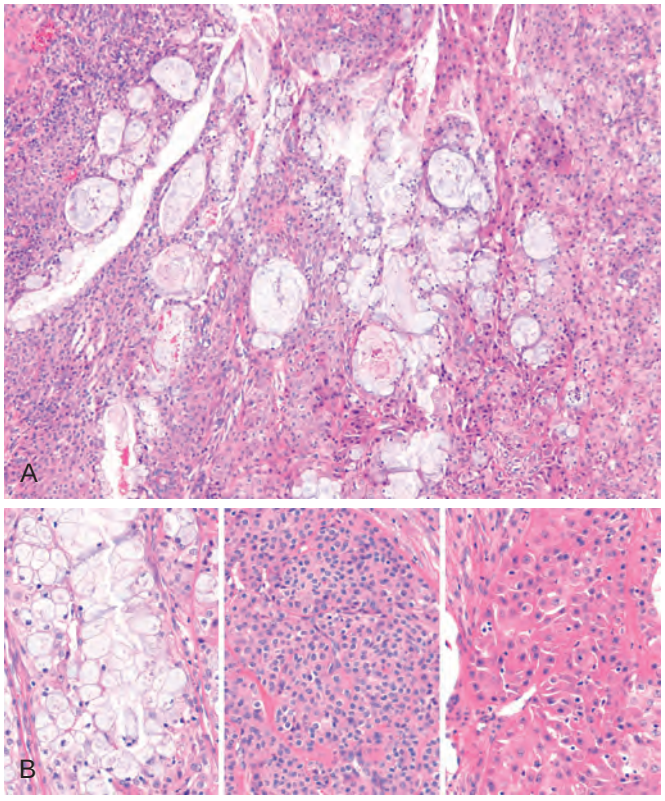

Figure 16.20 Mucoepidermoid carcinoma. (A) Low-power view showing sheets and microcysts containing cells of varying morphologies. (B) These cells vary from mucinous *(left)*, to intermediate *(center)*, to squamous *(right)*.

The clinical course and prognosis of mucoepidermoid carcinomas reflects the histologic grade. Low-grade tumors may invade locally and recur in about 15% of cases, but they rarely metastasize. The 5-year survival rate is more than 90%. In contrast, high-grade neoplasms and, to a lesser extent, intermediate-grade tumors are invasive and difficult to excise. Up to 30% recur and 30% metastasize to distant sites, yielding a 5-year survival of only 50%.

OTHER SALIVARY GLAND TUMORS

Two less common neoplasms merit brief description: adenoid cystic carcinoma and acinic cell carcinoma.

Adenoid cystic carcinomas. 50% of these relatively uncommon tumors occur in the minor salivary glands (particularly the palatine glands). Among major salivary glands, parotid and submandibular glands are most commonly affected. Adenoid cystic carcinomas also occur in the nose, sinuses, upper airways, lung, breast, and other sites. Although the pathogenesis is not defined, *MYB-NFIB* gene rearrangements are present in a subset of adenoid cystic carcinomas.

MORPHOLOGY

Grossly, adenoid cystic carcinomas are small, poorly encapsulated, infiltrative, gray-pink lesions composed of small cells with dark, compact nuclei and scant cytoplasm. The tumor cells are organized in a cribriform growth pattern that resembles swiss cheese. The spaces between the tumor cells are often filled with hyaline material thought to represent excess basement membrane (Fig. 16.21A). Less common histologic patterns are tubular and solid.

Adenoid cystic carcinomas are unpredictable, slow-growing tumors that tend to invade perineural spaces (see Fig. 16.21B). They regularly recur, and 50% or more eventually disseminate to distant sites including bone, liver, and brain, sometimes decades after attempted removal. Thus, although the 5-year survival rate is about 60% to 70%, it drops to about 30% at 10 years and 15% at 15 years. Adenoid cystic carcinomas arising in the minor salivary glands tend to have a poorer prognosis than those arising in the parotid glands.

Acinic cell carcinomas. These represent only 2% to 3% of salivary gland tumors and are generally small and well-circumscribed. Most develop in the parotid glands, with the remainder arising in the submandibular glands. Minor salivary glands, which normally have only a scant number of serous acinic cells, are rarely involved. Like Warthin tumors, acinic cell carcinomas can be bilateral or multicentric.

MORPHOLOGY

Histologically, acinic cell carcinomas are composed of cells that resemble normal serous acinar cells of the salivary glands, with small and round nuclei and variable morphology (Fig. 16.22). The cytoplasm typically contains purple granules (**zymogen granules**

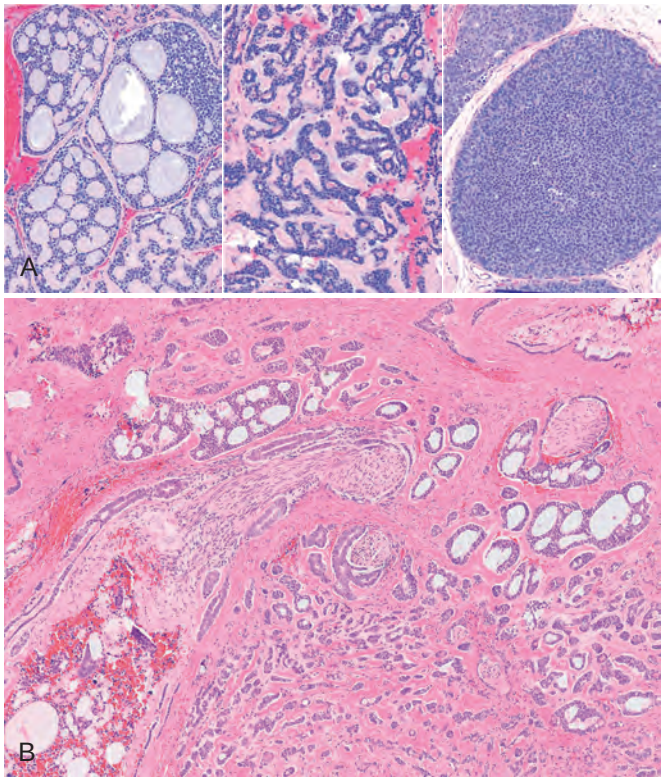

Figure 16.21 Adenoid cystic carcinoma. (A) Three typical growth patterns including cribriform *(left)*, tubular *(center)*, and solid *(right)*. (B) Perineural invasion by adenoid cystic carcinoma.

recapitulating the normal serous acinar digestive enzymes), but cells can also be clear or vacuolated. The neoplastic cells are organized into sheets, microcysts, glands, follicles, or papillae. Tumors with a sheetlike growth pattern, nuclear pleomorphism, mitoses, and necrosis are referred to as dedifferentiated or having undergone high-grade transformation.

The clinical course of acinic cell carcinomas reflects the degree of cytologic pleomorphism. Although recurrence is uncommon after resection, 10% to 15% of tumors metastasize to lymph nodes. The survival rate is approximately 90% at 5 years and 60% at 20 years.

KEY CONCEPTS

DISEASES OF SALIVARY GLANDS

- Sialadenitis is inflammation of the salivary glands and can be caused by trauma, infection, or autoimmune disease.
- Mucoceles are the result of trauma to or blockage of a salivary gland duct that allows saliva leakage into surrounding connective tissue.
- Pleomorphic adenoma is a benign, slow-growing neoplasm composed of a heterogenous mixture of epithelial and mesenchymal cells.
- Mucoepidermoid carcinoma is a malignant neoplasm of variable biological aggressiveness that is composed of a mixture of squamous and mucous cells.

CHAPTER 17

The Gastrointestinal Tract

CHAPTER CONTENTS

The gastrointestinal (GI) tract is a hollow tube extending from the oral cavity to the anus that consists of anatomically distinct segments including the esophagus, stomach, small intestine, colon, rectum, and anus. Each of these segments has unique, complementary, and highly integrated functions, which together serve to regulate the intake, processing, and absorption of ingested nutrients and the disposal of waste products. The regional variations in structure and function are reflected in diseases of the GI tract, which often affect one or another segment preferentially. Accordingly, following consideration of several important congenital abnormalities, the discussion is organized anatomically. Disorders affecting more than one segment of the GI tract, such as Crohn disease, are discussed with the region that is involved most frequently.

Congenital Abnormalities

Depending on both the nature and the timing of the insult during gestation, a variety of developmental anomalies can affect the GI tract. Importantly, because many organs develop simultaneously during embryogenesis and are susceptible to the same insults, the presence of congenital GI anomalies should prompt evaluation of other organs.

ATRESIA, FISTULAE, AND DUPLICATIONS

Atresia, fistulae, and duplications may occur in any part of the GI tract. When present within the esophagus they are discovered shortly after birth, usually due to regurgitation during feeding. Most of the lesions are incompatible with survival without prompt surgical repair. Absence, or agenesis, of the esophagus is extremely rare, but atresia, in which development is incomplete, is present in 1 to 5 infants per 10,000 live births. In atresia, a segment of the esophagus does not develop, leaving only a thin, noncanalized cord and causing a mechanical obstruction (Fig. 17.1A). Atresia occurs most commonly at or near the tracheal bifurcation and is usually associated with a fistula connecting the upper or lower esophageal segments to a bronchus or the trachea (Fig. 17.1B). In other cases a fistula can be present without atresia (Fig. 17.1C). Any of the three primary forms of tracheoesophageal fistula can lead to aspiration, suffocation, pneumonia, and severe fluid and electrolyte imbalances. Developmental abnormalities of the esophagus are associated with a range of congenital abnormalities, including VACTERL (malformations including vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects); TACRD (tracheal agenesis/atresia, complex congenital cardiac abnormalities, radial ray defects, and duodenal atresia); and other abnormalities involving the heart, lung, great vessels, genitourinary tract, and anus. The last-mentioned includes imperforate anus, which is due to a failure of the cloacal diaphragm to involute.

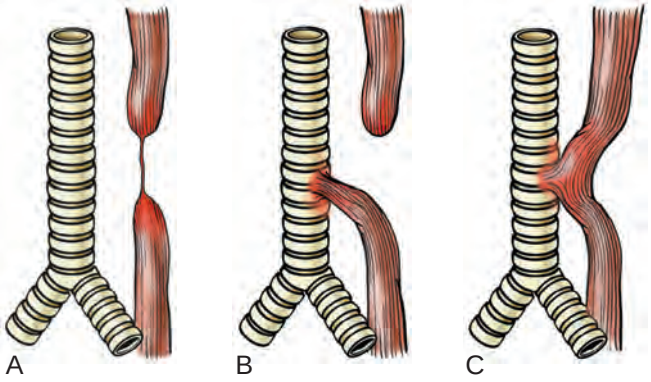

Figure 17.1 Esophageal atresia and tracheoesophageal fistula. (A) Blind upper and lower esophagus with thin cord of connective tissue linking the two segments. (B) Blind upper segment with fistula between lower segment and trachea. (C) Fistula (without atresia) between patent esophagus and trachea. The developmental anomaly shown in (B) is the most common. (Modified from Morson BC, Dawson IMP, editors: *Gastrointestinal Pathology*, Oxford, 1972, Blackwell Scientific Publications, p 8.)

Stenosis is an incomplete form of atresia in which the lumen is markedly reduced in caliber as a result of fibrous thickening of the wall. This results in either partial or complete obstruction. In addition to congenital forms, stenosis can be acquired as a consequence of inflammatory scarring, such as that caused by chronic gastroesophageal reflux, irradiation, systemic sclerosis, or caustic injury. It can involve any part of the GI tract, but because of their smaller caliber, clinically significant stenosis most often affects the esophagus and small intestine.

DIAPHRAGMATIC HERNIA, OMPHALOCELE, AND GASTROSCHISIS

Diaphragmatic hernia occurs when incomplete formation of the diaphragm allows the abdominal viscera to herniate into the thoracic cavity, most commonly on the left side. When severe, the space-filling effect of displaced viscera can lead to potentially fatal pulmonary hypoplasia.

Omphalocele occurs when the extraembryonic gut fails to return to the abdominal cavity and closure of the abdominal musculature is incomplete. As a result, abdominal viscera (including the liver) herniate ventrally into a membrane covered by amnion and peritoneum separated by Wharton jelly. Omphalocele is often associated with other birth defects as well as chromosomal abnormalities.

Gastroschisis is similar to omphalocele except that it involves all the layers of the abdominal wall, from the peritoneum to the skin, is usually limited to the intestine, and occurs as an isolated defect without other abnormalities. The incidence of gastroschisis is rising, possibly due to environmental factors including smoking and exposure to agricultural chemicals. Surgical repair of omphalocele and gastroschisis is generally successful.

ECTOPIA

Ectopic tissues (developmental rests) are common in the GI tract. The most frequent site of ectopic gastric mucosa is the upper third of the esophagus, where it is referred to as an inlet patch. While generally asymptomatic, acid released by gastric mucosa within the esophagus can result in dysphagia, esophagitis, Barrett esophagus, or, rarely, adenocarcinoma. Ectopic pancreatic tissue occurs less frequently and is found in the esophagus or stomach. These nodules are most often asymptomatic but may produce local damage and inflammation. When ectopic pancreatic tissue is present in the pylorus, inflammation and scarring may lead to obstruction. Because rests may be present within any layer of the gastric wall, they can mimic invasive cancer. Gastric heterotopia, small patches of ectopic gastric mucosa in the small bowel or colon, may present with occult blood loss due to peptic ulceration of adjacent mucosa.

MECKEL DIVERTICULUM

A true diverticulum is a blind outpouching of the alimentary tract that communicates with the lumen and includes all three layers of the bowel wall. The most common true diverticulum, and the most common congenital anomaly of the GI tract, is Meckel diverticulum, which occurs in the ileum. Meckel diverticulum occurs due to failed involution of the vitelline duct, which connects the lumen of the developing gut to the yolk sac. This solitary diverticulum extends from the antimesenteric side of the bowel (Fig. 17.2). The "rule of 2's" is often used to help remember characteristics of Meckel diverticula, which:

- Occur in approximately 2% of the population
- Are generally present within 2 feet (60 cm) of the ileocecal valve
- Are approximately 2 inches (5 cm) long
- Are twice as common in males
- Are most often symptomatic by age 2 (only approximately 4% are ever symptomatic).

The mucosal lining of Meckel diverticula may resemble that of normal small intestine, but ectopic pancreatic or gastric tissue may also be present. The latter may secrete acid, cause peptic ulceration of adjacent small intestinal mucosa, and present with occult bleeding or abdominal pain resembling acute appendicitis or obstruction.

Figure 17.2 Meckel diverticulum. The blind pouch is located on the antimesenteric side of the small bowel.

Virtually all other diverticula are acquired and either lack muscularis entirely or have an attenuated muscularis propria. These are, technically, pseudodiverticula, but are generally referred to simply as divericula. They occur most often in the sigmoid colon (discussed later).

PYLORIC STENOSIS

Pyloric stenosis may be either congenital or acquired. The most common congenital form is congenital hypertrophic pyloric stenosis. It is three to five times more common in males and has an overall incidence of 1 per 300 to 900 live births. Monozygotic twins have a high rate of concordance; risk is increased to a lesser degree in dizygotic twins and siblings of affected individuals. Turner syndrome and trisomy 18 also confer an increased risk. While the underlying mechanisms are not understood, erythromycin or azithromycin exposure, either orally or via mother's milk, in the first 2 weeks of life is associated with this disorder.

Congenital hypertrophic pyloric stenosis generally presents between the third and sixth weeks of life as new-onset regurgitation, projectile nonbilious vomiting after feeding, and frequent demands for refeeding. Physical examination reveals a firm, ovoid, 1- to 2-cm abdominal mass in up to 90% of cases; abnormal left-to-right hyperperistalsis just before vomiting is also common. Diagnosis is primarily by ultrasonography. Anatomically, the gastric outflow tract is obstructed by hyperplasia of the pyloric muscularis propria. Edema and inflammatory changes in the mucosa and submucosa may aggravate the narrowing. Surgical splitting of the muscularis (myotomy) is curative.

Acquired pyloric stenosis occurs in adults as a consequence of antral gastritis or peptic ulcers close to the pylorus. Carcinomas of the distal stomach and pancreas may also narrow the pyloric channel due to fibrosis or malignant infiltration.

HIRSCHSPRUNG DISEASE

Hirschsprung disease causes functional obstruction of the colon due to failure of ganglion cells to migrate to the wall of the colon resulting from a mutation in the receptor tyrosine kinase. Hirschsprung disease occurs in approximately 1 in 5000 live births. It may be isolated or occur in combination with other developmental abnormalities; 10% of all cases occur in children with Down syndrome, and serious neurologic abnormalities are present in 5% of infants with Hirschsprung disease.

Pathogenesis

The enteric neuronal plexus develops from neural crest cells that migrate into the bowel wall during embryogenesis. Hirschsprung disease, also known as congenital aganglionic megacolon, results when the migration of neural crest cells from cecum to rectum is arrested prematurely or when the ganglion cells undergo premature death. This produces a

distal intestinal segment that lacks both the Meissner submucosal plexus and the Auerbach myenteric plexus, termed aganglionosis. Coordinated peristaltic contractions are absent, and functional obstruction occurs, resulting in dilation proximal to the affected segment.

Heterozygous loss-of-function mutations in the receptor tyrosine kinase *RET* account for the majority of familial and approximately 15% of sporadic Hirschsprung disease cases. The association between Down syndrome and Hirschsprung disease may be linked to the Down syndrome cell adhesion molecule gene on chromosome 21, overexpression of which leads to neural defects in experimental models. In patients without trisomy 21, germline mutations in several genes that are required for normal gut innervation have been implicated, the most common of which involve *RET* and *EDNRB* or *EDN3* (which encode a receptor-ligand pair). These proteins appear to participate in signaling pathways that regulate development of the enteric nervous system. Defects in known genes cannot explain all cases, however, and penetrance in those carrying pathogenic mutations is incomplete, suggesting that modifying genes or environmental factors are also important. Some of these modifying genes may be sex-linked, since the disease is more common in males, but, when present in females, the affected aganglionic segment tends to be longer.

MORPHOLOGY

Diagnosis of Hirschsprung disease requires histologic confirmation that ganglion cells are absent within the affected segment. In addition to their characteristic morphology in hematoxylin and eosin–stained sections, ganglion cells can be identified using immunohistochemical stains for acetylcholinesterase.

The rectum is always affected, but the length of the additional involved segments varies widely. In most cases the abnormality extends to the sigmoid colon, but in severe cases, the entire colon may be involved. Disease limited to the rectosigmoid is termed *short-segment Hirschsprung disease*, while cases with more proximal extension are termed *long-segment Hirschsprung disease*.

The aganglionic region may have a grossly normal or contracted appearance. In contrast, the normally innervated proximal colon undergoes progressive dilation (Fig. 17.3) and may become massively distended **(megacolon)** as a result of the distal obstruction. The colonic wall may be stretched to the point of rupture, which occurs most frequently near the cecum. Mucosal inflammation or shallow ulcers may also be present in normally innervated segments, making gross identification of the extent of aganglionosis difficult. Hence, intraoperative histopathologic analysis (frozen section) is commonly used to confirm the presence of ganglion cells at the anastomotic site.

Clinical Features

Hirschsprung disease typically presents with a failure to pass meconium in the immediate postnatal period. Obstruction or constipation follows, often with visible but ineffective peristalsis. When only a few centimeters of rectum are involved, some stool may be passed, obscuring the diagnosis. More often, the obstruction is obvious and is marked by abdominal distention and bilious vomiting as luminal material backs up into the proximal colon. The major threats to life are enterocolitis, fluid and electrolyte disturbances, perforation, and peritonitis. Treatment consists of surgical resection of the aganglionic segment and anastomosis of the normal proximal colon to the rectum. Even after successful surgery, it may take years to attain normal bowel function and continence.

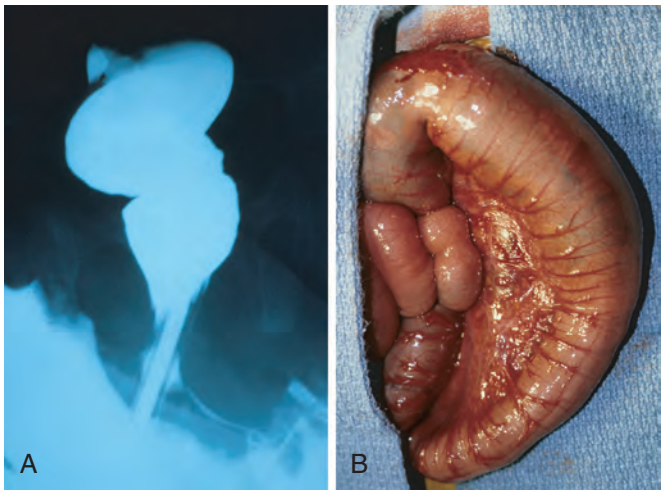

Figure 17.3 Hirschsprung disease. (A) Preoperative barium enema study showing constricted rectum (bottom of the image) and dilated sigmoid colon. (B) Corresponding intraoperative photograph showing constricted rectum and dilation of the sigmoid colon. (Courtesy Dr. Aliya Husain, The University of Chicago, Chicago, Ill.)

In contrast to the congenital megacolon of Hirschsprung disease, acquired megacolon may occur at any age as a result of Chagas disease, obstruction by a neoplasm or inflammatory stricture, a complication of ulcerative colitis, visceral myopathy, or in association with psychosomatic disorders. Of these, only Chagas disease (discussed later) shares the same pathophysiology as Hirschsprung disease; the loss of ganglion cells.

KEY CONCEPTS

CONGENITAL MALFORMATIONS OF THE GASTROINTESTINAL TRACT

- The GI tract is a common site of developmental abnormalities, often in association with congenital defects of other organ systems.
- Atresia and fistulae are developmental anomalies that typically present at birth. Imperforate anus is the most common form of congenital intestinal atresia, while the esophagus is the most common site of fistulization.
- Stenosis may be developmental or acquired. Both forms are characterized by a thickened wall and partial or complete luminal obstruction. Acquired forms are often due to inflammatory scarring.
- Diaphragmatic hernia is characterized by incomplete diaphragm development and herniation of abdominal organs into the thorax, often producing pulmonary hypoplasia. Omphalocele and gastroschisis refer to ventral herniation of abdominal organs.
- Ectopia refers to normally formed tissues at an abnormal site. This is common in the GI tract, with ectopic gastric mucosa in the upper third of the esophagus being the most common form.
- Meckel diverticulum is a true diverticulum, defined by the presence of all three layers of the bowel wall, that stems from failed

involution of the vitelline duct. It is a frequent site of gastric ectopia, which may result in peptic injury and occult bleeding.
- Congenital hypertrophic pyloric stenosis presents between the third and sixth weeks of life and is more common in males.
- Hirschsprung disease is caused by the failure of neural crest–derived ganglion cells to migrate into the distal colon. The defect, which always involves the rectum, extends proximally for variable distances.

Esophagus

The esophagus develops from the cranial portion of the foregut and is recognizable by the third week of gestation. It is a hollow, highly distensible muscular tube that extends from the epiglottis in the pharynx to the gastroesophageal junction. Acquired diseases of the esophagus run the gamut from highly lethal cancers to the heartburn of gastroesophageal reflux, which may be chronic and incapacitating or merely an occasional annoyance.

ESOPHAGEAL OBSTRUCTION

The primary function of the esophagus is to deliver ingested solid food and fluids to the stomach. This can be impeded by physical or functional obstruction. The latter results from disruption of coordinated peristalsis after swallowing. Esophageal dysmotility falls into three principal patterns.

- *Nutcracker esophagus* describes functional obstruction of the esophagus by intense, high amplitude, uncoordinated contractions of inner circular and outer longitudinal smooth muscle. Barium swallow can be normal or have a nutcracker-like appearance, with narrow and distended regions. Manometry is, however, required for diagnosis.
- *Diffuse esophageal spasm*, also known as corkscrew esophagus due to the appearance on barium swallow, is characterized by repetitive, simultaneous contractions of the distal esophageal smooth muscle. Unlike nutcracker esophagus, these contractions are of normal amplitude.
- *Lower esophageal sphincter dysfunction,* including high resting pressure or incomplete relaxation, may be present as an isolated anomaly or accompany nutcracker esophagus or diffuse esophageal spasm.

Because wall stress is increased, esophageal dysmotility may result in development of small diverticula, particularly in the epiphrenic region immediately above the lower esophageal sphincter. Similarly, impaired relaxation and spasm of the cricopharyngeus muscle after swallowing can result in increased pressure within the distal pharynx and development of a Zenker (pharyngoesophageal) diverticulum, located immediately above the upper esophageal sphincter. Zenker diverticula are uncommon, typically develop after age 50, and may reach several centimeters in size. When small they may be asymptomatic, but larger Zenker diverticula may accumulate significant amounts of food, producing a mass and symptoms that include regurgitation and halitosis. Mechanical obstruction caused by strictures or cancer typically presents as progressive dysphagia that begins with inability to swallow solids.

Benign esophageal stenosis is generally caused by fibrous thickening of the submucosa and is associated with atrophy of the muscularis propria and secondary epithelial damage. Although occasionally congenital, stenosis is most often due to inflammation and scarring that may be caused by chronic gastroesophageal reflux, irradiation, or caustic injury. In general, patients with functional obstruction or benign strictures maintain their appetite and weight. In contrast, malignant strictures are often associated with weight loss.

Esophageal mucosal webs are uncommon ledge-like mucosal protrusions. These usually occur in women older than age 40 and may be associated with gastroesophageal reflux, chronic graft-versus-host disease, or blistering skin diseases. In the upper esophagus, webs may be accompanied by iron deficiency anemia, glossitis, and cheilosis as part of *Plummer-Vinson syndrome.* Morphologically, esophageal webs are recognized as semi-circumferential lesions composed of a fibrovascular connective tissue and overlying epithelium. The main symptom of webs is partial obstruction, primarily of incompletely chewed food, and nonprogressive dysphagia.

Esophageal rings, or *Schatzki rings,* are similar to webs but are circumferential, are thicker, and include mucosa, submucosa, and occasionally hypertrophic muscularis propria. When present in the distal esophagus, above the gastroesophageal junction, they are termed *A rings* and are covered by squamous mucosa; in contrast, those located at the squamocolumnar junction of the lower esophagus are designated *B rings* and may have gastric cardia–type mucosa on their undersurface.

ACHALASIA

Achalasia is characterized by the triad of incomplete lower esophageal sphincter relaxation, increased lower esophageal sphincter tone, and aperistalsis of the esophagus. Symptoms include dysphagia, difficulty in belching, and chest pain. Although there is some increased risk for esophageal cancer, it is not considered great enough to warrant surveillance endoscopy.

Primary achalasia is rare and results from degeneration of nitric oxide–producing neurons that normally induce lower esophageal sphincter relaxation. Degenerative changes in the extraesophageal vagus nerve or the dorsal motor nucleus of the vagus may also occur. The cause is unknown; rare familial cases have been described.

Secondary achalasia may arise in Chagas disease, in which *Trypanosoma cruzi* infection causes destruction of the myenteric plexus, failure of peristalsis, and esophageal dilation. Duodenal, colonic, and ureteric myenteric plexuses can also be affected in Chagas disease. Other causes of achalasia-like disease include diabetic autonomic neuropathy; infiltrative

disorders such as malignancy, amyloidosis, and sarcoidosis; systemic sclerosis; or lesions of dorsal motor nuclei (e.g., following polio). Lower esophageal sphincter dysfunction also occurs in association with Down syndrome or as part of Allgrove (triple-A) syndrome, an autosomal recessive disorder characterized by achalasia, alacrima, and adrenocorticotropic hormone–resistant adrenal insufficiency. The association of some achalasia cases with remote herpes simplex virus 1 (HSV1) infection, linkage of immunoregulatory gene polymorphisms to achalasia, and occasional coexistence of Sjögren syndrome or autoimmune thyroid disease suggest that achalasia may also be driven by immune-mediated destruction of inhibitory esophageal neurons. Treatments for both primary and secondary achalasia aim to overcome the obstruction and include laparoscopic myotomy, pneumatic balloon dilation, and botulinum neurotoxin (Botox) injection to inhibit contraction-promoting cholinergic neurons.

ESOPHAGITIS AND RELATED DISORDERS

Lacerations

Longitudinal mucosal tears near the gastroesophageal junction, called Mallory-Weiss tears, are most often associated with severe retching or vomiting secondary to acute alcohol intoxication. Normally, a reflex relaxation of the gastroesophageal musculature precedes the antiperistaltic contractile wave associated with vomiting. It is speculated that this relaxation fails during prolonged vomiting, with the result that refluxing gastric contents overwhelm the gastric inlet and cause the esophageal wall to stretch and tear. The roughly linear lacerations of Mallory-Weiss syndrome are longitudinally oriented and range in length from millimeters to several centimeters. These tears usually cross the gastroesophageal junction and may also be located in the proximal gastric mucosa. Up to 10% of upper GI bleeding, which often presents as hematemesis (Table 17.1), is due to superficial esophageal lacerations such as those associated with Mallory-Weiss syndrome. These do not generally require surgical intervention, and healing tends to be rapid and complete. In contrast, Boerhaave syndrome is much less common but far more serious and is characterized by transmural tearing and rupture of the distal esophagus. This catastrophic event produces severe mediastinitis and generally requires surgical intervention. Because patients can present with severe chest pain, tachypnea, and shock, the initial differential diagnosis can include myocardial infarction.

Table 17.1 Esophageal Causes of Hematemesis

Lacerations (Mallory-Weiss syndrome)
Esophageal perforation (cancer or Boerhaave syndrome)
Varices (cirrhosis)
Esophageal-aortic fistula (usually with cancer)
Chemical and pill esophagitis
Infectious esophagitis (*Candida*, herpes)
Benign strictures
Vasculitis (autoimmune, cytomegalovirus)
Reflux esophagitis (erosive)
Eosinophilic esophagitis
Esophageal ulcers (many etiologies)
Barrett esophagus
Adenocarcinoma
Squamous cell carcinoma
Hiatal hernia

Chemical and Infectious Esophagitis

The stratified squamous mucosa of the esophagus may be damaged by a variety of irritants including alcohol, corrosive acids or alkalis, excessively hot fluids, and heavy smoking. Symptoms range from self-limited pain, particularly on swallowing, called *odynophagia,* to hemorrhage, stricture, or perforation in severe cases.

In children, esophageal chemical injury is often secondary to accidental ingestion of household cleaning products; severe damage may follow attempted suicide in adults. Less severe chemical injury to the esophageal mucosa can occur when medicinal pills lodge and dissolve in the esophagus, a condition termed *pill-induced esophagitis.* Iatrogenic esophageal injury may be caused by cytotoxic chemotherapy, radiation therapy, or graft-versus-host disease. The esophagus may also be involved by the desquamative skin diseases bullous pemphigoid, epidermolysis bullosa, and, rarely, Crohn disease.

Esophageal infections in otherwise healthy individuals are most often due to herpes simplex virus. Infections are more common in patients who are debilitated or immunosuppressed and may be caused by herpes simplex virus, cytomegalovirus (CMV), or fungal organisms. Among fungi, candidiasis is most common, although mucormycosis and aspergillosis also occur.

MORPHOLOGY

The morphology of chemical and infectious esophagitis varies with etiology. Dense infiltrates of neutrophils are usually present but may be absent following injury induced by chemicals (lye, acids, or detergent) that cause outright necrosis of the esophageal wall. Pill-induced esophagitis frequently occurs at the site of strictures that impede passage of luminal contents.

Esophageal irradiation causes damage similar to that seen in other tissues that is marked by intimal proliferation and luminal narrowing of submucosal and mural blood vessels. Concomitant mucosal damage is, in part, secondary to this radiation-induced vascular injury, as discussed in Chapter 9.

Infection by fungi or bacteria can either cause injury or complicate a preexisting ulcer. Nonpathogenic oral bacteria are frequently found in ulcer beds, while pathogenic bacteria and fungi, which account for about 10% of infectious esophagitis, may invade and cause mucosal necrosis. Candidiasis is characterized by adherent, gray-white **pseudomembranes** composed of densely matted fungal hyphae and inflammatory cells covering the esophageal mucosa.

The endoscopic appearance frequently indicates the cause of viral esophagitis. Herpesviruses typically cause punched-out ulcers (Fig. 17.4A). Biopsy specimens demonstrate viral nuclear inclusions in degenerating, multinucleate, epithelial cells at the margin of the ulcer (Fig. 17.4B). In contrast, CMV infection causes shallower ulcerations and is marked by characteristic nuclear and cytoplasmic

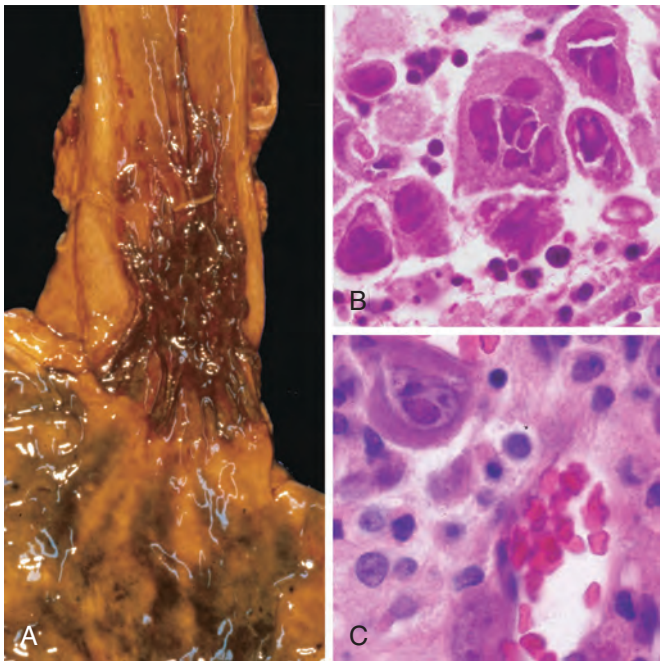

Figure 17.4 Viral esophagitis. (A) Postmortem specimen with multiple, overlapping herpetic ulcers in the distal esophagus. (B) Multinucleate squamous cells containing herpesvirus nuclear inclusions. (C) Cytomegalovirus-infected endothelial cells with nuclear and cytoplasmic inclusions.

inclusions within capillary endothelium and stromal cells (Fig. 17.4C). Although the histologic appearance is characteristic, immunohistochemical stains for virus-specific antigens are sensitive and specific ancillary diagnostic tools.

Histologic features of esophageal **graft-versus-host disease** are similar to those in the skin and include basal epithelial cell apoptosis, mucosal atrophy, and submucosal fibrosis without significant acute inflammatory infiltrates. The microscopic appearances of esophageal involvement in bullous pemphigoid, epidermolysis bullosa, and Crohn disease are also similar to those in the skin (Chapter 25).

Reflux Esophagitis

Reflux of gastric contents into the lower esophagus is the most frequent cause of esophagitis and the most common outpatient GI diagnosis in the United States. The associated clinical condition, termed gastroesophageal reflux disease (GERD), occurs because the esophageal epithelium is sensitive to acid despite being resistant to abrasive injury.

Pathogenesis

Transient lower esophageal sphincter relaxation is thought to be a major cause of GERD. This relaxation is mediated via vagal pathways and can be triggered by gastric distention. Gastroesophageal reflux can also occur following abrupt increases in intra-abdominal pressure, e.g., after coughing, straining, or bending. Other conditions that are associated with GERD include alcohol and tobacco use, obesity, central nervous system depressants, pregnancy, hiatal hernia (discussed later), delayed gastric emptying, and increased gastric volume.

MORPHOLOGY

Simple hyperemia, evident to the endoscopist as redness, may be the only alteration in mild GERD; mucosal histology is often unremarkable. More significant gastric reflux is associated with erosions (Fig. 17.5A) and influx of eosinophils into the squamous mucosa (Fig. 17.6A). Basal zone hyperplasia and elongation of lamina propria papillae are also common. Neutrophil infiltration is less frequent and is generally associated with bacterial or fungal infection or chemical damage.

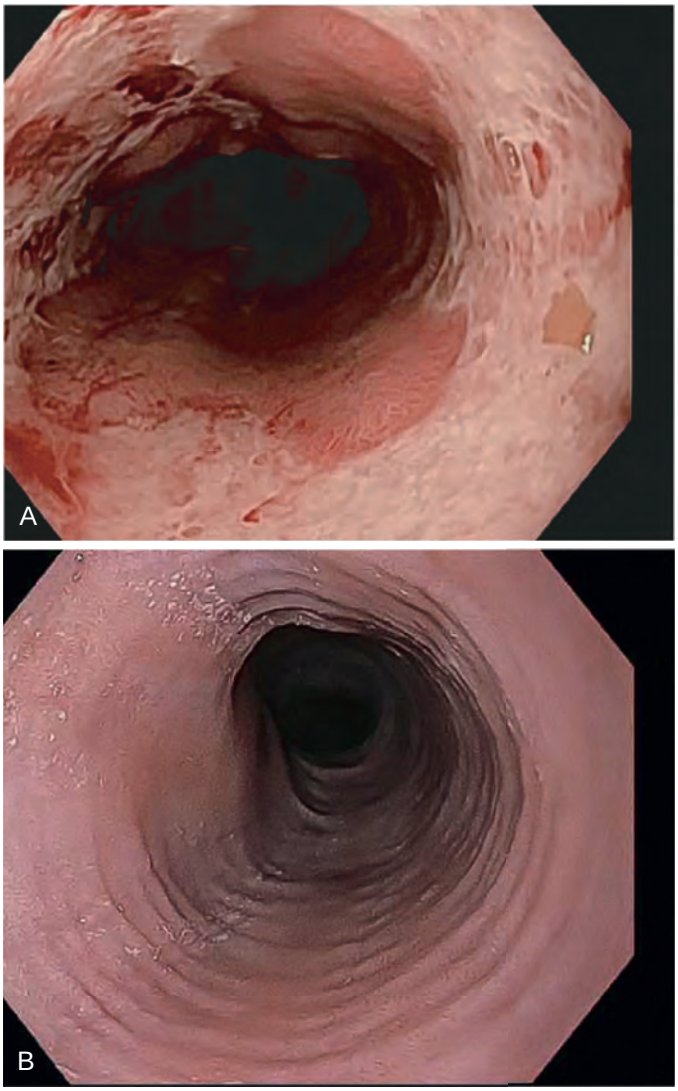

Figure 17.5 Esophagitis. (A) Endoscopic view of reflux esophagitis with multiple erosions within the squamous-lined esophagus, a metaplastic zone (Barrett esophagus, discussed later), and distal gastric mucosa. Note the tan islands of metaplastic epithelium within the white squamous mucosa. (B) The "feline" or "ringed" endoscopic appearance of the esophagus is typical of eosinophilic esophagitis. (Courtesy Dr. Linda S. Lee, Brigham and Women's Hospital and Harvard Medical School, Boston, Mass.)

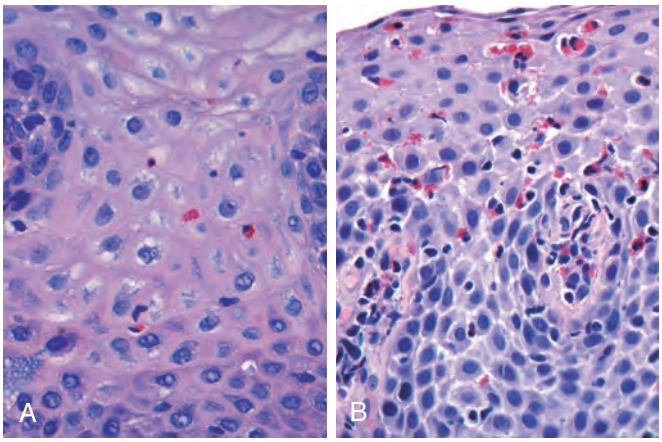

Figure 17.6 Esophagitis. (A) Reflux esophagitis with scattered intraepithelial eosinophils and mild basal zone expansion. (B) Eosinophilic esophagitis is characterized by numerous intraepithelial eosinophils.

Clinical Features

GERD has an estimated prevalence of 10% to 20% in the West, but less than 5% in Asia, and is most common in individuals older than age 40. Typical symptoms include heartburn, dysphagia, and regurgitation of sour-tasting gastric contents, most often postprandially. Rarely, GERD-associated chest pain may be mistaken for ischemic heart disease. Treatment with proton pump inhibitors to reduce gastric acidity typically provides symptomatic relief. Endoscopy is not required for the diagnosis and is usually reserved for those who are refractory to proton pump inhibitors. Endoscopic biopsy can also detect eosinophilic esophagitis as well as Barrett esophagus, strictures, ulcerations, and other GERD complications. Notably, the severity of symptoms is not closely related to the degree of histologic damage, and substantial histologic abnormalities may be found in those without typical GERD symptoms.

Hiatal hernia may cause lower esophageal sphincter incompetence and symptoms that are similar to GERD but it is symptomatic in fewer than 10% of adults. The majority of hiatal hernias are of the sliding type, in which the diaphragmatic crura are spread and the gastroesophageal junction herniates into the thorax. Less common paraesophageal hiatal hernias penetrate through a defect in the phrenoesophageal membrane, can involve the stomach and other organs, and generally require surgical repair.

Eosinophilic Esophagitis

Eosinophilic esophagitis is a form of acute eosinophil-dominated esophageal inflammation associated with atopic disease. Many patients have atopic dermatitis, allergic rhinitis, asthma, or modest peripheral eosinophilia. Consistent with this, recent data suggest that mast cells may also be important in pathogenesis. The incidence of eosinophilic esophagitis has increased dramatically, particularly in urban areas and among white males. In addition to GERD-like symptoms, patients experience food impaction, dysphagia, and vomiting. Infants may also suffer from feeding intolerance. On endoscopic examination the esophagus can take the appearance of stacked circular rings (referred to as feline esophagus because of supposed endoscopic resemblance to a striped cat's tail), strictures, and linear furrows (Fig. 17.5B). The cardinal histologic feature is large numbers of intraepithelial eosinophils, particularly superficially, that can form clusters and sheets (Fig. 17.6B). Their abundance can help to distinguish eosinophilic esophagitis from GERD, Crohn disease, and other causes of esophagitis. However, these histologic findings are not entirely specific, and some patients with extensive intraepithelial eosinophil infiltration may respond to proton pump inhibitors, particularly when given at high doses. Dietary restrictions to prevent exposure to food allergens are often helpful and can be targeted on the basis of skin patch or immunoglobulin E (IgE) testing. Alternatively, empirical elimination of cow's milk, eggs, soy or legumes, and wheat from the diet can be beneficial. When dietary treatment fails, topical or, less frequently, systemic corticosteroids can be used and are sometimes combined with proton pump inhibitors. In contrast to GERD, eosinophilic esophagitis is not associated with increased risk of Barrett esophagus.

Esophageal Varices

Esophageal varices are dilated veins within the lower esophagus. Although most small varices never bleed, rupture of large varices can result in exsanguination.

Pathogenesis

Esophageal varices are caused by portal hypertension, which is due to impaired blood flow through the portal venous system and liver. Increased portal venous pressure results in the development of collateral channels at sites where the portal and caval systems communicate. These collateral veins allow some drainage to occur, but also result in congestion and dilation of subepithelial and submucosal venous plexuses within the distal esophagus and proximal stomach. These dilated vessels, termed *varices,* are common in patients with cirrhosis, most frequently due to alcoholic liver disease. Worldwide, hepatic schistosomiasis is the second most common cause of varices. A more detailed consideration of portal hypertension is given in Chapter 18.

MORPHOLOGY

Esophageal varices are tortuous dilated veins within the mucosa and submucosa of the distal esophagus and proximal stomach (Fig. 17.7). Variceal rupture can result in hemorrhage into the lumen or the esophageal wall and may be associated with mucosal ulceration and necrosis. If rupture has occurred in the past, venous thrombosis, inflammation, and evidence of prior sclerotherapy may also be present.

Clinical Features

Gastroesophageal varices are present in 30% of those with compensated cirrhosis and in 60% of those with decompensated cirrhosis. Variceal hemorrhage is an emergency that can be treated medically by inducing splanchnic vasoconstriction or endoscopically by sclerotherapy (injection of thrombotic agents), balloon tamponade, or variceal ligation. Despite

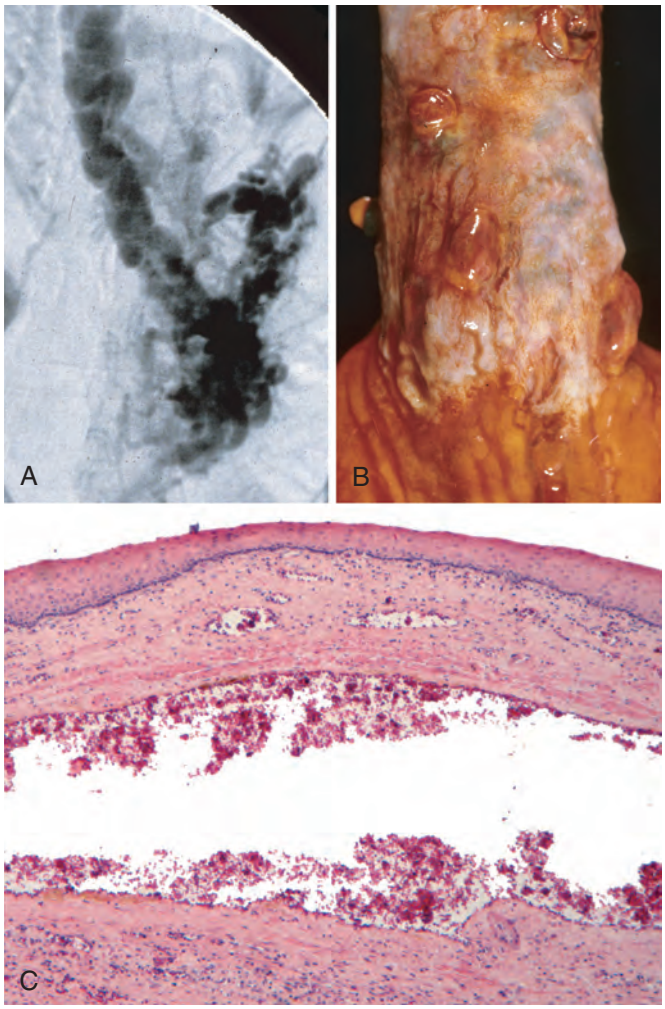

Figure 17.7 Esophageal varices. (A) Although no longer used as a diagnostic approach, this angiogram demonstrates several tortuous esophageal varices. (B) Collapsed varices are present in this postmortem specimen corresponding to the angiogram in (A). The polypoid areas represent previous sites of variceal hemorrhage that have been ligated with bands. (C) Dilated varices beneath intact squamous mucosa.

these interventions, each episode of variceal hemorrhage confers a 15% to 20% risk of mortality, and over half of patients who survive a first variceal bleed have recurrent hemorrhage within 1 year, with mortality risk similar to the first episode. Risk factors for hemorrhage include large or tortuous varices, elevated hepatic venous pressure gradient, previous bleeding, and advanced liver disease. Treatments include beta-blockers to reduce portal blood flow and endoscopic variceal ligation.

Barrett Esophagus

Barrett esophagus is a complication of chronic GERD that is characterized by intestinal metaplasia within the esophageal squamous mucosa and is associated with an increased risk of cancer. The incidence of Barrett esophagus is rising; it is estimated to occur in as many as 10% of individuals with symptomatic GERD and up to 2% of the general population. Barrett esophagus is most common in white males and typically presents between 40 and 60 years of age. The greatest clinical concern is that it confers an increased risk of esophageal adenocarcinoma. Genomic sequencing of biopsies involved by Barrett esophagus has revealed the presence of pathogenic driver mutations in cancer genes that are also found in esophageal adenocarcinoma. Potentially oncogenic mutations are more numerous when biopsies demonstrate dysplasia, a preinvasive neoplastic change that is associated with prolonged symptoms, longer segment length, increased patient age, and Caucasian race. The vast majority of esophageal adenocarcinomas occur in association with Barrett esophagus. Nevertheless, most individuals with Barrett esophagus do not develop esophageal tumors.

MORPHOLOGY

Barrett esophagus can be recognized as tongues of red, velvety mucosa extending upward from the gastroesophageal junction. This metaplastic mucosa alternates with residual smooth, pale squamous (esophageal) mucosa (see Fig. 17.5A) and interfaces with light-brown columnar (gastric) mucosa distally (Fig. 17.8A, B). Barrett esophagus can be subclassified as long segment (≥3 cm), or short segment (<3 cm). Patients with short-segment disease may not experience GERD symptoms and are at lower risk of developing dysplasia or carcinoma relative to those with long-segment disease.

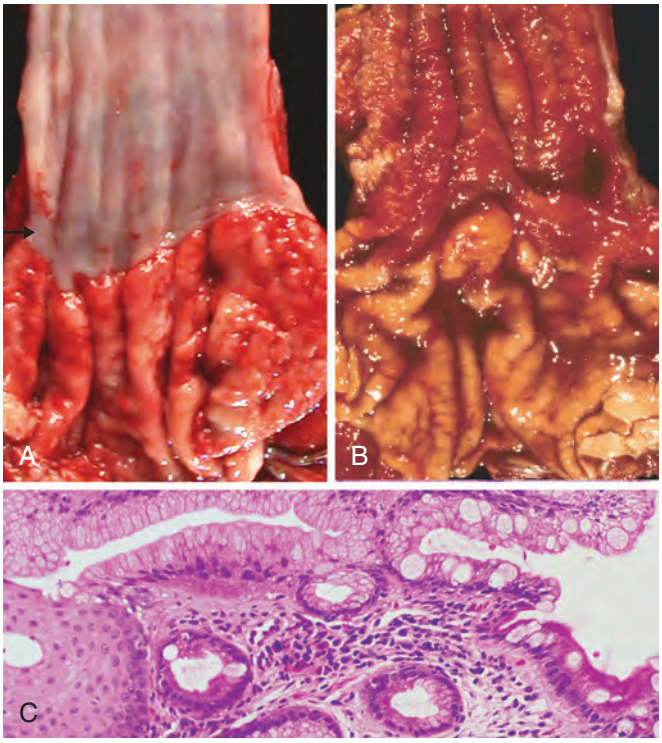

Figure 17.8 Barrett esophagus. (A) Normal gastroesophageal junction. (B) Barrett esophagus. Note the small islands of residual pale squamous mucosa within the Barrett mucosa. (C) Histologic appearance of the gastroesophageal junction in Barrett esophagus. Note the transition between esophageal squamous mucosa (left) and Barrett metaplasia, with abundant metaplastic goblet cells (right).

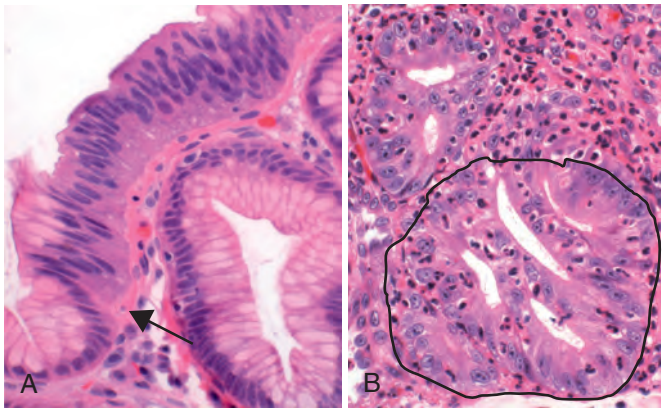

Figure 17.9 Dysplasia in Barrett esophagus. (A) Abrupt transition from metaplasia to low-grade dysplasia *(arrow)*. Note the nuclear stratification and hyperchromasia. (B) Architectural irregularities, including gland-within-gland, or cribriform, profiles in high-grade dysplasia *(encircled)*.

Diagnosis of Barrett esophagus requires endoscopic evidence of metaplastic columnar mucosa above the gastroesophageal junction. Microscopically, intestinal-type metaplasia is seen as replacement of the squamous esophageal epithelium with goblet cells. Goblet cells are diagnostic of Barrett esophagus and have distinct mucous vacuoles that stain pale blue and impart the shape of a wine goblet to the remaining cytoplasm (Fig. 17.8C). Non-goblet columnar cells, such as gastric-type foveolar cells, may also be present, but there is not universal agreement as to whether they are sufficient for the diagnosis.

Dysplasia is classified as low grade or high grade. Atypical mitoses, nuclear hyperchromasia, irregularly clumped chromatin, increased nuclear-to-cytoplasmic ratio, and failure of epithelial cells to mature as they migrate to the esophageal surface are present in both grades (Fig. 17.9A). Dysplastic glands display budding, irregular shapes, and cellular crowding. High-grade dysplasia (Fig. 17.9B) exhibits more severe cytologic and architectural changes than low-grade dysplasia. With progression, epithelial cells may invade the lamina propria, a feature that defines progression to intramucosal carcinoma.

Clinical Features

Barrett esophagus can be identified only thorough endoscopy and biopsy, which are usually prompted by GERD symptoms. Once diagnosed, the best course of management is a matter of debate. Many support surveillance by periodic endoscopy with biopsy, but randomized trials have failed to demonstrate that this improves overall survival. Furthermore, uncertainties regarding the potential of dysplasia, particularly low-grade dysplasia, to regress spontaneously and limited information on the risk of progression complicate clinical decisions.

Intramucosal or invasive carcinoma requires therapeutic intervention. Treatment options include surgical resection, or esophagectomy, as well as newer modalities such as photodynamic therapy, laser ablation, and endoscopic mucosectomy. Multifocal high-grade dysplasia, which carries a significant risk of progression to intramucosal or invasive carcinoma, is treated as intramucosal carcinoma. At present, many physicians follow low-grade dysplasia or a single focus of high-grade dysplasia with endoscopy and biopsy at regular intervals.

ESOPHAGEAL TUMORS

Nearly all esophageal cancers are either adenocarcinoma or squamous cell carcinoma. Squamous cell carcinoma is more common worldwide, but adenocarcinoma is on the rise in the United States and other Western countries. Other malignancies of the esophagus are far less common and include unusual forms of adenocarcinoma, undifferentiated carcinoma, neuroendocrine carcinoma, melanoma, lymphoma, and sarcoma; these are not discussed here. Benign tumors of the esophagus are generally mesenchymal, and arise within the esophageal wall, with leiomyomas being most common.

Adenocarcinoma

Esophageal adenocarcinoma typically arises in the background of Barrett esophagus and long-standing GERD. Thus, increased rates of esophageal adenocarcinoma may be partly due to the increased incidence of obesity-related gastroesophageal reflux and associated Barrett esophagus. Other major risk factors include tobacco use and exposure to radiation. Conversely, risk is reduced by diets rich in fresh fruits and vegetables. Some serotypes of *Helicobacter pylori* are associated with decreased risk of esophageal adenocarcinoma, perhaps because they cause gastric atrophy, which decreases acid secretion and reduces reflux-induced esophageal damage.

Esophageal adenocarcinoma occurs most frequently in Caucasians and shows a strong gender bias, being sevenfold more common in men. The incidence varies widely worldwide, with rates being highest in the United States, the United Kingdom, Canada, Australia, the Netherlands, and Brazil and lowest in Korea, Thailand, Japan, and Ecuador. In countries where esophageal adenocarcinoma is more common, the incidence has increased markedly since 1970, more rapidly than almost any other cancer. For unknown reasons, these increases have been restricted to white and Hispanic men and white women in the United States. As a result, esophageal adenocarcinoma, which represented less than 5% of esophageal cancers before 1970, now accounts for more than half of all esophageal cancers in the United States.

Pathogenesis

Molecular studies indicate that progression of Barrett esophagus to adenocarcinoma occurs over an extended period through the stepwise acquisition of genetic and epigenetic changes. Chromosomal abnormalities and mutations of the tumor suppressor genes *TP53* and *CDKN2A* are detected at early stages. In the case of *CDKN2A*, which you will recall encodes two tumor suppressor proteins, p16 and p19-ARF, both allelic loss and hypermethylation-induced epigenetic silencing have been described. With progression, there may be amplification of several oncogenes, including the *EGFR, ERBB2, MET, cyclin D1,* and *cyclin E* genes.

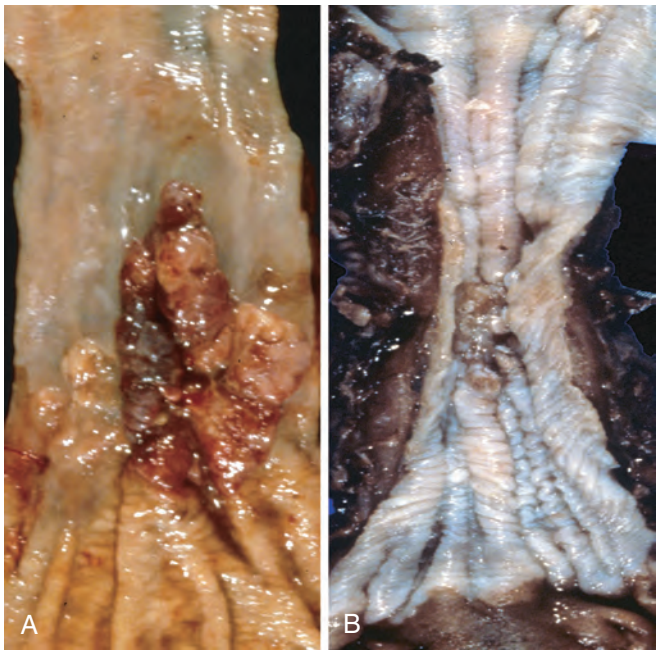

Figure 17.10 Esophageal cancer. (A) Adenocarcinoma usually occurs distally and, as in this case, often involves the gastric cardia. (B) Squamous cell carcinoma is most frequently found in the mid-esophagus, where it commonly causes strictures.

MORPHOLOGY

Esophageal adenocarcinoma usually occurs in the distal third of the esophagus and may invade the adjacent gastric cardia (Fig. 17.10A). It initially appears as flat or raised patches in otherwise intact mucosa, and may grow into large masses of 5 cm or more in diameter. Alternatively, tumors may infiltrate diffusely or ulcerate and invade deeply.

Microscopically, tumors typically produce mucin and form glands (Fig. 17.11A), often with intestinal-type morphology; less frequently, tumors are composed of diffusely infiltrative signet-ring cells (similar to those seen in diffuse gastric cancers) or, in rare cases, small poorly differentiated cells (similar to small cell carcinoma of the lung). Barrett esophagus is frequently present adjacent to the tumor.

Clinical Features

Although esophageal adenocarcinomas are occasionally discovered incidentally during the evaluation of GERD or surveillance of Barrett esophagus, they more commonly present with pain or difficulty in swallowing, progressive weight loss, hematemesis, chest pain, or vomiting. By the time symptoms appear, the tumor has often spread to submucosal lymphatic vessels. As a result, overall 5-year survival is less than 25%. In contrast, 5-year survival is approximately 80% in cases in which adenocarcinoma is limited to the mucosa or submucosa.

Squamous Cell Carcinoma

In the United States, esophageal squamous cell carcinoma occurs in adults older than age 45 and affects males four times more frequently than females. Risk factors include alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, Plummer-Vinson syndrome, diets that are deficient in fruits or vegetables, and frequent consumption of very hot beverages. Previous radiation to the mediastinum also predisposes individuals to esophageal carcinoma, with most cases occurring 5 to 10 or more years after exposure.

Esophageal squamous cell carcinoma incidence varies up to 180-fold between and within countries, being more common in rural and low income populations. The regions with highest incidence are Iran, central China, Hong Kong, Brazil, and South Africa. A pocket of extremely high incidence in western Kenya has been linked to consumption of a traditional fermented milk, termed *mursik,* which contains the carcinogen acetaldehyde (Chapter 9). In other geographic areas with high esophageal squamous cell carcinoma rates, regular ingestion of very hot tea is common. In the United States, it is nearly eightfold more frequent in African Americans than in Caucasians, a striking risk disparity that partially reflects differences in rates of alcohol and tobacco use but likely also reflects contributions of other factors that remain poorly understood.

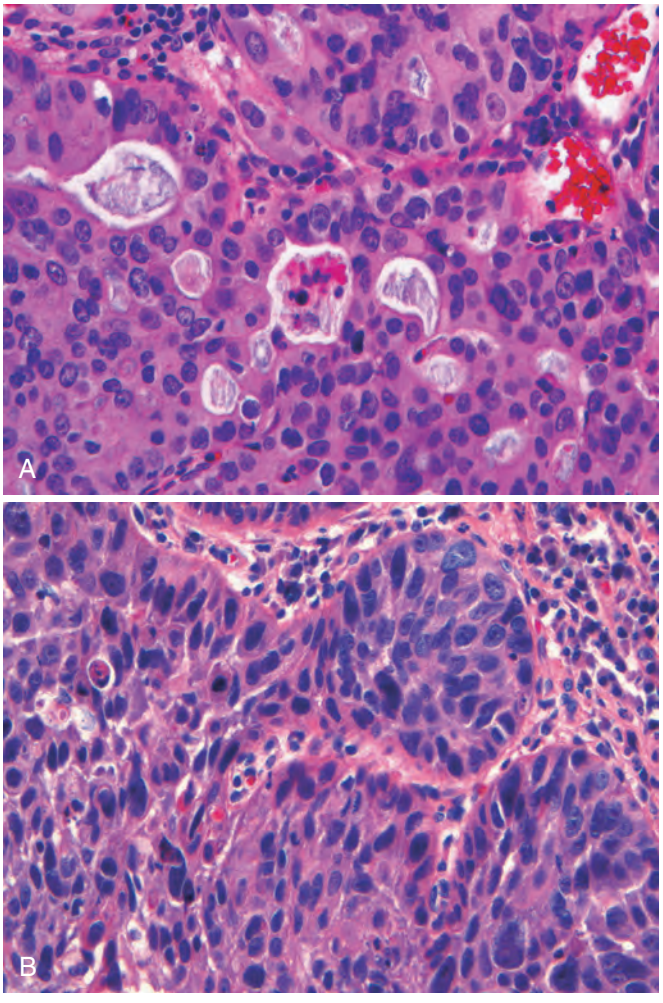

Figure 17.11 Esophageal cancer. (A) Esophageal adenocarcinoma organized into back-to-back glands. (B) Squamous cell carcinoma composed of nests of malignant cells that partially recapitulate the organization of squamous epithelium.

Pathogenesis

The majority of esophageal squamous cell carcinomas in Europe and the United States are linked to alcohol and tobacco use, which synergize to increase the risk. However, esophageal squamous cell carcinoma is also common in some regions where alcohol and tobacco use is uncommon. Thus, nutritional deficiencies, as well as polycyclic hydrocarbons, nitrosamines, and other mutagenic compounds, such as those found in fungus-contaminated foods must be considered. Some data suggest that human papillomavirus (HPV) infection may contribute to esophageal squamous cell carcinoma in high-risk, but not in low-risk, regions. The molecular pathogenesis of esophageal squamous cell carcinoma remains incompletely defined, but recurrent abnormalities include amplification of the transcription factor gene *SOX2,* which is involved in stem cell self-renewal; overexpression of the cell cycle regulator cyclin D1; and loss-of-function mutations in the tumor suppressor genes *TP53, CDH1* (which encodes E-cadherin), and *NOTCH1*.

Clinical Features

The onset of esophageal squamous cell carcinoma is insidious. Patients typically have dysphagia, odynophagia (pain on swallowing), or obstruction at presentation and may have unknowingly adjusted to progressive esophageal obstruction by altering their diet from solid to liquid foods. Weight loss and debilitation result from both impaired nutrition and tumor cachexia. Hemorrhage and sepsis may accompany tumor ulceration, and symptoms of iron deficiency are often present. Occasionally, the first symptoms are caused by aspiration of food via a tracheoesophageal fistula (caused by extension of the tumor into the trachea).

Increased prevalence of endoscopic screening has led to earlier detection of esophageal squamous cell carcinoma. This is significant because 5-year survival rates are 75% in individuals with superficial lesions but much lower in patients with more advanced tumors. Lymph node metastases are associated with poor prognosis. The overall 5-year survival rate in the United States remains less than 20% and varies by tumor stage and patient age, race, and sex.

MORPHOLOGY

In contrast to the distal location of adenocarcinoma, half of squamous cell carcinomas occur in the middle third of the esophagus (Fig. 17.10B). Squamous cell carcinoma begins as an in situ lesion termed **squamous dysplasia** (this histopathology is referred to as intraepithelial neoplasia or carcinoma in situ at sites outside the GI tract, e.g., uterine cervix). Early lesions appear as small, gray-white, plaque-like thickenings. Over months to years they grow into tumor masses that may be polypoid, or exophytic, and protrude into and obstruct the lumen. Other tumors are ulcerated or diffusely infiltrative lesions that spread within the esophageal wall and cause thickening, rigidity, and luminal narrowing. Tumors may invade surrounding structures including the respiratory tree (causing pneumonia), the aorta (causing catastrophic exsanguination), or the mediastinum and pericardium.

Most squamous cell carcinomas are moderately to well differentiated (Fig. 17.11B). Less common histologic variants include verrucous squamous cell carcinoma, spindle cell carcinoma, and basaloid squamous cell carcinoma. Regardless of histology, symptomatic tumors are generally large and invasive at diagnosis. The rich lymphatic network of the esophagus promotes metastases as well as circumferential and longitudinal spread; intramural satellite tumor nodules may be present several centimeters away from the principal mass. The sites of lymph node metastases vary with tumor location: cancers in the upper third of the esophagus favor cervical lymph nodes; those in the middle third favor mediastinal, paratracheal, and tracheobronchial nodes; and those in the lower third spread to gastric and celiac nodes.

KEY CONCEPTS

ESOPHAGEAL DISEASES

- Abnormalities of esophageal motility include nutcracker esophagus and diffuse esophageal spasm.
- Achalasia, characterized by incomplete lower esophageal sphincter relaxation, increased lower esophageal sphincter tone, and esophageal aperistalsis, is a common form of functional esophageal obstruction. It can be primary or secondary, with the latter form most commonly due to *Trypanosoma cruzi* infection.
- Mallory-Weiss tears of mucosa at the gastroesophageal junction develop as a result of severe retching or vomiting.
- Esophagitis can result from chemical or infectious mucosal injury. Infection is most common in immunocompromised individuals.
- The most prevalent cause of esophagitis is reflux of gastric acid into the esophagus (GERD).
- Eosinophilic esophagitis is strongly associated with food allergy, allergic rhinitis, or asthma. It is a common cause of GERD-like symptoms in children living in high income countries.
- Gastroesophageal varices are a consequence of portal hypertension and are present in half of cirrhosis patients.
- Barrett esophagus develops in patients with chronic GERD and represents columnar metaplasia of the esophageal squamous mucosa.
- Barrett esophagus is a risk factor for development of esophageal adenocarcinoma.
- Esophageal squamous cell carcinoma is associated with alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, and Plummer-Vinson syndrome.

Stomach

Disorders of the stomach are a frequent cause of clinical disease, with inflammatory and neoplastic lesions being most common. In the United States, diseases related to the stomach account for nearly one-third of all health care spending on GI disease. In addition, despite decreasing incidence in certain locales such as the United States, gastric cancer remains a leading cause of death worldwide.

The stomach is divided into four major anatomic regions: cardia, fundus, body, and antrum. The cardia and antrum are lined mainly with mucin-secreting foveolar cells that form small glands. The antral glands are similar but also contain endocrine cells such as G cells that release gastrin to stimulate luminal acid secretion by parietal cells within the gastric fundus and body. The well-developed glands

of the body and fundus contain parietal cells as well as chief cells that produce and secrete digestive enzymes.

GASTROPATHY AND ACUTE GASTRITIS

Inflammation of the gastric mucosa occurs in many conditions, and is called acute gastritis when neutrophils are present and gastropathy when inflammatory cells are rare or absent. Irritants including non-steroidal anti-inflammatory drugs (NSAIDs), alcohol, and bile are the most common causes of gastropathy. Both gastropathy and gastritis may be asymptomatic or associated with epigastric pain, nausea, and vomiting. In more severe cases there may be mucosal erosion, ulceration, hemorrhage, hematemesis, melena, or, rarely, massive blood loss.

Pathogenesis

The gastric lumen has a pH of close to 1, more than a million times more acidic than the blood. This harsh environment contributes to digestion but also has the potential to cause damage. Multiple mechanisms have evolved to protect the gastric mucosa (Fig. 17.12). Foveolar cell secretions form a thin layer of mucus and phospholipids that prevents large food particles from directly touching the epithelium. Mucus also promotes formation of an "unstirred" layer of fluid with a neutral pH as a result of bicarbonate ion secretion by surface epithelial cells. Beneath the mucus, gastric epithelial cells form a physical barrier that limits back diffusion of acid and leakage of other luminal materials, including digestive enzymes, into the lamina propria. Surface foveolar cells are replaced every 3 to 7 days, while parietal and chief cells are more long-lived. The rich mucosal vasculature delivers oxygen and nutrients and removes whatever gastric acid may have diffused into the lamina propria.

Gastropathy and gastritis occur when the damaging forces overwhelm the protective factors (Fig. 17.12). Disruption of protective mechanisms is illustrated by the following examples:

- *Inhibition of cyclooxygense (COX) by NSAIDs.* NSAIDs inhibit COX-dependent synthesis of prostaglandins E_2 and I_2, which contribute to nearly all of the above defense mechanisms, including: mucus, bicarbonate, and phospholipid secretion; mucosal blood flow; and epithelial restitution. They also reduce acid secretion. Although COX-1 plays a larger role than COX-2, both isoenzymes contribute to mucosal protection. Thus, while the risk of NSAID-induced gastric injury is greatest with nonselective inhibitors such as aspirin, ibuprofen, and naproxen, selective COX-2 inhibitors such as celecoxib can also cause gastropathy or gastritis.
- *Inhibition of gastric bicarbonate transporters* by ammonium ions can result in gastric injury in uremic patients and those infected with urease-secreting *H. pylori*.
- *Reduced mucin and bicarbonate secretion* have been suggested as factors that explain the increased susceptibility of older adults to gastritis.
- *Decreased oxygen delivery* may account for an increased incidence of acute gastritis at high altitudes.

Ingestion of harsh chemicals, particularly acids or bases, either accidentally or as a suicide attempt, causes severe gastric injury. Direct cellular damage also contributes to

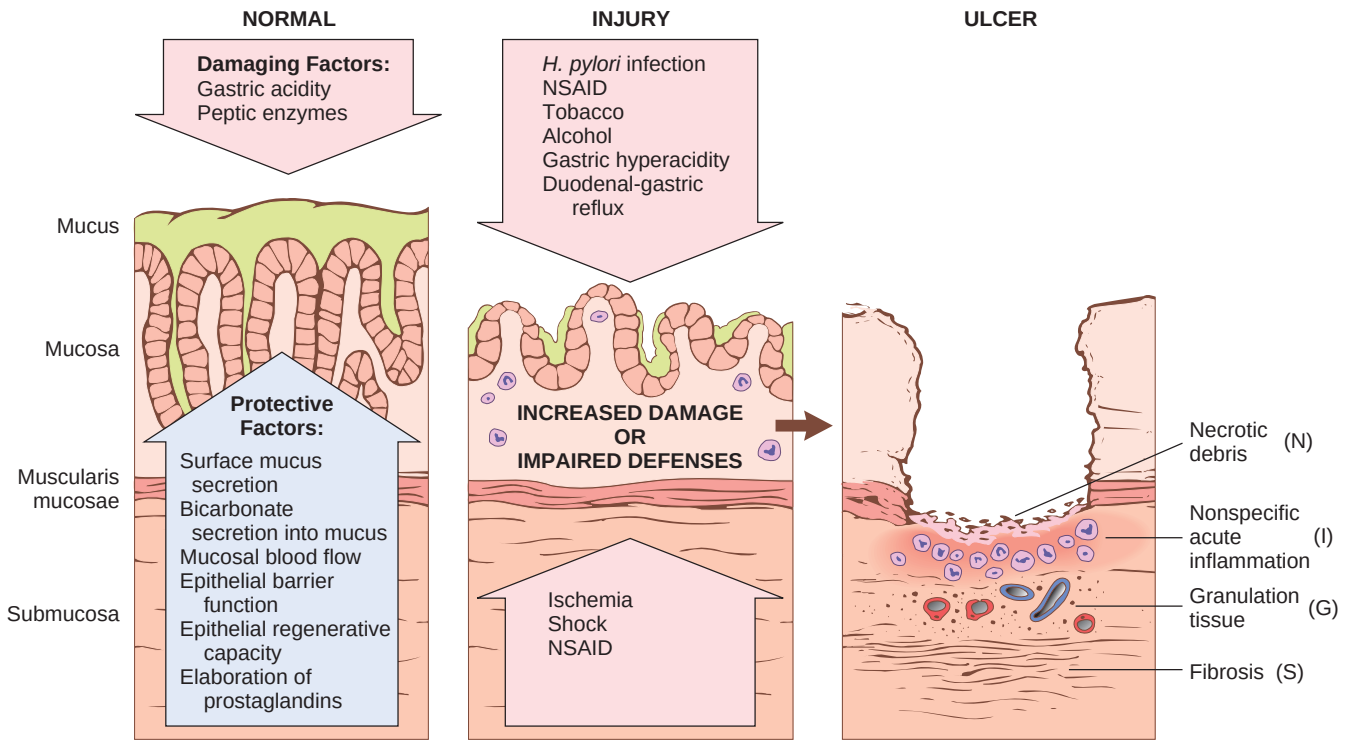

Figure 17.12 Mechanisms of gastric injury and protection. This diagram illustrates the progression from more mild forms of injury to ulceration that may occur with acute or chronic gastritis. Ulcers include layers of necrosis *(N)*, inflammation *(I)*, and granulation tissue *(G)*, but a fibrotic scar *(S)*, which takes time to develop, is present only in chronic lesions. *NSAID*, Non-steroidal anti-inflammatory drug.

gastritis induced by alcohol consumption, NSAIDs, radiation therapy, and chemotherapy. Agents that inhibit DNA synthesis or the mitotic apparatus, including those used in cancer chemotherapy, may cause generalized mucosal damage by inhibiting epithelial renewal.

MORPHOLOGY

Histologically, gastropathy and mild acute gastritis may be difficult to recognize, since the lamina propria shows only moderate edema and slight vascular congestion. The surface epithelium is intact, but foveolar cell hyperplasia, with characteristic corkscrew profiles and epithelial proliferation, is often present. Neutrophils may be found among the epithelial cells or within mucosal gland lumina in gastritis. The lamina propria contains only a few lymphocytes and plasma cells.

The presence of neutrophils above the basement membrane in direct contact with epithelial cells is abnormal in all parts of the GI tract and signifies active inflammation, or, in this case, gastritis (rather than gastropathy). The term *active inflammation* is preferred over acute inflammation, since neutrophils may be present in both acute and chronic disease states. Thus, within the GI tract, the term acute refers to disease duration rather than the inflammatory pattern.

As injury progresses, erosions, i.e., superficial mucosal defects, are accompanied by neutrophilic infiltrates and fibrin-containing exudate within the lumen. Hemorrhage may cause dark puncta within hyperemic mucosa. Concurrent erosion and hemorrhage is termed **acute erosive hemorrhagic gastritis.** Although large areas of the gastric surface may be denuded, the involvement is typically superficial.

STRESS-RELATED MUCOSAL DISEASE

Stress-related mucosal disease occurs in patients with severe trauma, extensive burns, intracranial disease, major surgery, serious medical disease, and other forms of severe physiologic stress. In some cases, stress-related ulcers are given specific names based on location and clinical associations. For example:

- *Stress ulcers* are most common in the setting of shock, sepsis, or severe trauma.
- *Curling ulcers* refer to ulcers occurring in the proximal duodenum in the context of severe burns or trauma.
- *Cushing ulcers* refer to gastric, duodenal, and esophageal ulcers arising in those with intracranial disease. They have an elevated risk of perforation.

Pathogenesis

The pathogenesis of stress-related gastric mucosal injury is most often related to local ischemia. This may be due to systemic hypotension or reduced blood flow caused by stress-induced splanchnic vasoconstriction. Upregulation and increased release of the vasoconstrictor endothelin-1 also contribute to ischemic gastric mucosal injury.

Lesions associated with intracranial injury are thought to be caused by direct stimulation of vagal nuclei, which causes hypersecretion of gastric acid. Systemic acidosis, a frequent finding in these settings, may also contribute to mucosal injury by lowering the intracellular pH of mucosal cells and reducing the pH gradient that promotes washout of acid that has back-diffused into the lamina propria.

MORPHOLOGY

Stress-related gastric mucosal injury ranges from shallow erosions to lesions that penetrate the mucosa. Ulcers are rounded, less than 1 cm in diameter, and have a base that is frequently stained brown to black by acid digestion of extravasated blood. Unlike peptic ulcers, which are usually solitary and located in the antrum, acute stress ulcers are found anywhere in the stomach and are often multiple. Microscopically, acute stress ulcers are sharply demarcated, with relatively normal adjacent mucosa. Serositis may be present, but the scarring and blood vessel thickening that characterize chronic peptic ulcers are conspicuously absent. Healing with complete re-epithelialization occurs within days to weeks after successful treatment of the underlying condition.

Clinical Features

Most critically ill patients admitted to hospital intensive care units have histologic evidence of gastric mucosal damage. Bleeding from these lesions is sufficiently severe to require red cell transfusions in 1% to 4% of such patients. Other complications, including perforation, can also occur. Prophylactic proton pump inhibitors may blunt the impact of stress ulceration, but the most important determinant of clinical outcome is whether the underlying condition can be corrected.

Non–stress-related causes of gastric bleeding include the following two conditions:

- *Dieulafoy lesion* consists of an abnormal submucosal arteriole that is usually found within the lesser curvature of the stomach near the gastroesophageal junction. Erosion of the overlying epithelium can cause recurrent gastric bleeding that, while usually self-limited, can be copious. NSAID use may enhance bleeding risk.
- *Gastric antral vascular ectasia (GAVE)* is responsible for 4% of non-variceal upper GI bleeding. It can be recognized endoscopically as longitudinal stripes of edematous, erythematous mucosa that alternate with less severely injured, paler mucosa and is sometimes referred to as watermelon stomach. The erythematous stripes are created by ectatic mucosal vessels. Histologically, the antral mucosa shows reactive gastropathy with dilated capillaries containing fibrin thrombi. While most often idiopathic, GAVE can be associated with cirrhosis and systemic sclerosis. Recurrent bleeding may produce a positive test for fecal blood and lead to iron deficiency anemia.

CHRONIC GASTRITIS AND ITS COMPLICATIONS

Chronic gastritis is most often caused by *H. pylori* infection. Other causes include autoimmune gastritis; radiation injury;

chronic bile reflux; mechanical injury (e.g., an indwelling nasogastric tube); and involvement by systemic diseases such as Crohn disease, amyloidosis, or graft-versus-host disease.

Relative to acute gastritis, the symptoms associated with chronic gastritis are typically less severe but more persistent. Nausea and upper abdominal pain are typical, sometimes with vomiting, but hematemesis is uncommon.

Helicobacter pylori Gastritis

H. pylori are spiral-shaped or curved bacilli present in gastric biopsy specimens of almost all patients with duodenal ulcers as well as most individuals with gastric ulcers or chronic gastritis. Acute *H. pylori* infection does not produce sufficient symptoms to come to medical attention in most cases; it is the chronic gastritis that ultimately causes the individual to seek treatment. *H. pylori* organisms are present in the majority of individuals with chronic antral gastritis.

Epidemiology. In the United States, *H. pylori* infection is associated with poverty, household crowding, limited education, residence in rural areas, birth outside of the United States, and age over 60 years. The prevalence of infection is also greater in those of African American or Mexican American ethnicity as well as some immigrant populations. Humans are the primary carriers, suggesting that transmission is primarily by the fecal-oral route. Infection is typically acquired in childhood and persists for life without treatment. Improved sanitation explains the marked reduction in *H. pylori* infection rates among younger people. In well-resourced countries, *H. pylori* infection is currently uncommon before 10 years of age, is found in only 10% of those between the ages of 18 and 30 years, but is present in up to 50% of those older than 65. It follows that environment during childhood is a critical risk factor for *H. pylori* colonization.

Pathogenesis

***H. pylori* infection most often presents as a predominantly antral gastritis with normal or increased acid production.** When inflammation remains limited to the antrum, modestly increased local gastrin production can augment parietal cell mass within the gastric body and increase acid secretion that leads to greater risk of gastric or duodenal peptic ulcer disease (see later). Alternatively, long-standing *H. pylori* gastritis may progress to involve the gastric body and fundus. This may result in atrophic gastritis with reduced parietal cell mass and intestinal metaplasia. In contrast to autoimmune gastritis (see later), atrophy induced by *H. pylori* is not associated with autoantibodies and is typically patchy. The loss of parietal cells leads to reduced acid secretion that, in turn, stimulates gastrin production. However, because some parietal cells survive, limited acid secretion continues and gastrin increases are not as great as those in autoimmune gastritis. Nevertheless, decreased acid secretion in *H. pylori* gastritis with atrophy reduces the risk of gastric and duodenal ulcers. This results in an inverse relationship between gastric adenocarcinoma, which is associated with atrophy and intestinal metaplasia, and duodenal ulcers, which are associated with increased acid secretion.

H. pylori organisms have adapted to the ecologic niche provided by gastric mucus. Its virulence is linked to the following factors:

- *Flagella,* which allow the bacteria to be motile in viscous mucus
- *Urease,* which generates ammonia from endogenous urea and thereby elevates local gastric pH and enhances bacterial survival
- *Adhesins* that enhance bacterial adherence to surface foveolar cells
- *Toxins,* such as cytotoxin-associated gene A *(CagA)*

Variation in these and other bacterial factors are strongly linked to outcome. For example, the *CagA* gene is present in 50% of *H. pylori* isolates overall but in 90% of *H. pylori* isolates in populations with an increased prevalence of gastric cancer. This may, in part, be because *CagA*-expressing strains colonize the gastric body and induce proinflammatory cytokine secretion, atrophy, and intestinal metaplasia more effectively than *CagA*-negative *H. pylori*.

Host factors also play an important role in the outcome of *H. pylori* infection. Genetic polymorphisms that lead to increased expression of the proinflammatory cytokines tumor necrosis factor (TNF) and interleukin (IL)-1β or decreased expression of the anti-inflammatory cytokine IL-10 seem to be associated with development of pangastritis, atrophy, intestinal metaplasia, and gastric cancer. The course of *H. pylori* gastritis is, therefore, the result of interplay between gastroduodenal mucosal defenses, host immune responses, and bacterial virulence factors.

MORPHOLOGY

Gastric biopsy specimens generally demonstrate *H. pylori* in infected individuals. The organism is concentrated within the superficial mucus overlying epithelial cells in the surface and neck regions. The distribution can be irregular, with areas of heavy colonization adjacent to those with few organisms. Organisms are most easily demonstrated with immunostains or histochemical stains (Fig. 17.13A).

The antrum is the preferred biopsy site for evaluation of *H. pylori* gastritis because it is most commonly infected. In dense colonization, organisms may also be found in oxyntic (acid-producing) mucosa of the fundus and body. *H. pylori*–infected antral mucosa is usually erythematous and has a coarse or even nodular appearance. The inflammatory infiltrate includes large numbers of plasma cells, often in clusters or sheets, within the superficial lamina propria. These are accompanied by increased numbers of lymphocytes, macrophages, and neutrophils within the lamina propria. Neutrophils infiltrate across the basement membrane (Fig. 17.13B) and accumulate in the lumens of gastric glands, or pits, to create pit abscesses. When intense, inflammatory infiltrates may create thickened rugal folds, mimicking the endoscopic appearance of early cancers. Lymphoid aggregates, some with germinal centers, are frequently present (Fig. 17.13C) and represent induced **mucosa-associated lymphoid tissue** (MALT) that has the potential to transform into lymphoma. Thus, chronic *H. pylori* gastritis is associated with increased risk of both gastric adenocarcinoma and lymphoma.

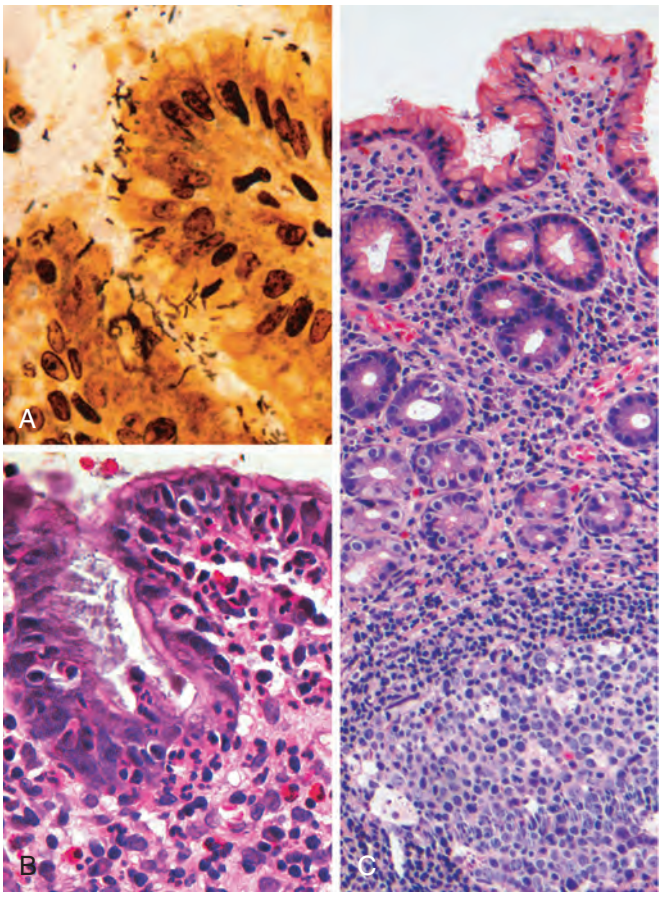

Figure 17.13 *Helicobacter pylori* gastritis. (A) Spiral-shaped *H. pylori* are highlighted in this Warthin-Starry silver stain. Organisms are abundant within surface mucus. (B) Intraepithelial and lamina propria neutrophils are prominent. (C) Lymphoid aggregates with germinal centers and abundant subepithelial plasma cells within the superficial lamina propria are characteristic of *H. pylori* gastritis.

Table 17.2 Characteristics of *Helicobacter pylori*–Associated and Autoimmune Gastritis

	H. pylori–Associated	Autoimmune
Location	Antrum	Body
Inflammatory infiltrate	Neutrophils, subepithelial plasma cells	Lymphocytes, macrophages
Acid production	Increased to slightly decreased	Decreased
Gastrin secretion	Normal to increased	Increased to markedly increased
Other lesions	Hyperplastic/ inflammatory polyps	Neuroendocrine hyperplasia
Serology	Antibodies to *H. pylori*	Antibodies to parietal cells (H^+,K^+-ATPase, intrinsic factor)
Sequelae	Peptic ulcer, adenocarcinoma, MALToma	Atrophy, pernicious anemia, adenocarcinoma, carcinoid tumor
Associations	Low socioeconomic status, poverty, residence in rural areas	Autoimmune disease: thyroiditis, diabetes mellitus, Graves disease

H^+,K^+ ATPase, Hydrogen potassium adenosine triphosphatase; *MALToma*, mucosa-associated lymphoid tissue lymphoma.

Clinical Features

The changes seen in atrophic *H. pylori* gastritis are sometimes referred to as environmental metaplastic atrophic gastritis, to distinguish it from autoimmune metaplastic atrophic gastritis (described next). In addition to histologic identification of the organism, several noninvasive diagnostic tests have been developed, including serology for antibodies to *H. pylori,* fecal bacterial detection, and the urea breath test, which is positive due to ammonia produced by the bacterial urease. Other diagnostic tests performed on biopsies include the rapid urease test, bacterial culture, or polymerase chain reaction (PCR)-based detection of *H. pylori* DNA.

Effective treatments for *H. pylori* infection include combinations of antibiotics and proton pump inhibitors. Individuals with *H. pylori* gastritis usually improve after treatment, although relapses can occur after incomplete eradication or re-infection, particularly in regions with high endemic colonization rates.

Autoimmune Atrophic Gastritis

Autoimmune atrophic gastritis, in contrast to *H. pylori*–associated gastritis, typically spares the antrum and is often associated with marked hypergastrinemia (Table 17.2). It accounts for less than 10% of cases of chronic gastritis and has an estimated prevalence of 2% in those over 60 years of age. Autoimmune atrophic gastritis is characterized by:

- Antibodies to parietal cells and intrinsic factor that can be detected in serum and gastric secretions
- Reduced serum pepsinogen I concentration
- Endocrine cell hyperplasia
- Vitamin B_{12} deficiency
- Defective gastric acid secretion (achlorhydria)

Pathogenesis

Autoimmune atrophic gastritis is associated with loss of parietal cells, which are responsible for secretion of gastric acid and intrinsic factor. The absence of acid production stimulates gastrin release, resulting in hypergastrinemia and hyperplasia of antral gastrin-producing G cells. Intrinsic factor loss results in defective ileal vitamin B_{12} absorption, which ultimately leads to vitamin B_{12} deficiency and *pernicious anemia* (a form of megaloblastic anemia described in Chapter 14). The high frequency of associated intestinal metaplasia has led to the term *autoimmune metaplastic atrophic gastritis*.

CD4+ T cells directed against parietal cell components, including hydrogen potassium adenosine triphosphatase (H^+,K^+-ATPase), are considered to be the principal agents of injury in autoimmune atrophic gastritis. This is supported by the observation that transfer of H^+,K^+-ATPase–reactive CD4+ T cells into naïve mice results in gastritis and production of H^+,K^+-ATPase autoantibodies. There is no evidence of an autoimmune reaction to chief cells, suggesting that these may be lost through gastric gland destruction

during autoimmune attack on parietal cells. If autoimmune destruction is controlled by immunosuppression, the glands can repopulate, demonstrating that gastric stem cells survive and are able to differentiate into parietal and chief cells.

Autoantibodies to parietal cell components, most prominently H^+,K^+-ATPase, or proton pump, and intrinsic factor are present in up to 80% of patients with autoimmune atrophic gastritis. However, these antibodies are not thought to be pathogenic because neither secreted intrinsic factor nor the luminally oriented proton pump is accessible to circulating antibodies, and passive transfer of these antibodies does not produce gastritis in experimental animals.

MORPHOLOGY

Autoimmune atrophic gastritis is characterized by diffuse damage to the oxyntic (acid-producing) mucosa within the body and fundus. The antrum and cardia are typically spared. With diffuse atrophy, oxyntic mucosa of the body and fundus appears markedly thinned, and rugal folds are lost. If vitamin B_{12} deficiency is severe, nuclear enlargement (megaloblastic change) occurs within epithelial cells. Neutrophils may be present, but the inflammatory infiltrate is typically composed of lymphocytes, macrophages, and plasma cells, often in association with lymphoid aggregates and follicles. In contrast to the superficial lamina propria inflammation that is typical of *H. pylori* gastritis, inflammation in autoimmune atrophic gastritis is deeper and centered on the gastric glands (Fig. 17.14A). Loss of parietal and chief cells can be extensive. When atrophy is incomplete, residual islands of oxyntic mucosa may give the appearance of multiple small polyps or nodules. In other areas, small surface elevations may represent sites of intestinal metaplasia, characterized by the presence of goblet cells and columnar absorptive cells (Fig. 17.14B). Endocrine and enterochromaffin-like cell hyperplasia is commonly present. Rarely, endocrine cell hyperplasia may progress to form small, multicentric, low-grade neuroendocrine (carcinoid) tumors.

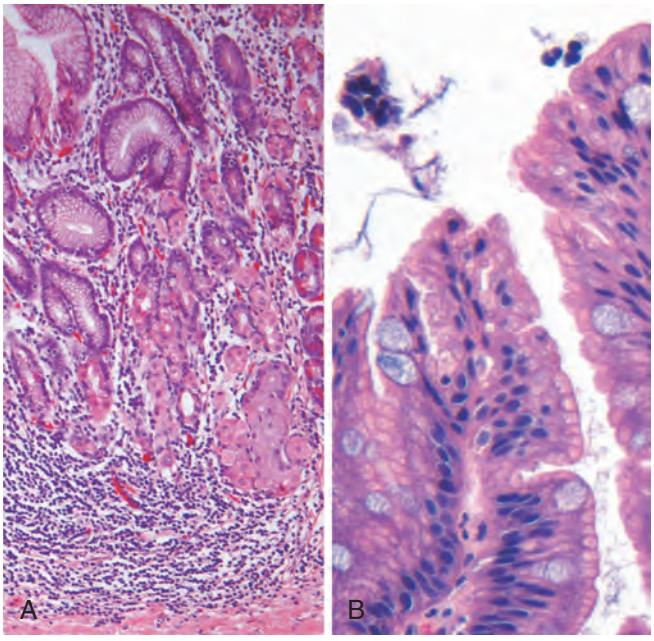

Figure 17.14 Autoimmune gastritis. (A) Low-magnification image of gastric body demonstrating deep inflammatory infiltrates, primarily composed of lymphocytes, and glandular atrophy. (B) Intestinal metaplasia, recognizable as the presence of goblet cells within gastric foveolar epithelium.

Clinical Features

Antibodies to parietal cells and intrinsic factor are present 2 to 3 decades before the appearance of gastric atrophy and other complications such as pernicious anemia; hence, progression to clinically evident disease is slow. The median age at diagnosis is 60. Slightly more women than men are affected, and there does not appear to be an ethnic or racial bias. Pernicious anemia and autoimmune atrophic gastritis are often associated with other autoimmune diseases including Hashimoto thyroiditis, type 1 diabetes mellitus, Addison disease, and others. These associations, along with concordance in some monozygotic twins and clustering of disease in families, support a genetic predisposition. Nevertheless, there is little evidence of linkage between autoimmune gastritis and specific human leukocyte antigen (HLA) alleles.

The clinical features are mainly related to vitamin B_{12} deficiency, including megaloblastic anemia (Chapter 14); atrophic glossitis, in which the tongue becomes smooth and beefy red; epithelial megaloblastosis; malabsorptive diarrhea; and many others (see Chapter 28). Clinical features and pathologic changes related to the effects of vitamin B_{12} deficiency in the marrow and the CNS (e.g., subacute combined degeneration of the spinal cord) are described in detail in Chapters 14 and 28, respectively.

Uncommon Forms of Gastritis

Eosinophilic Gastritis. Eosinophilic gastritis is characterized by tissue damage associated with dense infiltrates of eosinophils in the mucosa and muscularis, usually in the antral or pyloric region. The lesion may also be present at other sites within the GI tract and is associated with peripheral eosinophilia and increased serum IgE levels. Allergic reactions are one cause of eosinophilic gastritis, with cow's milk and soy protein being the most common allergens in children. Eosinophilic gastritis can also occur in association with immune disorders such as systemic sclerosis and inflammatory myopathy, parasitic infections, and even *H. pylori* infection.

Lymphocytic Gastritis. This disease preferentially affects women and produces nonspecific abdominal symptoms. It is idiopathic, but approximately 40% of cases are associated with celiac disease, suggesting an immune-mediated pathogenesis. Lymphocytic gastritis typically affects the entire stomach and is often referred to as *varioliform gastritis* based on the distinctive endoscopic appearance (characterized by thickened folds covered by small nodules with central aphthous ulceration). Histologically there is a marked increase in the number of intraepithelial T lymphocytes.

Granulomatous Gastritis. The descriptive term granulomatous gastritis is applied to any gastritis that contains

granulomas. It encompasses a diverse group of diseases with widely varying clinical and pathologic features. Many cases are idiopathic. In Western populations, gastric involvement by Crohn disease is the most common specific cause of granulomatous gastritis followed by sarcoidosis and infections (including mycobacteria, fungi, CMV, and *H. pylori*). In addition to the presence of histologically evident granulomas, narrowing and rigidity of the gastric antrum may occur secondary to transmural granulomatous inflammation.

Peptic Ulcer Disease

Peptic ulcer disease (PUD) refers to chronic mucosal ulceration affecting the duodenum or stomach and is almost always associated with *H. pylori* infection, NSAIDs, or cigarette smoking. The most common form of PUD occurs within the gastric antrum or duodenum as a result of chronic *H. pylori*–induced antral gastritis, which is associated with increased gastric acid secretion and decreased duodenal bicarbonate secretion. As mentioned earlier, *H. pylori* infection involving the gastric fundus or body is usually accompanied by more modestly increased acid secretion due to associated gastric atrophy. Because of reduced acid secretion, individuals with gastric mucosal atrophy are generally protected from antral and duodenal ulcers. Acid secreted by ectopic gastric mucosa within the duodenum, an ileal Meckel diverticulum, or esophageal ectopic gastric mucosa (an inlet patch) may also cause PUD.

Epidemiology. The incidence of PUD is falling along with reduced prevalence of *H. pylori* infection. However, PUD in patients older than 60 years has increased due to growing NSAID use. This can be amplified by *H. pylori* infection, which synergizes with low-dose aspirin (for cardiovascular benefits) to induce gastric injury. PUD is also associated with cigarette use and cardiovascular disease, likely due to reduced mucosal blood flow, oxygenation, and healing. Other risk factors for PUD are listed in Table 17.3.

Pathogenesis

PUD results from imbalances between defense mechanisms and damaging factors that cause chronic gastritis (discussed earlier). Thus, PUD generally develops on a background of chronic gastritis. The reasons why some people develop only chronic gastritis while others develop PUD are poorly understood. However, as with *H. pylori* gastritis, it is likely that host factors as well as variation in pathogenicity of bacterial strains are involved.

Table 17.3 Risk Factors for Peptic Ulcer Disease

- *Helicobacter pylori* infection
- Cigarette use (synergizes with *H. pylori* for gastric PUD)
- Chronic obstructive pulmonary disease
- Illicit drugs, e.g., cocaine, that reduce mucosal blood flow
- NSAIDs (potentiated by corticosteroids)
- Alcoholic cirrhosis (primarily duodenal PUD)
- Psychological stress (can increase gastric acid secretion)
- Endocrine cell hyperplasia (can stimulate parietal cell growth and gastric acid secretion)
- Zollinger-Ellison syndrome (PUD of stomach, duodenum, and jejunum)
- Viral infection (CMV, herpes simplex virus)

CMV, Cytomegalovirus; *NSAIDs,* non-steroidal anti-inflammatory drugs; *PUD,* peptic ulcer disease.

MORPHOLOGY

Peptic ulcers occur in the context of chronic gastritis but are most frequently found in the proximal duodenum, within a few centimeters of the pyloric valve. Foveolar metaplasia, in which gastric-type mucus cells are present, is common in chronic duodenal peptic disease and may be a protective response, as gastric epithelia are less sensitive to acid than intestinal epithelia. Gastric peptic ulcers are predominantly located along the lesser curvature near the interface of the body and antrum.

Peptic ulcers are solitary in more than 80% of patients and form a round to oval, **sharply punched-out defect** (Fig. 17.15A). The mucosal margin is usually level with the surrounding mucosa but may overhang the base, particularly on the proximal side. In contrast, **heaped-up margins are more characteristic of cancers.** The depth of ulcers correlates with diameter, and deep extension may be limited by the thick gastric muscularis propria, adherent pancreas, omental fat, or the liver. **Perforation** into the

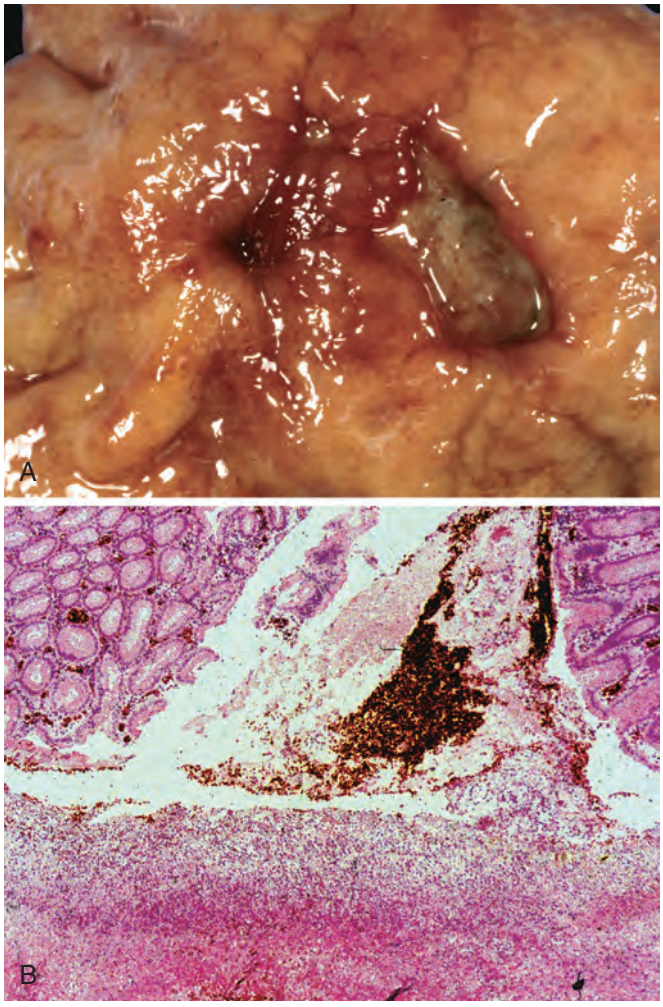

Figure 17.15 Acute gastric perforation in a patient presenting with free air under the diaphragm. (A) Mucosal defect with clean edges. (B) The necrotic ulcer base is composed of granulation tissue.

peritoneal cavity is a surgical emergency that may be identified as free air under the diaphragm on upright abdominal radiographs.

The base of peptic ulcers is smooth and clean as a result of peptic digestion of exudate. Active ulcers may be lined by a thin layer of fibrinoid debris with a predominantly neutrophilic inflammatory infiltrate. Beneath this, **granulation tissue** with immature vessels, mononuclear leukocytes, and a fibrous or collagenous scar forms the ulcer base (Fig. 17.15B). Larger vessels within the scarred area are typically thickened and are occasionally thrombosed. Bleeding from these vessels may cause life-threatening **hemorrhage.** Scarring may involve the entire thickness of the wall and draw the surrounding mucosa into folds that radiate outward.

Clinical Features

Peptic ulcers typically come to clinical attention because of epigastric burning or aching pain. Others present with iron deficiency anemia, hemorrhage, or perforation (Table 17.4). The pain tends to occur 1 to 3 hours after meals during the day, is worse at night (usually between 11 p.m. and 2 a.m.), and is relieved by alkali or food. Nausea, vomiting, bloating, belching, and significant weight loss are additional manifestations. With penetrating ulcers the pain is occasionally referred to the back, left upper quadrant, or chest, where it may be misinterpreted as cardiac in origin.

Current therapies for PUD are aimed at *H. pylori* eradication and neutralization of gastric acid, primarily with proton pump inhibitors. It is also important to withdraw other offending agents such as NSAIDs, including selective COX-2 inhibitors, that may interfere with mucosal healing. While peptic ulcers were previously notoriously difficult to eradicate, the recurrence rate is now less than 20% following successful clearance of *H. pylori*.

Other Complications of Chronic Gastritis

Mucosal Atrophy and Intestinal Metaplasia

As noted above, chronic gastritis may lead to significant loss of parietal cell mass. This oxyntic atrophy is frequently associated with intestinal metaplasia, recognized by the presence of goblet cells, and is strongly associated with increased risk of gastric adenocarcinoma. The risk of adenocarcinoma is greatest in autoimmune metaplastic atrophic gastritis. This may be because achlorhydria of gastric mucosal atrophy permits overgrowth of bacteria that produce carcinogenic nitrosamines. Intestinal metaplasia also occurs in chronic *H. pylori* gastritis but may regress after clearance of the organism.

Table 17.4 Complications of Peptic Ulcer Disease

Bleeding
Occurs in 15%–20% of patients
Most frequent complication
May be life threatening
Accounts for 25% of ulcer-related deaths
May be the first indication of an ulcer
Perforation
Occurs in up to 5% of patients
Accounts for two-thirds of ulcer-related deaths
Is rarely first indication of an ulcer
Obstruction
Mostly in chronic ulcers
Secondary to edema or scarring
Occurs in about 2% of patients
Most often associated with pyloric channel ulcers
May occur with duodenal ulcers
Causes incapacitating, crampy abdominal pain
Can rarely cause total obstruction and intractable vomiting

Dysplasia

Chronic gastritis exposes the epithelium to inflammation-related free radical damage and proliferative stimuli that include regenerative responses to injury and increased production of gastrin, a gastric epithelial mitogen. Over time this combination of stressors can lead to the accumulation and amplification of genetic alterations that result in carcinoma. Preinvasive in situ lesions can be recognized histologically as dysplasia. The morphologic hallmarks of dysplasia are variations in epithelial size, shape, and orientation along with coarse chromatin texture, hyperchromasia, and nuclear enlargement. The distinction between dysplasia and regenerative epithelial changes induced by active inflammation can be a challenge for the pathologist, since increased epithelial proliferation and mitotic figures may be prominent in both. One clue is that reactive epithelial cells mature as they reach the mucosal surface, while dysplastic lesions remain cytologically immature.

Gastritis Cystica

Gastritis cystica is an exuberant reactive epithelial proliferation associated with entrapment of epithelial-lined cysts. These may be found within the submucosa (gastritis cystica polyposa) or deeper layers of the gastric wall (gastritis cystica profunda). Because of the association with chronic gastritis and partial gastrectomy, it is presumed that gastritis cystica is trauma-induced, but the reasons for the development of epithelial cysts within deeper portions of the gastric wall are not clear. Regenerative epithelial changes can be prominent in the entrapped epithelium, and gastritis cystica can therefore be mistaken for invasive adenocarcinoma.

HYPERTROPHIC GASTROPATHIES

Hypertrophic gastropathies are uncommon diseases characterized by giant "cerebriform" enlargement of the rugal folds due to epithelial hyperplasia without inflammation. As might be expected, the hypertrophic gastropathies are linked to excessive growth factor release. Two well-defined examples are Ménétrier disease and Zollinger-Ellison syndrome, the morphologic features of which are compared with other gastric proliferations in Table 17.5.

Ménétrier Disease

Ménétrier disease is a rare disorder associated with excessive secretion of transforming growth factor (TGF)-α, which is an EGF receptor (EGFR) ligand, and hyperactivation of the epidermal growth factor receptor on gastric epithelial cells. Some cases occur in association with viral or *H. pylori* infection. Diffuse hyperplasia of foveolar epithelium within the body and fundus as well as hypoproteinemia due to

Table 17.5 Hypertrophic Gastropathies and Gastric Polyps

Parameter	Ménétrier Disease (Adult)	Zollinger-Ellison Syndrome	Inflammatory and Hyperplastic Polyps	Gastritis Cystica	Fundic Gland Polyps	Gastric Adenomas
Mean patient age, years	30–60	50	50–60	Variable	50	50–60

Predominant cell type	Mucous	Parietal > mucous, endocrine	Mucous	Mucous, cyst-lining	Parietal and chief	Dysplastic, intestinal
Inflammatory infiltrate	Limited, lymphocytes	Neutrophils	Neutrophils and lymphocytes	Neutrophils and lymphocytes	None	Variable
Symptoms	Hypoproteinemia, weight loss, diarrhea	Peptic ulcers	Similar to chronic gastritis	Similar to chronic gastritis	None, nausea	Similar to chronic gastritis
Risk factors	None	Multiple endocrine neoplasia	Chronic gastritis, *H. pylori*	Trauma, prior surgery	PPIs, FAP	Chronic gastritis, atrophy, intestinal metaplasia
Association with adenocarcinoma	Yes	No	Occasional	No	Syndromic (FAP) only	Frequent

FAP, Familial adenomatous polyposis; *PPIs*, proton pump inhibitors.

albumin loss, which can approach 10 g/day, across the gastric mucosa characterize Ménétrier disease. Secondary symptoms such as weight loss, diarrhea, and peripheral edema are commonly present. Systemic effects of TGF-α, including hyperplasia of the liver, pancreas, and GI tract (beyond the stomach), muscle and adipose tissue loss, and psoriasis, may also be present. Symptoms and pathologic features of Ménétrier disease in children are similar to those in adults, but pediatric disease is usually self-limited and often follows CMV or another respiratory infection. Risk of gastric adenocarcinoma is increased in adults with Ménétrier disease.

MORPHOLOGY

Ménétrier disease is characterized by irregular enlargement of the gastric rugae. Some areas may appear polypoid. Enlarged rugae are present in the body and fundus (Fig. 17.16A), but the antrum is generally spared. Histologically, the most characteristic feature is hyperplasia of foveolar mucous cells. The glands are elongated with a corkscrew-like appearance, and cystic dilation is common (Fig. 17.16B). Inflammation is usually modest, although some cases show marked intraepithelial lymphocytosis. Diffuse or patchy glandular atrophy, evident as hypoplasia of parietal and chief cells, is typically intermixed with epithelial hyperplasia.

Treatment of Ménétrier disease is supportive, with intravenous albumin and parenteral nutritional supplementation. In cases associated with herpesvirus, CMV, or *H. pylori,* treatment of the infection may be helpful. Antibodies that block epidermal growth factor receptor activation are effective in many cases. In severe cases gastrectomy remains a therapeutic option.

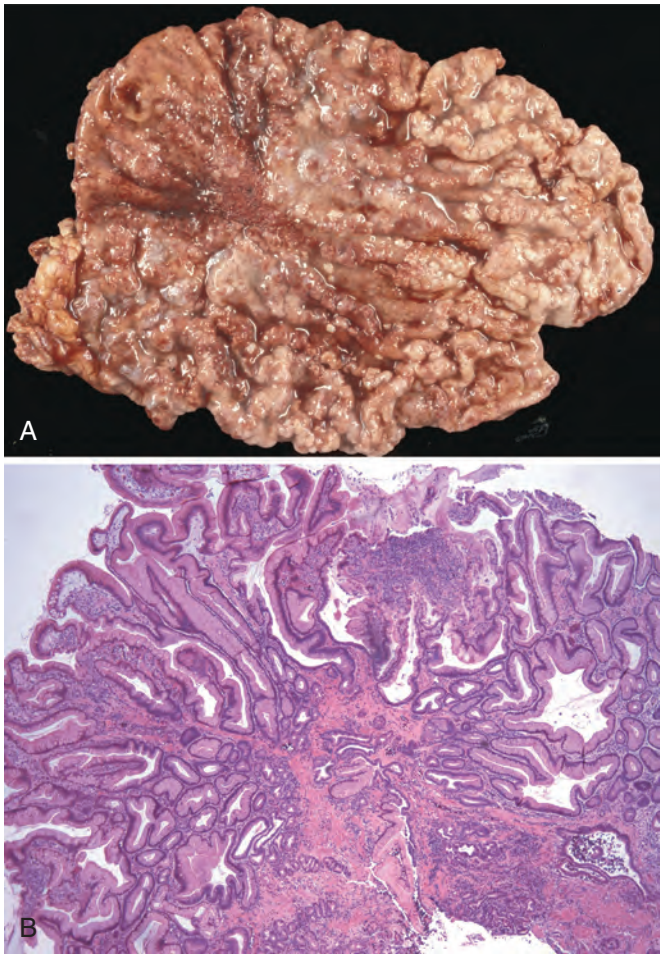

Figure 17.16 Ménétrier disease. (A) Marked hypertrophy of rugal folds. (B) Foveolar hyperplasia with elongated and focally dilated glands. (Courtesy Dr. M. Kay Washington, Vanderbilt University, Nashville, Tenn.)

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome is caused by gastrin-secreting neuroendocrine tumors. These gastrinomas are almost always found in the small intestine or pancreas. Patients often present with duodenal ulcers or chronic diarrhea. Within the stomach, the most remarkable feature is a marked increase in oxyntic mucosal thickness due to massive parietal cell hyperplasia. Gastrin also induces hyperplasia of mucous neck and endocrine cells within oxyntic mucosa.

Treatment of individuals with Zollinger-Ellison syndrome includes blockade of acid hypersecretion, typically with proton pump inhibitors. Acid suppression allows peptic ulcers to heal and prevents gastric perforation, allowing treatment to focus on the gastrinoma, which then becomes the main determinant of long-term survival.

Gastrinomas are sporadic, solitary lesions in 75% of patients. The remaining 25% of patients with gastrinomas have multiple endocrine neoplasia type 1 (MEN1). These patients are younger and primarily have duodenal tumors that commonly metastasize. *MEN1* gene mutations in sporadic gastrinomas are also associated with aggressive tumor behavior. Somatostatin receptor scintigraphy or endoscopic ultrasonography can help with identification. Patients with metastatic disease may benefit from treatment with somatostatin analogues.

KEY CONCEPTS

GASTRITIS

- Gastritis is a mucosal inflammatory process. When inflammatory cells are absent or rare, the term gastropathy can be applied.
- The clinical spectrum of acute gastritis ranges from asymptomatic disease to mild epigastric pain, nausea, and vomiting. Causative factors include any agent or disease that interferes with gastric mucosal protective mechanisms.
- The most common cause of chronic gastritis is *H. pylori* infection. Other injurious agents include NSAIDs and alcohol.
- *H. pylori* gastritis typically affects the antrum and is associated with increased gastric acid production. Later in the course of disease, the body can be involved, and resulting glandular atrophy can lead to mildly reduced acid production. Host immune responses and bacterial characteristics determine whether the infection remains antral or progresses to pangastritis and atrophy.
- *H. pylori* gastritis induces MALT that can give rise to B-cell lymphomas (MALTomas).
- After *H. pylori* and NSAIDs, autoimmune atrophic gastritis is the most frequent cause of chronic gastritis. It results in atrophy of the gastric body oxyntic glands, which leads to decreased gastric acid production, antral G-cell hyperplasia, and vitamin B_{12} deficiency. Anti–parietal cell and anti–intrinsic factor antibodies are typically present.
- Intestinal metaplasia develops in all forms of chronic gastritis and is a risk factor for gastric adenocarcinoma.
- Peptic ulcer disease is usually secondary to chronic *H. pylori*–induced gastritis and the resulting hyperchlorhydria. Ulcers can develop in the stomach or duodenum and usually heal after suppression of gastric acid production and *H. pylori* eradication.
- Ménétrier disease is a rare disorder caused by excessive secretion of TGF-α and characterized by diffuse foveolar hyperplasia and protein-losing enteropathy.
- Zollinger-Ellison syndrome is caused by gastrin-secreting tumors that cause parietal cell hyperplasia and acid hypersecretion; 60% to 90% of these gastrinomas are malignant.

GASTRIC POLYPS AND TUMORS

Polyps, nodules or masses that project above the level of the surrounding mucosa, are identified in up to 5% of upper GI endoscopies. Polyps may develop as a result of epithelial or stromal cell hyperplasia, inflammation, ectopia, or neoplasia. Only the most common types of gastric polyps will be discussed here (Peutz-Jeghers and juvenile polyps are discussed with intestinal polyps later).

Inflammatory and Hyperplastic Polyps

Up to 75% of all gastric polyps are inflammatory or hyperplastic polyps. Their incidence is correlated with the regional prevalence of *H. pylori* infection. These polyps are most common in individuals between 50 and 60 years of age and usually develop in association with chronic gastritis, which initiates the injury that leads to reactive hyperplasia and polyp growth. The risk of dysplasia in inflammatory polyps ranges from 1% to 20% and increases sharply in pedunculated polyps greater than 1 cm in diameter.

MORPHOLOGY

The majority of inflammatory or hyperplastic polyps are smaller than 1 cm in diameter. Polyps are frequently multiple, particularly in individuals with atrophic gastritis. Hyperplastic polyps are ovoid in shape and have a smooth surface; superficial erosions are common in inflammatory polyps. Microscopically, polyps have irregular, cystically dilated, and elongated foveolar glands (Fig. 17.17A). The lamina propria is typically edematous with variable degrees of acute and chronic inflammation (Fig. 17.17B).

Fundic Gland Polyps

Fundic gland polyps occur sporadically and in individuals with germline mutations in the *APC* gene (the cause of familial adenomatous polyposis) or the DNA repair gene *MUTYH* (both discussed later). The prevalence of sporadic fundic gland polyps has increased markedly in recent years as a result of increased use of proton pump inhibitors. These drugs inhibit acid production, which leads to increased gastrin secretion and, in turn, oxyntic gland growth. Fundic gland polyps may be asymptomatic or associated with nausea, vomiting, or epigastric pain.

MORPHOLOGY

Fundic gland polyps occur in the gastric body and fundus and are well-circumscribed lesions with a smooth surface. They may be

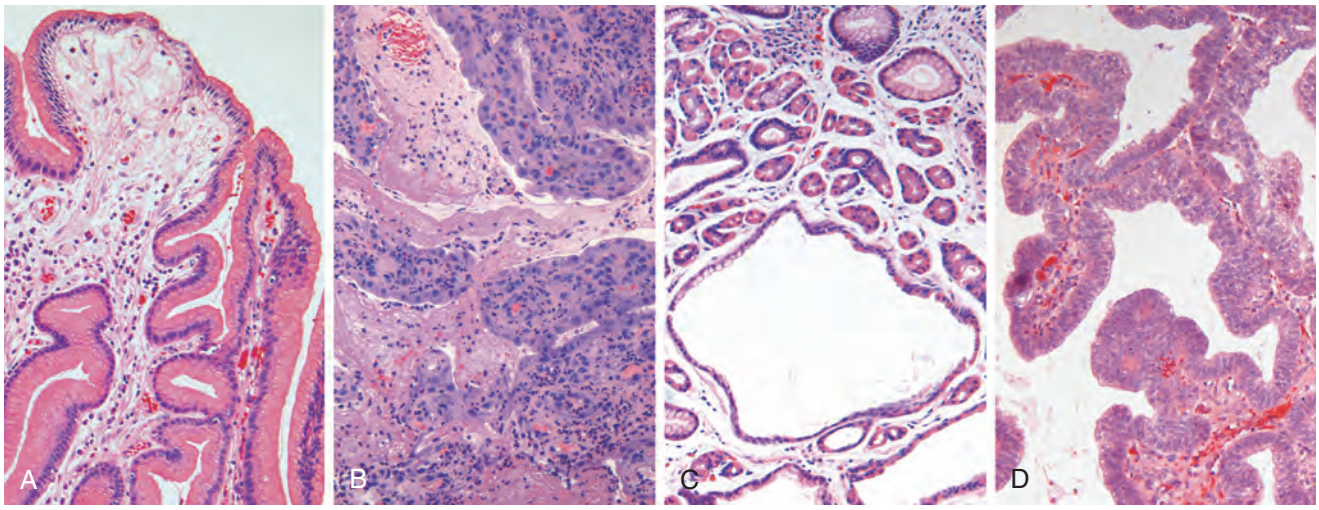

Figure 17.17 Gastric polyps. (A) Hyperplastic polyp containing corkscrew-shaped foveolar glands. (B) Hyperplastic polyp with extensive ulceration. (C) Fundic gland polyp composed of cystically dilated glands lined by parietal, chief, and foveolar cells. (D) Gastric adenoma with epithelial nuclear hyperchromasia and pseudostratification.

single or multiple and are composed of cystically dilated, irregular glands lined by parietal, chief, and foveolar mucus cells. Inflammation is typically absent or minimal (Fig. 17.17C). Dysplasia may occur in FAP-associated fundic gland polyps, and rare cancers have been reported. In contrast, sporadic fundic gland polyps, including those arising in association with proton pump inhibitor therapy, do not carry a significant risk of neoplasia.

Gastric Adenoma

Most gastric adenomas develop in a background of chronic gastritis with atrophy and intestinal metaplasia, with the exception of those associated with germline mutations in *APC* or *MUTYH*. They represent up to 10% of all gastric polyps (see Table 17.5). Their frequency increases progressively with age, and there is a marked variation in prevalence among different populations that parallels the incidence of gastric adenocarcinoma. Patients are usually between 50 and 60 years of age, and males are affected three times more often than females. The risk of adenocarcinoma within gastric adenomas correlates with size and is particularly elevated in lesions greater than 2 cm in diameter. Gastric adenomas have a greater risk of cancer (up to 30% when large) and must be managed more aggressively than colonic adenomas.

MORPHOLOGY

Gastric adenomas are usually solitary antral lesions. All GI adenomas exhibit dysplasia, which is classified as low- or high-grade (Fig. 17.17D). Both grades of dysplasia are characterized by nuclear enlargement, elongation, pseudostratification, and hyperchromasia. High-grade dysplasia is marked by more severe cytologic atypia and architectural abnormalities, including glandular budding and gland-within-gland, or cribriform, structures.

Gastric Adenocarcinoma

Adenocarcinoma is the most common malignancy of the stomach, comprising more than 90% of all gastric cancers. As discussed in more detail later, gastric adenocarcinoma is separated morphologically into intestinal type, which tends to form bulky masses, and diffuse type, which infiltrates and thickens the gastric wall. Early symptoms of both types of gastric adenocarcinoma resemble those of chronic gastritis and peptic ulcer disease, including dyspepsia, dysphagia, and nausea. As a result, these tumors are often discovered at advanced stages, when symptoms such as weight loss, anorexia, early satiety (primarily in diffuse cancers), anemia, and hemorrhage appear.

Epidemiology. Gastric cancer incidence varies markedly with geography. In Japan, Chile, Costa Rica, and Eastern Europe, the incidence is up to 20-fold higher than in North America, northern Europe, Africa, and Southeast Asia. Mass endoscopic screening programs have been successful in regions where the incidence is high, such as Japan, where 35% of newly detected cases are early gastric cancers, limited to the mucosa and submucosa. Unfortunately, mass screening programs are not cost-effective in low-incidence regions, and fewer than 20% of cases are detected at an early stage in North America and northern Europe. Metastases are often present at diagnosis. Sites most commonly involved include supraclavicular sentinel lymph nodes (Virchow node), periumbilical lymph nodes (Sister Mary Joseph nodule), ovaries (Krukenberg tumor), the left axillary lymph node, and the pouch of Douglas.

Gastric cancer is more common in lower socioeconomic groups and in individuals with multifocal mucosal atrophy and intestinal metaplasia. As noted earlier, peptic ulcer disease is associated with reduced risk of gastric cancer, but patients who have had partial gastrectomies for peptic ulcer disease have a slightly higher risk of developing cancer in the residual gastric stump, possibly due to hypochlorhydria and bile reflux.

Adenocarcinoma of the stomach was the most common cause of cancer death in the United States in 1930. However, since that time the incidence has fallen by 85%, and, gastric adenocarcinoma now accounts for only 2.5% of cancer deaths in the United States. Decreased gastric cancer incidence is largely attributed to reduced rates of *H. pylori* infection and primarily relates to intestinal-type cancers. Other environmental and dietary factors, including decreased consumption of dietary carcinogens such as N-nitroso compounds and benzo[*a*]pyrene (because of the reduced use of salt and smoking for food preservation) and the widespread availability of refrigeration may have also contributed to the decreased incidence. Consistent with an environmental, rather than genetic, cause, migrants from high- to low-risk regions maintain the risk of their original country, but their children have gastric cancer rates similar to those in the new country of residence.

Although the overall incidence of gastric adenocarcinoma is falling, cancer of the gastric cardia is on the rise. This is probably related to Barrett esophagus and may reflect the increasing incidence of chronic GERD and obesity. Consistent with this presumed shared pathogenesis, gastric cardia adenocarcinomas and distal esophageal adenocarcinomas are similar in morphology, clinical behavior, and therapeutic responses.

Pathogenesis

While the majority of gastric cancers are not hereditary, mutations identified in familial gastric cancer have provided important insights into mechanisms of carcinogenesis in sporadic cases. Familial gastric cancer is strongly associated with germline loss-of-function mutations in the tumor suppressor gene *CDH1,* which encodes the cell adhesion protein E-cadherin (discussed in Chapter 7). Loss-of-function mutations in *CDH1* are also present in about 50% of sporadic diffuse gastric tumors, while E-cadherin expression is drastically decreased in the remainder of diffuse tumors, often by hypermethylation and silencing of the *CDH1* promoter. **Thus, E-cadherin loss is a key step in the development of diffuse gastric cancer.** *CDH1* mutations are also common in sporadic and familial lobular carcinoma of the breast, which, like diffuse gastric cancer (see later), tends to infiltrate as single cells.

In contrast to diffuse gastric cancers, **intestinal-type gastric cancers are strongly associated with mutations that result in increased signaling via the Wnt pathway.** These include loss-of-function mutations in the adenomatous polyposis coli *(APC)* tumor suppressor gene and gain-of-function mutations in the gene encoding β-catenin. Other genes commonly affected by loss-of-function mutations or silencing include those involved in TGF-β signaling *(TGFβRII),* regulation of apoptosis *(BAX),* and cell cycle control *(CDKN2A),* all of which are discussed in more detail in Chapter 7. FAP patients with germline *APC* mutations have an increased risk of intestinal-type gastric cancer, particularly in those who reside in high-risk areas like Japan. Variants of pro-inflammatory genes such as IL-1β and IL-1 receptor, are associated with elevated risk of gastric cancer in those who have *H. pylori* gastritis. Thus, both host genetic background and environmental factors affect risk. Other associations between chronic inflammation and cancer are discussed later in the context of inflammatory bowel disease (IBD) and in Chapter 7.

MORPHOLOGY

Gastric adenocarcinomas are classified according to their location and gross and histologic morphology. Most distal gastric adenocarcinomas occur in the gastric antrum; the lesser curvature is involved more often than the greater curvature. Gastric tumors with an **intestinal morphology form bulky tumors** (Fig. 17.18A) and are composed of glandular structures (Fig. 17.19A), while cancers with a **diffuse infiltrative growth pattern** (Fig. 17.18B) are typically composed of **signet-ring cells** (Fig. 17.19B). Although they may penetrate the gastric wall, intestinal-type adenocarcinomas frequently grow along broad cohesive fronts to form either an exophytic mass or an ulcerated infiltrative tumor. The neoplastic cells often contain apical mucin vacuoles, and abundant mucin may be present in gland lumina. In contrast, diffuse cancers permeate the gastric wall as small clusters and individual discohesive cells due to the absence of E-cadherin. These cells do not form glands but instead have large mucin vacuoles that expand the cytoplasm and push the nucleus to the periphery, creating a signet-ring cell morphology. They be mistaken for inflammatory cells at low magnification. Release of extracellular

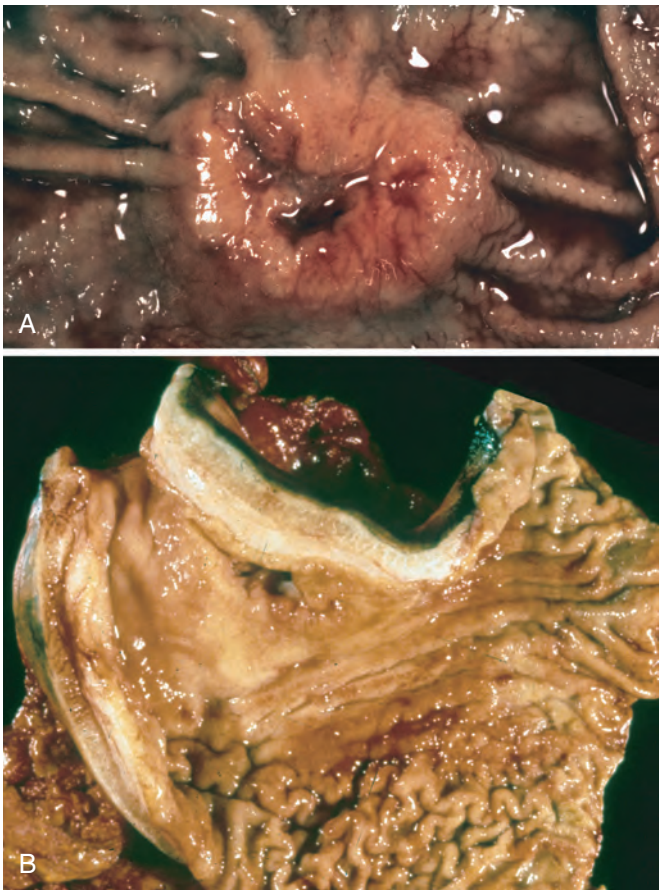

Figure 17.18 Gastric adenocarcinoma. (A) Intestinal-type adenocarcinoma consisting of an elevated mass with heaped-up borders and central ulceration. Compare to the peptic ulcer in Fig. 17.15A. (B) Infiltrative type (linitis plastica) gastric cancer. The gastric wall is markedly thickened, and rugal folds are partially lost, but there is no dominant mass.

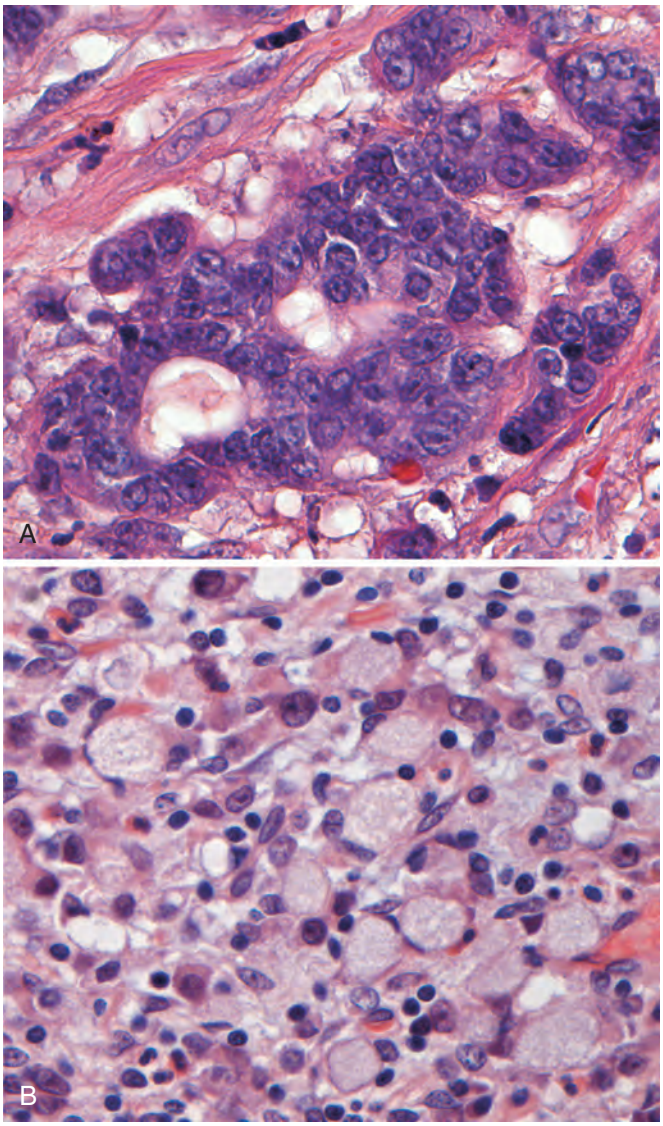

Figure 17.19 Gastric adenocarcinoma. (A) Intestinal-type adenocarcinoma composed of columnar, gland-forming cells infiltrating through desmoplastic stroma. (B) In infiltrative tumors, signet-ring cells can be recognized by their large cytoplasmic mucin vacuoles and peripherally displaced, crescent-shaped, thin nuclei. Note the absence of gland formation.

mucin in either type of gastric cancer can result in formation of large mucin lakes that dissect tissue planes.

A mass may be difficult to appreciate in diffuse gastric cancer, but these infiltrative tumors often evoke a **desmoplastic** reaction that stiffens the gastric wall. When there are large areas of infiltration, diffuse rugal flattening and a rigid, thickened wall may impart a leather bottle appearance termed **linitis plastica** (Fig. 17.18B).

Clinical Features

Intestinal-type gastric cancer predominates in high-risk areas and develops from precursor lesions including flat dysplasia and adenomas. The mean age of presentation is 55 years, and the male-to-female ratio is 2:1. In contrast, the incidence of diffuse gastric cancer is relatively uniform across countries, and there are no identified precursor lesions; prevalence is similar in males and females. Notably, the remarkable decrease in gastric cancer incidence applies only to the intestinal type. As a result, the incidences of intestinal- and diffuse-type gastric cancers are now similar in many regions.

The depth of invasion and the extent of nodal and distant metastases remain the most powerful prognostic indicators in gastric cancer. Local invasion into the duodenum, pancreas, and retroperitoneum is common. In such cases efforts are usually focused on chemotherapy or radiation therapy and palliative care. When possible, surgery remains the preferred treatment approach. With surgical resection, the 5-year survival rate of early gastric cancer can exceed 90%, even if lymph node metastases are present. In contrast, the 5-year survival rate for advanced gastric cancer remains less than 20%. Because of the advanced stage at which most gastric cancers are discovered in the United States, the overall 5-year survival is less than 30%.

Lymphoma

Although extranodal lymphomas can arise in virtually any tissue, they do so most commonly in the GI tract, particularly the stomach. In allogeneic hematopoietic stem cell and organ transplant recipients, the bowel is also the most frequent site for Epstein-Barr virus–positive B-cell lymphoproliferations. This preferential location is most likely because the deficits in T-cell function caused by oral immunosuppressive agents (e.g., cyclosporine) are greatest at intestinal sites of drug absorption. Nearly 5% of all gastric malignancies are primary lymphomas, the most common of which are indolent extranodal marginal zone B-cell lymphomas. In the gut these tumors are often referred to as lymphomas of MALT, or MALTomas. These and other lymphomas of the gut are discussed in Chapter 13.

Pathogenesis

Extranodal marginal zone B-cell lymphomas usually arise at sites of chronic inflammation. They can originate in the GI tract at sites of preexisting MALT such as the Peyer patches of the small intestine, but more commonly arise within tissues that are normally devoid of organized lymphoid tissue. MALT is not present in the normal stomach but can be induced, typically as a result of chronic gastritis. *H. pylori* infection is the most common inducer of gastric MALT and therefore is found in association with most gastric MALTomas.

Three translocations are associated with gastric MALToma: t(11;18)(q21;q21), the less common t(1;14)(p22;q32), and t(14;18)(q32;q21). The t(11;18)(q21;q21) translocation brings together the apoptosis inhibitor 2 *(API2)* gene on chromosome 11 with the "mutated in MALT lymphoma" *(MLT1)* gene on chromosome 18. This creates a chimeric *API2-MLT1* fusion gene that encodes an API2-MALT1 fusion protein. The t(14;18)(q32;q21) and t(1;14)(p22;q32) translocations cause increased expression of intact MALT1 and BCL-10 proteins, respectively.

Each of the three translocations leads to constitutive activation of nuclear factor kappa B (NF-κB), a transcription factor that promotes B-cell growth and survival. Antigen-dependent activation of NF-κB in normal B and T cells requires both BCL-10 and MALT1, which work together in a signal transduction pathway downstream of lymphocyte

antigen receptors. Thus, *H. pylori*–induced inflammation may trigger NF-κB activation through the MALT1/BCL-10 pathway in MALTomas that lack these translocations. Removal of this stimulus may explain why these tumors tend to respond to *H. pylori* eradication. In contrast, tumors bearing translocations involving *MALT1* or *BCL10* are generally insensitive to *H. pylori* clearance. Other tumor characteristics such as invasion into or through the muscularis propria and lymph node involvement also correlate with resistance to *H. pylori* eradication.

As with other low-grade lymphomas, MALTomas can transform into more aggressive tumors that are histologically identical to diffuse large B-cell lymphomas. This is often associated with additional genetic changes such as inactivation of the tumor suppressor genes that encode p53 and p16.

MORPHOLOGY

Histologically, gastric MALToma takes the form of a dense lymphocytic infiltrate in the lamina propria (Fig. 17.20A). The neoplastic lymphocytes infiltrate gastric glands to create **diagnostic lymphoepithelial lesions** (Fig. 17.20A, inset). Reactive-appearing B-cell follicles may be present, and in about 40% of tumors plasmacytic differentiation is observed. At other sites GI lymphomas may disseminate as discrete small nodules (Fig. 17.20B) or infiltrate the wall diffusely (Fig. 17.20C).

Like other tumors of mature B cells, MALTomas express the B-cell markers CD19 and CD20. They do not express CD5 or CD10, but are positive for CD43 in about 25% of cases, an unusual feature that can be diagnostically helpful. In cases lacking lymphoepithelial lesions, monoclonality may be demonstrated by restricted expression of either κ or λ immunoglobulin light chains or by molecular detection of clonal IgH rearrangements.

Clinical Features

The most common presenting symptoms are dyspepsia and epigastric pain. Hematemesis, melena, and constitutional symptoms such as weight loss can also be present. Because gastric MALTomas and *H. pylori* gastritis often coexist and have overlapping clinical symptoms and endoscopic appearances, diagnostic difficulties may arise, particularly in small biopsy specimens.

Neuroendocrine Neoplasms

These tumors arise from the diffuse components of the endocrine system. Those previously termed carcinoid tumors are now properly referred to as well-differentiated neuroendocrine tumors, although the term carcinoid continues to be used informally in the GI tract and formally at other sites. Most are found in the GI tract, and more than 40% occur in the small intestine. The tracheobronchial tree and lungs are the next most commonly involved sites. Gastric neuroendocrine neoplasms may be associated with endocrine cell hyperplasia, autoimmune chronic atrophic gastritis, MEN1, and Zollinger-Ellison syndrome. Gastric endocrine and enterochromaffin-like cell hyperplasia has been linked to proton pump inhibitor therapy, but the risk of progression to a neuroendocrine neoplasm in this circumstance is negligible.

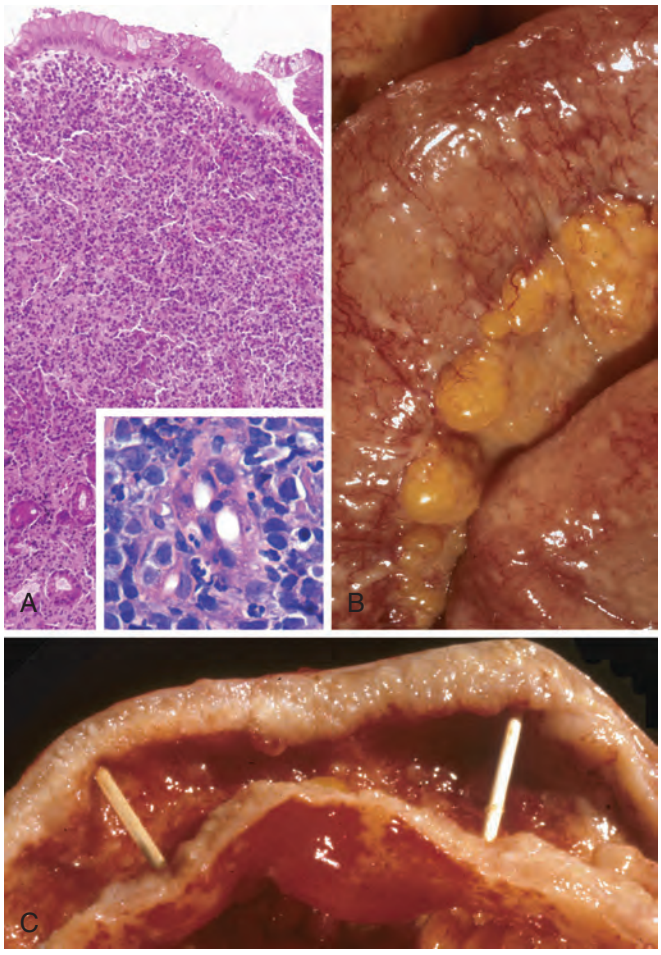

Figure 17.20 Lymphoma. (A) Gastric mucosa-associated lymphoid tissue lymphoma replacing much of the gastric epithelium. *Inset* shows lymphoepithelial lesions with neoplastic lymphocytes surrounding and infiltrating gastric glands. (B) Disseminated lymphoma within the small intestine with numerous small serosal nodules. (C) Large B-cell lymphoma infiltrating the small intestinal wall and producing diffuse thickening.

MORPHOLOGY

Grossly, neuroendocrine neoplasms are intramural or submucosal masses that create polypoid lesions (Fig. 17.21A). In the stomach they typically arise within oxyntic mucosa. The overlying mucosa may be intact or ulcerated, and in the intestines the tumors may invade deeply to involve the mesentery. Neuroendocrine neoplasms tend to be yellow or tan in color and are very firm as a consequence of intense desmoplasia, which may cause kinking and obstruction of the small bowel. Histologically, well-differentiated neuoroendocrine tumors are composed of islands, trabeculae, strands, glands, and sheets of uniform cells with scant, pink granular cytoplasm and a round to oval nucleus with a "salt and pepper" chromatin pattern (Fig. 17.21). Immunohistochemical stains are positive for endocrine granule markers such as synaptophysin and chromogranin A. Poorly differentiated neoplasms with high mitotic rates and Ki-67 proliferative indices are termed neuroendocrine carcinomas and subclassified as small cell or large cell types. Similar to neuroendocrine carcinomas at extraintesintal sites, mutation of *TP53* and *RB* is common.

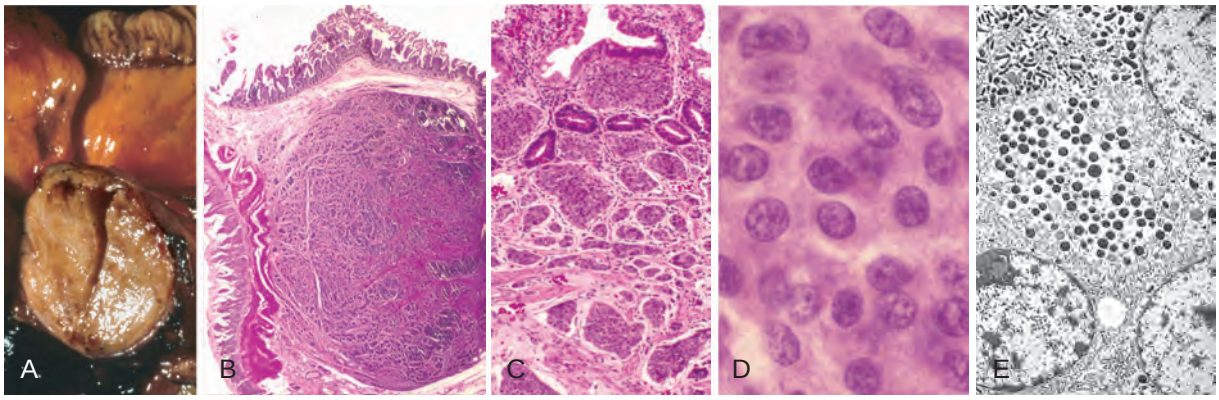

Figure 17.21 Neuroendocrine tumor (carcinoid tumor). (A) Gross cross section of a submucosal tumor nodule. (B) Microscopically the nodule is composed of tumor cells embedded in dense fibrous tissue. (C) In other areas the tumor has spread extensively within mucosal lymphatic channels. (D) High magnification shows the characteristically bland cytology. The chromatin texture, with fine and coarse clumps, is frequently described as a "salt and pepper" pattern. Despite their innocuous appearance, these tumors can be clinically aggressive. (E) Electron microscopy reveals cytoplasmic dense core neurosecretory granules.

Clinical Features

The peak incidence of GI neuroendocrine neoplasms is in the sixth decade, but they may appear at any age. Symptoms reflect hormones released by the tumor cells. For example, those that produce gastrin cause Zollinger-Ellison syndrome. Carcinoid syndrome, which develops in fewer than 10% of patients, is caused by vasoactive substances secreted by the tumor into the systemic circulation. This can lead to cutaneous flushing, sweating, bronchospasm, colicky abdominal pain, diarrhea, and right-sided cardiac valvular fibrosis. When neuroendocrine neoplasms are confined to the intestine, vasoactive substances released are metabolized to inactive forms by the liver, a "first-pass" effect similar to that exerted on oral drugs. Although this can be overcome by a large tumor burden or when tumors secrete hormones into a nonportal venous circulation, the carcinoid syndrome remains strongly associated with metastatic disease to sizes that allow tumor products to bypass the portal circulation and liver. Notably, although a marker of advanced disease, metastatic behavior alone is insufficient to classify a neoplasm as a neuorendocrine carcinoma.

The most important prognostic factors for GI neuroendocrine neoplasms are degree of histological differentiation, mitotic rate, and Ki-67 proliferative index. Behavior is also affected by size and location, and staging is region-specific.

- *Foregut neuroendocrine tumors* within the stomach and duodenum rarely metastasize and are generally cured by resection. This is particularly true for tumors that arise in association with atrophic gastritis. Gastric neuroendocrine tumors without predisposing factors are often more aggressive.
- *Midgut neuroendocrine tumors* arise in the jejunum and ileum, are often multiple, and tend to be aggressive.
- *Hindgut neuroendocrine tumors* arising in the appendix and colorectum are typically discovered incidentally. Those in the appendix occur at any age and are generally located at the tip. These tumors are rarely more than 2 cm in diameter and are almost always benign. Rectal neuroendocrine tumors tend to produce polypeptide hormones and, when symptomatic, present with abdominal pain and weight loss. Because they are usually discovered when small, metastasis of rectal neuroendocrine tumors is uncommon.

Gastrointestinal Stromal Tumor

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of the abdomen, with an annual incidence between 11 and 20 per 1 million people. More than half of these tumors occur in the stomach. The term *stromal* reflects historical confusion about the origin of this tumor, which is now recognized to arise from the interstitial cells of Cajal, or pacemaker cells. A wide variety of other mesenchymal neoplasms may arise in the stomach. Many are named according to the cell type they most resemble; for example, smooth muscle tumors are called leiomyomas or leiomyosarcomas, nerve sheath tumors are termed schwannomas, and tumors resembling glomus bodies (vascular structures found in the nail beds and other sites) are referred to as glomus tumors. These are all uncommon in the gut and are discussed in Chapter 26.

Epidemiology. Clinically silent, microscopic proliferations that may represent precursors to GIST are common. These foci have low mitotic rates and extremely low risk of neoplastic transformation. Changes associated with progression to overt GIST are not well defined, but loss or partial deletion of chromosomes 9, 14, or 22 is common.

GISTs are diagnosed at a peak age of 60 years, with fewer than 10% occurring before 40 years of age. Of the uncommon GISTs in children, some are related to the Carney triad, a nonhereditary syndrome of GIST, paraganglioma, and pulmonary chondroma that occurs primarily in females. There is also an increased incidence of GIST in individuals with neurofibromatosis type 1.

Pathogenesis

Approximately 75% of all GISTs have oncogenic, gain-of-function mutations in the receptor tyrosine kinase KIT. Another 8% of GISTs have mutations that activate the related receptor tyrosine kinase, platelet-derived growth factor receptor α (PDGFRA). Constitutively active KIT and PDGFRA trigger the same downstream signaling pathways. Mutations of the correspondence genes are therefore mutually exclusive. Rare individuals with germline mutations of these genes have diffuse hyperplasia of Cajal cells and develop multiple GISTs. GISTs without mutated *KIT* or *PDGFRA* often have mutations in genes encoding components of the mitochondrial succinate dehydrogenase complex *(SDHA, SDHB, SDHC, SDHD),* an interesting (and still poorly understood) example of oncogenic mutations affecting components of a metabolic pathway, specifically the Krebs cycle. These mutations, which cause loss of succinate dehydrogenase function, are often inherited in the germline and confer an increased risk for GIST and paraganglioma (Carney-Stratakis syndrome), with the second copy of the affected gene being either mutated or lost in the tumor.

MORPHOLOGY

Primary gastric GISTs can reach 30 cm in diameter. They usually form a solitary, well-circumscribed, fleshy mass. The overlying mucosa is frequently ulcerated, and the cut tumor surface has a whorled appearance. Metastases can form multiple serosal nodules throughout the peritoneal cavity or within the liver, but spread outside of the abdomen is uncommon. GISTs composed of thin elongated cells are classified as **spindle cell type** (Fig. 17.22A), while GISTs dominated by plumper, epithelial-appearing cells are termed **epithelioid type** (Fig. 17.22B); mixtures of the two patterns are common. The most useful diagnostic marker is KIT (CD117), which is immunohistochemically detectable in Cajal cells and 95% of gastric GISTs. Nuclear pleomorphism is uncommon.

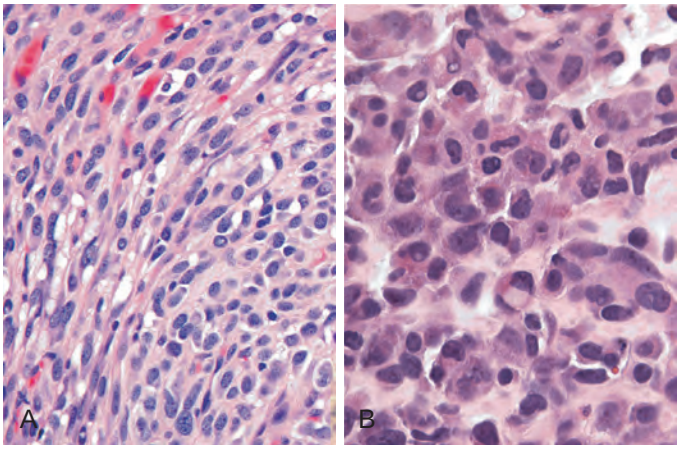

Figure 17.22 Gastrointestinal stromal tumor. (A) Histologically, typical spindle cell gastrointestinal stromal tumors are composed of bundles, or fascicles, of spindle-shaped tumor cells. (B) Epithelioid cell gastrointestinal stromal tumors are composed of plump, epithelial-appearing cells without well-defined fascicles. These tumors can mimic metastatic adenocarcinoma.

Clinical Features

Symptoms of GISTs at presentation are typically related to mass effects. Mucosal ulceration can cause blood loss, and approximately half of individuals with GISTs present with anemia or related symptoms. GISTs may also be discovered incidentally during radiologic imaging, endoscopy, or abdominal surgery performed for other reasons. Complete surgical resection is the primary treatment for localized gastric GIST. The prognosis correlates with tumor size, mitotic index, and location, with gastric GISTs being less aggressive than those arising in the small intestine. Recurrence or metastasis is rare for gastric GISTs smaller than 5 cm but common for mitotically active tumors larger than 10 cm. Many tumors fall into an intermediate category where the malignant potential of the lesion cannot be predicted.

The molecular phenotype is an important consideration in the treatment of patients with unresectable, recurrent, or metastatic GISTs. Tumors with mutations in *KIT* or *PDGFRA* often respond to the tyrosine kinase inhibitor imatinib, whereas tumors without these mutations are generally resistant. In treated patients, imatinib resistance often develops as a result of secondary *KIT* or *PDGFRA* mutations; such tumors may respond to other tyrosine kinase inhibitors that bypass the effects of mutations that convey resistance to imatinib.

KEY CONCEPTS

NEOPLASTIC AND NON-NEOPLASTIC PROLIFERATIONS OF THE STOMACH

- The majority of gastric polyps are inflammatory or hyperplastic polyps. These reactive lesions are associated with chronic gastritis.
- Fundic gland polyps occur sporadically, most often as a consequence of proton pump inhibitor therapy and in patients with familial adenomatous polyposis and *MUTYH*-associated polyposis.
- Gastric adenomas develop in a background of chronic gastritis and are strongly linked to intestinal metaplasia and mucosal (glandular) atrophy. Adenocarcinoma is frequent in gastric adenomas, which therefore require more aggressive therapy than adenomas of the colon.
- Gastric adenocarcinoma incidence varies markedly with geography. Individual tumors are classified according to location and gross and histologic morphology. Gastric tumors with an intestinal histology tend to form bulky tumors and may be ulcerated, while those composed of signet-ring cells typically display a diffuse infiltrative growth pattern that may thicken the gastric wall without forming a discrete mass. Gastric adenocarcinomas are linked to chronic gastritis.
- Primary gastric lymphomas are most often indolent B-cell tumors of mucosa-associated lymphoid tissue (MALTomas) that arise in the setting of chronic *H. pylori* gastritis.
- Neuroendocrine neoplasms arise from diffuse components of the endocrine system and are most common in the GI tract, particularly the small intestine. They can be subdivided into neuroendocrine tumors (previously termed carcinoid tumors)

and neuroendocrine carcinomas on the basis of histology and immunohistochemistry for the proliferative marker Ki-67. Prognosis is also affected by location; tumors of the small intestine tend to be most aggressive, while those of the appendix are typically benign.

- GIST is the most common mesenchymal tumor of the abdomen, occurs most often in the stomach, and develops from Cajal (pacemaker) cells. Most tumors have activating mutations in either *KIT* or *PDGFRA* tyrosine kinases and respond to targeted tyrosine kinase inhibitors.

Small Intestine and Colon

The small intestine and colon make up the majority of the GI tract and are the sites of a broad array of diseases. Some of these relate to nutrient and water transport, perturbation of which results in malabsorption and diarrhea. The intestines are also the principal site where the immune system interfaces with a diverse array of antigens present in food and gut microbes. Thus, it is not surprising that the small intestine and colon are frequently affected by infectious and inflammatory disorders. Finally, the colon is the most common site of GI neoplasia in Western populations.

INTESTINAL OBSTRUCTION

Obstruction of the GI tract may occur at any level, but the small intestine is most often involved because of its relatively narrow lumen. Collectively, hernias, intestinal adhesions, intussusception, and volvulus account for 80% of mechanical obstructions (Fig. 17.23). Tumors, infarction, and other causes of strictures, for example, Crohn disease, make up the remainder. The clinical manifestations of intestinal obstruction include abdominal pain and distention, vomiting, and constipation. Surgical intervention is usually required in cases where the obstruction has a mechanical basis or is associated with bowel infarction.

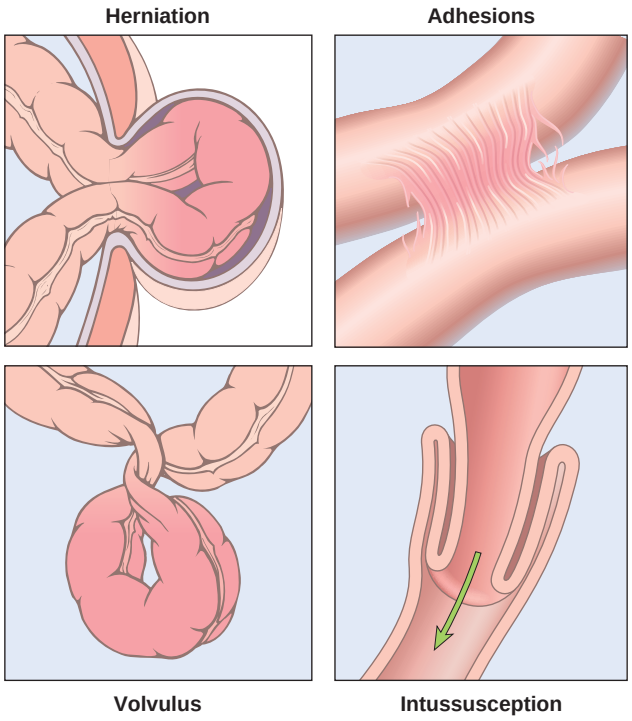

Figure 17.23 Intestinal obstruction. The four major causes of intestinal obstruction are (1) herniation of a segment in the umbilical or inguinal regions, (2) adhesion between loops of intestine, (3) volvulus, and (4) intussusception.

Hernias

Any weakness or defect in the abdominal wall may permit protrusion of a serosa-lined pouch of peritoneum called a hernia sac. Acquired hernias typically occur anteriorly, via the inguinal and femoral canals, via the umbilicus, or at sites of surgical defects and occur in up to 5% of the population. **Hernias are the most frequent cause of intestinal obstruction worldwide** and the third most common cause of obstruction in the United States. Obstruction usually occurs because of visceral protrusion (external herniation) and is most frequently associated with inguinal hernias, which tend to have narrow orifices and large sacs. Small bowel loops are typically involved, but omentum or large bowel may also protrude, and any of these may become entrapped. Pressure at the neck of the pouch may impair venous drainage of the entrapped viscus. The resultant stasis and edema increase the bulk of the herniated loop, leading to permanent entrapment (incarceration) and, over time, arterial and venous compromise (strangulation) and infarction (Fig. 17.24).

Adhesions

Surgical procedures, infection, or other causes of peritoneal inflammation, such as endometriosis, may lead to

Figure 17.24 Intestinal obstruction. Portion of bowel incarcerated within an inguinal hernia. Note dusky areas of serosa and associated hemorrhage that indicate ischemic damage.

development of adhesions between bowel segments, the abdominal wall, or operative sites. These fibrous bridges can create closed loops through which other viscera may slide and become entrapped, resulting in internal herniation. Sequelae, including obstruction and strangulation, are similar to external hernias.

Volvulus

Volvulus occurs when a loop of bowel twists about its mesenteric point of attachment and results in both luminal and vascular compromise. Thus, volvulus presents with features of both obstruction and infarction. It occurs most often in large redundant loops of sigmoid colon, followed in frequency by the cecum, small bowel, stomach, or, rarely, transverse colon. Because it is rare, volvulus can be overlooked clinically, often with catastrophic results.

Intussusception

Intussusception occurs when a segment of the intestine, constricted by a wave of peristalsis, telescopes into the immediately distal segment. Once trapped, the invaginated segment is propelled by peristalsis and pulls the mesentery along. Untreated, intussusception may progress to intestinal obstruction, compression of mesenteric vessels, and infarction. **Intussusception is the most common cause of intestinal obstruction in children younger than 2 years of age.** In idiopathic cases there is no underlying anatomic defect, and the patient is otherwise healthy. Other cases have been associated with viral infection and rotavirus vaccines, perhaps due to reactive hyperplasia of Peyer patches and other mucosa-associated lymphoid tissues that can act as the leading edge. Intussusception is uncommon in older children and adults and is generally caused by an intraluminal mass or tumor that serves as the initiating point of traction. Approximately 1% of patients with cystic fibrosis develop intussusception; here it is believed that inspissated stool serves as a point of traction. Contrast enemas can be used both diagnostically and therapeutically for idiopathic intussusception in infants and young children, in whom air enemas may also be used to reduce the intussusception. Surgical intervention is necessary when a mass is present.

ISCHEMIC BOWEL DISEASE

The majority of the GI tract is supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. As they approach the intestinal wall the superior and inferior mesenteric arteries ramify into the mesenteric arcades. Interconnections between arcades, as well as collateral vessels from the proximal celiac and distal pudendal and iliac circulations, make it possible for the small intestine and colon to tolerate slowly progressive loss of blood supply from one artery. In contrast to chronic, progressive hypoperfusion, acute compromise of any major vessel can lead to infarction of several meters of intestine. Damage can range from mucosal infarction extending no deeper than the muscularis mucosae to mural infarction of mucosa and submucosa to transmural infarction involving all three wall layers. While mucosal or mural infarctions can follow acute or chronic hypoperfusion, transmural infarction is typically due to acute vascular obstruction. In a large majority of cases, acute obstruction is caused by thrombosis or embolism. The most important risk factor for thrombosis is severe atherosclerosis (which is often prominent at the origin of mesenteric vessels). Less common causes of thrombosis include systemic vasculitides (Chapter 11). Obstructive emboli most commonly originate from aortic atheromas or cardiac mural thrombi. Mesenteric venous thrombosis, which can also lead to ischemic disease, is uncommon but can result from inherited or acquired hypercoagulable states, invasive neoplasms, cirrhosis, trauma, or abdominal masses that compress the portal drainage. Intestinal hypoperfusion may also occur in the absence of vascular obstruction in the setting of cardiac failure, shock, dehydration, or use of vasoconstrictive drugs.

Pathogenesis

Intestinal responses to ischemia occur in two phases. The initial hypoxic injury occurs at the onset of vascular compromise, but the greatest damage occurs during the second phase, reperfusion injury, which is initiated by restoration of the blood supply. While the underlying mechanisms of reperfusion injury are incompletely understood, they include leakage of gut lumen bacterial products (e.g., lipopolysaccharide) into the systemic circulation, free radical production, neutrophil infiltration, and release of additional inflammatory mediators (Chapter 2).

The severity of vascular compromise, the time frame during which it develops, and the vessels affected are the major variables that determine the severity of ischemic bowel disease. Intestinal vascular anatomy also contributes to the distribution of ischemic damage in two ways:

- *Intestinal segments at the end of their respective arterial supplies are particularly susceptible to ischemia.* These *watershed zones* include the splenic flexure where the superior and inferior mesenteric arterial circulations terminate and, to a lesser extent, the sigmoid colon and rectum, where inferior mesenteric, pudendal, and iliac arterial circulations end. Generalized hypotension or hypoxemia can cause localized injury at watershed zones, and ischemic disease should be considered in the differential diagnosis of focal colitis of the splenic flexure or rectosigmoid colon.
- *Intestinal capillaries run alongside the glands, from crypt to surface (villus), before making a hairpin turn and descending to the post-capillary venules. This arrangement makes the surface epithelium particularly vulnerable to ischemic injury,* relative to the crypts. This pattern of circulation protects the epithelial stem cells, which are located within the crypts and are necessary for recovery from epithelial injury. Surface epithelial atrophy with normal or hyperproliferative crypts is therefore a morphologic signature of ischemic intestinal disease.

MORPHOLOGY

Although the colon is the most common site of GI ischemia, mucosal and mural infarction may involve any level of the gut from stomach to anus. The lesions can be continuous but are most often segmental and patchy (Fig. 17.25A). The mucosa is hemorrhagic and often ulcerated (Fig. 17.25B). Edema may thicken

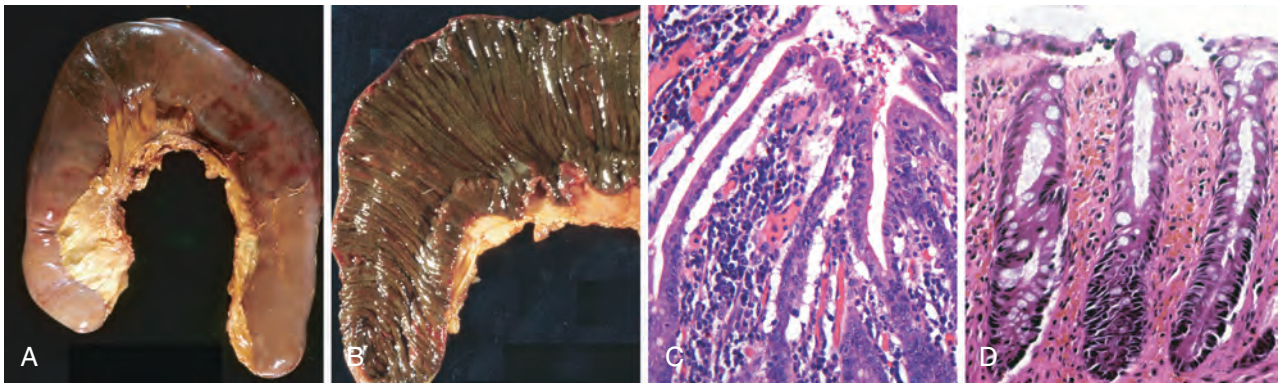

Figure 17.25 Ischemic bowel disease. (A) Jejunal resection with dusky serosa of acute ischemia (mesenteric thrombosis). (B) Mucosa is dark colored because of hemorrhage. (C) Characteristic attenuated villous epithelium in this case of acute mesenteric thrombosis. (D) Chronic colonic ischemia with atrophic surface epithelium and fibrotic lamina propria.

the bowel wall, particularly when damage extends into the submucosa and muscularis propria.

Substantial portions of the bowel are generally involved in **transmural infarction caused by acute arterial obstruction.** The demarcation between normal and ischemic bowel is sharply defined, and initially the infarcted bowel is intensely congested and dusky to purple-red. Later, blood-tinged mucus or frank blood accumulates in the lumen, and the wall becomes edematous, thickened, and rubbery. There is coagulative necrosis of the muscularis propria within 1 to 4 days, and perforation may occur. Serositis, with purulent exudates and fibrin deposition, may be prominent.

In **mesenteric venous thrombosis,** arterial blood continues to flow for a time, resulting in a less abrupt transition from affected to normal bowel. Propagation of the thrombus may lead to secondary involvement of the splanchnic bed. The ultimate result is similar to acute arterial obstruction because impaired venous drainage eventually prevents oxygenated arterial blood from entering the capillaries.

Microscopic examination of ischemic intestine demonstrates the characteristic atrophy or sloughing of surface epithelium (Fig. 17.25C), often with hyperproliferative crypts. Inflammatory infiltrates are initially absent, but neutrophils are recruited within hours of reperfusion. Chronic ischemia is accompanied by fibrous scarring of the lamina propria (Fig. 17.25D) and, uncommonly, stricture formation. In both acute and chronic ischemia, bacterial superinfection and enterotoxin release may induce **pseudomembrane formation** that resembles *Clostridioides* (formerly *Clostridium*) *difficile*–associated pseudomembranous colitis (discussed later).

Clinical Features

Ischemic disease of the colon is most common in patients older than 70 years of age and occurs slightly more often in women. **Acute colonic ischemia typically presents with sudden onset of cramping, left lower abdominal pain, a desire to defecate, and passage of blood or bloody diarrhea.** Patients may progress to shock and vascular collapse within hours in severe cases. Surgical intervention is necessary in approximately 10% of cases and should be considered if evidence of infarction (e.g., diminished peristaltic sounds, guarding, or rebound tenderness) develops. Because these physical signs overlap with those of other abdominal emergencies (e.g., acute appendicitis, perforated ulcer, and acute cholecystitis), the diagnosis of intestinal infarction may be delayed or missed, with disastrous consequences.

With appropriate management, mortality in the first 30 days is approximately 10%. Mortality is doubled in patients with right-sided colonic disease, who have a more severe course in general. This may be because the right side of the colon is supplied by the superior mesenteric artery, which also supplies much of the small intestine. Thus, right-sided colonic ischemia may be the initial presentation of more widespread compromise of intestinal perfusion. Other poor prognostic indicators include coexisting chronic obstructive pulmonary disease and persistence of symptoms for more than 2 weeks. Ischemic bowel injury can take a variety of subacute or chronic forms.

- *Limited zones of mucosal and mural infarctions* may progress to more extensive and transmural infarction if the vascular supply is not restored by correction of the insult or, in chronic disease, by development of adequate collateral supplies. The diagnosis of nonocclusive ischemic enteritis and colitis can be particularly difficult, as symptoms including intermittent bloody diarrhea and intestinal obstruction are often nonspecific.
- *Chronic ischemia* may masquerade as inflammatory bowel disease, with episodes of bloody diarrhea interspersed with periods of healing.
- *CMV infection* causes ischemic GI disease due to viral tropism for endothelial cells and resulting localized vascular obstruction. CMV infection, which can be a complication of immunosuppressive therapy, is discussed further in Chapter 8.
- *Radiation enterocolitis* occurs when the GI tract is irradiated and is due to a combination of epithelial and endothelial injury. Beyond clinical history, the presence of highly atypical "radiation fibroblasts" within the stroma may provide an important clue to the etiology. Acute radiation enteritis manifests as anorexia, abdominal cramps, and malabsorptive diarrhea, while chronic radiation enteritis or colitis is often more indolent and may present as an inflammatory enterocolitis.
- *Necrotizing enterocolitis* is an acute disorder of the small and large intestines that can result in transmural necrosis. It is the most common acquired GI emergency of neonates, particularly those who are premature or of low birth

weight, and frequently presents when oral feeding is initiated. It is discussed in more detail in Chapter 10 but is noted here because ischemic injury is thought to contribute to the pathogenesis.

ANGIODYSPLASIA

Angiodysplasia is characterized by malformed submucosal and mucosal blood vessels that are dilated and thin walled. They are most common in the cecum or right colon and, usually, come to clinical attention after the sixth decade of life. Although the prevalence is less than 1% in adults, angiodysplasia accounts for 20% of major episodes of lower intestinal bleeding in older populations. Presentation can range from chronic, intermittent to acute, massive hemorrhage.

The pathogenesis of angiodysplasia remains undefined but has been attributed to mechanical and congenital factors. Normal distention and contraction of the gut may intermittently occlude the submucosal veins that penetrate through the muscularis propria, leading to focal dilation and tortuosity of overlying submucosal and mucosal vessels. Because the cecum has the largest diameter of any colonic segment, it develops the greatest wall tension. This may explain the preferential distribution of angiodysplastic lesions in the cecum and right colon.

Morphologically, angiodysplastic lesions are characterized by ectatic nests of tortuous veins, venules, and capillaries. The vascular channels are often separated from the intestinal lumen by only the thin vessel wall and a layer of attenuated epithelial cells, making the vessels vulnerable to disruption by even minor injuries.

MALABSORPTION AND DIARRHEA

Malabsorption is characterized by defective absorption of fats, fat- and water-soluble vitamins, proteins, carbohydrates, electrolytes and minerals, and water. A hallmark of malabsorption is steatorrhea, characterized by excessive fecal fat and bulky, frothy, greasy, yellow or clay-colored stools. The chronic malabsorptive disorders most commonly encountered in the United States are pancreatic insufficiency, celiac disease, and Crohn disease (Table 17.6). Intestinal graft-versus-host disease is an important cause of malabsorption and diarrhea after allogeneic hematopoietic stem cell transplantation.

Malabsorption results from disturbance in at least one of the four phases of nutrient absorption:

- *Intraluminal digestion,* in which proteins, carbohydrates, and fats are broken down into forms suitable for absorption
- *Terminal digestion,* involving hydrolysis of carbohydrates and peptides by disaccharidases and peptidases in the brush border of the small intestinal mucosa
- *Transepithelial transport,* in which nutrients, fluid, and electrolytes are transported across and processed within the small intestinal epithelium
- *Lymphatic transport* of absorbed lipids

In many malabsorptive disorders a defect in one of these processes predominates, but several usually contribute. As a result, the symptoms and conseqences of malabsorption syndromes resemble each other more than they differ. Chronic malabsorption can lead to diarrhea, flatus, abdominal pain, weight loss, and muscle wasting, and is often associated with anorexia, abdominal distention, and borborygmi. Inadequate absorption of vitamins and minerals can result in anemia and mucositis due to pyridoxine, folate, or vitamin B_{12} deficiency; bleeding due to vitamin K deficiency; osteopenia and tetany due to calcium, magnesium, or vitamin D deficiencies; or peripheral neuropathy due to vitamin A or B_{12} deficiencies. A variety of endocrine and skin disturbances (e.g., goiter and vitiligo) may also develop as a consequence of nutrient, micronutrient, and vitamin deficiencies.

Table 17.6 Defects in Malabsorptive and Diarrheal Disease

Disease	Intraluminal Digestion	Terminal Digestion	Transepithelial Transport	Lymphatic Transport
Celiac disease		+	+	
Environmental enteropathy		+	+	
Chronic pancreatitis	+			
Cystic fibrosis	+			
Primary bile acid malabsorption	+		+	
Carcinoid syndrome			+	
Autoimmune enteropathy		+	+	
Disaccharidase deficiency		+		
Whipple disease				+
Abetalipoproteinemia			+	
Viral gastroenteritis		+	+	
Bacterial gastroenteritis		+	+	
Parasitic gastroenteritis		+	+	
Inflammatory bowel disease	+	+	+	

"+" indicates that the process is abnormal in the disease indicated.

Diarrhea is defined as an increase in stool mass, frequency, or fluidity, typically greater than 200 g per day. Both nutrient malabsorption and increased secretion of fluid by the intestine may contribute to diarrhea. In severe cases stool volume can exceed 14 L per day and, without fluid resuscitation, result in death. Painful, bloody, small-volume diarrhea is known as dysentery. Diarrhea can be classified into four major categories:

- *Secretory diarrhea* is characterized by isotonic stool and persists during fasting.
- *Osmotic diarrhea,* such as occurs with lactase deficiency, is due to the excessive osmotic force exerted by unabsorbed luminal solutes. The diarrhea fluid is more than 50 mOsm more concentrated than plasma, and diarrhea abates with fasting.
- *Malabsorptive diarrhea* follows generalized failure of nutrient absorption, is associated with steatorrhea, and is relieved by fasting.
- *Exudative diarrhea* due to inflammatory disease is characterized by purulent, often bloody stools that continue during fasting.

Cystic Fibrosis

Cystic fibrosis affects many organ systems, primarily the lungs, and is discussed in greater detail elsewhere (Chapter 10). Only the malabsorption associated with cystic fibrosis is considered here. Due to the absence of the epithelial cystic fibrosis transmembrane conductance regulator (CFTR), individuals with cystic fibrosis have defects in chloride and, in certain tissues, bicarbonate ion transport across epithelia. This interferes with bicarbonate, sodium, and water secretion, ultimately resulting in decreased hydration of luminal contents. The thick viscous stool may occasionally lead to intestinal obstruction, but more commonly results in formation of pancreatic intraductal concretions. The latter can begin in utero and result in duct obstruction, low-grade chronic pancreatitis with autodigestion of the pancreas, and eventually exocrine pancreatic insufficiency in more than 80% of patients. This in turn impairs the intraluminal phase of nutrient absorption, a defect that can be effectively treated by oral enzyme supplementation.

Celiac Disease

Celiac disease, also known as celiac sprue or gluten-sensitive enteropathy, is an immune-mediated disorder triggered by the ingestion of gluten-containing foods such as wheat, rye, or barley in genetically predisposed individuals. Celiac disease has an overall worldwide incidence of 0.6% to 1%, but its prevalence varies widely among countries and regions. Some of these differences correlate with variation in wheat consumption. While previously uncommon in many countries, the incidence of celiac disease is growing, possibly as a result of adoption of Western diets.

Pathogenesis

The alcohol-soluble fraction of gluten, gliadin, contains most of the disease-producing components. Gluten is digested by luminal and brush-border enzymes into amino acids and peptides, including a 33-amino acid α-gliadin peptide that is resistant to degradation by gastric, pancreatic, and small intestinal proteases (Fig. 17.26). Some gliadin peptides may induce epithelial cells to express IL-15, which in turn triggers activation and proliferation of CD8+ intraepithelial lymphocytes. These lymphocytes express NKG2D, a natural killer cell marker and receptor for MIC-A. Enterocytes that have been induced to express surface MIC-A in response

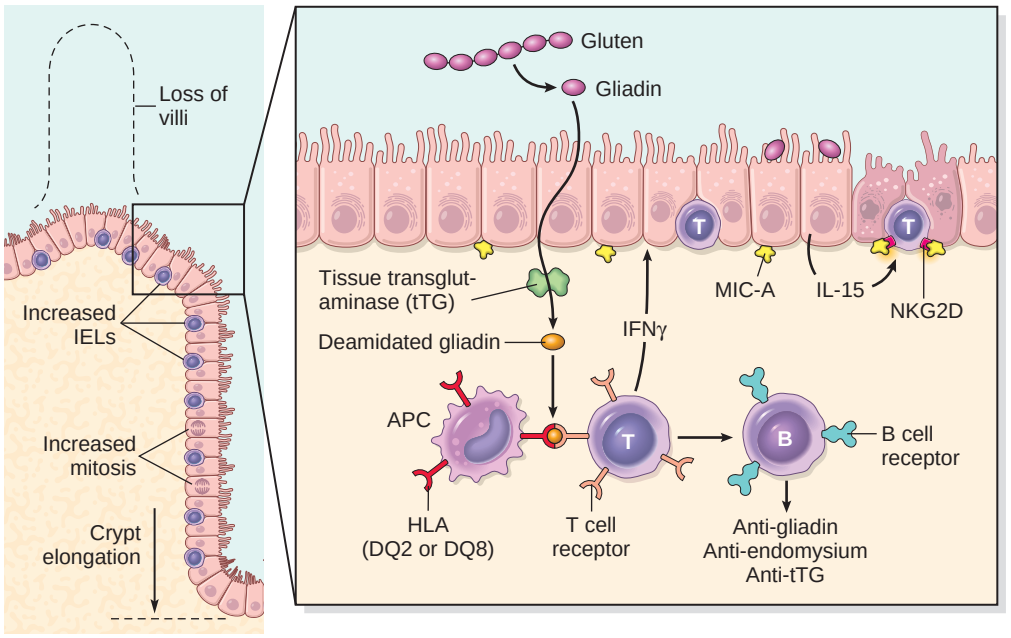

Figure 17.26 The *left panel* illustrates the morphologic alterations that may be present in celiac disease including villous atrophy, increased numbers of intraepithelial lymphocytes *(IELs)*, and epithelial proliferation with crypt elongation. The *right panel* depicts a model for the pathogenesis of celiac disease. Note that both innate (CD8+ intraepithelial T cells, activated by IL-15) and adaptive (CD4+ T cells and B cells sensitization to gliadin) immune mechanisms are involved in the tissue responses to gliadin.

to stress are then attacked by NKG2D-expressing intraepithelial lymphocytes. The resulting epithelial damage may enhance passage of other gliadin peptides into the lamina propria where they are deamidated by tissue transglutaminase. These gliadin peptides interact with HLA-DQ2 or HLA-DQ8 on antigen-presenting cells and in turn stimulate CD4+ T cells to produce cytokines that exacerbate tissue damage.

While most people eat grain and are exposed to gluten and gliadin, very few develop celiac disease. Thus, host factors determine whether disease develops. Among these, HLA proteins seem to be critical, since almost all people with celiac disease carry the class II HLA-DQ2 or HLA-DQ8 allele. However, the HLA locus accounts for less than half of the genetic component of celiac disease. Remaining genetic factors may include polymorphisms of genes involved in immune regulation and epithelial function. These genetic variables may also contribute to associations between celiac disease and other immune diseases including type 1 diabetes, thyroiditis, Sjögren syndrome, and IgA nephropathy.

MORPHOLOGY

Biopsy specimens from the second portion of the duodenum or proximal jejunum, which are exposed to the highest concentrations of dietary gluten, are generally diagnostic in celiac disease. The histopathology is characterized by increased numbers of intraepithelial CD8+ T lymphocytes (intraepithelial lymphocytosis), crypt hyperplasia, and villous atrophy (Fig. 17.27). This loss of mucosal and brush-border surface area contributes to malabsorption. Increased rates of epithelial turnover, reflected in increased crypt mitotic activity, may also limit the ability of absorptive enterocytes to fully differentiate and express proteins necessary for terminal digestion and transepithelial transport. Other features of fully developed celiac disease include increased numbers of plasma cells, mast cells, and eosinophils, especially within the upper part of the lamina propria. With increased serologic screening and early detection of disease-associated antibodies, it is now appreciated that increased numbers of intraepithelial lymphocytes, particularly within the villus, is a sensitive marker of celiac disease, even in the absence of epithelial damage and villous atrophy. However, intraepithelial lymphocytosis and villous atrophy are not specific for celiac disease and can be present in other diseases, including viral enteritis. The combination of histology and serology therefore is most specific for diagnosis of celiac disease.

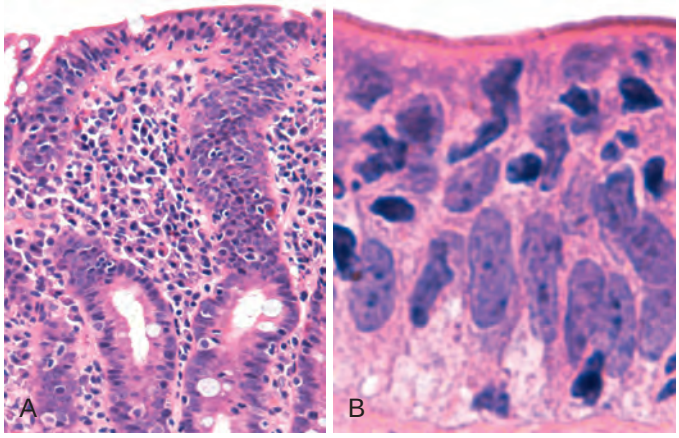

Figure 17.27 Celiac disease. (A) Advanced cases of celiac disease show complete loss of villi, or total villous atrophy. Note the dense plasma cell infiltrates in the lamina propria. (B) Infiltration of the surface epithelium by T lymphocytes, which can be recognized by their small, densely stained nuclei relative to larger, pale-staining epithelial nuclei.

Clinical Features

In adults, celiac disease presents most commonly between the ages of 30 and 60. Many cases of celiac disease escape clinical attention for extended periods because of atypical presentations. Other patients may have silent celiac disease, defined as positive serology and villous atrophy without symptoms, or latent celiac disease, in which positive serology is not accompanied by villous atrophy. Celiac disease may be associated with chronic diarrhea, bloating, or chronic fatigue, but can also be asymptomatic. These cases may present with anemia due to chronic iron and vitamin malabsorption. In adults, celiac disease is detected twice as frequently in women, perhaps because menstrual bleeding accentuates the effects of impaired iron absorption. A characteristic itchy, blistering skin lesion, dermatitis herpetiformis (Chapter 25), can be present in as many as 10% of patients.

Pediatric celiac disease, which affects males and females equally, may present with malabsorption or atypical symptoms affecting almost any organ. In those with classic symptoms, disease typically begins after introduction of gluten to the diet, between 6 and 24 months of age, and manifests as irritability, abdominal distention, anorexia, chronic diarrhea, failure to thrive, weight loss, or muscle wasting. Children with nonclassic symptoms tend to present at older ages with complaints of abdominal pain, nausea, vomiting, bloating, or constipation. Common extraintestinal complaints include arthritis or joint pain, aphthous stomatitis, iron deficiency anemia, delayed puberty, and short stature.

Unfortunately, the only treatment currently available for celiac disease is a gluten-free diet. Adherence to a gluten-free diet typically results in resolution of symptoms, reduced titers of anti–tissue transglutaminase or other celiac disease–associated antibodies, and restoration of normal or near-normal mucosal histology within 6 to 24 months. Therapeutic efforts are targeted at development of agents that minimize the impact of small quantities of ingested gluten. A gluten-free diet may also reduce the risk of long-term complications including anemia, female infertility, osteoporosis, and cancer (discussed below).

Noninvasive serologic tests are generally performed prior to biopsy. The most sensitive test is the measurement of IgA antibodies against tissue transglutaminase. IgA anti-endomysial antibodies can also be present. IgG anti–tissue transglutaminase antibodies may be detected in patients with IgA deficiency. The absence of HLA-DQ2 and HLA-DQ8 is useful for its negative predictive value, but the presence of these alleles is not helpful in confirming the diagnosis.

Individuals with celiac disease have an increased risk of malignancy. The most common cancer is enteropathy-associated T-cell lymphoma, an aggressive lymphoma of intraepithelial T lymphocytes. Small intestinal adenocarcinoma is also more frequent in individuals with celiac disease. Thus, when symptoms such as abdominal pain, diarrhea, and

weight loss develop despite a strict gluten-free diet, cancer or refractory sprue, in which the response to a gluten-free diet is lost, must be considered.

Environmental Enteric Dysfunction

Environmental enteric dysfunction, which has also been referred to as *environmental enteropathy, tropical enteropathy, or tropical sprue,* is a disorder prevalent in areas and populations with poor sanitation and hygiene, including severely under-resourced regions in parts of sub-Saharan Africa, such as Zambia; aboriginal populations in northern Australia; and some impoverished groups in South America and Asia. Affected individuals often suffer from malabsorption, malnutrition, and stunted growth. The relatively high oral vaccine failure rates in regions where environmental enteric dysfunction is endemic have been proposed to be due to defective mucosal immune function in environmental enteric dysfunction.

There are presently no accepted clinical, laboratory, or histopathologic criteria that allow diagnosis of environmental enteric dysfunction. Intestinal biopsy specimens have been examined in a small number of cases, and reported histologic features include more pronounced immune cell infiltration but less advanced villous atrophy relative to advanced celiac disease.

The underlying causes of environmental enteric dysfunction are unknown. Defective intestinal barrier and transport functions secondary to chronic exposure to fecal pathogens and other microbial contaminants, mucosal immune abnormalities, and repeated bouts of diarrhea within the first 2 or 3 years of life are likely involved. Although many pathogens are endemic in affected communities, no single infectious agent has been linked to environmental enteric dysfunction. Moreover, oral antibiotic treatment and nutritional supplementation do not reverse or prevent environmental enteric dysfunction. Irreversible failures in physical development, e.g., height and weight, may be accompanied by uncorrectable cognitive deficits. Thus, the global impact of environmental enteric dysfunction, which is estimated to affect more than 150 million children worldwide and may contribute to a large number of childhood deaths, is difficult to overstate.

Autoimmune Enteropathy

Autoimmune enteropathy is an X-linked disorder characterized by severe persistent diarrhea and autoimmune disease that occurs most often in young children. A particularly severe familial form, termed IPEX, an acronym denoting immune dysregulation, polyendocrinopathy, enteropathy, and X-linkage, is caused by germline loss of function mutations in the *FOXP3* gene, which is located on the X chromosome. FOXP3 is a transcription factor expressed in CD4+ regulatory T cells, and individuals with *FOXP3* mutations have defective development and function of these cells. Other defects in regulatory T-cell function have been linked to less severe forms of autoimmune enteropathy. Autoantibodies to enterocytes and goblet cells are common, and some patients have antibodies to parietal or islet cells. Within the small intestine, intraepithelial lymphocytes may be increased but not to the extent seen in celiac disease. In contrast to celiac disease, neutrophils are often seen infiltrating the intestinal mucosa. Therapy includes immunosuppressive drugs such as cyclosporine and hematopoietic stem cell transplantation.

Lactase (Disaccharidase) Deficiency

The disaccharidases, including lactase, are located in the apical brush-border membrane of the villus absorptive epithelial cells. In the absence of lactase, dietary lactose cannot be broken into glucose and galactose. Lactose cannot be absorbed and remains in the lumen where it exerts an osmotic force that attracts fluid and causes diarrhea. Because the defect is biochemical, histology is generally unremarkable. Lactase deficiency is of two types:

- *Congenital lactase deficiency,* caused by a mutation in the gene encoding lactase, is an autosomal recessive disorder. The disease is rare and presents as explosive diarrhea with watery, frothy stools and abdominal distention upon milk ingestion. Symptoms abate when exposure to milk and milk products is terminated. Congenital lactase deficiency was often fatal prior to the availability of soy-based infant formula.
- *Acquired lactase deficiency* is caused by downregulation of lactase gene expression and is particularly common among Native American, African American, and Chinese populations. Acquired lactase deficiency can develop with increased age, potentially because, until relatively recently (in evolutionary terms), people did not ingest milk after weaning. Lactase deficiency can also present following enteric viral or bacterial infections, where it may resolve over time. Symptoms, including abdominal fullness and diarrhea, follow ingestion of lactose-containing dairy products. Flatulence also occurs due to fermentation of the unabsorbed sugars by colonic bacteria.

Microvillus Inclusion Disease

Microvillus inclusion disease, sometimes referred to as Davidson disease, is an autosomal recessive disorder of vesicular transport that leads to deficient brush-border assembly. It is caused by mutations in the *MYO5B* gene, which encodes a motor protein that is required for delivery and retrieval of plasma membrane components and for normal nutrient, ion, and water transport. The disease occurs most commonly in European, Middle Eastern, and Navajo Native American populations. Severe, intractable diarrhea develops before 3 months of age (often in the first few days of life) as a result of defective terminal digestion and transepithelial transport functions. The factors responsible for early or later presentation have not been defined. The defect in plasma membrane trafficking leads to the accumulation of abnormal apical vesicles containing microvilli and various membrane components. The abnormal vesicles can be identified by electron microscopy or by immunostaining for the brush border protein villin. CD10 immunohistochemistry, which labels the microvillus inclusions as well as other cytoplasmic structures, is also used for diagnosis. Total parenteral nutrition and small bowel transplantation are the only treatments available for microvillus inclusion disease.

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disease characterized by an inability to assemble triglyceride-rich lipoproteins. It is caused by a mutation in microsomal triglyceride transfer protein (MTP), which is required for transfer of lipids to nascent apolipoprotein B polypeptide in the endoplasmic reticulum. Without MTP, lipids accumulate intracellularly. Triglyceride accumulation is evident as epithelial vacuolization and can be highlighted by special stains, such as oil red-O, particularly after a fatty meal.

Abetalipoproteinemia presents in infancy with failure to thrive, diarrhea, and steatorrhea. Because of the defect in lipoprotein assembly, the plasma is completely devoid of lipoproteins containing apolipoprotein B. Failure to absorb essential fatty acids leads to deficiencies of fat-soluble vitamins as well as lipid membrane defects that can be recognized by the presence of acanthocytes, red cells with spiky membrane protrusions, in peripheral blood smears.

KEY CONCEPTS

CONGENITAL AND ACQUIRED (NONINFECTIOUS) DISORDERS OF THE INTESTINES

- Abdominal hernias may occur through any weakness or defect in the wall of the peritoneal cavity including inguinal and femoral canals, the umbilicus, and sites of surgical scars.
- Intussusception occurs when a segment of intestine telescopes into the immediately distal segment. It is the most common idiopathic cause of intestinal obstruction in children younger than 2 years of age, but is driven by leading edge mass lesions in older individuals.
- Ischemic bowel disease of the colon is most common at the splenic flexure, sigmoid colon, and rectum; these are watershed zones where two arterial circulations terminate.
- Angiodysplasia is a malformation of submucosal and mucosal blood vessels and a common cause of lower intestinal bleeding in those older than 60 years of age.
- Diarrhea can be characterized as secretory, osmotic, malabsorptive, or exudative.
- The malabsorption associated with cystic fibrosis is the result of pancreatic insufficiency, leading to inadequate pancreatic digestive enzymes, and deficient luminal breakdown of nutrients.
- Celiac disease is an immune-mediated enteropathy triggered by the ingestion of gluten-containing grains. The malabsorptive diarrhea in celiac disease is due to loss of brush-border surface area including villous atrophy and, possibly, deficient enterocyte maturation as a result of immune-mediated epithelial damage.
- Environmental enteric dysfunction is prevalent in areas with poor sanitation. It is estimated to affect more than 150 million children worldwide and may contribute to a very large number of childhood deaths.
- Autoimmune enteropathy is characterized by persistent diarrhea associated with other forms of autoimmune disease. A particularly severe form is IPEX, caused by mutation in the *FOXP3* gene, which is necessary for regulatory T-cell development and function.
- Lactase deficiency causes an osmotic diarrhea due to the inability to break down lactose. The autosomal recessive form is rare and severe; the acquired form is common and usually presents in adulthood.
- Microvillus inclusion disease is a rare autosomal recessive disorder due to mutations in *MYO5B* that impair vesicular transport and brush-border assembly.

INFECTIOUS ENTEROCOLITIS

Enterocolitis can present with a broad range of symptoms including diarrhea, abdominal pain, urgency, perianal discomfort, incontinence, and hemorrhage (Table 17.7). This global problem is responsible for over 1 million deaths each year. Half of the mortality occurs in children under the age of 5, in whom diarrheal disease is the fourth most common cause of death worldwide. The specific pathogens vary widely as a function of age, nutrition, and host immune status as well as geography and other environmental influences such as the availability of clean drinking water. Bacterial infections, such as enterotoxigenic *E. coli* and *Salmonella* spp., are frequently responsible for acute diarrheal illnesses. Rotavirus and adenovirus are common causes of death in children under 5 years of age (see Table 17.7). Mycobacterial infections of the GI tract are considered in detail in Chapter 8.

Cholera

***Vibrio cholerae* are comma-shaped, gram-negative bacteria that cause cholera, a disease that has been endemic in the Ganges Valley of India and Bangladesh throughout history.** Since 1817 seven great pandemics have spread along trade routes to Europe, Australia, and the Americas, after each of which cholera retreated back to the Ganges Valley. Cholera also persists within the Gulf of Mexico but causes only rare cases of seafood-associated disease. This occurs because shell fish and plankton can be reservoirs of *Vibrio cholerae*. The incidence of cholera increases during summer, reflecting more rapid growth of *Vibrio* bacteria at warm temperatures. It is primarily transmitted by drinking contaminated water and may cause epidemics in areas where disasters such as earthquakes or war have destroyed sewage systems with resultant fecal contamination of drinking water supplies. For example, the 2010 Haitian earthquake led to a cholera epidemic that affected more than 5% of the population. Over half of cases required hospitalization, and 1% were fatal.

Pathogenesis

Severe diarrhea is caused by the toxin released by the bacteria. *Vibrio* organisms are noninvasive and remain within the intestinal lumen. Proteins involved in motility and attachment are necessary for efficient colonization. Hemagglutinin, a metalloproteinase, is important for bacterial detachment and shedding into the stool, which is key to dissemination.

Cholera toxin is encoded by a virulence phage. It is composed of five B subunits and a single A subunit. The B subunits bind GM1 ganglioside on the surface of intestinal epithelial cells, allowing the toxin to be carried by endocytosis to the endoplasmic reticulum (Fig. 17.28). Here, the A subunit

Table 17.7 Features of Bacterial Enterocolitides

Infection Type	Geography	Reservoir	Transmission	Epidemiology	Affected GI Sites	Symptoms	Complications
Cholera	India, Africa	Shellfish	Fecal-oral, water	Sporadic, endemic, epidemic	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
Campylobacter spp.	High income countries	Chickens, sheep, pigs, cattle	Poultry, milk, other foods	Sporadic; children, travelers	Colon	Watery or bloody diarrhea	Reactive arthritis, Guillain-Barré syndrome
Shigellosis	Worldwide, endemic in under-resourced countries	Humans	Fecal-oral, food, water	Children, migrant workers, travelers, nursing home residents	Left colon, ileum	Bloody diarrhea	Reactive arthritis, urethritis, conjunctivitis, hemolytic-uremic syndrome
Salmonellosis	Worldwide	Poultry, farm animals, reptiles	Meat, poultry, eggs, milk	Children, older adults	Colon and small intestine	Watery or bloody diarrhea	Sepsis, abscess
Enteric (typhoid) fever	India, Mexico, Philippines	Humans	Fecal-oral, water	Children, adolescents, travelers	Small intestine	Bloody diarrhea, fever	Chronic infection, carrier state, encephalopathy, myocarditis, intestinal perforation
Yersinia spp.	Northern and central Europe	Pigs, cows, puppies, cats	Pork, milk, water	Clustered cases	Ileum, appendix, right colon	Abdominal pain, fever, diarrhea	Reactive arthritis, erythema nodosum
Escherichia coli							
ETEC	Under-resourced countries	Unknown	Food or fecal-oral	Infants, adolescents, travelers	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
EPEC	Worldwide	Humans	Fecal-oral	Infants	Small intestine	Watery diarrhea	Dehydration, electrolyte imbalances
EHEC	Worldwide	Widespread, includes cattle	Beef, milk, produce	Sporadic and epidemic	Colon	Bloody diarrhea	Hemolytic-uremic syndrome
EIEC	Under-resourced countries	Unknown	Cheese, other foods, water	Young children	Colon	Bloody diarrhea	Unknown
EAEC	Worldwide	Unknown	Unknown	Children, adults, travelers	Colon	Nonbloody diarrhea, afebrile	Poorly defined
Pseudomembranous colitis (*C. difficile*)	Worldwide	Humans, hospitals	Antibiotics allow emergence	Immunosuppressed, antibiotic-treated	Colon	Watery diarrhea, fever	Relapse, toxic megacolon
Whipple disease	Rural > urban	Unknown	Unknown	Rare	Small intestine	Malabsorption	Arthritis, CNS disease
Mycobacterial infection	Worldwide	Unknown	Unknown	Immunosuppressed, endemic	Small intestine	Malabsorption	Pneumonia, infection at other sites

CNS, Central nervous system; *EAEC,* enteroaggregative *E. coli; EIEC,* enteroinvasive *E. coli; EHEC,* enterohemorrhagic *E. coli; EPEC,* enteropathogenic *E. coli; ETEC,* enterotoxigenic *E. coli; GI,* gastrointestinal.

of the toxin is reduced by protein disulfide isomerase, and a fragment of the A subunit is unfolded. This peptide fragment is then transported into the cytosol using host cell machinery that normally moves misfolded proteins from the endoplasmic reticulum to the cytosol. Once in the cytosol, the A subunit fragment refolds and then interacts with cytosolic ADP ribosylation factors (ARFs) to activate the stimulatory G protein $G_s\alpha$. This stimulates adenylate cyclase and the resulting increase in intracellular cyclic adenosine monophosphate (cAMP) opens the cystic fibrosis conductance regulator (CFTR), which releases chloride ions into the lumen. Chloride and sodium absorption are also inhibited by cAMP. The resulting accumulation of chloride, bicarbonate, and sodium within the intestinal lumen creates an osmotic force

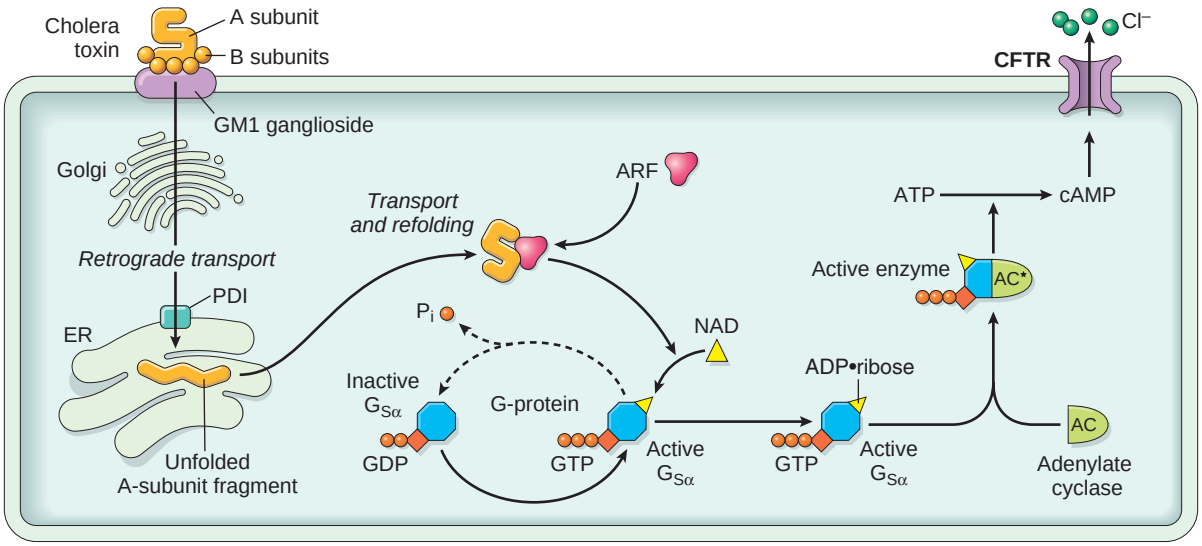

Figure 17.28 Cholera toxin transport and signaling. After retrograde toxin transport to the endoplasmic reticulum *(ER)*, the A subunit is released by the action of protein disulfide isomerase *(PDI)* and is then able to access the epithelial cell cytoplasm. In concert with an ADP-ribosylation factor *(ARF)*, the A subunit then ADP-ribosylates $G_s\alpha$, which locks it in the active, GTP-bound state. This leads to adenylate cyclase *(AC)* activation, and the cyclic adenosine monophosphate *(cAMP)* produced opens cystic fibrosis transmembrane conductance regulator *(CFTR)* to drive chloride secretion and diarrhea.

that draws water into the lumen and causes massive diarrhea. Remarkably, mucosal biopsies show only minimal histologic alterations.

Clinical Features

Most individuals exposed to *V. cholerae* are asymptomatic or develop only mild diarrhea. In those with severe disease there is an abrupt onset of watery diarrhea and vomiting following an incubation period of 1 to 5 days. The voluminous stools resemble rice water and are sometimes described as having a fishy odor. The rate of diarrhea may reach 1 L per hour, leading to dehydration, hypotension, muscular cramping, anuria, shock, loss of consciousness, and death. Mortality for severe cholera is about 50% without treatment, but timely fluid replacement can save more than 99% of patients. Oral rehydration is often sufficient but is unfortunately underutilized. Promising investigational therapies for acute therapy include CFTR inhibitors, which prevent diarrhea by blocking chloride secretion. Vaccination of at-risk individuals during cholera outbreaks can limit disease spread and is recommended, along with other prevention control strategies, by the World Health Organization (WHO). Prophylactic vaccination is a long-term goal, and some data indicate that this approach will convey sufficient herd immunity to reduce the incidence of cholera.

Campylobacter Enterocolitis

***Campylobacter jejuni* is the most common bacterial enteric pathogen in high income countries and is an important cause of traveler's diarrhea and food poisoning.** Infections are most often associated with ingestion of improperly cooked chicken, but outbreaks can also be caused by unpasteurized milk or contaminated water.

Pathogenesis

The pathogenesis of *Campylobacter* infection remains poorly defined, but the four major properties that contribute to virulence are motility, adherence, toxin production, and invasion. Flagella allow *Campylobacter* to be motile, which facilitates adherence and colonization. Some *C. jejuni* isolates also release cytotoxins that cause direct epithelial damage or a cholera toxin–like enterotoxin. Dysentery, i.e., bloody diarrhea, is generally associated with bacterial invasion and is caused by only a minority of *Campylobacter* strains. Enteric fever occurs when bacteria proliferate within the lamina propria and mesenteric lymph nodes.

***Campylobacter* infection can result in reactive arthritis, primarily in patients with HLA-B27 genotype.** Other extraintestinal complications, including erythema nodosum and Guillain-Barré syndrome, a flaccid paralysis caused by immunologically mediated inflammation of peripheral nerves (Chapter 27), are not HLA-linked. Molecular mimicry has been implicated in the pathogenesis of Guillain-Barré syndrome, as serum antibodies to *C. jejuni* lipopolysaccharide cross-react with peripheral and central nervous system gangliosides. The risk of developing Guillain-Barré syndrome following *Campylobacter* infection is estimated to be less than 0.1%, but up to 40% of Guillain-Barré cases have documented *Campylobacter* infection in the 2 weeks prior to presentation, and up to 50% have positive stool cultures or circulating antibodies to *Campylobacter*.

MORPHOLOGY

Campylobacter are comma-shaped, flagellated, gram-negative organisms. Diagnosis is primarily by stool culture, since biopsy findings are nonspecific. Mucosal and intraepithelial neutrophil infiltrates are prominent, particularly within the superficial mucosa (Fig. 17.29A); cryptitis (neutrophil infiltration of the crypt epithelium) and crypt abscesses (accumulations of neutrophils within crypt lumens) may also be present. Importantly, crypt architecture is preserved (Fig. 17.29D), although this can be difficult to assess in cases with severe mucosal damage.

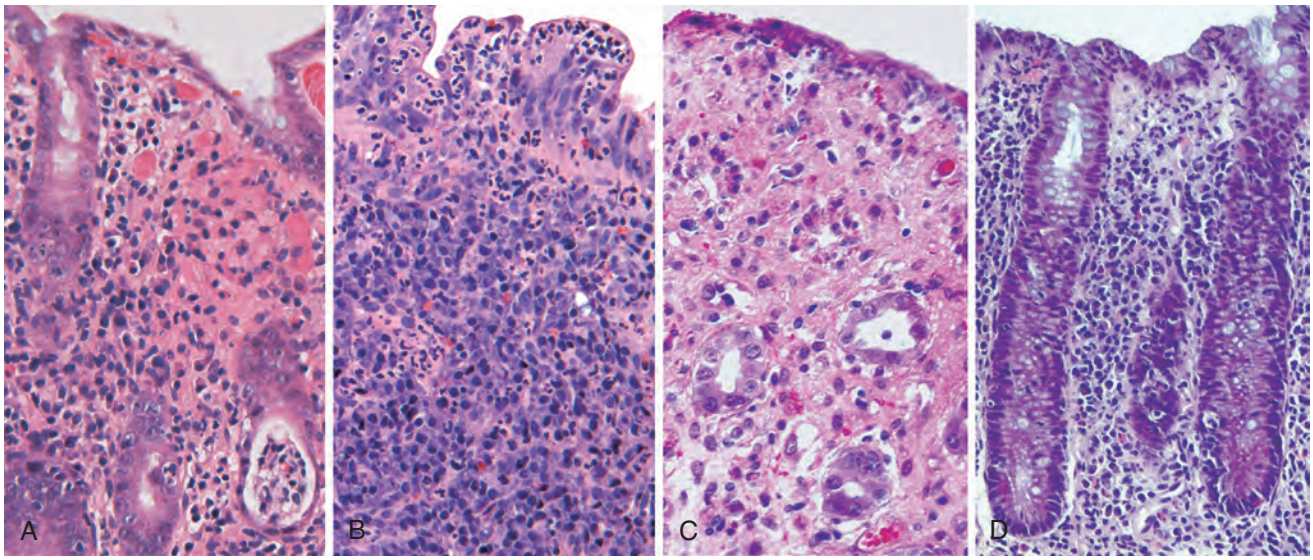

Figure 17.29 Bacterial enterocolitis. (A) *Campylobacter jejuni* infection produces acute, self-limited colitis. Neutrophils can be seen within the surface and crypt epithelia, and a crypt abscess is present at the lower right. (B) In *Yersinia* infection the surface epithelium can be eroded by neutrophils, and the lamina propria is densely infiltrated by sheets of plasma cells admixed with lymphocytes and neutrophils. (C) Enterohemorrhagic *Escherichia coli* O157:H7 results in an ischemia-like morphology with surface atrophy and erosion. (D) Enteroinvasive *E. coli* infection is similar to other acute, self-limited colitides such as those caused by *C. jejuni*. Note the maintenance of normal crypt architecture and spacing despite abundant intraepithelial neutrophils.

Clinical Features

Ingestion of as few as 500 *C. jejuni* organisms can cause disease after an incubation period of up to 8 days. Watery diarrhea, either acute or following an influenza-like prodrome, is the primary symptom, but dysentery develops in 15% of adults and more than 50% of children. Patients may shed bacteria for 1 month or more after clinical resolution. Antibiotic therapy is generally not required.

Shigellosis

***Shigella* are gram-negative unencapsulated, nonmotile, facultative anaerobes that belong to the *Enterobacteriaceae* family and are closely related to enteroinvasive *E. coli*.** Although humans are the only known reservoir, *Shigella* spp. remain one of the most common causes of bloody diarrhea, with a worldwide incidence of up to 165 million cases each year. Given the extremely low infective dose of several hundred organisms and the presence of as many as 10^9 organisms in each gram of stool during acute disease, *Shigella* are highly transmissible by the fecal-oral route or via contaminated water and food.

In the United States and Europe, children in daycare centers, migrant workers, travelers to low resource countries, and individuals in nursing homes are most commonly affected. Deaths are generally limited to children younger than 5 years of age. *Shigella* is endemic in countries with poor sanitation, where it is responsible for 10% of pediatric diarrheal disease and up to 75% of diarrheal deaths.

Pathogenesis

Shigella are resistant to gastric acid, thereby explaining the low infective dose. Once in the intestine, organisms are taken up by M, or microfold, cells, which are specialized for luminal antigen sampling and presentation. The bacteria proliferate within the M cells and then escape into the lamina propria, where they are phagocytosed by and induce apoptosis of macrophages. The inflammatory response damages surface epithelium and allows *Shigella* within the intestinal lumen as well as those within the lamina propria to gain access to the basolateral membranes of colonic epithelial cells, across which bacteria invade the cytoplasm more efficiently than from the apical surface. All *Shigella* spp. carry virulence plasmids, some of which encode a type III secretion system capable of directly injecting bacterial proteins into the host cytoplasm. *Shigella dysenteriae* serotype 1 also release the Shiga toxin Stx, which inhibits eukaryotic protein synthesis, resulting in host cell damage and death.

MORPHOLOGY

Shigella infections are most prominent in the left colon, but the ileum may also be involved, perhaps reflecting the abundance of M cells in the **dome epithelium** overlying Peyer patches. The mucosa is hemorrhagic and ulcerated, and pseudomembranes may be present. The histology of early cases is similar to other acute self-limited colitides such as *Campylobacter* colitis, but **because of the tropism for M cells, aphthous ulcers similar to those seen in Crohn disease may occur.** This and other factors lead to significant potential for confusion with inflammatory bowel disease.

Clinical Features

After an incubation period of up to 1 week, *Shigella* causes self-limited disease characterized by 7 to 10 days of diarrhea, fever, and abdominal pain. The initially watery diarrhea progresses to a dysenteric phase in approximately 50%

of patients, and constitutional symptoms can persist for as long as 1 month. Duration of symptoms is typically shorter in children, but severity is often much greater. In adults, an uncommon subacute presentation includes weeks of waxing and waning diarrhea that can mimic new-onset ulcerative colitis. Confirmation of *Shigella* infection requires stool culture. Antibiotic treatment shortens both the clinical course and the duration of bacterial shedding in stools. Conversely, antidiarrheal medications can prolong symptoms and delay *Shigella* clearance and are therefore contraindicated.

Long-term complications of *Shigella* infection are uncommon but include a triad of sterile reactive arthritis, urethritis, and conjunctivitis that preferentially affects HLA-B27–positive men between 20 and 40 years of age. *S. dysenteriae* serotype 1 that secrete Shiga toxin may also trigger hemolytic-uremic syndrome, although enterohemorrhagic *E. coli* (EHEC) are more commonly responsible (Chapter 20). Toxic megacolon and intestinal obstruction are uncommon complications.

Salmonella

***Salmonella*, which are classified within the Enterobacteriaceae family of gram-negative bacilli, are divided into *S. typhi*, the causative agent of typhoid fever (discussed in the next section), and nontyphoid *Salmonella* such as *S. enteritidis*.** The latter are the most common cause of salmonellosis, of which more than 1 million cases occur each year in the United States; the prevalence is even greater in under-resourced countries. Infection is most common in young children and older adults, with peak incidence in the summer and fall. Salmonella is transmitted via contaminated food, particularly raw or undercooked meat, poultry, eggs, and milk. Centralized food processing can lead to large outbreaks. Vaccines are available for both humans and farm animals, e.g., egg-laying hens.

Pathogenesis

Very few viable *Salmonella* are necessary to cause infection; the absence of gastric acid, in individuals with atrophic gastritis or those on acid-suppressive therapy, further reduces the required inoculum. *Salmonella* possess virulence genes that encode a type III secretion system capable of transferring bacterial proteins into M cells and enterocytes. The transferred proteins activate host Rho guanosine triphosphatases (GTPases), thereby triggering actin rearrangement and bacterial endocytosis which, in turn, facilitates bacterial growth within endosomes. *Salmonella* also secrete a molecule that induces epithelial cell release of the eicosanoid hepoxilin A3, a potent chemoattractant that stimulates neutrophil chemotaxis into the intestinal lumen and potentiates mucosal damage. Flagellin, the core protein of bacterial flagella, and bacterial lipopolysaccharide may activate TLR5 and TLR4, respectively, further augmenting inflammation and tissue damage. Both Th1 and Th17 T cells contribute to pathogen clearance, explaining why those with genetic defects in Th17 immunity are at risk for disseminated salmonellosis.

The gross and microscopic features of *Salmonella* enteritis are nonspecific and are similar to the acute self-limited colitis of *Campylobacter* and *Shigella*. Stool cultures are essential for diagnosis.

Clinical Features

Salmonella infections are clinically indistinguishable from those caused by other enteric pathogens. Symptoms range from loose stools to cholera-like profuse diarrhea to dysentery. Fever often resolves within 2 days, but diarrhea can persist for a week, and organisms can be shed in the stool for several weeks after resolution. Antibiotic therapy is not generally recommended because it can prolong the carrier state or even cause relapse and does not typically shorten the duration of diarrhea. Although *Salmonella* infections are typically self-limited, some complications, including reactive arthritis and meningitis, and even death may occur, particularly in patients with malignancies, immunosuppression, alcoholism, cardiovascular dysfunction, sickle cell disease, or hemolytic anemia.

Typhoid Fever

Typhoid fever, also referred to as enteric fever, has an annual worldwide incidence of 30 million individuals. The disease is caused by *Salmonella enterica* and its two subtypes, *typhi* and *paratyphi*. The majority of cases in endemic countries are due to *S. typhi,* while infection by *S. paratyphi* is more common among travelers, perhaps because they are often vaccinated against *S. typhi.* In endemic areas, children and adolescents are affected most often, but there is no age preference in non-endemic countries. Infection is strongly associated with travel to India, Mexico, the Philippines, Pakistan, El Salvador, and Haiti. Humans are the sole reservoir for *S. typhi* and *S. paratyphi;* transmission occurs from person to person or via food or contaminated water. Gallbladder colonization with *S. typhi* or *S. paratyphi* may be associated with gallstones and a chronic carrier state.

Pathogenesis

In contrast to *S. enteritidis*, *S. typhi* disseminate via lymphatic and blood vessels, which causes systemic reactive hyperplasia of phagocytes and lymphoid tissues. Similar to *Shigella, S. typhi* are resistant to gastric acid and, initially, invade via small intestinal M cells.

MORPHOLOGY

Salmonella infection causes **Peyer patches in the terminal ileum** to enlarge into sharply delineated, plateau-like elevations up to 8 cm in diameter. Draining mesenteric lymph nodes are also enlarged. Neutrophils accumulate within the superficial lamina propria together with macrophages containing bacteria, red cells, nuclear debris, lymphocytes, and plasma cells. Mucosal damage creates oval ulcers, oriented along the axis of the ileum, that may perforate.

In disseminated *S. typhi* infection, the spleen is enlarged and soft, with uniformly pale red pulp, obliterated follicular markings, and prominent phagocyte hyperplasia. The liver is punctuated by small, randomly scattered foci of parenchymal necrosis in which hepatocytes are replaced by macrophage aggregates, called **typhoid nodules,** which may also be found in the bone marrow and lymph nodes.

Clinical Features

Acute infection results in anorexia, abdominal pain, bloating, nausea, vomiting, and bloody diarrhea followed by a short asymptomatic phase that gives way to bacteremia and fever with flu-like symptoms. Abdominal tenderness may mimic appendicitis. Rose spots, small erythematous maculopapular lesions, develop on the chest and abdomen. Symptoms abate after several weeks but relapse can occur. **Systemic dissemination may cause extraintestinal complications including encephalopathy, meningitis, seizures, endocarditis, myocarditis, pneumonia, and cholecystitis.** Patients with sickle cell disease are particularly susceptible to *Salmonella* osteomyelitis. Blood cultures are positive in more than 90% of affected individuals during the febrile phase. Antibiotic treatment can prevent disease progression.

Yersinia

Three *Yersinia* species are human pathogens. *Y. enterocolitica* and *Y. pseudotuberculosis* cause GI disease and are discussed here; *Y. pestis,* the agent of pulmonic and bubonic plague, is discussed in Chapter 8. The incidence of GI *Yersinia* infections in Europe is greater than in North America, perhaps as a result of differing dietary practices. Infections are most frequently linked to ingestion of pork, raw milk, and contaminated water and tend to cluster in the winter.

Pathogenesis

Yersinia invade M cells and use specialized bacterial proteins, called adhesins, to bind to host cell β_1 integrins. A pathogenicity island encodes proteins that mediate iron capture and transport; similar iron transport systems are also present in *E. coli, Klebsiella, Salmonella,* and enterobacteria. In *Yersinia,* **iron enhances virulence and stimulates systemic dissemination, explaining why individuals with increased non-heme iron, such as those with certain chronic forms of anemia or hemochromatosis, are at greater risk for sepsis and death.**

MORPHOLOGY

Yersinia infections preferentially involve the ileum, appendix, and right colon (see Fig. 17.29B). The organisms proliferate extracellularly in lymphoid tissue, resulting in regional lymph node and Peyer patch hyperplasia as well as bowel wall thickening. The mucosa overlying lymphoid tissue may become hemorrhagic, and aphthous erosions and ulcers may appear along with neutrophil infiltrates (Fig. 17.29B) and granulomas. As with *Shigella,* these factors can cause diagnostic confusion with Crohn disease.

Clinical Features

Yersinia infection generally presents as abdominal pain, nausea, vomiting, and abdominal tenderness. **Extraintestinal symptoms of pharyngitis, arthralgia, and erythema nodosum occur frequently.** Fever and diarrhea are less common. Peyer patch invasion with subsequent involvement of regional lymphatics can mimic acute appendicitis in teenagers and young adults, but enteritis and colitis predominate in younger children. *Yersinia* can be detected by stool culture on *Yersinia*-selective agar. In cases with extraintestinal disease, lymph nodes or blood cultures may also be positive. Postinfectious complications include reactive arthritis with urethritis and conjunctivitis, myocarditis, erythema nodosum, and kidney disease.

Escherichia coli

E. coli are gram-negative bacilli that colonize the healthy GI tract; most are nonpathogenic, but a subset cause human disease. The latter are classified according to morphology, pathogenesis, and in vitro behavior. Subgroups with major clinical relevance include enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC).

***Enterotoxigenic* Escherichia coli. ETEC are the principal cause of traveler's diarrhea and spread via contaminated food or water.** In under-resourced countries, children younger than 2 years of age are particularly susceptible. ETEC are noninvasive but produce heat-labile (LT) and heat-stable (ST) toxins. LT is similar to cholera toxin and activates adenylate cyclase, resulting in increased intracellular cAMP and chloride secretion. ST binds to guanylate cyclase, and increases intracellular cyclic guanosine monophosphate (cGMP); the effects on epithelial ion transport are similar to those induced by LT. Like cholera, the secretory, non-inflammatory diarrhea induced by ETEC results in only mild histologic changes, despite having the potential to cause dehydration and, in severe cases, shock.

***Enteropathogenic* Escherichia coli. EPEC are prevalent worldwide and are an important cause of endemic diarrhea** as well as diarrheal outbreaks, particularly in children less than 2 years of age. EPEC are characterized by their ability to produce attaching and effacing (A/E) lesions in which bacteria attach tightly to small intestinal enterocyte apical membranes and cause local loss, i.e., effacement, of the microvilli. The proteins necessary for creating A/E lesions are encoded by a large genomic pathogenicity island, the locus of enterocyte effacement (LEE), which is also present in many EHEC strains. These proteins include Tir, which is inserted into the intestinal epithelial cell plasma membrane. Tir acts as a receptor for the bacterial outer membrane protein intimin, which is encoded by the *espE* gene and can be used for molecular detection and diagnosis of EPEC infection. The locus of enterocyte effacement also encodes a type III secretion system, similar to that in *Shigella,* that injects bacterial effector proteins into the epithelial cell cytoplasm. EPEC strains do not produce Shiga toxins.

***Enterohemorrhagic* Escherichia coli. EHEC are categorized as *E. coli* O157:H7 and non-O157:H7 serotypes.** *E. coli* O157:H7 outbreaks are often caused by consumption of inadequately cooked ground beef, reflecting the natural reservoir in cows. Contaminated milk and vegetables are also vehicles for infection. Both O157:H7 and non-O157:H7 serotypes produce Shiga-like toxins, and therefore lesions (see Fig. 17.29C) and clinical symptoms are similar to those resulting from *S. dysenteriae* infection. O157:H7 serotypes are more likely than non-O157:H7 serotypes to cause outbreaks of bloody diarrhea, hemolytic-uremic syndrome, and ischemic colitis. Importantly, antibiotics are not recommended

because killing the bacteria can lead to release of Shiga-like toxins and increased risk of hemolytic uremic syndrome, especially in children.

Enteroinvasive* Escherichia coli. EIEC organisms are bacteriologically similar to *Shigella and are transmitted via food or water or by person-to-person contact. While EIEC do not produce toxins, they invade epithelial cells and cause nonspecific features of acute self-limited colitis (see Fig. 17.29D). EIEC infections are most common among young children in under-resourced countries and are occasionally associated with outbreaks in more affluent regions.

***Enteroaggregative* Escherichia coli. EAEC has a unique "stacked brick" morphology when bound to epithelial cells.** These organisms cause diarrhea in children and adults worldwide, including traveler's diarrhea. The organisms attach to enterocytes via adherence fimbriae and are aided by dispersin, a bacterial surface protein that neutralizes the negative surface charge of lipopolysaccharide. EAEC organisms produce minimal histologic changes and cause nonbloody diarrhea that may be prolonged in individuals with immunodeficiency.

Pseudomembranous Colitis

Pseudomembranous colitis is generally caused by *Clostridioides* (formerly *Clostridium*) *difficile* and is also referred to as antibiotic-associated colitis or antibiotic-associated diarrhea. While other organisms such as *Salmonella, Clostridium perfringens* type A, or *Staphylococcus aureus* may also produce diarrhea in the context of antibiotic therapy, only *C. difficile* causes pseudomembranous colitis.

Pathogenesis

Disruption of the normal colonic microbiota by antibiotics allows *C. difficile* overgrowth. Almost any antibiotic may be responsible; the most important determinants of the disease are frequency of use and the effect on colonic microbiota. Toxins released by *C. difficile* cause the ribosylation of small GTPases such as Rho, leading to disruption of the epithelial cytoskeleton, tight junction barrier loss, cytokine release, and apoptosis. Toxin-mediated cytoskeletal disruption in other cell types, particularly neutrophils, may also contribute to development of purulent pseudomembranes, but the processes that produce pseudomembranous colitis remain incompletely understood.

MORPHOLOGY

The surface epithelium is denuded, and the superficial lamina propria contains a dense infiltrate of neutrophils and occasional fibrin thrombi within capillaries. **Pseudomembranes** (Fig. 17.30A, B), made up of an adherent layer of inflammatory cells and debris are not specific and may also be present in ischemia or necrotizing infections. However, **histopathology of *C. difficile*–associated colitis is pathognomonic.** Specific features include the mucopurulent exudate that characteristically erupts from damaged crypts to form "volcano" lesions (Fig. 17.30C) and coalesces to form pseudomembranes.

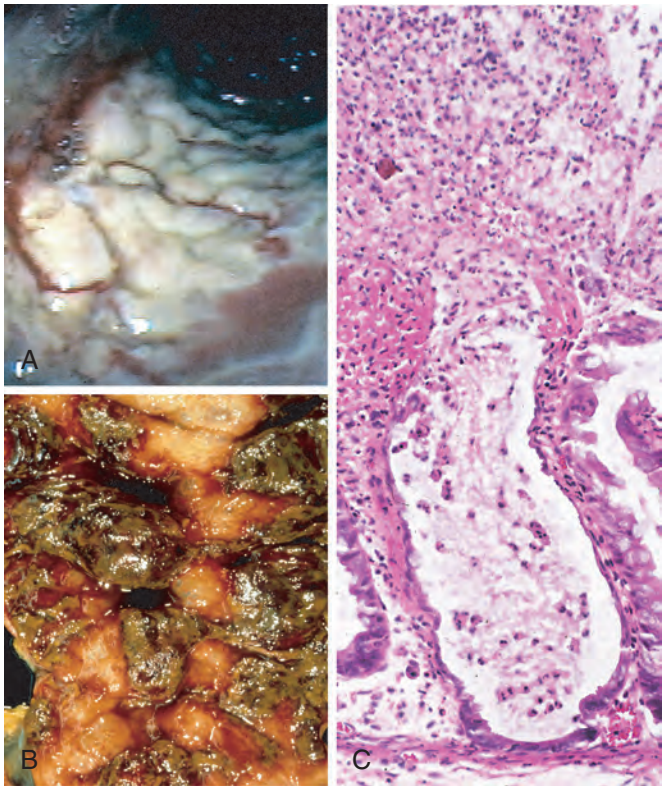

Figure 17.30 *Clostridioides* (formerly *Clostridium*) *difficile* colitis. (A) The colon is coated by tan pseudomembranes composed of neutrophils, dead epithelial cells, and inflammatory debris (endoscopic view). (B) Pseudomembranes are easily appreciated on gross examination. (C) Typical pattern of neutrophils emanating from a damaged crypt is reminiscent of a volcanic eruption.

Clinical Features

Risk factors for *C. difficile*–associated colitis include antibiotic treatment, advanced age, hospitalization, and immunosuppression. The organism is particularly prevalent in hospitals; as many as 30% of hospitalized adults are colonized with *C. difficile* (a rate 10-fold greater than the general population), but most colonized patients are free of disease. Individuals with *C. difficile*–associated colitis present with fever, leukocytosis, abdominal pain, cramps, watery diarrhea, and dehydration. Protein loss can give rise to hypoalbuminemia. Fecal leukocytes and occult blood may be present, but grossly bloody diarrhea is uncommon. Toxic magacolon, characterized by marked dilatation of the colon, is a potentially fatal complication resulting from marked injury to the colonic wall. The diagnosis is usually made by detection of *C. difficile* toxin, rather than by culture, and is supported by the characteristic histopathology. Metronidazole and vancomycin are generally effective therapies, but the prevalence of antibiotic-resistant and hypervirulent *C. difficile* strains is increasing. Recurrent *C. difficile*–associated colitis occurs in up to 40% of patients. Fecal microbial transplantation successfully prevents recurrent infection in some patients and is becoming an accepted therapy. Many investigators are working to develop defined microbial populations that can be administered in place of fecal preparations. New antibiotics as well as monoclonal antibodies against toxins A and B can also be effective, but are not yet in widespread use.

Whipple Disease

Whipple disease is a rare, multivisceral chronic disease first described as intestinal lipodystrophy in 1907 by George Hoyt Whipple, a pathologist who won the Nobel Prize for his work on pernicious anemia.

Pathogenesis

Whipple's original case report described an individual with malabsorption, lymphadenopathy, and arthritis of undefined origin. Postmortem examination demonstrated the presence of foamy macrophages filled with gram-positive microbes. The organism was identified as an actinomycete by PCR in 1992 and named *Tropheryma whipplei*. Clinical symptoms occur because bacteria-laden macrophages accumulate within the small intestinal lamina propria and mesenteric lymph nodes, causing lymphatic obstruction. Thus, **the malabsorptive diarrhea of Whipple disease is due to impaired lymph drainage.**

MORPHOLOGY

The morphologic hallmark of Whipple disease is a **dense accumulation of distended, foamy macrophages in the small intestinal lamina propria** (Fig. 17.31A). The macrophages contain periodic acid–Schiff (PAS)–positive, diastase-resistant granules that represent partially digested bacteria within lysosomes (Fig. 17.31B). Intact rod-shaped bacilli can also be identified by electron microscopy (Fig. 17.31C). A similar infiltrate of foamy macrophages is present in intestinal mycobacterial infections (Fig. 17.31D), and the organisms are PAS-positive in both diseases. The acid-fast stain can be helpful, since mycobacteria stain positively (Fig. 17.31E), while *T. whipplei* does not.

Villous expansion caused by dense macrophage infiltrates imparts a shaggy gross appearance to the mucosal surface. Lymphatic dilation and mucosal lipid deposition account for the endoscopically visible white to yellow mucosal plaques. In Whipple disease, bacteria-laden macrophages can accumulate within **mesenteric lymph nodes, synovial membranes, cardiac valves, brain,** and other sites.

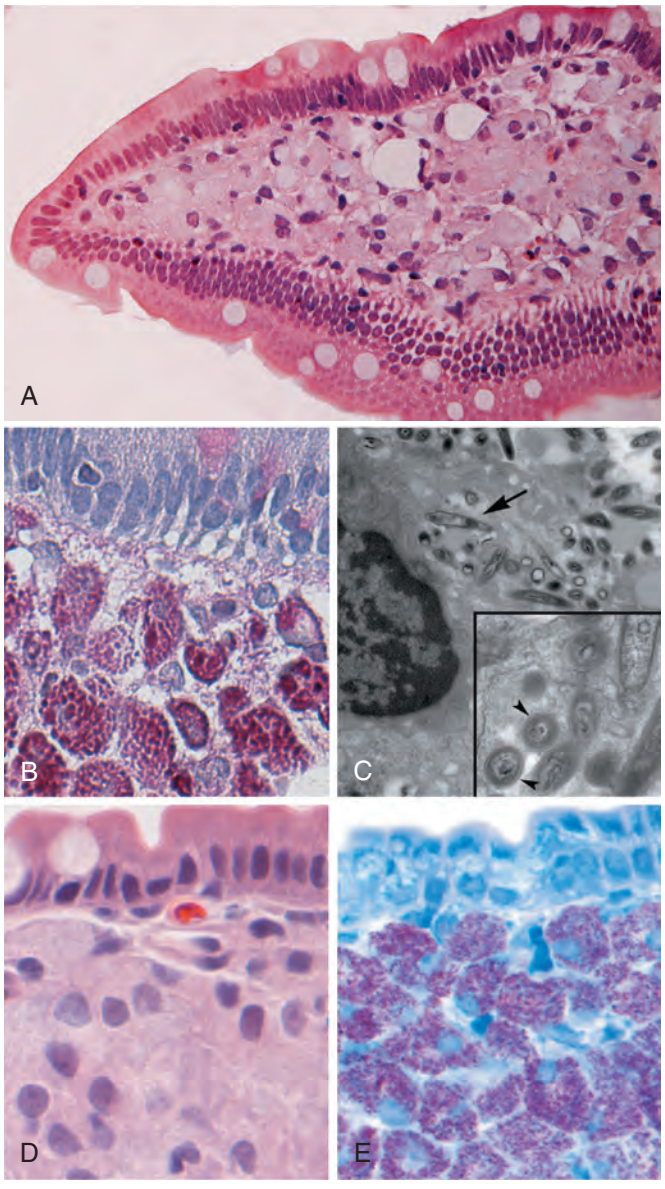

Figure 17.31 Whipple disease and mycobacterial infection. (A) Hematoxylin and eosin staining shows effacement of normal lamina propria by a sheet of distended macrophages. (B) Periodic acid–Schiff stain highlights macrophage lysosomes full of bacilli. (C) Electron micrograph of part of a macrophage shows bacilli within the cell *(top arrow);* also seen at higher magnification *(arrowheads in inset)*. (D) The morphology of mycobacterial infection can be similar to Whipple disease, particularly in the immunocompromised host. Compare with (A). (E) Unlike *T. whippelii,* mycobacteria are positive with stains for acid-fast bacteria. (C, Courtesy George Kasnic and Dr. William Clapp, University of Florida, Gainesville, Fla.)

Whipple disease is most common in Caucasian men, particularly farmers and others with occupational exposure to soil or animals. While there is no consistent familial clustering, the rarity of infection despite a large number of healthy carriers suggests that genetic risk factors exist.

The clinical presentation of Whipple disease is usually a triad of diarrhea, weight loss, and arthralgia. Extraintestinal symptoms may precede malabsorption by months or years and include arthritis; arthralgia; fever; lymphadenopathy; and neurologic, cardiac, or pulmonary disease.

Viral Gastroenteritis

Symptomatic human infection is caused by many viruses. The most common are discussed here.

Norovirus. This was previously known as Norwalk-like virus and is a common cause of nonbacterial gastroenteritis. Humans are the only known reservoir for these are small icosahedral viruses with a single-stranded RNA genome. **Approximately half of all gastroenteritis outbreaks worldwide are thought to be due to norovirus.** In the United States, noroviruses are the most common cause of acute gastroenteritis requiring medical attention. They cause more than 200,000 childhood deaths annually in under-resourced countries. With increasing use of the rotavirus vaccine, norovirus has become the most common cause of diarrhea worldwide.

Local norovirus outbreaks are usually initiated via contaminated food or water, but dissemination throughout a population occurs via person-to-person, fecal-oral transmission. Fecal-oral transmission is responsible for most sporadic cases. Infections spread easily within schools, hospitals, nursing homes, and other large groups in close quarters, such as on cruise ships. In these environments, vehicles include airborne droplets, environmental surfaces, and fomites. Some data suggest that strict enforcement of personal hygiene, enteric precautions, and regular environmental decontamination with alcohol-based hand sanitizers and quaternary ammonium wipes may reduce transmission. However, prevention is difficult to achieve due to the resistance of the virus to a wide range of temperatures, from freezing to 60°C, and the extraordinarily low infective dose of less than 20 particles.

Following an incubation period of up to 2 days, affected individuals develop vomiting; cramping abdominal pain; watery diarrhea; and nonspecific symptoms including headache, chills, and myalgias. The symptoms resolve within 2 to 3 days in most cases. Infectious viral particles can be shed prior to symptoms and for up to 8 weeks after infection in healthy, immunocompetent individuals.

Norovirus infection in immunocompromised patients is a significant problem. Some data suggest that nearly 20% of patients on immunosuppression after renal transplantation or as treatment for graft-versus-host disease after hematopoietic stem cell transplantation are infected with norovirus and have intermittent diarrhea. Many of these patients fail to clear the infection, suffer from chronic diarrhea, and shed infectious virus for up to 1 year. The malnutrition and dehydration that accompany infection can also increase morbidity of the underlying disease.

Some individuals are naturally resistant to norovirus infection due to mutations that inactivate galactoside 2-alpha-L-fucosyltransferase, *FUT2,* which contributes to the glycosylation of proteins destined for the cell surface in the Golgi complex. Approximately 20% of individuals of European and African descent are homozygous for these mutations. These individuals, termed non-secretors, neither shed blood group antigens in saliva nor express them on epithelial cells at many mucosal sites including the GI tract. Non-secretors are resistant to infection because they lack the carbohydrate groups on these antigens that serve as ligands for viral infection. In others, acquired immunity is difficult to achieve because there is a great diversity of norovirus strains, which limits cross protection, and because the viral genome regularly undergoes recombination that results in antigenic shift. As a result, a new pandemic strain emerges every 2 to 4 years.

MORPHOLOGY

Morphology is nonspecific but can include mild villous shortening, epithelial vacuolization, crypt hypertrophy, and lamina propria infiltration by neutrophils, lymphocytes, and monocytes (Fig. 17.32A). The microvillus brush border is also compromised, and reduced expression of digestive enzymes can lead to mild steatorrhea and carbohydrate malabsorption.

Rotavirus. **This encapsulated virus with a segmented, double-stranded RNA genome is highly prevalent and a significant cause of diarrheal deaths worldwide.** Children between 6 and 24 months of age are most vulnerable, probably because antibodies in breast milk confer protection during the first 6 months of life. Rotavirus vaccines are becoming widely used but are incompletely effective in under-resourced regions, possibly as a consequence of malnutrition. The WHO recommends that the first dose be given at 6 weeks of age.

Rotavirus outbreaks in hospitals and daycare centers are common, and infection spreads easily; the estimated minimal infective inoculum is only 10 viral particles. Rotavirus selectively infects and destroys mature enterocytes in the small intestine, and the villus surface is repopulated by immature epithelial cells. Enterocyte damage may be mediated by a viral factor called nonstructural protein 4 (NSP4), which can induce apoptosis. The loss of absorptive function and net secretion of water and electrolytes is compounded by an osmotic diarrhea caused by the incomplete absorption of nutrients. Like norovirus, rotavirus has a short incubation period followed by several days of vomiting and watery diarrhea.

Adenovirus. A common cause of pediatric diarrhea, adenovirus also affects immunocompromised patients. Small intestinal biopsy specimens can show epithelial degeneration but more often exhibit nonspecific villous atrophy and compensatory crypt hyperplasia. Viral nuclear inclusions are uncommon. Disease typically presents after an incubation period of 1 week with symptoms that include diarrhea, vomiting, and abdominal pain. Fever and weight loss may also be present. Symptoms generally resolve within 10 days.

Parasitic Enterocolitis

Although viruses and bacteria are the predominant enteric pathogens in the United States, parasitic disease and protozoal infections affect more than one-half of the world's population on a chronic or recurrent basis. The small intestine can provide a home for many as 20 species of parasites including nematodes, such as the roundworms *Ascaris* and *Strongyloides;* hookworms and pinworms; cestodes, including flatworms and tapeworms; trematodes, or flukes; and protozoa. Parasitic infections are covered in Chapter 8; those that are common in the intestinal tract are discussed briefly here.

Ascaris lumbricoides. This nematode infects 1 billion individuals worldwide. *Ascaris* eggs are shed in the feces of infected individuals, allowing spread via the direct fecal-oral route. Eggs may also be present in improperly cleaned and peeled fruits and vegetables that have grown in contaminated soil, explaining why *Ascaris*, *Strongyloides,* hookworm (*Necator duodenale* and *Ancylostoma duodenale*), and whipworm *(Trichuris trichiura)* are known as soil-transmitted helminths. Ingested eggs hatch in the intestine, and larvae penetrate the intestinal mucosa. Larvae then migrate from splanchnic to systemic circulations and finally enter the lungs to grow within the alveoli. Approximately 3 weeks later, the larvae are coughed up and swallowed.

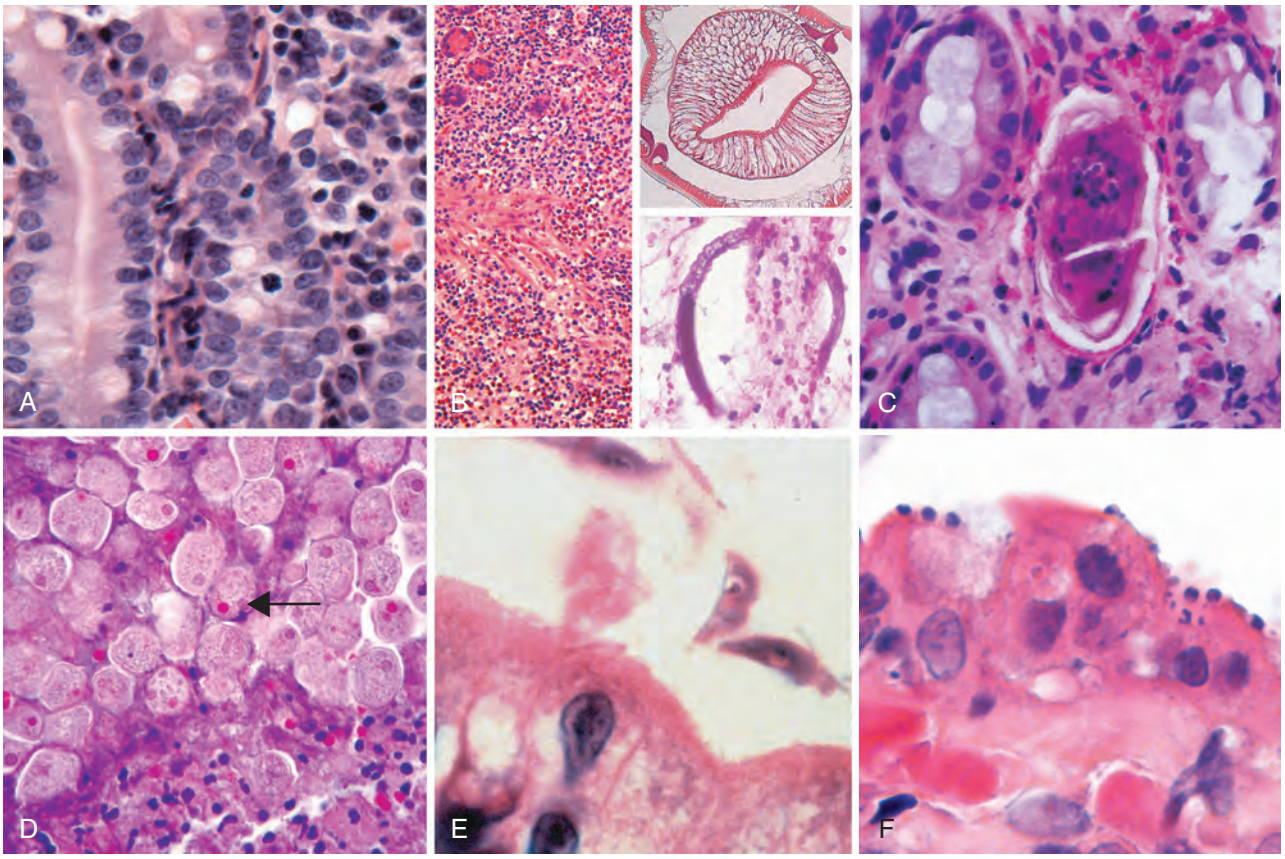

Figure 17.32 Infectious enteritis. (A) Histologic features of viral enteritis include increased numbers of intraepithelial and lamina propria lymphocytes and crypt hypertrophy. (B) Diffuse eosinophilic infiltrates in parasitic infection. This case was caused by *Ascaris (upper inset)*, but a similar tissue reaction could be caused by *Strongyloides (lower inset)*. (C) Schistosomiasis can induce an inflammatory reaction to eggs trapped within the lamina propria. (D) *Entamoeba histolytica* in a colon biopsy specimen. Note some organisms ingesting red blood cells *(arrow)*. (E) *Giardia lamblia*, which are present in the luminal space over nearly normal-appearing villi, are easily overlooked. (F) *Cryptosporidium* organisms are seen as small blue spheres that appear to lie on top of the brush border but are actually enveloped by a thin layer of host cell cytoplasm.

Upon return to the small intestine, the larvae mature into adult worms, which induce an eosinophil-rich inflammatory reaction (Fig. 17.32B) that can cause physical obstruction of the intestine or biliary tree. Larvae can also form hepatic abscesses and cause pneumonitis. Diagnosis is usually made by detection of eggs in stool samples.

Strongyloides. The larvae of *Strongyloides* live in fecally contaminated ground soil and can penetrate unbroken skin. They migrate through the lungs, where they induce inflammatory infiltrates, and then reside in the intestine while maturing into adult worms. Unlike other intestinal worms, which require an ova or larval stage outside the human, the eggs of *Strongyloides* can hatch within the intestine and release larvae that penetrate the mucosa, causing autoinfection (Fig. 17.32B). Hence *Strongyloides* infection can persist for life, and immunosuppressed individuals can develop overwhelming autoinfection. *Strongyloides* incite a strong tissue reaction and peripheral eosinophilia.

Necator duodenale *and* Ancylostoma duodenale. These hookworms infect 1 billion people worldwide and cause significant morbidity. Infection is initiated by larval penetration through the skin. After further development in the lungs, they migrate up the trachea and are swallowed. Worms attach to the duodenal mucosa, suck blood, and reproduce. This causes multiple superficial erosions, focal hemorrhage, inflammatory infiltrates, and, in chronic infection, iron deficiency anemia. Diagnosis can be made by detection of the eggs in fecal smears.

Trichuris trichiura. Whipworms primarily infect young children. Similar to *Enterobius vermicularis, T. trichiura* does not penetrate the intestinal mucosa and rarely causes serious disease. Heavy infections may cause bloody diarrhea and rectal prolapse.

Enterobius vermicularis *and* Enterobius gregorii. These organisms, also known as pinworms, infect people in both high income and low income countries; over 1 billion are infected worldwide. *E. vermicularis* is the more common species, but *Enterobius gregorii* have also been reported in Europe, Africa, and Asia. Because they do not invade host tissue and live their entire life within the intestinal lumen, pinworms rarely cause serious illness. Infection is primarily by the fecal-oral route. Adult worms living in the intestine migrate to the anal orifice at night, where the female deposits eggs on the perirectal mucosa. The eggs cause irritation and rectal and perineal pruritus. Scratching leads to contamination of the fingers, which promotes human-to-human transmission.

Both eggs and adult pinworms remain viable outside the body, and repeat infection is common. Diagnosis can be made by applying cellophane tape to the perianal skin and examining the tape under a microscope to identify eggs.

Schistosomiasis. This disease involving the intestines most commonly takes the form of adult worms residing within the mesenteric veins. Eggs are trapped within the mucosa and submucosa (Fig. 17.32C). The resulting immune reaction is often granulomatous and can cause bleeding and even obstruction. More details are presented in Chapter 8.

Intestinal Cestodes. The three primary species of cestodes that affect humans are *Diphyllobothrium latum,* fish tapeworms; *Taenia solium,* pork tapeworms; and *Hymenolepis nana,* dwarf tapeworms. They reside exclusively within the intestinal lumen and are transmitted by ingestion of raw or undercooked fish, meat, or pork that contains encysted larvae. Release of the larva allows attachment to the intestinal mucosa through its head, or scolex. The worm derives its nutrients from the food stream and enlarges by formation of egg-filled segments termed proglottids. Humans are usually infected by a single worm, and since the worm does not penetrate the intestinal mucosa, peripheral eosinophilia does not generally occur. Nevertheless, the parasite burden can be staggering. Adult worms can grow to many meters in length and shed large numbers of proglottids and eggs into the feces. Clinical symptoms include abdominal pain, diarrhea, and nausea, but most cases are asymptomatic. Occasionally, *D. latum* causes B_{12} deficiency and megaloblastic anemia because it competes with the host for dietary B_{12}. Identification of proglottids and eggs in stools is the most efficient method of diagnosis.

Entamoeba histolytica. This protozoan causes amebiasis and is spread by fecal-oral transmission. *E. histolytica* infects approximately 500 million people in countries such as India, Mexico, and Colombia and causes 40 million cases of dysentery and liver abscess annually. The cysts have four nuclei and a chitin wall that is resistant to gastric acid, a characteristic that allows them to pass through the stomach without harm. *E. histolytica* then colonize the epithelial surface of the colon and release trophozoites, ameboid forms that reproduce under anaerobic conditions.

Amebiasis affects the cecum and ascending colon most often, but sigmoid colon, rectum, and appendix can also be involved. Dysentery develops when the amebae attach to the colonic epithelium, induce apoptosis, invade crypts, and burrow laterally into the lamina propria. This recruits neutrophils, causes tissue damage, and creates a flask-shaped ulcer with a narrow neck and broad base. Histologic diagnosis can be difficult, since amebae can be similar to macrophages in size and appearance (Fig. 17.32D). Parasites penetrate splanchnic vessels and embolize to the liver to produce abscesses in about 40% of patients with amebic dysentery. Amebic liver abscesses can exceed 10 cm in diameter and have a scant inflammatory reaction at their margins with a shaggy fibrin lining. The abscesses persist after the acute intestinal illness has passed and may, rarely, reach the lung and the heart by direct extension. Amebae may also spread to the kidneys and brain via the bloodstream.

Individuals with amebiasis may present with abdominal pain, bloody diarrhea, or weight loss. Occasionally, acute necrotizing colitis and megacolon occur; both are associated with significant mortality. The parasites lack mitochondria or Krebs cycle enzymes and are thus obligate fermenters of glucose. Metronidazole, which inhibits pyruvate oxidoreductase, an enzyme required for fermentation, is the most effective treatment for systemic disease.

Giardia lamblia. These organisms, also referred to as *G. duodenalis* or *G. intestinalis,* were initially described by van Leeuwenhoek, the inventor of the microscope, who discovered the pathogen in his own stool. *G. lamblia* is the most common parasitic pathogen in humans and is spread by fecally contaminated water or food. Infection may occur after ingestion of as few as 10 cysts. Because cysts are resistant to chlorine, *Giardia* are endemic in unfiltered public water supplies. They are also common in rural streams, explaining infection in campers who use these as a water source. Infection may occur by the fecal-oral route, and because the cysts are stable, they may be accidentally swallowed while swimming in contaminated water.

Giardia are flagellated protozoans that cause decreased expression of brush-border enzymes, microvillous damage, and apoptosis of small intestinal epithelial cells. Secretory IgA and mucosal IL-6 responses are important for clearance of *Giardia* infections. Immunosuppressed, agammaglobulinemic, or malnourished individuals are often severely affected. *Giardia* can evade immune clearance through continuous modification of the major surface antigen, variant surface protein, and can persist for months or years, causing intermittent symptoms.

Giardia trophozoites can be identified in duodenal biopsies based on their characteristic pear shape and the presence of two equally sized nuclei. Despite large numbers of trophozoites, some of which are tightly bound to the brush border of villous enterocytes, there is no invasion, and small intestinal morphology may be normal (Fig. 17.32E); villous blunting with increased numbers of intraepithelial lymphocytes and mixed lamina propria inflammatory infiltrates can accompany heavy infections.

Giardiasis may be subclinical or accompanied by acute or chronic diarrhea, malabsorption, and weight loss. Infection is usually documented by immunofluorescent detection of cysts in stool samples. Oral antimicrobial therapy is effective, but recurrence is common.

Cryptosporidium. Like *Giardia,* cryptosporidia are an important cause of diarrhea worldwide. Cryptosporidiosis was first discovered in the 1980s as an agent of chronic diarrhea in acquired immunodeficiency syndrome (AIDS) patients and is now recognized as a cause of acute, self-limited disease in immunologically normal hosts. Cryptosporidiosis also causes persistent diarrhea in residents of under-resourced countries. The organisms are present worldwide, with the exception of Antarctica, perhaps, because the oocysts are killed by freezing. Oocysts are resistant to chlorine and may therefore persist in treated, but unfiltered, water. Contaminated drinking water continues to be the most common means of transmission. The largest documented outbreak, a result of inadequate water purification, occurred in 1993 in Milwaukee, Wisconsin, and affected

more than 400,000 people. Like giardiasis, cryptosporidiosis is readily spread to water sport participants. Food-borne infection occurs less frequently.

Humans are infected by several different *Cryptosporidium* species, including *C. hominis* and *C. parvum*. All are able to go through an entire life cycle, with asexual and sexual reproductive phases, in a single host. Once ingested, as few as 10 encysted oocytes are sufficient to cause symptomatic infection. Sporozoites are released following protease activation by gastric acid. They are motile and have a specialized organelle that attaches to the brush border and causes changes in the enterocyte cytoskeleton. These changes induce the enterocyte to engulf the parasite, which takes up residence in an endocytic vacuole. Sodium malabsorption, chloride secretion, and increased tight junction permeability cause the nonbloody, watery diarrhea that ensues.

Mucosal histology is often only minimally altered, but persistent cryptosporidiosis in children and heavy infection in immunosuppressed patients can result in villous atrophy, crypt hyperplasia, and inflammatory infiltrates. Although the sporozoite is intracellular, it appears, by light microscopy, to sit on top of the epithelial apical membrane (Fig. 17.32F). Organisms are typically most concentrated in the terminal ileum and proximal colon, but can be present throughout the gut, biliary tract, and even the respiratory tract of immunodeficient hosts. Diagnosis is based on finding oocysts in the stool.

KEY CONCEPTS

INFECTIOUS ENTEROCOLITIS

- *V. cholerae* secrete a preformed toxin that causes massive chloride secretion. Water follows the resulting osmotic gradient, leading to secretory diarrhea.
- *C. jejuni* is the most common bacterial enteric pathogen in high income countries and also causes traveler's diarrhea. Most isolates are noninvasive.
- *Salmonella* and *Shigella* spp. are invasive and associated with exudative bloody diarrhea (dysentery).
- *Salmonella enteritidis* infection is a common cause of food poisoning.
- *S. typhi* cause systemic disease (typhoid fever).
- Pseudomembranous colitis is often triggered by antibiotic therapy. The responsible organism, *C. difficile*, releases toxins that disrupt epithelial function and induce an inflammatory response that includes characteristic volcano-like eruptions of neutrophils from colonic crypts. These spread to form mucopurulent pseudomembranes.
- Norovirus is a common cause of self-limited diarrhea in adults and children. It spreads from person to person in sporadic cases and via contaminated water in epidemics.
- Rotavirus causes severe childhood diarrhea and significant mortality worldwide. Widespread vaccination has reduced the incidence of rotaviral infection.
- Parasitic and protozoal infections affect more than one-half of the world's population on a chronic or recurrent basis. Each parasite has a distinctive life cycle and tissue reaction. Those that invade are typically associated with tissue and systemic eosinophilia.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits. Despite very real symptoms, the endoscopic and microscopic evaluations are normal in IBS patients. Thus, the diagnosis depends on clinical symptoms and functional testing. It should be recognized that IBS is a syndrome and that multiple illnesses may be represented under this global descriptor. IBS is currently divided into diarrhea-predominant, constipation-predominant, and mixed subtypes, as defined by successive revisions of the Rome criteria.

Pathogenesis

The pathogenesis of IBS remains poorly defined, although there is clearly interplay between psychologic stressors, diet, perturbation of the gut microbiome, increased enteric sensory responses to GI stimuli, and abnormal GI motility. For example, patients with constipation-predominant or diarrhea-predominant IBS tend to have decreased or increased colonic contractions and transit rates, respectively. Excess bile acid synthesis or bile acid malabsorption has been identified as one cause of diarrhea-predominant IBS, likely due to the effects of bile acids on intestinal motility and epithelial ion transport.

Other data link disturbances in enteric nervous system function to IBS, suggesting a role for defective brain-gut axis signaling. Consistent with this, deep sequencing and genome-wide association studies have linked several candidate genes to IBS including serotonin reuptake transporters, cannabinoid receptors, and TNF-related inflammatory mediators. Further, 5-HT3 receptor antagonists are effective in many cases of diarrhea-predominant IBS. Opioids and psychoactive drugs with anti-cholinergic effects are also used to treat diarrhea-predominant IBS.

A separate group of IBS patients relate onset to a bout of infectious gastroenteritis, suggesting that immune activation or, alternatively, a shift in the gut microbiome may trigger disease.

Clinical Features

The peak prevalence of IBS is between 20 and 40 years of age, and there is a significant female predominance. Variability in diagnostic criteria makes it difficult to establish the incidence, but most authors report a prevalence in high income countries of between 5% and 10%. IBS is presently diagnosed using clinical criteria that require the occurrence of abdominal pain or discomfort at least 3 days per month over 3 months with improvement following defecation and a change in stool frequency or form. Other causes, such as enteric infection or inflammatory bowel disease, must be excluded.

INFLAMMATORY BOWEL DISEASE (IBD)

Inflammatory bowel disease (IBD) is a chronic condition resulting from complex interactions between intestinal microbiota and host immunity in genetically predisposed individuals that leads to inappropriate mucosal immune

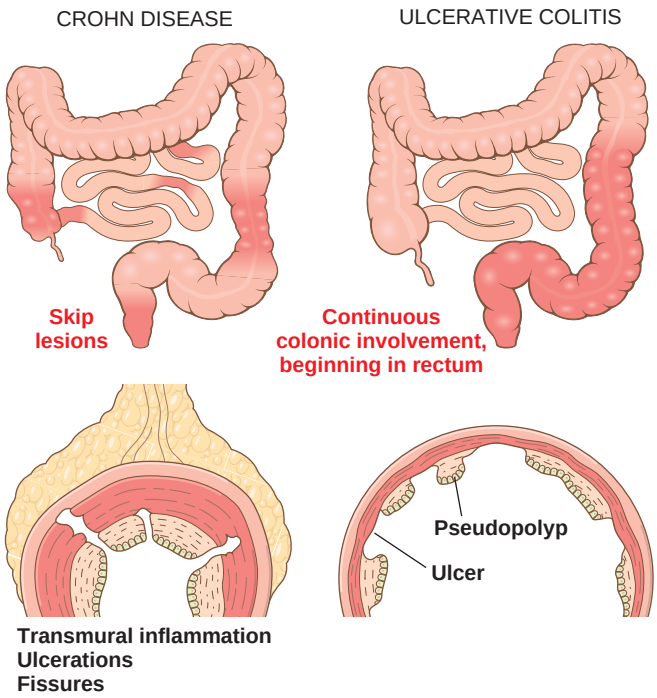

Figure 17.33 Distribution of lesions in inflammatory bowel disease. The distinction between Crohn disease and ulcerative colitis is primarily based on morphology.

Table 17.8 Features That Differ Between Crohn Disease and Ulcerative Colitis

Feature	Crohn Disease	Ulcerative Colitis
Macroscopic		
Bowel region	Ileum ± colon	Colon only
Distribution	Skip lesions	Diffuse
Stricture	Yes	Rare
Wall appearance	Thick	Normal
Microscopic		
Inflammation	Transmural	Limited to mucosa
Pseudopolyps	Moderate	Marked
Ulcers	Deep, knife-like	Superficial, broad-based
Lymphoid reaction	Marked	Moderate
Fibrosis	Marked	Mild to none
Serositis	Marked	Mild to none
Granulomas	Yes (~35%)	No
Fistulae/sinuses	Yes	No
Clinical		
Perianal fistula	Yes (in colonic disease)	No
Fat/vitamin malabsorption	Yes	No
Malignant potential	With colonic involvement	Yes
Recurrence after surgery	Common	No
Toxic megacolon	No	Yes

All features may not be present in a single case.

activation. The two disorders that comprise IBD are ulcerative colitis and Crohn disease. Descriptions of ulcerative colitis and Crohn disease date back to antiquity and at least the 16th century, respectively, but it took modern microbiologic techniques to exclude conventional infectious etiologies for these diseases. As will be discussed later, however, the luminal microbiota likely play an important role in IBD pathogenesis.

The distinction between ulcerative colitis and Crohn disease is primarily based on the distribution of affected sites (Fig. 17.33) and the morphologic expression of disease (Table 17.8) at those sites. **Ulcerative colitis involves only the colon and rectum and is generally limited to the mucosa and submucosa. In contrast, Crohn disease, which has also been referred to as regional enteritis (because of frequent ileal involvement) may involve any area of the GI tract and is typically transmural.**

Epidemiology. Ulcerative colitis and Crohn disease most frequently present in the teens and early 20s but can develop at any age. IBD is most common among Caucasians and in the United States occurs three to five times more often among eastern European (Ashkenazi) Jews than the general population. This is at least partly due to genetic factors, as discussed later. IBD is most common in North America, northern Europe, and Australia, but incidence worldwide is on the rise and is becoming significant in Africa, South America, and Asia, where prevalence was historically low. The hygiene hypothesis suggests that this increasing incidence is related to improved food storage conditions, decreased food contamination, and changes in gut microbiome composition that result in inadequate development of regulatory processes that limit mucosal immune responses. This in turn allows some mucosa-associated microbes to trigger persistent and chronic inflammation in susceptible hosts. Other potential explanations for increased IBD prevalence include the idea that preservatives and other materials added to processed foods induce low-grade mucosal damage that predisposes to IBD.

Pathogenesis

IBD results from a combination of abnormalities in immune regulation, host-microbe interactions, and epithelial barrier functions in genetically susceptible individuals. Over 200 IBD-associated genetic polymorphisms have been identified, but these account for less than 50% of disease risk in Crohn disease and make even smaller contributions to ulcerative colitis. For example, polymorphisms of *NOD2,* the strongest risk gene for Crohn disease, are associated with only a 10-fold increased risk of disease. Further, risk-associated *NOD2* alleles are found in about 35% of Caucasians with Crohn disease, or twice as often as in healthy Caucasians. Thus, while genetic predisposition is important, environmental factors are also critical to pathogenesis. The genetic and environmental elements that contribute to disease can be thought of in terms of immunity, autophagy and cellular stress responses, and host-microbial interactions.

- *Mucosal immunity.* A plethora of immune signaling and regulatory genes including those encoding HLA molecules and cytokines have been associated with IBD. In the case of the latter, polymorphisms in genetic loci that include genes in both proinflammatory, e.g., interferon-γ, and

anti-inflammatory (immunoregulatory), e.g., IL-10 and the IL-10 receptor, signaling are involved. Th1 polarization is present in both diseases, although there is also evidence of Th2 activation in ulcerative colitis, perhaps reflecting the underlying differences in genes associated with disease. Th17 signaling is also important to IBD pathogenesis, as both Crohn disease and ulcerative colitis are linked to polymorphisms in the IL-23 receptor and other molecules involved in Th17 signaling. These genetic data are consistent with the observation that Th17 T-cell populations are expanded within diseased intestine.

Many of the genes linked to IBD are also associated with other autoimmune diseases including diabetes mellitus, rheumatoid arthritis, and psoriasis. In most cases the risk alleles are consistent across diseases, but in a few cases alleles linked to increased risk in other diseases are protective in IBD. This may explain why some immunomodulatory therapies that are effective in IBD enhance progression of other diseases, while, conversely, some therapies that are effective in other diseases may exacerbate IBD.

Overall, multiple genetic polymorphisms contribute to IBD pathogenesis, and the specific genes involved vary between Crohn disease and ulcerative colitis, among individuals, and, in a few genes, across ethnic groups. For example, *NOD2* polymorphisms have not been associated with Crohn disease in Asian populations. Within ethnic groups, network analyses have demonstrated that the constellation of risk alleles present correlates with disease phenotype including the presence of colonic involvement, strictures, or fistulae in Crohn disease.

- *Autophagy and cellular stress responses.* Genetic associations as well as molecular analyses indicate that defects in autophagy and cellular stress responses contribute to IBD pathogenesis. The most studied of these genes include *ATG16L1* and *IRGM,* both of which are involved in autophagosome formation. Autophagy is a normal homeostatic mechanism that clears damaged organelles and is upregulated in response to cellular stress including nutrient deprivation and endoplasmic reticulum stress. Autophagy is also a means of clearing sources of reactive oxygen species and intracellular pathogens. The *ATG16L1* mutation that is linked to Crohn disease promotes ATG16L1 degradation, thereby limiting autophagy. The precise pathways by which loss of ATG16L1 function leads to disease are still being defined, but it is noteworthy that Paneth cell granules, which contain antibacterial peptides that are released into the crypt lumen, are structurally and functionally abnormal in patients and mice with *ATG16L1* defects.
- *Host-microbial interactions.* The gut microbiome, composed of bacteria, fungi, and viruses, has been the subject of intense investigation over the last decade. Because many of these organisms are not culturable by standard techniques, the studies have largely relied on high-throughput sequencing technologies.

  In general, the microbiome is populated by a small number of species at birth. This evolves to become a far more complex ecosystem with many more species after weaning and through childhood. Microbial complexity then declines in old age. Data from human subjects as well as experimental models have shown that microbes express proteins and other molecules and generate metabolites that can protect against or promote disease. Specific examples include *Clostridia* species, which stimulate development of regulatory T cells, and *Bifidobacterium,* which promote Th17 differentiation. In addition, multiple species produce butyrate, whose activities include enhancement of mucosal barrier function, increased epithelial proliferation, and immune regulation.

  Soluble microbial products activate host sensing proteins, including surface TLRs and dectin receptors and intracellular microbial-associated pattern receptors, e.g., *NOD2*. This is one means by which the microbiome can modulate mucosal immunity. Conversely, the immune system can markedly alter the microbiome by mechanisms that include luminal secretion of antimicrobial peptides and antibacterial IgA. This interplay between microbes and the immune system may contribute to the evolution of dysbiosis, characterized by shifts in microbial populations and reduced species diversity, in disease. Thus, although dysbiosis is often established at disease presentation, it is difficult to differentiate between microbial changes that trigger disease and those that are caused by disease.

  A notable exception to the polygenic nature of IBD is very early onset IBD, which can be driven by mutations in single genes required for epithelial ion transport, immune signaling, or host defense. Studies of these monogenic forms of IBD have shed light on mechanisms involved in more common forms of IBD. For example, it was learned that macrophages produce excessive IL-1β in infants with IL-10 receptor mutations (the most common mutation in very early onset IBD). These patients have benefited from IL-1 receptor antagonist treatment, and the efficacy of similar treatment is now being evaluated in polygenic IBD.

Crohn Disease

The eponym *Crohn disease* is based on a 1932 publication, but the entity was described centuries earlier. For example, Louis XIII of France (1601–1643) suffered relapsing bloody diarrhea, fever, rectal abscess, small intestinal and colonic ulcers, and fistulae beginning at age 20 years, all of which are classic features of Crohn disease.

MORPHOLOGY

Crohn disease may occur in any area of the GI tract but most commonly involves the terminal ileum, ileocecal valve, and cecum. Disease is limited to the small intestine in about 40% of cases; the small intestine and colon are both involved in 30% of patients; the remainder have only colonic involvement. The presence of multiple, separate, sharply delineated areas of disease, resulting in **skip lesions,** is characteristic, and when present, differentiates Crohn disease from ulcerative colitis. The presence of strictures, which occur commonly in Crohn disease but only rarely in long-standing ulcerative colitis, may also be helpful (Fig. 17.34A).

The earliest lesion of Crohn disease, the **aphthous ulcer,** may progress, and multiple lesions often coalesce into elongated, serpentine ulcers oriented along the axis of the bowel (Fig. 17.34B). Edema and loss of the normal mucosal folds are common. Ulceration with sparing of interspersed mucosa, a result of the patchy distribution of Crohn disease, results in an irregular, **cobblestone** appearance of the mucosa (Fig. 17.34B). **Fissures**

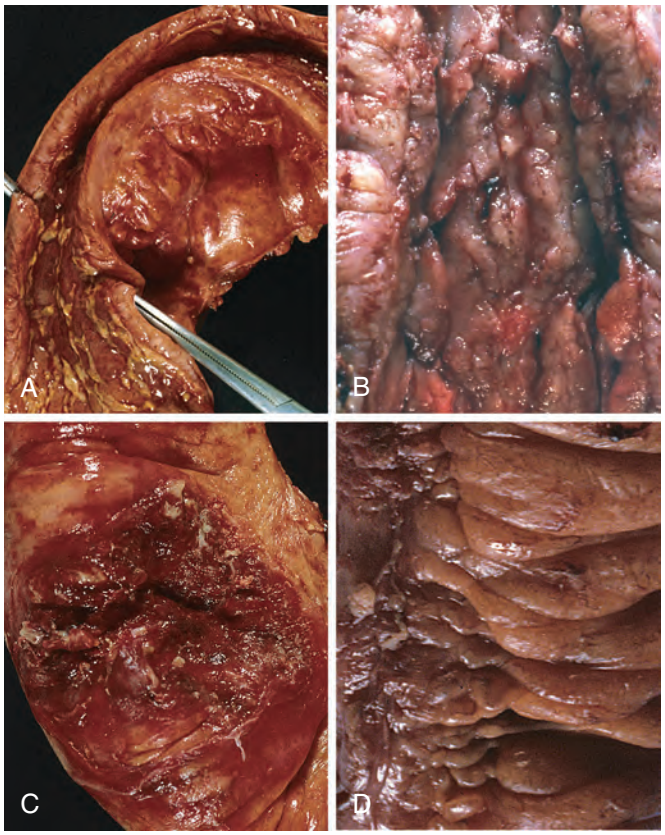

Figure 17.34 Gross pathology of Crohn disease. (A) Small intestinal stricture. (B) Linear mucosal ulcers, which impart a cobblestone appearance to the mucosa, and thickened intestinal wall. (C) Perforation and associated serositis. (D) Creeping fat.

frequently develop and may extend deeply to become fistula tracts or sites of perforation (Fig. 17.34C). The intestinal wall is thickened and rubbery as a consequence of transmural edema, inflammation, submucosal fibrosis, and hypertrophy of the muscularis propria, all of which contribute to stricture formation (see Fig. 17.34A). In cases with extensive transmural disease, mesenteric adipose tissue frequently extends over the serosal surface **(creeping fat)** (Fig. 17.34D).

The microscopic features of active Crohn disease include abundant neutrophils that infiltrate and damage crypt epithelium. Clusters of neutrophils within a crypt are referred to as **crypt abscesses** and are often associated with crypt destruction. Ulceration is common in Crohn disease, and there may be an abrupt transition between ulcerated and adjacent normal mucosa. Even in areas where gross examination suggests diffuse disease, microscopic pathology can appear patchy. Repeated cycles of crypt destruction and regeneration lead to **distortion and disorganzation of mucosal glands;** the normally straight and parallel crypts take on bizarre branching shapes and unusual orientations to one another (Fig. 17.35A). Epithelial metaplasia is another consequence of chronic relapsing injury. One form, **pseudopyloric metaplasia,** refers to the presence of gastric antral-appearing glands. **Paneth cell metaplasia** may also occur in the left colon, where Paneth cells are normally absent. These architectural and metaplastic changes may persist even when active inflammation has resolved. Mucosal atrophy, with loss of crypts, may also occur after years of disease. **Noncaseating granulomas** (Fig. 17.35C), a hallmark of Crohn disease, are found in approximately 35% of cases and may occur in areas of active disease (Fig. 17.35C) or uninvolved regions within any layer of the intestinal wall (Fig. 17.35D). Granulomas may also be present in draining mesenteric lymph nodes.

Clinical Features

The clinical manifestations of Crohn disease are extremely variable. In most patients, disease begins with intermittent attacks of relatively mild diarrhea, fever, and abdominal pain. Approximately 20% of patients present acutely with right lower quadrant pain, fever, and bloody diarrhea that may mimic acute appendicitis or bowel perforation. Periods of active disease are typically interrupted by asymptomatic periods that last for weeks to many months. Disease reactivation can be associated with a variety of external triggers, including physical or emotional stress, specific dietary items, and cigarette smoking. The latter is a strong risk factor for development of Crohn disease, and in some cases, disease onset is associated with initiation of smoking. Unfortunately, smoking cessation does not result in disease remission.

Iron deficiency anemia due to blood loss may develop in individuals with colonic disease, while extensive small bowel disease may result in protein loss sufficient to cause hypoalbuminemia and malabsorption of nutrients, vitamin B_{12}, and bile salts. Fibrosing strictures, particularly of the terminal ileum, are common and require surgical resection. Disease often recurs at the site of anastomosis, and as many as 40% of patients require additional resections within 10 years. Fistulae develop between loops of bowel and may also involve the urinary bladder, vagina, and abdominal or perianal skin. Perforation and peritoneal abscesses are common. Therapies include anti-inflammatory agents, e.g., salicylates; immunosuppressive drugs, e.g., corticosteroids; and biologic therapies, e.g., anti-TNF antibodies. Over the last two decades, anti-TNF antibodies have revolutionized treatment of Crohn disease. More recently, other biologic therapies including antibodies against other cytokines and cell adhesion proteins that are necessary for inflammatory cell migration as well as targeted kinase inhibitors are in various stages of testing and approved clinical use. It is not difficult to envision treatment algorithms that use the genetics, immune function, and microbial composition of individual patients to guide selection of targeted therapies.

Extraintestinal manifestations of Crohn disease include cutaneous nodules formed by granulomas, uveitis, migratory polyarthritis, sacroileitis, ankylosing spondylitis, erythema nodosum, cutaneous granulomas, and clubbing of the fingertips, any of which may develop before intestinal disease is recognized. Pericholangitis and primary sclerosing cholangitis occur in individuals with Crohn disease with a higher frequency than in those without Crohn disease, but are even more common in individuals with ulcerative colitis (see below and Chapter 18). As discussed later, risk of colonic adenocarcinoma is increased in patients with long-standing colonic disease.

Ulcerative Colitis

Ulcerative colitis is closely related to Crohn disease, but its intestinal involvement is limited to the colon and rectum.

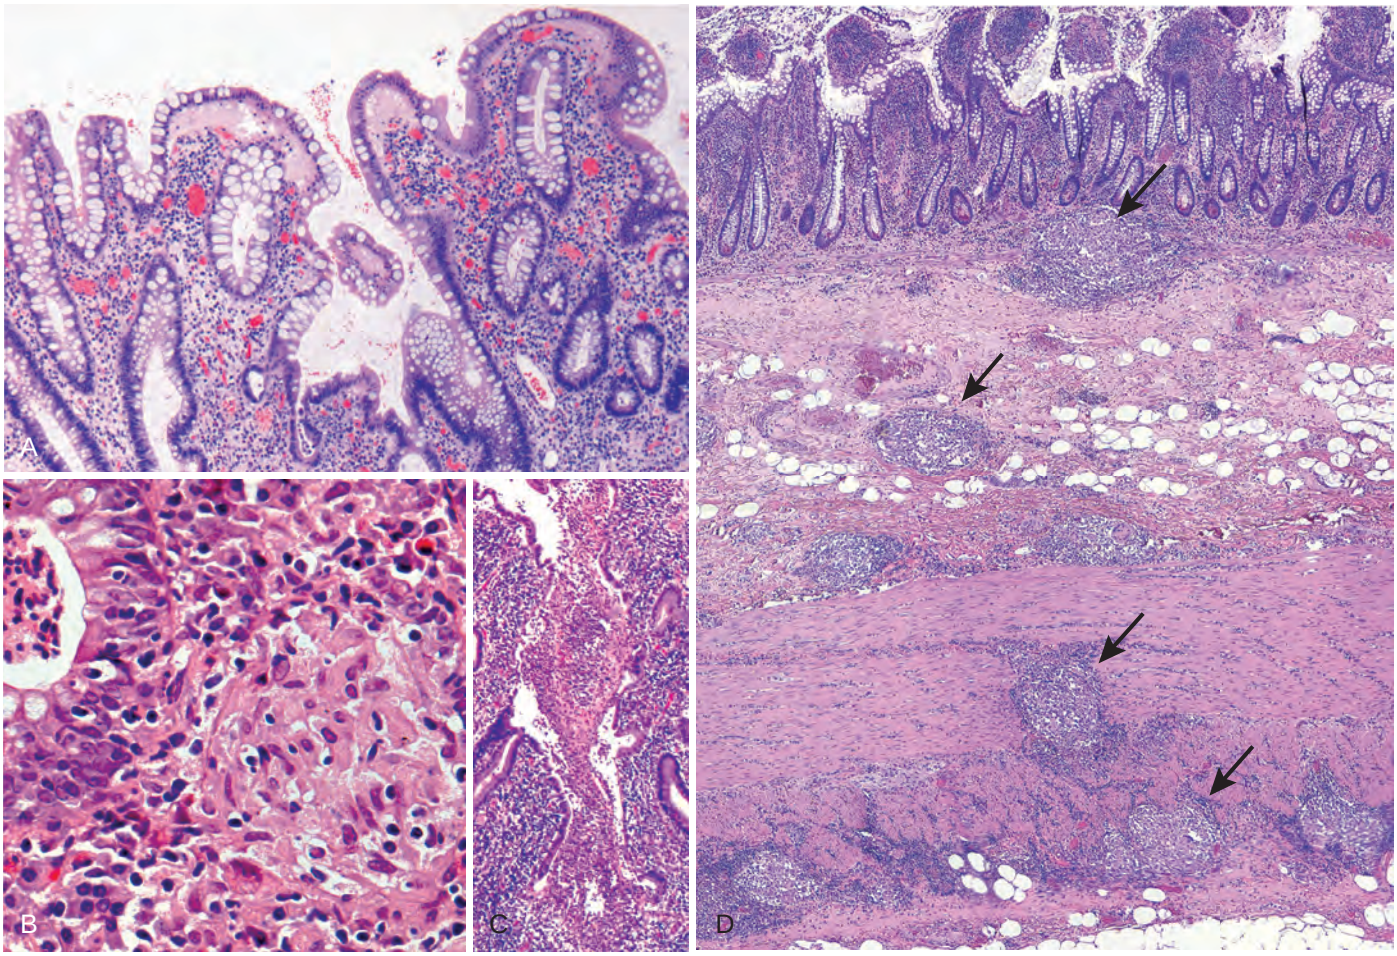

Figure 17.35 Microscopic pathology of Crohn disease. (A) Haphazard crypt organization results from repeated injury and regeneration. (B) Noncaseating granuloma. (C) Active Crohn disease, with ulceration and purulent exudate. (D) Transmural Crohn disease with submucosal and serosal granulomas *(arrows)*.

Extraintestinal manifestations of ulcerative colitis overlap with those of Crohn disease and include migratory polyarthritis, sacroiliitis, ankylosing spondylitis, uveitis, and skin lesions. Approximately 2.5% to 7.5% of individuals with ulcerative colitis also have primary sclerosis cholangitis (Chapter 18). The long-term outlook for ulcerative colitis patients depends on the severity of active disease and disease duration. Many of the therapies, including anti-TNF antibodies, that are effective in Crohn disease are also effective in ulcerative colitis. Some Crohn disease treatments are, however, ineffective in ulcerative colitis suggesting that the molecular mechanisms underlying these two forms of IBD are not entirely overlapping.

MORPHOLOGY

Grossly, ulcerative colitis always involves the rectum and extends proximally in a continuous fashion to involve part or all of the colon. Disease of the entire colon is termed **pancolitis** (Fig. 17.36A). Limited distal disease may be referred to descriptively as **ulcerative proctitis** or **ulcerative proctosigmoiditis.** The small intestine is normal, although mild mucosal inflammation of the distal ileum, termed *backwash ileitis,* may be present in severe cases of pancolitis. Skip lesions are not seen (although focal appendiceal or cecal inflammation may occasionally be present in ulcerative colitis that is otherwise limited to the distal colon).

Grossly, involved colonic mucosa may be slightly red and granular or have extensive, broad-based ulcers. There can be an abrupt transition between diseased and uninvolved colon (Fig. 17.36B). Ulcers are aligned along the long axis of the colon but do not typically replicate the serpentine ulcers of Crohn disease. Isolated islands of regenerating mucosa often bulge into the lumen to create **pseudopolyps** (Fig. 17.36C), and the tips of these polyps may fuse to create **mucosal bridges** (Fig. 17.36D). Chronic disease may lead to **mucosal atrophy** with a smooth mucosal surface that lacks normal folds. Unlike Crohn disease, ulcerative colitis is not transmural. As a result **the colon wall is not thickened, the serosal surface is normal, and strictures do not occur.** Uncommonly, severe cases are associated with inflammation of the muscularis propria and neuromuscular dysfunction leading to colonic dilation and **toxic megacolon,** which carries a significant risk of perforation.

Histologic features of mucosal disease in ulcerative colitis are similar to colonic Crohn disease and include inflammatory infiltrates, crypt abscesses (Fig. 17.37A), crypt distortion, and pseudopyloric epithelial metaplasia (Fig. 17.37B). In contrast to

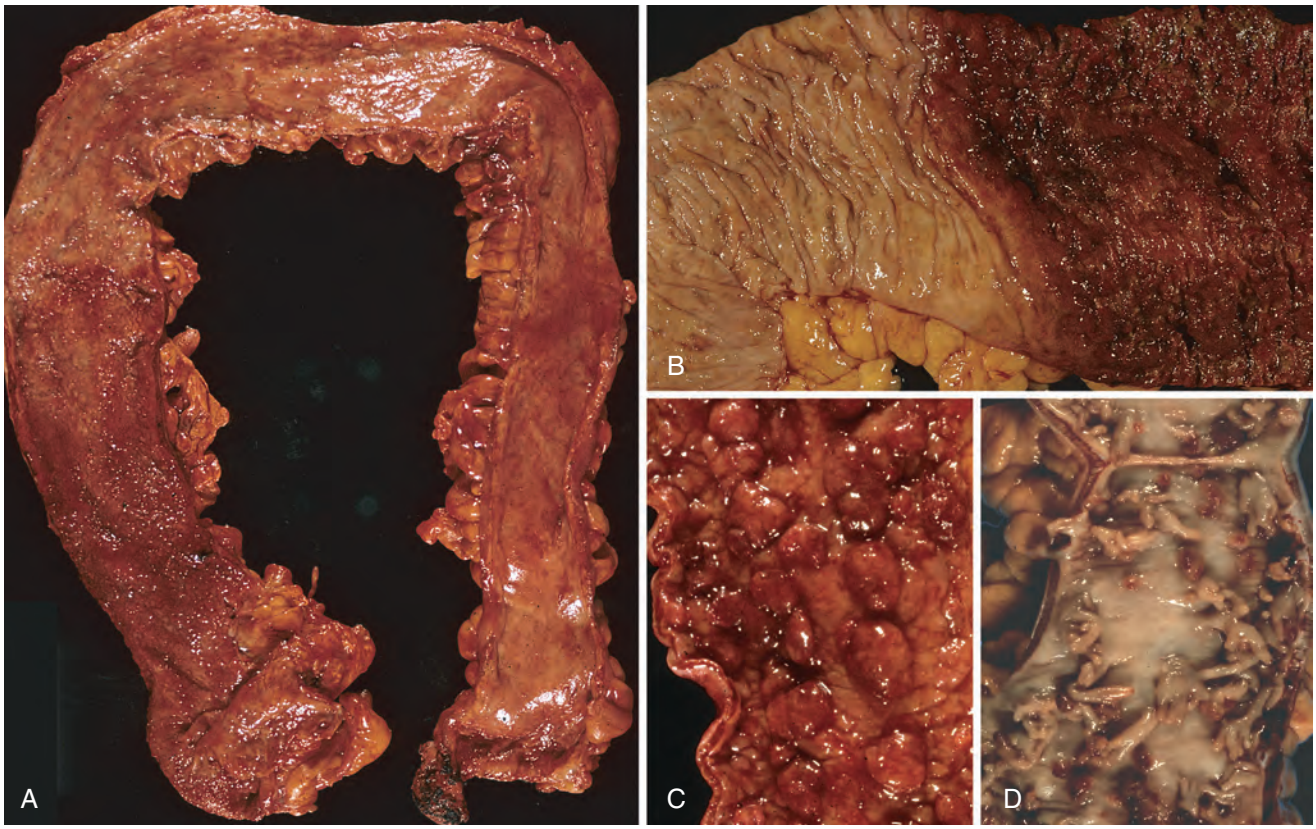

Figure 17.36 Gross pathology of ulcerative colitis. (A) Total colectomy with pancolitis showing active disease, with red, granular mucosa in the cecum (left) and smooth, atrophic mucosa distally (right). (B) Sharp demarcation between active ulcerative colitis (right) and normal mucosa (left). (C) Inflammatory polyps. (D) Mucosal bridges can join inflammatory polyps.

Crohn disease, granulomas are not present, and the diffuse inflammation is generally limited to the mucosa and superficial submucosa (Fig. 17.37C). In severe cases, extensive mucosal destruction may be accompanied by ulcers that extend into the submucosa, but the muscularis propria is rarely involved. Submucosal fibrosis, mucosal atrophy, and distorted mucosal architecture remain as residua of healed disease, but histology may also revert to near normal after prolonged remission.

Clinical Features

Ulcerative colitis is a relapsing disorder characterized by attacks of bloody diarrhea with stringy mucoid material, lower abdominal pain, and cramps that are temporarily relieved by defecation. These symptoms may persist for days, weeks, or months before they subside. The initial attack may, in some cases, be severe enough to constitute a medical or surgical emergency. More than half of patients have clinically mild disease, although almost all experience at least one relapse during a 10-year period. Historically, up to 30% of those affected required colectomy within the first 3 years after presentation because of uncontrollable symptoms, but the incidence of colectomy has fallen sharply with improvements in medical management. Colectomy effectively cures intestinal disease in ulcerative colitis, but extraintestinal manifestations may persist.

The factors that trigger development of ulcerative colitis in previously healthy individuals are not known. However, infectious enteritis precedes disease onset in some cases. It has been hypothesized that enteritis triggers mucosal immune activation and microbial changes that lead to disease in susceptible individuals. In other patients the first episode of disease is preceded by psychologic stress, which may also be linked to relapse during remission. The initial onset of symptoms has also been reported to occur shortly after smoking cessation in some patients; in these smoking may partially relieve symptoms.

Indeterminate Colitis

Because of the extensive genetic, pathologic, and clinical overlap between ulcerative colitis and Crohn disease (see Table 17.8), definitive diagnosis is not possible in up to 10% of IBD patients. These cases, termed indeterminate colitis, do not involve the small bowel and have colonic disease in a continuous pattern typical of ulcerative colitis but also have features suggestive of Crohn disease. These include patchy histologic disease, a family history of Crohn disease, and perianal lesions. Serologic studies can be useful in cases with overlapping features, as perinuclear anti-neutrophil cytoplasmic antibodies are found in 75% of individuals with ulcerative colitis and only 11% of individuals with Crohn disease. In contrast, antibodies to *Saccharomyces cerevisiae* are

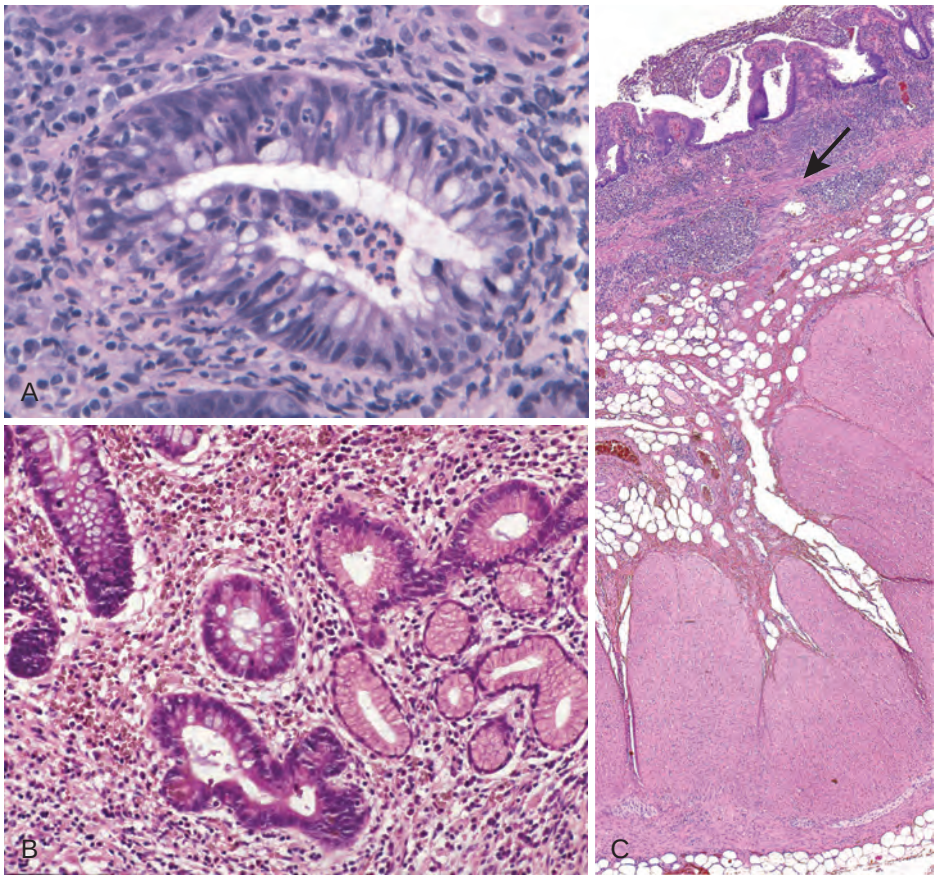

Figure 17.37 Histopathology of ulcerative colitis. (A) Crypt abscess. (B) Pseudopyloric metaplasia *(right)*. (C) Disease is limited to the mucosa (above the *arrow*). Compare to Fig. 17.35D.

often lacking in patients with ulcerative colitis and present in those with Crohn disease. However, the serologic results are frequently ambiguous in cases that are indeterminate on clinical grounds. Fortunately, overlap in medical management allows indeterminate colitis to be treated effectively.

Colitis-Associated Neoplasia

One of the most feared long-term complications of ulcerative colitis and colonic Crohn disease is the development of neoplasia. The risk of dysplasia and subsequent cancer is related to several factors:

- *Duration of the disease.* Risk increases sharply 8 to 10 years after disease onset.
- *Extent of the disease.* Patients with pancolitis are at greater risk than those with only left-sided disease. Crohn disease patients without colonic involvement are not at increased risk.
- *Nature of the inflammatory response.* Greater frequency and severity of active inflammation (characterized by the presence of neutrophils) confers increased risk.

To facilitate early detection of neoplasia, patients are typically enrolled in surveillance programs approximately 8 years after diagnosis of IBD. The major exception to this is patients with IBD and primary sclerosing cholangitis, who have a greater risk of developing cancer and are generally enrolled for surveillance at the time of diagnosis.

The goal of surveillance biopsies is to identify dysplastic epithelium, which is a precursor of colitis-associated carcinoma. Dysplasia can develop in flat areas of mucosa that are not grossly recognized as abnormal. High-resolution endoscopes and specialized endoscopic techniques, including chromoendoscopy, have helped target biopsies toward areas suspicious for dysplasia, but multiple surveillance biopsies and histological examination are still required. IBD-associated dysplasia is classified histologically as low grade or high grade (Fig. 17.38A, B) and may be multifocal. High-grade dysplasia may be associated with invasive carcinoma at the same site (Fig. 17.38C) or elsewhere in the colon and therefore often prompts colectomy. Low-grade dysplasia may be followed closely with frequent endoscopic surveillance, but colectomy is also common, particularly when multiple foci of flat (non-polypoid) dysplasia are present, in those with extensive or longstanding disease, and in older patients. Colonic adenomas (discussed later) also occur in IBD patients, and in some cases these may be difficult to differentiate from a polypoid focus of IBD-associated dysplasia. Fortunately, solitary polypoid lesions in ulcerative colitis without foci of flat dysplasia can often be managed by endoscopic resection and careful follow-up.

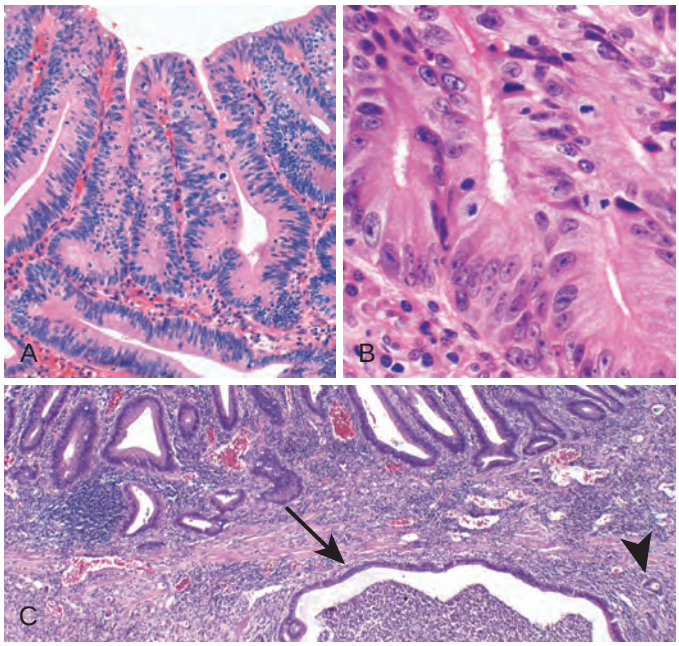

Figure 17.38 Colitis-associated dysplasia. (A) Dysplasia with extensive nuclear stratification and marked nuclear hyperchromasia. (B) Cribriform glandular arrangement in high-grade dysplasia. (C) Colectomy specimen with high-grade dysplasia on the surface and underlying invasive adenocarcinoma. A large cystic, neutrophil-filled space lined by invasive adenocarcinoma is apparent *(arrow)* beneath the muscularis mucosae. Also seen are small invasive glands *(arrowhead)*.

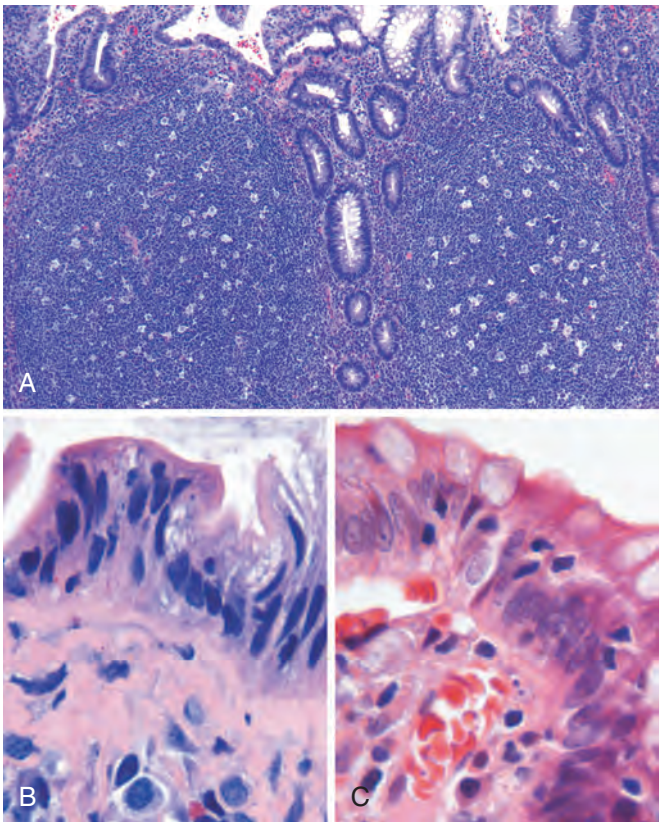

Figure 17.39 Uncommon causes of colitis. (A) Diversion colitis. Note the large lymphoid follicles with germinal centers. (B) Collagenous colitis with a dense subepithelial collagen band. (C) Lymphocytic colitis. Intraepithelial lymphocytes can be recognized by their densely stained, small nuclei.

OTHER CAUSES OF CHRONIC COLITIS

Diversion Colitis

Surgical treatment of ulcerative colitis, Hirschsprung disease, colon cancer, and other intestinal disorders sometimes requires creation of a temporary or permanent ostomy, resulting in a blind distal segment of colon from which the normal fecal flow is diverted. Colitis can develop within the diverted segment. Besides mucosal erythema and friability, the most striking feature of diversion colitis is the development of numerous mucosal lymphoid follicles (Fig. 17.39A). Increased numbers of lamina propria lymphocytes, monocytes, macrophages, and plasma cells may also be present. In severe cases the histopathology may resemble IBD and include crypt abscesses, mucosal architectural distortion, or, rarely, granulomas. The mechanisms responsible for diversion colitis are not well understood, but changes in the luminal microbiota and diversion of the fecal stream that provides nutrients to colonic epithelial cells have been proposed. Consistent with this, enemas containing short-chain fatty acids, a product of colonic bacterial metabolism that signals to and serves as an energy source for colonic epithelial cells, can promote mucosal recovery. Such enemas are, however, used infrequently because of butyrate's foul odor. Diversion colitis resolves after anastomosis and restoration of fecal flow.

Microscopic Colitis

Microscopic colitis encompasses two entities, collagenous colitis and lymphocytic colitis. These idiopathic diseases both present with chronic, nonbloody, watery diarrhea without weight loss. Radiologic and endoscopic studies are typically normal. Collagenous colitis, which occurs primarily in middle-aged and older women, is characterized by the presence of a dense subepithelial collagen layer, increased numbers of intraepithelial T lymphocytes, and a mixed inflammatory infiltrate within the lamina propria (Fig. 17.39B). Lymphocytic colitis is histologically similar, but the subepithelial collagen layer is of normal thickness and the increase in intraepithelial T lymphocytes is greater, frequently exceeding one per five colonocytes (Fig. 17.39C). Lymphocytic colitis shows a strong association with celiac disease and autoimmune diseases including Graves disease, rheumatoid arthritis, and autoimmune or lymphocytic gastritis. Similar histologic changes can be induced by NSAIDs and, possibly, proton pump inhibitors.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease occurs following allogeneic hematopoietic stem cell transplantation. The small bowel and colon are involved in most cases. Although graft-versus-host disease is secondary to donor T cells targeting antigens

on the recipient's GI epithelial cells, the lamina propria lymphocytic infiltrate is typically sparse. Epithelial apoptosis, particularly of crypt cells, is the most common histologic finding. The crypts may be completely destroyed in severe cases. Intestinal graft-versus-host disease often presents with watery diarrhea that may become bloody in severe cases. Intriguingly, the morphologic changes in graft-versus-host disease overlap with the enterocolitis and diarrhea that frequently develop in oncology patients treated with immune checkpoint inhibitors, complications that are becoming more frequent with increased use of these therapies. While the mechanisms of checkpoint inhibitor–induced enterocolitis are not well defined, they are likely to overlap, at least partially, with those of graft-versus-host disease.

SIGMOID DIVERTICULAR DISEASE

Diverticular disease is due to acquired pseudodiverticular outpouchings of the colonic mucosa and submucosa. Unlike true diverticula, such as Meckel diverticulum, these do not include all three layers of the colonic wall. Colonic diverticula are rare in persons younger than age 30, but the prevalence approaches 50% in Western adult populations older than age 60. Diverticulosis is less common in Japan as well as under-resourced countries, probably because of dietary differences. Moreover, most diverticula in Asia and Africa occur in the right colon, while right-sided diverticula are uncommon in Western countries. The reasons for this difference in distribution are not well defined.

Pathogenesis

Colonic diverticula are the product of the unique structure of the muscularis propria and elevated intraluminal pressure. Focal discontinuities are created in the inner circular muscle layer at sites where nerves and arterial vasa recta penetrate it. In the small intestine these gaps are reinforced by the external longitudinal layer of the muscularis propria, but in the colon this outer muscle layer is gathered into three bands, the taeniae coli. Intraluminal pressure, particularly in the sigmoid colon, is elevated by exaggerated peristaltic contraction, an effect that is enhanced by low-fiber diets with reduced stool bulk. This increased pressure leads to mucosal herniation through the anatomic weak points in the muscularis propria.

MORPHOLOGY

Colonic diverticula are small, flask-like outpouchings, usually 0.5 to 1 cm in diameter, that occur in a regular distribution (reflecting the anatomic contribution to pathogenesis) alongside the taeniae coli (Fig. 17.40A). These are most common in the sigmoid colon, but other parts of the colon may be affected. Colonic diverticula have a thin wall composed of a flattened or atrophic mucosa that can be surrounded by compressed submucosa and attenuated or absent muscularis (Fig. 17.40B, C). Hypertrophy of the circular layer of the muscularis propria in the affected bowel segment is common. Diverticular obstruction induces inflammation, termed diverticulitis. Because the wall of the diverticulum is supported only by the muscularis mucosae and a thin layer of subserosal adipose tissue, inflammation and increased pressure within an obstructed diverticulum can lead to perforation. With or without perforation, diverticulitis may cause segmental diverticular disease–associated colitis, fibrotic thickening in and around the colonic wall, or stricture formation. Perforation can result in pericolonic abscesses, sinus tracts, and, occasionally, peritonitis.

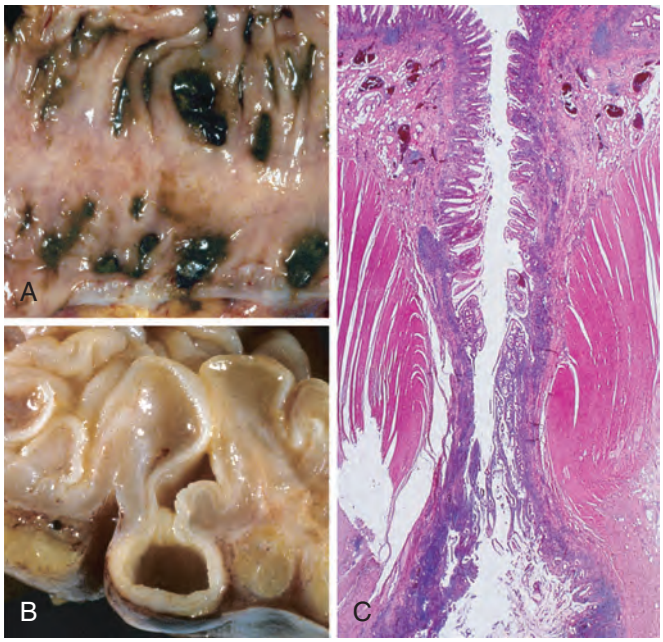

Figure 17.40 Sigmoid diverticular disease. (A) Stool-filled diverticula are regularly arranged. (B) Cross section showing the outpouching of mucosa through the muscularis propria. (C) Low-power photomicrograph of a sigmoid diverticulum showing protrusion of the mucosa through the muscularis propria.

Clinical Features

Most individuals with diverticular disease remain asymptomatic throughout their lives. However, about 20% develop manifestations such as intermittent cramping, continuous lower abdominal discomfort, constipation, distention, or a sensation of never being able to completely empty the rectum. Patients sometimes experience alternating constipation and diarrhea that mimics IBS. Whether a high-fiber diet prevents the development of diverticulosis or protects against diverticulitis is unclear, but diets supplemented with fiber may provide symptomatic improvement. Even when diverticulitis occurs, it most often resolves spontaneously. Surgical intervention is generally reserved for those with severe or recurrent diverticulitis.

KEY CONCEPTS

IRRITABLE BOWEL SYNDROME AND COLITIS

- Irritable bowel syndrome is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits without gross or histologic pathology. The pathogenesis is not defined, but likely includes contributions by psychologic stressors, diet,

the gut microbiome, abnormal GI motility, and increased enteric sensory responses to GI stimuli.
- IBD is an umbrella term for ulcerative colitis and Crohn disease. Indeterminate colitis is used for cases of IBD without definitive features of either ulcerative colitis or Crohn disease.
- Ulcerative colitis is limited to the colonic mucosa and submucosa, is continuous from the rectum, and ranges from only rectal disease to pancolitis; neither skip lesions nor granulomas are present.
- Crohn disease most commonly affects the terminal ileum and cecum, but can affect any site within the GI tract. Involvement is discontinuous, resulting in skip lesions. In affected areas disease can be transmural, affecting the full thickness of the entire bowel wall. Noncaseating granulomas are common.
- Both forms of IBD present most often in the teens and early 20s and are associated with extraintestinal manifestations.
- IBD is thought to arise from a synergy between genetic risk, mucosal immune dysfunction, and dysbiosis, i.e., disease-associated changes in microbial composition.
- The risk of colonic epithelial dysplasia and adenocarcinoma is increased in IBD patients who have had colonic disease for more than 8 to 10 years.
- The two forms of microscopic colitis, collagenous colitis and lymphocytic colitis, both cause chronic watery diarrhea. The intestines are endoscopically normal, and the diseases are identified by their characteristic histologic features.
- Diverticular disease of the sigmoid colon is common in Western populations older than age 60. The causes include low-fiber diets, colonic spasm, and the unique anatomy of the colon. Inflammation of diverticula, diverticulitis, affects a minority of those with diverticulosis, but can cause perforation in its most severe form.

POLYPS

Polyps are most common in the colon and rectum but, as discussed earlier, may occur in the esophagus, stomach, or small intestine. Most, if not all, polyps begin as small elevations of the mucosa. These are referred to as *sessile,* a term borrowed from botanists who use it to describe flowers and leaves that grow directly from the stem without a stalk. As sessile polyps enlarge, proliferation of cells adjacent to the mass and the effects of traction on the luminal protrusion may combine to create a stalk. Polyps with stalks are termed *pedunculated.* In general, intestinal polyps can be classified as nonneoplastic or neoplastic. The most common neoplastic polyp is the adenoma, which has the potential to progress to cancer. Nonneoplastic polyps can be classified as inflammatory, hamartomatous, or hyperplastic.

Hyperplastic Polyps

Colonic hyperplastic polyps are benign epithelial proliferations that are typically discovered in the sixth and seventh decades of life. The pathogenesis of hyperplastic polyps is incompletely understood, but they are thought to result from decreased epithelial cell turnover and delayed shedding of surface epithelial cells, leading to a "piling up" of goblet cells and absorptive cells. These lesions are without malignant potential. Their chief significance is that they must be distinguished from sessile serrated adenomas, which are histologically similar but have malignant potential, as described later. It is also important to remember that epithelial hyperplasia can occur as a nonspecific reaction adjacent to or overlying any mass or inflammatory lesion and therefore can be a clue to the presence of an adjacent, clinically important lesion.

MORPHOLOGY

Hyperplastic polyps are most commonly found in the left colon and are typically less than 5 mm in diameter. They are smooth, nodular protrusions of the mucosa, often on the crests of mucosal folds. They may occur singly but are more frequently multiple, particularly in the sigmoid colon and rectum. Histologically, hyperplastic polyps are composed of mature goblet and absorptive cells with a serrated surface architecture that is the morphologic hallmark of these lesions (Fig. 17.41). Serration is typically restricted to the upper third of the crypt.

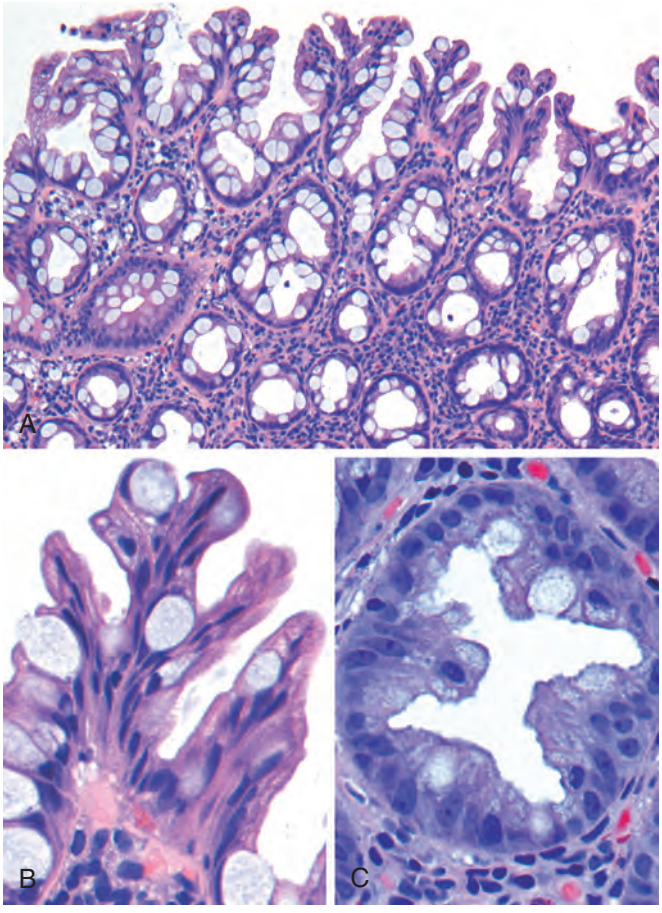

Figure 17.41 Hyperplastic polyp. (A) Polyp surface with irregular tufting of epithelial cells. (B) Tufting results from epithelial overcrowding. (C) Epithelial crowding produces a serrated architecture when crypts are cut in cross section.

Inflammatory Polyps

Polyps that form as part of the solitary rectal ulcer syndrome are an example of a purely inflammatory lesion. Patients present with a clinical triad of rectal bleeding, mucus discharge, and an inflammatory lesion of the anterior rectal wall. The underlying cause is impaired relaxation of the anorectal sphincter that creates a sharp angle at the anterior rectal shelf and leads to recurrent abrasion and ulceration of the overlying rectal mucosa. An inflammatory polyp may ultimately form as a result of chronic cycles of injury and healing. Entrapment of this polyp in the fecal stream leads to mucosal prolapse. The distinctive histologic features include mixed inflammatory infiltrates, erosion, and epithelial hyperplasia together with prolapse-induced lamina propria fibromuscular hyperplasia (Fig. 17.42).

Hamartomatous Polyps

Hamartomatous polyps occur sporadically or as components of genetically determined or acquired syndromes (Table 17.9).

Although they were originally thought to reflect developmental abnormalities, many hamartomatous polyp syndromes are caused by germline mutations in tumor suppressor genes or proto-oncogenes. Some of these syndromes are associated with increased cancer risk, either within the polyps or at other intestinal or extraintestinal sites. Thus, a subset of hamartomatous polyps can be considered to be premalignant, neoplastic lesions, much like adenomas. It is also important to recognize these polyps because of associated extraintestinal manifestations and the possibility that other family members are affected. Several of these syndromes are discussed below and others are summarized in Table 17.9.

Juvenile Polyps

Juvenile polyps are focal malformations of the epithelium and lamina propria that may be sporadic or syndromic. The majority occur in children younger than 5 years of age, but both sporadic and syndromic polyps can present at older ages. Many juvenile polyps are located in the rectum and cause rectal bleeding. In some cases intussusception, intestinal obstruction, or polyp prolapse (through the anal sphincter) may occur.

Sporadic juvenile polyps, which are also referred to as retention polyps, are usually solitary. In contrast, the autosomal dominant syndrome of juvenile polyposis is characterized by from three to hundreds of hamartomatous polyps. In these cases, colectomy may be necessary to limit the chronic and sometimes severe hemorrhage associated with polyp ulceration. A minority of patients also have polyps in the stomach and small bowel that can undergo malignant transformation. Pulmonary arteriovenous malformations and other congenital malformations are recognized extraintestinal manifestations of juvenile polyposis.

MORPHOLOGY

Most juvenile polyps are less than 3 cm in diameter. They are typically pedunculated, smooth-surfaced, reddish lesions with characteristic cystic spaces. Microscopic examination shows these cysts to be dilated glands filled with mucin and inflammatory debris (Fig. 17.43). The remainder of the polyp is composed of lamina propria expanded by mixed inflammatory infiltrates. The muscularis mucosae may be normal or attenuated.

Although the morphogenesis of juvenile polyps is incompletely understood, it has been proposed that mucosal hyperplasia is the initiating event. This hypothesis is consistent with the discovery that mutations in pathways that regulate cellular growth cause autosomal dominant juvenile polyposis. The most common mutation identified is of *SMAD4,* which encodes a signaling intermediate in the TGF-β pathway. These patients often have both juvenile polyposis and hereditary hemorrhagic telangiectasia. In other cases, mutations in *BMPR1A,* a kinase that is a member of the TGF-β superfamily, cause disease (see Table 17.9). Together these mutations account for fewer than half of patients. Thus, other genes responsible for autosomal dominant juvenile polyposis remain to be discovered.

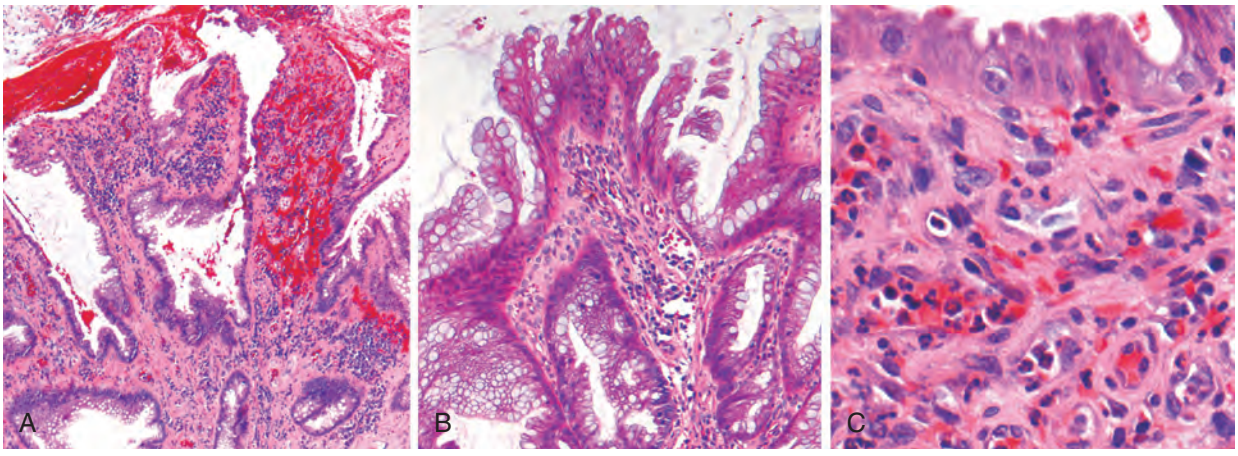

Figure 17.42 Solitary rectal ulcer syndrome. (A) The dilated glands, proliferative epithelium, superficial erosions, and inflammatory infiltrate are typical of an inflammatory polyp. However, the smooth muscle hyperplasia within the lamina propria indicates that mucosal prolapse has also occurred. (B) Epithelial hyperplasia. (C) Granulation tissue–like capillary proliferation within the lamina propria caused by repeated erosion.

Table 17.9 Gastrointestinal Polyposis Syndromes

Syndrome	Mean Age at Presentation (years)	Mutated Genes; Pathway	GI Lesions	Selected Extra-GI Manifestations
Juvenile polyposis	<5	*SMAD4,BMPR1A*; TGF-β signaling pathway	Juvenile polyps; risk of gastric, small intestinal, colonic, and pancreatic adenocarcinoma	Congenital malformations, digital clubbing
Peutz-Jeghers syndrome	10–15	*STK11*; AMP kinase-related pathways	Arborizing polyps; small intestine > colon > stomach; colonic adenocarcinoma	Pigmented macules; risk of colon, breast, lung, pancreatic, and thyroid cancer
Cowden syndrome, Bannayan-Ruvalcaba-Riley syndrome[a]	<15	*PTEN*: PI3K/AKT pathway	Hamartomatous/ inflammatory intestinal polyps, lipomas, ganglioneuromas	Benign skin tumors, benign and malignant thyroid and breast lesions; no increase in GI cancers
Cronkhite-Canada syndrome	>50	Nonhereditary, unknown cause	Hamartomatous polyps of stomach, small intestine colon; abnormalities in nonpolypoid mucosa	Nail atrophy, hair loss, abnormal skin pigmentation, cachexia, and anemia. Fatal in up to 50%
Tuberous sclerosis		*TSC1* (hamartin), *TSC2* (tuberin); mTOR pathway	Hamartomatous polyps	Intellectual disability, epilepsy, facial angiofibroma, cortical (CNS) tubers, renal angiomyolipoma
FAP				
Classic FAP	10–15	*APC*	Multiple adenomas	Congenital RPE hypertrophy
Attenuated FAP	40–50	*APC*	Multiple adenomas	
Gardner syndrome	10–15	*APC*	Multiple adenomas	Osteomas, thyroid and desmoid tumors, skin cysts
Turcot syndrome	10–15	*APC*	Multiple adenomas	Medulloblastoma, glioblastoma
MUTYH-associated polyposis	30–50	*MUTYH*	Multiple adenomas	Gastric and duodenal polyps

[a]Also called PTEN hamartoma-tumor syndrome.

CNS, Central nervous system; *FAP*, familial adenomatous polyposis; *GI*, gastrointestinal; *mTOR*, mammalian target of rapamycin; *RPE*, retinal pigmented epithelium; *TGF-β*, transforming growth factor beta.

Dysplasia is rare in sporadic juvenile polyps. In contrast, juvenile polyposis syndrome is associated with dysplasia, both within the juvenile polyps and in separate adenomas. As a result, 30% to 50% of patients with juvenile polyposis develop colonic adenocarcinoma by age 45.

Peutz-Jeghers Syndrome

This rare autosomal dominant syndrome presents at a median age of 11 years with multiple GI hamartomatous polyps and mucocutaneous hyperpigmentation. The latter takes the form of dark blue to brown macules on the lips, nostrils, buccal mucosa, palmar surfaces of the hands, genitalia, and perianal region. These lesions are similar to freckles but are distinguished by their presence in the buccal mucosa. Peutz-Jeghers polyps can initiate intussusception, which is occasionally fatal. Of greater importance, **Peutz-Jeghers syndrome is associated with a markedly increased risk of several malignancies.** Lifetime risk is approximately 40%, and regular surveillance is recommended beginning at birth for sex cord tumors of the testes; in late childhood for gastric and small intestinal cancers; and in the second and third decades of life for colon, pancreatic, breast, lung, ovarian, and uterine cancers.

Pathogenesis

Germline heterozygous loss-of-function mutations in the gene *STK11* are present in approximately half of individuals with familial Peutz-Jeghers syndrome as well as a subset of patients with sporadic Peutz-Jeghers syndrome. *STK11* is a tumor suppressor gene that regulates AMP-activated protein kinases (AMPK), which control cell polarization and act as a brake on growth and anabolic metabolism (Chapter 7). As is common with other tumor suppressor genes, the function of the second "normal" copy of *STK11* is often lost through somatic mutation in cancers occurring in Peutz-Jeghers syndrome, providing an explanation for the high risk of neoplasia in affected patients.

MORPHOLOGY

The polyps of Peutz-Jeghers syndrome are most common in the small intestine, although they may occur in the stomach and colon and, with much lower frequency, in the bladder and lungs. Grossly, the polyps are large and pedunculated with a lobulated contour. Histologic examination demonstrates a characteristic arborizing network of connective tissue, smooth muscle, lamina propria, and glands lined by normal-appearing intestinal epithelium (Fig. 17.44).

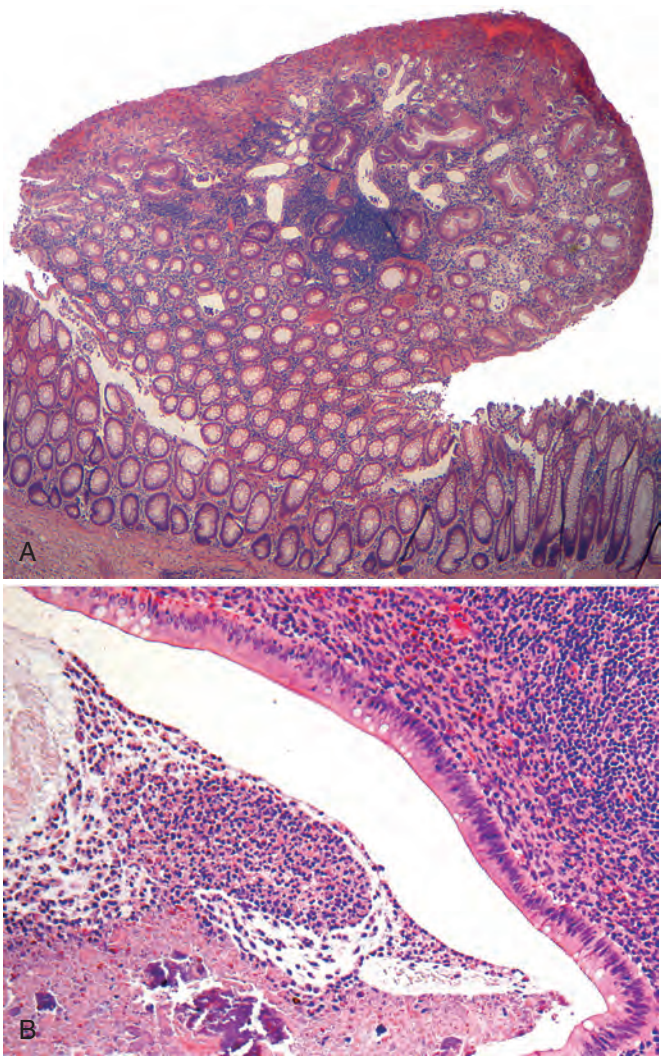

Figure 17.43 Juvenile polyposis. (A) Juvenile polyp. Note the surface erosion and cystically dilated crypts. (B) Inspissated mucus, neutrophils, and inflammatory debris can accumulate within dilated crypts.

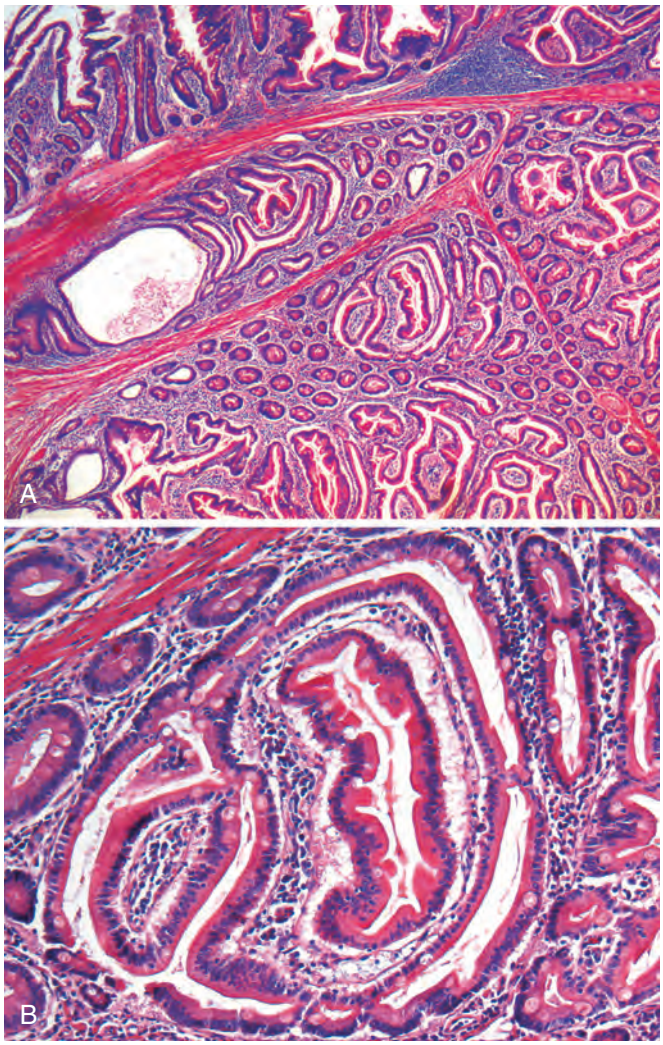

Figure 17.44 Peutz-Jeghers polyp. (A) Polyp surface (top) overlies stroma composed of smooth muscle bundles cutting through the lamina propria. (B) Complex glandular architecture and the presence of smooth muscle are features that distinguish Peutz-Jeghers polyps from juvenile polyps.

The arborization and presence of smooth muscle intermixed with lamina propria are helpful in distinguishing polyps of Peutz-Jeghers syndrome from juvenile polyps.

Clinical Features

Because the morphology of Peutz-Jeghers polyps can overlap with that of sporadic hamartomatous polyps, the presence of multiple polyps in the small intestine, mucocutaneous hyperpigmentation, and a positive family history are critical to the diagnosis. Detection of *STK11* mutations can be helpful diagnostically in patients with polyps who lack mucocutaneous hyperpigmentation. However, the absence of *STK11* mutations does not exclude the diagnosis, as these mutations are not present in all patients.

Neoplastic Polyps

The most common neoplastic polyps are colonic adenomas, which are precursors to the majority of colorectal adenocarcinomas. It is important, however, to realize that any neoplastic mass lesion in the GI tract may produce a polyp. This includes adenocarcinomas, neuroendocrine tumors, stromal tumors, lymphomas, and even metastatic cancers from distant sites.
